THE AVERAGE-CASE COMPLEXITY OF DETERMINING THE MAJORITY*

LAURENT ALONSO†, EDWARD M. REINGOLD‡, AND RENÉ SCHOTT§

Abstract. Given a set of n elements each of which is either red or blue, it is known that in the worst case $n - \nu(n)$ pairwise equal/not equal color comparisons are necessary and sufficient to determine the majority color, where $\nu(n)$ is the number of 1-bits in the binary representation of n. We prove that $\frac{2n}{3} - \sqrt{\frac{8n}{9\pi}} + O(\log n)$ such comparisons are necessary and sufficient in the *average case*.

1. Introduction.

Given a set $\{x_1, x_2, \ldots, x_n\}$, each element of which is colored either red or blue, we must determine an element of the majority color by making equal/not equal color comparisons $x_u : x_v$; when n is even, we must report that there is no majority if there are equal numbers of each color. How many such questions are necessary and sufficient?

In the worst case, exactly $n - \nu(n)$ questions are necessary and sufficient, where, following [4], $\nu(n)$ is the number of 1-bits in the binary representation of n. This result was first proved by Saks and Werman [9], who expressed the problem in terms of games and graphs and gave an intricate, technical argument based on generating functions to prove the lower bound. In [2] we gave a short, elementary proof of this result.

The present paper concerns the *average case*. We show in section 3 that any algorithm that correctly determines the majority must on the average use at least

$$\frac{2n}{3} - \sqrt{\frac{8n}{9\pi}} + \Theta(1) \tag{1}$$

color comparisons, assuming all 2^n distinct colorings of the n elements are equally probable. Furthermore, in section 4 we describe an algorithm that uses an average of

$$\frac{2n}{3} - \sqrt{\frac{8n}{9\pi}} + O(\log n) \tag{2}$$

color comparisons. Together these bounds imply that $\frac{2n}{3} - \sqrt{\frac{8n}{9\pi}} + O(\log n)$ such comparisons are necessary and sufficient in the average case to determine the majority. Some open problems are discussed in section 5.

2. The decision tree. The derivation of the average-case lower bound (1) is, as is the derivation of the worst-case lower bound in [2], based on analyzing the underlying binary decision tree (see [8], for example) of any algorithm based on equal/not equal comparisons. Each node of such a decision tree corresponds to a subset of the 2^n possible colorings of the n elements—the largest subset for which the answers to the questions posed are consistent with the coloring. The lower bound for the average case follows from a detailed analysis of the structure of such a tree.

At any node of the decision tree, the state of information obtained about the coloring can be described by a partition of $\{x_1, x_2, \ldots, x_n\}$ into disjoint sets $A_1 \cup B_1 \cup A_2 \cup B_2 \cup \cdots \cup A_m \cup B_m$, for some m, with the meaning that for all i, $1 \le i \le m$, all the elements in A_i are known to have one color and all the elements in B_i are known to have the opposite color. There are clearly 2^m colorings of the elements that are consistent with this partition. At the root of the decision tree we have $m = n$, $A_i = \{x_i\}$, and $B_i = \emptyset$, $1 \le i \le n$, and hence, 2^n consistent colorings. A leaf of the decision tree contains enough information for the algorithm to identify one of the subsets A_i or B_i as being of the majority color.

If we assume that no redundant questions are asked, each internal node of the decision tree reflects a color comparison $x_u : x_v$, $x_u \in A_i \cup B_i$ and $x_v \in A_j \cup B_j$, $i \ne j$. The answer to the question causes the two pairs of sets A_i, B_i and A_j, B_j to be replaced by a single pair of sets, either the pair $A_i \cup A_j$, $B_i \cup B_j$ or the pair $A_i \cup B_j$, $A_j \cup B_i$, depending on the answer to the question. Thus at each internal node the number of colorings splits half and half between the two children of that node, and therefore a node at depth d (the root having depth zero) corresponds to 2^{n-d} colorings.

Observe that a color comparison $x_u : x_v$, $x_u \in A_i \cup B_i$ and $x_v \in A_j \cup B_j$, $i \ne j$, is irrelevant if either $|A_i| = |B_i|$ or $|A_j| = |B_j|$ because, in either case, the cardinalities of the replacement pair of sets for the two pairs of sets A_i, B_i and A_j, B_j do not depend on the outcome of the color comparison. Hence the state of information at a node need not include pairs of sets A_i, B_i for which $|A_i| = |B_i|$, so we will assume that $|A_i| \ne |B_i|$, $1 \le i \le m$.

In considering the state of information at a node in the decision tree described by the partition $A_1 \cup B_1 \cup A_2 \cup B_2 \cup \cdots \cup A_m \cup B_m$, it is convenient to relabel these $2m$ sets so that

$$|A_i| > |B_i|,$$

for $1 \le i \le m$, and

$$|A_i| - |B_i| \ge |A_{i+1}| - |B_{i+1}|,$$

for $1 \le i < m$. Thus by defining, for $1 \le i \le m$,

$$\Delta_i = |A_i| - |B_i|,$$

we can encode all relevant information about the state at a node of the decision tree with the nonincreasing sequence of positive integers

$$\Delta_1 \ge \Delta_2 \ge \cdots \ge \Delta_m > 0.$$

The state of the algorithm at the root of the tree is thus described by a sequence of n ones. At an internal node $(\Delta_1, \Delta_2, \ldots, \Delta_m)$, a color comparison $x_u : x_v$, $x_u \in A_i \cup B_i$

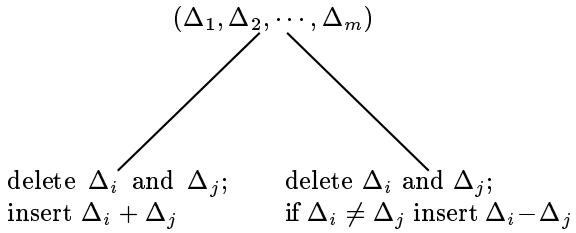

FIG. 1. *The effect on the* Δ*-vector of a color comparison at an internal node of the decision tree with the color comparison* $x_u : x_v$*,* $x_u \in A_i \cup B_i$ *and* $x_v \in A_j \cup B_j$*. If* $\Delta_i = \Delta_j$*, the node is* ordinary*; if* $\Delta_i \neq \Delta_j$*, the node is* unusual.

and $x_v \in A_j \cup B_j$, results in the two values Δ_i and Δ_j being deleted from the sequence and $\Delta_i + \Delta_j$ or $|\Delta_i - \Delta_j| > 0$ then being inserted into place in the sequence, one in the left subtree the other in the right subtree, respectively, depending on the result of the color comparison—in this case the sequence shrinks in length by 1 in passing to subtrees. However, zeroes are never in the sequence (since $\Delta_i = 0$ would mean $|A_i| = |B_i|$), so if $|\Delta_i - \Delta_j| = 0$, the sequence for that subtree shrinks in length by 2. (See Figure 1.) In other words, each internal node of the decision tree can have either both of its children with a Δ-vector one shorter in length than its own Δ-vector or its left child with a Δ-vector one shorter in length than its own and its right child with a Δ-vector two shorter in length than its own; in the former case we call the node *unusual*, and in the latter case we call it *ordinary*.

A leaf in the decision tree corresponds to an outcome of the algorithm, and hence the associated Δ-vector contains enough information to determine the majority. There are two cases: If the Δ-vector is empty ($m = 0$), there is no majority. Otherwise, we must have

$$\Delta_1 > \sum_{i \geq 2} \Delta_i, \tag{3}$$

in which case any element from the set A_1 is a member of the majority. Of course each $\Delta_i \geq 1$, so (3) implies that

$$\Delta_1 \geq m, \tag{4}$$

for every leaf in which there is a majority element; we consider that (4) holds vacuously when $m = 0$ and there is no majority. Thus (4) holds for every leaf in the tree.

3. The lower bound. Given an algorithm for the majority problem, consider its corresponding decision tree T and let $C(T)$ be the average number of color comparisons, assuming all 2^n colorings are equally likely. From the discussion in the previous section, we have

$$C(T) = \sum_{\substack{\text{leaves} \\ l \in T}} \frac{2^{n - \text{depth}(l)}}{2^n} \text{depth}(l)$$

because there are $2^{n-\text{depth}(l)}$ colorings in a leaf at depth depth(l), hence

$$C(T) = \sum_{\substack{\text{leaves} \\ l \in T}} \frac{\text{depth}(l)}{2^{\text{depth}(l)}},$$

and

$$C(T) = \sum_{\substack{\text{internal} \\ \text{nodes } v \in T}} \frac{1}{2^{\text{depth}(v)}} \tag{5}$$

by induction on the height of the tree.

We will evaluate the sum in (5) by relating it to the average length of the Δ-vector when the algorithm ends (that is, at the leaves, weighted by the number of colorings in a leaf),

$$L(T) = \sum_{\substack{\text{leaves} \\ l \in T}} \frac{\text{length}(l)}{2^{\text{depth}(l)}}, \tag{6}$$

where length(l) is the length of the Δ-vector at leaf l. This, in turn, we will express in terms of the classic ballot problem [3].

Observe that for any integer-valued function f of nodes, we have the identity

$$\sum_{\substack{\text{internal} \\ \text{nodes } v \in T}} [f(v) - f(\text{left}(v)) - f(\text{right}(v))] = f(\text{root}) - \sum_{\substack{\text{leaves} \\ l \in T}} f(l); \tag{7}$$

this follows by induction on the height of the tree (the sum on the left telescopes). Applying (7) to the function

$$f(v) = \frac{\text{length}(v)}{2^{\text{depth}(v)}},$$

we find that $f(\text{root}) = n$,

$$\sum_{\substack{\text{leaves} \\ l \in T}} f(l) = L(T),$$

and

$$f(v) - f(\text{left}(v)) - f(\text{right}(v)) = \begin{cases} \frac{3/2}{2^{\text{depth}(v)}}, & v \text{ ordinary}, \\ \frac{1}{2^{\text{depth}(v)}}, & v \text{ unusual}. \end{cases}$$

So, (7) becomes

$$\sum_{\substack{\text{ordinary internal} \\ \text{nodes } v \in T}} \frac{3/2}{2^{\text{depth}(v)}} + \sum_{\substack{\text{unusual internal} \\ \text{nodes } v \in T}} \frac{1}{2^{\text{depth}(v)}} = n - L(T).$$

Because every internal node is either ordinary or unusual, we can rewrite this last equation as

$$\frac{3}{2} \sum_{\substack{\text{internal} \\ \text{nodes } v \in T}} \frac{1}{2^{\text{depth}(v)}} - \frac{1}{2} \sum_{\substack{\text{unusual internal} \\ \text{nodes } v \in T}} \frac{1}{2^{\text{depth}(v)}} = n - L(T).$$

But by (5), this becomes

$$\frac{3}{2}C(T) - \frac{1}{2}\sum_{\substack{\text{unusual internal}\\ \text{nodes } v \in T}} \frac{1}{2^{\text{depth}(v)}} = n - L(T),$$

or

$$C(T) = \frac{2n}{3} - \frac{2}{3}L(T) + \frac{1}{3}\sum_{\substack{\text{unusual internal}\\ \text{nodes } v \in T}} \frac{1}{2^{\text{depth}(v)}} \tag{8}$$

$$\geq \frac{2n}{3} - \frac{2}{3}L(T)$$

$$\geq \frac{2n}{3} - \frac{2}{3}E(\Delta_1), \tag{9}$$

where $E(\Delta_1)$ is the expected value of Δ_1, assuming all 2^n colorings are equally likely, because (4) tells us that $L(T) \leq E(\Delta_1)$ and thus $-L(T) \geq -E(\Delta_1)$.

$E(\Delta_1) = M(n)$, the expected margin of victory in the n-vote ballot problem [3], for consider

$$M(n) = \frac{1}{2^n}\sum_{\substack{\text{colorings}\\ C}} (|\text{majority in } C| - |\text{minority in } C|)$$

$$= \frac{1}{2^n}\sum_{\substack{\text{leaves}\\ l \in T}}\sum_{\substack{\text{colorings}\\ C \in l}} (|\text{majority in } C| - |\text{minority in } C|).$$

But for a leaf l with Δ-vector $(\Delta_1, \Delta_2, \ldots, \Delta_m)$,

$$|\text{majority}| - |\text{minority}| = \Delta_1 \pm \Delta_2 \pm \cdots \pm \Delta_m,$$

where the sign of Δ_i is $+$ if $\text{color}(A_1) = \text{color}(A_i)$ and $-$ otherwise. A given leaf l contains the colorings with all 2^{m-1} sign combinations, so when these are added all terms cancel *except* the Δ_1 term. Thus

$$\sum_{\substack{\text{colorings}\\ C \in l}} (|\text{majority in } C| - |\text{minority in } C|) = 2^{n-\text{depth}(l)}\Delta_1,$$

since there are $2^{n-\text{depth}(l)}$ colorings associated with l, and so

$$M(n) = \frac{1}{2^n}\sum_{\substack{\text{leaves}\\ l \in T}} 2^{n-\text{depth}(l)}\Delta_1$$

$$= \sum_{\substack{\text{leaves}\\ l \in T}} \frac{\Delta_1}{2^{\text{depth}(l)}}$$

$$= E(\Delta_1),$$

as claimed. Inequality (9) now becomes

$$C(T) \geq \frac{2}{3}n - \frac{2}{3}M(n). \tag{10}$$

The value of $M(n)$ was the subject of problem A-4 in the 1974 Putnam competition [7] (see also [1, pp. 22 and 87]). We have,

$$\begin{aligned}
M(n) &= \frac{1}{2^{n-1}} \sum_{k \leq n/2} (n-2k)\binom{n}{k} \\
&= \frac{1}{2^{n-1}} \sum_{k \leq n/2} \left[(n-k)\binom{n}{k} - k\binom{n}{k}\right] \\
&= \frac{1}{2^{n-1}} \sum_{k \leq n/2} \left[n\binom{n-1}{k} - n\binom{n-1}{k-1}\right] \\
&= \frac{n}{2^{n-1}} \sum_{k \leq n/2} \left[\binom{n-1}{k} - \binom{n-1}{k-1}\right] \\
&= \frac{n}{2^{n-1}} \binom{n-1}{\lfloor \frac{n-1}{2} \rfloor} \\
&= \sqrt{\frac{2n}{\pi}} + \Theta(1) \qquad (11)
\end{aligned}$$

by Stirling's formula (see [4, equation (4.15)], for example). Therefore, (10) becomes

$$C(T) \geq \frac{2}{3}n - \sqrt{\frac{8n}{9\pi}} + \Theta(1),$$

as claimed.

4. An algorithm. Equation (8) holds for *any* tree and allows us to analyze the expected behavior of any algorithm by computing $L(T)$ and

$$\sum_{\substack{\text{unusual internal} \\ \text{nodes } v \in T}} \frac{1}{2^{\text{depth}(v)}}$$

for that algorithm. The algorithm from [2] has no unusual internal nodes and each leaf has a Δ-vector that is the binary representation of an integer between 0 and n, so the expected length must be $O(\log n)$. That algorithm, therefore, has an expected $2n/3 - O(\log n)$ color comparisons—in other words, although exactly optimal in the worst case, is only within an additive $O(\sqrt{n})$ of being optimal in the average case. We can do better, however.

For optimal average-case behavior, we seek to maximize

$$\frac{2}{3}L(T) - \frac{1}{3} \sum_{\substack{\text{unusual internal} \\ \text{nodes } v \in T}} \frac{1}{2^{\text{depth}(v)}}.$$

We will describe an algorithm (that is, a tree $T(n)$) for which this is $\sqrt{\frac{8n}{9\pi}} - O(\log n)$; this algorithm is thus within an additive $O(\log n)$ of being optimal.

Consider the tree $T(n)$ formed by starting with the Δ-vector $(1, 1, \ldots, 1)$ of n ones at the root and proceeding as follows. Suppose the Δ-vector has the form

$$((2t+1)2^{\delta_1}, 2^{\delta_2}, \ldots, 2^{\delta_m}), \tag{12}$$

$\delta_1 \geq \delta_2 \geq \cdots \geq \delta_m$ and $t \geq 0$; certainly, the initial Δ-vector $(1, 1, \ldots, 1)$ has this form. If $\Delta_1 > \Delta_2 + \cdots + \Delta_m$, it is a leaf. Otherwise, if $\Delta_1 \leq \Delta_2 + \cdots + \Delta_m$, that is, $(2t+1)2^{\delta_1} \leq 2^{\delta_2} + \cdots + 2^{\delta_m}$, the δ_i's cannot all be distinct, so let i be the smallest integer such that for which $\delta_i = \delta_{i+1}$; in other words, let i be the smallest integer such that Δ_i/Δ_{i+1} is odd. If

$$\sum_{j \leq i} \Delta_j > \sum_{j > i} \Delta_j, \tag{13}$$

we make a color comparison between an element from A_1 and one from A_2; otherwise, if

$$\sum_{j \leq i} \Delta_j \leq \sum_{j > i} \Delta_j,$$

we make a color comparison between an element from A_i and one from A_{i+1}. The resulting Δ-vector has the same form as (12) and it follows by induction on the depth in $T(n)$ that each Δ-vector thus obtained satisfies the invariant relationship

$$\text{sum of the non-ones} \leq 2 + \text{number of ones}. \tag{14}$$

Inequality (14) is a critical property of $T(n)$, as we shall see. Figure 2 shows the tree $T(8)$.

The only possible Δ-vectors in the leaves of $T(n)$ are

$$(\ ), \qquad (2), \qquad (i, \underbrace{1, 1, \ldots, 1}_{j}), \quad j = i-1 \text{ or } j = i-2. \tag{15}$$

For suppose, by way of contradiction, that a leaf l has $\Delta_2 \geq 2$. By (14),

$$\Delta_1 + \Delta_2 \leq \text{sum of the non-ones} \leq 2 + \text{number of ones},$$

or

$$\Delta_1 \leq (2 - \Delta_2) + \text{number of ones}.$$

But $2 - \Delta_2 \leq 0$, so

$$\Delta_1 \leq \text{number of ones}.$$

Hence the algorithm cannot correctly conclude at leaf l that A_1 is of the majority color, a contradiction.

Because each leaf has one of the forms in (15), the length of the Δ-vector in a leaf satisfies

$$\text{length(leaf)} = \Delta_1 + O(1). \tag{16}$$

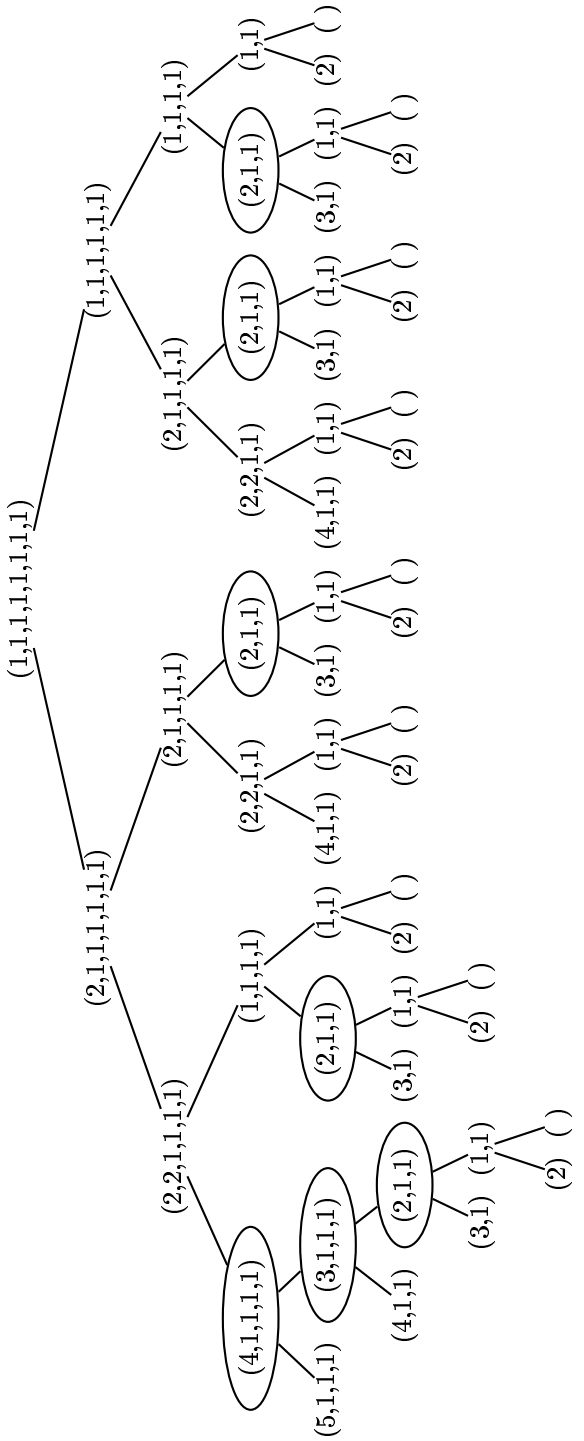

FIG. 2. *The tree $T(8)$. Unusual nodes are enclosed in ovals.*

So,

$$\begin{aligned} L(T(n)) &= E(\text{length(leaf)}) \\ &= E(\Delta_1) + O(1) \\ &= M(n) + O(1) \\ &= \sqrt{\frac{2n}{\pi}} + \Theta(1) \end{aligned}$$

by (11).

It remains to compute

$$\sum_{\substack{\text{unusual internal} \\ \text{nodes } v \in T(n)}} \frac{1}{2^{\text{depth}(v)}}.$$

Since $\sum_{j\geq 1} \Delta_j \leq n$, (12) tells us that the only possible values for Δ_2 are 2^i, $0 \leq i \leq \lfloor \lg n \rfloor$, so

$$\sum_{\substack{\text{unusual internal} \\ \text{nodes } v \in T(n)}} \frac{1}{2^{\text{depth}(v)}} = \sum_{i=0}^{\lfloor \lg n \rfloor} \sum_{\substack{\text{unusual internal} \\ \text{nodes } v \in T(n) \\ \text{with } \Delta_2 = 2^i}} \frac{1}{2^{\text{depth}(v)}}.$$

From inequality (20) in Corollary 4.5 below, we see that the inner sum here is $O(1)$. This implies that the outer sum is $O(\log n)$ and hence that

$$C(T(n)) = \frac{2n}{3} - \sqrt{\frac{8n}{9\pi}} + O(\log n),$$

whence we can conclude that $C(T(n))$ is within an additive $O(\log n)$ of being optimal in the average case. To reach the needed corollary we must study the arrangement of unusual internal nodes in $T(n)$.

PROPOSITION 4.1. *Let v with Δ-vector $(d_1, d_2, \ldots)$ be an ancestor of $\hat{v}$ with Δ-vector $(\hat{d}_1, \hat{d}_2, \ldots)$ in $T(n)$. Then*

$$\text{sum}(\hat{v}) \leq \text{sum}(v) - 2(d_1 - \hat{d}_1), \tag{17}$$

where $\text{sum}(x)$ *is the sum of all values in the Δ-vector of a node x.*

Proof. The proof is by induction on $\text{depth}(\hat{v}) - \text{depth}(v)$ because $\text{sum}(x) - 2\Delta_1(x)$, an integer-valued function of a node x, is nonincreasing as we go from parent to child in $T(n)$. □

PROPOSITION 4.2. *For any k, the highest unusual node in $T(n)$ with $\Delta_2 \leq k$ has Δ_1/Δ_2 even.*

Proof. It suffices to prove that any ancestor of such a node has a Δ-vector $(d_1, d_2, \ldots)$ in which d_1 is either a power of two or is a multiple of $2\Delta_2$. This is proved by induction on the depth of a node. □

PROPOSITION 4.3. *If $v \in T(n)$ is a unusual node with $\Delta_2 = k$, then* (a) *there is no unusual node with $\Delta_2 > k$ in the subtree rooted at v, and* (b) *there is no unusual node with $\Delta_2 = k$ in the subtree rooted at* $\text{left}(v)$.

Proof. Suppose there is such a node v. Let x be the highest ancestor of v that is unusual and has $\Delta_2 \leq k$ (of course, we could have $x = v$), and let $(d_1, d_2, \ldots)$ be the Δ-vector of x. Because x is the highest unusual node with $\Delta_2 \leq k$, we must have d_1/d_2 even—if it were odd, it would contradict Proposition 4.2—and hence if i is the smallest integer such that d_i/d_{i+1} is odd, then $i \geq 2$, and by (13),

$$\sum_{j \leq i} d_j > \sum_{j > i} d_j.$$

Furthermore, because $d_2/d_3, \ldots, d_{i-1}/d_i$ are all even, $d_2 > d_3 > \cdots > d_i$; since these are all powers of two, we have

$$d_2 \geq 1 + \sum_{3 \leq j \leq i} d_j$$

and hence

$$d_1 + 2d_2 \geq 1 + \sum_{j \leq i} d_j.$$

The inequalities above combine to tell us that

$$\begin{aligned} \sum_{j \geq 1} d_j &= \sum_{j \leq i} d_j + \sum_{j > i} d_j \\ &< 2 \sum_{j \leq i} d_j \\ &\leq 2d_1 + 4d_2 - 2. \end{aligned}$$

Thus

$$\operatorname{sum}(x) < 2d_1 + 4d_2 - 2. \tag{18}$$

For part (a), let y be an unusual descendant of v with $\Delta_2 > k$ and let $(\hat{d}_1, \hat{d}_2, \ldots)$ be the Δ-vector of y, $\hat{d}_2 > k \geq d_2$; we have $\hat{d}_1 > \hat{d}_2$ since y is unusual and, since Δ_2 must be a power of two, we have $\hat{d}_2 \geq 2d_2$. (See Figure 3(a).) Because y is also a descendant of x, we have by Proposition 4.1 that

$$\operatorname{sum}(y) \leq \operatorname{sum}(x) - 2(d_1 - \hat{d}_1).$$

Therefore, by (18),

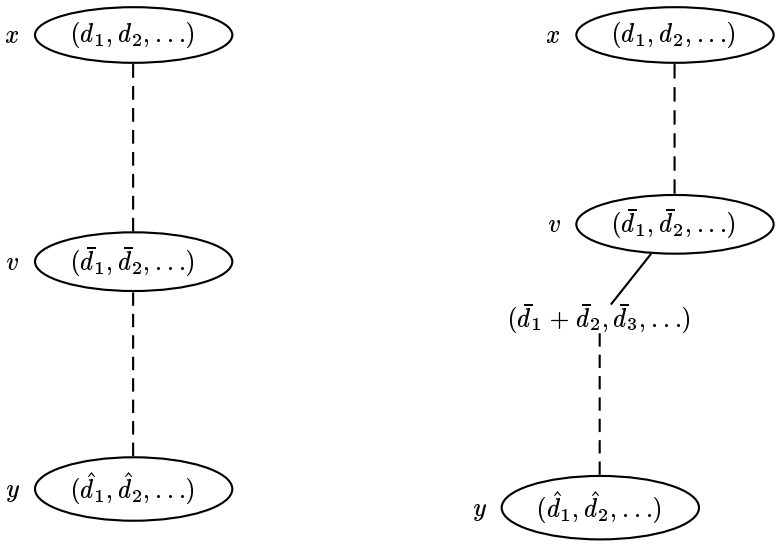
$$\begin{aligned} \operatorname{sum}(y) &< 2d_1 + 4d_2 - 2 - 2(d_1 - \hat{d}_1) \\ &= 2\hat{d}_1 + 4d_2 - 2 \\ &\leq 2\hat{d}_1 + 2\hat{d}_2 - 2. \end{aligned}$$

But

$$\text{number of ones in } y \leq \operatorname{sum}(y) - \hat{d}_1 - \hat{d}_2,$$

since $\hat{d}_1 > \hat{d}_2 \geq 2d_2 \geq 2$, and so

$$\text{number of ones in } y < \hat{d}_1 + \hat{d}_2 - 2,$$



(a) $\hat{d}_1 > \hat{d}_2 \geq 2d_2$ (b) $\hat{d}_1 > \hat{d}_2 = \bar{d}_2 \geq d_2$

FIG. 3. *The structure of the tree $T(n)$ in the two parts of Proposition* 4.3. *Unusual nodes are enclosed in ovals.*

contradicting (14).

For part (b), let y be an unusual descendant of left(v) with $\Delta_2 = k$. Let $(\bar{d}_1, \bar{d}_2, \ldots)$ be the Δ-vector of v and let $(\hat{d}_1, \hat{d}_2, \ldots)$ be the Δ-vector of y; we have $\hat{d}_1 > \hat{d}_2$ since y is unusual and $\hat{d}_2 = \bar{d}_2 \geq d_2$ by hypothesis. (See Figure 3(b).) Because y is a descendant of left(v), we have by Proposition 4.1 that

$$\begin{aligned} \text{sum}(y) &\leq \text{sum}(\text{left}(v)) - 2(\bar{d}_1 + \bar{d}_2 - \hat{d}_1) \\ &\leq \text{sum}(v) - 2(\bar{d}_1 + d_2 - \hat{d}_1) \end{aligned}$$

because $\text{sum}(v) = \text{sum}(\text{left}(v))$ and $\bar{d}_2 \geq d_2$. However, v is a descendant of x, so we have

$$\text{sum}(v) \leq \text{sum}(x) - 2(d_1 - \bar{d}_1)$$

and hence

$$\begin{aligned} \text{sum}(y) &\leq \text{sum}(x) - 2(d_1 - \bar{d}_1) - 2(\bar{d}_1 + d_2 - \hat{d}_1) \\ &= \text{sum}(x) - 2(d_1 + d_2 - \hat{d}_1). \end{aligned}$$

Therefore, by (18),

$$\begin{aligned} \text{sum}(y) &< 2d_1 + 4d_2 - 2 - 2(d_1 + d_2 - \hat{d}_1) \\ &= 2\hat{d}_1 + 2d_2 - 2 \\ &\leq 2\hat{d}_1 + 2\hat{d}_2 - 2, \end{aligned}$$

and we then reach the same contradiction to (14). □

PROPOSITION 4.4. *For any node $x \in T(n)$ and for any constant k,*

$$\sum_{\substack{\text{unusual internal nodes}\\ v \text{ with } \Delta_2 = k \text{ in the}\\ \text{subtree rooted at } x}} \frac{1}{2^{\text{depth}(v)}} \leq \frac{1}{2^{\text{depth}(x)-1}} \tag{19}$$

Proof. The proof is by induction on the height of the subtree rooted at x. If the x is a leaf, the result is immediate. Suppose the proposition holds for subtrees of height at most $h \geq 0$ and consider a subtree of height $h+1$ rooted at x. There are two cases. When the node x is an unusual node with $\Delta_2 = k$, by Proposition 4.3 we know that any unusual node in the left subtree of x has $\Delta_2 < k$ and any unusual node in the right subtree of x has $\Delta_2 \leq k$. Hence

$$\begin{aligned}
\sum_{\substack{\text{unusual internal nodes}\\ v \text{ with } \Delta_2 = k \text{ in the}\\ \text{subtree rooted at } x}} \frac{1}{2^{\text{depth}(v)}} &= \frac{1}{2^{\text{depth}(x)}} + \sum_{\substack{\text{unusual internal nodes}\\ v \text{ with } \Delta_2 = k \text{ in the}\\ \text{subtree rooted at left}(x)}} \frac{1}{2^{\text{depth}(v)}} \\
&\qquad + \sum_{\substack{\text{unusual internal nodes}\\ v \text{ with } \Delta_2 = k \text{ in the}\\ \text{subtree rooted at right}(x)}} \frac{1}{2^{\text{depth}(v)}} \\
&\leq \frac{1}{2^{\text{depth}(x)}} + 0 + \frac{1}{2^{\text{depth}(\text{right}(x))-1}} \\
&= \frac{1}{2^{\text{depth}(x)}} + \frac{1}{2^{\text{depth}(x)}} \\
&= \frac{1}{2^{\text{depth}(x)-1}},
\end{aligned}$$

as desired. Otherwise, direct application of the induction hypothesis to the two subtrees gives

$$\begin{aligned}
\sum_{\substack{\text{unusual internal nodes}\\ v \text{ with } \Delta_2 = k \text{ in the}\\ \text{subtree rooted at } x}} \frac{1}{2^{\text{depth}(v)}} &= \sum_{\substack{\text{unusual internal nodes}\\ v \text{ with } \Delta_2 = k \text{ in the}\\ \text{subtree rooted at left}(x)}} \frac{1}{2^{\text{depth}(v)}} \\
&\qquad + \sum_{\substack{\text{unusual internal nodes}\\ v \text{ with } \Delta_2 = k \text{ in the}\\ \text{subtree rooted at right}(x)}} \frac{1}{2^{\text{depth}(v)}} \\
&\leq \frac{1}{2^{\text{depth}(\text{left}(x))-1}} + \frac{1}{2^{\text{depth}(\text{right}(x))-1}} \\
&= \frac{1}{2^{\text{depth}(x)}} + \frac{1}{2^{\text{depth}(x)}} \\
&= \frac{1}{2^{\text{depth}(x)-1}}. \qquad \square
\end{aligned}$$

COROLLARY 4.5. *For any constant k,*

$$\sum_{\substack{\text{unusual internal} \\ \text{nodes } v \in T(n) \\ \text{with } \Delta_2 = k}} \frac{1}{2^{\text{depth}(v)}} \le 2. \tag{20}$$

Proof. Apply Proposition 4.4 to the root of the tree, which has depth zero. □

Corollary 4.5 can be interpreted probabilistically: The sum (20), which resembles Kraft's inequality, is the expected number of unusual internal nodes with $\Delta_2 = k$ encountered as we follow a random path down the tree from the root to a leaf. Proposition 4.4 says that if we encounter such a node, then half the time—whenever we go left—there will be no further such nodes as we continue, so the expected number of such nodes is at most $1 + 1/2 + 1/4 + \cdots = 2$.

5. Open problems. We conjecture that for our tree $T(n)$,

$$\sum_{\substack{\text{unusual internal} \\ \text{nodes } v \in T}} \frac{1}{2^{\text{depth}(v)}} = \Theta(\log n)$$

and that the algorithm departs by an additive logarithmic term from optimality as n increases. Moreover, the worst-case behavior of this algorithm is worse than the best possible $n - \nu(n)$: for $n = 12$, it can take 11 color comparisons. Two open questions are thus suggested:

- What are the exact average-case and worst-case analyses of our algorithm?
- Is there an algorithm that is optimal in *both* the average and worst cases?

Consider the tree formed by starting with the Δ-vector $(1, 1, \ldots, 1)$ at the root and proceeding as follows. Suppose the Δ-vector has the form (12). Let i be the smallest integer such that Δ_i/Δ_{i+1} is odd; if

$$\Delta_1 + \Delta_2 > \sum_{j \ge 3} \Delta_j,$$

make a color comparison between an element from A_1 and one from A_2; otherwise, make a color comparison between an element of A_i and one of A_{i+1}. We conjecture that this algorithm is optimal in the worst case and departs by at most an additive logarithmic term from optimality in the average case, but we are unable to analyze either case. Explicit computation of the trees verifies the optimality of this algorithm for $n \le 52$ in the worst case. In the average case, a similar computation verifies that this algorithm is optimal for $n \le 20$ but not for $n = 50$.

The majority problem is closely related to problems in system diagnosis [6], [10]. It is also similar to coin-weighing problems [5] and knight/knave problems [11]. These relationships deserve exploration.

Acknowledgments. We are indebted to Donald L. Burkholder for suggesting the method we originally used to calculate $M(n)$ in section 3. We are grateful to an anonymous referee who pointed out references [1] and [7] and who suggested several stylistic improvements.

AMPLIFICATION BY READ-ONCE FORMULAS*

MOSHE DUBINER† AND URI ZWICK‡

Abstract. Moore and Shannon have shown that relays with arbitrarily high reliability can be built from relays with arbitrarily poor reliability. Valiant used similar methods to construct monotone read-once formulas of size $O(n^{\alpha+2})$ (where $\alpha = \log_{\sqrt{5}-1} 2 \simeq 3.27$) that amplify $(\psi - \frac{1}{n}, \psi + \frac{1}{n})$ (where $\psi = (\sqrt{5}-1)/2 \simeq 0.62$) to $(2^{-n}, 1-2^{-n})$ and deduced as a consequence the existence of monotone formulas of the same size that compute the majority of n bits. Boppana has shown that any monotone read-once formula that amplifies $(p - \frac{1}{n}, p + \frac{1}{n})$ to $(\frac{1}{4}, \frac{3}{4})$ (where $0 < p < 1$ is constant) has size $\Omega(n^{\alpha})$ and that any monotone, not necessarily read-once, contact network (and in particular any monotone formula) that amplifies $(\frac{1}{4}, \frac{3}{4})$ to $(2^{-n}, 1-2^{-n})$ has size $\Omega(n^2)$.

We extend Boppana's results in two ways. We first show that his two lower bounds hold for general read-once formulas, not necessarily monotone, that may even include exclusive-or gates. We are then able to join his two lower bounds together and show that any read-once, not necessarily monotone, formula that amplifies $(p - \frac{1}{n}, p + \frac{1}{n})$ to $(2^{-n}, 1-2^{-n})$ has size $\Omega(n^{\alpha+2})$. This result does not follow from Boppana's arguments, and it shows that the amount of amplification achieved by Valiant is the maximal achievable using read-once formulas.

In a companion paper we construct monotone read-once contact networks of size $O(n^{2.99})$ that amplify $(\frac{1}{2} - \frac{1}{n}, \frac{1}{2} + \frac{1}{n})$ to $(\frac{1}{4}, \frac{3}{4})$. This shows that Boppana's lower bound for the first amplification stage does not apply to contact networks, even if they are required to be both monotone and read-once.

1. Introduction.

In a classical paper, Moore and Shannon [14] use what is now called the *amplification method* to show that relays with arbitrarily high reliability can be built from (so-called *crummy*) relays with arbitrarily poor reliability.

The amplification method was next used by several researchers to show that particular Boolean functions have small Boolean circuits and formulas. Bennett and Gill [3], extending a result of Adleman [1], used it to show that every language in the complexity class BPP has polynomial-size circuits. Ajtai and Ben-Or [2] used the amplification method to show that probabilistic constant-depth circuits can be simulated by deterministic constant-depth circuits with only a polynomial increase in size.

The main focus of attention in this paper is the elegant application of the amplification method by Valiant [19] to the construction of monotone formulas of size $O(n^{\alpha+2})$ (where $\alpha = \log_{\sqrt{5}-1} 2 \simeq 3.27$) for the majority function and its extension by Boppana [4] to the construction of $O(k^{\alpha+1} n \log n)$-size monotone formulas for the kth threshold function of n variables.

The research of this author was supported in part by the Basic Research Foundation administrated by the Israel Academy of Sciences and Humanities.

To show the existence of $O(n^{\alpha+2})$-size monotone formulas for the majority function, Valiant first constructs monotone read-once formulas that amplify $(\psi-\frac{1}{n},\psi+\frac{1}{n})$ (where $\psi=(\sqrt{5}-1)/2$) to $(2^{-n},1-2^{-n})$. Formal definitions of all of these terms will appear in the next section. The existence of monotone formulas of the same size for majority follows from a simple probabilistic argument.

Boppana [4] considered the question of whether Valiant had obtained an optimal amount of amplification in his construction and came very close to answering it positively. He observed that Valiant had actually constructed $O(n^{\alpha})$-size monotone read-once formulas that amplify $(\psi-\frac{1}{n},\psi+\frac{1}{n})$ to $(\frac{1}{4},\frac{3}{4})$ and $O(n^2)$-size monotone read-once formulas that amplify $(\frac{1}{4},\frac{3}{4})$ to $(2^{-n},1-2^{-n})$. The $O(n^{\alpha+2})$-size monotone read-once formulas that amplify $(\psi-\frac{1}{n},\psi+\frac{1}{n})$ to $(2^{-n},1-2^{-n})$ are easily obtained by combining these two subconstructions. Boppana was able to show that each one of these subconstructions achieved an optimal amount of amplification. However, it does not seem to follow from Boppana's arguments that the combined construction is also optimal.

We are able to join together the two lower bounds of Boppana and show that any monotone read-once formula that amplifies $(p-\frac{1}{n},p+\frac{1}{n})$ to $(2^{-n},1-2^{-n})$ (where $0<p<1$ is fixed) does indeed have to be of size $\Omega(n^{\alpha+2})$. This gives a complete positive answer to the question of whether Valiant's construction obtains an optimal amount of amplification.

We are also able to strengthen Boppana's results in another respect. We show that the combined $\Omega(n^{\alpha+2})$ lower bound applies even if the read-once formulas are allowed to use negations and exclusive-or (XOR) gates (as well as the monotone AND and OR gates). We deal with negations directly. XOR gates are dealt with by showing that for every formula with XOR gates there exists a probabilistic formula without XOR gates of the same size that achieves the same amount of amplification.

Boppana had used two different (we are tempted to say incompatible) methods to get his two lower bounds for the two amplification stages. To obtain the combined lower bound, we have to slightly strengthen his first lower bound and exhibit an alternative proof for his second. In particular, we obtain a slightly stronger version of what we call *Boppana's inequality* (see section 2) and present an analytical proof of it. (Boppana resorted to numerical experimentation in the proof of his inequality.) We also generalize Boppana's bound on the derivatives of univariate amplification functions to bounds on the partial derivatives of multivariate amplification functions.

As mentioned, Boppana's second lower bound applies to general monotone contact networks. Using a result of Lupanov [13], it can be shown that it does not apply to nonmonotone contact networks. Thus in the contact-networks model, negations do help amplify. More details can be found in [5] and [6]. We also note that negations and XOR gates seem to help in the construction of formulas for the majority function. In [15] and [16], nonmonotone formulas of size $O(n^{4.57})$ without XOR gates and of size $O(n^{3.13})$ with XOR gates were constructed.

In a companion paper [6] (see also [5]), we show that there exist monotone undirected contact networks of size $O(n^{2.99})$ that amplify $(\frac{1}{2}-\frac{1}{n},\frac{1}{2}+\frac{1}{n})$ to $(\frac{1}{4},\frac{3}{4})$. Certain conjectures in percolation theory imply that the size of the amplifying networks can be further reduced to $O(n^{8/3+o(1)})$ and perhaps even further. This extends the results of Moore and Shannon [14] and those of Valiant [19] and shows that Boppana's first lower bound does not apply to the contact networks, even if they are required to be both monotone and read-once. It also implies the existence of *undirected* monotone contact networks of size $O(n^{4.99})$ (or $O(n^{4.67})$, relying on the percolation conjectures)

that compute the majority of n bits. Smaller *directed* monotone networks for majority have recently been constructed by Radhakrishnan and Subrahmanyam [18].

Other works relevant to the subjects considered in this paper are [8], [9], [10], and [17].

The rest of the paper is organized as follows. Section 2 is mainly composed of definitions. In section 3 we present the strengthened version of Boppana's inequality. In section 4, we obtain the bounds on the derivatives of multivariate and univariate amplification functions. These bounds are used in section 5 to strengthen Boppana's bound for the first amplification stage. In section 6, we put forth a new approach to proving amplification lower bounds. This approach is based on a simple functional inequality. Using this approach, we present an alternative proof to Boppana's lower bound for the second amplification stage. In section 7, we show how to combine the methods of the two preceding sections and obtain our unified lower bound. In section 8, we show that read-once formulas that include XOR gates can be simulated (as far as amplification is concerned) by probabilistic read-once formulas without XOR gates with no increase in size. All the results of sections 5, 6, and 7 are valid for probabilistic, not only deterministic, formulas. Thus all of these results, proved so far only for formulas without XOR gates, remain valid even if XOR gates are used. We conclude in section 9 with some open problems.

Although the basic ideas used in this work are fairly simple, many proofs, especially those of inequalities, are extremely technical. To maintain the readability of the paper, the more technical and lengthy proofs have been put in the appendices.

A preliminary version of this paper (and of [6]) appeared in [5].

2. Preliminaries. Following Moore and Shannon [14] and Boppana [4], we introduce the following two definitions

DEFINITION 2.1 (amplification functions). *Given a Boolean function* $f : \{0,1\}^n \to \{0,1\}$*, we define its* multivariate amplification function $f : [0,1]^n \to [0,1]$ *as follows:* $f(p_1, p_2, \ldots, p_n) = \Pr[f(\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n) = 1]$*, where* $\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n$ *are independent random variables and* $\mathbf{x}_i$ *assumes the value* 1 *with probability* p_i *and the value* 0 *with probability* $1 - p_i$*. We define the* univariate amplification function *of* f *to be* $f(p) = f(p, p, \ldots, p)$*. Since the (multivariate) amplification function is an extension of the original Boolean function, we use the same notation for both.*

DEFINITION 2.2 (amplification from/to). *A Boolean function* $f : \{0,1\}^n \to \{0,1\}$ amplifies (p, q) *to* (p', q') *if* $f(p) = p'$ *and* $f(q) = q'$*. It amplifies* (p, q) *to* at least (p', q') *if* $f(p) \le p'$ *and* $f(q) \ge q'$*.*

The main objects considered in this paper are formulas.

DEFINITION 2.3 (formulas). *A* formula *of* n *variables is defined recursively as follows:* (i) *for* $1 \le i \le n$*, the variables* x_i *and their negations* $\overline{x_i}$ *are formulas*; (ii) *if* f *and* g *are formulas, then so are* $(\neg f)$*,* $(f \wedge g)$*,* $(f \vee g)$*, and* $(f \oplus g)$*. A formula in which no XOR gates are used is called* unate *or* de Morgan*. A unate formula in which no negations are used is called* monotone*. Formulas define Boolean functions in the obvious way. The size of a formula* f*, denoted by* $size(f)$*, is the number of occurrences of variables in it.*

DEFINITION 2.4 (probabilistic formulas). *A* probabilistic *(monotone, unate) formula is simply a discrete probability distribution over deterministic (monotone, unate) formulas. The size of a probabilistic formula* F *is defined to be the maximum size of a formula* f *whose probability according to the distribution induced by* F *is positive. The amplification function* $F(p_1, \ldots, p_n)$ *of a probabilistic formula* F *is simply*

$F(p_1, \ldots, p_n) = E_{f \in F} f(p_1, \ldots, p_n)$, where E denotes expectation relative to the distribution induced by F.

It is easy to see that monotone and unate formulas correspond to monotone and nonmonotone *series-parallel* contact networks. For more details the reader is referred to Boppana [4].

Most of the formulas encountered in this work will be read-once.

DEFINITION 2.5 (read-once). *A formula is said to be* read-once *if every variable appears in it at most once.*

We investigate the minimal size of formulas required to achieve given amplification goals.

DEFINITION 2.6 (amplification complexity). *If $0 < p_0, q_0, p_1, q_1 < 1$, we denote by $N(p_1, q_1 \mid p_0, q_0)$ the minimum size of a unate read-once formula that amplifies (p_0, q_0) to (p_1, q_1). We denote by $N_\oplus(p_1, q_1 \mid p_0, q_0)$ the corresponding measure for general read-once formulas.*

In what follows, we refer to the following two inequalities.

THEOREM 2.7 (Hölder's inequality). *If $\alpha, \beta > 1$ and $\frac{1}{\alpha} + \frac{1}{\beta} = 1$, then for any two real vectors x and y, we have*

$$\langle |x|, |y| \rangle = \sum_{i=1}^{n} |x_i y_i| \leq \left(\sum_{i=1}^{n} |x_i|^\alpha \right)^{1/\alpha} \cdot \left(\sum_{i=1}^{n} |y_i|^\beta \right)^{1/\beta} = \|x\|_\alpha \cdot \|y\|_\beta .$$

THEOREM 2.8 (Boppana's inequality). *Let $H(x) = -x \log_2 x - (1-x) \log_2 (1-x)$ be the usual binary entropy function and let $\beta = \log_{(\sqrt{5}+1)/2} 2 \simeq 1.44$. Then for every $0 < x, y \leq 1$, we have*

$$\left(\frac{H(x)}{x} \right)^\beta + \left(\frac{H(y)}{y} \right)^\beta \leq \left(\frac{H(xy)}{xy} \right)^\beta .$$

In what follows we say that a function F satisfies Boppana's inequality iff $F(x) = F(1-x) \geq 0$ for every $0 \leq x \leq 1$ and F (substituting for H) satisfies the inequality in the above theorem.

3. Strengthening Boppana's inequality. Boppana's inequality, stated in the previous section, forms the basis of his lower bound for the first amplification stage. To get some of our extended lower bounds, we need a slightly stronger version of his inequality. This version is obtained by replacing the entropy function $H(x)$ by a function $G(x)$ with the tightest possible asymptotic behavior near $x = 0$ and $x = 1$.

To prove his inequality, Boppana had to make many numerical checks involving functions of two variables. (In one point of the argument, for example, he has to estimate the third derivatives of the function $\widetilde{H}(x, y) = (H(xy)/xy)^\beta - (H(x)/x)^\beta - (H(y)/y)^\beta$ and show that the Hessian matrix of $\widetilde{H}$ is positive definite on the entire region $[0.55, 0.65] \times [0.55, 0.65]$.) We are able to exhibit a much simpler proof to our strengthened inequality. We show that it follows from some relatively simple one-variable inequalities.

Our new function $G(x)$ is defined as follows:

$$G(x) = \begin{cases} x \left(\ln \frac{\gamma}{x} \right)^{1/\beta} & \text{if } 0 \leq x \leq \frac{1}{2}, \\ (1-x) \left(\ln \frac{\gamma}{1-x} \right)^{1/\beta} & \text{if } \frac{1}{2} \leq x \leq 1, \end{cases}$$

where

$$\ln \gamma = \frac{2 - \psi - \ln 4}{\beta} \simeq -0.003005.$$

We claim that $G(x)$ satisfies Boppana's inequality.

LEMMA 3.1. *For every $0 < x, y \leq 1$, we have $(\frac{G(x)}{x})^\beta + (\frac{G(y)}{y})^\beta \leq (\frac{G(xy)}{xy})^\beta$.*

Proof. See Appendix A. □

The somewhat peculiar constant γ in the definition of $G(x)$ was chosen so that $\widehat{G}(\psi) = \widehat{G}(1-\psi)$ where $\widehat{G}(x) = x \cdot \frac{d}{dx}(\frac{G(x)}{x})^\beta$. As shown in the next lemma, this is a necessary condition that must be satisfied by any (symmetric) function that wishes to satisfy Boppana's inequality.

LEMMA 3.2. *If $G(x)$ is a symmetric function that satisfies Boppana's inequality and if $G(x)$ is differentiable at $x = \psi$, then $\widehat{G}(\psi) = \widehat{G}(1-\psi)$, where $\widehat{G}(x) = x \cdot \frac{d}{dx}(\frac{G(x)}{x})^\beta$.*

Proof. Since $\psi^2 = 1 - \psi$, $\psi^\beta = \frac{1}{2}$, and $G(\psi^2) = G(1-\psi) = G(\psi)$, we get that $2(\frac{G(\psi)}{\psi})^\beta = (\frac{G(\psi^2)}{\psi^2})^\beta$. It follows that Boppana's inequality is always satisfied with equality at the point (ψ, ψ). As a consequence, the point (ψ, ψ) must be a local minimum of the function $\widetilde{G}(x,y) = \widetilde{G}(xy) - \widetilde{G}(x) - \widetilde{G}(y)$, where $\widetilde{G}(x) = (\frac{G(x)}{x})^\beta$. It is easy to verify that

$$\frac{\partial \widetilde{G}(x,y)}{\partial x} = \frac{1}{x}\left[xy\widetilde{G}'(xy) - x\widetilde{G}'(x)\right] = \frac{1}{x}\left[\widehat{G}(xy) - \widehat{G}(x)\right].$$

Since this partial derivative must vanish at (ψ, ψ), we get that $\widehat{G}(1-\psi) = \widehat{G}(\psi^2) = \widehat{G}(\psi)$. □

Graphs of the function $G(x)$ are discussed in the appendices. It can be seen from these graphs that $G(x)$ has a small cusp at $x = \frac{1}{2}$. This will not cause us any trouble. A variant of the function $G(x)$ in which this cusp is replaced by a straight line connecting the two local maxima also satisfies Boppana's inequality. This variant is used by us in [7].

It is easy to see that for small values of x, we have $G(x) \approx x(\ln \frac{1}{x})^{1/\beta}$ while $H(x) \approx x \ln \frac{1}{x}$ and thus $G(x) \ll H(x)$. This allows us to get the improved amplification bounds.

4. Bounds on derivatives of amplification functions. The basic theorem from which all the results of this section follow is the following.

THEOREM 4.1. *If f is a unate read-once formula (or a read-once series-parallel contact network) that depends on n variables and if $I(x)$ satisfies Boppana's inequality, then*

$$\left(\sum_{i=1}^{n} \left| I(x_i) \cdot \frac{\partial f}{\partial x_i} \right|^\beta \right)^{1/\beta} \leq I(f).$$

Proof. The proof is by induction on the structure of f. If $f = x_i$ or $f = \overline{x_i}$, then the inequality is easily verified since $|\frac{\partial f}{\partial x_i}| = 1$ and $I(x_i) = I(1-x_i) = I(f)$. If $f = \neg g$, then the inequality follows easily from the induction hypothesis since $f = 1 - g$ and therefore $|\frac{\partial f}{\partial x_i}| = |\frac{\partial g}{\partial x_i}|$ and $I(f) = I(1-f) = I(g)$.

If $f = f_1 \wedge f_2$ and if $f_1(x_1, \ldots, x_n)$ and $f_2(y_1, \ldots, y_m)$ are the amplification functions of f_1 and f_2, then the amplification function of f is $f(x_1, \ldots, x_n, y_1, \ldots, y_m) =$

$f_1(x_1,\ldots,x_n)f_2(y_1,\ldots,y_m)$. As a consequence, $\frac{\partial f}{\partial x_i} = \frac{\partial f_1}{\partial x_i}\cdot f_2$ and $\frac{\partial f}{\partial y_j} = f_1\cdot\frac{\partial f_2}{\partial y_j}$. For convenience, we let $x_{n+1} = y_1,\ldots,x_{n+m} = y_m$.

Using the induction hypothesis and then Boppana's inequality, we therefore get

$$\begin{aligned}\sum_{i=1}^{n+m}\left|I(x_i)\cdot\frac{\partial f}{\partial x_i}\right|^\beta &\le f_2^\beta\cdot\sum_{i=1}^{n}\left|I(x_i)\cdot\frac{\partial f_1}{\partial x_i}\right|^\beta + f_1^\beta\cdot\sum_{i=n+1}^{n+m}\left|I(x_i)\cdot\frac{\partial f_2}{\partial x_i}\right|^\beta\\ &\le (f_2\cdot I(f_1))^\beta + (f_1\cdot I(f_2))^\beta \;=\; (f_1f_2)^\beta\cdot\left[\left(\frac{I(f_1)}{f_1}\right)^\beta + \left(\frac{I(f_2)}{f_2}\right)^\beta\right]\\ &\le (f_1f_2)^\beta\cdot\left(\frac{I(f_1f_2)}{f_1f_2}\right)^\beta \;=\; (I(f))^\beta.\end{aligned}$$

This completes the proof since any unate gate can be obtained by combining an $\wedge$-gate with negations. □

If in addition to satisfying Boppana's inequality, the function $I(x)$ also satisfies the inequality

$$\left(\frac{I\left(\frac{1-x}{2}\right)}{x}\right)^\beta + \left(\frac{I\left(\frac{1-y}{2}\right)}{y}\right)^\beta \le \left(\frac{I\left(\frac{1-xy}{2}\right)}{xy}\right)^\beta$$

for every $0 < x, y \le 1$, then we can show directly that the inequality in the above lemma holds for read-once formulas that may include XOR gates. Both the entropy function $H(x)$ and the function $G(x)$ introduced in section 3 satisfy this inequality. We omit the details since the same amplification bounds will follow from the more general arguments of section 8.

We denote by $\nabla f(x)$ the *gradient* $\nabla f = (\frac{\partial f}{\partial x_1},\ldots,\frac{\partial f}{\partial x_n})$ of f evaluated at the point $(x,\ldots,x)$. As an immediate corollary to the previous lemma, we get the following.

COROLLARY 4.2. *If f is a unate read-once formula, then*

$$\|\nabla f(x)\|_\beta \le \frac{I(f(x))}{I(x)},$$

and if p_c is the critical probability *for which $f(p_c) = p_c$, then*

$$\|\nabla f(p_c)\|_\beta \le 1.$$

As a second corollary to Theorem 4.1, we get the following result obtained by Boppana [4] for monotone read-once formulas.

COROLLARY 4.3. *If f is a unate read-once formula that depends on n variables, then*

$$|f'(x)| \le n^{1/\alpha}\cdot\frac{I(f(x))}{I(x)}.$$

Proof. A simple application of Hölder's inequality yields

$$\begin{aligned}|f'(x)| \le \sum_{i=1}^{n}\left|\frac{\partial f}{\partial x_i}(x)\right| &\;\le\; \left(\sum_{i=1}^{n}1\right)^{1/\alpha}\cdot\left(\sum_{i=1}^{n}\left|\frac{\partial f}{\partial x_i}(x)\right|^\beta\right)^{1/\beta}\\ &= n^{1/\alpha}\cdot\|\nabla f(x)\|_\beta \;\le\; n^{1/\alpha}\cdot\frac{I(f(x))}{I(x)}.\end{aligned}$$

□

It was pointed out by one of the referees that the inequality $\sum_{i=1}^{n} |x_i| \le n^{1/\alpha} \cdot (\sum_{i=1}^{n} |x_i|^{\beta})^{1/\beta}$ used in the proof above follows immediately from Jensen's inequality, which is more elementary than Hölder's inequality. This is interesting since it shows that our proof, in contrast to Boppana's proof, does not use the full power of Hölder's inequality.

Again, if $I(x)$ satisfies the additional inequality mentioned above, as G and H do, then Corollary 4.3 holds for general, not necessarily unate, read-once formulas. We claim that the inequality in Corollary 4.3 with $G(x)$ plugged into it is, up to constant factors, the strongest valid inequality of its kind. We do not elaborate on it here.

5. Local amplification bounds. Boppana [4] used Corollary 4.3 with the entropy function $H(x)$ plugged into it together with the mean-value theorem to get a lower bound on the size of the formulas required to amplify (p_0, q_0) to (p_1, q_1). A stronger lower bound is obtained by replacing the entropy function by the new function $G(x)$ and by integrating the upper bound obtained for $|f'(x)|$.

Let

$$M(x,y) = \left| \int_x^y \frac{du}{G(u)} \right|^{\alpha}.$$

THEOREM 5.1. *Any read-once formula that amplifies* (p_0, q_0) to (p_1, q_1) has size at least

$$N(p_1, q_1 \mid p_0, q_0) \ge \frac{M(p_1, q_1)}{M(p_0, q_0)}.$$

Proof. Let f be a read-once formula that depends on n variables and amplifies (p_0, q_0) to (p_1, q_1). Using Corollary 4.3 and a simple change of variables, we get that

$$\left| \int_{p_1}^{q_1} \frac{dx}{G(x)} \right| \le \left| \int_{p_0}^{q_0} \frac{f'(x)dx}{G(f(x))} \right| \le \left| \int_{p_0}^{q_0} \frac{n^{1/\alpha} dx}{G(x)} \right| = n^{1/\alpha} \left| \int_{p_0}^{q_0} \frac{dx}{G(x)} \right|. \qquad \square$$

Since

$$\int \frac{dx}{x \left(\ln \frac{\gamma}{x}\right)^{1/\beta}} = -\alpha \left(\ln \frac{\gamma}{x}\right)^{1/\alpha},$$

it is easily verified that

$$M(x,y) = \left| \int_x^y \frac{du}{G(u)} \right|^{\alpha} = C \cdot \begin{cases} m(x,y) & \text{if } x \le y \le \frac{1}{2}, \\ (m(x,\frac{1}{2})^{1/\alpha} + m(1-y,\frac{1}{2})^{1/\alpha})^{\alpha} & \text{if } x \le \frac{1}{2} \le y, \\ m(1-y,1-x) & \text{if } \frac{1}{2} \le x \le y, \\ M(y,x) & \text{if } y < x, \end{cases}$$

where $C = \alpha^{\alpha}$ and

$$m(x,y) = \left[\left(\ln \frac{\gamma}{x}\right)^{1/\alpha} - \left(\ln \frac{\gamma}{y}\right)^{1/\alpha} \right]^{\alpha}.$$

Clearly, $M(x,y) = M(y,x) = M(1-x,1-y)$.

In section 7, the function $M(x,y)$ will be compared with some other functions. It will be convenient to scale $M(x,y)$ before these comparisons and assume that $C = 10^6$. Of course, this will not affect the validity of Theorem 5.1.

As an immediate corollary of Theorem 5.1, we get the following.

COROLLARY 5.2. *Any unate read-once formula that amplifies* $(p-\frac{1}{n},p+\frac{1}{n})$ *to at least* $(\frac{1}{4},\frac{3}{4})$ *(where* $0<p<1$ *is fixed) is of size* $\Omega(n^{\alpha})$ *and any unate read-once formula that amplifies* $(p-\frac{1}{n},p+\frac{1}{n})$ *to at least* $(2^{-n},\frac{1}{2})$ *or to at least* $(\frac{1}{2},1-2^{-n})$ *is of size* $\Omega(n^{\alpha+1})$.

Proof. The proof follows easily since $M(p-\frac{1}{n},p+\frac{1}{n})=\Theta(n^{-\alpha})$ and $M(2^{-n},\frac{1}{2})$, $M(\frac{1}{2},1-2^{-n})=\Theta(n)$. □

It can be checked that both of these bounds are optimal. Valiant [19] obtained monotone formulas of size $O(n^{\alpha})$ that amplify $(p-\frac{1}{n},p+\frac{1}{n})$ to $(\frac{1}{4},\frac{3}{4})$. Boppana [4] obtained monotone formulas of size $O(n^{\alpha+1})$ that amplify $(p-\frac{1}{n},p+\frac{1}{n})$ to $(2^{-n},\frac{1}{2})$ or to $(\frac{1}{2},1-2^{-n})$. The fact that the second lower bound obtained using the function $G(x)$ is tight shows that the asymptotic behavior of $G(x)$ near $x=0$ and $x=1$ cannot be improved.

Since $M(2^{-n},1-2^{-n})$ is still $\Theta(n)$, the methods used so far imply only an $\Omega(n^{\alpha+1})$ lower bound on amplification from $(p-\frac{1}{n},p+\frac{1}{n})$ to $(2^{-n},1-2^{-n})$. This will be improved in section 7 to a tight $\Omega(n^{\alpha+2})$ lower bound.

We note that the use of the function $G(x)$ in place of $H(x)$ is essential in obtaining the $\Omega(n^{\alpha+1})$ lower bounds of Corollary 5.2. Had we used $H(x)$, we would have obtained only $\Omega(n^{\alpha}\log n)$ lower bounds.

6. Global amplification bounds. The main result of this section is the following simple yet powerful theorem. Let $(0,1)$ denote the open unit interval and let $(0,1)^2$ denote the open unit square in the plane.

THEOREM 6.1. *If* $L(x,y)$ *is defined on* $(0,1)^2$ *and satisfies the following two conditions,*

$$\begin{aligned} L(x_1x_2,y_1y_2) &\le L(x_1,y_1)+L(x_2,y_2) \quad \forall\ 0<x_1,x_2,y_1,y_2<1,\\ L(x,y) &= L(1-x,1-y) \qquad\qquad \forall\ 0<x,y<1, \end{aligned}$$

then for every $0<p_0,q_0,p_1,q_1<1$, *we have*

$$N(p_1,q_1 \mid p_0,q_0) \ge \frac{L(p_1,q_1)}{L(p_0,q_0)}\ .$$

Proof We prove by induction on the structure of f that if f amplifies (p_0,q_0) to (p_1,q_1), then $\mathit{size}(f)\ge L(p_1,q_1)/L(p_0,q_0)$. The basis of the induction is easily established.

If $f=\neg g$, then g amplifies (p_0,q_0) to $(1-p_1,1-q_1)$. Since $\mathit{size}(f)=\mathit{size}(g)$ and $L(1-p_1,1-q_1)=L(p_1,q_1)$, the required inequality follows immediately from the induction hypothesis.

If $f=f_1\wedge f_2$ and if f_1 and f_2 amplify (p_0,q_0) to (x_1,y_1) and (x_2,y_2), respectively, then $p_1=x_1x_2$ and $q_1=y_1y_2$. By the induction hypothesis and the first condition of L, we have

$$\begin{aligned} \mathit{size}(f) &= \mathit{size}(f_1)+\mathit{size}(f_2)\\ &\ge \frac{L(x_1,y_1)+L(x_2,y_2)}{L(x_0,y_0)} \ge \frac{L(x_1x_2,y_1y_2)}{L(p_0,q_0)} = \frac{L(p_1,q_1)}{L(p_0,q_0)}. \end{aligned}$$ □

Note that in both Theorems 5.1 and 6.1, the lower bounds obtained were of a similar form. Both involved a quotient of some two-variable *potential* function evaluated at the pre- and post-amplification probabilities.

The approach of Theorem 6.1 seems to be more general than the approach of the previous section. Numerical tests seem to suggest that the function $M(x, y)$ of section 5 satisfies the condition $M(x_1x_2, y_1y_2) \le M(x_1, y_1)+M(x_2, y_2)$ of Theorem 6.1. If this were indeed the case, then Theorem 5.1 would follow immediately from Theorem 6.1.

With some additional work, the numerical tests that we performed can probably be turned into a proof that is similar in spirit to the original proof that Boppana had given for his inequality—that the function $M(x, y)$ satisfies the inequality $M(x_1x_2, y_1y_2) \le M(x_1, y_1) + M(x_2, y_2)$. This would be tedious, however, since four, and not just two, variables are involved this time. We did not carry out this extra work since the direct proof given to Theorem 5.1 seems to be more informative.

We now use Theorem 6.1 to obtain an alternative proof to the lower bounds for the second amplification stage obtained by Moore and Shannon [14] and Boppana [4]. The new proof works only for read-once formulas and not for general read-once networks. However, it does work for general, not necessarily monotone, read-once formulas.

Perhaps the simplest function satisfying the conditions of Theorem 6.1 is the following function:

$$L'(x, y) = \begin{cases} \ln \frac{1}{x} \cdot \ln \frac{1}{1-y} & \text{if } x \le y, \\ \ln \frac{1}{1-x} \cdot \ln \frac{1}{y} & \text{if } x \ge y. \end{cases}$$

LEMMA 6.2. *The function $L'(x, y)$ satisfies the conditions of Theorem* 6.1.

Proof. The condition $L'(x, y) = L'(1 - x, 1 - y)$ is easily verified. Let $\ell'(x, y) = \ln \frac{1}{x} \cdot \ln \frac{1}{1-y}$. Note that $\ell'(1 - x, 1 - y) = \ell'(y, x)$. When $x \le y$, we have $\frac{1}{x} \ge \frac{1}{y}$ and $\frac{1}{1-y} \ge \frac{1}{1-x}$ and therefore

$$\ell'(x, y) = \ln \tfrac{1}{x} \cdot \ln \tfrac{1}{1-y} \ge \ln \tfrac{1}{1-x} \cdot \ln \tfrac{1}{y} = \ell'(y, x).$$

When $x \ge y$, the opposite inequality holds. Thus $L'(x, y) = \max\{\ell'(x, y), \ell'(y, x)\}$. We now have

$$\begin{aligned} \ell'(x_1x_2, y_1y_2) &= \ln \tfrac{1}{x_1x_2} \cdot \ln \tfrac{1}{1-y_1y_2} \\ &= \left(\ln \tfrac{1}{x_1} + \ln \tfrac{1}{x_2}\right) \cdot \ln \tfrac{1}{1-y_1y_2} \le \ln \tfrac{1}{x_1} \cdot \ln \tfrac{1}{1-y_1} + \ln \tfrac{1}{x_2} \ln \tfrac{1}{1-y_2} \\ &= \ell'(x_1, y_1) + \ell'(x_2, y_2) \le L'(x_1, y_1) + L'(x_2, y_2) \end{aligned}$$

and

$$\ell'(y_1y_2, x_1x_2) \le \ell'(y_1, x_1) + \ell'(y_2, x_2) \le L'(x_1, y_1) + L'(x_2, y_2).$$

Consequently,

$$L'(x_1x_2, y_1y_2) = \max\{\ell'(x_1x_2, y_1y_2), \ell'(y_1y_2, x_1x_2)\} \le L'(x_1, y_1) + L'(x_2, y_2),$$

as required. □

As an immediate corollary, we extend the lower bound of Moore and Shannon [14] to include nonmonotone read-once formulas.

COROLLARY 6.3. *Every unate read-once formula that amplifies $(\frac{1}{4}, \frac{3}{4})$ to at least $(2^{-n_1}, 1 - 2^{-n_2})$ is of size $\Omega(n_1n_2)$.*

Boppana [4] obtained a stronger version of this inequality when n_1 and n_2 are not within an exponent of each other. To extend his result, we use Theorem 6.1 in

conjunction with the more complicated function

$$L(x,y) = \begin{cases} \ell(x,y) & \text{if } x \le y \le 1-x, \\ \ell(1-y,1-x) & \text{if } x, 1-x \le y, \\ \ell(1-x,1-y) & \text{if } 1-x \le y \le x, \\ \ell(y,x) & \text{if } y \le x, 1-x, \end{cases}$$

where

$$\ell(x,y) = \ln\frac{1}{x} \cdot \ln\frac{\ln\frac{1}{x}}{\ln\frac{1}{y}}.$$

LEMMA 6.4. *The function $L(x,y)$ satisfies the conditions of Theorem* 6.1.

Proof. The proof is tedious and it is presented in Appendix B. □

Using $L(x,y)$, we extend Boppana's second lower bound to nonmonotone read-once formulas.

COROLLARY 6.5. *Every unate read-once formula that amplifies $(\frac{1}{4},\frac{3}{4})$ to at least $(2^{-n_1}, 1-2^{-n_2})$ is of size $\Omega(n_1 n_2 + n_1 \log n_1 + n_2 \log n_2)$.*

The results of this section are stated for unate read-once formulas. The validity of all the results for general read-once formulas will follow from the results of section 8.

7. A unified lower bound for amplification. Corollary 5.2 gives in particular an $\Omega(n^{\alpha+1})$ lower bound on the size of unate read-once formulas that amplify $(p-\frac{1}{n}, p+\frac{1}{n})$ to at least $(2^{-n}, 1-2^{-n})$ (for a fixed $0<p<1$). In this section, we combine the proof techniques of sections 5 and 6 and improve this to a tight $\Omega(n^{\alpha+2})$ lower bound. We begin with the following generalization of Theorem 6.1.

THEOREM 7.1. *If $K(x,y)$ is defined on $(0,1)^2$ and satisfies the conditions*

$$\begin{aligned} K(x_1x_2, y_1y_2) &\le \max\{K(x_1,y_1) + K(x_2,y_2),\ M(x_1x_2, y_1y_2)\}, \\ K(x,y) &\ge M(x,y), \\ K(x,y) &= K(1-x,1-y) \end{aligned}$$

for every $0 < x_1, x_2, y_1, y_2 < 1$ and $0 < x, y < 1$, and if it is already known for every $0 < p_0, p_1, q_0, q_1 < 1$ that

$$N(p_1,q_1 \mid p_0,q_0) \ge \frac{M(p_1,q_1)}{M(p_0,q_0)},$$

then we also have for every $0 < p_0, p_1, q_0, q_1 < 1$ that

$$N(p_1,q_1 \mid p_0,q_0) \ge \frac{K(p_1,q_1)}{K(p_0,q_0)}.$$

Proof. The proof is a trivial modification of the proof of Theorem 6.1. □

To get our unified lower bound, we apply Theorem 7.1 to a function $K(x,y)$ obtained by stitching together $M(x,y)$ of section 5 (with $C = 10^6$), which did well for the first amplification stage, and $L(x,y)$ of section 6, which did well for the second amplification stage. The function $K(x,y)$ will equal $M(x,y)$ when x and y are very close to one another and it will equal $L(x,y)$ when they are far apart.

The function $K(x,y)$ is defined as follows:

$$K(x,y) = \begin{cases} M(x,y) & \text{if } (x,y) \in \mathcal{A}, \\ \max\{M(x,y), L(x,y)\} & \text{if } (x,y) \notin \mathcal{A}, \end{cases}$$

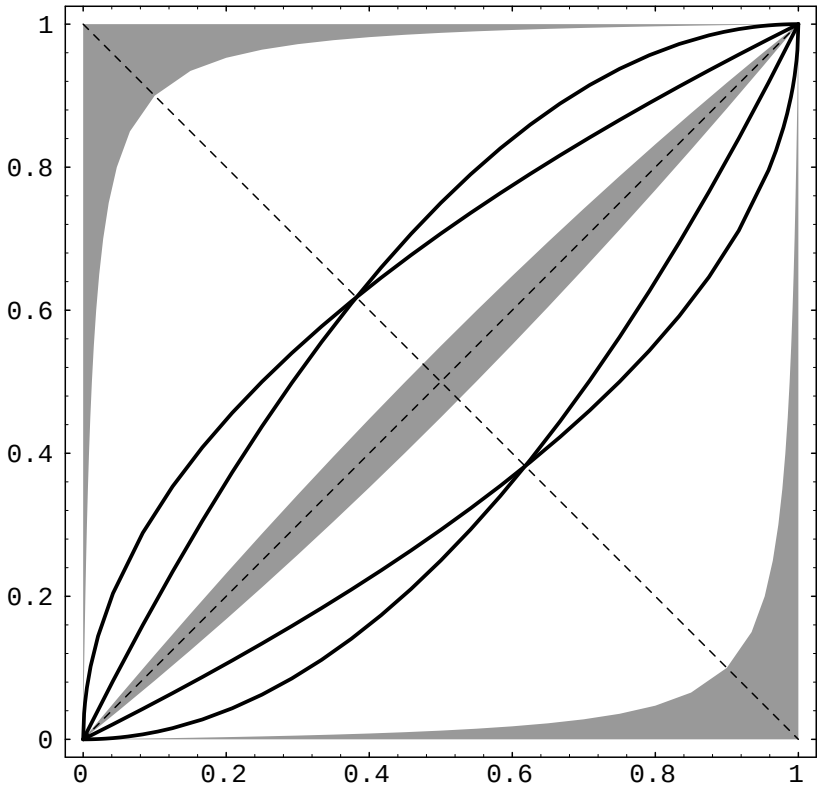

FIG. 1. *The region $\mathcal{A}$ (composed of $\mathcal{A}'$ and $\mathcal{A}''$) and the regions in which $L(x,y) \geq M(x,y)$.*

where

$$\mathcal{A} = \mathcal{A}' \cup \mathcal{A}'', \qquad \mathcal{A}' = \mathcal{R}'_2, \qquad \mathcal{A}'' = \mathcal{R}''_2$$

and

$$\mathcal{R}'_d = \left\{ (x,y) : \frac{1}{d} \leq \left| \frac{\ln \frac{1}{x}}{\ln \frac{1}{y}} \right| \leq d \right\}, \qquad \mathcal{R}''_d = \left\{ (x,y) : \frac{1}{d} \leq \left| \frac{\ln \frac{1}{1-x}}{\ln \frac{1}{1-y}} \right| \leq d \right\}.$$

Figure 1 gives a schematic description of the region $\mathcal{A}$ (composed of $\mathcal{A}'$ and $\mathcal{A}''$) and the two regions (shown shaded) in which $L(x,y) \geq M(x,y)$. These two extremely thin regions stretch along the diagonal and the boundary of the unit square. It can be checked (see the proof of Claim 7.4(a) in Appendix C) that when $x \leq y$ and when both x and y are very small, then $L(x,y)/M(x,y) \approx \ln u / C[1 - (1/u)^{1/\alpha}]^{\alpha}$, where $u = \ln \frac{1}{x} / \ln \frac{1}{y}$. Thus $L(x,y) \geq M(x,y)$ roughly when $u \leq 1.01$ or when $u \geq e^{10^6}$, i.e., when $y^{1.01} \leq x \leq y$ or when $y^{e^{10^6}} \geq x$. The definition of $\mathcal{A}$ was conveniently chosen to lie between these two regions. Note that although it is impossible to see it in Figure 1, the upper boundary of the inner region in which $L(x,y) \geq M(x,y)$ is also tangent to the y-axis.

It is immediate that $K(x,y)$ satisfies the last two conditions of Theorem 7.1. To show that it also satisfies the first, we define the following additional regions:

$$\begin{array}{lll} \mathcal{B}' = \mathcal{R}'_4, & \mathcal{B}'' = \mathcal{R}''_4, & \mathcal{B} = \mathcal{B}' \cup \mathcal{B}'', \\ \mathcal{C}' = \mathcal{R}'_6, & \mathcal{C}'' = \mathcal{R}''_6, & \mathcal{C} = \mathcal{C}' \cup \mathcal{C}''. \end{array}$$

Clearly, $\mathcal{A} \subseteq \mathcal{B} \subseteq \mathcal{C}$. Note that if $(x_1x_2, y_1y_2) \in \mathcal{A}$, then $K(x_1x_2, y_1y_2) = M(x_1x_2, y_1y_2)$. The fact that the function $K(x, y)$ satisfies the first condition of Theorem 7.1 will therefore follow from the following lemma.

LEMMA 7.2.

$$L(x_1x_2, y_1y_2) \leq \begin{cases} K(x_1, y_1) + K(x_2, y_2) & \text{if } (x_1x_2, y_1y_2) \notin \mathcal{C}, \\ M(x_1x_2, y_1y_2) & \text{if } (x_1x_2, y_1y_2) \in \mathcal{C} \setminus \mathcal{A}. \end{cases}$$

As an immediate corollary of Theorem 7.1 and Lemma 7.2, we get the following.

COROLLARY 7.3. (a) *Any unate read-once formula that amplifies* $(p - \frac{1}{n_1}, p + \frac{1}{n_1})$ (*where* $0 < p < 1$ *is fixed*) *to at least* $(2^{-n_2}, 1 - 2^{-n_3})$ *is of size* $\Omega(n_1^{\alpha}(n_2n_3 + n_2 \log n_2 + n_3 \log n_3))$. (b) *Any unate read-once formula that amplifies* $(p - \frac{1}{n}, p + \frac{1}{n})$ (*where* $0 < p < 1$ *is fixed*) *to at least* $(2^{-n}, 1 - 2^{-n})$ *is of size* $\Omega(n^{\alpha+2})$.

To prove Lemma 7.2 we need the following technical claims whose proofs may be found in Appendix C.

CLAIM 7.4. (a) $M(x, y) \geq L(x, y)$ *for* $(x, y) \in \mathcal{C} \setminus \mathcal{A}$. (b) $M(x, y) \geq \ell(x, y)$ *for* $(x, y) \in \mathcal{A}'' \setminus \mathcal{A}'$.

CLAIM 7.5. (a) $(\mathcal{A}')^t \subseteq \mathcal{A}'$. (b) $(\mathcal{A}'')^t \subseteq \mathcal{A}''$ *for every* $0 \leq t \leq 1$.

CLAIM 7.6. (a) $\mathcal{A}'\mathcal{C}' \subseteq \mathcal{C}'$. (b) $(\mathcal{A}'' \cap \{x + y \geq 1\})(\mathcal{B}'' \cap \{x + y \geq 1\}) \subseteq \mathcal{C}''$.

In Claims 7.5 and 7.6, we use the definitions

$$\mathcal{R}^t = \{(x^t, y^t) : (x, y) \in \mathcal{R}\},$$
$$\mathcal{RS} = \{(x_1x_2, y_1y_2) : (x_1, y_1) \in \mathcal{R}, (x_2, y_2) \in \mathcal{S}\}.$$

CLAIM 7.7. (a) *If* $(x_1, y_1) \in \mathcal{A}'$ *and* $(x_2, y_2) \in \{x \leq y\} \setminus \mathcal{C}'$, *then*

$$\frac{d}{dt}\ell({x_1}^t x_2, {y_1}^t y_2)\Big|_{t=0} \leq 0.$$

(b) *If* $(x_1, y_1) \in \mathcal{A}''$ *and* $(x_2, y_2) \in \{x + y \geq 1, x \leq y\} \setminus \mathcal{B}''$, *then*

$$\frac{d}{dt}\ell(1 - {y_1}^t y_2, 1 - {x_1}^t x_2)\Big|_{t=0} \leq \begin{cases} (2 \ln \frac{1}{y_1})^{1/4} & \text{always}, \\ 0 & \text{if } \frac{\ln \frac{1}{x_1}}{\ln \frac{1}{y_1}} \leq 1.15. \end{cases}$$

CLAIM 7.8. *If* $\ln \frac{1}{x} / \ln \frac{1}{y} \geq 1.15$ *and* $x + y \geq 1$, *then* $M(x, y) \geq (2 \ln \frac{1}{y})^{1/4}$.

The choice $C = 10^6$ was made to insure the validity of Claims 7.4 and 7.8. In the proofs of these claims, found in Appendix C, the main emphasis is on showing that there exists a value of C for which these claims are valid. The proof that the choice $C = 10^6$ is sufficient is a simple drudgery and will not be presented in full.

Relying on the preceding claims, we now prove Lemma 7.2.

Proof of Lemma 7.2. If $(x_1x_2, y_1y_2) \in \mathcal{C} \setminus \mathcal{A}$, then the claim follows from 7.4(a). We therefore assume that $(x_1x_2, y_1y_2) \notin \mathcal{C}$, in which case we have to show that $L(x_1x_2, y_1y_2) \leq K(x_1, y_1) + K(x_2, y_2)$.

Since all the functions and regions involved in the statement of the lemma are invariant under reflection by the line $y = x$ (which corresponds to switching the x and the y coordinates), we may assume without loss of generality that $x_1x_2 \leq y_1y_2$. We may further assume without loss of generality that $x_1 \leq y_1$. It is enough to prove the inequality for the case where $x_2 \leq y_2$. To see this, we note that if $x \leq x' \leq y' \leq y$, then $L(x', y') \leq L(x, y)$. Assume that we had proven the inequality for every $x_1 \leq y_1$ and $x_2 \leq y_2$. We now show how to deal with the case where $x_1 \leq y_1$ and $x_2 \geq y_2$.

Since $x_1y_2 \le x_1x_2 \le y_1y_2 \le y_1x_2$ and since $(x_1x_2, y_1y_2) \notin \mathcal{C}$ implies $(x_1y_2, y_1x_2) \notin \mathcal{C}$, we have

$$\begin{aligned} L(x_1x_2, y_1y_2) &\le L(x_1y_2, y_1x_2) \\ &\le K(x_1, y_1) + K(y_2, x_2) \\ &= K(x_1, y_1) + K(x_2, y_2) \end{aligned}$$

as required. Therefore, we will assume henceforth that $x_2 \le y_2$.

We now split the proof into two cases depending on whether (x_1x_2, y_1y_2) is below or above the line $x + y = 1$.

Case 1. $x_1x_2 + y_1y_2 \le 1$.

Note that $\mathcal{C} \cap \{x + y \le 1\} = \mathcal{C}'$. We therefore know that $(x_1x_2, y_1y_2) \notin \mathcal{C}'$.

If $(x, y) \notin \mathcal{A}'$, then $\ell(x, y) \le K(x, y)$. If $(x, y) \notin \mathcal{A}$, this follows from the definition of $K(x, y)$ and the fact that $\ell(x, y) \le L(x, y)$ (see Lemma B.1 in Appendix B), and if $(x, y) \in \mathcal{A}'' \setminus \mathcal{A}'$ this follows from Claim 7.4(b).

If $(x_1, y_1), (x_2, y_2) \notin \mathcal{A}'$, then using the inequality $\ell(x_1x_2, y_1y_2) \le \ell(x_1, y_1) + \ell(x_2, y_2)$, which is always valid (see Lemma B.1 in Appendix B) and the fact that in this case we have $L(x_1x_2, y_1y_2) = \ell(x_1x_2, y_1y_2)$, we get

$$\begin{aligned} L(x_1x_2, y_1y_2) &= \ell(x_1x_2, y_1y_2) \\ &\le \ell(x_1, y_1) + \ell(x_2, y_2) \\ &\le K(x_1, y_1) + K(x_2, y_2) \end{aligned}$$

as required.

We therefore assume without loss of generality that $(x_1, y_1) \in \mathcal{A}'$. Consider the continuous movement from (x_2, y_2) to (x_1x_2, y_1y_2) described parametrically by $({x_1}^t x_2, {y_1}^t y_2)$, where t ranges from 0 to 1. If for some $0 \le t \le 1$ we have $({x_1}^t x_2, {y_1}^t y_2) \in \mathcal{C}'$, then since $({x_1}^{1-t}, {y_1}^{1-t}) \in \mathcal{A}'$ (this follows from Claim 7.5(a)) we get using Claim 7.6(a) that $(x_1x_2, y_1y_2) = ({x_1}^{1-t} \cdot {x_1}^t x_2, {y_1}^{1-t} \cdot {y_1}^t y_2) \in \mathcal{C}'$, which is a contradiction.

The remaining possibility is therefore that $({x_1}^t x_2, {y_1}^t y_2) \notin \mathcal{C}'$ for every $0 \le t \le 1$. In particular $(x_2, y_2) \notin \mathcal{C}'$ and $\ell(x_2, y_2) \le K(x_2, y_2)$. We now rely on Claim 7.7(a), which states that in this case $\frac{d}{dt}\ell({x_1}^t x_2, {y_1}^t y_2) \le 0$ for every $0 \le t \le 1$ (since $\frac{d}{dt}\ell({x_1}^t x_2, {y_1}^t y_2)|_{t=t_0} = \frac{d}{dt}\ell({x_1}^t \cdot {x_1}^{t_0} x_2, {y_1}^t \cdot {y_1}^{t_0} y_2)|_{t=0}$), and get that

$$\begin{aligned} L(x_1x_2, y_1y_2) &= \ell(x_1x_2, y_1y_2) \\ &\le \ell(x_2, y_2) \ \le \ K(x_2, y_2), \end{aligned}$$

which is more than required.

We are left with the case where (x_1x_2, y_1y_2) is above the line $x + y = 1$.

Case 2. $x_1x_2 + y_1y_2 \ge 1$.

Note that in this case we also have $x_1 + y_1 \ge 1$, $x_2 + y_2 \ge 1$, and ${x_1}^t x_2 + {y_1}^t y_2 \ge 1$ for every $0 \le t \le 1$. We also know that $L(x_1x_2, y_1y_2) = \ell(1 - y_1y_2, 1 - x_1x_2)$.

We now repeat some of the reasonings used in the previous case. However, certain complications arise since we can rely only on Claim 7.7(b), which is weaker than its counterpart Claim 7.7(a).

If $(x, y) \notin \mathcal{A}$ (which is equivalent in this case to $(x, y) \notin \mathcal{A}''$), then by the definition of $K(x, y)$, we get that $L(x, y) \le K(x, y)$.

If $(x_1, y_1), (x_2, y_2) \notin \mathcal{A}$, then using the fact that $L(x, y)$ satisfies the condition $L(x_1x_2, y_1y_2) \leq L(x_1, y_1) + L(x_2, y_2)$ (which is the first condition of Theorem 6.1), we get that

$$\begin{aligned} L(x_1x_2, y_1y_2) &\leq L(x_1, y_1) + L(x_2, y_2) \\ &= K(x_1, y_1) + K(x_2, y_2) \end{aligned}$$

as required.

We may therefore assume without loss of generality that $(x_1, y_1) \in \mathcal{A}''$. Consider again the continuous movement from (x_2, y_2) to (x_1x_2, y_1y_2) described parametrically by $({x_1}^t x_2, {y_1}^t y_2)$, where t ranges from 0 to 1. Note that in this case the whole curve is above the line $x + y = 1$.

If for some $0 \leq t \leq 1$ we have $({x_1}^t x_2, {y_1}^t y_2) \in \mathcal{B}''$, then since $({x_1}^{1-t}, {y_1}^{1-t}) \in \mathcal{A}''$ (this follows from Claim 7.5(b)), we get using Claim 7.6(b) that $(x_1x_2, y_1y_2) \in \mathcal{C}''$, which is a contradiction.

The remaining possibility is therefore that $({x_1}^t x_2, {y_1}^t y_2) \notin \mathcal{B}''$ for every $0 \leq t \leq 1$. In particular, $(x_2, y_2) \notin \mathcal{B}''$. If $\ln \frac{1}{x_1} / \ln \frac{1}{y_1} \leq 1.15$, then using the lower part of Claim 7.7(b) and essentially the same argument as before, we are done.

Assume therefore that $\ln \frac{1}{x_1} / \ln \frac{1}{y_1} \geq 1.15$. From the upper part of Claim 7.7(b), we get that

$$\frac{d}{dt} L({x_1}^t x_2, {y_1}^t y_2) \leq (2 \ln \tfrac{1}{y_1})^{1/4} \quad \text{for every } 0 \leq t \leq 1,$$

which integrates to

$$L(x_1x_2, y_1y_2) - L(x_2, y_2) \leq (2 \ln \tfrac{1}{y_1})^{1/4} .$$

Using Claim 7.8 and the facts that $L(x_2, y_2) \leq K(x_2, y_2)$ (since $(x_2, y_2) \notin \mathcal{A}$) and $M(x_1, y_1) = K(x_1, y_1)$ (since $(x_1, y_1) \in \mathcal{A}$), we get that

$$\begin{aligned} L(x_1x_2, y_1y_2) &\leq (2 \ln \tfrac{1}{y_1})^{1/4} + L(x_2, y_2) \\ &\leq M(x_1, y_1) + K(x_2, y_2) \\ &= K(x_1, y_1) + K(x_2, y_2) \end{aligned}$$

as required. This completes the proof. □

8. Exclusive-or gates as convex combinations of unate gates. The main result of this section is the following theorem.

THEOREM 8.1. *If f is a read-once formula that amplifies (p, q) to (p', q'), then there exists a probabilistic unate read-once formula F with $size(F) \leq size(f)$ that also amplifies (p, q) to (p', q').*

Proof. The proof is by induction on the structure of f. If f is a variable, then the result is clear. If $f = \neg f_1$ or $f = f_1 \wedge f_2$, then the result follows immediately from the induction hypothesis. The interesting case is, of course, if $f = f_1 \oplus f_2$. Assume that f_1 and f_2 amplify (p, q) to (x_1, y_1) and (x_2, y_2), respectively. Let F_1 and F_2 be two probabilistic unate formulas with $size(F_1) \leq size(f_1)$ and $size(F_2) \leq size(f_2)$ that also amplify (p, q) to (x_1, y_1) and (x_2, y_2), respectively. The existence of F_1 and F_2 follows from the induction hypothesis. The next lemma proves the existence of a unate connective $\circ$ such that the point $(x_1, y_1) \oplus (x_2, y_2)$ lies in the convex hull of the points $(0, 0), (x_1, y_1) \circ (x_2, y_2)$ and $(1, 1)$. It follows that there exist three constants

$0 \le \alpha, \beta, \gamma \le 1$ with $\alpha+\beta+\gamma = 1$ such that $(x_1, y_1) \oplus (x_2, y_2) = \alpha \cdot (0,0) + \beta \cdot (x_1, y_1) \circ (x_2, y_2) + \gamma \cdot (1,1)$. Thus the unate probabilistic formula

$$F = \begin{cases} 0 & \text{with prob. } \alpha, \\ F_1 \circ F_2 & \text{with prob. } \beta, \\ 1 & \text{with prob. } \gamma \end{cases}$$

achieves the same amplification as f. Clearly, $size(F) \le size(F_1) + size(F_2) \le size(f_1) + size(f_2) = size(f)$. This completes the proof of the theorem. □

A unate connective here is one of the twelve connectives $(x^a \wedge y^b)^c$, x^a, and y^b, where $x^a = x \oplus a$, that may be obtained using one AND gate and some negations.

LEMMA 8.2. *For every $0 \le x_1, x_2, y_1, y_2 \le 1$, there exists a unate connective $\circ$ such that $(x_1, y_1) \oplus (x_2, y_2)$ is in the convex hull of the points $(0,0), (x_1, y_1) \circ (x_2, y_2)$ and $(1,1)$.*

Proof. We may assume without loss of generality that $x_1 \oplus x_2 \le y_1 \oplus y_2$ since if this is not the case, we can switch the roles of the x's and y's. By this assumption, the point $(x_1 \oplus x_2, y_1 \oplus y_2)$ is above the line $y = x$. It is therefore contained in the convex hull of the points $(0,0), (x_1, y_1) \circ (x_2, y_2)$, and $(1,1)$ iff

$$\frac{y_1 \circ y_2}{x_1 \circ x_2} \ge \frac{y_1 \oplus y_2}{x_1 \oplus x_2} \quad \text{and} \quad \frac{1 - y_1 \circ y_2}{1 - x_1 \circ x_2} \le \frac{1 - y_1 \oplus y_2}{1 - x_1 \oplus x_2}.$$

We consider four different cases.

Case 1. $x_1 \le y_1$ and $x_2 \le y_2$.

We take $\circ$ to be the OR operator, i.e., $a \circ b = a \vee b$. A simple manipulation shows that the first inequality is equivalent to the inequality

$$x_1 y_1 (y_2 - x_2) + x_2 y_2 (y_1 - x_1) \ge 0,$$

which is easily seen to hold since $x_1 \le y_1$ and $x_2 \le y_2$. A similar manipulation shows that the second inequality is equivalent in this case to the inequality

$$y_1 y_2 (1 - x_1 \vee x_2) \ge x_1 x_2 (1 - y_1 \vee y_2),$$

which is also easily seen to hold since $x_1 x_2 \le y_1 y_2$ and $x_1 \vee x_2 \le y_1 \vee y_2$.

Case 2. $x_1 \le y_1$ and $x_2 \ge y_2$.

We consider the points $(\overline{y}_1, \overline{x}_1)$ and (y_2, x_2). It is easy to check that $\overline{y}_1 \le \overline{x}_1$, $y_2 \le x_2$, and $\overline{y}_1 \oplus y_2 \le \overline{x}_1 \oplus x_2$. By Case 1, we get that the point $(\overline{y}_1 \oplus y_2, \overline{x}_1 \oplus x_2)$ lies in the convex hull of the points $(0,0), (\overline{y}_1 \vee y_2, \overline{x}_1 \vee x_2)$, and $(1,1)$. It follows immediately that the point $(x_1, x_2) \oplus (y_1, y_2) = (1,1) - (\overline{x}_1, x_2) \oplus (\overline{y}_1, y_2)$ lies in the convex hull of the points $(0,0), (x_1 \wedge \overline{x}_2, y_1 \wedge \overline{y}_2)$, and $(1,1)$. We can thus take $a \circ b = a \wedge \overline{b}$.

Case 3. $x_1 \ge y_1$ and $x_2 \le y_2$.

By switching the roles of (x_1, y_1) and (x_2, y_2), we are back in Case 2. We can thus take $a \circ b = \overline{a} \wedge b$.

Case 4. $x_1 \ge y_1$ and $x_2 \ge y_2$.

The points $(\overline{x}_1, \overline{y}_1)$ and $(\overline{x}_2, \overline{y}_2)$ satisfy the conditions of Case 1. We can thus take $a \circ b = \overline{a} \vee \overline{b}$.

This completes the proof of the lemma. □

It is easy to check that the lower bounds of the previous sections apply to probabilistic and not only to deterministic read-once formulas. All of the lower bounds claimed for unate read-once formulas are therefore valid for general read-once formulas. We also have the following connection between probabilistic and nonprobabilistic formulas.

THEOREM 8.3. *If F is a probabilistic formula that amplifies (p,q) to (p',q'), then there exists a deterministic formula f that amplifies (p,q) to (p'',q''), where $p'' \le 2p'$ and $1-q'' \le 2(1-q')$. Furthermore, if F is read-once, unate, or monotone, then so is f.*

Proof. Recall that $p' = F(p) = E_{f\in F} f(p)$, where the expectation is according to the distribution that F induces on the deterministic formulas that it assumes. Since for every nonnegative random variable X we have $\Pr[X > 2E(X)] < \frac{1}{2}$, we get that $\Pr[f(p) > 2p'] < \frac{1}{2}$, where again f is chosen according to the distribution induced by F. Applying a similar argument to $q' = F(q)$, we get that $\Pr[(1-f(q)) > 2(1-q')] < \frac{1}{2}$. As a consequence,

$$Pr[\ f(p) > 2p' \ \vee\ (1-f(q)) > 2(1-q')\ ] < 1,$$

and therefore a deterministic formula chosen according to the distribution of F will satisfy the required conditions with a positive probability. □

COROLLARY 8.4. $N_{\oplus}(p_1,q_1|p_0,q_0) \ge \min_{\substack{p'_1\le 2p_1 \\ 1-q'_1\le 2(1-q_1)}} N(p'_1,q'_1 \mid p_0,q_0)$.

9. Open problems. At least two major open problems are left in connection with the subjects discussed in this paper:

1. Do the lower bounds on amplifying formulas given in this paper apply to general, not necessarily read-once, formulas? Do they hold for general monotone formulas? Do they hold, say, for read-twice formulas?

2. Are the optimal monotone formulas for majority obtained by the use of the amplification method? Is it possible to obtain an $\Omega(n^{\alpha+2})$ lower bound on the monotone formula complexity of the majority function? The currently best lower bound on the monotone or unate formula size of the majority function is an $\Omega(n^2)$ lower bound obtained by Khrapchenko [11], [12].

One less important problem is the following:

3. Is there a simple and less technical proof of the unified amplification lower bound? Is there a simple and natural function that satisfies the conditions of Theorem 6.1 and by the use of which a direct simple proof of the unified lower bound may be obtained?

Appendix A. Proving the strengthened Boppana's inequality. Graphs of the function $G(x)$ are given in Fig. 2.

Proof of Lemma 3.1. Define

$$\widetilde{G}(x) = \left(\frac{G(x)}{x}\right)^{\beta} = \begin{cases} \ln\frac{\gamma}{x} & \text{if } \ 0 \le x \le \frac{1}{2}, \\ \left(\frac{1}{x}-1\right)^{\beta} \ln\frac{\gamma}{1-x} & \text{if } \ \frac{1}{2} \le x \le 1. \end{cases}$$

We have to show that for every $0 < x, y \le 1$ we have

$$\widetilde{G}(x,y) = \widetilde{G}(xy) - \widetilde{G}(x) - \widetilde{G}(y) \ge 0.$$

If $0 < y \le \frac{1}{2}$, then $0 < xy \le \frac{1}{2}$ and

$$\begin{aligned} \widetilde{G}(x,y) &= \ln\frac{\gamma}{xy} - \widetilde{G}(x) - \ln\frac{\gamma}{y} \\ &= \ln\frac{1}{x} - \widetilde{G}(x) = \begin{cases} \ln\frac{1}{\gamma} & \text{if } \ 0 \le x \le \frac{1}{2}, \\ \ln\frac{1}{x} - \left(\frac{1}{x}-1\right)^{\beta} \ln\frac{\gamma}{1-x} & \text{if } \ \frac{1}{2} \le x \le 1. \end{cases} \end{aligned}$$

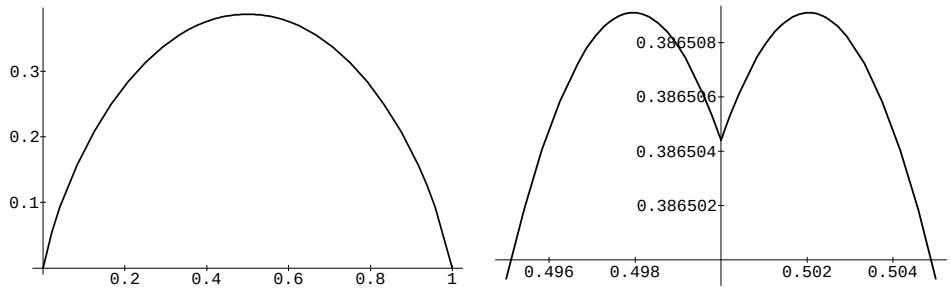

FIG. 2. *The function $G(x)$.*

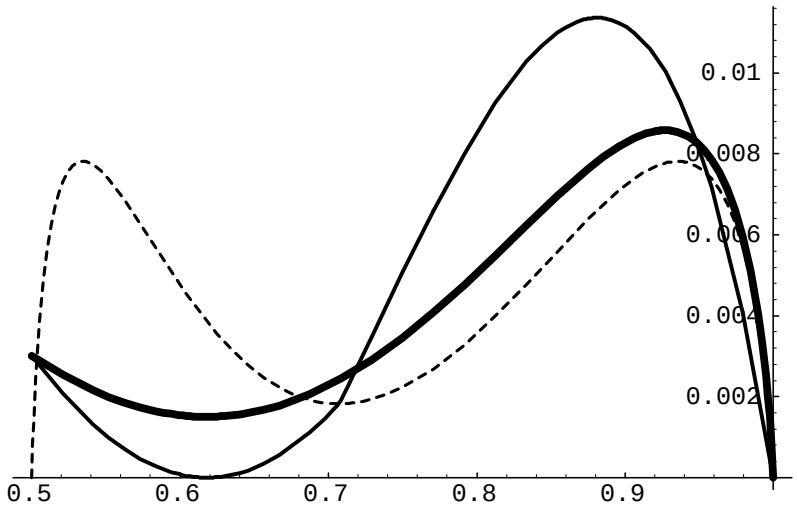

FIG. 3. *The three one-variable functions whose nonnegativity imply the strengthened Boppana's inequality.*

Since $\ln \frac{1}{\gamma} \simeq 0.003 > 0$, the inequality easily holds in the quadrant $0 < x, y \leq \frac{1}{2}$. A graph of the function $\ln \frac{1}{x} - \widetilde{G}(x) = \ln \frac{1}{x} - (\frac{1}{x} - 1)^\beta \ln \frac{\gamma}{1-x}$ for $\frac{1}{2} \leq x \leq 1$, is given by the bold line in Fig. 3. We see that the function is nonnegative for every $\frac{1}{2} \leq x \leq 1$, and this could be easily proved rigorously. (The local minimum is attained at $x = \psi$ and its value is about 0.0015.) This takes care of the rectangle $0 < y \leq \frac{1}{2}$ and by symmetry also of the rectangle $0 < x \leq \frac{1}{2}$.

We are left with the quadrant $\frac{1}{2} \leq x, y \leq 1$. Note that $\widetilde{G}(x, 1) = \widetilde{G}(1, y) = 0$, so the inequality is verified for all the points on the boundary of the quadrant. The function $\widetilde{G}(x, y)$ is nondifferentiable on the hyperbola $xy = \frac{1}{2}$ but is differentible anywhere else inside the quadrant. A graph of the function

$$\begin{aligned}\widetilde{G}\left(x, \frac{1}{2x}\right) &= \widetilde{G}\left(\frac{1}{2}\right) - \widetilde{G}(x) - \widetilde{G}\left(\frac{1}{2x}\right) \\ &= \ln 2\gamma - \left(\frac{1}{x} - 1\right)^\beta \ln \frac{\gamma}{1-x} - (2x-1)^\beta \ln \frac{\gamma}{1-\frac{1}{2x}}\end{aligned}$$

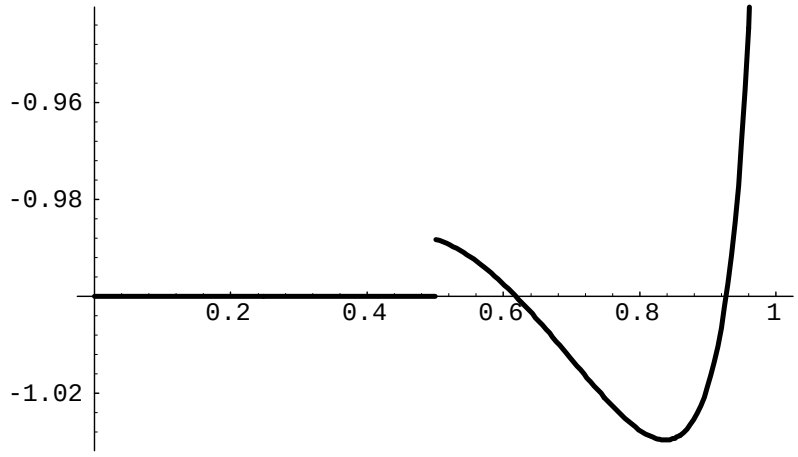

FIG. 4. *The function* $\widehat{G}(x)$. *No value* (*other than* -1) *is attained at three different* x *values.*

for $\frac{1}{2} \leq x \leq 1$ is given by the dotted line in Fig. 3. Again, it can be verified rigorously that it is nonnegative for every $\frac{1}{2} \leq x \leq 1$.

We now look for extremal points of the function $\widetilde{G}(x,y)$ inside the quadrant $\frac{1}{2} \leq x, y \leq 1$ that do not lie on the hyperbola $xy = \frac{1}{2}$. In these points, we must have

$$\frac{\partial \widetilde{G}(x,y)}{\partial x} = \frac{1}{x}\left[xy\widetilde{G}'(xy) - x\widetilde{G}'(x)\right] = 0,$$
$$\frac{\partial \widetilde{G}(x,y)}{\partial y} = \frac{1}{y}\left[xy\widetilde{G}'(xy) - y\widetilde{G}'(y)\right] = 0.$$

Define

$$\widehat{G}(x) = x\widetilde{G}'(x) = \begin{cases} -1 & \text{if } \ 0 < x < \frac{1}{2}, \\ -\left(\frac{\beta}{x}\ln\frac{\gamma}{1-x} - 1\right)\left(\frac{1}{x} - 1\right)^{\beta-1} & \text{if } \ \frac{1}{2} < x \leq 1. \end{cases}$$

If (x,y) is such an extremal point of $\widetilde{G}(x,y)$, then we must have

$$\widehat{G}(x) = \widehat{G}(y) = \widehat{G}(xy).$$

A graph of the function $\widehat{G}(x)$ is given in Fig. 4. It can be rigorously verified that the function $\widehat{G}(x)$ is unimodal for $\frac{1}{2} \leq x \leq 1$, so -1 is the only value attained by this function more than twice in the range $0 < x \leq 1$. The value -1 is attained at every $0 < x \leq \frac{1}{2}$, at $x = \psi = (\sqrt{5}-1)/2$, and at $x = \psi' \simeq 0.926812$.

Since $\psi\psi' \simeq 0.572801 > \frac{1}{2}$, we do not have $\widehat{G}(\psi\psi') = -1$. If $\widehat{G}(x) = \widehat{G}(y) = \widehat{G}(xy)$ for $\frac{1}{2} < x, y < 1$, then we must have $x = y$. All of the extremal points must therefore lie on the diagonal of the unit square. A graph of the function

$$\widetilde{G}(x,x) = \begin{cases} \ln\frac{\gamma}{x^2} - 2\left(\frac{1}{x} - 1\right)^{\beta}\ln\frac{\gamma}{1-x} & \text{if } \ \frac{1}{2} \leq x \leq \frac{\sqrt{2}}{2}, \\ \left(\frac{1}{x^2} - 1\right)^{\beta}\ln\frac{\gamma}{1-x^2} - 2\left(\frac{1}{x} - 1\right)^{\beta}\ln\frac{\gamma}{1-x} & \text{if } \ \frac{\sqrt{2}}{2} \leq x \leq 1 \end{cases}$$

is given by the solid line in Fig. 3. It can be checked that $x = y = \psi$ is indeed a local minimum and its value is 0. There is also a (global) maximum at $x = y \simeq 0.881135$. We conclude that the required inequality is therefore satisfied on the diagonal $x = y$ and consequently in the whole of the unit square. □

Appendix B. Proving the required properties of $L(x, y)$. Before proving Lemma 6.4, we establish some properties of the function $\ell(x, y)$. In what follows, we will always assume that x, y, x_1, y_1, x_2, and y_2 are in the interval $(0, 1)$, although we will not always write it explicitly.

LEMMA B.1.

1.	$\ell(x,y) \geq \ell(1-y,1-x)$	$\forall\ x \leq y \leq 1-x,$
2.	$\ell(x_1x_2, y_1y_2) \leq \ell(x_1,y_1) + \ell(x_2,y_2)$	$\forall\ x_1 \leq y_1,\ x_2 \leq y_2,$
3.	$\ell(1-y_1y_2, 1-x_1x_2) \leq \ell(1-y_1,1-x_1) + \ell(1-y_2,1-x_2)$	$\forall\ x_1 \leq y_1,\ x_2 \leq y_2.$

Relying on Lemma B.1, we can now prove Lemma 6.4.

Proof of Lemma 6.4. The function L automatically satisfies the conditions $L(x, y) = L(y, x) = L(1 - x, 1 - y)$. Therefore, we only have to prove condition 1 of Theorem 6.1. The symmetric properties of L allow us to assume that $x_1x_2 \leq y_1y_2$. (Otherwise, just change the roles of the x's and the y's.) We may also assume without loss of generality that $x_1 \leq y_1$. (If $x_1 > y_1$ and $x_2 > y_2$, then $x_1x_2 > y_1y_2$.)

As a consequence of first condition of Lemma B.1, we get that $L(x, y) = \max\{\ell(x, y), \ell(1 - y, 1 - x)\}$ for $x \leq y$. If $x_2 \leq y_2$, then

$$\begin{aligned} L(x_1x_2, y_1y_2) &= \max\{\ell(x_1x_2, y_1y_2), \ell(1-y_1y_2, 1-x_1x_2)\} \\ &\leq \max\{\ell(x_1,y_1) + \ell(x_2,y_2), \ell(1-y_1,1-x_1) + \ell(1-y_2,1-x_2)\} \\ &\leq \max\{\ell(x_1,y_1), \ell(1-y_1,1-x_1)\} + \max\{\ell(x_2,y_2) + \ell(1-y_2,1-x_2)\} \\ &= Ł(x_1,y_1) + Ł(x_2,y_2). \end{aligned}$$

In the passage from the first line to the second above, we used conditions 2 and 3 of Lemma B.1.

To finish the proof, note that if $x \leq x' \leq y' \leq y$ then $L(x', y') \leq L(x, y)$. This is easily seen since both $\ell(x, y)$ and $\ell(1 - y, 1 - x)$ are decreasing in x and inceasing in y. If $x_2 > y_2$, we have

$$\begin{aligned} L(x_1x_2, y_1y_2) &\leq L(x_1y_2, y_1y_2) \\ &\leq L(x_1,y_1) + L(y_2,y_2) = L(x_1,y_1) + 0 \\ &\leq L(x_1,y_1) + L(x_2,y_2). \end{aligned}$$

This completes the proof. □

We now turn to the proof of Lemma B.1.

Proof of Lemma B.1. 1. We have to show that $\ell(x, y) - \ell(1 - y, 1 - x) \geq 0$ for $0 < x \leq y \leq 1 - x$. If $y = x$ or $y = 1 - x$, then we have equality. Therefore, the claim will follow if we can show that $\ell(x, y) - \ell(1 - y, 1 - x)$ is decreasing in x. We therefore have to show that

$$\frac{\partial}{\partial x}[\ell(x,y) - \ell(1-y,1-x)] = -\frac{1}{x}\left(\ln\frac{\ln\frac{1}{x}}{\ln\frac{1}{y}} + 1\right) + \frac{1}{1-x}\cdot\frac{\ln\frac{1}{1-y}}{\ln\frac{1}{1-x}} \leq 0.$$

This claim is easily verified for $y = x$ (since $x \leq \frac{1}{2}$ and therefore $-\frac{1}{x} + \frac{1}{1-x} \leq 0$). It would therefore be enough to show that the above derivative is decreasing in y. We

therefore have to show that

$$\frac{\partial^2}{\partial y \partial x}[\ell(x,y) - \ell(1-y,1-x)] = -\frac{1}{xy}\cdot\frac{1}{\ln\frac{1}{y}} + \frac{1}{(1-x)(1-y)}\cdot\frac{1}{\ln\frac{1}{1-x}} \le 0$$

or, equivalently, that

$$\frac{1-x}{x}\ln\frac{1}{1-x} \ge \frac{y}{1-y}\ln\frac{1}{y}.$$

This is easily verified since the function $\frac{y}{1-y}\ln\frac{1}{y}$ is increasing in y (this follows from a further differentiation using the inequality $\ln\frac{1}{y} \ge 1-y$) and $y \le 1-x$.

2. A simple manipulation shows that

$$\begin{aligned}&\ell(x_1x_2,y_1y_2) - \ell(x_1,y_1) - \ell(x_2,y_2)\\ &\quad = -\ln\frac{1}{x_1}\cdot\left[\left(1+\frac{\ln\frac{1}{x_2}}{\ln\frac{1}{x_1}}\right)\ln\frac{1+\frac{\ln\frac{1}{y_2}}{\ln\frac{1}{y_1}}}{1+\frac{\ln\frac{1}{x_2}}{\ln\frac{1}{x_1}}} - \frac{\ln\frac{1}{x_2}}{\ln\frac{1}{x_1}}\cdot\ln\frac{\frac{\ln\frac{1}{y_2}}{\ln\frac{1}{y_1}}}{\frac{\ln\frac{1}{x_2}}{\ln\frac{1}{x_1}}}\right].\end{aligned}$$

We let

$$u = \frac{\ln\frac{1}{x_2}}{\ln\frac{1}{x_1}}, \qquad v = \frac{\ln\frac{1}{y_2}}{\ln\frac{1}{y_1}}.$$

To prove claim 2, we have to show that

$$f(u,v) = (1+u)\ln\frac{1+v}{1+u} - u\ln\frac{v}{u} \ge 0$$

for every $u,v>0$. This follows since the required inequality holds (with equality) if $u=v$, and it can be easily verified that $f(u,v)$ is increasing in u if $u \ge v$ and decreasing in u if $u \le v$.

3. We have to show that $\ell(1-y_1y_2,1-x_1x_2) - \ell(1-y_1,1-x_1) - \ell(1-y_2,1-x_2) \le 0$ for $0 < x_1 \le y_1 < 1$ and $0 < x_2 \le y_2 < 1$. We will prove this inequality in two stages:

$$\ell(1-y_1y_2,1-x_1x_2) - \ell(1-y_1,1-x_1) \le \ell(1-y_1y_2,1-y_1x_2)$$

and

$$\ell(1-y_1y_2,1-y_1x_2) \le \ell(1-y_2,1-x_2).$$

To obtain the first inequality, we show that $\ell(1-y_1y_2,1-x_1x_2) - \ell(1-y_1,1-x_1)$ is increasing in x_1. We have to show that

$$x_1\frac{\partial}{\partial x_1}[\ell(1-y_1y_2,1-x_1x_2) - \ell(1-y_1,1-x_1)] = -\frac{x_1x_2}{1-x_1x_2}\cdot\frac{\ln\frac{1}{1-y_1y_2}}{\ln\frac{1}{1-x_1x_2}} + \frac{x_1}{1-x_1}\cdot\frac{\ln\frac{1}{1-y_1}}{\ln\frac{1}{1-x_1}} \ge 0.$$

This inequality holds since

$$\ln\frac{1}{1-y_1y_2} \le \ln\frac{1}{1-y_1}, \qquad \frac{1-x_1x_2}{x_1x_2}\ln\frac{1}{1-x_1x_2} \ge \frac{1-x_1}{x_1}\ln\frac{1}{1-x_1}.$$

The second condition follows again from the fact that the function $\frac{1-x}{x}\ln\frac{1}{1-x}$ is decreasing in x.

To obtain the second inequality, we show that $\ell(1-y_1y_2, 1-y_1x_2)$ is increasing in y_1. We have to show that

$$y_1\frac{\partial}{\partial y_1}\ell(1-y_1y_2,1-y_1x_2) = \frac{y_1y_2}{1-y_1y_2}\left(\ln\frac{\ln\frac{1}{1-y_1y_2}}{\ln\frac{1}{1-y_1x_2}}+1\right) - \frac{y_1x_2}{1-y_1x_2}\cdot\frac{\ln\frac{1}{1-y_1y_2}}{\ln\frac{1}{1-y_1x_2}} \geq 0.$$

This can be done using similar methods. □

Appendix C. Proving Claims 7.4–7.8. To simplify the proofs of the claims involving $M(x,y)$, we first show how to bound this function using a slightly simpler expression. To this end, we define the function $\tilde{m}(x,y)$ by replacing the two appearances of the constant γ in the definition of $m(x,y)$ by the constant 1:

$$\tilde{m}(x,y) = \left[\left(\ln\frac{1}{x}\right)^{1/\alpha} - \left(\ln\frac{1}{y}\right)^{1/\alpha}\right]^{\alpha}.$$

On next lemma shows that $C\cdot\tilde{m}(x,y)$ can serve as a lower bound for $M(x,y)$.

LEMMA C.1. *$M(x,y) \geq C\cdot\tilde{m}(x,y)$ for every $0 < x \leq y < 1$.*

Proof. Consider the function $g(x) = x(\ln\frac{1}{x})^{1/\beta}$. It is easy to verify that $g(x) \geq G(x)$ for every $0 \leq x \leq 1$. As a consequence, we get that

$$M(x,y) = \frac{C}{\alpha^\alpha}\left|\int_x^y \frac{du}{G(u)}\right|^\alpha \geq \frac{C}{\alpha^\alpha}\left|\int_x^y \frac{du}{g(u)}\right|^\alpha = C\cdot\tilde{m}(x,y). \qquad \square$$

When y is bounded away from 1, the bound just given is tight up to a constant factor.

We now proceed with the proof of Claims 7.4–7.8.

Proof of Claim 7.4(a). Since all the functions and regions involved are symmetric with respect to the lines $y=x$ and $x+y=1$, it is enough to prove the claim for the region $(\mathcal{C}\setminus\mathcal{A})\cap\{x\leq y\leq 1-x\} = (\mathcal{C}'\setminus\mathcal{A}')\cap\{x\leq y\leq 1-x\}$. In this region, we have

$$M(x,y) \geq C\cdot\tilde{m}(x,y) = C\cdot\ln\tfrac{1}{x}\cdot\left[1-\left(\frac{\ln\frac{1}{y}}{\ln\frac{1}{x}}\right)^{1/\alpha}\right]^\alpha, \quad L(x,y) = \ell(x,y) = \ln\tfrac{1}{x}\cdot\ln\frac{\ln\frac{1}{x}}{\ln\frac{1}{y}}.$$

Let $u = \ln\frac{1}{x}/\ln\frac{1}{y}$ and note that in $(\mathcal{C}'\setminus\mathcal{A}')\cap\{x\leq y\leq 1-x\}$ we have $2\leq u\leq 6$. We therefore have

$$\frac{M(x,y)}{L(x,y)} \geq C\cdot\frac{\left[1-\left(\frac{1}{u}\right)^{1/\alpha}\right]^\alpha}{\ln u} \geq C\cdot\frac{\left[1-\left(\frac{1}{2}\right)^{1/\alpha}\right]^\alpha}{\ln 6} \gg 1. \qquad \square$$

Proof of Claim 7.4(b). Again, because of the symmetries involved, it is enough to prove the claim for $(x,y)\in\mathcal{A}''\setminus\mathcal{A}'\cap\{x,1-x\leq y\} = \{\sqrt{x}\leq y\leq x(2-x)\}$. Note that in this region $1-\psi\leq x<1$, where $\psi = (\sqrt{5}-1)/2 \simeq 0.62$. We now have

$$M(x,y) = M(1-y,1-x) \geq C\cdot\tilde{m}(1-y,1-x) = C\left[\left(\ln\tfrac{1}{1-y}\right)^{1/\alpha} - \left(\ln\tfrac{1}{1-x}\right)^{1/\alpha}\right]^\alpha.$$

Since both functions are increasing in y, we have

$$\min_{(x,y)\in\mathcal{A}''\setminus\mathcal{A}'}\frac{M(x,y)}{\ell(x,y)} \geq \min_{1-\psi\leq x<1}\frac{C\cdot\tilde{m}(1-\sqrt{x},1-x)}{\ell(x,x(2-x))}.$$

It can be checked that the minimum on the right is obtained at $x \approx 0.930677$ and its value is about $2450.5 \gg 1$. We will not give the (tedious) proof of this fact here. We will show instead that $\lim_{x\to 1} \tilde{m}(1-\sqrt{x}, 1-x)/\ell(x, x(2-x)) = +\infty$. This shows that the minimum appearing in the statement of the claim does exist and that its value is strictly positive. This would be enough to show that there exists a constant C for which the claim is valid. To that end, we note that as $x \to 1$, we have

$$\left(\left(\ln \tfrac{1}{1-\sqrt{x}}\right)^{1/\alpha} - \left(\ln \tfrac{1}{1-x}\right)^{1/\alpha}\right)^{\alpha} \approx \frac{1}{\left(\ln \frac{1}{1-x}\right)^{\alpha/\beta}},$$

$$\ln \tfrac{1}{x} \cdot \ln \frac{\ln \frac{1}{x}}{\ln \frac{1}{x(2-x)}} \approx (1-x) \ln \tfrac{1}{1-x},$$

where the sign $\approx$ here means that the quotient of the two sides tends to a positive constant as $x \to 1$. Therefore,

$$\frac{\tilde{m}(x, \sqrt{x})}{\ell(x, x(2-x))} \approx \frac{1}{(1-x)\left(\ln \frac{1}{1-x}\right)^{1+\alpha/\beta}} \to +\infty$$

as $x \to 1$, as promised. □

Proof of Claim 7.5(a). The proof is immediate from the definition of $\mathcal{A}'$. □

Proof of Claim 7.5(b). It is enough to prove the claim for the upper boundary of $\mathcal{A}''$, which is $(x, x(2-x))$ for $0 \le x \le 1$. To show that $(x^t, x^t(2-x)^t) \in \mathcal{A}''$, we have to show that $x^t(2-x)^t \le x^t(2-x^t)$ or, equivalently, that $x^t + (2-x)^t \le 2$ for every $0 \le x \le 1$ and $0 \le t \le 1$. To see this, note that equality holds for $t = 0$ and $t = 1$ and that $x^t + (2-x)^t$ is convex as a function of t since its second derivative is $(\ln x)^2 x^t + (\ln(2-x))^2 (2-x)^t \ge 0$. □

Proof of Claim 7.6(a). The proof is immediate since $\mathcal{A}'\mathcal{C}' \subseteq \mathcal{C}'\mathcal{C}' = \mathcal{C}'$. □

Proof of Claim 7.6(b). The upper boundary of $(\mathcal{A}'' \cap \{x+y \ge 1\})(\mathcal{B}'' \cap \{x+y \ge 1\})$ is all products of points on the upper boundary of $\mathcal{A}'' \cap \{x+y \ge 1\}$ and $\mathcal{B}'' \cap \{x+y \ge 1\}$. We therefore have to show that $(x_1, 1-(1-x_1)^2)(x_2, 1-(1-x_2)^4) \in \mathcal{C}''$, i.e., $[1-(1-x_1)^2][1-(1-x_2)^4] \le 1-(1-x_1x_2)^6$, whenever $x_1 \ge (1-x_1)^2$ and $x_2 \ge (1-x_2)^4$. This is easily verified. In fact, the claim remains true even if the exponent 6 is reduced to about 5.34. □

Proof of Claim 7.7(a). It is easily checked that

$$\frac{d}{dt}\ell({x_1}^t x_2, {y_1}^t y_2)\Big|_{t=0} = \ln \frac{1}{x_1}\left(\ln \frac{\ln \frac{1}{x_2}}{\ln \frac{1}{y_2}} + 1\right) - \ln \frac{1}{y_1} \cdot \frac{\ln \frac{1}{x_2}}{\ln \frac{1}{y_2}}$$

and that this expression is nonpositive iff

$$u = \frac{\ln \frac{1}{x_1}}{\ln \frac{1}{y_1}} \le \frac{\left(\frac{\ln \frac{1}{x_2}}{\ln \frac{1}{y_2}}\right)}{\ln\left(\frac{\ln \frac{1}{x_2}}{\ln \frac{1}{y_2}}\right) + 1} = \frac{v}{\ln v + 1},$$

where $v = \ln \frac{1}{x_2} / \ln \frac{1}{y_2}$. Since $(x_1, y_1) \in \mathcal{A}'$, we have $u \le 2$. Since $(x_2, y_2) \in \{x \le y\} \setminus \mathcal{C}'$, we have $v \ge 6$, and it is easy to verify that this implies $v/(\ln v + 1) \ge 2$. □

Proof of Claim 7.7(b). Simple manipulations yield

$$\frac{d}{dt}\ell(1-{y_1}^t y_2, 1-{x_1}^t x_2)\Big|_{t=0} = -\ln \frac{1}{y_1} \cdot (u-1)\left(\ln \frac{\ln u}{\ln v} + 1\right) + \ln \frac{1}{x_1} \cdot (v-1)\frac{\ln u}{\ln v},$$

where $v = \frac{1}{1-x_2}$ and $u = \frac{1}{1-y_2}$. Also let $w = (u-1)(\ln(\ln u/\ln v)+1)$. By the definition of $\mathcal{B}''$, we have $u \geq v^4$. Note that $x_2 \geq 0$ and $y_2 \geq \frac{1}{2}$ (since $(x_2, y_2) \in \{x+y \geq 1, x \leq y\}$) and therefore $v \geq 1$ and $u \geq 2$.

It can easily be checked that the conditions $u \geq 2, v^4$ and $v \geq 1$ imply that $(u-1)^{1/3}/\ln u > \frac{1}{2} \cdot \frac{v-1}{\ln v}$. (Note that for v large enough this is obvious. The constant $\frac{1}{2}$ was added to make the inequality valid for smaller values of v.) In particular,

$$(v-1)\frac{\ln u}{\ln v} < 2(u-1)^{1/3} \leq \frac{2}{(\ln 4+1)^{1/3}} \cdot w^{1/3} < 1.5 w^{1/3}$$

(since $w \geq (u-1)(\ln 4+1)$ and $2/(\ln 4+1)^{1/3} \approx 1.49666$) and therefore

$$\frac{d\ell}{dt}\Big|_{t=0} \leq -\ln\frac{1}{y_1} \cdot w + 1.5 \ln\frac{1}{x_1} \cdot w^{1/3}.$$

Note that $w \geq \ln 4 + 1$, so if

$$\frac{1.5 \ln \frac{1}{x_1}}{\ln \frac{1}{y_1}} \leq (\ln 4+1)^{2/3} \leq w^{2/3},$$

then $\frac{d\ell}{dt}|_{t=0}. \leq 0$. This proves the lower part of the claim since $(\ln 4+1)^{2/3}/1.5 \approx 1.19049 > 1.15$.

To get the upper part of the claim, we note that the expression $-\ln\frac{1}{y_1} \cdot w + 1.5 \ln\frac{1}{x_1} \cdot w^{1/3}$, considered as a function of w, is maximized when $w = (\ln\frac{1}{x_1}/2\ln\frac{1}{y_1})^{3/2}$. (This follows easily by differentiation.) Plugging this into the expression, we get that

$$\frac{d\ell}{dt}\Big|_{t=0} \leq \frac{\left(\ln\frac{1}{x_1}\right)^{3/2}}{\left(2\ln\frac{1}{y_1}\right)^{1/2}}.$$

Next, it is easily verified that if $(x_1, y_1) \in \mathcal{A}'' \cap \{x, 1-x \leq y\}$, then $\ln\frac{1}{y_1} > \frac{1}{2}(\ln\frac{1}{x_1})^2$. (In fact, the minimum of $\ln\frac{1}{y_1}/(\ln\frac{1}{x_1})^2$ over this region is attained at the point $(x_1, y_1) = (1-\psi, \psi)$, and its value is about 0.519.) We thus easily obtain

$$\frac{d\ell}{dt}\Big|_{t=0} \leq \frac{\left(\ln\frac{1}{x_1}\right)^{3/2}}{\left(2\ln\frac{1}{y_1}\right)^{1/2}} \leq \left(2\ln\frac{1}{y_1}\right)^{1/4}$$

as required. □

Proof of Claim 7.8. Since $M(x,y)$ is increasing in y, it is enough to prove that $M(x, x^{1/1.15}) \geq (\frac{2}{1.15}\ln\frac{1}{x})^{1/4}$ for every x such that $x + x^{1/1.15} \geq 1$, i.e., $x \geq 0.47579\ldots$. We will content ourselves by noting that $\lim_{x\to 1} M(x, x^{1/1.15})/(\ln\frac{1}{x})^{1/4} = +\infty$, which shows that the claim is valid for a sufficiently large choice of C. This limit can be obtained using essentially the same asymptotics as those used in the proof of Claim 7.4(b). Using some more uninspiring work it can be verified that the minimum of $\tilde{m}(1-x^{1/1.15}, 1-x)/(\frac{2}{1.15}\ln\frac{1}{x})^{1/4}$ is attained near $x = 0.999877$ and its value is about 1.84×10^{-6}. □

We note that the huge value of C was required only in the proof of Claim 7.8. For Claim 7.4, a much more modest value would have been enough. Also, no attempt to obtain the optimal value of C was made. We are sure that using a tighter yet even more tedious analysis, a much smaller value of C can be shown to suffice.

MINIMAL ASCENDING AND DESCENDING TREE AUTOMATA*

MAURICE NIVAT† AND ANDREAS PODELSKI‡

Abstract. We propose a generalization of the notion "deterministic" to "l-r-deterministic" for descending tree automata (also called root-to-frontier). The corresponding subclass of recognizable tree languages is characterized by a structural property that we name "homogeneous." Given a descending tree automaton recognizing a homogeneous tree language, it can be left-to-right (l-r) determinized and then minimized. The obtained minimal l-r-deterministic tree automaton is characterized algebraically. We exhibit a formal correspondence between the two evaluation modes on trees (ascending and descending) and the two on words (right-to-left and left-to-right). This is possible by embedding trees into the free monoid of pointed trees. We obtain a unified view of the theories of minimization of deterministic ascending and l-r-deterministic descending tree automata.

Key words. tree automata, minimization, Nerode congruence

1. Introduction and synopsis.

Automata on finite trees come up in various areas of computer science (compiler generation [13, 16, 25], type theory [19, 30, 28], constraint solving [3, 14, 15, 24, 31], rewriting [6], etc.) as a generic decision tool for problems over finite trees. Historically, their first application was a decision problem over strings, namely for monadic second-order logic formulas interpreted on the finite tree as a finite subset of the free monoid [7, 33].

The theory of tree automata and recognizable sets of trees has been introduced as a (seemingly) natural extension from the string case. The extension consists of going from unary to n-ary algebras, in the algebraic view of trees, or from one to multiple successors, in the logical view of the tree as a model. Recent works on structural properties of sets of finite trees [34, 17, 18, 32, 27], however, have exhibited some difficulties in carrying this extension further. The essence of the difference between strings and trees has not been revealed yet.

One important difference comes from the well-known fact that one cannot determinize every descending tree automaton.[1] In the string case, the direction of evaluation is usually assumed to be left-to-right, but this does not affect the family of recognizable languages. For the extension from the word to the tree case, where a word fga is considered a tree $f(g(a))$, it is the right-to-left evaluation which corresponds to the ascending[2] tree automaton. An automaton of this kind can always be transformed into a deterministic one which recognizes the same tree language. A finite deterministic ascending tree automaton is an algebraic notion (the quotient of the

[1] In our graphical representation of a tree, its root is on the top. Hence *descending* or *top-down* correspond to the more precise, but somewhat lengthy, identifier *root-to-frontier* which is used in [12].

[2] And *ascending* or *bottom-up* correspond to *frontier-to-root*.

tree algebra by a congruence with finitely many classes), and we can apply algebraic concepts in order to implement minimization.

Descending tree automata have, to our knowledge, not yet been investigated using algebraic concepts and methods. They are important, however, since they correspond naturally to tree grammars and rewriting systems. Certain type systems, for example, employ a class of tree grammars which correspond to deterministic descending tree automata [14, 36, 19]. Also, this lack of algebraic concepts [9, 26] is one of the reasons why the extension of the decision problem of [7, 33] to the infinite tree is so involved [10, 21] (obviously, the ascending evaluation is not possible here).

The minimization of the *deterministic* descending tree automata is done in [11] with a nonalgebraic state-reduction method. The class of corresponding tree languages is characterized as a proper subclass of the recognizable ones by the structural property called path closed in [35] and tuple distributive in [19]. This class is investigated in a logic framework in [34].

Given the lack of a suitable algebra framework for descending tree automata, we propose a monoid framework. Namely, we consider tree automata as automata on strings, i.e., elements of a suitable free monoid. Then ascending and descending correspond exactly to right-to-left and left-to-right, respectively.

In section 2, we introduce this monoid. Its elements are called pointed trees. It is freely generated by (infinitely many) basic pointed trees. For every set of trees L one can construct a set $\widehat{L}$ of pointed trees. One principal idea in this paper is to apply the formal framework of free monoids and the one-to-one correspondence between the sets L and $\widehat{L}$ on descending tree automata.

Pointed trees are related to special trees in [20, 34] or to terms over the free Σ algebra with exactly one occurrence of one variable. A free monoid structure, however, has not been exhibited. Also, the construction of the set $\widehat{L}$ from L is new.

In section 3, the representation of the minimization of deterministic finite *ascending* tree automata is novel in that the Nerode equivalence is defined on the free monoid of pointed trees. This allows us to extend the word case in the very direct way to the tree case. In fact, the only extension necessary is the one from a finitely to an infinitely generated free monoid.

By constructing the response function $\hat{\lambda}$ from the transition function λ, we assign essentially a word automaton to an ascending tree automaton, since the arguments of $\hat{\lambda}$ are a state and an element of the free monoid. The evaluation of that word automaton is a right-to-left one.

We recall that the standard way of defining the Nerode equivalence consists of using algebra congruences. There, the extension from the word to the tree case is the one from unary to binary function symbols for the signature of the algebra. This implies that the Nerode equivalence is viewed as a congruence on an (in the word case, unary) algebra. In contrast, we view the Nerode equivalence as a semicongruence (or right congruence) on the free monoid, in the word as well as the tree case.

It is a well-known result (attributed to Hall in [2]) that, in the algebra framework, translations can be used for defining the greatest congruence $\sim_L$ saturating a given subset L of the algebra. This has been exploited for tree automata in [12]. We have pushed the result one step further by defining a relation $\sim_{\hat{L}}$ on translations themselves and by exhibiting a free monoid structure on the set of translations in the free algebra

(which correspond to pointed trees). To summarize, section 3 uses the concept of *left-invariant* monoid semicongruences in order to define the minimal deterministic ascending tree automaton.

In section 4, we construct the response function $\hat{\lambda}$ from the transition function λ of a *descending* tree automaton. By this means, we assign it a word automaton with left-to-right evaluation. Using the response function, the characterization of the acceptance of a tree by a descending tree automaton becomes now concise and natural.

In section 5, we use the response function $\hat{\lambda}$ to introduce a new version of determinism for descending tree automata, defining it by the condition $card(\hat{\lambda}(\ldots)) = 1$. Generally, in automata theory it does not matter whether one requires the transition function λ or the response function $\hat{\lambda}$ to be deterministic: the two conditions are equivalent. Here, however, we obtain the notion of l-r determinism which is strictly more general than the standard notion of determinism for descending tree automata. That notion is based directly on the transition function, being defined by $card(\lambda(\ldots)) = 1$.

The class of tree languages which are recognized by l-r-deterministic finite descending tree automata strictly includes the class of tree languages which are recognized by deterministic ones but is itself included in the class of all recognizable tree languages. It can be characterized by a structural property that we will introduce. We call it homogeneous.

A theory of minimization of descending tree automata can seemingly not be based on the concept of algebra congruences. Given the presentation of minimization in section 3, we will use the fact that l-r-deterministic descending tree automata can also be embedded in the monoid framework. Namely, since they read the "words" of the free monoid $\Sigma^{(\#)}$ deterministically in left-to-right fashion, they induce a *right-invariant* monoid semicongruence on $\Sigma^{(\#)}$. It comes as no surprise now that we will define the Nerode equivalence relation that yields the states of the minimal descending tree automaton of a homogeneous tree language in the same way as is done for word languages [9]: we just have to apply this method on the language $\widehat{L}$ of words of $\Sigma^{(\#)}$ that corresponds to a tree language.

In section 6, we show the existence of a minimal l-r-deterministic finite descending tree automaton $\mathcal{A}(L)$ for every homogeneous recognizable tree language L. This automaton is minimal in the algebraic sense (using automata morphisms) and thus also in the number of states. It is reduced and unique up to isomorphism. Its states are the equivalence classes of the new *descending Nerode equivalence* of L which we introduce.

These results applied on path-closed tree languages yield (minimal) deterministic descending tree automata. For an arbitrary tree language L, we still can define $\mathcal{A}(L)$, which characterizes through its finiteness the recognizability of L.

For showing this last result, we just have to connect the two theories of minimal ascending and descending tree automata of a tree language L (not necessarily homogeneous and not necessarily recognizable). If and only if L is recognizable, then the language $\widehat{L}$ is a recognizable subset of the free monoid $\Sigma^{(\#)}$ and so is its reverse (the set of mirror images of its elements). Hence the minimal automaton recognizing $\widehat{L}$ with right-to-left evaluation is finite and so is the one with left-to-right evaluation. The first one can be transformed into an ascending tree automaton which recognizes L. The second one can be transformed into a descending tree automaton which recognizes L if L is homogeneous. In both cases, one obtains hereby the minimal automaton in that class. In general, the descending tree automaton obtained by the transformation recognizes the smallest homogeneous tree language containing L.

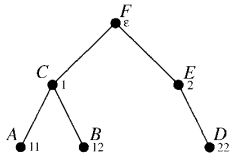

FIG. 1. *The tree* t_1.

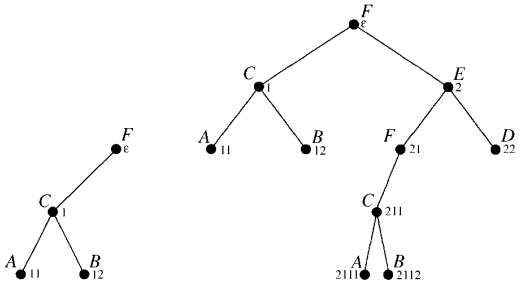

FIG. 2. *The trees* t_2 *and* $t_3 = t_1 + 21t_2$.

2. Tree monoids. For ease of notation, we only consider the case of binary trees on an unranked alphabet Σ.[3] This is the most standard case. One can give encodings of n-ary into binary trees as in [5, 8]. Also, the results of this article are straightforwardly extended to the general case. A (binary) *tree domain* is a set D of finite strings over 1 and 2 (which form the free monoid generated by $\{1, 2\}$, hence $D \subseteq \{1, 2\}^*$) such that for every element $fg \in D$ also $f \in D$. A subset of a free monoid with this closure property is called *left factorial* (cf. [1]).

A (finite, binary-ordered, labeled) *tree* on the alphabet Σ is the pair $t = (\mathrm{Supp}(t), \widehat{t}\,)$ formed by its support, which is a finite tree domain, $\mathrm{Supp}(t) \subset_{\text{finite}} \{1, 2\}^*$, and its labeling function, which goes from its support into the alphabet, $\widehat{t} : \mathrm{Supp}(t) \to \Sigma$.

We call $\Sigma^{\#}$ the set of trees on Σ. The elements of $\mathrm{Supp}(t)$ are the nodes of the tree t. Hence a node is identified with the string which corresponds to the path leading to it, where 1 and 2 stand for a step to the right and to the left, respectively. The tree t_1 given by $\mathrm{Supp}(t_1) = \{\varepsilon, 1, 11, 12, 2, 22\}$ and $\widehat{t_1} = \{(\varepsilon, F), (1, C), (11, A), (12, B), (2, E), (22, D)\}$ is presented in Figure 1.

We call the *border* of t the set $\mathcal{B}(t) = \{fi \mid f \in \mathrm{Supp}(t), i \in \{1, 2\},\ fi \notin \mathrm{Supp}(t)\}$ of all nodes "just outside the tree." Thus we might consider the border nodes as the unlabeled leaves of the tree. The border of the tree depicted in Figure 1 is the set $\mathcal{B}(t_1) = \{111, 112, 121, 122, 21, 221, 222\}$. The height of a tree t is the maximal length of a string in $\mathcal{B}(t)$.

The *empty tree*, denoted Ω, is the tree whose support is empty, $\mathrm{Supp}(\Omega) = \emptyset$. Its border is conveniently defined as $\mathcal{B}(\Omega) = \{\varepsilon\}$. A *punctual tree* is a tree of the form $t = (\{\varepsilon\}, \widehat{t}\,)$ consisting of exactly one node. If this node is labeled by $a \in \Sigma$ (i.e., $\widehat{t}(\varepsilon) = a$), then t is simply denoted a. By this identification, $\Sigma \subset \Sigma^{\#}$. The border of a punctual tree a is $\mathcal{B}(a) = \{1, 2\}$.

Given two trees t, $t' \in \Sigma^{\#}$ and a border node f of the tree t, $f \in \mathcal{B}(t)$, the *sum* of t and t' at f is the result of attaching t' to t at f [22]. Formally, it is the tree

[3] From now on, we assume the alphabet Σ given fixed. Hence we may simply use trees, automata, etc., for trees on Σ, Σ-automata, etc.

$s = t + ft'$, where

$$\mathrm{Supp}(s) = \mathrm{Supp}(t) \cup \{ff' | f' \in \mathrm{Supp}(t')\},$$
$$\widehat{s}(g) = \begin{cases} \widehat{t}(g) & \text{if } g \in \mathrm{Supp}(t), \\ \widehat{t'}(f') & \text{if } g = ff', f' \in \mathrm{Supp}(t'). \end{cases}$$

For example, if t_2 is the tree to the left in Figure 2, then $t_3 = t_1 + 21t_2$ is the tree to the right. Clearly, every tree $t \in \Sigma^{\#}$ can be represented as the sum of punctual trees $a \in \Sigma \subset \Sigma^{\#}$. This motivates the use of the symbol # for the set of trees, in reminiscence of the star operator $*$ for the set of strings. Our formalism reflects a geometric view of trees and their composition, as opposed to the standard one of substitution of terms.

We consider a tree t together with a fixed node f from its border. We shall call the pair (t, f) a *pointed tree* and f its pointed border node [23, 24]. The set of all pointed trees is denoted by $\Sigma^{(\#)}$.

If we attach to the tree t with pointed border node f the tree t' with pointed border node f', then the path of t leading to f is continued with the path of t' which leads to f'. The resulting path leads to ff', which is in the border of $t + ft'$. It thus seems natural to take as the result of this composition the tree $t + ft'$ with the pointed border node ff'. We thus obtain the *tree monoid*

$$\Sigma^{(\#)} = \{(t, f) \,|\, t \in \Sigma^{\#}, f \in \mathcal{B}(t)\},$$

where the composition of the pointed trees (t, f) and $t', f')$ is given by

$$(t, f)(t', f') = (t + ft', ff').$$

Clearly, the composition is associative and has (Ω, ε) as its neutral element. This operation can also be defined through the wreath product of two suitable monoids [29].

The following set of *basic* pointed trees will be of particular interest in the following.

$$\Gamma = \{(t, f) \in \Sigma^{(\#)} \,|\, f = 1 \ \text{ or } \ f = 2\}.$$

Every element of $(t, f) \in \Gamma$ is either of the form $(a + 2t', 1)$ or of the form $(a + 1t', 2)$ for some $a \in \Sigma$ and $t' \in \Sigma^{\#}$. In this notation, we use again that $\Sigma \subset \Sigma^{\#}$.

The set Γ consists of all pointed trees, different from the empty tree, which can no longer be decomposed into pointed trees other than themselves and the empty tree. This implies that $\Sigma^{(\#)}$ is not finitely generated. The tree monoid $\Sigma^{(\#)}$ is, however, a *free monoid*. Every pointed tree has a unique representation as a product of elements of Γ.

Given a set of trees $L \subseteq \Sigma^{\#}$, we define the set $\widehat{L} \subseteq \Sigma^{(\#)}$ of all its trees with a pointed border node

$$\widehat{L} = \{(t, f) \,|\, t \in L, f \in \mathcal{B}(t)\}.$$

Clearly, this yields a one-to-one mapping from sets of trees to sets of pointed trees.

3. Ascending tree automata. A [*finite*] (*nondeterministic*) *ascending tree automaton* $A = (Q, \lambda, q_0, Q_{\text{fin}})$ is given by its [finite] set of states Q, the initial state $q_0 \in Q$, the set of final states $Q_{\text{fin}} \subseteq Q$, and its (nondeterministic) transition function

$$\lambda : Q \times Q \times \Sigma \to \mathcal{P}(Q).$$

A *computation* of A on a tree $t \in \Sigma^{\#}$ starts by associating all border nodes (the "unlabeled leaves") of t with the initial state. It proceeds by associating a node $f \in \text{Supp}(t)$ with a state $q \in \lambda(q_1, q_2, a)$ if the node f is labeled with $a \in \Sigma$ and its left and right descendants $f1$ and $f2$ are already associated with states q_1 to the left and q_2 to the right (here $f1$ and $f2$ might be border nodes). A difficulty for the intuitive understanding of tree automata might be that this description of the evaluation of a tree does not yield an explicit algorithm. In fact, one can imagine different evaluation orders; of course, a state can be associated with a node only after this has been done for its two direct descendants, and so on.

Formally, a computation on a tree t is a tree S which has the same nodes as t plus its border nodes and is labeled, not over Σ but over Q; i.e., $S \in Q^{\#}$ and $\text{Supp}(S) = \text{Supp}(t) \cup \mathcal{B}(t)$ and

$$\begin{aligned} \forall f \in \mathcal{B}(t) : &\quad \widehat{S}(f) = q_0, \\ \forall f \in \text{Supp}(t) : &\quad \widehat{S}(f) \in \lambda(\widehat{S}(f1), \widehat{S}(f2), \widehat{t}(f)), \end{aligned} \tag{1}$$

A tree t is accepted by A if the result of the computation of A on t, the state that it associates with the root of t, is a final state. A tree language $L \subseteq \Sigma^{\#}$ is recognized by A, $L = \mathcal{L}(A)$ if L is the set of all trees t which are accepted by A. It is called *recognizable* if there exists a *finite* tree automaton that recognizes it.

We now consider the result of a computation of A on t which starts at some given border node $f \in \mathcal{B}(t)$ with a given state $q \in Q$ but at all other border nodes of t with the initial state. Formally, we define the *response function* $\hat{\lambda} : \Sigma^{(\#)} \times Q \to \mathcal{P}(Q)$, where $\hat{\lambda}(t, f, q)$ is the set of all states $\widehat{S}(\varepsilon)$, where S is a computation of A on (t, f) starting with q; that is $\text{Supp}(S) = \text{Supp}(t) \cup \mathcal{B}(t)$ and

$$\begin{aligned} &\widehat{S}(f) = q, \\ \forall g \in \mathcal{B}(t) - \{f\} : &\quad \widehat{S}(g) = q_0, \\ \forall g \in \text{Supp}(t) : &\quad \widehat{S}(g) \in \lambda(\widehat{S}(g1), \widehat{S}(g2), \widehat{t}(g)). \end{aligned}$$

Using this function we get a simple characterization of the fact that $L \subseteq \Sigma^{\#}$ is recognized by A, namely via the correspondence $L \leftrightarrow \widehat{L}$.

$$L = L(A) \quad \text{iff } \widehat{L} = \{(t, f) \mid \widehat{\lambda}(t, f, q_0) \in Q_{\text{fin}}\}.$$

We remark that $\widehat{\lambda}(t, f, q_0) = \widehat{\lambda}(t, f', q_0)$ for all f, $f' \in \mathcal{B}(t)$. This invariance will not hold for the response function of descending tree automata which we will define in the next section.

If we set $\widehat{\lambda}(t, f, q_0) = \tilde{\lambda}(t)$, we obtain a function $\tilde{\lambda} : \Sigma^{\#} \to Q$ which characterizes the set of recognized trees as $L(A) = \tilde{\lambda}^{-1}(Q_{\text{fin}})$. Both $\widehat{\lambda}$ and $\tilde{\lambda}$ can also be defined recursively.

We define the ascending tree automaton A to be *deterministic* if its response function $\widehat{\lambda}$ is deterministic, i.e., a function into the set of states Q. (We view Q as

a subset of $\mathcal{P}(Q)$, identifying a singleton with its element.) This coincides with the standard condition that λ be deterministic.

We recall that an equivalence relation $\sim$, here on the tree monoid $\Sigma^{(\#)}$, is a *left-invariant semicongruence* if $(t_1, f_1) \sim (t_2, f_2)$ implies $(t, f)(t_1, f_1) \sim (t, f)(t_2, f_2)$ for all $(t, f) \in \Sigma^{(\#)}$. Also, $\sim$ *saturates* the subset $\widehat{L} \subseteq \Sigma^{(\#)}$ of the tree monoid if $\widehat{L}$ is the union of some of its equivalence classes, i.e., $(t_1, f_1) \sim (t_2, f_2)$ implies $(t_1, f_1) \in \widehat{L}$ iff $(t_2, f_2) \in \widehat{L}$. Finally, a relation $\sim_1$ is *coarser* than another one $\sim_2$ if $x \sim_2 y$ implies $x \sim_1 y$; i.e., the relation $\sim_1$ as a set is included in $\sim_2$.

DEFINITION 1. *The Nerode equivalence of a tree language $L \subseteq \Sigma^{\#}$, denoted $\sim_L$, is the coarsest left-invariant semicongruence on the tree monoid $\Sigma^{(\#)}$ which saturates $\widehat{L}$.*

Another way to characterize $\sim_L$ is to define that $(t_1, f_1) \sim_L (t_2, f_2)$ iff

$$\forall (t, f) \in \Sigma^{(\#)} : (t, f)(t_1, f_1) \in \widehat{L} \quad \text{iff } (t, f)(t_2, f_2) \in \widehat{L}.$$

We say that two pointed trees (t, f) and (t', f') are *border equivalent* iff $t = t'$. We observe that border equivalence is coarser than the Nerode equivalence of any tree language, i.e., always $(t, f) \sim_L (t, f')$. This will not hold for the descending Nerode equivalence that we will define in section 5.

THEOREM 1. *The tree language $L \subseteq \Sigma^{\#}$ is recognizable iff its Nerode equivalence $\sim_L$ on the tree monoid has a finite index, which means that the set*

$$\Sigma^{(\#)}_{/\sim_L} = \{[(t, f)]_{\sim_L} \mid (t, f) \in \Sigma^{(\#)}\}$$

is finite. This set is the set of states of the minimal deterministic finite ascending tree automaton of L (which exists uniquely for every recognizable tree language).

Proof. Given that $card(\Sigma^{(\#)}_{/\sim_L})$ is finite, we can define a deterministic finite ascending tree automaton $A^L = (Q^L, \lambda^L, q_0^L, Q_{\text{fin}}^L)$ by $Q^L = \Sigma^{(\#)}_{/\sim_L}$, $q_0^L = [(\Omega, \varepsilon)]_{\sim_L}$, $Q_{\text{fin}}^L = \{[(t, f)]_{\sim_L} \mid (t, f) \in \widehat{L}\}$, and $\lambda^L([(t_1, f_1)]_{\sim_L}, [(t_2, f_2)]_{\sim_L}, a) = [(a + 1t_1 + 2t_2, 1f_1)]_{\sim_L}$.

Using the property mentioned above, one proves that the definition of λ^L is well founded and that $\widehat{\lambda^L}(t, f, q_0) = [(t, f)]_{\sim_L}$. This shows one direction, since a tree t is accepted by $\mathcal{A}^L$ if $\widehat{\lambda^L}(t, f, q_0) \in Q_{\text{fin}}^L$.

Conversely, consider a deterministic finite ascending tree automaton $A = (Q, \lambda, q_0, Q_{\text{fin}})$ which recognizes the tree language $L \subseteq \Sigma^{\#}$. We can attach to A the relation $\sim_A$ on $\Sigma^{(\#)}$ defined by $(t_1, f_1) \sim_A (t_2, f_2)$ iff $\widehat{\lambda}(t_1, f_1, q_0) = \widehat{\lambda}(t_2, f_2, q_0)$.

The following property proves that this equivalence relation is left invariant. It says that λ respects the composition of the tree monoid:

$$\widehat{\lambda}(t, f, \widehat{\lambda}(t', f', q)) = \widehat{\lambda}((t, f)(t', f'), q).$$

This equation implies that $\widehat{\lambda}((t, f)(t_1, f_1), q_0) = \widehat{\lambda}((t, f)(t_2, f_2), q_0)$. The left invariance of $\sim_A$ implies that $\sim_L$ is coarser than $\sim_A$, which means that $card(\Sigma^{(\#)}_{/\sim_L}) \leq card(\Sigma^{(\#)}_{/\sim_A})$. However, $card(\Sigma^{(\#)}_{/\sim_A}) \leq card(Q)$, and this again implies that the Nerode equivalence $\sim_L$ has finite index and that $\mathcal{A}^L$ has the minimal number of states among all deterministic finite ascending tree automata recognizing L. □

A stronger notion of minimality than the one based on the number of states is the following algebraic one. An automaton A is called *minimal* in a given class of automata iff every equivalent automaton A' in the class can be mapped onto A by

a corresponding automata morphism. Here a morphism π from $A = (Q, \lambda, q_0, Q_{\text{fin}})$ onto $A' = (Q', \lambda', q'_0, Q'_{\text{fin}})$ is a surjective mapping from Q onto Q' which satisfies that $\pi(\lambda(q_1, q_2, a)) = \lambda'(\pi(q_1), \pi(q_2), a)$, $\pi(q_0) = q'_0$, and $\pi(Q_{\text{fin}}) = Q'_{\text{fin}}$. It is not difficult to show that $\mathcal{A}^L$ is minimal in the algebraic sense.[4]

COROLLARY 1. *A tree language L is recognizable iff $\widehat{L}$ is saturated by a left-invariant equivalence relation $\sim$ on the tree monoid $\Sigma^{(\#)}$ which has finite index.* □

4. Descending tree automata. A [*finite*] (*nondeterministic*) *descending tree automaton* $A = (Q, \lambda, q_0, Q_{\text{fin}})$ is given by its [finite] set of states Q, the initial state q_0, and the subset Q_{fin} of Q of final states and the (nondeterministic) transition function

$$\lambda : Q \times \Sigma \to \mathcal{P}(Q \times Q).$$

We will carry over the notions from the case of ascending to the case of descending tree automata and sometimes use the same notation.

A *computation* of A on a tree t now starts at its root by associating the initial state with this node. At each node with, say, label, $A \in \Sigma$ and already associated state $q \in Q$, the computation proceeds by choosing nondeterministically a pair of successor states $(q_1, q_2) \in \lambda(q, a)$ and associating q_1 and q_2 with the left respective right son ("descendant") of this node.

Formally, we define a computation on t to be a tree $S \in Q^{\#}$ with support $\text{Supp}(S) = \text{Supp}(t) \cup \mathcal{B}(t)$ which satisfies the following conditions (instead of (1) for the ascending tree automaton).

$$\widehat{S}(\varepsilon) = q_0,$$
$$\forall f \in \text{Supp}(t): \quad (\widehat{S}(f1), \widehat{S}(f_2)) \in \lambda(\widehat{S}(f), \widehat{t}(f)).$$

The computation of A on t is called *successful* if it associates all border nodes with a final state, i.e., $\widehat{S}(g) \in Q_{\text{fin}}$ for all $g \in \mathcal{B}(t)$. A tree t is accepted by A if there exists a successful computation of A on t. The tree language L recognized by A, $L - \mathcal{L}(A)$ is the set of all accepted trees.

It is not evident how one can define a function that describes the evaluation of a tree by a descending tree automaton. We can, however, describe the evaluation of a pointed tree by defining the *response function* $\widehat{\lambda} : Q \times \Sigma^{(\#)} \to \mathcal{P}(Q)$ of a descending tree automaton as follows. (Note that we changed the order of the arguments of the response function of the ascending tree automaton.)

$$\begin{aligned}\widehat{\lambda}(q, t, f) = \{\widehat{S}(f) \mid \quad & S \text{ is a computation on } t,\\ & \widehat{S}(\varepsilon) = q,\\ & \forall g \in \mathcal{B}(t) - \{f\} : \widehat{S}(g) \in Q_{\text{fin}}\}\end{aligned}$$

That is, $q' \in \widehat{\lambda}(q, t, f)$ if q' is the state at the border node f of t obtained by a computation of A on t which starts at the root of t with the state q and which ends at all border nodes other than f with a final state. We also say that q' is the result of a computation on the pointed tree (t, f) starting in q.

We define the set of all pointed trees such that the response function assigns them a final state:

$$\widehat{L}_q = \{(t, f) \mid \widehat{\lambda}(q, t, f) \cap Q_{\text{fin}} \neq \emptyset\}.$$

[4]When considering the algebraic notion of minimality of automata, one excludes automata with nonaccessible states (a state is accessible if there exists a computation in which it occurs).

We can characterize the tree language recognized by A by $\widehat{L_{q_0}}$ as follows:

$$L = \mathcal{L}(A) \quad \text{iff } \widehat{L} = \{(t,f) \mid \widehat{\lambda}(q_0,t,f) \cap Q_{\text{fin}} \neq \emptyset\}.$$

If we define $L_q = \{t \in \Sigma^{\#} \mid (t,f) \in \widehat{L_q}\}$ (where it does not matter whether we require $(t,f) \in \widehat{L_q}$ for at least one or for all $f \in \mathcal{B}(t)$), then we obtain that $\mathcal{L}(A) = L_{q_0}$.

The following property expresses the "associativity of computation" for descending tree automata.

$$\widehat{\lambda}(\widehat{\lambda}(q,t,f),s,g) = \widehat{\lambda}(q,(t,f)(s,g)) \tag{2}$$

For this equation we assume the canonical extension of the response function from states to sets of states. Its proof proceeds by induction on the structure of (t,f), using the recursive definition of $\widehat{\lambda}$.

We use the response function in order to define some standard automata properties for a descending tree automaton A in a concise way. A state $q \in Q$ is called *accessible* if there exists a pointed tree (t,f) such that $\widehat{\lambda}(q_0,t,f) \ni q$, i.e., an "elsewhere successful" computation on t can reach this state at the border node f. For the concept of minimality of section 6, we need to assume that the states of the automata considered are all accessible. The state q is called *coaccessible* if there exists a pointed tree (t,f) such that $\widehat{\lambda}(q,t,f) \cap Q_{\text{fin}} \neq \emptyset$; that is, there exists a successful computation on t starting in this state. The automaton A is called *trim* if all states are accessible and coaccessible. Of course, every finite descending tree automaton can be effectively transformed into an equivalent trim one. Two states q, $q' \in Q$ are called *separable* if there exists a pointed tree (t,f) such that $\widehat{\lambda}(q,t,f) \cap Q_{\text{fin}} = \emptyset$ and $\widehat{\lambda}(q',t,f) \cap Q_{\text{fin}} \neq \emptyset$, or vice versa. The automaton A is called *reduced* if all states are pairwise separable.

Finally, we call two states $q, q' \in Q$ *disjoint* if L_q and $L_{q'}$ are disjoint sets, $L_q \cap L_{q'} = \emptyset$.

The function $\widehat{\lambda}$ can also be defined recursively on the set of pointed trees $\Sigma^{(\#)}$ by

$$\begin{aligned}
\widehat{\lambda}(q,\Omega,\varepsilon) &= \{q\},\\
\widehat{\lambda}(q,a+1t_1+2t_2,1f_1) &= \cup\{\widehat{\lambda}(q_1,t_1,f_1) \mid \exists q_2 \in Q : t_2 \in L_{q_2}, (q_1,q_2) \in \lambda(q,a)\},\\
\widehat{\lambda}(q,a+1t_1+2t_2,2f_2) &= \cup\{\widehat{\lambda}(q_2,t_2,f_2) \mid \exists q_1 \in Q : t_1 \in L_{q_1}, (q_1,q_2) \in \lambda(q,a)\}.
\end{aligned}$$

Observe that the condition $t_2 \in L_{q_2}$, which is $\widehat{\lambda}(q_2,t_2,f_2) \cap Q_{\text{fin}} \neq \emptyset$ for some $f_2 \in \mathcal{B}(t_2)$, as well as the condition $t_1 \in L_{q_1}$ are checked by recursion since t_1 and t_2 are smaller trees than $a+1t_1+2t_2$. We see that the recursive definition of $\widehat{\lambda}$ suggests a depth-first transversal of the tree t to be evaluated: for each two direct subtrees t_1 and t_2 of a subtree at some node f of t, the subtree t_1 is traversed once a computation on t_2 is successful.

5. Introducing l-r-determinism. We now define the counterpart of the notion of ascending deterministic tree automata.

DEFINITION 2. *A finite descending tree automaton A is* l-r-deterministic *if the response function $\widehat{\lambda}$ of A is deterministic; this means that, applied on any state and any pointed tree, its value is a singleton.*

Formally, the defining condition means that $card(\widehat{\lambda}(q,t,f)) = 1$ holds for all $q \in Q$ and all $(t,f) \in \Sigma^{(\#)}$. This is equivalent to the condition that $card(\widehat{\lambda}(q_0,t,f)) = 1$ holds for all $(t,f) \in \Sigma^{(\#)}$ and to the condition that $card(\widehat{\lambda}(q,t,f)) = 1$ holds for all $q \in Q$ and all $(t,f) \in \Gamma$.

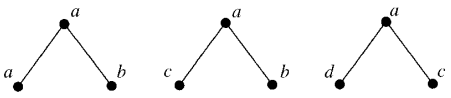

FIG. 3. *The trees of* L_0.

One can express l-r-determinism also without using the response function, namely by the following condition.[5] Whenever there is a nondeterministic transition with two successor state pairs, then the left successor states can be different only if the right successor states are disjoint, and vice versa. Formally, this condition says that if (q_1, q_2), $(q_1', q_2') \in \lambda(q, a)$, then

$$q_1 \neq q_1' \quad \text{implies} \quad L_{q_2} \cap L_{q_2'} = \emptyset,$$
$$q_2 \neq q_2' \quad \text{implies} \quad L_{q_1} \cap L_{q_1'} = \emptyset.$$

In particular, if the two left successor states q_1 and q_1' are different, then they are disjoint; if they are equal, then the corresponding right successor states q_2 and q_2' are also equal.

For the evaluation of an l-r-deterministic descending tree automaton, this means at a node f of a tree t several transitions might still be possible; the successor state to the right side, however, is unique for all the transitions that can be continued successfully on the left side (and vice versa).

That is, whichever of the transitions $(q_1^1, q_2^1), \ldots, (q_1^k, q_2^k)$ is chosen, where the subtree t' of t starting at $f2$ is recognized by the right successor state (i.e., t' lies in $L_{q_2^1}, \ldots, L_{q_2^k}$), then the left successor state is the same ($q_1^1 = \cdots = q_1^k$).

In order to compare the two notions of determinism, we consider the tree language $L_0 = \{a + 1a + 2b, a + 1c + 2b, a + 1d + 2c\}$ over $\Sigma = \{a, b, c, d\}$ depicted in Figure 3. Clearly, L_0 *cannot* be recognized by a deterministic descending tree automaton. If (q_1, q_2) were the only successor state pair in $\lambda(q_0, a)$, then $a, c \in L_{q_1}$ and $b, c \in L_{q_2}$ and hence also $a + 1c + 2c$ would be recognized. The same reasoning can be made for the tree language $L_0' = \{a+1a+2b, a+1d+2c\}$. One can give simple l-r-deterministic descending tree automata recognizing L_0 and L_0'. We will derive them in a way which will serve later as an example for the l-r-determinization algorithm (from the proof of Theorem 3) and illustrate its intrinsic difficulty.

The descending tree automaton $A_0 = (\{q_0, \ldots, q_6, q_{\text{fin}}\}, q_0, \lambda, \{q_{\text{fin}}\})$ recognizes L_0 if we set $\lambda(q_0, a) = \{(q_1, q_2), (q_3, q_4), (q_5, q_6)\}$ and $\lambda(q_1, a) = \lambda(q_2, b) = \lambda(q_3, c) = \lambda(q_4, b) = \lambda(q_5, d) = \lambda(q_6, c) = \{(q_{\text{fin}}, q_{\text{fin}})\}$.

We now set $P_1 = \{q_1, q_3\}$, $P_2 = \{q_2, q_4\}$, $P_3 = \{q_5\}$, and $P_4 = \{q_6\}$ and define the descending tree automaton $A_0^d = (\mathcal{P}(Q), \{q_0\}, \lambda^d, Q_{\text{fin}}^d)$, where $\lambda^d(\{q_0\}, a) = \{(P_1, P_2), (P_3, P_4)\}$ and $\lambda^d(P_i, x) = \{(q_{\text{fin}}, q_{\text{fin}})\}$ if $x \in L_q$ for some $q \in P_i$ and $Q_{\text{fin}}^d = \{P \in \mathcal{P}(Q) | P \cap \{q_{\text{fin}}\} \neq \emptyset\}$.

It is easy to see that A^d is l-r-deterministic and recognizes L_0. For example, if the subtree to the right side is the punctual tree b, then the successor state to the other side is determined to be P_1. Thus $\widehat{\lambda}(\{q_0\}, a + 2b, 1)$ contains only the one element P_1.

[5] In a strict sense, this condition is not equivalent to the one in Definition 2 since it allows the value of $\hat{\lambda}$ to be a singleton or the empty set. The two conditions coincide if we identify the empty set with the singleton containing a "trap state." This identification is natural when one considers minimal deterministic automata (which have either a partial transition function or a unique trap state).

The following lemma describes the set of successor state pairs (q_1, q_2) of a state q at a node with some label a. For every pair, there exists a tree $s = a+1s_1+2s_2$ which is accepted by the automaton starting in the state q, and the left successor state q_1 is determined by the right subtree of any such tree (and vice versa, the right successor state q_2 is determined by the left subtree of any such tree).

LEMMA 1. *Let $A = (Q, \lambda, q_0, Q_{\mathrm{fin}})$ be a trim l-r-deterministic descending tree automaton. Then*

$$\lambda(q,a) = \{(q_1,q_2) \mid \exists s_1, s_2 \in \Sigma^{\#} : \quad a + 1s_1 + 2s_2 \in L_q, \\ q_1 = \widehat{\lambda}(q, a + 2s_2, 1), \quad q_2 = \widehat{\lambda}(q, a + 1s_1, 2)\}.$$

Proof. We call K the set on the right-hand side. We will show $\lambda(q,a) \subseteq K$ first. Let $(q_1, q_2) \in \lambda(q,a)$. Since A is assumed trim, q_1 and q_2 are coaccessible. Thus there exist $s_1, s_2 \in \Sigma^{\#}$ such that

$$\forall g_1 \in \mathcal{B}(s_1) : \quad \widehat{\lambda}(q_1, s_1, g_1) \in Q_{\mathrm{fin}}, \\ \forall g_2 \in \mathcal{B}(s_2) : \quad \widehat{\lambda}(q_2, s_2, g_2) \in Q_{\mathrm{fin}}.$$

If we choose $s = a + 1s_1 + 2s_2$, then for $g \in \mathcal{B}(s)$, say, $g = 1g_1$, equation (2) implies that $\widehat{\lambda}(q, s, g) = \widehat{\lambda}(\widehat{\lambda}(q, a+2s_2, 1), s_1, g_1)$ and thus $\lambda(q, s, g) \in Q_{\mathrm{fin}}$. Together with the definition of $\widehat{\lambda}$ applied to $\widehat{\lambda}(q, a + 2s_2, 1)$, $\widehat{\lambda}(q, a + 1s_1, 2)$ this gives $(q_1, q_2) \in K$.

For the other inclusion, $\lambda(q,a) \supseteq K$, let (q_1, q_2) be an element in K and the tree $s = a+1s_1+2s_2$ satisfy the condition in the definition of K. Then $q_1 = \widehat{\lambda}(q, a+2s_2, 1)$ implies that there exists $q_2' \in Q$ such that $(q_1, q_2') \in \lambda(q,a)$ and $\widehat{\lambda}(q_2', s_2, f) \in Q_{\mathrm{fin}}$ for all $f \in \mathcal{B}(s_2)$. Symmetrically, $q_2 = \widehat{\lambda}(q, a + 1s_1, 2)$ implies that there exists $q_1' \in Q$ such that $(q_2, q_1') \in \lambda(q,a)$ and $\widehat{\lambda}(q_1', s_1, f) \in Q_{\mathrm{fin}}$ for all $f \in \mathcal{B}(s_1)$.

Finally, we use equation (2) and the fact that $\widehat{\lambda}(q, s, g) \in Q_{\mathrm{fin}}$ holds for all $g \in \mathcal{B}(s)$ to infer the following. For all $g_1 \in \mathcal{B}(s_1)$,

$$\begin{aligned} \widehat{\lambda}(q_1, s_1, g_1) &= \widehat{\lambda}(\widehat{\lambda}(q, a + 2s_2, 1), s_1, g_1) \\ &= \widehat{\lambda}(q, a + 1s_1 + 2s_2, 1g_1) \in Q_{\mathrm{fin}} \end{aligned}$$

since $g_1 \in \mathcal{B}(s_1)$ means that $1g_1 \in \mathcal{B}(s)$.

Thus $s_1 \in L_{q_1}$ and hence $q_2' \in \widehat{\lambda}(q, a + 1s_1, 2)$. The l-r-determinism then yields $q_2' = q_2$. Symmetrically, $q_1' = q_1$ and thus $(q_1, q_2) \in \lambda(q,a)$. □

The following corollary expresses the connection between the left and the right successor states in a pair (q_1, q_2). Namely, the right successor state recognizes the right subtree that, in turn, determines the left successor state, and vice versa.

COROLLARY 2. *Let $A = (Q, \lambda, q_0, Q_{\mathrm{fin}})$ be a trim l-r-deterministic descending tree automaton. Then*

$$\lambda(q,a) = \{(q_1,q_2) \mid \exists s_1 \in L_{q_1} : q_2 = \widehat{\lambda}(q, a + 1s_1, 2), \\ \exists s_2 \in L_{q_2} : q_1 = \widehat{\lambda}(q, a + 2s_2, 1)\}.$$

Proof. We use the notation of the previous proof and call K' the set on the right-hand side of the above equation. We will show that $K = K'$. The direction $\subseteq$ says that $a + 1s_1 + 2s_2 \in L_q$ implies $q_1 \in L_{q_1}$ and $q_2 \in L_{q_2}$, but this is clear: if $a + 1s_1 + 2s_2 \in L_q$, then there must exist $(q_1', q_2') \in \lambda(q,a)$ such that $s_1 \in L_{q_1'}$ and

$s_2 \in L_{q_2'}$. Hence $q_1' = \widehat{\lambda}(q, a + 2s_2, 1)$ and $q_2' = \widehat{\lambda}(q, a + 1s_1, 2)$ and thus $q_1' = q_1$ and $q_2' = q_2$.

Now if $q_2 = \widehat{\lambda}(q, a + 1s_1, 2)$, then there exists q_1' such that $s_1 \in L_{q_1'}$ and $(q_1', q_2) \in \lambda(q, a)$. Since $q_2 \in L_{q_2}, a + 1s_1 + 2s_2 \in L_q$. This shows the direction $\supseteq$. □

We now introduce the structural property which, as we will show, corresponds to the new notion of determinism.

DEFINITION 3. *A tree language $L \subseteq \Sigma^{\#}$ is called homogeneous if its membership relation is "subtree distributive" in the following manner. For all subtrees $s_1, s_2, t_1, t_2 \in \Sigma^{\#}$, all trees $t \in \Sigma^{\#}$ with border node $f \in \mathcal{B}(t)$, and all labels $a \in \Sigma$, the conjunction of*

$$\begin{aligned} t + f(a + 1t_1 + 2t_2) &\in L, \\ t + f(a + 1s_1 + 2t_2) &\in L, \\ t + f(a + 1t_1 + 2s_2) &\in L \end{aligned}$$

implies $t + f(a + 1s_1 + 2s_2) \in L$.

Thus in a homogeneous tree language L, if one has the three pairs (t_1, t_2), (s_1, t_2), and (t_1, s_2) for the left and right subtrees at the same node f of a tree in L, then the fourth pair (s_1, s_2) also yields a tree in L.

Remark 1. A tree language $L \subseteq \Sigma^{\#}$ is homogeneous iff for all sets of subtrees L_1, L_2, K_1, and K_2 such that the conjunction of

$$\begin{aligned} t + f(a + 1L_1 + 2L_2) &\subseteq L, \\ t + f(a + 1K_1 + 2K_2) &\subseteq L, \\ (L_1 \cap K_1 \neq \emptyset \quad &\text{or} \quad L_2 \cap K_2 \neq \emptyset) \end{aligned}$$

implies $t + f(a + 1(L_1 \cup K_1) + 2(L_2 \cup K_2)) \subseteq L$.

Proof. Let L be homogeneous and L_1, L_2, K_1, and K_2 be as in the statement with, say, $u_1 \in L_1 \cap K_1 \neq \emptyset$. Given $t_1 \in L_1$, $t_2 \in L_2$, $s_1 \in K_1$, and $s_2 \in K_2$, we will show that $t + f(a + 1s_1 + 2t_2) \in L$ and $t + f(a + 1t_1 + 2s_2) \in L$. The first follows from

$$\begin{aligned} t + f(a + 1s_1 + 2s_2) &\in L, \\ t + f(a + 1u_1 + 2s_2) &\in L, \\ t + f(a + 1u_1 + 2t_2) &\in L. \end{aligned}$$

The second membership statement follows from

$$\begin{aligned} t + f(a + 1t_1 + 2t_2) &\in L, \\ t + f(a + 1u_1 + 2t_2) &\in L, \\ t + f(a + 1u_1 + 2s_2) &\in L. \end{aligned}$$

In order to show that the condition in the remark implies that L is homogeneous, we take trees s_1, s_2, t_1, and t_2 as in the formulation of the definition and set $K_1 = \{s_1\}$, $K_2 = \{t_2\}$, $L_1 = \{t_1\}$, and $L_2 = \{s_2, t_2\}$. □

The class of homogeneous languages contains properly the class of languages which are called *path closed* in [12]. A path is a tree where each node has at most one descendant. A path of a tree t is a tree p with the same labeling on its support $\mathrm{Supp}(p) \subseteq \mathrm{Supp}(t)$. A tree is an element of a path-closed language L already if each

of its paths is a path of some tree of L. This condition characterizes path closedness; one can show that it is equivalent to the following:

$$t + f(a + 1s_1 + 2s_2) \in L,$$
$$t + f(a + 1t_1 + 2t_2) \in L$$

implies $t + f(a + 1s_1 + 2t_2) \in L$, or, equivalently (cf. Remark 1),

$$t + f(a + 1L_1 + 2L_2) \in L,$$
$$t + f(a + 1K_1 + 2K_2) \in L$$

implies $t + f(a + 1(L_1 \cup K_1) + 2(L_2 \cup K_2)) \in L$.

Just as the path-closed tree languages correspond to those recognizable by deterministic descending tree automata [12], the homogeneous tree languages correspond to those recognizable to l-r-deterministic descending tree automata.

THEOREM 2. *A [recognizable] tree language L is homogeneous iff it can be recognized by a [finite] l-r-deterministic descending tree automaton A.*

Proof. Let L be recognized by the trim l-r-deterministic descending tree automaton $A = (Q, \lambda, q_0, Q_{\text{fin}})$. Let $t, s_1, s_2, t_1, t_2 \in \Sigma^{\#}$, $a \in \Sigma$, and $f \in \mathcal{B}(t)$ be such that

$$t + f(a + 1t_1 + 2t_2) \in L, t + f(a + 1s_1 + 2t_2) \in L \quad \text{and} \quad t + f(a + 1t_1 + 2s_2) \in L.$$

Let $q = \widehat{\lambda}(q_0, t, f)$ be the result of a computation on the pointed tree (t, f), and let $q_1 = \widehat{\lambda}(q, a + 2s_2, 1)$ and $q_2 = \widehat{\lambda}(q, a + 1s_1, 2)$ be the results of a computation on the basic pointed trees $(a + 2s_2, 1)$ and $(a + 1s_1, 2)$ starting in q. Corollary 2 yields that $(q_1, q_2) \in \lambda(q, a)$. The definition of l-r-determinism now implies that $s_1, t_1 \in L_{q_1}$ and $s_2, t_2 \in L_{q_2}$. Thus $a + 1s_1 + 2s_2 \in L_1$, and hence $t + f(a + 1s_1 + s_2) \in \mathcal{L}(A)$.

This shows the homogeneity of L and the "if" direction. The "only if" direction will follow from Theorem 3 below (but also from Theorem 4 in the next section). □

THEOREM 3. *A finite descending tree automaton A recognizing a homogeneous tree language can be effectively transformed into an equivalent l-r-deterministic descending tree automaton A^d.*

The naïve extension of the powered construction would define

$$\lambda^d(P, a) = \{(\widehat{\lambda}(P, a + 2t_2, 1), \widehat{\lambda}(P, a + 1t_1, 2)) \mid a + 1t_1 + 2t_2 \in L_P\}.$$

However, the example of the tree automaton A_0 recognizing the tree language L_0 given above shows that this does not always yield an l-r-deterministic descending tree automaton. We will give a construction which yields A_0^d as in the example. The idea is to augment the successor states P_1 and P_2 in the pairs above with all successor states q_1 and q_2 of A such that $L_{q_1} \subseteq L_{P_1}$ and $L_{q_2} \subseteq L_{P_2}$.

Proof. We denote by λ^1 and λ^2 the projections of λ on the first and second component, respectively. As usual, we use the same symbol for a function and its canonical extension to subsets of its domain. Thus $\lambda(P, a) \cup \{\lambda(q, a) \mid q \in P\}$ for $P \subseteq Q$. Furthermore, let $L_P = \cup\{L_q \mid q \in P\}$.

Given $A = (Q, \lambda, q_0, Q_{\text{fin}})$ recognizing the homogeneous tree language L, we will construct the descending tree automaton $A^d = (Q^d, \lambda^d, q_0^d, Q_{\text{fin}}^d)$. For $P \subseteq Q$ and $a \in \Sigma$, we set

$$\lambda^d(P, a) = \{(\{q_1 \in \lambda^1(q, a) \mid a + 1L_{q_1} + 2t_2 \subseteq L_P\},$$
$$\{q_2 \in \lambda^2(q, a) \mid a + 1t_1 + 2L_{q_2} \subseteq L_P\}) \mid a + 1t_1 + 2t_2 \in L_P\}.$$

We define $q_0^d = \{q_0\}$, $Q^d \subseteq \mathcal{P}(Q)$ as the set of all accessible states in $\mathcal{P}(Q)$ and $Q^d_{\text{fin}} = \{P \in Q^d \mid P \cap Q_{\text{fin}} \neq \emptyset\}$.

Since we will need the homogeneity of L_P, we will first show that for every $P \in Q^d$ there exists a pointed tree $(t, f) \in \Sigma^{(\#)}$ such that $L_P = \{s \mid t + fs \in L\}$. Since we consider accessible states only, we can proceed by induction on $\Sigma^{(\#)}$. Clearly, q_0^d corresponds to $(t, f) = (\Omega, \varepsilon)$. Now if $P_1 \in \lambda^d(P, a + 2t_2, 1)$, where by induction hypothesis P corresponds to (t, f), we will show $L_{P_1} = \{s \mid (t + fa + f2t_2) + f1s \in L\}$. By the definition of λ^d, there exists a tree t_1 such that $t + f(a + 1t_1 + 2t_2) \in L$ and $t + f(a + 1L_{P_1} + 2t_2) \subseteq L$. However, for every tree t_1' such that $t + f(a + 1t_1' + 2t_2) \in L$, there exists a state q_1' such that $t_1' \in L_{q_1'}$ and $a + 1L_{q_1'} + 2t_2 \subseteq L_P$. Thus $q_1' \in P_1$ and the statement follows.

The fact that A^d recognizes $L = \mathcal{L}(A)$ is a special case (for $P = \{q_0\}$) of the equivalence

$$t \in L_P^d \quad \text{iff } t \in L_P, \tag{3}$$

which we will prove by induction over $\Sigma^{\#}$. The base step $t = \Omega$ is clear by the definition of Q^d_{fin}. Assuming the equivalence for the trees s_1 and s_2, we will show it for $s = a + 1s_1 + 2s_2$. If $s \in L_P^d$, then there exist states P_1 and P_2 of A^d such that

$$s_1 \in L^d_{P_1}, \qquad s_2 \in L^d_{P_2}, \qquad (P_1, P_2) \in \lambda^d(P, a).$$

Applying the induction hypothesis and the definition of λ^d yields $s_1 \in L_{P_1}$, $s_2 \in L_{P_2}$ and there exist trees t_1 and t_2 such that

$$\begin{aligned} a + 1L_{P_1} + 2t_2 &\subseteq L_P, \\ a + 1t_1 + 2L_{P_2} &\subseteq L_P, \\ a + 1t_1 + 2t_2 &\in L_P. \end{aligned}$$

The homogeneity of L_P yields directly that $s \in L_P$. Vice versa, if $s = a + 1s_1 + 2s_2 \in L_P$, say $s \in L_q$, where $q \in P$, then there exist states q_1 and q_2 of A such that $s_1 \in L_{q_1}$, $s_2 \in L_{q_2}$, and $(q_1, q_2) \in \lambda(q, a)$. Hence there exist sets P_1 and P_2 of states of A which include q_1 and q_2 (hence $s_1 \in L_{P_1}$ and $s_2 \in L_{P_2}$) such that $(P_1, P_2) \in \lambda^d(q, a)$. Applying the induction hypothesis yields $s_1 \in L^d_{P_1}$ and $s_2 \in L^d_{P_2}$ and thus $s \in L_P^d$. In order to show that A^d is l-r-deterministic, we only show the left determinism; the proof of the right determinism is symmetrical. Assuming two successor state pairs (P_1, P_2) and (P_1', P_2') in $\lambda^d(P, a)$ with $L^d_{P_2} \cap L^d_{P_2'} \neq \emptyset$, we will show $P_1 = P_1'$.

The assumption together with (3) yields

$$\begin{aligned} a + 1L_{P_1} + 2L_{P_2} &\subseteq L_P, \\ a + 1L_{P_1'} + 2L_{P_2'} &\subseteq L_P, \\ L_{P_2} \cap L_{P_2'} &\neq \emptyset. \end{aligned}$$

The homogeneity of L_P and Remark 1 imply that $a+1(L_{P_1} \cup L_{P_1'})+2(L_{P_2} \cup L_{P_2'}) \subseteq L_P$, but this, together with the definition of λ^d, yields $P_1 = P_1'$.

If L is recognizable and A is chosen finite, then A^d is also finite. The determinization described above can then be done effectively by restricting all occurring sets of trees to sets of trees of height $h \leq 2^{|Q|}$. This is not a real restriction since the above statements are true iff they are true when quantified over the trees of height $h \leq 2^{|Q|}$. □

If $\mathcal{L}(A)$ is path closed, then the above construction yields a deterministic descending tree automaton. If $\mathcal{L}(A)$ is not homogeneous, then A^d recognizes just a homogeneous superset of $\mathcal{L}(A)$.

6. Introducing l-r-minimization. The following definition is the analogue of Definition 1.

DEFINITION 4. *The* descending Nerode equivalence relation $\approx_L$ *of a tree language* $L \subseteq \Sigma^{\#}$ *is the coarsest right invariant equivalence relation on the tree monoid* $\Sigma^{(\#)}$ *which saturates* $\widehat{L}$.

That is, for all $(t_1, f_1), (t_2, f_2) \in \Sigma^{(\#)}$ if $(t_1, f_1) \approx_L (t_2, f_2)$, then

$$(t_1, f_1)(t, f) \approx_L (t_2, f_2)(t, f) \quad \forall (t, f) \in \Sigma^{(\#)}$$

and

$$(t_1, f_1) \in \widehat{L} \quad \text{iff } (t_2, f_2) \in \widehat{L}.$$

Furthermore, if $\approx$ is another equivalence relation with these two properties, then $\approx_L$ is coarser than $\approx$, i.e., $(t_1, f_1) \approx (t_2, f_2)$ always implies $(t_1, f_1) \approx_L (t_2, f_2)$.

We can define $\approx_L$ equivalently by the following condition. For all $(t_1, f_1), (t_2, f_2) \in \Sigma^{(\#)}$, $(t_1, f_1) \approx_L (t_2, f_2)$ iff

$$\forall (s, g) \in \Sigma^{(\#)} : \quad ((t_1, f_1)(s, g) \in \widehat{L} \quad \text{iff } (t_2, f_2)(s, g) \in \widehat{L}). \tag{4}$$

If we define $(t, f)^{-1}\widehat{L} = \{(s, g) \in \Sigma^{(\#)} \mid (t, f)(s, g) \in \widehat{L}\}$, then (4) is the same as $(t_1, f_1)^{-1}\widehat{L} = (t_2, f_2)^{-1}\widehat{L}$. If we set

$$(t, f)^{-1}L = \{s \in \Sigma^{\#} \mid t + fs \in L\},$$

then (4) becomes, more simply,

$$(t_1, f_1) \approx_L (t_2, f_2) \quad \text{iff } (t_1, f_1)^{-1}L = (t_2, f_2)^{-1}L. \tag{5}$$

Given the descending Nerode equivalence of a tree language L, we define the descending tree automaton $\mathcal{A}(L) = (Q^L, \lambda^L, q_0^L, Q_{fin}^L)$ where

$$\begin{aligned} Q^L &= \{(s, g)^{-1}L \mid (s, g) \in \Sigma^{(\#)}\}, \\ q_0^L &= L, \\ Q_{\text{fin}}^L &= \{K \in Q^L \mid \Omega \in K\}, \quad \text{and} \\ \lambda^L(K, a) &= \{((a + 2s_2, 1)^{-1}K, (a + 1s_1, 2)^{-1}K) \mid a + 1s_1 + 2s_2 \in K\}. \end{aligned}$$

Note that $q_0^L \in Q^L$ since $L = (\Omega, \varepsilon)^{-1}L$.

LEMMA 2. *The descending tree automaton* $\mathcal{A}(L)$ *of a homogeneous tree language* L *is l-r-deterministic and recognizes* L.

Proof. We will first prove, by structural induction on (t, f), the validity of the equation

$$\widehat{\lambda^L}((s, g)^{-1}L, t, f) = (t, f)^{-1}((s, g)^{-1}L). \tag{6}$$

The base step $(t, f) = (\Omega, \varepsilon)$ follows from the definition of $\widehat{\lambda}$, since generally $\widehat{\lambda}(q, \Omega, \varepsilon) = q$ for any state q and any transition function λ. For the induction step, we suppose (6)

for (t_1, f_1) and (t_2, f_2) and show that for $(t, f) = (a+1t_1+t_2, 1f_1)$, if $q \in \widehat{\lambda^L}((s, g)^{-1}L, t, f)$, then $q = ((s, g)(t, f))^{-1}L$.

By (2), there exists a state $q_1 \in \widehat{\lambda^L}((s, g)^{-1}L, a+2t_2, 1)$ such that $q \in \widehat{\lambda^L}(q_1, t_1, f_1)$. By the definition of $\widehat{\lambda^L}$, there exists a state $q_2 \in Q^L$ such that

$$(q_1, q_2) \in \lambda^L((s, g)^{-1}L, a), \tag{7}$$

$$\widehat{\lambda^L}(q_2, t_2, f_2) \cap Q^L_{\mathrm{fin}} \neq \emptyset \quad \text{for } f_2 \in \mathcal{B}(t_2). \tag{8}$$

The definition of λ^L and (7) imply the existence of $s_1, s_2 \in \Sigma^{\#}$ such that

$$a + 1s_1 + 2s_2 \in (s, g)^{-1}L, \tag{9}$$

$$q_1 = (a + 2s_2, 1)^{-1}(s, g)^{-1}L, \tag{10}$$

$$q_2 = (a + 1s_1, 2)^{-1}(s, g)^{-1}L. \tag{11}$$

We can write (9) as

$$s + g(a + 1s_1 + 2s_2) \in L. \tag{12}$$

If we put the induction hypothesis on (t_2, f_2) and (11) together, we obtain that $\widehat{\lambda^L}(q_2, t_2, f_2) = ((s, g)(a + 1s_1, 2)(t_2, f_2))^{-1}L$. According to (8), $\Omega \in \widehat{\lambda^L}(q_2, t_2, f_2)$ or

$$s + g(a + 1s_1 + 2t_2) \in L. \tag{13}$$

We will use the two facts above and the homogeneity of L in order to show that the state q is of the form $q = ((s, g)(t, f))^{-1}L$. Since $q \in \widehat{\lambda^L}(q_1, t_1, f_1)$ and q_1 is of the form given by (10), the induction hypothesis applied to (t_1, f_1) yields

$$q = ((s, g)(a + 2s_2, 1)(t_1, f_1))^{-1}L. \tag{14}$$

In order to show the conjectured equality, which is $q = ((s, g)(a + 2t_2, 1)(t_1, f_1))^{-1}L$, let $\bar{t} \in q$; that is,

$$s + g(a + 1(t_1 + f_1\bar{t}) + 2s_2) \in L. \tag{15}$$

The homogeneity of L together with (12), (13), and (15) now implies

$$s + g(a + 1(t_1 + f_1\bar{t}) + 2t_2) \in L, \tag{16}$$

which is the same as $\bar{t} \in ((s, g)(a + 2t_2, 1)(t_1, f_1))^{-1}L$. Vice versa, the homogeneity of L applied to (12), (13), and (16) implies (15), which proves $\bar{t} \in q$ and hence the statement on the form of q.

Thus the only element of $\widehat{\lambda^L}((s, g)^{-1}L, t, f)$ is $q = ((s, g)(t, f))^{-1}L$, which proves the left determinism and, by symmetry, the l-r determinism. The equivalences

$$\begin{aligned}(t, f) \in \widehat{\mathcal{L}}(\mathcal{A}(L)) \quad &\text{iff } (\Omega, \varepsilon) \in \widehat{\lambda^L}(L, t, f),\\ &\text{iff } (\Omega, \varepsilon) \in (t, f)^{-1}L,\\ &\text{iff } (t, f) \in \widehat{L}\end{aligned}$$

show that $L = \mathcal{L}(\mathcal{A}(L))$ and complete the proof of Lemma 2. □

The l-r-deterministic descending tree automaton $\mathcal{A}(L)$ is reduced. Clearly, for a state $M = (t, f)^{-1}L \in Q^L$, $\widehat{L}_M = \{(s, g) \in \Sigma^{(\#)} \mid \widehat{\lambda}(M, s, g) \in Q^L_{\text{fin}}\}$ and hence $L_M = M$. Therefore, the two equivalent states are equal.

We recall that an automaton A' is called *minimal* (in the algebraic sense) in a given class of automata iff every equivalent automaton A in the class can be mapped onto A' by an automaton morphism. A morphism π from $A = (Q, \lambda, q_0, Q_{\text{fin}})$ to $A' = (Q', \lambda', q'_0, Q'_{\text{fin}})$ is a mapping $\pi : Q \to Q'$ (which is canonically extended to $\pi : \mathcal{P}(Q \times Q) \to \mathcal{P}(Q' \times Q')$) such that $\pi(q_0) = q'_0$, $\pi(Q_{\text{fin}}) \subseteq Q'_{\text{fin}}$ and $\pi(\lambda(q, a)) = \lambda'(\pi(q), a)$. This condition implies, of course, the minimality of the number of states. As already stated in footnote 4, one excludes automata with nonaccessible states when considering the algebraic notion of minimality of automata.

THEOREM 4. *For every homogeneous tree language L there exists a minimal l-r-deterministic descending tree automaton recognizing L. It is given by $\mathcal{A}(L)$. This is the unique (up to isomorphism) reduced l-r-deterministic descending tree automaton recognizing L. It is finite iff L is recognizable.*

Proof. We assume a l-r-deterministic descending tree automaton $A = (Q, \lambda, q_0, Q_{\text{fin}})$ whose states are all accessible and which recognizes L. The morphism π from A on $\mathcal{A}(L)$ is given by the mapping $\pi : Q \to Q^L$, $\pi(q) = L_q$.

First we show that π is indeed a function into Q^L. Let $q \in Q$ be a state of A and $(t, f) \in \Sigma^{\#}$ be a pointed tree such that $\widehat{\lambda}(q_0, t, f) = q$.

By equation (2), the state $\widehat{\lambda}(q, s, g) = \widehat{\lambda}(\widehat{\lambda}(q_0, t, f), s, g)$ which is equal to $\widehat{\lambda}(q_0, (t, f)(s, g))$. This is a final state of A iff $(t, f)(s, g) \in \widehat{L}$. Thus $L_q = (t, f)^{-1}L$ and $\pi(q)$ is indeed a state of $\mathcal{A}(L)$.

Clearly, π is surjective. Given $(t, f)^{-1}L \in Q^L$, we have $(t, f)^{-1}L = \pi(q)$ where $q = \widehat{\lambda}(q_0, t, f)$, since $L_q = (t, f)^{-1}L$.

If $(t, f)^{-1}L \neq \emptyset \in Q^L$, then $\lambda^L(q^L_0, t, f) \neq \emptyset$, and setting $q = \widehat{\lambda}(q_0, t, f)$, we have $L_q = (t, f)^{-1}L = \pi(q)$ and thus π is surjective. (The empty set $\emptyset \in Q^L$ is the image of any not accessible or not coaccessible state of A. If A is assumed to be trim, we define Q^L without the element $\emptyset$.)

In order to show that $(q_1, q_2) \in \lambda(q, a)$ iff $(\pi(q_1), \pi(q_2)) \in \widehat{\lambda}(\pi(q), a)$, it is sufficient to show that $\pi(\widehat{\lambda}(q, t, f)) = \widehat{\lambda^L}(\pi(q), t, f)$, thanks to Corollary 2, but this is trivially clear from the l-r determinism of A.

By Lemma 2, $\mathcal{A}(L)$ is l-r deterministic and recognizes L. If A is reduced, then π is bijective, which proves the second statement of Theorem 4 if L is recognizable, then there exists, by Theorem 2, a l-r-deterministic finite descending tree automaton recognizing L. By *reducing* A, that is, by identifying unseparable states, $\mathcal{A}^L$ can be obtained effectively and is, of course, finite if A is finite. □

If the tree language L is path closed, then $\mathcal{A}(L)$ is not only l-r deterministic but also deterministic. Of course, every deterministic descending tree automaton recognizing L is also l-r deterministic. Together, this implies the following corollary whose first part has been shown in [12].

COROLLARY 3. *For every path-closed tree language L there exists a unique (up to isomorphism) reduced deterministic descending tree automaton recognizing L. This minimal deterministic descending tree automaton recognizing L is given by $\mathcal{A}(L)$ with, as a set of states, the left residuals of L (or the descending Nerode equivalence classes).*

Thus we have obtained the main result of [12, section II.11], with elegant methods

and sharpened it: $\mathcal{A}(L)$ is minimal not only in the class of all deterministic, but also in the larger class of l-r-deterministic descending tree automata. Moreover, we are able to describe $\mathcal{A}(L)$ algebraically solely by means of the tree language L.

We will now investigate the meaning of $\mathcal{A}(L)$ is the general case, where L is not necessarily a homogeneous tree language. We note that the intersection of any family of homogeneous sets is again homogeneous. Hence there exists a smallest homogeneous set containing L. We call it the *homogeneous closure* of L, written $\mathcal{HC}(L)$. Also in the general case, we call $\mathcal{A}(L)$ the minimal l-r-deterministic descending tree automaton of L; this is justified by the following characterization.

THEOREM 5. *For any tree language L, the minimal l-r-deterministic descending tree automaton $\mathcal{A}(L)$ is finite iff L is recognizable. It recognizes the homogeneous closure of L.*

Hence $\mathcal{A}(L)$ recognizes always an approximation of L (i.e., a superset).

Proof. The class $[(t,f)]_{\sim_L}$ of the ascending Nerode congruence $\sim_L$ is characterized exactly by (1), the set of all sets $(s,g)^{-1}L$ which contain (t,f), and (2), the set of all those sets which do not contain (t,f). Hence there are finitely many congruence classes iff there are finitely many sets $(s,g)^{-1}L$. According to property (5) from section 6, this holds iff there are finitely many descending Nerode congruence classes $[(t,f)] \approx_L$.

Next, we show that every $t \in \Sigma^{\#}$ which is recognized by $\mathcal{A}(L)$ starting in the state $(s,g)^{-1}L$ is an element of the homogeneous closure of $(s,g)^{-1}L$. We proceed by induction over t. If $t = \Omega$, the statement is true by definition of $\mathcal{A}(L)$. If $t = a + 1t_1 + 2t_2$, where we assume the statement for t_1 and t_2 to hold by induction hypothesis, then there exist trees s_1 and s_2 such that $a+1s_1+2s_2 \in (s,g)^{-1}L$, and t_1 and t_2 are recognized by $\mathcal{A}(L)$ starting in the corresponding left and right successor states, which are, respectively, $(a + 2s_2, 1)(s,g)^{-1}L$ and $(a + 1s_2, 2)(s,g)^{-1}L$. By induction hypothesis, $a + 1t_1 + 2s_2$ and $a + 1s_1 + 2t_2$ are in the homogeneous closure of the set $(s,g)^{-1}L$. This yields the statement for $t = a + 1t_1 + 2t_2$.

By definition, $\mathcal{A}(L)$ recognizes a homogeneous tree language which includes every tree of L. Hence the homogeneous closure $\mathcal{HC}(L)$ is a subset of $\mathcal{L}(\mathcal{A}(L))$, and, together with the above, the two sets are equal. □

COROLLARY 4. *A tree language L is recognizable iff the descending Nerode equivalence of L has a finite index iff there exists a frontier invariant equivalence relation on $\Sigma^{(\#)}$ which saturates $\widehat{L}$ and has a finite index.* □

7. Conclusion. The two existing notions of descending tree automata being either too restrictive or not amenable to algebraic tools, we have introduced a third, intermediate family. The investigation in this work has shown that this family of l-r-deterministic descending tree automata is a natural algebraic notion on which the usual automata theoretic methods apply. Our characterization of the corresponding family of homogeneous tree languages offers the possibility to approximate a recognizable set of trees by a homogeneous superset and to represent it by an l-r-deterministic descending tree automaton. As an immediate practical application, a type system like the one of [19], for example (for others, cf. [28]), can be made more powerful by incorporating this approximation.

Also with respect to the application on type systems, it would be useful to characterize the corresponding family of regular systems of equations. It seems less interesting, and also less feasible, to try the same for regular expressions. Another branch of further work would consist of exploring the algorithmic aspects. Here one can exploit

the relationship between l-r-deterministic descending tree automata and automata on strings that we have exhibited.

Acknowledgments. We thank A. Arnold and B. Courcelle for fruitful discussions and the anonymous referees for their useful detailed comments.

THRESHOLD COMPUTATION AND CRYPTOGRAPHIC SECURITY*

YENJO HAN†, LANE A. HEMASPAANDRA‡, AND THOMAS THIERAUF§

Abstract. Threshold machines are Turing machines whose acceptance is determined by what portion of the machine's computation paths are accepting paths. Probabilistic machines are Turing machines whose acceptance is determined by the probability weight of the machine's accepting computation paths. In 1975, Simon proved that for unbounded-error polynomial-time machines these two notions yield the same class, PP. Perhaps because Simon's result seemed to collapse the threshold and probabilistic modes of computation, the relationship between threshold and probabilistic computing for the case of bounded error has remained unexplored.

In this paper, we compare the bounded-error probabilistic class BPP with the analogous threshold class, $\mathrm{BPP}_{\mathrm{path}}$, and, more generally, we study the structural properties of $\mathrm{BPP}_{\mathrm{path}}$. We prove that $\mathrm{BPP}_{\mathrm{path}}$ contains both $\mathrm{NP}^{\mathrm{BPP}}$ and $\mathrm{P}^{\mathrm{NP}[\log]}$ and that $\mathrm{BPP}_{\mathrm{path}}$ is contained in $\mathrm{P}^{\Sigma_2^p[\log]}$, $\mathrm{BPP}^{\mathrm{NP}}$, and PP. We conclude that, unless the polynomial hierarchy collapses, bounded-error threshold computation is strictly more powerful than bounded-error probabilistic computation.

We also consider the natural notion of secure access to a database: an adversary who watches the queries should gain no information about the input other than perhaps its length. We show for both BPP and $\mathrm{BPP}_{\mathrm{path}}$ that if there is *any* database for which this formalization of security differs from the security given by oblivious database access, then $\mathrm{P} \neq \mathrm{PSPACE}$. It follows that if any set lacking small circuits can be securely accepted, then $\mathrm{P} \neq \mathrm{PSPACE}$.

1. Introduction.

In 1975, Simon [27] defined threshold machines. A threshold machine is a nondeterministic Turing machine that accepts a given input if more than half of all computation paths on that input are accepting paths. Gill [13] defined the class PP as the class of sets for which there exists a probabilistic polynomial-time Turing machine that accepts exactly the members of the set with probability greater than $\frac{1}{2}$. Simon [27] showed that the class of sets accepted by polynomial-time threshold machines characterizes the unbounded-error probabilistic class PP.

In this paper, we extend the notion of threshold computation to bounded-error probabilistic classes, and we study the degree to which threshold and probabilistic database ("oracle") computations hide information from observers.

In particular, we introduce $\mathrm{BPP}_{\mathrm{path}}$ and $\mathrm{R}_{\mathrm{path}}$ as the threshold analogues of BPP and R [13]. We give evidence that, unlike the case for PP, these threshold classes are different from their probabilistic counterparts. Section 3 studies the

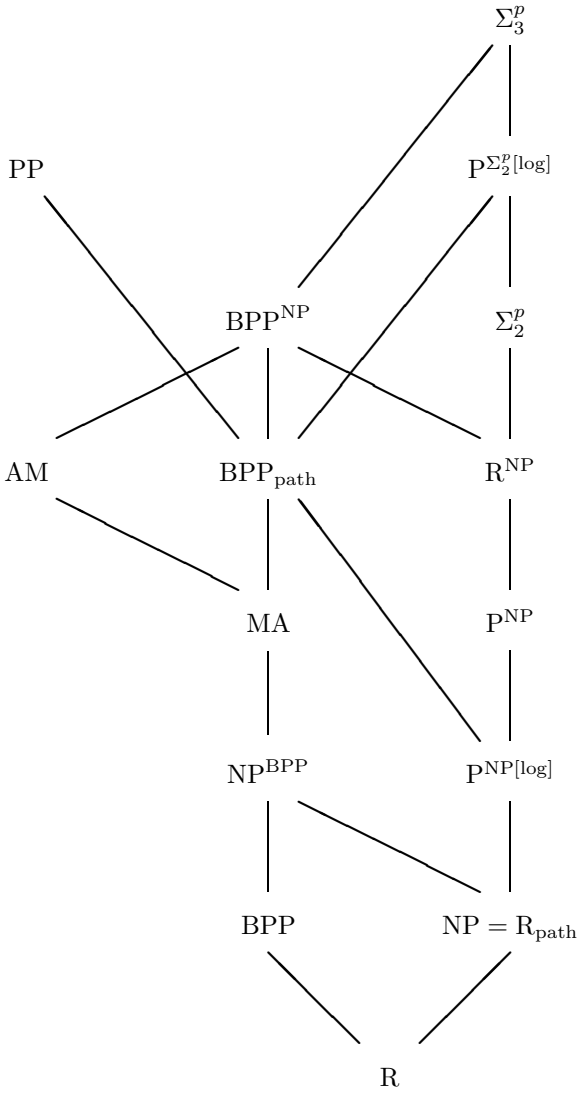

FIG. 1. *Inclusion relations between* $\mathrm{BPP}_{\mathrm{path}}$ *and other complexity classes. Not shown are the inclusions* $\mathrm{BPP} \subseteq \mathrm{R}^{\mathrm{NP}}$ *and* $\mathrm{AM} \subseteq \mathrm{P}^{\Sigma_2^p[\log]}$ *(in fact,* $\mathrm{AM} \subseteq \Pi_2^p$*). As an open problem, we ask whether* $\mathrm{BPP}_{\mathrm{path}}$ *is contained in* Σ_2^p *or even* R^{NP}*. There is an oracle relative to which* $\mathrm{BPP}_{\mathrm{path}}$ *is not in* P^{NP}*.*

properties of the class $\mathrm{BPP}_{\mathrm{path}}$ and its relationship to other complexity classes. For example, we show—in contrast to the BPP case—that $\mathrm{BPP}_{\mathrm{path}}$ is self-low (i.e., ${\mathrm{BPP}_{\mathrm{path}}}^{\mathrm{BPP}_{\mathrm{path}}} = \mathrm{BPP}_{\mathrm{path}}$) only if the polynomial hierarchy collapses. We also show that BPP is low for $\mathrm{BPP}_{\mathrm{path}}$, that there is a relativized world in which $\mathrm{BPP}_{\mathrm{path}}$ does not contain the smallest reasonable counting class, and that $\mathrm{BPP}_{\mathrm{path}}$ has many closure properties. Figure 1 gives an overview of the inclusion relations that we establish between $\mathrm{BPP}_{\mathrm{path}}$ and other complexity classes; in particular, note that though contained in the polynomial hierarchy, $\mathrm{BPP}_{\mathrm{path}}$ contains NP and coNP.

Section 4 studies, for threshold and probabilistic computations that have Turing (that is, adaptive) access to a database, the degree to which the input can be hidden from an observer. In particular, we consider the least restrictive possible notion ensuring that a powerful observer should gain no information about the input other than its length [5]. For the cases of unbounded-error probabilistic and threshold computation, we note that this optimal degree of security can be achieved in all cases. For the cases of bounded-error probabilistic and threshold computations, we prove the following result: if there exists any database D to which secure access yields more power than oblivious access (a notion in which the querying machine—until finished querying—is wholly denied access to the input other than the length of the input [9]), then P $\neq$ PSPACE.

2. Definitions and discussion. Throughout this paper, we use the alphabet $\Sigma = \{0, 1\}$. For a string $x \in \Sigma^*$, $|x|$ denotes the length of x. For a set $A \subseteq \Sigma^*$, $A(x)$ denotes the characteristic function of A, $A^{=n}$ denotes $\{\, y \mid y \in A \text{ and } |y| = n \,\}$, $A^{\leq n}$ denotes $\{\, y \mid y \in A \text{ and } |y| \leq n \,\}$, and $\|A\|$ denotes the cardinality of A. The complement of A is $\overline{A} = \Sigma^* - A$, and for a class $\mathcal{C}$ of sets, $\mathrm{co}\,\mathcal{C} = \{\, \overline{A} \mid A \in \mathcal{C} \,\}$.

Let $(\cdot, \cdot)_b : \Sigma^* \times \Sigma^* \to \Sigma^*$ be a polynomial-time computable, polynomial-time invertible, one-to-one, onto function. For any string z, let $z+1$ denote the string that lexicographically follows z, and for any string $z \neq \epsilon$, let $z-1$ denote the string that lexicographically precedes z. Let k_s be the lexicographically kth string in Σ^*. We define our (multi-arity, onto) pairing function by $(x_1, x_2, \ldots, x_k)$ equals (a) $(\epsilon, \epsilon)_b$ when $k = 0$, (b) $(\epsilon, x_1 + 1)_b$ when $k = 1$, and (c) $(k_s, (x_1, (x_2, (\cdots (x_{k-1}, x_k)_b \cdots)_b)_b)_b)_b$ when $k \geq 2$.

P (NP) denotes the class of languages that are accepted by polynomial-time deterministic (nondeterministic) Turing machines. For nondeterministic Turing machines, we assume without loss of generality that the nondeterministic branching degree is at most two. M is polynomial-normalized (henceforward denoted *normalized*) if there is a polynomial p such that on every input x the machine M makes exactly $p(|x|)$ nondeterministic moves on each computation path. FP is the class of polynomial-time computable functions. One can define relativized classes such as P^{NP} (respectively, $\mathrm{P}^{\mathrm{NP[log]}}$) by employing P machines having some NP oracle that can be asked polynomially (respectively, logarithmically) many queries, i.e., so-called oracle machines [3]. This is called a *Turing reduction* (to NP). If the queries are made nonadaptively (i.e., in parallel), we call this a *truth-table reduction* (see Ladner, Lynch, and Selman [22]). By $\mathrm{P}_{\mathrm{tt}}^{\mathrm{NP}}$ we denote the class of sets that are truth-table reducible to NP—but, in fact, $\mathrm{P}_{\mathrm{tt}}^{\mathrm{NP}} = \mathrm{P}^{\mathrm{NP[log]}}$ [15].

The *polynomial hierarchy* [25], [29] is defined as follows:

$$\begin{aligned} \Sigma_1^p &= \mathrm{NP}, \\ \Sigma_{k+1}^p &= \mathrm{NP}^{\Sigma_k^p} \quad (\text{for } k \in \{1, 2, 3, \ldots\}), \quad \text{and} \\ \mathrm{PH} &= \bigcup_{k \geq 1} \Sigma_k^p. \end{aligned}$$

P/poly [19] denotes the class of sets having small circuits.

For a nondeterministic polynomial-time Turing machine M, let $acc_M(x)$ ($rej_M(x)$) denote the number of accepting (rejecting) paths of M on input x and let $total_M(x)$ denote the total number of paths of M on input x. #P is the class of functions f such that for some nondeterministic polynomial-time Turing machine M it holds that $(\forall x)\,[f(x) = acc_M(x)]$.

2.1. Probabilistic and threshold computation. A *probabilistic polynomial-time Turing machine* [13] is a nondeterministic polynomial-time Turing machine M such that M chooses with equal probability each of the nondeterministic choices at each choice point. $\Pr[M(x) = 1]$ denotes the probability weight of those paths on which M accepts x and $\Pr[M(x) = 0]$ denotes the probability weight of those paths on which M rejects x.

We now define some complexity classes in terms of probabilistic polynomial-time Turing machines.

DEFINITION 2.1 (probabilistic classes).

1. PP [13] *is the class of all sets L such that there exists a probabilistic polynomial-time Turing machine M such that for all $x \in \Sigma^*$ it holds that* $\Pr[M(x) = L(x)] > \frac{1}{2}$.

2. BPP [13] *is the class of all sets L such that there exist a probabilistic polynomial-time Turing machine M and an $\epsilon > 0$ such that for all $x \in \Sigma^*$ it holds that* $\Pr[M(x) = L(x)] > \frac{1}{2} + \epsilon$.

3. R [13] *is the class of all sets L such that there exists a probabilistic polynomial-time Turing machine M such that for all $x \in \Sigma^*$ it holds that*

$$x \in L \Longrightarrow \Pr[M(x) = 1] > \frac{1}{2} \quad \textit{and}$$
$$x \notin L \Longrightarrow \Pr[M(x) = 0] = 1.$$

By definition, we clearly have $\mathrm{R} \subseteq \mathrm{BPP} \subseteq \mathrm{PP}$ [13].

The class PP can also be characterized as the class of sets L such that there exist a nondeterministic polynomial-time Turing machine M and a function $f \in \mathrm{FP}$ such that for all $x \in \Sigma^*$ it holds that $x \in L \iff acc_M(x) \geq f(x)$.

By looking at the portion of accepting paths rather than the probability weight of the accepting paths, we now introduce the threshold analogues of the above probabilistic classes. Let $\#[M(x) = 1]$ denote $acc_M(x)$ and let $\#[M(x) = 0]$ denote $rej_M(x)$.

DEFINITION 2.2 (threshold classes).

1. $\mathrm{PP}_{\mathrm{path}}$ [27] *is the class of all sets L such that there exists a nondeterministic polynomial-time Turing machine M such that for all $x \in \Sigma^*$ it holds that* $\#[M(x) = L(x)] > \frac{1}{2}\, total_M(x)$.

2. $\mathrm{BPP}_{\mathrm{path}}$ *is the class of all sets L such that there exist a nondeterministic polynomial-time Turing machine M and an $\epsilon > 0$ such that for all $x \in \Sigma^*$ it holds that* $\#[M(x) = L(x)] > (\frac{1}{2} + \epsilon)\, total_M(x)$.

3. $\mathrm{R}_{\mathrm{path}}$ *is the class of all sets L such that there exists a nondeterministic polynomial-time Turing machine M such that for all $x \in \Sigma^*$ it holds that*

$$x \in L \Longrightarrow acc_M(x) > \frac{1}{2}\, total_M(x) \quad \textit{and}$$
$$x \notin L \Longrightarrow rej_M(x) = total_M(x).$$

It is easy to see that $\mathrm{R}_{\mathrm{path}} \subseteq \mathrm{BPP}_{\mathrm{path}} \subseteq \mathrm{PP}_{\mathrm{path}}$. For all threshold classes in this paper, as a notational convenience we will place oracles above the word "path" (e.g., $\mathrm{BPP}_{\mathrm{path}}^{\mathrm{BPP}}$ denotes $(\mathrm{BPP}_{\mathrm{path}})^{\mathrm{BPP}}$).

It is known that R, BPP, and PP sets can be accepted via normalized probabilistic polynomial-time Turing machines: just extend each computation path of a given machine up to a fixed polynomial length and, on each new path, accept if the path that was extended accepted and reject otherwise. The modified machine has the same

acceptance probability as the original one. Observe that for normalized machines, the probabilistic interpretation of the machine accepts the same set as the threshold interpretation of the machine. Thus each of the probabilistic classes is contained in the corresponding threshold class, i.e., $\mathrm{PP} \subseteq \mathrm{PP}_{\mathrm{path}}$, $\mathrm{BPP} \subseteq \mathrm{BPP}_{\mathrm{path}}$, and $\mathrm{R} \subseteq \mathrm{R}_{\mathrm{path}}$.

In fact, Simon [27] has already shown that $\mathrm{PP}_{\mathrm{path}}$ is not a bigger class than PP. For completeness, we give a proof here.

THEOREM 2.3 ([27]). $\mathrm{PP}_{\mathrm{path}} = \mathrm{PP}$.

Proof. It suffices to show that $\mathrm{PP}_{\mathrm{path}} \subseteq \mathrm{PP}$. Let $L \in \mathrm{PP}_{\mathrm{path}}$ via $\mathrm{PP}_{\mathrm{path}}$ machine M with polynomial q bounding M's runtime. Consider the machine M' that on input x extends each path y of M by appending a full binary subtree of depth $q(|x|) - |y|$. Furthermore, on the leftmost path of this appended subtree, M' branches into two accepting (rejecting) paths if M accepted (rejected) on the path y. On each remaining path of the subtree, M' branches into one accepting and one rejecting path.

M' on input x has $2^{q(|x|)+1}$ paths and of these $2^{q(|x|)} + acc_M(x) - rej_M(x)$ are accepting paths. This shows that $L \in \mathrm{PP}$ via M'. □

Interestingly, this equivalence between probabilistic and threshold classes cannot hold for R and BPP unless the polynomial hierarchy collapses to its second level. This follows from the fact that NP is contained in $\mathrm{R}_{\mathrm{path}}$ and thus is also contained in $\mathrm{BPP}_{\mathrm{path}}$.

PROPOSITION 2.4. $\mathrm{R}_{\mathrm{path}} = \mathrm{NP}$.

Proof. $\mathrm{R}_{\mathrm{path}} \subseteq \mathrm{NP}$ is immediate from the definition. For the reverse inclusion, let M be a nondeterministic Turing machine and let polynomial p bound the runtime of M.

Consider the machine M' that on input x first simulates M on input x, and if the simulation ends in an accepting path y, then M' appends $2^{p(|x|)+1}$ accepting paths to y and otherwise M' rejects.

Now more than half of all paths of M' on input x are accepting if $x \in L(M)$, and M' has no accepting paths otherwise. This shows that $L(M) \in \mathrm{R}_{\mathrm{path}}$. □

COROLLARY 2.5. $\mathrm{NP} \subseteq \mathrm{BPP}_{\mathrm{path}}$.

It follows that if $\mathrm{BPP}_{\mathrm{path}}$ is equal to BPP, then $\mathrm{BPP}_{\mathrm{path}}$, and hence NP, has small circuits, which in turn, by the result of Karp, Lipton, and Sipser (see [19]), implies that the polynomial hierarchy collapses. Thus we cannot expect $\mathrm{BPP}_{\mathrm{path}}$ to have normalized machines. For different, contemporaneous work related to normalized versus nonnormalized computation, see Hertrampf et al. [16] and Jenner, McKenzie, and Thérien [17].

We have now seen that there are some crucial differences between BPP and its threshold analogue, $\mathrm{BPP}_{\mathrm{path}}$. We will study $\mathrm{BPP}_{\mathrm{path}}$ in more detail in section 3 and, especially, we will strengthen Corollary 2.5.

2.2. Secure computation. In this subsection and in section 4, we study notions of secure adaptive access to databases in the presence of a powerful spying observer. We give below what we feel are the most natural definitions. In these definitions, we obtain security by requiring that an observer (seeing a path drawn uniformly from all the machine's paths) should learn nothing about the input string other than perhaps its length. For threshold computation, this notion is new. For probabilistic computation, the appendix proves that this definition is equivalent to the notion of "one-oracle instance-hiding schemes that leak at most the length of their inputs" [5]. The original motivation for such classes, as explained, for example, by Beaver and Feigenbaum [5], is, very roughly, to study whether weak devices can solve hard problems by asking some powerful device questions in such a way that no observer can tell which problem

was actually solved by the weak device. Since NP $\subseteq$ $\mathrm{BPP}_{\mathrm{path}}$, $\mathrm{BPP}_{\mathrm{path}}$ is clearly not a computationally weak class. It nonetheless makes sense to consider the same interactive model in the case that applies here: studying whether a relatively powerful class ($\mathrm{BPP}_{\mathrm{path}}$) can use a (potentially powerful) information source while shielding information on the problem being solved even from extremely powerful observers.

DEFINITION 2.6 (secure threshold computation). *For any set D, a set A is said to be in* secure$\mathrm{BPP}^D_{\mathrm{path}}$ *(that is, is said to be "securely accepted by a bounded-error threshold polynomial-time machine via access to database D") if there is a nondeterministic polynomial-time Turing machine N such that the following hold:*

1. *[$A \in \mathrm{BPP}^D_{\mathrm{path}}$ via machine N.] There exists an $\epsilon > 0$ such that for all $x \in \Sigma^*$ it holds that $\#[N^D(x) = A(x)] > (\frac{1}{2} + \epsilon)\, total_{N^D}(x)$ (see part 2 of Definition 2.2).*

2. *[The queries of N^D reveal no information to an observer other than perhaps the length of the input.] For every $k \in \{0, 1, 2, \ldots\}$, every vector $\boldsymbol{v} = (v_1, v_2, \ldots, v_k)$, $v_1, v_2, \ldots, v_k \in \Sigma^*$, and every pair of strings $x \in \Sigma^*$ and $y \in \Sigma^*$ such that $|x| = |y|$, it holds that*

$$\frac{path\text{-}occurences_{N^D(x)}(\boldsymbol{v})}{total_{N^D}(x)} = \frac{path\text{-}occurences_{N^D(y)}(\boldsymbol{v})}{total_{N^D}(y)},$$

where $path\text{-}occurences_{N^D(z)}(\boldsymbol{v}) = ||\{p \mid p$ is a path of $N^D(z)$ on which $\boldsymbol{v}$ is the sequence of queries asked to the oracle (in the order asked, possibly with duplications if the same query is asked more than once)[1]$\}||$.

Similarly, for the probabilistic class BPP, we have the following definition of secure access.

DEFINITION 2.7 (secure probabilistic computation). *For any set D, a set A is said to be in* secureBPP^D *(that is, is said to be "securely accepted by a bounded-error probabilistic polynomial-time machine via access to database D") if there is a probabilistic polynomial-time Turing machine N such that the following hold:*

1. *[$A \in \mathrm{BPP}^D$ via machine N.] There exists an $\epsilon > 0$ such that for all $x \in \Sigma^*$ it holds that $\Pr[N^D(x) = A(x)] > \frac{1}{2} + \epsilon$ (see part 2 of Definition 2.1).*

2. *[The queries of N^D reveal no information to an observer other than perhaps the length of the input.] For every $k \in \{0, 1, 2, \ldots\}$, every vector $\boldsymbol{v} = (v_1, v_2, \ldots, v_k)$, $v_1, v_2, \ldots, v_k \in \Sigma^*$, and every pair of strings $x \in \Sigma^*$ and $y \in \Sigma^*$ such that $|x| = |y|$, it holds that*

$$\Pr[\text{the query vector of } N^D(x) \text{ is } \boldsymbol{v}] = \Pr[\text{the query vector of } N^D(y) \text{ is } \boldsymbol{v}].$$

Oblivious self-reducibility was discussed in [9], and we now define complexity classes capturing the notion of oblivious access.

DEFINITION 2.8 (oblivious probabilistic and threshold classes). *For any set D, a set A is said to be in* oblivious$\mathrm{BPP}^D_{\mathrm{path}}$ *(respectively,* obliviousBPP^D*) if there is a nondeterministic (respectively, probabilistic) polynomial-time Turing machine N such that the following hold:*

1. *[$A \in \mathrm{BPP}^D_{\mathrm{path}}$ (respectively, $A \in \mathrm{BPP}^D$) via machine N.] There exists an $\epsilon > 0$ such that for all $x \in \Sigma^*$ it holds that $\#[N^D(x) = A(x)] > (\frac{1}{2} + \epsilon)\, total_{N^D}(x)$ (respectively, $\Pr[N^D(x) = A(x)] > \frac{1}{2} + \epsilon$).*

2. *N is an oblivious machine in the sense that on an input z it initially is given access to a "preinput" tape on which $0^{|z|}$ is written. N then performs its adaptive queries to D. Then after making all queries to D, machine N is given access to z.*

[1] Henceforth, we will refer to this as a *query vector*.

We clearly have that, for every D,

$$\mathrm{BPP}^D_{\mathrm{path}} \supseteq \mathrm{secureBPP}^D_{\mathrm{path}} \supseteq \mathrm{obliviousBPP}^D_{\mathrm{path}} \quad \text{and}$$
$$\mathrm{BPP}^D \supseteq \mathrm{secureBPP}^D \supseteq \mathrm{obliviousBPP}^D.$$

Are these inclusions proper? In other words, does using security against observers as the *definition* of secure computation ($\mathrm{secureBPP}^D_{\mathrm{path}}$, $\mathrm{secureBPP}^D$) yield a more flexible notion of security than does blinding the machine to its input ($\mathrm{obliviousBPP}^D_{\mathrm{path}}$, $\mathrm{obliviousBPP}^D$)? Formally, is $\mathrm{obliviousBPP}^D_{\mathrm{path}} \neq \mathrm{secureBPP}^D_{\mathrm{path}}$ or $\mathrm{obliviousBPP}^D \neq \mathrm{secureBPP}^D$? Our intuition says that both inequalities hold. However, section 4 shows that establishing that "yes" is the answer implies that P $\neq$ PSPACE (and even implies the stronger result that BPP $\neq$ PP). Since it is commonly believed that P $\neq$ PSPACE, this does not provide evidence that equality holds; rather, it merely suggests that witnessing a separation will be hard with current techniques. We note that results (such as Theorem 4.1 and Corollary 4.2) that connect the existence of an oracle separation to the existence of a real-world separation (see, e.g., the survey [7]) usually occur in cases in which the oracle is tremendously restricted (e.g., to the class of tally sets or the class of sparse sets [4], [24]); in contrast, section 4 provides such a relativization result that applies without restriction of the database D.

Note that we could also define classes partially-secure-$\mathrm{BPP}^D_{\mathrm{path}}$ and partially-secure-BPP^D based on the notion (see, e.g., [9] and the papers cited therein) that an observer watching *one* query should get no information other than perhaps about the length (clearly, for all D, $\mathrm{BPP}^D_{\mathrm{path}} \supseteq$ partially-secure-$\mathrm{BPP}^D_{\mathrm{path}} \supseteq \mathrm{secureBPP}^D_{\mathrm{path}}$ and $\mathrm{BPP}^D \supseteq$ partially-secure-$\mathrm{BPP}^D \supseteq \mathrm{secureBPP}^D$), and, more generally, one could study a variety of classes between BPP^D and $\mathrm{secureBPP}^D$ (or between $\mathrm{BPP}^D_{\mathrm{path}}$ and $\mathrm{secureBPP}^D_{\mathrm{path}}$) based upon security against observers using various strengths of query access. (For example, one could require security against observers who could see two queries, or against observers who could make $\mathcal{O}(\log n)$ adaptive queries into the query vector, or so on.) However, we restrict our attention to what we feel are the most natural security classes: $\mathrm{secureBPP}^D$ and $\mathrm{secureBPP}^D_{\mathrm{path}}$.

There is no point in defining security classes for unbounded-error computation since it is easy to see that, for every D, $\mathrm{PP}^D = \mathrm{securePP}^D = \mathrm{obliviousPP}^D = \mathrm{PP}^D_{\mathrm{path}} = \mathrm{securePP}^D_{\mathrm{path}} = \mathrm{obliviousPP}^D_{\mathrm{path}}$.

Finally, we note that all sets that are accepted by an oblivious machine relative to some database D have small circuits. Let $\mathrm{obliviousBPP}^\star$ denote $\bigcup_{D \in 2^{\Sigma^*}} \mathrm{obliviousBPP}^D$. We have the following result.

PROPOSITION 2.9. $\mathrm{obliviousBPP}^\star = \mathrm{P/poly}$.

COROLLARY 2.10. $(\exists L)\,[L \notin \mathrm{obliviousBPP}^L]$.

Though for most common classes $\mathcal{C}$ it holds that $(\forall L)\,[L \in \mathcal{C}^L]$, Corollary 2.10 should not be surprising; it is natural that weak machines, when accepting a hard set via a hard database, may leak some information to an observer. Interestingly, a similar result holds for secure computation. Namely, Abadi, Feigenbaum, and Kilian [1] have shown that $\mathrm{secureBPP}^D \subseteq \mathrm{NP/poly} \cap \mathrm{coNP/poly}$ for any database D. Thus for any set D, no NP-hard set is in $\mathrm{secureBPP}^D$ unless the polynomial hierarchy collapses.

3. $\mathbf{BPP_{path}}$. We have already argued that BPP and $\mathrm{BPP}_{\mathrm{path}}$ differ unless the polynomial hierarchy collapses. These classes nonetheless share certain properties. For example, as is also the case for BPP [36], $\mathrm{BPP}_{\mathrm{path}}$ has a strong amplification property.

THEOREM 3.1. *Let L be in $\mathrm{BPP}_{\mathrm{path}}$. For each polynomial q, there is a nondeterministic polynomial-time Turing machine M such that for all $x \in \Sigma^*$ it holds that*

$$\#[M(x) = L(x)] > \left(1 - 2^{-q(|x|)}\right) \mathit{total}_M(x).$$

The proof is analogous to the corresponding proof for BPP.

BPP is closed under Turing reductions [20], [34]. However, no relativizable proof can establish the closure of $\mathrm{BPP}_{\mathrm{path}}$ under Turing reductions. In particular, Beigel [6] constructed an oracle relative to which P^{NP} is not contained in PP. Since $\mathrm{BPP}_{\mathrm{path}}$ is clearly contained in PP (and the proof relativizes), it follows that, relative to the same oracle, P^{NP} is not contained in $\mathrm{BPP}_{\mathrm{path}}$, and hence, since $\mathrm{NP} \subseteq \mathrm{BPP}_{\mathrm{path}}$, $\mathrm{BPP}_{\mathrm{path}}$ is not closed under Turing reductions relative to this oracle. That is, there exists an A such that $\mathrm{BPP}^A_{\mathrm{path}} \neq \mathrm{P}^{\mathrm{BPP}^A_{\mathrm{path}}}$.

For $\mathrm{BPP}_{\mathrm{path}}$, we can prove closure under truth-table reductions.

THEOREM 3.2. $\mathrm{BPP}_{\mathrm{path}}$ *is closed under polynomial-time truth-table reductions.*

Proof. Let $A \leq^p_{tt} B$ for $B \in \mathrm{BPP}_{\mathrm{path}}$, i.e., there exists a polynomial-time Turing machine M such that $L = L(M^B)$ and, for each input x of length n, machine M makes at most $q(n)$ queries (nonadaptively) to B. Without loss of generality, we may assume that all queries have the same length $l(n)$, $l(n) \geq n$, and that $q(n)$ is a nondecreasing function.

Let N be a $\mathrm{BPP}_{\mathrm{path}}$ machine for B such that on input y,

$$\#[N(y) = B(y)] > \left(1 - \frac{1}{3q(|y|)}\right) \mathit{total}_N(y).$$

Consider the machine M' that on input x, $|x| = n$, computes $y_1, \ldots, y_k$, the truth-table queries of M on input x, where $k \leq q(n)$, and for each query y_i, machine M' guesses a path of N on input y_i and takes the output of this path as the answer to query y_i, for $i = 1, \ldots, k$. Using these answers instead of the oracle B, M' simulates M on input x and outputs the result.

M' has $\mathit{total}_{M'}(x) = \prod_{i=1}^k \mathit{total}_N(y_i)$ paths. At least on those paths on which all the answers to the oracle queries are correct, M' decides correctly whether x is in A, i.e., we have

$$\begin{aligned}
\#[M'(x) = A(x)] &\geq \prod_{i=1}^k \#[N(y_i) = B(y_i)] \\
&\geq \prod_{i=1}^k \left(1 - \frac{1}{3q(l(n))}\right) \mathit{total}_N(y_i) \quad \text{by assumption} \\
&\geq \left(1 - \frac{1}{3q(n)}\right)^k \prod_{i=1}^k \mathit{total}_N(y_i) \quad \text{since } l(n) \geq n \\
&\geq \left(1 - \frac{k}{3q(n)}\right) \prod_{i=1}^k \mathit{total}_N(y_i) \\
&\geq \frac{2}{3} \mathit{total}_{M'}(x).
\end{aligned}$$

This shows that $A \in \mathrm{BPP}_{\mathrm{path}}$. □

COROLLARY 3.3. $\mathrm{BPP}_{\mathrm{path}}$ *is closed under complementation, intersection, and union.*

Since NP is contained in $\mathrm{BPP}_{\mathrm{path}}$, it follows that the closure of NP under truth-table reductions is contained in $\mathrm{BPP}_{\mathrm{path}}$.

COROLLARY 3.4. $\mathrm{P}^{\mathrm{NP[log]}} \subseteq \mathrm{BPP}_{\mathrm{path}}$.

It is known that BPP is low for PP [21] and for itself [20], [34], i.e., $\mathrm{PP}^{\mathrm{BPP}} = \mathrm{PP}$ and $\mathrm{BPP}^{\mathrm{BPP}} = \mathrm{BPP}$. We show in the next theorem that BPP is also low for $\mathrm{BPP}_{\mathrm{path}}$. Observe that relative to Beigel's previously mentioned oracle making P^{NP} not contained in PP, we must also have that NP, and hence $\mathrm{BPP}_{\mathrm{path}}$, cannot be low for PP. That is, there exists an A such that $\mathrm{PP}^{\mathrm{BPP}^{A}_{\mathrm{path}}} \neq \mathrm{PP}^{A}$. Furthermore, by an easy induction, we have that if $\mathrm{BPP}_{\mathrm{path}}$ is low for itself then the polynomial hierarchy, PH, is contained in $\mathrm{BPP}_{\mathrm{path}}$. However, as we will see in Theorem 3.11 below, $\mathrm{BPP}_{\mathrm{path}}$ is contained in some level of the polynomial hierarchy. Thus $\mathrm{BPP}_{\mathrm{path}}$ is not low for $\mathrm{BPP}_{\mathrm{path}}$ unless the polynomial hierarchy collapses.

THEOREM 3.5. $\mathrm{BPP}^{\mathrm{BPP}}_{\mathrm{path}} = \mathrm{BPP}_{\mathrm{path}}$.

Proof. Let $L \in \mathrm{BPP}^{\mathrm{BPP}}_{\mathrm{path}}$ via a machine M and a set $A \in \mathrm{BPP}$ such that polynomial p bounds the runtime of M^A and for all $x \in \Sigma^*$ it holds that $\#[M^A(x) = L(x)] > \frac{7}{8}\ total_{M^A}(x)$.

Let $B = \{\, (0^n, w_1, a_1, \ldots, w_k, a_k) \mid k \leq p(n) \text{ and } (\forall i : 1 \leq i \leq k)\, [|w_i| \leq p(n) \text{ and } A(w_i) = a_i] \,\}$. Since BPP is closed under truth-table reductions [20], [34], $B \in \mathrm{BPP}$. Hence there exist a probabilistic polynomial-time Turing machine M_B and a polynomial q such that for any input $z = (0^n, w_1, a_1, \ldots, w_k, a_k)$, M_B's error probability is bounded by $2^{-(p(n)+4)}$ and M_B's computation tree is a full binary tree with $total_{M_B}(z) = 2^{q(n)}$.

Consider the machine M' that on input x, $|x| = n$, performs the following steps.

1. M' simulates M^A on input x. Whenever M queries the oracle, M' nondeterministically guesses the answer. Let $(w_1, a_1), \ldots, (w_k, a_k)$ be the sequence of queried strings and guessed answers along a computation path y.

2. To verify the guessed answers, M' simulates M_B on input $(0^n, w_1, a_1, \ldots, w_k, a_k)$.

3. M' amplifies the output of M on path y from the first step if the guessed answers there are certified in the second step. More precisely, M' now appends $2^{p(n)+4}$ accepting (rejecting) paths if path y was accepting (rejecting) and the simulation in the second step ended in an accepting path of M_B. Otherwise, M' rejects.

After the first two steps, M' has at most $2^{p(n)}\, 2^{q(n)}$ computation paths. In the last step, M' amplifies all paths (a) in which the guessed oracle answers are correct and that are certified by M_B in the second step, i.e., at most $total_{M^A}(x)\, 2^{q(n)}$ paths, and (b) all paths in which the guessed oracle answers are false but are wrongly certified by M_B, i.e., at most $2^{p(n)}\, 2^{-(p(n)+4)}\, 2^{q(n)}$ paths. Thus we have

$$total_{M'}(x) \leq 2^{p(n)}\, 2^{q(n)} \ + \ 2^{p(n)+4} \left(total_{M^A}(x)\, 2^{q(n)} \ + \ 2^{p(n)}\, 2^{-(p(n)+4)}\, 2^{q(n)} \right).$$

The paths on which M' decides correctly include at least those paths that correspond to correct paths of M in the first step and are subsequently certified in the second step. Since these paths are amplified in the last step, we have

$$\#[M'(x) = L(x)] \geq \left(\frac{7}{8}\ total_{M^A}(x) \right) \left((1 - 2^{-(p(n)+4)})\, 2^{q(n)} \right)\ 2^{p(n)+4}.$$

Now it is not hard to see that $\#[M'(x) = L(x)] > \frac{2}{3}\ total_{M'}(x)$. Thus $L \in \mathrm{BPP}_{\mathrm{path}}$. ∎

If we define a function class $\mathrm{FBPP}_{\mathrm{path}}$ in the natural manner (see the analogous class FBPP of Ko [20]), then it is not hard to see that the same proof technique also establishes that $\mathrm{FBPP}_{\mathrm{path}}^{\mathrm{BPP}} = \mathrm{FBPP}_{\mathrm{path}}$.

COROLLARY 3.6. $\mathrm{NP}^{\mathrm{BPP}} \subseteq \mathrm{BPP}_{\mathrm{path}}$.

Indeed, we even have $\mathrm{P}^{\mathrm{NP}^{\mathrm{BPP}}[\log]\oplus\mathrm{BPP}} \subseteq \mathrm{BPP}_{\mathrm{path}}$.

Babai [2] introduced the Arthur–Merlin classes MA and AM. It is known that $\mathrm{NP}^{\mathrm{BPP}} \subseteq \mathrm{MA} \subseteq \mathrm{AM} \subseteq \mathrm{BPP}^{\mathrm{NP}}$ [2], [35]. It is not known whether any of the inclusions is strict or not, though various relevant oracle separations are known (e.g., Fenner et al. [11] have constructed an oracle world in which $\mathrm{NP}^{\mathrm{BPP}}$ and MA differ). Below, we strengthen Corollary 3.6 to show that even MA is contained in $\mathrm{BPP}_{\mathrm{path}}$. This improves the result of Vereshchagin [33] that $\mathrm{MA} \subseteq \mathrm{PP}$.

THEOREM 3.7. $\mathrm{MA} \subseteq \mathrm{BPP}_{\mathrm{path}}$.

Proof. Let $L \in \mathrm{MA}$. By standard amplification techniques, there exist a polynomial-time predicate Q and polynomials p and q such that for all $x \in \Sigma^*$,

$$x \in L \Longrightarrow (\exists y \in \Sigma^{p(|x|)})\ [\Pr[Q(x,y,z)] > 1 - 2^{-(p(|x|)+4)}],$$
$$x \notin L \Longrightarrow (\forall y \in \Sigma^{p(|x|)})\ [\Pr[Q(x,y,z)] < 2^{-(p(|x|)+4)}],$$

where the probability is taken uniformly over all $z \in \Sigma^{q(|x|)}$.

Consider the machine M that on input x guesses $y \in \Sigma^{p(|x|)}$ and $z \in \Sigma^{q(|x|)}$, and if $Q(x,y,z)$ is false, M rejects; otherwise, M produces $2^{p(|x|)+2}$ accepting paths.

It is not difficult to see that $\#[M(x) = L(x)] > \frac{2}{3}\ total_M(x)$. Thus $L \in \mathrm{BPP}_{\mathrm{path}}$. □

It is an open question whether AM is contained in $\mathrm{BPP}_{\mathrm{path}}$. Vereshchagin [33] constructed an oracle A such that relative to A the class AM is not a subset of PP, i.e., $\mathrm{AM}^A \not\subseteq \mathrm{PP}^A$. Thus AM is not a subset of $\mathrm{BPP}_{\mathrm{path}}$ relative to A. On the other hand, $\mathrm{BPP}_{\mathrm{path}}$ is not a subset of AM unless the polynomial hierarchy collapses. This follows from the result of Boppana, Håstad, and Zachos [8] that if $\mathrm{coNP} \subseteq \mathrm{AM}$, then the polynomial hierarchy collapses to its second level. Since $\mathrm{coNP} \subseteq \mathrm{BPP}_{\mathrm{path}}$, we get the same consequence from the assumption that $\mathrm{BPP}_{\mathrm{path}}$ is contained in AM.

Sipser and Gács [28] (see also [23]) showed that $\mathrm{BPP} \subseteq \mathrm{R}^{\mathrm{NP}}$. It is an open question whether the same inclusion holds for $\mathrm{BPP}_{\mathrm{path}}$. However, we show that $\mathrm{BPP}_{\mathrm{path}} \subseteq \mathrm{BPP}^{\mathrm{NP}}$. As a first step, we show that a $\mathrm{BPP}_{\mathrm{path}}$ set can be decided by a deterministic polynomial-time Turing machine making logarithmically many queries to a Σ_2^p oracle, and hence $\mathrm{BPP}_{\mathrm{path}}$ is in the polynomial hierarchy. A randomized version of this algorithm can decide a $\mathrm{BPP}_{\mathrm{path}}$ set with an NP oracle. The proof applies Sipser's Coding Lemma for universal hashing [28].

We mention that we could get a shorter proof by applying the results of Stockmeyer [30] to approximate #P functions and those of Jerrum, Valiant, and Vazirani [18], who showed a probabilistic version of Stockmeyer's theorem. However, we prefer to give a self-contained proof here, thereby encouraging the reader to see whether he or she can improve our result, for example, by getting a one-sided error probabilistic algorithm (in part 2 of Theorem 3.11). Since there is an oracle relative to which BPP is not contained in P^{NP} [30], one cannot obtain a deterministic algorithm with relativizable techniques.

DEFINITION 3.8 ([28]). *Let $X \subseteq \Sigma^m$ and let $H_1, \ldots, H_k : \Sigma^m \to \Sigma^k$ be a collection of linear functions given as $k \times m$ 0–1 matrices. The predicates Separate and Hash are defined as follows.*

1. *Separate*$_X(H_1, \ldots, H_k) \iff (\forall\, y \in X)\,(\exists\, i : 1 \le i \le k)\,(\forall\, z \in X : y \neq$

$z)\,[H_i(y) \neq H_i(z)]$, *where* $H_i(y)$ *means multiplication of the* $k \times m$ *matrix* H_i *with the* m *vector* y, *yielding a* k *vector, with the arithmetic done in GF*[2].

2. $\mathit{Hash}_X(k) \iff (\exists H_1, \ldots, H_k \in \Sigma^{km})\,[\mathit{Separate}_X(H_1, \ldots, H_k)]$.

The intuition about predicate *Hash* is that the size of the range of the hash functions (which is determined by k) has to be sufficiently large with respect to the size of X for a collection $H_1, \ldots, H_k$ that separates X to exist.

LEMMA 3.9 ([28]). *Let* $X \subseteq \Sigma^m$ *and let* $k = \lfloor \log \|X\| \rfloor + 2$. *For a random collection of functions* $H_1, \ldots, H_k : \ \Sigma^m \to \Sigma^k$,

$$\Pr[\mathit{Separate}_X(H_1, \ldots, H_k)] \ \geq \ \frac{7}{8}.$$

As a consequence of this lemma, we get a lower bound for the size of a set X. The upper bound follows by the pigeonhole principle (see [30]).

COROLLARY 3.10 ([28]). *If* $X \subseteq \Sigma^m$ *and* k_X *is the smallest* k *such that* $\mathit{Hash}_X(k)$ *is true, then* $2^{k_X - 3} \leq \|X\| \leq k_X\, 2^{k_X}$.

THEOREM 3.11.

1. $\mathrm{BPP}_{\mathrm{path}} \subseteq \mathrm{P}^{\Sigma_2^p[\log]}$.
2. $\mathrm{BPP}_{\mathrm{path}} \subseteq \mathrm{BPP}^{\mathrm{NP}}$.

Proof. Let $L \in \mathrm{BPP}_{\mathrm{path}}$. There exist a nondeterministic Turing machine M and a polynomial p that bounds the runtime of M such that for all $x \in \Sigma^*$ it holds that $\#[M(x) = L(x)] > (1 - 2^{-|x|})\ \mathit{total}_M(x)$.

Sipser's proof that BPP $\subseteq \Sigma_2^p$ uses the fact that $\mathit{total}_M(x)$ is known a priori. However, here we have only an upper bound.

Fix $x \in \Sigma^*$; let n denote $|x|$. Define

$$A = \{y\ 0^{p(n)-|y|} \mid y \text{ is an accepting computation of } M \text{ on input } x\} \quad \text{and}$$
$$R = \{y\ 0^{p(n)-|y|} \mid y \text{ is a rejecting computation of } M \text{ on input } x\}.$$

Clearly, $\|A\| = \mathit{acc}_M(x)$ and $\|R\| = \mathit{rej}_M(x)$.

Observe that *Separate* is a coNP predicate in x and the hash functions $H_1, \ldots, H_k$ when applied to A or R, and *Hash* is a Σ_2^p predicate in x and k.

Let k_A (k_R) denote the minimal k such that $\mathit{Hash}_A(k)$ ($\mathit{Hash}_R(k)$) is true. k_A and k_R can be computed by a binary search making at most $\log p(n)$ many queries to Hash_A and $\mathit{Hash}_R(k)$, respectively. From Corollary 3.10, it follows that $2^{k_A - 3} \leq \mathit{acc}_M(x) \leq k_A\, 2^{k_A}$ and that $2^{k_R - 3} \leq \mathit{rej}_M(x) \leq k_R\, 2^{k_R}$. Now it is not difficult to see that, for all but finitely many x, we have $x \in L \iff k_R < k_A$. This proves $L \in \mathrm{P}^{\Sigma_2^p[\log]}$.

Next, we show that $L \in \mathrm{BPP}^{\mathrm{NP}}$. Consider the following probabilistic procedure, which tries to approximate k_A and k_R by randomly generating a collection of functions $H_1, \ldots, H_k$ and directly asking the oracle $\mathit{Separate}_X$ about $(H_1, \ldots, H_k)$, for a given set X and increasing k.

```
APPROXIMATE(x, X)
k ← 0
repeat
    k ← k + 1
    randomly choose H_1, ..., H_k
until Separate_X(H_1, ..., H_k) or k = p(n)
return k.
```

The following main algorithm decides whether x is in L, and is correct with high probability.

MAIN(x)
$k_a \leftarrow$ APPROXIMATE(x, A)
$k_r \leftarrow$ APPROXIMATE(x, R)
if $k_a > k_r$ **then** accept
else reject.

By the definition of k_A, we always have $k_A \leq k_a$. Note that by the upper bound of Corollary 3.10 and since $k_A \leq p(n)$, it follows that $\log(\|A\|/p(n)) \leq k_A$. From Lemma 3.9, it follows that $k_a \leq \lfloor \log \|A\| \rfloor + 2$ holds with probability at least $\frac{7}{8}$. Since the same bounds hold for k_r, we have that with probability at least $\frac{3}{4}$ it holds that both (a) $\log \frac{acc_M(x)}{p(n)} \leq k_a \leq \log acc_M(x)+2$ and (b) $\log \frac{rej_M(x)}{p(n)} \leq k_r \leq \log rej_M(x)+2$. This implies that for all but finitely many x it holds that $x \in L \iff k_a > k_r$, with probability at least $\frac{3}{4}$. Thus $L \in \mathrm{BPP}^{\mathrm{NP}}$. □

As already mentioned just before Theorem 3.5, $\mathrm{BPP}_{\mathrm{path}}$ cannot be low for itself unless the polynomial hierarchy collapses to $\mathrm{BPP}_{\mathrm{path}}$. From Theorem 3.11, we thus have the following claim (see also the discussion just before Theorem 3.5).

COROLLARY 3.12. *If* $\mathrm{BPP}_{\mathrm{path}}^{\mathrm{BPP}_{\mathrm{path}}} = \mathrm{BPP}_{\mathrm{path}}$, *then* $\mathrm{PH} = \mathrm{P}^{\Sigma_2^p[\log]} = \mathrm{BPP}_{\mathrm{path}}$.

Zachos [35] has shown that NP $\subseteq$ BPP implies PH = BPP. Since this result relativizes (i.e., for all A, $\mathrm{NP}^A \subseteq \mathrm{BPP}^A$ implies $\mathrm{PH}^A = \mathrm{BPP}^A$), we obtain the following corollary from Theorem 3.11.

COROLLARY 3.13. $\Sigma_2^p \subseteq \mathrm{BPP}_{\mathrm{path}} \Longrightarrow \mathrm{PH} = \mathrm{BPP}^{\mathrm{NP}}$.

Toda [31] and Toda and Ogiwara [32] showed that $\mathrm{PH} \subseteq \mathrm{BPP}^{\mathcal{C}}$ for any class $\mathcal{C}$ among $\{\mathrm{PP}, \mathrm{C_{=}P}, \oplus\mathrm{P}\}$. As a consequence, none of these classes can be contained in the polynomial hierarchy unless the polynomial hierarchy collapses. Thus none of these classes can be contained in $\mathrm{BPP}_{\mathrm{path}}$ unless the polynomial hierarchy collapses.

Ogiwara and Hemachandra [26] and Fenner, Fortnow, and Kurtz [10] independently defined the counting class SPP as follows.

DEFINITION 3.14 ([26], [10]). SPP *is the class of all sets L such that there exist a nondeterministic polynomial-time Turing machine M and an* FP *function f such that for all $x \in \Sigma^*$ it holds that*

$$x \in L \Longrightarrow acc_M(x) = f(x) + 1 \quad \text{and}$$
$$x \notin L \Longrightarrow acc_M(x) = f(x).$$

Fenner, Fortnow, and Kurtz [10] argue that SPP is in some sense the smallest class that is definable in terms of the number of accepting and rejecting computations. In particular, SPP is low for PP, $\mathrm{C_{=}P}$, and $\oplus$P [10]. Though it is an open question whether SPP is contained in $\mathrm{BPP}_{\mathrm{path}}$, there is an oracle relative to which this is not the case.[2]

THEOREM 3.15. *There is an oracle A such that* $\mathrm{SPP}^A \not\subseteq \mathrm{BPP}_{\mathrm{path}}^A$.

Proof. Let $M_1, M_2, \ldots$ be an enumeration of nondeterministic polynomial-time Turing machines and let $p_1, p_2, \ldots$ be an enumeration of polynomials such that polynomial p_i bounds the runtime of machine M_i. Without loss of generality, we assume $p_i(n) = n^i + i$. Let $s(i)$, $i = 1, 2, \ldots$, be a sequence of integers defined by $s(1) = 5$ and, for $i > 1$, $s(i+1) = 2^{s(i)}$.

[2] Very recently, Fortnow [12] has improved our result by constructing an oracle relative to which SPP is not contained in the polynomial hierarchy.

We define the test language

$$L(A) = \{1^n \mid (\exists j)\,[n = s(j) \text{ and } \|A^{=n}\| = 2^{n-1}]\}.$$

Below, we will construct a set A such that for every $i \geq 1$, $\|A^{=s(i)}\|$ is either $2^{s(i)-1}$ or $2^{s(i)-1} - 1$. For such an A, we have $L(A) \in \mathrm{SPP}^A$. Furthermore, we will construct A such that, for each $i \geq 1$, at least one of the following requirements holds.

(R1) M_i^A is not a $\mathrm{BPP}^A_{\mathrm{path}}$ machine. That is, there exists an $x \in \Sigma^*$ such that

$$\frac{1}{4}\, total_{M_i^A}(x) \leq acc_{M_i^A}(x) \leq \frac{3}{4}\, total_{M_i^A}(x).$$

(R2) There exists an $n \geq 1$ such that $M_i^A(1^n)$ accepts if and only if $1^n \notin L(A)$.

It follows from Theorem 3.1 that the existence of such an oracle establishes the theorem.

We construct the set A in stages. In stage i, we diagonalize against machine M_i. Initially, $i = 1$ and $A_1 = \emptyset$.

Stage i. Let $n = s(i)$. We will add only strings of length n to A_i. Since $p_j(s(j)) < n$ for all $j < i$, this will not effect the construction done in earlier stages.

Define

$$\mathcal{A} = \{A_i \cup Z \mid Z \subseteq \Sigma^n \text{ and } \|Z\| = 2^{n-1}\} \quad \text{and}$$
$$\mathcal{B} = \{A_i \cup Z \mid Z \subseteq \Sigma^n \text{ and } \|Z\| = 2^{n-1} - 1\}.$$

If there is a set $X \in \mathcal{A} \cup \mathcal{B}$ such that X fulfills requirement (R1), i.e., M_i^X is not a $\mathrm{BPP}^X_{\mathrm{path}}$ machine, then define $A_{i+1} = X$ and go to the next stage. Otherwise, we show that there is a set in $\mathcal{A} \cup \mathcal{B}$ such that requirement (R2) is fulfilled.

Let X be a set such that the number of paths of M_i^X on input 1^n is maximal for all $X \in \mathcal{A} \cup \mathcal{B}$. That is, we have

$$(\star) \qquad (\forall\, Y \in \mathcal{A} \cup \mathcal{B})\ [total_{M_i^Y}(1^n) \leq total_{M_i^X}(1^n)].$$

Suppose $X \in \mathcal{A}$. If $1^n \notin L(M_i^X)$, then we are done since $1^n \in L(X)$. Thus suppose that $1^n \in L(M_i^X)$. For $w \in X \cap \Sigma^n$, define $X_w = X - \{w\}$. By definition, $1^n \notin L(X_w)$. We claim that there exists a $w \in X \cap \Sigma^n$ such that $1^n \in L(M_i^{X_w})$. For such a w, define $A_{i+1} = X_w$. Then requirement (R2) is fulfilled.

To prove our claim, assume that, for all $w \in X \cap \Sigma^n$, it holds that $1^n \notin L(M_i^{X_w})$. By taking w out of X, at least $acc_{M_i^X}(1^n) - acc_{M_i^{X_w}}(1^n)$ accepting paths of M either change to rejecting paths or disappear, and hence w must have been queried on those paths. Since

$$\begin{aligned} acc_{M_i^X}(1^n) - acc_{M_i^{X_w}}(1^n) &\geq \frac{3}{4}\, total_{M_i^X}(1^n) - \frac{1}{4}\, total_{M_i^{X_w}}(1^n) \\ &\geq \frac{1}{2}\, total_{M_i^X}(1^n) \quad \text{by } (\star), \end{aligned}$$

each $w \in X \cap \Sigma^n$ is queried by M_i^X on input 1^n on at least half of all paths. Thus M_i^X asks at least $2^{n-1}\,\frac{1}{2}\, total_{M_i^X}(1^n) = 2^{n-2}\, total_{M_i^X}(1^n)$ queries to its oracle. On the other hand, M_i^X cannot ask more than $p_i(n)\, total_{M_i^X}(1^n)$ queries to its oracle. Since $p_i(n) < 2^{n-2}$, this yields a contradiction.

The case $X \in \mathcal{B}$ is symmetric. Here one has to define X_w by *adding* a string $w \in \Sigma^n - X$ to X, and then, in case $1^n \in L(M_i^{X_w})$ for all $w \in \Sigma^n - X$, argue regarding the number of rejecting instead of accepting paths of M_i. □

4. If secure and oblivious computation differ, then P $\neq$ PSPACE. We show, for both threshold and probabilistic computation, that secure computation is more powerful than oblivious computation only if BPP $\neq$ PP (which would resolve in the affirmative the important question of whether polynomial time differs from polynomial space).

THEOREM 4.1. *If there is a database D such that* $\text{secureBPP}^D_{\text{path}} \neq \text{obliviousBPP}^D_{\text{path}}$, *then* BPP $\neq$ PP.

Proof. Assume BPP = PP. Note that this implies that BPP = $\text{P}^{\#\text{P}}$ (since $\text{P}^{\text{PP}} = \text{P}^{\#\text{P}}$ [4] and BPP = P^{BPP}). Let D be a database and let L be a language such that $L \in \text{secureBPP}^D_{\text{path}}$. We will show that $L \in \text{obliviousBPP}^D_{\text{path}}$, thereby proving the theorem.

Let N be the machine of Definition 2.6 certifying that $L \in \text{secureBPP}^D_{\text{path}}$. We may assume without loss of generality (since it is easy to see that $\text{secureBPP}^D_{\text{path}}$ machines can be amplified in the standard way and still remain secure) that the ϵ of Definition 2.6 satisfies $\epsilon > \frac{1}{4}$. Also, let $p(n)$ be a polynomial, of the form $n^i + i$ for some integer $i \geq 1$, such that for all sets L the runtime of N^L is at most $p(n)$.

Very informally summarized, in the following, a secure computation of N is decomposed (query vector by query vector) to allow an oblivious BPP_{path} machine to mimic N's computation. This will be possible because our assumption gives #P-like computational power to our oblivious BPP_{path} machine.

We will now define an oblivious machine Q such that Q^D certifies that $L \in \text{obliviousBPP}^D_{\text{path}}$. Let x, $|x| = n$, be the input for N^D. The computation of Q^D has essentially two stages. In the first stage, as long as the oblivious machine Q^D asks oracle queries, it only has 0^n available as input. What it does is the following: Q^D simulates N^D on input 0^n. At the end of each path, Q^D has defined a query vector, say $\boldsymbol{v}$. By the definition of secure computation, the proportion of occurrences of $\boldsymbol{v}$ is the same in $N^D(0^n)$ and $N^D(x)$, that is,

$$\frac{\textit{path-occurences}_{N^D(0^n)}(\boldsymbol{v})}{\textit{total}_{N^D}(0^n)} = \frac{\textit{path-occurences}_{N^D(x)}(\boldsymbol{v})}{\textit{total}_{N^D}(x)}. \tag{1}$$

In the second stage, Q gets access to its input x (and thus cannot ask anymore oracle queries). Let $\alpha_{N^D(x)}(\boldsymbol{v})$ denote the number of accepting paths of $N^D(x)$ that have query vector $\boldsymbol{v}$. Roughly speaking, at each path with query vector $\boldsymbol{v}$ found in the first stage, Q will append a full binary tree having approximately a portion of $\alpha_{N^D(x)}(\boldsymbol{v})/\textit{path-occurences}_{N^D(x)}(\boldsymbol{v})$ accepting paths. Therefore, Q^D will have approximately the same overall acceptance behavior as N^D.

More formally, we partition the unit interval into 2^q intervals of equal length, for some appropriately chosen q, and take the largest $k/2^q$, $k \in \{0, \ldots, 2^q - 1\}$, that is still less than $\alpha_{N^D(x)}(\boldsymbol{v})/\textit{path-occurences}_{N^D(x)}(\boldsymbol{v})$ as an approximation for it. This is done as follows. For a query vector $\boldsymbol{v}$ let $V = \{ v \mid v \in D \text{ and } v \text{ is a component of } \boldsymbol{v} \}$. Now, Q guesses k of length q and tests whether $(x, \boldsymbol{v}, V, k) \in A$, where A is defined as follows. For $y \in \Sigma^*$, a vector $\boldsymbol{w}$ of at most $p(|y|)$ strings each of length at most $p(|y|)$, a set of strings W each occurring as a component of vector $\boldsymbol{w}$, and a string j of length q, interpreted as a binary number between 0 and $2^q - 1$,

$$(y, \boldsymbol{w}, W, j) \in A \iff j \leq 2^q \frac{\alpha_{N^W(y)}(\boldsymbol{w})}{\textit{path-occurences}_{N^W(y)}(\boldsymbol{w})} - 1.$$

Clearly, $A \in \text{P}^{\#\text{P}}$, and thus A is in BPP by assumption. Hence there exist a probabilistic machine M_A and a polynomial h such that M_A accepts A with error probability

bounded by 2^{-q}, and furthermore, for any input $(y, \boldsymbol{w}, W, j)$, the computation tree of M_A is a full binary tree with $2^{h(|y|)}$ paths.

In order to test whether $(x, \boldsymbol{v}, V, k)$ is in A, Q simulates M_A on input $(x, \boldsymbol{v}, V, k)$. Q accepts x if and only if the simulation ends in an accepting state of M_A. This completes the definition of Q.

We will argue that the machine Q has the desired properties. By the definition of Q, it is clearly an oblivious machine. Furthermore, for any given input x, let $\boldsymbol{v}$ be a query vector that actually occurs in the run of $N^D(x)$. From equation (1), we get that the portion of paths in the tree of Q^D that have query vector $\boldsymbol{v}$ is identical to the portion in the tree of $N^D(x)$ that have query vector $\boldsymbol{v}$. We now argue that those paths in $Q^D(x)$ having query vector $\boldsymbol{v}$ have almost the same portion accepting as do those paths in $N^D(x)$. Since $\boldsymbol{v}$ was an arbitrary occurring query vector, it will follow that $Q^D(x)$ has appropriate behavior.

By our construction, we can bound $\alpha_{Q^D(x)}(\boldsymbol{v})$, the number of accepting paths of Q^D that have query vector $\boldsymbol{v}$ as follows. Let V be the associated answer set for $\boldsymbol{v}$. Note that $\alpha_{N^V(x)}(\boldsymbol{v}) = \alpha_{N^D(x)}(\boldsymbol{v})$ and $\mathit{path\text{-}occurences}_{N^V(x)}(\boldsymbol{v}) = \mathit{path\text{-}occurences}_{N^D(x)}(\boldsymbol{v})$. Hence we have $(x, \boldsymbol{v}, V, k) \in A$ if and only if $0 \leq k \leq \lfloor 2^q \left(\alpha_{N^D(x)}(\boldsymbol{v}) / \mathit{path\text{-}occurences}_{N^D(x)}(\boldsymbol{v})\right) \rfloor - 1$. Since M_A has error probability at most 2^{-q}, we get the following lower bound for $\alpha_{Q^D(x)}(\boldsymbol{v})$:

$$\mathit{path\text{-}occurences}_{Q^D(x)}(\boldsymbol{v}) \frac{\left\lfloor 2^q \frac{\alpha_{N^D(x)}(\boldsymbol{v})}{\mathit{path\text{-}occurences}_{N^D(x)}(\boldsymbol{v})} \right\rfloor}{2^q} (1 - 2^{-q}) \leq \alpha_{Q^D(x)}(\boldsymbol{v}).$$

For an upper bound, we have to count the small number of extra accepting paths caused by the error probability of M_A:

$$\alpha_{Q^D(x)}(\boldsymbol{v}) \leq \mathit{path\text{-}occurences}_{Q^D(x)}(\boldsymbol{v}) \frac{2^q \frac{\alpha_{N^D(x)}(\boldsymbol{v})}{\mathit{path\text{-}occurences}_{N^D(x)}(\boldsymbol{v})} + 1}{2^q}.$$

With these bounds on $\alpha_{Q^D(x)}(\boldsymbol{v})$, it is now easy to bound the error of Q^D for query vector $\boldsymbol{v}$. Namely, let

$$\mathit{error}(\boldsymbol{v}) = \left| \frac{\alpha_{Q^D(x)}(\boldsymbol{v})}{\mathit{path\text{-}occurences}_{Q^D(x)}(\boldsymbol{v})} - \frac{\alpha_{N^D(x)}(\boldsymbol{v})}{\mathit{path\text{-}occurences}_{N^D(x)}(\boldsymbol{v})} \right|;$$

then we get from the above bounds on $\alpha_{Q^D(x)}(\boldsymbol{v})$ that $\mathit{error}(\boldsymbol{v}) \leq 2^{-q+1}$. Since this holds for each occurring query vector $\boldsymbol{v}$, it certainly holds that 2^{-q+1} bounds the overall error portion: the difference between the portion of accepting paths of $N^D(x)$ and the portion of accepting paths of $Q^D(x)$ is at most 2^{-q+1}. Now define $q = 4$. Since N^D had an ϵ (of Definition 2.6) of at least $\frac{1}{4}$, and since we have $\frac{1}{4} - \frac{1}{8} = \frac{1}{8}$, we may conclude that Q^D is an oblivious machine accepting the same language as N^D and having ϵ (of Definition 2.8) equal to $\frac{1}{8}$. □

The proof of Theorem 4.1 can easily be modified to show the corresponding result for probabilistic classes.

COROLLARY 4.2. *If there is a database D such that* secureBPP$^D \neq$ obliviousBPP^D, *then* BPP $\neq$ PP.

Recall that sets in obliviousBPP^D have small circuits. Thus the existence of a set in secureBPP^D not having a small circuit would separate obliviousBPP^D from secureBPP^D.

COROLLARY 4.3. *If there is a database D such that* $\text{secureBPP}^D \not\subseteq \text{P/poly}$*, then* $\text{BPP} \neq \text{PP}$.

Since $\text{P} \subseteq \text{BPP} \subseteq \text{PP} \subseteq \text{PSPACE}$, we immediately have the result promised in the section title.

COROLLARY 4.4. *If there is a database D such that* $\text{secureBPP}^D_{\text{path}} \neq \text{obliviousBPP}^D_{\text{path}}$*, then* $\text{P} \neq \text{PSPACE}$.

5. Open problems. There are several open problems regarding BPP_{path}. Is BPP_{path} contained in Σ^p_2 or even in R^{NP}? It seems that the proof technique of Theorem 3.11 does not suffice to establish either of these relationships. Does BPP_{path} have complete sets? There is a relativized world in which BPP lacks complete sets [14]; we conjecture that the same holds for BPP_{path}.

Regarding secure computation, does there exist a structural condition that completely characterizes the conditions under which $(\forall D)\,[\text{secureBPP}^D = \text{obliviousBPP}^D]$ or that completely characterizes the conditions under which $(\forall D)\,[\text{secureBPP}^D_{\text{path}} = \text{obliviousBPP}^D_{\text{path}}]$? The study, mentioned in section 2.2, of classes between BPP^D and secureBPP^D and of classes between $\text{BPP}^D_{\text{path}}$ and $\text{secureBPP}^D_{\text{path}}$ also remains an interesting open area.

Appendix. Randomized databases do not strengthen secure probabilistic computation. The secure probabilistic computation of Definition 2.7 can be considered a special case of two-player interactive computation. In particular, the database can be considered a powerful player that truthfully answers difficult questions asked by a polynomial-time player. When the powerful player in a secure probabilistic computation answers a query, it is unable to take the past history of transactions into consideration. In contrast, players in the usual interactive computation models can remember the history of past transactions. Nonetheless, the secure probabilistic computation model is quite powerful. Even if the database is replaced with a deterministic player that has unlimited computation power and memory, it is clear that the resulting interactive computation can be simulated by a polynomial-time player with a new database that is merely a set.

In this section, we consider the effect of allowing the powerful player to be probabilistic. The resulting model is called a one-oracle instance-hiding scheme that leaks at most the length of its input [5]. We present a slightly modified but equivalent definition.

DEFINITION A.1 (one-oracle instance-hiding scheme that leaks at most the length of its input). *For a set L, a* one-oracle instance-hiding scheme that leaks at most the length of its input *is a synchronous protocol executed by two players, M_A and M_B. The number of rounds is bounded by a polynomial in the length of the input. In each round, M_A does a randomized polynomial-time local computation and sends a message (i.e., query) to M_B. Upon receiving the query from M_A, M_B does an unbounded amount of local computation (possibly using an oracle and a random tape) and sends a message (i.e., answer) to M_A. The round is completed when M_A receives the answer sent by M_B. Let τ denote the sequence of messages sent and received by M_A along a computation path, and let T_A denote the random tape of M_A. After the last round, M_A uses τ, T_A, and the input x to compute a value $M_A(x)$. The interactive computation scheme should satisfy the following two conditions:*

1. [*Probability of acceptance is bounded away from $\frac{1}{2}$*]. *There exists an $\epsilon > 0$ such that for all $x \in \Sigma^*$ it holds that $\Pr[M_A(x) = L(x)] > \frac{1}{2} + \epsilon$. (Note that the probability depends on the combined effect of the randomness of both M_A and M_B.)*

2. [*The messages reveal no information to an observer other than perhaps the length of the input.*] *For every* $k \in \{0, 1, 2, \ldots\}$, *every vector* $\boldsymbol{v} = (q_1, a_1, q_2, a_2, \ldots, q_k, a_k)$, $q_1, a_1, q_2, a_2, \ldots, q_k, a_k \in \Sigma^*$, *and every pair of strings* $x \in \Sigma^*$ *and* $y \in \Sigma^*$ *such that* $|x| = |y|$, *it holds that*

$$\Pr[\tau = \boldsymbol{v} \text{ on input } x] = \Pr[\tau = \boldsymbol{v} \text{ on input } y].$$

For any polynomial $p(\cdot)$, the above probability $\frac{1}{2} + \epsilon$ can be amplified to $1 - 2^{-p(|x|)}$ via the standard technique of repeating computations and using the most frequent result. Clearly, if $L \in \text{secureBPP}^D$ for some database D, then L has a one-oracle instance-hiding scheme that leaks at most the length of its input. The following theorem, pointed out to us by an anonymous conference referee, shows that the converse is also true.

THEOREM A.2. *If* L *is a language that has a one-oracle instance-hiding scheme that leaks at most the length of its input, then there exists a database* D *such that* $L \in \text{secureBPP}^D$.

Proof. Let L be a language that has a one-oracle instance-hiding scheme that leaks at most the length of its input. In this proof, we use the notation of Definition A.1. Following [1], we use the term *transcript* to denote τ, the sequence of queries and answers along a computation path. Without loss of generality, we assume that no transcript is a proper prefix of another transcript and that the length of an input is passed to M_B as the first query. In this proof, we first show that M_B can be modified so that it needs only a polynomial number of random bits. Then we show that these random bits can be supplied by M_A, thereby eliminating the need for M_B to be random. It follows that the resulting powerful but deterministic player can be replaced with a set as claimed in the theorem. In the rest of the proof, we call the machines M_A and M_B the *client* and the *server*, respectively.

Given an input of length n, the set of transcripts that have nonzero probabilities define a tree whose depth is bounded by a polynomial in n. Let's call this a *strategy tree*. (As will become clear later in this proof, the strategy tree effectively defines the strategy of the server. Also, it serves as a convenient template for modifying the strategy of the server.) There are two types of nodes in a strategy tree: server nodes and client nodes. These two types of nodes alternate in each path from the root to a leaf. The root is a client node. The leaves are also client nodes. Each edge from a client node is labeled with a query string; each edge from a server node is labeled with an answer string. Each leaf represents a transcript that has a nonzero probability; the transcript consists of labels read from the edges along the path from the root to the leaf. Edges from the same node have distinct labels so that a transcript defines a unique path in a strategy tree. Corresponding to each internal node in a strategy tree, there exists a *partial transcript* that consists of the labels that are read from the edges along the path from the root to the node.

Associated with each leaf is the probability with which the transcript corresponding to the leaf occurs. Clearly, based on this probability distribution, we can associate with each internal node the probability with which the partial transcript corresponding to the node occurs. To each edge from a node, we associate the conditional probability with which its label occurs as the next query or answer in a computation, given that the current partial transcript of the computation is the one represented by the node. Note that the sum of the probabilities associated with all the edges from a node is one and that the probability associated with each node is the product of the probabilities associated with the edges along the path from the root to the node.

It is easy to see that an interactive computation reveals at most the length of the input (in the sense of part 2 in Definition A.1) if and only if its strategy tree is the same for all inputs of the same length. In particular, the strategy of the server (that is, the probability distribution among edges from each server node) is the same for all inputs of the same length. Further, if we modify the server but (i) we do not add new transcripts to the strategy tree and (ii) the client is not changed, then the resulting strategy tree is the same for all inputs of the same length. Hence we may arbitrarily adjust the probability distribution among the existing edges from each server node without affecting the instance-hiding nature of the computation. However, such change could affect the acceptance probabilities of input strings. Therefore, in the following, we carefully modify the behavior of the server so that the acceptance of each input string remains intact. In particular, assuming without loss of generality that the probability of correctness (in the sense of part 1 in Definition A.1) of the original instance-hiding computation is greater than $\frac{3}{4}$, we will ensure that the probability of correctness of the modified instance-hiding computation is greater than $\frac{5}{8}$.

Let $q(n)$ be a polynomial that bounds both the length of the label of each edge and the depth of the strategy tree. The main obstacle in transforming the randomized server to a deterministic one is the fact that the probability of an edge from a server node can be an arbitrary value. In order to get around the obstacle, we adjust the probability of each edge from server nodes so that it is an integral multiple of $2^{-q^2(n)-q(n)-3}$ and that it differs from the original probability by less than $2^{-q^2(n)-q(n)-3}$. Thus the probability change at each leaf of the strategy tree is less than $q(n)2^{-q^2(n)-q(n)-3}$. Since there are at most $2^{q^2(n)}$ leaves, it is easy to see that the change in the probability of correctness of the whole computation is less than $\frac{1}{8}$. Therefore, the probability of correctness of the modified secure computation is greater than $\frac{5}{8}$. Note that the resulting strategy tree can be constructed by the server upon receiving the first query (i.e., the length of the input). The server uses this strategy tree to answer all the queries.

The server modified in this way needs at most a polynomial number $(q(n)(q^2(n)+q(n)+3))$ of random bits. Hence the necessary random bits can be supplied to the server by the client at the beginning of a computation. Note that this modification affects neither the instance-hiding nature of the computation nor the probability of correctness of the computation. The resulting server is deterministic, but it may not yet be considered a deterministic function oracle since it may give different answers to different instances of the same queried string. By prefixing each query with an ppropriate public information with which the server can uniquely locate the current stage of computation in the strategy tree (for example, $\langle q_1, \ldots, q_{i-1} \rangle$ can be used as a prefix to the ith query along a computation path on which q_j $(0 < j < i)$ is the jth query), the server can be transformed into a deterministic function oracle. It is easy to see that we can further modify the client so that it securely accepts the same language with a set oracle (D) instead of a function oracle. Clearly, the resulting computation is a secure probabilistic computation. □

DISJOINT ROOTED SPANNING TREES WITH SMALL DEPTHS IN DEBRUIJN AND KAUTZ GRAPHS*

ZHENGYU GE† AND S. LOUIS HAKIMI†

Abstract. The problem of broadcasting long messages on store-and-forward communication networks, where a processor (node) can send and receive messages simultaneously to and from all its neighbors, was studied by Bermond and Fraigniaud. In such networks, the delays encountered by a message from a node v to all other nodes over a broadcast spanning tree is directly proportional to the length of the paths in the tree over which the message is sent. Furthermore, the speed of the broadcast can be improved by the segmentation of the message at v into equal-length segments and then the broadcast of these segments over arc-disjoint broadcast spanning trees simultaneously. These observations lead Bermond and Fraigniaud to look for the maximum number of arc-disjoint spanning trees in a deBruijn network rooted at an arbitrary node with small depths. This paper improves and extends the results of the above authors.

1. Introduction.

The deBruijn and Kautz networks represent a useful class of interconnection architecture for multiprocessor systems [1, 2, 3, 4]. The normal definitions of the deBruijn and Kautz networks yield digraphs; interesting and challenging problems also arise when the directions of the arcs of these digraphs are ignored, thus converting all arcs into edges and digraphs into graphs. We will denote the normal deBruijn and Kautz digraphs by $B(\Delta, D)$ and $K(\Delta, D)$, where Δ is the out-degree (and in-degree) of each node and D is the diameter of these digraphs. We will also denote the associated undirected graphs by $UB(\Delta, D)$ and $UK(\Delta, D)$.

The deBruijn and Kautz digraphs have many desirable properties such as large number of nodes (Δ^D for deBruijn and $\Delta^D + \Delta^{D-1}$ for Kautz digraphs), small diameter D, nearly optimal connectivities ($\Delta - 1$ for $B(\Delta, D)$ and Δ for $K(\Delta, D)$), and very simple routing procedures [1, 2, 6].

The arcs in digraphs represent directional communication links while edges in graphs represent communication links that permit communication in either direction but in one direction at a time. We will consider the store-and-forward model for communication between nodes [5]. We will also assume that a node can simultaneously send (receive) messages to (from) all its neighbors.

Broadcasting, that is, sending a message from a given node v to all other nodes in the network, is an important network function that is often encountered in distributed computing or paralleled algorithms. To effectively broadcast a message from a node v to all other nodes, one must accomplish this task at high transmission rates (throughput) and with small delays. In a store-and-forward network, broadcasting a message from node v occurs over the arcs of a (broadcast) spanning tree rooted at v. The maximum delay that the message at v encounters is directly proportional to the depth of this broadcast tree. Thus if we wish to broadcast a message at v to all

other nodes with the least delay, we select a shortest-path spanning tree rooted at v in the network as our broadcast tree. In fact, this choice would guarantee that the message from v is received at every node with the least amount of time delay. Suppose that we are also interested in the rate of transmission of the message at v. Barring improvements in hardware, the way to achieve the improvement is through parallel broadcasting. Parallel broadcasting involves the segmentation of the message at v into d equal-length segments and then the broadcast of each of these d segments over one of the d arc-disjoint broadcast trees in the network rooted at v. Improvement in delay can also be achieved by pipelining the packets in the segmentation of the message in each of these trees [1, 5, 9]. Since pipelining can be carried out independently of the parallel-broadcasting technique discussed here, it will not be further elaborated.

The above observation lead Bermond and Fraigniaud [1] to look for the maximum number of arc-disjoint broadcast trees rooted at node v with small depths in deBruijn digraphs. More precisely, they showed that in $B(\Delta, D)$, there are $\Delta - 1$ arc-disjoint broadcast trees rooted at any node v, with the depth of each tree not exceeding $D + 2\lfloor \frac{D}{2} \rfloor + 1 (\geq 2D)$. This represents the speedup of the rate of transmission by a factor of $\Delta - 1$ and an increase in the maximum delay by $2\lfloor \frac{D}{2} \rfloor + 1$ over the shortest-path broadcast tree.

In this paper, we say that two spanning trees are *arc disjoint* if no arc appears in both trees, and we say that two trees are *pseudo node disjoint* if no node can be internal nodes in both trees, where an *internal* node in a tree is a node which is neither the root nor a leaf node of that tree. Thus in a group of rooted pseudo-node-disjoint spanning trees, if a node is an internal node in one tree, it will be a leaf node in all other trees. It is easy to see that if two spanning trees rooted at node v are pseudo node disjoint, then they are also arc disjoint, with the possible exception of arcs emanating from root v. However pseudo-node-disjoint trees generated in this paper never share any arcs emanating from the root. Thus pseudo-node-disjoint trees generated here are also arc disjoint.

In this paper, we present methods for generating pseudo-node-disjoint spanning trees (PNDSTs) rooted at an arbitrary node in $B(\Delta, D)$ and arc-disjoint spanning trees (ADSTs) rooted at an arbitrary node in $K(\Delta, D)$. More precisely, we will demonstrate that there are $\Delta - 1$ PNDSTs of depth no greater than $\lceil \frac{3D}{2} \rceil$ in $B(\Delta, D)$ and there are Δ ADSTs of depth no greater than $\lceil \frac{3D}{2} \rceil + 1$ in $K(\Delta, D)$.

One of the shortcomings of the above results is that they are obtained for digraphs which are neither the normal model of the computer networks nor the interconnection architecture of multiprocessor systems. We will present a proof for the existence of Δ PNDSTs in $UB(\Delta, D)$, with the bound on the depths of these trees being at most $2D$. Although the removal of the directions on the arcs of $K(\Delta, D)$ may actually reduce the depths of the Δ spanning trees in $UK(\Delta, D)$, we have not been able to prove that the bound on the depths can always be reduced.

In the concluding section of this paper, the relations between the results of this paper and certain measures of reliability of networks are explained.

2. Disjoint spanning trees in deBruijn and Kautz digraphs: Preliminary considerations. $B(\Delta, D)$ is a digraph whose node set corresponds the set of all sequences of length D on the alphabet $\{1, 2, \ldots, \Delta\}$. For the Kautz digraph $K(\Delta, D)$, the node set corresponds to all sequences of length D over the alphabet $\{1, 2, \ldots, \Delta + 1\}$ provided no two consecutive letters in such a sequence can be the same. We will refer to the sequences with this feature as *Kautz sequences*. The set of arcs of $B(\Delta, D)$ corresponds the set of all sequences of length $D + 1$ on

the alphabet $\{1, 2, \ldots, \Delta\}$ and the set of arcs in $K(\Delta, D)$ corresponds to the set of all Kautz sequences of length $D+1$ on the alphabet $\{1, 2, \ldots, \Delta+1\}$. The arc $e = (a_1, a_2, \ldots, a_{D+1})$ in $B(\Delta, D)$ and in $K(\Delta, D)$ is from node $(a_1, a_2, \ldots, a_D)$ to node $(a_2, a_3, \ldots, a_{D+1})$. There are exactly Δ arcs into and out of each node in $B(\Delta, D)$ and $K(\Delta, D)$.

Let $R = (r_1, r_2, \ldots, r_D)$ be a node in $B(\Delta, D)$ or $K(\Delta, D)$. We intend to broadcast the message at R to all other nodes. We are, in fact, seeking $\Delta - 1$ PNDSTs (respectively, Δ ADSTs) rooted at R in $B(\Delta, D)$ (respectively, in $K(\Delta, D)$). We refer to these sets of trees as $TB(D, R)$ and $TK(D, R)$, respectively.

The *depth* of a tree is the length of a longest path in the tree starting at the root R. Furthermore, if a node u (respectively, an arc e) is the ith node (arc) in a path in the tree from R, then the node u is said to be at the $(i-1)$th level and the arc e is at the ith level, while the root R itself is considered at the 0th level.

We call $u = (a_1, a_2, \ldots, a_D) \in B(\Delta, D)$ a *corner* node if $a_1 = a_2 = \cdots = a_D$. There are exactly Δ corner nodes in $B(\Delta, D)$. If $R = (r_1, r_2, \ldots, r_D)$ is a corner node, then R has $\Delta - 1$ outgoing arcs, excluding the loop, in $B(\Delta, D)$ and thus each of the $\Delta - 1$ trees in $TB(D, R)$ rooted at R has exactly one outgoing arc incident at R. Otherwise, R will have Δ outgoing arcs; thus all but one of the $\Delta - 1$ trees in $TB(D, R)$ have exactly one outgoing arc incident at R and the exceptional tree in $TB(D, R)$ may have two arcs incident at R. We call the other end nodes of these outgoing arcs from R the *subroots*. For $K(\Delta, D)$, which does not have the corner nodes, all the Δ trees in $TK(D, R)$ have exactly one subroot.

Let $G(V, E)$ be a digraph with node set $V = V(G)$ and arc set $E = E(G)$. For $v \in V$, let $\Gamma v = \{u \in V \mid (v, u) \in E\}$ and $\Gamma^{-1} v = \{u \in V \mid (u, v) \in E\}$. We will call Γv the *successors* of v and $\Gamma^{-1} v$ the *predecessors* of v. If G is a rooted directed tree, the successors of v are called *child* nodes of v and the predecessor of v is called the *parent* node of v.

The line digraph of digraph G, denoted by $L(G)$, is a digraph with $V(L(G)) = E(G)$, that is, there is a node in $L(G)$ for each arc in $E(G)$; and, furthermore, there is an arc in $L(G)$ from e_1 to e_2 if the sequence of arcs $e_1 e_2$ forms a directed path in G.

LEMMA 2.1. (See [3, 6, 7].) *Let $B(\Delta, D)$ and $K(\Delta, D)$ be the deBruijn and Kautz digraphs as previously defined. Then for each $D \geq 1$, $B(\Delta, D+1) = L(B(\Delta, D))$ and $K(\Delta, D+1) = L(K(\Delta, D))$ and consequently $B(\Delta, D) = L^D(B(\Delta, 1))$ and $K(\Delta, D) = L^D(K(\Delta, 1))$, where $L^D(G) = L(L^{D-1}(G))$, $B(\Delta, 1)$ is a complete digraph on Δ nodes with a loop on each node, and $K(\Delta, 1)$ is a complete digraph on $\Delta + 1$ nodes without any loops.*

Let $a, b \in \{1, 2, \ldots, \Delta\}$ and $\Delta > 2$. (Since our problem is trivial when $\Delta = 2$, this case will not be considered.) An *$a - b$ node* is a node $u = (a_1, a_2, \ldots, a_D)$ such that $a_i \in \{a, b\}$ for $i = 1, 2, \ldots, D$. Note that a corner node is a special case of the $a - b$ nodes when $a = b$. Thus the following theorem is a generalization of a result in [1].

THEOREM 2.2. *Let $R = (r_1, r_2, \ldots, r_D)$ be an $a - b$ node in $B(\Delta, D)$. Then there is a set $TB(D, R)$ of $\Delta - 1$ PNDSTs rooted at R in $B(\Delta, D)$ with depths equal to $D + 1$.*

Proof. An algorithm is offered in this proof which provides the $\Delta - 1$ PNDSTs described in Theorem 2.2. Actually, we will prove a stronger result as follows. If u is an internal node in one tree of $TB(D, R)$, then it must be a node at the last level, $D + 1$, in all other trees in $TB(D, R)$. Thus the trees in $TB(D, R)$ are definitely pseudo node disjoint.

Consider the set of $\Delta - 2$ shortest-path spanning trees $T'(s_i)$ in $B(\Delta, D)$ rooted at the $\Delta - 2$ nodes $S_i = (r_2, \ldots, r_D, s_i)$ with $s_i \in \{1, 2, \ldots, \Delta\} - \{a, b\}$. We first prove that these trees $\{T'(s_i) \mid s_i \in \{1, 2, \ldots, \Delta\} - \{a, b\}\}$ are pseudo node disjoint.

Consider two such trees $T'(s_i)$ and $T'(s_j)$ with $s_i \neq s_j$. Note that the depths of these trees are D. For convenience, though an abuse of notation, we say that the root S_i is at level 1 in $T'(s_i)$ and thus the last level nodes in $T'(s_i)$ are at level $D + 1$. Let u and v be nodes in $T'(s_i)$ and $T'(s_j)$ at levels p and q from the roots S_i and S_j, respectively. Assume that both u and v are not nodes at the last levels, $D + 1$. Then if $1 \leq p \leq D - 1$ and $1 \leq q \leq D - 1$, we can write

$$\begin{array}{lll} u = (r_{p+1}, \ldots, r_D, \mathbf{s_i}, x_1, \ldots, x_{p-1}), & x_s \in \{1, 2, \ldots, \Delta\} & \text{for } s = 1, \ldots, p-1, \\ v = (r_{q+1}, \ldots, r_D, \mathbf{s_j}, y_1, \ldots, y_{q-1}), & y_t \in \{1, 2, \ldots, \Delta\} & \text{for } t = 1, \ldots, q-1, \end{array}$$

and if $p = D$ and $q = D$,

$$\begin{array}{lll} u = (\mathbf{s_i}, x_1, \ldots, x_{D-1}), & x_s \in \{1, 2, \ldots, \Delta\} & \text{for } s = 1, \ldots, D-1; \\ v = (\mathbf{s_j}, y_1, \ldots, y_{D-1}), & y_t \in \{1, 2, \ldots, \Delta\} & \text{for } t = 1, \ldots, D-1. \end{array}$$

Because R is an $a - b$ node, $r_k \in \{a, b\}$ $\forall k, s_i, s_j \in \{1, 2, \ldots, \Delta\} - \{a, b\}$, and $s_i \neq s_j$, we have $u \neq v$. Therefore, any node $u \in B(\Delta, D)$ could be an internal node in at most one of the trees in $\{T'(s_i) \mid s_i \in \{1, 2, \ldots, \Delta\} - \{a, b\}\}$. This implies that $T'(s_i)$ and $T'(s_j)$ are pseudo node disjoint.

Since $s_i \notin \{a, b\}$, all $a - b$ nodes, including node R, are in level $D + 1$ of $T'(s_i)$, and thus they are leaves. This implies that if we remove the arc into R from $T'(s_i)$ and add the arc $(R, S_i) \in B(\Delta, D)$ to it, we obtain a new tree denoted by $T(s_i)$. It is easy to see that $\{T(s_i) \mid s_i \in \{1, 2, \ldots, \Delta\} - \{a, b\}\}$ are directed spanning trees rooted at R and that they are pseudo node disjoint of depths $D + 1$.

Before proceeding to construct the last tree in $TB(D, R)$, we would like to clarify the relation between the levels of the nodes in the trees in $\{T(s_i) \mid s_i \in \{1, 2, \ldots, \Delta\} - \{a, b\}\}$ and the labels (i.e., sequences) associated with the nodes. For example, consider the nodes in $T(s_i)$ in the following order. The root R at level 0 followed by the subroot S_i at level 1, a node at level k, $1 < k < D$, a node at level D, and finally a node at level $D + 1$ will have the following labels:

$$\begin{aligned} R = (r_1, r_2, \ldots, r_D) \to S_i = (r_2, \ldots, r_D, \mathbf{s_i}) \to \cdots \to (r_{k+1}, \ldots, r_D, \mathbf{s_i}, x_1, \ldots, x_{k-1}) \\ \to \cdots \to (\mathbf{s_i}, x_1, \ldots, x_{D-1}) \to (x_1, \ldots, x_D). \end{aligned}$$

We will use this notation to designate a node at a particular level, say in tree $T(s_i)$.

We will now prove that there is one more tree rooted at R in $B(\Delta, D)$ of depth $D + 1$ which is pseudo node disjoint from the trees in $\{T(s_i) \mid s_i \in \{1, 2, \ldots, \Delta\} - \{a, b\}\}$. (The special case of the above claim, when $a = b$, has already been established in [1]). Toward this goal, we proceed as follows. Let $S_a = (r_2, \ldots, r_D, a)$ and $S_b = (r_2, \ldots, r_D, b)$, $a \neq b$, be the two subroots, and let $T'(ab)$ be a constrained shortest-path spanning tree rooted at R in $B(\Delta, D)$ in which every path starting at R passes through the subroot S_a or S_b. Note that the length of a path in $T'(ab)$ from R to any node whose first letter is in $\{a, b\}$ is at most D, and otherwise, this length is $D + 1$. It is easy to see that the depth of $T'(ab)$ will be $D + 1$.

Let $T'(a)$ and $T'(b)$ be the partial trees of $T'(ab)$ rooted at nodes S_a and S_b, respectively. Note that $V(T'(ab)) = V(T'(a) \cup T'(b) \cup R)$. Without loss of generality, let $u \in T'(a)$ be a node of $T'(ab)$ at level p, $1 \leq p \leq D$. If u is identical to a node $v \in T(s_i)$, $s_i \in \{1, 2, \ldots, \Delta\} - \{a, b\}$, at level q, $1 \leq q \leq D$, then we have

$$v = (r_{q+1}, r_{q+2}, \ldots, \ldots, \ldots, \ldots, \ldots, \ldots, r_D, \mathbf{s_i}, x_1, \ldots, x_{q-1}),$$

where $x_1, \ldots, x_{q-1}$ is an arbitrary sequence over $\{1, 2, \ldots, \Delta\}$. Since $u = v$ and $s_i \notin \{a, b\}$, we may write

$$u = (r_{p+1}, r_{p+2}, \ldots, r_D, \mathbf{a}, a_1, a_2, \ldots, a_{p-q-1}, \mathbf{s_i}, x_1, \ldots, x_{q-1}),$$

where $a_1, a_2, \ldots, a_{p-q-1}$ is an $a - b$ sequence. Since the length of the $a - b$ sequence, $a_1, a_2, \ldots, a_{p-q-1}$, is nonnegative, we have $p - q - 1 \geq 0$, or

$$q \leq p - 1.$$

Note that u and v may or may not be internal nodes in their respective trees.

Suppose an internal node u' at level h, $h \leq D$, of $T'(ab)$ is a node at level $D+1$ in all other trees $T(s_i)$, $s_i \in \{1, 2, \ldots, \Delta\} - \{a, b\}$. Then we claim that all nodes on the path in $T'(ab)$ from R to u' excluding R are also nodes at level $D+1$ in all other trees $T(s_i)$, $s_i \in \{1, 2, \ldots, \Delta\} - \{a, b\}$. To see this, suppose otherwise; that is, there is at least one node on the path from R to u' in $T'(ab)$ that is not at level $D+1$ in all other trees $T(s_i)$, $s_i \in \{1, 2, \ldots, \Delta\} - \{a, b\}$. Among all such nodes, let w be the closest one to u'. Suppose w is at level p, $p \leq h - 1 \leq D - 1$, in $T'(ab)$, and assume w is at level q, $q \leq D$, in some other tree $T(s_i)$. As before, we must have $q \leq p - 1 \leq D - 2$. Since $T(s_i)$ was produced from the shortest-path spanning tree $T'(s_i)$ rooted at S_i, the successor nodes of w in $B(\Delta, D)$ are at a level at most $q + 1 \leq D - 1$ in $T(s_i)$. This implies the child node, say z, of w which is on the path from w to u' in $T'(ab)$ is also not at level $D + 1$ in all other trees. This is a contradiction since w was the closest one to u'.

The above claim states that if $T'(ab)$ contains some internal nodes, denoted by $I_n(T'(ab))$, that are not at level $D + 1$ in all other trees $T(s_i)$ $\forall s_i \in \{1, 2, \ldots, \Delta\} - \{a, b\}$, then the child nodes of any node in $I_n(T'(ab))$ are either in $I_n(T'(ab))$ or are leaves of $T'(ab)$. This in turn implies that there is a node in $I_n(T'(ab))$ whose child nodes are all leaves. Without loss of generality, let $u \in T'(a)$ be such an internal node at level p, $p \leq D$, of $T'(ab)$ whose child nodes are all leaves. Suppose u is identical to $v \in T(s_i)$, $s_i \in \{1, 2, \ldots, \Delta\} - \{a, b\}$, at level q, $q \leq p - 1$. Let the node $u^* \in T'(ab)$ be defined as follows:

$$u^* = (\mathbf{r^*_{p+1}}, r_{p+2}, \ldots, r_D, \mathbf{a}, a_1, \ldots, a_{p-q-1}, \mathbf{s_i}, x_1, \ldots, x_{q-1})$$

or, equivalently,

$$u^* = (\mathbf{r^*_{q+1}}, r_{q+2}, \ldots, \ldots, \ldots, \ldots, r_D, \mathbf{s_i}, x_1, \ldots, x_{q-1}),$$

where $r^*_{p+1} = r^*_{q+1} \in \{a, b\}$, $r^*_{p+1} \neq r_{p+1}$. Note that u^* and u have the same successor nodes in $B(\Delta, D)$. Let $T''(ab)$ be obtained from $T'(ab)$ by transferring the child nodes from u in $T'(ab)$ to u^* in $T''(ab)$. We will establish that (i) the depth of $T''(ab)$ is still $D + 1$ and (ii) all nodes on the path from R to u^*, excluding R but including u^*, correspond to nodes at level $D + 1$ in all other trees $T(s_i)$, $s_i \in \{1, 2, \ldots, \Delta\} - \{a, b\}$.

We will explain shortly that the validity of the two statements above enables one to use the above process of transferring child nodes to eliminate all internal nodes in $T'(ab)$ which could possibly be internal nodes in any other tree $T(s_i)$, $s_i \in \{1, 2, \ldots, \Delta\} - \{a, b\}$.

(i) Since the first letter in u^* is in $\{a, b\}$, the distance from R to u^* in $T'(ab)$ is at most D. Since the child nodes of u in $T'(ab)$ are leaves, the depth of $T''(ab)$ is not more than $D + 1$.

(ii) Let w be a node on path from R to u^* in $T'(ab)$ at level, say k. Note that if $k \geq p-q+1$, then

$$w = (r_{k+1}, r_{k+2}, \ldots, r_p, \mathbf{r^*_{p+1}}, r_{p+2}, \ldots, r_D, \mathbf{a}, a_1, \ldots, a_{p-q-1}, \mathbf{s_i}, x_1, \ldots, x_{k+q-p-1})$$

or, equivalently,

$$(1) \quad w = (r_{k+q-p+1}, \ldots, r_q, \mathbf{r^*_{q+1}}, r_{q+2}, \ldots, \ldots, \ldots, \ldots, r_D, \mathbf{s_i}, x_1, \ldots, x_{k+q-p-1}).$$

On the other hand, if $k < p-q+1$, then w will be an $a-b$ node. However, if w is an $a-b$ node, we already know that w will be at level $D+1$ in all trees $T(s_i)$, $s_i \in \{1, 2, \ldots, \Delta\} - \{a, b\}$. Therefore, we need to examine the case when w is not an $a-b$ node. To the contrary, suppose w is at level m, $m \leq D$, in some other tree, say, $T(s_h)$, $s_h \in \{1, 2, \ldots, \Delta\} - \{a, b\}$. Then we have

$$(2) \qquad w = (r_{m+1}, r_{m+2}, \ldots, \ldots, \ldots, \ldots, r_D, \mathbf{s_h}, y_1, y_2, \ldots, y_{m-1}),$$

where $y_1, y_2, \ldots, y_{m-1}$ is an arbitrary sequence over $\{1, 2, \ldots, \Delta\}$. Since the subsequence in equation (1) up to s_i and the subsequence in equation (2) up to s_h are $a-b$ sequences, we have $s_i = s_h$. This implies that w is in $T(s_i) = T(s_h)$ at level $m = k+q-p$, but this is impossible because then equation (2) becomes

$$(3) \quad w = (r_{k+q-p+1}, \ldots, r_q, \mathbf{r_{q+1}}, r_{q+2}, \ldots, \ldots, \ldots, \ldots, r_D, \mathbf{s_i}, x_1, \ldots, x_{k+q-p-1});$$

this is a contradiction to (1) as $r_{q+1} \neq r^*_{q+1}$.

At this stage, we can conclude that if $u \in T'(ab)$ whose child nodes are all leaves in $T'(ab)$ is not at level $D+1$ of all other trees $T(s_i)$, $s_i \in \{1, 2, \ldots, \Delta\} - \{a, b\}$, we can always transfer the child nodes of u to u^*, consequently forcing u to be a leaf in $T''(ab)$, and the path length from R to the child nodes will not exceed $D+1$.

We do this examination and adjustment from all parent nodes of the leaf nodes in $T'(ab)$ backward to lower levels until we meet the internal nodes such as u' which are at level $D+1$ of all other trees $T(s_i)$, $s_i \in \{1, 2, \ldots, \Delta\} - \{a, b\}$. The resulting directed tree, denoted by $T(ab)$, will be pseudo node disjoint from the other $\Delta - 2$ trees. This completes the proof of Theorem 2.2. □

We will now present the counterpart of Theorem 2.2 for $K(\Delta, D)$. Let a and b belong to $\{1, 2, \ldots, \Delta, \Delta+1\}$, $a \neq b$, and $\Delta \geq 2$. Note that there are exactly two $a-b$ nodes in $K(\Delta, D)$ for the specified a and b, $(\ldots abab)$ and $(\ldots baba)$. Thus the total number of $a-b$ nodes in $K(\Delta, D)$ is $2\binom{\Delta+1}{2}$. For simplicity, we will denote the Kautz sequence $(\ldots abab)$ of length p ending with letter b by $\{\mathbf{ab}\}_\mathbf{p}$ and the Kautz sequence $(\ldots baba)$ of length q ending with letter a by $\{\mathbf{ba}\}_\mathbf{q}$.

THEOREM 2.3. *Let R be an $a-b$ node in $K(\Delta, D)$. Then 1. there are $\Delta - 1$ PNDSTs rooted at R in $K(\Delta, D)$ of depths $D+1$ and 2. there are Δ ADSTs rooted at R in $K(\Delta, D)$ of depths $D+2$.*

Proof. We begin with an algorithm for constructing the $\Delta - 1$ PNDSTs rooted at R in $K(\Delta, D)$ of depths $D+1$ for the proof of part 1 of Theorem 2.3.

1. Without loss of generality, let $R = (\ldots abab) = (\{ab\}_D)$. For $s_i \in \{1, 2, \ldots, \Delta+1\} - \{a, b\}$, let $S_i = (\ldots ababs_i) = (\{ab\}_{D-1}s_i)$, and let $T'(s_i)$ be the shortest-path spanning tree in $K(\Delta, D)$ rooted at S_i. The depth of $T'(s_i)$ is D, the root S_i is considered at level 1, and the last level is $D+1$. Note that there are $\Delta - 1$ such trees. Consider two of them, $T'(s_i)$ and $T'(s_j)$ with $s_i \neq s_j$. We will now show that $T'(s_i)$ and $T'(s_j)$ are pseudo node disjoint. Let u and v be possible internal nodes in $T'(s_i)$

and $T'(s_j)$ at levels p and q from the roots S_i and S_j respectively, $1 \le p \le D$ and $1 \le q \le D$.

$$u = \big(\{ab\}_{D-p} s_i \{1, 2, \ldots, \Delta+1\}_{p-1}^{-s_i}\big),$$
$$v = \big(\{ab\}_{D-q} s_j \{1, 2, \ldots, \Delta+1\}_{q-1}^{-s_j}\big),$$

where $\{1, 2, \ldots, \Delta+1\}_{p-1}^{-s_i}$ is an arbitrary Kautz sequence of length $p-1$ on $\{1, 2, \ldots, \Delta+1\}$ whose first letter is not s_i. It is now easy to see that because $s_i \neq s_j, s_i \notin \{a, b\}$, and $s_j \notin \{a, b\}$, we have $u \neq v$. This implies that $T'(s_i)$ and $T'(s_j)$ are pseudo node disjoint.

Note that all nodes at levels from 1 to D in $T'(s_i)$ contain the letter s_i in their labels; thus since R is an $a-b$ node, R is at level $D+1$ of $T'(s_i)$, $s_i \in \{1, 2, \ldots, \Delta+1\} - \{a, b\}$. Then the arc into R is removed from $T'(s_i)$ and the arc (R, S_i) of $K(\Delta, D)$ is added to $T'(s_i)$. The resulting tree is denoted by $T(s_i)$, $s_i \in \{1, 2, \ldots, \Delta+1\} - \{a, b\}$. The set $\{T(s_i) \mid s_i \in \{1, 2, \ldots, \Delta+1\} - \{a, b\}\}$ constitutes a set of $\Delta - 1$ PNDSTs rooted at R in $K(\Delta, D)$ of depths $D+1$.

Similar to the deBruijn case, the nodes, say in $T(s_i)$, at level 0, level 1, level $p, 1 < p < D$, level D, and finally at level $D+1$ will have the following labels:

$$R = (\{ab\}_D) \to S_i = (\{ab\}_{D-1}\mathbf{s_i}) \to \cdots \to (\{ab\}_{D-p}\mathbf{s_i}\{1, 2, \ldots, \Delta+1\}_{p-1}^{-s_i})$$
$$\to \cdots \to (\mathbf{s_i}\{1, 2, \ldots, \Delta+1\}_{D-1}^{-s_i}) \to (\{1, 2, \ldots, \Delta+1\}_D^{-s_i}).$$

2. We will build a new tree of depth $D+2$ denoted by $T(ab)$ which is arc disjoint from all trees in the above set. Let $T''(ab)$ be the shortest-path spanning tree rooted at the subroot $S_{ab} = (\ldots ababa) = (\{ba\}_D)$. We now wish to characterize the nodes in $T''(ab)$. We say that the node $S_{ab} = (\{ba\}_D)$ is at level 1 of $T''(ab)$, and it is easy to see that the nodes at level 2 of $T''(ab)$ are

$$(\{ba\}_{D-1} s_k), s_k \in \{1, 2, \ldots, \Delta+1\} - \{a\}.$$

Note that $R = (\{ab\}_D)$ is at level 2 with $s_k = b$. Generally, the nodes at level p of $T''(ab)$, $2 \le p \le D+1$, have the form

$$(\{ba\}_{D-p+1} s_k \{1, 2, \ldots, \Delta+1\}_{p-2}^{-s_k}), s_k \in \{1, 2, \ldots, \Delta+1\} - \{a\}, \quad 2 \le p \le D+1.$$

By removing the arc (Sab, R) from $T''(ab)$, discarding the partial tree rooted at R in $T''(ab)$, and adding the arc (R, S_{ab}) of $K(\Delta, D)$ to $T''(ab)$, we build a subtree in $K(\Delta, D)$, denoted by $T'(ab)$. $T'(ab)$ can be characterized as follows. Beginning with root R and then subroot $S_{ab} = (\ldots ababa) = (\{ba\}_D)$, the tree $T'(ab)$ proceeds as the maximum breadth-first subtree with depth up to $D+1$ which contains as many nodes of $K(\Delta, D)$ as possible. At this stage, $T'(ab)$ is not a spanning tree, and every path from R to any node u in it is the shortest path in $K(\Delta, D)$ which begins with R and then S_{ab}. In fact, the node set at level p, $2 \le p \le D+1$, in $T'(ab)$, denoted by $V_{\text{in}}(T'(ab))$, has the form

$$V_{\text{in}}(T'(ab))$$
$$= \{(\{ba\}_{D-p+1} s_i \{1, 2, \ldots, \Delta+1\}_{p-2}^{-s_i}) \mid s_i \in \{1, 2, \ldots, \Delta+1\} - \{a, b\}, 2 \le p \le D+1\}.$$

It can be easily seen that the nodes that are missing from $T'(ab)$ may be described by

$$V_{\text{mis}}(T'(ab))$$
$$= \{(\{ab\}_{D-p} s_i \{1, 2, \ldots, \Delta+1\}_{p-1}^{-s_i}) \mid s_i \in \{1, 2, \ldots, \Delta+1\} - \{a, b\}, 1 \le p \le D-1\},$$

which are the nodes of the partial tree in $T''(ab)$ rooted at R. Note that $V(K(\Delta, D)) = \{R \cup S_{ab} \cup V_{\text{in}}(T'(ab)) \cup V_{\text{mis}}(T'(ab))\}$.

We first claim that the subtree $T'(ab)$ is pseudo node disjoint from those trees in $\{T(s_i) \mid s_i \in \{1, 2, \ldots, \Delta + 1\} - \{a, b\}\}$. To see this, we observe that the set of the nodes at level q, $1 \le q \le D$, say in $T(s_i)$, may be described as follows:

$$V_{\text{in}}(T(s_i)) = \{(\{ab\}_{D-q} s_i \{1, 2, \ldots, \Delta + 1\}_{q-1}^{-s_i}) \mid s_i \in \{1, 2, \ldots, \Delta + 1\} - \{a, b\}, 1 \le q \le D\}.$$

Now let us consider the above set of nodes. If $1 \le q \le D - 1$, it is easy to see that these nodes belong to $V_{\text{mis}}(T'(ab))$. If $q = D$, these nodes all belong to $V_{\text{in}}(T'(ab))$ at level $p = D + 1$. This proves the claim.

To complete the proof, we will show that for each node $u \in V_{\text{mis}}(T'(ab))$, there exists a node $u' \in V_{\text{in}}(T'(ab))$ at level $D + 1$ of $T'(ab)$ such that the arc (u', u) is not in any tree in the set $\{T(s_i) \mid s_i \in \{1, 2, \ldots, D + 1\} - \{a, b\}\}$. Let

$$u = (\{ab\}_{D-p} s_i \{1, 2, \ldots, \Delta + 1\}_{p-1}^{-s_i}), \quad 1 \le p \le D - 1.$$

If $p = 1$, we select

$$u' = (s_i \{ab\}_{D-1});$$

if $2 \le p \le D - 1$, we select

$$u' = (s_i \{ab\}_{D-p} s_i \{1, 2, \ldots, \Delta + 1\}_{p-2}^{-s_i}).$$

We first observe that u' is at level $D + 1$ in the trees $T(s_j)$, $s_j \ne s_i$. Thus the arc (u', u) cannot exist in these trees $T(s_j)$ in this case. In $T(s_i)$, node u is at level p, $p \le D - 1$, and u' is at level D, which implies that the arc (u', u) cannot belong to $T(s_i)$ either. Note, however, that u' is an internal node in $T(s_i)$ and $T(ab)$. □

3. Disjoint spanning trees in deBruijn and Kautz networks: General case. We first consider the problem of constructing $\Delta - 1$ PNDSTs in $B(\Delta, D)$ rooted at an arbitrary node $R = (r_1, r_2, \ldots, r_D)$. This set of trees will be denoted by $TB(D, R)$. We call the reader's attention to two groups of nodes around R in $B(\Delta, D)$. The first group consists of the *subroots*, denoted by $\mathbf{S_b(R)}$, that are the successor nodes of R; more precisely,

$$S_b(R) = \Gamma(R) = \{u \mid u = (r_2, \ldots, r_D, s_i), s_i \in \{1, 2, \ldots, \Delta\}\}.$$

The second group is the other $\Delta - 1$ predecessors of the subroots, called *adopters*, denoted by $\mathbf{A_d(R)}$,

$$A_d(R) = \{u \mid u = (d, r_2, \ldots, r_D), d \in \{1, 2, \ldots, \Delta\} \text{ and } d \ne r_1\}.$$

Note that $R \cup A_d(R)$ are the whole set of the Δ predecessors of the subroots.

Let p be the minimum nonnegative integer such that the last $D - p$ letters in $R = (r_1, r_2, \ldots, r_D)$ are an $a - b$ subsequence for some letters a and b which belong to $\{1, 2, \ldots, \Delta\}$. Let $R(0) = (r_{p+1}, r_{p+2}, \ldots, r_D)$ represent this subsequence and note that $D - p \ge 2$. Our process for obtaining the $\Delta - 1$ PNDSTs in $TB(D, R)$ is based on a recursive algorithm involving $p + 1$ stages.

Let $D(i)$, $R(i)$, and $B(\Delta, D(i))$ denote the diameter, the root, and the deBruijn digraph in stage i, $0 \le i \le p$. Note that $D(i) = D - p + i$ and $R(i) =$

$(r_{p-i+1}, r_{p-i+2}, \ldots, r_D)$. Initially, in the 0th stage of our algorithm, let $D(0) = D - p$, $R(0) = (r_{p+1}, r_{p+2}, \ldots, r_D)$; we find the $\Delta - 1$ PNDSTs in $TB(D(0), R(0))$ in $B(\Delta, D(0))$. Since $R(0)$ is an $a - b$ sequence, Theorem 2.2 establishes that the $\Delta - 1$ PNDSTs in $TB(D(0), R(0))$ exist, and these trees have depths $D - p + 1$. In the following stages, $1 \leq i \leq p$, we recursively use the following algorithm, whose ith stage involves finding the $\Delta - 1$ PNDSTs, $TB(D(i), R(i)) = \{t^j(i), j = 1, 2, \ldots, \Delta - 1\}$, in digraph $B(\Delta, D(i))$, where $t^j(i)$ denotes a tree in $TB(D(i), R(i))$. Note that when $i = p$, we obtain the desired set $TB(D(p), R(p))$, where $D(p) = D$, $R(p) = R$.

Assuming that we have obtained $TB(D(i-1), R(i-1))$, which are PNDSTs for $B(\Delta, D(i-1))$, we will now present the ith stage of the algorithm, which consists of three steps. Also, we present a number of simple observations within the description of the algorithm; most of the proofs for the observations are elementary and are left out.

ALGORITHM. (For the ith stage, $1 \leq i \leq p$.)

Step 1. Note that the root $R(i) = (r_{p-i+1}, r_{p-i+2}, \ldots, r_D) \in B(\Delta, D(i))$ corresponds to the arc directed toward $R(i-1)$ in $B(\Delta, D(i-1))$. We add an auxiliary node $x(i-1) = (r_{p-i+1}, r_{p-i+2}, \ldots, r_{D-1})$ with the arc $R(i) = (x(i-1), R(i-1))$ to each of the $\Delta - 1$ PNDSTs in $TB(D(i-1), R(i-1))$. We denote these augmented trees by $TB^*(D(i-1), R(i-1)) = \{t^{*j}(i-1), j = 1, 2 \ldots, \Delta - 1\}$, and we say that the arc $R(i)$ is at the 0th level of trees in $TB^*(D(i-1), R(i-1))$. We find the line digraph $t_L^j(i)$ of each tree in $TB^*(D(i-1), R(i-1))$, denote the resulting set by $TB_L(D(i), R(i)) = \{t_L^j(i), j = 1, 2 \ldots, \Delta - 1\}$, and refer to the set of the trees as the *line trees*.

We make the following observations: 1. Let $t_L^j(i) \in TB_L(D(i), R(i))$ be the line tree of the tree $t^{*j}(i-1) \in TB^*(D(i-1), R(i-1))$; then we have $V(t_L^j(i)) = E(t^{*j}(i-1))$, where $E(t^{*j}(i-1))$ is the arc set of tree $t^{*j}(i-1)$ which contains all of the arcs in $t^j(i-1)$ plus the arc $R(i)$. 2. Each digraph $t_L^j(i)$ in $TB_L(D(i), R(i))$ is a subtree of $B(\Delta, D(i))$ rooted at $R(i)$. 3. Since the trees in $TB(D(i-1), R(i-1))$ are pseudo node disjoint and therefore also arc disjoint, the line trees in $TB_L(D(i), R(i))$ are strictly node disjoint except at $R(i)$, and thus each node of $B(\Delta, D(i))$ except $R(i)$ is in at most one tree in $TB_L(D(i), R(i))$. 4. The depth of the trees $TB_L(D(i), R(i))$ are the same as those of the trees in $TB(D(i-1), R(i-1))$, and an arc at level m in a tree in $TB^*(D(i-1), R(i-1))$ becomes a node at the same level in a tree in $TB_L(D(i), R(i))$.

Step 2. We extend the line trees $t_L^j(i) \in TB_L(D(i), R(i))$ as follows. We take each node, except $R(i)$, in each $t_L^j(i)$ and add as many as possible outgoing arcs which are available at that node in $B(\Delta, D(i))$ and whose other end nodes are not already in $t_L^j(i)$, to this node. The resulting digraph is denoted by $t_{LE}^j(i)$. We do this for all line trees $t_L^j(i) \in TB_L(D(i), R(i))$, and we denote the set of $t_{LE}^j(i)$ for all j by $TB_{LE}(D(i), R(i))$. We call this set of digraphs the *extended line trees*, and we will show later that the extended line trees are in fact trees within the observation 1 below and its proof.

We now make the following observations; the proofs for observations 1 and 5 are given at the end of this algorithm and the proofs of the other observations are simple and thus are left out: 1. Each extended line tree $t_{LE}^j(i) \in TB_{LE}(D(i), R(i))$ is a subtree of $B(\Delta, D(i))$ rooted at $R(i)$. 2. The extended line trees in $TB_{LE}(D(i), R(i))$ are pseudo node disjoint because the line trees in $TB_L(D(i), R(i))$ are strictly node disjoint and we only do breadth-first extension to the nodes in $TB_L(D(i), R(i))$; thus no nodes can be internal nodes in more than one tree. 3. From observation 1 in Step

1, these nodes added to a line tree $t_L^j(i)$ correspond to the arcs which did not belong to the tree $t^{*j}(i-1)$ in $TB^*(D(i-1), R(i-1))$, and they are leaf nodes in the extended line tree $t_{LE}^j(i)$ in $TB_{LE}(D(i), R(i))$. 4. The depths of the extended line trees increase by one from those of the trees in $TB(D(i-1), R(i-1))$. 5. The nodes of $B(\Delta, D(i))$ which do not already belong to an extended line tree $t_{LE}^j(i) \in TB_{LE}(D(i), R(i))$, denoted by $V_{\text{mis}}(t_{LE}^j(i))$, are given by

$$V_{\text{mis}}(t_{LE}^j(i)) = \{u = (r_{p-i+2}, \ldots, r_D, x) \mid x \in \{1, 2, \ldots, \Delta\}, u \text{ is not a subroot of } t_{LE}^j(i)\}.$$

Note that the set $V_{\text{mis}}(t_{LE}^j(i))$ corresponds to the outgoing arcs from $R(i-1)$ in $B(\Delta, D(i-1))$.

Step 3. Consider the set of adopters

$$A_d(R(i)) = \{a_d^j(i) = (dj, r_{p-i+2}, \ldots, r_D) \mid d_j \in \{1, 2, \ldots, \Delta\} \text{ and } d_j \neq r_{p-i+1}\}.$$

Note that the set of adopters corresponds to the incoming arcs into $R(i-1)$ in $B(\Delta, D(i-1))$, and such arcs do not belong to any tree in $TB(D(i-1), R(i-1))$. From observation 3 in Step 2, the adopters are leaves in every tree of $TB_{LE}(D(i), R(i))$. Furthermore, because $R(i-1)$ is not a corner node and thus has no loop at it, $A_d(R(i)) \cap V_{\text{mis}}(t_{LE}^j(i)) = \emptyset \ \forall j$. Also note that the $\Delta - 1$ adopters are the other predecessors of $V_{\text{mis}}(t_{LE}^j(i))$, we can easily establish a 1–1 mapping between nodes in $A_d(R(i))$ and the extended line trees in $TB_{LE}(D(i), R(i))$ by arbitrarily selecting one adopter $a_d^j(i) \in A_d(R(i))$ to map to one tree $t_{LE}^j(i) \in TB_{LE}(D(i), R(i)) \forall j$ and add the missing nodes $V_{\text{mis}}(t_{LE}^j(i))$ to $t_{LE}^j(i)$ by adding the arcs from $a_d^j(i)$ to each missing node of $V_{\text{mis}}(t_{LE}^j(i))$, thus making $t_{LE}^j(i)$ a spanning tree, denoted by $t^j(i)$. The set of these new trees $t^j(i)$ is denoted by $TB(D(i), R(i))$. From observation 2 in Step 2, it is clear that the trees in $TB(D(i), R(i))$ are PNDSTs. Obviously, if adopter $a_d^j(i)$ at the last level of $t_{LE}^j(i)$ is selected for $t_{LE}^j(i)$, then after adding the missing nodes $V_{\text{mis}}(t_{LE}^j(i))$ to $a_d^j(i)$ in $t_{LE}^j(i)$, the depth of $t^j(i)$ will increase by one from that of $t_{LE}^j(i)$. Otherwise, the depth of $t^j(i)$ will remain the same as that of $t_{LE}^j(i)$.

Proof of observations 1 *and* 5 *of Step* 2. To prove observation 1 in Step 2, we must show that the resulting graph $t_{LE}^j(i) \in TB_{LE}(D(i), R(i))$ is a rooted tree, in particular, we are going to show that there is no node, say $w \in B(\Delta, D(i))$, which is not in $t_L^j(i)$ that can have two or more distinct predecessors in $t_L^j(i)$. Suppose otherwise; then there must be nodes $u \in t_L^j(i)$ and $v \in t_L^j(i)$ and a node $w \notin t_L^j(i)$ such that arcs (u, w) and $(v, w) \in B(\Delta, D(i))$. Note that the nodes u, v, and w correspond to arcs, say e_u, e_v, and e_w in $B(\Delta, D(i-1))$, and that both arcs e_u and e_v are directed to the tail node of arc e_w in $B(\Delta, D(i-1))$. On the other hand, since nodes u and $v \in t_L^j(i)$, from observation 1 of Step 1, we have that both arcs e_u and e_v belong to $t^j(i-1)$. This is impossible because $t^j(i-1)$ is a tree and thus each node has only one incoming arc in it.

We will now prove observation 5 of Step 2. Note that each node u of $B(\Delta, D(i))$ corresponds to an arc $e_u = (u', u'')$ of $B(\Delta, D(i-1))$. We consider two cases. *Case* 1: node $u' \neq R(i-1)$. Since $u' \in B(\Delta, D(i-1))$ belongs to every tree in $TB(D(i-1), R(i-1))$, u' has $\Delta - 1$ incoming arcs in $TB(D(i-1), R(i-1))$, one arc belonging to each tree in the set. Note that these $\Delta - 1$ arcs are adjacent to arc e_u through node u' in $B(\Delta, D(i-1))$. Therefore, these $\Delta - 1$ arcs become $\Delta - 1$ nodes, one node in each tree in $TB_L(D(i), R(i))$ after Step 1, and thus node u belongs to all of the $\Delta - 1$ trees

of $TB_{LE}(D(i), R(i))$ definitively after Step 2 in this case. *Case* 2: if $u' = R(i-1)$, those incoming arcs to $u' = R(i-1)$ correspond to the set of nodes $R(i) \cup A_d(R(i))$, and these arcs do not belong to the trees in $TB(D(i-1), R(i-1))$. In this case, node u must belong to the set $S_b(R(i))$. For any $t^j_{LE}(i) \in TB_{LE}(D(i), R(i))$, note that $t^j_{LE}(i)$ has already had one (or possibly two) member(s) of $S_b(R(i))$ in it as its subroot(s). From observation 3 of Step 2, the nodes in $A_d(R(i))$ are leaf nodes without children in $TB_{LE}(D(i), R(i))$; thus all the other members of $S_b(R(i))$ have to be absent from $t^j_{LE}(i) \in TB_{LE}(D(i), R(i))$. This proves that $V_{\text{mis}}(t^j_{LE}(i))$ is as claimed. □

A trivial bound of $2D-1$ on the depths of the trees in $TB(D, R)$ may be established as follows. From the above algorithm, observe that the depths increase by one in Step 2 and by at most one in Step 3. Since initially the depths in $TB(D(0), R(0))$ are $D-p+1$, after p stages, the depths will increase to at most $D-p+1+2p = D+p+1 \le 2D-1$ since $p \le D-2$. However, we will prove a much stronger result in the following theorem.

THEOREM 3.1. *There are* $\Delta-1$ *PNDSTs rooted at any node in* $B(\Delta, D)$ *of depths not exceeding* $\lceil \frac{3D}{2} \rceil$.

Proof. We prove this theorem by induction on the stage number, i, $0 \le i \le p$. Note the that the diameter of $B(\Delta, D(0))$ is $D(0) = D-p$, the depth of the trees in $TB(D(0), R(0))$ is $D-p+1$ by Theorem 2.2, and since $D-p \ge 2$, $D-p+1 \le \lceil \frac{3}{2}(D-p) \rceil$. Thus the theorem is correct when $i = 0$.

Assume that Theorem 3.1 is true for $TB(D(i-1), R(i-1))$. The proof of observations 1 and 5 of Step 2 of the algorithm implies that we will be able to obtain the trees in $TB(D(i), R(i))$ from $TB(D(i-1), R(i-1))$; this would in turn imply the correctness of the algorithm. We will now prove the bound on the depth of the trees in $TB(D, R)$.

If in the ith stage, an adopter $a^j_d(i) = (dj, r_{p-i+2}, \ldots, r_D)$, $dj \ne r_{p-i+1}$, at the last level of a tree $t^j_{LE}(i) \in TB_{LE}(D(i), R(i))$ is chosen, then the depth of $t^j(i) \in TB(D(i), R(i))$ will increase by two from the depth of $t^j(i-1) \in TB(D(i-1), R(i-1))$ in stage i. In this case, note that the nodes in the last level of $t^j(i)$ are the nodes $u \in V_{\text{mis}}(t^j_{LE}(i))$, that is, $u = (r_{p-i+2}, \ldots, r_D, s_h)$ for some s_h, and u is not a subroot of $t^j_{LE}(i)$. Then after Step 2 of the next stage, stage $i+1$, the nodes at the last level of tree $t^j_{LE}(i+1) \in TB_{LE}(D(i+1), R(i+1))$ will have the form

$$u' = (r_{p-i+2}, r_{p-i+3}, \ldots, r_D, s_h, x), \quad x \in \{1, 2, \ldots, \Delta\}. \tag{4}$$

We claim that the nodes at the last level of $t^j_{LE}(i+1)$ cannot belong to the adopter set $A_d(R(i+1))$. This would mean that the depth of $t^j_{LE}(i+1)$ will not increase by the action of Step 3 of stage $i+1$, which in turn implies that the depth of $t^j(i+1)$ will increase by at most three in two contiguous stages from that of $t^j(i-1)$. Therefore, after $p \le D-2$ stages, the depths will increase by at most $\lceil \frac{3p}{2} \rceil$. Since the depths of the initial tree rooted at an $a-b$ node are $D-p+1$, the depths of the trees in $TB(D, R)$ are less than or equal to $D-p+1+\lceil \frac{3p}{2} \rceil = D+\lceil \frac{p}{2} \rceil + 1 \le D+\lceil \frac{D-2}{2} \rceil + 1 \le \lceil \frac{3D}{2} \rceil$.

To prove this claim, assume $u' \in A_d(R(i+1))$. By the definition of the adopter set,

$$u' = (d_j, r_{p-i+1}, \ldots, r_D), \quad d_j \ne r_{p-i}. \tag{5}$$

From equations (4) and (5), we have $r_{p-i+1} = r_{p-i+3}$, $r_{p-i+2} = r_{p-i+4}$, and $r_{p-i+3} = r_{p-i+5}, \ldots, r_{D-2} = r_D$. However, this would imply that the root $R(i) = (r_{p-i+1}, r_{p-i+2}, \ldots, r_D)$ is an $a-b$ node like $(abab\ldots)$. This is a contradiction since $R(i)$ is not an $a-b$ node for $i \ge 1$. □

Our next goal in this section is to show that there are Δ ADSTs in $K(\Delta, D)$ rooted at an arbitrary node $R = (r_1, r_2, \ldots, r_D)$. This set of trees will be denoted by $TK(D, R)$. Two sets of nodes around R in $K(\Delta, D)$ are of particular interest (as in the deBruijn digraph case): the subroots $\mathbf{S_b(R)}$,

$$S_b(R) = \Gamma(R) = \{u \mid u = (r_2, \ldots, r_D, s_i), s_i \in \{1, 2, \ldots, \Delta + 1\} \text{ and } s_i \neq r_D\};$$

and the adopters $\mathbf{A_d(R)}$,

$$A_d(R) = \{u \mid u = (d, r_2, \ldots, r_D), d \in \{1, 2, \ldots, \Delta + 1\}, d \neq r_1 \text{ and } d \neq r_2\},$$

where the sequences are Kautz sequences.

Let p be the minimum nonnegative integer such that the last $D-p$ letters in $R = (r_1, r_2, \ldots, r_D)$ form an $a-b$ Kautz sequence of two letters a and b in $\{1, 2, \ldots, \Delta+1\}$. Let $R(0) = (r_{p+1}, r_{p+2}, \ldots, r_D)$ represent this sequence and note that $D-p \geq 2$. Our process for obtaining the Δ ADST in $TK(D, R)$ is similar to that in the previous case.

THEOREM 3.2. *There are Δ ADSTs rooted at any node in $K(\Delta, D)$ of depths not exceeding $\lceil \frac{3D}{2} \rceil + 1$.*

Proof. We follow the same algorithm as in the previous case with the following two exceptions: 1. We begin with the set $TK(R(0), D(0))$, where $R(0)$ is an node represented by an $a - b$ Kautz sequence. By Theorem 2.3, $TK(R(0), D(0))$ consists of Δ ADSTs of depths $D(0) + 2 = D - p + 2$. 2. In this case, in Step 3 of the ith stage, $1 \leq i \leq p$,

$$A_d(R(i))$$
$$= \{a_d^j(i) = (d_j, r_{p-i+2}, \ldots, r_D) \mid d_j \in \{1, 2, \ldots, \Delta + 1\}, d_j \neq r_{p-i+1} \text{ and } d_j \neq r_{p-i+2}\}.$$

Thus we have $|A_d(R(i))| = \Delta - 1$ adopters, but we have a set of Δ extended line trees in $TK_{LE}(D(i), R(i))$. Therefore, we cannot expect to establish the 1–1 mapping between the adopters $A_d(R(i))$ and the extended line trees $TK_{LE}(D(i), R(i))$ as before. To overcome this difficulty, for $j = 1, \ldots, \Delta - 1$, we chose one adopter, say $a_d^j(i) \in A_d(R(i))$, for tree $t_{LE}^j(i) \in TK_{LE}(D(i), R(i))$ with subroot $S_j = (r_{p-i+2}, \ldots, r_D, s_j)$ to add the missing node set $V_{\text{mis}}(t_{LE}^j(i)) = \Gamma(R(i)) - \{S_j\}$ to $t_{LE}^j(i)$. This leads to the spanning trees $t^j(i) \in TK(D(i), R(i))$ for $j = 1, \ldots, \Delta - 1$.

We now consider the last extended line tree $t_{LE}^{\Delta}(i) \in TK_{LE}(D(i), R(i))$. Observe that the arc $(a_d^j(i), S_j)$ is not used for constructing $t^j(i)$ for $j = 1, \ldots, \Delta - 1$ and that $V_{\text{mis}}(t_{LE}^{\Delta}(i)) = \Gamma(R(i)) - S_{\Delta} = \{u \mid u = S_j, j = 1, \ldots, \Delta - 1\}$. To construct $t^{\Delta}(i)$, we start with $t_{LE}^{\Delta}(i)$ and then add the arcs $(a_d^j(i), S_j), j = 1, \ldots, \Delta - 1$, to $t_{LE}^{\Delta}(i)$ to obtain the spanning tree $t^{\Delta}(i)$. This produces the set of Δ ADSTs $TK(D(i), R(i)) = \{t^j(i), j = 1, \ldots, \Delta\}$.

Since the remaining parts in the proof are identical to the proof of Theorem 3.1, they will not be given. Due to difference 1 above, the bound on the depths is $\lceil \frac{3D}{2} \rceil + 1$. □

We now briefly consider the disjoint spanning trees in the undirected deBruijn and Kautz graphs. We define undirected deBruijn graphs $UB(\Delta, D)$ and Kautz graphs $UK(\Delta, D)$ as follows. We begin with the digraph $B(\Delta, D)$ (respectively, $K(\Delta, D)$). Then 1. ignore the directions of the arcs, thus replacing arcs with edges; 2. if for some nodes u and v in $B(\Delta, D)$ (respectively, in $K(\Delta, D)$), both arcs (u, v) and (v, u) belong to $B(\Delta, D)$ (respectively, to $K(\Delta, D)$), we would have both edges joining u and

v in $UB(\Delta, D)$ (respectively, in $UK(\Delta, D)$); and 3. remove the loops from $B(\Delta, D)$. We note that graphs $UB(\Delta, D)$ and $UK(\Delta, D)$ are not simple graphs and $UB(\Delta, D)$ is no longer a regular graph because the corner nodes have degree equal to $2(\Delta - 1)$ while the others have degree equal to 2Δ.

By Theorem 3.1, it is clear that there are $\Delta - 1$ PNDSTs of depth at most $\lceil \frac{3D}{2} \rceil$ in $UB(\Delta, D)$ rooted at an arbitrary node R. We will now show that there are Δ PNDSTs in $UB(\Delta, D)$. We note that there are $|V| = \Delta^D$ nodes and $|E| = \Delta^{D+1} - \Delta = \Delta(\Delta^D - 1) = \Delta(|V| - 1)$ edges in $UB(\Delta, D)$, and thus total number of edges $|E|$ in $UB(\Delta, D)$ is exactly the number of edges required in the Δ edge-disjoint spanning trees. Thus we know that there are at most Δ PNDST in $UB(\Delta, D)$. Actually, we have the following result, which is a direct consequence of a result in [1].

COROLLARY 3.3. (See [1, Proposition 5.1].) *There are Δ PNDSTs rooted at any node R in $UB(\Delta, D)$ of depths no larger than $2D$.*

Proof. We begin with the digraph $B(\Delta, D)$. For $a \in \{1, 2, \ldots, \Delta\}$, let $T(a)$ be the shortest-path spanning tree rooted at the corner node $(aa \ldots a)$. It is known that $T(1), T(2), \ldots, T(\Delta)$ are all arc disjoint and of depth D [1]. Furthermore, it can be seen that each node in $T(a)$ except the root $(aa \ldots a)$ is of degree either $\Delta + 1$ or 1. Let the undirected tree $UT(a)$ be obtained from $T(a)$ by ignoring the directions of arcs in $T(a)$. Note that the diameter of the tree $UT(a)$ is exactly $2D$. Let R be an arbitrary node in $UB(\Delta, D)$; then the set of trees $\{UT(1), UT(2), \ldots, UT(\Delta)\}$ can be considered to be a set of edge-disjoint spanning trees rooted at R of depths less than or equal to $2D$. Furthermore, since each internal node in $T(a)$ has degree $\Delta + 1$, no node can be an internal node in more than one tree; thus the above set of trees are pseudo-node-disjoint trees in $UB(\Delta, D)$. □

We now consider the case of $UK(\Delta, D)$. Note that the numbers of nodes and edges in $UK(\Delta, D)$ are $|V| = \Delta^D + \Delta^{D-1}$ and $|E| = \Delta^{D+1} + \Delta^D$, respectively, and the Δ ADSTs $TK(\Delta, R)$ have used $T = \Delta(|V| - 1) = |E| - \Delta$ edges; thus there are only Δ free edges which do not belong to the directed trees in $TK(\Delta, R)$. Actually, they are the Δ incoming arcs to the root R. The following result is a direct consequence of Theorem 3.2.

COROLLARY 3.4 (corollary to Theorem 3.2). *There are Δ edge-disjoint spanning trees rooted at any node R in $UK(\Delta, D)$ of depths not exceeding $\lceil \frac{3D}{2} \rceil + 1$.*

4. Conclusions and fault-tolerance considerations. The deBruijn and Kautz graphs and digraphs have become contenders for interconnect architectures of multiprocessor systems and computer networks. Since broadcasting is an important function in such systems, the results of this paper further enhance the viability of these graphs for such applications.

The results of this paper also have fault-tolerance implications. The fact that there are $\Delta - 1$ pseudo-node-disjoint trees rooted at a particular node R in $B(\Delta, D)$ implies that the network can tolerate up to $\Delta - 2$ node failures and still perform its broadcast function. More precisely, let $\mathbf{DN}(\mathbf{f}, \mathbf{G})$ (respectively, $\mathbf{DL}(\mathbf{f}, \mathbf{G})$) be the maximum depth of a spanning tree rooted at arbitrary node R in a graph $\mathbf{G}$ if up to $\mathbf{f}$ nodes (respectively, links) failed. This notion is similar to the previously introduced notion of f-node-diameter vulnerability [6, 8]. Our results imply that $DN(f, B(\Delta, D)) \leq \lceil \frac{3D}{2} \rceil$ if $f = \Delta - 2$ and $DN(f, UB(\Delta, D)) \leq 2D$ if $f = \Delta - 1$. The same relations apply to $DL(f, B(\Delta, D))$ and $DL(f, UB(\Delta, D))$. It is easy to see that $DL(f, K(\Delta, D)) \leq \lceil \frac{3D}{2} \rceil + 1$ if $f = \Delta - 1$, and a similar statement would also hold for $UK(\Delta, D)$. However, the situation for $DN(f, K(\Delta, D))$ is a bit more complex.

We claim that $DN(f, K(\Delta, D)) \leq \lceil \frac{3D}{2} \rceil + 1$ if $f = \Delta - 2$. To see the validity of

this claim, we refer the reader to the last stage, stage p, in our algorithm. After Step 2 of the algorithm, the trees in $TK_{LE}(D(p+1), R(p+1))$ are pseudo node disjoint. However, after Step 3, each adopter, say $a_d^j(p+1)$, becomes an internal node in both the tree $t^j(p+1)$ and the tree $t^{\Delta}(p+1)$. Thus the failure of adopter $a_d^j(p+1)$ would destroy the two spanning trees $t^j(p+1)$ and $t^{\Delta}(p+1)$. However, each additional node failure would destroy at most one more tree. Thus even if $\Delta - 2$ nodes failed, there is at least one remaining tree of depth at most $\lceil \frac{3D}{2} \rceil + 1$. The above result also remain valid for $UK(\Delta, D)$. In all of the above cases, if the number of failures $f' < f$, then we would have $f - f' + 1$ remaining rooted spanning trees with the above depths.

Finally, the bounds on the depths in this paper are not tight bounds. In particular, we believe that the bound on the depths in Theorem 3.1 can be further improved if a more suitable 1–1 mapping between the adopters $A_d(R(i))$ and the extended line trees $TB_{LE}(D(i), R(i))$ in Step 3 of each stage of our algorithm is selected.

POLYNOMIAL-TIME RECOGNITION OF 2-MONOTONIC POSITIVE BOOLEAN FUNCTIONS GIVEN BY AN ORACLE*

ENDRE BOROS†, PETER L. HAMMER†, TOSHIHIDE IBARAKI‡, AND KAZUHIKO KAWAKAMI‡

Abstract. We consider the problem of identifying an unknown Boolean function f by asking an oracle the functional values $f(a)$ for a selected set of test vectors $a \in \{0,1\}^n$. Furthermore, we assume that f is a positive (or monotone) function of n variables. It is not yet known whether or not the whole task of generating test vectors and checking if the identification is completed can be carried out in polynomial time in n and m, where $m = |\min T(f)| + |\max F(f)|$ and $\min T(f)$ (respectively, $\max F(f)$) denotes the set of minimal true (respectively, maximal false) vectors of f. To partially answer this question, we propose here two polynomial-time algorithms that, given an unknown positive function f of n variables, decide whether or not f is 2-monotonic and, if f is 2-monotonic, output both sets $\min T(f)$ and $\max F(f)$. The first algorithm uses $O(nm^2 + n^2m)$ time and $O(nm)$ queries, while the second one uses $O(n^3m)$ time and $O(n^3m)$ queries.

1. Introduction.

In this paper, we investigate the problem of identifying an unknown Boolean function f by successively constructing test vectors $a \in \{0,1\}^n$ and asking an oracle their functional values $f(a)$ (i.e., membership queries). We propose two polynomial-time algorithms for a specific class of 2-monotonic positive Boolean functions.

Recall that a Boolean function (or simply a *function*) f of n variables is a mapping $f{:}\{0,1\}^n \to \{0,1\}$. We shall write $g \leq f$ if $g(a) = 1$ implies $f(a) = 1$ for all vectors $a \in \{0,1\}^n$. If $g \leq f$ and there exists a vector a satisfying $g(a) = 0$ and $f(a) = 1$, we shall write $g < f$. A function f is called *positive* (or *monotone*) if $a \leq b$ (i.e., $a_i \leq b_i$ for $i = 1, 2, \ldots, n$) always implies $f(a) \leq f(b)$. A vector $a \in \{0,1\}^n$ is a *true* (resp. *false*) vector if $f(a) = 1$ (resp. $f(a) = 0$) holds. The set of true vectors and false vectors of f are, respectively, denoted $T(f)$ and $F(f)$. A true vector is called a *minimal* (resp. *maximal*) if there is no true vector (resp. false vector) b such that $b \leq a$ (resp. $b \geq a$) and $b \neq a$. The sets of minimal true vectors and maximal false vectors are, respectively, denoted $\min T(f)$ and $\max F(f)$. The definition of 2-monotonicity is given in section 2. We only point out here that the class of 2-monotonic positive functions properly includes the class of positive threshold functions [20, 26].

The problem of identifying Boolean functions arises in various settings of theory and practice. A first application is the testing of logic circuits, i.e., the identification of

the Boolean function realized by the circuit. This identification requires the selection of a (possibly small) set of binary vectors on which the circuit is to be tested. Another example is found in the process of forming a "concept" from partially observed data [6, 11], in which hypotheses for the functional form of a hidden Boolean function are generated. It is assumed that the hidden function belongs to a specified subclass of Boolean functions, known a priori.

Probably the most rigorous mathematical basis for our problem is provided by the recent development of computational learning theory. The problem discussed in this paper is an example of exact learning (see, e.g., [1]), in which only membership queries are allowed. Our result shows that a polynomial-time exact learning of this type is possible for the class of 2-monotonic positive Boolean functions.

If no a priori information is available about the Boolean function f, it is obvious that it cannot be identified unless the values $f(a)$ for all 2^n vectors $a \in \{0,1\}^n$ are tested. Therefore, the problem becomes interesting only when some knowledge about f is at hand. An important class in the above problem setting of concept formation and learning theory is that of positive functions.

In this paper, a positive function will be considered *identified* if both the sets of minimal true vectors, $\min T(f)$, and maximal false vectors, $\max F(f)$, are explicitly obtained. We shall call these two sets the output of the identification algorithm, where the length of output is denoted by

$$m = |\min T(f)| + |\max F(f)|. \tag{1}$$

This definition, while it may appear somewhat redundant since either of these sets can be computed from the other, is justified by the following two reasons. First of all, in general, the computation of one of these sets from the other can take exponential time in the size of these sets. Second, the knowledge of both sets, $\min T(f)$ and $\max F(f)$, is necessary to ensure that the function obtained at the end of the algorithm is indeed completely specified. It is known that the total size m of these sets can become as large as

$$\binom{n}{\lfloor \frac{n}{2} \rfloor} + \binom{n}{\lfloor \frac{n}{2} + 1 \rfloor},$$

and therefore polynomiality in n only cannot be expected. However, the complexity of an identification algorithm in terms of both the input and the output sizes is not known.

The papers by Angluin [1] and Gainanov [14] contain an algorithm that identifies $\min T(f)$ of a positive function f of n variables by issuing $O(n|\min T(f)|)$ membership and equivalence queries. (Equivalence queries test whether the target function f is equivalent to the hypothesis f'.) This means that the identification can be done in polynomial time if both membership and equivalence queries are allowed. An explanation for this is the fact that if f and f' are not equivalent, the equivalence oracle returns a binary vector a at which f and f' disagree and which is then sent to the membership oracle. However, when only membership queries are allowed, the time to generate such query vectors must be taken into account, and, in spite of intensive studies on this topic (see, e.g., [4, 14, 15, 16, 24]), it is not yet known whether or not this can be accomplished in polynomial time. Note, however, that upon measuring the complexity only by n and $m_1 = |\min T(f)|$ (instead of m), Angluin obtained a negative result (see [1]), showing that there exists a positive Boolean function f which cannot be identified by a polynomial (in n and m_1) number of membership queries

even if unlimited computation time is allowed. The underlying reason for this is that, for any vector $a \in \max F(f)$, there exists another positive Boolean function f' for which $\min T(f') = \min T(f) \cup \{a\}$. Hence the information necessary to distinguish between f and f' assumes a membership query for all such vectors a. This implies that the identification of f requires at least as many as $m_0 = |\max F(f)|$ membership queries, and this quantity m_0 is known to be exponential in n and m_1 for many positive Boolean functions. This is another reason to introduce in this paper the parameter $m = m_0 + m_1$ for evaluating the complexity of an identification algorithm.

It is being realized that the problem of identifying a general positive function by membership queries is equivalent to many other problems in the sense that the former is solvable in polynomial time in n and m if and only if the latter problems are solvable in polynomial time. Among the many problems of this type (see, e.g., [4, 12]), we mention the dualization of positive Boolean functions, the recognition of self-dual positive functions, the recognition of saturated simple hypergraphs, and so forth. Although the exact complexity of these problems is still open, the recent result by Fredman and Khachiyan [13] shows that these problems can be solved in $O(m^{o(\log m)})$ time, suggesting that it is quite unlikely that they are NP-hard.

The main results in this paper are two polynomial-time algorithms (more precisely, incrementally polynomial-time algorithms [17, 18]), which, for a given unknown positive function f of n variables, decide whether or not f is 2-monotonic or not and, if it is 2-monotonic, output both $\min T(f)$ and $\max F(f)$. The first algorithm uses $O(nm^2 + n^2m)$ time and $O(nm)$ queries, while the second one uses $O(n^3m)$ time and $O(n^3m)$ queries. (Throughout this paper, the stated computation time does not include the time spent on the oracle to answer the given membership queries.) The proposed algorithms make use of the results of Gainanov [14] and Valiant [25] to generate a vector in $\min T(f) \cup \max F(f)$ and of a new characterization of 2-monotonic positive functions in terms of their sets of minimal true and maximal false vectors. They are also related to the results in [3, 5, 10, 21, 22] showing that the dualization of 2-monotonic positive functions can be done in $O(mn)$ time. We also note that there are some other classes of positive functions for which polynomial-time identification algorithms are known [19], which are based on the concept of maximum latency of function classes.

In concluding this section, we comment that there is a wide spectrum of research about the exact learning of Boolean functions. Most of this research, however, is based on the model of using both membership and equivalence queries. In this model, in addition to the class of positive functions, there are a number of classes such as read-once functions (see, e.g., [2, 9]), which are learnable in polynomial time in n and the length of the formula expressing the function. Recently, Bshouty [8] showed that any Boolean function is polynomially learnable either as DNF (disjunctive normal form) or CNF (conjunctive normal form).

2. Definitions and basic properties. Let f be a positive function of n variables. f is completely characterized by one of the sets $\min T(f)$ and $\max F(f)$ since f is defined, for example, by

$$f(a) = \begin{cases} 1 & \text{if } a \geq b \text{ for some } b \in \min T(f), \\ 0 & \text{otherwise.} \end{cases}$$

It is known in Boolean algebra that another characterization of a positive function f is that f has a disjunctive form in which all literals appear uncomplemented. In this case, each prime implicant of f corresponds one to one to a minimal true vector of f.

The *dual* f^d of a function f is defined by

$$f^d(x) = \bar{f}(\bar{x}),$$

where $\bar{f}$ (respectively, $\bar{x}$) denotes the complement of f (respectively, x). The Boolean expression of f^d is obtained from that of f by exchanging $\wedge$ (and) and $\vee$ (or) as well as the constants 1 and 0.

An assignment A of binary values 0 or 1 to k variables $x_{i_1}, x_{i_2}, \ldots, x_{i_k}$ out of all n variables is called a *k-assignment* and is denoted by

$$A = \{x_{i_1} \leftarrow a_1, x_{i_2} \leftarrow a_2, \ldots, x_{i_k} \leftarrow a_k\}, \tag{2}$$

where each of the values $a_1, \ldots, a_k$ is either 1 or 0. Let the complement of A, denoted by $\bar{A}$, represent the assignment obtained from A by complementing all the 1's and 0's of A. When a function $f(x)$ of n variables and a k-assignment A are given,

$$f_A(x) = f(x; x_{i_1} \leftarrow a_1, x_{i_2} \leftarrow a_2, \ldots, x_{i_k} \leftarrow a_k)$$

denotes the function of $(n-k)$ variables obtained by fixing the variables x_{i_1}, x_{i_2}, ..., x_{i_k} as specified by A.

Let f be a Boolean function of n variables. If either $f_A \leq f_{\bar{A}}$ or $f_A \geq f_{\bar{A}}$ holds for every k-assignment A, then f is said to be *k-comparable*. If a function f is k-comparable for every k such that $1 \leq k \leq m$, then f is said to be *m-monotonic*. (For more detailed discussion on these topics, see, e.g., [20, 26].) In particular, f is 1-monotonic if $f_{(x_i \leftarrow 1)} \geq f_{(x_i \leftarrow 0)}$ or $f_{(x_i \leftarrow 1)} \leq f_{(x_i \leftarrow 0)}$ holds for any $i \in \{1, 2, \ldots, n\}$. It can be shown that if f is positive, then it is 1-monotonic and $f_{(x_i \leftarrow 1)} \geq f_{(x_i \leftarrow 0)}$ holds for every i.

Now consider a 2-assignment $A = \{x_i \leftarrow 1, x_j \leftarrow 0\}$. The relation $f_A \geq f_{\bar{A}}$ (respectively, $f_A > f_{\bar{A}}$) will be denoted by $x_i \succeq_f x_j$ (respectively, $x_i \succ_f x_j$). Two variables x_i and x_j are said to be *comparable* if either $x_i \succeq_f x_j$ or $x_i \preceq_f x_j$ holds. When $x_i \succeq_f x_j$ and $x_i \preceq_f x_j$ hold simultaneously, we shall write $x_i \approx_f x_j$. If f is 2-monotonic, the binary relation $\succeq_f$ over the set of variables is known to be a total preorder. A 2-monotonic positive function f of n variables is called *regular* if

$$x_1 \succeq_f x_2 \succeq_f x_3 \succeq_f \cdots \succeq_f x_n. \tag{3}$$

Any 2-monotonic positive function becomes regular by permuting the variables.

As an example, consider a function $f = x_2 \vee x_1 x_3$ of three variables. It can be easily checked that $f(x; x_i \leftarrow 1) \geq f(x; x_i \leftarrow 0)$ for $i = 1, 2, 3$, and hence f is 1-monotonic and positive. The 2-monotonicity of f can be checked in the same way, and $x_2 \succ_f x_1 \approx_f x_3$ holds. Although f is not regular, after the relabeling $x'_1 = x_2$, $x'_2 = x_1$, and $x'_3 = x_3$, it becomes regular.

The property of 2-monotonicity was originally introduced in conjunction with threshold functions (e.g., [20, 26]). A positive function f is called *threshold* if there exist $n+1$ nonnegative real numbers $c_1, c_2, \ldots, c_n \geq 0$ and t such that:

$$f = \begin{cases} 1 & \text{if } \sum_{i=1}^n c_i x_i \geq t, \\ 0 & \text{if } \sum_{i=1}^n c_i x_i < t. \end{cases}$$

Since $c_i > c_j$ implies $x_i \succeq_f x_j$ and $c_i = c_j$ implies $x_i \approx_f x_j$, a threshold function is always 2-monotonic. The converse, however, is not true.

3. Outline of the algorithms. We shall present an outline of our algorithms which, for a given unknown positive function f, decide whether or not f is 2-monotonic and, if the function f is 2-monotonic, output $\min T(f)$ and $\max F(f)$. Both of the presented algorithms will be based on an oracle to obtain the values $f(a)$ for a selected set of vectors a, i.e., on membership queries. The details of the steps of the algorithms and the analysis of their time complexity will be given in the subsequent sections.

In the proposed algorithms, we shall maintain two subsets of vectors MT and MF such that

$$MT \subseteq \min T(f) \quad \text{and} \quad MF \subseteq \max F(f). \tag{4}$$

Let us define the sets of vectors T and F by

$$\begin{aligned} T &= \{a \in \{0,1\}^n | a \geq a' \text{ for some } a' \in MT\}, \\ F &= \{b \in \{0,1\}^n | b \leq b' \text{ for some } b' \in MF\}, \end{aligned} \tag{5}$$

and let us call a vector a *unknown* if

$$a \notin T \cup F$$

since $f(a)$ for such a vector a cannot be deduced from the knowledge of MT and MF. Given a binary vector $a = (a_1, a_2, \ldots, a_n)$, let $\bar{a} = (\bar{a}_1, \bar{a}_2, \ldots, \bar{a}_n)$ denote its *complement*. Let us further define two positive functions g_1 and g_0 by

$$\begin{aligned} g_1(a) &= \begin{cases} 1 & \text{if } a \in T, \\ 0 & \text{otherwise,} \end{cases} \\ g_0(a) &= \begin{cases} 1 & \text{if } \bar{a} \in F, \\ 0 & \text{otherwise.} \end{cases} \end{aligned} \tag{6}$$

In each iteration of the algorithms, given the current sets MT and MF, we test whether the two functions g_0 and g_1 satisfy the following two conditions:

(a) Both g_1 and g_0 are 2-monotonic.

(b) The orders of variables for g_1 and g_0 coincide, i.e., $x_i \preceq_{g_1} x_j$ if and only if $x_i \preceq_{g_0} x_j$ for any $i \neq j$.

If these conditions do not hold, we shall distinguish two cases:

(i) We can conclude that f is not 2-monotonic and the algorithms stop.

(ii) We can find an unknown vector a with respect to the current MT and MF. In this case, with the aid of membership queries, another vector c is generated from a for which we have

$$c \in (\min T(f) \cup \max F(f)) \setminus (MT \cup MF). \tag{7}$$

Then MT or MF is augmented with c, and the algorithms proceed to the next iteration.

On the other hand, if g_1 and g_0 satisfy both conditions (a) and (b) above, we test whether the current MT and MF satisfy

$$MT = \min T(f) \text{ and } MF = \max F(f). \tag{8}$$

The following outcomes are possible:

(iii) Condition (8) holds. Then $g_1 = f$ and f is identified (also $g_0 = g_1^d = f^d$ holds). Our algorithms stop here.

(iv) Condition (8) does not hold. Then an unknown vector a is found and the algorithms proceed as in (ii) above.

The above procedure is repeated until it stops in (i) or (iii).

The key tasks in an efficient implementation of these steps are the following:

Task 1: initializing the sets MT and MF.

Task 2: checking whether both conditions (a) and (b) hold for the current g_1 and g_0 of (6) and, if not, either concluding that f is not 2-monotonic or providing an unknown vector a.

Task 3: checking whether or not the termination condition (8) holds and, if not, providing an unknown vector a.

Task 4: given an unknown vector a, finding a vector c which satisfies (7).

These points will be separately discussed in the subsequent sections. As we shall see, Task 1 is quite easy, and a polynomial-time solution for Task 4 is already well known. The contribution of this paper consists mainly in providing polynomial-time algorithms for Tasks 2 and 3 above.

4. Construction of a minimal true vector or a maximal false vector. Given an unknown vector a of a positive function f, Gainanov [14] and Valiant [25] present an algorithm to enlarge the set $MT \cup MF$ by finding a vector c satisfying (7). It proceeds as follows.

Assume that an unknown vector $a^0 = a$ satisfies $f(a) = 1$. For $i = 1, 2, \ldots, n$, define

$$a^i = \begin{cases} a^{i-1} & \text{if } a_i = 0, \text{ or if } a_i = 1 \text{ and } f(a^{i-1} - e^i) = 0, \\ a^{i-1} - e^i & \text{if } a_i = 1 \text{ and } f(a^{i-1} - e^i) = 1, \end{cases}$$

where e^i denotes the ith unit vector. Then $c = a^n$ satisfies $c \in \min T(f)$ and $c \leq a$, implying that c satisfies (7).

The case of $f(a) = 0$ is treated symmetrically, and the algorithm produces a vector $c \in \max F(f)$. In either case, at most $n + 1$ vectors are tested by membership queries and the total time required for this task is $O(n)$.

As an example, consider a positive function f of five variables and assume that $MT = \emptyset$ and $\min T(f) = \{10100, 01010\}$. Let us test the vector $a = (11110)$. Clearly, $f(a) = 1$ (since $a > 10100$), and the following sequence is generated:

$$\begin{array}{ll} a^0 = (11110), & f(a^0) = 1, \\ a^1 = (01110) & \text{since } f(a^0 - e^1) = f(01110) = 1, \\ a^2 = (01110) & \text{since } f(a^1 - e^2) = f(00110) = 0, \\ a^3 = (01010) & \text{since } f(a^2 - e^3) = f(01010) = 1, \\ a^4 = (01010) & \text{since } f(a^3 - e^4) = f(01000) = 0, \\ a^5 = (01010) & \text{since } a_5 = 0. \end{array}$$

Consequently, $c = a^5 = (01010)$ is a minimal true vector.

5. An algorithm for identifying 2-monotonic functions. In this section, we present an algorithm IDENTIFY-1 for identifying a 2-monotonic positive function in $O(nm^2 + n^2m)$ time by asking $O(nm)$ queries. Another procedure that requires $O(n^3m)$ time and $O(n^3m)$ queries will be presented in the next section.

5.1. Initialization. If $MT = \emptyset$ and $MF = \emptyset$, any a is an unknown vector. It is convenient to start with $a^1 = (111\ldots1)$. If $f(a^1) = 0$, then the positivity of f implies that f is identically 0 (i.e., f is identified). Let us assume therefore that $f(a^1) = 1$,

and let c^1 be the vector (satisfying (7)) obtained by the algorithm described in section 4. A similar procedure is then applied to $a^0 = (000\ldots0)$. If $f(a^0) = 1$, then f is identically 1 (i.e., f is identified); otherwise, a vector c^0 satisfying (7) is produced. Our algorithms initialize MT and MF as

$$MT := \{c^1\} \quad \text{and} \quad MF := \{c^0\}.$$

5.2. Checking the 2-monotonicity of g_i. Since g_1 and g_0 of (6) can be treated in a similar manner, in this subsection, we shall refer to either of g_1 and g_0 as g and to either of the corresponding sets MT and

$$CMF = \{\bar{a} | a \in MF\}$$

as M. In other words, $\min T(g) = M$ holds. The algorithm described below decides if g is 2-monotonic or not, and if g is 2-monotonic, it also computes the $\preceq_g$ order of the variables. The cases in which g is not 2-monotonic or the orders $\preceq_{g_1}$ and $\preceq_{g_0}$ do not coincide will be discussed in the next two subsections.

Let us note that the existence of a pair of vectors a and b for which

$$a \in M, \qquad g(b) = 0, \tag{9}$$

and

$$\begin{array}{llll} a_i = 1, & a_j = 0, & b_i = 0, & b_j = 1, \\ a_k = b_k & \text{for } k \neq i, j & & \end{array} \tag{10}$$

implies $g_A \not\leq g_{\bar{A}}$ for the assignment $A = \{x_i \leftarrow 1, x_j \leftarrow 0\}$, that is, $x_i \not\preceq x_j$. Conversely, if $x_i \not\preceq x_j$, then there exist vectors a' and b' such that $g(a') = 1$ (possibly $a' \notin M$), $g(b') = 0$, and (10) holds for a' and b'. By the definition of g, there exists a vector $a \leq a'$ for which $a \in M$. For this vector a, $g(a) = 1$ holds and hence $a \not\leq b'$, which implies that $a_i = 1$ and $a_j = 0$. Let us then define a vector b by

$$b_k = \begin{cases} 0 & \text{if } k = i, \\ 1 & \text{if } k = j, \\ a_k & \text{otherwise.} \end{cases}$$

Since $b \leq b'$ follows from $a \leq a'$, the vectors a and b satisfy conditions (9) and (10). Therefore, the existence of a pair of vectors a and b satisfying (9) and (10) is a necessary and sufficient condition for $x_i \not\preceq x_j$. In other words, $x_i \preceq x_j$ if and only if there is no pair a and b that satisfy (9) and (10), which is then equivalent to saying that, for every vector $a \in M$ and indices $i \neq j$ for which

$$a_i = 1 \quad \text{and} \quad a_j = 0, \tag{11}$$

there exists a vector $d \in M$ satisfying

$$d_i = 0, \qquad d_j = 1, \quad \text{and} \quad d_k \leq a_k \quad \text{for } k \neq i, j. \tag{12}$$

We obtain the following.

LEMMA 5.1. *Given a positive Boolean function g with $M = \min T(g)$ and indices $i \neq j$, the following three conditions are equivalent:*

(i) $x_i \preceq_g x_j$.

(ii) *There is no pair of vectors a and b satisfying* (9) *and* (10).

(ii) *For every vector* $a \in M$ *satisfying* (11)*, there exists a vector* $d \in M$ *satisfying* (12).

Let us observe that the existence of indices $i \neq j$ for vectors $a, d \in M$ satisfying (11) and (12) is equivalent to

$$\begin{array}{ll} d_j = 1, & a_j = 0 \quad \text{hold for exactly one } j, \\ d_k \leq a_k & \text{for all } k \neq j \end{array} \tag{13}$$

since the minimality of vectors in M guarantees the existence of an index i for which $d_i < a_i$.

To test conditions (11) and (12), we shall construct for each $a \in M$ an $n \times n$ matrix $P(a)$ such that

$$P_{ij}(a) = \begin{cases} 1 & \text{if } a \text{ satisfies (11) and there is no } d \in M \text{ satisfying (12),} \\ 0 & \text{otherwise} \end{cases} \tag{14}$$

and let

$$P = \sum_{a \in M} P(a). \tag{15}$$

The next lemma follows immediatly from Lemma 5.1 and from the definition of P.

LEMMA 5.2. *For a positive function* g*, we have*

(i) $x_i \prec_g x_j$ *if and only if* $P_{ij} = 0$ *and* $P_{ji} > 0$,

(ii) $x_i \approx_g x_j$ *if and only if* $P_{ij} = 0$ *and* $P_{ji} = 0$,

(iii) x_i *and* x_j *are not comparable* (*implying that* g *is not* 2*-monotonic*) *if and only if* $P_{ij} > 0$ *and* $P_{ji} > 0$.

The 2-monotonicity of g can be tested by constructing the matrix P and applying Lemma 5.2. If g is 2-monotonic, the order $\preceq_g$ of the variables can also be obtained from P.

Let us now consider the computation of the matrices $P(a)$ and P. Initially, we start with $P \equiv 0$ corresponding to $M = \emptyset$. Let us assume in the general step that P for the current M has already been computed, and a new vector c is added to M.

Step 1. Initialize the matrix $P(c)$ by setting

$$P_{ij}(c) := \begin{cases} 1 & \text{if } c_i = 1 \text{ and } c_j = 0, \\ 0 & \text{otherwise,} \end{cases} \tag{16}$$

and let $M := M \cup \{c\}$ and $P := P + P(c)$.

Step 2. Compare c with each $e(\neq c) \in M$ to see if condition (13) holds. If c and e can be regarded as a and d in (13), respectively, then let $P_{ij}(c) := 0$ for all i and j satisfying (11) and (12). Similarly, if c and e can be regarded as d and a in (13), respectively, then let $P_{ij}(e) := 0$ for all i and j satisfying (11) and (12).

Step 3. Update the matrix P to reflect all modifications in Step 2.

The time required in Step 1 is clearly $O(n^2)$. As noted in condition (13), there is a unique index j used in modifying matrices $P_{ij}(c)$ or $P_{ij}(e)$ in Step 2, and thus Step 2 requires $O(n)$ time for each vector $e \in M$. Hence the total time for Step 2 is $O(n|M|)$. Finally, Step 3 to update P as a result of the changes of $P_{ij}(c)$ and $P_{ij}(e)$ in Step 2 can be done in $O(n|M|)$ time. Therefore, the time required to increment M by a vector c is $O(n|M| + n^2)$.

Since the sets MT and MF can be incremented by at most $|\min T(f)|$ and $|\max F(f)|$ times, respectively, the total time required for this part is $O(n(|\min T(f)|^2 + |\max F(f)|^2) + n^2(|\min T(f)| + |\max F(f)|)) = O(nm^2 + n^2 m)$.

5.3. When g is not 2-monotonic. Assuming that the g tested in the previous subsection is not 2-monotonic, we show here that one can either conclude that f is not 2-monotonic or find an unknown vector (as discussed in (i) and (ii) of section 3).

If g is not 2-monotonic, there must exist indices $i \neq j$ for which $P_{ij} > 0$ and $P_{ji} > 0$. This implies by the definition of P that there exist vectors $a, b \in M$ for which

$$a_i = 1, \qquad a_j = 0, \qquad b_i = 0, \qquad b_j = 1.$$

Let us define the vectors a' and b' by complementing the ith and jth components of a and b, respectively. We shall consider the cases $g = g_1$ and $g = g_0$ separately.

If $g = g_1$ (and hence $M = MT$), then the vectors a' and b' do not belong to T, i.e., there is no $a'' \in MT$ or $b'' \in MT$ such that $a' \geq a''$ or $b' \geq b''$ since the existence of such an $a'' \in MT$ (respectively, $b'' \in MT$) would contradict the assumption $P_{ij}(a) > 0$ (respectively, $P_{ji}(b) > 0$) (in view of condition (13) with $d = a''$ or $d = b''$).

(i) If $f(a') = f(b') = 0$, then we can conclude that f is not 2-monotonic. Indeed, $x_i \not\preceq_f x_j$ follows from $f(a) = 1$ and $f(a') = 0$, and $x_j \not\preceq_f x_i$ follows from $f(b) = 1$ and $f(b') = 0$.

(ii) If at least one of $f(a')$ and $f(b')$ is 1, say $f(a') = 1$, then $a' \notin T \cup F$ (since $a' \notin T$, as seen above, and $a' \notin F$ because $f(a') = 1$), and hence a' is an unknown vector.

On the other hand, if $g = g_0$ (and hence $M = CMF$), we consider $\bar{a}$, $\bar{b}$, $\bar{a'}$, and $\bar{b'}$, where $\bar{a}$ denotes the complement of a, etc. By definition (6) of g_0, we have the following.

(i′) If $f(\bar{a'}) = f(\bar{b'}) = 1$, then f is not 2-monotonic.

(ii′) If at least one of $f(\bar{a'})$ and $f(\bar{b'})$ is 0, say $f(\bar{a'}) = 0$, then $\bar{a'}$ is an unknown vector.

5.4. When the variable orders of g_1 and g_0 do not coincide. Assume that g_1 and g_0 of (6) are both 2-monotonic but the orders $\preceq_{g_1}$ and $\preceq_{g_0}$ of the variables do not coincide. In this case, we shall identify an unknown vector.

For simplicity, let $x_i \succ_{g_1} x_j$ but $x_i \approx_{g_0} x_j$ or $x_i \prec_{g_0} x_j$. In order to avoid confusion, let us denote $P_{ij}(a)$ for g_1 (respectively, for g_0) by $P^1_{ij}(a)$ (respectively, by $P^0_{ij}(a)$). Then as discussed in section 5.2, there is a vector $a \in MT$ with

$$P^1_{ij}(a) > 0 \quad \text{and} \quad a_i = 1, \qquad a_j = 0, \tag{17}$$

and the vector a' obtained from a by complementing the components a_i and a_j does not belong to T (since there is no $d \in MT$ satisfying (13) for this a). This a' does not belong to F either, i.e., it is an unknown vector. Indeed, if $a' \in F$, then there is a vector $a'' \geq a'$ with $a'' \in MF$. It is easy to see that $a'_i = 0, a'_j = 1, a''_i = 0, a''_j = 1$, and $a''_k \geq a'_k$ for $k \neq i, j$. Therefore, $\bar{a''}_i = 1, \bar{a''}_j = 0, \bar{a}_i = 0, \bar{a}_j = 1$, and $\bar{a''}_k \leq \bar{a}_k$ for $k \neq i, j$. Then $\bar{a''} \in CMF$ (i.e., $g_0(\bar{a''}) = 1$) and $a \in MT$ (i.e., $g_0(\bar{a}) = 0$) together imply that there is no vector d for which the pair $\bar{a''}$ and d satifies (13). Thus $P^0_{ij}(\bar{a''}) > 0$, in contradiction to the assumption that $x_i \approx_{g_0} x_j$ or $x_i \prec_{g_0} x_j$.

Similarly, if $x_i \succ_{g_0} x_j$ but $x_i \approx_{g_1} x_j$ or $x_i \prec_{g_1} x_j$, then there is a vector $a \in CMF$ satisfying (17). Defining a' similarly as above, we see that $\bar{a'}$ is an unknown vector.

5.5. Checking if $g_1 = f$. Assume now that both g_1 and g_0 are 2-monotonic, and the orders $\preceq_{g_1}$ and $\preceq_{g_0}$ coincide. We show how to test condition (8) of section 3

and how to obtain an unknown vector if (8) does not hold (i.e., steps (iii) and (iv) of section 3). For simplicity of discussion, we assume in this subsection that

$$x_1 \succeq_{g_i} x_2 \succeq_{g_i} \cdots \succeq_{g_i} x_n \quad \text{for } i = 0, 1, \tag{18}$$

i.e., g_1 and g_0 are regular. The order (18) can be obtained in $O(n \log n)$ time by applying a sorting algorithm to the preorder $\preceq_{g_i}$. If the sets T and F are defined by (5), then the definition of g_1 and g_0 shows that

$$T \cap F = \emptyset. \tag{19}$$

From assumption (18) and the definition of the $\preceq_{g_i}$ order, it follows that the set T is *left-shift stable*, i.e.,

$$\begin{aligned} &a \in T \quad \text{implies} \quad a + e^i - e^j \in T \quad \text{for any } \ i < j \\ &\qquad \text{such that } \ a_i = 0 \quad \text{and} \quad a_j = 1, \end{aligned} \tag{20}$$

where e^i is the ith unit vector, and similarly, F is *right-shift stable*, i.e.,

$$\begin{aligned} &b \in F \quad \text{implies} \quad b - e^i + e^j \in F \quad \text{for any } \ i < j \\ &\qquad \text{such that } \ b_i = 1 \quad \text{and} \quad b_j = 0. \end{aligned} \tag{21}$$

Our test algorithm for condition (8) is based on the following lemma.

LEMMA 5.3. *Assume that both of the functions g_1 and g_0 defined from MT and MF are 2-monotonic and satisfy* (18). *If MT, MF, and T, F of* (5) *further satisfy the properties that*

(i) *$a - e^j \in F$ for all $a \in MT$ and for all j with $a_j = 1$, and*

(ii) *$b + e^j \in T$ for all $b \in MF$ and for all j with $b_j = 0$,*

then there is no unknown vector, i.e., $MT = \min T(f)$ and $MF = \max F(f)$ (hence $g_1 = f$).

Proof. Taking any vector $c \notin F$, we show that $c \in T$. (This proves that there is no unknown vector $c \notin T \cup F$.) Let us choose the maximum k such that the vector c^k defined by

$$c_j^k = \begin{cases} c_j, & j = 1, 2, \ldots, k, \\ 0, & j = k+1, \ldots, n \end{cases} \tag{22}$$

satisfies

$$c^k \in F.$$

Obviously, $k < n$ and

$$c_{k+1} = 1 \tag{23}$$

by the maximality of k. Let us then choose a vector $d \in MF$ such that $d \geq c^k$. By the maximality of k, this d satisfies $d_{k+1} = 0$. Moreover,

$$d_j = c_j, \quad j = 1, 2, \ldots, k, \tag{24}$$

since if $d_i = 1$ and $c_i = 0$ for some $i \leq k$, then property (21) shows that the vector d' obtained from d by complementing d_i and d_{k+1} belongs to F, implying that the vector c^{k+1} defined by (22) satisfies $c^{k+1} \leq d' \in F$, in contradiction with the maximality of k.

Now let the vector d'' be obtained from d by flipping $d_{k+1} = 0$ to 1. Because of assumption (ii), the vector d'' belongs to F; hence there is a $d^* \in MT$ such that

$$d^* \leq d''. \tag{25}$$

If there are several vectors in MT satisfying (25), we shall choose for d^* the "leftmost" one in the sense that

$$d^* + e^i - e^h \not\leq d'' \quad \text{for all } i < h \quad \text{such that } d^*_i = 0 \quad \text{and} \quad d^*_h = 1. \tag{26}$$

This d^* satisfies $d^*_{k+1} = 1$ since otherwise $d^* \leq d$ and hence $d^* \in F$, a contradiction.

We claim that

$$d^*_j = 0, \quad j = k+2, k+3, \ldots, n, \tag{27}$$

that is, $d^* \leq c$ by (23), (24), and (25). This implies $c \in T$, proving the lemma.

To prove (27), assume that $d^*_h = 1$ for some $h > k+1$. If there is an $i \leq k+1$ such that $c_i = 1$ and $d^*_i = 0$, we have

$$d^* + e^i - e^h \leq d'' \quad \text{(by (24) and the definition of } d''),$$

in contradiction with the selection rule (26) of d^*. Therefore,

$$d^*_j = c_j, \quad j = 1, 2, \ldots, k+1,$$

and hence $c^{k+1} \in F$ is implied by assumption (i) applied to $d^* \in MT$. However, this contradicts the maximality of k, and hence (27) holds. □

In order to check conditions (i) and (ii) of this lemma, we shall need the following characterization, which follows directly from the definition of regularity.

LEMMA 5.4. *Let us consider the sets MT and MF and functions g_1 and g_0 of Lemma* 5.3. *Then we have the following:*

(i) *Condition* (i) *of Lemma* 5.3 *holds if and only if, for every $a \in MT$, there exists a $b \in MF$ such that $b \geq a - e^j$, where j denotes the maximum index with $a_j = 1$.*

(ii) *Condition* (ii) *of Lemma* 5.3 *holds if and only if, for every $b \in MF$, there exists an $a \in MT$ such that $a \leq b + e^j$, where j is the maximum index with $b_j = 0$.*

Furthermore, as pointed out in [23], the existence of $a \in MT$ (respectively, $b \in MF$) satisfying $a \leq y$ (respectively, $b \geq y$) for a given vector y can be tested in $O(n)$ time if g_1 defined by MT (respectively, g_0 defined by MF) is regular. Such a procedure will be described below for the case of MT since MF can be handled analogously.

Let us store all the vectors of MT in a binary tree $B(MT)$ of height n, in which the left edge (respectively, right edge) from a node in depth $j-1$ represents the case $x_j = 0$ (respectively, $x_j = 1$). A leaf node v of $B(MT)$ in depth n stores the vector $a \in MT$, the components of which correspond to the edges of the path from the root to v. In order to have a compact representation, edges with no descendants are removed from $B(MT)$. An example for such a binary tree is shown in Fig. 1, corresponding to the set $MT = \{011, 101, 110\}$.

Given a vector y, the algorithm starts from the root v^0 of $B(MT)$ and follows the edges down to the leaf corresponding to a vector a satisfying $a \leq y$. At each node v^{j-1} of depth $j-1$ in $B(MT)$, an edge is selected by the following rule:

1. If $j \leq n$ and $y_j = 0$, then follow the left edge from v^{j-1} to the next node v^j. If there is no left edge to follow, then stop (there is no $a \in MT$ satisfying $a \leq y$).

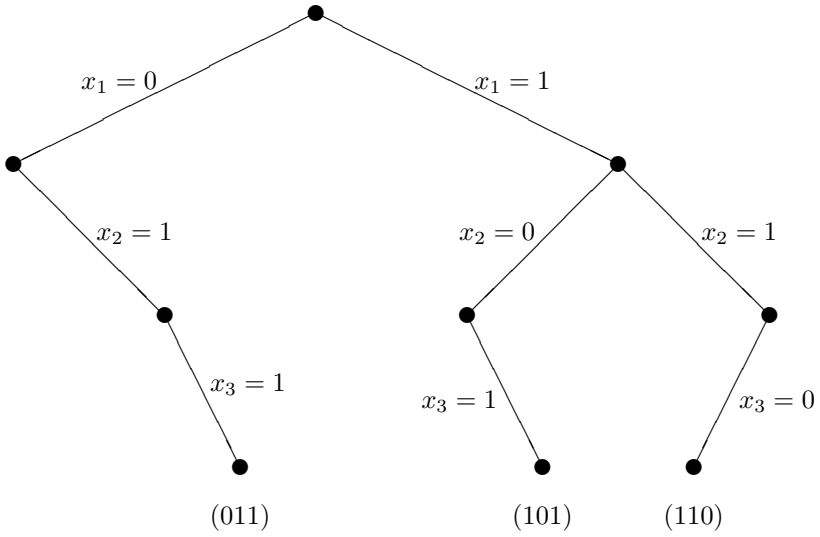

FIG. 1. *A data structure* $B(MT)$.

2. If $j \leq n$ and $y_j = 1$, then follow the right edge from v^{j-1}. If there is no right edge from v^{j-1}, then follow the left edge to the next node v^j.

3. If $j = n+1$, then stop (the vector a associated with the current leaf v^n satisfies $a \leq y$).

Based on Lemma 5.4 and on this algorithm, it is easy to see that condition (i) of Lemma 5.3 for a vector $a \in MT$ and condition (ii) for a vector $b \in MF$ can be checked in $O(n)$ time, respectively. In the algorithm of this section, the sets MT and MF are gradually augmented. Therefore, in each iteration, conditions (i) and (ii) have to be checked only for the newly added vectors $a \in MT$ and $b \in MF$. Therefore, the total time needed for this part is $O(n|MT| + n|MF|) = O(nm)$.

In this process, if condition (i) or (ii) of Lemma 5.3 fails to hold (i.e., either no $b \in MF$ satisfies $b \geq a - e^j$ or no $a \in MT$ satisfies $a \leq b + e^j$), then the vector $a - e^j$ or $b + e^j$ is an unknown vector for the current MT and MF. In other words, the computation in this subsection either concludes that $g_1 = f$ holds or provides a new unknown vector.

Remark. Although we did not need it in our algorithm, the condition $MT = \min T(f)$ can also be checked by utilizing a polynomial-time algorithm for dualizing a regular function [3, 5, 10, 21, 22]. Since

$$\max F(g_1) = \{\bar{a} \mid a \in \min T(g_1^d)\},$$

$\max F(g_1)$ can be computed by applying such a dualization algorithm to g_1. Then $MT = \min T(f)$ holds if and only if $\max F(g_1) = MF$. The time required for dualization is $O(n|MT| + n|MF|) = O(nm)$ [3, 22], and $\max F(g_1) = MF$ can be checked in $O(n|MF|)$ time if we sort both sets lexicographically in $O(n|MF|)$ time and then compare them.

5.6. Description of the algorithm. The algorithm described so far is summarized as follows.

1 PROGRAM IDENTIFY-1
2 **begin**
3 Initialize MT and MF as described in section 5.1.
{$f = 0$ or $f = 1$ may be concluded here. All vectors in $MT \cup MF$ are unscanned.}
4 **repeat**
5 **while** (g_1 or g_0 is not 2-monotonic, or the orders $\preceq_{g_1}$ and $\preceq_{g_0}$ do not coincide)
{The functions g_1 and g_0 are defined by $\min T(g_1) = MT$ and $\min T(g_0) = \{\bar{a} | a \in MF\}$, and the 2-monotonicity of g_i as well as the $\preceq_{g_i}$ orders are checked as in section 5.2.}
6 **do** {See sections 5.2, 5.3, and 5.4.}
8 **if** (f is concluded not to be 2-monotonic)
9 **then** {See (i) or (i′) of section 5.3.}
STOP.
10 **else**
Using an unknown vector a found as in (ii) or (ii′) of section 5.3 or in section 5.4, obtain a vector c satisfying (7) as described in section 4.
Set $MT := MT \cup \{c\}$ if $f(c) = 1$, and set $MF := MF \cup \{c\}$ if $f(c) = 0$.
{The added c is unscanned. Although not explicitly stated, the matrices $P(a)$ for $a \in M$ and P are updated as described in section 5.2.}
11 **endif**
12 **endwhile** {g_1 and g_0 are 2-monotonic, and satisfy (18).}
13 **repeat** {Check if $\min T(f) = MT$ and $\max F(f) = MF$ hold.}
14 **if** (there is an unscanned vector $a \in MT$ or $b \in MF$)
15 **then**
Test if conditions (i) and (ii) of Lemma 5.4 hold for the vector a as described in section 5.5 (vector a is now scanned).
16 **endif**
17 **until** (either new unknown vectors are found as explained in section 5.5,
or there are no more unscanned vectors in $MT \cup MF$)
18 **if** (unknown true vectors $a^1, a^2, \ldots, a^k$ and unknown false vectors $b^1, b^2, \ldots, b^h$ have been found in the above repeat-loop $\{k + h > 0\}$)
19 **then**
Construct minimal true vectors $c^1, c^2, \ldots, c^k$ from $a^1, a^2, \ldots, a^k$ as in section 4, and set $MT := MT \cup \{c^1, c^2, \ldots, c^k\}$. {These c^i's are unscanned.}
Construct maximal false vectors $d^1, d^2, \ldots, d^h$ from $b^1, b^2, \ldots, b^h$ as in section 4, and set $MF := MF \cup \{d^1, d^2, \ldots, d^h\}$. {These d^i's are unscanned.}
20 **endif**
21 **until** (no unknown vector remains)
22 STOP. {f is identified, i.e., $\min T(f) = MT$ and $\max F(f) = MF$.}
23 **endprogram**

Let us now analyze the time complexity. Each time the while-loop of lines 5–12 or the if-block of lines 18–20 is executed, MT or MF is augmented by new vectors. Thus these sets are updated at most $m = |\min T(f)| + |\max F(f)|$ times.

Let us note next that checking the 2-monotonicity of g_1 and g_0 and computing their orders $\preceq_{g_1}$ and $\preceq_{g_0}$ is done by maintaining the matrices $P(a)$ and P for MT and MF, as explained in section 5.2. As discussed there, the total time required for this computation is

$$O(nm^2 + n^2m).$$

Conditions (i) and (ii) of Lemma 5.4 are tested in the inner repeat-loop of lines 13–17. As explained in section 5.5, the total time needed for this step is

$$O(nm).$$

Finally, whenever an unknown vector is found, a new vector c in $MT \cup MF$ is computed by the algorithm of section 4. Since each execution requires $O(n)$ time, the total time needed for this is $O(nm)$. Summing these terms, we see that the time complexity of IDENTIFY-1 is

$$O(nm^2 + n^2m).$$

The number of queries, i.e., test vectors a for which $f(a)$ are evaluated, is $O(nm)$. This can be shown as follows. First, the values $f(a)$ are evaluated to find unknown vectors in the while-loop of lines 5–12 and in the repeat-loop of lines 13–17. From the discussion of sections 5.3, 5.4, and 5.5, it is easy to see that at most two vectors are evaluated to find one unknown vector. The number of unknown vectors obtained in the entire algorithm is m since one new vector in $MT \cup MF$ is generated from each unknown vector. In the process of obtaining a vector in $MT \cup MF$ from each unknown vector, $O(n)$ vectors are evaluated by the method of section 4. This argument proves the stated bound for the number of queries to the oracle.

THEOREM 5.5. *Given an unknown positive function f of n variables, algorithm* IDENTIFY-1 *decides whether or not f is 2-monotonic, and if f is 2-monotonic, it outputs* $\min T(f)$ *and* $\max F(f)$. *The time required is $O(nm^2+n^2m)$ and the number of queries to the oracle is $O(nm)$, where $m = |\min T(f)| + |\max F(f)|$.*

6. Another algorithm for identifying 2-monotonic functions. An algorithm that requires $O(n^3m)$ time and $O(n^3m)$ queries will be presented in this section.

6.1. Reducing time complexity of IDENTIFY-1. Since $m > n$ frequently holds, the computation of the matrices $P(a)$ and P for $M = MT$ and $M = CMF$ (see section 5.2), requiring $O(nm^2 + n^2m)$ time, represents the most time-consuming portions of IDENTIFY-1. We shall show here that in case $m > n^2$, the total complexity can be reduced at the cost of increasing the number of queries.

We first consider the computation of $P(a)$ and P. For simplicity, consider the case of $M = MT$ and $g = g_1$. Instead of conditions (9) and (10) of section 5.2, we look for the pairs of vectors a and b such that

$$\begin{gathered} a \in MT, \\ a_i = 1, \qquad a_j = 0, \\ b \text{ is obtained from } a \text{ by complementing } a_i \text{ and } a_j, \\ f(b) = 0 \end{gathered} \tag{28}$$

and compute the $n \times n$ matrices $P(a), a \in MT$, redefined here by

$$P_{ij}(a) = \begin{cases} 1 & \text{if } a \text{ and } b \text{ satisfy (28)}, \\ 0 & \text{otherwise.} \end{cases} \tag{29}$$

The matrix P is then defined by (15). Since here the condition $g(b) = 0$ in (9) is replaced by $f(b) = 0$, $P(a)$ is independent of other members of MT. Therefore, once $P(a)$ is computed at the time of generating $a \in MT$, it will not change later on. Also, it is not difficult to show that Lemma 5.2 of section 5.2 holds for the matrix P defined in this way.

The computation of the values $P_{ij}(a)$ for $a \in MT$ is carried out by generating vectors b obtained by complementing the components a_i and a_j of a for all pairs of indices $i \neq j$ for which $a_i = 1$ and $a_j = 0$ and then asking the oracle whether or not $f(b) = 0$ holds. Since there are $O(n^2)$ vectors b, the time and the number of queries required to construct $P(a)$ is $O(n^2)$ for each $a \in MT$.

If $f(b) = 1$ holds for the vector b generated as above, then there are two cases: either $b \in T$ (i.e., $g(b) = 1$) or $b \notin T$ (i.e., $g(b) = 0$). In the latter case, b is an unknown vector and can be treated as in (ii) of section 3. The task of checking if $b \in T$ requires $O(n|MT|)$ time for each b (e.g., by comparing b with every $c \in MT$ to check the inequality $b \geq c$). If we allow the use of additional queries, this task can be reduced to $O(n)$ time as follows. By applying the procedure of section 4 and using $O(n)$ queries, we can obtain a vector $c \in \min T(f)$ in $O(n)$ time from a vector b with $f(b) = 1$. Let us assume that all the vectors $a \in MT$ are stored in a binary tree $B(MT)$ of $O(nm)$ size, which was introduced after Lemma 5.4 in section 5.5. Then condition $c \in MT$ can be decided in $O(n)$ time by directly checking the existence of the path leading to the node that stores c. Obviously, $b \in T$ if and only if $c \in MT$. (Let us remark that the technique described after Lemma 5.4 in section 5.5 to check the condition $b \geq c$ directly on $B(TM)$ could not be used here since g may not be 2-monotonic.)

In conclusion, the total time and the number of queries required in this part are both $O(n^3)$.

The above argument can be easily modified to the case of $M = CMF$ and $g = g_0$. Condition (28) becomes

$$\begin{gathered} a \in MF, \\ a_i = 0, \qquad a_j = 1, \\ b \text{ is obtained from } a \text{ by complementing } a_i \text{ and } a_j, \\ f(b) = 1, \end{gathered} \tag{30}$$

and the rest of the procedure follows the above outline.

6.2. Description of the algorithm. The identification algorithm with the above modifications is very similar to IDENTIFY-1 given in section 5.6. The algorithm IDENTIFY-2 is obtained from IDENTIFY-1 by modifying only the while-loop of lines 5–12 in IDENTIFY-1.

while (g_1 or g_0 is not 2-monotonic, or orders $\preceq_{g_1}$ and $\preceq_{g_0}$ do not coincide)
do
  begin
    if (f is found not to be 2-monotonic) **then** STOP **else**
      begin
        Using an unknown vector a found as in (ii) or (ii′) of section 5.3 or in section 5.4, obtain a vector c satisfying (7) as in section 4. Set $MT := MT \cup \{c\}$ if $f(c) = 1$, and set $MF := MF \cup \{c\}$ if $f(c) = 0$.
          {The added c is unscanned.}
      end;
    while (there is an unscanned vector $a \in MT \cup MF$) **do**
      begin
        Compute $P(a)$ as described in section 6.1.
          {Vector a is now scanned.}

if (new vectors $c \notin MT \cup MF$ are generated while computing $P(a)$)
then {See section 6.1.}
If $f(c) = 1$, set $MT := MT \cup \{c\}$.
If $f(c) = 0$, set $MF := MF \cup \{c\}$.
{The added vector c is unscanned.}
end
end

The analysis of the time and the number of queries proceeds in a manner similar to that of section 5.6. The time required to construct each $P(a)$, $a \in MT \cup MF$, is $O(n^2)$ as discussed in section 6.1, and therefore the total time of these operations is

$$O(n^2|\min T(f)| + n^2|\max F(f)|) = O(n^2m).$$

The number of queries in this part is also $O(n^2m)$. The operations related to determining if the vector b is unknown or not and the generation of new vectors c require both $O(n^3)$ time and queries for every vector $a \in MT \cup MF$. Therefore, both the total time and the total number of queries of all these operations are

$$O(n^3|\min F(f)| + n^3|\max F(f)|) = O(n^3m).$$

The total time and the number of queries to check conditions (i) and (ii) of Lemma 5.4 is $O(nm)$ as described in section 5.5. The rest of the computation can be treated as in section 5.6 and will not increase the total complexity.

THEOREM 6.1. *Given an unknown positive function f of n variables, algorithm* IDENTIFY-2 *decides whether or not f is 2-monotonic, and if f is 2-monotonic, it outputs* $\min T(f)$ *and* $\max F(f)$. *The time required is $O(n^3m)$ and the number of queries to the oracle is $O(n^3m)$.*

7. Discussion. Two polynomial-time identification algorithms are presented in this paper for 2-monotonic positive functions. It would be important to reduce the time complexity and the number of queries further. It appears not unreasonable to conjecture that there is an algorithm with $O(n^2m)$ time and $O(n^2m)$ queries.

Another more ambitious goal is to develop a polynomial-time algorithm for identifying positive (not necessarily 2-monotonic) functions (or to disprove its existence). However, it is known for this case that Lemma 5.3 is no longer true [19], and hence different novel approaches are needed.

Acknowledgments. The discussion with Yves Crama of Universite de Liege, and Kazuhisa Makino of Kyoto University was very beneficial. The authors also appreciate the comments given by the anonymous reviewers, which helped improve the readability of this paper.

NAVIGATING IN UNFAMILIAR GEOMETRIC TERRAIN*

AVRIM BLUM†, PRABHAKAR RAGHAVAN‡, AND BARUCH SCHIEBER§

Abstract. Consider a robot that has to travel from a start location s to a target t in an environment with opaque obstacles that lie in its way. The robot always knows its current absolute position and that of the target. It does not, however, know the positions and extents of the obstacles in advance; rather, it finds out about obstacles as it encounters them. We compare the distance walked by the robot in going from s to t to the length of the shortest (obstacle-free) path between s and t in the scene. We describe and analyze robot strategies that minimize this ratio for different kinds of scenes. In particular, we consider the cases of rectangular obstacles aligned with the axes, rectangular obstacles in more general orientations, and wider classes of convex bodies both in two and three dimensions. For many of these situations, our algorithms are optimal up to constant factors. We study scenes with nonconvex obstacles, which are related to the study of maze traversal. We also show scenes where randomized algorithms are provably better than deterministic algorithms.

1. Motivation and results.

Practical work on robot motion planning falls into two categories: motion planning through a *known scene*, in which the robot has a complete map of the environment, and motion planning through an *unknown scene*, in which an autonomous robot must find its way through a new environment (see, for example, [9, 13, 15, 21, 24] and references therein). Virtually all previous *theoretical* work (see [32] and references therein) has focused on the former problem. Papadimitriou and Yannakakis [26] studied the latter problem, which is also the subject of this paper: the design and evaluation of strategies for navigation in an unknown environment. The unfamiliar environment may be either a warehouse or factory floor whose contents are frequently moved or a remote terrain such as Mars [30]. The design and evaluation of algorithms for such navigation is a natural algorithmic problem that deserves more theoretical study.

1.1. Model.

A *scene* $\mathcal{S}$ is a region (of $\mathbf{R}^2$ or $\mathbf{R}^3$) containing a start point s and a target t together with a set of opaque, impenetrable, nonoverlapping obstacles, none of which contains s or t. Most of this paper will consider two-dimensional scenes. The target t may be a point, a polygon/polyhedron, or an infinite wall. To avoid certain degeneracies, we assume that a unit diameter circle (unit cube in three dimensions) can be inscribed in each obstacle; this guarantees that the obstacles have a certain minimum "thickness."

A point robot has to travel from s to t, and it knows both its current absolute position and the position of t. In walking towards t, it must circumvent the obstacles

in $\mathcal{S}$. The robot does not know the positions and extents of these obstacles in advance; rather, it finds out about obstacles as it encounters them. Where two obstacles touch, we assume that the robot can "squeeze" between them. Thus a scene that consists only of convex obstacles cannot have a nonconvex obstacle composed of abutting convex obstacles.

The most natural mechanism for the robot to learn about a scene is vision: the robot discovers obstacles as they come into its view and uses this information to decide how to proceed towards t. For simplicity of exposition, we describe our algorithms assuming that when the robot first sees an obstacle, it is given the shape, size, and position of the obstacle (even though much of that obstacle may be invisible from where it stands). However, we show how many of our algorithms can be made to work with essentially the same upper bounds (up to a constant factor) under a considerably weaker assumption—a *tactile robot* that learns about obstacles only by bumping into them and moving along them. For this we use variants on the "doubling" strategies of Baeza-Yates et al. [1].

Let $R(\mathcal{S})$ be the total distance walked by a robot R in going from s to t in scene $\mathcal{S}$, and let $d(\mathcal{S})$ denote the length of the shortest (obstacle-free) path in the scene between s and t. (Because of the obstacles, this may be substantially larger than the Euclidean distance between s and t.) Let $\mathcal{S}(n)$ denote the set of scenes in which the Euclidean distance between s and t is n. Following the lead of [26], we use as the figure of merit for the robot the *ratio*

$$\rho(R, n) = \sup_{\mathcal{S} \in \mathcal{S}(n)} \frac{R(\mathcal{S})}{d(\mathcal{S})}$$

and study its growth as a function of n.

For convenience, we put the scene in Cartesian coordinates, using "north"/"south" to denote the direction of increasing/decreasing y value, "east"/"west" for the direction of increasing/decreasing x value, and "up"/"down" for the direction of increasing/decreasing z value, respectively. In two dimensions, we also use "vertical" to mean parallel to the y-axis and "horizontal" to mean parallel to the x-axis. The start point s is always assumed to be at the origin, and unless otherwise specified, we will assume that the current scene belongs to $\mathcal{S}(n)$. Finally, we use $\log n$ to denote $\log_2 n$.

1.2. Summary of results. For most of this paper, we consider two-dimensional scenes where t is a point and the obstacles are rectangles with sides parallel to the axes (rather than squares as in [26]). Surprisingly, even this problem turns out to be quite complicated. We solve this problem by breaking it into the following two subproblems:

The wall problem: scenes in which t is an *infinite vertical line* and the obstacles are oriented rectangles. The goal is to reach a point on t of the robot's choosing.

The room problem: scenes in which the obstacles are oriented rectangles that are confined to lie within a square "room." Here s is a point on a wall of the room and t is the point at the center of the room. The robot can "squeeze" between any two obstacles or between the walls and any obstacle. This intriguing special case is of interest in its own right as a model for navigation in a bounded region such as a warehouse.

Section 2 describes an optimal algorithm for the wall problem. The algorithm achieves an upper bound of $O(\sqrt{n})$ on the ratio $\rho(R, n)$, matching the lower bound of [26]. To devise this algorithm, we develop a general "sweep" paradigm that is fairly natural: a human lost in a strange city would probably do a similar search.

Section 3 considers the room problem. The algorithm for this problem achieves a ratio $\rho(R, n)$ that is $O(2^{\sqrt{3 \log n}})$. Following and building upon our result, Bar-Eli et al. [2] have established a tight bound of $\Theta(\log n)$ on the ratio of deterministic algorithms for the room-problem. The approach taken by the room-problem algorithm is different from the one taken for the wall problem. Here we develop a "caliper" method that pins the target down to lie within a sequence of advancing paths. Intriguingly, in the room problem, the shortest path from s to t has length $O(n)$. To see this, suppose that s is the southwest corner of the room. Therefore, the *greedy* path from the target t that travels due south if possible and otherwise due west will reach s and have as its length the L_1 distance between s and t. (If s is not in the corner, then by traveling along the room boundaries, one can reach s at an additional constant factor cost.) In contrast, greedy paths from s are not guaranteed to go anywhere near t. Thus getting out of a room is easy, but getting in towards a small target seems to be hard.

Section 4 shows how to combine our solutions for the wall and room problems to obtain a tight bound of $\Theta(\sqrt{n})$ for point-to-point navigation in scenes consisting of oriented rectangular obstacles.

Section 5 describes how our algorithms work (with at worst a constant factor degradation in ratio) when the robot is tactile: it learns about obstacles by "feeling" them. In this case, our algorithms bump into obstacles and slide along their edges in a manner reminiscent of *compliant* motion planning [7] in the context of navigation with a map.

Section 6.1 considers the room problem with arbitrary rectangular obstacles. We show that $d(\mathcal{S})$ can now be $\Omega(n^{3/2})$. Unlike the case of oriented rectangles, the greedy path is no longer guaranteed to find an inexpensive way out of the room. For these scenes, we give lower and upper bounds on $\rho(R, n)$.

Section 6.2 extends our algorithms for the room problem to the case of more general convex polygonal obstacles.

Section 7 gives extensions of our algorithm for the wall problem to three dimensions and also for point-to-point navigation in three dimensions. Both of these algorithms work provided the obstacles are oriented rectangular cuboids, achieving optimal ratios. (A cuboid is a rectangular parallelepiped.)

In section 8, we give a randomized algorithm for certain cases of the wall problem. We show that the (expected) ratio of our algorithm is $2^{O(\sqrt{\log n \log \log n})}$, which is much smaller than the corresponding deterministic lower bound. This demonstrates the power of randomization in navigation.

Section 9 deals with nonconvex obstacles (and therefore mazes). We give a lower bound for randomized algorithms and show that a deterministic algorithm of Rao et al. [28] meets this bound. The algorithm is memory intensive, and so we offer an alternative algorithm that is very simple, memoryless, and randomized and that achieves the same upper bound in the plane.

We conclude with a list of some open problems in section 10.

1.3. Related theoretical work. The ratio $\rho(R, n)$ is studied by Papadimitriou and Yannakakis [26] and independently by Eades, Lin, and Wormald [14]. Papadimitriou and Yannakakis proved that when s and t are points in the plane and all obstacles are squares, $\rho(R, n)$ is at least 1.5, and they complement this with an algorithm that attains $\rho(R, n) \leq 1.5 + o(1)$ for all n. It is also shown in [14, 26] that when t is an infinite wall at distance n from s and the obstacles are oriented rectangles, then $\rho(R, n)$ is $\Omega(\sqrt{n})$. Coffman and Gilbert [12] study the performance of simple heuris-

tics in the presence of randomly placed obstacles. Kalyanasundaram and Pruhs [16] and Mei and Igarashi [22] consider scenes in which all obstacles have bounded aspect ratios. Klein [18] has given a small constant upper bound on the ratio for scenes that are *streets*, a class of simple polygons. Earlier, Lumelsky and Stepanov [21] gave a simple navigation algorithm that guarantees $R(\mathcal{S})$ to be bounded by $d(\mathcal{S})$ plus the sum of the perimeters of all obstacles with no restrictions on the aspect ratios or the convexity of the obstacles. Their algorithm does not minimize the ratio ρ. Several papers (see [25, 28, 29] and references therein) give algorithms for building up a map of a scene by exploring it entirely. Maze traversal has received considerable attention in the past in various papers [5, 19, 27], none of which considers the ratio metric. The reader is referred to [20] for a comprehensive survey of the results in these papers.

The ratio measure $\rho(R, n)$ has close connections to the *competitiveness* measure used in the study of on-line algorithms [6, 23, 31]; indeed, our problem resembles an on-line setting in which the obstacles encountered by the robot form a sequence of "requests," and we compare its total cost $R(\mathcal{S})$ to the "off-line cost" $d(\mathcal{S})$. It is therefore worth pointing out some key differences between the models: (a) In the navigation problem, the robot has a definite target towards which it moves, while there is no such notion in on-line paging [31], for example. (b) The robot can move back and forth through the scene, revisiting previously seen obstacles, thus having some control on the requests it encounters in the future. (c) Competitive analysis deals with request sequences of arbitrary (possibly infinite) length, whereas here we have a fixed number of obstacles in the scene. Thus we cannot cast our navigation problem in a standard on-line framework such as the server problem [23] or metrical task systems [6]. Nevertheless, the analogy with on-line algorithms proves useful in the study of randomized navigation (section 8).

2. The wall problem. In this section, we consider scenes in which t is an infinite vertical wall at distance n to the east of s and the obstacles are rectangles whose sides are parallel to the axes. At the end of the section, we show how to modify our algorithm to work also when t is not vertical. We call the *width* of an obstacle its length in the x-direction and the *height* of an obstacle its length in the y-direction. To make the presentation clearer, we assume below that $\sqrt{n}$ is an integer. However, our algorithm and analysis can trivially be adapted to the general case.

We present an algorithm that achieves ratio $\rho(R, n) = O(\sqrt{n})$. This matches the lower bound proven in [26], so our algorithm is optimal up to constant factors.

The algorithm maintains four variables: the *window size* W, a *threshold* τ, a *sweep direction*, and a *sweep counter*. Initially, W is set to n, the sweep direction is south, and the sweep counter is set to zero. The threshold τ is always set to $W/\sqrt{n}$.

We begin with a high-level view of the algorithm and its analysis. The algorithm maintains a window of varying size around the x-axis. The robot makes $\sqrt{n}$ sweeps in directions alternating between north and south for each window size. Upon completion of these $\sqrt{n}$ sweeps, the window size is doubled. Given a window of size W (which ranges from $y = +W/2$ to $y = -W/2$), the distance walked by the robot in sweeping is $O(W\sqrt{n})$. We show that the shortest path that cuts through all of the $\sqrt{n}$ sweeps has length $\Omega(\sqrt{n}\tau) = \Omega(W)$. Let W_f be the window size at the time the robot reaches t. We prove that the total distance walked by the robot is $O(W_f\sqrt{n})$, while $d(\mathcal{S}) = \Omega(W_f)$.

We now describe the algorithm. Starting from point s, the robot travels due east until it either reaches t or hits an obstacle, say at (x, y). Below, we assume that the current sweep direction is south; the other case is symmetric. The next steps are

determined by the following rules:

Rule 1. If the distance to the nearest corner is less than τ, then the robot just goes "around" the obstacle. Specifically, it travels either south or north to the nearest corner, then east along the width of the obstacle to the opposite corner, and finally back along the height of the obstacle to the point $(x + w, y)$, where w is the width of the obstacle. (See Fig. 1(a).) From this point, it continues to travel due east until it hits the next obstacle (or reaches t and stops).

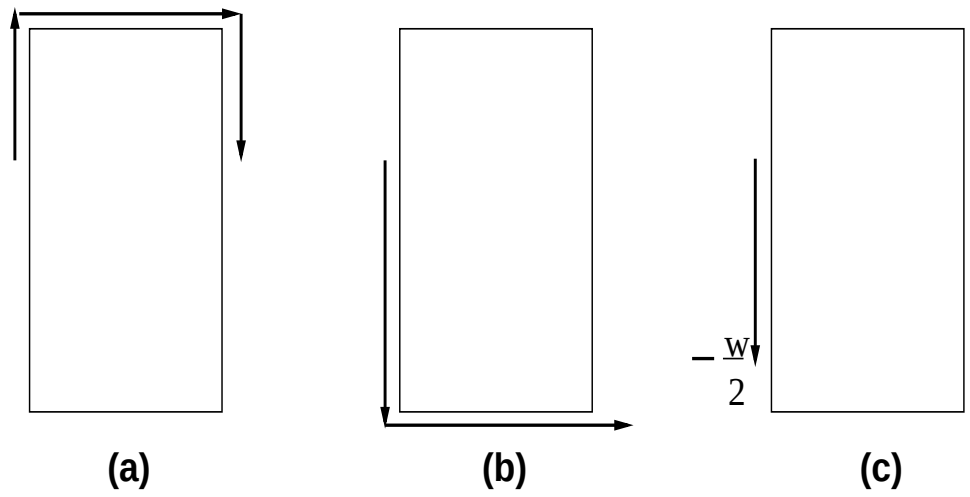

FIG. 1. *Going around an obstacle in the sweep algorithm.*

Rule 2. If the obstacle extends past both sides of the window (i.e., its north edge has y-coordinate greater than $W/2$ and its south edge has y-coordinate less than $-W/2$), then the robot doubles the window width W and threshold τ and resets the sweep counter to 0 and the sweep direction to south. Note that the ratio W/τ remains $\sqrt{n}$.

Rule 3. Otherwise (i.e., the distance to the nearest corner is more than τ, and the obstacle does not extend past both sides of the window), the robot travels south along the obstacle until it either hits the obstacle's southwest corner or reaches the window boundary (y-coordinate $-W/2$). In the first case, the robot just continues due east to the next obstacle (or t). (See Fig. 1(b).) In the second case, the robot increments the sweep counter by 1 and flips the sweep direction. If the counter is greater than $\sqrt{n}$, the robot resets the counter to zero and doubles the window size and the threshold. (See Fig. 1(c).)

Let W_f be the window size at the time the robot arrives at t.

THEOREM 2.1. *The total distance walked by the robot is* $O(W_f\sqrt{n})$.

Proof. To prove that the distance is bounded by $O(W_f\sqrt{n})$, we divide the path taken by the robot into three components: (1) horizontal segments, (2) segments walked south and north "along" obstacles using Rule 1, and (3) segments walked south and north using Rule 3.

Notice that (i) the total distance walked east is $n \leq W_f\sqrt{n}$ since $W_f \geq n$, and (ii) since the width of each obstacle is at least one unit, the total distance walked south and north using Rule 1 is bounded by $2n\tau_f \leq 2W_f\sqrt{n}$, where τ_f is the final threshold. It suffices to bound the third component as well. Fix a window size W. The distance walked by the robot using Rule 3 to complete one sweep is $O(W)$. Since

the robot makes at most $\sqrt{n}+1$ sweeps for each window size, the total distance for a fixed window size is $O(W\sqrt{n})$. The window size is doubled each time it is changed, and thus the total distance traveled over all window sizes is also $O(W_f\sqrt{n})$. □

THEOREM 2.2. *The length of the shortest path from s to t, $d(\mathcal{S})$, is $\Omega(W_f)$.*

Proof. Since we are just interested in the length of the shortest path up to a constant factor, we may assume that the path consists only of horizontal and vertical segments. The length of the horizontal segments is clearly at least n. If $W_f = n$, then we are done. Also, if W_f is determined by Rule 2 (there is an obstacle that extended past both sides of the previous window), we are done as well. Therefore, assume that neither of these is the case, which means that the robot has completed at least $\sqrt{n}$ full sweeps for some window size $W \geq \frac{1}{2}W_f$. We now show that the vertical component of the shortest path has length $\Omega(W) = \Omega(W_f)$.

Consider a point on the shortest path with y-coordinate of maximum absolute value. If this absolute value is at least $W/2 - \tau$, then clearly the shortest path has length at least $W/2 - \tau = \Omega(W)$. Suppose that this is not the case. Given a shortest path, for each of the $\sqrt{n}$ sweeps, define its first entry point to be the first point on the shortest path whose x-coordinate is the same as the x-coordinate of the starting point of the sweep. Similarly, define its first exit point to be the first point on the shortest path whose x-coordinate is the same as that of the end point of the sweep. Note that since sweeps do not overlap in their x-coordinates, the exit point of sweep i appears before the entry point of sweep $i+1$. Thus to lower bound the length of the shortest path, we can add together for each sweep i the vertical components of the shortest path from the ith entry point to the ith exit point. Consider the obstacles touched by the robot during some sweep—let's say it is a "south" sweep—that require the use of Rule 3. Each such obstacle extends at least τ to the north of the southernmost point of the previous such obstacle. Therefore, to travel from the entry point of the sweep (which is not between any two such obstacles) to the exit point of the sweep (also not between any two such obstacles) requires traveling a vertical distance of at least τ. Since there are $\sqrt{n}$ sweeps, the total vertical component is at least $\tau\sqrt{n} = W$. □

COROLLARY 2.3. *Our sweep algorithm achieves a ratio of $O(\sqrt{n})$ for the wall problem provided every obstacle is an oriented rectangle.*

A simple transformation of our algorithm allows it to achieve the same bounds even if the wall t is not vertical.

THEOREM 2.4. *The modified sweep algorithm below achieves a ratio of $O(\sqrt{n})$ for the wall problem with oriented rectangular obstacles, even if the wall is not vertical.*

Proof. The algorithm depends on the angle θ that t makes with the y-axis. Assume that $0 \leq \theta < \pi/4$ and that the wall runs from southwest to northeast. (The other three possibilities are analogous.) Here n is the shortest Euclidean distance between s and t. We distinguish between two cases:

Case 1: $\sin\theta \geq 1/\sqrt{n}$. In this case, the robot walks to t using the *greedy* east–south path from s (a path that travels due east if possible and otherwise due south). Observe that the length of this greedy path is the L_1 distance between s and the point of t that the path hits. The x-component of this L_1 distance is no more than $\sqrt{2}n$. Since $\sin\theta \geq 1/\sqrt{n}$, the y-component is bounded by $O(n^{1.5})$, implying that $\rho(R,n) = O(\sqrt{n})$.

Case 2: $\sin\theta < 1/\sqrt{n}$. We run the sweep algorithm exactly as described above until the first time the robot reaches a point (x_0, y_0) such that the point $(x_0, -W/2)$ is on or below t, where W is the width of the current window. Then the robot walks to t using the greedy east–south path. By Theorem 2.1, the distance walked by the

robot until reaching (x_0, y_0) is $O(W\sqrt{n})$, and it is clear that the length of the greedy path from there to t is $O(n + W)$. By an argument identical, to the one in the proof of Theorem 2.2, the shortest path from s to the vertical line $x = x_0$ has length $\Omega(W)$. By the requirement on θ, the shortest path from s to t has length $\Omega(W)$ as well. □

3. The room problem. In this section, we consider the *room problem*: scenes in which the obstacles are oriented rectangles confined to lie within a square room such that no obstacle touches the room walls; the point s is on the border of the room and t is in the center. (See Fig. 2.)

Later, we extend our results to rectangular rooms. Since travel along the room walls is "cheap," we may assume that s is in the southwest corner of the room, and for convenience we let t have coordinates (n, n), so the distance from s to t is in fact $n\sqrt{2}$.

Define a *greedy* $\langle +x, +y\rangle$ path to be a path that travels due east if possible and otherwise due north. Similarly, define greedy $\langle +y, +x\rangle$ paths, $\langle +x, -y\rangle$ paths, and so forth, to be ones that travel in the first direction if possible and otherwise the second direction. A *brute-force* $\langle +x\rangle$ path is one that travels due east, going around obstacles in its way along the shorter direction, but otherwise maintaining a constant y-coordinate. A *monotone* path from (x_1, y_1) to (x_2, y_2) is a path that does not both increase and decrease in any coordinate. For example, if $x_2 > x_1$ and $y_2 < y_1$, then the x-coordinate will never decrease and the y-coordinate will never increase. Notice that a greedy path is always monotone.

We now describe an algorithm that achieves $R(\mathcal{S}) = O(n^{3/2})$ and thus $\rho(R, n) = O(\sqrt{n})$. An improvement that uses this algorithm recursively achieves $\rho(R, n) = O(2^{\sqrt{3 \log n}})$.

The algorithm maintains the following invariant at the start of each iteration: the robot knows of a monotone obstacle-free path from a point (x_0, n) to a point (n, y_0), where $0 \le x_0, y_0 \le n$. Furthermore, the robot is positioned on a point of this monotone path. We begin with $x_0 = y_0 = 0$, where the known path is just a path along the room borders. Each loop through the algorithm will increase either x_0 or y_0 by at least an amount $\sqrt{n}$, walking a distance of only $O(n)$. (If the value increased (x_0 or y_0) is within $\sqrt{n}$ of n, then it is increased only up to n.) Since each of x_0 and y_0 can be increased by this amount only $\lceil\sqrt{n}\rceil$ times, the total distance walked by the robot to reach t is $O(n^{3/2})$.

For this first version of the algorithm, let $m = \sqrt{n}$. We will describe the algorithm as if t were allowed to be inside an obstacle, in which case the goal is simply to reach the obstacle containing t; this will allow for easier recursive application.

Algorithm Oriented-Room-Find (See Fig. 3.)

Initialization. Set x_0 and y_0 to 0. Set the monotone path to be the path along the room boundary from (x_0, n) to (n, y_0).

Step 1. Define $\tilde{t}$ to be the point with x-coordinate $\min\{x_0+m, n\}$ and y-coordinate $\min\{y_0 + m, n\}$. That is, unless we are close to t along some dimension, we have $\tilde{t} = (x_0 + m, y_0 + m)$. The goal of this step is to travel to some point t' not inside an obstacle that is to the northeast of $\tilde{t}$ and southwest of t inclusive. If no such point exists, we wish to travel to some point on the obstacle containing both $\tilde{t}$ and t.

For this (nonrecursive) version of the algorithm, we may reach t' as follows. First, traverse the monotone path to a point with y-coordinate equal to that of $\tilde{t}$. Then, if this is to the west of $\tilde{t}$, travel in a brute-force $\langle +x\rangle$ path until $\tilde{t}$ is reached or an obstacle containing $\tilde{t}$ is first encountered. In the latter case, unless the obstacle contains both

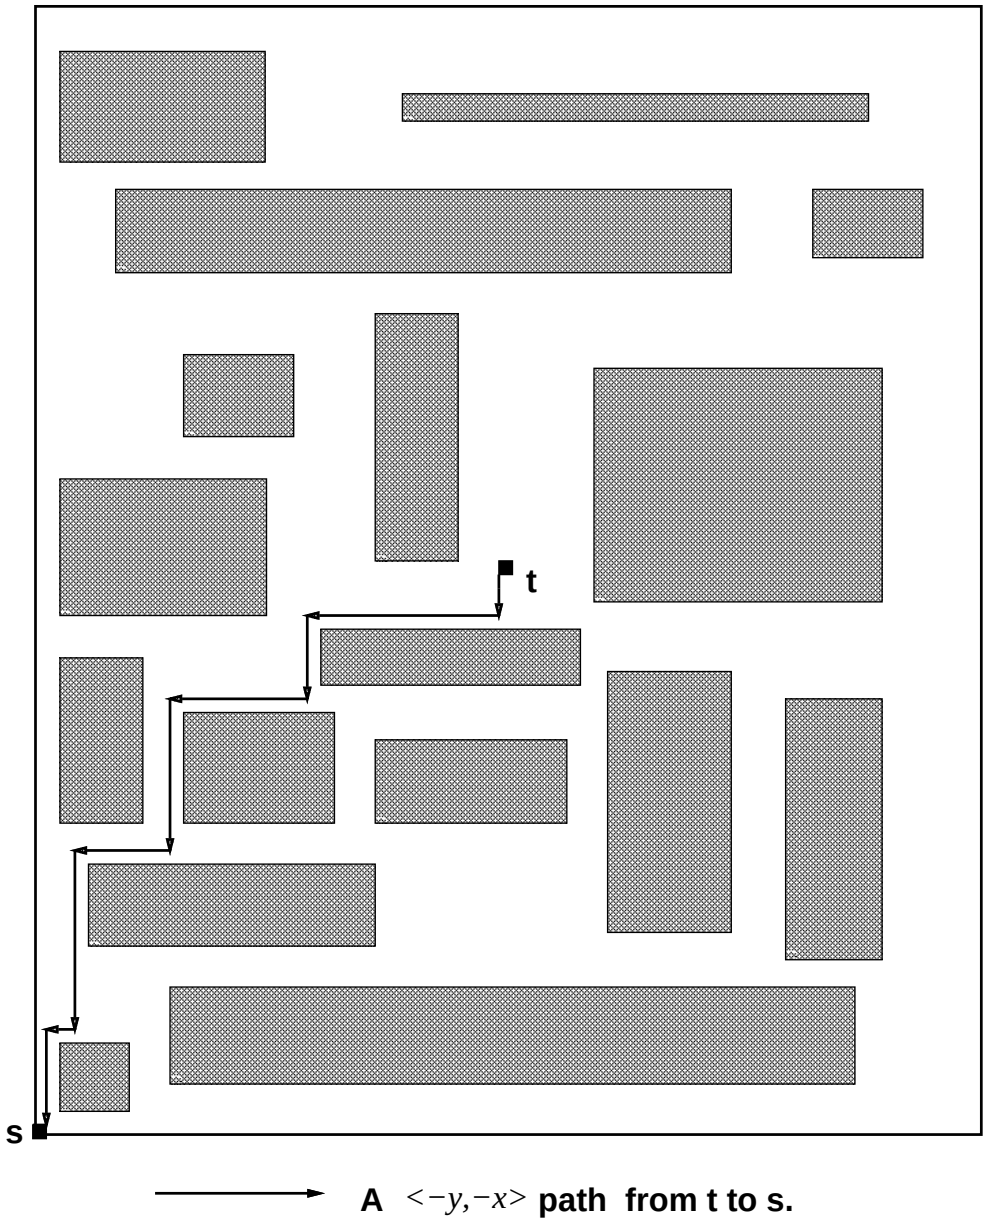

FIG. 2. *The room problem.*

$\tilde{t}$ and t (and we are done), we can just follow the obstacle boundary to a point in the desired region.

Step 2. Make a greedy $\langle +x, +y \rangle$ path from t' until either the x- or y-coordinate equals n. If we are at t, then halt. Otherwise, without loss of generality, assume that the robot has traveled to the west of t, so the current coordinates are $(\hat{x}, n)$ for $\hat{x} < n$. Notice that $\hat{x} \geq x_0 + m$ since the path was greedy.

Step 3. Let $x_0 = \hat{x}$. Travel a greedy $\langle +x, -y \rangle$ path from $(\hat{x}, n)$ until either a point

$(n, \hat{y})$ is reached (in which case let $y_0 = \hat{y}$) or the previous monotone path is hit. In either case, we have a new monotone path from (x_0, n) to (n, y_0) with x_0 increased by at least m. If the greedy $\langle +x, -y \rangle$ path was such that it reached (n, y_0) and in doing so followed the border of a single obstacle, then we must be at an obstacle containing t and so we are done. (Similarly, the robot would travel a greedy $\langle +y, -x \rangle$ path if it had hit to the south of target t in Step 2.)

Now go back to Step 1.

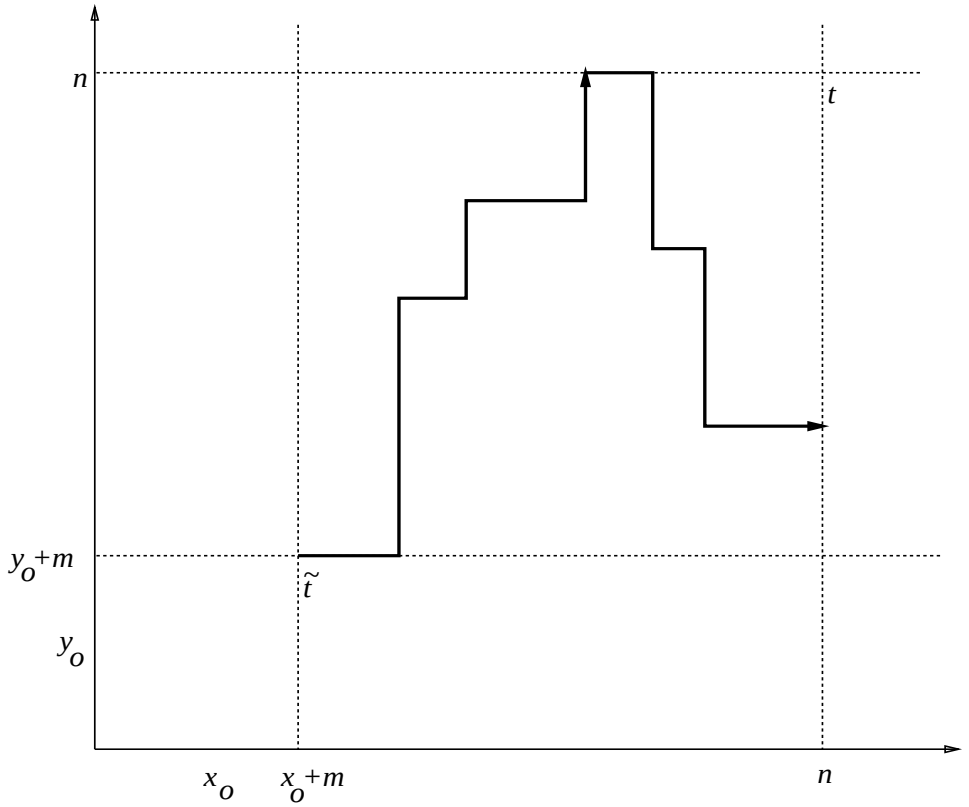

FIG. 3. *The algorithm for the room problem. Here* $\tilde{t} = t'$.

The distance walked performing Step 1 is $O(n)$ for traversing the monotone path and final obstacle and $O(m^2) = O(n)$ for the brute-force path traveled since the lower end of any obstacle encountered cannot extend below the monotone path (so there is at most $2m$ cost for every unit of progress made). Steps 2 and 3 together require traveling at most a distance $3n$ since each consists of a single greedy path, and in the two paths together, at least one coordinate is nondecreasing. Since these steps are iterated at most $2\lceil n/m \rceil$ times, the total distance traveled is at most $O(n^{3/2})$.

We can reduce the distance traveled to $O(n \cdot 2^{\sqrt{3 \log n}})$ by using algorithm Oriented-Room-Find recursively to reach $\tilde{t}$ (or an obstacle containing $\tilde{t}$) in Step 1 and optimizing the value of m. This works because to begin the algorithm needs only a monotone path of the form mentioned in the invariant, and not a true "room." In particular, there need not be any boundary "above" the obstacles at all. Define $T(n)$ to be the total distance traveled using this strategy to reach point $t = (n, n)$ (or a point on

the boundary of the obstacle containing t if t is inside some obstacle), given that the robot is on a known monotone obstacle-free path from $(0, n)$ to $(n, 0)$. As a base case, say if $n \leq 8$, we just use a brute-force path to reach t. Thus the distance traveled at each iteration of Step 1 is at most $2n$ for traversing the monotone path, $T(m)$ for the recursive call, and $3n$ for following the boundary of the final obstacle encountered.[1] Since the number of iterations is at most $2\lceil n/m \rceil$, we can bound the total cost $T(n)$ by

$$T(n) \;\leq\; 2\lceil n/m \rceil \, [T(m) + 8n] \quad \text{for } n > 8.$$

By substituting $m = n/(2^{\sqrt{3 \log n}})$ and using the inequality $\sqrt{x - k\sqrt{x}} \leq \sqrt{x} - k/2$ for $k > 0$, we get $T(n) \leq cn \cdot 2^{\sqrt{3 \log n}}$ for $c = 16(2 + \sqrt{2})$. We therefore have the following theorem.

THEOREM 3.1. *The algorithm for the room problem achieves* $\rho(R, n) = O(2^{\sqrt{3 \log n}})$.

If we consider a version of the room problem in which s and t are arbitrary points in the room, then the following strategy can be used to walk from s to t at a total cost that is $O(n2^{\sqrt{3 \log n}})$: simply walk from s out to a corner of the room, then use the above algorithm. Note, however, that in this case the length of the shortest path between s and t may be $o(n)$.

A generalization that will be used for the general point-to-point problem is when the room is rectangular with dimensions $2N \times 2n$, for $N \geq n$, and $t = (N, n)$. We use the same algorithm as for the square room, with one difference: we define point $\tilde{t} = (\min\{x_0 + mr, N\}, \min\{y_0 + m, n\})$ for $r = N/n$. (Again, if $n \leq 8$, we can just use a brute-force strategy to reach t traveling distance $O(N)$.) The value of m is optimized as follows. Define $T(n, r)$ to be the total distance traveled to reach point $t = (nr, n)$, given that the robot is on a known monotone obstacle-free path from $(0, n)$ to $(nr, 0)$. For a fixed value of m, the distance traveled at each iteration of Step 1 is at most $T(m, r) + 5nr$, while the distance traveled at each iteration of Steps 2 and 3 is at most $n + 2N \leq 3nr$. The number of iterations is at most $2\lceil n/m \rceil$, so we have

$$T(n, r) \leq 2\lceil n/m \rceil \, [T(m, r) + 8nr] \quad \text{for } n \geq 8.$$

The substitution used above $[m = n/(2^{\sqrt{3 \log n}})]$ results in $T(n, r) = O(rn \cdot 2^{\sqrt{3 \log n}})$.

Because we only needed a monotone path to start with, and not an entire room, we in fact have the following theorem.

THEOREM 3.2. *Given a monotone obstacle-free path between* $(0, n)$ *and* $(N, 0)$*, for* $N \geq n$*, the above algorithm will reach point* (N, n) *starting from that path with total cost* $O(N \cdot 2^{\sqrt{3 \log n}})$.

4. Point-to-point navigation. We combine the algorithms for the wall and room problems to obtain an algorithm for navigation in scenes where t is a point at (n, n) and the obstacles are oriented rectangles with no upper bounds on their extents.

The robot starts by taking a greedy $\langle +x, +y \rangle$ path from the start point s until it reaches a point s' with either x- or y-coordinate equal to that of t. Suppose that s' and t have the same y-coordinate. The robot now uses the sweep algorithm for the wall problem to travel to a point (n, y_0) with the same x-coordinate as t. Without

[1] The cost of traveling along the final obstacle can actually be amortized away at the expense of additional sentences of analysis.

loss of generality, assume $y_0 \geq n$. Notice that the path from s' to (n, y_0) taken by the robot in the sweep algorithm never decreases in the x-direction and that $y_0 - n$ is at most the final window width W_f. This path guarantees us that the *greedy* $\langle -y, -x \rangle$ path P from (n, y_0) will reach a point (x_0, n) with $x_0 \geq 0$. (In fact, x_0 is at least the x-coordinate of s'.) Now we invoke the algorithm for the room problem (Theorem 3.2) to arrive at t using the monotone path P as the room walls.

We analyze the distance walked by the robot. The distance traveled using the algorithm for the wall problem is at most $O(W_f\sqrt{n})$, where W_f is the size of the last window considered. The size of the (rectangular) room then created is at most $n \times W_f$. Therefore, using the algorithm of Theorem 3.2, the distance walked to reach t is $O(W_f\sqrt{n})$. By Theorem 2.2, the length of the shortest path from s' to t is at least cW_f for some constant $c > 0$. Now if $W_f \leq 4n/c$, then we have an $O(\sqrt{n})$ ratio since $d(\mathcal{S}) \geq n$. If $W_f > 4n/c$, then since the length of the shortest path from s' to s is at most $2n$, $d(\mathcal{S}) \geq cW_f - 2n \geq (c/2)W_f$, so we also have an $O(\sqrt{n})$ ratio. We therefore have the following theorem.

THEOREM 4.1. *For two-dimensional scenes $\mathcal{S}$ in which s and t are points and every obstacle is a rectangle whose sides are parallel to the axes, our algorithm achieves a ratio of $\rho(R, n) = O(\sqrt{n})$.*

5. A tactile robot suffices. In this section, we use a technique due to Baeza-Yates et al. [1] to demonstrate that all of our algorithms given so far can be modified to work with essentially the same ratio bounds even if the robot is tactile: it learns about obstacles on bumping into them and can infer the size of an obstacle only by moving along its boundary.

Suppose that the robot hits a side of a rectangular obstacle. Let d be the distance from its present position p to the nearest corner of the obstacle; it does not know d or the direction in which this nearest corner lies. The robot can reach this corner traveling a distance at most $9d + 2$ by applying the following "doubling" procedure suggested by Baeza-Yates et al. until a corner is reached. Walk along the side of the obstacle one unit in one direction, then turn back and walk two units past p in the other direction; turn back, and continue in this manner walking 2^{i-1} units past p on the ith iteration. If desired, in case a corner is reached which the robot is not certain is the nearest to p, the robot can simply walk an equal distance from p in the opposite direction to check. A simple analysis shows that the total length of the walk is at most $9d + 2$.

It remains to show that in each of the deterministic algorithms we have described, we can use this procedure to ensure that a tactile robot suffices (with a constant-factor overhead in the ratio). In our sweep algorithm for the wall problem of section 2, note that in negotiating an obstacle our decision is essentially based on the distance to the nearest corner of the obstacle. By using the above doubling procedure, we thus travel at most nine times the distance that the visual robot does, plus a low-order term for the additive constant.

Next, consider the room problem. In our algorithm Oriented-Room-Find, the only parts that required vision were the brute-force path, and finding a point between $\tilde{t}$ and t if $\tilde{t}$ was inside an obstacle in Step 1. Both can be handled with constant-factor overhead by the procedure of Baeza-Yates et al.

6. More general obstacle types.

6.1. Arbitrary rectangular obstacles. What if rectangular obstacles with sides not parallel to the axes are allowed in the room problem? We begin by proving

two theorems that demonstrate the difference between scenes containing only oriented rectangular obstacles and scenes containing arbitrary rectangular obstacles.

THEOREM 6.1. *For infinitely many n, there exist scenes $\mathcal{S}$ for the room problem containing rectangular obstacles whose sides are at arbitrary angles for which $d(\mathcal{S}) \geq \pi n^{3/2}/81$.*

Thus the length of the shortest path between s and t is not always bounded above by the L_1 distance as in the oriented case.

THEOREM 6.2. *For any deterministic robot R, there exist scenes $\mathcal{S}$ for the room problem containing rectangular obstacles whose sides are at arbitrary angles for which $\rho(R, n) = \Omega(\sqrt{n})$.*

Thus the upper bound for oriented rectangles cannot be achieved in this case.

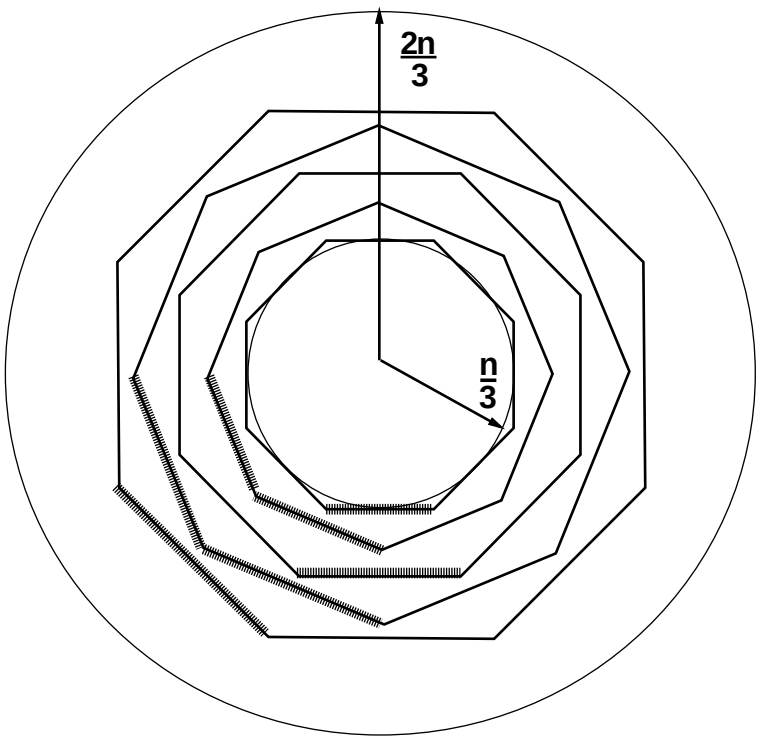

FIG. 4. *The lower bound in Theorem* 6.2. *The obstacles touched by the robot are shaded.*

Proof of Theorem 6.1. Consider $\lfloor n/27 \rfloor + 1$ circles centered at t with radii $\lceil n/3 \rceil + 1 + 9i$, $i = 0, \ldots, \lfloor n/27 \rfloor$. (See Fig. 4.) Inscribe in each a regular $\lfloor \sqrt{n} \rfloor$-gon, aligning all these polygons. Rotate all the polygons inscribed in circles of radii $\lceil n/3 \rceil + 9i$ for even i by an angle $\pi/\sqrt{n}$. Each edge of each polygon can now be replaced by a rectangular obstacle of unit width (in the radial direction) and length very nearly the length of that edge. The length of each obstacle is at least $2\pi\sqrt{n}/3$. Now any obstacle-avoiding path between s and t has to walk a distance of at least $2\pi\sqrt{n}/3$ going from a vertex of the polygon (i.e., gap between the obstacles) on the circle with radius $\lceil n/3 \rceil + 18i$ to a vertex on the circle with radius $\lceil n/3 \rceil + 18i + 18$ for $0 \leq i < n/54$. □

Proof of Theorem 6.2. Consider the scene described in the proof of Theorem 6.1.

We allow a (deterministic) robot to walk from s to t. We now remove from the scene any obstacle not touched by the robot. Let T be the number of obstacles it touches. There is a constant c_1 such that the distance walked by the robot between touching a corner of every *fourth* new obstacle is at least $c_1\sqrt{n}$. This sums to a distance of at least $c_1 T\sqrt{n}/4$. The total area of the obstacles touched by the robot is bounded from above by $2c_1 T\sqrt{n}$. Thus there exists an angle $2i\pi/\sqrt{n}$, $1 \le i \le \sqrt{n}$, such that the path from t to s given by staying on the radius at this angle and going "around" obstacles encountered is of distance at most $c_2 T$ for some constant c_2. This implies that $\rho(R, n) = \Omega(\sqrt{n})$. Notice that the lower bound holds only if the robot is tactile and cannot use any visual information. To make the lower bound work in the case of a robot that uses visual information, we use a slightly different construction together with a technique given in [26].

Again consider $\lfloor n/27 \rfloor + 1$ circles centered at t with radii $\lceil n/3 \rceil + 1 + 9i$, $i = 0, \ldots, \lfloor n/27 \rfloor$, and inscribe in each a regular $\lfloor \sqrt{n} \rfloor$-gon, aligning the polygons. This time, however, rotate all the polygons inscribed in circles of radii $\lceil n/3 \rceil + 18i$ and $\lceil n/3 \rceil + 18i + 9$ for even i by an angle $\pi/\sqrt{n}$. For each i, call the polygons inscribed in circles of radii $\lceil n/3 \rceil + 18i$ and $\lceil n/3 \rceil + 18i + 9$ a *layer*. Each edge of the inner polygon of each layer is replaced by a rectangular obstacle as above, except that it has thin openings spaced at unit distances. The outer polygon has similar obstacles in all edges but one, which has a solid rectangular obstacle with no holes. The holes in each inner polygon are out of alignment with the corresponding holes in the outer polygon; thus the robot cannot see through any layer.

We run the robot algorithm layer by layer, and we make the first obstacle seen by the robot in each outer polygon a solid obstacle. By the same argument as above, it follows that the robot walks $\Omega(\sqrt{n})$ between every fourth layer. □

We now turn to upper bounds. Define the angle of a rectangle to be the angle of its longest edge with the x-axis. We first describe a modification of algorithm Oriented-Room-Find to handle not just obstacles of angles of 0 and $\pi/2$ but obstacles angled in the range $[0, \pi/2]$ as well. Note that we do *not* allow obstacles angled in the remaining range of $(\pi/2, \pi)$. Then we describe how this new algorithm can be modified for scenes $\mathcal{S}$ where there is a fixed known excluded range (d_1, d_2) of angles (for example, $d_1 = \pi/5$ and $d_2 = \pi/4$). Let $\tilde{n} = n/\alpha$, where $\alpha = d_2 - d_1$. Our algorithm achieves $R(\mathcal{S}) = (\tilde{n} \cdot 2^{3\sqrt{\log \tilde{n} \log\log \tilde{n}}})$. The length of the shortest path in such scenes is $O(n)$. We remark that for "practical" cases, it may be enough to consider scenes where there is a known excluded range, especially when the number of different angles is small. Finally, we give a randomized algorithm that achieves $\rho(R, n) = \sqrt{n} \cdot 2^{O(\sqrt{\log n \log\log n})}$ regardless of the angles of the obstacles.

Suppose that the obstacles are angled in the range $[0, \pi/2]$. We describe our algorithm for this case in two steps. We first show that we need only consider the case where obstacles are zero-width line segments angled in the range $[0, \pi/2]$ such that at most some constant number of obstacles cross any line of length one. We then give an algorithm for that special case.

The idea for translating into the zero-width case is to view each obstacle as either two or four line-segment obstacles consisting of its edges that are in the legal angle range. (All four edges are in the legal range only if the obstacle is oriented.) One can easily verify that this implies a constant upper bound on the number of obstacles that cross any given line segment of length one. Let us first assume that when the robot touches an obstacle, it is given its entire description (as has been our standard model). Therefore, the robot can simulate an algorithm for the zero-width case,

and if the simulated algorithm enters a real obstacle, the robot just waits until that algorithm exits and then meets it at the exit point and continues. By going around the obstacle in the shortest way, the (actual) robot travels at most twice as much as the simulated algorithm. To do the simulation with a tactile robot, notice that when an obstacle edge is touched, the robot can determine whether it should be treated as a zero-width obstacle or as empty space based on its angle. If the obstacle is to be treated as empty space, the robot can use the technique of Baeza-Yates et al. to find the point where the simulated algorithm would exit the (actual) obstacle with only a constant factor additional cost. The key point here and in the previous case is that the longer edges of an obstacle are never treated as empty space.

We now describe the algorithm for the zero-width case. The reason for reducing to this case is that since every obstacle edge now has an angle in the range $[0, \pi/2]$, we can perform greedy $\langle +x, +y\rangle$ and $\langle +y, +x\rangle$ paths. The reason we cannot immediately use algorithm Oriented-Room-Find, however, is that we can no longer make the greedy $\langle +x, -y\rangle$ and $\langle +y, -x\rangle$ paths required in Step 3. Instead, we will replace that portion of the algorithm with a less efficient binary-search strategy.

More precisely, let us say our start point is (x_0, y_0) and t is at (n, n). In contrast to Oriented-Room-Find, our invariant will be that we have *two* monotone paths: a $\langle +y, +x\rangle$ path from (x_0, y_0) to some point to the west of t (i.e., a point (x, n), where $x \leq n$) and a $\langle +x, +y\rangle$ path from (x_0, y_0) to some point to the south of t. As in Oriented-Room-Find, we begin by recursively (or using brute-force if the distance to t is sufficiently small) traveling to a temporary point t' defined as in that algorithm at distance $O(m)$ from s. Now in place of Steps 2 and 3 of that algorithm, we will instead use a binary search (described below) to find a point with either the same x-coordinate or the same y-coordinate as t' (and to the northeast of (x_0, y_0)) with the following property P: the greedy $\langle +x, +y\rangle$ and $\langle +y, +x\rangle$ paths from this point pass to the south and west of t, respectively. Thus we will maintain our invariant, increasing either the x- or y-coordinate of the new "start point" as in Oriented-Room-Find.

We now show how to find the desired point. First, if t' is such a point, we are done. Otherwise, suppose that both greedy $\langle +x, +y\rangle$ and greedy $\langle +y, +x\rangle$ paths starting at t' hit points to the south of t. (The other case is analogous.) Let s' be a point with the same y-coordinate as t' on the $\langle +y, +x\rangle$ path from (x_0, y_0) given by our invariant. Since the $\langle +y, +x\rangle$ path from s' hits a point to the west of t, if the $\langle +x, +y\rangle$ path from s' hits a point to the south of t, then we are done as well. Otherwise, we travel to a point t'' halfway between s' and t'—using the same procedure as that used to reach t'—and examine the $\langle +x, +y\rangle$ and $\langle +y, +x\rangle$ paths from t''. (If t'' as defined is inside an obstacle, we examine the two points to the west and east of t'' on that obstacle boundary.) Depending on the outcomes of these greedy paths, we either halt with success or continue the binary search with a new t''' and so on. We stop the binary search when either success is discovered or the interval under consideration has length at most 1. Thus at most $\lceil \log n \rceil$ iterations of the binary search will be made. If the binary search stops because the interval remaining is too short, a point with property P can easily be found by traveling from the west endpoint to the east endpoint of the interval and, each time an obstacle is hit (this can happen at most a constant number of times), testing it for property P before going around the obstacle, which costs only $O(n)$. This strategy succeeds because if two points a and b have the same y-coordinate and there is either no obstacle, between them or both are at the boundary of the same obstacle, then the $\langle +x, +y\rangle$ path from the leftmost point intersects the $\langle +y, +x\rangle$ path from the rightmost point.

We get that the total distance is given by:

$$T(n) \;\le\; \lceil 2n/m \rceil \, \lceil \log n \rceil \, [T(m) + cn] \quad \text{for some constant } c.$$

Substituting $m = \lceil n/2^{\sqrt{\log n \log\log n}} \rceil$ yields

$$T(n) = O\left(n \cdot 2^{3\sqrt{\log n \log\log n}}\right).$$

This strategy can be used for a smaller range (d_1, d_2) of excluded angles by just performing a rotation and a coordinate transformation on the space. Essentially, instead of writing t as $n\vec{x} + n\vec{y}$ for orthogonal unit vectors $\vec{x}$ and $\vec{y}$, we may write t as $(n'\vec{d_1} + n''\vec{d_2})$, where $\vec{d_1}$ and $\vec{d_2}$ are unit vectors in the d_1 and d_2 directions. It is not difficult to see that both n' and n'' are $O(n/\alpha)$, where $\alpha = d_2 - d_1$. Let $\tilde{n} = n/\alpha$. The performance of the previous algorithm after the transformation is $R(\mathcal{S}) = O(\tilde{n} \cdot 2^{3\sqrt{\log \tilde{n} \log\log \tilde{n}}})$ since the lengths are changed by at most a factor of $1/\alpha$.

THEOREM 6.3. *There is a deterministic algorithm for the room problem with an excluded angular range of size α that achieves $R(\mathcal{S}) = O(\tilde{n}2^{3\sqrt{\log \tilde{n} \log\log \tilde{n}}})$. Here $\tilde{n} = n/\alpha$.*

Now consider the general case where the angles of the obstacles may be in any range. A simple pigeonholing argument implies that a constant fraction of the ranges $[i\pi/\sqrt{n}, (i+1)\pi/\sqrt{n}]$ for $0 \le i < \sqrt{n}$ have the property that the total perimeter of the obstacles angled in this range is no more than $2/\sqrt{n}$ of the total perimeter. To bound the total perimeter, note that from our assumption that a unit circle can be inscribed in each obstacle, it follows that the perimeter of an obstacle, is always less than four times its area. Since the total area of all obstacles is at most n^2, the total perimeter of obstacles in such a range is $O(n^{3/2})$.

Consider a randomized algorithm that first guesses such a range. It then applies the above algorithm assuming that there are no obstacles with angles in this range. On actually encountering any obstacle in this range, it just goes around the obstacle at cost at most the perimeter of the obstacle. From the definition of the "forbidden angle range," it follows that on any given greedy path, the robot will go around any such obstacle at most once. Therefore, the expected total distance walked by this algorithm is given by the recursion given above where $\tilde{n} = n^{3/2}$, and a constant times $n^{3/2}$ is added to the $c\tilde{n}$ term (which remains $O(\tilde{n})$). Thus we obtain the solution $T(n) = n^{3/2} \cdot 2^{O(\sqrt{\log n \log\log n})}$.

THEOREM 6.4. *There is a randomized algorithm that achieves a ratio of $\sqrt{n} \cdot 2^{O(\sqrt{\log n \log\log n})}$ for the room problem provided that every obstacle is a rectangle within which a unit circle can be inscribed.*

6.2. Arbitrary convex polygons. We now describe how our randomized algorithm for the room problem can be extended to handle arbitrary convex polygons provided that a unit circle can be inscribed in each obstacle and that the entire description of an obstacle is given to the robot when that obstacle is touched. (The only part of the description of the obstacle that is required is the angle that its longest diagonal makes with the x-axis.) We do not have a solution for the wall problem with arbitrary convex obstacles, and thus we have no solution for point-to-point navigation with convex obstacles.

We define the *angle* of a convex polygonal obstacle to be the angle its longest diagonal makes with the x-axis. The idea for the conversion is that each time the

robot encounters an obstacle, it picks a longest diagonal D and treats that obstacle as a collection of line segments parallel to D. In particular, it imagines a line segment at D and then additional segments (if any) parallel to and at distance 1, 2, 3, etc. from D, each as long as possible to still be contained within the obstacle. It then feeds this collection of line segments to the algorithm for rectangular obstacles. As in the case for unoriented rectangular obstacles, suppose the line-segment algorithm wishes to travel a path along line segments that leads through one of the convex obstacles: say the path is between points a and b on some obstacle's border. The robot then simply travels the shortest path from a to b along the obstacle boundary. Since the line segments are parallel to the longest diagonal of the obstacle and the obstacle is convex, we are guaranteed that the shortest path along the obstacle between a and b is at most a constant multiple of the straight-line path.

We note that in case there is a fixed known excluded range of angles, then the algorithm of Theorem 6.3 can be extended as well.

7. Extensions to three dimensions. This section summarizes extensions of our techniques to three dimensions. We begin by extending our study of the wall problem to three dimensions, and then we extend our optimal algorithm for point-to-point navigation to three dimensions.

7.1. The wall problem in three dimensions. Suppose that t is an infinite plane perpendicular to the x-axis at distance n from the origin s. We begin by extending the lower bound of [26] to three dimensions, showing a lower bound of $\Omega(n^{2/3})$. We then give a generalization of the two-dimensional sweep algorithm that achieves a matching upper bound.

THEOREM 7.1. *For any deterministic robot, there are scenes $\mathcal{S}$ of the three-dimensional wall problem for which $\rho(R, n) = \Omega(n^{2/3})$.*

Proof. To prove the lower bound, it will be convenient to assume a tactile robot. Using the technique of [26] used in section 6.1, this proof can be extended to robots with visual capabilities.

As the robot walks in the direction of t, the adversary places obstacles as follows. Each obstacle is a cuboid whose cross-section parallel to the yz-plane is a square of side $n^{2/3}$ and whose width in the x-direction is one. Whenever the robot first reaches x-coordinate i for each $i \in \{0, 1, \ldots, n-1\}$, a cuboid is placed directly in front of it. Thus the robot must travel a distance at least $\frac{1}{2}n^{2/3}$ perpendicular to the x-axis in order to advance one unit parallel to the x-axis. Thus $R(\mathcal{S}) \geq \frac{1}{2}n^{5/3}$.

We now show that $d(\mathcal{S}) \leq 3n$. Since the cross-sectional area of each cuboid is $n^{4/3}$, by the pigeonhole principle, there is a line ℓ parallel to the x-axis with the following properties: (a) its distance from the x-axis is at most n; (b) it cuts at most $n^{1/3}$ cuboids. Consider a path that starts from s and first goes to the leftmost point of ℓ. It then goes along ℓ parallel to the x-axis, traveling around each cuboid it encounters.

The distance from s to the leftmost point of ℓ is at most n. The distance traveled parallel to the x-axis is also n. The total perpendicular distance traveled in circumventing the cuboids cut by ℓ is at most $n^{1/3} \times n^{2/3} = n$. Therefore, $d(\mathcal{S}) \leq 3n$ and the ratio $\rho(R, n) = \Omega(n^{2/3})$. □

We now give an algorithm that matches this lower bound to within a constant. At a high level, the algorithm can be viewed as an extension of the two-dimensional sweep algorithm. The window, which in the plane was the region between two lines parallel to the x-axis, now becomes a cylinder whose axis is the x-axis. The radius of

this cylinder is initially n and is subsequently increased at certain points. The sweep used in the plane is now replaced by a spiral about the x-axis.

For simplicity, we first describe the algorithm as if every obstacle were a cylinder of circular cross-section with its axis parallel to the x-axis and its center placed directly in front of the robot. The radii and lengths of these obstacles can vary. Following the analysis of this simple case, we outline the extension of the algorithm to more general obstacles.

Consider a point orbiting around a fixed point, with the radius of the orbit increasing linearly with angular position at a rate of D units for every 2π radians of angular position. We call the path of the moving point a *spiral* and D the *spacing* of this spiral. (See Fig. 5.)

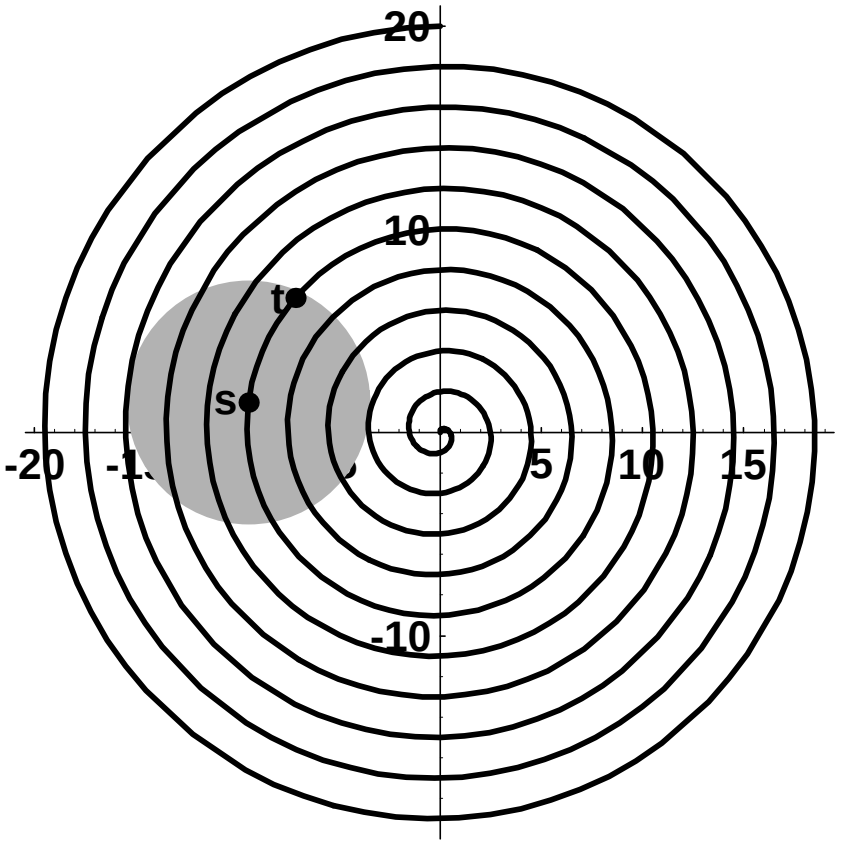

FIG. 5. *A projection of a spiral with radius* 20 *and spacing* 2*, overlaid with a projection of a cylinder of radius* 6*. The point s is the projection of the point where the robot encountered the obstacle, and point t is the projection of the nearest point on the outward spiral that is not covered.*

Our algorithm begins with $W = n$; at all times, $\tau = W/n^{1/3}$. Consider a spiral whose center is on the x-axis and whose orbits lie in a plane perpendicular to the

x-axis. The spacing will be $\tau/3$. Thus there are at most $3n^{1/3}$ orbits in the spiral within the current window.

The y- and z-coordinates of the robot will always lie on such a spiral. Analogous to the sweep direction in the plane (north or south), the robot now maintains a spiral direction that is either "outwards" or "inwards" along the spiral. On encountering a (cylinder) obstacle directly in front of it, the robot first checks if the radius of the cylinder exceeds τ. If not, the robot "goes around" the cylinder, retaining its current yz-coordinates. On the other hand, if the radius does exceed τ, the robot proceeds to the nearest point p on the spiral along its current spiral direction (outwards or inwards) that is not covered by the cylinder, proceeding as far along the x-direction as it can in the process. If this nearest point lies at a distance W' from the x-axis that exceeds W, the robot increases W to $2W$, resets the sweep counter to zero, and proceeds to begin a new spiral inwards from this point. Whenever the robot completes an inward spiral by reaching the x-axis or an outward spiral by reaching a point at distance W from the x-axis, it increments the sweep counter. Whenever the sweep counter reaches $n^{1/3}$, the robot doubles W (and τ), resets the sweep counter to zero, and continues.

THEOREM 7.2. *The spiral algorithm achieves a ratio of $O(n^{2/3})$, provided that every obstacle is a cylinder whose center is directly in front of the robot when it is first encountered.*

Proof. The analysis is essentially identical to that of Theorems 2.1 and 2.2. Let W_f be the final window radius. Since there are at most $3n^{1/3}$ orbits in each spiral, the distance walked by the robot in the last completed spiral is $O(n^{1/3}W_f)$. Since there are at most $\lceil n^{1/3} \rceil$ complete spirals in each window, the total distance walked by the robot is $O(n^{2/3}W_f)$.

We show that the length of the shortest path is $\Omega(W_f)$. First, we may assume that the robot has completed $\lceil n^{1/3} \rceil$ spirals for some window size $W \geq \frac{1}{2}W_f$, or else we are immediately done. (This is by the same reasoning used for the two-dimensional wall problem.) Consider a point on the shortest path that is farthest from the x-axis. If the distance of this point to the x-axis is at least W, then clearly the shortest path has length at least W, so we may assume that this is not the case.

Given a shortest path, for each of the completed spirals, define its first entry point to be the first point on the shortest path whose x-coordinate is the same as the x-coordinate of the starting point of the spiral. Similarly, define its first exit point to be the first point on the shortest path whose x-coordinate is the same as that of the end point of the spiral. As in the two-dimensional problem, the exit point of spiral i appears before the entry point of spiral $i+1$. Therefore, we need only show that for each spiral in some window of size W, the yz-plane component of the shortest path from the entry point to the exit point of the spiral is $\Omega(\tau)$. This will imply that the total yz-plane component of the shortest path is $\Omega(\tau n^{1/3}) = \Omega(W)$. Therefore, imagine projecting the completed spiral onto the yz-plane, projecting all the cylinders encountered in that spiral onto circles in the yz-plane. Observe that every point on the spiral is at distance at most $\tau/2$ from the center of one such circle of radius at least τ. Since the orbits of the spiral are at distance $\tau/3$ from one another, for any point of distance at most W from the origin, there exists a circle such that the distance of this point from the periphery of the circle is $\Omega(\tau)$. In particular, this also holds for the projection of the entry point of the sweep. Thus the yz component of any path from the entry point to the exit point must be $\Omega(\tau)$. □

The extension to the case of general cylindrical obstacles is similar. We define a

general cylindrical obstacle to be one for which there is a simple closed curve C in the yz-plane such that the obstacle's intersection with any plane perpendicular to the x-axis when translated to the yz-plane is either empty or it is C and its interior. As long as the robot moves in the positive x-direction, it will hit an obstacle only at some point of its unique "west face" in the yz-plane. On encountering such an obstacle, the robot measures the shortest distance from its present position to a point p on the spiral not touched by the obstacle. If this quantity is less than τ, it uses this shortest path to circumvent the obstacle and retain its yz-coordinates. Otherwise, it goes to p and proceeds as far along the x direction as it can. The analysis is very similar to the case of unit-height cylinders.

THEOREM 7.3. *For three-dimensional scenes $\mathcal{S}$ with general cylindrical obstacles and in which s and t are points, our spiral algorithm achieves a ratio of $\rho(R, n) = O(n^{2/3})$ for the wall problem.*

7.2. Point-to-point navigation in three dimensions. We now give an upper bound for point-to-point navigation in three dimensions that matches the lower bound to within a constant factor provided that every obstacle is a cuboid whose sides are parallel to the axes. As in two dimensions, our upper bound for point-to-point navigation comes from combining an algorithm for point-to-plane navigation and another for the room problem. However, in the three-dimensional case, it suffices to combine the three-dimensional wall algorithm with the two-dimensional room algorithm to obtain a three-dimensional point-to-point navigation algorithm. For simplicity of analysis, we assume that all obstacles have vertices at integral coordinates. However, our algorithm would still work provided that a unit cube can be inscribed within every cuboid in the scene.

Suppose without loss of generality that the x-, y-, and z-coordinates of s are less than those of t. The algorithm consists of three stages. In the first stage, the robot reaches a point s'' such that at least two of its coordinates are the same as t. This is done as follows. The robot starts by taking a greedy $\langle +x, +y, +z\rangle$ path until one of the three coordinates is the same as t. Call this point s' and without loss of generality say the y-coordinates of s' and t are the same. Next, fixing the y-coordinate (i.e., staying in the xz-plane of point s'), the robot takes a greedy $\langle +x, +z\rangle$ path from s' until one of the other two coordinates is the same as t. The endpoint of this path is the desired point s''. Without loss of generality, assume that the y- and z-coordinates of s'' are the same as t and let $n_x \leq n$ be the distance between s'' and t. The total distance walked in the first stage is $O(n)$.

In the second stage, the robot uses the three-dimensional wall algorithm from s'' to reach a point t' with the same x-coordinate as t. See Fig. 6. The total distance walked in this step is at most $O(n^{2/3})$ times $d(\mathcal{S})$. Let n_w be the distance between t' and t.

Assume that t' is not t (otherwise we are done). Consider the plane that contains the three points s'', t', and t. (See Fig. 6.) In the third stage, the robot will stay in this plane. Notice that since all of the obstacles are cuboids, the intersections of all obstacles with this plane are oriented rectangles. Define w to be a linear combination of y- and z-directions so that points on this plane can be written in (x, w) coordinates, and translate these so that $s'' = (0, n_w)$, $t' = (n_x, 0)$, and $t = (n_x, n_w)$ in this system.

From t' do a greedy $\langle +w, -x\rangle$ path until either the w-coordinate is n_w or else the x-coordinate is 0, whichever comes first. If the first case occurs, then the greedy path is a monotone boundary and we can apply the room-problem algorithm of Theorem 3.2. (The two-dimensional slice may technically violate our conditions for the

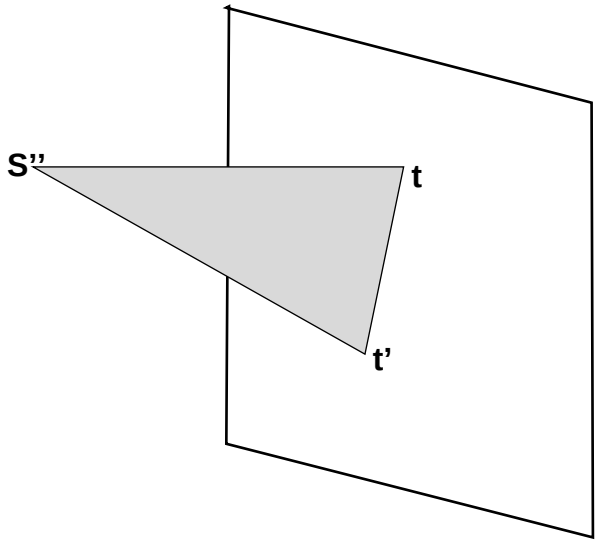

FIG. 6. *The plane that contains the points s'', t', and t.*

room problem by having obstacles that are too "thin." However, because a unit cube can be inscribed in each of the three-dimensional obstacles, there is sufficient separation for the room-problem algorithm to work.) If the second case occurs (we reached a point with x-coordinate 0), then go back to s'', retracing all our steps if we have to, and perform a greedy $\langle +x, -w \rangle$ path from there. This is guaranteed to hit a point with x-coordinate of n_x and w-coordinate at least 0 since it cannot cross our previous greedy path. Therefore, we again have a room and can run the room algorithm. The distance walked in this stage is $O(\sqrt{n} \cdot d(\mathcal{S}))$ since $n_w \leq d(\mathcal{S})$. We therefore have the following theorem.

THEOREM 7.4. *For three-dimensional scenes $\mathcal{S}$ in which s and t are points and every obstacle is a cuboid whose sides are parallel to the axes, our algorithm achieves a ratio of $\rho(R, n) = O(n^{2/3})$.*

To extend this result to a tactile robot, we again use the technique due to Baeza-Yates et al. [1]. Their strategy allows one to start from a face of a cuboid and travel to the nearest edge (at distance d), walking distance $O(d)$ in the process, without prior knowledge of d or the direction to the nearest edge. As in section 5, this allows our algorithm for point-to-point navigation in three dimensions to work for tactile robots with the same asymptotic ratio bounds.

8. The power of randomization. We now consider randomized robots that toss coins as they walk from s to t. The scene $\mathcal{S}$ is fixed in advance by an *oblivious* adversary [3] who knows the randomized algorithm but not the coin tosses made by the robot during a walk. The cost of robot R on scene $\mathcal{S}$ is now a random variable; we thus define the ratio $\rho(R, n)$ to be $\sup_{\mathcal{S} \in \mathcal{S}(n)} E[R(\mathcal{S})]/d(\mathcal{S})$. The main result of this section is a randomized algorithm for the two-dimensional wall problem that achieves a ratio of $2^{O(\sqrt{\log n \log \log n})}$ provided that the obstacles are all vertical line segments with endpoints at integral x-coordinates and the robot is allowed *vision*. Notice that for this situation, the robot can see the entire "column" of obstacles directly in front of it; that is, if the robot is at a point with x-coordinate in the range $(i-1, i)$ for integer

i, it can see all obstacles of x-coordinate i. To keep with our previous conventions on the thickness of obstacles, we could equivalently consider obstacles of width between one and two having their left walls only at even x-coordinates; this would still allow the robot to see an entire "column" at once.

The Papadimitriou–Yannakakis lower bound of $\Omega(\sqrt{n})$ still holds for deterministic algorithms for this restricted class of scenes [26]. Therefore, for such scenes, a randomized algorithm is provably better than a deterministic one. We leave as an open question whether one can achieve similar bounds for the more general wall problem.

The idea for the randomized algorithm is to view the problem as a k-server problem on $(k+1)$ equally spaced points on a line and then use as a subroutine known randomized strategies [4] for that server problem. For the benefit of the reader, we now define the *k-server problem*, first defined in [23]. An on-line algorithm manages k mobile servers located at the vertices of a graph G whose edges have positive real lengths. The algorithm has to satisfy on-line a sequence of requests, each of which is some vertex v of G, by moving a server to v unless it already has a server there. Each time it moves a server, it pays a cost equal to the distance moved by that server. We compare the cost of such an algorithm to the cost of an adversary that, in addition to moving its servers, also generates the sequence of requests. In fact, our problem can be better described as a *metrical task system* of [6], but we will use the language of servers here. In the lower bound direction, a recent result of Karloff et al. for the server problem shows that even for the special case of scenes we consider, no randomized algorithm can achieve a constant ratio [17].

We now present our randomized algorithm. There is a randomized strategy for k servers on $k+1$ equally spaced points on the line that achieves competitiveness $2^{O(\sqrt{\log k \log\log k})}$ against the oblivious adversary [4]. (For completeness, details are given in the appendix.) We map the navigation problem to this k-server problem as follows. Let $k = n-1$ and define the spacing between adjacent points on the line to be W/n, where W is the width of a window of y-coordinates currently considered by the robot; the value of W will be specified below. Each point in the server problem corresponds to a range of W/n y-coordinates for the navigation problem. The "hole" (the point without a server) represents the range currently inhabited by the robot.

We begin with $W = n$ and start the hole at the center of the line. Each time the robot sees a column of obstacles, the robot notes all points in the server problem corresponding to ranges that are completely blocked by obstacles. It then makes enough requests to the server algorithm on those points so that for the server algorithm of [4], the hole no longer resides on such points. Note that this request sequence is determined by the scene and thus obeys the definition of an oblivious adversary. The robot then moves to the range occupied by the hole (if it is not already there) and then moves a vertical distance at most W/n to find a point where it can go forward in the $+x$ direction to the next column. Thus the distance moved by the robot is at most the on-line server cost plus $W/n+1$ for each unit moved in the $+x$ direction. If the off-line server cost reaches W, the robot doubles the window width and restarts the server algorithm; each point now corresponds to a larger range of y-values.

THEOREM 8.1. *The randomized algorithm above achieves a ratio of* $2^{O(\sqrt{\log n \log\log n})}$ *for the wall problem in the plane where the robot uses vision and the obstacles are vertical line segments at integral x-coordinates.*

Proof. For a fixed window width, the off-line server cost in the above transformation is a lower bound on the length of the shortest path for the robot problem (assuming the off-line hole is also started at the center of the line). The off-line server

cost could be a bit lower than the length of the shortest path since we do not make requests to points corresponding to y-value ranges only partially blocked by obstacles. Note that when the off-line cost exceeds W, the shortest path might escape the window, which is why W is doubled.

As mentioned previously, the on-line cost for the robot is a most the on-line cost for the server problem plus $W/n + 1$ for each unit advance in the x-direction. Therefore, if W_f is the final window width used, the total distance traveled by the robot is at most $(W_f + n) + W_f 2^{O(\sqrt{\log n \log\log n})} = d(\mathcal{S})2^{O(\sqrt{\log n \log\log n})}$. □

9. Nonconvex obstacles and mazes. When the obstacles are nonconvex, the scene can be a maze. In this case, it is easy to see that $\rho(R, n)$ cannot be bounded by any function of n (the Euclidean distance between s and t). Instead, we prove a ratio between $R(\mathcal{S})$ and $d(\mathcal{S})$ as a function of the total number of vertices in all the obstacles, $|V|$.

THEOREM 9.1. *No randomized algorithm achieves a ratio better than* $(|V| - 10)/6$.

Proof. Consider the maze in Fig. 7 and its obvious generalization.

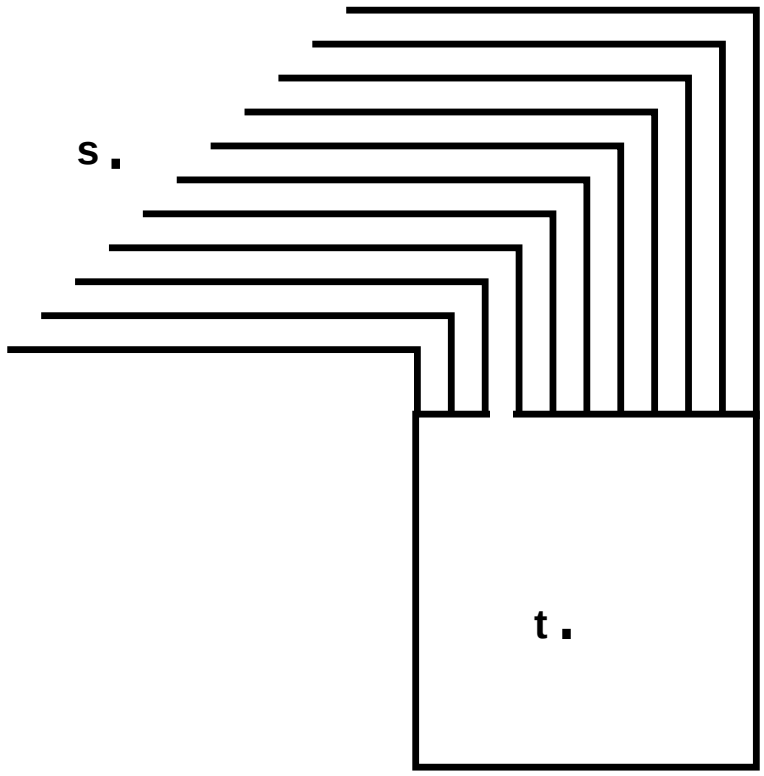

FIG. 7. *A maze achieving the lower bound. Each line segment corresponds to an obstacle with four vertices.*

The maze has $(|V| - 10)/6$ passages that could lead from s to t. An algorithm attempts various passages in turn until it finds the sole passage open to t. For any randomized algorithm, there is one passage whose expected "time to attempt" is at

least (number of passages − 1)/2; this passage is left open to t. The robot walks $2d(\mathcal{S})$ on every failure before that attempt, and $d(\mathcal{S})$ on that attempt. □

The bound applies a fortiori to deterministic algorithms. Rao et al. [28] give a deterministic algorithm that explores a maze by building a map of the scene, proceeding at each step to that unexplored vertex of the maze nearest to the vertices that have already been visited. It is easy to show that this algorithm achieves a ratio of at most $2|V|$, matching the above lower bound to within a constant. This algorithm is memory intensive, and this may be a handicap when space is limited or the scene changes quickly enough that a map is not worth building. We now give a simple, memoryless, randomized alternative based on a random walk that works for scenes in the plane. We first define a graph $G(\mathcal{S})$ on the vertices of the polygons in $\mathcal{S}$ and prove a simple geometric property of this graph. We then describe how the robot can perform a random walk on this graph, and we invoke a result on random walks to prove that the robot's ratio is $O(|V|)$.

The graph $G(\mathcal{S})$ is defined as follows: each vertex of a polygon in $\mathcal{S}$ is a node in the graph. A node v in $G(\mathcal{S})$ chooses up to twelve neighbors, defined as follows. Consider the twelve cones defined by angular intervals $[\pi i/6, \pi(i+1)/6)$, $i = 1, 2, \ldots, 12$ about v. There is an edge joining v to the nearest visible vertex (if any) in each cone. Thus $G(\mathcal{S})$ has at most $12|V|$ edges. A construction similar to $G(\mathcal{S})$ appears in Clarkson [11], where a result similar to the following lemma was given:

LEMMA 9.2. *Let $d_{st}(\mathcal{S})$ be the distance between two vertices s and t in the scene $\mathcal{S}$. There is a path in $G(\mathcal{S})$ between s and t of length at most $2.1d_{st}(\mathcal{S})$.*

Proof. For two vertices u and v in the scene that are mutually visible, denote by d_{uv} the distance between them. The shortest path in $\mathcal{S}$ between s and t is a path in the *visibility graph* of $\mathcal{S}$ [32]: a graph whose nodes are the vertices of obstacles in $\mathcal{S}$, with two nodes being joined by an edge if they are visible from each other. We now show that given this shortest path (of length $d_{st}(\mathcal{S})$) in the visibility graph, we can find a path in $G(\mathcal{S})$ between s and t whose length is at most $2.1d_{st}(\mathcal{S})$. Note that we can afford to find this path "off-line": we only wish to exhibit the existence of a short path in $G(\mathcal{S})$ from s to t.

We use an iterative strategy: we take the first edge of the visibility graph on the shortest path, say (s, a). If (s, a) is an edge in $G(\mathcal{S})$, we proceed to a and continue from there. Otherwise, we show that there is an edge (s, b) in $G(\mathcal{S})$ with the following property: $d_{bt}(\mathcal{S}) \leq d_{st}(\mathcal{S}) - 0.48d_{sb}$. (Note that s and b are mutually visible.) We therefore go from s to b in the first step of our path in $G(\mathcal{S})$ from s to t, having ensured that (1) we move to a node whose distance to t in $\mathcal{S}$ is less than from s and (2) the distance we have walked is proportional to the reduction in the remaining distance. We now continue the iteration from b, with b playing the role of s. In fact, since our distance to t diminishes at each iteration, we will have at most $|V| - 1$ iterations before arriving at t.

It remains for us to bound the first step (s, b) when (s, a) is not an edge in $G(\mathcal{S})$. Since s and a are mutually visible, the only reason that segment sa is not an edge in $G(\mathcal{S})$ is that the cone containing the line segment sa has a node b in it such that (s, b) is an edge in $G(\mathcal{S})$, i.e., $d_{sb} \leq d_{sa}$. Consider the sector of the circle with center s and radius d_{sb} that lies in the cone containing the segment sa. Let c be the point where this sector cuts segment sa. Since b is the closest vertex to s in the cone, no obstacle vertex lies in this sector. Further, since both a and b are visible from s, no portion of any obstacle lies in this sector. Therefore, b and c are mutually visible, as

are a and c. Figure 8 illustrates these facts. Thus

$$d_{bt}(\mathcal{S}) \leq d_{bc} + d_{ca} + d_{at}(\mathcal{S}).$$

On the other hand,

$$d_{st}(\mathcal{S}) = d_{sc} + d_{ca} + d_{at}(\mathcal{S}).$$

Using some elementary trigonometry and the fact that the angle between segments sa and sb is at most $\pi/6$, we have

$$d_{bt}(\mathcal{S}) \leq d_{st}(\mathcal{S}) - d_{sc} + d_{bc} \leq d_{st}(\mathcal{S}) - 0.48 d_{sb}. \qquad \square$$

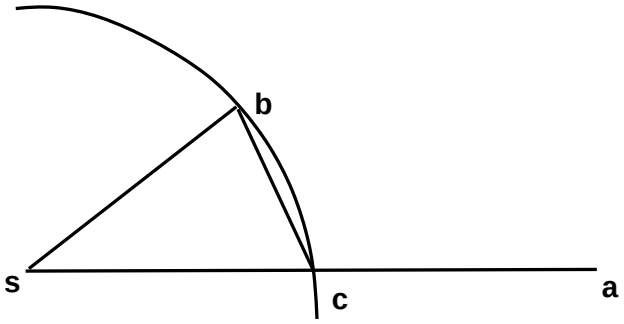

FIG. 8. $d_{bc} < 0.52 d_{sc}$ *and* $d_{sb} = d_{sc}$.

We now describe the random walk that the robot executes in going from s to t. At each node, it looks out to see the nearest node in each of the twelve cones, if such a node exists; let them be $v_1, v_2, \ldots, v_k$ at distances $d_1, d_2, \ldots, d_k$, respectively. Then it chooses to go to v_i with probability

$$\frac{1/d_i}{\sum_{j=1}^{k} 1/d_j}.$$

Note that this probabilistic decision is a local choice that does not need knowledge of $G(\mathcal{S})$ in advance; at each vertex, the robot measures the distance to the nearest visible node in each cone and chooses each with probability inversely proportional to its distance. The robot stops the process on arriving at t.

THEOREM 9.3. *The expected distance traveled by the robot is at most* $50.4|V| d_{st}(\mathcal{S})$. *Thus it achieves a ratio of at most* $50.4|V|$.

Proof. Chandra et al. [8] have studied the following general walk in a graph with positive real edge lengths: at each node, the walk chooses the next edge to walk along with probability inversely proportional to its length. They show that the expected distance traversed by the walk in going from a node a to a node b is at most $2m\ell_{ab}$, where m is the number of edges and ℓ_{ab} is the length of the shortest path in the graph between a and b.

In our case, $m \leq 12|V|$, and $\ell_{st} \leq 2.1 d_{st}(\mathcal{S})$ by Lemma 9.2; combining these facts with the result in [8] yields the theorem. $\square$

Clearly, there is a tradeoff between the number of cones in the graph $G(\mathcal{S})$ that we define and the factor 2.1 in Lemma 9.2; had we used 36 cones each of angle $\pi/18$, we could have gotten a tighter factor there but the number of edges in the graph (which figures in the ratio achieved by the random walk) would have gone up. Our choice of twelve cones optimizes this tradeoff.

10. Open problems. We conclude with some open problems.

- What are the tight bounds (deterministic as well as randomized) for the room problem with general obstacles?
- Can a randomized algorithm for the room problem beat deterministic algorithms?
- Extend the sweep algorithm for the wall problem to handle arbitrary polygonal obstacles and hence or otherwise obtain an algorithm for point-to-point navigation with such obstacles.
- Extend all of the above to three dimensions.
- Give an algorithm that achieves a provably good ratio for three-dimensional scenes with nonconvex obstacles (three-dimensional mazes).
- Blum and Kozen [5] show that a planar maze can be traversed in a number of steps polynomial in the number of vertices in the maze by a deterministic automaton using two pebbles. We have seen that the deterministic algorithm of Rao et al. achieves an optimal ratio but is memory intensive, whereas the random walk achieves a similar ratio without using memory to build a map. Is there a deterministic automaton using few pebbles (small memory) that achieves a good ratio? It seems reasonable to expect that the automaton would need a distance counter as well.

Appendix. We outline the randomized k-server algorithm invoked in section 8 and the proof of its competitiveness.

THEOREM A.1 (see [4]). *There is a randomized algorithm for $k = n - 1$ servers on n equally spaced points on a line that achieves an expected competitiveness ratio of $2^{O(\sqrt{\log n \log\log n})}$ against an oblivious adversary.*

Proof. Without loss of generality, assume that the points are spaced at unit distance. For convenience, we call the point without any server the "hole" and think of the algorithm as being on the hole position and having to move when it is "hit" by a request. The idea of the algorithm is to break the line into a collection of equal-sized intervals and then to stay within some interval until the adversary has made "enough" requests inside it. Once the adversary has made enough requests, the algorithm moves the hole to a different interval, choosing at random from those intervals into which "not too many" requests have been made.

More specifically, the algorithm proceeds as follows. Let $m = \lceil n/2^{\sqrt{\log n \log\log n}} \rceil$.

ALGORITHM RANDOMIZED-LINE

Step 1. Break the line into $\lceil n/m \rceil$ intervals, each of m points except possibly the last. We label these intervals $I_1, \ldots, I_{\lceil n/m \rceil}$. Initialize each interval to be "unmarked."

Step 2. For each point i $(1 \le i \le n)$, initialize a variable $C(i)$ to zero. Each $C(i)$ represents the minimum possible off-line cost of ending at point i given the sequence of requests seen since the last initialization (and assuming the off-line server may start at any point). Updating $C(i)$ is easy: after a request is made at point i, $C(i) \leftarrow \min\{C(i-1)+1, C(i+1)+1\}$. To handle the endpoints, initialize $C(0)$ and $C(n+1)$ to infinity.

Step 3. Randomly choose one unmarked interval I_j. Stay inside the larger interval $I_{j-1} \cup I_j \cup I_{j+1}$, running Randomized-Line recursively within that region, until the

minimum cost $C(i)$ for $i \in I_j$ has risen to be greater than $m/2$. As a base case, for a small enough interval, any deterministic algorithm will do (e.g., the deterministic algorithm given in [10]). For consistency at the endpoints, define I_0 and $I_{\lceil n/m \rceil + 1}$ to be empty and always marked.

Remark. The reason for staying within a larger interval of size $3m$ is a technical one to handle the "edge effects" that occur at the boundaries of the intervals I_j, as discussed in the analysis.

Step 4. Mark all intervals I_j such that the minimum cost $C(i)$ for all $i \in I_j$ is at least $m/2$. If there is some unmarked interval left, then go back to Step 3.

Step 5. All intervals are now marked, so the off-line cost since the last initialization of the $C(i)$'s is at least $m/2$. Go back to Step 2 and reinitialize.

Analysis. Let $T(n)$ be the expected cost of algorithm Randomized-Line for $n-1$ servers on a line of n unit-spaced points for a sequence of requests yielding a minimum off-line cost of $\lceil n/6 \rceil$.

Each application of Step 3 costs the algorithm at most an expected $n + T(3m)$: n for moving to the chosen interval and $T(3m)$ for the cost inside that interval. Notice that the cost function $C(i)$ for $i \in I_{j-1} \cup I_j \cup I_{j+1}$ may not yield values as high as those computed by the recursive application. The reason is the "edge effects": in the recursive application, the off-line costs of the endpoints of the range are not constrained by the costs of points outside it. However, the range is large enough so that *for all i in the middle region I_j*, the cost $C(i)$ is at least that computed by the recursive application as long as $C(i) \le \lceil m/2 \rceil$.

Each application of Step 3 results in half of the unmarked intervals becoming marked in Step 4 on average since the central interval I_j inhabited by the hole is chosen randomly from the unmarked intervals. Thus after $O(\log n)$ applications of Step 3, with high probability all intervals have been marked. Once we repeat Steps 2–5 $\lceil n/(3m) \rceil$ times, the off-line cost has increased by at least $n/6$.

Therefore, we get the following recurrence:

$$\begin{aligned} T(n) &\le \lceil n/3m \rceil \left[O(\log n)[T(3m) + n] \right] \quad \text{for, say, } n \ge 16 \\ &\le \frac{c(n \log n)}{m} [T(3m) + n] \quad \text{for some constant } c. \end{aligned}$$

Substituting $m = \lceil n/2^{\sqrt{\log n \log\log n}} \rceil$ yields

$$T(n) = O\left(n \cdot 2^{3\sqrt{\log n \log\log n}} \right). \qquad \square$$

FINITE MONOIDS: FROM WORD TO CIRCUIT EVALUATION*

MARTIN BEAUDRY†, PIERRE MCKENZIE‡, PIERRE PÉLADEAU§, AND DENIS THÉRIEN¶

Abstract. The problem of evaluating a circuit whose wires carry values from a finite monoid M and whose gates perform the monoid operation provides a meaningful generalization to the well-studied problem of evaluating a *word* over M. Evaluating words over monoids is closely tied to the fine structure of the complexity class NC^1, and in this paper analogous ties between evaluating *circuits* over monoids and the structure of the complexity class P are exhibited. It is shown that circuit evaluation in the case of any nonsolvable monoid is P complete, while circuits over solvable monoids can be evaluated in $DET \subseteq NC^2$. Then the case of aperiodic monoids is completely elucidated: their circuit evaluation problems are either in AC^0 or L- or NL-complete, depending on the precise algebraic properties of the monoids. Finally, it is shown that the evaluation of circuits over the cyclic group $\mathbb{Z}_q$ for fixed $q \geq 2$ is complete for the logspace counting class *co*-MOD_qL, that the problem for p-groups (p a prime) is complete for MOD_pL, and that the more general case of nilpotent groups of exponent q belongs to the Boolean closure of MOD_qL.

1. Introduction.

Fix a finite monoid M, that is, a finite set with an associative binary operation $*$ for which an element of the set acts as an identity. Define a *circuit over monoid* M as a circuit whose inputs are elements of M and whose gates perform the operation $*$.

The circuit evaluation problem over the monoid M, denoted CEP(M), is that of determining the monoid element computed at a designated output gate in a circuit over M prescribed on input.

CEP(M) can be thought of as a generalization of the *word problem* over M, in which a sequence $m_1, m_2, \ldots, m_k$ of elements of M is given and the task is to evaluate $m_1 * m_2 * \cdots * m_k$. CEP(M) is thus particularly interesting in view of the role played by word problems over monoids in the algebraic characterization of NC^1 and its subclasses [4, 7, 6, 14, 28]. In this paper, we investigate the complexity of CEP(M) for various M. Our results suggest that in a strong sense, circuit evaluation problems

over monoids are to the complexity class P what word problems over monoids are to the complexity class NC^1.

Boolean circuit evaluation over the basis $\{\vee, \wedge, \neg\}$ or over the singleton basis {NAND} is a well-known P-complete problem [27]. Viewing CEP(M) as a circuit evaluation over a "basis" consisting of a single *associative* operator, one might expect CEP(M) for any M to be markedly easier than circuit evaluation in the Boolean case. This is *not* so, however. We prove that whenever M is a nonsolvable monoid, i.e., includes a subset which forms a nonsolvable group, CEP(M) is P-complete. Such an increase in complexity associated with nonsolvability of the monoid has already been encountered in another context: the *word* problem over a fixed monoid M is complete for the complexity class NC^1 if M is nonsolvable [4] and believed to be contained in a proper subclass of NC^1 otherwise [7].

What happens, then, when M is solvable, i.e., contains no subset which forms a nonsolvable group? The complexity of CEP(M) then apparently drops significantly. We prove that CEP(M) then belongs to DET, a subclass of NC^2 defined as the closure of the integer determinant problem under NC^1 (Turing) reducibility [20]. This proof relies on a nondeterministic algorithm, which is an interesting application of language-theoretical concepts described in section 3, and on the fact, discussed and proved in section 2, that the logspace counting class MOD_qL appropriately relativized to a DET oracle is contained in DET. (Here MOD_qL is the set of languages Y for which some nondeterministic logspace Turing machine N satisfies the property that $x \in Y$ iff the number of accepting paths of N on input x is not divisible by q [18].)

In the absence of groups altogether, we are able to completely elucidate the complexity of CEP(M), assuming that the classes L and NL are distinct. Indeed let M be an aperiodic monoid, i.e., a monoid none of whose subsets forms a nontrivial group. If M is commutative and idempotent, then CEP(M) $\in AC^0$. Otherwise, if M contains at least one nonidempotent element and every idempotent of M commutes with each element of M, then CEP(M) is L-complete. Otherwise, CEP(M) is NL-complete. The different cases coincide with *varieties of monoids*, namely $\mathbf{J_1}$, the variety of all commutative and idempotent monoids, $\mathbf{M_{nil}}$, the idempotent central monoids, and the variety $\mathbf{A}$ of all aperiodic monoids. (Terms used in this paragraph are defined in a later section.)

Further, write $\mathbb{Z}_q$ for the cyclic group of order $q \geq 2$. We prove that CEP($\mathbb{Z}_q$) is *co*-MOD_qL complete. Moreover, if G is any p-group (i.e., a group of order a power of the prime p), then CEP(G) is MOD_pL-complete. Finally, in the general case of a nilpotent group G of exponent q, CEP(G) belongs to the Boolean closure of MOD_qL.

Table 1 summarizes our results; some of the notation and terminology used in this table is explained in sections 2 and 3.

Section 2 gives preliminaries and proves that MOD_qL relativized to DET is contained in DET. Section 3 presents the minimal background on monoids required for what follows. The main section is section 4, which discusses the complexity of CEP(M). Section 5 concludes with a discussion and suggestions for further work.

2. Preliminaries and definitions. Fix a finite monoid M and let "product" refer to its associative binary operation. We define the unconnected circuit evaluation problem UCEP(M) and its connected variant CEP(M).

DEFINITION. *Problem UCEP(M):*

Given *an element $x \in M$ and a directed acyclic graph of arbitrary indegree and arbitrary outdegree in which each in-degree-0 (input) node is labeled with an element*

TABLE 1.1
Our results on the complexities of CEP(M) and UCEP(M) as the algebraic properties of M vary. $\langle MOD_qL\rangle$ denotes the Boolean closure of the class MOD_qL.

Monoid M	CEP(M)	UCEP(M)
Nonsolvable Solvable	P-complete $\in DET$	P-complete $\in DET$
APERIODIC CASE: $M \in \mathbf{J_1}$ $M \in \mathbf{M_{nil}} - \mathbf{J_1}$ $M \notin \mathbf{M_{nil}}$	 $\in AC^0$ L-complete NL-complete	 NL-complete NL-complete NL-complete
SELECT GROUP CASES: Nilpotent, exponent q Cyclic group Z_q p-group, p-prime	 $\in \langle MOD_qL\rangle$ co-MOD_qL-complete MOD_pL-complete	 $\in \langle MOD_qL\rangle$ co-MOD_qL-complete MOD_pL-complete

from M and some out-degree-0 node is designated as the output node.

Determine *whether x is the value computed at the output node, where computation proceeds by having each internal node broadcast along its "output wires," the product of the sequence of monoid elements received along its "input wires."*

DEFINITION. *Problem* CEP(M)*: restricted variant of* UCEP(M) *in which there is a unique out-degree-0 node, accessible from each and every other node in the graph.*

Clearly an upper bound on the complexity of UCEP(M) applies to CEP(M) as well, and a hardness result on the complexity of CEP(M) applies to UCEP(M).

A circuit is prescribed on input by a variant of its direct connection language (see [19]). Since the operation performed at a gate is in general noncommutative, we add the condition that the tuples encoding the connections between a node and its inputs be numbered in a manner consistent with the order of evaluation at that node.

We assume familiarity with NP, P, NL, and L and with AC^0 and NC^k in their uniform settings. The precise choice of uniformity will not matter, but for definiteness we adopt $DLOGTIME$ uniformity for AC^0 [5] and U_{E^*} uniformity for NC^k [30, 20]. The class DET is defined as the closure of the integer determinant problem under NC^1 (Turing) reducibility [20]:

$$AC^0 \subset NC^1 \subseteq L \subseteq NL \subseteq DET \subseteq NC^2 \subseteq P$$

In general, we let the context distinguish between classes of languages and classes of functions, for example, between L and the class FL of functions computed in logspace. Throughout this paper, we will say that language A "NC^1 reduces" to language B, written $A \leq_m^{NC^1} B$, iff A "many–one" reduces to B via an NC^1-computable function.

Let $t \geq 0$ and $q \geq 1$ be natural numbers. Define the $\theta_{t,q}$ relation on $\mathbb{N}$ as follows:

$$i\theta_{t,q}j \iff [(i = j) \vee ((i \geq t) \wedge (j \geq t))] \wedge [i \equiv j (\mathrm{mod}\ q)].$$

The $\theta_{t,q}$ relations have algebraic significance because they are the only equivalence relations on $\mathbb{N}$ which are in fact finite index congruences (see [35]). Let $MOD_{t,q}L$ denote the set of languages Y such that for some $i \in \mathbb{N}$ and some nondeterministic logspace Turing machine M the following holds for each input x:

$$x \notin Y \iff i\theta_{t,q}|\mathrm{ACCEPT}(M, x)|,$$

where ACCEPT(M, x) denotes the set of accepting paths of M on input x. Observe that $MOD_{0,q}L$ is exactly the class MOD_qL as defined in [18]; this is because not just zero but any other single congruence class (mod q) could have been used in the definition of MOD_qL [18] without affecting the complexity class (see [13]). Observe further that $MOD_{1,1}L = NL \cup co\text{-}NL = NL$ [34, 24].

In order to analyze the complexity of problems CEP(M) in the case of solvable monoids, it will be convenient to first obtain a structural complexity result which is of independent interest (Theorem 2.1 below). This result deals with relativized counting classes and requires a suitable definition of relativized space. Here we borrow the definition proposed by Ruzzo, Simon, and Tompa [31].

DEFINITION (space-bounded oracle machine model). *Define M^A as the language recognized by a (possibly nondeterministic) machine M using oracle A in the following controlled manner: M has a write-only query tape not subject to a space bound and operates deterministically from the time some symbol is written onto the tape until the time the next oracle query is made, after which the query tape is erased.*

As pointed out in [31, Lemma 7], a language Y is equal to M^A for a logspace bounded machine M iff Y is logspace Turing reducible to some B (using queries which *are* subject to the space bound) and B is many–one reducible to A via a logspace transducer also having access to M's input.

When C is a complexity class and D is a set of languages, C^D represents the set of languages M^A such that M is a machine obeying the resource bounds associated with C and $A \in D$.

THEOREM 2.1. *$(MOD_{t,q}L)^{DET} \subseteq DET$ and $(co\text{-}MOD_{t,q}L)^{DET} \subseteq DET$ for any $t \geq 0$ and any $q \geq 1$.*

Proof. We do the proof for $(MOD_{t,q}L)^{DET}$. A desirable consequence of the above definition of relativized space is that (even) a nondeterministic logspace machine cannot make more than a polynomial number of distinct oracle queries in the course of its computation on any given input. This is because each query is the image, under transduction, of a logspace bounded "prequery." The simulation of a $MOD_{t,q}L$ machine M with oracle $A \in DET$ on input x will thus

1. list all possible queries,
2. compute all query answers and insert them into the list,
3. compute $|\text{ACCEPT}(M^A, x)|$, and
4. reject iff $i\theta_{t,q}|\text{ACCEPT}(M^A, x)|$, where i is the target number specified with M.

The first step is a logspace computation, which an NC^1 circuit with DET oracle gates can simulate because $L \subseteq DET$ [20]. The second step involves another layer of NC^1 circuitry with DET oracle gates because $A \in DET$. The fourth step is a pure NC^1 computation involving binary subtraction and division by a constant.

Now consider step three. It is easy to simulate machine M, which uses A as oracle, with a logspace bounded machine M' with no oracle, provided we input to M' the list computed in step two together with x. This simulation is easily made to preserve the number of accepting paths. But then computing the number of accepting paths of M' from its input is a $\#L$ computation. Since $\#L \subseteq DET$ [1], step three can also be carried out by an NC^1 circuit layer with DET oracle gates. □

An argument similar to the above is used in [18] to prove the (probably) weaker statement that $L^{\#L} \subseteq DET$.

In section 4, we will freely apply Theorem 2.1 to the situation in which a $MOD_{t,q}L$ machine queries *several* oracles $L_0, L_1, \ldots, L_s \in DET$. The standard technical justifi-

cation for this is the obvious fact that if $A \in DET$ and $B \in DET$ then $A \uplus B \in DET$, where $A \uplus B$ is the *disjoint union* of A and B defined as $\{w0 : w \in A\} \cup \{w1 : w \in B\}$ (see [3]). Thus, instead of querying L_i directly, a $MOD_{t,q}L$ machine can query the oracle $(\cdots((L_0 \uplus L_1) \uplus L_2) \cdots \uplus L_s)$ and obtain the desired answer. Since this holds for each $i, 0 \leq i \leq s$, the single oracle $(\cdots((L_0 \uplus L_1) \uplus L_2) \cdots \uplus L_s) \in DET$ suffices to answer all L_i queries.

3. Background on monoids, languages, and varieties. Recall that a monoid is a set equipped with an associative binary operation and an identity for this operation. We will use M to denote both the monoid and its underlying set and represent the operation as a concatenation (i.e., the product of $a \in M$ and $b \in M$ will be denoted ab).

Let A be a finite set or *alphabet*. We write A^* for the *free monoid* over A with concatenation as operation and the empty word as identity. Given a monoid M, let $\phi : M^* \to M$ be the canonical morphism. We will call a *word problem* of M any set or *language* of the form $Q\phi^{-1}$, where $Q \subseteq M$.

We write $\mathbb{Z}_q$ for the cyclic group modulo q and $C_{t,q}$ for the monoid performing addition modulo $\theta_{t,q}$ on the set $\{0, 1, \ldots, t + q - 1\}$. In particular, the operation of monoid $C_{1,1} = \{0, 1\}$ corresponds to the Boolean OR.

The *reverse* of a monoid M has the same underlying set as M but its operation is read in reverse order, i.e., evaluating abc in the reverse of M is equivalent to evaluating cba in M.

The usual notations for the monoid identity element and the universally absorbing element, when it is present, are 1 and 0, respectively. We depart from this convention and use 0 for the identity, however, when we speak of the $\mathbb{Z}_q$ and $C_{t,q}$, as above.

It is extremely useful to classify monoids according to their algebraic complexity, and the tool to do this is the *variety*. A variety of monoids is a set of monoids which is closed under *division* (the operation of taking a homomorphic image of a submonoid) and finite direct products. See [22] and [29] for references on this subject. Notice that the natural ordering of monoids induced by division has bearing on the relative complexities of the CEP problems: indeed if N divides M, then clearly CEP(N) NC^1 reduces to CEP(M).

Varieties of monoids explicitly mentioned in this paper are the set of all nilpotent groups (i.e., direct products of groups of prime power order); the set of all *solvable* monoids (i.e., from which the only simple groups that can be obtained are cyclic); the set of all *aperiodic* (i.e., group-free) monoids, which is denoted by $\mathbf{A}$; the smallest nontrivial aperiodic variety, denoted $\mathbf{J_1}$, which consists of all idempotent (i.e., satisfying $x^2 = x$ for each x) and commutative monoids; its superset the variety $\mathbf{J}$ of *J-trivial* monoids, consisting of all monoids M such that for each $m, n \in M$ if $MmM = MnM$ then $m = n$ (see [29]); the variety $\mathbf{M_{nil}}$ of the *idempotent central* monoids, which contains $\mathbf{J_1}$ and is contained in $\mathbf{J}$ and consists of those monoids M such that for all $e, m \in M$ such that $e^2 = e$, $em = me$ [33].

Each of the varieties $\mathbf{J_1}$, $\mathbf{J}$, and $\mathbf{M_{nil}}$ has the property that there is a finite set of *minimal* aperiodic monoids outside it, that is, a set of aperiodic monoids such that any monoid outside of the variety is divided by at least one of the monoids in the minimal set. For example, $T_2 = \{1, a, a^2\}$ is the smallest J-trivial monoid outside of $\mathbf{J_1}$. The monoid $R_1 = \{1, a, b\}$ with operation satisfying $aa = ab = a$ and $ba = bb = b$ and its reverse L_1, monoid $BA_2 = \{1, a, b, ab, ba, 0\}$ with operation satisfying $aa = bb = 0$, $aba = a$, and $bab = b$, and monoid $BH_2 = \{1, a, b, ab, ba, 0\}$ with operation satisfying

$aa = aba = a$, $bb = 0$, and $bab = b$ (each of BA_2 and BH_2 is equal to its reverse), are the minimal aperiodic monoids which are not J-trivial. (Also, $C_{1,1}$ is the minimal nontrivial aperiodic monoid.) To our knowledge the minimal monoids outside of $\mathbf{M_{nil}}$ had not been identified until now.

Let M_{ba^*} be the syntactic monoid of the language ba^* over the alphabet $\{a, b\}$. This monoid has four elements $\{1, a, b, 0\}$ with products $aa = a$, $ba = b$, and $ab = bb = 0$.

LEMMA 3.1. *R_1, M_{ba^*}, and their reverses, along with BA_2 and BH_2, are the minimal aperiodic monoids outside of $\mathbf{M_{nil}}$.*

Proof. If M is not J-trivial, then it is divided by R_1 or its reverse, by BA_2, or by BH_2. Thus we only need to show that M_{ba^*} and its reverse are the minimal J-trivial monoids outside of $\mathbf{M_{nil}}$.

Let M be a J-trivial monoid outside of $\mathbf{M_{nil}}$. There are therefore e, $m \in M$ such that $e^2 = e$ and $em \neq me$. Let $\alpha = em$ and $\beta = me$. We first show that monoid M satisfies the property

$$(^*) \qquad (e\beta \neq \beta e \wedge \forall k \geq 2 : \beta^k \neq \beta) \vee (e\alpha \neq \alpha e \wedge \forall k \geq 2 : \alpha^k \neq \alpha),$$

from which the lemma will be proved. Denoting by $f \leq_J g$ the relation $MfM \subseteq MgM$, observe that if $(e\beta \neq \beta e \wedge \forall k \geq 2 : \beta^k \neq \beta)$ does not hold, then $\beta \leq_J \alpha$, and similarly $\alpha \leq_J \beta$ if $(e\alpha \neq \alpha e \wedge \forall k \geq 2 : \alpha^k \neq \alpha)$ is false. Since M is J-trivial and $\alpha \neq \beta$, both $\beta \leq_J \alpha$ and $\alpha \leq_J \beta$ cannot be true. This proves $(^*)$.

To conclude the lemma from $(^*)$, we distinguish two cases. If $(e\beta \neq \beta e \wedge \forall k \geq 2 : \beta^k \neq \beta)$ holds, then let M' be the monoid generated by e and β. It is easy to see that $M' = \{1, e, \beta\} \cup \{\beta^k : k \geq 2\} \cup \{e\beta^k : k \geq 1\}$. Let the function $\phi : M' \to M_{ba^*}$ be defined by $\phi(1) = 1$, $\phi(e) = a$, $\phi(\beta) = b$, and $\phi(\beta^{k+1}) = \phi(e\beta^k) = 0$ for any $k \geq 1$. The definition of ϕ is unambiguous. Indeed, note that 1, e, and β are distinct. Next, since M is J-trivial, $\beta \leq_J e$ implies $e \not\leq_J \beta$; hence for $k \geq 1, \beta^{k+1}$ and $e\beta^k$ are different from 1 and e. Meanwhile, $\beta^{k+1} \neq \beta$ by assumption. Finally, assuming that $e\beta^k = \beta$, we have $e\beta = e\beta^k = e\beta^k e = \beta e$, which contradicts the assumption. Verifying that ϕ is a surjective morphism is a standard exercise. Therefore, monoid M_{ba^*} divides M.

The other case where $(e\alpha \neq \alpha e \wedge \forall k \geq 2 : \alpha^k \neq \alpha)$ is treated dually and yields the conclusion that the reverse of M_{ba^*} divides M. □

Another way to look at monoids is through the languages they recognize (via morphisms). A language $Y \subseteq A^*$ is *recognized* by a monoid M iff Y is the inverse image of a subset of M under some homomorphism from A^* to M. The *syntactic monoid* of a language $Y \subseteq A^*$ is the smallest monoid (in the ordering induced by monoid division) which recognizes Y. Straubing [33] identified the languages recognized by the idempotent central monoids.

THEOREM 3.2. *A language $Y \subseteq A^*$ is recognized by a monoid in $\mathbf{M_{nil}}$ iff it is a Boolean combination of languages of the form $B^*a_1B^*a_2 \cdots B^*a_kB^*$ where $a_1, \ldots, a_k \in A$ and $B = A - \{a_1, \ldots, a_k\}$.*

Note that in Theorem 3.2 the a_i are not assumed to be distinct.

At the other end of the spectrum, Straubing [32] and Thérien [35] have developed a useful parametrization of the languages recognized by solvable monoids. Recall the $\theta_{t,q}$ congruence defined in section 2. If $L_0, \ldots, L_s$ are languages over A^* and $a_1, \ldots, a_s \in A$, we denote by $[L_0, a_1, L_1, \ldots, a_s, L_s]_{i;t,q}$ the set of those words $w \in A^*$ for which the number of factorizations $w = u_0a_1u_1 \cdots a_su_s$, $u_j \in L_j$, $0 \leq j \leq s$ is congruent to i with threshold t and period q. Also, if $\mathcal{L}$ denotes a class of languages, let

$\langle\mathcal{L}\rangle$ denote its Boolean closure. We take from [35] the following two parametrizations of the languages recognized by solvable monoids.

THEOREM 3.3. *A language $L \subseteq A^*$ has a syntactic monoid which is finite and solvable iff $L \in \mathcal{M}_{t,q}^k$, where $\mathcal{M}_{t,q}^0 = \langle A^* \rangle$ and for $k \geq 1$:*

$$\mathcal{M}_{t,q}^k = \langle \{ [L_0, a, L_1]_{i;t,q} : L_0, L_1 \in \mathcal{M}_{t,q}^{k-1}, i \in \mathbb{N} \} \rangle.$$

THEOREM 3.4. *A language $L \subseteq A^*$ has a syntactic monoid which is finite and solvable iff $L \in \mathcal{N}_{t,q}^k$, where $\mathcal{N}_{t,q}^0 = \langle A^* \rangle$ and for $k \geq 1$:*

$$\mathcal{N}_{t,q}^k = \langle \{ [L_0, a_1, L_1, \ldots, a_s, L_s]_{i;t,q} : L_0, \ldots, L_s \in \mathcal{N}_{t,q}^{k-1}, i, s \in \mathbb{N} \} \rangle.$$

If we choose to work in the $\mathcal{M}_{t,q}^k$ hierarchies of languages, membership of x in language L is determined by counting (with respect to $\theta_{t,q}$) those occurrences of the character a that occur in the context of a prefix in L_0 and a suffix in L_1. In the $\mathcal{N}_{t,q}^k$ hierarchies, we would instead count occurrences of subwords $a_1, \ldots, a_s$ within contexts $L_0, \ldots, L_s$. Contrary to [7], where the former hierarchies were used, we find here that the $\mathcal{N}_{t,q}^k$ hierarchies seem more appropriate to the study of problem CEP.

The following results are taken from [35] and [36]. They describe some of the main special cases of solvable monoids.

THEOREM 3.5. *A language Y is recognizable by a finite aperiodic monoid iff Y is in $\mathcal{N}_{t,1}^k$ for some $k, t \geq 0$ iff Y is in $\mathcal{N}_{1,1}^k$ for some $k \geq 0$.*

THEOREM 3.6. *A language Y is recognizable by a finite solvable group iff Y is in $\mathcal{N}_{0,q}^k$ for some $k \geq 0$, $q \geq 1$.*

THEOREM 3.7. *A language Y is recognizable by a finite nilpotent group iff Y is in $\mathcal{N}_{0,q}^1$ for some $q \geq 1$.*

THEOREM 3.8. *A language Y is recognizable by a finite solvable monoid iff Y is in $\mathcal{N}_{t,q}^k$ for some $k, t \geq 0, q \geq 1$ iff Y is in $\mathcal{N}_{1,q}^k$ for some $k \geq 0, q \geq 1$.*

A byproduct of these theorems is that given a finite solvable monoid M, one can find parameters k, t, and q such that every word problem of M lies in $\mathcal{N}_{t,q}^k$. (Recall that word problems and the canonical morphism ϕ were defined at the beginning of this section.) In fact, given any $Q \subseteq M$, one can actually compute an expression that represents $Q\phi^{-1}$ involving M^*, the characters of M, the Boolean operations, and the operation $L_0, a_1, L_1, \ldots, a_s, L_s \to [L_0, a_1, L_1, \ldots, a_s, L_1]_{i;t,q}$. Notice that parameter q is a multiple of the exponents of all maximal subgroups of M (of M itself if M is a group).

4. Complexity of circuit problems. This section contains our upper bounds and hardness results on the complexities of UCEP(M) and CEP(M). Except when M is aperiodic (see subsection 4.2), the two problems have identical complexities.

4.1. The impact of solvability. In this subsection we exhibit a significant gap in the complexity of CEP(M), depending on whether M is solvable or not (within the hypothesis that $NC^2 \neq P$). We prove that CEP(M) and UCEP(M) are P-complete under $\leq_m^{NC^1}$ reducibility if M is nonsolvable and belong to DET, hence to NC^2, otherwise. Then we investigate the special cases of cyclic groups, p-groups, and nilpotent groups, and we prove an NL upper bound in the aperiodic case.

Throughout this subsection, each result obtained applies equally well to CEP(M) and to UCEP(M), even when this is not stated explicitly.

LEMMA 4.1. *If M contains a nonsolvable group, then* CEP(M) *is P-complete.*

Proof. Membership in P is obvious. To prove hardness, as shown below, we merely adapt Barrington's simulation of the Boolean operations AND, OR, and NOT

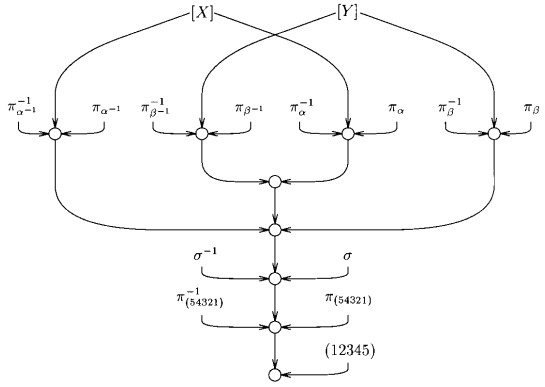

FIG. 4.1. *Circuit over $\mathcal{A}_5$ simulating X* NAND *Y.*

by products within the alternating group $\mathcal{A}_5$ [4, Theorem 1]. The generalization to the case of any nonsolvable group follows as in [4, Theorem 5]. (Alternatively, Zalcstein pointed out that a construction related to Barrington's had been investigated independently by Bergman [15] and others.)

It suffices to explain how to simulate a NAND gate, because evaluating a Boolean circuit with NAND gates is clearly P-hard [27]. Let $\alpha, \beta \in \mathcal{A}_5$ be 5 cycles such that $\alpha^{-1}\beta^{-1}\alpha\beta$ is also a 5 cycle. Let $\sigma \in \mathcal{A}_5$ satisfy

$$\sigma^{-1}\alpha^{-1}\beta^{-1}\alpha\beta\sigma = (12345).$$

Furthermore, for any 5 cycle $\gamma \in \mathcal{A}_5$, write π_γ for the unique element of $\mathcal{A}_5$ satisfying $\pi_\gamma^{-1}(12345)\pi_\gamma = \gamma$. Then we simulate a NAND gate with Boolean inputs X and Y using the constant-fan-in, constant-depth subcircuit given by Figure 1.

Let $[X]$ denote the subcircuit over $\mathcal{A}_5$ which encodes the work of gate X. Assuming inductively that $[X]$ evaluates to the identity of $\mathcal{A}_5$ (resp., (12345)) iff X outputs the Boolean value 0 (resp., 1), and similarly for $[Y]$, then the subcircuit on Figure 1 evaluates to the identity (resp., (12345)) iff X NAND $Y = 0$ (resp., X NAND $Y = 1$). □

Remark. The circuit over $\mathcal{A}_5$ built in the proof of hardness has gates of bounded fan-in. Recall however that the definition of problem CEP(M) allows gates with arbitrary fan-in and that associativity can be used to collapse a depth d instance of CEP(M) into a depth 1 instance consisting of the inputs and of one gate with fan-in $2^{O(d)}$. Thus gate fan-in can be traded for circuit depth. Using this idea, it can be shown that problem CEP(M) restricted to depth-$O(\log^k n)$ circuits is complete for NC^{k+1} under logspace reducibility. The proof repeats that of Lemma 4.1; in the NC^{k+1} hardness part, the depth $O(\log^{k+1} n)$, constant fan-in instance of CEP($\mathcal{A}_5$) obtained as an intermediate result, is divided into depth d subcircuits, $d \in O(\log n)$, which are then collapsed into gates of polynomial fanin, reducing the depth to $O(\log^k n)$. For further details we refer the reader to [10], where a technique for an analogous deterministic logspace reduction is described.

THEOREM 4.2. *If M is a solvable monoid then* UCEP(M) *belongs to DET.*

Proof. Consider the circuit in a UCEP(M) instance. The idea behind the algorithm developed below is that a word of M^* can be associated with each node in the circuit: a one-character word for the input gates, otherwise the concatenation of

the words associated with those nodes from which the gate receives its inputs. Thus determining the element of M computed at the output gate g is equivalent to applying M's canonical homomorphism ϕ to the word $W(g)$ associated with g, which in turn amounts to testing whether $W(g)$ belongs to a language recognized by M. This enables us to exploit the hierarchical parametrizations of the languages recognized by a solvable monoid.

Let M be a solvable monoid and $\phi : M^* \to M$ denote its canonical homomorphism. By Theorem 3.8, for each $m \in M$, $m\phi^{-1}$ belongs to $\mathcal{N}_{t_m,q_m}^{k_m}$ for some $k_m, t_m \geq 0$, and $q_m \geq 1$. Setting $k = \max\{k_m\}$, $t = \max\{t_m\}$, and $q = \operatorname{lcm}\{q_m\}$ yields $m\phi^{-1} \in \mathcal{N}_{t,q}^{k}$ for each $m \in M$.

Let g be the output gate specified in the instance of UCEP(M); testing for output g amounts to testing for membership of $W(g)$ in a language $[L_0, a_1, L_1, \ldots, a_s, L_s]_{i;t,q}$ recognized by M. Let M_r with operation $*_r$ be the syntactic monoid of L_r for $0 \leq r \leq s$. Let $B_r \subseteq M_r$ be the image of L_r under an appropriate morphism $\phi_r : M^* \to M_r$. The testing will be done by counting the successful computations of the following nondeterministic algorithm, that is, counting the accepting computations of a nondeterministic logspace Turing machine with oracles for UCEP(M_r), $0 \leq r \leq s$. From Theorem 2.1 and the closure of DET under Boolean operations, it will follow inductively that UCEP(M) belongs to DET. (Remark that the algorithm works on a circuit with in-degree-2 gates, which can be obtained from an arbitrary circuit through a logspace transduction.)

- Let $u_1, \ldots, u_s$ be pointers to nodes of the input circuit over M, each initialized to g.
- Let $b_0, \ldots, b_s$ be Boolean values initialized to false, except for b_0 and for b_s, which are true.
- Let $x_1 = \cdots = x_s = 1$, where each x_r is regarded as an element of monoid M_{r-1}.
- Let $y_1 = \cdots = y_s = 1$, where each y_r is regarded as an element of monoid M_r.
- *Repeat* until each u_r is an input node, or the instance is rejected:
  - nondeterministically pick a child v_r for each u_r (let $v_r = u_r$ if u_r is a leaf);
  - *if* there is an $r < s$ such that $b_r =$ false and v_r and v_{r+1} are the right and left child, respectively, of node $u_r = u_{r+1}$, *then* reject the instance; (*comment: subword characters a_r and a_{r+1} would then be accessed in the wrong order*)
  - *for* $r = 1 \ldots s$ *do*
    - *if* $b_{r-1} =$ true and v_r is the right child of u_r, *then* evaluate the subcircuit rooted at the left child of node u_r as if it were on monoid M_{r-1}, that is, for each $m \in M_{r-1}$, test whether the subcircuit, having each of its input gate labels appropriately translated through morphism ϕ_{r-1} into the corresponding element of M_{r-1}, evaluates to m. Denote by z the value thus obtained. Then let $x_r = x_r *_{r-1} z$.
    - *if* $b_r =$ true and v_r is the left child of u_r, *then* evaluate the subcircuit rooted at the right child of node u_r as if it were on monoid M_r; that is, for each $m \in M_r$, test whether the subcircuit, having each of its input gate labels appropriately translated through morphism ϕ_r into the corresponding element of M_r, evaluates to m. Denote by z the value thus obtained. Then let $y_r = z *_r y_r$.
- *for* $r = 1 \ldots s$ *do*: *If* $b_r =$ false and $v_r \neq v_{r+1}$, *then* let $b_r =$ true.
- *for* $r = 1 \ldots s$ *do*: Let $u_r = v_r$.

- *If* each u_r is an input node carrying value a_r *and* $x_1 \in B_1$ *and* $y_r *_r x_{r+1} \in B_r$ for $1 \le r \le s-1$ *and* $y_s \in B_s$ *and* $b_r = \mathsf{true}$ for $0 \le r \le s$, *then* accept; *else* reject.

The algorithm is a nondeterministic logspace computation with oracle. Here the u_r's and v_r's are pointers used for top-down traversal of the circuit; each path from g to an input node coincides with a character of $W(g)$, and the orderings of the paths and of the characters are consistent. Each Boolean variable b_r indicates whether the paths to characters a_r and a_{r+1} still coincide ($b_r = \mathsf{false}$) or have split apart. From the observation that the number α of accepting computations of the algorithm is the number of ways in which circuit inputs labeled $a_1, \ldots, a_s$ can appear in the word $W(g)$ within the appropriate contexts in $L_0, \ldots, L_s$, we obtain that $W(g) \in [L_0, a_1, L_1, \ldots, a_s, L_s]_{i;t,q}$ iff $i \,\theta_{t,q}\, \alpha$.

The analysis goes by induction on k. The base case $k = 0$ is clear because then $x\phi^{-1} = M^*$ or $x\phi^{-1} = \emptyset$, where x is the target element, and the algorithm can output an answer without looking at its input. Now for the induction step. In general, $x\phi^{-1}$ is a Boolean combination of languages of the kind $[L_0, a_1, L_1, \ldots, a_s, L_s]_{i;t,q}$. Testing for membership in such a language is done by counting accepting computations of our algorithm, which runs in nondeterministic logspace with calls to an oracle for UCEP$(M_0), \ldots,$ UCEP(M_s), but then we are done by applying Theorem 2.1 inductively. □

Intuition might suggest that a preliminary step to the above algorithm would be to compute that portion of the (unconnected) circuit which is connected to the output node. However this is not necessary, for the evaluation problem amounts to counting (context-dependent) paths from the root to certain input nodes, and this is precisely what the algorithm does through nondeterministic descents in the circuit. A good way to see this is to apply the algorithm to the case in which the monoid is a cyclic group of order q: problem UCEP(M) is then equivalent to the mod-q accessibility problem in an acyclic-directed graph (see Lemma 4.6).

We now apply the algorithm to some special cases of solvable monoids.

COROLLARY 4.3. *If M is an aperiodic monoid then* CEP(M) *belongs to NL.*

Proof. By Theorem 3.5, the algorithm deals with a language $x\phi^{-1} \in \mathcal{N}_{1,1}^k$. Hence the counting involved amounts to determining whether the number of accepting computations is zero or at least one. The analysis therefore gives an inductive step complexity in NL^{NL}. The result follows from the fact that $NL^{NL} = NL$ [24, 34]. □

COROLLARY 4.4. *Let M be the cyclic group $\mathbb{Z}_q$. Then problem* CEP(M) *belongs to co-MOD_qL.*

Proof. This is a special case in which the above algorithm deals with a language in $\mathcal{N}_{0,q}^1$, so that the recursive calls require no computation at all. Indeed, an instance of CEP$(\mathbb{Z}_q)$ can be thought of as a circuit with two leaves, carrying inputs 0 and 1; then the value of the output equals the number of paths from the 1 leaf to the output node, counted modulo q. Thus testing whether the circuit evaluates to a given target value reduces to testing whether the number of paths between two given nodes in an acyclic-directed graph is congruent to 0 modulo q; this "zero mod-q accessibility problem" is *co-MOD_qL* complete [18]. □

COROLLARY 4.5. *Let M be a nilpotent group of exponent q for $q \ge 2$. Then problem* CEP(M) *belongs to the Boolean closure of MOD_qL.*

Proof. We reason as in Corollary 4.3, noting that every language recognized by a nilpotent group of exponent q belongs to $\mathcal{N}_{0,q}^1$ by Theorem 3.7. □

The following hardness result completes the picture afforded by the last two corollaries.

LEMMA 4.6. *Let $q \geq 2$. If M contains an element of period q, then* CEP(M) *is hard for co-MOD_qL under $\leq_m^{NC^1}$ reducibility.*

Proof. It suffices to show that CEP($\mathbb{Z}_q$) is hard for *co-MOD_qL*. We reduce from the problem of determining whether the number of paths from u (of in-degree 0) to v (of out-degree 0) in an acyclic-directed graph is a multiple of q [18]. Assign 1 to u and 0 to any other in-degree-0 node. Then for each node $w \neq v$ of out-degree 0, add a gadget connecting w to node v through exactly q distinct paths. The resulting graph viewed as a circuit over $\mathbb{Z}_q$ evaluates to 0 at the unique output gate v iff the number of paths from u to v in the original graph was a multiple of q. □

THEOREM 4.7. *For $q \geq 2$ a fixed integer, problem* CEP($\mathbb{Z}_q$) *is co-MOD_qL-complete under $\leq_m^{NC^1}$ reducibility.* □

In the special case where q is prime, Corollary 4.5 and the fact that $MOD_qL = MOD_{q^n}L$, $n \geq 1$ is closed under Boolean operations [18] combine with Theorem 4.7 to yield a stronger statement.

COROLLARY 4.8. *For $p \geq 2$ a fixed prime integer and any p-group M, problem* CEP(M) *is MOD_pL-complete under $\leq_m^{NC^1}$ reducibility.* □

4.2. The aperiodic case. In this section, we discuss the computational complexity of problems CEP(M) and UCEP(M) when M is aperiodic. In the aperiodic case the complexities of the two variants differ. Indeed, counting in an aperiodic monoid implies distinguishing between "zero" and "at least one," which in the context of circuit evaluation means deciding whether at least one input node carrying a nontrivial value is connected with the output node. Consequently, UCEP(M) is NL-hard for any nontrivial aperiodic monoid M (Proposition 4.14). However the main result in this section is the following striking characterization of the complexities of CEP(M) as M ranges over the set of all finite aperiodic monoids.

THEOREM 4.9. *When M is an aperiodic monoid, exactly three cases arise:*

- *If M belongs to variety $\mathbf{J_1}$, then* CEP(M) *belongs to AC^0 (Lemma* 4.10*).*
- *If M belongs to variety $\mathbf{M_{nil}}$ and is nonidempotent, then* CEP(M) *is L-complete (Lemmas* 4.11 *and* 4.12*).*
- *If M does not belong to $\mathbf{M_{nil}}$, then* CEP(M) *is NL-complete. (Lemma* 4.13 *and Corollary* 4.3*).*

Corollary 4.3 was proved in subsection 4.1; we complete the proof of the theorem with the following four lemmas.

LEMMA 4.10. *If M belongs to $\mathbf{J_1}$, then* CEP(M) *can be solved in AC^0.*

Proof. When the expression for an element of an idempotent and commutative monoid is evaluated, each character involved contributes exactly once. To see this, take an arbitrary expression and first apply commutativity to regroup together all occurrences of the same character. Then, since $a^2 = a$ for all $a \in M$, replace them with a single occurrence. Thus by looking only at the content of the leaves and ignoring the rest of the circuit (thus relying heavily on the hypothesis that the circuit is connected), we obtain for the output a fixed-length expression which can be evaluated using table lookup. □

LEMMA 4.11. *If M is a nonidempotent aperiodic monoid, then* CEP(M) *is L-hard under $\leq_m^{NC^1}$ reducibility.*

Proof. This follows by reduction from the accessibility problem in a directed forest [21] to problem CEP(T_2), where $T_2 = \{1, a, a^2\}$ divides all nonidempotent aperiodic monoids (see section 3). Let an instance of the accessibility problem consist of asking

whether leaf u belongs to the tree rooted at v; let all edges in a tree be oriented toward the root. The reduction consists of first creating two new nodes named v' and w and adding an edge from each child of v to v' and then an edge from each out-degree-0 node to w. We obtain a graph with one root w and with nodes of out-degree at most 1, except for the children of v which have out-degree 2. Next, we label all interior nodes with the operation of T_2, leaf u with element a, and all other leaves with 1. If v can be reached from u, then there are exactly two paths from u to w (through v and v'), so that the circuit evaluates to a^2. Else there is exactly one path, and the output is a. □

LEMMA 4.12. *If M belongs to variety $\mathbf{M_{nil}}$ then problem* CEP(M) *belongs to L.*

Proof. Let $M \in \mathbf{M_{nil}}$. From Theorem 3.2, for each $x \in M$ the language $x\phi^{-1}$ is a Boolean combination of languages $B^*a_1B^*a_2 \cdots B^*a_kB^*$, with $a_1, \ldots, a_k \in M$ and $B = M - \{a_1, \ldots, a_k\}$ (the a_i not necessarily distinct). Using the closure of L under Boolean operations, we evaluate the circuit by checking, for each such language in the Boolean combination for $x\phi^{-1}$, whether the ordered sequence of all paths from the leaves to the root yields a word in the language. Given one such language $B^*a_1B^*a_2 \cdots B^*a_kB^*$, let $A' = \{a'_1, \ldots, a'_{k'}\}$ be the set of characters in $S = \{a_1, \ldots, a_k\}$. For each character a'_i, count the number of paths from the leaves labeled a'_i to the root; if it differs from the number of occurrences of a'_i in S, reject the instance. Otherwise, there are m_i paths from the leaves labeled a'_i to the root, and we must next verify that all $\sum m_i = k$ paths are combined in the appropriate order (unless M is commutative, in which case the algorithm stops here). Create a fixed-length register for each pair (r, s) of those paths, with possible values first (path r comes before s in the lexicographic order of root-leaf paths), second (r comes after s), and neither (ordering unknown). Initialize all registers to neither. Then, start every path at the appropriate leaf and advance along them toward the root, synchronously, one node at a time. If the paths are of different lengths, then start the shorter ones with an appropriate delay in such a way that all paths reach the root at the same time. Whenever two paths meet at a node, we obtain information on their relative ordering, depending on the edges used to reach the node; we store this information in the appropriate register. The paths may later part (the register is then reset to neither), but since all paths eventually reach the same node at the same time, we are certain to obtain their ordering, i.e., a setting of the registers which tells whether the inputs combine to give an element of $B^*a_1B^* \cdots B^*a_kB^*$.

Since the number of relevant paths involved in a positive CEP(M) instance depends only on the monoid and therefore is a constant, the above algorithm can be executed in deterministic logspace. In particular, making critical use of the CEP(M) assumption that a path exists in the circuit from each node to the output node, the breadth-first-search procedure (from leaf to output) invoked to count the number of paths from a leaf to the output node can be aborted when the number of stacked nodes exceeds the constant. □

LEMMA 4.13. *If monoid M does not belong to $\mathbf{M_{nil}}$, then problem* CEP(M) *is NL hard under $\leq_m^{NC^1}$ reducibility.*

Proof. By Lemma 3.1, at least one of monoids R_1, M_ba^* or their reverses, BA_2, or BH_2 divides M. Thus it suffices to prove hardness for these five minimal monoids. In all cases, we reduce from the accessibility problem in directed acyclic graphs. Let an instance consist in asking whether root v and leaf u are connected. We describe the reduction for the case of monoid R_1. First, we arbitrarily order the roots, placing v in the leftmost position. Then we create two new nodes v' and w, and we add an

edge from every root to w, plus one from v' to w, in such a way that the ordering of the roots is respected and that v' is inserted in this ordering immediately to the right of v. Next, we label all interior nodes with the operation of R_1, leaf u with element a, leaf v' with element b, and every other leaf with 1. The circuit evaluates to a at the output gate w iff the edge from v to w carries value a; that is, iff node v can be reached from u. Otherwise, the circuit evaluates to b.

The reduction for monoid M_{ba^*} is identical; there the modified circuit evaluates to $ab = 0$ if u and v are connected and to b otherwise. The reduction for the reverse of one of the above two monoids is obtained by simply reversing the order of the children of the output node w.

Finally, the reductions for monoids BA_2 and BH_2 are also similar; set $u = ab$, $v' = b$, and all the other leaves to 1, then if u is connected to v the circuit evaluates to 0, and if u is not connected to v the circuit will evaluate to b. □

We conclude this section with the case of UCEP(M).

PROPOSITION 4.14. *If M is a nontrivial aperiodic monoid, then problem* UCEP(M) *is NL-complete.*

Proof. Corollary 4.3 provides the upper bound. For *NL*-hardness, consider the minimal nontrivial aperiodic monoid, $C_{1,1}$. A reduction from the accessibility problem in a directed acyclic graph to UCEP(M) is obtained by labeling the source node with value 1 and all other in-degree-0 nodes with value 0. □

5. Conclusion. Finite monoids play a crucial role in the algebraic theory of finite automata. In particular, the algebraic classification of finite monoids maps to a classification of regular languages, and vice versa. In more general complexity theory, two recent streams of results have linked the classification of finite monoids to fundamental complexity classes. The first characterized the fine structure of the complexity class NC^1 in terms of word problems over monoids (see [4, 7, 28]). The second linked the classification of finite monoids to the discrete jumps in complexity, from membership in AC^0 to $PSPACE$ completeness, of the membership problem in transformation monoids (see [8, 9, 12, 26] and also [2]). In this paper, a third link between the structure of monoids and fundamental complexity classes was established, via the circuit evaluation problem.

When M is nonsolvable, CEP(M) is P-complete. When M is aperiodic, CEP(M) is either *NL*-complete, *L*-complete, or in AC^0, depending on further basic algebraic properties of M. Assuming $L \neq NL \neq P$, the complexity of CEP(M) is therefore completely determined in these cases. In the remaining solvable cases, CEP(M) $\in DET \subseteq NC^2$.

As an open question, our analysis in the solvable case needs refinement. For example, in the study of *word* problems over solvable monoids, the derived length[1] is closely related to the precise circuit depth of the corresponding NC^1 subclasses. What parameter associated with natural DET subclasses corresponds to the derived length in the context of CEP(M)?

Along those lines, we suspect a close connection between problem CEP(M) and the concept of *leaf languages* studied in [16, 17, 23]. Leaf languages provide a way to use regular languages as a basis for defining more general languages, as follows. Let each final configuration of a nondeterministic polynomial time Turing machine M

[1]For a solvable group G, the *derived length* of G is the length of the series $G_0 = \{1\} \triangleleft G_1 \triangleleft \cdots \triangleleft G_k = G$ in which G_i/G_{i-1} is an Abelian quotient of G_i, $1 \leq i \leq k$: it is also the smallest k such that all languages recognized by G belong to $\mathcal{M}^k_{0,q}$. By analogy, we define the derived length of a solvable monoid M to be the smallest k such that all languages recognized by M belong to $\mathcal{M}^k_{1,q}$.

emit a character from a fixed alphabet A. Ordering nondeterministic choices, let the *leaf string of M on input x* be the sequence of characters emitted at the leaves of M's computation tree on input x. Then, via M, any "leaf language" $Y \subseteq A^*$ defines a language, namely the set of inputs x such that the leaf string of M on x belongs to Y. A wealth of complexity classes, including $PSPACE$ and the polynomial hierarchy, were characterized as sets of languages definable via appropriately chosen regular leaf languages [16, 17, 23].

Now write $\mathcal{R}(\mathbf{V})$ for the class of languages definable via a regular leaf language recognized by a monoid from variety $\mathbf{V}$ (using nondeterministic *logspace* Turing machines). The hierarchy of solvable monoid varieties induces a (perhaps collapsing) hierarchy of classes $\mathcal{R}(\mathbf{V})$. What is the exact relationship between this hierarchy and problem CEP(M)? (This question has been partially investigated in [25].) Can such a relationship be exploited in order to define a useful parametrization of complexity classes like DET? In particular, adapting the several equivalent definitions of the polynomial hierarchy yields several possible meaningful definitions for complexity hierarchies built above MOD_qL and contained in DET. It would seem useful to know how these definitions relate to one another and whether the levels of these hierarchies have complete CEP(M) problems.

Acknowledgments. We thank the anonymous referees for their very thoughtful reading of our manuscript and for a more streamlined proof of Lemma 3.1.

PARALLELISM ALWAYS HELPS*

LOUIS MAK†

Abstract. It is shown that every unit-cost random-access machine (RAM) that runs in time T can be simulated by a concurrent-read exclusive-write parallel random-access machine (CREW PRAM) in time $O(T^{1/2} \log T)$. The proof is constructive; thus it gives a mechanical way to translate any sequential algorithm designed to run on a unit-cost RAM into a parallel algorithm that runs on a CREW PRAM and obtain a nearly quadratic speedup. One implication is that there does not exist any recursive function that is "inherently not parallelizable."

Key words. computational complexity, time complexity, random-access machine, parallel random-access machine, simulation, speedup

1. Introduction.

1.1. Motivation.

For some problems, the direct parallelization of a sequential algorithm gives a faster parallel algorithm. An example is matrix multiplication. The brute-force sequential algorithm for matrix multiplication runs in $O(n^3)$ time for $n \times n$ matrices. It is straightforward to parallelize this sequential algorithm to get an $O(\log n)$-time parallel algorithm using $O(n^3/\log n)$ processors. On the other hand, some problems are very difficult to parallelize. For example, depth-first search does not seem to admit itself to parallelization [7]. In this paper, we address the following question: Are all sequential algorithms parallelizable?

Cook and Reckhow [3] defined the unit-cost random-access machine (RAM). Fortune and Wyllie [6] introduced the parallel random-access machine (PRAM). These two models are, respectively, the most commonly used machine models for analyzing sequential and parallel algorithms. Thus the above question can be rephrased as follows: Given any unit-cost RAM R that runs in time T, is it always possible to construct a PRAM that simulates R in time $T' = o(T)$? We answer this question affirmatively by exhibiting such a construction with $T' = O(T^{1/2} \log T)$. Several variants of the PRAM have appeared in the literature since it was first introduced. The original model of Fortune and Wyllie has become known as the concurrent-read exclusive-write (CREW) PRAM, which is the model we use in our construction.

Parberry and Schnitger [15] considered the WRAM, a powerful variant of the PRAM. The WRAM differs from the CREW PRAM in three respects:

1. The WRAM is a concurrent-read concurrent-write (CRCW) priority PRAM [5].

2. The WRAM has a richer instruction set for arithmetic operations. The CREW PRAM supports only addition and subtraction, whereas the WRAM also allows unit-time unrestricted right shifts and modulus operations.

3. The WRAM and the CREW PRAM differ in the manner in which the processors are activated. In the WRAM, an arbitrary number of processors are self-activated at the beginning of the computation. In the CREW PRAM, only one processor is

active initially. An active processor activates an idle processor explicitly by executing a FORK instruction. Consequently, in t steps, a PRAM can activate at most 2^t processors.

Parberry and Schnitger showed that every Turing machine that runs in time T can be simulated in constant time by a WRAM with $2^{O(T)}$ processors. The best-known simulation of unit-cost RAMs by Turing machines incurs a cubic overhead in the running time [3]. It follows that every unit-cost RAM with time complexity T can be simulated in constant time by a WRAM with $2^{O(T^3)}$ processors. It is desirable to reduce this huge number of processors used in the simulation for two reasons. The first reason is, obviously, to reduce the hardware requirement.

The second and more important reason is that the ability of the WRAM to use an arbitrary number of processors renders this model unreasonably powerful. The above result of Parberry and Schnitger essentially says that every decidable problem can be decided in constant time by a WRAM. This anomaly arises mainly from allowing self-activated processors. The *parallel-computation thesis* [8, 14] asserts that the class of languages accepted by any reasonable parallel-machine model in polynomial time is equivalent to PSPACE, where PSPACE, as usual, denotes the class of languages that can be accepted by deterministic Turing machines in polynomial space. The WRAM violates the parallel-computation thesis and is considered unreasonably powerful [13]. In contrast, the PRAM is considered reasonable because it obeys the parallel-computation thesis [6]. So the challenge is to speed up a unit-cost RAM by a PRAM with a reasonable number of processors; the number of processors should be small enough so that all processors can be activated explicitly within the simulation time.

1.2. Comparison with previous results. Dymond and Tompa [4] showed that every deterministic Turing machine running in time T can be simulated by a CREW PRAM in time $O(T^{1/2})$. However, the random-access memory of the PRAM is much more flexible than the linear tapes of the Turing machine, which forbid random access into individual tape cells. It was unclear whether it is the parallelism, the more flexible storage structure, or the combination of both that realizes such a quadratic speedup. Our result demonstrates that parallelism alone suffices to achieve an almost quadratic speedup.

To the best of our knowledge, in all previous speedup results [4, 10, 13, 15, 16, 18, 20], the machine being simulated is limited to the Turing machine. All these results depend on the fact that the changes in the configuration of a Turing machine in t steps are localized to the $2t-1$ cells around each tape head. In contrast, the random-access memory of a unit-cost RAM allows the RAM to change the contents of registers with widely different addresses in consecutive steps. The versatility of the random-access memory of a unit-cost RAM has defied all prior attempts to speed up a unit-cost RAM by a PRAM. This paper presents the first speedup theorem of unit-cost RAMs by PRAMs.

Reif [17] demonstrated that every probabilistic unit-cost RAM that runs in time T can be simulated by a probabilistic CREW PRAM in time $t(T, L) = O((T \log T \log(LT))^{1/2})$, where L is the largest integer manipulated by the probabilistic RAM during its computation. It is straightforward to modify Reif's proof to show that every unit-cost RAM running in time T can be simulated by a CREW PRAM in time $t(T, L)$. With unit-time addition, however, a RAM can generate integers as large as $2^{O(T)}$ in time T. Reif's result does not guarantee a speedup since $t(L, T) = O(T(\log T)^{1/2})$ when $L = 2^{O(T)}$. Our result gives a definite speedup of unit-cost RAMs by PRAMs, regardless of the value of L. It is routine to generalize our

proof to establish a speedup theorem of probabilistic unit-cost RAMs by probabilistic CREW PRAMs. This paper subsumes the above result of Reif. Thus all algorithms (deterministic and probabilistic) are parallelizable.

In summary, all previous simulation results suffer from one or more of the following drawbacks:

1. No definite speedup is guaranteed (Reif [17]).
2. The machine being sped up is limited to the Turing machine [4, 10, 13, 15, 16, 18, 20].
3. The speedup result fails to isolate the effect of parallelism; that is, apart from the parallelism, the simulator enjoys some additional advantage over the machine being simulated—for example, a more flexible storage structure (Dymond and Tompa [4]).
4. The simulator is too strong to be called reasonable because it violates the parallel computation thesis (Parberry and Schnitger [15]).

Our result does not suffer from any of the above drawbacks.

The rest of this paper is organized as follows. Section 2 defines the RAM and the PRAM models precisely. In section 3, we build up a repertoire of techniques for programming a PRAM efficiently. We use these techniques in section 4 to establish our main result: for every unit-cost RAM R with time complexity T, we construct a CREW PRAM that simulates R in time $O(T^{1/2} \log T)$. We conclude with a few comments in section 5. All logarithms are taken to base 2.

2. Definitions.

2.1. The unit-cost RAM. A RAM R consists of a *memory*, and a *program*. The memory is an infinite sequence of registers $(r(i))$, $i = 0, 1, \ldots$. The *address* of $r(i)$ is the integer i. Each register can hold an integer. Let $\langle r(i) \rangle$ denote the content of $r(i)$ and $|\langle r(i) \rangle|$ denote the absolute value of $\langle r(i) \rangle$. The program consists of a finite number of *statements*, numbered $1, 2, \ldots, Q$. Each statement contains one instruction. The allowed instructions are shown in Table 1. The input of R is a binary number $\alpha = \alpha_0 \alpha_1 \ldots \alpha_{n-1}$, where each $\alpha_i \in \{0, 1\}$. Initially, $r(0), r(1), \ldots, r(K-1)$ hold some constant values required in the computation of R, where K is a constant that depends on R; $r(K+i)$ holds α_i for $0 \leq i < n$, and $r(K+n)$ holds -1 to mark the end of the input. All other registers contain 0. A unit-cost RAM executes each instruction in one step. Each step takes unit time. Thus step t takes a unit-cost RAM from time $t-1$ to time t. The running time of a unit-cost RAM is the number of steps performed.

TABLE 1
Instructions of a RAM.

Instruction	Meaning
$r(i) \leftarrow r(j)$	$r(i)$ gets $\langle r(j) \rangle$.
$r(i) \leftarrow (r(0))$	$r(i)$ gets $\langle r(j) \rangle$, where $j = \lvert\langle r(0) \rangle\rvert$.
$(r(0)) \leftarrow r(j)$	$r(i)$ gets $\langle r(j) \rangle$, where $i = \lvert\langle r(0) \rangle\rvert$.
$r(i) \leftarrow r(j) + r(k)$	$r(i)$ gets $\langle r(j) \rangle + \langle r(k) \rangle$.
$r(i) \leftarrow r(j) - r(k)$	$r(i)$ gets $\langle r(j) \rangle - \langle r(k) \rangle$.
JUMP q	If $\langle r(0) \rangle \leq \langle r(1) \rangle$, then jump to statement q.
ACCEPT	Accept and halt.
REJECT	Reject and halt.

2.2. The PRAM. A PRAM P comprises a collection of processors $P(0)$, $P(1)$, ..., which communicate via a global memory $(g(i))$. The initial contents of the global memory are as follows: the first K' global registers hold some constants, where K'

is another constant that depends on P; the next $n+1$ global registers hold the n input bits, followed by the end-of-input marker, and all other global registers contain 0. Every processor is a unit-cost RAM. Each $P(p)$ has its own local memory $(r_p(i))$ and can use every global memory register in the same manner as it uses a local memory register. In addition, each processor has an extra FORK q instruction for processor activation. Initially, only $P(0)$ is active. Whenever a processor executes a FORK q instruction, a new processor is activated and starts running at statement q. When $P(p)$ executes the FORK instruction the tth time, processor $P(2^{t-1}(2p+1))$ is activated. The *processor id* (PID) of $P(p)$ is the integer p. When $P(p)$ is activated, its local register $r_p(0)$ is initialized with its PID p, and all other local registers of $P(p)$ contain 0. The PRAM P accepts if and only if $P(0)$ executes an ACCEPT instruction.

In a PRAM, several processors may attempt to access the same memory cell at the same time. A PRAM may allow concurrent-read and concurrent-write (CRCW) operations, concurrent-read and exclusive-write (CREW) operations, or exclusive-read and exclusive-write (EREW) operations [2, 22, 25]. In a CRCW PRAM, some mechanism is necessary to resolve the simultaneous write conflicts [2, 8, 21]. Fich et al. [5] studied the relationships between CRCW PRAMs with different conflict-resolution mechanisms.

In what follows, we restrict our attention to CREW PRAMs. Unless otherwise stated, our results also hold for CRCW PRAMs.

3. Techniques for programming PRAMs. In this section, we present several techniques for programming the PRAM. First, we show how to perform the following operations quickly on a PRAM: logical AND, summation, and multiplication of "small" integers. Second, we describe a fast implementation of multidimensional memory on a PRAM. Third, we explain how every processor can extract useful information from its PID efficiently.

3.1. Logical AND, summation, and multiple memories. It is convenient to interpret integers as logical values. We interpret a nonzero integer as true and 0 as false.

LEMMA 3.1. [folklore] *Suppose in a PRAM P, the global memory registers $g(1)$, $g(2), \ldots, g(n)$ store n integers $k_1, k_2, \ldots, k_n$. Then P can find the sum and the logical AND of these n integers in $O(\log n)$ time.*

By interleaving memory registers, Cook and Reckhow [3] demonstrated that a unit-cost RAM with a single memory can simulate a unit-cost RAM with multiple memories with merely a constant factor overhead in the running time. By applying the same technique to the PRAM, it is easy to prove the following lemma.

LEMMA 3.2. [folklore] *Let $\gamma > 1$. Every PRAM with time complexity T and γ global memories $(g_1(i)), (g_2(i)), \ldots, (g_\gamma(i))$ can be simulated in time $O(T)$ by a PRAM with one global memory.*

3.2. Multiplication of small integers. Trahan et al. [24] studied PRAMs with unit-time multiplication. By the following lemma, we may assume that ordinary PRAMs can perform unit-time multiplication of "small" integers.

LEMMA 3.3. *Let P be a PRAM that* (i) *runs in time T and* (ii) *can perform unit-time multiplication on T-bit integers. Then P can be simulated by an ordinary PRAM in time $O(T)$.*

Proof. We use a PRAM P' with multiple memories to simulate P. Lemma 3.3 then follows from Lemma 3.2. P' simulates P step by step. We only need to show that P' can multiply two T-bit integers in $O(1)$ time. Multiplication reduces to squaring and halving via the identity $xy = ((x+y)^2 - x^2 - y^2)/2$. For two T-bit integers x

and y, $x+y$ and $2xy$ are, respectively, at most $T+1$ and $2T+1$ bits long. It suffices to show that P' can perform in $O(1)$ time (i) squaring on $(T+1)$-bit positive integers and (ii) halving (right shift) on $(2T+1)$-bit positive integers. Before simulating P, P' precomputes a Square Table of size 2^{T+1} and a Right-Shift Table of size 2^{2T+1}. Then during the simulation, P' can perform squaring and halving in $O(1)$ time by table lookup. It remains to demonstrate that the Square Table and the Right-Shift Table can be precomputed in $O(T)$ time.

P' uses four global memories $(ls(i))$, $(rs(i))$, $(lsb(i))$, and $(sq(i))$ to implement four tables:

1. Left-Shift Table: $\langle ls(i)\rangle = 2i$;
2. Right-Shift Table: $\langle rs(i)\rangle = \lfloor i/2 \rfloor$;
3. Least-Significant-Bit Table: $\langle lsb(i)\rangle =$ least significant bit of i;
4. Square Table: $\langle sq(i)\rangle = i^2$.

P' initializes the first three tables for $0 \le i < 2^{2T+1}$ as follows. In $O(T)$ time, P' activates processors $P(0), P(1), \ldots, P(2^{2T+1}-1)$. Each processor does the following:

1. Store PID + PID in ls(PID).
2. Store PID in rs(PID + PID) and rs(PID + PID + 1).
3. Store PID $-$ $ls(rs(\text{PID}))$ in lsb(PID).

Obviously, steps 1, 2, and 3 take $O(1)$ time. After the Left-Shift Table, the Right-Shift Table, and the Least-Significant-Bit Table are initialized, then for $0 \le i < 2^{T+1}$, each $P(i)$ computes the square of its PID using the paper–pencil multiplication method (repeated shift and add) and stores the result in $sq(i)$. This takes $O(T)$ time. Hence all four tables can be precomputed in $O(T)$ time.

We have assumed that P' knows the value of T a priori. This assumption can be removed easily; P' just tries successive powers of two as an estimate of T. This modification does not increase the asymptotic running time of P'. □

3.3. Multidimensional memory. A d-dimensional RAM is one with memory $(r(i_1, i_2, \ldots, i_d))$, where $i_1, i_2, \ldots, i_d \ge 0$. A d-dimensional PRAM is one with global memory $(g(i_1, i_2, \ldots, i_d))$; each processor of a d-dimensional PRAM is a d-dimensional RAM. Robson [19] showed that ordinary RAMs can simulate multidimensional RAMs with only a constant-factor overhead in the running time. However, the proof of Robson cannot be adapted directly to prove the analogous result for PRAMs. Briefly, the reason is as follows. To simulate a RAM R with two-dimensional memory $(r(i,j))$ by an ordinary RAM R' with memory $(r'(i))$, Robson devised a mapping from the $r(i,j)$'s to the $r'(i)$'s. This mapping depends on the sequence of $r(i,j)$'s accessed during the computation of R, and R' constructs this mapping incrementally as it simulates R step by step. Consider applying the same idea to simulate a PRAM P with two-dimensional global memory $(g(i,j))$ by an ordinary PRAM P' with global memory $(g'(i))$. If we simulate each processor of P by a corresponding processor of P' as in the proof of Robson, then different processors of P may access the $g(i,j)$'s in different ways, and hence different processors of P' may have different mappings. Thus some processor of P' may think that the value of $g(0,0)$ is stored in $g'(0)$, whereas another processor of P' thinks that the same value is stored in $g'(1)$. Obviously, such a simulation of P by P' does not work.

All in all, the analogous result for PRAMs does hold, as shown by the next lemma.

LEMMA 3.4. *Every d-dimensional PRAM P running in time T can be simulated by an ordinary PRAM P' in time $O(T)$.*

Proof. P' uses processor $P'(i)$ to simulate the corresponding processor $P(i)$ of P. Every $P'(i)$ simulates $P(i)$ step by step. It suffices to explain how to emulate d-dimensional memories by one-dimensional memories. We demonstrate how $P'(i)$

emulates an access of $P(i)$ to the d-dimensional global memory of P by an access to the one-dimensional global memory of P'. $P'(i)$ uses its one-dimensional local memory to emulate the d-dimensional local memory of $P(i)$ in a similar fashion.

P has global memory $(g(i_1, i_2, \ldots, i_d))$; P' has global memory $(g'(i))$. In time T, $P(i)$ can produce integers no longer than CT bits for some constant C. Define $b = 2^{CT}$ and $\eta(i_1, i_2, \ldots, i_d) = \sum_{j=1}^{d} i_j b^{j-1}$. We map $g(i_1, i_2, \ldots, i_d)$ of P to $g'(\eta(i_1, i_2, \ldots, i_d))$ of P'. It is easy to verify that the $\eta(i_1, i_2, \ldots, i_d)$'s are distinct for $0 \leq i_1, i_2, \ldots, i_d < 2^{CT}$. To emulate an access to $g(i_1, i_2, \ldots, i_d)$ by $P(i)$, $P'(i)$ computes $\eta(i_1, i_2, \ldots, i_d)$ and accesses $g'(\eta(i_1, i_2, \ldots, i_d))$.

It remains to show that computing η takes $O(1)$ time. By repeated doubling, $b = 2^{CT}$ can be precomputed in $O(T)$ time. For $i_1, i_2, \ldots, i_d < 2^{CT}$, η is at most dCT bits long. By Lemma 3.3, we may assume that $P'(i)$ can perform multiplication on dCT-bit integers in $O(1)$ time. Thus $P'(i)$ can compute η in $O(1)$ time.

Again, we have presumed that the value of T is available. This assumption can be removed in the same way as in the proof of Lemma 3.3. □

Lemma 3.4 shows that without loss of generality, we may assume that CREW PRAMs have multidimensional memories. Apparently, some authors have used this fact without proof [4, 17].

3.4. Extracting information from the PID. The advantage of a PRAM over a RAM is that in a PRAM, many processors can work together in parallel. Clearly, this advantage is defeated if all processors just do the same thing on the same data, in which case one processor is as good as many. To take advantage of the parallelism, therefore, different processors have to operate differently. This is easily achieved by exploiting the distinctness of the PIDs; each processor consults its PID to determine its operation. For our later purpose, we require each processor to be able to look at successive single bits and successive $O(\log T)$ bits of its PID in order to determine its operation. Next, we demonstrate that every PRAM can be modified to fulfill this requirement.

Let P be a PRAM with time complexity T. In time T, P can activate at most 2^T processors. The PID of every processor is at most T bits long. We modify P as follows.

1. P activates all 2^T processors before any actual computation.

2. P starts its computation by initializing in $O(1)$ time a Least-Significant-Bit Table, a Right-Shift Table, and a Left-Shift Table, all of size 2^T, as described in the proof of Lemma 3.3. Using the first two tables, each processor can extract successive single bits of its PID, spending $O(1)$ time per bit.

3. P implements two additional tables with global memories $(lsb'(i))$ and $(rs'(i))$:

(i) $lsb'(i)$ = the least significant $\lfloor \log T \rfloor$ bits of i.

(ii) $rs'(i) = \lfloor i/2^{\lfloor \log T \rfloor} \rfloor$, i.e., i right-shifted $\lfloor \log T \rfloor$ bits.

These two tables can be precomputed in $O(\log T)$ time as follows. We presume the availability of the three tables mentioned in modification 2. For $0 \leq i < 2^T$, processor $P(i)$ does the following:

(i) Right shift its PID $\lfloor \log T \rfloor$ times and store the result in $rs'(i)$.

(ii) Left shift $rs'(i)$ $\lfloor \log T \rfloor$ times, subtract the result from its PID, and store the difference in $lsb'(i)$.

Then each processor can extract successive $\lfloor \log T \rfloor$ bits of its PID by table lookup, spending $O(1)$ time per $\lfloor \log T \rfloor$ bits. We have assumed that P knows a priori the values of T and $\lfloor \log T \rfloor$. The knowledge of T is justifiable, as argued in the proof of Lemma 3.3, and $\lfloor \log T \rfloor$ is simply the number of bits in the binary representation

of T.

These modifications increase the running time of P by at most a constant factor.

4. Speedup of RAMs by PRAMs. We now prove that the PRAM is always faster than the RAM.

THEOREM 4.1. *Every unit-cost RAM running in time T can be simulated by a CREW PRAM in time $O(T^{1/2}\log T)$ with $T^{O(T^{1/2})}$ processors.*

Let R be a unit-cost RAM with memory $(r(i))$ and time complexity $T = T(n)$. We devise a CREW PRAM P with multiple multidimensional memories that simulates R in time $O(T^{1/2}\log T)$. Theorem 4.1 then follows from Lemmas 3.2 and 3.4. Let A be a large enough constant so that every address in the program of R can be encoded in A bits; we choose A to be at least $3\log 3 + 1$ to suit our later purpose. As the input length n tends to infinity, so does T since $T(n) \geq n$. Consequently, if n exceeds some constant n_0, then $AT^{1/2} > \log(2(T+K+n+1))$, where K is a constant that depends on R as explained in section 2.1. It suffices to argue that P runs in $O(T^{1/2}\log T)$ time for $n > n_0$ since we can modify P to handle inputs of length less than n_0 by table lookup. We assume that P knows the value of $T^{1/2}$ in advance. Otherwise, P tries successive powers of two as an estimate of $T^{1/2}$.

4.1. Overview of simulation. Dymond and Tompa [4] proved that every Turing machine with time complexity t can be sped up by a CREW PRAM in time $O(t^{1/2})$; briefly, their proof is as follows. In $O(t^{1/2})$ time, the PRAM precomputes a transition table that represents the $t^{1/2}$-step transition function of the Turing machine. Then the PRAM can simulate a block of $t^{1/2}$ steps of the Turing machine in $O(1)$ time by consulting this table. The PRAM accesses this table $t^{1/2}$ times to simulate the Turing machine for t steps. We would like to point out that this standard technique of precomputing a transition table, though useful for simulating the Turing machine, cannot be applied to speed up the unit-cost RAM by the CREW PRAM. Below we explain why this technique works for the Turing machine but not the unit-cost RAM.

In $t^{1/2}$ steps, the changes in the configuration of a Turing machine M depend only on the *local configuration* of M, i.e., the state of M and the contents of $O(t^{1/2})$ cells around each tape head. Consider a transition table that maps the current local configuration of M to the local configuration $t^{1/2}$ steps afterwards. Such a table contains $2^{O(t^{1/2})}$ entries since there are $2^{O(t^{1/2})}$ different local configurations. A CREW PRAM can build this table in $O(t^{1/2}) = o(t)$ time. Thus an asymptotic speedup is possible.

Now consider the unit-cost RAM R (with time complexity T). In $T^{1/2}$ steps, the changes in the configuration of R are not localized to $O(T^{1/2})$ consecutive registers; the PRAM P cannot build a transition table for local configurations as in the case of the Turing machine. In time T, R can construct integers as large as $2^{\Theta(T)}$. With indirect addressing, R may use these integers as addresses and assigns to register $r(i)$ an integer j, where $0 \leq i, j \leq 2^{\Theta(T)}$. In T steps, R can write to $\Theta(T)$ different registers. Hence there are at least $(2^{\Theta(T)})^{\Theta(T)} = 2^{\Omega(T^2)}$ different configurations of R. A transition table that maps the current configuration of R to the configuration $T^{1/2}$ steps afterwards will have $2^{\Omega(T^2)}$ entries. To generate such a huge table, P requires $\Omega(T^2) = \omega(T)$ time; this results in an asymptotic slowdown. Therefore, the technique of precomputing a transition table does not work for the unit-cost RAM. The novel idea in this paper is to simulate the unit-cost RAM without building its transition table.

Fix an input $\alpha = \alpha_0\alpha_1 \ldots \alpha_{n-1}$ and consider the computation of R on α. Formally, the configuration of R at time t consists of the statement number of R at time

t and the contents of all registers at time t. Denote the configuration of R at time t by *config*(t).

Our simulation comprises two phases. In phase I, P uses $O(T^{1/2}\log T)$ time to activate $T^{1/2}$ groups of $T^{O(T^{1/2})}$ processors. For $1 \le m \le T^{1/2}$, the processors in group m perform some preprocessing such that after the preprocessing, *config*$(mT^{1/2})$ can be computed from *config*$((m-1)T^{1/2})$ in $O(\log T)$ time. All groups do the preprocessing simultaneously. In phase II, P finds *config*(T) as follows. The initial configuration of R, *config*(0), can be determined trivially. For $m = 1, 2, \ldots, T^{1/2}$, P computes *config*$(mT^{1/2})$ from *config*$((m-1)T^{1/2})$ in $O(\log T)$ time. Let q^* be the statement number in *config*(T). P accepts if and only if statement q^* contains an ACCEPT instruction. Both phases take $O(T^{1/2}\log T)$ time. Next, we present an efficient representation of the configuration of R and then provide the details of phases I and II.

4.2. Representing the configuration of *R*. The PRAM P uses a data structure CONFIG to represent the configuration of R. One difficulty is that P cannot use a single register to store the content of a corresponding register of R. This is because R can generate integers as large as $2^{O(T)}$ in time T, but P can produce integers no larger than $T^{O(T^{1/2})}$ within the intended $O(T^{1/2}\log T)$ time bound. To overcome this difficulty, P divides every $O(T)$-bit integer into $N = O(T^{1/2})$ blocks, each $B = AT^{1/2}$ bits long. Without loss of generality, we assume that R represents negative integers using sign-and-magnitude representation; thus R works with nonnegative integers exclusively. With this simplifying assumption, every block in our blockwise representation is a nonnegative integer.

Initially, all registers of R contain 0, except for $r(0), r(1), \ldots, r(K+n)$. By convention, the first step of R is step 1, and $r(0), r(1), \ldots, r(K+n)$ are first written to in step 0 (i.e., they are initialized at time 0). For $0 \le i \le K+n$, let u_i denote $r(i)$. For $i > K+n$, if a new register of R is written to in step $i-K-n$, then let u_i denote this register; otherwise, u_i is undefined. To describe the configuration of R at time t, it suffices to specify the statement number of R at time t and the address and content at time t of u_i for $0 \le i \le t+K+n$.

CONFIG consists of three global memories $(a(i,j))$, $(c(i,j))$, and $(b(i))$. To represent the configuration of R at time t, register $b(0)$ holds the statement number of R at time t. If $0 \le i \le t+K+n$ and u_i is defined, then $c(i,j)$ holds the jth block of B bits in $\langle u_i \rangle$. Thus $\langle u_i \rangle = \sum_{j=0}^{N-1} \langle c(i,j) \rangle 2^{jB}$. For brevity, we say that $c(i)$ holds $\langle u_i \rangle$, or $\langle c(i) \rangle = \langle u_i \rangle$, implying the blockwise representation. Register $a(i)$ holds the address of u_i in the same blockwise format. If $t < i-K-n \le T$ or u_i is undefined, then $a(i)$ holds -1, and $c(i)$ is not used. The number of registers that CONFIG uses is therefore $O(NT) = O(T^{3/2})$.

Henceforth, when we mention *config*(t), we imply the above representation.

4.3. Phase I.

4.3.1. Static, dynamic, and effective instructions. Due to conditional jumps, a program statement may be executed more than once. For clarity, we distinguish between a *static instruction* and a *dynamic instruction*. The former is a static entity in a program statement of R. The latter is an executed instruction—an instance of a static instruction during the computation of R. A static instruction may correspond to none or many dynamic instructions.

Divide the dynamic instructions of R into three types:

1. ACCEPT, REJECT, and JUMP;

2. direct and indirect load and store instructions: $r(i) \leftarrow r(j)$, $r(i) \leftarrow (r(0))$, and $(r(0)) \leftarrow r(j)$;

3. arithmetic operations: $r(i) \leftarrow r(j) + r(k)$ and $r(i) \leftarrow r(j) - r(k)$.

Consider the effect of each dynamic instruction on the memory of R. A type-1 instruction does not change the content of any register. As far as the effect on the memory is concerned, a type-1 instruction is equivalent to a $u_0 \leftarrow u_0$ instruction. An instruction of type-2 copies the content of one register to another. Without loss of generality, we assume that $r(K-1)$ always holds 0. Reading from an uninitialized register is the same as reading from $r(K-1) = u_{K-1}$ since all uninitialized registers contain 0. The effect of a type-2 instruction is thus $u_{i'} \leftarrow u_{j'}$ for some $0 \le i', j' \le T+K+n$. A type-3 instruction finds the sum or difference of the contents of two registers and stores the result in a third register. The effect of a type-3 instruction is either $u_{i'} \leftarrow u_{j'} + u_{k'}$ or $u_{i'} \leftarrow u_{j'} - u_{k'}$ for some $0 \le i', j', k' \le T + K + n$. Therefore, each dynamic instruction is, in effect, of the form $u_{i'} \leftarrow u_{j'}$, $u_{i'} \leftarrow u_{j'} + u_{k'}$, or $u_{i'} \leftarrow u_{j'} - u_{k'}$ for some $0 \le i', j', k' \le T + K + n$. Since $T = T(n) \ge n$, there are $O(T^3)$ *effective instructions* of the above forms. Note that one static instruction may correspond to several dynamic instructions, each equivalent to a different effective instruction.

4.3.2. The preprocessing. We fix m and describe the processors in group m. Let π_m be the triple (q_m, β_m, σ_m), where q_m is the statement number of R at time $(m-1)T^{1/2}$, σ_m is the sequence of $T^{1/2}$ effective instructions from time $(m-1)T^{1/2}$ to $mT^{1/2}$, and β_m is a binary string that encodes the outcomes of all conditional jumps between time $(m-1)T^{1/2}$ and $mT^{1/2}$. For uniformity, we view every static and dynamic instruction as a conditional jump. An ACCEPT instruction, for example, may be viewed as a conditional jump where the condition is always false, and the destination of the jump is statement 1. In this way, β_m is always of length $T^{1/2}$. The triple π_m specifies the behavior of R between time $(m-1)T^{1/2}$ and $mT^{1/2}$. Using the information contained in π_m, group m performs some preprocessing that enables *config*$(mT^{1/2})$ to be computed from *config*$((m-1)T^{1/2})$ quickly. One problem is that group m does not know π_m in advance. To surmount this problem, group m uses enough processors to try all possible triples. Let Q be the number of statements in the program of R. The number of possible triples is thus $Q \times 2^{T^{1/2}} \times O(T^3)^{T^{1/2}} = T^{O(T^{1/2})}$. Group m uses $T^{O(T^{1/2})}$ processors, which can be activated in $O(T^{1/2} \log T)$ time. Each processor is responsible for a distinct triple, which is encoded in the processor's PID. All processors in all groups carry out their preprocessing simultaneously in parallel.

We focus on one specific processor P_π of group m, which is responsible for one particular triple $\pi = (q, \beta, \sigma)$. Notice the difference in notation: the PID of $P(p)$ is p, whereas the PID of P_π is not π, but the triple π is encoded in the PID of P_π. P_π decodes its PID to obtain q, β, and σ. To obtain the sequence of $T^{1/2}$ effective instructions σ, P_π extracts the least significant $O(T^{1/2} \log T)$ bits from its PID, $O(\log T)$ bits at a time. Every effective instruction can be encoded in $O(\log T)$ bits since there are $O(T^3)$ different effective instructions. To recover the individual bits of β, P_π extracts the next $T^{1/2}$ bits from its PID, one bit at a time. The next $\lfloor \log Q \rfloor + 1$ bits of the PID constitute q. Using the techniques prescribed in section 3.4, P_π can decode its PID in $O(T^{1/2})$ time. P_π saves all decoded information in tables so that it can access each bit of β and each effective instruction in $O(1)$ time by table lookup.

To facilitate our discussion, we say the triple π "happens" if the actual behavior of R conforms with the information contained in π. Now π may or may not happen. In phase I, P_π performs some preprocessing so that in phase II, once *config*$((m-1)T^{1/2})$ has been computed, P_π is able to decide in $O(\log T)$ time whether π actually happens

and, if so, computes *config*$(mT^{1/2})$ from *config*$((m-1)T^{1/2})$ in $O(\log T)$ time. Because of the way we represent the configuration of R (section 4.2), to compute *config*$(mT^{1/2})$ from *config*$((m-1)T^{1/2})$, it suffices to determine the following:

1. the statement number of R at time $mT^{1/2}$;
2. for $(m-1)T^{1/2} < i - K - n \le mT^{1/2}$, the address of u_i if u_i is defined;
3. for $0 \le i \le mT^{1/2} + K + n$, the content of u_i at time $mT^{1/2}$ if u_i is defined.

Below we explain the preprocessing that enables P_π to determine each of the above three items efficiently in phase II, assuming π actually happens.

4.3.3. The statement number. Starting from statement q, P_π steps through the program of R statement by statement, following the flow of control defined by β. Meanwhile, P_π keeps track of the statement number of R. After $T^{1/2}$ steps, P_π obtains the statement number of R at time $mT^{1/2}$. This preprocessing takes $O(T^{1/2})$ time.

4.3.4. The addresses of the u_i's. In $O(\log T)$ time, P_π activates $T^{1/2}$ processors P_i, where $(m-1)T^{1/2} < i - K - n \le mT^{1/2}$. Each P_i is responsible for finding the address of u_i.

We fix i and describe P_i. P_i considers the effective instruction in step $s = i-K-n$ given by σ. Suppose this effective instruction is of the form $u_{i'} \leftarrow u_{j'}$. Other cases are handled similarly. If $i' \ne i$, then no new register is written to in step s, and u_i is undefined. Otherwise, u_i is the register first written to in step s. P_i steps through the program of R in the same manner as described in section 4.3.3 and finds the dynamic instruction in step s. If this dynamic instruction is of the form $r(j) \leftarrow r(k)$ or $r(j) \leftarrow (r(0))$, then the address of u_i is j. The blockwise representation of j is readily obtained since all addresses in the program of R are at most $A \le B$ bits long; the least significant B-bit block of j is just j itself, and all other blocks are 0. If the dynamic instruction in step s is of the form $(r(0)) \leftarrow r(k)$, then the address of u_i is the content of $r(0)$ at time $s-1$. Denote by $\langle u_i, t\rangle$ the content of u_i at time t. In section 4.3.5, we explain the preprocessing for finding $\langle u_i, mT^{1/2}\rangle$. P_i performs the preprocessing for finding $\langle r(0), s-1\rangle = \langle u_0, s-1\rangle$ in a similar fashion.

4.3.5. The contents of the u_i's. Since the sole arithmetic operations permitted are addition and subtraction, it follows that for a fixed π, $\langle u_i, mT^{1/2}\rangle$ is a linear combination of the $\langle u_i, (m-1)T^{1/2}\rangle$'s. Let

$$\langle u_i, mT^{1/2}\rangle = \sum_{j=0}^{T+K+n} C_{ij}\langle u_j, (m-1)T^{1/2}\rangle,$$

where the C_{ij}'s are integer coefficients which depend only on π. In $O(\log T)$ time, P_π deploys $O(T^2)$ processors P_{ij}, where $0 \le i, j \le T+K+n$. Each P_{ij} finds C_{ij} in phase I.

We fix i and j and describe P_{ij}. P_{ij} creates an empty directed multigraph G and then processes the effective instructions specified by σ one by one. As P_{ij} considers each effective instruction, it inserts nodes and edges into G. P_{ij} marks each edge either "positive" or "negative." Node w is a positive child of node v if the edge (v, w) is positive. A negative child is defined analogously. Let v^+ and v^-, respectively, be the set of positive and negative children of v.

P_{ij} maintains a counter τ to keep track of the step corresponding to the effective instruction currently under consideration. P_{ij} initializes τ to $(m-1)T^{1/2}+1$ and increments τ after every effective instruction. P_{ij} names each node either $[u_k, (m-1)T^{1/2}]$ or $[u_k, \tau]$ for some $0 \le k \le T+K+n$. Intuitively, node $[u_k, t]$ represents

$\langle u_k, t\rangle$. For a node $v = [u_k, t]$, we write $\langle v\rangle$ for $\langle u_k, t\rangle$. The edges are marked such that

$$\langle v\rangle = \sum_{w\in v^+} \langle w\rangle - \sum_{w\in v^-} \langle w\rangle \quad \text{for each node } v. \tag{1}$$

This will become clear after we explain how P_{ij} constructs G. After processing all $T^{1/2}$ effective instructions, P_{ij} uses G to obtain C_{ij}.

4.3.6. Constructing G. P_{ij} considers the $T^{1/2}$ effective instructions specified by σ one by one and constructs G as follows. For a $u_{i'} \leftarrow u_{j'}$ instruction, P_{ij} does the following. Create node $[u_{i'}, \tau]$. If G does not contain a node $[u_{j'}, \tau']$ for some $\tau' < \tau$, then create node $[u_{j'}, (m-1)T^{1/2}]$. Let $\tau_{j'} < \tau$ be maximum such that G contains node $[u_{j'}, \tau_{j'}]$. Insert edge $([u_{i'}, \tau], [u_{j'}, \tau_{j'}])$ and mark it positive.

P_{ij} processes a $u_{i'} \leftarrow u_{j'} - u_{k'}$ instruction as follows. Create node $[u_{i'}, \tau]$. If G does not contain a node $[u_{j'}, \tau']$ for some $\tau' < \tau$, then create node $[u_{j'}, (m-1)T^{1/2}]$. Similarly, if G does not contain a node $[u_{k'}, \tau']$ for some $\tau' < \tau$, then create node $[u_{k'}, (m-1)T^{1/2}]$. Let $\tau_{j'}, \tau_{k'} < \tau$ be maximum such that G contains nodes $[u_{j'}, \tau_{j'}]$ and $[u_{k'}, \tau_{k'}]$. Insert a positive edge $([u_{i'}, \tau], [u_{j'}, \tau_{j'}])$ and a negative edge $([u_{i'}, \tau], [u_{k'}, \tau_{k'}])$. A $u_{i'} \leftarrow u_{j'} + u_{k'}$ instruction is processed in the same way except that both of the inserted edges are positive.

It is mechanical to verify that the above construction yields a graph which satisfies (1), and every node of the graph has out-degree at most two. We illustrate the above construction with an example for P_π of group $m = 1$ with $T^{1/2} = 5$. Figure 1 shows the effective instructions specified by π. The graph constructed by P_{ij} appears in Fig. 2.

Step	Instruction
1	$u_0 \leftarrow u_1$
2	$u_0 \leftarrow u_0 + u_0$
3	$u_0 \leftarrow u_0 - u_2$
4	$u_1 \leftarrow u_1 + u_0$
5	$u_0 \leftarrow u_0 + u_1$

Effect on memory: $\langle u_0, 5\rangle = 5\langle u_1, 0\rangle - 2\langle u_2, 0\rangle$,
$\langle u_1, 5\rangle = 3\langle u_1, 0\rangle - \langle u_2, 0\rangle$.

In this example, $C_{01} = 5$, $C_{02} = -2$, $C_{11} = 3$, and $C_{12} = -1$.

FIG. 1. *The $T^{1/2} = 5$ effective instructions specified by π and their effect on the memory (example).*

4.3.7. Computing C_{ij}. We explain how P_{ij} uses G to compute C_{ij}. P_{ij} checks whether G contains a node $[u_i, \tau']$ for some $\tau' > (m-1)T^{1/2}$.

Case I (no such node exists). By construction of G, P_{ij} will create node $[u_i, \tau']$ if R writes to u_i in step τ'. The hypothesis thus implies that R does not write to u_i between time $(m-1)T^{1/2}$ and $mT^{1/2}$. It follows that $\langle u_i, mT^{1/2}\rangle = \langle u_i, (m-1)T^{1/2}\rangle$. Ergo, $C_{ij} = 0$ for $j \neq i$, and $C_{ii} = 1$.

Case II (otherwise). Let τ_i be maximum such that G contains node $[u_i, \tau_i]$. Similar arguments as in Case I give $\langle u_i, mT^{1/2}\rangle = \langle u_i, \tau_i\rangle$.

Consider the subgraph H of G induced by node $[u_i, \tau_i]$ and all its descendants. By construction, G (and hence H) is a directed acyclic multigraph. P_{ij} sorts the nodes in H topologically and labels each edge in H with an integer as follows. P_{ij} considers the nodes in H in topological order. For each node v, P_{ij} labels the outgoing edges of v. When P_{ij} considers node v, all incoming edges of v are labeled since P_{ij} considers the

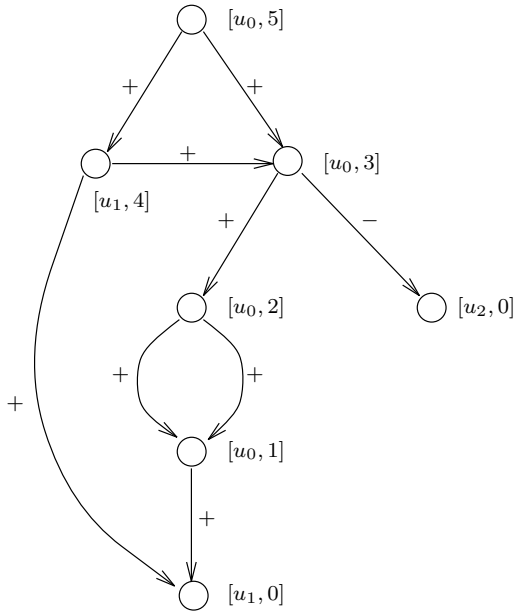

FIG. 2. *The graph G constructed by P_{ij} after processing the effective instructions in Fig.* 1.

nodes in topological order. Evidently, the first node considered is $[u_i, \tau_i]$. P_{ij} labels every positive and negative outgoing edge of $[u_i, \tau_i]$ with 1 and -1, respectively. For each remaining node v in topological order, let $\lambda(H, v)$ be the sum of the labels on the incoming edges of v in H. P_{ij} labels each positive and negative outgoing edge of v with $\lambda(H, v)$ and $-\lambda(H, v)$, respectively. Figure 3 shows the result of applying the above labeling algorithm to the graph in Fig. 2.

For $s > 0$, let H_s be the subgraph of H induced by all labeled edges after s nodes are considered. The *leaves* of H_s, denoted by $L(H_s)$, are the nodes in H_s with no outgoing edges. The following invariant is a consequence of (1): After s nodes are considered, $\langle u_i, \tau_i \rangle = \sum_{v \in L(H_s)} \lambda(H_s, v)\langle v \rangle$. Therefore, after all edges in H are labeled, $\langle u_i, mT^{1/2} \rangle = \sum_{v \in L(H)} \lambda(H, v)\langle v \rangle$. By construction, every leaf of H is named $[u_j, (m-1)T^{1/2}]$ for some j. Hence $C_{ij} = \lambda(H, [u_j, (m-1)T^{1/2}])$ if $[u_j, (m-1)T^{1/2}]$ is a leaf of H; otherwise, $C_{ij} = 0$. For the example in Fig. 3, P_{01} determines that $C_{01} = 4 + 1 = 5$, and P_{02} concludes that $C_{02} = -2$.

In the above labeling algorithm, the sum of the absolute values of all the labels on the edges of H_s is at most triple that of H_{s-1} since every node in H has out-degree at most two. The number of nodes in H is $|H| \leq |G| \leq 3T^{1/2}$ because at most three nodes are created for each of the $T^{1/2}$ effective instructions. Therefore, $|C_{ij}| \leq 3^{3T^{1/2}}$ for all i and j. Each C_{ij} is at most $B = AT^{1/2}$ bits long, since $A \geq 3 \log 3 + 1$.

The number of edges in G is $O(|G|)$, since each node has bounded out-degree. Constructing G and H, topologically sorting H, labeling the edges of H, and computing $\lambda(H, [u_j, (m-1)T^{1/2}])$ all take $O(|G|) = O(T^{1/2})$ time. Thus the bottleneck in phase I is the activation of enough processors to try all possible π, which takes $O(T^{1/2} \log T)$ time.

4.3.8. Table precomputation. In phase II, P has to extract efficiently the most and least significant B bits of a $2B$-bit integer. In phase I, P precomputes two tables $(h1(i))$ and $(h2(i))$ so that the first and second half of i can be ex-

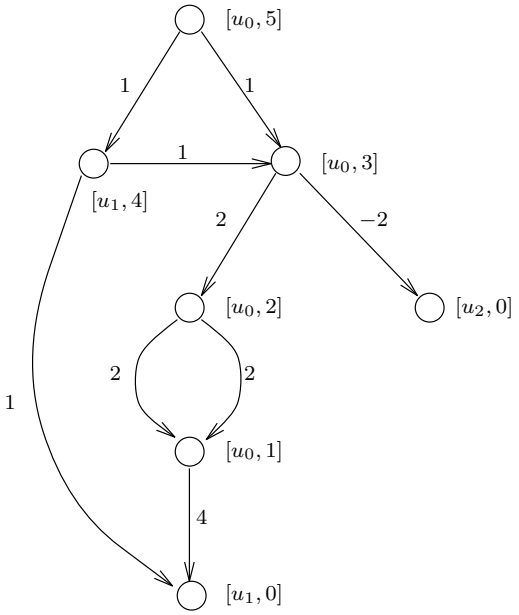

FIG. 3. *The result of applying the labeling algorithm of section* 4.3.7 *to the graph in Fig.* 2.

tracted in $O(1)$ time by table lookup. P uses $O(T^{1/2})$ time to activate processors $P(0), P(1), \ldots, P(2^{2B}-1)$ and builds up a Left-Shift Table and a Right-Shift Table of size 2^{2B} as in the proof of Lemma 3.3. Next, for $0 \le i < 2^{2B}$, each $P(i)$ extracts in $O(T^{1/2})$ time the first and second halves of its PID as follows. The first half is obtained by shifting the PID right B times using the Right-Shift Table. The second half is obtained by shifting the first half left B times and subtracting the (shifted) first half from the PID. $P(i)$ stores the first and second halves in $h1(i)$ and $h2(i)$, respectively. Hence the two tables $(h1(i))$ and $(h2(i))$ can be precomputed in $O(B) = O(T^{1/2})$ time.

4.4. Phase II. The data structure CONFIG has $O(T^{3/2})$ registers. In phase II, P initializes CONFIG in parallel using $O(\log T)$ time so that CONFIG contains *config*(0). For $m = 1, 2, \ldots, T^{1/2}$, the $T^{O(T^{1/2})}$ processors in group m do the following:

1. Each processor P_π in group m checks in $O(\log T)$ time whether π actually happens.

2. If so, compute *config*$(mT^{1/2})$ from *config*$((m-1)T^{1/2})$ (stored in CONFIG) in $O(\log T)$ time and update CONFIG accordingly.

After $T^{1/2}$ updates, CONFIG contains *config*(T). P accepts if and only if statement q^* contains an ACCEPT instruction, where q^* is the statement number in *config*(T). Notice that in step 1, exactly one P_π determines that π happens. So in step 2, no write conflicts arise when updating CONFIG.

Next, we demonstrate that P_π can compute *config*$(mT^{1/2})$ from *config*$((m-1)T^{1/2})$ in $O(\log T)$ time, provided that π actually happens. In section 4.5, we prove that $O(\log T)$ time suffices to verify whether π actually happens. The preprocessing of section 4.3.3 yields the statement number at time $mT^{1/2}$ directly. For $(m-1)T^{1/2} < i - K - n \le mT^{1/2}$, the preprocessing of section 4.3.4 either gives the address of u_i directly or reduces the problem of finding the address of u_i to that of finding the content of u_0. It remains to explain how to determine the contents of the u_i's.

4.4.1. Computing contents of registers. We now explain how P_π computes the contents of the u_i's at time $mT^{1/2}$ from the contents of the u_i's at time $(m-1)T^{1/2}$. Suppose *config*$((m-1)T^{1/2})$ is available in CONFIG as described in section 4.2. Then $c(j,k)$ holds the kth B-bit block of $\langle u_j, (m-1)T^{1/2}\rangle$. Recall that

1. $\langle u_i, mT^{1/2}\rangle = \sum_{j=0}^{T+K+n} C_{ij}\langle u_j, (m-1)T^{1/2}\rangle$;
2. in phase I, P_π dispatches processor P_{ij} to calculate C_{ij};
3. C_{ij} is a B-bit integer.

The product $C_{ij}\langle c(j,k)\rangle$ is thus a $2B$-bit integer. In phase II, the P_{ij}'s cooperate to compute $\langle u_i, mT^{1/2}\rangle$ in $O(\log T)$ time as follows. The P_{ij}'s use four multidimensional global memories $(g(i_1,i_2,i_3,i_4))$, $(g'(i_1,i_2,i_3,i_4))$, $(h(i_1,i_2,i_3))$, and $(h'(i_1,i_2,i_3))$. Let p be the PID of P_π. In $O(\log T)$ time, every P_{ij} activates $O(T)$ processors P'_k, where $0 \le k \le T+K+n$. Each P'_k multiplies C_{ij} with $\langle c(j,k)\rangle$ and puts the most and least significant B bits of the product in $g'(p,i,j,(k+1))$ and $g(p,i,j,k)$, respectively. By Lemma 3.3, we may assume that the multiplication requires $O(1)$ time. Extracting the most and least significant B bits also takes $O(1)$ time as discussed in section 4.3.8. Then

$$\langle u_i, mT^{1/2}\rangle = \sum_{j=0}^{T+K+n} C_{ij}\langle c(j)\rangle, \tag{2}$$

$$\langle c(j)\rangle = \sum_{k=0}^{N-1} \langle c(j,k)\rangle 2^{kB}, \tag{3}$$

$$C_{ij}\langle c(j,k)\rangle = \langle g'(p,i,j,(k+1))\rangle 2^B + \langle g(p,i,j,k)\rangle. \tag{4}$$

From (2), (3), and (4),

$$\langle u_i, mT^{1/2}\rangle = \sum_{j=0}^{T+K+n}\sum_{k=0}^{N} (\langle g'(p,i,j,k)\rangle + \langle g(p,i,j,k)\rangle)2^{kB}. \tag{5}$$

Next, P_π uses $O(\log T)$ time to deploy $O(T^{3/2})$ processors P'_{ik}, where $0 \le i \le T+K+n$ and $0 \le k \le N$. Each P'_{ik} computes the sum

$$\phi_{ik} = \sum_{j=0}^{T+K+n} (\langle g'(p,i,j,k)\rangle + \langle g(p,i,j,k)\rangle)$$

in $O(\log T)$ time (Lemma 3.1). The sum of $2(T+K+n+1)$ integers, each B bits long, is at most $B + \log(2(T+K+n+1)) \le 2B$ bits long. P'_{ik} extracts the most and least significant B bits of ϕ_{ik} and places them in $h'(p,i,(k+1))$ and $h(p,i,k)$, respectively. Therefore,

$$\sum_{j=0}^{T+K+n} (\langle g'(p,i,j,k)\rangle + \langle g(p,i,j,k)\rangle) = h'(p,i,(k+1))2^B + h(p,i,k). \tag{6}$$

Let $\psi_i = \sum_{k=0}^{N+1}\langle h(p,i,k)\rangle 2^{kB}$ and $\psi'_i = \sum_{k=0}^{N+1}\langle h'(p,i,k)\rangle 2^{kB}$. From (5) and (6),

$$\langle u_i, mT^{1/2}\rangle = \sum_{k=0}^{N+1} (\langle h'(p,i,k)\rangle + \langle h(p,i,k)\rangle)2^{kB} = \psi'_i + \psi_i. \tag{7}$$

Consider the carries into and out of the kth B-bit block when we add ψ and ψ' together. By (7), the kth block of $\langle u_i, mT^{1/2}\rangle$ is (roughly) $\langle h'(p,i,k)\rangle + \langle h(p,i,k)\rangle$,

except that we have to adjust for the carries into and out of the kth block. A carry into the block amounts to an increment by 1, whereas a carry out of the block is offset by subtracting 2^B. The value 2^B is precomputed during phase I in $O(B) = O(T^{1/2})$ time by repeated doubling. In section 4.4.2, we show that all block-to-block carries can be determined in $O(\log T)$ time. To update $c(i)$ with $\langle u_i, mT^{1/2}\rangle$, every P'_{ik} finds the kth block of $\langle u_i, mT^{1/2}\rangle$ (by adding $\langle h'(p,i,k)\rangle$ and $\langle h(p,i,k)\rangle$ and adjusting for the carries) and updates $c(i,k)$ accordingly. Hence P_π is able to compute *config*$(mT^{1/2})$ from *config*$((m-1)T^{1/2})$ in $O(\log T)$ time during phase II.

In the above discussion, we have presumed that all C_{ij}'s are positive. Strictly speaking, to calculate $\langle u_i, mT^{1/2}\rangle = \sum_{j=0}^{T+K+n} C_{ij}\langle c(j)\rangle$, we have to sum up the positive and the negative components separately using the above method, do a blockwise subtraction, and adjust for the block-to-block borrows. The calculation of the borrows is analogous to that of the carries.

4.4.2. Computing the carries. Consider adding two $O(T)$-bit integers together. By parallel-prefix computation [1, 11], it is possible to determine all the bit-to-bit carries in $O(\log T)$ time, provided that the individual bits of the integers are immediately accessible. In our case, however, the integers are represented in a blockwise instead of bitwise format. To apply the parallel-prefix technique, we formulate the computation of the block-to-block carries as a prefix-sum problem in a way slightly different from that in the bitwise case. The idea is to let a block take the place of a bit. Define a binary operation $\otimes$ on $\{\bar{g}, \bar{s}, \bar{p}\}$ as follows:

$$x \otimes y = \begin{cases} y & \text{if } y \neq \bar{p}, \\ x & \text{otherwise.} \end{cases} \tag{8}$$

It is routine to check that $\otimes$ is associative. For $0 \le k \le N+1$, let

$$x_k = \begin{cases} \bar{g} & \text{if } \langle h'(p,i,k)\rangle + \langle h(p,i,k)\rangle \ge 2^B, \\ \bar{p} & \text{if } \langle h'(p,i,k)\rangle + \langle h(p,i,k)\rangle = 2^B - 1, \\ \bar{s} & \text{otherwise.} \end{cases}$$

Intuitively, $x_k = \bar{g}$ if a carry is "generated" in the kth block; $x_k = \bar{p}$ if a carry is "propagated" through the kth block (i.e., there is a carry out of the kth block if and only if there is a carry into the kth block); and $x_k = \bar{s}$ if a carry is "stopped" in the kth block (i.e., no carry out of the kth block regardless of whether there is a carry into the kth block). Let $x_{-1} = \bar{s}$, and for $-1 \le k \le N+1$, let $y_k = x_{-1} \otimes x_0 \otimes x_1 \cdots \otimes x_k$. By (8), $y_k = x_{k'}$, where $k' \le k$ is maximum such that $x_{k'} \neq \bar{p}$. This implies $y_k = \bar{g}$ if and only if there is a carry out of the kth block. By parallel-prefix computation, we can determine all the y_k's, and hence all block-to-block carries, in $O(\log N) = O(\log T)$ time.

4.5. Verifying π. During phase I, P_π performs some additional preprocessing so that during phase II, P_π can decide in $O(\log T)$ time whether π actually happens. We first outline the verification process and then supply the details.

4.5.1. The outline. Now π specifies the behavior of R between time $(m-1)T^{1/2}$ and $mT^{1/2}$. We say that π "happens up to time t" if the behavior of R from time $(m-1)T^{1/2}$ to time t agrees with π. Similarly, we say that π "happens in step t" if the behavior of R from time $t-1$ to time t agrees with π. P_π uses $T^{1/2}$ processors P_t^*, where $(m-1)T^{1/2} \le t < mT^{1/2}$. Each P_t^* checks whether π happens in step $t+1$, assuming that π happens up to time t. Each P_t^* obtains a true or false answer. Clearly, π happens if and only if all these answers are true. P_π calculates the logical AND

of these $T^{1/2}$ answers in $O(\log T)$ time (Lemma 3.1) and decides whether π actually happens.

4.5.2. Preprocessing for verification. P_π activates all P_t^*'s in phase I using $O(\log T)$ time. Recall that in phase I, P_π performs some preprocessing based on the triple $\pi = (q, \beta, \sigma)$; if π happens, then this preprocessing enables P_π to compute *config*$(mT^{1/2})$ from *config*$((m-1)T^{1/2})$ in $O(\log T)$ time. During phase I, every P_t^* performs the analogous preprocessing using the triple $(q, \beta(t), \sigma(t))$, where $\beta(t)$ and $\sigma(t)$ are prefixes of β and σ respectively that define the behavior of R between time $(m-1)T^{1/2}$ and t. If π happens up to time t, then this preprocessing enables P_t^* to compute *config*(t) from *config*$((m-1)T^{1/2})$ in $O(\log T)$ time. As argued in section 4.3, this preprocessing takes $O(T^{1/2})$ time.

4.5.3. The actual verification. In section 4.4, we discussed how P_π computes *config*$(mT^{1/2})$ from *config*$((m-1)T^{1/2})$, provided that π actually happens. In an analogous manner, each P_t^* computes *config*(t) from *config*$((m-1)T^{1/2})$ during phase II, assuming that π actually happens up to time t. Using *config*(t), P_t^* verifies whether π happens in step $t+1$ in $O(\log T)$ time.

If π actually happens, then every P_t^* obtains a positive answer (true), and P_π deduces that π actually happens. Otherwise, let t' be maximum such that π happens up to time t'. Then $P_{t'}^*$ determines *config*(t') correctly and discovers that π does not happen in step $t'+1$. $P_{t'}^*$ answers false, and P_π infers that π does not happen. Note that for $t > t'$, the preprocessing of P_t^* yields nothing useful, and P_t^* cannot compute *config*(t) correctly. This does not concern us, however, since the negative answer of $P_{t'}^*$ renders other answers immaterial. We merely need to guarantee that P_t^* finishes its preprocessing within $O(T^{1/2})$ time and produces some answer within $O(\log T)$ time. This is readily accomplished by having each P_t^* count the number of steps it executes.

4.5.4. Verifying a single step. It remains to explain how P_t^* uses *config*(t) to check whether $\pi = (q, \beta, \sigma)$ happens in step $t+1$. Recall the following facts:

1. The integer q specifies the statement number of R at time $(m-1)T^{1/2}$.
2. We treat every static and dynamic instruction as a conditional jump, and β is a binary string of length $T^{1/2}$. For each dynamic instruction from step $(m-1)T^{1/2}+1$ to step $mT^{1/2}$, β stipulates whether the condition of the jump is true or false.
3. Every dynamic instruction is equivalent to an effective instruction, and σ gives the sequence of effective instruction from step $(m-1)T^{1/2}+1$ to step $mT^{1/2}$.
4. Every uninitialized register of R contains 0, and $r(K-1) = u_{K-1}$ contains 0 throughout the computation of R.

To decide whether π happens in step $t+1$, P_t^* performs the following checks:

1. *Check for* q. Let q' be the statement number in *config*(t). If $t = (m-1)T^{1/2}$, then P_t^* checks that $q = q'$.
2. *Check for* β. Let $s = t - (m-1)T^{1/2} + 1$. The sth bit of β specifies whether the condition is true or false for the dynamic instruction in step $t+1$. This dynamic instruction corresponds to the static instruction in statement q'. P_t^* checks that the sth bit of β is 1 if and only if statement q' indeed contains a JUMP instruction, and the condition of the jump is true, i.e., $\langle u_0, t\rangle \le \langle u_1, t\rangle$ according to *config*(t).
3. *Check for* σ. P_t^* checks that the effective instruction in step $t+1$ specified by σ is equivalent to the dynamic instruction in step $t+1$.

The first two checks need no further explanation. We supply the details of the third check below. In section 4.3.1, we showed that every dynamic instruction is equivalent to an effective instruction of the form $u_{i'} \leftarrow u_{j'}$, $u_{i'} \leftarrow u_{j'} + u_{k'}$, or $u_{i'} \leftarrow u_{j'} -$

$u_{k'}$ for some $0 \le i', j', k' \le T + K + n$. The dynamic instruction in step $t+1$ corresponds to the static instruction in statement q'. Consider the effective instruction in step $t+1$ specified by σ. P_t^* checks that the form of this effective instruction is "compatible" with the static instruction in statement q'. Table 2 shows the four categories of compatible instruction pairs. P_t^* performs some further checks according to the category of the compatible pair.

TABLE 2
Compatible effective and static instruction pairs.

Category	Effective Instruction	Static Instruction
1	$u_0 \leftarrow u_0$	ACCEPT, REJECT, and JUMP
2	$u_{i'} \leftarrow u_{j'}$	$r(i) \leftarrow r(j)$, $r(i) \leftarrow (r(0))$, and $(r(0)) \leftarrow r(j)$
3	$u_{i'} \leftarrow u_{j'} + u_{k'}$	$r(i) \leftarrow r(j) + r(k)$
4	$u_{i'} \leftarrow u_{j'} - u_{k'}$	$r(i) \leftarrow r(j) - r(k)$

Category 1. No further check is necessary.

Category 2. The static instruction in statement q' is either $r(i) \leftarrow r(j)$, $r(i) \leftarrow (r(0))$, or $(r(0)) \leftarrow r(j)$; σ stipulates that the effective instruction in step $t+1$ is $u_{i'} \leftarrow u_{j'}$. Let a_{w} be the address of the register that is written to in step $t+1$, and let a_{r} be the address of the register that is read from in step $t+1$. More precisely,

$$a_{\mathrm{w}} = \begin{cases} i & \text{if the static instruction in statement } q' \text{ is } r(i) \leftarrow r(j) \text{ or } r(i) \leftarrow (r(0)), \\ \langle r(0), t\rangle & \text{if the static instruction in statement } q' \text{ is } (r(0)) \leftarrow r(j), \end{cases}$$

$$a_{\mathrm{r}} = \begin{cases} j & \text{if the static instruction in statement } q' \text{ is } r(i) \leftarrow r(j) \text{ or } (r(0)) \leftarrow r(j), \\ \langle r(0), t\rangle & \text{if the static instruction in statement } q' \text{ is } r(i) \leftarrow (r(0)). \end{cases}$$

According to σ, R reads from $u_{j'}$ and writes to $u_{i'}$ in step $t+1$. P_t^* compares a_{r} with the addresses of all u_k's in *config*(t) in parallel. By definition, the addresses of all u_k's are distinct. If a_{r} equals the address of u_k for some k, then P_t^* checks that $j' = k$. Otherwise, R reads from an uninitialized register in step $t+1$; P_t^* checks that $j' = K - 1$.

If $i' = t + 1 + K + n$, then according to σ, a new register is written to in step $t+1$; P_t^* checks that a_{w} is different from the addresses of all u_k's in *config*(t). If $i' < t + 1 + K + n$, then according to σ, R writes to $u_{i'}$ in step $t+1$, but not for the first time; P_t^* checks that a_{w} is the address of $u_{i'}$ in *config*(t). If $i' > t + 1 + K + n$, then σ stipulates that in step $t+1$, R writes to $u_{i'}$, which by definition is the register first written to in step $i' - K - n > t+1$. The information contained in σ contradicts itself; P_t^* simply answers false.

P_t^* uses N processors (comparators) to compare two addresses in the blockwise format for equality. Each comparator checks for equality in a corresponding block and obtains a true or false answer; P_t^* calculates the logical AND of these answers in $O(\log N) = O(\log T)$ time (Lemma 3.1). To compare a_{r} and a_{w} against the addresses of all u_k's in parallel, P_t^* requires $O(NT) = O(T^{3/2})$ comparators. Observe that although these comparators are used in phase II, all comparators can be preactivated in phase I using $O(\log T)$ time. We will need this observation in section 4.6.

Categories 3 *and* 4. These cases are similar to those in Category 2.

Hence P_π can verify whether π actually happens in $O(\log T)$ time. This concludes the proof of Theorem 4.1.

4.6. Time–processor tradeoffs. In this section, we discuss how to reduce the number of processors used in the simulation at the expense of increasing the simulation time. The following theorem is a generalization of Theorem 4.1.

THEOREM 4.2. *Let $\rho > 1$. Every unit-cost RAM that runs in time T can be simulated by a CREW PRAM in time $O(\rho \log T + (T \log \rho)/\rho)$ with $T^{O(\rho)}$ processors.*

Proof. The proof of Theorem 4.2 is similar to that of Theorem 4.1. We explain how to modify the proof of Theorem 4.1 to establish Theorem 4.2. Instead of dividing each integer into $N = O(T^{1/2})$ blocks, we divide every $O(T)$-bit integer into $N' = O(\rho)$ blocks, each $O(T/\rho)$ bits long. We use T/ρ groups of processors. During phase I, group m performs the preprocessing based on the triple $(q'_m, \beta'_m, \sigma'_m)$, where q'_m is the statement number at time $(m-1)\rho$, β'_m is a binary string that encodes the outcomes of all condition jumps from time $(m-1)\rho$ to time $m\rho$, and σ'_m is the sequence of ρ effective instructions between time $(m-1)\rho$ and $m\rho$. In phase I, group m uses $O(\rho \log T)$ time to activate $T^{O(\rho)}$ processors to try all possible triples. Similar analysis as in section 4.3 reveals that the preprocessing takes $O(\rho)$ time. Again, the bottleneck in phase I is the activation of enough processors to try all triples, which takes $O(\rho \log T)$ time.

The content of each u_i at time $m\rho$ is a linear combination of the $\langle u_i, (m-1)\rho\rangle$'s. Let $\langle u_i, m\rho\rangle = \sum_j C'_{ij} \langle u_j, (m-1)\rho\rangle$. Observe that such a linear combination has at most $O(\rho)$ nonzero coefficients since all arithmetic operations between time $(m-1)\rho$ and $m\rho$ involve at most $O(\rho)$ registers. Let $J = \{j \mid C'_{ij} \neq 0\}$. In section 4.4.1, we described how to compute $\sum_{j=0}^{T+K+n} C_{ij} \langle u_j, (m-1)T^{1/2}\rangle$ in $O(\log N + \log(T + K + n)) = O(\log T)$ time. Using the same method, we can compute $\langle u_i, m\rho\rangle = \sum_{j \in J} C'_{ij} \langle u_j, (m-1)\rho\rangle$ in $O(\log N' + \log |J|) = O(\log \rho)$ time. Verification of the triple also takes $O(\log \rho)$ time. Note that the verification of the triple requires $O(T\rho)$ comparators, which can be preactivated in $O(\log T + \log \rho)$ time during phase I. The preprocessing thus enables group m to compute *config*$(m\rho)$ from *config*$((m-1)\rho)$ in $O(\log \rho)$ time during phase II.

In phase II, the PRAM P computes *config*(T) in $O((T \log \rho)/\rho)$ time as follows. For $m = 1, 2, \ldots, T/\rho$, group m computes *config*$(m\rho)$ from *config*$((m-1)\rho)$ in $O(\log \rho)$ time. Let q^* be the statement number in *config*(T). P accepts if and only if statement q^* contains an ACCEPT instruction. This simulation takes $O(\rho \log T + (T \log \rho)/\rho)$ time and uses $T^{O(\rho)}$ processors. ∎

5. Discussion.

5.1. Parallelism always helps. We have shown that we can always speed up a sequential computation on a unit-cost RAM by a CREW PRAM. We mentioned in section 1.1 that the unit-cost RAM is the most commonly used machine model for analyzing sequential algorithms. There are, however, other machine models of sequential computation, for example, the Turing machine, tree Turing machine, multidimensional Turing machine, and log-cost RAM. In a separate paper [12], we show that a sequential computation on each of these other models can also be sped up by a corresponding parallel machine model:

1. Every tree Turing machine that runs in time T can be simulated by an alternating Turing machine in time $O(T/\log T)$.

2. Every d-dimensional Turing machine that runs in time T can be simulated by an alternating Turing machine in time $O(T5^{d \log^* T}/\log T)$.

3. Every log-cost RAM that runs in time T can be simulated by an alternating log-cost RAM in time $O(T \log \log T/\log T)$.

We conclude that parallelism always helps us speed up a sequential computation.

5.2. Speedup using a polynomial number of processors. It is well known that the Turing machine enjoys the constant speedup theorem [26]: Let $\epsilon > 0$ and M be a Turing machine with time complexity T; then M can be simulated by another Turing machine in time $\epsilon T + n$. Hence efforts on speeding up the Turing machine

have focused on asymptotic speedup [4, 10, 16]. The unit-cost RAM, however, does not enjoy the constant speedup theorem [23]; that is, there exist an $\epsilon > 0$ and a unit-cost RAM R with time complexity T such that R cannot be simulated by any unit-cost RAM in time $\epsilon T + n$. Thus it is not trivial to speed up the computation of a unit-cost RAM by a constant factor. Theorem 4.2 shows that it is possible to speed up a unit-cost RAM by an arbitrary constant factor with a CREW PRAM using a polynomial number of processors.

5.3. Is result optimal? We have constructed a simulator that runs in time $O(T^{1/2} \log T)$. We do not know whether our result is optimal, but we believe that it is difficult to reduce the simulation time by more than a $\log T$ factor because this would imply improvements over some best-known results, as explained below. We would like to call the reader's attention to the following previously established results:

1. Every CREW PRAM that runs in time T can be simulated by a Turing machine in space $O(T^2)$ (Fortune and Wyllie [6]).

2. Every Turing machine that runs in time T can be simulated by a unit-cost RAM in time $O(T/\log T)$ (Hopcroft, Paul, and Valiant [10]).

3. Every Turing machine that runs in time T can be simulated by another Turing machine in space $O(T/\log T)$ (Hopcroft, Paul, and Valiant [9]).

4. Every Turing machine that runs in time T can be simulated by a CREW PRAM in time $O(T^{1/2})$ (Dymond and Tompa [4]).

These are the best-known results for the respective simulations. For our problem, namely, simulation of unit-cost RAMs by CREW PRAMs, reducing the simulation time to $o((T \log T)^{1/2})$, together with the first result of Hopcroft et al. above, implies an improvement over the result of Dymond and Tompa. By the same reasoning, if we manage to reduce the simulation time to $o(T^{1/2})$, then we can simulate every Turing machine with time complexity T by a CREW PRAM in time $o((T/\log T)^{1/2})$. It then follows from the above result of Fortune and Wyllie that for Turing machines, time T can be simulated in space $o(T/\log T)$, improving the second result of Hopcroft et al. above. This would be a significant breakthrough in simulating time by space for Turing machines.

Acknowledgments. Many thanks go to my advisor, Professor Michael Loui, for his many contributions to this paper; he proposed the problem, suggested generalizing Theorem 4.1 to Theorem 4.2, and provided useful references. His extensive comments significantly improved the disposition of this paper. Also, I would like to thank Professor Larry Ruzzo for bringing to my attention the work of Reif.

STOCHASTIC SCHEDULING WITH VARIABLE PROFILE AND PRECEDENCE CONSTRAINTS*

ZHEN LIU† AND ERIC SANLAVILLE‡

Abstract. In this paper, we consider the stochastic profile scheduling problem of a partially ordered set of tasks on uniform processors. The set of available processors varies in time. The running times of the tasks are independent random variables with exponential distributions. We obtain a sufficient condition under which a list policy stochastically minimizes the makespan within the class of preemptive policies. This result allows us to obtain a simple optimal policy when the partial order is an interval order, an in-forest, or an out-forest.

Key words. stochastic scheduling, profile scheduling, makespan, precedence constraint, interval order, in-forest, out-forest, uniform processors, stochastic ordering.

1. Introduction.

Consider the following scheduling problem. We are given a set of tasks to be run in a system consisting of uniform processors (i.e., processors having different speeds). The executions of these tasks must satisfy some precedence constraints which are described by a directed acyclic graph, referred to as the task graph. The processing requirements of the tasks are independent random variables with a common exponential distribution. The set of processors available to these tasks varies in time. The availability of the processors is referred to as the profile, and it can be arbitrary. The goal is to find preemptive schedules that stochastically minimize the makespan.

Our study of scheduling under variable profile is motivated by situations where processors are subject to failures and repairs. The failure and repair times are arbitrary. Another motivation is scheduling of multiprogrammed systems. In such a system, execution of tasks of a program may be preempted by tasks of higher-priority programs.

When the task graph is an in-forest and the profile is a constant set of two processors, Chandy and Reynolds [2] proved that the highest-level-first (HLF) policy minimizes the expected makespan. Here the level of a task is simply the distance from it to the root of the tree in which it appears. Bruno [1] subsequently showed that HLF stochastically minimizes the makespan when the system has two identical parallel processors. Pinedo and Weiss [14] extended this last result to the case where tasks at different levels may have different expected task running times. Frostig [7] further generalized the result of Pinedo and Weiss to include increasing likelihood ratio distributions for the task running times. Recently, Kulkari and Chimento [9] extended the result of [1] to the case of variable profile (with two identical parallel processors). When the number of identical parallel processors in the system is arbitrarily fixed and the task running times have a common exponential distribution, Papadimitriou

and Tsitsiklis [12] proved that HLF is asymptotically optimal as the number of tasks tends to infinity.

Coffman and Liu [3] investigated the stochastic scheduling of out-forest on identical parallel processors with constant profile. For a uniform out-forest where all subtrees are ordered by an embedding relation (see definition in section 4.3), they showed that an intuitive priority scheduling policy induced by the embedding relation, referred to as the most-successors (MS) policy in this paper, stochastically minimizes the makespan when there are two processors. If, in addition, the out-forest satisfies a uniform root-embedding constraint, then the greedy policy stochastically minimizes the makespan on an arbitrary number of processors.

Papadimitriou and Yannakakis [13] studied the deterministic scheduling of interval-ordered tasks. Under the assumptions of unit execution time and constant profile, they showed that for an arbitrary number of identical processors, the simple list scheduling induced by the interval order, still referred to as the MS policy in this paper, minimizes the makespan.

The notion of profile scheduling was first introduced by Ullman [16] and later by Garey et al. [8] in the complexity analysis of deterministic scheduling algorithms. Dolev and Warmuth [4, 5, 6] carried out various studies on the deterministic nonpreemptive profile scheduling with parallel identical processors. In such a case, the profile is simply the number of available processors at any time. When the tasks have unit execution time, Dolev and Warmuth obtained polynomial algorithms for specific profiles (e.g., zigzag profile, bounded profile, etc.) and specific task graphs (e.g., in-forest, out-forest, opposing forest, flat graph, etc.). Some of their results were extended to deterministic preemptive profile scheduling by Liu and Sanlaville [11].

In this paper, we investigate profile scheduling in the stochastic setting with uniform processors. The scheduling is allowed to be preemptive; the profile is arbitrary and may be unknown a priori. We obtain a sufficient condition under which a list-scheduling policy is optimal among preemptive policies, such that the makespan is stochastically minimized. This result allows us to prove the optimality of MS policy when the task graph has an interval-order structure, an in-forest structure, or a uniform out-forest structure.

The results concerning interval-ordered tasks are new, even for constant profile and parallel identical processors. The optimality of the MS policy extends the result of [9] for in-forests to uniform processors and the result of [3] for out-forests to variable profile and uniform processors.

Our paper is organized as follows. In section 2, the scheduling problem is described in detail, and some preliminaries are presented. In section 3, a sufficient condition for a list-scheduling policy to stochastically minimize the makespan is established. In section 4, this result is applied to MS policies for the stochastic minimization of makespan for interval-order task graphs, in-forests, and uniform out-forests. Concluding remarks are provided in section 5.

2. Problem description and preliminaries. A *task graph* $G = (V, E)$ is a directed acyclic graph, where $V = \{1, 2, \ldots, |V|\}$ is the set of vertices representing the tasks and $E \subset V \times V$ is the set of edges representing the *precedence constraints*: $(i, j) \in E$ implies that task i must complete execution before task j can start. Denote by $p(i)$ and $s(i)$ the sets of immediate *predecessors* and *successors* of $i \in V$, i.e.,

$$p(i) = \{j : (j, i) \in E\}, \qquad s(i) = \{j : (i, j) \in E\}.$$

A task without predecessors will be called *initial task*. Let $S(i)$ be the set of (not necessarily immediate) successors of $i \in V$, i.e.,

$$\forall i: \quad \text{if} \quad s(i) = \emptyset, \quad \text{then} \quad S(i) = \emptyset \quad \text{else} \quad S(i) = s(i) \bigcup \left(\bigcup_{j \in s(i)} S(j) \right).$$

When necessary, notation $S_G(i)$ is used to indicate that $S(i)$ is defined with respect to graph G.

Particular attention will be paid to the following three classes $\mathcal{C}_{i.o}$, $\mathcal{C}_{i.f}$, and $\mathcal{C}_{o.f}$ of task graphs.

Interval order $G \in \mathcal{C}_{i.o}$: Each vertex i corresponds to an interval b_i in the real line such that $(i, j) \in E$ if and only if $x \in b_i$ and $y \in b_j$ imply $x < y$.

In-forest $G \in \mathcal{C}_{i.f}$: Each vertex has at most one immediate successor: $|s(i)| \leq 1$, $i \in V$. A vertex $i \in V$ is called a leaf of in-forest G if $p(i) = \emptyset$. A vertex $i \in V$ is called a root of in-forest G if $s(i) = \emptyset$.

Out-forest $G \in \mathcal{C}_{o.f}$: Each vertex has at most one immediate predecessor: $|p(i)| \leq 1$, $i \in V$. A vertex $i \in V$ is called a leaf of out-forest G if $s(i) = \emptyset$. A vertex $i \in V$ is called a root of out-forest G if $p(i) = \emptyset$.

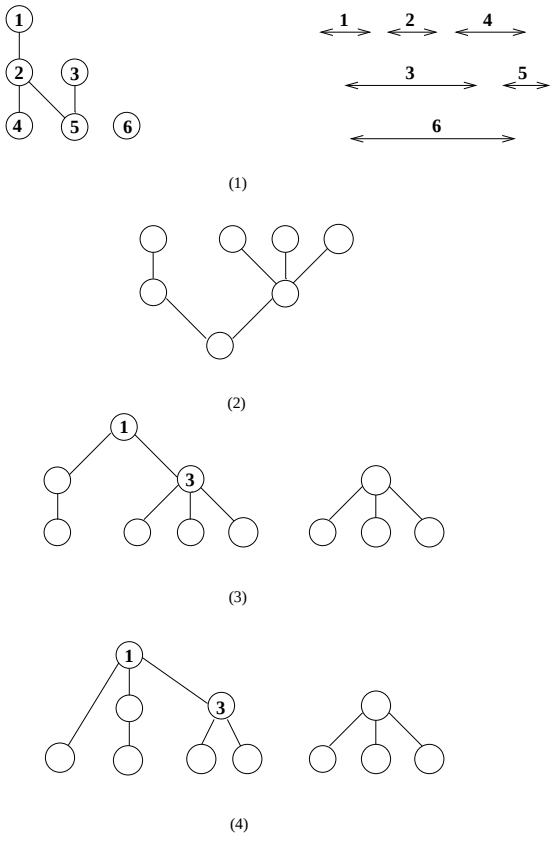

FIG. 1. *Examples of task graphs.*

Four graphs belonging to these classes are illustrated in Figure 1. Graph 1 is an

interval-order graph, with the associated collection of real intervals beside it. Graph 2 is an in-forest. Graphs 3 and 4 are out-forests.

Note that these classes of graphs have the following closure property: for all $\mathcal{C} \in \{\mathcal{C}_{i.o}, \mathcal{C}_{i.f}, \mathcal{C}_{o.f}\}$, if $G = (V, E) \in \mathcal{C}$, then $G - \{v\} \in \mathcal{C}$ for all $v \in V$ such that $p(v) = \emptyset$, where $G - \{v\}$ is the graph obtained by deleting vertex v and its adjacent edges. This *closure property* (by deletion) will be used in establishing our results.

The processing requirements of the tasks are independent and identically distributed (i.i.d.) random variables with a common exponential distribution of a constant parameter, say 1. The running time of a task is the processing requirement of the task divided by the speed of the processor on which the task is running.

There are $K \geq 1$ *uniform processors*, indexed by $1, 2, \ldots, K$. The speed of processor k, $1 \leq k \leq K$, is denoted by α_k. The running times of tasks on processor k are thus i.i.d. random variables with exponential distribution of parameter α_k. We assume, by convention, that $\alpha_1 \geq \alpha_2 \geq \cdots \geq \alpha_K$.

The set of processors available to these tasks varies in time due to, e.g., failures of the processors or executions of higher-priority tasks. The availability of the processors is referred to as the *profile*, and is specified by the sequence $\{a_n, M_n\}_{n=1}^{\infty}$, where the random variables $0 = a_1 < a_2 < \cdots < a_n < \cdots$ are the time epochs where the profile is changed and M_n, $n \geq 1$, is a random set whose elements are the indices of the processors available during the time interval $[a_n, a_{n+1})$. The profile $\{a_n, M_n\}_{n=1}^{\infty}$ is assumed to be independent of the running times of the tasks. Without loss of generality, we assume that for all $n \geq 1$, $M_n \neq \emptyset$. We will also assume that the profile is not changed infinitely often during any finite time interval: for all $x \in I\!R^+$, there is some finite $n \geq 1$ such that $a_n > x$. The profile is said to be *bounded* by $p \in I\!N_+ \equiv \{1, 2, \ldots\}$ if for all $n \in I\!N_+$, $|M_n| \leq p$.

The *scheduling policies* decide when an *enabled task*, i.e., an unfinished task all of whose predecessors have finished, should be assigned to an available processor. At any time, a task can be assigned to at most one processor, and a processor can execute at most one task. Throughout this paper, we assume that the scheduling policies are preemptive. We assume that the scheduler has no information on the samples of the (remaining) processing requirements of the tasks. Let Ψ denote the class of such policies. For any $\pi \in \Psi$, denote by $\pi(G)$ the makespan of the partially ordered set of tasks G, i.e., the maximum of the completion times of the tasks in G.

The goal of the paper is to find policies in Ψ that *stochastically minimize* the makespan of G. A policy π_o is said to be optimal within a class $\mathcal{C}$ if for any policy $\pi \in \Psi$, $\pi_o(G) \leq_{st} \pi(G)$ for all $G \in \mathcal{C}$, where the symbol $\leq_{st}$ refers to the standard stochastic inequality. Random variable $X \in I\!R$ is *stochastically smaller* than random variable $Y \in I\!R$, denoted by $X \leq_{st} Y$, if and only if for any increasing function $f : I\!R \to I\!R$, the inequality $E[f(X)] \leq E[f(Y)]$ holds, provided the expectations exist.

The proofs of our main results will use a coupling argument based on the following well-known result due to Strassen, where $=_{st}$ denotes equality in distribution.

LEMMA 2.1 (Strassen [15]). *Two random variables $X, Y \in I\!R$ satisfy $X \leq_{st} Y$ if and only if there exist two random variables $\hat{X}$ and $\hat{Y}$ defined on a common probability space such that $X =_{st} \hat{X}$, $Y =_{st} \hat{Y}$, and $\hat{X} \leq \hat{Y}$ almost surely (a.s.).*

In order to simplify the proofs of the main results in the paper, we make some restrictions on the class of policies Ψ.

Observe first that due to the memoryless property of exponential distributions, at any time, the distribution of the remaining running time of a task assigned to

processor k is still exponential with parameter α_k, $1 \leq k \leq K$. If we represent the state of the system by the set of available processors, the remaining task graph, and the distributions of the remaining running times of the tasks, then the state does not change between the instants of task completions and of profile modifications. Therefore, we can without loss of generality confine ourselves to the class of policies where preemptions and new task assignments occur only at the instants of task completions and profile modifications. These instants are referred to as the *decision epochs*. Hence we assume that all the policies in Ψ make their scheduling decisions at these time instants only.

A policy is *idling* if it allows a processor to remain idle when there is an initial task waiting for execution. It is easy to see that an optimal policy should never be idling since the distributions of the task running times have infinite support and preemptions are allowed. Furthermore, an optimal policy should always use the *fastest* available processors. (See [10] for a complete proof of these basic properties.) Throughout this paper, we will assume that all the policies in Ψ are nonidling and use the fastest available processors at all decision epochs.

3. Optimal list-scheduling policies. We will pay particular attention to a class of simple scheduling policies, referred to as *list schedules*. A policy λ is called a list schedule if for any task graph $G = (V, E)$, a *priority list* is defined on the set of tasks $V = (v_1, v_2, \ldots, v_n)$, given by, e.g., $v_1 >_\lambda v_2 >_\lambda \cdots >_\lambda v_n$, where $v_i >_\lambda v_j$ means that task v_i has higher priority than v_j in the list. At any decision time epoch, policy λ assigns the enabled tasks with the highest priorities to the fastest available processors. Clearly, all list schedules are in the class Ψ and satisfy the properties mentioned at the end of last section. Note that the priority list can be changed dynamically, i.e., for a given policy, the relative priority order between two tasks can be changed when a task is removed from the graph.

Let $\mathcal{C}$ be a class of graphs which is closed under deletion. The class $\mathcal{C}$ will be said to be $\lambda(p)$-*monotonic* for some list schedule λ and some $p \in I\!N_+$ if for any $G \in \mathcal{C}$ and any initial tasks $u, v \in G$, relation $u >_\lambda v$ implies that for any profile bounded by p,

$$\lambda(G - \{u\}) \leq_{st} \lambda(G - \{v\}),$$

where recall that $\lambda(G)$ denotes the makespan of G under schedule λ.

Observe that according to the definition, if $\mathcal{C}$ is $\lambda(p)$-monotonic, then it is $\lambda(p-1)$-monotonic, Trivially, any class of graphs is $\lambda(1)$-monotonic for any list schedule λ. However, it will be seen in the next section that few classes are $\lambda(2)$-monotonic for some list schedule λ.

THEOREM 3.1. *Let $\mathcal{C}$ be a class of graphs closed under deletion and $\lambda(p)$-monotonic for some list schedule λ and some $p \in I\!N_+$. Then for any $G \in \mathcal{C}$, policy λ stochastically minimizes the makespan of G under any profile $\{a_n, M_n\}_{n=1}^{\infty}$ bounded by p:*

$$\forall \pi \in \Psi : \quad \lambda(G) \leq_{st} \pi(G). \tag{1}$$

The proof of the theorem needs the following lemma.

LEMMA 3.2. *Let $\mathcal{C}$ be a class of graphs which is closed under deletion and is $\lambda(p)$-monotonic for some list schedule λ and some $p \in I\!N_+$. Let $G \in \mathcal{C}$ be a task graph, $\pi, \rho \in \Psi$ two policies of G which follow the priority list of λ all the time except at the first decision epoch. At the first decision epoch, policy π assigns tasks*

$v_1, v_2, \ldots, v_k$ to the available processors $q_1, q_2, \ldots, q_k$, respectively, with, by assumption, $v_1 >_\lambda v_2 >_\lambda \cdots >_\lambda v_k$, whereas policy ρ assigns tasks $v_1, v_2, \ldots, v_k$ to the processors $q_{\chi(1)}, q_{\chi(2)}, \ldots, q_{\chi(k)}$, respectively, where χ is the permutation on $\{1, 2, \ldots, k\}$ such that $q_{\chi(1)} < q_{\chi(2)} < \cdots < q_{\chi(k)}$. Then

$$\rho(G) \leq_{st} \pi(G).$$

Proof. If $q_1 < q_2 < \cdots < q_k$, then ρ is identical to π so that the assertion trivially holds. Assume that there are integers $1 \leq i < j \leq k$ such that $q_i > q_j$. Let χ_1 be the permutation on $\{1, 2, \ldots, k\}$ defined as follows:

$$\chi_1(i) = j, \quad \chi_1(j) = i, \quad \chi_1(n) = n \quad \forall n \in \{1, 2, \ldots, k\} - \{i, j\}.$$

Let $\rho_1 \in \Psi$ be a policy which follows the priority list of λ all the time except at the first decision epoch. At the first decision epoch, policy ρ_1 assigns tasks $v_1, v_2, \ldots, v_k$ to the processors $q_{\chi_1(1)}, q_{\chi_1(2)}, \ldots, q_{\chi_1(k)}$, respectively. We will show that

$$\rho_1(G) \leq_{st} \pi(G). \tag{2}$$

We couple the running times on processors $q_1, \ldots, q_k$ in such a way that under both policies π and ρ_1, the running time on processor q_n starting from time 0 is τ_n, $1 \leq n \leq k$. In such a coupled model, the second decision epoch occurs at the same time under both policies. Let this time epoch be fixed, referred to as d_2,

$$d_2 = \min(a_2, \tau_1, \ldots, \tau_k).$$

If this decision epoch corresponds to a profile modification, i.e., $d_2 = a_2$, then $\rho_1(G) =_{st} \pi(G)$.

Now assume that the second decision epoch corresponds to a task completion. It is easy to see that for any increasing function $f : \mathbb{R} \to \mathbb{R}$,

$$E\left[f\left(\pi(G) - d_2\right)\right] = \frac{1}{\beta} \sum_{n=1}^{k} \alpha_{q_n} E\left[f\left(\lambda(G - \{v_n\})\right)\right], \tag{3}$$

$$E\left[f\left(\rho_1(G) - d_2\right)\right] = \frac{1}{\beta} \sum_{n=1}^{k} \alpha_{q_{\chi_1(n)}} E\left[f\left(\lambda(G - \{v_n\})\right)\right], \tag{4}$$

where $\beta = \sum_{n=1}^{k} \alpha_{q_n}$.

Since $\mathcal{C}$ is $\lambda(p)$-monotonic, we have that $\lambda(G - \{v_i\}) \leq_{st} \lambda(G - \{v_j\})$ so that

$$E\left[f\left(\lambda(G - \{v_i\})\right)\right] \leq E\left[f\left(\lambda(G - \{v_j\})\right)\right].$$

Thus the fact that $q_i > q_j$ (so that $\alpha_{q_i} \leq \alpha_{q_j}$) implies that

$$\begin{aligned} &\alpha_{q_j} E\left[f\left(\lambda(G - \{v_i\})\right)\right] + \alpha_{q_i} E\left[f\left(\lambda(G - \{v_j\})\right)\right] \\ &\quad \leq \alpha_{q_i} E\left[f\left(\lambda(G - \{v_i\})\right)\right] + \alpha_{q_j} E\left[f\left(\lambda(G - \{v_j\})\right)\right]. \end{aligned}$$

Hence for any increasing function $f : \mathbb{R} \to \mathbb{R}$,

$$E\left[f\left(\rho_1(G) - d_2\right)\right] \leq E\left[f\left(\pi(G) - d_2\right)\right],$$

which implies

$$\rho_1(G) - d_2 \leq_{st} \pi(G) - d_2.$$

Unconditioning on d_2 in the above relation yields (2).

Consider now policy ρ_1. If $\chi_1 = \chi$, then we are done. Otherwise, there are integers $1 \le i' < j' \le k$ such that $q_{\chi_1(i')} > q_{\chi_1(j')}$. Let χ_2 be the permutation on $\{1, 2, \ldots, k\}$ defined as follows:

$$\chi_2(i') = \chi_1(j'), \quad \chi_2(j') = \chi_1(i'), \quad \chi_2(n) = \chi_1(n) \quad \forall n \in \{1, 2, \ldots, k\} - \{i', j'\}.$$

Let $\rho_2 \in \Psi$ be a policy which follows the priority list of λ all the time except at the first decision epoch. At the first decision epoch, policy ρ_2 assigns tasks $v_1, v_2, \ldots, v_k$ to the processors $q_{\chi_2(1)}, q_{\chi_2(2)}, \ldots, q_{\chi_2(k)}$, respectively. As above, we can show that

$$\rho_2(G) \le_{st} \rho_1(G).$$

Repeating this procedure for at most $k(k-1)/2$ times finally yields policy ρ such that

$$\rho(G) \le_{st} \cdots \le_{st} \rho_2(G) \le_{st} \rho_1(G) \le_{st} \pi(G). \qquad \square$$

Proof of Theorem 3.1. We prove by induction on n that for any $G = (V, E) \in \mathcal{C}$ such that $|V| \le n$, the relation

$$\lambda(G) \le_{st} \pi(G) \tag{5}$$

holds for any profile.

If G is a singleton, i.e., $|V| = 1$, then (5) is trivial since both policies λ and π assign the task to the fastest available processor.

Assume that for some $n \ge 1$, relation (5) holds for all G such that $|V| \le n$. Now consider the task graphs $G \in \mathcal{C}$ such that $|V| = n + 1$.

Fix the task graph $G \in \mathcal{C}$, the profile $\{a_n, M_n\}_{n=1}^{\infty}$, and the policy $\pi \in \Psi$. Denote by $\{d_n\}_{n=1}^{\infty}$ the sequence of decision epochs of π for finishing tasks in G, with $d_1 = 0$. Without loss of generality, we assume that d_2 corresponds to a task completion. The other case can be analyzed similarly.

Since all policies of Ψ are nonidling and use the fastest available processors, the numbers of tasks assigned for execution at the first decision epoch are the same under policies λ and π. At the first decision epoch, policy π assigns initial tasks $v_1, v_2, \ldots, v_k$ to the available processors $q_1, q_2, \ldots, q_k$, respectively, where $v_1 >_\lambda v_2 >_\lambda \cdots >_\lambda v_k$, whereas policy λ assigns initial tasks $u_1, u_2, \ldots, u_k$ to the processors $q_{\chi(1)}, q_{\chi(2)}, \ldots, q_{\chi(k)}$, respectively, where $u_1 >_\lambda u_2 >_\lambda \cdots >_\lambda u_k$ and χ is the permutation on $\{1, 2, \ldots, k\}$ such that $q_{\chi(1)} < q_{\chi(2)} < \cdots < q_{\chi(k)}$.

We construct an intermediate policy ρ which follows the priority list of λ all the time except at the first decision epoch. At the first decision epoch, policy ρ assigns tasks $u_1, u_2, \ldots, u_k$ to the processors $q_1, q_2, \ldots, q_k$, respectively.

According to Lemma 3.2, $\lambda(G) \le_{st} \rho(G)$. We show below that

$$\rho(G) \le_{st} \pi(G), \tag{6}$$

which will complete the proof.

Under the assumption that d_2 corresponds to a task completion, we have that for any increasing function $f : \mathbb{R} \to \mathbb{R}$,

$$E\left[f\left(\rho(G) - d_2\right)\right] = \frac{1}{\beta} \sum_{i=1}^{k} \alpha_{q_i} E\left[f\left(\lambda(G - \{u_i\})\right)\right], \tag{7}$$

$$E\left[f\left(\pi(G) - d_2\right)\right] = \frac{1}{\beta} \sum_{i=1}^{k} \alpha_{q_i} E\left[f\left(\pi(G - \{v_i\})\right)\right], \tag{8}$$

where $\beta = \sum_{i=1}^{k} \alpha_{q_i}$.

The definition of the list schedule λ implies that $u_i >_\lambda v_i$, $1 \le i \le k$, where relation $>_\lambda$ is understood to be antisymmetric. Therefore, the $\lambda(p)$-monotonicity of G implies that

$$\lambda(G - \{u_i\}) \le_{st} \lambda(G - \{v_i\}),$$

which, together with the inductive assumption, implies

$$\lambda(G - \{u_i\}) \le_{st} \lambda(G - \{v_i\}) \le_{st} \pi(G - \{v_i\}).$$

Therefore (cf. (7) and (8)), $E[f(\rho(G) - d_2)] \le E[f(\pi(G) - d_2)]$, which readily implies (6). □

4. Optimality of MS policies. A class of intuitively good list schedules is the MS policies, where the priority of a task is defined by the number of (not necessarily immediate) successors, i.e., $|S(u)| > |S(v)|$ implies $u \prec_{MS} v$. The difference between MS policies is the way that ties are broken (the ways of assigning priorities to tasks having the same number of successors). In this section, we will show that these policies are optimal for some special classes of task graphs, i.e., interval-order graphs, in-forests, and uniform out-forests.

In order to prove these optimality properties, we need to compare task graphs, which is done using the following majorization. Let $G^1 = (V^1, E^1)$ and $G^2 = (V^2, E^2)$ be two task graphs, with the vertices of $V^1 = \{v_1^1, \ldots, v_{n_1}^1\}$ and $V^2 = \{v_1^2, \ldots, v_{n_2}^2\}$ ordered according to the number of successors: $g^1 = |S_{G^1}(v_1^1)| \ge |S_{G^1}(v_2^1)| \ge \cdots \ge |S_{G^1}(v_{n_1}^1)| = 0$ and $g^2 = |S_{G^2}(v_1^2)| \ge |S_{G^2}(v_2^2)| \ge \cdots \ge |S_{G^2}(v_{n_2}^2)| = 0$. We say that G^1 is *majorized* by G^2, denoted by $G^1 \prec_s G^2$, if

$$n_1 \le n_2 \quad \text{and} \quad \forall i,\ 1 \le i \le n_1 : \quad |S_{G^1}(v_i^1)| \le |S_{G^2}(v_i^2)|.$$

In our proofs, the following equivalent definition will also be used. Let V^1 and V^2 be partitioned into sets $T_0^1, T_1^1, T_2^1, \ldots, T_{g^1}^1$ and $T_0^2, T_1^2, T_2^2, \ldots, T_{g^2}^2$, where $T_k^j = \{i \in V^j, |S_{G^j}(i)| = k\}$, $j = 1, 2$, $1 \le k \le g^j$. In words, T_k^j is the set of vertices having k successors in graph G^j. As an example, for the interval-order graph in Figure 1, $T_3 = \{1\}$, $T_2 = \{2\}$, $T_1 = \{3\}$, and $T_0 = \{4, 5, 6\}$. When the graph is an in-forest, T_k is the set of vertices at level k. Now the equivalent definition is given as follows. Graph G^1 is majorized by G^2 if

$$g^1 \le g^2 \quad \text{and} \quad \forall i,\ 0 \le i \le g^1 : \quad \sum_{k=i}^{g^1} |T_k^1| \le \sum_{k=i}^{g^2} |T_k^2|.$$

4.1. Stochastic profile scheduling of interval-order graphs. Let $G = (V, E) \in \mathcal{C}_{i.o}$ be an interval-order graph. Note that except for a possible set of isolated vertices (i.e., vertices without predecessors and without successors), an interval-order graph is connected.

An equivalent definition of interval-order graphs (cf. [13]) is that for all $i, j \in V$, either $S(i) \subseteq S(j)$ or $S(j) \subseteq S(i)$. An immediate consequence of this definition is that if $|S(i)| \le |S(j)|$, then $S(i) \subseteq S(j)$, and consequently, if $|S(i)| = |S(j)|$, then $S(i) = S(j)$. Thus any subset $T_k = \{i \in V, |S(i)| = k\}$ of V contains vertices whose sets of successors are identical (and of cardinality k).

THEOREM 4.1. *For any profile* $\{a_n, M_n\}_{n=1}^{\infty}$ *and any set of interval-ordered tasks* $G \in \mathcal{C}_{i.o}$,

$$\forall \pi \in \Psi: \quad MS(G) \leq_{st} \pi(G). \tag{9}$$

Proof. In view of Theorem 3.1, we only need to show that $\mathcal{C}_{i.o}$ is $MS(p)$-monotonic for any positive integer p, i.e., for any two initial tasks u and v of G, if $|S(u)| \geq |S(v)|$, then

$$MS(G - \{u\}) \leq_{st} MS(G - \{v\}). \tag{10}$$

Let $G^1 = (V^1, E^1) = G - \{u\}$ and $G^2 = (V^2, E^2) = G - \{v\}$. We will show that there is a common probability space such that

$$MS(G^1) \leq MS(G^2) \quad \text{a.s.} \tag{11}$$

Further, applying Strassen's theorem (cf. Lemma 2.1) yields (10).

Owing to the memoryless property of the exponential distributions, we can consider a coupled processing model where all processors $1, \ldots, K$, whenever they are available, are continually executing tasks. When a completion occurs and there is no task assigned to that processor, it corresponds to the completion of a fictitious task. When a task is assigned to a processor, it is assigned a running time equal to the remainder of the running time already underway at that processor. Thus if tasks $u \in G^1$ and $v \in G^2$ are assigned to the same processor at some time, they have the same (remaining) running time.

Denote by $\{c_n\}_{n=1}^{\infty}$ the (increasing) sequence of completion times of the tasks in G^1 and G^2 at the available processors under the MS policy. Let $\{d_n\}_{n=1}^{\infty}$ be the superposition of the sequences of the decision epochs of MS for G^1 and G^2 in such a probability space. More specifically, $\{d_n\}_{n=1}^{\infty}$ is the superposition of the sequences of profile modification times $\{a_n\}_{n=1}^{\infty}$ and of the task completion times $\{c_n\}_{n=1}^{\infty}$. Clearly, $d_1 = a_1 = 0$.

For $j = 1, 2$ and $n \geq 1$, let $G^j(n) = (V^j(n), E^j(n))$ be the remaining graph of G^j at time d_n under MS in the coupled model. Let $g = \max_{i \in V} |S(i)|$. Denote $T_k^j(n) = \{i \in V^j(n), |S(i)| = k\}$, $j = 1, 2$, $0 \leq k \leq g$, and $n \geq 1$. We show that for all $n \geq 1$,

$$G^1(n) \prec_s G^2(n), \tag{12}$$

which immediately implies (11).

Relation (12) is proved by induction on n. For $n = 1$, it is trivial that

$$G^1(1) = G^1 \prec_s G^2 = G^2(1).$$

Assume that (12) holds for some $n \geq 1$.

Let there be m available processors at time d_n^+. Without loss of generality, we assume that the processors $1, 2, \ldots, m$ are available. Recall that, by convention, these processors are ordered by their speed: $\alpha_1 \geq \alpha_2 \geq \cdots \geq \alpha_m$.

Under the MS policy, the initial tasks with the largest sets of successors are assigned to the fastest processors. Let $u_1, u_2, \ldots, u_{m_1}$ be the tasks of $G^1(n)$ that are assigned to the processors $1, 2, \ldots, m_1$, respectively, under the MS policy. Similarly, let $v_1, v_2, \ldots, v_{m_2}$ be the tasks of $G^2(n)$ that are assigned to the processors $1, 2, \ldots, m_2$, respectively, under the MS policy. By definition, $m \geq \max(m_1, m_2)$, and

$$S(u_1) \supseteq S(u_2) \supseteq \cdots \supseteq S(u_{m_1}), \qquad S(v_1) \supseteq S(v_2) \supseteq \cdots \supseteq S(v_{m_2}).$$

If $G^1(n)$ is empty, then (12) trivially holds for $n+1$. If the time epoch d_{n+1} corresponds to a profile modification, then

$$G^1(n+1) = G^1(n) \prec_s G^2(n) = G^2(n+1)$$

so that relation (12) holds for $n+1$. Now assume that $G^1(n)$ is not empty and that d_{n+1} corresponds to a completion at some processor, say processor h, $1 \le h \le \max(m_1, m_2)$. Let u_h, if any, belong to $T_a^1(n)$, and v_h, if any, belong to $T_b^2(n)$. Tasks u_h and/or v_h finish at time d_{n+1}. There are three cases to be investigated.

Case 1: $m_1 > m_2$ *and* $m_2 + 1 \le h \le m_1$. In this case, only task u_h is finished. It is easy to see that

$$\forall i,\ 0 \le i \le g: \quad \sum_{k=i}^{g} |T_k^1(n+1)| \le \sum_{k=i}^{g} |T_k^1(n)| \le \sum_{k=i}^{g} |T_k^2(n)| = \sum_{k=i}^{g} |T_k^2(n+1)|$$

so that relation (12) holds for $n+1$.

Case 2: $h \le \min(m_1, m_2)$. In this case, both tasks u_h and v_h are finished. There are two subcases:

Case 2.1: $b \le a$. It is simple that

$$\begin{aligned}
\forall i,\ a+1 \le i \le g: \quad & \sum_{k=i}^{g} |T_k^1(n+1)| = \sum_{k=i}^{g} |T_k^1(n)| \le \sum_{k=i}^{g} |T_k^2(n)| = \sum_{k=i}^{g} |T_k^2(n+1)|, \\
\forall i,\ b+1 \le i \le a: \quad & \sum_{k=i}^{g} |T_k^1(n+1)| = -1 + \sum_{k=i}^{g} |T_k^1(n)| \le -1 + \sum_{k=i}^{g} |T_k^2(n)| \\
& = -1 + \sum_{k=i}^{g} |T_k^2(n+1)| \le \sum_{k=i}^{g} |T_k^2(n+1)|, \\
\forall i,\ 0 \le i \le b: \quad & \sum_{k=i}^{g} |T_k^1(n+1)| = -1 + \sum_{k=i}^{g} |T_k^1(n)| \\
& \le -1 + \sum_{k=i}^{g} |T_k^2(n)| = \sum_{k=i}^{g} |T_k^2(n+1)|.
\end{aligned}$$

Therefore, relation (12) holds for $n+1$.

Case 2.2: $b > a$. Observe first that

$$\begin{aligned}
\forall i,\ b+1 \le i \le g: \quad & \sum_{k=i}^{g} |T_k^1(n+1)| = \sum_{k=i}^{g} |T_k^1(n)| \le \sum_{k=i}^{g} |T_k^2(n)| = \sum_{k=i}^{g} |T_k^2(n+1)|, \\
\forall i,\ 0 \le i \le a: \quad & \sum_{k=i}^{g} |T_k^1(n+1)| = -1 + \sum_{k=i}^{g} |T_k^1(n)| \\
& \le -1 + \sum_{k=i}^{g} |T_k^2(n)| = \sum_{k=i}^{g} |T_k^2(n+1)|.
\end{aligned}$$

We examine the case $a+1 \le i \le b$. Let $0 \le i_1, i_2 \le g$ be the integers defined as follows:

$$\begin{aligned}
T_g^1(n) = \cdots = T_{i_1+1}^1(n) = \emptyset, & T_{i_1}^1(n) \ne \emptyset, \\
T_g^2(n) = \cdots = T_{i_2+1}^2(n) = \emptyset, & T_{i_2}^2(n) \ne \emptyset.
\end{aligned}$$

Note that i_1 and i_2 are uniquely defined. Under the inductive assumption, one has that

$$\sum_{k=i_1}^{g} |T_k^2(n)| \geq \sum_{k=i_1}^{g} |T_k^1(n)| > 0.$$

Thus $i_1 \leq i_2$.

For $0 \leq i, k \leq g$, let $n_k(i) = |T_k \cap S(T_i)|$, where $S(T_i) \equiv S(w)$ for some $w \in T_i$. Note that $n_k(i) = 0$ if $k \geq i$. Note also that $n_k(i) \leq n_k(i+1)$. According to the definitions, $n_k(i_j)$ is the number of noninitial tasks of $T_k^j(n)$ in $G^j(n)$, $j = 1, 2$, $1 \leq k \leq g$.

For all i, $a+1 \leq i \leq b$, we have $u_h \notin T_g \cup \cdots \cup T_i$ so that there are at most $h-1$ initial tasks $u_1, u_2, \ldots, u_{h-1}$ in $T_g^1(n) \cup \cdots \cup T_i^1(n)$. Thus

$$\sum_{k=i}^{g} |T_k^1(n)| \leq h - 1 + \sum_{k=i}^{g} n_k(i_1).$$

On the other hand, $v_h \in T_b$ implies that the h initial tasks $v_1, v_2, \ldots, v_h$ are in $T_g^2(n) \cup \cdots \cup T_i^2(n)$. Hence

$$\sum_{k=i}^{g} |T_k^2(n)| \geq h + \sum_{k=i}^{g} n_k(i_2).$$

The two inequalities above together with the fact that $n_k(i_1) \leq n_k(i_2)$ imply that

$$\sum_{k=i}^{g} |T_k^1(n)| \leq -1 + \sum_{k=i}^{g} |T_k^2(n)|.$$

Therefore, for all i, $a+1 \leq i \leq b$,

$$\sum_{k=i}^{g} |T_k^1(n+1)| = \sum_{k=i}^{g} |T_k^1(n)| \leq -1 + \sum_{k=i}^{g} |T_k^2(n)| = \sum_{k=i}^{g} |T_k^2(n+1)|,$$

which completes the proof of (12) for $n+1$ in Case 2.2.

Case 3: $m_1 < m_2$ *and* $m_1 + 1 \leq h \leq m_2$. In this case, only task v_h finishes.

It is clear that for all $b+1 \leq i \leq g$,

$$\sum_{k=i}^{g} |T_k^1(n+1)| = \sum_{k=i}^{g} |T_k^1(n)| \leq \sum_{k=i}^{g} |T_k^2(n)| = \sum_{k=i}^{g} |T_k^2(n+1)|.$$

Since $m \geq m_2 \geq m_1 + 1$, and since only m_1 tasks of $G^1(n)$ are assigned to the available processors, we obtain that for all $i \leq b$,

$$\sum_{k=i}^{g} |T_k^1(n)| \leq m_1 + \sum_{k=i}^{g} n_k(i_1). \tag{13}$$

On the other hand, $v_h \in T_b$ implies that the h initial tasks $v_1, v_2, \ldots, v_h$ are in $T_g^2(n) \cup \cdots \cup T_i^2(n)$. Hence for all $i \leq b$,

$$\sum_{k=i}^{g} |T_k^2(n)| \geq h + \sum_{k=i}^{g} n_k(i_2) \geq m_1 + 1 + \sum_{k=i}^{g} n_k(i_2) \geq m_1 + 1 + \sum_{k=i}^{g} n_k(i_1). \tag{14}$$

Inequalities (13) and (14) imply that

$$\sum_{k=i}^{g} |T_k^1(n)| \le -1 + \sum_{k=i}^{g} |T_k^2(n)|.$$

Therefore, for all $i \le b$,

$$\sum_{k=i}^{g} |T_k^1(n+1)| = \sum_{k=i}^{g} |T_k^1(n)| \le -1 + \sum_{k=i}^{g} |T_k^2(n)| = \sum_{k=i}^{g} |T_k^2(n+1)|$$

so that (12) holds for $n+1$ in Case 3.

Therefore, by induction, relation (12) holds for all $n \ge 1$. Consequently, $MS(G^1) \le MS(G^2)$ a.s. in that probability space. □

4.2. Stochastic profile scheduling of in-forests. Let $G = (V, E) \in \mathcal{C}_{i.f}$ be an in-forest. A task of in-forest G is an initial task if and only if it is a leaf of G. For any task, the number of its successors is equal to its level in the in-forest, i.e., the distance from it to the root of the tree in which it appears. (The level of the roots is zero by convention.) Thus the MS policy coincides with the HLF policy.

THEOREM 4.2. *For any profile* $\{a_n, M_n\}_{n=1}^{\infty}$ *bounded by* 2 *and for any in-forest* $G \in \mathcal{C}_{i.f}$,

$$\forall \pi \in \Psi : \quad MS(G) \le_{st} \pi(G). \tag{15}$$

The proof of the theorem is similar to that of Theorem 4.1, using the fact that $\mathcal{C}_{if}$ is $MS(2)$-monotonic, and is omitted here. The reader is referred to [10] for a detailed proof.

Note that the above theorem generalizes the result of Kulkari and Chimento [9] to uniform processors (with a different scheme of proof). Note also that such a result holds only when $|M_n| \le 2$. Simple counterexamples can be found when there are three processors (see [2]).

4.3. Stochastic profile scheduling of out-forests. Let $G = (V, E) \in \mathcal{C}_{o.f}$ be an out-forest. A task of out-forest G is an initial task if and only if it is a root of G. Vertex $v \in V$ and all its successors is a subtree of G, denoted by $T_G(v)$ or simply $T(v)$ when there is no ambiguity.

In general, MS policies are not optimal within the class of out-forests $\mathcal{C}_{o.f}$. Counterexamples are provided in [3]. However, we will show that within the classes of *uniform* and *r-uniform* out-forests (introduced in Coffman and Liu [3]), a policy is optimal if and only if it is MS.

Let $T_1, T_2 \in \mathcal{C}_{o.f}$ be two out-trees. The out-tree T_2 is said to *embed* the out-tree T_1, or T_1 is *embedded* in T_2, denoted by $T_2 \succ_e T_1$ or $T_1 \prec_e T_2$, if T_1 is isomorphic to a subgraph of T_2. Formally, T_2 embeds T_1 if there exists an injective function f from T_1 into T_2 such that $\forall u, v \in T_1$, $v \in s(u)$ implies $f(v) \in s(f(u))$. The function f is called an *embedding function*.

Let r_1 and r_2 be the roots of the out-trees T_1 and T_2, respectively. If $T_2 \succ_e T_1$ and if there is an embedding function f such that $f(r_1) = r_2$, then f is a *root-embedding function*, and we write $T_2 \succ_r T_1$ or $T_1 \prec_r T_2$.

An out-forest $G \in \mathcal{C}_{o.f}$ is said to be *uniform* (respectively, *r-uniform*) if all of its subtrees $\{T(v),\ v \in G\}$ can be ordered by the embedding (respectively, root-embedding) relation. The class of uniform (respectively, r-uniform) out-forests is

denoted by $\mathcal{C}_{u.o.f}$ (respectively, $\mathcal{C}_{r.o.f}$). It is clear that $\mathcal{C}_{r.o.f} \subset \mathcal{C}_{u.o.f} \subset \mathcal{C}_{o.f}$. In Figure 1, graph 3 is a uniform out-forest but not a r-uniform out-forest. Graph 4 is a r-uniform out-forest.

The embedding relation is extended to uniform out-forests as follows. Let $G^1 = (V^1, E^1)$ and $G^2 = (V^2, E^2)$ be two uniform out-forests. Denote by $T_G(v)$ the subtree of out-forest G composed of v and all the successors of v in G. Assume that the vertices of G^1 and G^2 are indexed in such a way that

$$T_{G^1}(1) \succ_e T_{G^1}(2) \succ_e \cdots \succ_e T_{G^1}(|V^1|),$$

$$T_{G^2}(1) \succ_e T_{G^2}(2) \succ_e \cdots \succ_e T_{G^2}(|V^2|).$$

Out-forest G^1 is embedded in G^2, referred to as $G^1 \prec_e G^2$, if and only if

$$|V^1| \leq |V^2|, \quad \text{and} \quad \forall i,\ 1 \leq i \leq |V^1| : \quad T_{G^1}(i) \prec_e T_{G^2}(i).$$

Similarly, $G^1 \prec_r G^2$ if and only if

$$T_{G^1}(1) \succ_r T_{G^1}(2) \succ_r \cdots \succ_r T_{G^1}(|V^1|),$$

$$T_{G^2}(1) \succ_r T_{G^2}(2) \succ_r \cdots \succ_r T_{G^2}(|V^2|),$$

$$|V^1| \leq |V^2|, \quad \text{and} \quad \forall i,\ 1 \leq i \leq |V^1| : \quad T_{G^1}(i) \prec_r T_{G^2}(i).$$

We will show that MS policies are optimal for uniform out-forests and profiles bounded by 2, as well as for r-uniform out-forests and arbitrary profiles. In order to establish these optimality properties, we first prove that $\mathcal{C}_{u.o.f}$ (resp. $\mathcal{C}_{r.o.f}$) is $MS(2)$-monotonic (resp. $MS(p)$-monotonic for any positive integer p).

Observe that for any two roots u and v of a uniform out-forest $G \in \mathcal{C}_{u.o.f}$ (resp. r-uniform out-forest $G \in \mathcal{C}_{r.o.f}$), $T(u) \succ_e T(v)$ (resp. $T(u) \succ_r T(v)$) if and only if $|S(u)| \geq |S(v)|$. Thus for any two subgraphs G^1 and G^2 of G which are obtained from deleting initial tasks of G, $G^1 \prec_e G^2$ (resp. $G^1 \prec_r G^2$) if and only if $G^1 \prec_s G^2$. This last property allows us to use the arguments of Coffman and Liu [3] for the establishment of the following MS-monotonicities.

LEMMA 4.3. *Let $G \in \mathcal{C}_{r.o.f}$ be an arbitrary r-uniform forest and let u and v be two roots of G such that $|S(u)| \geq |S(v)|$. Then for any profile $\{a_n, M_n\}_{n=1}^{\infty}$ bounded by 2,*

$$MS(G - \{u\}) \leq_{st} MS(G - \{v\}).$$

The proof of the above lemma is analogous to the proof of Theorem 1 of Coffman and Liu [3]. Although the proof of Theorem 1 in [3] was given for constant profile and parallel identical processors, the fact that both graphs $G - \{u\}$ and $G - \{v\}$ are scheduled by an MS policy allows us to use the same argument. The detailed proof is left to the interested reader.

LEMMA 4.4. *Let $G \in \mathcal{C}_{r.o.f}$ be an arbitrary r-uniform forest and let u and v be two roots of G such that $|S(u)| \geq |S(v)|$. Then for any profile $\{a_n, M_n\}_{n=1}^{\infty}$,*

$$MS(G - \{u\}) \leq_{st} MS(G - \{v\}).$$

The assertion of the lemma can be shown by mimicking the proof of Theorem 2 of Coffman and Liu [3]. The detailed proof is omitted.

Now applying Theorem 3.1 yields the following result.

THEOREM 4.5. *For any profile* $\{a_n, M_n\}_{n=1}^{\infty}$ *bounded by* 2*, and for any uniform out-forest* $G \in \mathcal{C}_{u.o.f}$*,*

$$\forall \pi \in \Psi : \quad MS(G) \leq_{st} \pi(G). \tag{16}$$

THEOREM 4.6. *For any profile* $\{a_n, M_n\}_{n=1}^{\infty}$ *and any r-uniform out-forest* $G \in \mathcal{C}_{r.o.f}$*,*

$$\forall \pi \in \Psi : \quad MS(G) \leq_{st} \pi(G). \tag{17}$$

5. Concluding remarks. We have considered the scheduling problem for the stochastic minimization of the makespan of task graphs under a variable profile. Under the assumption that task running times are independent random variables with exponential distributions, we have established a general condition for a list-scheduling policy to stochastically minimize the makespan. This result has allowed us to show the optimality of MS policies when the partial order is an interval order, an in-forest, or an out-forest.

We can further show that, except in the degenerate case where there is a single available processor all the time, MS is the only optimal policy for the stochastic minimization of the makespan. The reader is referred to [10] for details.

All results of the paper hold if the speed of the processors, as well as their availability, is allowed to vary. The task assignment will change whenever the speed ratio between two processors is reversed. Such an extension allows one to analyze systems with processor sharing among different jobs (i.e., sets of tasks).

Acknowledgments. We would like to thank the referees for various constructive comments which helped to improve both the contents and the presentation of the paper.

ON BOUNDED QUERIES AND APPROXIMATION*

RICHARD CHANG†, WILLIAM I. GASARCH‡, AND CARSTEN LUND§

Abstract. This paper investigates the computational complexity of approximating several NP-optimization problems using the number of queries to an NP oracle as a complexity measure. The results show a tradeoff between the closeness of the approximation and the number of queries required. For an approximation factor $k(n)$, $\log\log_{k(n)} n$ queries to an NP oracle can be used to approximate the maximum clique size of a graph within a factor of $k(n)$. However, this approximation cannot be achieved using fewer than $\log\log_{k(n)} n - c$ queries to *any oracle* unless P = NP, where c is a constant that does not depend on k. These results hold for approximation factors $k(n) \geq 2$ that belong to a class of functions which includes any integer constant function, $\log n$, $\log^a n$, and $n^{1/a}$. Similar results are obtained for Graph Coloring, Set Cover, and other NP-optimization problems.

1. Introduction.

The approximability of NP-optimization problems is a central theme both in the study of algorithms and in computational complexity theory. Most NP-optimization problems have decision versions that are NP-complete and are hence equivalent to each other as decision problems. However, the approximability of the optimization problems may vary greatly. For some NP-optimization problems, there are efficient algorithms that find good approximate solutions. For others, no such algorithm can exist unless some standard intractability assumption is violated (e.g., P = NP or the polynomial hierarchy (PH) collapses). Recently, Arora et al. [3] showed that the problem of finding the largest clique in a graph is in the latter category. Following a series of breakthrough results [4, 5, 18, 26, 29], they showed that there exists a constant ϵ such that no deterministic polynomial-time algorithm can approximate the maximum clique size $\omega(G)$ of a graph G with n vertices within a factor of n^ϵ unless P = NP. While this result strongly suggests that no efficient algorithm can find good approximations to the maximum-clique problem, it does not resolve all of the questions about the computational complexity of approximating the maximum clique size of a graph. In particular, it is not clear what computational resources are sufficient and/or necessary to compute an approximation of the maximum clique size using any of the traditional resource-bounded measures (e.g., time, space, random bits, and alternation).

In this paper, we use the number of queries to an NP-complete oracle as a complexity measure. Krentel [24] used this measure to show that the maximum clique size

TABLE 1.1
Upper and lower bounds for approximating the maximum clique size.

Factor	Upper bound	Lower bound (unless P = NP)
2	$\log\log n$	$\log\log n - \log 1/\epsilon$
k	$\log\log n - \log\log k$	$\log\log n - \log\log k - \log 1/\epsilon$
$\log^a n$	$\log\log n - \log\log\log^a n$	$\log\log n - \log\log\log^a n - \log 1/\epsilon$
$n^{1/a}$	$\log a$	$\log a - \log 1/\epsilon$

is complete for polynomial-time functions which use only $O(\log n)$ queries, denoted $\mathrm{PF}^{\mathrm{NP}[O(\log n)]}$. Since Krentel's original work, many connections between bounded query classes and standard complexity classes have been discovered [1, 2, 6, 7, 13, 14, 20, 23, 32, 33]. In many circumstances, these results show that one cannot decrease the number of queries needed to solve a problem by even a single query unless P = NP or PH collapses. For example, Hoene and Nickelsen [21] showed that to determine how many of the formulas in $F_1, \ldots, F_r$ are satisfiable, $\lceil \log(r+1) \rceil$ queries are both sufficient and necessary (unless P = NP). A naïve binary search can determine the number of satisfiable formulas using $\lceil \log(r+1) \rceil$ queries to the NP oracle. The number of queries needed is $\lceil \log(r+1) \rceil$ rather than $\lceil \log r \rceil$ because there are $r+1$ possible answers ranging from 0 to r. A tree-pruning technique shows that no polynomial-time machine can determine the number of satisfiable formulas using one fewer query to any oracle unless P = NP. Thus the algorithm which uses the fewest queries is simply the naïve binary search algorithm. In this paper, we show that for several NP-optimization problems, binary search is also the approximation algorithm that uses the fewest queries. In the first parts of the paper, we will focus on the complexity of approximating the size of the maximum clique in a graph.

In order to state the results in this paper correctly, we need to be more precise with the term "approximation." Let $\omega(G)$ denote the size of the maximum clique in the graph G. We say that a number x is an approximation of $\omega(G)$ within a factor of $k(n)$ if $\omega(G)/k(n) \leq x \leq \omega(G)$. Our results show a tradeoff between the closeness of the approximation and the number of queries needed to solve the approximation problem—finding closer approximations requires more queries.

For example we can approximate $\omega(G)$ within a factor of 2 using only $\log\log n$ queries to NP, where n is the number of vertices in the graph G. In contrast, computing $\omega(G)$ exactly can be done with $\log n$ queries and requires $\Omega(\log n)$ queries (unless P = NP) [24]. Moreover, we show that no function using fewer than $(\log\log n) - \log 1/\epsilon$ queries to *any oracle* can approximate $\omega(G)$ within a factor 2 unless P = NP. (Here ϵ is the constant given in Corollary 3 of [3].) In general, our results show that for any "nice" approximation factor $k(n) \geq 2$, $\omega(G)$ can be approximated within a factor of $k(n)$ using $\log\log_{k(n)} n$ queries but not with fewer than $\log\log_{k(n)} n - \log 1/\epsilon$ queries to any oracle unless P = NP. In Corollary 3.3, we show that the difference, $\log 1/\epsilon$, between the upper and lower bounds has a natural interpretation. Table 1.1 summarizes our results for some common approximation factors.

We make a few observations about these results. First, since ϵ is a constant, for a large enough constant k, $\log\log k$ would exceed $\log 1/\epsilon$. Hence for this k, the upper bound on approximating $\omega(G)$ within a factor of k will be strictly less than the lower bound for approximating within a factor of 2. Hence for this large k, the problem of approximating $\omega(G)$ within a factor k has strictly lower complexity in terms of the number of queries than approximating within a factor of 2 unless P = NP. Similarly,

approximating within a factor of $\log n$ has a lower complexity than approximating within any constant; and approximating within a factor of $n^{1/k}$ has an even lower complexity. We believe that these are the first results which show a tradeoff between complexity and closeness of approximation. In contrast, Garey and Johnson [19] showed that if $\omega(G)$ can be approximated within a constant factor in P, then it can be approximated within *any* constant factor in P. While these are not contradictory theorems, they certainly have very different flavors.

In the next section, we state the lemmas, definitions, and notations needed to prove the results. In section 3, we show that a uniform binary search routine provides the upper bounds we have mentioned. To prove the lower bound results, we start in section 4.2 with a simple proof which shows that no function in $\mathrm{PF}^{X[1]}$ for any oracle X can approximate $\omega(G)$ within a factor of 2 unless P = NP. We go on to the proof of the general lower-bound results. In section 5, we discuss how these results extend to other NP optimization problems (e.g., Chromatic Number). In section 6, we ponder the value of the constant ϵ. Finally, in section 7, we combine our techniques with the results of Lund and Yannakakis [27] on the hardness of approximating the Set Cover problem to derive upper and lower bounds on the query complexity of approximating the minimum set-cover size.

2. Preliminaries.

DEFINITION 2.1. *For every graph G, let $|G|$ denote the number of vertices in the graph and let $\omega(G)$ denote the size of the largest clique in G. We say that a function $A(G)$ approximates the maximum clique size within a factor of $k(n)$ if for all graphs G with n vertices,*

$$\omega(G)/k(n) \leq A(G) \leq \omega(G).$$

Some papers use the alternative condition that $\omega(G)/k(n) \leq A(G) \leq k(n) \cdot \omega(G)$, but we find it unintuitive to consider $A(G)$ an approximation of $\omega(G)$ if there does not exist a clique of size $A(G)$ in G. However, the results in this paper still hold under the alternative definition.

To prove the lower bounds, we need the result of Arora et al. [3], which showed that there exists an $\epsilon > 0$ such that the maximum clique size cannot be approximated within a factor of n^ϵ in deterministic polynomial time unless P = NP, where n is the number of vertices in the graph. Their construction yields the next lemma.

LEMMA 2.2 (see [3]). *There exist constants s, b, and d, $0 < s < b < d$, such that given a Boolean formula F with t variables, we can construct in polynomial time a graph G with $m = t^d$ vertices, where*

$$F \in \mathrm{SAT} \Longrightarrow \omega(G) = t^b \quad \textit{and}$$
$$F \notin \mathrm{SAT} \Longrightarrow \omega(G) < t^s.$$

The constants b, s, and d will be fixed for the remainder of the paper. Of particular interest is the ratio $(b-s)/d$ because it is equal to the ϵ mentioned before Lemma 2.2. To prove the intractability of n^ϵ approximation, first assume that we have a polynomial-time algorithm to approximate $\omega(G)$ within n^ϵ. Take any Boolean formula F, and let t be the number of variables in F. Construct G as described in Lemma 2.2. Use the polynomial-time algorithm to obtain an approximation x of $\omega(G)$. Since $|G| = t^d$, an n^ϵ approximation is within a factor of $(t^d)^\epsilon = t^{b-s}$. Therefore, if $F \in \mathrm{SAT}$, the algorithm must guarantee that $x \geq t^b/t^{b-s} = t^s$. On the other hand, if $F \notin \mathrm{SAT}$, then $x < t^s$. Thus $F \in \mathrm{SAT} \iff x \geq t^s$.

DEFINITION 2.3. *Let* $\mathrm{PF}^{X[q(n)]}$ *be the class of functions computed by polynomial-time oracle Turing machines which ask at most* $q(n)$ *queries to the oracle* X*. Since the queries are adaptive, the query strings may depend on answers to previous queries.*

3. Upper bounds. We first examine the upper bounds on the complexity of approximating NP-optimization problems in terms of bounded query classes. The general idea is to use each query to SAT to narrow down the range where the optimal solution exists. For example, for a graph G with n nodes, $1 \le \omega(G) \le n$. We can compute $\omega(G)$ exactly using binary search and $\log n$ queries of the form: "Is $\omega(G)$ greater than x?"

On the other hand, to approximate $\omega(G)$ within a factor of 2, we only need to find a number x such that $x \le \omega(G) \le 2x$. Thus we first partition the numbers from 1 to n into the intervals

$$[1,2],\ (2,4],\ (4,8],\ldots,\left(2^{\lceil \log n\rceil -1}, 2^{\lceil \log n\rceil}\right].$$

If $\omega(G)$ is in the interval $(2^i, 2^{i+1}]$, then we can simply use 2^i as a factor-2 approximation of $\omega(G)$. Thus our strategy is to use binary search on the left endpoints of the intervals to determine which interval contains $\omega(G)$. Since there are only $\lceil \log n\rceil$ intervals, we only need $\lceil \log \lceil \log n\rceil\rceil$ queries to SAT to perform this binary search. In the general case, if we want to find an approximation of $\omega(G)$ that is within a factor of $k(n)$, there will be $\lceil \log_{k(n)} n\rceil$ intervals of the form $\left(k(n)^i, k(n)^{i+1}\right]$ and binary search would use $\lceil \log \lceil \log_{k(n)} n\rceil\rceil$ queries to SAT. Thus, we have the following lemma.

LEMMA 3.1. *Let* $k(n)$ *be a polynomial-time-computable function such that* $1 < k(n) < n$*. Then there exists a function in* $\mathrm{PF}^{\mathrm{SAT}[\lceil \log \lceil \log_{k(n)} n\rceil\rceil]}$ *which approximates* $\omega(G)$ *within a factor of* $k(n)$ *for all graphs* G *with* n *vertices.*

The lemma is stated for the maximum-clique-size problem, but it obviously holds for any NP-optimization problem where the solution is an integer ranging from 1 to n. Note that it does not matter if $k(n)$ is not an integer because checking whether $\omega(G)$ is greater than x is still an NP question when x is a fractional number. Once we have determined that $\omega(G)$ is contained in the interval $(k(n)^i, k(n)^{i+1}]$, we can output $\lceil k(n)^i\rceil$ as an approximation to $\omega(G)$. Also, if we drop the ceilings from our notation, then we can derive more readable upper bounds on the complexity of approximating $\omega(G)$ for some common approximation factors (see Table 1.1).

The binary search strategy used to find the approximation to $\omega(G)$ may seem naïve. However, we shall see later that the upper bounds differ from the lower bounds by at most an additive constant. In any case, we can improve the upper bounds if there exists a polynomial-time algorithm which gives an approximate solution within a factor of $f(n)$. Then our strategy is to first use the polynomial-time algorithm to obtain an approximation x. We know that the solution is between x and $x \cdot f(n)$. Now, to find an approximation that is within a factor of $k(n)$, we divide the numbers from x to $x \cdot f(n)$ into intervals:

$$[x, xk(n)],\ \left(xk(n), xk(n)^2\right],\ldots,\left(x\frac{f(n)}{k(n)}, xf(n)\right].$$

In this case, the number of intervals is $\lceil \log_{k(n)} f(n)\rceil$, and we have the following lemma.

LEMMA 3.2. *Let* $k(n)$ *be a polynomial-time-computable function such that* $1 < k(n) < n$*. Suppose that there exists a polynomial-time algorithm which approximates*

$\omega(G)$ within a factor of $f(n)$. Then there exists a function in $\mathrm{PF}^{\mathrm{SAT}[\lceil \log \lceil \log_{k(n)} f(n) \rceil \rceil]}$ *which approximates $\omega(G)$ within a factor of $k(n)$ for all graphs G with n vertices.*

Again, we note that this lemma applies to any NP-optimization problem whose solutions range from 1 to n. This lemma may seem somewhat useless since the best known polynomial-time algorithm can only approximate the size of the maximum clique within a factor of $O(n/(\log n)^2)$ [10]. If we were to use the new strategy outlined above, we would reduce the number of queries needed to find a factor-2 approximation of $\omega(G)$ to $\log(\log n - 2 \log \log n)$, which would save us at most one query for various values of n. However, the following corollary of the lemma does allow us to gauge the quality of our lower bound results.

COROLLARY 3.3. *If no function in* $\mathrm{PF}^{\mathrm{SAT}[\log \log_{k(n)} n - \log 1/\delta]}$ *approximates $\omega(G)$ within a factor of $k(n)$, then no polynomial-time algorithm can approximate $\omega(G)$ within a factor of n^δ.*

Corollary 3.3 gives us a natural interpretation of the difference between the upper bound of $\log \log_{k(n)} n$ in Lemma 3.1 and the lower bound of $\log \log_{k(n)} - \log 1/\epsilon$ (Theorem 4.8). This difference of $\log 1/\epsilon$ reflects the fact that we do not know if there exists a polynomial-time algorithm which approximates $\omega(G)$ within a factor of n^δ for $\epsilon < \delta < 1$. Thus an improvement of either the upper or the lower bound is possible.

Moreover, the observations about Lemma 3.2 are most useful when they are applied to NP-optimization problems such as Set Cover. In the Set Cover problem, we are given a finite collection C of subsets of $\{1, \ldots, n\}$ and asked to find the size of the smallest subcollection $C' \subseteq C$ that covers $\{1, \ldots, n\}$. Since the size of the smallest set cover *can* be approximated within a factor $\ln(n) + 1$ [22, 25], we have the following lemma.

LEMMA 3.4. *Let $k(n)$ be a polynomial-time-computable function such that $1 < k(n) < n$. Then there exists a function in* $\mathrm{PF}^{\mathrm{SAT}[\lceil \log \lceil \log_{k(n)} (\ln n + 1) \rceil \rceil]}$ *which approximates the size of the minimum set cover within a factor of $k(n)$.*

Now, by comparing Lemma 3.1 against Lemma 3.4, we can obtain a quantitative difference between the complexity of approximating $\omega(G)$ and the complexity of approximating the size of the minimum set cover—not just a qualitative difference. For example, if we are allowed to make $\log \log(\ln n + 1)$ queries to SAT, then we can approximate the minimum set cover within a factor of 2. However, using the same number of queries, we can only approximate $\omega(G)$ within a factor of $n^{1/\log(\ln n + 1)}$. Thus we can conclude that approximating the set cover within a factor of 2 has about the same complexity as approximating $\omega(G)$ within a factor of $n^{1/\log(\ln n + 1)}$. Such a comparison is only possible by taking a quantitative view of the complexity of approximations in terms of the number of queries.

Note that the existence of a "good" polynomial-time approximation algorithm for a problem has a greater effect on the complexity of approximating the problem than on the complexity of finding the exact solution. For example, suppose that we have some NP-optimization problem where the solution ranges from 1 to n. Without the help of an approximation algorithm, we would need $\log n$ queries to find the exact solution and $\log \log n$ queries to find a factor-2 approximation. Now suppose that we are given a polynomial-time algorithm that guarantees a factor-4 approximation. To find the exact solution we would still need $\log(n - n/4) = O(\log n)$ queries. However, we only need one query ($\log \log 4 = 1$) to approximate within a factor of 2.

The upper bounds proven in this section use a naïve binary search strategy to determine an interval that contains the optimal solution. One might suspect that a more clever algorithm could use substantially fewer queries to the oracle. In the rest

of the paper, we show that unless some intractability assumption is violated (e.g., P = NP and RP = NP), no polynomial-time algorithm can reduce the number of queries by more than an additive constant. These results give us relative lower bounds on the number of queries needed to approximate the maximum clique size of a graph. We are also able to extend these techniques to determine the query complexity of approximating the chromatic number of a graph and the minimum set cover.

4. Lower bounds.

4.1. Promise problems and clique arithmetic. To prove our lower-bound results, we need to introduce some more definitions and notations.

DEFINITION 4.1. *Let* $\#^{\mathrm{SAT}}_{r(n)}(F_1, \ldots, F_{r(n)})$ *be the number of formulas in* $\{F_1, \ldots, F_{r(n)}\}$ *which are satisfiable. In other words,* $\#^{\mathrm{SAT}}_{r(n)}(F_1, \ldots, F_{r(n)}) = |\{F_1, \ldots, F_{r(n)}\} \cap \mathrm{SAT}|$.

DEFINITION 4.2. *Let* $r(t)$ *be a polynomially bounded polynomial-time function. We define* $\mathcal{P}_{r(t)}$ *to be the following promise problem. Given a sequence of Boolean formulas* $F_1, \ldots, F_{r(t)}$*, where each* F_i *has* t *variables, and the promise that for all* i*,* $2 \le i \le r(t)$*,* $F_i \in \mathrm{SAT}$ *implies that* $F_{i-1} \in \mathrm{SAT}$*, output* $\#^{\mathrm{SAT}}_{r(t)}(F_1, \ldots, F_{r(t)})$.

Technically, the size of the input to the promise problem is $|F_1, \ldots, F_{r(t)}|$. This size is $O(tr(t))$ when the Boolean formulas are restricted to ones where each variable occurs only a constant number of times. To simplify our notation, in the following lemma, we count the queries as a function of t rather than $|F_1, \ldots, F_{r(t)}|$. The following lemma provides a tight lower bound on the complexity of $\mathcal{P}_r$ and can be proven using the self-reducibility of SAT and a tree-pruning technique [21]. We include the proof for the sake of completeness.

LEMMA 4.3. *Let* $r(t)$ *be a logarithmically bounded polynomial-time-computable function. If there exists an oracle* X *such that some polynomial-time function solves* $\mathcal{P}_{r(t)}$ *using fewer than* $\lceil \log(r(t)+1) \rceil$ *queries to* X*, then* P = NP.

Proof. Let $q(t) = \lceil \log(r(t)+1) \rceil - 1$ and let M be a polynomial-time oracle Turing machine which solves $\mathcal{P}_r$ using $q(t)$ queries to X. We know that $q(t) = O(\log \log n)$, so the entire oracle computation tree of M on input $F_1, \ldots, F_{r(t)}$ is polynomially bounded and can be searched deterministically. In fact, the oracle computation tree has at most $r(t)$ leaves since for all x, $2^{\lceil \log x \rceil} < 2x$. One of these leaves represents the correct computation of $M^X(F_1, \ldots, F_{r(t)})$ and contains the value of $\#^{\mathrm{SAT}}_{r(t)}(F_1, \ldots, F_{r(t)})$. However, there are $r(t)+1$ possible answers for $\#^{\mathrm{SAT}}_{r(t)}(F_1, \ldots, F_{r(t)})$ ranging from 0 to $r(t)$. Therefore, one possible answer, call it z, does not appear in any leaf. Moreover, one of the leaves contains the correct answer, so $z \neq \#^{\mathrm{SAT}}_{r(t)}(F_1, \ldots, F_{r(t)})$. Thus we can construct a polynomial time Turing machine M' which on input $F_1, \ldots, F_{r(t)}$ prints out a number $z \le r(t)$ such that $z \neq \#^{\mathrm{SAT}}_{r(t)}(F_1, \ldots, F_{r(t)})$.

Now we show that P = NP under this condition. Given a Boolean formula F, consider its disjunctive self-reduction tree. Each node in the tree is a formula; the children of a node are the two formulas obtained by instantiating one of the variables in the formula by 0 and by 1. With F at the root of the tree, the tree has height t and exponential size. However, we will only examine $r(t)$ levels of the tree at a time. Now let $F = F_1, \ldots, F_{r(t)}$ be a path in this tree. Suppose that $F_{i+1} \in \mathrm{SAT}$. Since F_{i+1} is a child of F_i, we can assume that $F_i \in \mathrm{SAT}$. Thus the promise condition of $\mathcal{P}_{r(t)}$ holds and we can use M' to find a number z such that $z \neq \#^{\mathrm{SAT}}_{r(t)}(F_1, \ldots, F_{r(t)})$. Now replace the subtree rooted at F_z with the subtree rooted at F_{z+1}. If $F_z \notin \mathrm{SAT}$, then $F_{z+1} \notin \mathrm{SAT}$ by the promise condition. If $F_z \in \mathrm{SAT}$ and $F_{z+1} \notin \mathrm{SAT}$, then z would equal $\#^{\mathrm{SAT}}_{r(t)}(F_1, \ldots, F_{r(t)})$, which contradicts our construction of M'. Thus

$F_{z+1} \in \text{SAT}$ iff $F_z \in \text{SAT}$ and we have shortened the path by 1. Repeat this process for all paths in any order until all the paths in the tree have length less than $r(t)$. Now the original formula F is satisfiable iff one of the leaves (in which all the variables have been instantiated) evaluates to true. Since the final tree is polynomially bounded, we can check every leaf exhaustively. □

In the proofs that follow, we need to construct graphs in which the maximum clique size can occur only at restricted intervals. To assist in this construction, we define two operators on graphs: $\oplus$ and $\otimes$. We also use K_i to denote the complete graph with i vertices.

DEFINITION 4.4. *Given two graphs G_1 and G_2, the graph $H = G_1 \oplus G_2$ is constructed by taking the disjoint union of the vertices of G_1 and G_2. The edges of H are all the edges of G_1 and G_2, plus the edges (u, v) for each vertex u in G_1 and v in G_2. (Thus every vertex in G_1 is connected to every vertex in G_2).*

DEFINITION 4.5.[1] *Given two graphs G_1 and G_2, the graph $H = G_1 \otimes G_2$ is constructed by replacing each vertex of G_1 with a copy of G_2. Furthermore, for each edge (u, v) in G_1, each vertex in the copy of G_2 replacing u is connected to every vertex in the copy of G_2 replacing v. Note that $\otimes$ is not commutative and that we give $\otimes$ higher precedence than $\oplus$.*

LEMMA 4.6. *Let G_1 and G_2 be any two graphs, then*

$$\omega(G_1 \oplus G_2) = \omega(G_1) + \omega(G_2) \quad \textit{and}$$
$$\omega(G_1 \otimes G_2) = \omega(G_1) \cdot \omega(G_2).$$

4.2. A simple lower bound. As a first lower-bound result, we show that for all oracles X, no function in $\text{PF}^{X[1]}$ can approximate $\omega(G)$ within a factor of 2 unless P = NP. To do this, we start with the assumption that some function $f \in \text{PF}^{X[1]}$ does approximate $\omega(G)$ within a factor of 2 and show that using this function we can solve the promise problem $\mathcal{P}_2$ using only one query to X. Then P = NP by Lemma 4.3.

In our construction, we start with the input to the promise problem $\mathcal{P}_2$, which is a pair of Boolean formulas F_1 and F_2, each with t variables. Now, using the reduction from Lemma 2.2, we construct two graphs G_1 and G_2 with t^d vertices such that

$$F_i \in \text{SAT} \Longrightarrow \omega(G_i) = t^b \quad \text{and}$$
$$F_i \notin \text{SAT} \Longrightarrow \omega(G_i) < t^s.$$

Then let $H = G_1 \oplus (K_2 \otimes G_2)$. By Lemma 4.6, $\omega(H) = \omega(G_1) + 2 \cdot \omega(G_2)$. Also, assume that t is sufficiently large so that $t^b > 6 \cdot t^s$.

Consider the effect of the satisfiability of F_1 and F_2 on $\omega(H)$. If $F_1 \notin \text{SAT}$ and $F_2 \notin \text{SAT}$, then

$$\omega(H) = \omega(G_1) + 2 \cdot \omega(G_2) < 3 \cdot t^s.$$

On the other hand, if $F_1 \in \text{SAT}$ and $F_2 \notin \text{SAT}$, then $t^b \leq \omega(H) < t^b + 2 \cdot t^s$. Finally, if $F_1 \in \text{SAT}$ and $F_2 \in \text{SAT}$, then $\omega(H) = 3 \cdot t^b$.

Because of the promise condition of the promise problem, we do not have the case where $F_1 \notin \text{SAT}$ and $F_2 \in \text{SAT}$. This restricts the value of $\omega(H)$ to three nonoverlapping intervals. In fact, these intervals are separated by a factor of 2. Thus a factor-of-2 approximation of $\omega(H)$ will tell us which formulas are satisfiable. For

[1] This is identical to graph composition in Garey and Johnson [19]. The cover of [19] is the picture of a 3-clique composed with a graph that has three points connected by two edges.

example, if we are given an approximation x guaranteed to be within a factor of 2, and $x \geq 1.5 \cdot t^b$, then we know that both F_1 and F_2 are satisfiable. If this approximation can be achieved using only one query to X, then we can solve the promise problem $\mathcal{P}_2$ in $\mathrm{PF}^{X[1]}$ and P = NP.

4.3. The general construction. In this section, we prove the general theorem for the lower bound on approximating the size of the maximum clique in a graph. First, we define a class of approximation factors.

DEFINITION 4.7. *We call a function $k : \mathbb{N} \to \mathbb{R}$ a* nice approximation factor *if it is computable in polynomial time and all of the following hold:*

1. $\exists n_0\ \forall n > n_0,\ 2 \leq k(n) < n$.
2. $\exists n_0\ \forall m > n > n_0,\ k(m) \geq k(n)$.
3. $\forall \delta > 0,\ \exists n_0,\ \forall m > n > n_0$,

$$(1+\delta)\frac{\log m}{\log k(m)} > \frac{\log n}{\log k(n)}.$$

Please note that $k(n)$ is nice if $k(n)$ equals $n^{1/a}$, $\log n$, $(\log n)^a$, or a constant ≥ 2. The natural interpretation of the third condition is the following. Consider the function $f(n) = (\log n)/(\log k(n))$. The function $f(n)$ is also related to $k(n)$ by $k(n) = n^{1/f(n)}$. The third condition is satisfied if $f(n)$ is increasing, if $f(n)$ is constant, or if $f(n)$ is decreasing but converges to a limit (e.g., when $k(n) = \sqrt{n}/2$). Since $k(n) < n$, $f(n)$ is bounded below by 1. Thus if $f(n)$ is decreasing almost everywhere, it must converge to a limit. Hence the third condition is not satisfied only when $f(n)$ alternates between increasing and decreasing infinitely often. We rule out these functions as approximation factors.

THEOREM 4.8. *Let $k(n)$ be a nice approximation factor which* (1) *is unbounded,* (2) *converges to an integral constant, or* (3) *converges to a sufficiently large constant. Then for all oracles X, no polynomial-time function can approximate $\omega(G)$ within a factor of $k(n)$ using $\lfloor \log \log_{k(n)} n - c \rfloor$ or fewer queries to X unless* P = NP*, where $c = 1 + \log(1/\epsilon)$.*

Proof. The general strategy of this proof is to reduce the promise problem $\mathcal{P}_r$ to the problem of approximating the maximum clique size of a graph H within a factor of $k(n)$. Since Lemma 4.3 provides us with a lower bound on the complexity of $\mathcal{P}_r$ (assuming that P $\neq$ NP), we obtain a lower bound on the complexity of approximating $\omega(H)$.

Therefore, we begin with the input to the promise problem $\mathcal{P}_r$, the Boolean formulas $F_1, \ldots, F_r$, each with t variables. (The actual value of r will be chosen later.) We convert each formula F_i into a graph G_i with $m = t^d$ vertices according to the construction described in Lemma 2.2. The values of $\omega(G_i)$ are restricted by

$$F_i \in \mathrm{SAT} \Longrightarrow \omega(G_i) = t^b \quad \text{and}$$
$$F_i \notin \mathrm{SAT} \Longrightarrow \omega(G_i) < t^s.$$

Then we choose a gap size g. In the simple example above, g is 2. In this proof, the value of g and r will depend on t. However, for notational convenience, we do not make this dependency explicit. Moreover, we can only choose g to be a whole number. Now, given the choices of r and g, we construct the graph H as follows:

$$H = G_1 \oplus (K_g \otimes G_2) \oplus (K_{g^2} \otimes G_3) \oplus \cdots$$
$$\oplus (K_{g^{i-1}} \otimes G_i) \oplus \cdots \oplus (K_{g^{r-1}} \otimes G_r).$$

At first glance, this does not appear to be a polynomial-time construction because we could double the size of each succeeding graph. However, r will turn out to be logarithmically bounded, so $|H|$ will be polynomially bounded. Finally, let

$$\nu_j = \sum_{i=0}^{j-1} g^i = \frac{g^j - 1}{g - 1};$$

then $n = |H| = \nu_r \cdot m = \nu_r \cdot t^d$.

Now suppose there exists a polynomial-time function which approximates $\omega(H)$ within a factor of $k(n)$ using $\log\log_{k(n)} n - c$ queries to X. We want to show that the factor-$k(n)$ approximation of $\omega(H)$ also tells us the value of $\#_r^{\mathrm{SAT}}(F_1, \ldots, F_r)$. Also, we want to constrain the choice of g and r so that $\log\log_{k(n)} n - c < \lceil \log(r+1) \rceil$. Then by Lemma 4.3, being able to approximate $\omega(H)$ within a $k(n)$ factor using only $\log\log_{k(n)} n - c$ queries to X would imply that P = NP. To make this claim, our choices of g and r are critical. We have already encountered one constraint on g and r. The other constraints arise when we analyze the possible values of $\omega(H)$.

For the moment, assume that there are exactly z satisfiable formulas in $F_1, \ldots, F_r$. Then $F_1, \ldots, F_z$ are in SAT and $F_{z+1}, \ldots, F_r$ are in $\overline{\mathrm{SAT}}$ by the promise condition of $\mathcal{P}_r$. We can calculate $\omega(H)$ as follows:

$$\begin{aligned}
\omega(H) &= \sum_{i=1}^{r} g^{i-1} \omega(G_i) \\
&= \left(\sum_{i=1}^{z} g^{i-1} \omega(G_i) \right) + \left(\sum_{i=z+1}^{r} g^{i-1} \omega(G_i) \right) \\
&= \nu_z t^b + \left(\sum_{i=z+1}^{r} g^{i-1} \omega(G_i) \right).
\end{aligned}$$

Since F_i is unsatisfiable, for $z+1 \le i \le r$, we can estimate the size of the second term by $\nu_r \cdot t^s$. Then we can bound the size of the maximum clique of H:

$$\nu_z t^b \le \omega(H) \le \nu_z t^b + \nu_r t^s.$$

We want to show that an approximation of $\omega(H)$ within a factor of g will also allow us to calculate $\#_r^{\mathrm{SAT}}(F_1, \ldots, F_r)$. Therefore, assume that we are provided with a function which approximates $\omega(H)$ within a factor g. To distinguish the case where z formulas are satisfiable from the case where $z+1$ formulas are satisfiable, we must have $g \cdot (\nu_z t^b + \nu_r t^s) < \nu_{z+1} t^b$. That is, the upper bound on $\omega(H)$ when z formulas are satisfiable must be smaller by a factor of g than the lower bound on $\omega(H)$ when $z+1$ formulas are satisfiable. Since $\nu_{z+1} = g\nu_z + 1$, this condition is satisfied if we have the constraint that $g\nu_r t^s < t^b$. Similarly, under this constraint, we would also have $g(\nu_{z-1} t^b + \nu_r t^s) < \nu_z t^b$. Hence we have restricted the possible values of $\omega(H)$ to $r+1$ disjoint intervals which are separated by a factor of g. Thus given a number x which is guaranteed to be an approximation of $\omega(H)$ within a factor of $k(n)$, $k(n) \le g$, we can find the largest z such that $gx \ge \nu_z t^b$. This largest z is equal to $\#_r^{\mathrm{SAT}}(F_1, \ldots, F_r)$. It is important to note here that the approximation factor $k(n)$ depends on n which is the size of H and not the size of the original input. Furthermore, the value of n depends on the value of g. Thus it is not a simple task to choose g and have $k(n) \le g$. (Recall that $n = \nu_r t^d$.)

In summary, we must choose g and r such that the following constraints hold. (Recall that we use g and $g(t)$ interchangeably.)

Constraint 1. $g(t)\nu_r t^s \stackrel{\text{def}}{=} g \cdot (g^r - 1)/(g-1) \cdot t^s < t^b$.

Constraint 2. $k(n) \le g(t)$.

Constraint 3. $\lfloor (\log \log_{k(n)} n) - c \rfloor < \lceil \log(r(t)+1) \rceil$.

The main difficulty of this proof is to choose the correct values for the parameters. For example, we can satisfy Constraint 3 by picking a large value for r. However, if r is large, then Constraint 1 is harder to satisfy. We also satisfy Constraint 2 easily by choosing a large g, but a large g would force us to pick a small r, which then violates Constraint 3. Let $n' = t^{b-s+d}$. We will show that the following choices satisfy the constraints:

- $g = \lceil k(t^{b-s+d}) \rceil \stackrel{\text{def}}{=} \lceil k(n') \rceil$.
- $r = \lfloor \log_g t^{b-s}(g-1)/g \rfloor$.

Note that g and r are chosen to be integers. This is important for our construction, but it is also the source of some difficulties in our calculations. The reader may find the proof easier to follow by substituting 2 or $\sqrt{n}$ for g. These are the two extreme possibilities.

First, we show that Constraint 1 holds. By our choice of r, $r \le \log_g(t^{b-s}(g-1)/g)$. By removing the $\log_g$, isolating t^b, and using the fact that $g^r - 1 < g^r$, we obtain the following, and hence Constraint 1 holds:

$$g\nu_r t^s = g \cdot \frac{g^r - 1}{g-1} \cdot t^s < g \cdot \frac{g^r}{g-1} \cdot t^s \le t^b. \tag{4.1}$$

We can also use equation (4.1) to estimate n in terms of t. From our construction, we know that $n = \nu_r t^d$. From equation (4.1), we know that $\nu_r < t^{b-s}$. Hence $n < t^{b-s+d} = n'$. Since $k(n)$ is a nice approximation factor, it is monotonic after some point. Hence for large enough t, $k(n) \le k(n') \le \lceil k(n') \rceil = g(t)$. Thus Constraint 2 holds.

Finally, we have to show that Constraint 3 holds. Since $c = 1 + \log(1/\epsilon)$, $2^{-c} = \epsilon/2$. It suffices to show that $(\log \log_{k(n)} n) - c < \log(r+1)$ or that $(\epsilon/2)\log_{k(n)} n < r+1$. By substituting the definition of r and being careful with the floor notation, we can satisfy Constraint 3 by showing that

$$\frac{2}{\epsilon} \log_g \frac{g}{g-1} + \log_{k(n)} n < \frac{2}{\epsilon} \log_g t^{b-s}. \tag{4.2}$$

In the next step, we rewrite $(2/\epsilon)$ as follows. Recall that $\epsilon = (b-s)/d$.

$$\frac{2}{\epsilon} = \frac{2}{(1+\epsilon)} \frac{(1+\epsilon)}{\epsilon} = \left(\frac{1-\epsilon}{2+2\epsilon} + \frac{3+\epsilon}{2+2\epsilon} \right) \frac{b-s+d}{b-s}.$$

Thus

$$\frac{2}{\epsilon} \log_g t^{b-s} = \frac{1-\epsilon}{2+2\epsilon} \log_g n' + \frac{3+\epsilon}{2+2\epsilon} \log_g n'.$$

Since ϵ must be less than 1, $(3+\epsilon)/(2+2\epsilon) > 1$ and $(1-\epsilon)/(2+2\epsilon) > 0$. We can satisfy Constraint 3 by showing the following two inequalities:

$$\frac{2}{\epsilon} \log_g \frac{g}{g-1} < \frac{1-\epsilon}{2+2\epsilon} \log_g n', \tag{4.3}$$

$$\log_{k(n)} n < \frac{3+\epsilon}{2+2\epsilon} \log_g n'. \tag{4.4}$$

Equation (4.3) holds since $g/(g-1)$ is bounded by 2 and $n' = t^{b-s+d}$ is unbounded.

Now we have to show that equation (4.4) holds. First, pick $\delta > 0$ small enough so that

$$(1+\delta)^2 < \frac{3+\epsilon}{2+2\epsilon}.$$

Recall that $g = \lceil k(n') \rceil$. Thus

$$\frac{3+\epsilon}{2+2\epsilon} \log_g n' > (1+\delta)^2 \cdot \frac{\log n'}{\log k(n')} \cdot \frac{\log k(n')}{\log \lceil k(n') \rceil}.$$

Consider the ratio $\log k(n')/\log \lceil k(n') \rceil$. If $k(x)$ is always an integer, then the ratio is just 1. If $k(x)$ is growing monotonically, then the ratio converges to 1 from below and will eventually rise above the constant $1/(1+\delta)$. In fact, it is sufficient to assume that $k(x)$ is an unbounded function. The proof also works when $k(x)$ converges to an integral constant or a sufficiently large constant. The proof *does not* work when $k(x)$ is a small fractional constant (e.g., 2.5). Hence we exclude this case in the hypothesis of the theorem. (In that case, however, we can prove the same theorem with $c = 2 + \log(1/\epsilon)$, which results in a worse lower bound.) Thus we may assume that for sufficiently large t,

$$\frac{3+\epsilon}{2+2\epsilon} \log_g n' > (1+\delta) \frac{\log n'}{\log k(n')}.$$

Using the third niceness property of $k(x)$, for sufficiently large t,

$$(1+\delta) \frac{\log n'}{\log k(n')} > \frac{\log n}{\log k(n)} = \log_{k(n)} n.$$

Thus, equations (4.3) and (4.4) are true, and all of the constraints are satisfied for large enough t. □

In the preceding theorem, we make some additional assumptions about $k(n)$ beyond niceness to show that equation (4.4) holds. If we are willing to settle for a slightly worse lower bound, we can prove a similar result for all nice approximation functions $k(n)$. Alternatively, we can make the assumption that $\epsilon \leq 1/4$. The proof for each case is nearly identical to the proof of Theorem 4.8 except we use the fact that the ratio $\log k(n')/\log \lceil k(n') \rceil$ is bounded below by $\log 2/\log 3 \approx 0.6309$ since $k(n) \geq 2$ for all n.

COROLLARY 4.9. *Let $k(n)$ be a nice approximation factor. Then for all oracles X, no polynomial-time function can approximate $\omega(G)$ within a factor of $k(n)$ using $\lfloor \log \log_{k(n)} n - c \rfloor$ or fewer queries to X unless* P = NP*, where $c = 2 + \log(1/\epsilon)$.*

COROLLARY 4.10. *Let $k(n)$ be a nice approximation factor. If $\epsilon \leq 1/4$, then for all oracles X, no polynomial-time function can approximate $\omega(G)$ within a factor of $k(n)$ using $\lfloor \log \log_{k(n)} n - c \rfloor$ or fewer queries to X unless* P = NP*, where $c = 1 + \log(1/\epsilon)$.*

5. Approximating the chromatic number. The results that we have stated so far also hold for many other NP-optimization problems. For any NP-optimization problem where the solutions range from 1 to n (or even n^a), the upper bound on the number of queries needed to approximate the problem can be easily derived from the techniques in section 3. To show that the lower bounds hold, we need a reduction

from SAT to the new problem similar to the one for Clique in Lemma 2.2. Recently, Lund and Yannakakis have discovered such reductions for Graph Coloring and some related problems [27]. To repeat the proof, special attention must be given to any differences that may arise between minimization and maximization (see section 7). Thus we could obtain results analogous to the ones in Theorem 4.8 for the problem of approximating the chromatic number of a graph.

In this section, we take an alternative approach and prove the lower bounds using an approximation-preserving reduction from the maximum-clique-size problem to the chromatic number of a graph [27]. However, this reduction increases the size of the graphs, so the proof does not produce the best lower bounds. This approach can be extended to most of the problems which Lund and Yannakakis show to have approximability properties similar to that of Graph Coloring. We can show that Clique Partition, Clique Cover and Biclique Cover have similar lower bounds. This follows from approximation preserving reductions due to Simon [30] for Clique Cover and Biclique Cover. These reductions preserve the approximation ratio within $1+\epsilon$ for any $\epsilon > 0$ where the new problems have size $n^{O(1/\epsilon)}$. On the other hand, we have not been able to obtain a similar result for Fractional Chromatic Number. The reason is that the reduction there only preserves the approximation ratio with a $\log n$ multiplicative factor.

In the following, let $\alpha(G)$ and $\chi(G)$ denote, respectively, the size of the largest independent set and the chromatic number of a graph G. The next lemma is an application of the results of Lund and Yannakakis.

LEMMA 5.1. *There exists a polynomial-time transformation $T(G)$ such that for all graphs G with n vertices and for all primes p with $n \le p \le 2n$, $H = T(G)$ has the property that*

$$\frac{p^3 n^2}{\alpha(G)} \le \chi(H) \le \frac{p^3 n^2 (1+1/n)}{\alpha(G)}.$$

Furthermore, $|H| = n^2 \cdot p^5 \le 32 \cdot n^7$.

Proof. By Proposition 4.1[2] in the appendix of Lund and Yannakakis [27], there exists a polynomial-time transformation $T'(G,p,r)$ such that if G is a graph, p is a prime, r is a number, $p^2 \ge r \ge \alpha(G)$, $p \ge n$, and $H = T'(G,p,r)$, then

$$p^3 \cdot \frac{r}{\alpha(G)} \le \chi(H) \le p^3 \cdot \left\lceil \frac{r}{\alpha(G)} \right\rceil.$$

Given a graph G on n vertices, we define T as follows. Let $r = n^2$ and find a prime p such that $n \le p \le 2n$. (Such primes exist by Bertrand's theorem and can be found easily since the length of the input is n not $\log n$.) Let $T(G) = T'(G,p,r)$. If $H = T(G)$, then

$$p^3 \cdot \frac{n^2}{\alpha(G)} \le \chi(H) \le p^3 \cdot \left\lceil \frac{n^2}{\alpha(G)} \right\rceil < p^3 \cdot \frac{n^2(1+1/n)}{\alpha(G)}. \qquad \square$$

The following theorem shows that we can derive a lower bound on the complexity of approximating the chromatic number of a graph using the lemma above.

[2]Proposition 4.1 as stated by Lund and Yannakakis requires that $p > r$, but the proofs show that in fact $p^2 > r$ and $p \ge n$ are sufficient. We use this proposition instead of their main theorem because it deals with general graphs instead of the special graphs produced by the reduction in Lemma 2.2.

THEOREM 5.2. *Let $k(n)$ be a nice approximation factor such that for large n, $k(n^8) < n/2$. Then for all oracles X, no polynomial-time function can approximate $\chi(G)$ within a factor of $k(n)$ using $\lfloor \log\log_{k(n)} n - c \rfloor$ or fewer queries to X unless* P = NP*, where $c = 6 + \log(1/\epsilon)$.*

Proof. We reduce approximating the clique size of a graph Q to approximating the chromatic number of a graph H. If $\chi(H)$ can be approximated using too few queries, then the lower bound on approximating $\omega(Q)$ from Corollary 4.9 would be violated and we can conclude that P = NP.

We are given a nice approximation factor $k(n)$. Suppose that some polynomial-time algorithm $A(G)$ approximates $\chi(G)$ within a factor of $k(n)$ using $\lfloor \log\log_{k(n)} n - c \rfloor$ queries to X for all graphs G with n vertices. Let $k'(n) = k(n^8)$. It is simple to check that $2k'(n)$ is also a nice approximation factor.

Now, given any graph Q with n vertices, we approximate $\omega(Q)$ within a factor of $2k'(n)$ as follows. Construct $H' = T(Q')$ using Lemma 5.1, where Q' is the complement of Q. Thus we know that $\alpha(Q') = \omega(Q)$ and $|H'| \leq 32 \cdot n^7$. Now we construct the graph H by adding dummy vertices to H' so that $|H| = n^8 = N$ and $\chi(H) = \chi(H')$. Finally, we use the algorithm A to compute an approximation of $\chi(H)$ within a factor of $k(N)$. This uses no more than

$$\lfloor \log\log_{k(N)} N - 6 - \log(1/\epsilon) \rfloor = \lfloor \log\log n - \log\log k(n^8) - 3 - \log(1/\epsilon) \rfloor$$

queries to X. Since $A(H)$ is a factor-$k(N)$ approximation, we know that

$$\chi(H) \leq A(H) \leq k(N)\chi(H).$$

From Lemma 5.1, we also know that

$$\frac{p^3 n^2}{\alpha(Q')} \leq \chi(H') < \frac{p^3 n^2 (1 + 1/n)}{\alpha(Q')}.$$

Since $\alpha(Q') = \omega(Q)$ and $\chi(H) = \chi(H')$, we obtain

$$\frac{\omega(Q)}{k(N)(1 + 1/n)} \leq \frac{p^3 n^2}{A(H)} \leq \omega(Q).$$

Thus the value $p^3 n^2 / A(H)$ approximates $\omega(Q)$ within a factor of

$$k(N)\left(1 + \frac{1}{n}\right) \leq 2k(n^8) = 2k'(n).$$

Since $2k'(n)$ is a nice approximation factor, by Corollary 4.9, approximating $\omega(Q)$ within factor $2k'(n)$ has a lower bound of

$$\left\lfloor \log\log_{2k'(n)} n - 2 - \log\left(\frac{1}{\epsilon}\right) \right\rfloor = \left\lfloor \log\log n - \log\log 2k(n^8) - 2 - \log\left(\frac{1}{\epsilon}\right) \right\rfloor.$$

Finally, since $(\log\log k(n^8)) + 1 > \log((\log k(n^8)) + 1)$, computing $A(H)$ used no more than $\lfloor \log\log_{2k'(n)} n - 2 - \log(1/\epsilon) \rfloor$ queries to X. Thus if such an algorithm exists, P = NP. □

Theorem 5.2 decreases the lower bound of Corollary 4.9 by four queries. This decrease is due in part to the fact that $|H| \approx |Q|^7$. Thus a more efficient reduction from clique size to chromatic number would yield a tighter lower bound. Also, for specific approximation factors, especially where the relationship between $k(n)$ and $k(n^7)$ is explicit, we can obtain slightly better lower bounds by reproducing the proof of Theorem 4.8.

6. The value of ϵ. The lower-bound results in the preceding sections depend on the value of the constant ϵ, where $0 < \epsilon \leq 1$. Recall that this is the same ϵ used by Arora et al. to show that no polynomial-time algorithm can approximate $\omega(G)$ within a factor of n^{ϵ} unless P = NP. Note that a larger value of ϵ indicates a better nonapproximability result which in turn provides tighter upper and lower bounds in the results of previous sections. Also, recall that for bounded query classes, even an improvement of one query is significant.

Currently, the exact value of ϵ is not known. However, by weakening the assumption that P $\neq$ NP to BPP $\neq$ NP, Bellare et al. [8] have shown that no polynomial-time algorithm can approximate $\omega(G)$ within a factor of $n^{1/30-o(1)}$. A further improvement was made by Bellare and Sudan [9], who showed that no polynomial-time algorithm can approximate $\omega(G)$ within a factor of $n^{1/5-o(1)}$ unless NP = ZPP. In this section, we use these results to obtain explicit lower bounds on the number of queries needed to approximate $\omega(G)$ under the stronger assumption that RP $\neq$ NP.

To prove these lower bound results, we need to adapt the proof techniques of the previous section to work with randomized functions instead of deterministic functions. A naïve approach would use a straightforward modification of Lemma 2.2 to produce a randomized reduction f from SAT to Clique Size such that

$$F \in \text{SAT} \Longrightarrow \text{Prob}_z[\omega(f(F,z)) = t^b] = 1,$$
$$F \notin \text{SAT} \Longrightarrow \text{Prob}_z[\omega(f(F,z)) < t^s] \geq 1 - \delta.$$

The difficulty with this approach is that the randomized version of Lemma 4.3 will use this randomized reduction polynomially many times. Thus when we show that RP = NP if the lower bounds are violated, we have to be very careful with the value of δ to make certain that the success probability of the overall procedure remains high enough. Such detailed analysis is possible using the techniques developed by Rohatgi [28]. However, the analysis can be made much simpler by observing that the randomized reduction from SAT to Clique Size can be achieved with "uniform" probability—that is, the same random string z can be used to correctly reduce any instance of SAT of a certain length. In the following, let $|F|$ denote the length of the encoding of the Boolean formula F.

LEMMA 6.1. *There exist constants s, b, and d with $0 < s < b < d$, polynomials $p(\cdot)$ and $q(\cdot)$, and a deterministic polynomial-time function f such that*

$$(\forall z \leq p(t))(\forall F,\ |F| = t)[F \in \text{SAT} \Longrightarrow \omega(f(F,z)) = t^b] \quad \textit{and}$$

$$\text{Prob}_{z \leq p(t)}[(\forall F,\ |F| = t)[F \notin \text{SAT} \Longrightarrow \omega(f(F,z)) < t^s]] \geq 1 - 2^{-q(t)},$$

where for each Boolean formula F, $|F| = t$, and each random string $z \leq p(t)$, $f(F,z)$ produces a graph with t^d vertices.

Proof sketch. This reduction is implicit in the work of Zuckerman [34]; we include a proof sketch for completeness. In this proof, the reduction f constructs a graph G from the formula F and a random string z. The random string z is used to choose a disperser graph H which allows f to amplify probability bounds. Choosing this disperser is the only random step used by f. If the randomly chosen H is indeed a disperser, then the same H can be used to reduce any formula F with t variables to a graph G. Hence the success probability of the reduction is independent of the particular formula F.

The starting point of the proof is not the deterministic reduction in Lemma 2.2 but the probabilistically checkable proof for SAT. As reported by Arora et al., there is

a probabilistically checkable proof for SAT where the verifier V uses $c_1 \log n$ random bits and looks at c_2 bits of the proof such that

$$F \in \text{SAT} \Longrightarrow \exists \pi,\ \forall z \in \{0,1\}^{c_1 \log n},\ V^{\pi}(F,z) \text{ accepts},$$

$$F \notin \text{SAT} \Longrightarrow \forall \pi,\ \text{Prob}_{z \in \{0,1\}^{c_1 \log n}}[V^{\pi}(F,z) \text{ accepts}] < \frac{1}{2}.$$

From the verifier V and the input F with t variables, we can use the construction of Feige et al. [18] to construct a graph G such that

$$F \in \text{SAT} \Longrightarrow \omega(G) = t^{c_1},$$
$$F \notin \text{SAT} \Longrightarrow \omega(G) < \frac{1}{2} \cdot t^{c_1}.$$

In this construction, each vertex of G represents one computation path of the verifier V (for every possible random string and every sequence of answer bits from the proof). An edge is added between two vertices if some proof π contains the answer bits which agree with both computation paths.

The construction above gives an approximation "gap" of only $1/2$. To obtain better results, we have to decrease the probability that V accepts an incorrect proof when $F \notin \text{SAT}$ *without using too many additional random bits.* This decrease can be achieved deterministically [15], which leads to Lemma 2.2, but then we lose track of the values of b, s, and d. Alternatively, as Zuckerman [34] pointed out, we can decrease the verifier's error randomly.

The key idea to Zuckerman's construction is to use special graphs called dispersers which were first introduced by Sipser [31]. For our purposes, a disperser may be defined as a bipartite graph with t^{c_3} vertices on the left and t^{c_1} vertices on the right such that each left vertex has degree $D = c_3 \log t + 2$ and every set of t^{c_1} left vertices is connected to at least $t^{c_1}/2$ right vertices. The value of the constant c_3 will be chosen later. By a theorem which Zuckerman attributes to Sipser [34, Theorem 3], such a disperser can be randomly generated with probability $1 - 2^{-t^{c_1}}$ by choosing the D neighbors of each left vertex randomly.

Suppose that we have a disperser H. We use H to construct a new verifier V'. We interpret each left vertex of H as a random string for V' and each right vertex of H as a random string for V. V' simulates V by randomly choosing a left vertex of H. This uses $c_3 \log t$ random bits. Let $z_1, \ldots, z_D$ be the right vertices connected to the chosen left vertex. V' simulates V D times using each of $z_1, \ldots, z_D$ as the random string for V. If every simulation of V accepts the proof π, then V' accepts the proof π. The complete simulation uses $c_3 \log t$ random bits and looks at Dc_2 bits of the proof.

Clearly, if $F \in \text{SAT}$, then V' will always accept. In fact, V' will accept even when H does not have the desired properties. Conversely, consider the case when $F \notin \text{SAT}$. We want to show that V' accepts with probability less than t^{c_1}/t^{c_3}. Therefore, suppose that V' accepted with probability $\geq t^{c_1}/t^{c_3}$. Then t^{c_1} of the left vertices cause V' to accept. Thus all the right vertices connected to these left vertices must cause V to accept. Since H is a disperser with the properties mentioned above, at least $t^{c_1}/2$ right vertices must cause V to accept. This contradicts our assumption about the error probability of V. Thus when $F \notin \text{SAT}$, V' accepts a proof π with probability less than t^{c_1}/t^{c_3}.

Now we construct a graph G from V' as described above. Since V' uses $c_3 \log t$ random bits and looks at Dc_2 bits of the proof, the graph G will have $n = 2^{c_3 \log t + Dc_2}$

vertices. When $F \in \mathrm{SAT}$, G has a "big" clique of size t^{c_3}. When $F \notin \mathrm{SAT}$, G has a "small" clique of size no more than t^{c_1}. The ratio of the size of the "big" clique to the size of the "small" clique expressed in terms of n is

$$t^{c_3-c_1} = n^{(c_3-c_1)\log t/(c_3 \log t + Dc_2)}.$$

Substituting $c_3 \log t + 2$ for D, we derive

$$\epsilon = \frac{b-s}{d} = \frac{1 - c_1/c_3}{1 + c_2 + 2c_2/(c_3 \log t)}.$$

Thus for all $\delta > 0$, we can have $\epsilon > (1+c_2)^{-1} - \delta$ by choosing c_3 to be large enough. Recall that c_2 is the number of bits in the proof that the verifier reads. This calculation shows the effect of c_2 on the value of ϵ. Finally, observe that the only random step used in the reduction is choosing the disperser H. □

The results of Bellare et al. [8] can be used to show that in Lemma 6.1 the ratio $(b-s)/d = 1/30 - o(1)$ because they produce a verifier for SAT that uses only 29 bits of the proof and follow Zuckerman's construction as described above. However, we are unable to exploit the results of Bellare and Sudan [9] because they use randomness for sampling—not just to generate pseudorandom bits. Nevertheless, we can give explicit lower bounds on the query complexity of approximating $\omega(G)$.

THEOREM 6.2. *Let $k(n)$ be a nice approximation factor. Then for all oracles X, no polynomial-time function can approximate $\omega(G)$ within a factor of $k(n)$ using $\lfloor \log \log_{k(n)} n - 6 \rfloor$ or fewer queries to X unless* RP = NP.

Proof sketch. To prove this theorem, we simply follow the proof of Theorem 4.8 except that we use $\epsilon = 1/31$ and Lemma 6.1 instead of Lemma 2.2 to reduce SAT to Clique Size. Since the success probability of the reduction is independent of the formula F, repeated use of the reduction does not decrease the success probability of the overall procedure. Again, the only random step in the entire procedure is randomly choosing a disperser graph H. This is also the case when we use the tree-pruning procedure in Lemma 4.3 to look for a satisfying assignment for the given Boolean formula. Since our procedure accepts a formula only when a satisfying assignment is found, it will never accept an unsatisfiable formula. The procedure may reject a satisfiable formula if the graph H turns out not to be a disperser. However, the probability of this happening is small. Thus the overall procedure is an RP algorithm for SAT.

Finally, note that in equation (4.2) of Theorem 4.8, we need to show that

$$\frac{2}{\epsilon} \log_g \frac{g}{g-1} + \log_{k(n)} n < \frac{2}{\epsilon} \log_g t^{b-s}.$$

In this proof, the value of ϵ is known, so we can rewrite the $2/\epsilon$ as

$$\frac{2}{\epsilon} = \frac{2}{(1+\epsilon)} \frac{(1+\epsilon)}{\epsilon} = 1.9375 \cdot \frac{1+\epsilon}{\epsilon} = (0.1375 + 1.8) \cdot \frac{b-s+d}{b-s}.$$

Then, as before,

$$\frac{2}{\epsilon} \log_g \frac{g}{g-1} < 0.1375 \cdot \log_g n'$$

because $g/(g-1) \le 2$. Also, we do not need any additional assumptions on $k(n)$ to show that

$$1.8 \cdot \log_g n' = 1.8 \cdot \frac{\log n'}{\log k(n')} \cdot \frac{\log k(n')}{\log \lceil k(n') \rceil} > (1+\delta) \frac{\log n'}{\log k(n')}$$

because $\log k(n')/\log\lceil k(n')\rceil \geq \log 2/\log 3 \approx 0.6309$. Hence $1.8 \cdot \log k(n')/\log\lceil k(n')\rceil > 1.1$ and we can let $\delta = 0.1$. Thus the assumption that $k(n)$ is nice and $c = 1 + \log 31 < 6$ suffices. □

Using the proof techniques described above, we can also extend our results to lower bounds for approximating the chromatic number.

COROLLARY 6.3. *Let $k(n)$ be a nice approximation factor such that for large n, $k(n) < n/2$. Then for all oracles X, no polynomial-time function can approximate $\chi(G)$ within a factor of $k(n)$ using $\lfloor \log\log_{k(n)} n - 10\rfloor$ or fewer queries to X unless* RP = NP.

7. Lower bounds for set cover. An instance of the Set Cover problem is a set system $\mathcal{S} = (n; S_1, \ldots, S_m)$ such that for all i, $S_i \subseteq \{1, \ldots, n\}$. We are asked to find the size of the smallest collection of S_i which covers $\{1, \ldots, n\}$. We denote the size of the minimum cover of $\mathcal{S}$ as $\texttt{SETCOVER}(\mathcal{S})$.

As we have discussed in the section on upper bounds, the Set Cover problem has a different complexity compared to Clique or Chromatic Number because there exist polynomial-time algorithms that approximate the size of the minimum set cover within a factor of $\ln n + 1$. In this section, we derive a lower bound on the complexity of approximating the size of the minimum set covering in terms of the number of queries to SAT.

One difficulty arises when we apply our techniques to minimization problems. To illustrate this, consider the construction of the graph H in section 4.2. We use the reduction from SAT to Clique to construct a graph G_1 from a formula F_1. This reduction has the special property that if $F_1 \in$ SAT, then $\omega(G_1) = t^b$. This *equality* is very important because it allows us to put only two copies of G_2 in H. If we only knew that $\omega(G_1) \geq t^b$, then $\omega(G_1)$ could be as large as m. Thus to ensure a large enough gap between the case where $F_1 \in$ SAT and $F_2 \notin$ SAT and the case where $F_1, F_2 \in$ SAT, we would have to use $2m/t^b$ copies of G_2. This would make the graph H too big and produce very bad lower bounds in the general theorem.

If equality is not possible, then we can settle for a good upper bound. For example, if the reduction from SAT to Clique guaranteed that $F_1 \in \text{SAT} \Longrightarrow t^b \leq \omega(G_1) \leq 3t^b$, then we only need to put six copies of G_2 in H. In the general case, we would obtain a lower bound of $\log\log_{3k(n)} n - c$.

The reduction from SAT to Set Cover in [27] does not give an upper bound on the size of the minimum set cover when the original formula is unsatisfiable. Thus we must use the following lemma and theorem.

LEMMA 7.1. *There exists a constant* $\texttt{CONST}$ *such that for all $l, m \geq \texttt{CONST}$ where $l \leq m$ and $\log\ln m < 0.09l$, there exist a set B and subsets $C_1, C_2, \ldots, C_m \subseteq B$ such that the following hold:*

1. *For any sequence of indices $1 \leq i_1 < i_2 < \cdots < i_l \leq m$, no collection $D_{i_1}, D_{i_2}, \ldots, D_{i_l}$ covers B where D_{i_j} is either C_{i_j} or the complement of C_{i_j}.*
2. *$C_1, \ldots, C_{1.1l}$ do cover B.*
3. *$|B| = (l + l\ln(m) + 2)2^l$.*

Furthermore, there exists a probabilistic Turing machine which on input l, m (in binary) produces such a set system with probability 2/3.

Proof. Let $B = \{1, \ldots, (l + l\ln(m) + 2)2^l\}$. Let the subsets $C_1, \ldots, C_m$ be a collection of subsets of B chosen randomly and independently—i.e., for each $x \in B$ and each C_i, $x \in C_i$ with probability one half. We show that with probability over 2/3 this collection suffices. Fix $D_{i_1}, D_{i_2}, \ldots, D_{i_l}$ as in the statement of the lemma. The probability that $B = D_{i_1} \cup \cdots \cup D_{i_l}$ is $(1 - (1/2)^l)^{|B|}$. The number of different D_{i_j}'s

is at most $2^l\binom{m}{l}$. Thus the probability that some collection of $D_{i_1}, \ldots, D_{i_l}$ covers B is bounded by

$$2^l\binom{m}{l}\left(1-\left(\frac{1}{2}\right)^l\right)^{|B|} \le e^{l+l\ln(m)-|B|/2^l} < \frac{1}{6}.$$

Hence the probability that item 1 occurs is at least 5/6.

Second, note that the probability that the first $1.1l$ sets cover B is

$$\left(1-\left(\frac{1}{2}\right)^{1.1l}\right)^{|B|} \ge e^{-2(l+l\ln(m)+2)2^l/2^{1.1l}} = e^{-2(l+l\ln(m)+2)2^{-0.1l}},$$

using the fact that $(1-x) \ge e^{-2x}$ for $x \in [0, 1/2]$. We need this quantity to be greater than $5/6 = e^{-c}$, where $c = \ln(6/5) > 0$. Hence we need

$$\begin{aligned} 2(l + l\ln(m) + 2)2^{-0.1l} &< \frac{5}{6}, \\ \frac{12}{5}(l + l\ln(m) + 2) &< 2^{0.1l}, \\ \log\frac{12}{5} + \log l + \log(\ln(m) + 2) &< 0.1l. \end{aligned}$$

Since $\log\ln m < 0.09l$, this holds for large enough l and m. Therefore, the desired constant `CONST` can be found. Hence the probability of satisfying item 2 is at least 5/6. Since the probability of satisfying item 1 is $\ge 5/6$ and the probability of satisfying item 2 is $\ge 5/6$, the probability of satisfying both is at least 2/3. ∎

THEOREM 7.2. *Given a formula φ, let $\mathcal{S}_\varphi$ be the instance of Set Cover described below. Let N be the size of $\mathcal{S}_\varphi$. Then there exists an integer K (depending only on the size of φ) such that*

$$\begin{aligned} &\varphi \in \text{SAT} \Longrightarrow \texttt{SETCOVER}(\mathcal{S}_\varphi) = K, \\ &\varphi \notin \text{SAT} \Longrightarrow \frac{0.99K}{2}\log N \le \texttt{SETCOVER}(\mathcal{S}_\varphi) \le \frac{1.1K}{2}\log N, \end{aligned}$$

where the last property holds with probability at least 2/3. Furthermore, the reduction can be applied to any number of formulas φ of the same size, and with probability 2/3, all the instances of Set Cover obtained will have the property above.

Proof. The proof of this theorem is a modification of the construction by Lund and Yannakakis [27]. In the rest of this proof, we assume that the reader is familiar with the notation and the proof in [27]. Given a formula φ, we carry out the construction in section 3.1 of [27] except that we use the sets $B, C_1, \ldots, C_m$ as specified in Lemma 7.1 as our building blocks. Using the ideas in [27], we obtain the following:

1. $\varphi \in$ SAT implies $\texttt{SETCOVER}(\mathcal{S}_\varphi) = K$, where $K = |Q_1| + |Q_2|$.
2. $\varphi \notin$ SAT implies $\texttt{SETCOVER}(\mathcal{S}_\varphi) \ge \frac{l}{2}(1-o(1))K$. Moreover, $\texttt{SETCOVER}(\mathcal{S}_\varphi) \le 1.1l(|Q_2|)$ since the first $1.1l$ answers for every query in Q_2 cover all the points by Lemma 7.1. Then since $|Q_1| = |Q_2|$,

$$\frac{l}{2}(1-o(1))K \le \texttt{SETCOVER}(\mathcal{S}_\varphi) \le \frac{1.1l}{2}K.$$

Now the theorem follows since l can be chosen such that $l = (1-\epsilon)\log N$ for any $\epsilon > 0$. Also, note that $m = 2^{O(l)}$ and thus we can apply Lemma 7.1.

Furthermore, note that once we have chosen one set system from Lemma 7.1, we can use it in any number of reductions involving instances of the same size. Thus if the set system has the required property, then all the reduced instances will have the required properties. □

The consequence of this theorem is that there exists a *randomized* reduction from SAT to Set Cover which runs in time $O(n^{\text{polylog}\, n})$. This reduction allows us to duplicate the construction of Theorem 4.8 for Set Cover and obtain the following lower bound.

THEOREM 7.3. *Let $k : \mathbb{N} \to \mathbb{R}$ be a function such that for all n large enough, $2 \le k(n) < n$; $m > n$ implies $k(m) \ge k(n)$; and $\forall \delta > 0,\ m > n$ implies that*

$$(1+\delta)\frac{\log\log m}{\log k(m)} > \frac{\log\log n}{\log k(n)}.$$

Let $\mathcal{S}$ be an instance of Set Cover. Then for all oracles X, no polynomial-time function can approximate the size of the minimum set cover within a factor of $k(n)$ using $\log\log_{k(n)} \ln n - 1$ or fewer queries to X unless NP $\subseteq$ RTIME$[n^{\text{polylog}\, n}]$.

Proof. This proof is analogous to the proof of Theorem 6.2. We start with the promise problem $\mathcal{P}_r$ with r to be chosen later. Since our construction is in time $O(n^{\text{polylog}\, n})$, we need a different lower bound on the complexity of $\mathcal{P}_r$. Using the proof technique of Lemma 4.3, one can show that for $r = O(\text{polylog}\, n)$, if some DTIME$[n^{\text{polylog}\, n}]$ machine solves $\mathcal{P}_r$ using fewer than $\lceil \log(r+1) \rceil$ queries to any oracle X, then NP $\subseteq$ DTIME$[n^{\text{polylog}\, n}]$. As in Theorem 6.2, it is important that in Theorem 7.2 the randomized reduction from SAT to Set Cover can be used repeatedly without decreasing the success probability of the overall procedure.

Now let $F_1, \ldots, F_r$ be a sequence of Boolean formulas with t variables each which satisfies the promise condition of the promise problem $\mathcal{P}_r$. We use Theorem 7.2 to construct r instances of Set Cover $\mathcal{S}_1, \ldots, \mathcal{S}_r$. Let m be the size of the underlying set of $\mathcal{S}_i$. Since the construction takes time $O(n^{\text{polylog}\, n})$, m is $O(t^{\text{polylog}\, t})$. We know with probability $2/3$ that for each i,

$$F_i \in \text{SAT} \Longrightarrow \texttt{SETCOVER}(\mathcal{S}_i) = K,$$
$$F_i \notin \text{SAT} \Longrightarrow \frac{0.99K}{2}\log m \le \texttt{SETCOVER}(\mathcal{S}_i) \le \frac{1.1K}{2}\log m.$$

We will now restrict our attention to this case. We combine the r instances of Set Cover into a single instance of Set Cover $\mathcal{T}$:

$$\mathcal{T} = g^{r-1} \otimes \mathcal{S}_1 \oplus g^{r-2} \otimes \mathcal{S}_2 \oplus \cdots \oplus g \otimes \mathcal{S}_{r-1} \oplus \mathcal{S}_r.$$

Let n be the size of the underlying set for $\mathcal{T}$. We define $\oplus$ and $\otimes$ so that

$$\texttt{SETCOVER}(\mathcal{S}_1 \oplus \mathcal{S}_2) = \texttt{SETCOVER}(\mathcal{S}_1) + \texttt{SETCOVER}(\mathcal{S}_2),$$

and for any positive integer a,

$$\texttt{SETCOVER}(a \otimes \mathcal{S}) = a \cdot \texttt{SETCOVER}(\mathcal{S}).$$

This is accomplished as follows. Let $\mathcal{S}_1 = (n_1; S_{1,1}, \ldots, S_{1,p})$ and $\mathcal{S}_2 = (n_2; S_{2,1}, \ldots, S_{2,q})$ be two instances of Set Cover. We define $\mathcal{S}_1 \oplus \mathcal{S}_2$ to be

$$(n_1 + n_2; S_{1,1}, \ldots, S_{1,p}, S'_{2,1}, \ldots, S'_{2,q}),$$

where $S'_{2,i} = \{x + n_1 \mid x \in S_{2,i}\}$. Then we can define $a \otimes \mathcal{S}$ simply as $\mathcal{S} \oplus \cdots \oplus \mathcal{S}$ repeated a times.

As in the proof of Theorem 4.8, the value of g in the construction of $\mathcal{T}$ will be chosen later. Note that we construct $\mathcal{T}$ using g^{r-1} copies of $\mathcal{S}_1$ instead of g^{r-1} copies of $\mathcal{S}_r$. This is "backwards" compared to the construction H in Theorem 4.8. We need to make this change because $\texttt{SETCOVER}(\mathcal{S}_i)$ is small when $F_i \in \text{SAT}$ and large when $F_i \notin \text{SAT}$ (again, backwards compared to Clique). Then a good approximation of $\texttt{SETCOVER}(\mathcal{T})$ will solve the promise problem $\mathcal{P}_r$. However, here the approximation must be within a factor of $0.9g$ instead of g because we only know that $\texttt{SETCOVER}(\mathcal{S}_i)$ is in the interval between $(0.99/2)K \log m$ and $(1.1/2)K \log m$ when $F_i \notin \text{SAT}$.

In this construction, when there are exactly z satisfiable formulas in $F_1, \ldots, F_r$, we have the following bounds:

$$\frac{0.99}{2} v_{r-z} K \log m \le \texttt{SETCOVER}(\mathcal{T}) \le v_r K + \frac{1.1}{2} v_{r-z} K \log m.$$

Thus we can obtain a lower bound for approximating the size of the minimum set cover (assuming NP $\not\subseteq$ RTIME$[n^{\text{polylog}\, n}]$) if we show that there exist r and g which satisfy the following constraints. Recall that m and n are the sizes of the underlying sets for $\mathcal{S}$ and $\mathcal{T}$, respectively. The value of m is expressible in terms of t. To make our notation simpler, we express g and r in terms of m instead of t or drop the argument altogether.

Constraint 1. $g(m)\nu_r < (1.1/2) \log m$.

Constraint 2. $k(n) \le 0.9g(m)$.

Constraint 3. $\lfloor \log \log_{k(n)} \ln n - 1 \rfloor < \lceil \log(r(m) + 1) \rceil$.

For this proof, we let $n' = (1.1/2)m \log m$ and choose g and r as follows:

- $g(m) = \lceil k(n')/0.9 \rceil$.
- $r = \lfloor \log_g (((1.1/2) \log m) \cdot (g-1)/g) \rfloor$.

As in the proof of Theorem 4.8, our choice of r implies that Constraint 1 holds and that $n' > n$. Since $k(n)$ is nondecreasing almost everywhere, it follows that $k(n) \le 0.9g(m)$ and that Constraint 2 also holds.

Finally, we show that Constraint 3 holds. It suffices to show that the following equations hold. (They are analogous to equations (4.3) and (4.4) in Theorem 4.8.)

$$2 \cdot \log_g \frac{g}{g-1} < 0.25 \cdot \log_g \left(\frac{1.1}{2} \log m \right), \tag{7.1}$$

$$\log_{k(n)} \ln n < 1.75 \cdot \log_g \left(\frac{1.1}{2} \log m \right). \tag{7.2}$$

Equation (7.1) is satisfied for m large since $g \ge 2$, $g/(g-1) \le 2$. Equation (7.2) is proved as follows. We start with the "niceness" assumptions on $k(n)$ and obtain

$$\log_{k(n)} \ln n \le \frac{\log \log n}{\log k(n)} < 1.05 \cdot \frac{\log \log n'}{\log k(n')}.$$

Recall that $n' = (1.1/2)m \log m$. Then for large m, $(\log n')^{1.05} < (\log m)^{1.1}$. Thus we have

$$1.05 \cdot \frac{\log \log n'}{\log k(n')} < 1.1 \cdot \frac{\log \log m}{\log k(n')}.$$

Then using the fact that for $x \geq 2$, $\log 3 \cdot \log x / \log\lceil x/0.9 \rceil > 1$, we have

$$1.1 \cdot \frac{\log\log m}{\log k(n')} < 1.1 \cdot \log 3 \cdot \frac{\log\log m}{\log k(n')} \cdot \frac{\log k(n')}{\log\lceil k(n')/0.9 \rceil} = 1.1 \cdot \log 3 \cdot \frac{\log\log m}{\log g}.$$

Now $\log 3 \approx 1.584963\ldots$, so $1.1 \cdot \log 3 < 1.75 - 0.005$. Also, we know that for m large enough, $0.005 \log\log m > 1.75 \cdot \log(2/1.1)$. Therefore,

$$1.1 \cdot \log 3 \cdot \frac{\log\log m}{\log g} < \frac{1.75 \cdot \log\log m - 0.005 \cdot \log\log m}{\log g} < 1.75 \cdot \log_g \left(\frac{1.1}{2} \log m \right).$$

Therefore, equation (7.2) holds and we have completed the proof. □

8. Updates. Since the original submission of this paper, additional connections between bounded query classes and NP-approximation problems have been discovered. Chang [11] showed that approximating clique size is actually complete for certain bounded query classes. This completeness produces reductions between NP-approximation problems (e.g., from approximating the chromatic number to approximating clique size). In addition, bounded query classes can also be used to measure the difficulty of finding the vertices of an approximate clique, not just its size [12]. Also, Crescenzi et al. [16] have shown that finding the vertices of the largest clique cannot be reduced to finding the vertices of an approximate clique unless the polynomial hierarchy collapses. Bounded query classes have also been used to measure the hardness of optimization problems [17] and to compare various kinds of approximation preserving reductions [16].

Acknowledgments. The authors would like to thank Richard Beigel and Suresh Chari for many helpful discussions. Thanks also go to Samir Khuller, Martin Kummer, and Frank Stephan for proofreading drafts of this paper.

SPARSE DYNAMIC PROGRAMMING FOR EVOLUTIONARY-TREE COMPARISON*

MARTIN FARACH† AND MIKKEL THORUP‡

Abstract. Constructing evolutionary trees for species sets is a fundamental problem in biology. Unfortunately, there is no single agreed upon method for this task, and many methods are in use. Current practice dictates that trees be constructed using different methods and that the resulting trees should be compared for consensus. It has become necessary to automate this process as the number of species under consideration has grown. We study one formalization of the problem: the *maximum agreement-subtree* (`MAST`) *problem*.

The `MAST` problem is as follows: given a set A and two rooted trees $\mathcal{T}_0$ and $\mathcal{T}_1$ leaf-labeled by the elements of A, find a maximum-cardinality subset B of A such that the topological restrictions of $\mathcal{T}_0$ and $\mathcal{T}_1$ to B are isomorphic. In this paper, we will show that this problem reduces to unary weighted bipartite matching (`UWBM`) with an $O(n^{1+o(1)})$ additive overhead. We also show that `UWBM` reduces linearly to `MAST`. Thus our algorithm is optimal unless `UWBM` can be solved in near linear time. The overall running time of our algorithm is $O(n^{1.5}\log n)$, improving on the previous best algorithm, which runs in $O(n^2)$. We also derive an $O(nc^{\sqrt{\log n}})$-time algorithm for the case of bounded degrees, whereas the previously best algorithm runs in $O(n^2)$, as in the unbounded case.

1. Introduction.

An evolutionary tree, or phylogeny, is a model of the evolutionary history for a set of species. Constructing such trees from observations on a set of living species is one of the fundamental tasks of computational biology. This is because the evolutionary relation of species provides a great deal of information about their biochemical machinery. For example, RNA's secondary structure is most accurately determined by selecting correlated mutations of a class of related species.

To construct a tree from a set of species, one must have a model of what makes one tree better than another. Many criteria have been proposed, but in general, these turn out to be NP-hard to optimize [15, 24]. There is also no consensus in the biology community as to what makes a good tree. As is typically the case when there is no really good solution to a problem, the number of solutions actually in use is quite large. Within the biology literature, various heuristics have been proposed (see, e.g., [8, 9, 11, 19, 22, 20]). More recently, a variety of solutions have been examined rigorously [1, 6, 16]. Not surprisingly, these various methods do not always give the same answer on the same inputs. Given that there is no "gold standard" for constructing evolutionary trees, current practice dictates that several different methods be applied to the data. The resulting trees may agree in some parts and

differ in others. In general, one is interested in finding the largest set of species on which the trees agree [18]. In other settings, a particular method may be applied to different data sets for the same set of species [13] or on a single data set which has been permuted some number of times for statistical analysis [9]. The resulting trees are then compared in order to arrive at some consensus. Many consensus techniques have been proposed and are currently in use (see [5] for a review). One of the most extensively studied consensus methods was defined by Finden and Gordon [10] as follows.

Let A be a set of species. We will define an *evolutionary tree* T on A to be a rooted tree with no degree-1 nodes such that the leaves of T are uniquely labeled with the elements of A. In such a tree, the leaves represent the species under consideration, and the internal nodes represent posited ancestors. Now suppose that we are given two trees T_0 and T_1 which are evolutionary trees on the same species set A. If the two trees differ, it is reasonable to ask for the "intersection" of the information contained in the trees. By viewing the input trees as the outcomes of experiments performed to discover the history of some species, we will typically have more confidence in information given in the "intersection" than in information unique to each tree. But what is the intersection of two evolutionary trees?

Finden and Gordon's answer to this question involves the notion of a "topological restriction" of an evolutionary tree to a subset of the species. Given an evolutionary tree T on set A and given $B \subseteq A$, then the *topological restriction of* T *to* B, written $T|B$, is the evolutionary tree on B such that B has the same history in $T|B$ as it does in T. More formally, first, given any rooted tree T, by a *topological subtree of* T, we mean a rooted tree U with no degree-1 nodes, obtained from a normal subtree S of T by replacing dipaths with single arcs. That is, U can be obtained from the subtree S by repetition of the following operation: if a vertex v has only one child w, we may delete ("jump") v, making the original parent of v the parent of w. Note that the topological subtree U is uniquely defined in terms of its leaf set. The full vertex set of U is the closure of the leaf set under the least-common-ancestor operation in T. Now, formally, $T|B$ denotes the topological subtree of T whose leaves are the the leaves of T with labels in B. This restriction operator immediately implies the following similarity measure on trees.

Problem. The maximum agreement-subtree (`MAST`) problem.

Input. A pair (T_0, T_1) of evolutionary trees for some common set A of species.

Output. A maximum-cardinality subset B of A such that $T_0|B$ and $T_1|B$ have a leaf-label preserving isomorphism.

Finden and Gordon [10] gave a heuristic method for computing the maximum agreement subtree of two binary trees. However, their algorithm, which has an $O(n^5)$ running time, does not guarantee an optimal solution. In [17], Kubicka et al. presented an $O(n^{(\frac{1}{2}+\epsilon)\log n})$-time algorithm for the binary `MAST` problem. Steel and Warnow [21] gave the first polynomial algorithm, which we will refer to as SW. The SW algorithm is a dynamic-programming approach which runs in $O(n^2)$-time on bounded-degree trees and in $O(n^{4.5}\log n)$ time on unbounded-degree trees. We showed in [7] that the SW algorithm can be modified to yield an $O(n^2)$-time algorithm for the unbounded case.

Both the SW algorithm and our modification of it perform some computation—a weighted bipartite matching—for each pair of nodes from the input trees. Hence this approach cannot give a $o(n^2)$-time algorithm for the `MAST` problem. We therefore run into the dynamic-programming bottleneck which is endemic in computational molecular biology. A wide variety of biocomputing problems, e.g., in the string-

edit-distance problem, RNA secondary structure, etc., have solutions which involve dynamic programming. To avoid the too costly quadratic complexity of these algorithms, researchers have either turned to heuristics (e.g., the BLAST program [2]) or to the design of *input-sensitive* algorithms. Notable in the latter class is the algorithm of Hunt and Szymanski [14]. This latter class of algorithms has the property that they speed up various dynamic programs to almost linear time in the *best case* but have at least quadratic-time worst cases.

In this paper, we use sparsity conditions to break the dynamic-programming bottleneck and have subquadratic running times in the worst case. In fact, we show tight bounds. Our main result is an algorithm which solves MAST within the same asymptotic time bound as that for solving *unary weighted bipartite matching* (UWBM), i.e., a weighted bipartite matching where the size of the input is measured as the sum of the weights of all edges—so unweighted bipartite matching is a special case (see [12] for definitions of matchings, etc.). More precisely, we show that $\texttt{time}(\texttt{MAST}(n)) = O(n^{1+o(1)} + \texttt{time}(\texttt{UWBM}(n)))$.[1] Using the best known algorithm [12] for weighted bipartite matching, this gives us an $O(n^{1.5} \log n)$-time algorithm for the MAST problem, thus breaking the $\Omega(n^2)$ bottleneck. If the degrees are bounded, our algorithm runs in $O(nc^{\sqrt{\log n}}) = O(n^{1+o(1)})$ time, beating the previous $O(n^2)$ bound [21] for this case.

While UWBM does not often appear as a natural upper bound, and typically one sees reference to either unweighted or fully weighted bipartite matching instead, we show that the unary weighting is inherent in bounding the complexity of MAST by observing that, in fact, $\texttt{time}(\texttt{MAST}(n)) = \Omega(\texttt{time}(\texttt{UWBM}(n)))$. Thus, for all intents and purposes, our reduction is optimal since getting the complexity of UWBM, or just bipartite matching, down anywhere near $O(n^{1+o(1)})$ is a long-standing open problem.

The fact that our algorithm works by sparsity means that we identify a small set of *significant computations* in the dynamic program. The exact size of this set depends on the running time of the bipartite-matching algorithm used; thus we carefully balance the time spent at a single node pair in the dynamic program with the number of such node pairs that we evaluate. The key to this balancing is the *parameterized core trees* which we introduce in this paper. The core tree is a generalization of the separator of a tree, which will turn out to be useful in guiding our computation.

Finally, we note that two variants of the MAST problem have been investigated. First, the unrooted version was the primary focus of the Steel and Warnow paper [21]. The above cited complexities for their algorithms ($O(n^{4.5} \log n)$ for unbounded degrees and $O(n^2)$ for bounded degrees) apply to the unrooted case. However, they noticed that the rooted case reduces to the unrooted case and hence that these complexities carry over to the rooted case. In [7], our main result was to improve the complexity of the unbounded unrooted case to $O(n^2 c^{\sqrt{\log n}})$. We believe that the unrooted case is much harder than the rooted case and know of no $O(n^2)$ algorithm for this problem. Another variant is that of considering three or more trees. Amir and Keselman [3] showed that the MAST problem on three or more trees is NP-hard for trees of unbounded degree, while polynomial if just one of the trees has bounded degree. While the constant-degree restriction may be suitable in some settings, the unbounded-degree algorithm is important since there are many tree-construction techniques available which place no restrictions on the degree of the trees produced [22].

Another problem related to our MAST problem is the tree-homeomorphism prob-

[1] This complexity is understood to be modulo a class of "well-behaved" functions explicitly defined in Theorem 4.6.

lem. In [4], Chung presents an $O(n^{2.5})$ algorithm for the rooted-tree-homeomorphism problem of deciding whether one rooted tree (no leaf labels) is a topological subtree of another. This algorithm is quite similar to the SW algorithm. Unfortunately, none of our optimizations to the SW algorithm apply to the tree-homeomorphism problem since they all rely on the restriction that the agreement isomorphism should be leaf-label preserving.

In section 2, we show the reduction from UWBM to MAST. In section 3, we give some basic definitions and an overview of our algorithm. In section 4, we prove the correctness of the algorithm and give a general sketch of its time complexity. In section 5, we reduce the number of comparisons in the dynamic program and finish the time analysis for the bounded-degree case. In section 6, we describe how to reduce the work of the matchings and finish the time analysis for the unbounded-degree case.

2. Lower bound. We show a reduction from a size-n UWBM problem to an $O(n)$-leaf MAST problem. We define the size of a UWBM instance to be the sum of the edge weights; hence an n-size UWBM instance can code a WBM instance with total integer edge weight n and up to $O(n)$ edges and $O(n)$ nodes. Using the the best algorithm known [12] for WBM, such a problem can be solved in $O(n^{1.5} \log n)$.

We now show a reduction from UWBM to MAST. Given a connected weighted bipartite graph $G = (U \cup V, E, W : E \to \mathbb{N})$ such that $\sum_{e \in E} W(e) = n$, construct evolutionary trees T_U and T_V with $O(n)$ labels as follows. For each $X \in \{U, V\}$, set r_X to be the root of T_X, and for each $x \in X$, create a child c_x of r_X. For each $e = \{u, v\} \in E$, add $W(e)$ leaf children to c_u in T_U and label them $\langle x, y, i \rangle$, $1 \le i \le W(e)$. Add leaf children with the same labels to c_v in T_V. Finally, pick $n + 2$ new labels and build a star tree $\mathcal{S}$ on the labels. Attach the root of one copy of $\mathcal{S}$ to the root of T_X and attach the root of another copy of $\mathcal{S}$ to the root of T_Y. The size of the star $\mathcal{S}$ guarantees that any solution to MAST will map the roots to each other. Hence there is a bijection between the maximum-weight matchings M and the maximum-agreement subsets B such that if $\{v, w\} \in M$ then $\mathtt{A}(c_v) \cap \mathtt{A}(c_w) \subseteq B$.

THEOREM 2.1. *There is a linear reduction from* UWBM *to* MAST. □

In [3], Amir and Keselman use a similar reduction from *three-dimensional matching* to prove that the MAST problem on three or more trees is NP-Hard.

3. Ideas and outline.

3.1. Preliminaries. In this subsection, we will describe a rooted version of the SW algorithm. This algorithm will form the basis of our discussion of more efficient algorithms. For simplicity, all algorithms presented will compute only the maximal cardinality of an agreement set, i.e., the cardinality of the output set for the MAST problem. However, after this cardinality has been found, the computation can easily be traced back in order to derive a concrete set. In this subsection, we will also introduce the main notation and terminology for the rest of the paper.

Given an evolutionary tree T, by $\mathtt{V}(T)$ we denote the set of its vertices, by $\mathtt{r}(T)$ its root, by $\mathtt{A}(T)$ the set of its leaf labels. For $v \in \mathtt{V}(T)$, let $\mathtt{p}(v)$ be the parent of v, $\mathtt{C}(v)$ be the set of its children, and $\mathtt{d}(v)$ be its degree. If $v \in \mathtt{V}(T)$, then $\mathtt{t}(v)$ denotes the subtree descending from v. For a set of nodes $V \subseteq \mathtt{V}(T)$, we define $\mathtt{LCA}(V)$ to be the closure of V with respect to least common ancestors.

For the rest of the paper, fix an instance of the MAST problem consisting of two evolutionary trees $\mathcal{T}_0$ and $\mathcal{T}_1$ for some common set A of species. We measure the size n of the problem as the cardinality of A, which equals the number of leaves for both $\mathcal{T}_0$ and $\mathcal{T}_1$. To simplify some boundary cases in the discussion below, we allow the situation where $\mathcal{T}_0$ and $\mathcal{T}_1$ are empty. In this case, $\mathtt{MAST}(\mathcal{T}_0, \mathcal{T}_1) = |\mathtt{A}| = n = 0$. Finally,

fix an arbitrary left to the right ordering of the children of each node. Thus $\mathcal{T}_0$ and $\mathcal{T}_1$ are henceforth considered ordered.

The roles of the evolutionary trees $\mathcal{T}_0$ and $\mathcal{T}_1$ are symmetric. In order to avoid unnecessary repetitions in our definitions, we will commonly use $\bar{0}$ to mean 1 and vice versa. Also, we introduce the generic term *opposing pair*, by which we refer to a pair $\{x, y\}$ where x is contained in $\mathcal{T}_i$ and y is contained in $\mathcal{T}_{\bar{i}}$. Here x and y might be of different types. For example, x might be a vertex of $\mathcal{T}_i$ while y is a subset of the vertices of $\mathcal{T}_{\bar{i}}$.

For any opposing pair $\{v, w\}$ of vertices, let $\mathtt{mast}\{v, w\}$ denote the MAST of the subtrees rooted, respectively, at v and w. Here the subtrees are understood to be topologically restricted to the intersection of their label sets. Thus $\mathtt{mast}\{v, w\}$ is the MAST of $\mathcal{T}_0|B$ and $\mathcal{T}_1|B$, where $B = \mathtt{A}(\mathtt{t}(v)) \cap \mathtt{A}(\mathtt{t}(w))$.

The following lemma appears with some minor modifications in [21] and is the basis for their dynamic-program approach to the unrooted version of this problem.

LEMMA 3.1 (see [21]). *For all $v \in V(\mathcal{T}_0)$ and $w \in V(\mathcal{T}_1)$,*

$$\mathtt{mast}\{v, w\} = \begin{cases} |\mathtt{A}(\mathtt{t}(v)) \cap \mathtt{A}(\mathtt{t}(w))| & \text{if } v \text{ or } w \text{ is a leaf;} \\ \max\{\mathtt{Diag}\{v, w\}, \mathtt{match}\{v, w\}\} & \text{otherwise,} \end{cases}$$

where $\mathtt{Diag}(v, w) = \{\mathtt{mast}\{v, w_1\} | w_1 \in \mathtt{C}(w)\} \cup \{\mathtt{mast}\{v_0, w\} | v_0 \in \mathtt{C}(v)\}$ *and where* $\mathtt{match}\{v, w\}$ *is the value of the maximum-weight matching of the weighted bipartite graph* $((\mathtt{C}(v) \cup \mathtt{C}(w), \mathtt{C}(v) \times \mathtt{C}(w), \mathtt{mast}\{\cdot, \cdot\})$.

The lemma is illustrated in Figure 3.1. It is clear from this lemma that we need some values on subtrees in order to compute the mast of two nodes. To simplify the discussion, we introduce the following notation. By the *base pairs* of an opposing vertex pair $\{x_0, x_1\}$, we understand the set of opposing pairs $\{w_0, w_1\}$ such that either $w_0 \in \mathtt{C}(v_0)$ and $w_1 \in \mathtt{C}(v_1) \cup \{v_1\}$ or, conversely, $w_0 \in \mathtt{C}(v_0) \cup \{v_0\}$ and $w_1 \in \mathtt{C}(v_1)$. By the *base* of $\{x_0, x_1\}$, we mean the set of values $\mathtt{mast}\{w_0, w_1\}$ for all base pairs of $\{x_0, x_1\}$. Thus the base forms the set of values needed by a dynamic program to compute the mast values for $\{x_0, x_1\}$.

Later in the paper, we will need a generalized version of a base defined over pairs of opposing *sets* of vertices. First, for any set V of vertices in a tree, set $\mathtt{C}(V) = \bigcup\{\mathtt{C}(v) | v \in V\} \setminus V$. We call the members of $\mathtt{C}(V)$ the *proper children* of V. Now if V_0 and V_1 are subsets of $\mathtt{V}(\mathcal{T}_0)$ and $\mathtt{V}(\mathcal{T}_1)$, then the *base pairs* of $\{V_0, V_1\}$ are the opposing vertex pairs $\{w_0, w_1\}$ such that either $w_0 \in \mathtt{C}(V_0)$ and $w_1 \in \mathtt{C}(V_1) \cup V_1$ or, conversely, $w_0 \in \mathtt{C}(V_0) \cup V_0$ and $w_1 \in \mathtt{C}(V_1)$. By the *base* of $\{V_0, V_1\}$, we mean the values $\mathtt{mast}\{w_0, w_1\}$ for all base pairs of $\{V_0, V_1\}$. Thus the base of $\{V_0, V_1\}$ contains all the values needed for a dynamic bottom-up computation of $\mathtt{mast}\{v_0, v_1\}$ for all $v_0 \in V_0$ and $v_1 \in V_1$.

Lemma 3.1 suggests the following dynamic-programming algorithm for the MAST problem.

ALGORITHM A: first algorithm for MAST:

A.1. Input $\mathcal{T}_0$ and $\mathcal{T}_1$.

A.2. Let $\mathcal{O}$ be the lexicographic ordering of $\mathtt{V}(\mathcal{T}_0) \times \mathtt{V}(\mathcal{T}_1)$, where the vertices in each $\mathcal{T}_i$ are postordered.

A.3. For each (v_0, v_1) in increasing order in $\mathcal{O}$ do

A.3.1. Compute $\mathtt{mast}\{v_0, v_1\}$.

A.4. Return $\mathtt{mast}\{\mathtt{r}(\mathcal{T}_0), \mathtt{r}(\mathcal{T}_1)\}$.

Algorithm A computes MAST by applying Lemma 3.1 to all the $O(n^2)$ pairs of opposing vertex pairs. The bottom-up ordering of $\mathcal{O}$ guarantees that the base of a

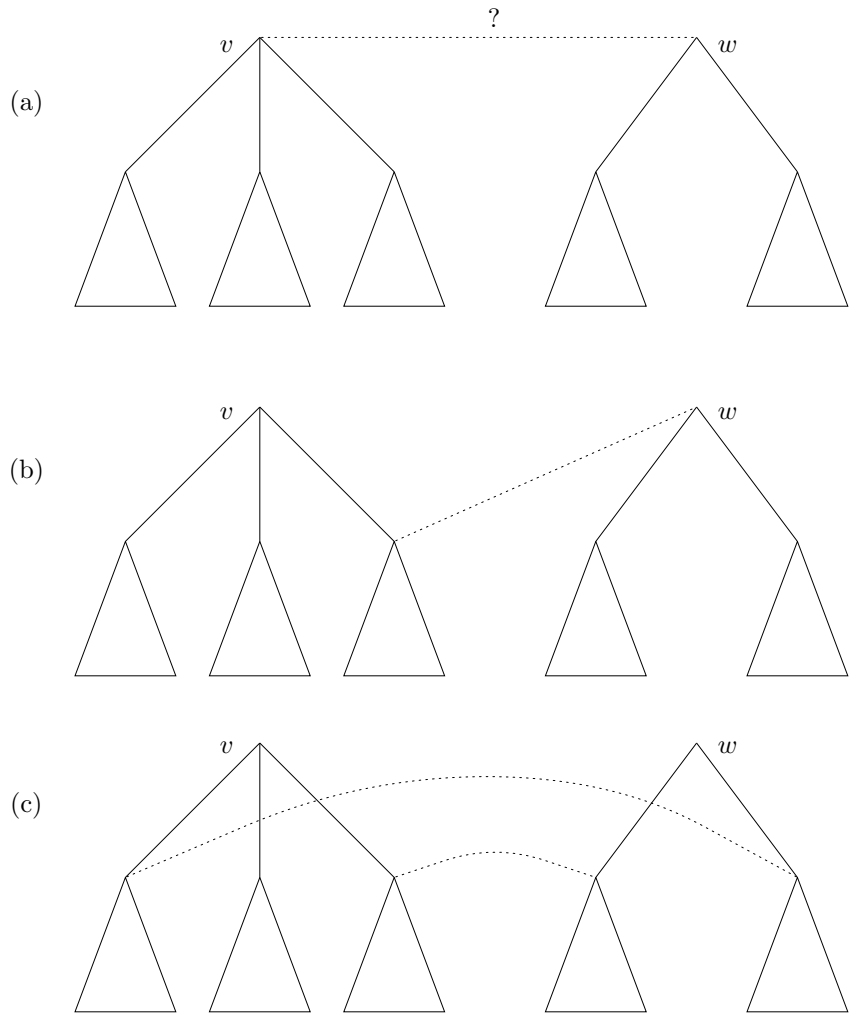

FIG. 3.1. *In order to find* $\texttt{mast}\{v, w\}$ *as in* (a)*, we can either try a "diagonal," as in* (b)*, or we can find a maximum-weight matching between the sets of children, as in* (c).

node pair is ready whenever `mast` is evaluated. For bounded degree, `mast` can be computed in $O(1)$ time, thus giving $O(n^2)$ total work. For unbounded degree, the bottleneck in the comparisons is the matchings, which sum up to $O(\sum_{v \in \texttt{V}(T_1), w \in \texttt{V}(T_2)} \texttt{d}(v) \cdot \texttt{d}(w) \sqrt{\texttt{d}(v) + \texttt{d}(w)} \log n) = O(n^2 \sqrt{n} \log n)$ using Gabow and Tarjan's matching algorithm [12]. Note that the Gabow–Tarjan algorithm is not only the fastest known for normal weighted bipartite matching where the weights are assumed to be in a binary encoding, but it is also the fastest known for the case of unary weighted matching, i.e., the case where the input is measured as the sum of all of the edge weights in the graph. It is in this latter sense that we are interested in the Gabow–Tarjan algorithm.

In [7], we showed that most matching graphs can be preprocessed so that they are quite sparse. We were able to show a bound of $O(n^2)$ time for all computations of `mast`, thus showing that the `MAST` of two trees can be computed in $O(n^2)$, even when the degree is unbounded.

We improve this result by two types of sparsification. First of all, we reduce

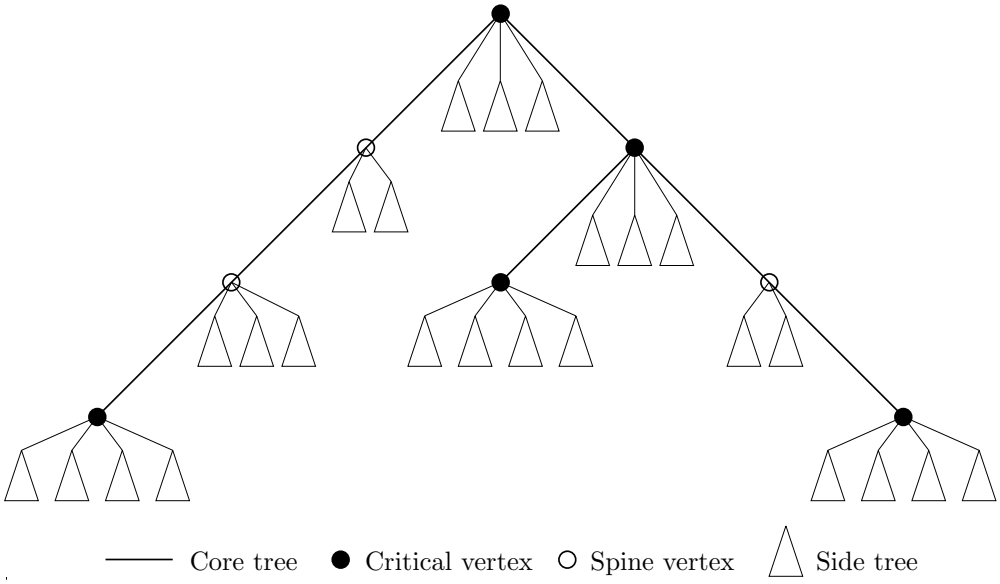

FIG. 3.2. *The core-tree-related concepts.*

the number of `mast` values evaluated in the dynamic program. Second, we reduce the work done in the matchings. This second phase is analogous to our previous work [7] in reducing the matching work, but here we require stronger techniques in order to achieve optimality in the sense of equivalence to *one* unary weighted bipartite matching. For the moment, we will focus entirely on reducing the number of comparisons, returning to weighted matchings in section 6.

3.2. A faster algorithm. Our key to sparsifying the dynamic program is the *core tree*, which is defined in terms of some parameter κ (which will turn out to be 16 for unbounded degrees and $4^{\sqrt{\log n}}$ for bounded degrees). We say that a node is a *core node* if it has more than n/κ descendant leaves. Otherwise, it is a *side node*. Then the *core tree* is the component induced by the core nodes and the *side trees* are the components induced by side nodes. We denote by $\mathcal{U}_i$ the core tree of tree $\mathcal{T}_i$. Note that the core tree is indeed a tree since it is connected. Further, note that the core tree has at most κ leaves since the leaves are roots of disjoint subtrees, each with at least n/κ leaves.

We make one final distinction within the core tree. We partition the nodes of the core tree into *critical nodes* and *spine nodes*. A critical node is either the root, a leaf of the core tree, or a branching node, i.e., a core node with at least two children which are core nodes. If a core node is not a critical node, then it is a spine node. Notice that the spine nodes can be further partitioned into connected components. In fact, each such connected component forms a chain of nodes where all nodes but the last have exactly one core child—but possibly $\Omega(n)$ side children. We call each such component a *spine*. The concepts are illustrated at Figure 3.2. Note that we have $O(\kappa)$ critical nodes and spines but $O(n)$ spine nodes. The following trivial fact gives one of the main uses of side trees.

FACT 3.2. *Let $S_1, \ldots, S_x$ and $S'_1, \ldots, S'_y$ be partitionings of the side trees of $\mathcal{T}_0$ and $\mathcal{T}_1$, respectively. Let $l_{ij} = |\bigcup_{t \in S_i} \mathtt{A}(t) \cap \bigcup_{t \in S'_j} \mathtt{A}(t)|$. Then $\sum_{i=1}^{x} \sum_{j=1}^{y} l_{ij} = n$.*

Given the core trees, we naturally divide the `MAST` computation into two phases.

First, we compute the base of the opposing core trees, that is, `mast` values of opposing vertex pairs where one is the root of a side tree and the other is either the root of a side tree or a core vertex. Second, we concentrate on computing `mast` values for opposing pairs of core nodes, including the root pair. For the base computation, we note that the base of the core trees is of size $\Theta(n^2)$, so we cannot afford to compute the whole base. Instead, we will build a data structure allowing us to retrieve any desired base value quickly. More specifically, we will implement the following procedure.

PROCEDURE 1. CORE-BASE: *This procedure computes a data structure such that every* `mast` *value in the base of the opposing core trees, i.e., of* $\{\mathtt{V}(\mathcal{U}_0), \mathtt{V}(\mathcal{U}_1)\}$*, can be determined in* $O(\log n)$ *time.*

This data structure will be computed by a routine which recurses on all side trees. Thus within the recursion, all subproblems considered are of size proportional to that of the side trees ($O(n/\kappa)$). Using this fact, we will show that for unbounded-degree trees, the recursion will have no asymptotic consequence for the overall computation time. More precisely, we will show that we have a dominating bottleneck in the maximum-weighted-matching evaluations in computing `match` for opposing pairs of core vertices. For bounded-degree trees, `match` takes constant time, and in this case, it will turn out that the recursion contributes to the overall running time by multiplicative factor of $O(c^{\sqrt{\log n}})$ for some constant c.

Second, we will find an efficient implementation of the following procedure.

PROCEDURE 2. CORE-TREES: *Given the base of the opposing core trees (which we can compute as needed by the* CORE-BASE *data structure), this procedure computes* $\mathtt{mast}\{\mathtt{r}(\mathcal{U}_0), \mathtt{r}(\mathcal{U}_1)\} = \mathtt{mast}\{\mathtt{r}(\mathcal{T}_0), \mathtt{r}(\mathcal{T}_1)\} = \mathtt{MAST}(\mathcal{T}_0, \mathcal{T}_1)$.

This procedure will be implemented by a sparse version of the dynamic program described in Algorithm A. In $O(\kappa n \ \mathrm{polylog}\, n)$ time, it will select $O(\kappa n)$ significant `mast` values to be computed, including, in particular, $\mathtt{mast}\{\mathtt{r}(\mathcal{U}_0), \mathtt{r}(\mathcal{U}_1)\}$. For bounded degrees, each of these `mast` values can be computed in constant time. For unbounded degrees, it will be shown that they can be computed in the same total time as that of *one* unary weighted bipartite matching of size $O(n)$. Thus, very generally, `MAST` is implemented as follows.

ALGORITHM B:

B.1. Input $\mathcal{T}_0$ and $\mathcal{T}_1$.

B.2. Find their core trees $\mathcal{U}_0$ and $\mathcal{U}_1$.

B.3. Compute CORE-BASE.

B.4. Compute CORE-TREES.

B.5. Return $\mathtt{mast}\{\mathtt{r}(\mathcal{T}_0), \mathtt{r}(\mathcal{T}_1)\}$.

As noted above, a naïve algorithm would simply apply Lemma 3.1 to each core–core pair. This would yield once again an $\Omega(n^2)$ algorithm, the bottleneck of which is in comparing spines. The following procedure will be used to circumvent this bottleneck. We will use it to complete a sketch of CORE-TREES.

PROCEDURE 3. SPINES$\{S_0, S_1\}$: *For opposing spines* S_0 *and* S_1*, this procedure computes* $\mathtt{mast}\{\mathtt{r}(S_i), v_{\bar{i}}\}$ *for* $i = 0, 1$*, and for all* $v_{\bar{i}} \in \mathtt{V}(S_{\bar{i}})$.

With this procedure we get the following algorithm for CORE-TREES.

ALGORITHM C:

C.1. For $i \in \{0, 1\}$, let $\mathcal{U}_i'$ denote the tree obtained by identifying each spine of $\mathcal{U}_i$ with a single vertex.

C.2. Let $\mathcal{O}$ be the lexicographic ordering of $\mathtt{V}(\mathcal{U}_0') \times \mathtt{V}(\mathcal{U}_1')$ where the vertices in each $\mathcal{U}_i'$ are postordered.

C.3. For each (c_0, c_1) in increasing order in $\mathcal{O}$ do
C.3.1. Case: c_0 and c_1 are critical. Do
C.3.1.1. Compute $\texttt{mast}\{c_0, c_1,\}$.
C.3.2. Case: c_i is a spine node and $c_{\bar{i}}$ is a critical node, for $i \in \{0,1\}$. Do:
C.3.2.1. Let $s_1, \ldots, s_k$ be the spines nodes of c_i in ascending order.
C.3.2.2. For $j \leftarrow 1$ to k compute $\texttt{mast}\{c_{\bar{i}}, s_j\}$.
C.3.3. Case: c_0 and c_1 are spine representing nodes. Do:
C.3.3.1. Compute SPINES$\{c_0, c_1\}$.

OBSERVATION 3.3. CORE-TREES *makes* $O(\kappa n)$ *direct* `mast` *computations* (*Steps* C.3.1.1 *and* C.3.2.2) *and calls* SPINES $O(\kappa^2)$ *times* (*Step* C.3.3.1). *All other processing is done in time* $O(\kappa n)$.

4. Computing CORE-BASE. The goal of CORE-BASE is to preprocess $\mathcal{T}_0$ and $\mathcal{T}_1$ so that we may quickly retrieve values from the base of the core trees, that is, `mast` values of opposing vertex pairs where one is the root of a side tree and the other is either the root of a side tree or a core vertex. This will be done recursively using the following extension of `MAST`, which for both roots computes the `mast` value against all opposing vertices.

PROCEDURE 4. TREES$\{T_0, T_1\}$, *where each* T_i *is an evolutionary tree: For* $i = 0, 1$, *this procedure computes* $\texttt{mast}\{\texttt{r}(T_i), v_{\bar{i}}\}$ *for all* $v_{\bar{i}} \in \texttt{V}(T_{\bar{i}})$.

Assuming an appropriate implementation of TREES, we will apply it to each side tree s against the opposing tree restricted to the label set of s. Thus all problems considered are of size $O(n/\kappa)$. The following lemma shows that such a computation for all side trees essentially gives us the whole base of the core trees, or even more: for each root of a side tree, it allows us to derive the `mast` value against any opposing vertex.

LEMMA 4.1. *Let* s *be a side tree of* $\mathcal{T}_i$, $t_s = \mathcal{T}_{\bar{i}}|\texttt{A}(s)$, *and let* $W = \texttt{V}(t_s)$. *Then for all* $v \in \texttt{V}(\mathcal{T}_{\bar{i}})$, $\texttt{mast}\{\texttt{r}(s), v\} = 0$ *if* v *has no descendant in* W; *otherwise,* $\texttt{mast}\{\texttt{r}(s), v\} = \texttt{mast}\{\texttt{r}(s), w\}$, *where* w *is the unique first descendant of* v *in* W.

Proof. Set $B = \texttt{A}(s) \cap A(\texttt{t}(v))$. Then $\texttt{V}(\mathcal{T}_{\bar{i}}|B)$ is exactly the set of descendants of v in $W = \texttt{V}(t_s) = \texttt{V}(\mathcal{T}_{\bar{i}}|\texttt{A}(s))$. By definition, $\texttt{mast}\{\texttt{r}(s), v\} = \texttt{MAST}\{\mathcal{T}_0|B, \mathcal{T}_1|B\}$. Thus $\texttt{mast}\{\texttt{r}(s), v\} = 0$ if $B = \emptyset$, but then v has no descendants in W. We may therefore assume that $B \neq \emptyset$. Then $\texttt{r}(\mathcal{T}_{\bar{i}}|B)$ is the first descendant of v in W. Moreover, $\texttt{A}(\texttt{t}(v)) \supseteq \texttt{A}(\texttt{t}(\texttt{r}(\mathcal{T}_{\bar{i}}|B))) \supseteq B$, so $\texttt{A}(s) \cap \texttt{A}(\texttt{t}(\texttt{r}(\mathcal{T}_{\bar{i}}|B))) = B$, and hence $\texttt{mast}\{\texttt{r}(s), v)\} = \texttt{mast}\{\texttt{r}(s), \texttt{r}(\mathcal{T}_{\bar{i}}|B)\}$. This completes the proof. □

Notice that TREES is a strengthening of `MAST` in that it computes more values. Algorithm B implements TREES except for the `mast` values between the roots and their opposing side nodes. Call these missing values the *side values*. In order to make Algorithm B implement TREES completely, we extend our specification of CORE-BASE to compute the side values as well. That is, CORE-BASE should make retrievable not only the values from the base of the core trees but also these side values. However, the following trivial lemma shows that this is already done by our recursion over the side trees.

LEMMA 4.2. *For any* $v \in \texttt{V}(s)$, *where* s *is a side tree of* $\mathcal{T}_i$, $t_s = \mathcal{T}_{\bar{i}}|\texttt{A}(s)$, $\texttt{mast}\{v, \texttt{r}(\mathcal{T}_{\bar{i}})\} = \texttt{mast}\{v, \texttt{r}(t_s)\}$. □

We have now shown that we can compute all values needed for CORE-BASE by recursively applying TREES on all side trees s along with their opposing restrictions t_s. Thus the remaining question is how to implement the various steps described in an efficient manner. First, we need to compute the t_s's. The following lemma states that all t_s's can be computed in linear time since the label set of different side trees of the same evolutionary tree are disjoint.

LEMMA 4.3 (see [7]). *Let T be a rooted tree with vertex set V, and let $\{V_1, \ldots, V_k\}$ be a family of subsets of V. Then in time $O(\sum |V_i| + |V|)$, we can compute all of the topological subtrees T_i with $\mathtt{V}(T_i) = \mathtt{LCA}(V_i)$.*

Thus given a partition $L_0, \ldots, L_k$ of the labels of an evolutionary tree T of size n, we can compute all of $T|L_0, \ldots, T|L_k$ in $O(n)$ total time.

Now in order to implement the descendant operation from Lemma 4.1, we need the following technical lemma.

LEMMA 4.4. *Let T be a rooted tree with vertex set V, and let $\{W_1, \ldots, W_k\}$ be a family of subsets of V, each of which is closed under least common ancestors. Then in $O(\sum |W_i| + |V|)$ time, we can build a data structure such that given any vertex $v \in V$ and index $i \leq k$, we can return the nearest descendant of v in W_i, if any, in time $O(\log |W_i|)$.*

Proof. First, we organize the vertices of T in an Euler tour E, that is, we make a depth-first traversal from the root, noting each time we visit every vertex. For every vertex v, denote the first occurrence in E by $f(v)$ and the last occurrence in E by $l(v)$. Now w is a descendant of v if and only if $f(v) \leq f(w) < l(v)$. Next, for $i = 1, \ldots, k$, we construct the subsequence E_i^f of E containing $f(w)$ for each vertex w in W_i. Clearly, both the Euler tour and the splitting of it into the E_i^f's can all be done in time $O(\sum |W_i| + |V|)$.

Now, given a vertex $v \in V$ and index $i \leq k$, by an $O(\log |E_i^f|) = O(\log |W_i|)$-time binary search, we find the first element $f(w)$ in E_i^f greater than or equal to $f(v)$. If $f(w) \geq l(v)$, we may conclude that v has no descendant in t_s. Otherwise, $f(w) < l(v)$. Since W_i is closed under the least-common-ancestor operation, we may then conclude that w is the unique first descendant v in W_i. □

Summing up, we have the following result.

PROPOSITION 4.5. CORE-BASE *can be computed in time*

$$O(n) + 2 \max_{\substack{\sum n_i = n, \\ n_i \in \{1, \ldots, \lfloor n/\kappa \rfloor\}}} \sum \mathtt{time}(\textsc{Trees}(n_i)).$$

Proof. Lemma 4.3 allows us to compute all $\{s, t_s\}$ pairs in $O(n)$ time. Clearly, $\sum_s |\mathtt{A}(s)| = n$, and for each s, $|\mathtt{A}(s)| < n/\kappa$. We can compute $\textsc{Trees}\{s, t_s\}$ for all s in time bounded by

$$2 \max_{\substack{\sum n_i = n, \\ n_i \in \{1, \ldots, \lfloor n/\kappa \rfloor\}}} \sum \mathtt{time}(\textsc{Trees}(n_i)).$$

By Lemma 4.2, we are now done with the side values. Concerning the base of the core trees, now preprocess for any queries of the form $\mathtt{mast}\{\mathtt{r}(s), v\}$, where s is a side tree and v is any opposing vertex. For simplicity, we assume that s is a side tree of $\mathcal{T}_0$ and v is a vertex of $\mathcal{T}_1$. The case where s is a side tree of $\mathcal{T}_1$ and v is a vertex of $\mathcal{T}_0$ is symmetric.

By Lemma 4.1, our problem is to decide if v has a descendant in t_s and, if so, to return the first such descendant of v in t_s. Such a query can be answered in time $O(\log |\mathtt{V}(t_s)|) = O(\log n)$ if we first apply the preprocessing of Lemma 4.4 to all the sets $\mathtt{V}(t_s)$. The time for this preprocessing is

$$O\left(|\mathtt{V}(\mathcal{T}_0)| + \sum_s |\mathtt{V}(t_s)|\right) = O\left(n + \sum_s (2|\mathtt{A}(s)| - 1)\right) = O(n).$$

Thus all the preprocessing is completed within the desired bounds. □

4.1. A master theorem. The following theorem will be used to bound the overall work for the bounded-degree and general versions of the MAST problem throughout the remainder of the paper. Our goal is to make our result apply, even if the complexity of maximum-weighted matching is improved. Thus we must allow our recurrence to hold for a wide possible set of choices for the complexity of maximum-weighted matching. While general theorems have been proven for solving recurrences (see, e.g., Verma [23]), we know of no results that directly apply. Thus we offer the following "master theorem" for solving the types of recurrence we need.

THEOREM 4.6. *Assume for some monotone function* $C : \mathbb{R}_{\geq 1} \to \mathbb{R}$ *that* CORE-TREES *can be computed in time at most* $C(\kappa^a n)$*, where* a *is a constant independent of our parameter* κ*. Moreover, assume that* $C(x) = x^{1+\varepsilon} f(x)$*, where* $\varepsilon \geq 0$ *is a constant,* $f(x) = O(x^{o(1)})$*,* f *is monotone, and for some constants* b_1 *and* b_2*,* $\forall x, y \geq b_1 : f(xy) \leq b_2 f(x) f(y)$*. If* $\varepsilon = 0$*, there is a constant* c *such that we can compute* MAST *in time* $O(C(n)c^{\sqrt{\log n}})$*. Otherwise, if* $\varepsilon > 0$*, setting* $\kappa = 4^{\sqrt{\log n}}$*, we can compute* MAST *in time* $O(C(n))$*. Thus* MAST *is computable in time* $O(n^{1+o(1)} + C(n))$*.*

Proof. By Proposition 4.5 and the definition of C, using Algorithm B, we compute TREES in time

$$O(n) + 2 \max_{\substack{\sum n_i = n, \\ n_i \in \{1, \ldots, \lfloor n/\kappa \rfloor\}}} \sum \mathtt{time}(\textsc{Trees}(n_i)) + C(k^a n).$$

Thus for any constant $n_0 \geq 1$ (to be fixed later), we may choose a constant k_1 such that

$$\forall n \in \mathbb{N} : 1 \leq n \leq n_0 \Rightarrow \mathtt{time}(\textsc{Trees}(n)) \leq k_1 C(n), \tag{1}$$

$$\forall n \in \mathbb{N} : n_0 < n \Rightarrow \Big\langle \forall \kappa \in \mathbb{R} : 1 \leq \kappa \leq n \Rightarrow$$

$$\mathtt{time}(\textsc{Trees}(n)) \leq k_1 C(\kappa^a n) + 2 \max_{\substack{\sum n_i = n, \\ n_i \in \{1, \ldots, \lfloor n/\kappa \rfloor\}}} \sum \mathtt{time}(\textsc{Trees}(n_i)) \Big\rangle. \tag{2}$$

Inductively from (1) and (2), it follows that the time complexity for TREES is bounded by any monotone function $T : \mathbb{R}_{\geq 1} \to \mathbb{R}$ that satisfies

$$\forall x \in \mathbb{R} : 1 \leq x \leq n_0 \Rightarrow$$

$$T(x) \geq k_1 C(x), \tag{3}$$

$$\forall x \in \mathbb{R} : n_0 < x \Rightarrow \Big\langle \exists \kappa \in \mathbb{R} : 1 \leq \kappa \leq x \wedge$$

$$T(x) \geq k_1 C(\kappa^a x) + 2 \max_{\substack{\sum x_i = n, \\ 1 \leq x_i \leq n/\kappa}} \sum T(n_i) \Big\rangle. \tag{4}$$

In our search for such an adequate function T, we will restrict ourselves to superlinear functions that satisfies

$$\exists \text{monotone } g : \mathbb{R}_{\geq 1} \to \mathbb{R} \; \forall x \in \mathbb{R}_{\geq 1} : T(x) = x g(x). \tag{5}$$

As a convenient consequence, for any $x, x_1, \ldots, x_l \in \mathbb{R}_{\geq 1}$ such that $\sum x_i = x$ and $1 \leq x_i \leq x/\kappa$, we have that $\sum T(x_i) = \sum (x_i g(x_i)) \leq \sum (x_i g(x/\kappa)) = x g(x/\kappa) =$

$\kappa T(x/\kappa)$. Thus (4) follows if

$$(6)\quad \forall x \in \mathbb{R} : x > n_0 \Rightarrow \langle \exists \kappa \in \mathbb{R} : 1 \le \kappa \le x \ \wedge\ T(x) \ge k_1 C(\kappa^a x) + 2\kappa T(x/\kappa)\rangle.$$

The rest of the proof divides into cases depending on ε.

$\varepsilon = 0$. For this case, we let n_0 be the least number such that $n_0 \ge b_1$, $4^a\sqrt{\log n_0} \ge b_1$, and $4\sqrt{\log n_0} \le n_0$. The last inequality is satisfied if and only if $n_0 \ge 16$. Recall that our choice of n_0 affects k_1. Since $\varepsilon = 0$, $C(x) = O(x^{1+o(1)})$, so we may choose a constant $k_2 \ge (2b_2)^{-1}$ such that $\forall x \in \mathbb{R}_{\ge 1} : C(x) \le k_2 x^{1.5}$. For a solution to our problem, we define T such that

$$(7)\qquad \forall x \in \mathbb{R}_{\ge 1} : T(x) = 2b_2 k_1 k_2 c^{\sqrt{\log x}} C(x), \quad \text{where } c = \max\{8^a, 4\}.$$

Clearly, (3) is satisfied since

$$\forall x \in \mathbb{R}_{\ge 1} : T(x) = 2b_2 k_1 k_2 c^{\sqrt{\log x}} C(x) \ge 2b_2 k_1 (2b_2)^{-1} C(x) = k_1 C(x).$$

Also, (5) is satisfied because for the function that maps x to

$$T(x)/x = 2b_2 k_1 k_2 c^{\sqrt{\log x}} C(x)/x = 2b_2 k_1 k_2 c^{\sqrt{\log x}} x f(x)/x = 2b_2 k_1 k_2 c^{\sqrt{\log x}} f(x)$$

is monotone since f is monotone. Hence (4) follows if we can settle (6). Fix $x > n_0$ and set $\kappa = 4^{\sqrt{\log x}}$. Notice that $1 < \kappa < x$, $\kappa^a > b_1$, and $x > b_1$. Now

$$\begin{aligned} k_1 C(\kappa^a x) &\le k_1 b_2 C(\kappa^a) C(x) \le b_2 k_1 k_2 (\kappa^a)^{1.5} C(x) = b_2 k_1 k_2 4^{1.5a\sqrt{\log x}} C(x) \\ &\le b_2 k_1 k_2 c^{\sqrt{\log x}} C(x) \le T(x)/2. \end{aligned}$$

Moreover,

$$\sqrt{\log(x/\kappa)} = \sqrt{\log(x/4^{\sqrt{\log x}})} = \sqrt{\log x - 2\sqrt{\log x}} \le \sqrt{\log x} - 1,$$

and hence

$$\begin{aligned} \kappa T(x/\kappa) &\le \kappa 2b_2 k_1 k_2 c^{\sqrt{\log(x/\kappa)}} C(x/\kappa) \le \kappa 2b_2 k_1 k_2 c^{\sqrt{\log x}-1}(x/\kappa) f(x/\kappa) \\ &\le 2b_2 k_1 k_2 (c^{\sqrt{\log x}}/c) x f(x) \le 2b_2 k_1 k_2 c^{\sqrt{\log x}} C(x)/c \le T(x)/4. \end{aligned}$$

Thus

$$k_1 C(\kappa^a x) + 2\kappa T(x/\kappa) \le T(x)/2 + 2T(x)/4 = T(x),$$

so (6) and hence (4) is satisfied. We may therefore conclude that with $\varepsilon = 0$, we can compute TREES on a problem of size n in time $2b_2 k_1 k_2 c^{\sqrt{\log n}} C(n) = O(C(n) c^{\sqrt{\log n}}) = O(n^{1+o(1)})$, as desired.

$\varepsilon > 0$. In this case, we fix $\kappa = \max\{4^{1/\varepsilon}, \sqrt[a]{b_1}\}$ and set $n_0 = \kappa b_1$. For a solution to our problem, we define T such that

$$(8)\qquad \forall x \in \mathbb{R}_{\ge 1} : T(x) = k_1 k_3 C(x) \quad \text{where } k_3 = \max\{1, 2b_2 C(\kappa^a)\}.$$

Clearly, (3) and (5) are satisfied. Fix $x > n_0$. Now

$$k_1 C(\kappa^a x) \le b_2 C(\kappa^a) k_1 C(x) \le T(x)/2$$

and

$$\kappa T(n/\kappa) = \kappa b_2 k_3 (n/\kappa)^{1+\varepsilon} f(x/\kappa) \leq b_2 k_3 n^{1+\varepsilon} \kappa^{-\varepsilon} f(x) \leq b_2 k_3 n^{1+\varepsilon} f(x)/4 = T(x)/4,$$

so

$$k_1 C(\kappa^a x) + 2\kappa T(x/\kappa) \leq T(x)/2 + 2T(x)/4 = T(x),$$

Thus (6) and hence (4) is satisfied. We may therefore conclude that with $\varepsilon > 0$, we can compute TREES on a problem of size n in time $b_2 k_1 k_3 C(n) = O(C(n))$, completing the proof. □

5. Computing SPINES. To implement MAST for bounded-degree trees, we need only show how to quickly compute SPINES (Procedure 3). To this end, we introduce the concept of intervals. For spine S with c the critical child of the lowest vertex, let $v, w \in \mathtt{V}(S) \cup \{c\}$, where w is an ancestor of v. Then v and w characterize an *interval* I of S, denoted by $]v, w]$. If $I =]v, w]$, we set $\mathtt{c}(I) = v$ and $\mathtt{r}(I) = w$. By $\mathtt{V}(I)$ we denote the set of vertices that are descendants of w and strict ancestors of v. If $v \neq w$, $\mathtt{V}(I)$ induces a segment of S, and we will often identify I with this segment. If $v = w$, the interval I corresponds to the empty segment together with a position. For any interval I, we define $\mathtt{SideT}(I)$ to be the forest of side trees whose roots are children of vertices in I. Let I_0 and I_1 be intervals from opposing core trees. We say that the pair of opposing intervals $\{I_0, I_1\}$ is *interesting* if and only if $\mathtt{A}(\mathtt{SideT}(I_0)) \cap \mathtt{A}(\mathtt{SideT}(I_1)) \neq \emptyset$. A pair which is not interesting is said to be *boring*. We will show how to implement SPINES quickly by giving an efficient method for dealing with boring interval pairs.

For specificity, fix $\{S_0, S_1\}$ to be a pair of opposing spines for which we wish to compute SPINES$\{S_0, S_1\}$. To ease the presentation, we will identify S_0 and S_1 with the intervals with the same vertex sets. Moreover, we set $m_0 = |\mathtt{V}(S_0)|$, $m_1 = |\mathtt{V}(S_1)|$, and $l = |\mathtt{A}(\mathtt{SideT}(S_0)) \cap \mathtt{A}(\mathtt{SideT}(S_1))|$. Notice that the number of maximal boring interval pairs can be as bad as $\Omega(l^2)$. However, we are going to identify $O(m_0 + m_1 + l \log n)$ boring interval pairs together with $O(m_0 + m_1 + l)$ vertex pairs, representing all computations needed to implement SPINES$\{S_0, S_1\}$.

Our algorithm for SPINES will proceed as follows. In section 5.1, we will choose a small subset of interval pairs on which to compute certain values. We will organize these intervals into an *interval tree*. In section 5.2, we will prove the main technical lemmas needed for dealing with boring interval pairs. In section 5.3, we will show how to actually implement SPINES in terms of the interval tree.

5.1. The interval tree. Consider an interval $I =]v, w]$, and let u be the vertex such that $|\mathtt{V}(]u, w])| = \lceil |\mathtt{V}(I)|/2 \rceil$. Then I^l denotes $]v, u]$ and I^r denotes $]u, w]$. Note that $\mathtt{V}(I^l)$ and $\mathtt{V}(I^r)$ are disjoint. Also note that if $I =]v, v]$ then $I^l = I^r = I$.

Given an opposing pair $\{I_0, I_1\}$ of intervals, we call $\mathtt{mast}\{\mathtt{c}(I_0), \mathtt{c}(I_1)\}$ the *floor*, $\mathtt{mast}\{\mathtt{c}(I_0), \mathtt{r}(I_1)\}$ and $\mathtt{mast}\{\mathtt{r}(I_0), \mathtt{c}(I_1)\}$ the *diagonals*, and $\mathtt{mast}\{\mathtt{r}(I_0), \mathtt{r}(I_1)\}$ the *ceiling* of the pair. Thus if I_0 and I_1 are intervals of spines S_0 and S_1, then the diagonals, together with the floor, are exactly the values from the base of $\{\mathtt{V}(I_0), \mathtt{V}(I_1)\}$ that are not in the base of $\{\mathtt{V}(S_0), \mathtt{V}(S_1)\}$.

We are now going to construct a rooted tree $\mathcal{E}$ whose nodes are opposing interval pairs. The root pair is (S_0, S_1). Suppose (I_0, I_1) is a node in $\mathcal{E}$ and that one of the following conditions is satisfied:

(i) $\{I_0, I_1\}$ is interesting and one of I_0 and I_1 contains more than one vertex.

(ii) One of I_0 and I_1 has the spine root as root, and the other contains more than one vertex.

Then $\{I_0, I_1\}$ has four children: (I_0^l, I_1^l), (I_0^l, I_1^r), (I_0^r, I_1^l), and (I_0^r, I_1^r); otherwise, $\{I_0, I_1\}$ is a leaf.

We are going to compute the ceiling and the diagonals of all the pairs in $\mathcal{E}$. Clearly, we will thereby implement SPINES since if r is the root of one of the spines and v is a vertex from the other spine, then the second condition defining $\mathcal{E}$ ensures that $\mathtt{mast}\{r, v\}$ is the ceiling of some pair in $\mathcal{E}$.

PROPOSITION 5.1. *The size and construction time for $\mathcal{E}$ is $O(m_0+m_1+l\log n)$.*

Proof. In our argument, we will focus on the size of $\mathcal{E}$. However, a corresponding construction will be indicated on the side. The depth of $\mathcal{E}$ is no more than $\max\{\lceil\log_2|\mathtt{V}(S_0)|\rceil, \lceil\log_2|\mathtt{V}(S_1)|\rceil\}$. Clearly, we only need to bound the number of internal nodes since the number of leaves is less than a factor of four larger. We will separately count the number of nodes made internal by the two conditions. Thereby, we accept a certain overlap where a node $\{I_0, I_1\}$ satisfies both conditions.

Concerning condition (i), by induction starting at the root, for each $a \in \mathtt{A}(\mathtt{SideT}(S_0)) \cap \mathtt{A}(\mathtt{SideT}(S_1)$, there is exactly one node $\{I_0, I_1\}$ at each level in $\mathcal{E}$ such that $a \in \mathtt{A}(\mathtt{SideT}(I_0)) \cap \mathtt{A}(\mathtt{SideT}(I_1)$. Thus at each level, we have at most $l = |\mathtt{A}(\mathtt{SideT}(S_0))\cap\mathtt{A}(\mathtt{SideT}(S_1)|$ satisfying condition (i), so in total we have at most $l\log n$ nodes in $\mathcal{E}$ satisfying (i). In order to find these nodes, starting from the root, with each node $\{I_0, I_1\}$ we store the set $\mathtt{A}(\mathtt{SideT}(I_0))\cap\mathtt{A}(\mathtt{SideT}(I_1))$—$\{I_0, I_1\}$ is interesting if the set is nonempty. If condition (i) is satisfied, in time $O(|\mathtt{A}(\mathtt{SideT}(I_0)) \cap \mathtt{A}(\mathtt{SideT}(I_1)|)$, we partition $\mathtt{A}(\mathtt{SideT}(I_0))\cap\mathtt{A}(\mathtt{SideT}(I_1)$ into $\mathtt{A}(\mathtt{SideT}(I_0^l))\cap\mathtt{A}(\mathtt{SideT}(I_1^l)$, $\mathtt{A}(\mathtt{SideT}(I_0^r)\cap \mathtt{A}(\mathtt{SideT}(I_1^l)$, and $\mathtt{A}(\mathtt{SideT}(I_0^r))\cap\mathtt{A}(\mathtt{SideT}(I_1^r)$ for the children. For each of the $O(\log n)$ levels, the total size of these sets is no more than l, so the construction time is $O(l\log n)$.

Concerning the internal nodes satisfying (ii), ignoring the symmetric case, we restrict (ii) to

(ii)$_0$ $\mathtt{r}(I_0) = \mathtt{r}(S_0)$ and I_1 contains more than one vertex.

Consider a node (I_0, I_1) of $\mathcal{E}$ satisfying (ii)$_0$. Then due to the first part of the condition, the only children of (I_0, I_1) that can satisfy (ii)$_0$ are (I_0^r, I_1^l) and (I_0^r, I_1^r). Since there is no freedom in choosing first coordinate of the children, the number of internal nodes in $\mathcal{E}$ satisfying (ii)$_0$ is

$$\begin{aligned}|\{S_1^\alpha : \alpha \in \{l,r\}^*, |\mathtt{V}(S_1^\alpha)| > 1\}| &< |\{S_1^\alpha : \alpha \in \{l,r\}^*, |\mathtt{V}(S_1^\alpha)| = 1\}| \\ &= |\mathtt{V}(S_1)| \;\le\; |\mathtt{A}(\mathtt{SideT}(S_1))| \;=\; m_1.\end{aligned}$$

The first inequality follows from the fact that the number of internal nodes of a binary tree is smaller than the number of leaves.

Equivalently, for the symmetric case (ii)$_1$, where $\mathtt{r}(I_1) = \mathtt{r}(S_1)$ and I_0 contains more than one vertex, we get at most m_0 internal nodes in $\mathcal{E}$. Thus there are at most m_0+m_1 internal nodes in $\mathcal{E}$ satisfying (ii) [$=$ (ii)$_0 \vee$ (ii)$_1$], so we conclude that in total there are at most $O(m_0+m_1+l\log n)$ nodes in $\mathcal{E}$. Moreover, $\mathcal{E}$ can be generated from the root (S_0, S_1), adding each new node in constant time. □

We are going to compute the ceiling and the diagonals of all the pairs in $\mathcal{E}$ respecting the linear order $<$ such that for each internal pair (I_0, I_1) of $\mathcal{E}$, we have $(I_0^l, I_1^l) < (I_0^l, I_1^r) < (I_0^r, I_1^l) < (I_0^r, I_1^r) < (I_0, I_1)$. Thus whenever we compute a pair, we can assume that all previous pairs have been computed.

OBSERVATION 5.2. *For any internal pair of $\mathcal{E}$, the ceiling and diagonals are the ceiling and diagonals of its children. The floor of any pair in $\mathcal{E}$ is the ceiling or diagonal of some preceding pair.* □

Thus we need only concern ourselves with computations at the leaves, which are either boring interval pairs or interesting node pairs.

5.2. Handling boring interval pairs.

LEMMA 5.3. *If the interval pair* $\{I_0, I_1\}$ *is boring, then*

$$\texttt{mast}\{\texttt{r}(I_0), \texttt{r}(I_1)\} = \max\left\{ \begin{array}{l} \texttt{mast}\{\texttt{c}(I_0), \texttt{r}(I_1)\}, \texttt{mast}\{\texttt{c}(I_1), \texttt{r}(I_0)\}, \\ \texttt{side-mast}\{\texttt{c}(I_0), I_1\} + \texttt{side-mast}\{\texttt{c}(I_1), I_0\} \end{array} \right\}.$$

Here $\texttt{side-mast}\{v, I\} = \max\{\texttt{mast}\{v, \texttt{r}(t)\} | t \in \texttt{SideT}(I)\}$.

Proof. Let lhs and rhs denote the left- and right-hand side of the equality of the lemma. First we prove lhs $\geq$ rhs. Clearly, $\texttt{mast}\{\texttt{r}(I_0), \texttt{r}(I_1)\} \geq \max\{\texttt{mast}\{\texttt{c}(I_0), \texttt{r}(I_1\}, \texttt{mast}\{\texttt{c}(I_1), \texttt{r}(I_0)\}\}$. For $i = 0, 1$, let $t_{\bar{i}}$ be a side tree in $\texttt{SideT}(I_{\bar{i}})$ such that $\texttt{mast}\{\texttt{c}(I_i), \texttt{r}(t_{\bar{i}})\} = \texttt{side-mast}\{\texttt{c}(I_i), I_{\bar{i}}\}$. Let p_i and c_i denote the parent and core sibling of $\texttt{r}(t_{\bar{i}})$. By application of Lemma 3.1, we get the following inequalities:

$$\begin{aligned} \texttt{mast}\{c_i, \texttt{r}(t_{\bar{i}})\} &\geq \texttt{mast}\{\texttt{c}(I_i), \texttt{r}(t_{\bar{i}})\} \text{ for } i = 0, 1, \\ \texttt{mast}\{f_0, f_1\} &\geq \texttt{mast}\{c_0, \texttt{r}(t_1)\} + \texttt{mast}\{\texttt{r}(t_0), c_1\}, \\ \texttt{mast}\{\texttt{r}(I_0), \texttt{r}(I_1)\} &\geq \texttt{mast}\{f_0, f_1\}. \end{aligned}$$

Hence it follows that $\texttt{mast}\{\texttt{r}(I_0), \texttt{r}(I_1\} \geq \texttt{side-mast}\{\texttt{c}(I_0), I_1\} + \texttt{side-mast}\{\texttt{c}(I_1), I_0\}$, and we may therefore conclude that lhs $\geq$ rhs.

We show that lhs $\leq$ rhs by contradiction. Assume that there is a pair $(f_0, f_1) \in \texttt{V}(I_0) \times \texttt{V}(I_1)$ such that $\texttt{mast}\{f_0, f_1\} >$ rhs and fix (f_0, f_1) to be a minimal such pair. First, we observe that the strict inequality implies that $s_0 \neq \texttt{c}(I_0)$ and $s_1 \neq \texttt{c}(I_1)$. For $i = 0, 1$, let c_i denote the core child of f_i. By the minimality of (f_0, f_1), we cannot have $\texttt{mast}\{f_i, f_{\bar{i}}\} = \texttt{mast}\{c_i, f_{\bar{i}}\}$. Also by minimality, we cannot have $\texttt{mast}\{f_i, f_{\bar{i}}\} = \texttt{mast}\{s_i, f_{\bar{i}}\}$, where s_i is a side child of f_i, because since our pair of intervals is boring, $\texttt{mast}\{s_i, f_{\bar{i}}\} = \texttt{mast}\{s_i, c_{\bar{i}}\} \leq \texttt{mast}\{f_i, c_{\bar{i}}\}$. Thus by Lemma 3.1, we have $\texttt{mast}\{f_0, f_1\} = \texttt{match}\{f_0, f_1\}$. Let M be a minimal matching in $\texttt{C}(f_0) \times \texttt{C}(f_1)$ such that $\texttt{match}\{f_0, f_1\} = \sum_{(v_0, v_1) \in M} \texttt{mast}\{v_0, v_1\}$. Since our interval pair is boring, we can only have an edge in M if either its head or its tail is core. By the minimality of (f_0, f_1), we cannot have $M = \{(c_0, c_1)\}$. Thus we have $M \subseteq \{(c_0, s_1), (c_1, s_0)\}$, where s_i is a specific side child of f_i. Putting everything together, we get

$$\begin{aligned} \text{rhs} &< \texttt{match}\{f_0, f_1\} \\ &= \sum_{(v_0, v_1) \in M} \texttt{mast}\{v_0, v_1\} \\ &= \texttt{mast}\{c_0, s_1\} + \texttt{mast}\{c_1, s_0\} \\ &= \texttt{mast}\{\texttt{c}(I_0), s_1\} + \texttt{mast}\{\texttt{c}(I_1), s_0\} \\ &\leq \texttt{side-mast}\{\texttt{c}(I_0), I_1\} + \texttt{side-mast}\{\texttt{c}(I_1), s_0\} \\ &\leq \text{rhs}, \end{aligned}$$

and hence we have the desired contradiction. □

What makes this useful is the following technical lemma.

LEMMA 5.4. *After an* $O(n \log n)$ *preprocessing based on the base of the core trees, given any pair of a vertex* v *from one core tree and an interval* I *from the other core tree, we can compute* $\texttt{side-mast}\{v, I\}$ *in time* $O(\log^2 n)$.

Proof. For simplicity, we assume that v is from $\mathcal{T}_0$ and I is from $\mathcal{T}_1$. A symmetric preprocessing is needed for the opposite case where I is from $\mathcal{T}_0$ and v is from $\mathcal{T}_1$. First, for each spine S in $\mathcal{T}_1$, we construct a balanced binary tree $\mathcal{I}_S$ over some nonempty intervals of S. The root of $\mathcal{I}_S$ is S itself, and given any node I in $\mathcal{I}_S$, I is a leaf if it consists of a single vertex; otherwise, I has children I^l and I^r. $\mathcal{I}_S$ has depth

$\lceil \log_2 |\mathtt{V}(S)| \rceil$. Denote by $\mathcal{I}$ the forest of the $\mathcal{I}_S$'s. Now the spines of $\mathcal{T}$ constitute the top level of $\mathcal{I}$. Generally, we have that all intervals at any specific level are mutually disjoint.

Our goal is to find an $O(n \log n)$ preprocessing such that given any vertex from $\mathcal{T}_0$ and interval I from $\mathcal{I}$, we can derive $\mathtt{side\text{-}mast}(v, I)$ in time $O(\log n)$. Assume that this is done. Then any interval I from $\mathcal{T}_1$ is the concatenation $I_1 \cdots I_l$ of at most $2 \log n$ intervals from $\mathcal{I}$, and then $\mathtt{side\text{-}mast}(v, I) = \max_i\{\mathtt{side\text{-}mast}(v, I_i)\}$. Thus such a preprocessing allows us to compute $\mathtt{side\text{-}mast}$ in time $O(\log^2 n)$, as desired.

For $i = 0, 1$ and for every label a, let $\mathtt{sr}_i(a)$ denote the root of the side tree of $\mathcal{T}_i$ containing the leaf with label a. By contraction of the side trees, we precompute all values of $\mathtt{sr}$ in time $O(n)$.

The remaining preprocessing is divided into $O(\log n)$ separate $O(n)$ preprocessings: one for each level in $\mathcal{I}$. Let $I_1, \ldots, I_k$ be all the intervals at some specific level in $\mathcal{I}$. Then $I_1, \ldots, I_k$ are mutually disjoint, so, in particular, $\mathtt{A}(\mathtt{SideT}(I_1)), \ldots, \mathtt{A}(\mathtt{SideT}(I_k))$ are mutually disjoint.

Consider an arbitrary fixed interval I of $\mathcal{T}_0$, and note the following recursion formula for $\mathtt{side\text{-}mast}(\cdot, I)$:

$$\mathtt{side\text{-}mast}(v, I) = \max\{$$

$$\max\{\mathtt{mast}(v, \mathtt{r}(t)) | t \in \mathtt{SideT}(I)\}, \tag{9}$$

$$\max\{\mathtt{side\text{-}mast}(w, I) | w \text{ is a descendant } v\}\} \tag{10}$$

Set $V_I = \{\mathtt{p}(\mathtt{sr}_0(a)) | a \in \mathtt{A}(\mathtt{SideT}(I))\}$ and $W_I = \mathtt{LCA}(V_I)$. Then V_I contains all core vertices v for which (9) is relevant. Moreover, W_I contains all the values of w that are relevant for (10). Let t_I denote the topological subtree of $\mathcal{T}_0$ with vertex W_I. All of the sets V_{I_i} are easily computed in time $O(n)$, and by Lemma 4.3, in time $O(n)$ we can compute all the t_{I_i}'s.

Consider any specific t_{I_i}. We want to compute $\mathtt{side\text{-}mast}(v, I_i)$ for all $v \in \mathtt{V}(t_{I_i}) = W_{I_i}$. For this purpose, we introduce an variable $sm(v)$ for each $v \in W_{I_i}$. Initially $sm(v) := 0$ for all $v \in W_{I_i}$. Now, corresponding to (9), for all $a \in \mathtt{A}(\mathtt{SideT}(I_i))$, set

$$sm(\mathtt{p}(\mathtt{sr}_0(a))) := \max\{sm(\mathtt{p}(\mathtt{sr}_0(a))), \mathtt{mast}\{\mathtt{p}(\mathtt{sr}_0(a))), \mathtt{sr}_1(a)\}.$$

Next, corresponding to (10), go through the vertices of t_{I_i} in post-order. When visiting the vertex v, set

$$v := \max\{sm(v), \max\{sm(w) | w \text{ is a child of } v \text{ in } t_{I_i}\}\}.$$

When the computation is finished $sm(v) = \mathtt{side\text{-}mast}(v, I_i)$ for all $v \in \mathtt{V}(t_{I_i}) = W_{I_i}$. The time of the computation is $O(|\mathtt{A}(\mathtt{SideT}(I_i))| + |W_{I_i}|) = O(|\mathtt{A}(\mathtt{SideT}(I_i))|)$. Thus we can precompute $\mathtt{side\text{-}mast}(v, I_i)$ for all $I_i, w \in W_{I_i}$ in time $O(\sum |\mathtt{A}(\mathtt{SideT}(I_i))|) = O(n)$.

Now consider any query $\mathtt{side\text{-}mast}(v, I_i)$ where $v \notin W_{I_i}$. Then $\mathtt{side\text{-}mast}(v, I) = \mathtt{side\text{-}mast}(w, I)$, where w is the nearest descendant of v in W_{I_i}, if any; otherwise, $\mathtt{side\text{-}mast}(v, I) = 0$. We solve the nearest-descendant query in $O(\log n)$ time by first applying the preprocessing from Lemma 4.4 to all the W_{I_i}s. This preprocessing takes time $O(\sum_{I_i} |W_{I_i}|)$, where

$$\sum_{I_i} |W_{I_i}| < 2 \sum_{I_i} |V_{I_i}| \leq 2 \sum_{I_i} |\mathtt{A}(\mathtt{SideT}(I_i))| = 2n.$$

Thus all preprocessing of $I_1, \ldots, I_k$ is done in time $O(n)$, so the total preprocessing is done in time $O(n \log n)$, as desired. □

5.3. Using the interval tree.

PROPOSITION 5.5. *Any diagonal of a pair in $\mathcal{E}$ can be computed in time $O(\log^2 n)$.*

Proof. Let (I_0, I_1) be any pair in $\mathcal{E}$. By symmetry, it is sufficient to show the computation of $\mathtt{mast}\{\mathtt{c}(I_0), \mathtt{r}(I_1)\}$. Suppose there is a vertex $v_0 \in \mathtt{V}(S_0)$ below or equal to $\mathtt{c}(I_0)$ which is interesting with respect to some vertex in I_1. Fix v_0' to be the highest such vertex, i.e., the one closest to $\mathtt{c}(I_0)$. Let I_0' be the interval in $\mathcal{I}_0$ which contains v_0 and which is on the same level as I_0 and hence as I_1 in $\mathcal{I}_1$. Thus I_0' is interesting with respect to I_1, and since they are on the same level in their respective interval trees, we can conclude that $(I_0', I_1) \in \mathcal{E}$. Trivially, $(I_0', I_1) < (I_0, I_1)$, so we can assume that the ceiling $\mathtt{mast}\{\mathtt{r}(I_0'), \mathtt{r}(I_1)\}$ is computed.

Set $I_0'' =]\mathtt{r}(I_0'), \mathtt{c}(I_0)]$. By choice of v_0', the pair (I_0'', I_1) is boring—but typically not in $\mathcal{E}$. The diagonal $\mathtt{mast}\{\mathtt{c}(I_0''), \mathtt{r}(I_1)\}$ is exactly the ceiling of (I_0', I_1) which we saw was computed, and the diagonal $\mathtt{mast}\{\mathtt{r}(I_0'), \mathtt{c}(I_1)\}$ is the floor of (I_0, I_1) which is computed by Lemma 5.2. Thus by Lemmas 5.3 and 5.4, we can compute the ceiling $\mathtt{mast}\{\mathtt{r}(I_0''), \mathtt{r}(I_1)\}$ in time $O(\log^2 n)$. However, this ceiling is exactly the desired diagonal of (I_0, I_1). □

COROLLARY 5.6. *Any boring pair in $\mathcal{E}$ can be computed in time $O(\log^2 n)$.*

Proof. By Proposition 5.5, we can compute the diagonals in time $O(\log^2 n)$, but then we can apply Lemmas 5.3 and 5.4 to get the ceiling in time $O(\log^2 n)$. □

For any opposing pair $\{v_0, v_1\}$, by $\mathtt{time}(\mathtt{mast}\{v_0, v_1\})$ we refer to the time it takes to compute $\mathtt{mast}\{v_0, v_1\}$ assuming that every value in the base of $\{v_0, v_1\}$ is available in time $O(\log n)$.

COROLLARY 5.7. *Any interesting leaf pair (I_0, I_1) in $\mathcal{E}$ can be computed in time $O(\log^2 n + \mathtt{time}(\mathtt{mast}\{\mathtt{r}(I_0), \mathtt{r}(I_1)\})$.*

Proof. Again, the diagonals are computed by Proposition 5.5, and the floor follows by Lemma 5.2. Hence we have the whole basis of $\{\mathtt{V}(I_0), \mathtt{V}(I_1)\}$ available. Since (I_0, I_1) is an interesting leaf pair, it follows that $\mathtt{V}(I_i) = \{\mathtt{r}(I_i)\}$ for $i = 0, 1$. Thus, in fact, we have the basis of $\{\mathtt{r}(I_0), \mathtt{r}(I_1)\}$ available, so the ceiling $\mathtt{mast}\{\mathtt{r}(I_0), \mathtt{r}(I_1)\}$ can be computed directly. □

Summing up, we conclude as following.

PROPOSITION 5.8. SPINES$\{S_0, S_1\}$ (*Procedure* 3) *can be computed in time $O((m_0 + m_1 + l \log n) \log^2 n + (\sum_{\{v_0, v_1\} \in F} \mathtt{time}(\mathtt{mast}\{v_0, v_1\}))$, where $m_0 = |\mathtt{V}(S_0)|$, $m_1 = |\mathtt{V}(S_1)|$, $l = |\mathtt{A}(\mathtt{SideT}(S_0)) \cap \mathtt{A}(\mathtt{SideT}(S_1))|$, and $F \subseteq \mathtt{V}(S_0) \times \mathtt{V}(S_1)$ contains at most l pairs.*

Proof. We observed above that, indeed, computing all the ceilings of pairs in $\mathcal{E}$ is sufficient for implementing SPINES; and now, from Proposition 5.1, Lemma 5.2, and Corollaries 5.6 and 5.7 together with the observation that there are at most l interesting leaf pairs, it follows that we can compute all ceilings and diagonals of the pairs in $\mathcal{E}$ within the desired time bound. □

THEOREM 5.9. CORE-TREES (*Procedure* 2) *can be computed in time $O(\kappa n \log^3 n + \sum_{\{v_0, v_1\} \in E} \mathtt{time}(\mathtt{mast}\{v_0, v_1\}))$. Here E divides into two sets E_1 and E_2. The set E_1 contains all the $O(\kappa n)$ pairs of core vertices where one is critical. The set E_2 contains the at most n interesting pairs of spine vertices.*

Proof. Let S denote the set of pairs of spines from opposing core trees. Since there can be at most κ spines in each core tree, we get $(\sum_{\{S_0, S_1\} \in S} |\mathtt{V}(S_0)| + |\mathtt{V}(S_1)|) \leq \kappa n$. Moreover, by Fact 3.2, we get that $(\sum_{\{S_0, S_1\} \in S} |\mathtt{A}(\mathtt{SideT}(S_0)) \cap \mathtt{A}(\mathtt{SideT}(S_1))|) \leq n$. Thus the result follows directly from Observation 3.3 together with Proposition 5.8. □

COROLLARY 5.10. *For trees T_0 and T_1 with bounded degree,* TREES$\{T_0, T_1\}$ *can be computed in time $O(nc^{\sqrt{\log n}})$.*

Proof. For bounded degrees, $\texttt{time}(\texttt{mast}\{v_0, v_1\})) = O(\log n)$, so the result follows from Theorem 4.6 with $\kappa = 4^{\sqrt{\log n}}$ and Theorem 5.9. □

6. Computing the matchings. The aim of this section is to reduce the work of computing the $O(\kappa n)$ mast values of the set E specified in Theorem 5.9 when the trees given have unbounded degree. Recall that $\texttt{mast}\{v, w\}$ is found as the maximum value over $\texttt{Diag}\{v, w\}$ and $\texttt{match}\{v, w\}$. The maximum diagonal of the $O(\kappa n)$ pairs in E can easily be computed in $O(\kappa n \log n)$ time by a bottom-up dynamic program, so our problem is to bound the work on matchings. Recall that the matching associated with a pair $\{v, w\}$ is on the weighted bipartite graph whose vertex sets are $\texttt{C}(v)$ and $\texttt{C}(w)$ and whose edges (u, v) are weighted by $\texttt{mast}\{u, v\}$. We denote this graph by G_{vw}. For any weighted bipartite graph G, let $\texttt{match}(G)$ be the value of the maximal weighted bipartite matching on G. Thus $\texttt{match}\{v, w\} = \texttt{match}(G_{vw})$ for all opposing vertex pairs $\{v, w\}$. We will reduce the size of the matchings by reducing the number of nodes and edges and the total sum of the edge weights involved. Initially, these values are $O(n^2)$, $O(n^2)$, and $O(n^3)$, respectively. Our goal is to reduce them to $O(\kappa n)$, $O(\kappa n)$, and $O(\kappa^2 n)$. We will do this by deleting some edges and reducing the weights of others. In general, we will be building a set of matching graphs H_{vw} from the original matching graphs G_{vw} such that the maximum weight of a matching in G_{vw} can be deduced from the maximum weight of a matching in H_{vw}. Note that we will not explicitly build the G_{vw} since their total size can be as large as $\Omega(n^2)$.

The vertices will be bounded by the number of edges. Recall that nodes come in three types: side, critical, and spine. All edges in the matching are between children of core nodes. Let a *side–side* edge be a nonzero edge between opposing side children. For matching graph G_{vw}, we will let l_{vw} be the number of side–side edges in the graph. By Fact 3.2, there can be no more than n side–side edges, and the sum of their weights is also bounded by n.

Recall that the opposing pairs in E from Theorem 5.9 come in two varieties: E_1 contains all the pairs of core vertices where one is critical; E_2 contains the at most n interesting pairs of spine vertices. We will bound the size of the E_1 and E_2 matchings separately.

LEMMA 6.1. *There are graphs H_{vw} for all $\{v, w\} \in E_1$ such that $\texttt{match}(H_{vw}) = \texttt{match}(G_{vw})$ and such that $\sum_{\{v,w\}\in E_1} |\texttt{E}(H_{vw})| = O(\kappa n)$.*

Proof. As note above, there are at most n side–side edges. All other edges are incident on a core child of a critical node. There are a total of $O(\kappa)$ such core children, and no node can be involved in more than $O(n)$ matching edges. Thus just by consideration of nonzero edges, we see that in total we need only $O(\kappa n)$ edges for the H_{vw}. □

LEMMA 6.2. *There are graphs H_{vw} for all $\{v, w\} \in E_2$ such that $\texttt{match}(H_{vw}) = \texttt{match}(G_{vw})$, $|\texttt{E}(H_{vw})| \le 3l_{vw} + 3$ and $\sum_{\{v,w\}\in E_2} |\texttt{E}(H_{vw})| = O(n)$.*

Proof. First of all, our reduced matching graph H_{vw} contains all side–side edges and the edge between the two opposing core nodes. This gives at most $l_{vw} + 1$ edges. The question is which edges we need to include between the two core nodes and their opposing side nodes.

Let c be one of the core nodes. From c to the opposing side nodes, we will include all of the at most l_{vw} edges to side nodes incident with side–side edges. Moreover, we will include one of the maximum-weight remaining edges to side nodes. Let this edge be $\{c, c^s\}$. Thus H_{vw} contains a total of at most $l_{vw} + 1 + 2(l_{vw} + 1) = 3l_{vw} + 3$ edges, as required.

We need to prove that that $\texttt{match}(H_{vw}) = \texttt{match}(G_{vw})$. Consider an arbitrary maximal matching M in G_{vw}. We assume that M has no zero-weight edges. Suppose

that M contains an edge outside H_{vw}. Then this edge must be between a core node c and an opposing side node u which is not incident on a side–side edge and which is different from c^s. Then c^s cannot be matched in M, so we get a new matching M' in G_{vw} if we replace $\{c, u\}$ by the edge $\{c, c^s\}$ from H_{vw}. Moreover, from our choice of c^s, it follows that the weight of M' is at least that of M. We may therefore conclude that one of the maximal matchings in G_{vw} is a maximal matching in H_{vw}.

Finally, we must bound the summation $\sum_{\{v,w\}\in E_2} 3l_{vw} + 3$. However, $|E_2| \leq n$ and $\sum l_{vw} \leq n$ by Fact 3.2. □

LEMMA 6.3. *We can compute all of the H_{vw}'s in $O(n \log^3 n)$ time.*

Proof. The matching graphs H_{vw} from Lemma 6.1 come automatically from only considering nonzero-weight matching edges. In order to sparsify matching graphs of Lemma 6.2, we first choose an arbitrary ordering of the side children of each vertex. It is now meaningful to talk about intervals of side children. With the same technique that was used in the proof of Lemma 5.4, we can make an $O(n \log n)$ preprocessing such that given any vertex v and interval I of side children of some opposing vertex, we can compute $\max\{\texttt{mast}\{v, w\} | w \in \texttt{V}(I)\}$ in time $O(\log^2 n)$.

Recall our problem: we are given a vertex v together with a vertex w and a subset S of the side children which already participate in the matching since they share labels with the side trees of w. Let w^c be the core children of w. We want to find the side child v^s of v outside S which has the MAST with w^c.

This is done in time $O(|S| \log^2 n)$ because removing the vertices from S leaves us with no more than $|S| + 1$ intervals, each of which we can deal with in time $O(\log^2 n)$, and afterwards we just need to find the maximum, which is done in time $O(|S|)$. □

Having reduced the number of edges in our matching to $O(\kappa n)$, we can trivially conclude that the total weight is (κn^2). We will now show that we can reduce some edge weights before applying the matching algorithm so that the total becomes $O(\kappa^2 n)$. We will further show that the weight reductions are reversible in that we will easily be able to retrieve the maximum-weighted matching on the original graph from the matching on the weight-reduced graph. With the current best algorithm for (unary) weighted bipartite matching [12], this reduction of the weights has no significance because the weights only effect the running time by a logarithmic factor. However, the point of this paper is to show an equivalence to unary weighted bipartite matching which holds even if more weight-sensitive algorithms for unary weighted bipartite matching are found. For the weight reduction, we will use the following technical observation.

OBSERVATION 6.4. *Let $G = (V_0 \cup V_1, E, W)$ be a weighted bipartite graph, and let $v \in V_0$. For all edges $\{v, w\}$, set $\Delta\{v, w\} = W\{v, w\} - \max(\{0\} \cup \{W\{v', w\} | v' \in V_0 \setminus \{v\})$. Moreover, set $\Delta(v) = \max\{\Delta\{v, w\} | \{v, w\} \in E\}$.*

If $\Delta(v) > 1$, let G' be the weighted bipartite graph obtained by reducing the weights of all edges incident with v by $\Delta(v) - 1$. Then $\Delta'(v) = 1$, and then the maximal weight matchings in G' are the same as those in G and their weights are exactly $\Delta(v) - 1$ smaller.

Proof. The observation follows directly from the fact that v has to be in any maximal matching if $\Delta(v) \geq 1$. □

Clearly, we can find $\Delta(v)$ in time linear in the number of edges. Thus for each of our matchings, we may choose a constant number of vertices v that we *reduce*, getting $\Delta'(v) \leq 1$, before we apply a matching procedure.

PROPOSITION 6.5. *The total weight of matching edges can be reduced to $O(\kappa^2 n)$ in time $O(\kappa n)$.*

Proof. The total weight of the side–side edges is at most n, so if for each matching

based on spine nodes we apply the reduction to their two core children, the total sum of their matching weights becomes $O(n)$, and if for each matching based on a spine node and a critical node we apply the reduction to the core child of the spine node, the total sum of their matching weights becomes $O(\kappa n)$. With regards to the $O(\kappa^2)$ matchings based on two critical nodes, their sum cannot exceed $O(\kappa^2 n)$ in total weight. Thus, since we have a total of $O(\kappa n)$ edges involved in the matchings, in time $O(\kappa n)$, we can reduce the total sum of the matching weights to $O(\kappa^2 n)$. □

THEOREM 6.6. *Let $M : \mathbb{R}_{\geq 1} \to \mathbb{R}$ be a monotone function bounding the time complexity* UWBM. *Moreover, let M satisfy that $M(x) = x^{1+\varepsilon} f(x)$, where $\varepsilon \geq 0$ is a constant, $f(x) = O(x^{o(1)})$, f is monotone, and for some constants b_1 and b_2, $\forall x, y \geq b_1 : f(xy) \leq b_2 f(x) f(y)$. Then, with $\kappa = \sqrt[\varepsilon]{4}$,* MAST *is computable in time $O(n^{1+o(1)} + M(n))$.*

Proof. We spend $O(n \text{ polylog } n + \texttt{time}(\texttt{UWBM}(\kappa^2 n)))$ on the matchings. Therefore, by Theorem 5.9, we have that CORE-TREES can be computed in time $O(n \text{ polylog } n + \texttt{time}(\texttt{UWBM}(\kappa^2 n)))$. Applying Theorem 4.6 gives the desired complexity. □

Inserting the best known bounds for unary weighted bipartite matching [12], with $\kappa = \sqrt[1/2]{4} = 16$, we get the following result.

COROLLARY 6.7. MAST *is computable in time $O(n^{1.5} \log n)$.* □

As a general remark, we note that we can get somewhat tighter bounds as follows. Let $\texttt{UWBM}(n, b)$ be the unary weighted bipartite matching problem in which the independent sets can be no larger than b and the sum of the weights in bounded by n. Let the $\texttt{MAST}(n, b)$ problem be the MAST problem on two n leaf trees with degree bound b. We can generalize our results to show that $\texttt{UWBM}(n, b)$ reduces linearly to $\texttt{MAST}(n, b)$. We cannot, in general, bound the work on $\texttt{MAST}(n, b)$ by $O(n^{1+o(1)} + \texttt{time}(\texttt{UWBM}(n, b)))$, but we note that using the Gabow–Tarjan algorithms gives a time of $O(n\sqrt{b} \log n)$ for $\texttt{UWBM}(n, b)$. In this case, we can bound the total work for $\texttt{MAST}(n, b)$ by $O(n^{1+o(1)} + n\sqrt{b} \log n)$, thus unifying the complexities of the bounded and general cases.

Acknowledgments. We thank the referees for their careful reading and helpful comments.

TOTAL PROTECTION OF ANALYTIC-INVARIANT INFORMATION IN CROSS-TABULATED TABLES*

MING-YANG KAO†

Abstract. To protect sensitive information in a cross-tabulated table, it is a common practice to suppress some of the cells in the table. An *analytic invariant* is a power series in terms of the suppressed cells that has a unique feasible value and a convergence radius equal to $+\infty$. Intuitively, the information contained in an invariant is not protected even though the values of the suppressed cells are not disclosed. This paper gives an optimal linear-time algorithm for testing whether there exist nontrivial analytic invariants in terms of the suppressed cells in a given set of suppressed cells. This paper also presents NP-completeness results and an almost linear-time algorithm for the problem of suppressing the minimum number of cells in addition to the sensitive ones so that the resulting table does not leak analytic-invariant information about a given set of suppressed cells.

1. Introduction.

Cross-tabulated tables are used in a wide variety of documents to organize and exhibit information, often with the values of some cells suppressed in order to conceal sensitive information. Concerned with the effectiveness of the practice of cell suppression [12], statisticians have raised two fundamental issues and developed computational heuristics to various related problems [5, 7, 8, 9, 10, 11, 28, 29, 30, 31]. The *detection* issue is whether an adversary can deduce significant information about the suppressed cells from the published data of a table. The *protection* issue is how a table maker can suppress a small number of cells in addition to the sensitive ones so that the resulting table does not leak significant information.

This paper investigates the complexity of how to protect a broad class of information contained in a two-dimensional table that publishes (1) the values of all cells except a set of sensitive ones, which are *suppressed*, (2) an upper bound and a lower bound for each cell, and (3) all row sums and column sums of the complete set of cells. The cells may have real or integer values. They may have different bounds, and the bounds may be finite or infinite. The upper bound of a cell should be strictly greater than its lower bound; otherwise, the value of that cell is immediately known even if that cell is suppressed. The cells that are not suppressed also have upper and lower bounds. These bounds are necessary because some of the unsuppressed cells may later be suppressed to protect the information in the sensitive cells. (See Tables 1 and 2 for an example of a complete table and its published version.)

An *unbounded feasible assignment* to a table is an assignment of values to the suppressed cells such that each row or column adds up to its published sum. A *bounded* feasible assignment is an unbounded one that also obeys the bounds of the suppressed

Note: Let $X_{p,q}$ denote the cell at row p and column q. The lower and upper bounds for all suppressed cells except $X_{2,c}$ and $X_{3,c}$ are $-\infty$ and $+\infty$. The lower and upper bounds for $X_{2,c}$ and $X_{3,c}$ are 0 and 9.5.

cells. An *analytic function* of a table is a power series of the suppressed cells, each regarded as a variable, such that the convergence radius is ∞ [1, 4, 21, 22, 26, 27]. An *analytic invariant* is an analytic function that has a unique value at all the bounded feasible assignments. If an analytic invariant is formed by a linear combination of the suppressed cells, then it is called a *linear invariant* [17, 19]. Similarly, a suppressed cell is called an *invariant cell* [14, 15] if it is an invariant by itself. For instance, in Table

2, a published table, let $X_{p,q}$ be the cell at row p and column q. $X_{6,i}$ is an invariant because it is the only suppressed cell in row 6. $X_{2,c}$ and $X_{3,c}$ are invariant cells because their values are between 0 and 9.5, their sum is 19, and both cells are forced to have the same unique value 9.5. Consequently, $(X_{3,c} \cdot X_{2,c} + 0.5 \cdot X_{2,c} - 95)^2 \cdot X_{1,b} + \sin(X_{2,c} \cdot X_{2,a} - 9.5 \cdot X_{2,a})$ is also an invariant.

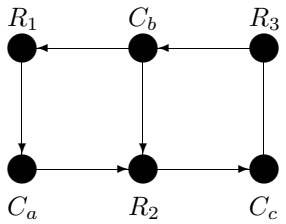
Intuitively, the information contained in an analytic invariant is unprotected because its value can be uniquely deduced from the published data. In this paper, a set of suppressed cells is *totally protected* if there exists no analytic invariant in terms of the suppressed cells in the given set, except the trivial invariant that contains no nonzero terms. Since the analytic power series form a very broad family of mathematical functions, total protection conceals from the adversary a very large class of information. This paper gives a very simple algorithm for testing whether a given set of suppressed cells is totally protected. When a graph representation, called the *suppressed graph*, of a table is given as input, this algorithm runs in optimal $O(m+n)$ time, where m is the number of suppressed cells and n is the total number of rows and columns. This paper also considers the problem of computing and suppressing the minimum number of additional cells so that a given set of original suppressed cells becomes totally protected. This problem is shown to be NP-complete. For a large class of tables, this optimal-suppression problem can be solved in $O((m+n) \cdot \alpha(n, m+n))$ time, where α is an Ackerman's inverse function and its value is practically a small constant [2, 3, 6, 16]. Moreover, for this class of tables, every optimal set of cells for additional suppression forms a spanning forest of some sort. As a consequence, at most $n-1$ additional cells need to be suppressed to achieve the total protection of a given set of original suppressed cells. Since the size of a table may grow quadratically in n, the suppression of $n-1$ additional cells is a negligible price to pay for total protection for a reasonably large table.

Previously, four other levels of data security have been considered that protect information contained, respectively, in individual suppressed cells [14, 15], in a row or column as a whole, in a set of k rows or k columns as a whole, and in a table as a whole [18]. These four levels of data security and total protection differ in two major aspects. First, these four levels of data security primarily protect information expressible as linear invariants, whereas total protection protects the much broader class of analytic-invariant information. Second, these four levels of data security emphasize protecting regular regions of a table, whereas total protection protects any given set of suppressed cells and is more flexible. These four levels of data security and total protection share some interesting similarities. As total protection corresponds to spanning forests in suppressed graphs, these four levels of data security are equivalent to some forms of 2-edge connectivity [14, 15], 2-vertex connectivity, k-vertex connectivity, and graph completeness [18]. In this paper, the NP-completeness results and efficient algorithms for total protection rely heavily on its graph characterizations. Similarly, the equivalence characterizations of these four levels of data security have been key in obtaining efficient algorithms [14, 15, 18] and NP-completeness proofs [18] for various detection and protection problems.

Section 2 discusses basic concepts. Section 3 formally defines the notion of total protection and gives a linear-time algorithm to test for this notion. Sections 4 and 5 give NP-completeness results and efficient algorithms for optimal suppression problems of total protection. Section 6 concludes this paper with discussions.

2. Basics of two-dimensional tables. This section discusses basic relationships between tables and graphs.

row column index	a	b	c	row sum
1	[0]	[9]	1	10
2	[9]	[9]	[0]	18
3	6	[0]	[5]	11
column sum	15	18	6	



In the above 3×3 table, the number in each cell is the value of that cell. A cell with a box is a suppressed cell. The lower and upper bounds of the suppressed cells are 0 and 9. The graph below the table is the suppressed graph of the table. Vertex R_p corresponds to row p, and vertex C_q to column q.

FIG. 1. *A table and its suppressed graph.*

A *mixed* graph is one that may contain both undirected and directed edges. A *traversable* cycle or path in a mixed graph is one that can be traversed along the directions of its edges. A *direction-blind* cycle or path is one that can be traversed if the directions of its edges are disregarded. The word direction-blind is often omitted for brevity. A mixed graph is *connected* (respectively, *strongly connected*) if each pair of vertices are contained in a direction-blind path (respectively, traversable cycle). A *connected component* (respectively, *strongly connected component*) of a mixed graph is a maximal subgraph that is connected (respectively, strongly connected). A set of edges in a mixed graph is an *edge cut* if its removal disconnects one or more connected components of that graph. An edge cut is a *minimal* one if it has no proper subset that is also an edge cut.

Henceforth, let $\mathcal{T}$ be a table, and let $\mathcal{H}' = (A, B, E')$ and $\mathcal{H} = (A, B, E)$ be the bipartite mixed graphs constructed below. $\mathcal{H}'$ and $\mathcal{H}$ are called the *total graph* and the *suppressed graph* of $\mathcal{T}$, respectively [15]. For each row (respectively, column) of $\mathcal{T}$, there is a unique vertex in A (respectively, B). This vertex is called a *row* (respectively, *column*) vertex. For each cell $X_{i,j}$ at row i and column j in $\mathcal{T}$, there is a unique edge e in E between the vertices of row i and column j. If the value of $X_{i,j}$ is strictly between its bounds, then e is undirected. Otherwise, if the value is equal to the lower (respectively, upper) bound, then e is directed towards to its column (respectively, row) endpoint. Note that $\mathcal{H}'$ is a *complete* bipartite mixed graph, i.e., there is exactly one edge between each pair of vertices from the two vertex sets of the graph. The graph $\mathcal{H}$ is the subgraph of $\mathcal{H}'$ whose edge set consists of only those corresponding to the suppressed cells of $\mathcal{T}$. Figure 1 illustrates a table and its suppressed graph. For

convenience, a row or column of $\mathcal{T}$ will be regarded as a vertex in $\mathcal{H}$ and a cell as an edge, and vice versa.

THEOREM 2.1 (see [15]). *A suppressed cell of $\mathcal{T}$ is an invariant cell if and only if it is not in an edge-simple traversable cycle of $\mathcal{H}$.*

The *effective area* of an analytic function F of $\mathcal{T}$, denoted by $EA(F)$, is the set of variables in the nonzero terms of F. The function F is called *nonzero* if $EA(F) \neq \emptyset$. Note that because the convergence radius of F is ∞, $EA(F)$ is independent of the point at which F is expanded into a power series.

THEOREM 2.2 (see [17]). *For every minimal edge cut Y of a strongly connected component of $\mathcal{H}$, $\mathcal{T}$ has a linear invariant F with $EA(F) = Y$.*

The *bounded kernel* (respectively, *unbounded kernel*) of $\mathcal{T}$, denoted by $BK(\mathcal{T})$ (respectively, $UK(\mathcal{T})$), is the real vector space consisting of all linear combinations of $x - y$, where x and y are arbitrary bounded (respectively, unbounded) feasible assignments of $\mathcal{T}$.

Because $\mathcal{H}$ is bipartite, every cycle of $\mathcal{H}$ is of even length. Thus the edges of an edge-simple direction-blind cycle of $\mathcal{H}$ can be alternately labeled with $+1$ and -1. Such a labeling is called a *direction-blind labeling*. A direction-blindly labeled cycle is regarded as an assignment to the suppressed cells of $\mathcal{T}$. If the corresponding edge of a suppressed cell is in the given cycle, then the value assigned to that cell is the label of that edge; otherwise, the value is 0. Note that this assignment needs not be an unbounded feasible assignment of $\mathcal{T}$.

THEOREM 2.3 (see [19]).

1. *$UK(\mathcal{T}) = BK(\mathcal{T})$ if every connected component of $\mathcal{H}$ is strongly connected.*
2. *Every direction-blindly labeled cycle of $\mathcal{H}$ is a vector in $UK(\mathcal{T})$.*

3. Total protection. A set Q of suppressed cells of $\mathcal{T}$ is *totally protected* in $\mathcal{T}$ if there is no nonzero analytic invariant F of $\mathcal{T}$ with $EA(F) \subseteq Q$. The goal of total protection can be better understood by considering Q as the set of suppressed cells that contain sensitive data. The total protection of Q means that no precise analytic information about these data, not even their row and column sums, can be deduced from the published data of $\mathcal{T}$. Since analytic power series form a very large class of functions in mathematical sciences, this notion of protection requires a large class of information about Q to be concealed from the adversary.

The next lemma and theorem characterize the notion of total protection in graph concepts.

LEMMA 3.1. *If F is a nonzero analytic invariant of $\mathcal{T}$ such that the edges in $EA(F)$ are contained in the strongly connected components of $\mathcal{H}$, then for some strongly connected component D of $\mathcal{H}$, $EA(F) \cap D$ is an edge cut of D.*

Remark. The converse of this lemma is not true; for a counterexample, consider the linear combination $X_{1,a} + 2{\cdot}X_{1,b}$ for the table in Figure 1. Also, if F is a nonzero linear invariant, then for every strongly connected component D of $\mathcal{H}$, the set $D \cap EA(F)$ is either empty or is an edge cut of D [17].

Proof. Let $\mathcal{T}_s$ be the table constructed from $\mathcal{T}$ by also publishing the suppressed cells that are not in the strongly connected components of $\mathcal{H}$. By Theorem 2.1, F remains a nonzero analytic function of $\mathcal{T}_s$. Also, the connected components of the suppressed graph $\mathcal{H}_s$ of $\mathcal{T}_s$ are the strongly connected components of $\mathcal{H}$. Thus to prove the lemma, it suffices to prove it for $\mathcal{T}_s$, $\mathcal{H}_s$, and F.

Let x_0 be a fixed bounded feasible assignment of $\mathcal{T}_s$. Let $K = \{x - x_0 | x$ is a bounded feasible assignment of $\mathcal{T}_s\}$. Since F is an analytic invariant of $\mathcal{T}_s$, the function $G(x) = F(x) - F(x_0)$ is an analytic invariant of $\mathcal{T}_s$ with $EA(G) = EA(F)$ and its value

is zero over x_0+K. Because K contains a nonempty open subset of $BK(\mathcal{T}_s)$, G is zero over $x_0 + BK(\mathcal{T}_s)$. By Theorem 2.3(1) and the strong connectivity of the connected components of $\mathcal{H}_s$, $BK(\mathcal{T}_s) = UK(\mathcal{T}_s)$ and G is zero over $x_0+UK(\mathcal{T}_s)$. Thus it suffices to show that if $D - EA(F)$ is connected for all connected components D of $\mathcal{H}_s$, then $G(x_0 + z_0) \neq 0$ for some $z_0 \in UK(\mathcal{T}_s)$. To construct z_0, let $EA(G) = \{e_1, \ldots, e_k\}$. Let D_i be the connected component of $\mathcal{H}_s$ that contains e_i. By the connectivity of $D_i - EA(F)$, there is a vertex-simple path P_i in $D_i - EA(F)$ between the endpoints of e_i. Let C_i be the vertex-simple cycle formed by e_i and P_i. Next, direction-blindly label C_i with e_i labeled $+1$. Since G is a nonzero power series, $G(x_0+y_0) \neq 0$ for some vector y_0. Note that y_0 is not necessarily in $UK(\mathcal{T}_s)$. Therefore, let $z_0 = \sum_{i=1}^{k} h_i \cdot C_i$, where h_i is the component of y_0 at variable e_i. Then by Theorem 2.3(2), $z_0 \in UK(\mathcal{T}_s)$. Because P_i is in $\mathcal{H}_s - EA(F)$, e_i appears only in the term C_i in $\sum_{i=1}^{k} h_i \cdot C_i$. Thus z_0 and y_0 have the same component values at the variables in $EA(G)$. Since the variables not in $EA(G)$ do not appear in any expansion of G, $G(x_0 + z_0) = G(x_0 + y_0) \neq 0$, proving the lemma. □

THEOREM 3.2. *A set Q of suppressed cells is totally protected in $\mathcal{T}$ if and only if the two statements below are both true:*

1. *The edges in Q are contained in the strongly connected components of $\mathcal{H}$.*
2. *For each strongly connected component D of $\mathcal{H}$, the graph $D-Q$ is connected.*

Proof. It is equivalent to show that Q is not totally protected if and only if Q contains some edges not in the strongly connected components of $\mathcal{H}$ or for some strongly connected component D of $\mathcal{H}$, the graph $D - Q$ is not connected. The $\Rightarrow$ direction follows from Lemma 3.1. As for the $\Leftarrow$ direction, if Q contains some edges not in the strongly connected components of $\mathcal{H}$, then by Theorem 2.1, Q contains some invariant cells of $\mathcal{T}$ and thus cannot be totally protected. If for some strongly connected component D of $\mathcal{H}$, the graph $D - Q$ is not connected, then some subset Y of Q is a minimal edge cut of D. By Theorem 2.2, $\mathcal{T}$ has a linear invariant F with $EA(F) = Y$ and thus Q is not totally protected. □

This paper investigates the following two problems concerning how to achieve total protection.

PROBLEM 1 (protection test).

- *Input*: The suppressed graph $\mathcal{H}$ and a set Q of suppressed cells of a table $\mathcal{T}$.
- *Output*: Is Q totally protected in $\mathcal{T}$?

THEOREM 3.3. *Problem 1 can be solved in linear time in the size of $\mathcal{H}$.*

Proof. This problem can be solved within the desired time bound by means of Theorem 3.2 and linear-time algorithms for computing connected components and strongly connected components [2, 3, 6, 16]. □

PROBLEM 2 (optimal suppression).

- *Input*: A table $\mathcal{T}$, a subset Q of E, and an integer $p \geq 0$, where E is the set of all suppressed cells in $\mathcal{T}$.
- *Output*: Is there a set P consisting of at most p published cells of $\mathcal{T}$ such that Q is totally protected in the table $\overline{\mathcal{T}}$ formed by $\mathcal{T}$ with the cells in P also suppressed?

This problem is clearly in NP. Section 4 shows that this problem with $Q = E$ is NP-complete. In contrast, section 5 proves that if the total graph of $\mathcal{T}$ is undirected, then this problem with general Q can be solved in almost linear time.

4. NP-completeness of optimal suppression. Throughout this section, the total graph of $\mathcal{T}$ may or may not be undirected.

THEOREM 4.1. *Problem* 2 *with* $Q = E$ *is NP-complete.*

To prove this theorem, the idea is to first transform Problem 2 with $Q = E$ to the following graph problem and then prove the NP-completeness of the graph problem.

PROBLEM 3.

- *Input*: A complete bipartite mixed graph $\mathcal{H}' = (A, B, E')$, a subgraph $\mathcal{H} = (A, B, E)$, and an integer $p \geq 0$.
- *Output*: Does any set P of at most p edges in $E' - E$ hold the following two properties?

  Property N1: Every connected component of $(A, B, E \cup P)$ is strongly connected.

  Property N2: The vertices of each connected component of $\mathcal{H}$ are connected in (A, B, P), i.e., contained in a connected component in (A, B, P).

LEMMA 4.2. *Problem* 2 *with* $Q = E$ *and Problem* 3 *can be reduced to each other in linear time.*

Proof. Given an instance $\mathcal{T}$ and p of Problem 2 with $Q = E$, the desired instance of Problem 3 is the total graph $\mathcal{H}' = (A, B, E')$, the suppressed graph $\mathcal{H} = (A, B, E)$ of $\mathcal{T}$, and p itself. This transformation can easily be computed in linear time. There are two directions to show that it reduces Problem 2 to Problem 3. Assume that P is a desired set for Problem 3. By Property N1, statement 1 in Theorem 3.2 is true. Also, every strongly connected component of $(A, B, E \cup P)$ is a union of edge-disjoint connected components in $\mathcal{H}$ and (A, B, P). Therefore, by Property N2, statement 2 of Theorem 3.2 holds. As a result, P itself is a desired set for Problem 2. On the other hand, assume that P is a desired set for Problem 2. Let P' be the set of all edges in P that are also in the strongly connected components of $(A, B, E \cup P)$. By statement 1 of Theorem 3.2 and the total protection of E in $\overline{\mathcal{T}}$, the connected components of $(A, B, E \cup P')$ are the strongly connected components of $(A, B, E \cup P)$. Thus P' holds Property N1. Next, because a connected component of $\mathcal{H}$ is included in a strongly connected component of $(A, B, E \cup P')$, by statement 2 of Theorem 3.2, P' also holds Property N2 and thus is a desired set for Problem 3.

Given an instance $\mathcal{H}'$, $\mathcal{H}$, and p of Problem 3, the desired instance of Problem 2 with $Q = E$ is p itself and the table defined as follows. For each vertex in A (respectively, B), there is a row (respectively, column). The upper and lower bounds for each cell are 2 and 0. For each edge e in E', its corresponding cell is at the row and column corresponding to its endpoints. The value of that cell is 1 (respectively, 0 and 2) if e is undirected (respectively, directed from A to B or directed from B to A). For each edge e in $\mathcal{H}$, its corresponding cell is suppressed. Note that the total and suppressed graphs of this table are $\mathcal{H}'$ and $\mathcal{H}$ themselves. Thus the remaining proof details for this reduction are essentially the same as for the other reduction. □

Both Problem 2 with $Q = E$ and Problem 3 are clearly in NP. To prove their completeness in NP, by Lemma 4.2, it suffices to reduce the following NP-complete problem to Problem 3.

PROBLEM 4 (hitting set [13]).

- *Input*: A finite set S, a nonempty family W of subsets of S, and an integer $h \geq 0$.
- *Output*: Is there a subset S' of S such that $|S'| \leq h$ and S' contains at least one element in each set in W?

Given an instance $S = \{s_1, \ldots, s_q\}$, $W = \{S_1, \ldots, S_r\}$, h of Problem 4, an instance $\mathcal{H}' = (A, B, E')$, $\mathcal{H} = (A, B, E)$, p of Problem 3 is constructed as follows:

- *Rule* 1: Let $A = \{a_0, a_1, \ldots, a_q\}$. The vertices $a_1, \ldots, a_q$ correspond to

$s_1, \ldots, s_q$, but a_0 corresponds to no s_i.

- *Rule* 2: Let $B = \{b_0, b_1, \ldots, b_r\}$. The vertices $b_1, \ldots, b_r$ correspond to $S_1, \ldots, S_r$ of S, but b_0 corresponds to no S_j.
- *Rule* 3: Let E' be the union of the following sets of edges:
  1. $\{b_0 \to a_0\}$;
  2. $\{a_0 \to b_j \mid \forall\ j \text{ with } 1 \le j \le r\}$;
  3. $\{a_i \to b_0 \mid \forall\ i \text{ with } 1 \le i \le q\}$;
  4. $\{b_j \to a_i \mid \forall\ s_i \text{ and } S_j \text{ with } s_i \in S_j\}$;
  5. $\{a_i \to b_j \mid \forall\ s_i \text{ and } S_j \text{ with } s_i \notin S_j\}$.
- *Rule* 4: Let $E = \{a_0 \to b_1, \ldots, a_0 \to b_r\}$.
- *Rule* 5: Let $p = h + r + 1$.

The above construction can easily be computed in polynomial time. The next two lemmas show that it is indeed a desired reduction.

LEMMA 4.3. *If some set $S' \subseteq S$ with $|S'| \le h$ contains at least one element in each S_j, then there is a set $P \subseteq E' - E$ consisting of at most p edges that holds Properties* N1 *and* N2.

Proof. For each S_j, let s_{i_j} be an element in $S' \cap S_j$; by the assumption of this lemma, these elements exist. Next, let $P_1 = \{b_1 \to a_{i_1}, \ldots, b_r \to a_{i_r}\}$ and $P_2 = \{a_{i_1} \to b_0, \ldots, a_{i_r} \to b_0\}$; by Rule 3, these two sets exist. Now let $P = P_1 \cup P_2 \cup \{b_0 \to a_0\}$. Note that $P \subseteq E' - E$. Since P_1 consists of r edges and P_2 consists of at most $|S'|$ edges, P has at most p edges. P holds Property N1 because $E \cup P$ consists of the edges in the traversable cycles $b_0 \to a_0$, $a_0 \to b_j$, $b_j \to a_{i_j}$, and $a_{i_j} \to b_0$. Property N2 of P follows from the fact that P connects $\{a_0, b_1, \ldots, b_r\}$, which forms the only connected component of $\mathcal{H}$ with more than one vertex. □

LEMMA 4.4. *If some set $P \subseteq E' - E$ consisting of at most p edges holds Properties* N1 *and* N2, *then there exists a set $S' \subseteq S$ with $|S'| \le h$ that contains at least one element in each S_j.*

Proof. By Property N1, P must contain some edge $b_j \to a_{i_j}$ for each j with $1 \le j \le r$. By Rule 3(4), $s_{i_j} \in S_j$. Now let $S' = \{s_{i_1}, \ldots, s_{i_r}\}$. To calculate the size of S', note that by Property N1, P must also contain $b_0 \to a_0$ and at least one edge leaving a_{i_j} for each j. Thus $|P| \ge |S'| + r + 1$. Then $|S'| \le h$ because $|P| \le p = r + h + 1$. □

The above lemma completes the proof of Theorem 4.1.

5. Optimal suppression in almost linear time. Under the assumption that the total graph of $\mathcal{T}$ is undirected, this section considers the following optimization version of Problem 2.

PROBLEM 5 (optimal suppression).

- *Input*: The suppressed graph $\mathcal{H} = (A, B, E)$ of a table $\mathcal{T}$ and a subset Q of E.
- *Output*: A set P consisting of the smallest number of published cells in $\mathcal{T}$ such that Q is totally protected in the table $\overline{\mathcal{T}}$ formed by $\mathcal{T}$ with the cells in P also suppressed.

For all positive integers n and m, let α denote the best known function such that $m + n$ unions and finds of disjoint subsets of an n-element set can be performed in $O((m+n)\cdot\alpha(n, m+n))$ time [2, 3, 6, 16].

THEOREM 5.1. *Problem* 5 *can be solved in $O((m+n)\cdot\alpha(n, m+n))$ time, where m is the number of suppressed cells and n is the total number of rows and columns in $\mathcal{T}$.*

To prove Theorem 5.1, Problem 5 is first converted to the next problem.

PROBLEM 6.

- *Input*: An undirected bipartite graph $\mathcal{H} = (A, B, E)$ and a subset Q of E.
- *Output*: A forest P formed by the smallest number of undirected edges between A and B but not in E such that the vertices of each connected component of (A, B, Q) are connected in $(A, B, (E - Q) \cup P)$, i.e., contained in a connected component of $(A, B, (E - Q) \cup P)$.

LEMMA 5.2. *Problems* 5 *and* 6 *can be reduced to each other in linear time.*

Proof. The proof uses arguments similar to those in the proof of Lemma 4.2. The strong connectivity properties in Problem 3 and Theorem 3.2 can be ignored because this section assumes that the total graph of $\mathcal{T}$ is undirected. The forest structure of P follows from its minimality. □

Note that because $Q \subseteq E$, the vertices of each connected component of (A, B, Q) are connected in $(A, B, (E - Q) \cup P)$ if and only if the vertices of each connected component of $\mathcal{H}$ are connected in $(A, B, (E - Q) \cup P)$. Using this equivalence, the next stage of the proof of Theorem 5.1 further reduces Problem 6 to another graph problem with the steps below:

M1. Compute the connected components $D_1, \ldots, D_r$ of $\mathcal{H}$.

M2. For each D_i, compute a maximal forest K_i over the vertices of D_i using only the edges in $E - Q$.

M3. For each D_i, extend K_i to a maximal forest L_i over the vertices of D_i using additional edges only from the complement graph D_i^c of D_i.

M4. Construct a graph $\hat{\mathcal{H}}$ from $\mathcal{H}$ by contracting each tree in each L_i into a single vertex.

M5. For each D_i, compute its contracted version $\hat{D}_i$ in $\hat{\mathcal{H}}$.

M6. Divide the vertices of $\hat{\mathcal{H}}$ into three sets, V_A, V_B, and V_{AB}, where a vertex in V_A (respectively, V_B) consists of a single vertex from A (respectively, B) and a vertex in V_{AB} contains at least two vertices (thus with at least one from each of A and B).

A set of undirected edges between vertices in V_A, V_B, and V_{AB} is called *semitripartite* if every edge in that set is between two of the three sets or is between two vertices in V_{AB}. Note that the set of edges in $\hat{\mathcal{H}}$ is semitripartite.

PROBLEM 7.

- *Input*: Three disjoint finite sets V_A, V_B, and V_{AB} and a partition $\hat{D}_1, \ldots, \hat{D}_r$ of $V_A \cup V_B \cup V_{AB}$.
- *Output*: A semitripartite set $\hat{P}$ consisting of the smallest number of edges such that no edge in $\hat{P}$ connects two vertices in the same D_i and the vertices in each D_i are connected in the graph formed by is $\hat{P}$.

LEMMA 5.3. *Problem* 6 *can be reduced to Problem* 7 *in* $O((m + n) \cdot \alpha(n, m + n))$ *time, where* m *is the number of edges and* n *is the number of vertices in* $\mathcal{H}$.

Proof. The key idea is that an optimal P for Problem 6 can be obtained by connecting the vertices of each D_i first with edges in $E - Q$, which can be used for free, next with edges in D_i^c, and then with edges outside $D_i \cup D_i^c$. Let P' be a set of $|\hat{P}|$ edges in the complement of $\mathcal{H}$ that becomes $\hat{P}$ after step M4. Then $P' \cup (L_1 - K_1) \cup \cdots \cup (L_r - K_r)$ is a desired output P for Problem 6, showing that steps M1–M6 can indeed reduce Problem 6 to Problem 7. Step M3 is the only step that requires more than linear time. It is important to avoid directly computing D_i^c at step M3. Computing these complement graphs takes $\Theta(|A| \cdot |B|)$ time if some D_i contains a constant fraction of the vertices in $\mathcal{H}$. In such a case, if $\mathcal{H}$ is sparse, then the time spent on computing D_i^c alone is far greater than the desired complexity. Instead of this naïve approach, step M3 uses efficient techniques recently developed

for complement-graph problems [20] and takes the desired $O((m+n)\cdot\alpha(n,m+n))$ time. □

The last stage of the proof of Theorem 5.1 is to give a linear-time algorithm for Problem 7. A component $\hat{D}_i$ is *good* if it has at least two vertices with at least one from V_{AB}; it is *bad* if it has at least two vertices with none from V_{AB} (and thus with at least one from each of V_A and V_B). The goal is to use as few edges as possible to connect the vertices in each of these components. Let w_g and w_b be the numbers of good and bad components, respectively. There are three cases based on the value of w_g.

Case 1: $w_g = 0$. If $w_b = 0$, then let $\hat{P} = \emptyset$ because no $\hat{D}_i$ needs to be connected. If $w_b > 0$ and $|V_{AB}| > 0$, then include in $\hat{P}$ an edge between each vertex in the bad components and an arbitrary vertex in V_{AB}. If $w_b > 0$ and $|V_{AB}| = 0$, then there does not exist a desired $\hat{P}$ and the given instance of Problem 7 has no solution.

Case 2: $w_g = 1$. Let $\hat{D}_j$ be the unique good component.

If $w_b > 0$, then find a bad component $\hat{D}_k$ and three vertices $u \in V_{AB} \cap \hat{D}_j$, $v_1 \in V_A \cap \hat{D}_k$, and $v_2 \in V_B \cap \hat{D}_k$. Next, include in $\hat{P}$ an edge between v_2 and each vertex in $(\hat{D}_j \cap (V_A \cup V_{AB})) - \{u\}$, an edge between v_1 and each vertex in $\hat{D}_j \cap V_B$, and an edge between u and each vertex in the bad components.

If $w_b = 0$ and $V_{AB} - \hat{D}_j \neq \emptyset$, then include in $\hat{P}$ an edge between every vertex in $\hat{D}_j$ and an arbitrary vertex in $V_{AB} - \hat{D}_j$.

If $w_b = 0$ and $V_{AB} - \hat{D}_j = \emptyset$, then there are sixteen subcases depending on whether $V_A \cap \hat{D}_j = \emptyset$, $V_A - \hat{D}_j = \emptyset$, and $V_B \cap \hat{D}_j = \emptyset$, $V_B - \hat{D}_j = \emptyset$. If $V_A \cap \hat{D}_j \neq \emptyset$, $V_A - \hat{D}_j \neq \emptyset$, $V_B \cap \hat{D}_j \neq \emptyset$, and $V_B - \hat{D}_j \neq \emptyset$, then include in $\hat{P}$ an edge between each vertex in $V_A \cap \hat{D}_j$ and a vertex $v_2 \in V_B - \hat{D}_j$, an edge between each vertex in $V_B \cap \hat{D}_j$ and a vertex $v_1 \in V_A - \hat{D}_j$, and an edge between v_1 and each vertex in $V_{AB} \cup \{v_2\}$. The other fifteen subcases are handled similarly.

Case 3: $w_g \geq 2$. Let d be the total number of vertices in the good and bad components. Let w' be the number of connected components in $\hat{P}$ that contain the vertices of at least one good or bad $\hat{D}_i$; let d' be the number of vertices in these connected components of $\hat{P}$ that are not in any good or bad $\hat{D}_i$. By its minimality, $\hat{P}$ forms a forest and $|\hat{P}| = d' + d - w'$. The techniques for Cases 1 and 2 can be used to show that there exists an optimal $\hat{P}$ with $d' = 0$. Thus to minimize $|\hat{P}|$ is to maximize w'. Because two bad components cannot be connected by edges between them alone, the strategy for maximizing w' is to pair a good component with a bad one, whenever possible, and include in $\hat{P}$ edges between them to connect their vertices into a tree. After this step, if there remain unconnected bad components but no unconnected good ones, then add to P an edge between each vertex in the remaining bad components and an arbitrary vertex in the intersection of V_{AB} and a good component. On the other hand, if there remain good components but no bad ones, then pair up these good components similarly. After this step, if there remains a good component, then add to $\hat{P}$ an edge between each vertex in this last good component and an arbitrary vertex in the intersection of V_{AB} and another good component. (As a result, if $w_g \leq w_b$, then $|\hat{P}| = d - w_g$; otherwise, $|\hat{P}| = d - \lfloor \frac{w_g + w_b}{2} \rfloor$.)

The above discussion yields a linear-time algorithm for Problem 7 in a straightforward manner. This finishes the proof of Theorem 5.1.

6. Discussions. Lemma 5.2 has several significant implications. Since P is a forest, it has at most $n-1$ edges. Thus for a table with an undirected total graph, no more than $n-1$ additional cells need to be suppressed to achieve total protection. This

is a small number compared to the size of the table, which may grow quadratically in n. Moreover, when $\mathcal{H}$ is connected and $E = Q$, (A, B, P) is a spanning tree. In this case, many well-studied tree-related computational concepts and tools, such as minimum-cost spanning trees, can be applied to consider other optimal suppression problems for total protection.

Acknowledgments. The author is deeply grateful to Dan Gusfield for his constant encouragement and help. The author wishes to thank an anonymous referee for very helpful and thorough comments. The referee has also pointed out that some very interesting materials related to Theorems 2.2 and 2.3 have been developed in the context of protecting sums of suppressed cells [23, 24, 25].

ON THE POWER OF REAL TURING MACHINES OVER BINARY INPUTS*

FELIPE CUCKER† AND DIMA GRIGORIEV‡

Abstract. In this paper, we study the computational power of real Turing machines over binary inputs. Our main result is that the class of binary sets that can be decided by real Turing machines in parallel polynomial time is exactly the class PSPACE/*poly*.

Key words. real-number machines and computations, complexity classes

AMS subject classifications. 68Q05, 68Q15

PII. S0097539794270340

Introduction. In recent years, the study of the complexity of computational problems involving real numbers has been an increasing research area. A foundational paper has been [5], where a computational model—the real Turing machine—for dealing with the above problems was developed.

One research direction that has been studied intensively during the last two years is the computational power of real Turing machines over binary inputs. The general problem can be roughly stated in the following way. Let us consider a class C of real Turing machines that work under some resource bound (for instance, polynomial time, branching only on equality, etc.). If we restrict these machines to work on binary inputs (i.e., finite words over $\{0,1\}$), they define a class of binary languages D. The question is, what can we say about D depending on C?

More formally, let us denote by $\mathbb{R}^\infty$ the direct sum of countably many copies of $\mathbb{R}$ and let $\mathcal{P}(\mathbb{R}^\infty)$ be the set of its subsets. Also, let us denote by Σ the subset $\{0,1\}$ of $\mathbb{R}$ and—as usual—by Σ^* the subset of $\mathbb{R}^\infty$ consisting of those vectors whose components are in Σ. Given any complexity class $\mathcal{C} \subseteq \mathcal{P}(\mathbb{R}^\infty)$, we define its Boolean part to be the class of binary languages

$$\mathrm{BP}(\mathcal{C}) = \{X \cap \Sigma^* : X \in \mathcal{C}\}.$$

Our problem now can be stated as follows: given a complexity class of real sets $\mathcal{C}$ characterize $\mathrm{BP}(\mathcal{C})$.

A possible origin of the problem is the recent interest in the computational power of neural networks. The first results characterized the power of nets with rational weights working within polynomial time by showing that they compute exactly the sets in P (cf. [28]). The same problem was then considered for neural networks with real weights, and it was shown that the power of these nets working within polynomial time is exactly P/*poly* (cf. [29] and [23]).

This latter problem considers in a natural way a setting in which an algebraic model having real constants operates over binary inputs. A next step was then taken

by Koiran, who passed from a structured model—the neural net—to a general one—the real Turing machine. However, he did not deal with the real Turing machine as it was introduced in [5] but with a restricted version of it that can do only a moderate use of multiplication, namely, all rational functions intermediately computed (in the input variables as well as in the machine's constants) must have degree and coefficient size bounded by the running time. For this weak model, he considered the class P_{W} of sets accepted in polynomial time and he proved that $\mathrm{BP}(\mathrm{P}_{\mathrm{W}}) = \mathrm{P}/\mathit{poly}$ (see [20]).

Subsequently, several papers exhibited new results on Boolean parts. In [13], it was shown that $\mathrm{BP}(\mathrm{PAR}_{\mathrm{W}}) = \mathrm{PSPACE}/\mathit{poly}$, where $\mathrm{PAR}_{\mathrm{W}}$ is the class of subsets of $\mathbb{R}^\infty$ decided in weak parallel polynomial time. Also, for additive machines (i.e., real Turing machines that do not perform multiplications at all), it was shown in [21] that $\mathrm{BP}(\mathrm{P}_{\mathrm{add}}) = \mathrm{P}/\mathit{poly}$ and $\mathrm{BP}(\mathrm{NP}_{\mathrm{add}}) = \mathrm{NP}/\mathit{poly}$. Here $\mathrm{P}_{\mathrm{add}}$ and $\mathrm{NP}_{\mathrm{add}}$ denote the obvious classes, but we recall that the nondeterministic guesses in this model are real numbers. Moreover, if the machines are order free, i.e., they are required to branch only on equality tests, we now have that $\mathrm{BP}(\mathrm{P}^{=}_{\mathrm{add}}) = \mathrm{P}$ and that $\mathrm{BP}(\mathrm{NP}^{=}_{\mathrm{add}}) = \mathrm{NP}$ [21]. These results were subsequently generalized in [11] to all the levels of the polynomial hierarchy constructed upon $\mathrm{NP}_{\mathrm{add}}$ (or $\mathrm{NP}^{=}_{\mathrm{add}}$) as well as to the class $\mathrm{PAR}_{\mathrm{add}}$ (or $\mathrm{PAR}^{=}_{\mathrm{add}}$) of sets computed in parallel polynomial time whose Boolean part is proven to be PSPACE/*poly* (respectively, PSPACE).

None of the results mentioned was done for the (unrestricted) real Turing machine. In fact, for this case, it was even asked whether there exists a subset of Σ^* not belonging to the $\mathrm{BP}(\mathrm{P}_{\mathbb{R}})$ (cf. [14]). First steps in this direction were done in [22], where it was shown that if we consider order-free machines, then we have the inclusion $\mathrm{BP}(\mathrm{P}^{=}_{\mathbb{R}}) \subseteq \mathrm{BPP}$ (the class of sets decided by randomized machines in polynomial time with bounded probability error; see [1, Chapter 6]) as well as a positive answer to the question above. In fact, if $\mathrm{PH}_{\mathbb{R}}$ is the polynomial hierarchy constructed upon $\mathrm{NP}_{\mathbb{R}}$, the existence of binary languages not belonging to $\mathrm{BP}(\mathrm{PH}_{\mathbb{R}})$ (and a fortiori not belonging to $\mathrm{BP}(\mathrm{P}_{\mathbb{R}})$) was also proved in [22].

The aim of this paper is to prove that $\mathrm{BP}(\mathrm{PAR}_{\mathbb{R}}) = \mathrm{PSPACE}/\mathit{poly}$, where $\mathrm{PAR}_{\mathbb{R}}$ is the class of sets computed in parallel polynomial time by (ordinary) real Turing machines. As a consequence, we obtain the existence of binary sets that do not belong to the Boolean part of $\mathrm{PAR}_{\mathbb{R}}$ (an extension of the result in [22] since $\mathrm{PH}_{\mathbb{R}} \subseteq \mathrm{PAR}_{\mathbb{R}}$). Also, a separation of complexity classes in the real setting follows. If we consider the class $\mathrm{EXP}_{\mathrm{W}}$ of subsets of $\mathbb{R}^\infty$ accepted by RTM in weak exponential time as defined in [20], the Boolean part above implies that the inclusion $\mathrm{PAR}_{\mathbb{R}} \subset \mathrm{EXP}_{\mathrm{W}}$ is strict.

Refining our main theorem a bit, we show that it is even possible to allow a polynomial advice (i.e., a polynomially long sequence of real numbers) to $\mathrm{PAR}_{\mathbb{R}}$ without modifying its Boolean part—in other words, that we have $\mathrm{BP}(\mathrm{PAR}_{\mathbb{R}})/\mathit{poly} = \mathrm{PSPACE}/\mathit{poly}$. Since it is known from [11] that the Boolean part of $\mathrm{PAR}_{\mathrm{add}}$ (where no multiplications are allowed) is PSPACE/*poly*, we deduce that multiplication or nonuniformity (under the form of a polynomial advice) are of no help to decide binary sets in the presence of parallelism.

1. Some geometrical background. In this paper, $\mathbb{N}, \mathbb{Z}, \mathbb{Q}, \mathbb{R}$, and $\mathbb{C}$ denote the sets of natural, integer, rational, real, and complex numbers, respectively. By $\mathbb{R}_{\mathrm{alg}}$ we denote the real closure of $\mathbb{Q}$, i.e., the field of all real algebraic numbers. Also, for any polynomial f with integer coefficients, we shall denote by $|\mathrm{coeff}(f)|$ the maximal absolute value of its coefficients.

The aim of this section is to show how to find real algebraic points in the connected components of nonempty open sets. We closelly follow [16]. Thus let $g_1, \ldots, g_N \in$

$\mathbb{Z}[X_1, \ldots, X_k]$ and let

$$V = \{x \in \mathbb{R}^k : g_1(x) > 0 \& \cdots \& g_N(x) > 0\}$$

be an open nonempty semialgebraic set. For the rest of this section, we consider d a bound on the degree of each g_i and consider L a bound for all $|\text{coeff}(g_i)|$.

LEMMA 1.1 (see [16, Lemma 10]). *Let $g = \prod_{i=1}^{N} g_i$ and d_g be the degree of g. Then there exists a positive integer γ_1 such that any connected component of V has a nonempty intersection with the ball $B(R)$, where*

$$R = L^{{d_g}^{k\gamma_1}}. \qquad \square$$

Let us now recall (see [6, section 9.5]) that a point $a \in \mathbb{R}^k$ is a *critical point* for a function $f : \mathbb{R}^k \to \mathbb{R}$ when it satisfies

$$\frac{\partial f}{\partial X_1}(a) = \cdots = \frac{\partial f}{\partial X_k}(a) = 0.$$

In this case, the value $b = f(a)$ is said to be a *critical value* of f. In the case when f is a polynomial function, Sard's lemma (see [6, Théorème 9.5.2] or [24]) implies that there are only a finite number of critical values of f.

This last fact was used in [16] (and in several subsequent papers) to reduce the dimension of nonempty semialgebraic sets to zero (thus avoiding cascading of projections) in the algorithm for deciding emptiness of semialgebraic sets.

Let us now consider the polynomials

$$g_0 = R^2 - \sum_{i=1}^{k} X_i^2$$

and

$$G = g_0 \prod_{i=1}^{N} g_i.$$

We have that $\deg G = d_G < Nd + 2$ and $L_G = |\text{coeff}(G)| \leq L^{{d_G}^{O(k)}} (Ld^k)^{O(N)}$ due to Lemma 1.1.

The following result gives a bound on the small critical values of G.

LEMMA 1.2. *There exists a positive integer γ_2 such that for every nonzero critical value b of G, we have $|b| > C^{-1}$, where*

$$C = L_G^{{d_G}^{k\gamma_2}}.$$

Proof. Let us consider the system of equations in the variables $X_1, \ldots, X_k, Z$,

$$G - Z = \frac{\partial G}{\partial X_1} = \cdots = \frac{\partial G}{\partial X_k} = 0,$$

as well as its set of solutions $S \subseteq \mathbb{R}^{k+1}$. On any connected component of S, the coordinate Z, being the critical value of G, is constant since G is continuous and due to Sard's lemma. Now, since the degrees and the coefficients of the polynomials appearing in this system are bounded by d_G and $O(L_G d_G)$, respectively, if we apply

the quantifier-elimination algorithm given in [18] or [25] along $X_1, \ldots, X_k$ onto Z, we get a finite set of points in $\mathbb{R}$ (just the critical values) such that each nonzero point has absolute value greater than

$$\left(L_G^{d_G{}^{k\gamma_2}}\right)^{-1}. \qquad \square$$

Remark 1. In the preceding proof, the use of quantifier elimination is not strictly necessary. One can instead use the bounds for the representative points from the connected components of S given in the main theorem of [16].

Because of the preceding lemma, we have that the algebraic set

$$W_0 = \{x \in \mathbb{R}^k : G(x) = C^{-1}\}$$

is a nonsingular, closed hypersurface with the property that each connected component of $V \cap B(R)$ contains at least one (bounded) connected component of W_0 (cf. [24]). Note that W_0 do not intersect the boundary of $B(R)$.

Now Lemma 5 of [16] asserts the existence of integers $0 \leq v_2, \ldots, v_n \leq (2d_G)^k$ such that the system

$$G - C^{-1} = \left(\frac{\partial G}{\partial X_2}\right)^2 - \frac{v_2}{(2d_G)^k k}\Delta = \cdots = \left(\frac{\partial G}{\partial X_k}\right)^2 - \frac{v_k}{(2d_G)^k k}\Delta = 0,$$

where $\Delta = \sum_{i=1}^k (\frac{\partial G}{\partial X_i})^2$, has a finite number of solutions in $\mathbb{R}^k$. Moreover, each of these solutions is an absolutely irreducible zero–dimensional component of the variety in C^k given by this system of equations. Due to Bezout's inequality, the number of real solutions is bounded by $(2d_G)^k$. Besides (cf. Lemma 4 in [16]), each bounded connected component of W_0 contains a point satisfying the system.

We can summarize the preceding results in the following theorem, which will be our main technical tool in the next section.

THEOREM 1.3. *Let $g_1, \ldots, g_N \in \mathbb{Z}[X_1, \ldots, X_k]$ satisfy for every $i \leq N$ the bounds $\deg(g_i) \leq d$ and $|\mathrm{coeff}(g_i)| \leq L$. Then with the notations introduced above, there are integers $0 \leq v_2, \ldots, v_k \leq (2d_G)^k$ such that the set $W \subseteq \mathbb{R}^k$ defined by*

$$G - C^{-1} = \left(\frac{\partial G}{\partial X_2}\right)^2 - \frac{v_2}{(2d_G)^k k}\Delta = \cdots = \left(\frac{\partial G}{\partial X_k}\right)^2 - \frac{v_k}{(2d_G)^k k}\Delta = 0$$

is finite. Moreover, the number of its points does not exceed $(2d_G)^k$ and every connected component of

$$V = \{x \in \mathbb{R}^k : g_1(x) > 0 \,\&\, \cdots \,\&\, g_N(x) > 0\}$$

contains at least one point of W. $\square$

2. Some background on machine models. In the following sections, we shall deal with real Turing machines (or RTMs for short) as introduced in [5].

Let us give a brief description of them for the finite-dimensional case. A finite-dimensional RTM is specified by an input space $\mathbb{R}^n$, an output space $\mathbb{R}^m$, and a state space $\mathbb{R}^s$ $(s \geq n, m)$ together with a finite directed graph whose nodes, labeled $\{1, \ldots, N\}$, are of four different types. The first one is the *input* node that initializes the computation by locating the input $x = (x_1, \ldots, x_n) \in \mathbb{R}^n$ in the first n coordinates of the ouput space and 0 in all of the others. It has only one next node. Then there

are *computation* nodes. They have associated a rational function in some of the s coordinates of the state space and they replace one such coordinate by the real number obtained by evaluating this rational function in the actual content of the state space. They also have only one next node. There are also *branch* nodes. They check whether $z_i \geq 0$ for a certain coordinate of the state space and select one of their two possible next nodes according to the answer. Finally, there is one *output* node. It has no next node, and therefore when it is reached, the computation halts. Moreover, the first m coordinates of the state space are mapped into the output space and constitute the output of the machine.

If the computation takes time at most t for all inputs, the RTM M computes a total function from $\mathbb{R}^n$ to $\mathbb{R}^m$. A key fact in what follows is that in this case, M can also be "unwound" into an algebraic computation tree T_M (see [3]) that has depth t and computes the same function, and at each branching node i of this tree, the value whose sign is tested can be written as $h_i(\alpha_1, \ldots, \alpha_k, x_1, \ldots, x_n)$, where $x = (x_1, \ldots, x_n) \in \mathbb{R}^n$ is the input, $\alpha_1, \ldots, \alpha_k \in \mathbb{R}$ are the possible coefficients of the functions associated with the computation nodes of M, and

$$h_i \in \mathbb{Q}(Z_1, \ldots, Z_k, X_1, \ldots, X_n).$$

For the infinite-dimensional case, we want to consider as inputs and outputs real vectors of arbitrary dimension. Recall that we denote by $\mathbb{R}^\infty$ the direct sum $\bigoplus_{i\in\mathbb{N}} \mathbb{R}$. Then we want to replace the input, output, and state spaces in the description above for $\mathbb{R}^\infty$. Since the number of computation nodes is finite, the same thing happens for the number of coordinates that can be accessed or modified. Thus some mechanism for "moving" information inside the state space is needed. We refer the reader to [5] for the details of how this is done as well as for a comprehensive introduction to these machines. We recall from there that we denote by $\mathrm{P}_{\mathbb{R}}$ the class of subsets of $\mathbb{R}^\infty$ that can be decided by an RTM in polynomial time.

It is important to note that if we again have a bound t on the running time of an RTM M, the number of accessed coordinates of the input, output, and state space is bounded by t. Therefore, we can find a finite-dimensional machine M_f that computes the same function (by replacing the moving operations by rational functions on $\mathbb{R}^t$). Thus, following the discussion above, we can associate with the pair (M, t) an algebraic computation tree $T_{M,t}$ that computes the same function and branching as discussed above. This will be central in the proof of Theorem 3.2.

In the following sections, we will also be concerned with parallel computations. Therefore, let us recall from [10] the definition of a computational model for parallelism in the real Turing machine setting together with the complexity class it defines when restricted to polynomial time.

DEFINITION 1. *An* algebraic circuit $\mathcal{C}$ *over* $\mathbb{R}$ *is a directed acyclic graph where each node has in-degree* 0, 1, *or* 2. *Nodes with in-degree* 0 *are labeled either as inputs or with elements of* $\mathbb{R}$. *(We shall call the latter constant nodes.) Nodes with in-degree* 2 *are labeled with* "+","−","∗", *or* "/". *Finally, nodes with in-degree* 1 *are of a unique kind and are called sign nodes. There is one node with out-degree* 0 *called an output node. In what follows, the nodes of a circuit will be called* gates.

We inductively associate with each gate a function of the input variables in the usual way. In particular, we shall refer to the function associated with the output gate as the function computed by the circuit. Note that sign gates return 1 if their input is greater than or equal to 0 and return 0 otherwise.

DEFINITION 2. *For an algebraic circuit* $\mathcal{C}$, *we define its* size *to be the number*

of gates in $\mathcal{C}$ and its depth *to be the length of the longest path from some input or constant gate to the output gate.*

DEFINITION 3. *Given an algebraic circuit $\mathcal{C}$, the* canonical encoding *of $\mathcal{C}$ is a sequence of 4-tuples of the form $(g, op, g_l, g_r) \in \mathbb{R}^4$, where g represents the gate label, op is the operation performed by the gate, g_l is the gate which provides the left input to g, and g_r provides its right input. By convention, g_l and g_r are 0 if gate g is an input gate, and g_r is 0 if gate g is a sign gate (whose input is then given by g_l) or a constant gate (the associated constant then being stored in g_l). Also, we shall suppose that the first n gates are the input gates and the last gate is the output gate.*

DEFINITION 4. *Let $\{\mathcal{C}_n\}_{n\in\mathbb{N}}$ be a family of algebraic circuits. We shall say that the family is* P-uniform *if there exists a real Turing machine M that generates the encoding of the ith gate of $\mathcal{C}_n$ with input (i, n) in time polynomial in n.*

DEFINITION 5. *We shall say that a set S can be decided in* parallel polynomial time ($S \in \mathrm{PAR}_{\mathbb{R}}$ *for short*) *when there is a P-uniform family of circuits $\{\mathcal{C}_n\}$ with depth polynomial in n and such that $\mathcal{C}_n$ computes the characteristic function of S restricted to inputs of size n.*

Remark 2. It is possible to define [10] parallel polynomial time in a different way, namely, by putting an exponential number of RTMs to work together with the same program and in polynomial time. One can prove, however, that this model defines the same class $\mathrm{PAR}_{\mathbb{R}}$ that we just introduced.

The definition above closely follows the one given in the classical seting (i.e., over $\{0, 1\}$) of parallel machines. In this case, one uses Boolean circuits instead of algebraic ones and the uniformity condition is provided by a classical Turing machine. A description of this computational model and the classes it defines can be found in [2]. A particular feature of the classical setting is that the class defined by polynomial parallel time requirements coincides with PSPACE, the class defined by polynomial space bounds. This is an old result of Borodin (see [7] or [2, Chapter 4]) that we shall use repeatedly in this paper.

3. Computing with binary inputs. The goal of this section is to prove that the Boolean part of $\mathrm{P}_{\mathbb{R}}$ is included in PSPACE/*poly*, i.e., that any subset of Σ^* that can be decided in polynomial time by a real Turing machine can be decided by a (classical) Turing machine in polynomial space using a polynomial advice. In the next section, we will prove a more general result, namely, a similar inclusion for parallel real Turing machines. However, because of clarity of exposition, we will first show the inclusion for the Boolean part of $\mathrm{P}_{\mathbb{R}}$.

We begin by recalling the definition of nonuniform classes as given in [19], which we extend to complexity classes over the reals.

DEFINITION 6. *Let $\mathcal{C} \subseteq \Sigma^*$ (resp. $\mathcal{C} \subseteq \mathbb{R}^\infty$) be a class of sets and $\mathcal{F}$ be any class of functions from $\mathbb{N}$ to Σ^* (resp. from $\mathbb{N}$ to $\mathbb{R}^\infty$). The class $\mathcal{C}/\mathcal{F}$ is defined to be the class of all subsets $B \subseteq \Sigma^*$ (resp. $B \subseteq \mathbb{R}^\infty$) for which there exists a set $A \in \mathcal{C}$ and a function $f \in \mathcal{F}$ such that $B = \{x : \langle x, f(|x|)\rangle \in A\}$.*

We will be interested mainly in the case $\mathcal{F} = poly$, the class of functions f such that for some polynomial p, we have $|f(n)| \le p(n)$ for each $n \in \mathbb{N}$. For the Boolean case, one can find the main properties and characterizations of classes like $\mathrm{P}/poly$ or PSPACE/*poly* (as well as of some other nonuniform complexity classes) in Chapter 5 of [1].

A final result that we want to recall before proceeding to the main theorem of this section is the following.

PROPOSITION 3.1 (see [17, Proposition 12]). *Let W be a real algebraic set*

defined by a set of m polynomials with integer coefficients bounded in absolute value by L. Then we can determine the dimension of W within parallel time $(n \log(md \log L))^{O(1)}$. □

THEOREM 3.2. *The inclusion* $\mathrm{BP}(\mathrm{P}_{\mathbb{R}}) \subseteq \mathrm{PSPACE}/poly$ *holds.*

Proof. Let M be an RTM working in polynomial time, say n^q, and let $\alpha_1, \ldots, \alpha_k$ be its real constants.

For any $n \in \mathbb{N}$, machine M has an associated algebraic computation tree $T_{M,n}$ with depth n^q and size bounded by 2^{n^q}. To each branching node i of this tree, there corresponds a rational function $h_i \in \mathbb{Q}(Z_1, \ldots, Z_k, X_1, \ldots, X_n)$ such that the branching is done according to whether the actual input $x \in \mathbb{R}^n$ satisfies $h_i(\alpha, x) \geq 0$ or $h_i(\alpha, x) < 0$ for $\alpha = (\alpha_1, \ldots, \alpha_k)$.

The idea of the proof is to find $\beta_1, \ldots, \beta_p \in \mathbb{R}_{\mathrm{alg}}$ such that for every $x \in \Sigma^n$, the path followed by x in the tree $\widetilde{T}_{M,n}$ obtained by replacing the constants α_j by β_j is the same as the path followed in $T_{M,n}$. This ensures that the tree $\widetilde{T}_{M,n}$ accepts the same subset of Σ^n as $T_{M,n}$. On the other hand, we will require some codification of the β's that allows us to perform the operations in $\widetilde{T}_{M,n}$ in PSPACE together with a short way of writing this codification that will make possible to give it as a polynomial advice.

Before obtaining a description of the β's, let us do a final modification on $T_{M,n}$ that was first used in [20]. Let I be the set of branching nodes of $T_{M,n}$. For every $i \in I$ and every $x \in \Sigma^n$, we consider the rational functions

$$g_{i,x} \in \mathbb{Q}(Z_1, \ldots, Z_k)$$

defined by $g_{i,x} = h_i(Z_1, \ldots, Z_k, x_1, \ldots, x_n)$ and the real numbers $\tau_{i,x} = g_{i,x}(\alpha_1, \ldots, \alpha_k)$ The accepted subset of Σ^n can be characterized by the set of signs

$$\sigma_{i,x} = \mathrm{sign}(\tau_{i,x}),$$

where $\mathrm{sign}(z)$ is 1 if $z > 0$, -1 if $z < 0$, and 0 otherwise. Now for some i and x, the element $\tau_{i,x}$ can be zero. However, since the set of values

$$\{\tau_{i,x} : i \in I, x \in \Sigma^n\}$$

is finite, there exists an $\varepsilon > 0$ such that all of the negative values in the above set are strictly smaller than $-\varepsilon$, and for this ε the following equivalences hold:

$$\begin{aligned} g_{i,x}(\alpha_1, \ldots, \alpha_k) \geq 0 \quad &\text{iff} \quad g_{i,x}(\alpha_1, \ldots, \alpha_k) + \varepsilon > 0, \\ g_{i,x}(\alpha_1, \ldots, \alpha_k) < 0 \quad &\text{iff} \quad g_{i,x}(\alpha_1, \ldots, \alpha_k) + \varepsilon < 0. \end{aligned}$$

Replacing the tests $g_i(X) \geq 0$ by $g_i(X) + \varepsilon \geq 0$, we thus have that the new computation tree (which has real constants $\alpha_1, \ldots, \alpha_k, \varepsilon$) satisfies the following property: for every $x \in \Sigma^n$, all of the test values are different from zero.

Assuming that the rational functions $g_{i,x}(Z_1, \ldots, Z_k)$ are polynomials (something that we can do by simply replacing $g_{i,x}$ by the product of its numerator and denominator), we can rephrase the above remarks in the following way: the elements $\alpha_1, \ldots, \alpha_k, \varepsilon$ satisfy a system of polynomial inequations of the form

$$g_{i,x}\sigma_{i,x} > 0 : \quad i \in I, \quad x \in \Sigma^n \tag{1}$$

and any other real numbers $\beta_1, \ldots, \beta_k, \xi$ satisfying this system will, when used as constants in the tree $T_{M,n}$, produce the same outcome for every $x \in \Sigma^n$.

We can now describe how to obtain such numbers.

First, we construct the g_0 and G of the preceding section for the set of polynomials $\{g_{i,x}^2 \in \mathbb{Z}[Z_1, \ldots, Z_k, Y] : i \in I, x \in \Sigma^n\}$. Then, applying Theorem 1.3, we deduce the existence of integer vectors $\vec{v} = (v_2, \ldots, v_k, v_{k+1})$ such that the set W described in the statement of Theorem 1.3 is finite and nonempty. Let $\vec{v^*}$ be the first such vector for the lexicographical ordering in $\mathbb{N}^k$ and let W^* be its corresponding set of solutions. We then have that any connected component of the semialgebraic set S given by system (1) contains a point of W^*. (Note that by squaring all the $g_{i,x}$'s, we ensure that each connected component of S is one connected component of the set V defined by the conditions $g_{i,x}^2 > 0$.) Thus we take $\beta_1, \ldots, \beta_k, \xi$ to be any point of W^* belonging to S, and we distinguish it among the other points of W^* by its position p for the lexicographical ordering in $\mathbb{R}^{k+1}$. Note that from the equations defining W^* and this p, we can code (cf. [18] or [25]) each coordinate of this point (see the complexity analysis below).

The following nonuniform parallel algorithm then decides the same language as M when restricted to binary inputs.

input$(a_1, \ldots, a_n)$
get the advice p corresponding to n
for all $x \in \Sigma^n$ **in parallel do** (s1)
  for all path γ **in parallel do**
    for all i branch node in γ **do**
      compute the polynomial $g_{i,x}$
    od
  od
od
compute g_0 and G (s2)
compute C (s3)
compute $\vec{v^*}$ (s4)
code the coordinates of the pth point β of (s5)
the set W^* given by $\vec{v^*}, C$, and G
simulate the computation of M over $a_1, \ldots, a_n$ (s6)
replacing the $\alpha_1, \ldots \alpha_k, \varepsilon$ by the point β coded in (s5)

Let us estimate the complexity of the algorithm above. As we have seen, the number of nodes of the tree $T_{M,n}$ is bounded by 2^{n^q}. Therefore, the number of polynomials $g_{i,x}$ is bounded by $2^{n^q}2^n = 2^{n^q+n}$. Each of these polynomials is computed by a straight-line program of length n^q, and thus we get again a bound of 2^{n^q} for their degrees and $2^{2^{n^q}}$ for the absolute value of their coefficients. The degree d_G of G is then bounded by $2^{n^q} \cdot 2^{n^q} = 2^{O(1)n^q}$ and the absolute value of its coefficients L_G is bounded by

$$(2^{2^{n^q}})^{2^{n^q}} = 2^{2^{2n^q}}$$

(and thus by 2^{2n^q} in bit length). We can then—according to Theorem 1.3—bound by

$$(2d_G)^{k+1} = 2^{O(1)n^q}$$

the integers $v_2, \ldots, v_k, v_{k+1}$ and by

$$(2d_G)^{k+1} = 2^{O(1)n^q}$$

the number of points in W^*. A first consequence of these last two upper bounds is the fact that the advice above has polynomial size.

Concerning the running time, it is clear that step (s1) can be done in polynomial time using an exponential number of processors because, given an $x \in \Sigma^n$ and a path γ, the—at most—n^q polynomials that appear in that path have exponential degree in a constant number ($k+1$, in fact) of variables and therefore an exponential number of monomials. Any arithmetical operation between two such polynomials can be done within these resources, and we have a polynomial number of such operations.

The product G is computed with a binary tree of products having polynomial depth. Since each product can be done in parallel polynomial time, the same applies for the whole tree and then for step (s2). A similar remark holds for the constant C and thus for step (s3).

The determination of $\vec{v^*}$ can be done by checking in parallel for all possible vectors $\vec{v}$ whether the dimension of the resulting W is zero and then selecting the first one that gives a positive answer. However, the determination of the dimension of each W can be done in parallel time bounded by $(kn)^{O(q)}$ by a direct application of Proposition 3.1. Thus the overall parallel time needed to compute $\vec{v^*}$ is bounded by $(kn)^{O(q)}$.

For step (s5), one can apply the algorithms given in [18] or [26]. However, we remark here that a cylindrical algebraic decomposition together with the coding *à la Thom* (see [8] for the algorithms and [27] and [12] for complexity analysis) suffices because the double-exponential behavior of this algorithm is only in the number of variables—which is constant in our case—and it is NC in the rest of the parameters. This results on a procedure for (s5) working in parallel polynomial time.

Finally, note that each arithmetical operation of M is translated in step (s6) into an operation of elements in $\mathbb{Z}[Z_1, \ldots, Z_k]$, and this is also done in parallel polynomial time. On the other hand, at each test of the form $g(Z_1, \ldots, Z_k) \geq 0$, we use the same algorithm of step (s5) for determining the sign of $g(Z_1, \ldots, Z_k)+Y$ on the point coded in (s5).

The above considerations show that the algorithm runs in parallel polynomial time. Since this is equivalent to polynomial space, we have shown that the set decided by the algorithm above belongs to PSPACE/*poly*. □

4. Binary inputs for parallel real Turing machines. Our next goal is to extend our previous result to the class $\mathrm{PAR}_{\mathbb{R}}$ of sets decided in parallel polynomial time. Before going into the next theorem, we will recall a result concerning the number of satisfiable sign conditions of a polynomial system.

LEMMA 4.1 (see [15, Lemma 1]). *Let $f_1, \ldots, f_s \in \mathbb{R}[X_1, \ldots, X_k]$ be a finite family of polynomials and $D = \sum_{i=1}^{s} \mathrm{degree}(f_i)$. Then the number of satisfiable systems of the form*

$$f_1(X_1, \ldots, X_k)\sigma_1 \ \& \cdots \& \ f_s(X_1, \ldots, X_k)\sigma_s,$$

where σ_i belongs to $\{\geq 0, > 0\}$ for $i = 1, \ldots, s$, is bounded by $D^{O(k)}$. □

THEOREM 4.2. *The equality* $\mathrm{BP}(\mathrm{PAR}_{\mathbb{R}}) = \mathrm{PSPACE}/\mathit{poly}$ *holds.*

Proof. Let S be a set in $\mathrm{PAR}_{\mathbb{R}}$ and $\{\mathcal{C}_n\}$ be the family of circuits deciding S. Also, let M be the RTM that generates these circuits and $\alpha_1, \ldots, \alpha_k$ be its real constants.

Given any $n \in \mathbb{N}$, we consider for any sign gate i of $\mathcal{C}_n$ and any binary string $x \in \Sigma^n$ the rational function $g_{i,x,\alpha} \in \mathbb{Q}(\alpha_1, \ldots, \alpha_k)(X_1, \ldots, X_n)$ that the gate receives as input. Note that besides the trivial dependence of the coefficients of $g_{i,x,\alpha}$ on α, there is a more subtle dependence on x since these coefficients also depend on the output of previous sign gates. Since the number of possible answers to previous sign gates is doubly exponential, we obtain an a priori doubly exponential number of

rational functions, and therefore we cannot directly apply the construction of Theorem 3.2. However, we can use Lemma 4.1 to reduce this number.

Let us fix $x \in \Sigma^n$ and plug x into the input gates of $\mathcal{C}_n$. This will force us to consider rational functions in $\mathbb{Q}(Z_1, \ldots, Z_k)$. Also, let n^q be a bound on the depth of $\mathcal{C}_n$. At depth 1, there are at most 2^{n^q} sign gates whose input functions have degree bounded by 1. By Lemma 4.1, the number of possible outputs of these sign gates is bounded by

$$(2^{n^q})^{O(k)} = 2^{O(k)n^q}.$$

For each set of outputs ω at depth 1, we consider the sign gates at depth 2. There are at most 2^{n^q-1} of them, and their associated functions have degree bounded by 2. Thus, again by Lemma 4.1, we bound by

$$(2^{n^q})^{O(k)} = 2^{O(k)n^q}$$

the number of possible outputs for ω. Multiplying both expressions, we deduce that the total number of possible outputs at depths 1 and 2 is bounded by

$$2^{2O(k)n^q}.$$

Inductively, we prove that the number of possible outputs over all of the sign gates is bounded by

$$2^{O(k)n^q n^q} = 2^{O(k)n^{2q}},$$

a number which is singly exponential in n.

Let us then consider for any $x \in \Sigma^n$ the set of all rational functions $g_{i,x,\omega}(Z_1, \ldots, Z_k)$ obtained by varying i over all sign gates of $\mathcal{C}_n$ and ω over all possible outputs of the set of sign gates. If we now consider this set for any $x \in \Sigma^n$, we will have that the set decided by the circuit $\mathcal{C}_n$ is determined by the signs that the functions in this set take when evaluated at $\alpha_1, \ldots, \alpha_k$.

As in Theorem 3.2, we can assume the functions $g_{i,x,\omega}$ to be polynomials and we can also assume that they do not vanish on $\alpha_1, \ldots, \alpha_k$ by adding a new real number ε.

Since the number of polynomials $g_{i,x,\omega}$ is singly exponential in n, we can apply the method of Theorem 3.2. However, note that the corresponding step (s1) will now be required to select for any $x \in \Sigma^n$ and any depth l the possible sign conditions for the test gates at depth l. This is done sequentially in l in order to avoid dealing with a doubly exponential number of sign conditions. Once these possible sign conditions are known, the rest of the algorithm works like the one in Theorem 3.2, simulating the circuit $\mathcal{C}_n$ instead of the tree. This shows that the binary elements of S are a language in PSPACE/*poly*.

On the other hand, the inclusion of PSPACE/*poly* in $\mathrm{BP}(\mathrm{PAR}_{\mathbb{R}})$ is trivial. □

An immediate corollary of Theorem 4.2 is the following separation, left open in [13]. Recall that $\mathrm{EXP}_{\mathrm{W}}$ is the class of subsets of $\mathbb{R}^\infty$ accepted by RTMs in weak exponential time, i.e., in exponential time but such that for all intermediately computed rational functions g $\deg(g)$ and the bit length of $|\mathrm{coeff}(g)|$ are exponentialy bounded (see [20] or [13] for a formal definition of the weak model).

COROLLARY 4.3. *The inclusion* $\mathrm{PAR}_{\mathbb{R}} \subset \mathrm{EXP}_{\mathrm{W}}$ *is strict.*

Proof. The Boolean part of $\mathrm{EXP}_{\mathrm{W}}$ is the class of all subsets of Σ^*. Therefore, it strictly contains PSPACE/*poly*. □

Remark 3. Corollary 4.3 improves the separation $\mathrm{PAR}_{\mathbb{IR}} \neq \mathrm{EXP}_{\mathbb{IR}}$ shown in [9]. In this latter case, the fact that a real Turing machine working in exponential time can produce polynomials of doubly exponential degree (while a circuit of polynomial depth cannot) together with an irreducibility argument sufficed to show the separation. The arguments used now are much more delicate and, somewhat surprisingly, pass through the Boolean part of these classes.

We can still improve Theorem 4.2 a bit by allowing the real machine to take advice.

THEOREM 4.4. *The equality* $\mathrm{BP}(\mathrm{PAR}_{\mathbb{IR}}/poly) = \mathrm{PSPACE}/poly$ *holds.*

Proof. The polynomial advice in $\mathrm{PAR}_{\mathbb{IR}}/poly$ introduces a polynomial number of real constants, say n^h, for each input size n. One can now simply check that replacing the constant value k in the proof of Theorem 4.2 by n^h does not affect the exponential character of the bounds there, and thus the same arguments apply. The only limitation is that in steps (s5) and (s6), one cannot use cylindrical algebraic decomposition (because of the exponential dependence that it has in the number of variables for its parallel running time) and is restricted to using the "faster" algorithms given in [18] and [25]. □

5. Conclusions and open problems. Theorems 4.2 and 4.4 are rather surprising since they show that multiplication or nonuniformity (under the form of a polynomial advice function) do not help in the presence of parallelism to decide binary sets. Note that results weaker than Theorem 4.2, namely, that the Boolean part of $\mathrm{PAR}_{\mathrm{add}}$ (where no multiplications are allowed) or of $\mathrm{PAR}_{\mathrm{W}}$ (where few multiplications are allowed) coincide both with PSPACE/*poly*, were proved in [11] and [13].

On the other hand, a main question that remains open is whether $\mathrm{BP}(\mathrm{P}_{\mathbb{IR}}) = \mathrm{PSPACE}/poly$. We know that this Boolean part contains $\mathrm{P}/poly$, but its exact power is still to be determined. Note that for integer RAMs, it is known that the computational power of this model in polynomial time is exactly PSPACE for several sets of primitive operations. However, in all of these cases, there is a primitive operation that cannot be efficiently simulated by a real Turing machine. Thus, for instance, it is shown in [4] that integer RAMs with operations $(+, -, *, \div)$ have the power of PSPACE. However, the simulation of integer division by a real Turing machine over integers of exponential length takes exponential time, and therefore the arguments of [4] cannot be used to show the inclusion $\mathrm{PSPACE}/poly \subseteq \mathrm{BP}(\mathrm{P}_{\mathbb{IR}})$.

Acknowledgment. Thanks are due to Pascal Koiran for pointing out to us the possibility of allowing advice in the real complexity classes that lead from Theorem 4.2 to Theorem 4.4.

AN $\mathcal{NC}$ ALGORITHM FOR MINIMUM CUTS*

DAVID R. KARGER† AND RAJEEV MOTWANI‡

Abstract. We show that the minimum-cut problem for weighted undirected graphs can be solved in $\mathcal{NC}$ using three separate and independently interesting results. The first is an (m^2/n)-processor $\mathcal{NC}$ algorithm for finding a $(2+\epsilon)$-approximation to the minimum cut. The second is a randomized reduction from the minimum-cut problem to the problem of obtaining a $(2+\epsilon)$-approximation to the minimum cut. This reduction involves a natural combinatorial *set-isolation problem* that can be solved easily in $\mathcal{RNC}$. The third result is a derandomization of this $\mathcal{RNC}$ solution that requires a combination of two widely used tools: pairwise independence and random walks on expanders. We believe that the set-isolation approach will prove useful in other derandomization problems.

The techniques extend to two related problems: we describe $\mathcal{NC}$ algorithms finding minimum k-way cuts for any constant k and finding all cuts of value within any constant factor of the minimum. Another application of these techniques yields an $\mathcal{NC}$ algorithm for finding a *sparse k-connectivity certificate* for all polynomially bounded values of k. Previously, an $\mathcal{NC}$ construction was only known for polylogarithmic values of k.

Key words. randomized algorithms, derandomization, parallel algorithms, minimum cut, multiway cut, edge connectivity, connectivity certificate

1. Introduction.

Some of the central open problems in the area of parallel algorithms are those of devising $\mathcal{NC}$ algorithms for s-t minimum cuts and maximum flows, maximum matchings, and depth-first search trees. There are $\mathcal{RNC}$ algorithms for all of these problems [1, 24, 29]. The problem of finding *global* minimum cuts belongs to this category of unsolved derandomization problems, and it is representative in that obtaining an $\mathcal{NC}$ algorithm for the case of *directed* graphs would resolve the other derandomization questions [18]. We take a (possibly small) step towards resolving these open problems by presenting the first $\mathcal{NC}$ algorithm for the min-cut problem in *weighted undirected* graphs. Our results extend to minimum multiway cuts and to the problem of enumerating all approximately minimal cuts.

The *min-cut problem* is defined as follows: given a multigraph with n vertices and m (possibly weighted) edges, we wish to partition the vertices into two nonempty sets S and T so as to minimize the number of edges crossing from S to T (if the graph is weighted, we wish to minimize the total weight of crossing edges). We distinguish the minimum-cut problem from the s-t minimum-cut problem, where we require that two specified vertices s and t be on opposite sides of the cut; in the minimum-cut

problem there is no such restriction. Our work deals only with minimum cuts. We assume that the graph is connected since otherwise the problem is trivial. The value of a minimum cut in an unweighted graph is also called the graph's *edge connectivity*.

The min-cut problem has numerous applications in many fields. The problem of determining the connectivity of a network arises frequently in the study of network design and network reliability [9]. (Recently, Karger [21] has shown that enumerating all nearly minimum cuts is the key to a fully polynomial-time approximation scheme for the all-terminal network-reliability problem.) Picard and Queyranne [32] survey many other applications of weighted minimum cuts. In information retrieval, minimum cuts have been used to identify clusters of topically related documents in hypertext systems [5]. Padberg and Rinaldi [31] discovered that the solution of minimum-cut problems was the computational bottleneck in cutting-plane-based algorithms for the traveling-salesman problem and many other combinatorial problems whose solutions induce connected graphs. Applegate [3] also observed that a faster algorithm for finding all minimum cuts might accelerate the solution of traveling-salesman problems.

The approach we take is typical of derandomization techniques that treat random bits as a resource. We develop a randomized algorithm and then show that it can be made to work using few random bits. If we can reduce the number of bits the algorithm needs to examine for a size-n problem to $O(\log n)$ without affecting its probability of correctness, then we know that it runs correctly on at least some of these small random inputs. Therefore, by trying all $n^{O(1)}$ possible $O(\log n)$-bit random inputs, we ensure that we will run correctly at least once and thus find the correct answer (this requires that we can check which of our many answers is correct, but here that just involves comparing the values of the cuts that are found).

The $\mathcal{NC}$ algorithm we devise is clearly impractical; it serves to demonstrate the existence of a deterministic parallel algorithm rather than to indicate what the "right" such algorithm is.

A preliminary version of this paper has appeared earlier as an extended abstract [22]. A more extensive version of this article and its context can be found in the first author's dissertation [19].

1.1. Previous work. The first minimum-cut algorithms used the duality between s-t minimum cuts and maximum flows [11, 12]. An s-t max-flow algorithm can be used to find an s-t minimum cut, and by taking the minimum over all $\binom{n}{2}$ possible choices of s and t, a minimum cut may be found. Until recently, the best sequential algorithms for finding minimum cuts used this approach [15]. Parallel solutions to the min-cut problem have also been studied. Goldschlager, Shaw, and Staples [14] showed that the s-t min-cut problem on weighted directed graphs is $\mathcal{P}$-complete. A simple reduction [18, 19] shows that the (unrestricted) min-cut problem is also $\mathcal{P}$-complete in such graphs.

For unweighted graphs, any $\mathcal{RNC}$ matching algorithm can be combined with a well-known reduction of s-t maximum flows to matching [24] to yield $\mathcal{RNC}$ algorithms for s-t minimum cuts. By performing n of these computations in parallel, we can solve the min-cut problem in $\mathcal{RNC}$. For an input graph with n vertices and m edges, the $\mathcal{RNC}$ matching algorithm of Karp, Upfal, and Wigderson [24] runs in $O(\log^3 n)$ time using $O(n^{6.5})$ processors, while the one due to Mulmuley, Vazirani, and Vazirani [29] runs in $O(\log^2 n)$ time using $O(n^{3.5}m)$ processors. The processor bounds are quite large, and the technique does not extend to graphs with large edge weights. No deterministic parallel algorithm is known. Indeed, derandomizing max-flow on

unweighted, undirected graphs is equivalent to derandomizing maximum bipartite matching—a problem that has long been open. A reduction in [18, 19] shows that the global min-cut problem for *directed* graphs is also equivalent.

1.2. Contraction-based algorithms. Recently, a new paradigm has emerged for finding minimum cuts in undirected graphs [18, 23, 30]. This approach is based on *contracting* graph edges. Given a graph G and an edge (u, v), contracting (u, v) means replacing u and v with a new vertex w and transforming each edge (x, u) or (x, v) into a new edge (x, w). Any (u, v) edge turns into a self loop on w and can be discarded.

A key fact is that contracting edges cannot decrease the minimum cut. The reason is that any cut in the contracted graph corresponds to a cut of exactly the same value in the original graph—if u and v were contracted to w, then a vertex partition (A, B) in the contracted graph with $w \in A$ corresponds to a partition $(A \cup \{u, v\} - \{w\}, B)$ in the original graph that cuts the same edges. Let us fix a particular minimum cut, which from now on we will refer to as *the* minimum cut (there may be as many as $\binom{n}{2}$ [10, 18]). The power of contractions comes from their interaction with cuts. If we contract an edge that is not in the minimum cut, then the minimum cut in the contracted graph is equal to the minimum cut in the original graph.

Several contraction-based minimum-cut algorithms have recently been developed. They all work by contracting non-min-cut edges until the graph has been reduced to two vertices. These two vertices define a cut in the original graph. If no min-cut edge is contracted, then the corresponding cut must be a minimum cut. The edges connecting the two vertices correspond to the cut edges.

Nagamochi and Ibaraki [30] used graph contraction to develop an $O(mn+n^2 \log^2 n)$-time algorithm for the min-cut problem. In $O(m + n \log n)$ time, they find a *sparse connectivity certificate* (i.e., a subgraph that contains all the min-cut edges) that excludes some edge of the graph. This edge can be contracted without affecting the minimum cut. Constructing a sparse certificate to identify an edge to contract requires $O(m + n \log n)$ time and must be done n times; thus the running time. Matula [27] used the Nagamochi–Ibaraki certificate algorithm in a linear-time algorithm for finding a $(2 + \epsilon)$-approximation to the minimum cuts—the change is to use the sparse certificate to identify a large number of edges that can be contracted simultaneously.

Karger [18] observed that a randomly selected graph edge is unlikely to be in the minimum cut; it followed that repeated random selection and contraction of graph edges could be used to find a minimum cut. This led to the contraction algorithm, the first $\mathcal{RNC}$ algorithm for the weighted min-cut problem, which used mn^2 processors. Karger and Stein [23] improved the processor cost of the contraction algorithm, as well as its sequential running time, to $\tilde{O}(n^2)$; this is presently the most efficient known min-cut algorithm for weighted graphs.[1] A side effect of the analysis of [18] was a bound on the number of *approximately minimal* cuts in a graph; this plays an important role in our analysis.

Luby, Naor, and Naor [26] observed that in the contraction algorithm, it is not necessary to choose edges randomly one at a time. Instead, given that the min-cut size is c, they randomly mark each edge with probability $1/c$ and contract all of the marked edges. With constant probability, no min-cut edge is marked while the number of graph vertices is reduced by a constant factor. Thus after $O(\log n)$ phases of contraction, the graph is reduced to two vertices that define a cut. Since

[1] The notation $\tilde{O}(f(n))$ denotes $O(f(n) \operatorname{polylog} n)$.

the number of phases is $O(\log n)$ and there is a constant probability of missing the minimum cut in each phase, there is an $n^{-O(1)}$ probability that no min-cut edge is ever contracted; if this happens, then the cut determined at the end is the minimum cut. Observing that pairwise-independent marking of edges can be used to achieve the desired behavior, they show that $O(\log n)$ random bits suffice to run a phase. Thus $O(\log^2 n)$ bits suffice to run this modified contraction algorithm through its $O(\log n)$ phases.

Unfortunately, this algorithm cannot be fully derandomized. It is indeed possible to try all (polynomially many) random seeds for a phase and be sure that one of the outcomes is good (i.e., contracts nonmin-cut edges incident on a constant fraction of the vertices); however, there is no way to determine *which* outcome is good. In the next phase, it is thus necessary to try all possible random seeds on each of the polynomially many outcomes of the first phase, squaring the number of outcomes after two phases. In all, $\Omega(n^{\log n})$ combinations of seeds must be tried to ensure that we find the desired sequence of good outcomes leading to a minimum cut.

1.3. Overview of results. Our main result is an $\mathcal{NC}$ algorithm for the min-cut problem. Our algorithm is not a derandomization of the contraction algorithm but is instead a new contraction-based algorithm. Throughout, we take G to be a multigraph with n vertices, m edges, and min-cut value c. Most of the paper discusses unweighted graphs; in section 6.4, we reduce the weighted graph problem to the unweighted graph problem. Our algorithm extends to finding *minimum multiway cuts* that partition the graph into $r \geq 2$ disconnected pieces.

Our algorithm depends upon three major building blocks. The first building block (sections 2 and 3) is an $\mathcal{NC}$ algorithm that uses m^2/n processors to find a $(2+\epsilon)$-approximation to the minimum cut. Recall that Matula's sequential algorithm [27] was based on the sequential sparse certificate algorithm of Nagamochi and Ibaraki [30] (discussed in the previous section). It repeatedly finds a sparse certificate containing all min-cut edges and then contracts the edges not in the certificate, terminating after a small number of iterations. Our $\mathcal{NC}$ algorithm uses a new parallel sparse certificate algorithm to parallelize Matula's algorithm. A parallel sparse k-connectivity certificate algorithm with running time $\tilde{O}(k)$ was given by Cheriyan, Kao, and Thurimella [6]; we improve this in a necessary way by presenting an algorithm that runs in $O(\log m)$ time using km processors and is thus in $\mathcal{NC}$ for all $k = n^{O(1)}$.

Our next building block (section 4) uses a result obtained from the analysis of the contraction algorithm. Karger [18] proved that there are only polynomially many cuts whose size is within a constant factor of the minimum cut. If we find a collection of edges that contains one edge from every such cut except for the minimum cut, then contracting this set of edges yields a graph with no small cut except for the minimum cut. We can then apply the $\mathcal{NC}$ approximation algorithm mentioned in the previous paragraph. Since the minimum cut will be the unique contracted-graph cut within the approximation bounds, it will be found by the approximation algorithm. One can view this approach as a variant on the isolating lemma approach used to solve the perfect matching problem [29]. As was the case there, the problem is relatively easy to solve if the solution is unique, so the goal is to destroy all but one solution to the problem and then to easily find the unique solution.

Randomization yields a simple solution to this problem: contract each edge independently with probability $\Theta(\log n/c)$. Because the number of small cuts is polynomially bounded, there is a sufficient (larger than one over a polynomial) probability

that no edge from the minimum cut is contracted but one edge from every other small cut is contracted. Of course, our goal is to do away with randomization.

A step towards this approach is a modification of the Luby, Naor, and Naor technique. If we contract each edge with probability $\Theta(1/c)$, then with constant probability we contract no min-cut edge while contracting edges in a constant fraction of the other small cuts. Pairwise independence in the contracting of edges is sufficient to make such an outcome likely. However, this approach seems to contain the same flaw as before: $\Omega(\log n)$ phases of selection are needed to contract edges in all the small cuts, and thus $\Omega(\log^2 n)$ random bits are needed.

We work around this problem with our third building block (section 5). The problem of finding a good set of edges to contract can be formulated abstractly as the *set-isolation problem*: given an unknown collection of sets (the cuts) over a known universe, with one of the unknown sets declared "safe," find a collection of elements that intersects every set except for the safe one. After giving a simple randomized solution, we show that this problem can be solved in $\mathcal{NC}$ by combining the techniques of pairwise independence [7, 25] with the technique of random walks on expanders [2]. We feel that this combination should have further application in derandomizing algorithms; similar ideas were used previously to save random bits, e.g., in the work of Bellare, Goldreich, and Goldwasser [4].

Finally, in section 6, we apply the above results to finding minimum cuts, minimum multiway cuts, and weighted minimum cuts and to enumerating approximately minimum cuts.

2. An approximation algorithm. In the next two sections, we describe an $\mathcal{NC}$ algorithm that, for any constant $\epsilon > 0$, finds a cut whose value is less than $(2+\epsilon)$ times that of the minimum cut. We use the fact that contracting a non-min-cut edge does not change the value of the minimum cut. We first formalize this notion of contraction. To contract an edge (v_1, v_2), we replace both endpoints by a vertex v and let the set of edges incident on v be the union of the sets of edges incident on v_1 and v_2. We do not merge edges from v_1 and v_2 that have the same other endpoint; instead, we create multiple instances of those edges. However, we remove self loops formed by edges originally connecting v_1 to v_2. Formally, we delete all edges (v_1, v_2) and replace each edge (v_1, w) or (v_2, w) with an edge (v, w). The rest of the graph remains unchanged.

Since contracting a non-min-cut edge does not affect the minimum cut, we can find the minimum cut by repeatedly finding and contracting non-min-cut edges. Each time we do this, the number of graph vertices decreases by one; thus after $n-2$ iterations, we will have a two-vertex graph with an obvious minimum cut. The need to find non-min-cut edges motivates the following definition and lemma.

DEFINITION 2.1. *A* k-jungle *is a set of* k *disjoint forests in* G. *A* maximal k-jungle *is a* k*-jungle such that no other edge in* G *can be added to any one of the jungle's forests without creating a cycle in that forest.*

LEMMA 2.2 (see [30]). *A maximal* k*-jungle contains all the edges in any cut of* k *or fewer edges.*

Proof. Consider a maximal k-jungle J, and suppose it contains fewer than k edges of some cut C. Then some forest F in J must have no edge crossing C. Now suppose some edge e from C is not in the forest (if all cut-edges are in the forest, we are done). There is no path in F connecting the endpoints of e since such a path would have to cross C. Thus e can be added to F, contradicting the maximality of J. Thus all edges in C must already be in J. □

Nagamochi and Ibaraki [30] gave an algorithm for constructing a k-jungle that excluded one non-min-cut edge which could then be contracted. This led to an algorithm with running time $O(mn)$. Subsequently, Matula [27] observed that if we were willing to settle for a $(2+\epsilon)$-approximation to the minimum cut, we could construct a k-jungle, $k > c$, that excluded many edges, all of which could then be contracted in one step. This allows much faster progress towards a two-vertex graph, leading to a linear-time min-cut algorithm. We show how this algorithm can be parallelized.

The approximation algorithm is described in Figure 1. We give it as an algorithm to approximate the cut value; it is easily modified to find a cut with the returned value. The basic idea is to consider the minimum graph degree δ as an approximation to the minimum cut c. Clearly, $c < \delta$. If $(2+\epsilon)c > \delta$, then our approximation is good enough. Otherwise, we will see that a k-jungle that excludes many edges can be constructed with $k > c$.

PROCEDURE APPROX-MIN-CUT(multigraph G)
1. Let δ be the minimum degree of G.
2. Let $k = \delta/(2+\epsilon)$.
3. Find a maximal k-jungle.
4. Construct G' from G by contracting all nonjungle edges.
5. Return $\min(\delta, \text{Approx-Min-Cut}(G'))$.

FIG. 1. *The approximation algorithm*

LEMMA 2.3. *Given a graph with minimum cut c, the approximation algorithm returns a value between c and $(2+\epsilon)c$.*

Proof. Clearly, the value is at least c because it corresponds to some cut the algorithm encounters. That is, the minimum-degree vertex in a contracted intermediate graph corresponds to a cut of the same value in the original graph. For the upper bound, we use induction on the size of G. We consider two cases. If $\delta < (2+\epsilon)c$, then since we return a value of at most δ, the algorithm is correct. On the other hand, if $\delta \geq (2+\epsilon)c$, then $k \geq c$. It follows from Lemma 2.2 that the jungle we construct contains all the min-cut edges. Thus no edge in the minimum cut is contracted while forming G', so G' has minimum cut c. By the inductive hypothesis, the recursive call returns a value between c and $(2+\epsilon)c$. □

LEMMA 2.4. *There are $O(\log m)$ levels of recursion in the approximation algorithm.*

Proof. If G has minimum degree δ, then summing over vertices, G must have at least δn edge-endpoints and thus at least $\delta n/2$ edges. On the other hand, the graph G' that we construct contains only jungle edges; since each forest of the jungle contains only $n-1$ edges, G' can have at most $k(n-1) = \delta(n-1)/(2+\epsilon)$ edges. It follows that each recursive step reduces the number of edges in the graph by a constant factor; thus at a recursion depth of $O(\log m)$, the problem can be solved trivially. □

Note that the extra ϵ factor above 2 is needed to ensure a significant reduction in the number of edges at each stage and thus keep the recursion depth small. The depth of recursion is in fact $\Theta(\epsilon^{-1} \log m)$.

Each step of this algorithm, except for step 3, can be implemented in $\mathcal{NC}$ using m processors. Since the number of iterations is $O(\log m)$, the running time of this algorithm is $O(T(m,n) \operatorname{polylog} m)$, where $T(m,n)$ is the time needed to construct a maximal jungle. It only remains to show how to construct a maximal k-jungle in $\mathcal{NC}$.

3. Finding maximal jungles. The notation needed to describe this construction is somewhat complex, so first we give some intuition. To construct a maximal jungle, we begin with an empty jungle and repeatedly *augment* it by adding additional edges from the graph until no further augmentation is possible. Consider one of the forests in the jungle. The nonjungle edges that may be added to that forest without creating a cycle are just the edges that cross between two different trees of that forest. We let each tree claim some such edge incident upon it. Hopefully, each forest will claim and receive a large number of edges, thus significantly increasing the number of edges in the jungle.

Two problems arise. The first is that several trees may claim a particular edge. However, the arbitration of these claims can be transformed into a matching problem and solved in $\mathcal{NC}$. Another problem is that since each tree is claiming an edge, a cycle might be formed when the claimed edges are added to the forest—for example, two trees may each claim an edge connecting those two trees. We will remedy this problem as well.

3.1. Augmentations.

DEFINITION 3.1. *An* augmentation *of a k-jungle $J = \{F_1, \ldots, F_k\}$ is a collection $A = \{E_1, \ldots, E_k\}$ of k disjoint sets of nonjungle edges from G. At least one of the sets E_i must be nonempty. The edges of E_i are added to forest F_i.*

DEFINITION 3.2. *A* valid augmentation *of J is one that does not create any cycles in any of the forests of J.*

FACT 3.3. *A jungle is maximal if and only if it has no valid augmentation.*

Given a jungle, it is convenient to view it in the following fashion. We construct a *reduced (multi)graph* G_F for each forest F. For each tree T in F, the reduced graph contains a *reduced vertex* v_T. For each edge e in G that connects trees T and U, we add an edge e_F connecting v_T and v_U. Thus the reduced graph is what we get if we start with G and contract all the forest edges. Since many edges can connect two forests, the reduced graph may have parallel edges. An edge e of G may induce many different edges, one in each forest's reduced graph.

Given any augmentation, the edges added to forest F can be mapped to their corresponding edges in G_F, inducing an *augmentation subgraph* of the reduced graph G_F.

FACT 3.4. *An augmentation is valid if and only if the augmentation subgraph it induces in each forest's reduced graph is a forest.*

Care should be taken not to confuse the forest F with the forest that is the augmentation subgraph of G_F.

3.2. The augmentation algorithm. Our construction proceeds in a series of $O(\log m)$ phases in which we add edges to the jungle J. In each phase, we find a valid augmentation of J whose size is a constant fraction of the largest possible valid augmentation. Since we reduce the maximum possible number of edges that can be added to J by a constant fraction each time, and since at the beginning the maximum number of edges we can add is at most m, J will have to be maximal after $O(\log m)$ phases.

To find a large valid augmentation, we solve a maximal matching problem on a bipartite graph H. Let one vertex set of H consist of the vertices v_T in the various reduced multigraphs, i.e., the trees in the jungle. Let the other vertex set consist of one vertex v_e for each nonjungle edge e in G. Connect each reduced vertex v_T of G_F to v_e if e_F is incident on v_T in G_F. Equivalently, we are connecting each tree in the jungle to the edges incident upon it in G. Note that this means each edge in G_F is a

valid augmenting edge for F. To bound the size of H, note that each vertex v_e will have at most $2k$ incident reduced-graph edges because it will be incident on at most two trees of each forest. Thus the total number of edges in H is $O(km)$.

LEMMA 3.5. *A valid augmentation of J induces a matching in H of the same size.*

Proof. Consider a valid augmentation of the jungle. We set up a corresponding matching in H between the edges of the augmentation and the reduced vertices as follows. For each forest F in J, consider its reduced multigraph G_F. Since the augmentation is valid, the augmenting edges in G_F form a forest (Fact 3.4). Root each tree in this forest arbitrarily. Each nonroot reduced vertex v_T has a unique augmentation edge e_F leading to its parent. Since edge e is added to F, no other forest F' will use edge $e_{F'}$, so we can match v_T to v_e. It follows that every augmentation edge is matched to a unique reduced vertex. □

LEMMA 3.6. *Given a matching in H, a valid augmentation of J of size at least half the size of the matching can be constructed in $\mathcal{NC}$.*

Proof. If edge $e \in G$ is matched to reduced vertex $v_T \in G_F$, tentatively assign e to forest F. Consider the set A of edges in G_F that correspond to the G-edges assigned to F. The edges of A may induce cycles in G_F, which would mean (Fact 3.4) that A does not correspond to a valid augmentation of F. However, if we find an acyclic subset of A, then the G-edges corresponding to this subset will form a valid augmentation of F.

To find this subset, arbitrarily number the vertices in the reduced graph G_F. Direct each edge in A away from the reduced vertex to which it was matched (so each vertex has out-degree one) and split the edges into two groups: $A_0 \subseteq A$ are the edges directed from a smaller-numbered to a larger-numbered vertex, and $A_1 \subseteq A$ are the edges directed from a larger-numbered to a smaller-numbered vertex. One of these sets, say A_0, contains at least half the edges of A. However, A_0 creates no cycles in the reduced multigraph. Its (directed) edges can form no cycle obeying the edge directions since such a cycle must contain an edge directed from a larger-numbered to a smaller-numbered vertex. On the other hand, any cycle disobeying the edge directions must contain a vertex with out-degree two, an impossibility. It follows that the edges of A_0 form a valid augmentation of F of at least half the size of the matching.

If we apply this construction to each forest F in parallel, we get a valid augmentation of the jungle. Furthermore, each forest will gain at least half the edges assigned to it in the matching, so the augmentation has the desired size. □

THEOREM 3.7. *Given G and k, a maximal k-jungle of G can be found in $\mathcal{NC}$ using $O(km)$ processors.*

Proof. We begin with an empty jungle and repeatedly augment it. Given the current jungle J, construct the bipartite graph H as previously described and use it to find an augmentation. Let a be the size of a maximum augmentation of J. Lemma 3.5 shows that H must have a matching of size a. It follows that any maximal matching in H must have size at least $a/2$, since at least one endpoint of each edge in any maximum matching must be matched in any maximal matching. Several $\mathcal{NC}$ algorithms for maximal matching exist—for example, that of Israeli and Shiloach [17]. Lemma 3.6 shows that after we find a maximal matching, we can (in $\mathcal{NC}$) transform this matching into an augmentation of size at least $a/4$. If we add these augmentation edges, the resulting graph has a maximum augmentation of at most $3a/4$ (since it can be combined with the previous size-$a/4$ augmentation to get an augmentation of the

starting graph). Since we reduce the maximum augmentation by 3/4 each time, and since the maximum jungle size is m, the number of augmentations needed to make a J maximal is $O(\log m)$. Since each augmentation is found in $\mathcal{NC}$, the maximal jungle can be found in $\mathcal{NC}$.

The processor cost of this algorithm is dominated by that of finding the matching in the graph H. The algorithm of Israeli and Shiloach requires a linear number of processors and is run on a graph of size $O(km)$. □

COROLLARY 3.8. *A $(2+\epsilon)$-approximate minimum cut can be found in $\mathcal{NC}$ using m^2/n processors.*

Proof. A graph with m edges has a vertex with degree $O(m/n)$; the minimum cut can therefore be no larger. It follows that our approximation algorithm will construct k-jungles with $k = O(m/n)$. □

4. Reducing to approximation. In this section, we show how the problem of finding a minimum cut in a graph can be reduced to that of finding a 3-approximation.[2] Our technique is to "kill" all cuts of size less than $3c$ other than the minimum cut itself. The minimum cut is then the only cut of size less than $3c$, and thus it must be the output of the $(2+\epsilon)$-approximation algorithm of section 2 if we run it with $\epsilon = 1$. To implement this idea, we focus on a particular minimum cut that partitions the vertices of G into two sets A and B. Consider the graphs induced by A and B.

LEMMA 4.1. *The minimum cuts in A and in B have value at least $c/2$.*

Proof. Suppose A has a cut into X and Y of value less than $c/2$. Only c edges go from $A = X \cup Y$ to B, so one of X or Y (say X) must have at most $c/2$ edges leading to B. Since X also has less than $c/2$ edges leading to Y, the cut $(X, \overline{X})$ has value less than c, a contradiction. □

THEOREM 4.2 (see [18]). *There are $O(n^{2\alpha})$ cuts of value at most α times the minimum.*

Combining Lemma 4.1 and Theorem 4.2, it follows that in each of A and B, every cut has value at least $c/2$ and there are $O(n^6)$ cuts of value less than $3c$. Note that these are *not* the small cuts in G but rather those in the graphs induced by A and B. Call these cuts the *target cuts*.

LEMMA 4.3. *Let Y be a set containing edges from every target cut but not the minimum cut. If every edge in Y is contracted, then the contracted graph has a unique cut of weight less than $3c$—the one corresponding to the original minimum cut.*

Proof. Clearly, contracting the edges of Y does not affect the minimum cut. Now suppose this contracted graph had some other cut C of value less than $3c$. It corresponds to some cut of the same value in the original graph. Since it is not the minimum cut, it must induce a cut in either A or B, and this induced cut must also have value less than $3c$. This induced cut is then a target cut, so one of its edges will have been contracted. However, this prevents C from being a cut in the contracted graph, a contradiction. □

It follows that after contracting Y, running the approximation algorithm of section 2 on the contracted graph will reveal the minimum cut since the actual minimum cut is the only one that is small enough to meet the approximation criterion. Our goal is thus to find a collection of edges that intersects every target cut but not the minimum cut. This problem can be phrased more abstractly as follows: Over some universe U, an adversary selects a polynomially sized collection of "target" sets of

[2] We reduce to 3-approximation for simplicity. Should this approach ever become practical, it will most likely be more efficient to reduce to $(2+\epsilon)$-approximation for some smaller ϵ.

roughly equal size (the small cuts' edge sets), together with a disjoint "safe" set of about the same size (the min-cut edges). We want to find a collection of elements that intersects every target set but not the safe set. Note that we do not know what the target or safe sets are, but we do have an upper bound on the number of target sets. We proceed to formalize this problem as the *set-isolation problem.*

5. The set-isolation problem. We describe a general form of the set-isolation-problem. Fix a universe $U = \{1, \ldots, u\}$ of size u.

DEFINITION 5.1. *A* (u, k, α) set-isolation instance *consists of a* safe set $S \subseteq U$ *and a collection of* k target sets $T_1, \ldots, T_k \subseteq U$ *such that*

- $\alpha > 0$ *is a constant,*
- *for* $1 \leq i \leq k$, $|T_i| \geq \alpha |S|$, *and*
- *for* $1 \leq i \leq k$, $T_i \cap S = \emptyset$.

We will use the notation that $s = |S|$, $t_i = |T_i|$, and $t = \alpha s \leq t_i$. It is important to keep in mind that the value of s is not specified in a set-isolation instance but, as will become clear shortly, it is reasonable to assume that it is known explicitly. Finally, while the safe set S is disjoint from all of the target sets, the target sets may intersect each other.

DEFINITION 5.2. *An* isolator *for a set-isolation instance is a set that intersects all of the target sets but not the safe set.*

An isolator is easy to compute (even in parallel) for any given set-isolation instance provided the sets $S, T_1, \ldots, T_k$ are explicitly specified. However, our goal is to find an isolator in the setting where only u, k, and α are known but the actual sets S, T_1, $\ldots, T_k$ are not specified. We can formulate this as the problem of finding a universal isolating family.

DEFINITION 5.3. *A* (u, k, α)-universal isolating family *is a collection of subsets of* U *that contains an isolator for any* (u, k, α) *set-isolation instance.*

To see that this general formulation captures our cut-isolation problem, note that the minimum cut is the safe set in an (m, k, α) set-isolation instance. The universe is the set of edges and is of size m; the target sets are the small cuts of the two sides of the minimum cut; k is the number of such small cuts and (by Lemmas 4.1 and 4.2) can be bounded by a polynomial in $n < m$; and $\alpha = 1/2$ since each target cut has size at least $c/2$ (by Lemma 4.1). The safe-set size s is the min-cut size c.

If we had an (m, k, α)-universal isolating family, then one of the sets in it would be an isolator for the set-isolation instance corresponding to the minimum cut. By Lemma 4.3, contracting all of the edges in this set would isolate the minimum cut as the only small cut. If the size of the universal family were polynomial in m and k, we could try each set in the universal family in parallel in $\mathcal{NC}$ and be sure that one such set isolates the minimum cut so that the approximation algorithm can find it.

In section 7, we give an $\mathcal{NC}$ algorithm for constructing a polynomial-size (in u and k) (u, k, α)-universal isolating family. Before doing so, we give the details of how it can be used to solve the minimum-cut problem in $\mathcal{NC}$.

6. Minimum cuts and extensions. We start by solving the min-cut problem for unweighted graphs. To extend this result to weighted graphs, we must first digress to finding *minimum multiway cuts* (minimum sets of edges that partition the graph into more than two parts) and *approximately minimum cuts* (cuts with value nearly equal to the minimum-cut). The weighted minimum-cut problem is then solved by reduction to these problems.

6.1. Unweighted minimum cuts. We first consider the unweighted min-cut problem. We have already shown (in section 4) that all we need to do is solve the set-isolation problem for the $n^{O(1)}$ small cuts on both sides of the minimum cut. In our case, the universe size u is just the number of graph edges m, the safe-set size is $c = O(m/n)$ (which we can estimate to within a factor of 3 using the approximation algorithm), and there are $n^{O(1)}$ target sets. Thus in $\mathcal{NC}$ we can generate and try all members of a universal isolating family of $m^{O(1)}$ sets. One of the sets we try will be an isolator for our problem, intersecting all small cuts except for the minimum cut. When we contract the edges in this set, running the approximation algorithm on the contracted graph will find the minimum cut. The number of processors used is $m^{O(1)}$, and the running time is polylogarithmic in m. In other words, the minimum cut can be found in $\mathcal{NC}$.

6.2. Extension to multiway cuts. The r-way min-cut problem is to partition a graph's vertices into r nonempty groups so as to minimize the number of edges crossing between groups. An $\mathcal{RNC}$ algorithm for constant r appears in [18], and a more efficient one appears in [23]. For constant r, we can use the set-isolation technique to solve the r-way cut problem in $\mathcal{NC}$. The next lemma reduces to Lemma 4.3 when $r = 2$.

LEMMA 6.1. *In an r-way min-cut $(X_1, \ldots, X_r)$ of value c, each X_i has minimum cut at least $2c/(r-1)(r+2)$.*

Proof. Assume that set X_1 has a cut (A, B) of value w. We prove the lemma by lower-bounding w.

Suppose that two sets X_i and X_j are connected by more than w edges (where $1 \neq i \neq j \neq 1$). Then merging X_i and X_j and splitting X_1 into A and B would yield an r-way cut of smaller value, a contradiction. Summing over $\binom{r-1}{2}$ pairs X_i and X_j, it follows that the total number of cut-edges not incident on X_1 can be at most $\binom{r-1}{2}w$.

Now suppose that more than $2w$ edges connect X_1 and some X_j for $j \neq 1$. Then more than w edges lead from X_j to either A or B, say A. Thus splitting X_1 into A and B and merging A with X_j would produce a smaller r-way cut, a contradiction. It follows that the number of edges incident on X_1 can be at most $2(r-1)w$.

Combining the previous two arguments, we see that the r-way cut value c must satisfy

$$c \leq \binom{r-1}{2} w + 2w(r-1),$$

implying the desired result. □

Combining the two previous lemmas shows that there is a polynomial-sized set of target cuts that we can eliminate with the set-isolation technique to isolate the minimum r-way cut.

THEOREM 6.2. *On unweighted graphs, the r-way min-cut problem can be solved in $\mathcal{NC}$ for any constant r.*

Proof. We proceed exactly as in the two-way min-cut case. Consider the minimum r-way cut $(X_1, \ldots, X_r)$ of value c. By the previous lemma, the minimum cut in each component is at least $2c/(r-1)(r+2)$. Thus by Lemma 4.3, the number of cuts in each X_i whose size is less than $2c$ is $O(n^{2(r-1)(r+2)})$, a polynomial for constant r. It follows that we can find a universal isolating family containing an isolator for the minimum r-way cut. Contracting the edges in this isolator yields a graph in which each component of the r-way minimum cut has no small cut. Then the (two-way) minimum cut in this contracted graph must be a "part of" the r-way minimum cut.

More precisely, it cannot cut any one of the X_i's, so each X_i is entirely on one or the other side of the cut. We can now find minimum cuts in each of the sides of the minimum cut; again, they must be part of the r-way minimum cut. If we repeat this process r times, we will find the r-way minimum cut. □

6.3. Extension to approximate cuts. We can similarly extend our algorithm to enumerate all cuts with value within any constant-factor multiple of the minimum cut. This plays an important role in our extension to weighted graphs.

LEMMA 6.3 (see [18]). *The number of r-way cuts with value within a multiplicative factor of α of the r-way min-cut is $O(n^{2\alpha(r-1)})$.*

LEMMA 6.4. *Let c be the min-cut value in a graph. If (A, B) is a cut with value αc, then the minimum r-way cut in A has value at least $(r - \alpha)c/2$.*

Proof. Let $\{X_i\}_{i=1}^r$ be the optimum r-way cut of A, with value β. Let us contract each X_i to a single vertex (removing resulting self loops) and sum the degrees of these r vertices two different ways. There are β edges (the r-way cut edges) with one endpoint in each of two different X_i's. This contributes 2β to the sum of contracted-vertex degrees. There are also αc edges with exactly one endpoint in A (and thus in sum X_i), namely, the edges crossing cut (A, B). These contribute an additional αc to the sum of degrees. Thus the sum of the degrees of the X_i's is $2\beta + \alpha c$. Counting a different way, we know that each X_i has degree no less than the minimum cut, so the sum of degrees is at least rc. Thus $2\beta + \alpha c \geq rc$, and the result follows. □

THEOREM 6.5. *For any constant α, all cuts with value at most α times the minimum cut's can be found in $\mathcal{NC}$.*

Proof. For simplicity, assume without loss of generality that α is an integer. Fix a particular cut (A, B) of value αc. Let $r = \alpha + 2$. By Lemma 6.4, the minimum r-way cut in A (and in B) has value at least c. Lemma 6.3 says that as a consequence there are $n^{O(1)}$ r-way cuts in A (or B) with value less than $3r\alpha c$. Define a set-isolation instance whose target sets are all such multiway cuts and whose safe set is the cut (A, B). By finding an isolator for the instance and contracting the edges in it, we ensure that the minimum r-way cut in each of A and B exceeds $3r\alpha c$.

Suppose that after isolating the cut we want, we run our parallelization of Matula's algorithm, constructing k-jungles with $k = \alpha c$. Since the r-way cut is at least $3r\alpha c$ in each of A and B, at most $(r - 1)$ vertices in each set have degree less than $6\alpha c$. It follows that so long as the number of vertices exceeds $4r$, the number of edges will reduce by a constant factor in each iteration of the algorithm. In other words, in $O(\log m)$ steps, the number of vertices will be reduced to $4r$ in such a way that the cut of value αc is preserved. We can find it by examining all possible partitions of the $4r$ remaining vertices since there are only a constant number. □

There is an obvious extension to approximate multiway cuts; however, we omit the notationally complicated exposition.

6.4. Extension to weighted graphs. If the weights in a graph are polynomially bounded integers, we can transform the graph into a multigraph with a polynomial number of edges by replacing an edge of weight w with w parallel unweighted edges. Then we can use the unweighted multigraph algorithm to find the minimum cut.

If the edge weights are reals, we use the following reduction from [18, 19] to the case of integral polynomial edge weights. We first estimate the minimum cut to within a multiplicative factor of $O(n^2)$. To do so, we simply compute a maximum spanning tree of the weighted graph and then let w be the weight of the minimum-weight edge of this maximum spanning tree. Removing this edge partitions the maximum spanning tree into two sets of vertices such that no edge of G connecting them has

weight greater than w (or else it would be in the maximum spanning tree). Therefore, the minimum cut is at most n^2w. On the other hand, the maximum spanning tree has only edges of weight at least w, so one such edge crosses every cut. Thus the minimum cut is at least w. This estimate can clearly be done in $\mathcal{NC}$.

Given this estimate, we can immediately contract all edges of weight exceeding n^2w since they cannot cross the min-cut. Afterwards, the total amount of weight remaining in the graph is at most n^4w. Now multiply each edge weight by n^3/w so that that the minimum cut is scaled to be between n^3 and n^5. If we now round each edge weight to the nearest integer, we will be changing the value of each cut by at most n^2 in absolute terms, implying a relative change by at most a $(1 + 1/n)$ factor. Thus the cut of minimal weight in the original graph has weight within a $(1 + 1/n)$ factor of the minimum cut in the new graph. By Theorem 6.5, all such nearly minimum cuts can be found in $\mathcal{NC}$ with the previously described algorithms. All we need to do to find the actual minimum cut is inspect every one of the small cuts we find in the scaled graph and compute its value according to the original edge weights.

7. Solving the set-isolation problem. It remains to show how to construct a universal isolating family in $\mathcal{NC}$. Our goal is, given U and k, to generate a (u, k, α)-universal isolating family of size polynomial in u and k in $\mathcal{NC}$. We first give an existence proof for universal families of the desired size. The proof uses the probabilistic method; for this and other ideas in this section involving randomization, refer to the book by Motwani and Raghavan [28].

THEOREM 7.1. *There exists a (u, k, α)-universal isolating family of size $uk^{O(1)}$ for any constant α.*

Proof. First, assume that the safe-set size s is known explicitly. We use a standard probabilistic existence argument. Fix attention on a particular set-isolation instance with safe-set size s. Suppose we mark each element of the universe with probability $(\log 2k)/\alpha s$ and let the marked elements form one member of the universal family. With probability $k^{-O(1)}$, the safe-set is not marked but all the target sets are. If so, then the marked elements form an isolator for the given instance. Thus if we perform $k^{O(1)}$ trials, we can reduce the probability of not producing an isolator for this instance to $1/2$. If we do this $uk^{O(1)}$ times, then the probability of failure on the instance is $2^{-uk^{O(1)}}$. If we now consider all $2^{uk^{O(1)}}$ set-isolation instances, the probability that we fail to to generate an isolator for all of them during all the trials is less than 1.

Now consider the assumption that s is known. It can be removed by performing the above randomized marking trial for each value of s in the range $1, \ldots, u$; their union would be a universal isolating family. This would increase the size of the family by a factor of u. More efficiently, since a constant-factor estimate of s suffices, we could apply the construction for $s = 1, 2, 4, 8, \ldots, u$ and take the union of the results. This would increase the number of sets in the universal isolating family by a factor of $\log u$ but would increase the total size (in number of elements) of all sets in the family by only a constant factor. □

It is not very hard to see that this existence proof can be converted into a randomized ($\mathcal{RNC}$) construction of a polynomial-size (u, k, α)-universal isolating family. In the application to the minimum-cut problem, we only know of an upper bound on the value of k, but it is clear that this suffices for the existence proof and the randomized construction. Furthermore, since we can get a constant-factor approximation to the minimum cut, we do not in fact need to construct isolators for all possible values of s but only for the estimate.

7.1. Deterministically constructing universal families. We proceed to derandomize the construction of a universal isolating family. As in the randomized construction, we can assume that the safe-set size s is known. While performing the derandomization, we fix our attention on a particular set-isolation instance and show that our construction will contain an isolator for that instance. It will follow that our construction contains an isolator for every instance.

Our derandomization happens in two steps. We first replace the randomized construction's fully independent marking by pairwise-independent marking and show that despite this change we have a good chance of marking any *one* target set while avoiding the safe set. We then use random walks on expanders to let us mark *all* the target sets simultaneously while avoiding the safe set.

7.1.1. Pairwise independence. We first show how pairwise-independent marking isolates any one target set from the safe set. The analysis of the use of pairwise instead of complete independence is fairly standard [7, 25, 28], and the particular proof given below is similar to that of Luby, Naor, and Naor [26].

Choose $p = 1/(2+\alpha)s$. Suppose each element of U is marked with probability p *pairwise independently* to obtain a *mark set* $M \subseteq U$. For any element $x \in U$, we define the following two events under the pairwise-independent marking:

- $\mathcal{M}_x$: the event that element x is marked;
- $\mathcal{S}_x$: the event that element x is marked but no element of the safe set S is marked.

We have that $\Pr[\mathcal{M}_x] = p$ and the events $\{\mathcal{M}_x\}$ are pairwise independent. We say that a mark set is *good for* T_i if some element of T_i is marked but no element of S is marked, and in that case the set of marked elements M is called a *good set for* T_i. The mark set is an isolator if it is good for every T_i.

Observe that the mark set M is good for a target set T_i if and only if the event $\mathcal{S}_x$ occurs for some element $x \in T_i$. The following lemmas help to establish a constant lower bound on the probability that M is good for T_i.

LEMMA 7.2. *For any element* $x \in U \setminus S$,

$$\Pr[\mathcal{S}_x] \geq p(1 - sp).$$

Proof. The probability that x is marked but no element of S is marked can be written as the product of the following two probabilities:

- the probability that x is marked, and
- the probability that no element of S is marked conditional upon x being marked.

We obtain that

$$\begin{aligned}
\Pr[\mathcal{S}_x] &= \Pr[\cap_{j\in S}\overline{\mathcal{M}}_j \cap \mathcal{M}_x] \\
&= \Pr[\cap_{j\in S}\overline{\mathcal{M}}_j \mid \mathcal{M}_x] \times \Pr[\mathcal{M}_x] \\
&= (1 - \Pr[\cup_{j\in S}\mathcal{M}_j \mid \mathcal{M}_x]) \times \Pr[\mathcal{M}_x] \\
&\geq \left(1 - \sum_{j\in S} \Pr[\mathcal{M}_j \mid \mathcal{M}_x]\right) \times \Pr[\mathcal{M}_x].
\end{aligned}$$

Since $x \notin S$, we have that $j \neq x$. The pairwise independence of the marking now

implies that $\Pr[\mathcal{M}_j \mid \mathcal{M}_x] = \Pr[\mathcal{M}_j]$, and so we obtain that

$$\begin{aligned}\Pr[\mathcal{S}_x] &\geq \left(1 - \sum_{j \in S} \Pr[\mathcal{M}_j]\right) \times \Pr[\mathcal{M}_x] \\ &= (1 - sp)p. \qquad \square\end{aligned}$$

LEMMA 7.3. *For any pair of elements x, $y \in U \setminus S$,*

$$\Pr[\mathcal{S}_x \cap \mathcal{S}_y] \leq p^2.$$

Proof. Using conditional probabilities as in the proof of Lemma 7.2, we have that

$$\begin{aligned}\Pr[\mathcal{S}_x \cap \mathcal{S}_y] &= \Pr[(\mathcal{M}_x \cap \mathcal{M}_y) \cap (\cap_{j \in S} \overline{\mathcal{M}}_j)] \\ &= \Pr[\cap_{j \in S} \overline{\mathcal{M}}_j \mid \mathcal{M}_x \cap \mathcal{M}_y] \times \Pr[\mathcal{M}_x \cap \mathcal{M}_y] \\ &\leq \Pr[\mathcal{M}_x \cap \mathcal{M}_y] \\ &= p^2,\end{aligned}$$

where the last step follows from the pairwise independence of the marking. $\square$

THEOREM 7.4. *The probability that the pairwise-independent marking is good for any specific target set T_i is bounded from below by a positive constant.*

Proof. Recall that $|T_i| \geq t = \alpha s$ and arbitrarily choose a subset $T \subseteq T_i$ such that $|T| = t = \alpha s$, assuming without loss of generality that t is a positive integer. The probability the mark set M is good for T_i is given by $\Pr[\cup_{x \in T_i} \mathcal{S}_x]$. We can lower bound this probability as follows:

$$\begin{aligned}\Pr[\cup_{x \in T_i} \mathcal{S}_x] &\geq \Pr[\cup_{x \in T} \mathcal{S}_x] \\ &\geq \sum_{x \in T} \Pr[\mathcal{S}_x] - \sum_{x,y \in T} \Pr[\mathcal{S}_x \cap \mathcal{S}_y],\end{aligned}$$

using the principle of inclusion-exclusion. Invoking Lemmas 7.2 and 7.3, we obtain that

$$\begin{aligned}\Pr[\cup_{x \in T_i} \mathcal{S}_x] &\geq tp(1 - sp) - \binom{t}{2} p^2 \\ &\geq tp(1 - sp) - t^2 p^2 \\ &= \alpha sp(1 - sp) - (\alpha sp)^2 \\ &= \frac{\alpha}{2(2 + \alpha)},\end{aligned}$$

where the last expression follows from our choice of $sp = 1/(2 + \alpha)$. Clearly, for any positive constant α, the last expression is a positive constant. $\square$

A pairwise-independent marking can be achieved using $O(\log u + \log s)$ random bits as a seed to generate pairwise-independent variables for the marking trial [7]. The $O(\log u)$ term comes from the need to generate u random variables; the $O(\log s)$ term comes from the fact that the denominator in the marking probability is proportional to s. Since $s \leq u$, the number of random bits needed to generate the pairwise-independent marking is $O(\log u)$.

We can boost the probability of success to any desired constant β by using $O(1)$ independent iterations of the random marking process, each yielding a different mark

set. This increases the size of the seed needed by only a constant factor. We can think of this pairwise-independent marking algorithm as a function f that takes a truly random seed R of $O(\log u)$ bits and returns $O(1)$ subsets of U. Randomizing over seeds R, the probability that $f(R)$ contains at least one good set for target T_i is at least β.

7.1.2. Expander walks. The above construction lets us isolate any *one* target set from the safe set with reasonable probability. The next step is to isolate *all* target sets simultaneously. We do so by reducing the probability of failure from a constant $1-\beta$ to $k^{-O(1)}$, making it unlikely that we fail to mark any one target set. This relies on the behavior of random walks on expanders.

We need an explicit construction of a family of bounded-degree expanders, and a convenient construction is that of Gabber and Galil [13]. They show that for sufficiently large n, there exists a graph G_n on n vertices with the following properties: the graph is 7-regular; it has a constant expansion factor; and, for some constant ϵ, the second eigenvalue of the graph is at most $1-\epsilon$. The following is a minor adaptation of a result due to Ajtai, Komlós, and Szemerédi [2] which presents a crucial property of random walks on the expander G_n. (Refer to Cohen and Wigderson [8], Impagliazzo and Zuckerman [16], and Motwani and Raghavan [28] for a formal definition of expanders and further details about random walks on expanders.)

THEOREM 7.5 (see [2]). *There exist constants $\beta, \gamma > 0$ such that for any subset $B \subseteq V(G_n)$ of size at most $(1-\beta)n$ and for a random walk of length $\gamma \log k$ on G_n, the probability that the vertices visited by the random walk are all from B is $O(k^{-2})$.*

Notice that performing a random walk of length $\gamma \log k$ on G_n requires $O(\log n + \log k)$ random bits—choosing a random starting vertex requires $\log n$ random bits and, since the degree is constant, each step of the walk requires $O(1)$ random bits. We use this random walk result as follows. Each vertex of the expander corresponds to a seed for the mark-set generator f described above; thus $\log n = O(\log u)$, implying that we need a total of $O(\log u + \log k)$ random bits for the random walk. Choosing B to be the set of bad seeds for T_i, i.e., those that generate set families containing no good sets for T_i, and noting that by construction B has size $(1-\beta)n$ allows us to prove the following theorem.

THEOREM 7.6. *A (u, k, α) universal family for U of size $(uk)^{O(1)}$ can be generated in $\mathcal{NC}$ for any constant α.*

Proof. Use $\Theta(\log u + \log k)$ random bits in the expander walk to generate $\Theta(\log k)$ pseudorandom seeds. Then use each seed as an input to the mark-set generator f. Let H denote the $\Theta(\log k)$ sets generated throughout these trials (we give $\Theta(\log k)$ inputs to f, each of which generates $O(1)$ sets). Since the probability that f generates a good-for-i set on a random input is β, we can choose constants and apply Theorem 7.5 to ensure that with probability $1 - 1/k^2$, one of our pseudorandom seeds is such that H contains a good set for T_i. It follows that with probability $1 - 1/k$, H contains good sets for every one of the T_i's. Note that the good sets for different targets might be different. However, consider the collection C of all possible unions of sets in H. Since H has $O(\log k)$ sets, C has size $2^{|H|} = k^{O(1)}$. One set in C consists of the union of all the good-for-some-i sets in H; this set intersects every T_i but does not intersect the safe set, and it is thus an isolator for our instance.

We have shown that with $O(\log u + \log k)$ random bits, we generate a family of $k^{O(1)}$ sets such that there is a nonzero probability that one of the sets isolates the safe set. It follows that if we try all possible $O(\log u + \log k)$-bit seeds, one of them must yield a collection that contains an isolator. All these seeds together will generate

$(uk)^{O(1)}$ sets, one of which must be the desired one.

For a given input seed, the pairwise-independent generation of sets by f is easily parallelizable. Given a particular $O(\log u + \log k)$-bit seed for the expander walk, Theorem 7.5 says that performing the walk to generate the seeds for f takes $O(\log u + \log k)$ time. We can clearly do this in parallel for all possible seeds. The various sets that are output as a result must contain a solution for any particular set-isolation instance; it follows that the output collection is a (u, k, c)-universal isolating family. □

It should be noted that by itself, this set-isolation construction is not sufficient for derandomization. Combined directly with the technique of Luby, Naor, and Naor [26], it can find a set of edges that contains an edge incident on each vertex but not any of the minimum-cut edges. Unfortunately, contracting such an edge set need only halve the number of vertices (e.g., if the edge set is a perfect matching), so $\Omega(\log n)$ phases would still be necessary. This approach would therefore use $\Omega(\log^2 n)$ random bits, just as [26] did. The power of the technique comes through its combination with the approximation algorithm, which allows us to solve the entire problem in a single phase with $O(\log n)$ random bits. This, of course, lets us fully derandomize the algorithm.

8. Conclusion. We have shown that, in principle, the minimum-cut problem can be solved in $\mathcal{NC}$. This should be viewed as a primarily theoretical result since the algorithm in its present form is extremely impractical. A natural open problem is to find an efficient $\mathcal{NC}$ algorithm for minimum cuts. An easier goal might be to improve the efficiency of the approximation algorithm. Our algorithm uses m^2/n processors. Matula's sequential approximation algorithm uses only linear time, and the $\mathcal{RNC}$ min-cut algorithm of [23] uses only n^2 processors. Also, an $\mathcal{RNC}$ $(2+\epsilon)$-approximation algorithm using only a linear number of processors is given in [20]. These facts suggest that a more efficient $\mathcal{NC}$ algorithm might be possible.

We also introduced a new combinatorial problem, the set-isolation problem. This problem seems very natural, and it would be nice to find further applications for it. Other applications of the combination of pairwise independence and random walks would also be interesting.

RESOURCE BOUNDS FOR SELF-STABILIZING MESSAGE-DRIVEN PROTOCOLS*

SHLOMI DOLEV†, AMOS ISRAELI‡, AND SHLOMO MORAN§

Abstract. Self-stabilizing message-driven protocols are defined and discussed. The class *weak exclusion* that contains many natural tasks such as *ℓ-exclusion* and *token passing* is defined, and it is shown that in any execution of any self-stabilizing protocol for a task in this class, the configuration size must grow at least in a logarithmic rate. This last lower bound is valid even if the system is supported by a time-out mechanism that prevents communication deadlocks. Then we present three self-stabilizing message-driven protocols for token passing. The rate of growth of configuration size for all three protocols matches the aforementioned lower bound. Our protocols are presented for two-processor systems but can be easily adapted to rings of arbitrary size. Our results have an interesting interpretation in terms of automata theory.

Key words. self-stabilization, message passing, token passing, shared memory

1. Introduction.

A distributed system is a set of state machines, called *processors*, which communicate either by *shared variables* or by *message-passing*. In the first case, the system is a *shared-memory* system; in the second case, the system is a *message-passing* system. A distributed system is *self-stabilizing* if it can be started in any *possible* global state. Once started, the system regains its consistency by itself, without any kind of an outside intervention. The self-stabilization property is very useful for systems in which processors may crash and then recover spontaneously in an arbitrary state. When the intermediate period in between one recovery and the next crash is long enough, the system stabilizes. Self-stabilizing systems were defined and discussed first in the fundamental paper of Dijkstra [7]. The work of [7] as well as most of the following work on self-stabilizing systems assume the communication model of shared variables. Among these papers are [2], [4], [6], [8], [9], [11], [14], [15], [17], [19], [20], and [22].

In the study of fault-tolerant message-passing systems, it is customarily assumed that messages might be corrupted over links; hence processors may enter arbitrary states and link contents may be arbitrary. Self-stabilizing protocols treat these problems naturally since they are designed to recover from inconsistent global states. Surprisingly, there are very few papers which address self-stabilizing message-passing systems. The earliest research in this model was done by Gouda and Multari in [13], [21]. In that work, they have developed a self-stabilizing sliding-window protocol and two-way handshake that use unbounded counters. They proved that any self-stabilizing message-passing protocol must use time-outs and have infinite number of safe states. Following [13], two additional works dealt with self-stabilizing protocols

in this model. The work of Katz and Perry [16] presents a general tool for extending an arbitrary message-passing protocol to a self-stabilizing protocol. The work of Afek and Brown [1] presents a self-stabilizing version of the well-known alternating-bit protocol (see, e.g., [5]).

In this work, we research complexity issues related to self-stabilizing message-passing systems; to do this, we define a *configuration* of any message-passing system as a list of the states of the processors and of the messages which are in transit on each link. The *size* of a configuration of a message-passing system is the number of bits required to encode the configuration entirely. A protocol for a message-passing system is *message driven* if any action of the processors is initiated by receiving a message. In the work of Gouda and Multari [13], it is proven that any message-driven protocol has a possible configuration in which all processors are waiting for messages but there are no messages on any link. This unwanted situation is called *communication deadlock*. A self-stabilizing system should stabilize when started from any possible initial configuration, including a configuration with communication deadlock. This implies that a nontrivial, completely asynchronous, self-stabilizing system cannot be message-driven. This problem can be dealt with in at least two methods. Gouda and Multari [13] proposed the use of a time-out mechanism which preserves the message-driven structure of the protocol at the expense of compromising the complete asynchronicity. On the other hand, Katz and Perry [16] chose to give up the message-driven structure and present protocols for which at any configuration there is at least one processor whose next operation is sending a message. Thus there is an execution in which in every atomic step a message is sent, and no message is ever received. In this execution, the size of the configurations grows *linearly*.

In this work, we define and study the class of *self-stabilizing message-driven* protocols. By the argument of [13], there exists no self-stabilizing message-driven protocol which is completely asynchronous. Since we look for protocols whose configuration size does not grow at a linear rate, we resort to slightly limited assumptions of asynchronous behavior. For lower bounds, we assume an abstract time-out device which detects communication deadlocks and initiates the system upon their occurrence. Consequently, the lower bounds we present take into account only executions in which no communication deadlock occurs. Our upper bounds assume that in every initial configuration, there is at least one message on some link. This assumption is much weaker than the assumption on a general time-out mechanism.

A specific task which we study in details is *token passing*. Informally, the *token-passing* task is to pass a single token fairly among the system's processors. Usually, it is assumed that in the system's predefined initial configuration, there exists a single token. In self-stabilizing system in which there is no predefined initial configuration, each execution should reach a configuration in which exactly one token is present in the entire system. Token passing is a very basic task in fault-tolerant systems; among other works, it was studied in [12] for some fault-tolerant message-passing systems and in [14] for self-stabilizing shared-memory systems. The token-passing task can be looked at as a special case of mutual exclusion since possession of the single token can be interpreted as a permission to enter the critical section.

In the first part of the presentation we prove a lower bound on the configuration size for protocols for a large class of tasks called *weak exclusion*. The weak-exclusion class contains all nontrivial tasks which require continuous changes in the system's configuration; in particular, this class includes both ℓ*-exclusion* and *token passing*. We show that the configuration size of any self-stabilizing protocol which realizes any

weak-exclusion task is at least logarithmic in the number of steps executed by the protocol. The lower bound holds for message-driven protocols for any weak-exclusion task, including protocols for systems equipped with time-out mechanism. This result should be compared with a result of [13] where it is shown that any message-driven self-stabilizing protocol (not necessarily for weak-exclusion tasks) must have infinitely many safe system configurations, but it is not shown that each specific execution must contain infinitely many distinct configurations, as implied by our results. Our lower bound does not specify which *part* of the system grows; is it the size of the memory used by the state machines, the size of messages stored on the links, the number of messages stored on the links, or all of these together?

We then present three self-stabilizing message-driven protocols for token passing. The communication-deadlock problem is avoided by the assumption that at least a single message is present on some communication link. Using this assumption, we present three token-passing protocols for two processors each. The rate of growth of configuration size for all three protocols matches the aforementioned lower bound. All protocols are presented for systems with two processors but can be easily adapted to work on rings of arbitrary size *without increasing their asymptotic complexity.* This is done by considering the ring as a single virtual link.

In the first protocol, the sizes of both processors' memory and messages grow unboundedly with time; this protocol uses ideas similar to the ideas of the sliding-window protocol of [13]. The second protocol is an improvement on the first protocol in which the size of the memory of the processors grows (in logarithmic rate) while the size of the link content is bounded. The second protocol is an improvement of the deterministic alternating-bit protocol of [1]. The third protocol is a self-stabilizing token-passing protocol in which processors are *deterministic* finite-state machines and messages are of fixed size. The only growing part of the system is the number of messages on the links; the rate of growth matches the lower bound mentioned above.

Our results can also be described in terms of automata theory, as follows. Let Σ be an alphabet. Define a *queue machine* Q to be a finite-state machine which is equipped with a queue, which initially contains an arbitrary nonempty word from Σ^+. Initially, Q is in an arbitrary state, and in each step it performs the following: (a) reads and deletes a letter from the head of the queue, (b) adds one or more letters from Σ to the tail of the queue, and (c) moves to a new state. The computational power of a queue machine is severely limited by the fact that its input alphabet and its work alphabet are *identical.* In particular, a queue machine cannot perform simple tasks like computing the length of the input word or even deciding whether the input word contains a specific letter.

Assume that the alphabet contains a specified subset τ of *token letters.* A queue machine is a *token controller* if, starting with a nonempty queue of arbitrary content, the queue eventually contains exactly one occurrence of a letter from τ forever. Our lower-bound result implies that if a token controller exists, then in every computation, the size of the queue must grow at least logarithmically in the number of moves of the machine. Our third protocol implies that a token controller whose configuration size growth matches the lower bound exists. In view of the fact that a queue machine *cannot* compute any estimation of the number of occurrences of letters from τ in the input word, this latter result appears to be somewhat counterintuitive.

2. Self-stabilizing message-driven systems.

2.1. Asynchronous message-driven systems. An *asynchronous, distributed, message-passing system* contains n processors, where each processor is a state machine.

Processors communicate using message passing along *links*. An edge $e = (i, j)$ of G stands for two directed links, one from P_i to P_j and the other from P_j to P_i. A message sent from P_i to P_j can be delayed for an unbounded amount of time on the connecting link. Messages which did not yet reach their destination are stored on the link and transferred in first-in first-out (FIFO) order.

A processor is uniquely defined by the set of its *atomic steps*. Whenever a processor is active, it executes one of its atomic steps. In a *message-driven* protocol, an atomic step of any processor P begins with a **receive** operation in which P receives a message from one of its incoming links. The atomic step ends with zero or more **send** operations in which P sends messages along some of its outgoing links. An atomic step a of P_i is defined by $a = (i,\ s_{i_1},\ (e, \mathrm{msg}),\ (e_1, \mathrm{msg}_1),\ (e_2, \mathrm{msg}_2), \ldots, (e_\ell, \mathrm{msg}_\ell), s_{i_2})$, meaning that P_i is in state s_{i_1}, e is the link through which P_i receives the message msg, $e_1, e_2, \ldots, e_\ell$ are the outgoing links along which P_i sends $\mathrm{msg}_1, \mathrm{msg}_2, \ldots, \mathrm{msg}_\ell$, respectively, and s_{i_2} is the state of P_i following the execution of this atomic step.

Let n and m be the number of processors and links, respectively, in the system. For $1 \le i \le n$, denote the set of states of P_i by S_i. A *configuration* of the system is a vector of states of all processors together with m lists—a list for every link—of messages stored on that link. A configuration is denoted by $c = (s_1, s_2, \ldots, s_n, M_{e_1}, M_{e_2}, \ldots, M_{e_j}, \ldots, M_{e_m})$, where $s_i \in S_i$, $1 \le i \le n$, and M_{e_j} is a list of the messages stored on e_j for $1 \le j \le m$. Let c be a configuration as above, and let $a = (i, s_{i_1}, (e, \mathrm{msg}), (e_1, \mathrm{msg}_1), (e_2, \mathrm{msg}_2), \ldots, (e_\ell, \mathrm{msg}_\ell), s_{i_2})$ be an atomic step. a is *applicable* to (P_i in) c if P_i is in state s_{i_1} in c and msg is the first message stored on e in c.

Application of a to c yields the *result* configuration c'. We denote this fact by $c \xrightarrow{a} c'$. A sequence of atomic steps, $A = (a_1, a_2, \ldots)$, is applicable to configuration c_0 if the first atomic step in the sequence, a_1, is applicable to c_0, the second atomic step is applicable to c_1, where $c_0 \xrightarrow{a_1} c_1$, and so on. An *execution* $E = (c_0, a_1, c_1, a_2, \ldots)$ is a (finite or infinite) sequence which starts with some arbitrary configuration c_0 and for every $i > 0$, $c_{i-1} \xrightarrow{a_i} c_i$; that is, the sequence of atomic steps $A = (a_1, a_2, \ldots)$ is applicable to c_0. *Note:* Since we deal with self-stabilizing systems, we do not assume any particular initial configuration; every configuration is a valid initial configuration. Execution E is *fair* if every atomic step that is applicable infinitely often is executed infinitely often.

Each execution E defines a partial order on the atomic steps of E by the relation *happened before* of Lamport in [18]:

1. If a_i and a_j are atomic steps executed by the same processor in E and a_i appears before a_j in E, then a_i *happened before* a_j.
2. If during a_i the message msg is sent and during a_j the same message msg is received, then a_i *happened before* a_j.
3. If a_i *happened before* a_j and a_j *happened before* a_k, then a_i *happened before* a_k.

We also adopt the definition of *concurrent* atomic steps from [18]: atomic steps $a_1, \ldots, a_k$ are said to be *concurrent* in an execution E if for $1 \le i < j \le k$, a_i does not *happen before* a_j and a_j does not *happen before* a_i in E. The following proposition gives a sufficient condition for a set of steps to be concurrent in some execution.

PROPOSITION 2.1. *Let $P_{i_1}, \ldots, P_{i_k}$ be k distinct processors and let $\{a_1, \ldots, a_k\}$ be a set of atomic steps where a_j is applicable to P_{i_j}, $1 \le j \le k$, in some configuration c. Then there exists an execution in which the atomic steps $a_1, \ldots, a_k$ are concurrent.*

Proof. Observe that once step a is applicable to processor P in configuration

c, step a remains applicable to P in all subsequent configurations. The execution E is defined as the execution that starts from c in which processors $P_{i_1}, \ldots, P_{i_k}$ are activated one after the other and each processor P_{i_j} executes a_j. The proof follows since the processors are distinct and since in E, no message that was sent during a_j, $1 \leq j \leq k$, is received before a_k is executed. Note that the proposition holds for any system in which once some step is applicable, it remains applicable as long as it is not executed. □

An asynchronous protocol PR is defined by a set of n processors. By the above definitions, an asynchronous protocol defines a set of executions that satisfy the following:

1. Let $E = (c_0, a_1, c_1, a_2, \ldots)$ be an arbitrary execution of PR. Then every prefix of E is also an execution of PR.

2. Let $E = (c_0, a_1, c_1, a_2, \ldots, a_r, c_r)$ be arbitrary finite execution of PR. Then for every atomic step a and configuration c satisfying $c_r \xrightarrow{a} c$ PR has an execution $E \circ (a, c)$.[1]

2.2. Self-stabilizing message-driven protocols. A self-stabilizing system demonstrates a *legitimate behavior* some time after it is started from an arbitrary configuration. A natural way to specify a behavior in an abstract way is by a set of sequences of configurations. We define *tasks* as sets of *legitimate sequences*. The semantics of any specific task is expressed by requirements on its sequences. Intuitively, each legitimate sequence can be thought of as an execution of a protocol, but we do not require this formally. For instance, the mutual-exclusion task is defined as the set of sequences of configurations which satisfy the following: Each processor has a subset of its states called *critical section*; in each configuration, at most one processor is in its critical section, and every processor is in its critical section in infinitely many configurations. To formally define a task T, one should specify for each possible system ST a set of *legitimate sequences* for ST. The *task* T is defined as the union of the legitimate sequence set over all possible systems. A configuration c of a system is *safe* with respect to a task T and a protocol PR if any fair execution of PR starting from c belongs to T.

In proving lower-bound results on self-stabilizing message-driven protocols, we assume that the system can recover from a *communication deadlock* (called deadlock from now on). In other words, when we prove our lower bounds, we assume only that the protocol stabilizes in executions in which no deadlock occurs. For this purpose, we distinguish between two types of deadlocks: *global* and *local*. A configuration c is a global deadlock configuration if no atomic step is applicable to c. Our first lower bound holds for asynchronous systems that can recover from global deadlocks by applying a *global time-out* mechanism. This abstract mechanism initiates a system in a global deadlock configuration to a default initial configuration, after which no deadlock occurs. Below we present the requirement for self-stabilizing systems equipped with a global time-out mechanism. In this definition, the system is required to reach a safe configuration in every infinite fair execution. Note that by our definition, an infinite fair execution does not have a deadlock configuration.

Self-stabilization (*assuming global time-out mechanism*). Let PR and LE be a message-driven protocol and set of legitimate sequences, respectively. Protocol PR is self-stabilizing relative to LE if for every c, there is an execution of PR that starts with c and every such infinite fair execution reaches a safe configuration with respect

[1] For sequences S_1 and S_2, $S_1 \circ S_2$ denotes the concatenation of S_1 and S_2.

to LE and PR.

Later on, we prove a lower bound that holds for systems immune to a stronger type of communication deadlock called local deadlock. Processor P is in a *local deadlock* during execution E if P is activated (i.e., executes an atomic step) only finitely many times during E. The second lower bound holds for systems equipped with an abstract *local* time-out mechanism which prevents such executions (e.g., by enabling each processor which is idle for a sufficiently long time to initiate the system to some default configuration after which no deadlock is possible). Note that a local time-out mechanism is strictly stronger than a global time-out mechanism.

Self-stabilization (*assuming local time-out mechanism*). Let PR and LE be a message-driven protocol and set of legitimate sequences, respectively. Protocol PR is sellf-stabilizing relative to LE if for every c, there is an execution of PR that starts with c, and every such infinite fair execution, in which each processor is activated infinitely often, reaches a safe configuration with respect to LE and PR.

3. Lower bound. In this section, we prove a lower bound on the rate in which the configuration size grows along every execution of any protocol for a large class of tasks called *weak exclusion*. This class contains all nontrivial tasks which require continuous changes in the system's configuration; in particular, this class includes both *ℓ-exclusion* and *token passing*. For an execution E, denote by $\mathcal{A}_i(E)$ the set of distinct atomic steps executed by P_i during E. A task belongs to the class *weak exclusion* if its set of legitimate sequences, LE, satisfies the following:

WE. For any $E \in LE$, there exists a set of two or more atomic steps $B = \{a_{i_1}, \ldots, a_{i_k}\}$, $k \leq n$, where $a_j \in \mathcal{A}_{i_j}(E)$, such that the atomic steps in B are never concurrent during E.

We first consider self-stabilizing protocols for systems equipped with a global time-out mechanism. For these protocols, we prove that in every execution (in which no communication deadlock occurs), all configurations are distinct. From this we conclude that the configuration size of every self-stabilizing protocol which realizes any weak-exclusion task is at least logarithmic in the number of steps executed by the protocol. Throughout the proof, we assume that PR is a self-stabilizing message-driven protocol for an arbitrary weak-exclusion task in a system with a global time-out mechanism. At the end of this section, we present a slightly weaker lower bound for systems with a local time-out mechanism.

For any configuration c and any link e, denote by M_e^c the sequence of messages present on e in c. For any execution E, denote by $M_{e,s}^E$ ($M_{e,r}^E$) the sequence of messages sent (received) along e during E.

PROPOSITION 3.1. *For every execution $E = (c_0, a_1, \ldots, a_r, c_r)$ and for every link e, $M_e^{c_0} \circ M_{e,s}^E = M_{e,r}^E \circ M_e^{c_r}$.*

Proof. The left-hand side of the equation contains the messages present on e in c_0 concatenated with the messages sent during E through e. The right-hand side of the equation contains the messages received during E through e concatenated with the messages left on e in c_r. It is not hard to verify that both sides of the equation represent the same sequence of messages. □

An execution $E = (c_0, a_1, \ldots, c_{\ell-1}, a_\ell, c_\ell)$ whose result configuration c_ℓ is equal to its initial configuration c_0 is called a *circular* execution. A link e is *active* in a circular execution E if some messages are received (and hence, by the circularity of E, some messages are sent) along e in E. Repeating a circular execution E forever yields an infinite execution E^∞ which is not necessarily fair—the original execution may have an applicable step a which is never executed during E. The step a is

applicable throughout E^∞, but it is never executed. To avoid this problem, the original circular execution is changed by removing all messages from links that are not active throughout E. The resulting execution, which is still called E, is still circular, and its infinite repetition E^∞ is a fair infinite execution. Observe that an execution in which a certain configuration appears more than once has a circular subexecution, $\overline{E} = (c_i, a_{i+1}, \ldots, a_{i+\ell}, c_{i+\ell}) \equiv (\overline{c_0}, \overline{a_1}, \ldots, \overline{a_\ell}, \overline{c_\ell})$, where $c_i = c_{i+\ell} = \overline{c_0} = \overline{c_\ell}$. Thus to show that in every execution of PR, all the configurations are distinct, we assume that PR has a circular subexecution $\overline{E}$ and reach a contradiction by showing that PR is not self-stabilizing.

Using $\overline{E}$, we now construct an initial configuration c_{init} by changing the list of messages in transit on the system's links. For each link e, the list of messages in transit on e at c_{init} is obtained by concatenating the list of messages in transit on e at $\overline{c_0}$ with the list of all messages sent on e during $\overline{E}$. Roughly speaking, the effect of this change is creating an additional "layer" of messages that helps to decouple each **send** from its counterpart **receive** and achieve an additional flexibility in the system which enables the proof of the lower bound. Formally, c_{init} is obtained from $\overline{c_0}$ as follows:

- The state of each processor in c_{init} is equal to its state in $\overline{c_0}$.
- For any active link in $\overline{E}$, $M_e^{c_{\text{init}}} = M_e^{\overline{c_0}} \circ M_{e,s}^{\overline{E}}$, and for any nonactive link in $\overline{E}$, $M_e^{c_{\text{init}}}$ is empty.

Let $\overline{A}(i)$ be the sequence of atomic steps executed by P_i during $\overline{E}$. Define $merge(\overline{A})$ to be the set of sequences obtained by all possible mergings of all sequences $\overline{A}(i)$, $1 \le i \le n$, while keeping the internal order in each $\overline{A}(i)$. Note that all of the sequences in $merge(\overline{A})$ have the same finite length and contain the same atomic steps in different orders.

LEMMA 3.2. *Every $A \in merge(\overline{A})$ is applicable to c_{init}, and the resulting execution, $E_A = (c_{\text{init}}) \circ A$, is a circular execution of PR.*

Proof. Let A be an arbitrary sequence in $merge(\overline{A})$ and let P_i be an arbitrary processor of the system. Then we have the following: (i) The initial state of P_i in c_{init} is equal to its initial state in $\overline{c_0}$. (ii) In c_{init}, all messages which P_i receives during $\overline{E}$ are stored on P_i's appropriate incoming links in the right order. (iii) The atomic steps of P_i appear in A in the same order in which they appear in $\overline{A}(i)$. (i)–(iii) imply that the sequence A is applicable to c_{init}, and the application of A to c_{init} yields an execution E_A with resulting configuration c_{res}, whose state vector is equal to the state vector of c_{init} and in which for every active link, $M_{e,s}^{E_A} = M_{e,s}^{\overline{E}}$ and $M_{e,r}^{E_A} = M_{e,r}^{\overline{E}}$.

To prove that the execution obtained is circular, it remains to be shown that the content of every link in the resulting configuration c_{res} is equal to its content in c_{init}, i.e., $M_e^{c_{\text{init}}} = M_e^{c_{\text{res}}}$. For any arbitrary link e it holds that

1. $M_e^{c_{\text{init}}} \circ M_{e,s}^{\overline{E}} = M_{e,r}^{\overline{E}} \circ M_e^{c_{\text{res}}}$ (by Proposition 3.1 and by the fact that $M_{e,s}^{E_A} = M_{e,s}^{\overline{E}}$ and $M_{e,r}^{E_A} = M_{e,r}^{\overline{E}}$) and
2. $M_e^{\overline{c_0}} \circ M_{e,s}^{\overline{E}} = M_{e,r}^{\overline{E}} \circ M_e^{\overline{c_0}}$ (by Proposition 3.1 and the circularity of $\overline{E}$).

Replacing $M_e^{c_{\text{init}}}$ in equation 1 with its explicit contents yields

3. $M_e^{\overline{c_0}} \circ M_{e,s}^{\overline{E}} \circ M_{e,s}^{\overline{E}} = M_{e,r}^{\overline{E}} \circ M_e^{c_{\text{res}}}$.

Using equation 2 to replace $M_e^{\overline{c_0}} \circ M_{e,s}^{\overline{E}}$ by $M_{e,r}^{\overline{E}} \circ M_e^{\overline{c_0}}$ in equation 3 gives

4. $M_{e,r}^{\overline{E}} \circ M_e^{\overline{c_0}} \circ M_{e,s}^{\overline{E}} = M_{e,r}^{\overline{E}} \circ M_e^{c_{\text{res}}}$.

Dropping $M_{e,r}^{\overline{E}}$ from the two sides of equation 4 yields the desired result: $M_e^{c_{\text{init}}} = M_e^{\overline{c_0}} \circ M_{e,s}^{\overline{E}} = M_e^{c_{\text{res}}}$, which proves the lemma. □

Define *blowup*($\overline{E}$) to be the set of executions whose initial sate is c_{init} and whose sequence of atomic steps belongs to *merge*($\overline{A}$). Notice that for every circular execution $\overline{E}$ and for every execution $E \in$ *blowup*($\overline{E}$), it holds that $\mathcal{A}_i(\overline{E}) = \mathcal{A}_i(E)$.

LEMMA 3.3. *For any set of atomic steps $B = \{a_1, \ldots, a_k\}$, $k \leq n$, where $a_j \in \mathcal{A}_{i_j}(\overline{E})$, there is an execution $E \in$ blowup($\overline{E}$) that contains a configuration for which all the atomic steps in B are concurrent.*

Proof. For notational simplicity, assume that $k = n$ and that $B = \{a_1, a_2, \ldots, a_n\}$. Let $A \in$ *merge*($\overline{A}$) be the sequence constructed as follows: first take all the steps in $\overline{A}(1)$ that precede a_1, then take all the steps in $\overline{A}(2)$ that precede $a_2, \ldots$, then take all the steps in $\overline{A}(n)$ that precede a_n. Applying the sequence constructed so far to c_{init} results in a configuration in which all of the a_i's are applicable. This sequence is completed to a sequence A in *merge*($\overline{A}$) by taking the remaining atomic steps in an arbitrary order, which keeps the internal order of each $\overline{A}_i$. □

LEMMA 3.4. *Let PR be a self-stabilizing message-driven protocol for an arbitrary weak-exclusion task T in a system with a global time-out mechanism. If PR has a circular execution $\overline{E}$, then PR has an infinite fair execution E^∞ none of whose configurations are safe for T.*

Proof. Let E be an arbitrary execution in *blowup*($\overline{E}$). Define E^∞ to be the infinite execution obtained by repeating E forever. By the definition of *blowup*($\overline{E}$), E^∞ is fair. Thus it remains to show that no configuration in E^∞ is safe.

Assume by way of contradiction that some configuration c_0 in E^∞ is safe. Now we construct a finite circular execution E' whose sequence of atomic steps A' is obtained by concatenating sequences from *merge*($\overline{A}$), that is, $\mathcal{A}_i(E') = \mathcal{A}_i(\overline{E})$. Since PR is a protocol for some weak-exclusion task, E' should have some set of atomic steps $B = \{a_1, \ldots, a_k\}$, where $a_j \in \mathcal{A}_{i_j}$, that are never applicable for a single configuration c during E'. We reach a contradiction by refuting this statement for E'. For this we choose some arbitrary enumeration $\mathcal{B} = B_1, \ldots, B_s$, of all the sets containing n atomic steps of n distinct processors. Execution E' is constructed by first continuing the computation from c_0 as in E until configuration c_{init} is reached. Then apply Lemma 3.3 to extend E' by s consecutive executions $E_1, \ldots, E_s$, where E_k, $1 \leq k \leq s$, contains a configuration in which all the steps in B_k are applicable and that ends with c_{init}. The proof follows. *Note:* Execution E' can be repeated forever to obtain an infinite execution which does not have any suffix in LE; thus the protocol PR is not even pseudo-self-stabilizing (see [3]). □

The proof for the lower bound is completed by the following theorem.

THEOREM 3.5. *Let PR be a self-stabilizing message-driven protocol for an arbitrary weak-exclusion task in a system with a global time-out mechanism. For every execution E of PR, all the configurations of E are distinct. Hence for every $t > 0$, the size of at least one of the first t configurations in E is at least $\lceil \log_2(t) \rceil$.*

Proof. Assume by way of contradiction that there exists an execution E of PR in which not all the configurations are distinct; then E contains a circular subexecution $\overline{E}$. By Lemma 3.4, there exists an infinite execution E' of PR which is obtained by an infinite repetition of some execution from *blowup*($\overline{E}$) and which never reaches a safe configuration—a contradiction. □

To prove a similar lower bound for systems with a *local* time-out mechanism, the definition of a circular execution must be modified. Removing messages from nonactive links to construct an infinite execution from $\overline{E}$ as in the proof of Theorem 3.5 may yield an infinite execution in which some processor is enabled only finitely many times. In order to allow repetitions of finite executions to form an infinite fair

execution, in which every processor is active infinitely often, we require that each such finite execution contains an atomic step of each processor in the system. For this we need the concept of a *round* of an execution. Let E' be a minimal prefix of an execution E in which every processor receives a message; E' is the first *round* of E. Let E'' be the suffix of E which satisfies $E = E' \circ E''$. The second round of E is the first round of E'', and so on. Let E_i be the prefix that contains the first i atomic steps of E. Let $t_i = R(E_i)$ be the number of rounds in E_i. The next theorem presents a lower bound for systems equipped with a local time-out mechanism. The proof is similar to the proof of Theorem 3.5.

THEOREM 3.6. *Let PR be a self-stabilizing message-driven protocol for an arbitrary weak-exclusion task in a system with a local time-out mechanism. For every execution E of PR, E does not contain a circular subexecution which contains a complete round. From this we conclude that in each execution of PR, E, the first t rounds contain at least t distinct configurations. Hence for every $t > 0$, the size of at least one configuration in E_i at least $\lceil \log_2(t_i) \rceil$. In particular, in any fair execution, the configuration size is unbounded.*

4. Upper bound. The *token-passing* task is defined informally as a set of executions in which a single token is present in the entire system and is passed fairly among the system's processors. Token passing is a special case of mutual exclusion since possession of the single token can be interpreted as permission to enter the critical section. For this reason, token passing also satisfies the weak-exclusion property, and hence the lower bound of section 3 holds for it. In particular, it means that any self-stabilizing message-driven protocol PR for token passing must use some unbounded resource since in any infinite execution, the system size grows beyond any bound. In this section, we present three self-stabilizing token-passing protocols for systems of two processors. In each protocol, the configuration size grows during every execution at a rate that matches the lower bound. Each of these protocols can be easily adapted to work on rings of arbitrary size *without increasing its asymptotic complexity* by considering the ring as a single virtual link. Similar ideas can be used for adapting the protocols to arbitrary rooted tree systems.

By a standard symmetry argument, there exists no self-stabilizing, deterministic, token-passing protocol if the processors are identical. Hence in this section, we assume that the system consists of two distinct processors, called *sender* and *receiver*, connected by two links. The first link carries messages from the sender to the receiver while the second link carries messages from the receiver back to the sender. The receiver processor is identical in all three protocols and it is probably the simplest possible finite-state machine. Its program is to copy each message it receives from its incoming link to its outgoing link without any alteration. To the outside world, the combined behavior of the receiver and the two links looks like the behavior of a single queue whose head and tail are used by the receiver. In our analysis, we ignore the receiver and consider systems with a single processor, the sender, communicating with itself using a single link on which messages are kept in FIFO order. In each step, the sender consumes a message from the head of the link and puts one (or more) messages back at the tail of the link. Tokens are represented by a special symbol, T, which is appended to some of the messages. Our protocols specify the messages that carry a token, but they do not explicitly use the token symbol T. The protocol should guarantee that there is eventually a unique message in the system to which T is appended. All of our protocols assume that there is initially at least one message on the link (this assumption is weaker than both the global and the local versions of the

time-out mechanism). With this last assumption, the requirement that the link never becomes empty is equivalent to the requirement that whenever a message is received, at least one message is sent. Hence in every step of the protocol, the sender receives the message on the head of the (single) link and then puts one or more messages at the link's end. The three protocols we present are as follows:

Protocol 1. In this protocol, the sender is an infinite-state machine, and in every execution, the link capacity is unbounded.

Protocol 2. In this protocol, the sender is an infinite-state machine, but in each infinite execution, the link capacity is bounded (the bound for each specific execution depends on its initial configuration).

Protocol 3. In this protocol, both processors are finite-state machines.

```
1 do forever
2     receive(msg_counter)
3     if msg_counter ≥ counter then (* token arrives *)
4     begin (* send new token *)
5        counter:= msg_counter +1
6        send(counter, T)
7     end
8     else send(counter)
9 end
```

FIG. 1. *Protocol* 1.

Protocol 1 (of the sender) appears in Figure 1. The sender uses a variable called *counter*. Each message consists of the present value of *counter*, possibly with the token symbol T. Whenever the sender receives a message whose counter value, msg_*counter*, is not smaller than *counter*, it sets *counter* := msg_*counter* + 1 and sends this new value of *counter* together with the token T; otherwise, the sender just sends the current value of *counter* (without the token T). The token letter T is not used by the protocol itself. The correctness of the protocol is based on the fact that eventually the value of *counter* will be larger than all the values that appear in the messages present on the link in the initial configuration. The asymptotic size of *counter* in each execution is $\Omega(\log t)$, where t is the number of messages sent. The details of the proof are omitted.

4.1. Aperiodic sequences. Protocols 2 and 3 use the following method: each message is associated with some ternary number which is called *color*. The protocol considers any message whose color is different from the color of the previous message as carrying a token. The sender has a local variable called *token_color*. At any given configuration the sender is sending a sequence of messages whose color is equal to (the value of) *token_color*, at the same time, the sender waits for a message whose color is equal to *token_color*. As long as the sender receives messages of different colors, it sends messages whose color is equal to *token_color*. Once the sender receives a message whose color is equal to *token_color*, it chooses a new *token_color* and initiates a new sequence of messages whose color is the new *token_color* by sending the first message in this new sequence. This first message is carrying a (virtual) token. Then the sender continues sending messages of the new *token_color* (without tokens), until it receives a message of the new *token_color*, and so on. Our goal is to reach a configuration after which the link always holds at most two consecutive sequences of messages where the colors of all messages in each sequence are equal.

In every step, the sender consumes a single message from the first sequence whose color is the previous *token_color* and produces one or more messages whose color is equal to the present *token_color*. After the last message whose color is the previous *token_color* is consumed, the link contains a single sequence of messages whose color is *token_color*. In the next step, the sender receives the (single) token carried by this sequence and sends it once again by initiating a new sequence of messages whose color is the new *token_color*. In each of the configurations described, there exists a single token which is carried by the first message of the sequence whose color is *token_color*. The correctness of the protocols follows from the fact that the sequences of token colors sent by the receiver is *aperiodic*, as defined below.

DEFINITION. *A sequence* $A = (a_1, a_2, \ldots)$ *is* periodic *if for some positive integer* k *and for all* $i \geq 1$, $a_i = a_{i+k}$. *The sequence* A *is* eventually periodic *if it has a suffix which is periodic.* A *is* aperiodic *if it is not eventually periodic.*

Aperiodic sequences over the integers $\{0, 1, 2\}$ were used in [1] in order to obtain self-stabilizing data-link protocols. Such sequences are created there by either a random-number generator or an infinite-state machine (in the first case, the algorithm is randomized). The elements of this sequence are used by the protocol of [1] whenever it has to decide on the ternary number to be sent with a new message. In this paper, aperiodic sequences are generated by using a counter and the sequence *xor* defined below.

DEFINITION. *For an integer* i, $xor(i)$ *is the sum of the bits* (mod 2) *in the binary representation of* i (*e.g.,* $xor(1) = xor(2) = 1, xor(3) = 0$). *The sequence* $(xor(1), xor(2), \ldots)$ *is denoted by xor.*

As we show later, the sequence *xor* is aperiodic.

```
1 do forever
2     receive(color)
3     if color = token_color then (* token arrives *)
4     begin (* send new token *)
5        token_color:= (color +xor(counter) + 1) (mod 3)
6        counter := counter +1
7     end
8     send(token_color)
9 end
```

FIG. 2. *Protocol* 2.

Protocol 2 (of the sender), which appears in Figure 2, is an improvement of the protocol that appears in [1] in the sense that it achieves the lower bound of the previous section. (The amount of memory used for producing the aperiodic sequence is neither addressed nor specified in [1].) In Protocol 2, the sender keeps a counter in its local memory; whenever a message with a new color is sent, the counter is incremented. The new color $\in \{0, 1, 2\}$ is determined by the previous color and by applying *xor* to the counter. Roughly speaking, the correctness of the protocol is implied by the fact that since *xor* is aperiodic, the sequence of *colors* generated by the sender is aperiodic as well. The nature of the variables and the correctness proof of Protocol 2 are easily derived from the description of Protocol 3 and from its correctness proof; hence they are omitted.

4.2. Informal description of Protocol 3. We now present Protocol 3, in which both processors are finite-state machines. It is easily observed that when an

aperiodic sequence is supplied by some external device, a finite-state machine can use this sequence to perform the protocol in [1]. Our construction uses the fact that the finite-state machine augmented with the previously described FIFO link can generate an aperiodic sequence. The finite-state machine uses the link both for message passing and for generating the aperiodic sequence, while its size is kept within the optimal bound. Protocol 3 can be easily transformed to a self-stabilizing data-link protocol in which both processors are finite-state machines.

Protocol 3 appears in Figure 3. In this protocol, each message is a pair $(color, bit)$, where $color \in \{0, 1, 2\}$ and $bit \in \{0, 1\}$. The local variables *color* and *token_color* are ternary variables while the local variables *counter_bit, counter_xor, carry,* and *new_counter_bit* are binary. The binary *xor* operation is denoted by $\oplus$. For a sequence $s = ((color_1, bit_1), \ldots, (color_k, bit_k))$ of such messages, $N(s)$ denotes the integer whose binary representation is bit_k, $bit_{k-1}, \ldots, bit_1$ (bit_1 is the least significant bit). A maximal sequence of consecutive messages of the same color sent by the sender is called a *block*. For each block b, $N(b)$ denotes the integer described above and $|b|$ denotes the number of messages in b. The first message in each block is viewed as a token. To show that the protocol is self-stabilizing, we have to prove that eventually the link contains exactly one message which is the first message in a block. This goal is achieved by making the sequence of the colors of the blocks aperiodic.

The sender uses a local variable called *token_color*, which denotes the color of the block it is now sending. It continues to send messages of this color as long as the colors of the messages it receives are different from *token_color*. Once the sender receives a message whose color is equal to *token_color* (which eventually means that all messages on the link belong to the same block), it (a) possibly sends one last message of the current block, (b) changes the value of *token_color*, and (c) sends the first message of a new block with this new color.

```
1  do forever
2     receive(color,counter_bit)
3     if color = token_color then (* token arrives *)
4       begin
5           if carry = 1 then send (color, 1)
            (* new token *)
6           token_color := (color + counter_xor + 1) (mod 3)
7           counter_xor := 0
8           carry := 1
9       end
10    counter_xor := counter_xor ⊕ counter_bit
11    new_counter_bit := carry ⊕ counter_bit
12    carry := carry ∧ counter_bit
13    send (token_color,new_counter_bit)
14 end
```

FIG. 3. *Protocol* 3.

In Lemma 4.1, we show that in every execution, the sender initiates infinitely many blocks. Let $b_1, b_2, \ldots$ be the sequence of blocks initiated by the sender, where the color of b_i is $color(b_i)$ and the integer it represents is $N(b_i)$, as defined above. The protocol is designed so that the following properties are kept:

(p1) The sequence $(color(b_1), color(b_2), \ldots)$ is aperiodic.

(p2) For every large enough i, $N(b_{i+1}) = N(b_i) + 1$, and the *bit* field in the last message of b_i is 1; that is, $N(b_i) = i + const$ for some constant *const*, and the representation of $N(b_i)$ by b_i has no leading zeroes, implying that $|b_i| = \lceil \log_2 N(b_i) \rceil$.

We will prove that (p1) implies that there is eventually only one token in the system, while (p2) guarantees that the size of the system is logarithmic in the number of steps. We now show that the protocol indeed satisfies (p1) and (p2). For this we describe the two rules by which the sender computes the bits and the colors it sends. We need the following definition.

DEFINITION. *Let $k \geq 1$. Denote by s_k the sequence of messages whose colors are different from color(b_k) which are received by the sender while it sends the block b_k, and denote by $N(s_k)$ the integer represented by s_k. Note that s_k consists of one or more complete blocks.*

Rule 1 (rule for computing *counter_bit*s). The *counter_bit* sent with each message is sent so that for each k, $N(b_k) = N(s_k)+1$, and $|b_k| = \max\{|s_k|, \lceil \log_2(N(b_k)) \rceil\}$. In other words, the *counter_bit*s sent in block b_k are obtained by adding 1 to the binary number represented by the messages received while this block is sent.

Rule 2 (rule for computing *token_color*). When receiving a message whose color is equal to the value of *token_color*, the new value of *token_color*, which is the color of the next block, b_{k+1}, is determined as follows: $color(b_{k+1}) = color(b_k) + xor(N(s_k)) + 1 \pmod 3$.

Note that Rule 1 can be implemented by a binary adder which is set to zero at the initiation of each new block, and Rule 2 can be implemented by a counter (mod 2). Thus both rules are easily implemented by a finite-state machine.

4.3. Correctness and complexity proofs of Protocol 3.

LEMMA 4.1. *In every fair execution E, the sender initiates an infinite number of blocks.*

Proof. The sender initiates a new block whenever it receives a message whose *color* is equal to the current value of *token_color*. In every atomic step in which the sender receives a message whose *color* is not equal to *token_color*, it sends a message—say M'—whose color is *token_color*. Since the link carries messages in FIFO order, the message M is eventually received by the sender and it initiates a new block not later than upon receipt of M. The lemma follows. □

A configuration in an execution is called a *limit configuration* if in the next step of the sender, a new *token_color* is computed; that is, the color of the next arriving message is equal to the present value of *token_color*. Observe that at a limit configuration c, the link contains a finite (possibly zero) number of complete blocks and one possibly incomplete block at the tail of the link. (This block may be incomplete since upon receipt of the next message, the sender may send one more message in this block by executing line 5 of the code.) The first block has the same color as the last (possibly incomplete) block. For an execution E, we denote by i_k the index of the kth limit configuration in E. In other words, c_{i_k} is the limit configuration just before b_k is initiated.

Next, we prove that the number of blocks in consecutive limit configurations does not increase.

LEMMA 4.2. *Let ℓ_k be the number of blocks in the limit configuration c_{i_k} (including the possibly incomplete block). Then $\ell_k \geq \ell_{k+1}$ with equality only if s_k is a single block.*

Proof. Let $m_k \geq 1$ be the number of blocks in s_k. In the subexecution starting with c_{i_k} and ending with $c_{i_{k+1}}$, one block is added to the link (namely b_k), and m_k

blocks of s_k are removed from it. Therefore, $\ell_{k+1} = \ell_k + 1 - m_k \leq \ell_k$. □

Next, we show that the number of blocks in the limit configurations must eventually get down to one. First, we need a technical lemma.

LEMMA 4.3.

(a) *The sequence xor is aperiodic.*

(b) *Let $(a_1, a_2, \ldots)$ be an eventually periodic sequence, and let $b_i = a_{i+1} - a_i$. Then the sequence $B = (b_1, b_2, \ldots)$ is also eventually periodic.*

(c) *Let $(a_1, a_2, \ldots)$ be an eventually periodic sequence. Then for each $i, p > 0$, the sequence $A(i,p) = (a_i, a_{i+p}, a_{i+2p}, \ldots)$ is also eventually periodic.*

Proof. (a) Assume in contradiction that the sequence $xor = (xor(1), xor(2), \ldots)$ is eventually periodic. Then there exist i and ℓ such that $xor(j) = xor(j + \ell)$ for every $j \geq i$. Let q be a nonnegative integer such that $2^q \leq \ell < 2^{q+1}$ and let d be an integer satisfying $d \geq q + 2$ and $2^d \geq i$. Consider the following cases:

- $xor(\ell) = 1$: By the definition of d, it holds that $xor(2^d + \ell) = 0$. Thus $1 = xor(2^d) \neq xor(2^d + \ell) = 0$.
- $xor(\ell) = 0$: Then $xor(\ell) = xor(2^q + \ell) = 0$, and $2^q + \ell < 2^d$. Hence $xor(2^d + 2^q + \ell) = 1$. Thus $0 = xor(2^d + 2^q) \neq xor(2^d + 2^q + \ell) = 1$.

Thus there exist a and b such that (1) $a > i$ and $b > i$, (2) $a - b = \ell$, and (3) $xor(a) \neq xor(b)$—a contradiction.

(b) This claim is trivial.

(c) Let j and ℓ be such that $xor(k) = xor(k + \ell)$ for every $k \geq j$. Then for every $p > 1$ and $k \geq j$, it holds that $a_k = a_{k+\ell p}$. Thus the sequence $A(i,p)$ is eventually periodic with period length $\leq \ell$. □

LEMMA 4.4. *In every fair execution E, there exists a suffix in which the number of blocks in the limit configurations is always one.*

Proof. By Lemma 4.2, this number never increases, and hence it eventually remains L for some constant $L > 0$ forever. We shall assume that $L > 1$ and derive a contradiction.

Call a limit configuration c_{i_k} *ultimate* if ℓ_k, the number of blocks in c_{i_k} is L. If c_{i_k} is ultimate, then $\ell_{k+1} = \ell_k$ and hence by Lemma 4.2, s_k is a single block, which must be b_{k-L}. Thus the first block that follows s_k is b_{k-L+1}. By the protocol, b_k is terminated when the sender receives a message whose color is equal to the color of b_k. Therefore, we have that the color of (the messages in) the block b_{k-L+1} is equal to the color of the messages in b_k, i.e., $color(b_{k-L+1}) = color(b_k)$. Hence the sequence $COLORS = (color(b_1), color(b_2), \ldots)$ is eventually periodic with period length $L - 1 > 0$. Let $BXOR = (xor(N(b_1)), xor(N(b_2)), \ldots)$. By the way in which $color(b_{k+1})$ is computed, we have that for an ultimate configuration c_{i_k}, $xor(N(b_k - L)) - [color(b_{k+1}) - color(b_k)] \pmod 3 - 1$. Hence by Lemma 4.3(b), if $COLORS$ is eventually periodic, so is $BXOR$. We shall derive a contradiction by showing that the sequence $BXOR$ is aperiodic.

Lemma 4.3(c) implies that in order to show that $BXOR$ is aperiodic, it is sufficient to show that for some positive i and p, the sequence $BXOR(i,p) = (xor(N(b_i)), xor(N(b_{i+p})), xor((N(b_{i+2p})), \ldots)$ is aperiodic. For this observe that for an ultimate configuration c_{i_k}, it must hold that $N(b_k) = N(s_k) + 1 = N(b_{k-L}) + 1$. Hence for any integer i, we have that $BXOR(i,L) = (xor(N(b_i)), xor(N(b_{i+L})), xor((N(b_{i+2L})), \ldots) = (xor(N), xor(N+1), xor(N+2), \ldots)$, where $N = N(b_i)$. Thus $BXOR(i,L)$ is a suffix of the sequence xor, which is aperiodic by Lemma 4.3(a). Hence $BXOR(i,L)$ is also aperiodic. This yields the desired contradiction. □

Lemma 4.4 and its proof imply that properties (p1) and (p2) hold. Property (p1)

holds since the proof of Lemma 4.4 shows that the sequence $COLORS$ is aperiodic. Property (p2) is proved as follows: Let E' be a suffix of E satisfying Lemma 4.4, and let c_{i_k} be any limit configuration in E'. Then by Rule 1, $N(b_{k+1}) = N(s_{k+1}) + 1 = N(b_k) + 1$, which easily implies (p2).

We now show that the space complexity of Protocol 3 indeed matches the lower bound of the previous section. Since both the number of states of a processor and the number of distinct messages in our protocol are constants, the size of a configuration is proportional to the number of messages in it. Therefore, to bound the size of a configuration from above, it is enough to bound the number of messages in it. In the next lemma we show that for each execution $E = (c_0, a_1, c_1, \ldots)$ of the protocol, the size of the ith configuration of E, c_i, is $O(\log_2(i))$. Let c_{i_k} denote the kth limit configuration of E, and let b_k be the corresponding block. We shall prove that $|b_k| = O(\log k)$.

LEMMA 4.5. *For every large enough k, the number of messages in the limit configuration c_{i_k} is $\lceil \log_2 N(b_{k-1}) \rceil$.*

Proof. By Lemma 4.4, there exists a suffix E' of E such that every limit configuration in E' contains one block. Clearly, it is suffices to prove the lemma for E'. As observed above, property (p2) eventually holds for every limit configuration in E'. The lemma follows. □

COROLLARY 4.6. *The number of messages in c_ℓ, the ℓth configuration of E, is $O(\log_2(\ell))$.*

Proof. Let E' be a suffix of E as in Lemma 4.5, and assume that ℓ is large enough so that c_ℓ belongs to E'. Then the number of messages in c_ℓ is equal to the number of messages in the next limit configuration, c_{i_k}, which is $O(\log_2 k)$ (for some k). The proof is completed by the observation that since $i_j \geq j$ for all j and since configuration $c_{i_{k-1}}$ precedes c_ℓ in E, we have that $\ell \geq i_{k-1} + 1 \geq (k-1) + 1 = k$. □

4.4. Larger systems. We now describe how to use our protocols in directed rings with more than two processors. The processors of the ring are denoted by $P_1, \ldots, P_n$, where P_1 is a sender while $P_2, \ldots, P_n$ are receivers. Whenever a processor P_i, $1 < i < n$, receives a message M from P_{i-1}, P_i sends M to P_{i+1}. Similarly, whenever P_n receives a message M from P_{n-1}, it sends M to P_1. Thus the ring behaves like a virtual link from the sender P_1 to itself. It is not hard to see that the existence of a single message on the entire ring prevents communication deadlocks; thus we assume that there is a time-out mechanism that guarantees this condition (this time-out mechanism is invoked only once to recover from the initial deadlock configuration). It can be proved in a way similar to our previous proofs that our protocols guarantee that there is eventually exactly one token that encircles the ring from the sender to itself. Actually, our protocols can be used in any connected system by hardwiring a directed ring that spans the entire system.

4.5. Construction of a token controller. In this subsection, we define queue machines and token controllers and interpret our results in these terms.

A *queue machine* Q is a finite-state machine which is equipped with a queue, which initially contains a nonempty word from Σ^+ for some (finite) alphabet Σ. In each step of its computation Q performs the following: (a) reads and deletes a letter from the head of the queue, (b) adds zero or more letters from Σ to the tail of the queue, and (c) moves to a new state. The computation terminates when Q halts or when its queue becomes empty, which prevents Q from performing any further steps.

The main difference between queue machines and various types of Turing machines is that the input alphabet and the work alphabet of a queue machine are identical.

For this reason, a queue machine cannot perform simple tasks like deciding the length of the input word or even deciding whether the input word contains a specific letter.[2]

We now define a *token controller*, which is a special type of queue machine. Assume that the alphabet Σ contains a specified subset τ of *token letters*. A queue machine is a *token controller* if, starting with a nonempty queue of arbitrary content, the queue eventually contains exactly one occurrence of a letter from τ forever.

A priori, it is not clear that a token controller exists. Observe that if a token controller exists, then its queue never becomes empty (since once the queue is empty, it remains so forever). More importantly, a token controller (if it exists) can never halt since it cannot guarantee that upon halting, the queue contains exactly one occurrence of a token letter. The last two observations imply that a token controller can be viewed as a special case of a token-passing system in which Σ is the set of messages sent by the protocol and τ is the set of messages that carry the token. We show below how to transform the sender from Protocol 3 to a token controller.

Define the alphabet Σ to be a set of triplets $(color, bit, t)$, where *color* and *bit* are as in Protocol 3 and t is either T in case the message carries a token (i.e., it is the first message of some block) or *nil* in case it does not. The set τ is defined as the set of all possible triplets whose third component is T. The two antiparallel FIFO links between the sender and the receiver are considered as a single queue. Receiving a message is regarded as deleting a letter from the head of the queue, while sending a message is regarded as appending a message to the end of the queue.

Since Protocol 3 guarantees that eventually exactly one message in every configuration is carrying a token, the queue machine described above is a token controller. Moreover, our lower bound results imply that this token controller is optimal with respect to the rate in which the size of the queue grows.

5. Self-stabilizing simulation of shared memory. In this section, we present a method for simulating self-stabilizing shared-memory protocols by self-stabilizing message-driven protocols. The simulated protocols are assumed to be in the shared-memory model defined in [9]. In this model, communication between neighbors P_i and P_j is carried out using a two-way link. The link is implemented by two shared registers which support **read** and **write** atomic operations. Processor P_i reads from one register and writes in the other while these functions are reversed for P_j. In the implementing system, every link is simulated by two directed links: one from P_i to P_j and the other from P_j to P_i. The heart of the simulation is a self-stabilizing implementation of the **read** and **write** operations.

The proposed simulation implements these operations by using a self-stabilizing token-passing protocol. For any pair of neighbors, we run the protocol on the two links connecting them. In order to implement our self-stabilizing token-passing protocol, we need to define for each link which of the processors acts as the sender and which of the processors acts as the receiver. We assume that the processors have distinct identifiers. Every message sent by each of the processors carries the identifier of that processor. Eventually, each processor knows the identifier of all its neighbors. In each link, the processor with the larger identifier acts as the sender while the other processor acts as the receiver. Since each pair of neighbors uses a different instance of the protocol, a separate time-out mechanism is needed for every such pair. In other words, a correct operation of the simulation requires that for any pair of neighbors,

[2] A variant of queue machine which can use arbitrary work alphabet is, in fact, an oblivious Turing machine, which is as powerful as a standard Turing machine.

there exists at least a single message on one of the two links connecting the neighbors.

We now describe the simulation of some arbitrary link e connecting P_i and P_j: In the shared-memory model, e is implemented by a register $R_{i,j}$ in which P_i writes and from which P_j reads and by a register $R_{j,i}$ for which the roles are reversed. In the simulating protocol, processor P_i (P_j) keeps a local variable called $r_{i,j}$ ($r_{j,i}$), which keeps the values of $R_{i,j}$ (respectively, $R_{j,i}$). Every token has an additional field called *VALUE*. Every time P_i receives a token from P_j, P_i writes the current value of $r_{i,j}$ in the *VALUE* field of that token. A **write** operation of P_i into $R_{i,j}$ is implemented simply by locally writing into $r_{i,j}$. A **read** operation of P_i from $R_{j,i}$ is implemented by the following steps:

1. P_i receives a token from P_j and then
2. P_i receives another token from P_j. The value read is the *VALUE* attached to the second token.

The correctness of the simulation is proved by showing that for every execution E whose initial configuration contains at least one message on each link, it is possible to linearize all the simulated **read** and **write** operations executed in E so that eventually every simulated **read** operation from $R_{i,j}$ returns the last value that was written to it (i.e., that the protocol simulates executions in the shared-memory model in which the registers are eventually atomic; see [20]). Define the time of a simulated **write** operation to $R_{i,j}$ to be the time in which the local write operation to $r_{i,j}$ is executed. Define the time of a simulated **read** operation of P_j from $R_{i,j}$ to be the time in which P_i sends the value of its local variable $r_{i,j}$ attached to the token that later reaches P_j in step 2 of the simulated **read**. Once each link holds a single token, all of the operations to register $r_{i,j}$ are linearized, and every read operation from $r_{i,j}$ returns the last value written to $r_{i,j}$.

Acknowledgment. We thank Alan Fekete for helpful remarks.

FAIL-STOP SIGNATURES*

TORBEN PRYDS PEDERSEN† AND BIRGIT PFITZMANN‡

Abstract. Fail-stop signatures can briefly be characterized as digital signatures that allow the signer to prove that a given forged signature is indeed a forgery. After such a proof has been published, the system can be stopped. This type of security is strictly stronger than that achievable with ordinary digital signatures as introduced by Diffie and Hellman in 1976 and formally defined by Goldwasser, Micali, and Rivest in 1988, which was widely regarded as the strongest possible definition.

This paper formally defines fail-stop signatures and shows their relation to ordinary digital signatures. A general construction and actual schemes derived from it follow. They are efficient enough to be used in practice. Next, we prove lower bounds on the efficiency of any fail-stop signature scheme. In particular, we show that the number of secret random bits needed by the signer, the only parameter where the complexity of all our constructions deviates from ordinary digital signatures by more than a small constant factor, cannot be reduced significantly.

Key words. cryptography, authentication, digital signatures, fail-stop, discrete logarithm, factorization, randomization, computational security, information-theoretic security

1. Introduction and overview of results.

Traditional digital signatures, as introduced in [12] and formally defined in [20], allow a person, A (for Alice), to make signatures that everyone who knows A's public key can test. Such signatures are only computationally secure for the signer because they can be forged by persons with sufficiently large computing power. A person able to factor large integers can, for example, very easily forge RSA (Rivest–Shamir–Adleman) signatures (see [38]). Hence the security of these schemes relies on a computational assumption. Moreover, if a signature should be forged, it will be difficult for A to convince the bearer of the signed document or a third party that she did not make that signature.

Fail-stop signatures solve this problem by offering the signer a method for proving that a forgery has taken place. More precisely, even if a forger with unlimited com-

*Received by the editors March 11, 1993; accepted for publication (in revised form) April 3, 1995. This paper is the full version of the extended abstracts [E. van Heyst and T. P. Pedersen, "How to make efficient fail-stop signatures," in *Proc.* 1992 *Eurocrypt*, Lecture Notes in Comput. Sci. 658, Springer-Verlag, Berlin, 1993, pp. 366–377] and [E. van Heijst, T. P. Pedersen, and B. Pfitzmann, "New constructions of fail-stop signatures and lower bounds," in *Proc.* 1992 *Crypto*, Lecture Notes in Comput. Sci. 740, Springer-Verlag, Berlin, 1993, pp. 15–30] together with the definitions of fail-stop signatures, including their relations to ordinary digital signatures. A preliminary version of the definitions was only available in "grey" literature as parts of [B. Pfitzmann, "Für den Unterzeichner unbedingt sichere digitale Signaturen und ihre Anwendung," Diploma thesis, Institut für Rechnerentwurf und Fehlertoleranz, Universität Karlsruhe, Karlsruhe, Germany, 1989] and [B. Pfitzmann and M. Waidner, "Formal aspects of fail-stop signatures," Technical Report 22/90, Fakultät für Informatik, Universität Karlsruhe, Karlsruhe, Germany, 1990]. Several intermediate papers with previous, less efficient constructions and discussions of applications are only referred to.

puting power makes an "optimal" forgery, a polynomially bounded signer can prove that the underlying computational assumption has been broken when she sees the forgery (except with negligible probability). Thus the signer can be protected from an arbitrarily powerful forger. Moreover, after the first forgery, all participants, or the system operator, know that the signature scheme has been broken, so that it can be stopped. Hence the name "fail-stop."

1.1. More about ordinary digital signatures. Digital signatures were introduced in [12] and became popular with the RSA scheme [38]. However, it was subsequently discovered that the security requirements made in [12] were too weak, and the structure of signature schemes described there did not allow the desired stronger security. A satisfactory definition was finally published in [20], together with a construction that is secure in this sense (see [20] for the intermediate history). We call such signature schemes "ordinary."

However, the notion of security was always only computational. For signature schemes of the original structure, [12] already showed that this is unavoidable: The signer has a secret key, which she uses to make signatures, and the signatures can be tested by everyone who knows her corresponding public key. Since signing and testing are polynomial-time, one can forge signatures, i.e., find values that pass the test, in nondeterministic polynomial time simply by guessing among all values up to a certain length. Additionally, nonpolynomial lower bounds for problems within NP are not known; hence to prove the security of any ordinary digital signature scheme, one has to make a computational assumption. The same argument also applies to the more general construction in [20]. Hence the effort in the theoretical treatment of signature schemes after [20] concentrated on weakening the necessary assumptions [1, 30, 39].

Note, additionally, that with ordinary digital signatures, it is always the signer whose security relies on the computational assumption. If the signer were allowed to disavow forged signatures, she could also disavow her real signatures (because there is no difference between them), even if the assumption was not broken at all. The recipient's security is unconditional, i.e., all signatures that he has accepted will definitely also be accepted by any third party asked to settle a dispute.

1.2. More about the fail-stop property. The fail-stop property can best be described by considering a judge in a dispute between the signer and a recipient of a digital signature. Usually, the judge will test if the signature is correct and give his verdict—"ok" or "not ok"—accordingly. Fail-stop signatures supply the judge with a third possibility: If the signer can prove that the signature is forged, the judge may say "forgery proved," which can be interpreted as saying that the basic assumption of the system has been broken. Naturally, this possibility of distinguishing forged signatures from authentic signatures only exists as long as the forger has not stolen the signer's key.

The definition of fail-stop signatures does not specify for how much of a system a particular proof of forgery is valid. As long as forging a single signature is provably as hard as breaking a particular computational assumption, it is wise to stop the whole system after any forgery because if one signature could be forged, one must expect that the same forger can make more forgeries. Therefore, the constructions usually assume that there is only one type of proof of forgery. However, it is no problem to make proofs of forgery specific to the keys of individual signers or even (although currently with some loss in efficiency) to each particular signature.

Furthermore, it is not a matter of the definition how one acts after the output "forgery proved." In particular, one obtains exactly the properties of ordinary digital signatures again if the technical verdict "forgery proved" is interpreted just like "signature correct" by the judge and everybody else. On the other hand, if it is agreed that all signatures for which forgery can be proved are rejected, one obtains a signature scheme in which the signer is unconditionally protected against forgeries, whereas the recipient is only computationally protected, i.e., an unrestricted adversary may achieve that a signature accepted by the recipient is later rejected by an honest judge. We call such a signature scheme a "dual signature scheme" because it is dual to ordinary digital signatures with respect to the security for the signer and recipients. Hence fail-stop signatures constitute the first (published) examples of dual signature schemes. Since fail-stop signatures furthermore allow the system to be stopped as soon as the basic assumption has been broken, they are a strictly stronger notion than each of these types of signatures.

As an example where fail-stop signatures, in their special role as dual signatures, may be advantageous, consider an electronic payment system where a customer signs her requests to the bank digitally. Since the bank most likely has much more computing power than the customer and since it can select the system and choose the security parameters, it is reasonable to protect the customer unconditionally, whereas the bank can rely on the customer not having sufficient computing power to repudiate her signatures. Thus the customer should sign with dual signatures and the bank with ordinary digital signatures. For more details about possible benefits of fail-stop signatures and possible advantages for the acceptability of digital signatures in law, see [36, 32].

1.3. Construction idea. Fail-stop signatures work very much like ordinary digital signatures. The signer has a secret key, which she uses to make signatures, and the signatures can be tested by everyone who knows her corresponding public key. A signature that passes this test is called *acceptable*. Now, the basic idea of the existing constructions of fail-stop signatures is that every message has many different acceptable signatures, of which the signer can only construct one (unless she breaks the underlying assumption); this one is called the *correct* signature. However, even an arbitrarily powerful forger does not have sufficient (Shannon) information to determine which of the many acceptable signatures is the correct signature on a new message. Consequently, with very high probability, a forged signature is different from the correct signature. Given a forged signature, the signer can exploit the knowledge of two different signatures on the same message (the forged signature and the correct one) to compute a proof of forgery.

Note that this construction allows an unrestricted signer to disavow her real signatures. However, since this can only occur if the computational assumption has in fact been broken, this is no problem. A proof of forgery does not indicate by *whom* the assumption has been broken, and hence it may have been the signer; but in any case, if this has happened, the system should be stopped.

1.4. Previous results. Fail-stop signatures were first mentioned in [43], and in the reports [31, 35], it was proved that such signatures exist if claw-free pairs of permutations exist; this is a computational assumption known from [20] (see also [4, 36] for descriptions). In particular, this shows that fail-stop signatures exist if factoring large integers or computing discrete logarithms is hard. The construction uses one-time signatures, similar to [25], i.e., messages are basically signed bit by bit.

Therefore, although messages can be hashed before signing and tree authentication is used (similar to [26]), this general construction is not very efficient.

In [32], an efficient variant especially suited for making customers unconditionally secure in on-line payment systems was presented. However, in this scheme, all signatures by one customer with the same key must have the same recipient (e.g., the bank in a payment system), and it is only a dual signature scheme, not a fail-stop signature scheme. Furthermore, signing is a three-round protocol between the signer and the recipient.

1.5. Related types of schemes. In [8], a dual undeniable signature scheme was presented. Undeniable signatures, introduced in [7], are a type of signature in which there is no public predicate that everyone can use to test signatures. Instead, signatures are verified and disavowed using interactive protocols that must be carried out with the signer. This construction was the first signature scheme to achieve unconditional security for signers without bit-by-bit signing. However, it is not as efficient as the following schemes. Although the signatures themselves are efficient, the verification protocol requires quite a lot of computation because it needs σ challenges (similar to signatures) to achieve an error probability of $2^{-\sigma}$. A similar scheme, but with so-called convertible undeniable signatures (cf. [5]), is contained in [22].

In [9], unconditionally secure signatures were introduced, i.e., signature-like schemes where both the signer and the recipients are unconditionally secure. In [37], a transferable version was presented, i.e., signatures can be passed on from one recipient to another. With this extension, unconditionally secure signatures could in principle replace other signatures in many applications. However, these constructions are too inefficient to be used in practice because they require a complicated interactive key-generation protocol and the signatures are very long. We showed in [23] (proofs in [34]) that the latter is unavoidable: to achieve an error probability of $2^{-\sigma}$, the length of unconditionally secure signatures that can be tested by M participants, including those that only have to settle disputes, is at least $M \cdot \sigma$.

1.6. Results in this paper. This paper presents fail-stop signatures in a unified way by giving definitions, efficient constructions, and lower bounds. Preliminary versions of the definitions appeared in [31, 35], and preliminary versions of the constructions and lower bounds appeared in [22, 23].

Definition (see section 3). The formal definition of fail-stop signatures is somewhat more general than that in the report [35] because it allows a more general method for key generation and more memory in the signing algorithm. This increases the scope of validity of the lower bounds.

Constructions (see sections 4 and 5). The first step in our constructions of fail-stop signatures is a general construction based on the concept of bundling homomorphisms, which allows only one message to be signed. This construction has as special cases the two schemes from the extended abstracts [22, 23], which we describe. Signing in the first of these two schemes requires two modular multiplications, whereas signing in the second requires approximately one exponentiation. In both schemes, testing a signature requires approximately two exponentiations. Thus these signatures compare very well with the currently proposed ordinary digital signatures. We then show extensions for signing an arbitrary number N of messages. In special cases, no efficiency is lost; in the general case, the length of signatures and the time needed for testing signatures on short messages grow by a factor of $\log(N)$.

Lower bounds (see section 6). Based on the definition of fail-stop signatures, we prove lower bounds on the size of the keys and the size of fail-stop signatures. For

these bounds, we assume that the probability that a forgery cannot be repudiated is smaller than $2^{-\sigma}$ for some security parameter σ and that the recipients have a similar level of security against very simple brute-force algorithms. Then the most important result is as follows:

- If N messages are to be signed, the signer needs at least $(N+1)(\sigma-1)$ secretly chosen random bits.

Thus the secret key in fail-stop signature schemes is basically a one-time key. However, this does not prevent efficient fail-stop signatures where many messages can be signed: We present an efficient construction where the size of the secret storage space is logarithmic in the number of messages to be signed, and an otherwise less efficient variant where this size is constant. This does not contradict the lower bounds because many secret bits can be deleted soon after they have been generated and used, i.e., the stored secret key varies with time. These constructions with small secret storage are important because secret storage is quite hard to realize since one needs a tamper-resistant device.

Additionally, we show the following:

- The entropy, and hence the length, of a signature is at least $2\sigma - 1$, and the entropy of the public key is at least σ.

These bounds are not much larger than similar bounds for ordinary digital signatures because they concern parameters where the difference between fail-stop signatures and ordinary digital signatures is quite small.

A comparison of the efficient constructions of fail-stop signatures with the lower bounds on unconditionally secure signatures mentioned in section 1.5 shows that fail-stop signatures provide the most viable way of protecting the signer unconditionally.

2. Notation. For a given probability space S (which will always be clear from the context), $\mathrm{P}(E)$ denotes the probability of the event E, and $[S]$ denotes the set of elements with positive probability. Choosing a value from S and assigning it to a variable, x, is denoted by $x \leftarrow S$.

If a is a probabilistic algorithm, $a(i)$ denotes the probability space defined by running a on input i. If $a_1, \ldots, a_n$ are n probabilistic algorithms and p is an n-ary predicate ($n \in \mathbb{N}$), then $\mathrm{P}(p(x_1, \ldots, x_n) :: x_1 \leftarrow a_1(i_1); \ldots; x_n \leftarrow a_n(i_n))$ denotes the probability that the predicate $p(x_1, \ldots, x_n)$ is true after the result of running a_j on input i_j has been assigned to x_j, for $j := 1, 2, \ldots, n$ (in this order). We also allow assignments from other probability spaces, like $x_j \leftarrow S_j$, in such a formula.

The notion "for k sufficiently large" means "$\exists k_0 \forall k \geq k_0$." The characteristic function of a predicate *pred* is denoted by 1_{pred} and the length of a string by $|\cdot|$. The length of a number is the length of the binary representation of that number. This is denoted by $|\cdot|_2$.

The ring of integers modulo a number n is denoted by $\mathbb{Z}_n$, and its multiplicative group, which contains only the integers relatively prime to n, by $\mathbb{Z}_n^*$.

3. Definition of fail-stop signatures. Briefly, a digital signature scheme is defined by three algorithms (see [20]),

1. a key generator,
2. a method for signing, and
3. a method for testing signatures,

such that if the keys are generated correctly using the key generator, then we have the following:

- If the signer signs a message correctly, everyone who knows the signer's public key accepts the signature.

• A polynomially bounded forger cannot make any signature that passes the signature test.

In a fail-stop signature scheme, a protocol is added that allows the (polynomially bounded) signer to prove to third parties that a forged signature is indeed a forgery. It consists of two more algorithms:

4. a method for constructing proofs of forgery, and
5. a method for verifying proofs of forgery (which everyone who knows the public key can carry out).

A proof of forgery is always noninteractive so that it can subsequently be shown to others, and the system can be stopped in consensus. The proof must satisfy two new security requirements:

• The ability to prove forgeries must work independently of the computing power of potential forgers.

• It must be infeasible for the signer to construct signatures that she can later prove to be forgeries.

It can be shown that these two properties imply security against forgery (see section 3.2); hence this security is omitted in the formal definitions.

Until now, nothing has been said about the generation of the secret and public key. In an ordinary digital signature scheme, the primary purpose of the secret key is to enable the signer to make signatures that nobody else can construct, and this key is therefore chosen by either the signer herself or a key-authentication center trusted by the signer. Since it is equally important that fail-stop signatures cannot be forged, the signer still has to take part in choosing the keys. However, since the signer in these schemes is allowed to repudiate (forged) signatures despite the fact that they pass the public signature test, the recipients of signatures must be sure that the signer cannot disavow her own signatures. It is therefore necessary that the recipients or a center trusted by the recipients also participate in the key generation. In particular, such a center is needed if the recipients are not known at the time of choosing the keys. When the signer's public key has been selected, it will usually be stored in a public directory with accepted integrity.

In the following, we first formalize the definition for the case where the signer and a center generate the keys (section 3.1). Section 3.2 shows that every scheme satisfying this definition is secure against forgery, and section 3.3 discusses how the recipients can participate in the key generation.

3.1. Definition. In this section, we consider the situation where the signer and an entity trusted by the recipients generate the keys. This entity is called the *center* and denoted by C.

It should be noted that we use uniform complexity. In particular, the computational assumptions in the next section are described uniformly. It is not difficult to modify the definitions in order to cope with nonuniform complexity, and reductions in the uniform model are automatically valid in the nonuniform model as well.

The security of a cryptographic scheme is usually determined by a security parameter, which specifies the size of the instances of the hard problem used. A fail-stop signature scheme can be broken by either the signer, if she succeeds in constructing a signature that she can later prove to be a forgery, or a forger, if he succeeds in constructing a false signature that the signer cannot repudiate. Since these two attacks have completely different consequences for the participants, it is natural to define the security parameter of a fail-stop signature scheme as a pair (k, σ) of positive integers, where k measures the (computational) security for the recipients and σ determines

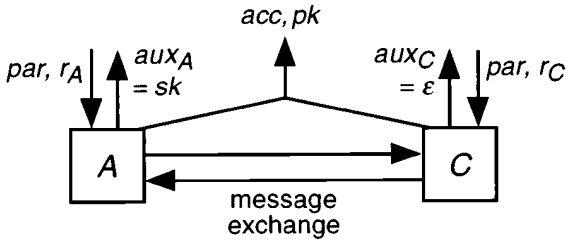

FIG. 1. *Notation used for a correct execution of the key generation G.*

the (unconditional) security for the signer. As is common practice, we shall implicitly assume that these security parameters are represented in unary whenever they are input to an algorithm or protocol.

We allow signing and proving forgeries to be probabilistic and to depend on the history of previously given signatures. Actually, the signatures in our constructions depend only on the *number* of previous signatures. However, the general definition ensures that the lower bounds in section 6 are valid for everything that might reasonably be called a fail-stop signature scheme. We cover all these cases by regarding the random bits as part of the secret key and signing as a deterministic function of the secret key and the sequence of all (previous) messages. This will simplify the notation.

The number of the current message is usually denoted by $i \in \mathbb{N}$.

In addition to σ and k, a fail-stop signature scheme has a parameter $N \in \mathbb{N}$, which is the maximal number of signatures that the signer is willing to construct using the same secret key (hence $1 \leq i \leq N$). As with the security parameters, it is assumed that N is always represented in unary. We often write $par := (k, \sigma, N)$ as an abbreviation of these three parameters.

DEFINITION 3.1. *A* fail-stop signature scheme (*abbreviated* FSS scheme) *with message space* $M \subseteq \{0,1\}^+$ *is a* 5*-tuple* (*G, sign, test, prove, verify*)*, where we have the following:*

- *G is a polynomial-time two-party protocol for generating the keys. The protocol is executed by the signer, A, and C, who both get par as input. Furthermore, each party has a secret random string,* r_A *and* r_C*, respectively. The participants each have a private output channel and there is a* (*broadcast*) *channel for common outputs; see Figure* 1*. The common output is* (acc, pk)*, where* $acc \in \{accept, reject\}$ *and pk is the public key* (*only well defined if* $acc = accept$)*. The common broadcast channel can be realized with a usual broadcast channel if one participant outputs pk and the other outputs acc. We generally denote the outputs on the private output channels of the two participants by* aux_A *and* aux_C*, respectively, and we say that G outputs* (acc, pk, aux_A, aux_C)*. If A is executed correctly,* aux_A *is simply the secret key, denoted by sk. If C is executed correctly,* aux_C *is the empty string,* ε*.*

- *sign is a polynomial-time algorithm that on input the secret key, a message number i, and a message sequence* $\underline{m} = (m_1, \ldots, m_i)$ *from M constructs a signature on* m_i*. Thus sign*(*sk, i,* $\underline{m}$) *denotes the signature on* m_i *if the previously signed messages were* $m_1, \ldots, m_{i-1}$*, and all random bits used are regarded as part of sk* (*and thus originally of* r_A)*. It is called the* correct *signature.*

- *test is a polynomial-time algorithm that on input the public key, a message* $m \in M$*, and a possible signature s on m outputs either ok or notok. If test*$(pk, m, s) =$ *ok, we say that s is an* acceptable *signature on m.*

• *prove is a polynomial-time algorithm that on input the secret key, a message* $m \in M$*, a possible*[1] *signature* s *on* m*, and the history hist of previously signed messages* (*plus their signatures*) *either outputs the string "not a forgery" or a bit string proof* $\in \{0,1\}^*$.

• *verify is a polynomial-time algorithm that on input the public key, a message* $m \in M$*, a possible signature* s *on* m *and a string proof outputs either accept or reject. If the result is accept, the string proof is called a valid proof of forgery.*

This 5*-tuple must satisfy the following basic correctness property* (*security is defined separately*)*. For all* $k, \sigma, N \in \mathbb{N}$*, if* A *and* C *follow the computations prescribed by* G*, each output* $(acc, pk, sk, \varepsilon)$ *of* G *satisfies* $acc =$ *accept and for all message numbers* $i \in \{1, \ldots, N\}$ *and message sequences* $\underline{m} = (m_1, \ldots, m_i)$ *from* M*,*

• *if* $s = sign(sk, i, \underline{m})$*, then* $test(pk, m_i, s) = ok$*, i.e., correct signatures are acceptable.*

The output "*not a forgery*" of *prove* signals that *prove* is not able to construct a valid proof of forgery.

Note that *test* and *verify* are not as general as *sign* and *prove* because we have not allowed them to depend on the history of previous signatures: In general, all signatures may go to different recipients. Hence one cannot assume that a recipient (or a verifier) knows anything about the history. Everything he has to know must therefore be included in the signature. One can make an exception only in applications where all signatures of one signer have a fixed recipient or very few recipients.

Before continuing, we introduce some notation to be used with the key-generation protocol. A signer or center who does not necessarily follow the prescribed protocol is denoted by $\tilde{A}$ or $\tilde{C}$, respectively. $G_{\tilde{A},C}$ and $G_{A,\tilde{C}}$ denote the resulting protocols, and $aux_{\tilde{A}}$ and $aux_{\tilde{C}}$ the private outputs. A cheating participant can also use the input par. We denote by $G_{\tilde{A},C}(par)$ the distribution of the outcome of $G_{\tilde{A},C}$ over the random bits r_C of C and $r_{\tilde{A}}$ of $\tilde{A}$ if the common input is par. Similarly, $G_{A,\tilde{C}}(par)$ denotes the distribution of the outcome of $G_{A,\tilde{C}}$.

DEFINITION 3.2. *An FSS scheme is* secure for the recipients *iff the following holds for all probabilistic polynomial-time algorithms* $\tilde{A}$ *and* $\tilde{A}^*$ (*representing the two steps of an attacking signer*)*: If* C *follows the prescribed protocol in an execution of* G *with* $\tilde{A}$ *and if* $\tilde{A}^*$*, on input the private output* $aux_{\tilde{A}}$ *of* $\tilde{A}$*, constructs a triple* $(m, s,$ *proof*)*, then the probability that proof is a valid proof of forgery tends to zero faster than the inverse of any polynomial in* k*. This probability is over the random* (*uniformly distributed*) *choices of* r_C*,* $r_{\tilde{A}}$ *and the random choices used in* $\tilde{A}^*$*.*

More formally, $\forall \tilde{A}$ *and* $\tilde{A}^*$ (*probabilistic polynomial-time*)*,* $\forall \sigma$*,* N*, and* c*, and for* k *sufficiently large,*

$$\mathrm{P}(acc = accept \wedge verify(pk, m, s, proof) = accept :: \\ (acc, pk, aux_{\tilde{A}}, \varepsilon) \leftarrow G_{\tilde{A},C}(par); (m, s, proof) \leftarrow \tilde{A}^*(aux_{\tilde{A}})) < k^{-c}.$$

(*Remember:* $par = (k, \sigma, N)$.)

We now turn to the definition of the security for the signer. Since we have not required that the signer trusts the center, she should be protected no matter what the center does in the key-generation protocol as long as she follows the protocol herself. Furthermore, the purpose of fail-stop signatures is that the signer should be secure

[1]The algorithm is primarily intended to be used on acceptable signatures. However, it is more convenient for the notation to define it more generally. If s is not an acceptable signature, the output will usually be "*not a forgery.*"

even against arbitrarily powerful forgers. We therefore consider arbitrarily powerful centers $\tilde{C}$. Remember that $[G_{A,\tilde{C}}(par)]$ denotes the set of possible outcomes of the protocol if *par* is given.

DEFINITION 3.3. *Let an FSS scheme with message space $M \subseteq \{0,1\}^+$ and parameters $par = (k, \sigma, N)$ be given, and consider an arbitrarily powerful center $\tilde{C}$. If A and $\tilde{C}$ have executed G and the outcome was $(acc, pk, sk, aux_{\tilde{C}})$ with $acc = accept$, we define the following:*

(a) *The set of possible* histories *is*

$$Hist(sk) := \{((m_1, \ldots, m_j), (s_1, \ldots, s_j)) | 1 \le j \le N \\ \wedge\ (m_i \in M \wedge s_i = sign(sk, i, (m_1, \ldots, m_i)) \text{ for } i = 1, \ldots, j)\}.$$

For a given history hist, let $M(hist)$ denote the set of sign messages in hist.

(b) *The set of* possible secret keys (*from the point of view of an unrestricted forger*) *given $pk, aux_{\tilde{C}}$, and a history hist is*

$$SK_{\tilde{C}}(pk, hist, aux_{\tilde{C}}) \\ := \{sk | (accept, pk, sk, aux_{\tilde{C}}) \in [G_{A,\tilde{C}}(par)] \wedge hist \in Hist(sk)\}.$$

$SK_{\tilde{C}}(pk, hist, aux_{\tilde{C}})$ is equipped with a distribution induced by the random bits of the signer and corresponds to the remaining uncertainty that an attacker has about the real secret key when he tries to choose an "optimal" forgery.

(c) *The set of* successful forgeries *given pk and a history hist is*

$$Forg(pk, hist) := \{f = (m, s) | m \in M \backslash M(hist) \wedge test(pk, m, s) = ok\},$$

i.e., the set of acceptable signatures on messages not contained in the history.

(d) *A value $f = (m, s) \in Forg(pk, hist)$ is a* provable forgery *after a history hist, abbreviated provable$(sk, pk, hist, f)$, iff*

$$verify(pk, m, s, prove(sk, m, s, hist)) = accept,$$

i.e., if applying prove to it yields a valid proof of forgery.

Intuitively, the following definition says that no matter what an arbitrarily powerful center does during the key generation, no matter what messages A signs, and no matter what message and signature the forger selects as a forgery given all this knowledge, A can repudiate the forged signature with high probability. The probability is over the possible secret keys (among which, roughly speaking, the forger must guess which one A really has). For the first similar definition of security against an unrestricted adversary, see [42].

There are two possible sources for a small error probability: One is during key generation, where A might be tricked into accepting a bad key pair; the other is that a forger happens to find exactly A's correct signature.

DEFINITION 3.4. *Let an FSS scheme be given.*

(a) *For any given parameters $k, \sigma, N \in \mathbb{N}$ and any arbitrarily powerful center $\tilde{C}$, define a set $Good_{\tilde{C}}$ of "good" outcomes of the key generation as follows:*

$$(sk, pk, aux_{\tilde{C}}) \in Good_{\tilde{C}} :\Leftrightarrow \forall hist \in Hist(sk), \forall f \in Forg(pk, hist):$$

$$\mathrm{P}(provable(sk', pk, hist, f) :: sk' \leftarrow SK_{\tilde{C}}(pk, hist, aux_{\tilde{C}})) \ge 1 - 2^{-\sigma}.$$

Thus an outcome is called good if it guarantees that after any history, an unrestricted forger still has so much uncertainty about the secret key that his forgery will be provable with very high probability.

(b) *The FSS scheme is* secure for the signer *iff* $\forall\sigma$, $\forall par = (k, \sigma, N)$, *and for any arbitrarily powerful center* $\tilde{C}$,

$$\mathrm{P}((sk, pk, aux_{\tilde{C}}) \notin Good_{\tilde{C}} \wedge acc = accept :: (acc, pk, sk, aux_{\tilde{C}}) \leftarrow G_{A,\tilde{C}}(par)) \leq 2^{-\sigma}.$$

(c) *If both A and C follow G, each output is good, i.e.,* $(sk, pk, \varepsilon) \in Good_C$.

DEFINITION 3.5. *A* secure FSS scheme *is an FSS scheme that is secure for both the signer and the recipients.*

3.2. Relation to ordinary digital signatures: Security against forgery. In the above definition of secure fail-stop signatures, we have not explicitly demanded that it be difficult for a forger to construct acceptable signatures. Clearly, a signature scheme is useless if it is easy to make forgeries, even if they can be repudiated. We now show that Definition 3.5 actually implies that forging is hard for polynomially bounded enemies. More precisely, we show that existential forgery is infeasible even after an adaptive chosen-message attack (see [20]).

In an adaptive chosen-message attack against a signature scheme with security parameter l (which is used as an input in key generation) a forger F does the following, given the public key as an input:

1. Repeat a polynomial number of times (in l): Generate (in some way) a message m and receive the correct signature on m from the signer.
2. Output a pair (m', s'). (This should be a new message–signature pair.)

DEFINITION 3.6. *A signature scheme with security parameter* l *is* secure against an adaptive chosen-message attack *iff for all* $c > 0$ *and for all probabilistic polynomial-time forgers* F *as above, the probability that* F *outputs a pair* (m', s') *such that* m' *is different from all messages chosen in step* 1 *and* s' *is an acceptable signature on* m' *is less than* l^{-c} *for* l *sufficiently large.*

The probability is over the random bits used in the key generation, the random bits of F*, and the random choices of the signatures, if the signing algorithm is probabilistic.*

We now consider the security of fail-stop signatures against a forger who has not participated in the key generation.

THEOREM 3.1. *A secure FSS scheme is secure against an adaptive chosen-message attack by forgers who do not participate in G, i.e., who have only* par *and the result pk of a correct execution of G as inputs; the parameter k of the FSS scheme plays the role of the parameter l in Definition* 3.6.

Proof. Let a secure FSS scheme be given as in Definitions 3.1 and 3.5. Assume further that there exists a probabilistic polynomial-time forger F as above that on input (par, pk) outputs a pair of a new message and an acceptable signature (m', s') with probability $p(par)$. This probability is over all the random bits used in key generation and in F. Since F runs in polynomial time, a signer who tries to cheat a recipient can use the same algorithm:

1. Execute G correctly with C. This yields a key pair (sk, pk).
2. Execute F alternating with the real signing algorithm to obtain a history *hist* and a pair (m', s').
3. Use *prove* to compute a proof of forgery for (m', s'), given sk and *hist*.

Roughly, the argument is as follows: On one hand, the security for the signer against a forger with algorithm F implies that step 3 leads to a valid proof of forgery

with nonnegligible probability. On the other hand, this means that when the signer alone carries out the whole algorithm (i.e., step 1 as $\tilde{A}$ and steps 2 and 3 as $\tilde{A}^*$), it contradicts the security for the recipients.

We now proceed more formally. The history and message–signature pair generated in step 2 have exactly the same distribution as those that the forger would have constructed (i.e., the distribution used in Definition 3.6). This implies two things: First, (m', s') is a successful forgery with probability $p(par)$. Second, whenever this is the case, the signer can repudiate the forgery, i.e., step 3 yields a valid proof of forgery with probability at least $q := 1 - 2^{-\sigma}$, because $(sk, pk, \varepsilon) \in \mathit{Good}$ (see Definition 3.4(a, c)). Here q is the a posteriori probability over the possible secret keys, given any history. We omit the tedious details needed to combine these different types of probabilities formally before one obtains the expected result:

With probability at least $p(par)(1 - 2^{-\sigma}) \geq p(par)/2$, a signer executing steps 1, 2, and 3 obtains an acceptable signature together with a valid proof of forgery for it. Since the FSS scheme is secure for the recipients, this implies that $p(par)$ must be negligible as a function of k. This proves the theorem. □

This theorem can be interpreted as saying that fail-stop signatures are a stronger notion of signatures than that defined in [20] in two ways. The first way is described in the following theorem.

THEOREM 3.2. *Every secure fail-stop signature scheme can be used to construct an (equally efficient) secure digital signature scheme in the sense of* [20].

Proof. The main reason that a fail-stop signature scheme itself does not fulfill the definition in [20] is the interactive key generation. However, one can construct such a scheme as follows: On input (k, N), the signer executes both A and C in the key generation with $\sigma := 1$. The algorithms *sign* and *test* remain the same, and *prove* and *verify* are omitted. Theorem 3.1 implies that this is a secure signature scheme in the sense of [20]. □

As the second way, section 3.3 shows how Theorem 3.1 can be strengthened for the fail-stop signature scheme itself so that unconditional security for the signer is combined with security against an adaptive chosen-message attack by anyone, i.e., without even trusting a center.

3.3. Fail-stop signatures with known recipients. In the definitions in section 3.1, the keys were generated by the signer and a center trusted by the recipients. This section briefly discusses how fail-stop signature schemes work if the recipients themselves participate in the key generation. More precisely, one should distinguish recipients and risk bearers. Risk bearers are those who have a disadvantage if a proof of forgery is accepted and thus a signature becomes invalid. For instance, a recipient might have an insurance that covers his losses if signatures that he had accepted are proved to be forgeries. Then the insurance company—and not the recipient—is the risk bearer and has to trust the key generation process. We continue to say recipient for simplicity.

One recipient. In this case, we can simply replace the trusted center by the recipient. Note that a fail-stop signature scheme with only one recipient is not useless because everyone who knows the public key can still test the signatures and verify the proofs of forgery. The only restriction is that only the intended recipient is guaranteed that the signer cannot repudiate her own signatures. Such a scheme can, e.g., be applied in electronic payment systems for signing the customers' requests to the bank.

Many recipients. The definition of FSS schemes with many known recipients also follows the previous definitions very closely. In such a scheme, all the recipients participate in a key-generation protocol with the signer. Each participant has the input *par* and a secret random string, and the common output is either *reject* or $(accept, pk)$. (We assume that all recipients are satisfied with the same parameter k for their computational security.) The signer gets the secret key corresponding to pk as private output. The security for the signer can be defined as before, and the security for the recipients is essentially defined by requiring Definition 3.2 for each of them. In other words, if a recipient follows the key-generation protocol correctly, he is assured that a (polynomially bounded) signer cannot repudiate her own signatures, even if the signer and the remaining recipients cooperate.

We now show how FSS schemes with many known recipients can be constructed from FSS schemes in the sense of section 3.1. In some FSS schemes, the only task of the center in the key-generation protocol is to select a random string. In these schemes, it is quite easy to replace the center by many recipients because they only have to perform a multiparty coin-flipping protocol.

In the general case, one can apply a protocol for general secure multiparty computations in a certain way. For some details, see [35, 34]. However, in the present state of cryptography, the following simpler method is much more efficient. Its disadvantage is that the keys are long and thus signing and testing are relatively inefficient.

Construction 3.1 (many keys). Let R be the number of recipients. Each recipient executes protocol G with the signer once. This results in R key pairs, $(sk_j, pk_j)_{j=1,\ldots,R}$. The secret key of the signer is defined as $(sk_1, \ldots, sk_R)$ and the public key as $(pk_1, \ldots, pk_R)$. All signatures as well as proofs of forgery consist of R parts, one for each of the R key pairs. Note that everyone can test all parts of each signature or proof of forgery. ◇

The security for the jth recipient is guaranteed because if he carries out his execution of G correctly, it is computationally infeasible to compute valid proofs of forgery for pk_j. The security for the signer is guaranteed because given a successful forgery, she can compute proofs of forgery for it for each key pair with high probability.

As an immediate consequence of Theorem 3.1, this scheme is secure against an adaptive chosen-message attack if at least one of the recipients executes G correctly with the signer—even if the forger cooperates with the remaining $R - 1$ recipients. We can even achieve security if the forger may cooperate with all recipients by letting the signer take part in the key generation in the role of a recipient as well, i.e., she generates an additional key pair (sk_{R+1}, pk_{R+1}) all on her own, which is then treated like any other key pair.

4. Constructions of fail-stop signature schemes. This section first presents a general construction of a fail-stop signature scheme, which is subsequently used in actual instantiations. We describe two such instantiations based on the assumptions that it is hard to compute discrete logarithms and to factor integers, respectively. These are the two best-known concrete computational assumptions used in cryptography, and they are therefore well investigated and fairly trustworthy.

The constructions as described in this section allow only one message to be signed; hence they are called one-time signature schemes. Section 5 presents extensions for signing an arbitrary number of messages.

4.1. Bundling homomorphisms. In order to present our general construction of fail-stop signatures, we first define bundling homomorphisms. They are a special type of cryptographic hash functions and may have other uses in cryptography. Briefly,

a bundling homomorphism h is a homomorphism $h : G \to H$ between two Abelian groups $(G, +, 0)$ and $(H, \cdot, 1)$ that satisfies the following:

- Every image $h(x)$ has at least 2^τ preimages. (The bundling homomorphism is said to be of degree 2^τ.)
- It is infeasible to find collisions, i.e., two different elements that are mapped to the same value by h.

In order to make the second of these requirements precise, we have to consider a family of such functions. The individual functions of this family are indexed by a key K. The key is chosen depending on two security parameters: τ, which determines the bundling degree, and k, which measures the computational security against collision-finding. The parameters τ and k are part of the index to this function, but we only write K instead of (K, τ, k). This leads to the following definition.

DEFINITION 4.1. *A* family of bundling homomorphisms *is a quadruple* $(g, h, \mathcal{G}, \mathcal{H})$, *where we have the following:*

- g, *the key generator, is a probabilistic polynomial-time algorithm that on input parameters* $k, \tau \in \mathbb{N}$ *outputs a value* K. *Let* $\mathcal{K}$ *be the set of all possible keys, i.e., the union of the sets* $[g(k, \tau)]$ *for all* $k, \tau \in \mathbb{N}$.
- $\mathcal{G}$ *and* $\mathcal{H}$ *are families of Abelian groups, one for each key. More formally,* $\mathcal{G} = (G_K, +, 0)_{K \in \mathcal{K}}$ *and* $\mathcal{H} = (H_K, \cdot, 1)_{K \in \mathcal{K}}$.
- h *is a polynomial-time algorithm that on input* $K \in \mathcal{K}$ *and* $x \in G_K$ *outputs a value* $z \in H_K$. *The restriction of* h *to a particular key* K *is abbreviated as* h_K.

This quadruple must satisfy the following properties:

(a) *Each* h_K *is a group homomorphism from* $(G_K, +, 0)$ *to* $(H_K, \cdot, 1)$.

(b) *For all* $k, \tau \in \mathbb{N}$, $K \in [g(k, \tau)]$, *each* $z \in h_K(G_K)$ *has at least* 2^τ *preimages under* h_K.

(c) *The family is collision-resistant: For every* $c > 0$ *and for every probabilistic polynomial-time algorithm* $\tilde{A}$, *the probability that* $\tilde{A}$ *on input* $K \in [g(k, \tau)]$ *outputs a pair* (x, x') *such that* $x \neq x'$ *and* $h_K(x) = h_K(x')$ *is less than* k^{-c} *for* k *sufficiently large. More precisely,* $\forall \tau \forall c \, \exists k_0 \forall k \geq k_0$,

$$\mathrm{P}(h_K(x) = h_K(x') \wedge x \neq x' :: K \leftarrow g(k, \tau); (x, x') \leftarrow \tilde{A}(K)) < k^{-c}.$$

(*A more common name for collision-resistant is collision-free, but collision-resistant emphasizes the computational aspect better.*)

Additionally, there must be polynomial-time algorithms (*which do not need explicit names in the following*) *that on input* K

- *compute the operations in the two groups* $(G_K, +, 0)$ *and* $(H_K, \cdot, 1)$,
- *select elements of* G_K *uniformly at random, and*
- *test membership in* H_K *and* G_K.

Note that k_0 depends on τ in the definition of collision resistance. Actually, all of our constructions satisfy the stronger requirement where k_0 is independent of τ, as long as τ is polynomial in k (because an arbitrarily long input τ would give the collision finder time more than polynomial in k).

4.2. The general construction. The general construction yields a rather special case of the definition of fail-stop signature schemes. First, only one message is signed. Second, the key generation of this scheme (like all previous constructions in the literature) is quite simple. These two properties are now defined formally because the constructions to sign many messages in section 5 can be based on any FSS scheme with these properties.

DEFINITION 4.2. *A* one-time fail-stop signature scheme with prekey *is defined like a general FSS scheme in Definition* 3.1*, except that the parameter* N *is* 1 *and the key-generation protocol* G *is of a special, simpler form: It is constructed from a triple* $(gen_C, (P,V), gen_A)$*, where we have the following:*

- gen_C *is a probabilistic polynomial-time algorithm that on input par generates values prek (the* prekey*) and* w *(called witness).*
- (P,V)*, the prekey verification protocol, is a polynomial-time two-party protocol where* P *gets the input* $(par, prek, w)$ *and* V *only gets* $(par, prek)$*. As a result,* V *outputs accept or reject. Correct outputs of the prekey generation should always be accepted, i.e., if* $(prek, w) \in [gen_C(par)]$*, the output of* V *should be accept. The most efficient special case is where* P *does not do anything, i.e.,* V *decides locally whether or not to accept prek.*
- gen_A *is a probabilistic polynomial-time algorithm that on input a prekey prek outputs a key pair* (sk, pk)*. It is called the main key-generation algorithm.*

The protocol G *is constructed from these subprotocols as follows: First, the center* C *executes* gen_C *and publishes the resulting prekey. Next,* (P,V) *is executed for this prekey by the center* (P) *and the signer* (V)*, where the center has* w *as an additional input. (The purpose of this step is to prove some desired property of prek to the signer.) Finally, the signer* A *carries out* gen_A *on input prek. We say that she generates a key pair based on the prekey prek. The public key in the sense of Definition* 3.1 *is the pair* $(prek, pk)$*. However, we often omit prek in the notation because it is clear from the context.*

The signer, using V, may also accept if *prek* is not a possible outcome of the correct prekey generation; we only use (P,V) to prove those properties of *prek* to the signer that are necessary for the signer's security. This is often much more efficient than proving correct generation. Note that (P,V) is similar to an interactive proof system [19], but our prover is polynomial-time and needs the witness w.

Schemes with prekey have the following advantage if there are several signers. The center can publish the prekey without knowing which signers will take part. Every signer carries out the interactive proof with the center once and can then base many successive secret keys on this prekey without further interaction with the center. This is exploited in section 5. The security is not weakened if many signers base their key pairs on the same prekey because of the following:

- If this led to signers being able to repudiate their own signatures, one cheating signer alone could generate many key pairs based on that prekey and experiment with them locally until she could repudiate a signature, and only then would she publish the corresponding public key.
- If this allowed forgers to make unprovable forgeries with nonnegligible probability (over the choice of the key pairs of all the signers), the probability for each key pair would also be nonnegligible because all key pairs are identically distributed.

We now describe a framework for constructing a one-time FSS scheme with prekey from a family of bundling homomorphisms. A few parameters are left open; they depend on the choice of the family of bundling homomorphisms. We then present two theorems that reduce the security of the scheme to one property of the bundling homomorphisms and those parameters. This property will be proved and the parameters specified in the instantiations in sections 4.3 and 4.4.

Since the message number i is always 1, it will be omitted in the notation, and instead of a message sequence $\underline{m}$ of length 1, a message m is written.

Construction 4.1 (general construction). Let a family of bundling homomor-

phisms with a key generator g be given. Then the various components of a one-time fail-stop signature scheme with prekey are defined as follows:

- Key generation: Let security parameters k and σ be given. The parameter τ for the degree of the bundling homomorphisms is a function of σ, which will be specified later.
- Prekey generation gen_C: The center computes $K \leftarrow g(k, \tau)$ and publishes it, i.e., $prek := K$. This corresponds to choosing one homomorphism h_K of the family. Henceforth, let $h := h_K$, $G := G_K$, and $H := H_K$. Instead of g, an algorithm g' may be used that outputs K with the same probability distribution as g but also outputs a witness w.
- Prekey verification (P, V): The signer must be assured that K is a possible outcome of $g(k, \tau)$, or at least that h is a homomorphism and satisfies Definition 4.1(b). The choice of a predicate between these two extremes that can be proved most efficiently depends on the choice of the family of bundling homomorphisms. A prekey K is called *good* if it fulfills this predicate; otherwise, it is called *bad*. If possible, this protocol is a local test by the signer. Otherwise, it is a zero-knowledge proof from the center to the signer (see [19, 18]—except we require P to be polynomial-time and to use a witness w). The probability that the signer accepts the proof for a bad prekey K must be at most $2^{-\sigma}$ for each K.[2]
- Main key generation gen_A: The signer generates her secret key $sk := (sk_1, sk_2)$ by choosing sk_1 and sk_2 randomly in G, and she computes her public key $pk := (pk_1, pk_2)$, where $pk_i := h(sk_i)$ for $i = 1, 2$.
- The message space M is a subset of $\mathbb{Z}$ depending on the choice of the prekey.
- Signing: The correct signature on a message m in the message space is

$$sign(sk, m) := sk_1 + m\, sk_2.$$

(Multiplication with elements of $\mathbb{Z}$ is, as usual, defined by repeated addition.)

- Test: The algorithm *test*, which determines whether a signature $s \in G$ is acceptable, is defined so that $test(pk, m, s) = ok$ iff $pk_1 \cdot pk_2^m = h(s)$.
- Proof of forgery: Given an acceptable signature $s' \in G$ on m such that $s' \neq sign(sk, m)$, the signer computes $s := sign(sk, m)$ and $proof := (s, s')$.
- Verification of proof of forgery: Given a pair (x, x'), verify that x and x' are elements of G, that $x \neq x'$, and that $h(x) = h(x')$. $\diamond$

This concludes the description of the general construction. The following theorem shows that any instantiation of this construction works and that it is secure for the recipients.

THEOREM 4.1. *For any family of bundling homomorphisms, and with any choice of the parameters that have been left open, the general construction has the following properties:*

(a) *Correct signatures pass the test* (*i.e., Definition* 3.1 *is fulfilled*).

(b) *A polynomially bounded signer cannot construct a signature and a valid proof that it is a forgery* (*i.e., Definition* 3.2 *is fulfilled*).

(c) *If s^* is an acceptable signature on m^* and $s^* \neq sign(sk, m^*)$, the signer obtains a valid proof of forgery* (*this is a step towards fulfilling Definition* 3.4).

(d) *If all values $(sk, (K, pk), aux_{\tilde{C}})$ where K is good are contained in $Good_{\tilde{C}}$, the scheme is secure for the signer* (*another step towards fulfilling Definition* 3.4).

[2] Note that the definition of zero-knowledge proofs from [19] only requires that the probability that a bad value is accepted decreases faster than the inverse of any polynomial, but the actual proofs in [18] have the strictly exponential decrease that we need.

Proof. Part (a) follows from the fact that h is a homomorphism:

$$h(s) = h(sk_1 + m\,sk_2) = h(sk_1) \cdot h(sk_2)^m = pk_1 \cdot pk_2^m.$$

Part (c) is a trivial consequence of the fact that both s and s^* pass the test. Part (d) follows immediately from the requirement that we have made on the error probability of the prekey verification. For part (b), note that a proof of forgery is exactly a collision of the bundling homomorphism h_K, where K is chosen by the center in gen_C with the correct probability distribution. Hence part (b) follows immediately from the collision resistance of the bundling homomorphisms, except that we have to show that the zero-knowledge proof does not make it easier for the signer to find collisions, which is intuitively clear (although a formal proof is lengthy; see [34]). □

This theorem shows that the general construction is secure for the recipients and that it is also secure for the signer if an arbitrarily powerful forger cannot guess a correct signature $sign(sk, m^*)$, except with a very small probability, whenever the prekey is good. In order to estimate the probability with which a forger can find such a signature, we first note that given a public key, at least $2^{2\tau}$ secret keys are possible. Given a correct signature on another message m, the forger has more information about sk, but Theorem 4.2 gives a condition under which this information is not sufficient to guess the correct signature on m^* with too high a probability.

THEOREM 4.2. *Consider Construction* 4.1. *Let parameters k and σ, a good prekey K, and two messages $m \neq m^*$ from the corresponding message space be given. Let*

$$T := \{d \in G | h(d) = 1 \wedge (m^* - m)d = 0\}.$$

Then for all key pairs $(sk, pk) \in [gen_A(K)]$ and all values $s^* \in G$ (a forgery) satisfying $test(pk, m^*, s^*) = ok$, the probability that $s^* = sign(sk, m^*)$, given $s := sign(sk, m)$, is at most $|T|/2^\tau$, i.e., for any center $\tilde{C}$,

$$\mathrm{P}(s^* = sign(sk', m^*) :: sk' \leftarrow SK_{\tilde{C}}(pk, (m, s), aux_{\tilde{C}})) \leq |T|/2^\tau.$$

Note that the probability in this theorem resembles Definition 3.4(a).

Proof. Since K is good, h is at least a homomorphism and satisfies Definition 4.1(b). Note that $aux_{\tilde{C}}$ can contain additional information about K but that the only information that the signer divulges about sk is pk and a correct signature s on one message m. The set of possible keys given this information is

$$\begin{aligned} SK_{\tilde{C}} &= \{(sk'_1, sk'_2) \in G \times G | h(sk'_1) = pk_1 \wedge h(sk'_2) = pk_2 \wedge sk'_1 + m\,sk'_2 = s\} \\ &= \{(s - m\,sk'_2, sk'_2) | h(sk'_2) = pk_2\} \end{aligned}$$

because h is a homomorphism and $s = sk_1 + m\,sk_2$. The size of $SK_{\tilde{C}}$ is therefore at least 2^τ. We must now find out how many of these keys satisfy $s^* = sign(sk', m^*)$, i.e.,

$$(*) \qquad sk'_1 + m^*\,sk'_2 = s^*.$$

Since we only consider keys in $SK_{\tilde{C}}$, we can replace sk'_1 by $s - m\,sk'_2$. Hence $(*)$ is equivalent to

$$(m^* - m)sk'_2 = s^* - s.$$

This equation might be unsolvable, but if there is any solution sk_2'', the set of all solutions in $SK_{\tilde{C}}$ is

$$\{(s - m\,sk_2', sk_2') | h(sk_2') = h(sk_2'') \wedge (m^* - m)(sk_2' - sk_2'') = 0\}.$$

Hence the number of solutions is $|T|$ (where d corresponds to the difference $sk_2' - sk_2''$). Since sk is uniformly distributed in Construction 4.1, all elements of $SK_{\tilde{C}}$ are equally probable, and the attacker is successful with probability at most $|T|/|SK_{\tilde{C}}| \leq |T|/2^\tau$, as claimed. □

COROLLARY. *Theorem* 4.2, *together with Theorem* 4.1(c, d), *shows that the general construction is secure for the signer* (*as in Definition* 3.4) *if* τ *is chosen so that* $|T|/2^\tau \leq 2^{-\sigma}$, *i.e.,* $\tau \geq \sigma \log_2(|T|)$.

Consequently, we must find the maximal size of

$$T_{m'} := \{d \in G | h(d) = 1 \wedge \mathrm{ord}_G(d) | m'\}$$

over all possible differences m' of two messages. The size of this set depends on the chosen family of bundling homomorphisms.

Note that the collision resistance of h was only needed in Theorem 4.1(b), i.e., to ensure the security for the recipients. This is the reason why the center need not prove to the signer that h has this property.

4.3. A scheme based on discrete logarithms. We now construct a family of bundling homomorphisms for which finding collisions is equivalent to computing discrete logarithms.

Let p and q be large primes such that q divides $p - 1$, and let H_q be the unique subgroup of $\mathbb{Z}_p^*$ of order q. (Recall the theorem that all groups $\mathbb{Z}_p^*$ are cyclic and of order $p - 1$.) Remember that all elements of H_q except 1 are generators. We shall assume that it is hard to compute discrete logarithms in H_q (as already sketched in [12]). For elements a and b of H_q, where $a \neq 1$, the discrete logarithm $\log_a(b)$ is defined as the number $e \in \{0, \ldots, q - 1\}$ with $a^e = b$.

Assumption DL. For all probabilistic polynomial-time algorithms D, for all $c \in \mathbb{N}$, and for k sufficiently large, the probability that D, on input two primes p and q, where q is a k-bit prime dividing $p - 1$ and $q > (p - 1)/q$, and two generators a and b of H_q, outputs $\log_a(b)$ is less than k^{-c}. The probability is over the random bits used by D and the uniform random choices of p, q, a, and b with the given constraints. ◇

The scheme presented below actually works for any groups of prime order, but for the sake of concreteness, we shall assume the above setup.

Construction 4.2 (discrete logarithm homomorphisms).

- Key generator g: On input k and τ, it chooses primes p and q as above with $|q|_2 = \max(k, \tau)$ and two random generators a and b of H_q. It outputs the key $K := (p, q, a, b)$.
- Families of groups: Define

$$G_q := \mathbb{Z}_q \times \mathbb{Z}_q$$

with pairwise addition (modulo q). With a slight misuse of the notation, we abbreviate $G_{(p,q,a,b)} =: G_q$ and $H_{(p,q,a,b)} =: H_q$.

- The homomorphisms are defined as

$$h_{(p,q,a,b)}\colon G_q \to H_q; \qquad h_{(p,q,a,b)}(x, y) := a^x b^y.$$

The corresponding algorithm h is clear. ◇

Similar constructions were first used in [6].

THEOREM 4.3. *Under Assumption* DL*, Construction* 4.2 *is a family of bundling homomorphisms.*

Proof. It is easy to see that all necessary operations are efficiently computable. In particular, g generates q first and then searches for a prime p among the numbers of the form $tq+1$. Now the properties from Definition 4.1(a–c) must be verified.

(a) Obviously, each $h_{(p,q,a,b)}$ is a group homomorphism. (Recall that the order of H_q is q.)

(b) For every $z \in H_q$, there are exactly q elements (x, y) of G_q that h maps to z: For each x, there is exactly one y with $b^y = za^{-x}$ because b is a generator.

(c) Assume that a probabilistic polynomial-time algorithm $\tilde{A}$ could compute collisions of h with nonnegligible probability. We then construct an algorithm D that on input (p, q, a, b) computes the discrete logarithm of b with respect to a as follows: First, D runs $\tilde{A}$, and if $\tilde{A}$ outputs a collision, i.e., $(x, y) \neq (x', y')$ with $a^x b^y = a^{x'} b^{y'}$, then D computes $\log_a(b)$ as $(x'-x)(y-y')^{-1} \bmod q$. (Note that $y = y'$ is impossible.) D is successful with the same probability as $\tilde{A}$ and almost equally efficient. Hence it contradicts Assumption DL. □

This theorem implies that we can construct an FSS scheme that is secure for the recipients under the discrete logarithm assumption. Before we go into the details of the security for the signer, the resulting scheme is described, and the parameters that were left open in the general construction are fixed.

Construction 4.3 (the Discrete Logarithm Scheme).

- Key generation: On input k and σ, the parameter τ for the degree of the bundling homomorphisms is set to σ.
- Prekey generation: The center selects primes p and q and generators a and b (with the algorithm g) and publishes them.
- Prekey verification: The signer can verify by herself that p and q are primes and that a and b are generators of H_q by verifying that their order is q. Hence key generation is extremely simple in this scheme.
- Main key generation: The secret key consists of four numbers x_1, y_1, x_2, and y_2 between 0 and $q-1$ (more precisely $(x_1, y_1), (x_2, y_2) \in G_q$), and the corresponding public key is the pair (pk_1, pk_2) with

$$pk_1 := a^{x_1} b^{y_1} \quad \text{and} \quad pk_2 := a^{x_2} b^{y_2}.$$

- The message space is defined as $\{0, 1, \ldots, q-1\}$.
- Signing: The correct signature on a message m from this space is

$$(x, y) := (x_1, y_1) + m(x_2, y_2) = (x_1 + m\ x_2, y_1 + m\ y_2).$$

- Test: A pair (x, y) is an acceptable signature on the message m iff

$$a^x b^y = pk_1 pk_2^m.$$

- Proofs of forgery and their verification: According to the general construction, a proof of forgery is a collision of h. Hence such a proof consists of four numbers. However, the signer can just as well show $e := \log_a(b)$ as a proof of forgery because this is equivalent to the other proof but shorter and easier to verify. (e yields a collision $a^e b^0 = a^0 b^1$.)

We now return to proving that this scheme is also secure for the signer.

THEOREM 4.4. *The Discrete Logarithm Scheme is secure for the signer.*

Proof. According to the end of section 4.2, we have to find the maximal size of the set

$$T_{m'} = \{d \in G_q | h(d) = 1 \wedge \mathrm{ord}(d) | m'\}$$

for all values of m' between 1 and $q-1$ (m' is the difference between two different legal messages; negative values need not be considered separately), given that the prekey is good. Thus q is prime, and the order of all nonzero elements of G_q is q. Hence $(0,0)$ is the only element of $T_{m'}$.

Together with the corollary to Theorem 4.2, this implies that it suffices to choose $\tau := \sigma$ in the proposed scheme, as we did in Construction 4.3. □

The choice of $\tau := \sigma$ means that $|q|_2$ is chosen as $\max(k, \sigma)$. For reasonable parameters k and σ, this means $|q|_2 = k$.

We conclude this section with a short evaluation of the efficiency of the proposed scheme:

- Signing requires two multiplications modulo q.
- Testing a signature requires less than two exponentiations modulo p. This is because the recipient can test the signature (x, y) by computing $a^x b^y\, pk_2^{-m}$ and verifying that it equals pk_1. This corresponds to between k and $2k$ modular multiplications, depending on the message, with a suitable exponentiation algorithm.
- The length of the secret key (for one message) is $4k$.
- The length of the public key is $2|p|_2$ bits.
- The length of a signature on a k-bit message is $2k$.

4.4. A scheme based on factoring. This section shows how the general construction can be used to construct fail-stop signatures where the security for the recipients relies on the intractability of factoring. The family of bundling homomorphisms was defined in [4], using ideas from [20, 17]. A similar homomorphism was already used in [2]. We denote the group of quadratic residues modulo an integer n by $QR_n := \{x \in \mathbb{Z}_n^* \,|\, \exists w\colon\ w^2 \equiv x \bmod n\}$. The basic assumption of this scheme is that it is hard to factor large integers.

Assumption F (see [20]). For all probabilistic polynomial-time algorithms F, for all $c \in \mathbb{N}$, and for k sufficiently large, the probability that F, on input a k-bit integer n which is the product of two primes p and q of equal length and with $p \equiv 3$ and $q \equiv 7 \bmod 8$, outputs one of the factors is less than k^{-c}. The probability is over the random bits used by F and the uniform random choice of n with the given constraints. ◇

Construction 4.4 (factoring homomorphisms).

- Key generator g: On input k and τ, it chooses a k-bit integer $n = pq$ such that p and q are primes with $p \equiv 3$ and $q \equiv 7 \bmod 8$. It outputs $K := (\tau, n)$.
- Families of groups: We slightly abbreviate the groups for a key $K = (\tau, n)$ as

$$H_n := (\pm QR_n)/\{1, -1\} \quad \text{and} \quad G_{\tau,n} := \mathbb{Z}_{2^\tau} \times H_n.$$

The group operation in H_n is induced by multiplication modulo n. Each element of H_n, which is a coset $\{x, -x\}$, will be identified with its smaller member, i.e., a number between 0 and $n/2$. The reason for using the factor group H_n instead of QR_n is that membership in H_n can be tested efficiently: A number between 0 and $n/2$ belongs to H_n iff its Jacobi symbol is $+1$. (Hence it is also easy to test membership in $G_{\tau,n}$.) The operation in $G_{\tau,n}$ is defined by

$$(a, x) \circ (b, y) := ((a + b) \bmod 2^\tau, xy4^{(a+b)\mathrm{div}2^\tau}),$$

and the unit element of $G_{\tau,n}$ is $(0,1)$.

- The homomorphism $h_{\tau,n}$ mapping $G_{\tau,n}$ to H_n is defined by

$$h_{\tau,n}((a,x)) := \pm(4^a x^{2^\tau}),$$

i.e., either $4^a x^{2^\tau}$ or $-4^a x^{2^\tau}$, depending on which of them is smaller than $n/2$. The corresponding (unoptimized) probabilistic polynomial-time algorithm h is clear. ◇

THEOREM 4.5.

(a) *Under Assumption* F*, Construction* 4.4 *is a family of bundling homomorphisms.*

(b) *For any* $\tau \in \mathbb{N}$ *and any odd* $n \in \mathbb{N}$ *(i.e., not only for those chosen according to Construction* 4.4*),* $h_{\tau,n}$ *is a homomorphism satisfying Definition* 4.1(b)*.*

(c) *If* $n = p^r q^s$*, where* p *and* q *are primes with* $p \equiv 3$ *and* $q \equiv 7 \bmod 8$ *and* r *and* s *are odd, then for any* $a \in \mathbb{Z}_{2^\tau}$ *and* $z \in H_n$*, there exists exactly one* $x \in H_n$ *so that* $h_{\tau,n}((a,x)) = z$*. (The reason we consider numbers* n *of this more general form is that we want to use the fairly efficient zero-knowledge protocol from* [21]*; see below.)*

Proof. See [4]. The last claim is only proved for $r = s = 1$, but the same proof also works in the more general case. □

Given this family of bundling homomorphisms, we can construct a fail-stop signature scheme called the *Factoring Scheme*. We only have to fill in the three parameters that were left open in Construction 4.1:

- The message space is $\{0, \ldots, 2^\rho - 1\}$ for any $\rho \in \mathbb{N}$.
- The parameter τ for the bundling degree is computed as $\tau := \sigma + \rho$.
- A prekey n is good if it is of the form defined in Theorem 4.5(c). By Theorem 4.5(b, c), such prekeys fulfill the conditions required in Construction 4.1. The zero-knowledge proof for this predicate is as follows:

1. The center, who has chosen n and therefore knows p and q, uses the zero-knowledge protocol from [21] to prove to the signer that $n = p^r q^s$, where p and q are primes and congruent to 3 modulo 4 and r and s are odd. This proof must be executed such that the probability of cheating the signer into accepting an incorrect n is at most $2^{-\sigma}$.
2. The signer verifies on her own that $n \equiv 5 \bmod 8$ to exclude the case $p \equiv q \bmod 8$.

Given all this, it is straightforward to write down the details of the Factoring Scheme in the same manner as in Construction 4.3. The following theorem completes the security considerations.

THEOREM 4.6. *The Factoring Scheme is secure for the signer.*

Proof. According to the corollary to Theorem 4.2, it only remains to show $|T_{m'}| \leq 2^\rho$ for all m' whenever the prekey is good because then

$$|T_{m'}|/2^\tau \leq 2^{-\sigma}.$$

Note that in $G_{\tau,n}$,

$$(a,x)^{m'} = (0,1) \Rightarrow m'a \bmod 2^\tau = 0 \Rightarrow \mathrm{ord}(a) | m'.$$

Hence

$$T_{m'} \subseteq \{(a,x) \in G_{\tau,n} | h_{\tau,n}((a,x)) = 1 \wedge \mathrm{ord}(a) | m'\}.$$

According to Theorem 4.5(c), for each a, there is exactly one x such that $h_{\tau,n}((a,x)) = 1$. Thus

$$|T_{m'}| \le |\{a \in \mathbb{Z}_{2^\tau} | \mathrm{ord}(a) | m'\}| = \gcd(2^\tau, m').$$

By the choice of the message space, m' is between 1 and $2^\rho - 1$ (m' is the difference between two different legal messages; negative values need not be considered separately), and therefore $\gcd(2^\tau, m') < 2^\rho$. □

As for the efficiency, first note that a multiplication by 4 modulo n can be replaced by two shifts and at most two subtractions and is therefore negligible compared with a general multiplication modulo n. A group operation in $G_{\tau,n}$ is therefore essentially one modular multiplication because the exponent of 4 is 0 or 1. This yields the following:

- Signing: The term $m\,sk_2$ with $sk_2 \in G_{\tau,n}$ can be evaluated with any exponentiation algorithm. Since we just saw that a group operation in $G_{\tau,n}$ is essentially a modular multiplication, this corresponds to an exponentiation modulo n with the exponent m. In other words, it needs between ρ and $(3/2)\rho$ modular multiplications with a suitable exponentiation algorithm.
- Test: A signature $s = (a, x)$ on the message m is acceptable iff

$$pk_1\, pk_2^m = h_{\tau,n}((a,x)) \Leftrightarrow pk_1 = \pm 4^a x^{2^\tau} pk_2^{-m}.$$

Since the message is ρ bits long and $\tau = \rho + \sigma$, we see that a signature can be tested using at most $\tau + \rho = 2\rho + \sigma$ modular multiplications. With a good exponentiation algorithm, one can get close to $\rho + \sigma$ modular multiplications.

- The length of the secret key (for one message) is $2(k + \tau) = 2(k + \rho + \sigma)$ bits.
- The length of the public key is $2k$.
- The signature length (for a ρ-bit message) is $k + \tau = k + \rho + \sigma$ bits.

Thus the two schemes require almost the same amount of computation and storage for keys and signatures. The main difference is that the key generation in the first scheme is simpler. A variant of the Factoring Scheme that does not need a zero-knowledge proof, at the cost of an additional summand k in most of the lengths and numbers of multiplications, is given in [34]. Table 1 compares the two schemes for $k = \rho = |q|_2 \approx |p|_2$; remember that k is also the length of the message.

TABLE 1
Complexity of the two instantiations of the general construction.

	Discrete logarithm	Factoring
sign	2 multiplications	$\approx k$ multiplications
test	$< 2k$ multiplications	$< 2k + \sigma$ multiplications
Length of sk	$4k$	$4k + 2\sigma$
Length of pk	$2k$	$2k$
Length of a signature	$2k$	$2k + \sigma$

5. Signing many long messages. In section 4, constructions of fail-stop signature schemes for one short message were presented. We now extend these constructions so that an arbitrary number of messages of arbitrary length can be signed.

5.1. Overview. The easiest way to sign more than one message is to use a scheme from section 4 and to prepare as many keys as one intends to sign messages.

However, this is not very practical. In particular, the distribution of public keys assumes that each signer has access to a reliable broadcast channel (which may be realized by a certification hierarchy or a kind of phone book in practice). The use of such a channel should be minimized. In fact, some authors even require of ordinary digital signature schemes that after the initial key generation of fixed length, signing can go on "polynomially forever" [1, 30]. Hence one important result of the next two constructions is that they guarantee very short public keys.

The basic idea behind these constructions is tree authentication. The same ideas underlie all published provably secure ordinary digital signature schemes; however, some variations necessitate a new proof each time. Actually, there are two types of tree authentication, that of [29, 26, 27] and that of [28, 20], which we call bottom-up and top-down, respectively, corresponding to how the tree is constructed. The former leads to shorter signatures; the latter is more flexible. We sketch their fail-stop versions in sections 5.3 and 5.4, respectively.

In both of these constructions, the length of the secret key is linear in the number of messages to be signed. We prove in section 6 that this cannot be avoided if one defines "secret key" as in Definition 3.1, i.e., including all of the secret random bits that the signer will ever need. However, we show that this secret key never needs to exist completely at the same time: In section 5.4, we modify the top-down construction so that only a small amount of secret storage is needed.

In addition, we show in section 5.2 how long messages can be hashed before signing so that the length of signatures and keys is independent of the message length. In section 5.5, we present a special variant of the constructions based on discrete logarithms that shortens the secret key by approximately a factor of 2. This will be interesting in comparison with the lower bounds; see section 6. In section 5.6, we sketch more efficient constructions for the case where all the signatures by one signer have the same recipient.

5.2. Collision-resistant hash functions and message hashing. Message hashing means that a hash function is applied to each message before it is signed, which reduces messages of arbitrary length to a fixed length. At first sight, it could seem impossible to do this with fail-stop signatures. Given a correct signature s on a message m, an arbitrarily powerful forger can find another message m' that is mapped to the same string by the hash function. Hence this forger knows that s is also the correct signature on m'. Thus the signer cannot use the idea described in section 1.3 to repudiate the successful forgery (m', s). Fortunately, this is not a problem because such a forgery gives the signer a collision of the hash function, which she can present as a proof of forgery. Under the assumption that the hash function is collision-resistant, the signer cannot construct such a collision by herself.

Collision-resistant hash functions have been formally defined in [10]. Under Assumptions DL and F, efficient collision-resistant hash functions exist that need about one multiplication per message bit and where the length of the output is the length of the modulus used in the hash function [10, 8]. In practice, one may decide to use much faster hash functions whose security cannot be proved under well-known assumptions (or cannot even be defined, e.g., if they have no keys), such as RIPEMD-160 [13] (follow the references for more such functions and known attacks).

If a hash function is used in a fail-stop signature scheme, the key for the hash function, i.e., the particular instance of the hash function, must be chosen by the center (or the recipients according to section 3.3), i.e., in our constructions, it is part of the prekey. The parameters must be chosen so that the output of the hash function

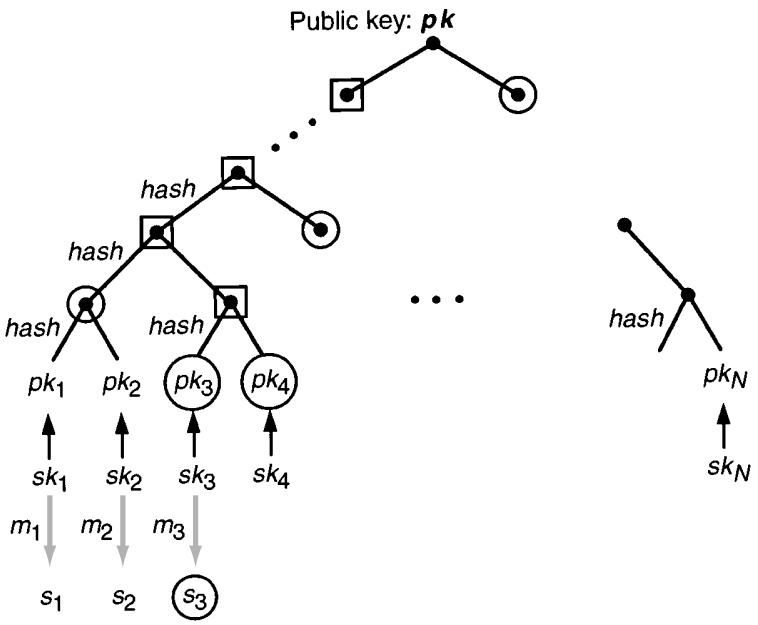

FIG. 2. *Fail-stop signature scheme with bottom-up tree authentication. Thin black arrows denote the relation between a one-time secret key and the corresponding one-time "public" key, broad grey arrows denote one-time signatures, and the tree is constructed by repeatedly hashing pairs of values. For instance, the complete signature on m_3 consists of the encircled nodes. To test it, the recipient reconstructs the nodes in squares.*

fits into the message length of the underlying fail-stop signature scheme. Then it is easy to prove that such a combination of a secure collision-resistant hash function and a secure fail-stop signature scheme is a secure fail-stop signature scheme for messages of arbitrary length.

5.3. Bottom-up tree authentication. The construction of bottom-up tree authentication is sketched in Figure 2. It is based on any collision-resistant hash function and any one-time fail-stop signature scheme with prekey (all constructions in section 4 are of this form). We distinguish signatures and keys in the underlying one-time FSS scheme and the scheme now to be constructed by calling them *one-time* and *complete*, respectively, and put one-time "public" keys in quotes because they are no longer public.

A prekey and an instance of the hash function are chosen once and for all (by the center or the recipients). The signer generates N one-time key pairs (sk_j, pk_j) based on this prekey. She hashes them pairwise in the form of a binary tree. Only the final hash value, i.e., the root of the tree, is published as the complete public key pk of the new scheme.

The complete signature on the jth message, m_j, starts with the one-time signature s_j on m_j using sk_j. Secondly, it contains the corresponding value pk_j. Moreover, to authenticate pk_j, the branch from pk_j to the root is needed; thus the complete signature also contains the other children of the nodes on this branch (see Figure 2). Hence its length is logarithmic in N.

The recipient tests the one-time signature s_j using pk_j, reconstructs the values on the path to the root, and tests if this path ends at the correct public key pk.

A proof of forgery in the new scheme is either a proof of forgery in the one-time scheme or a collision of the hash function.

A complete formal description and a proof can be found in [35]. Here we concentrate on top-down tree authentication instead.

5.4. Top-down tree authentication and a construction with a small amount of secret storage. In this section, we proceed in two steps:

1. We present a natural fail-stop version of top-down tree authentication. It can be based on any one-time FSS scheme with prekey where arbitrarily long messages can be signed and thus, in particular, on the schemes from section 4 together with message hashing. In this construction, the public key is short and only a small amount of secret storage is needed immediately after the keys are chosen. However, a long secret key accumulates as more and more messages are signed.

2. We add measures so that the amount of secret storage is also small all the time. These measures are constructed specifically for the general construction described in section 4.2, i.e., for the efficient schemes based on factoring and discrete logarithms.

As in section 5.3, we use *one-time* and *complete* to distinguish signatures and keys in the underlying scheme and in the scheme to be constructed.

Construction 5.1 (top-down tree authentication). Let a one-time FSS scheme with prekey for the message space $\{0,1\}^+$ be given (see Definition 4.2). We construct a scheme for signing N messages as follows (see Figure 3).

- Key generation:
  - A prekey *prek* for the one-time FSS scheme is chosen and the protocol (P, V) is carried out for it.
  - The signer generates one one-time key pair (sk, pk) based on *prek* and publishes pk (and N, if it is not globally fixed) as the complete public key of the new scheme.
- Signing: Signing takes place in a binary tree with N leaves. The nodes are denoted by bit strings j and labeled with one-time key pairs (sk_j, pk_j). The root is Node ε and labeled with (sk, pk). The children of Node j are Node $j0$ and Node $j1$. All one-time key pairs are randomly generated by the signer based on the same prekey *prek*. A one-time secret key at an inner node is used to sign the pair of one-time "public" keys of its two children; a one-time secret key at a leaf is used to sign a real message. A complete signature s in the new scheme is one branch of these one-time signatures. To sign the first real message $m_{0\ldots0}$, only the one-time keys on the leftmost branch and their immediate other children have to be generated. Figure 3 shows the situation after $m_{0\ldots0}$ has been signed. Generally, a complete signature on m_j consists of the one-time signature on m_j using sk_j and the sequence of pairs of one-time "public" keys with their one-time signatures on the path from m_j to the root (see Figure 3). Thus the tree is gradually constructed from left to right.
- Test: Given a complete signature s, i.e., a branch of a tree, the recipient tests all the one-time signatures in it and checks that the path ends at the correct public key pk.
- Proof of forgery: Given a successfully forged complete signature s^*, i.e., a branch that ends at pk, the signer finds a node j where it "links in" to the correct tree, i.e., the same pk_j is used in s^* and in her current tree, but the message m_j^* signed at this node in s^* has not been signed by her. (Depending on the position of Node j, m_j^* may be a real message or a pair of one-time "public" keys.) She computes a proof of forgery, $proof_j$, for this forged one-time signature s_j^* in the one-time scheme. The complete proof of forgery, *proof*, consists of $proof_j$, pk_j, m_j^*, and s_j^*.

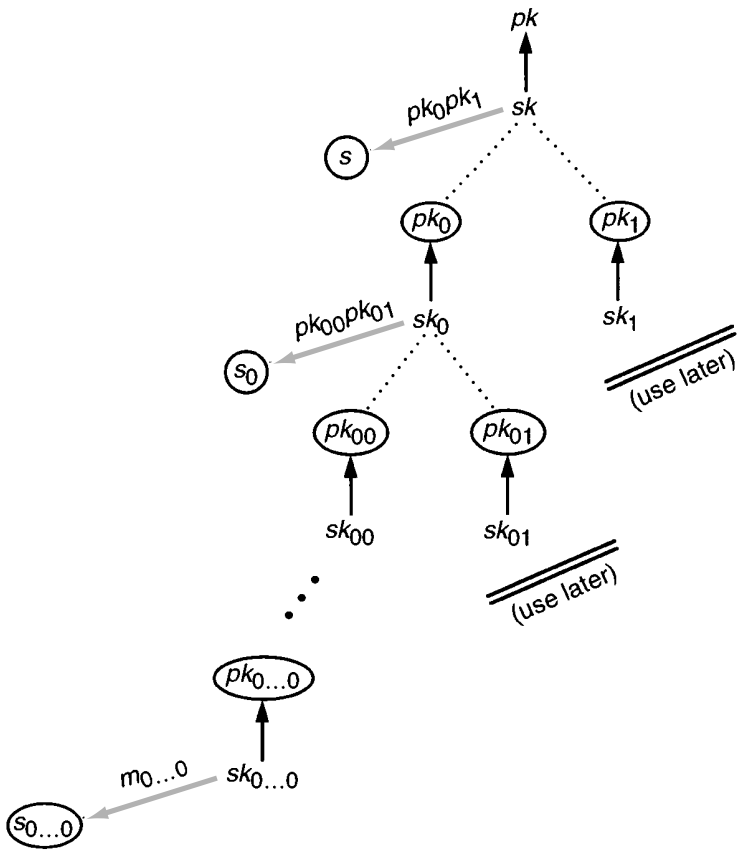

FIG. 3. *Fail-stop signature scheme with top-down tree authentication. Thin black arrows denote the relation between a one-time secret key and the corresponding one-time "public" key, broad grey arrows denote one-time signatures, and dotted lines only indicate a tree but are not related to a computation. For instance, the complete signature on* $m_{0\ldots0}$ *consists of the encircled nodes.*

• Verification of a proof of forgery: Given a value $proof = (proof_j, pk_j, m_j^*, s_j^*)$, verify that it is a valid proof of forgery in the one-time scheme, i.e., compute $verify(pk_j, m_j^*, s_j^*, proof_j)$. ◇

THEOREM 5.1. *If the underlying one-time FSS scheme is secure, Construction* 5.1 *describes a secure FSS scheme for* N *messages.*

Proof. The requirement from Definition 3.1 is obviously fulfilled. The security for the recipients, i.e., the fact that a polynomially bounded signer cannot construct signatures that she can later prove to be forgeries, follows immediately from that of the one-time scheme because any valid proof of forgery in the complete scheme is also a valid proof of forgery in the one-time scheme. (Remember that repeated use of the same prekey does not weaken the security; see the remarks after Definition 4.2.)

As to the security for the signer, first note that the probability that the signer accepts a bad prekey is the same in the one-time and the complete scheme. We show that all outcomes of the key generation based on a good prekey are in $Good_{\tilde{C}}$. For any successful forgery, the forger must select at least one node j where his complete signature links in to the correct tree, i.e., where he must forge a one-time signature. Given the forgery, the signer will find such a node (with probability 1) and can prove

the forgery at that node with the same probability as in the one-time scheme. □

A large amount of secret storage is still needed in Construction 5.1 because all the values sk_j must be stored secretly so that forgeries at any node can be proved. The basic idea used to reduce secret storage in Construction 5.2 is to store those sk_j's that are no longer used for signing in encrypted form (reliably, but not secretly) and to store only the encryption key secretly. However, information-theoretically secure encryption is needed, and a one-time pad (which is the only absolutely secure encryption scheme) is of no use because the key would be just as long as the encrypted message [42]. Hence special care must be taken that each individual sk_j remains secret, although information about the ensemble of sk_j's may become known.

We show how this can be done for the general Construction 4.1, taking into account that a forger has a priori information about the encrypted sk_j's because he may know the corresponding one-time "public" keys and signatures.

Construction 5.2 (scheme with small amount of secret storage). Let a one-time FSS scheme according to Construction 4.1 together with message hashing be given, and apply top-down tree authentication (Construction 5.1) to it with the following modifications:

- In key generation, the signer additionally chooses a value $e \in G$ randomly as an encryption key. She keeps e secret all the time.
- In signing: Whenever the signer has used up a one-time secret key $sk_j = (sk_{j,1}, sk_{j,2})$ by signing a message m_j (which may be a real message or a pair of one-time "public" keys), she proceeds as follows:
  - She encrypts $sk_{j,2}$ as $c_j := sk_{j,2} + e$.
  - She stores m_j, the one-time signature s_j, and the ciphertext c_j reliably but not necessarily secretly.
- For a proof of forgery: If the signer needs a one-time secret key sk_j to prove a forgery, she reconstructs it as follows: She decrypts $sk_{j,2} = c_j - e$ and recomputes $sk_{j,1} = s_j - m\, sk_{j,2}$, where $m := hash(m_j)$. ◇

THEOREM 5.2. *If the underlying one-time FSS scheme is secure, Construction* 5.2 *describes a secure FSS scheme for N messages. At any time, only the encryption key e and the one-time secret keys that have been generated but not yet used for signing* (*marked "use later" in Figure* 3)*, i.e., at most one per level of the tree, must be stored secretly.*

Proof. In addition to Theorem 5.1, we only have to show that the extra information stored nonsecretly, i.e., the ciphertexts c_j, does not help a forger to produce unprovable forgeries.

In every successfully forged complete signature, the signer still finds at least one successfully forged one-time signature s_j^* on a message m_j^*. If m_j^* and a message m_j that the signer has signed at this node are a collision of the hash function, this collision is already a proof of forgery. Otherwise, Theorem 4.1(c) guarantees that the forgery can be proved if s_j^* is different from the correct one-time signature that the signer would have produced for m_j^* at Node j. Thus it remains to be shown that the additional information does not help a forger to find exactly this signature. This signature depends only on sk_j, i.e., not on the values sk_l at other nodes. We consider the worst case, where the signer has already signed a message m_j at Node j. Let $m := hash(m_j)$. In the one-time scheme, the set of possible values sk_j from the point of view of a forger was $SK_{\bar{C},j} = \{(s_j - m\, sk'_{j,2}, sk'_{j,2}) | h(sk'_{j,2}) = pk_{j,2}\}$ with uniform distribution (see the proof of Theorem 4.2). Hence it suffices to show that all of these values are still possible if the forger has seen c_j and all the other ciphertexts c_l.

Let such a value $sk'_{j,2}$ be given. It corresponds to exactly one encryption key $e' := c_j - sk'_{j,2}$. This implies that the other one-time secret keys must be given by

$$sk'_{l,2} := c_l - e' = sk'_{j,2} + c_l - c_j.$$

The only question is whether these are possible secret keys, i.e., whether $h(sk'_{l,2}) = pk_{l,2}$. On one hand,

$$h(sk'_{l,2}) = h(sk'_{j,2}) \cdot h(c_l)/h(c_j) = pk_{j,2} \cdot h(c_l)/h(c_j),$$

and on the other hand,

$$h(c_l) = h(sk_{l,2}) \cdot h(e) = pk_{l,2} \cdot h(e) \quad \text{and} \quad h(c_j) = pk_{j,2} \cdot h(e).$$

Hence $h(sk'_{l,2}) = pk_{l,2}$. □

If this construction is applied to a usual complete tree, the amount of information that must be stored secretly is logarithmic in N (see Table 2 in section 6.5 for an example).

If we use a list-shaped tree, i.e., the left child of each node is a real message, at any time only two sk_j's have been generated but not yet used for signing. Thus the amount of secret storage is constant (as a function of N). However, later signatures are very long. Thus list-shaped trees should only be used with a single recipient; see section 5.6.

One can also use trees of other shapes, e.g., ternary trees or trees where one decides dynamically whether the message m_j signed at a node is a real message or a pair of one-time "public" keys and specifies this by one additional bit in m_j.

5.5. Improvement for the discrete logarithm constructions. In this section, we present a fail-stop signature scheme for signing N messages where the total length of the secret key is $(2N + 2)k$. The smallest upper bound in the previous sections was $4Nk$, achieved by pure repetition of the one-time Discrete Logarithm Scheme and also in bottom-up tree authentication based on it.

The scheme is a variant of pure repetition of the Discrete Logarithm Scheme where half of each one-time secret key is reused in the next signature.

Construction 5.3.

- Key generation:
  - As in Construction 4.3, a prekey (p, q, a, b) is chosen and verified, where p and q are primes with $q|(p-1)$ and a and b are generators of the group H_q, the unique subgroup of $\mathbb{Z}_p^*$ of order q.
  - The signer chooses a secret key

$$sk := ((x_1, y_1), (x_2, y_2), \ldots, (x_{N+1}, y_{N+1}))$$

consisting of numbers between 0 and $q - 1$. The corresponding public key is

$$pk := (pk_1, \ldots, pk_{N+1}) := (a^{x_1} b^{y_1}, \ldots, a^{x_{N+1}} b^{y_{N+1}}).$$

- The message space is restricted to $\mathbb{Z}_q^*$.
- Signing: The correct signature on the jth message, m_j, is the triple

$$s := (j, x_j + m_j x_{j+1}, y_j + m_j y_{j+1}).$$

- Test: A triple (j, x, y) is an acceptable signature on the jth message, m_j, iff
$$a^x b^y = pk_j pk_{j+1}^{m_j}.$$
- Proofs of forgery are constructed and verified as in Construction 4.3. ◇

THEOREM 5.3. *Under Assumption* DL*, Construction* 5.3 *describes a secure FSS scheme.*

Proof. It is clear that correct signatures pass the test because individual signatures are identical to those in Construction 4.3. Similarly, the security for the recipients is fulfilled because proofs of forgery are identical to those in Construction 4.3. Furthermore, every successful forgery f that is not the correct signature, i.e., $f = (m_j^*, (j, x, y))$ with $(j, x, y) \neq sign(sk, j, m_j^*)$, can be proved as before. It remains to show that the reuse of halves of the one-time secret keys does not make it too easy for a forger to guess correct signatures.

It suffices to show this for the worst case, where the signer has already issued N signatures on messages $m_1, \ldots, m_N$, possibly chosen by the forger, and the forger therefore has maximum information. We first determine the size of the set $SK_{\tilde{C}}$ of possible secret keys given these signatures and the public key. $SK_{\tilde{C}}$ is the set of solutions to the equations defining the public key and the signatures. With $e := \log_a(b)$, all of these equations can be written as linear equations over GF(q). They are described by the following $(3N+1) \times (2N+2)$ matrix A. The columns correspond to the elements of sk in the order as above, the first $2N$ rows to the signatures, and the last $N+1$ rows to the components of the public key.

$$A = \begin{pmatrix}
1 & 0 & m_1 & & & & & & & \\
 & 1 & 0 & m_1 & & & & & & \\
 & & 1 & 0 & m_2 & & & & & \\
 & & & 1 & 0 & m_2 & & & & \\
 & & & & & \ddots & & & & \\
 & & \mathbf{0} & & & & & & & \\
 & & & & & & 1 & 0 & m_N & \\
 & & & & & & & 1 & 0 & m_N \\
\cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\
1 & e & & & & & & & & \\
 & & 1 & e & & & & & & \\
 & & & & & \ddots & & & & \\
 & & \mathbf{0} & & & & & & & \\
 & & & & & & & & 1 & e
\end{pmatrix}.$$

We now show that the rank of A is $2N+1$. For this, consider the following submatrix of A:

$$\begin{pmatrix}
1 & 0 & m_j & 0 \\
0 & 1 & 0 & m_j \\
1 & e & 0 & 0 \\
0 & 0 & 1 & e
\end{pmatrix}.$$

One can easily see that this submatrix has rank 3 and that the third row can be removed. By repeating this step for $j := 1, \ldots, N$, we delete all rows $(0 \ldots 0\, 1\, e\, 0 \ldots 0)$ except for the last one. The resulting matrix clearly has rank $2N + 1$.

Hence $|SK_{\bar{C}}| = q$. We now show that each of these q possible secret keys yields a different correct signature on the new message m_j^*. For this it suffices to show that any additional signature determines the secret key uniquely. The additional signature introduces two new equations corresponding to the rows

$$\begin{array}{ccccccc} 0 \ldots 0 & 1 & 0 & m_j^* & 0 & 0 \ldots 0 \\ 0 \ldots 0 & 0 & 1 & 0 & m_j^* & 0 \ldots 0 \end{array}.$$

One can easily see that the rank of the new matrix is $2N+2$. (Remember that $m_j \neq 0$ for all j.) Hence an additional, forged signature is correct only for one out of the q possible secret keys. This completes the proof. □

Construction 5.3 can be combined with bottom-up tree authentication; this yields public keys as short as in section 5.3 and secret keys as short as in Construction 5.3.

5.6. The case of a single recipient. In some important applications, all signatures of a signer have the same recipient, while any third party is able to settle a dispute (otherwise, one would not need a signature scheme). In this case, significant efficiency improvements are possible because the recipient can store information from previously received signatures. Now the most efficient construction is top-down tree authentication with a list-shaped tree so that only one new node of the tree must be produced, sent, and tested each time. Thus signing and testing are reduced to the following procedures:

- Signing: Assume that the current one-time secret key is sk_j. The signer generates a new one-time key pair (sk_{j+1}, pk_{j+1}); this can be done off-line before the new message m_j is known. The complete signature on m_j consists of the new one-time "public" key pk_{j+1} and a one-time signature with sk_j on the pair (m_j, pk_{j+1}).
- Test: The recipient tests the new one-time signature with his current one-time "public" key pk_j and then sets pk_{j+1} as his current one-time "public" key.

The old one-time secret and "public" keys can be stored as in Construction 5.2. If a third party has to settle a dispute, it must test the signature with respect to the original public key pk. This can be done with overhead logarithmic in the length of the list: With logarithmic search, one first finds an index $j' \leq j$ where the signer and the recipient agree on $pk_{j'}$ but not on the pair $(m_{j'}, pk_{j'+1})$ signed with respect to it. Then it suffices to solve the dispute regarding this one-time signature.

6. Lower bounds on the efficiency of fail-stop signatures. In this section, we try to answer the following two questions:

1. How close to the optimum are the existing constructions?

2. Is there a certain price in efficiency to pay for information-theoretic security instead of computational security?

We do this by giving lower bounds on the length (more precisely, the entropy) of keys and signatures. In practice, these parameters correspond to the communication and storage complexity of both key generation and the transmission of signed messages. Similar lower bounds have been investigated for other cryptographic schemes with information-theoretic security requirements, e.g., encryption schemes [42], au-

thentication codes (starting with [16]; see, e.g., [40]), and unconditionally secure signature schemes [23].[3]

Section 6.1 sketches the information-theoretic background, section 6.2 introduces the random variables, section 6.3 investigates the length of the secret key, section 6.4 investigates the length of signatures and public keys, and section 6.5 answers the questions posed above, i.e., it compares the lower bounds to the known upper bounds and to ordinary digital signature schemes.

6.1. Information-theoretic background. Since a random variable with entropy σ cannot be coded with less than σ bits on average, it is sufficient to prove lower bounds on the entropy of random variables in order to have lower bounds on the length of the values of these random variables.

For the formal theorems and proofs, we assume that the reader is familiar with elementary information theory (see [41] and [15, sections 2.2 and 2.3]). We briefly repeat the most important notions in the notation of [15]. Assume that a common probability space is given. Capital letters denote random variables and small letters their corresponding values, and $\mathrm{P}(X = x)$ is abbreviated as $\mathrm{P}(x)$, etc. The joint random variable of X and Y is written as X, Y. The entropy of a random variable X is

$$\mathrm{H}(X) := -\sum_x \mathrm{P}(x) \log \mathrm{P}(x).$$

$\mathrm{H}(X \mid Y)$ denotes the conditional entropy of X if Y is known, and $\mathrm{I}(X;Y)$ denotes the mutual information between X and Y. They are defined as follows:

$$\mathrm{H}(X \mid Y) : = -\sum_{x,y} \mathrm{P}(x,y) \log \mathrm{P}(x \mid y),$$

$$\mathrm{I}(X;Y) := \mathrm{H}(X) - \mathrm{H}(X \mid Y).$$

Furthermore, the conditional mutual information is defined as

$$\mathrm{I}(X;Y \mid Z) := \mathrm{H}(X \mid Z) - \mathrm{H}(X \mid Y,Z).$$

The following important rules will often be used:

$$\mathrm{H}(X) \geq 0, \qquad \mathrm{H}(X \mid Y) \geq 0, \tag{6.1}$$

$$\mathrm{H}(Y,Z \mid X) = \mathrm{H}(Y \mid X) + \mathrm{H}(Z \mid Y,X), \tag{6.2}$$

$$\mathrm{I}(X;Y) = \mathrm{I}(Y;X). \tag{6.3}$$

Additionally, we often need Jensen's inequality for the special case of the logarithm [14]: If $p_i \geq 0$ and $x_i > 0$ for all i and the sum of the p_i's is 1, then

$$\log\left(\sum_i p_i x_i\right) \geq \sum_i p_i \log(x_i).$$

[3] However, the lower bounds in the following cannot be derived entirely from information-theoretic security requirements; this makes some new proof techniques necessary.

6.2. The random variables. The common probability space for all of the random variables arising in a fail-stop signature scheme is given by the random bits used in key generation; here we made use of the fact that we could define all of the other algorithms as deterministic by regarding all random bits as part of the secret key.

For the lower bounds, we only need the case where all parties execute G honestly, and we always consider a fixed triple of parameters $par = (k, \sigma, N)$. Then the probabilities of sk and pk are uniquely determined. Hence we can define the following random variables:

- SK and PK are the random variables of the secret and public key, respectively.
- If a message sequence $\underline{m} = (m_1, \ldots, m_j)$ with $j \leq N$ has been fixed, random variables S_i for $i = 1, \ldots, j$ are defined as the correct signature on m_i in this context, i.e.,

$$S_i := sign(SK, i, (m_1, \ldots, m_i)).$$

Since the signature is a deterministic function of the secret key and the message sequence, we have

$$\mathrm{H}(S_i \mid SK) = 0.$$

- Similarly, for the given message sequence $\underline{m} = (m_1, \ldots, m_j)$, the random variable of the history up to the ith signature (for $i \leq j$) is defined as

$$Hist_i := ((m_1, \ldots m_i), (S_1, \ldots, S_i)).$$

6.3. Lower bound on the number of secret random bits needed. As mentioned in section 5, the largest difference between fail-stop signatures and ordinary digital signatures is the length of the secret key. We have shown in Theorem 5.2 that the signer need not store a lot of secret information at the same time; however, the overall number of secret random bits chosen was still linear in the number of messages to be signed. We now show that this cannot be avoided.

If all fail-stop signature schemes followed the construction idea in section 1.3, this would be quite easy to see:

1. Even an arbitrarily powerful forger must not be able to guess the signer's correct signature.
2. Hence the entropy of the correct signature is large.
3. Since this holds for each additional signature, even if some signatures are already known, the entropies of the signatures can be added, and therefore the overall entropy of the signer's secrets is large.

Our proof follows this outline; however, only a weaker average version of statement 1 can be derived from the definitions. If we required that applying *prove* to the signer's correct signature never yielded a valid proof of forgery, a formal proof would be easy and would yield

$$\mathrm{H}(SK \mid PK) \geq (N+1)\sigma.$$

However, e.g., in fail-stop signature schemes with message hashing, an arbitrarily powerful forger sometimes *does* know correct signatures on new messages (those with the same hash value as the original message), and the signer can prove them to be forgeries.

Furthermore, note that the desired lower bound cannot possibly be proved from the signer's security alone. As a counterexample, suppose that the signer were allowed

to disavow all signatures in an ordinary digital signature scheme; then she would be unconditionally secure without using many random bits (but the recipient would not be secure at all). This is a problem because Definition 3.2, like all computational cryptographic definitions, is asymptotic, i.e., security is only guaranteed for "k sufficiently large." Thus in a certain sense, we can only derive lower bounds for $k \geq k_0$ for an unknown k_0. This may seem unsatisfactory: No one would have doubted that we need arbitrarily long keys if we made k sufficiently large.

However, the real purpose of lower bounds is to say "whenever we have certain requirements on the security, we have to pay the following price in terms of efficiency." In this section, this means, more precisely, "if the signer wants the probability of unprovable forgery to be at most $2^{-\sigma}$, and the recipients want some security, too, then at least the following number of random bits is needed (as a function of σ and the security for the recipients)."

To quantify the security for the recipients, it suffices for our purpose to consider the probability that the signer can prove that her own signatures are "forgeries" simply by applying the algorithm *prove*. In practice, one will require this probability to be at most, say, 2^{-100}, or, more generally, $2^{-\sigma^*}$ for some σ^*. We will prove the lower bounds as a function of this parameter σ^* (in addition to σ). Now we can proceed formally.

DEFINITION 6.1. *Let a fail-stop signature scheme and parameters σ and N be given. For every message sequence $\underline{m} = (m_1, \ldots, m_{N+1})$, we define a polynomial-time algorithm $\tilde{A}_{\underline{m}}$ that describes how a dishonest signer could try to disavow her own correct signatures. (This algorithm should be rather useless!)*

1. *Execute G correctly (with the center) to obtain sk and pk.*

2. *Compute the signatures $s_1, \ldots, s_N$ on $m_1, \ldots, m_N$ and the histories $hist_1, \ldots, hist_N$ correctly. Then because m_{N+1} is one message too much, compute its signature s_{N+1} as if m_N had not been signed, i.e., $s_{N+1} := sign(sk, N, (m_1, \ldots, m_{N-1}, m_{N+1}))$.*

3. *If $provable(sk, pk, hist_{i-1}, (m_i, s_i))$ for an $i \in \{1, \ldots, N+1\}$, then output the proof $prove(sk, m_i, s_i, hist_{i-1})$.*

We say that k is large enough to provide security level σ^* for the recipients against $\tilde{A}_{\underline{m}}$ *if the success probability of $\tilde{A}_{\underline{m}}$ is at most $2^{-\sigma^*}$.*[4] *This probability is over the random bits of $\tilde{A}_{\underline{m}}$ and the random bits of the center in step 1.*

THEOREM 6.1. *Let a fail-stop signature scheme with actual parameters σ and N and a security level σ^* be given. Let $\sigma' := \min(\sigma, \sigma^*)$. Then for all k large enough to provide security level σ^* for the recipients against the algorithm $\tilde{A}_{\underline{m}}$ for at least one sequence $\underline{m}$ of $N+1$ pairwise-distinct messages,*[5]

$$\mathrm{H}(SK \mid PK) \geq (N+1)(\sigma' - 1).$$

[4]The formal definition of the recipient's security immediately implies the existence of k_0 such that $\tilde{A}_{\underline{m}}$ has this property for all $k \geq k_0$. We have now bypassed the problem that we do not know how large k_0 is because we simply know that it must be large enough in a practical application.

Note that it would be impossible to require k to be large enough to provide the same level of security against all polynomial-time algorithms instead of only $\tilde{A}_{\underline{m}}$ because for a fixed k, we have a finite problem, and all finite problems can be solved perfectly by some constant-time algorithm. However, our $\tilde{A}_{\underline{m}}$ is not only asymptotically polynomial-time but definitely feasible at the given k because it is of the same complexity as *sign* and *prove*. Requirements of the same type are well known in practice, e.g., when one requires k to be large enough to make the success probability of all known factoring algorithms small.

[5]Note that this is a very weak condition on k. The contrary is that the signer can sign an arbitrary message sequence $\underline{m}$ and disavow it with significant probability using $\tilde{A}_{\underline{m}}$.

Since $\underline{m}$ is fixed throughout the proof, we can omit it in the notation, i.e., all random variables S_i and $Hist_i$ are implicitly assumed to belong to this message sequence. We also omit $\underline{m}$ in the histories, i.e., we abbreviate $Hist_i := (S_1, \ldots, S_i)$ for $i = 1, \ldots, N+1$. The first lemma formalizes statement 1 above, i.e., that it is hard to guess correct signatures.

LEMMA 6.1. *With the notation of Theorem* 6.1*, for each* $i \leq N+1$ *and each pair* $(pk, hist_{i-1})$*, fix an optimal guess* $s^*(pk, hist_{i-1})$ *at the correct signature on* m_i *if* pk *and* $hist_{i-1}$ *are known, i.e., for all values* s*,*

$$\mathrm{P}(S_i = s^*(pk, hist_{i-1}) \mid pk, hist_{i-1}) \geq \mathrm{P}(S_i = s \mid pk, hist_{i-1}).$$

Then this guess is still not very good on average:

$$\mathrm{P}(S_i = s^*(PK, Hist_{i-1})) \leq 2^{-\sigma'+1}.$$

Proof. Let i and $(pk, hist_{i-1})$ be given. We have

$$\begin{aligned}
&\mathrm{P}(S_i = s^*(PK, Hist_{i-1})) \\
&\quad = \mathrm{P}(S_i = s^*(PK, Hist_{i-1}) \wedge provable(SK, PK, Hist_{i-1}, (m_i, S_i))) \\
&\qquad + \mathrm{P}(S_i = s^*(PK, Hist_{i-1}) \\
&\qquad\quad \wedge \neg provable(SK, PK, Hist_{i-1}, (m_i, s^*(PK, Hist_{i-1})))) \\
&\quad \leq \mathrm{P}(provable(SK, PK, Hist_{i-1}, (m_i, S_i))) \\
&\qquad + \mathrm{P}(\neg provable(SK, PK, Hist_{i-1}, (m_i, s^*(PK, Hist_{i-1})))).
\end{aligned}$$

The first term is bounded by the success probability of $\tilde{A}_{\underline{m}}$ and therefore by $2^{-\sigma^*}$. The second term can be bounded using the security for the signer (Definition 3.4):

$$\begin{aligned}
&\mathrm{P}(\neg provable(SK, PK, Hist_{i-1}, (m_i, s^*(PK, Hist_{i-1})))) \\
&= \sum_{pk, hist_{i-1}} \mathrm{P}(pk, hist_{i-1}) \mathrm{P}(\neg provable(SK, PK, Hist_{i-1}, (m_i, s^*(PK, Hist_{i-1}))) \\
&\qquad\qquad \mid PK = pk, Hist_{i-1} = hist_{i-1}) \\
&\leq \sum_{pk, hist_{i-1}} \mathrm{P}(pk, hist_{i-1}) 2^{-\sigma} \\
&= 2^{-\sigma}.
\end{aligned}$$

Together, these two bounds yield the lemma. □

Lemma 6.2 uses Lemma 6.1 to give a lower bound corresponding to statement 2 of the informal proof sketch.

LEMMA 6.2. *With the notation of Theorem* 6.1*, for each* $i \leq N+1$*,*

$$\mathrm{H}(S_i \mid PK, Hist_{i-1}) \geq \sigma' - 1.$$

Proof. We can write the conditional entropy as

$$\mathrm{H}(S_i \mid PK, Hist_{i-1}) = -\sum_{s_i,pk,hist_{i-1}} \mathrm{P}(s_i, pk, hist_{i-1}) \log(\mathrm{P}(s_i \mid pk, hist_{i-1}))$$

$$\geq -\log\left(\sum_{s_i,pk,hist_{i-1}} \mathrm{P}(s_i, pk, hist_{i-1})\mathrm{P}(s_i \mid pk, hist_{i-1})\right)$$

using Jensen's inequality. (Note that one *cannot* prove that the individual values $\log(\mathrm{P}(s_i \mid pk, hist_{i-1}))$ are at least σ.) Now it suffices to show that the sum in the logarithm is at most $2^{-\sigma'+1}$. In fact, with Lemma 6.1,

$$\sum_{s_i,pk,hist_{i-1}} \mathrm{P}(s_i, pk, hist_{i-1})\mathrm{P}(s_i \mid pk, hist_{i-1})$$

$$\leq \sum_{s_i,pk,hist_{i-1}} \mathrm{P}(s_i, pk, hist_{i-1})\mathrm{P}(S_i = s^*(pk, hist_{i-1}) \mid pk, hist_{i-1})$$

$$= \sum_{pk,hist_{i-1}} \left(\mathrm{P}(S_i = s^*(pk, hist_{i-1}) \mid pk, hist_{i-1}) \sum_{s_i} \mathrm{P}(s_i, pk, hist_{i-1})\right)$$

$$= \mathrm{P}(S_i = s^*(PK, Hist_{i-1}))$$

$$\leq 2^{-\sigma'+1}. \qquad \square$$

Proof of Theorem 6.1. Theorem 6.1 can be proved from Lemma 6.2 using rule (2) from section 6.1. Recall the abbreviation $Hist_i = (S_1, \ldots, S_i)$ for $i \leq N+1$. First, we show by induction over i that the entropy of all of these signatures together is large, i.e., for all $i \leq N+1$,

$$\mathrm{H}(Hist_i \mid PK) \geq i(\sigma' - 1). \tag{4}$$

For $i = 1$, (4) is Lemma 6.2. If (4) has already been proved for $i-1$, it holds for i because

$$\begin{aligned}\mathrm{H}(Hist_i \mid PK) &= \mathrm{H}(Hist_{i-1} \mid PK) + \mathrm{H}(S_i \mid PK, Hist_{i-1}) \\ &\geq (i-1)(\sigma'-1) + (\sigma'-1) \\ &= i(\sigma'-1).\end{aligned}$$

We now use the fact that signing is deterministic, i.e., SK uniquely determines $Hist_{N+1}$. This implies $\mathrm{H}(Hist_{N+1} \mid PK, SK) = 0$, and therefore

$$\begin{aligned}\mathrm{H}(SK \mid PK) &= \mathrm{H}(SK, Hist_{N+1} \mid PK) - \mathrm{H}(Hist_{N+1} \mid PK, SK) \\ &= \mathrm{H}(SK, Hist_{N+1} \mid PK) \\ &\geq \mathrm{H}(Hist_{N+1} \mid PK) \\ &\geq (N+1)(\sigma'-1). \qquad \square\end{aligned}$$

6.4. Length of signatures and public keys. Signatures and public keys are not much longer in current fail-stop signature schemes than in ordinary digital signature schemes. Hence the lower bounds are also very small. The basic idea why fail-stop signatures might be longer at all is as follows:

1. First, there must be at least 2^σ acceptable signatures; otherwise, the correct signature could be guessed too easily.

2. Second, it must be hard for a forger to guess acceptable signatures at all. Thus the density of the set of acceptable signatures within the signature space should be small, e.g., at most $2^{-\sigma^*}$ for some σ^*.

Hence we expect the size of the signature space to be at least $2^{\sigma+\sigma^*}$. We will prove a slightly lower bound but more generally on the entropy of each signature.

We deal with the asymptotic character of the security against forgery in the same way as in section 6.3, i.e., we fix one simple algorithm that a forger might use to guess acceptable signatures.

DEFINITION 6.2. *Let a fail-stop signature scheme and parameters σ and N be given. For every message sequence $\underline{m} = (m_1, \ldots, m_i)$ with $i \leq N$, we define a (very efficient and stupid) polynomial-time forging algorithm $\tilde{F}_{\underline{m}}$. On input pk, do the following:*

1. *Choose a new key pair (sk^*, pk^*) by carrying out both roles of G correctly.*

2. *Compute a signature $s_i := sign(sk^*, i, \underline{m})$ with the new key and output (m_i, s_i) as a proposed forgery for the given key pk.*

We say that k is large enough to provide security level σ^* against forgery by $\tilde{F}_{\underline{m}}$ *if the probability that $\tilde{F}_{\underline{m}}$ outputs an acceptable signature on m_i is at most $2^{-\sigma^*}$.*[6]

THEOREM 6.2. *Let a fail-stop signature scheme with actual parameters σ and N and a security level σ^* be given. Let $\sigma' := \min(\sigma, \sigma^*)$. Then for all k large enough to provide security level σ^* both against forgery by $\tilde{F}_{\underline{m}}$ and against $\tilde{A}_{\underline{m}}$ for at least one sequence $\underline{m}$ of $i \leq N$ pairwise-distinct messages,*

$$\mathrm{H}(S_i) \geq \sigma' + \sigma^* - 1$$

and

$$\mathrm{H}(PK) \geq \sigma^*.$$

The following lemma formalizes step 2 of the informal proof sketch. The fact that the number of acceptable signatures, given the public key, is much smaller than the complete signature space is generalized as follows: The public key contains a lot of information about the correct signature.

LEMMA 6.3. *With the notation of Theorem* 6.2*,*

$$\mathrm{I}(S_i; PK) \geq \sigma^*.$$

[6] The security against forgery, Theorem 3.1, implies the existence of k_0 such that all $k \geq k_0$ have this property.

Proof. By the definitions and Jensen's inequality,

$$\begin{aligned}
\mathrm{I}(S_i; PK) &= - \sum_{s_i, pk : \mathrm{P}(s_i, pk) \neq 0} \mathrm{P}(s_i, pk) \log(\mathrm{P}(s_i)\mathrm{P}(pk)/\mathrm{P}(s_i, pk)) \\
&\geq - \log \left(\sum_{s_i, pk : \mathrm{P}(s_i, pk) \neq 0} \mathrm{P}(pk, s_i)\mathrm{P}(s_i)\mathrm{P}(pk)/\mathrm{P}(s_i, pk) \right) \\
&= - \log \left(\sum_{s_i, pk : \mathrm{P}(s_i, pk) \neq 0} \mathrm{P}(s_i)\mathrm{P}(pk) \right).
\end{aligned}$$

It suffices to show that the argument of the logarithm is bounded above by $2^{-\sigma^*}$. First, the fact that all correct signatures pass the test, i.e.,

$$\mathrm{P}(s_i, pk) \neq 0 \Rightarrow test(pk, m_i, s_i) = ok,$$

yields

$$\begin{aligned}
\sum_{s_i, pk : \mathrm{P}(s_i, pk) \neq 0} \mathrm{P}(s_i)\mathrm{P}(pk) &= \sum_{s_i, pk} \mathrm{P}(s_i)\mathrm{P}(pk) 1_{\mathrm{P}(s_i, pk) \neq 0} \\
&\leq \sum_{s_i, pk} \mathrm{P}(pk)\mathrm{P}(s_i) 1_{test(pk, m_i, s_i) = ok}.
\end{aligned}$$

Now we use the security against $\tilde{F}_{\underline{m}}$, which can be written formally as

$$\begin{aligned}
\mathrm{P}(test(pk, m_i, s_i) = ok :: (acc, pk, sk, \varepsilon) \leftarrow G; (acc^*, pk^*, sk^*, \varepsilon) \leftarrow G; \\
s_i := sign(sk^*, i, \underline{m})) \leq 2^{-\sigma^*}.
\end{aligned}$$

This means that if a public key pk is chosen according to the distribution of PK and, independently of this, a signature is chosen according to the distribution of S_i, this signature is acceptable with respect to pk with probability at most $2^{-\sigma^*}$. Hence

$$\sum_{s_i, pk} \mathrm{P}(pk)\mathrm{P}(s_i) 1_{test(pk, m_i, s_i) = ok} \leq 2^{-\sigma^*}.$$

This is exactly what remained to be shown. □

Proof of Theorem 6.2. Lemma 6.3 implies $\mathrm{H}(S_i) - \mathrm{H}(S_i \mid PK) \geq \sigma^*$, and a special case of Lemma 6.2 implies $\mathrm{H}(S_i \mid PK) \geq \sigma' - 1$. (Here we exploit the security against $\tilde{A}_{\underline{m}}$.) As a consequence, $\mathrm{H}(S_i) \geq \mathrm{H}(S_i \mid PK) + \sigma^* \geq \sigma' + \sigma^* - 1$. Furthermore, $\mathrm{H}(PK) \geq \mathrm{I}(S_i; PK)$. □

For the case with a prekey (see section 4.2), we obtain slightly stronger results by using a forging algorithm $\tilde{F}^*_{\underline{m}}$ that generates its new key pair (sk^*, pk^*) based on the same prekey *prek*. In this case, the same proof yields

$$\mathrm{H}(S_i \mid Prek) \geq \sigma' + \sigma^* - 1 \quad \text{and} \quad \mathrm{H}(PK \mid Prek) \geq \sigma^*.$$

If, as usual in such schemes, pk is a function of sk and *prek*, we obtain one more result about the secret key.

TABLE 2
Comparison of constructions and lower bounds for fail-stop signatures.

Length of	Construction 5.1	Construction 5.2	Construction 5.3	Bottom-up	Single recipient	Lower bound
sk	$8Nk$	$8Nk$	$(2N+2)k$	$4Nk$	$4Nk$	$(N+2)(\sigma'-1)$
secret storage	$8Nk$	$4k\log(N)$	$(2N+2)k$	$4Nk$	$10k$	?
pk	$2k$	$2k$	$(N+1)k$	$2\sigma^*$	$2k$	σ^*
signature	$6k\log(N)$	$6k\log(N)$	$2k+\log(N)$	$6k+2\sigma^*\log(N)$	$4k$	$\sigma'+\sigma^*-1$

THEOREM 6.3. *In a fail-stop signature scheme with prekey and where the public key is a function of the secret key and the prekey, with the notation of Theorems* 6.1 *and* 6.2*,*

$$\mathrm{H}(SK \mid Prek) \geq (N+2)(\sigma'-1).$$

Proof. By rule (2), we get

$$\begin{aligned}\mathrm{H}(SK \mid Prek) &= \mathrm{H}(SK, PK \mid Prek) - \mathrm{H}(PK \mid SK, Prek)\\ &= \mathrm{H}(PK \mid Prek) + \mathrm{H}(SK \mid PK, Prek) - 0\\ &= \mathrm{H}(PK \mid Prek) + \mathrm{H}(SK \mid PK).\end{aligned}$$

In the last line, we used the fact that the prekey is part of the public key. Hence

$$\mathrm{H}(SK \mid Prek) \geq \sigma^* + (N+1)(\sigma'-1) \geq (N+2)(\sigma'-1). \qquad \square$$

6.5. Comparison. This section answers the two questions raised at the beginning of this section by evaluating how well our constructions meet the lower bounds and by comparing the lower bounds with similar bounds on ordinary digital signature schemes.

Table 2 approximately shows the length of the secret key (including all of the random bits needed later), the maximal amount of secret storage needed, the length of the public key and the length of a signature for Constructions 5.1, 5.2, and 5.3, bottom-up tree authentication, and the case of a single recipient. The table also shows the corresponding lower bounds; remember that all schemes use a prekey. All constructions are assumed to be based on the Discrete Logarithm Scheme from Construction 4.3 with parameters as in Table 1. Remember that $2k$ bits are needed to represent an element of the group G, k bits are needed for an element of H, and the total number of one-time secret keys in the tree in Figure 3 is $2N-1$. The bottom-up construction is shown for the case where the recipients trust a fast hash function with output length $2\sigma^*$.

It should be mentioned that [22] also presents a scheme for signing N messages where the signature length is only $2k$, and the key lengths and secret storage are the same as in Construction 5.3. However, the complexity of signing then grows linearly in N, and $\log(N)$ will be dominated by k anyway.

The difference between k in the upper bounds and σ and σ^*, and thus $\sigma' = \min(\sigma, \sigma^*)$, in the lower bounds is as follows: Usually, σ and σ^* would be chosen of equal size, say 100, whereas k must be at least 500 to give sufficient computational

security. If one believes that variants of the discrete logarithm problem exist that cannot be solved in subexponential time, e.g., on nonsupersingular elliptic curves (cf. [24]), one can choose k very close to σ^*, and then the lower bounds are met by the upper bounds except for small factors.

By disregarding the difference between k, σ, and σ^*, the current upper bound on the length of the secret key is $(2N+2)\sigma$ in contrast to the lower bound $(N+2)(\sigma-1)$. For the signature length, both bounds are 2σ, and for the public key, the upper bound is 2σ and the lower bound σ. However, having both public keys and signatures of length independent of N was only achieved if the signatures of each signer have a single recipient (or very few recipients). If every new signature may have a new recipient, there is a tradeoff: If the public key is of constant length, the signatures grow logarithmically in N because of the tree authentication. It is an interesting open question whether this can be avoided.

If we compare fail-stop signatures with ordinary digital signatures, the most obvious difference in terms of complexity is that the number of secret random bits needed for fail-stop signatures is linear in the number of messages to be signed. The lower bound on the length of fail-stop signatures is $\sigma'+\sigma^*-1$; for ordinary digital signatures, σ^* is a lower bound. Hence the two types of schemes differ by a factor of about 2. For public keys, the same lower bound σ^* holds for ordinary digital signature schemes, and in fact, even in the constructions, public keys of fail-stop signature schemes are not longer than in ordinary digital signature schemes.

7. Conclusion and outlook. We have defined fail-stop signature schemes formally and shown that their security is in fact stronger than that of ordinary digital signature schemes. In particular, one can use fail-stop signatures either as ordinary digital signatures or as signatures with dual security, where the signers instead of the recipients are secure in an information-theoretic sense. Based on the definition, we proved general lower bounds on the length of the keys and signatures in these schemes.

We presented a general construction of fail-stop signature schemes and showed how to instantiate this construction under either of the well-known assumptions that factoring large integers or computing discrete logarithms is hard. These constructions come quite close to the lower bounds; see Table 2.

There are some recent additional results about fail-stop signature schemes. In [11], it was shown that fail-stop signature schemes exist if statistically hiding bit-commitment schemes of a certain type exist. This implies that they exist if one-way permutations exist, which is a potentially weaker assumption than the existence of claw-free pairs of permutations (see section 1.4). Furthermore, a practical construction from arbitrary collision-resistant hash functions was given, and the existence of certain types of fail-stop signature schemes and bit-commitment schemes was shown to be equivalent. In [33], the open question from section 6.5, whether a fail-stop signature scheme exists where the length of both public keys and signatures is independent of the number N of messages to be signed, was answered positively under a strong computational assumption (with a construction based on the one-way accumulators from [3]).

In conjunction with a theorem from [23] which shows that the length of unconditionally secure signatures (see section 1.5) is linear in the number of participants who can test them (whereas the length of fail-stop signatures and ordinary digital signatures does not depend on this number), our constructions show that fail-stop signatures provide the most viable way of protecting signers unconditionally.

Acknowledgments. It is a pleasure to thank many people for their contributions, primarily, Eugène van Heijst, who was a coauthor of preliminary versions of parts of this paper and would have been a coauthor again if he were still working in this field, and Michael Waidner, who allowed us to use some material from joint publications here. We also thank Ivan Damgård and Andreas Pfitzmann for several good ideas and Joachim Biskup, Gerrit Bleumer, David Chaum, and the anonymous referees for interesting comments.

THE VERTEX-DISJOINT MENGER PROBLEM IN PLANAR GRAPHS*

HEIKE RIPPHAUSEN-LIPA†, DOROTHEA WAGNER‡, AND KARSTEN WEIHE‡

Abstract. We consider the problem of finding a maximum collection of vertex-disjoint paths in undirected, planar graphs from a vertex s to a vertex t. This problem is usually solved using flow techniques, which lead to $\mathcal{O}(nk)$ and $\mathcal{O}(n\sqrt{n})$ running times, respectively, where n is the number of vertices and k the maximum number of vertex-disjoint (s,t)-paths. The best previously known algorithm is based on a divide-and-conquer approach and has running time $\mathcal{O}(n \log n)$. The approach presented here is completely different from these methods and yields a linear-time algorithm.

Key words. graph algorithms, disjoint paths, planar graphs

1. Introduction.

The general Menger problem is a classical problem in both structural and algorithmic graph theory [2, 9, 15]. In general, it consists in finding the maximum number of vertex-disjoint or edge-disjoint paths in a graph from some designated vertex to another one. This problem has many practical applications, for example, in the design of reliable communication networks and the design of integrated circuits. Because of this practical background, the special case where the underlying graph is undirected and planar is particularly interesting.

In this paper, we consider the *vertex-disjoint* Menger problem in undirected, planar graphs. This means the following. Let $G = (V, E)$ be an undirected, planar graph, and let $s, t \in V$, $s \neq t$. A vertex $v \in V$ is called an *inner vertex* of path p if p contains v and v is neither of the end vertices of p. Two (s,t)-paths are said to be *internally vertex-disjoint*, or simply *vertex-disjoint*, if neither path contains an inner vertex of the other path. The problem is to find as many pairwise vertex-disjoint (s,t)-paths as possible.

The general vertex-disjoint Menger problem, directed or undirected, can be solved by reduction to a bipartite maximum-flow problem with unit capacities [3, 5]. When using the famous labeling algorithm [1, 4], this approach yields an $\mathcal{O}(km)$ algorithm, where k is the maximum number of (s,t)-paths and m is the number of edges. When the algorithm of Malhotra, Kumar, and Maheshwari is used instead, $\mathcal{O}(n^{1/2}m)$ is achieved, where n is the number of vertices [10, 11].

For planar graphs, these upper bounds reduce to $\mathcal{O}(kn)$ and $\mathcal{O}(n^{3/2})$, respectively, since $m \in \mathcal{O}(n)$. The best previously known algorithm for the special case of undirected, planar graphs was introduced by Suzuki, Akama, and Nishizeki and requires $\mathcal{O}(n \log n)$ time [16]. This algorithm is based on divide-and-conquer techniques that were originally developed in [13] and [6] for the maximum-flow problem in undirected planar graphs.

In this paper, we present an *asymptotically optimum* algorithm for the vertex-disjoint Menger problem, that is, with running time $\mathcal{O}(n)$. Moreover, we shall state that the algorithm is not too hard to implement and that the constant factor for the linear-time bound is reasonably small.

Besides the practical background mentioned above, our result can be applied to design a linear-time algorithm for a special case of the problem of finding vertex-disjoint Steiner trees for several sets of vertices. Namely, the underlying graph is undirected and planar and each terminal is incident to either of two designated faces. This special case was investigated by Suzuki, Akama, and Nishizeki [16]. They proposed an $\mathcal{O}(n \log n)$ algorithm, where the solution of an auxiliary vertex-disjoint Menger problem is the bottleneck task. In [14], a linear-time algorithm for this particular Steiner tree problem was introduced which uses the new linear-time algorithm for the vertex-disjoint Menger problem as a subroutine.

When the number of (s,t)-paths, say k, can be fixed in advance, the vertex-disjoint Menger problem in planar graphs can trivially be solved in linear time using the flow-theoretic approach. (Even vertex-disjoint paths between k different pairs of vertices, k fixed, can be found in linear time [12].)

On the other hand, the problem is straightforwardly solvable in linear time whenever an instance is (s,t)-planar, which means that s and t have a face of G in common. In fact, in this case, we may apply the following simple algorithm: For convenience, G is embedded such that s is the lowest and t the highest vertex, respectively. In the beginning, the solution is empty. Then while there is a path from s to t in G, add the "rightmost" one to the solution and (temporarily) drop all vertices and edges on this path and on its right side.

In contrast, in this paper, k is unbounded and s and t may be in general position.

The straightforward algorithm for the (s,t)-planar case demonstrates a special technique for routing and flow problems in planar graphs, which is the basis of our algorithm as well. Throughout the paper, we will call this technique *right-first search*. (In previous work, it is also called the *uppermost path algorithm* [7].) This is a depth-first search where in each search step, all arcs leaving the current vertex are searched "from right to left." More precisely, in each step, the next candidate arc for going forward, if any, is the counterclockwise next arc after the leading arc in the incidence list of the leading vertex. Clearly, the straightforward algorithm for the (s,t)-planar case amounts to a repeated application of right-first search, where each search starts with s and disregards all vertices and arcs hit in previous searches.

Very recently, the *edge*-disjoint version of the problem considered here could be solved in linear time as well [17]. A generalization of the vertex-disjoint Menger problem, where each vertex may belong to more than one path but each vertex has a fixed capacity, was also considered by Khuller and Naor [8].

The paper is organized as follows. In section 2, the new algorithm to solve the planar, vertex-disjoint Menger problem in linear time is introduced. Then in section 3, we will prove its correctness. In section 4, we will prove some properties of the results of our algorithm, which are useful for applications to vertex-disjoint Steiner trees such as those mentioned above.

2. The algorithm. We will now introduce a linear-time algorithm for the vertex-disjoint Menger problem. A formal description of the algorithm is given in Fig. 2, and an example is illustrated in Figs. 3–6. For technical reasons, we will consider a certain *directed* version of the Menger problem instead of the *undirected* problem itself. In contrast to *undirected edges*, which we denote by $\{v,w\}$, we denote the *arc directed*

from v to w by (v, w).

DIRECTED VERSION. *We transform the input graph $G = (V, E)$ into a directed graph $G_0 = (V, A_0)$: we replace each edge $\{v, w\} \in E$ with $v, w \in V \setminus \{s, t\}$ by the arcs (v, w) and (w, v), each edge $\{s, v\} \in E$ by (s, v) only, and each edge $\{v, t\}$ by (v, t) only. The problem is now to find as many vertex-disjoint (s, t)-paths as possible, that is, paths* directed *from s to t.*

Obviously, there is a linear-time algorithm for the original Menger problem if there is a linear-time algorithm for this directed version.

OVERALL ASSUMPTIONS. *Without loss of generality, we assume that t is on the outer face boundary, that G is connected, and that G is embedded in the plane* (*at least* combinatorially*, which means that all edges are sorted according to the same fixed, geometric embedding in the plane*).

Let $a_1, \ldots, a_k$ denote the arcs leaving s, in arbitrary order. The core of our algorithm for the directed version is a loop over $1, \ldots, k$. In the ith iteration, we try to draw a cycle-free (s, t)-path. This is done by a right-first search which starts with a_i. (The final path resulting from the ith iteration, if any, need not start with a_i.) The ith iteration is finished when we either reach t or return to s. Obviously, in the latter case, this is done by a backtrack step since by construction of G_0, no arc enters s.

During such a right-first search, we have to consider conflicts of the search path with itself and with paths drawn in previous searches. That is, the search meets a vertex which already belongs to some path. In other words, a conflict is a situation where one vertex has *two* in-going arcs. We resolve each conflict through a backtrack step with one of these in-going arcs. The main idea is to handle all conflicts in a way that enables us to *remove each arc from G_0 once we perform a backtrack step on it.* Since any step of such a right-first search is a forward step or a backtrack step, the number of search steps *in total* is thus linear in the size of the instance. Moreover, we will show how to realize these search steps in constant time, which immediately yields the overall worst-case bound. In principle, the following conflicts may occur (see Fig. 1):

1. The search path hits another path from the left side.
2. The search path hits itself from the left side.
3. The search path hits another path from the right side.
4. The search path hits itself from the right side.

The second and fourth cases mean that the leading vertices and arcs of the search path form a cycle. In the second case, this is a clockwise cycle if and only if s is enclosed in the cycle, and vice versa in the fourth case.

In the first two cases, we simply perform a backtrack step with the search path, where we remove the leading arc not only from the search path but also from A_0. After that, we continue our right-first search with the remainder of the search path. In particular, we need not distinguish between the first and second types of conflict in our algorithm.

In the third case, we resolve the conflict in the following way (see Fig. 1, part (3)). Let r denote the search path and let p denote the path hit by r at, say, vertex v. Moreover, let p_1 be the subpath of p from s to v and p_2 be the subpath of p from v to t. We now concatenate r with p_2 and let p_1 be the "new" search path. After that, the situation is the same as in the first case, and we resolve the conflict in the same manner. That is, we then perform a backtrack step with the new search path p_1, remove the leading arc of p_1 from G_0, and continue our search with the remainder of p_1.

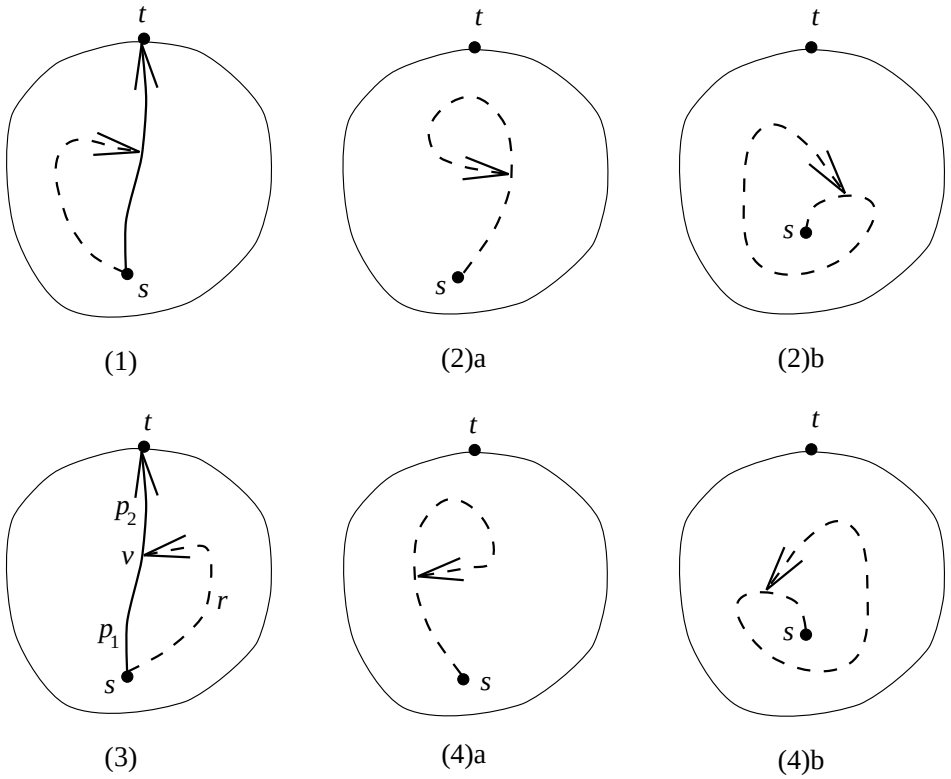

FIG. 1. *The four different cases of conflicts. The search path is dashed, and the other path involved in the conflict, if any, is solid.*

We are not able to cope with conflicts of the fourth type. Therefore, we want to avoid those conflicts *in advance*. In particular, we need not distinguish between the third and fourth types of conflict in our algorithm as well. To avoid all conflicts of the fourth type in advance, we maintain a global *time counter* and, for each vertex, a local *time stamp*. The global time counter is increased by 1 whenever the search path changes, that is, when either a new iteration of the overall loop starts or a conflict of the third type occurs. The time stamp of a vertex is set to the current value of the global time counter whenever this vertex becomes the leading vertex of the search path (in fact, before doing anything else with this vertex).

By the following modification, we prevent all conflicts of the fourth type. Consider a single forward step of the algorithm, let v be the leading vertex of the search path, and let (v, w) be the arc chosen to leave v. First, we compare the time stamps of v and w and make a case distinction. If the time stamps of v and w are different, we actually use (v, w) for going forward. On the other hand, if the time stamps of v and w are equal, we do *not* use (v, w) for going forward in our search, but we remove this arc *immediately*. In this case, we proceed with the arc leaving v that appears next after (v, w) in right-first order (if any).

In our correctness proof, we will show in particular the following two facts to justify this procedure (see Figs. 7 and 8):

1. If a conflict of the fourth type were to occur, it would be preceded and thus "announced" by a conflict of the second type where the same cycle is involved, but

PROCEDURE 2.1. *make_single_step* (VAR $v \in V$);
time_stamp $[v]$:= *time_counter*;
IF the search path hits some path at v from the left side
THEN (* conflict types 1 and 2 *) remove the last arc, say (w, v), from the search path and set $v := w$;
ELSEIF the search path hits some path at v from the right side
THEN (* conflict type 3 *)
let p_1 be the subpath of this path from s to v and let p_2 be the remaining subpath;
concatenate the search path with p_2;
make p_1 the new search path;
remove the last arc, say (w, v), from p_1 and set $v := w$;
time_counter := *time_counter* + 1;
ELSEIF at least one arc leaving v is not yet searched (except of the reverse of the in-going arc)
THEN let (v, w) be the counterclockwise first such arc after the in-going arc around v;
IF *time_stamp* $[v]$ = *time_stamp* $[w]$
THEN remove (v, w)
ELSE append (v, w) to the search path and set $v := w$;
ELSE remove the last arc, say (w, v), from the search path and set $v := w$;

PROCEDURE 2.2. *right_first_search* $((s, u) \in A)$;
time_counter := *time_counter* + 1;
let $s \to u$ be the new search path;
$v := u$;
REPEAT
make_single_step (v);
UNTIL $v \in \{s, t\}$;

ALGORITHM 2.3.
time_counter := 0;
time_stamp $[s]$:= 1;
FOR $v \in V \setminus \{s\}$ DO *time_stamp* $[v]$:= 0;
FOR $i := 1$ TO k DO $right\_first\_search(a_i)$;

FIG. 2. *Formal description of the algorithm.*

in the reverse direction. Let (w, v) be the arc removed to resolve this announcing conflict.

2. When we later select (v, w) for going forward from v, the global time counter has not changed in the meantime.

Hence (v, w) is removed at the latter stage and *not* used for going forward from v. Clearly, this makes the "announced" conflict of the fourth type impossible because (v, w) is an arc of the cycle involved.

The reader might wonder why (v, w) is not removed at the former stage when (w, v) is removed. For this, however, we must know whether the conflict at the former stage is of the first or the second type because, of course, we must not remove (v, w) in a conflict of the first type. This means that we had to maintain additional information to distinguish the individual paths from each other. However, updating

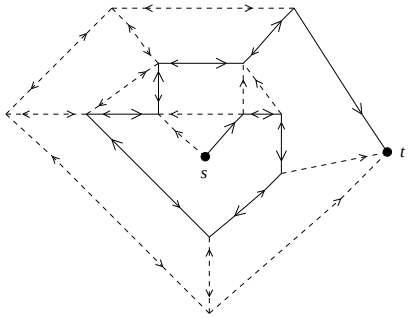

FIG. 3. *The directed, symmetric graph $G_0 = (V, A_0)$ after the first iteration, along with the path p drawn in the first iteration (solid). Two opposite arrows indicate the presence of two opposite arcs. The orientation of p from s to t is indicated by emphasized arrows. Note that there is no longer an arc leaving p on the right side because all of these arcs have been searched—and hence removed—in the first iteration.*

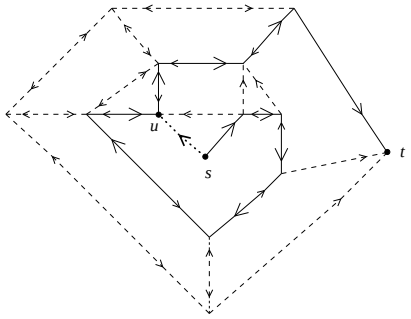

FIG. 4. *After one step of the second iteration. The search path, that is, $s \to u$ (dotted), hits the path drawn in the first iteration from the right side at vertex u.*

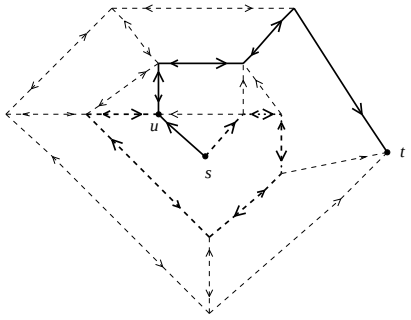

FIG. 5. *The subpath of p from s to u becomes the new search path (dotted), and the previous search path is concatenated with the subpath of p from u to t (solid).*

this information after each conflict of the third type takes too much time. In contrast, the time stamps can be maintained efficiently enough.

The principle of announcing conflicts is the reason why the algorithm does not apply to directed planar graphs in general. In fact, we need as a prerequisite that for each clockwise cycle in the graph, the reverse counterclockwise cycle exists as well.

The following theorem summarizes the discussion.

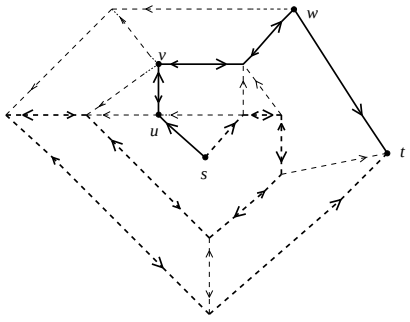

FIG. 6. *All further conflicts in the second iteration are conflicts where the search path hits the other path from the left side: twice at v and, later, once at w.*

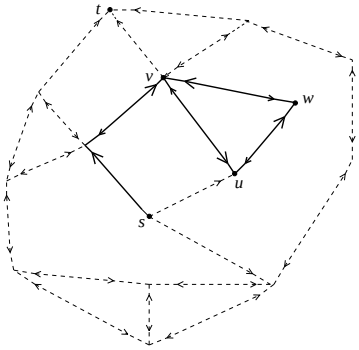

FIG. 7. *Another instance, where a conflict of the second type occurs (cycle $v \to u \to w \to v$) which "announces" a conflict of the fourth type with the reverse cycle involved.*

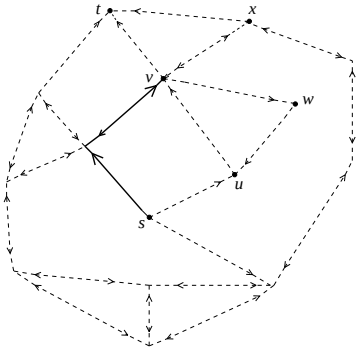

FIG. 8. *After three backtrack steps. Now (v, w) is the next arc to be considered. Note that the time stamps of v and w are equal at this stage, which means that (v, w) is not chosen for going forward but is removed from G_0 immediately, and (v, x) is chosen instead. If the algorithm were to choose (v, w) and proceed as usual, the search would now run into the cycle $v \to w \to u \to v$. This would be a disaster because resolving this conflict by removing (u, v) decreases the cardinality of an optimum solution. On the other hand, removing the other in-going arc of v would leave a cycle (namely $v \to w \to u \to v$) in the solution. This cycle* must *be cracked later on because we need (u, v) for any optimum solution. However, detecting and cracking cycles like this throughout the rest of the algorithm seems hopeless.*

THEOREM 2.4. *Algorithm* 2.3 *can be implemented such that it requires linear time in the worst case.*

Proof. For each vertex v, we manage a cyclic incidence list, where each item corresponds to an arc leaving this vertex and its reverse arc. Of course, there are pointers between corresponding items in the incidence lists of adjacent vertices. This enables us to perform each forward and backtrack/remove step in constant time. It remains to show how to perform two further tasks in constant time: finding the next arc for going forward and determining whether a conflict is from the left side (type 1 or 2) or the right side (type 3 or 4). Remember that we must distinguish neither type 1 from type 2 nor type 3 from type 4.

To see how to find the next possibility for going forward from $v \in V \setminus \{s,t\}$ in constant time, we note that at any stage, the set of all arcs leaving v that have not yet been dropped forms a connected interval of the original incidence list of v and the next arc to be considered is always the counterclockwise first arc in this interval. Clearly, maintaining a variable pointer to this arc does the job.

Now we show how to decide in constant time whether a conflict is from the left or the right side. To this end, in the overall initialization phase, we number the arcs incident to vertex $v \in V \setminus \{s,t\}$ clockwise, starting anywhere. Additionally, we store the number, say, i_v of the current in-going arc and the number, say, j_v of the current out-going arc. Suppose a conflict occurs at v, and let l be the number of the leading arc of the search path with respect to the numbering around v. If $i_v < j_v$, this is a conflict from the *left* side if and only if $i_v < l < j_v$, and if $i_v > j_v$, it is a conflict from the *right* side if and only if $i_v > l > j_v$. Altogether, this proves Theorem 2.4. □

3. Correctness. Essentially, the correctness proof consists of three parts, which are handled separately in three subsections. Before going into the details, we first outline the ideas behind our proof.

Let $\overline{a}_1, \ldots, \overline{a}_m$ be the arcs that are removed *in this order* during the algorithm. Further, let $A_i := A_{i-1} \setminus \{\overline{a}_i\}$ for $i = 1, \ldots, m$. (Recall that $G_0 = (V, A_0)$ is the initial directed graph constructed from G in the beginning of section 2.) Finally, let $G_i := (V, A_i)$, $i = 1, \ldots, m$, that is, G_i is the rest of G_0 after $\overline{a}_1, \ldots, \overline{a}_i$ are removed.

Notice that the final set of paths provided by the algorithm is maximum for G_m because any arc of G_0 that leaves s and still belongs to G_m is occupied by one of the final paths. However, we have to show that our solution is optimum for G_0, not for G_m. For this, we prove the following invariant facts by induction on the forward and backtrack/remove steps of the algorithm. The second fact immediately yields the claim.

INVARIANT 3.1. *The following two facts are maintained as invariants by Algorithm* 2.3.

1. *No conflict of the fourth type occurs.*
2. *Optimum solutions in G_0, G_1, $G_2, \ldots, G_m$, respectively, have the same cardinality. In other words, for each $i = 1, \ldots, m$, there is an optimum solution for G_{i-1} that does not contain $\overline{a}_i$.*

In section 3.1, we show that Invariant 3.1(1) is maintained at least as long as Invariant 3.1(2) is. Of course, Invariant 3.1(2) is trivially maintained when $\overline{a}_i$ is a dead end, that is, no arc leaves the head of $\overline{a}_i$ in G_{i-1}. Therefore, it suffices to show maintenance of Invariant 3.1(2) for the case where $\overline{a}_i$ is removed either because of a conflict or because of equal time stamps.

However, our case distinction is slightly different, mainly for proof-technical rea-

sons. Note that often an arc (v, w) that is removed because $time\_stamp[v] = time\_stamp[w]$ would be removed anyway in the very next search step, namely because of a conflict at w or because w is a dead end. An arc (v, w) is called *unusual* if it is removed because $time\_stamp[v] = time\_stamp[w]$ at some stage of the algorithm but would *not* have been removed anyway in the very next search step. In any other case, it is called *usual*. Maintenance of Invariant 3.1(2) is proved separately for unusual arcs in section 3.2 and for usual arcs in section 3.3. The former proof relies on the assumption that Invariant 3.1(1) is valid.

Sections 3.1 and 3.2 are necessary to prove that our procedure for avoiding conflicts of the fourth type works well. The heart of the proof is section 3.3. To get an idea of this, remember the simple algorithm for the (s, t)-planar case given in the introduction. This algorithm works because it always "packs" the paths as tightly to the right boundary as possible. That is, no path can be drawn more to the right unless another path is removed. The key insight for the *non*-(s, t)-planar case is that, in principle, we may use a very similar argument, although there is no such boundary to lean on at all. In fact, in some sense, such boundaries are "constructed" by Algorithm 2.3 during its execution. This is formalized in the following lemma.

LEMMA 3.2. *At any stage of Algorithm* 2.3*, no arc leaves any path on the right side.*

Proof. All of those arcs have been searched and hence removed at previous stages. □

3.1. Proof of Invariant 3.1(1). In this section, we will show by contradiction that no conflict of the fourth type occurs during the execution of Algorithm 2.3 as long as Invariant 3.1(2) is valid. Therefore, throughout this section we assume that at least one conflict of the fourth type *does* occur. Let C be the cycle formed by the leading part of the search path.

Note that by construction of G_0, neither s nor t belongs to C because no arc enters s and no arc leaves t. Moreover, since t is without loss of generality assumed to be incident to the outer face, t is outside C.

LEMMA 3.3. *The source s cannot be inside C as long as Invariant* 3.1(1) *is valid.* (*Fig.* 1*, part* 4(b)).

Proof. Suppose s is inside C (see Fig. 9).

Lemma 3.2 implies that at this stage, there is no longer an arc pointing from C to the exterior of C. Since t belongs to the exterior of C, there is no longer an (s, t)-path at this stage. This means that the cardinality of an optimum situation is zero for the current graph. However, since G_0 is connected, the cardinality of an optimum solution for G_0 is positive, but this contradicts Invariant 3.1(2) for the stage immediately before the assumed conflict occurs. □

In the rest of this section, we prove that the case where s is outside C (see Fig. 1, part 4(a)) is also impossible. Therefore, for a contradiction, let S_{first} denote the first stage where a conflict of the fourth type occurs with s outside the cycle C involved. Let vertex w_0 be the leading vertex of the search path at that stage and let $C = (w_0 \to w_1 \to w_2 \to \cdots \to w_{l-1} \to w_l = w_0)$. We will investigate the "past history" of the conflict at stage S_{first}.

LEMMA 3.4. *For all $i = 1, \ldots, l-1$, occupying arc (w_{i-1}, w_i) did not cause a conflict.*

Proof. Let S be the stage where (w_{i-1}, w_i) is occupied. Suppose this causes a conflict at w_i. This is no conflict of the first or the second type because otherwise the arc occupied last, namely (w_{i-1}, w_i), would be removed at S to resolve the conflict,

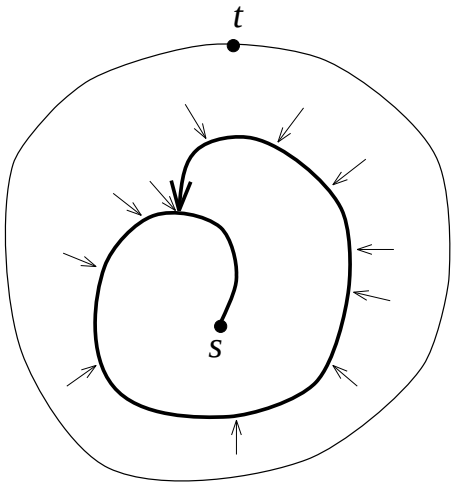

FIG. 9. *The situation in the proof of Lemma* 3.3. *No arc points from the cycle C to its exterior, only possibly the other way round.*

and this would contradict the assumed conflict at stage S_{first}. Moreover, this is not a conflict of the fourth type either, for the following reason: the assumption that s is inside the cycle formed by the leading arcs of the search path contradicts Lemma 3.3, and the assumption that s is outside this cycle contradicts the specific choice of S_{first} to be the first stage where such a conflict occurs. In summary, this is a conflict of the third type.

Let p denote the (s,t)-path hit by the search path at stage S, and let a be the arc of p leaving w_i. Then either a belongs to the exterior of $\mathcal{C}$ or the interior of $\mathcal{C}$ or is just (w_i, w_{i+1}). We consider all three cases separately (see Fig. 10).

Case 1. The arc a belongs to the exterior of $\mathcal{C}$ (see Fig. 10, part (1)).

Since this is a conflict of the third type, (w_{i-1}, w_i) appears counterclockwise around w_i after the in-going arc and before the out-going arc of w_i with respect to p. Since a is this out-going arc, (w_i, w_{i+1}) leaves p on the right side. By Lemma 3.2, (w_i, w_{i+1}) has already been removed at stage S, which contradicts the assumed situation at the later stage S_{first}.

Case 2. The arc a belongs to the interior of $\mathcal{C}$ (see Fig. 10, parts (2) and (3)).

Note that p must leave $\mathcal{C}$ and enter the exterior of $\mathcal{C}$ at least once after w_i in order to reach t. (Recall that t belongs to the exterior of any directed cycle of G_0.) In particular, let w_j be the first vertex after w_i on p where this happens. Then the in-going arc of w_j with respect to p either belongs to the interior of $\mathcal{C}$ or is just (w_{j-1}, w_j) or (w_{j+1}, w_j) (see Fig. 10, part (2) for the first case and Fig. 10, part (3) for the third case). In the first two cases, (w_j, w_{j+1}) has already been removed until stage S because of Lemma 3.2. Clearly, this is again a contradiction. Therefore, consider the last case. Then there is $\mu \in \{1, \ldots, l\}$ such that $(w_\mu, w_{\mu-1})$, $(w_{\mu-1}, w_{\mu-2}), \ldots, (w_{j+1}, w_j)$ belong to p but $(w_{\mu+1}, w_\mu)$ does not. By the specific choice of w_j, the in-going arc of w_μ with respect to p does not belong to the exterior but to the interior of $\mathcal{C}$. Therefore, $(w_\mu, w_{\mu+1})$ has already been removed because of Lemma 3.2. This is the same contradiction as in the first case.

Case 3. $a = (w_i, w_{i+1})$ (see Fig. 10, part (4)).

Then there is $\nu \in \{1, \ldots, l\}$ such that all of (w_i, w_{i+1}), $(w_{i+1}, w_{i+2}), \ldots, (w_{\nu-1}, w_\nu)$

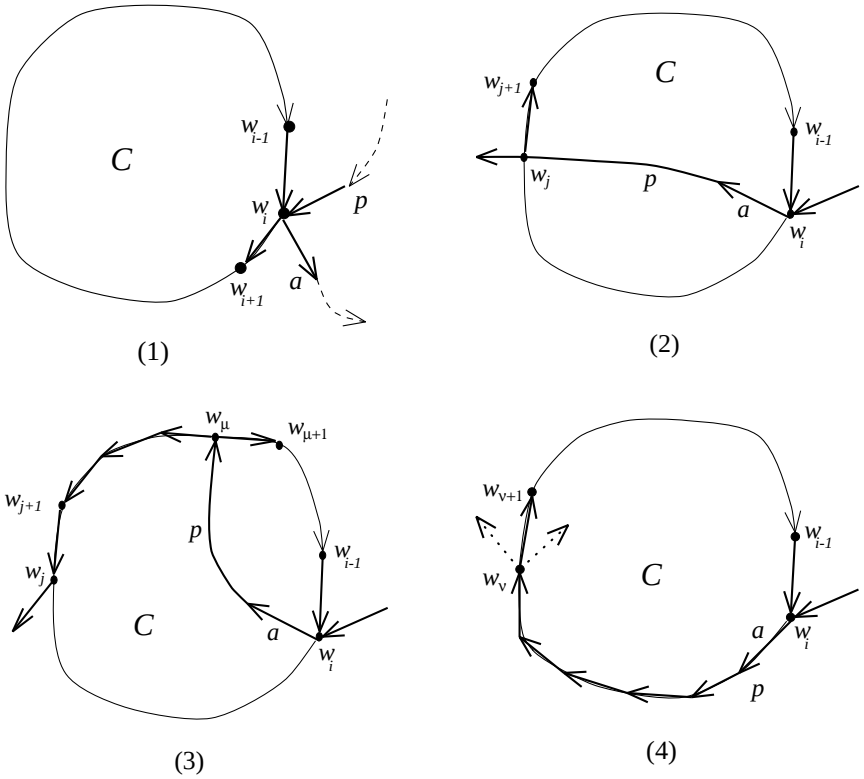

FIG. 10. *Typical situations in the different cases considered in the proof of Lemma* 3.4 *for conflicts of the third type: Case* 1: (1); *Case* 2: (2) *and* (3); *Case* 3: (4).

belong to p but $(w_\nu, w_{\nu+1})$ does not. Thus the out-going arc of w_ν with respect to p belongs to either the exterior of $\mathcal{C}$ or the interior of $\mathcal{C}$. If this arc belongs to the *exterior* of $\mathcal{C}$, then $(w_\nu, w_{\nu+1})$ has already been removed by Lemma 3.2. On the other hand, if this arc belongs to the *interior* of $\mathcal{C}$, the proof is literally the same as for Case 2 (just replace i by ν). □

To continue, we need a more general, technical lemma, which will also be used later. A vertex is called *released* at some stage if it was occupied by some path immediately before this stage and is not occupied anymore (because of a backtrack step in fact).

LEMMA 3.5. *When a vertex v is released at some stage S, all arcs leaving v have been removed even before, except possibly the reverse of the current in-going arc. If the in-going arc has changed at least once before S,* all *arcs have been removed.*

Proof. When vertex v is released, all of the arcs that we could use for going forward from v have already been searched and hence removed. This means all arcs leaving v except possibly the reverse of the in-going arc. This proves the first claim. Therefore, consider the second claim. Because of the first claim, we only have to show that the reverse of the in-going arc is removed as well. Let a denote the in-going arc of v at stage S. Suppose the in-going arc of v has changed at least once at some stage S' preceding stage S. Then either v is released at S' or a conflict of the third type occurs at this stage. In particular, let S' be the last such stage before S and let a' be the arc entering v that was the in-going arc of v at stage S'.

If v was released at this stage, the first claim implies that all arcs leaving v except the reverse of a' have been removed before S'. In particular, the reverse of a has also been removed, which implies the second claim. Now assume there was a conflict of the third type at S'. Then there is already an (s,t)-path p occupying v, and a points to p at v from the right side. Now Lemma 3.2 implies that the reverse of a has been removed as well. □

LEMMA 3.6. *All arcs* (w_i, w_{i-1}), $i = 1, \ldots, l$, *are removed before stage* S_{first}.

Proof. The proof is by induction on $i = l, l-1, \ldots, 1$. Because of Lemma 3.2, arc (w_l, w_{l-1}) is removed before stage S_{first} since this arc leaves the search path of stage S_{first} on the right side. Therefore, assume that arc (w_i, w_{i-1}), $i > 1$, is removed at some stage S_i preceding S_{first}. It suffices to show that S_{i-1} precedes S_i, that is, (w_{i-1}, w_{i-2}) is removed even before (w_i, w_{i-1}). To this end, we distinguish the different possible reasons for removing (w_i, w_{i-1}) from each other.

First, suppose (w_i, w_{i-1}) is removed as an unusual arc. Since w_i has a positive time stamp at S_i, the time stamp of w_{i-1} at S_i must also be positive. Hence there is a stage S preceding S_i where w_{i-1} was the leading vertex of the search path. In particular, let S be the last such stage. Since (w_i, w_{i-1}) is removed at S_i as an unusual arc, w_{i-1} is not occupied at stage S_i. Therefore, w_{i-1} was released at stage S. Clearly, (w_i, w_{i-1}) cannot be the leading arc of the search path at stage S because otherwise (w_i, w_{i-1}) would be removed even at S, not at S_i. Thus by the first part of Lemma 3.5, (w_{i-1}, w_i) has already been removed at S, which contradicts the assumed conflict at S_{first}.

Now suppose that (w_i, w_{i-1}) is removed because of a conflict (or, completely analogously, we have $\mathit{time\_stamp}\,[w_i] = \mathit{time\_stamp}\,[w_{i-1}]$, but (w_i, w_{i-1}) would be removed anyway in the very next step because of a conflict). Then w_{i-1} is occupied by some path at stage S_i and, by Lemma 3.4, w_{i-1} is released at some intermediate stage S between S_i and S_{first}. Since (w_i, w_{i-1}) no longer exists at stage S, the leading arc of the search path must be another arc entering w_{i-1} at that stage. Consequently, the first part of Lemma 3.5 implies that (w_{i-1}, w_i) has already been removed at S, which is again a contradiction to the assumed situation at S_{first}.

Finally, if removing (w_i, w_{i-1}) releases w_{i-1} (or, analogously, the time stamps are equal but w_{i-1} had been released anyway in the very next step), the claim that S_{i-1} precedes S_i is immediate from the first part of Lemma 3.5.

This completes the case distinction and the proof of Lemma 3.6. □

Now we are able to prove that any conflict of the fourth type is "announced" by the reverse conflict of the second type.

LEMMA 3.7. *Arc* (w_1, w_0) *is removed before stage* S_{first} *because of a conflict of the second type at* w_0*, with the reverse of* C *being the cycle involved.*

Proof. Consider the stage S_1 where (w_1, w_0) is removed. By Lemma 3.6, S_1 precedes S_{first}. Suppose (w_1, w_0) is *not* removed because of a conflict of the second type at w_0 with the reverse of C involved. Then at stage S_1, there must be a vertex w_i, $i \in \{1, \ldots, l-1\}$, such that all of $(w_i, w_{i-1}), (w_{i-1}, w_{i-2}), \ldots, (w_1, w_0)$ belong to the search path but (w_{i+1}, w_i) does not. Because of Lemma 3.4, vertex w_i is released at some intermediate stage between S_1 and S_{first}. Lemma 3.5 implies that (w_i, w_{i+1}) has already been removed before S_{first}, for the following reason. If the in-going arc of w_i has never changed, all arcs leaving w_i except the reverse of the in-going arc are removed, and by assumption, the in-going arc of w_i at S_1 is *not* (w_{i+1}, w_i). On the other hand, if the in-going arc of w_i *did* change, the second claim of Lemma 3.5 implies that *all* arcs leaving w_i, and (w_i, w_{i+1}) in particular, have been removed. Clearly, the

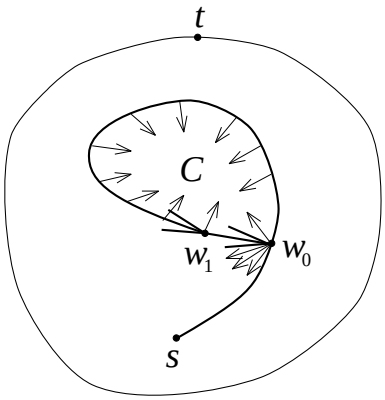

FIG. 11. *The situation in the proof of Lemma* 3.8. *By Lemma* 3.2, *no arc points from* C *to the* exterior *of* C (*except possibly arcs leaving* w_0 *as indicated*). *Hence the search does not reenter the exterior of* C *before* (w_0, w_1) *is seen.*

fact that (w_i, w_{i+1}) is removed before S_{first} is a contradiction. □

Lemma 3.7 now enables us to prove that no conflict of the fourth type occurs at all.

LEMMA 3.8. *While Invariant* 3.1(2) *is valid, no conflict of the fourth type occurs.*

Proof. Suppose a conflict of the fourth type *does* occur. Let C again be the cycle involved. Then s is outside C by Lemma 3.3 (see Fig. 11). Because of our right-first strategy, Lemma 3.2 implies that after (w_1, w_0) is removed, the search cannot enter the exterior of C before (w_0, w_1) is seen. Therefore, we consider (w_0, w_1) before we reach t or any path different from the search path. Hence the global time counter cannot change in the meantime unless a conflict of the fourth type has occurred before S_{first}. (Clearly, the global time counter would change if a conflict of the fourth types occurred because the algorithm does not distinguish between the third and fourth types of conflict.) However, this contradicts the definition of S_{first}. Consequently, (w_0, w_1) is removed because $time\_stamp\,[w_0] = time\_stamp\,[w_1]$, which makes the assumed situation at S_{first} impossible. □

3.2. Unusual arcs. We will now prove that for $i = 1, \ldots, m$, there is an optimum solution for G_{i-1} that does not contain $\overline{a}_i = (v, w)$, where $\overline{a}_i$ is an unusual arc. More precisely, we will show that there is no *cycle-free* (s, t)-path in G_{i-1} that contains $\overline{a}_i$. Clearly, this suffices.

Throughout this section, we need some additional terminology. Let S_2 be the stage where $\overline{a}_i = (v, w)$ is removed. Since v clearly has a positive time stamp at stage S_2 and since (v, w) is unusual, w also has a positive time stamp at S_2. Therefore, w was at least once the leading vertex of the search path before S_2. Let S_1 be the last stage before S_2 where w was the leading vertex of the search path. Moreover, since (v, w) is unusual, w was released at stage S_1. Thus Lemma 3.5 implies that (w, v) has been removed even before S_1 because (v, w) was never before the in-going arc of w. Let S_0 be the stage immediately after (w, v) is removed. In summary, S_0 precedes or equals S_1 and S_1 strictly precedes S_2.

Consider the search paths r_0, r_1, and r_2, at stages S_0, S_1, and S_2, respectively. All three paths start with s, r_0 and r_1 end with w, and r_2 ends with v. The paths r_1 and r_2 coincide up to, say, vertex u. Notice that $u \neq s$ because otherwise the global

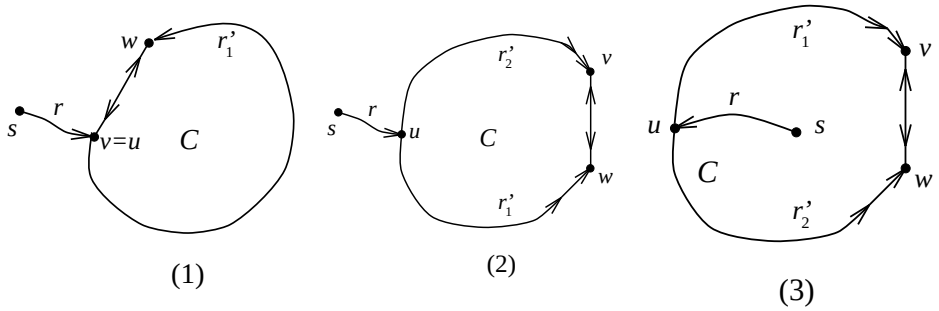

FIG. 12. *The situations in Lemmas* 3.10 (*part* (1)) *and* 3.11 (*part* (2)). *Lemma* 3.9 *states that the situation in part* (3) *is impossible.*

time counter would change between stages S_1 and S_2 and hence (v, w) would not be unusual. Let r be the common subpath from s to u, let r'_1 be the remainder of r_1, and let r'_2 be the remainder of r_2. Finally, let C be the cycle formed by r'_1, r'_2, and $\overline{a}_i$ (see Fig. 12). Lemma 3.5 implies that r'_1 and r'_2 are vertex-disjoint except for u, which means that C is actually a single, simple cycle.

LEMMA 3.9. *Vertex s belongs to the exterior of cycle C.*

Proof. Assume that s is not in the exterior of C. Then s either lies on C or is in the interior of C. The former case implies $u = s$, which contradicts the above remarks. Therefore, focus on the latter case. In the latter case, any (s, t)-path must contain an arc a that leaves C and points to the exterior of C because t is in the exterior of C. However, any such arc is considered for going forward between stages S_1 and S_2 unless it is removed even before S_1, for the following reasons. For an arc leaving r_2 on the right side, this follows from Lemma 3.2, and for an arc leaving r'_1 on the left side, it follows from Lemma 3.5. Therefore, all of those arcs are removed before S_2. Hence the cardinality of an optimum solution for G_{i-1} is zero, whereas it is positive for G_0 since G is connected. This contradicts the induction hypothesis, namely that Invariant 3.1(2) is valid before $\overline{a}_i = (v, w)$ is removed. □

Now we make a case distinction. First, we consider the case where r'_2 is trivial, that is, r'_2 consists solely of u or, equivalently, $u = v$. We will show that in this case, there is no cycle-free (s, t)-path containing $\overline{a}_i$ in G_{i-1} (Lemma 3.10). After that, we will show that otherwise no (s, t)-path in G_{i-1} contains $\overline{a}_i$ at all (Lemma 3.11).

LEMMA 3.10. *If r'_2 is trivial, no cycle-free (s, t)-path in G_{i-1} contains $\overline{a}_i$ (see Fig.* 12, *part* (1)).

Proof. Lemma 3.2 implies that at stage S_1, there is no longer an arc leaving C and pointing to its exterior except possibly arcs leaving v because all other arcs leave r'_1 on the right side. Therefore, any (s, t)-path that contains $\overline{a}_i = (v, w)$ must finally return to v in order to reach t. Consequently, such a path is *not* cycle-free. □

LEMMA 3.11. *If r'_2 is* not *trivial, no (s, t)-path in G_{i-1} contains $\overline{a}_i$ (see Fig.* 12, *part* (2)).

Proof. Let a and a' denote the in-going arcs of w with respect to r_0 and r_1, respectively. We make a case distinction. We show that the claim is true in the second case and that the other two cases do not occur.

Case 1. The global time counter does not change between stages S_0 and S_1.

Since (v, w) is unusual, the global time counter does not change between stages S_1 and S_2 either. Therefore, the global time counter does not change at all between stages S_0 and S_2. This means that vertex v and the last inner vertex of r_2, say v',

have equal time stamps when the last arc, that is, (v', v), is added to r_2. In this case, however, arc (v', v) would immediately be removed and *not* added to r_2. This contradicts the assumed situation at stage S_2.

Case 2. $a \neq a'$.

In particular, the in-going arc of w has changed at least once before stage S_1, where w is released. Hence the second claim of Lemma 3.5 implies that there is no longer an arc leaving w at stage S_1, which means that no (s,t)–path contains (v,w) at all.

Case 3. $a = a'$ and the global time counter does change between stages S_0 and S_1.

Since a is occupied at S_0 and at S_1, a is occupied all the time between S_0 and S_1. In particular, a is occupied at, say, any intermediate stage S where the global time counter changes.

First, we show that at this stage S, a belongs to some (s,t)-path p in the current graph which solely consists of occupied arcs. To this end, we make a case distinction. If the global time counter changes at S because a new search phase starts, the current solution at S decomposes into (s,t)-paths. In particular, a belongs to such a path. On the other hand, if the global time counter changes at S because of a conflict, it must be a conflict of the third type because by the induction hypothesis, the fourth type has not occurred so far. In this case, the current solution consists of some vertex-disjoint (s,t)-paths and the search path. We assume that a belongs to the search path because otherwise the same argument as in the former case applies. Therefore, let x denote the vertex where the conflict occurs. Then we define p to be the concatenation of the search path with the subpath from x to t of the (s,t)-path involved in the conflict. Obviously, p is an (s,t)-path, contains a, and consists solely of occupied arcs.

In any case, the path p must leave C somewhere so as to enter the exterior of C and to reach t. Let y be the first vertex of p after w where this happens, that is, y belongs to C, but the out-going arc a'' of y with respect to p belongs to the exterior of C. By Lemma 3.2, a'' does not leave C on the right side of r_1. Hence a'' leaves C on the left side of the concatenation $r_2 + (v,w)$, and y belongs to r_2' (see Fig. 13).

Since y is the first vertex after w where p enters the exterior of C, p must cross the interior of C from w to y at least once. Let z be the last vertex before y where p leaves the interior of C and enters C. If p runs clockwise (resp., counterclockwise) along C from z to y, the out-going arc of y (resp., z) with respect to $r_2' + (v,w)$ leaves p on the right side. Hence Lemma 3.2 implies that this arc has already been removed before stage S, which contradicts the assumed situation at stage S_2. If p runs neither clockwise nor counterclockwise along C from z to y, we have $y = z$, and of course, we obtain the same contradiction for the out-going arc of $y = z$ with respect to r_2'. □

3.3. Usual arcs. We are now going to prove that for $i = 1, \ldots, m$, there is an optimum solution for G_{i-1} that does not contain $\overline{a}_i$, if, say, $\overline{a}_i = (v,w)$ is a usual arc.

LEMMA 3.12. *If $\overline{a}_i = (v,w)$ is a usual arc, there is an optimum solution for G_{i-1} that does not contain $\overline{a}_i$.*

Proof. Since, (v,w) is usual, the removal of this arc either releases w or resolves a conflict at w (or we have $time\_stamp[v] = time\_stamp[w]$, and either of these situations would otherwise occur). Clearly, if w is released by removing $\overline{a}_i$, we are immediately done since w is a dead end and no (s,t)-path contains $\overline{a}_i$ at all. Thus we focus our attention on the case of a conflict. Let S be an optimum solution for G_{i-1}. We assume that $\overline{a}_i = (v,w)$ is contained in some path p belonging to S because otherwise there is nothing to show. Let p_1 denote the subpath of p from s to w.

Consider the situation immediately before (v,w) is removed. In this situation,

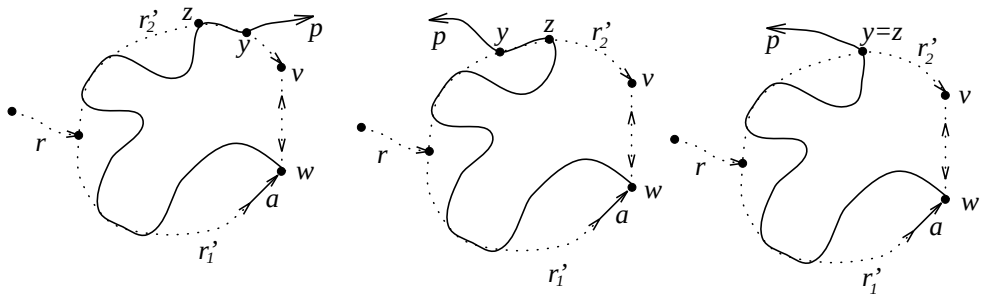

FIG. 13. *The situation in Case* 3 *in the proof of Lemma* 3.11. *Compare this with Fig.* 12*, part* (2). *The three cases of how* z *and* y *may be related are distinguished from each other.*

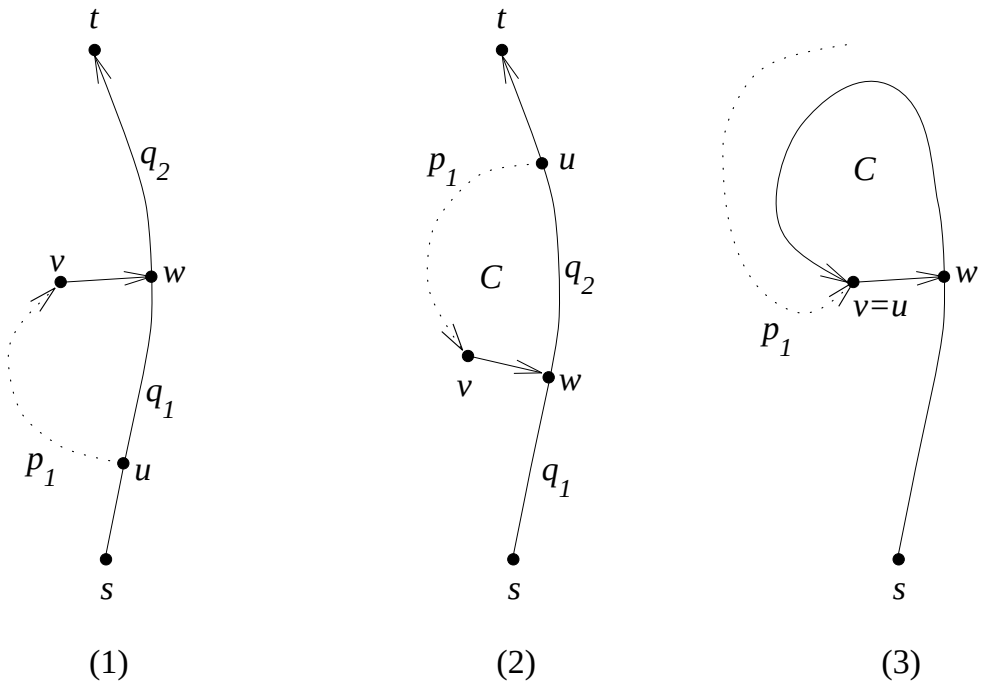

FIG. 14. *The different possible situations in the proof of Lemma* 3.12: (1) u *belongs to* q_1; (2) u *belongs to* q_2; (3) *conflict of the second type.*

there is a unique path q in the current set of paths that contains w as an inner vertex. For example, in a conflict of the second type, q is the search path itself. However, in *any* case, the arc (v, w) points to q from the left side. Let q_1 and q_2 denote the subpath of q from s to w and the remaining subpath, respectively.

There are two different possibilities of how p_1 may be related to q (see Fig. 14).

1. The last vertex of p_1 before w, say u, that is also occupied by q belongs to q_1.
2. The last vertex of p_1 before w, say u, that is also occupied by q belongs to q_2.

Note that all conflicts of the second type belong to the latter class because then $u = v$ is shared by p_1 and q_2. We will now consider both cases separately.

1. *The last vertex of* p_1 *before* w*, say* u*, that is also occupied by* q *belongs to* q_1

(*see Fig.* 14*, part* (1)).

Let $\tilde{q}_1$ denote the subpath of q_1 between u and w. Assume that some path $p' \neq p$ belonging to S shares some vertex with $\tilde{q}_1$. Since p_1 contains (v, w), p_1 separates the *left* side of $\tilde{q}_1$ from t, which implies that p' must leave q_1 somewhere on the *right* side of q_1. This contradicts Lemma 3.2. Therefore, no other path belonging to S hits $\tilde{q}_1$, and we obtain an optimum solution again when we replace the subpath of p_1 from u to w by $\tilde{q}_1$ in S and, since the new path may not be cycle-free, remove all cycles from the new path. The resulting solution does not contain $\overline{a}_i$.

2. *The last vertex of* p_1 *before* w*, say* u*, that is also occupied by* q *belongs to* q_2 (*see Fig.* 14*, parts* (2) *and* (3)).

Let $\tilde{q}_2$ be the subpath of q_2 between w and u. We simply replace the subpath of p_1 between u and w by the reverse of $\tilde{q}_2$ (and remove cycles if necessary). For this we only have to show that all arcs on this reverse path still exist. Note that $\tilde{q}_2$ and the subpath of p_1 from u to w together form a counterclockwise cycle which excludes s. Hence we may apply the following lemma to the *reverse* cycle and obtain that if any arc of the reverse path of $\tilde{q}_2$ is removed, at least one arc of p_1 or $\tilde{q}_2$ is removed as well. Clearly, this contradicts the assumed situation. □

LEMMA 3.13. *Let* $C = (w_0 \to w_1 \to \cdots \to w_l = w_0)$ *be a clockwise cycle of* G_0 *which excludes* s*. If some arc contained in* C *is removed at some stage of the algorithm, at least one of the reverse arcs of* C *has been removed previously.*

Proof. Let, say, arc (w_i, w_{i+1}) be removed at some stage. At this moment, (w_i, w_{i+1}) is the leading arc of the search path. This path must enter C at some vertex. Let w_j be the last of all vertices where the search path enters C from outside. (This happens at least once since C excludes s.) If the path is not continued with (w_j, w_{j-1}), the claim follows from Lemma 3.2 because then (w_j, w_{j-1}) has already been removed. Otherwise, the search path runs along C in the counterclockwise direction and must hence leave C once more at some vertex w_μ so as to enter C again and then run along C in the clockwise direction through (w_i, w_{i+1}). Since w_j was the last vertex where the search path entered C from the outside, it must enter the *interior* of C at w_μ. Then, however, $(w_\mu, w_{\mu-1})$ has already been removed, which again follows from Lemma 3.2. □

Summarizing this section, we obtain the following result.

THEOREM 3.14. *Algorithm* 2.3 *is correct.*

4. Useful insight. As already mentioned in the introduction, this section is devoted to certain properties of the result of our algorithm which have turned out to be very useful in some applications. These properties reflect our idea to always draw paths as far to the right as possible. In fact, we will show that the solutions provided by our algorithm are in some sense "rightmost." For a formal description, however, we first need some terminology.

Let p be a cycle-free (s, t)-path in the undirected input graph G. An *elementary transformation* of p is done as follows. Let F be a face of G such that p contains at least one edge of F and all vertices and edges of F that are contained in p form a connected interval I of the boundary of F. In the elementary transformation, all edges of I are removed from p and all other edges of the boundary of F are inserted in p instead. In other words, if the interior of F is immediately on the right side of p before transforming p in this way, it is on the left side from then on and vice versa. The result is again a cycle-free (s, t)-path; we have simply routed p along F the other way round.

An elementary transformation is called a *homotopic transformation*, if neither s

nor t is incident to F. An elementary transformation is called *right-turning* if t is incident to F and F appears (before the transformation) on the right side of p as p is seen from s to t.

Two (s,t)-paths are *homotopic* if one path can be constructed from the other path by homotopic transformations only. An (s,t)-path p is said to be *more right than* another (s,t)-path q if p can be constructed from q using a sequence of homotopic and right-turning transformations with at least one right-turning transformation. Clearly, "homotopic" defines an equivalence relation on all (s,t)-paths and "more right" defines a strict partial ordering. An (s,t)-path p is called *rightmost* if there is no path more to the right than p, that is, p is a minimal element in that partial ordering.

An undirected input instance (G,s,t) is called *complete* if the cardinality of an optimum solution equals the number of arcs incident to s. In other words, the vertices adjacent to s form a minimum (s,t)-separator and all arcs leaving s are occupied.

Two maximum solutions $(p_1,\dots,p_k)$ and $(p'_1,\dots,p'_k)$ for a complete instance are called *homotopic* if p_i is homotopic to p'_i for $i=1,\dots,k$. Finally, a maximum solution $(p_1,\dots,p_k)$ for a complete instance is *rightmost* if for $i=1,\dots,k$, there is no solution $(p'_1,\dots,p'_k)$ such that p'_i is more to the right than p_i. Note that the rightmost solution is in general not unique (if it exists at all); any solution homotopic to a rightmost solution is rightmost as well. Now we are able to state our result.

THEOREM 4.1. *The solution determined by Algorithm* 2.3 *for a* complete *instance is a rightmost solution.* (*In particular, a rightmost solution is actually guaranteed to exist.*)

Proof. We first define elementary, homotopic, and right-turning transformations for *directed* graphs in a similar manner. Therefore, let $\vec{G}=(\vec{V},\vec{A})$ be a directed graph and $s,\ t\in\vec{V}$, $s\neq t$. For any pair (v,w) and (w,v) of corresponding arcs in $\vec{G}$, we assume for convenience that there is an additional face separating (v,w) from (w,v). Let p be a cycle-free (s,t)-path in $\vec{G}$ that possibly contains not only forward arcs but also backward arcs. Then an elementary transformation is again done as described above, that is, by routing p along an incident face F the other way around. This yields another (s,t)-path, which may again contain forward *and* backward arcs. An (s,t)-path p containing only forward arcs is called *rightmost directed* if there is no other path that contains only forward arcs and is more to the right than p.

Now it is obvious that a rightmost path in G immediately induces a rightmost directed path in G_0 and vice versa. Also, by Lemma 3.2, any of the paths $p_1,\dots,p_k$ is rightmost directed in the final graph G_m. In other words, the resulting solution is rightmost in G_m. Therefore, it suffices to show that for any cycle-free solution S for G_{i-1}, there is a homotopic solution that does not contain $\overline{a}_i$. This implies that at least one rightmost solution of G_0 will "survive" throughout Algorithm 2.3.

Consider the situation where arc $\overline{a}_i$ is removed. Let $p\in S$ be a path in G_{i-1} containing $\overline{a}_i$. First, note that $\overline{a}_i$ cannot be unusual because otherwise p cannot be cycle-free by Lemmas 3.10 and 3.11. On the other hand, if $\overline{a}_i$ is usual, we may construct from p a path that is feasible in G_i by applying the construction used in the proof of Lemma 3.12 (see Fig. 14). Now it is easy to see that in each of the distinct cases in that proof, the resulting solution is homotopic to S. □

RANDOMIZED DISTRIBUTED EDGE COLORING VIA AN EXTENSION OF THE CHERNOFF–HOEFFDING BOUNDS*

ALESSANDRO PANCONESI† AND ARAVIND SRINIVASAN‡

Abstract. Certain types of routing, scheduling, and resource-allocation problems in a distributed setting can be modeled as edge-coloring problems. We present fast and simple randomized algorithms for edge coloring a graph in the synchronous distributed point-to-point model of computation. Our algorithms compute an edge coloring of a graph G with n nodes and maximum degree Δ with at most $1.6\Delta + O(\log^{1+\delta} n)$ colors with high probability (arbitrarily close to 1) for any fixed $\delta > 0$; they run in polylogarithmic time. The upper bound on the number of colors improves upon the $(2\Delta - 1)$-coloring achievable by a simple reduction to vertex coloring.

To analyze the performance of our algorithms, we introduce new techniques for proving upper bounds on the tail probabilities of certain random variables. The *Chernoff–Hoeffding bounds* are fundamental tools that are used very frequently in estimating tail probabilities. However, they assume stochastic independence among certain random variables, which may not always hold. Our results extend the Chernoff–Hoeffding bounds to certain types of random variables which are not stochastically independent. We believe that these results are of independent interest and merit further study.

1. Introduction.

An important limitation for a distributed network without global memory is *locality of computation*: since sending messages to faraway nodes is expensive, communication should only take place between nearby nodes. Models of parallel computation like the PRAM abstract this problem of locality away by assuming the existence of a global shared memory with fast concurrent access. We are interested in studying how fast individual processors can compute their portion of the output in a message-passing distributed system with such "local" information alone. The model we consider is the synchronous distributed point-to-point model, in which the processors are arranged as the vertices of an n-vertex graph $G = (V, E)$ and where all communication is via the edges of G alone. In this model, we study the edge-coloring problem, a basic combinatorial problem with many applications to distributed computing. Edge colorings can be used to model certain types of jobshop-scheduling, packet-routing, and resource-allocation problems in a distributed setting. For example, the problem of scheduling I/O operations in a certain parallel architecture can be modeled as follows (see Jain et al. [9]). We are given a set of processes $\mathcal{P}$ and a set of resources $\mathcal{R}$ such that each process $p \in \mathcal{P}$ needs a subset

$f(p) \subseteq \mathcal{R}$ of the resources where (i) each process p needs every resource in $f(p)$ for a unit of time each and (ii) p can use the resources in $f(p)$ in any order. From this we can construct a bipartite graph $G_{\mathcal{P},\mathcal{R}} = (\mathcal{P}, \mathcal{R}, E_{\mathcal{P},\mathcal{R}})$, where $E_{\mathcal{P},\mathcal{R}} = \{(p,r) |\ p \in \mathcal{P} \wedge r \in f(p)\}$. An edge coloring of $G_{\mathcal{P},\mathcal{R}}$ with c colors yields a schedule for the processes to use the resources within c time units. Optimal colorings correspond to optimal schedules.

Edge coloring can also be used in distributed models in situations where broadcasts are infeasible or undesirable: an edge coloring of the network results in a schedule for each processor to communicate with at most one neighbor at every step; at time step i, processors communicate via the edges colored i only. Using a "small" number of colors reduces the wastage of time in this schedule.

1.1. Related work. Note that Δ colors are necessary to edge color a graph with maximum degree Δ. Vizing showed that it is always possible to edge color a graph with $\Delta + 1$ colors and gave a polynomial-time algorithm to compute such a coloring [22] (see, for instance, Bollobás [3]). Efforts to parallelize Vizing's theorem have failed so far. The best known algorithm is an RNC algorithm of Karloff and Shmoys using $\Delta + O(\Delta^{1/2+\epsilon})$ colors for any fixed $\epsilon > 0$; this algorithm has been derandomized in NC (see Berger and Rompel [2] and Motwani, Naor, and Naor [15]). In the distributed model, the best edge-coloring algorithm known prior to this work was to apply a vertex-coloring algorithm to the line graph $L(G)$ of G. There are fast (polylogarithmic) randomized vertex-coloring algorithms that use $(\Delta+1)$ and Δ colors, which translate to $(2\Delta-1)$- and $(2\Delta-2)$-edge-coloring algorithms, respectively (see Luby [13] and Panconesi and Srinivasan [17]). In the deterministic case, there are no known $(2\Delta-1)$-edge-coloring algorithms of polylogarithmic running time; the best running time is $2^{O(\sqrt{\log n})}$, which is asymptotically better than any fixed root of n but which grows faster than any polylogarithmic function of n [17]. Interestingly, distributed Δ-edge coloring for bipartite graphs requires $\Omega(\mathit{diameter}(G))$ time even with randomization [17], whereas this can be done in $O(\log n)$ time deterministically in the PRAM model [11].

1.2. Our contributions. In this paper, we present fast and simple randomized algorithms to edge color G with at most $1.6\Delta + O(\log^{1+\delta} n)$ colors with high probability for any fixed $\delta > 0$, where Δ is the maximum degree of the vertices of G. At the heart of our analysis is an extension of the *Chernoff–Hoeffding bounds*, which are key tools in bounding the tail probabilities of the sums of independent random variables (see Chernoff [4], Hoeffding [8], and Raghavan [18]).

Our edge-coloring algorithm is based on a very simple randomized algorithm to color bipartite graphs, which can be explained in a few lines. Given a bipartite graph $G = (A, B, E)$ with maximum degree Δ, each vertex in B picks distinct colors from $\{1, 2, \ldots, \Delta\}$ at random for its edges without replacement, i.e., edges incident to the same vertex in B get different colors. Then each vertex $v \in A$ checks for each color α if more than one of its incident edges has color α and, if so, chooses one of them at random as the *winner*, and all the other edges of color α which are incident to v are decolored. The key claim is that for every vertex, the number of decolored edges incident to it is at most $\Delta(1+\epsilon)/e$ with high probability for any fixed $\epsilon > 0$, where e is the base of natural logarithms. Assuming that this holds, we can repeat the above iteration with a set of $\Delta(1+\epsilon)/e$ *fresh* colors, and so on. In spite of its simplicity, the algorithm requires an interesting probabilistic analysis; this is based upon an extension of the Chernoff–Hoeffding bounds to a certain case of dependence among the random variables, which we call λ-correlation. We believe that these results have

the potential for further applications and merit further study.

A preliminary version of this work appeared in [16], where we showed how to edge color using at most $1.6\Delta + O(\log^{2+\delta} n)$ colors. By presenting a tighter analysis of the tail probabilities, we improve this to $1.6\Delta + O(\log^{1+\delta} n)$ colors here.

In section 2, we define the basic notation used, and in section 3, we describe our main analytical tool—the extension of the Chernoff–Hoeffding bounds. Section 4 presents our algorithm, whose performance is analyzed in section 5. Some extensions and applications of this work are described in section 6.

2. Notation. A *message-passing distributed network* is an undirected graph $G = (V, E)$ where vertices, or nodes, correspond to processors and edges correspond to bidirectional communication links. Each node has its unique ID. There is no shared memory and processors can communicate only by sending messages through the network. The network is *synchronous*, i.e., computation takes places in a sequence of *rounds*; in each round, each node does any amount of local computation, sends messages to its neighbors in the graph, and reads messages sent to it by its neighbors. The time complexity of a distributed algorithm, or *protocol*, is given by the number of rounds needed to compute a given function.

Though each node has no knowledge about the topology of the entire network, it knows upper bounds n and Δ on the total number of nodes and maximum degree of the network, respectively. We also sketch an alternative algorithm if Δ and n are unknown, but the constant factor in the $O(\log^{1+\delta} n)$ term in the number of colors used is higher in this case.

Notice that in this model the cost of sending a message from one vertex to another is proportional to the length of a shortest path between the two vertices. Hence if we want a protocol to run for t rounds, then each vertex can communicate only with vertices at distance at most t from it. This is not so in the PRAM model, where the shared memory allows any two processors to communicate in one unit of time. Lower bounds for distributed computation imposed by this locality have been presented by Linial [12]. Also, as mentioned before, distributed Δ-edge coloring for bipartite graphs requires $\Omega(\mathit{diameter}(G))$ time, even with randomization [17]. In particular, we cannot two-color the *vertices* of a bipartite graph G distributively in $o(\mathit{diameter}(G))$ time.

Given an undirected graph $G = (V, E)$, we denote by Δ its maximum degree, i.e., the maximum number of edges incident with any node; by d_u we denote the degree of vertex u, by $N(u)$ we denote the set of neighbors of u, and by $\delta(u)$ we denote the set of edges incident with u.

Given a positive integer n, $[n]$ denotes the set $\{1, 2, \ldots, n\}$. The permanent of a (possibly nonsquare) matrix M with c columns and r rows, where $c \le r$, is defined as the natural extension of the permanent of square matrices. Let $\mathcal{P} = \{\pi \mid \pi : [c] \to [r],\ \pi \text{ is one–to–one}\}$. Then

$$\mathit{perm}(M) \doteq \sum_{\pi \in \mathcal{P}} \prod_{i=1}^{n} M_{\pi(i),i}.$$

An event $\mathcal{A}$ is said to happen *with high probability* (w.h.p.) if $\Pr(\mathcal{A}) \ge 1 - 1/f(n)$ for some superpolynomial function $f(n)$ (i.e., $n^c = o(f(n))$ for all fixed $c > 0$).

In our algorithms, we will use Luby's vertex-coloring algorithm [13] as a subroutine. When applied to the line graph of G, the algorithm computes a $(2\Delta(G)-1)$-edge coloring of G, with its running time being $O(\log n)$ w.h.p. The algorithm only needs local information—a vertex only needs to know its own degree. Another property

of the algorithm that we will use is that vertices can be added dynamically to the graph, each vertex u with its own palette of $\deg(u)+1$ colors, and the algorithm still works as claimed (the running time is $O(\log n)$ from the time of the last insertion). Other algorithms could be used as well, but we refer to this algorithm of Luby for conciseness.

3. The Chernoff–Hoeffding bounds extension. In this section, we introduce our extension of the Chernoff–Hoeffding bounds, which are important tools used in estimating the tail probabilities of random variables. Given n *independent* random variables $X_1, X_2, \ldots, X_n$, these bounds are used in deriving an upper bound on the upper tail probability $\Pr(X \geq (1+\epsilon)\mu)$, where $X = \sum_{i=1}^{n} X_i$, $\mu = E[X]$, and $\epsilon > 0$. We extend these bounds to a certain case of dependency among the X_i's, which we call λ-correlation.

Let us review Chernoff's approach to upper bound the upper tail probability of a random variable X when X is the sum of *independent* binary random variables $X_1, X_2, \ldots, X_n$ [4]. (This idea is apparently originally due to Bernstein [8].) The idea is to use Markov's inequality on the random variable e^{tX} for an arbitrary $t > 0$ and minimize with respect to t, that is, to use the fact that

$$\begin{aligned}\Pr(X > (1+\epsilon)\mu) &= \Pr(e^{tX} > e^{t(1+\epsilon)\mu}) \\ &\leq \frac{E[e^{tX}]}{e^{t(1+\epsilon)\mu}}\end{aligned}$$

and minimize the last ratio for $t > 0$. This is achieved by finding a good upper bound for the numerator $E[e^{tX}]$ by using the fact that X is the sum of *independent* random variables. It is standard (see, e.g., Raghavan [18]) to use this to show that in this case, if $X_i \in \{0,1\}$ for each i, then

$$\min_{t>0} \frac{E[e^{tX}]}{e^{t(1+\epsilon)\mu}} \leq F(\mu,\epsilon) \doteq \left[\frac{e^{\epsilon}}{(1+\epsilon)^{1+\epsilon}}\right]^{\mu}. \tag{1}$$

Hoeffding [8] considered a more general case where X is the sum of n independent and *bounded* random variables $X_i \in [a_i, b_i]$, and he used the above approach to show that if $E[X] = \mu$, then for $\epsilon > 0$,

$$\min_{t>0} \frac{E[e^{tX}]}{e^{t(1+\epsilon)\mu}} \leq G(\mu,\epsilon,\vec{a},\vec{b}) \doteq \exp\left[-\frac{2\,\mu^2\epsilon^2}{\sum_{i\in[n]}(b_i-a_i)^2}\right]. \tag{2}$$

The bounds (1) and (2) will be used in our proofs. Henceforth, we refer to these bounds of Chernoff and Hoeffding as the CH bounds. If ϵ is a fixed positive quantity no greater than 1 (which will be true in all of our applications), then $F(\mu,\epsilon) \leq e^{-\epsilon^2\mu/3}$. Hence if $\mu = \Omega(\log^{1+\delta} n)$, then $F(\mu,\epsilon)$ is the inverse of a superpolynomial function of n, for any fixed $\delta > 0$. (Similar considerations apply to $G(\mu,\epsilon,\vec{a},\vec{b})$.) This fact makes the CH bounds a powerful tool for deriving strong performance guarantees for randomized algorithms and will be used repeatedly in this paper.

3.1. The general case. We now introduce λ-correlation and prove the general extension of the CH bounds. In section 3.2, we will then discuss an important special case of the results of this section.

Our proof is based on the observation that if we can upper bound each term $E[X^k]$ of the Maclaurin expansion of $E[e^{tX}]$ by $\lambda\, E[\hat{X}^k]$, where $\hat{X}$ is the sum of independent

random variables, and if $E[e^{t\hat{X}}] \leq B$, then $E[e^{tX}] \leq \lambda B$. We start with the following definition.

DEFINITION 3.1. *Let $X_1, X_2, \ldots, X_n$ be bounded random variables such that $X_i \in [a_i, b_i]$ and let $X = \sum_{i\in[n]} X_i$. The X_i's are* λ-correlated *if there exists a collection of independent twin random variables $\hat{X}_i \in [a_i, b_i]$ such that*

(i) *$E[X] \leq E[\hat{X}]$, where $\hat{X} = \sum_{i\in[n]} \hat{X}_i$, and*

(ii) *for all $I \subseteq [n]$ and positive integers s_i, $i \in I$,*

$$E\left[\prod_{i\in I} X_i^{s_i}\right] \leq \lambda \prod_{i\in I} E[\hat{X}_i^{s_i}].$$

Our main theorem is now the following.

THEOREM 3.2. *Let X be the sum of λ-correlated random variables $X_1, X_2, \ldots, X_n$, where $X_i \in [a_i, b_i]$, and let $\hat{X}$ be the sum of the n twin variables $\hat{X}_i$. Then*

$$\Pr(X > (1+\epsilon)\, E[\hat{X}]) \leq \lambda G(E[\hat{X}], \epsilon, \vec{a}, \vec{b}).$$

Proof. Let $\mu = E[\hat{X}]$. As in the classical proof, we start by introducing a positive parameter t and by applying Markov's inequality to the variable e^{tX}:

$$\begin{aligned}\Pr(X > (1+\epsilon)\mu) &= \Pr(e^{tX} > e^{t(1+\epsilon)\mu}) \\ &\leq \frac{E[e^{tX}]}{e^{t(1+\epsilon)\mu}}.\end{aligned}$$

By the hypotheses of the boundedness of X, we may apply linearity of expectation to an infinite series:

$$E[e^{tX}] = E\left[\sum_{k=0}^{\infty} \frac{t^k X^k}{k!}\right] = \sum_{k=0}^{\infty} \frac{t^k E[X^k]}{k!}.$$

Now $X^k = (\sum_{i=1}^n X_i)^k$ is a sum of terms of the form $\prod_{i\in I} X_i^{s_i}$ for some $I \subseteq [n]$ and positive integers s_i. Hence by linearity of expectation and the assumption of λ-correlation,

$$E[X^k] \leq \lambda E[\hat{X}^k].$$

Thus

$$E[e^{tX}] \leq \lambda \sum_{k=0}^{\infty} \frac{t^k E[\hat{X}^k]}{k!} = \lambda E[e^{t\hat{X}}].$$

By the already discussed result of Hoeffding [8], when $\hat{X}$ is the sum of n independent bounded random variables $\hat{X}_i \in [a_i, b_i]$,

$$\min_{t>0} \frac{E[e^{t\hat{X}}]}{e^{t(1+\epsilon)\mu}} \leq G(\mu, \epsilon, \vec{a}, \vec{b}). \qquad \square$$

In this paper, we will use the special case of Theorem 3.2 where $X_i \in [0, 1]$, $i \in [n]$. In this case, $F(\mu, \epsilon)$ is also an upper bound for the upper tail of X.

COROLLARY 3.3. *Let X be the sum of n λ-correlated random variables $X_i \in [0, 1]$. Then*

$$\Pr(X > (1+\epsilon)E[\hat{X}]) \leq \lambda F(\mu, \epsilon).$$

Proof. Let $E[\hat{X}] = \mu$. When $\hat{X}$ is the sum of n independent random variables $\hat{X}_i \in [0,1]$, Hoeffding (cf. Theorem 1 of [8]) shows that if $t \in (0, 1-\mu/n)$ and $\epsilon = nt/\mu$, then

$$\Pr\left(\frac{\hat{X}-\mu}{n} \geq t\right) \leq \min_{s>0} \frac{E[e^{s\hat{X}}]}{e^{s(1+\epsilon)\mu}} \leq \left(\frac{\mu}{\mu+nt}\right)^{\mu+nt} \left(1+\frac{n\,t}{n-\mu-nt}\right)^{n-\mu-nt}.$$

By the proof of Theorem 3.2, we see that $E[e^{sX}] \leq \lambda E[e^{s\hat{X}}]$ for any $s > 0$. Thus by applying the standard approximation $1 + x \leq e^x$ for $x = nt/(n-\mu-nt)$, we get

$$\Pr(X \geq (1+\epsilon)\mu) \leq \lambda \left(\frac{e^\epsilon}{(1+\epsilon)^{(1+\epsilon)}}\right)^\mu = \lambda F(\mu, \epsilon). \qquad \square$$

3.2. Binary random variables. An important special case of Definition 3.1 is when $X_i \in \{0,1\}$. In this case, the condition on the expectations simplifies considerably to become

$$\Pr\left(\bigwedge_{i\in I} X_i = 1\right) \leq \lambda \prod_{i\in I} \Pr(\hat{X}_i = 1)$$

for all $I \subseteq [n]$.[1] This special case is interesting in its own right and hence we record it as the following theorem.

THEOREM 3.4. *Let $X_1, X_2, \ldots, X_n$ be given* 0–1 *random variables with $X = \sum_i X_i$. If there exist* independent *random variables $\hat{X}_1, \hat{X}_2, \ldots, \hat{X}_n$ with $\hat{X} = \sum_i \hat{X}_i$ and $E[X] \leq E[\hat{X}]$ such that for all $I \subseteq [n]$,*

$$\Pr\left(\bigwedge_{i\in I} X_i = 1\right) \leq \lambda \prod_{i\in I} \Pr(\hat{X}_i = 1),$$

then

$$\Pr(X > (1+\epsilon)E[\hat{X}]) \leq \lambda F(E[\hat{X}], \epsilon).$$

The statement follows immediately from Corollary 3.3. Notice that λ-correlation follows if the X_i's are "negatively correlated" in the following sense:

$$\Pr\left(\bigwedge_{i\in I} X_i = 1\right) \leq \prod_{i\in I} \Pr(X_i = 1)$$

for all $I \subseteq [n]$. We now present an example where precisely this kind of situation arises and which will also be used later in this paper.

Suppose we have n balls that are thrown uniformly and independently at random into n bins, and we want to estimate the number B of empty (missed) bins. Let B_i be an indicator random variable that is 1 if bin i is empty and 0 otherwise. For any $i \in [n]$,

$$\Pr(B_i = 1) = \left(1 - \frac{1}{n}\right)^n \leq \frac{1}{e}.$$

[1] This was defined as "self-weakening with parameter λ" in [16].

It follows that $E[B] = E[\sum_i B_i] \leq n/e$. The B_i's are 1-correlated. To see this, consider a subset $J \subseteq [n]$ and any $i \in [n] - J$. Then

$$\begin{aligned}\Pr\left(B_i = 1 \mid \bigwedge_{j\in J} B_j = 1\right) &= \left(1 - \frac{1}{n - |J|}\right)^n \\ &\leq \left(1 - \frac{1}{n}\right)^n \\ &= \Pr(B_i = 1).\end{aligned}$$

By straightforward induction, this implies that for all $I \subseteq [n]$,

$$\Pr\left(\bigwedge_{i\in I} B_i = 1\right) \leq \prod_{i\in I} \Pr(B_i = 1).$$

Thus the B_i's are 1-correlated, where we may take the twin variables $\hat{B}_i$ to be i.i.d. 0–1 random variables with $\Pr(B_i = 1) = 1/e$ for each i. Hence not only is $E[B] \leq n/e$, but by Theorem 3.4,

$$Pr\left(B > \frac{(1+\epsilon)n}{e}\right) \leq F\left(\frac{n}{e}, \epsilon\right).$$

Remarks. The above fact can also be given a completely different (and simple) proof via the theory of martingales using Azuma's inequality (see, for example, Alon, Spencer, and Erdős [1] or McDiarmid [14].) We have presented this proof to illustrate our techniques. Also, Jain has proved the following lemma [19].

Let $a_1, a_2, \ldots, a_n$ be n random trials (not necessarily independent) such that the probability that trial a_i "succeeds" is bounded above by p regardless of the outcomes of the other trials. Then if X is the random variable that represents the number of "successes" in these n trials and Y is a binomial variable with parameters (n, p), then $\Pr[X \geq k] \leq \Pr[Y \geq k]$, $0 \leq k \leq n$.

The assumptions of Jain's lemma are strictly stronger than those of 1-correlation. For instance, in the balls and bins example,

$$\Pr\left(B_n = 1 | \bigwedge_{i\in[n-1]} B_1 = 0\right) = \frac{n-1}{n+1},$$

which for $n \geq 3$ is greater than $\Pr(B_n = 1)$ ($\approx 1/e$). Note, however, that our result does not subsume Jain's lemma since his result upper bounds $\Pr(X \geq k)$ by the true binomial upper bound, while we only upper bound it by the CH bound.

4. The edge-coloring algorithm. We now present our randomized distributed edge-coloring algorithm. The algorithm uses an idea of Karloff and Shmoys to reduce the problem of edge coloring general graphs to that of edge coloring a special class of bipartite graphs [10]. The Karloff–Shmoys scheme uses the fact that bipartite graphs can be edge colored optimally in the PRAM model of computation, which is provably impossible in our distributed model [17]. Instead, we use a distributed subroutine that computes a "good" coloring. Also different is the handling of the "leftover" graphs at the end of the recursion, which we color by making use of Luby's vertex-coloring algorithm.

The input to the algorithm is a distributed network $G = (V, E)$ and some fixed $\epsilon, \delta > 0$. In addition, each node knows upper bounds n and Δ on $|V|$ and the maximum degree $\Delta(G)$ of G, respectively. This information is not necessary but yields better multiplicative constants. The case where Δ and n are unknown is sketched towards the end of section 5.1.

The algorithm is recursive and computes an edge coloring of G using at most $1.6\Delta + O(\log^{1+\delta} n)$ colors and runs in $O(\log n)$ time; both of these bounds hold w.h.p. Let THRESHOLD $= \log^{1+\delta} n$, and $new(\Delta) = \Delta/2 + \sqrt{\Delta \log^{1+\delta/2} n}$; the algorithm is as follows.

If $\Delta \leq 16$THRESHOLD, **then** edge color G with $2\Delta - 1$ colors using Luby's algorithm and exit;[2] **else** execute the following:

1. Compute a random partition of $V(G)$ into black and white vertices. (All vertices flip a fair coin independently and in parallel.) Let $G[B]$ be the subgraph induced by the black vertices, $G[W]$ be the subgraph induced by the white vertices, and $G[B, W]$ be the bipartite subgraph formed by the edges having endpoints of different colors.

2. Edge color $G[B, W]$ using our bipartite edge-coloring algorithm described below with the parameters $new(\Delta)$, ϵ, and δ.

3. Set $\Delta := new(\Delta)$ and recurse on $G[B]$ and $G[W]$ using the *same* set of fresh new colors on both graphs with the same parameters ϵ and δ as before. (*Remark.* Though the bipartite algorithm modifies its first parameter $new(\Delta)$ in the course of its execution, we assume that it is passed "by value," i.e., that the value of $new(\Delta)$ referred to here and in step 2 above is the same.)

Remark. $new(\Delta)$ is meant to be an upper bound on $G[B]$, $G[W]$, and $G[B, W]$. It is easily seen via the standard CH bounds that it is indeed so w.h.p. if $\Delta \geq$ THRESHOLD and hence if $\Delta \geq 16$THRESHOLD [10].

We now present our main algorithm—a distributed algorithm to color the bipartite graphs produced above.

4.1. Distributed edge coloring of bipartite graphs. Given a bipartite graph $G = (A, B, E)$, we assume that each vertex knows whether it belongs to A or B. This is an important assumption because such information cannot be computed fast distributively as mentioned in section 2, but it is verified for the bipartite graphs generated by the Karloff–Shmoys scheme. Henceforth, we will refer to vertices in A as the *top* vertices and to the vertices in B as the *bottom* vertices.

Given parameters Δ_C, ϵ, and δ such that Δ_C is an upper bound on the degree of G, the algorithm takes $O(\log n)$ time and colors the bipartite graph G with at most $1.6\Delta_C + O(\log^{1+\delta} n)$ colors w.h.p., as long as $\delta > 0$ is any constant (ϵ is used in the algorithm). During any iteration of the algorithm, Δ_C is meant to be an upper bound on the degree of the current graph; we will prove later that *this holds w.h.p. as long as* $\Delta_C \geq \log^{1+\delta} n =$ THRESHOLD. From the remark in section 4, we can assume that this is valid when the bipartite algorithm is called first. As we will briefly discuss in section 5.1, this is not needed but gives better constants. The algorithm is as follows.

1. *Part* I. While $\Delta_C \geq$ THRESHOLD, do the following:

Let G_C be the current graph. Pick a set χ of Δ_C *fresh new* colors.

(i) (random proposal of bottom vertices) In parallel and independently of the other vertices in B, each vertex $v \in B$ assigns a temporary color to each edge in $\delta(v)$

[2] When $\Delta = O(\text{polylog}(n))$, we can compute a $2\Delta - 1$ coloring *deterministically* in $O(\text{polylog}(n))$ time using an algorithm based on the idea of removing maximal matchings. We prefer to use Luby's algorithm here for conciseness.

with uniform probability *without replacement*, i.e., edge e_1 is assigned color $\alpha \in \chi$ with probability $1/\Delta_C$, e_2 is assigned $\beta \in \chi - \{\alpha\}$ with probability $1/(\Delta_C - 1)$, and so on.

(ii) (lottery of top vertices) (*Remark*. The coloring so far is consistent around any vertex $v \in B$ but can be inconsistent around a vertex $u \in A$.) For each $u \in A$, let $C_u(\alpha)$ be the set of edges in $\delta(u)$ with temporary color α. Each vertex $u \in A$ selects a *winner* uniformly at random in $C_u(\alpha)$ for each nonempty $C_u(\alpha)$. All other edges, the *losers*, are decolored and assigned $\perp$.

(iii) Set $\Delta_C := \Delta_C(1+\epsilon)/e$. $G_\perp$, the subgraph of G_C induced by the losers (i.e., by the $\perp$-edges), becomes the new current graph.

2. *Part* II. Let G_r be the remaining graph. Edge color G_r with at most $2\Delta(G_r)-1$ colors by executing Luby's vertex coloring algorithm on the line graph of G_r.

Since we use new colors in each iteration, it is clear that when the algorithm terminates, G has been edge colored legally. It is also apparent that the algorithm works based on local information alone. We now turn to placing bounds on the number of colors used and the running time.

5. Analysis of the algorithm. Since the analysis is fairly involved, we first present a higher-level description of it.

5.1. The basic structure of the analysis. Our key claim will be that in every iteration of Part I of the bipartite edge-coloring algorithm, the maximum degree of the graph shrinks by a factor of at least $(1+\epsilon)/e$ w.h.p., as long as $\Delta_C \geq$ THRESHOLD. That is,

$$\Delta(G_\perp) \leq (1+\epsilon)\frac{\Delta(G_C)}{e}$$

w.h.p. for any fixed $\epsilon > 0$. The condition $\Delta_C \geq$ THRESHOLD ensures that the failure probability given by the extension of the CH bounds is the inverse of a superpolynomial function. Hence w.h.p., no vertex will violate the degree condition. The reason for setting THRESHOLD $= \log^{1+\delta} n$ will be apparent from the probabilistic analysis.

Once the key claim is established, we can bound both the total number of colors used, and the running time of the algorithm. To bound the number of colors used, observe that if the degree of the graph shrinks at every iteration by at least a $(1+\epsilon)/e$ factor w.h.p., then the maximum degree of G_r is at most $\log^{1+\delta} n$ w.h.p.

Hence if $\Delta_C \geq$ THRESHOLD, then w.h.p., the number of colors used by the bipartite algorithm is at most

$$BC(\Delta_C) \leq \Delta_C + \frac{\Delta_C}{e}(1+\epsilon) + \cdots + \frac{\Delta_C}{e^k}(1+\epsilon)^k + 2\log^{1+\delta} n,$$

where k is the smallest integer such that $\Delta_C(1+\epsilon)^k/e^k \leq \log^{1+\delta} n$. Thus for a suitable $\epsilon' > 0$ which depends on ϵ and which can be made arbitrarily small, $BC(\Delta_C)$ is at most

$$\begin{aligned} BC(\Delta_C) &\leq \left(\frac{e}{e-1} + \epsilon'\right)\Delta_C + \left(2 - \frac{e}{e-1} - \epsilon'\right)\log^{1+\delta} n \\ &< 1.585\Delta_C + 0.4\log^{1+\delta} n \\ &< 1.59\Delta_C \end{aligned}$$

when $\Delta_C > 8\ \log^{1+\delta} n$. The running time of the algorithm is $O(\log n)$ because Part I takes $O(\log \Delta_C)$ time and Part II, i.e., Luby's algorithm, takes $O(\log n)$ time.

Note that if $\Delta \geq 16\text{THRESHOLD}$ in the main algorithm, then $\Delta_C > 8 \log^{1+\delta} n$ is true for the bipartite algorithm and hence the above analysis is valid; also note that if $\Delta \leq 16 \log^{1+\delta} n$, then we use Luby's subroutine directly in our main algorithm.

Thus if $\Delta \geq 16\text{THRESHOLD}$ in the main algorithm, then the recurrence for the total number of colors used is

$$\begin{aligned} TC(\Delta) &\leq BC\left(\frac{\Delta}{2} + \sqrt{\Delta \log^{1+\delta/2} n}\right) + TC\left(\frac{\Delta}{2} + \sqrt{\Delta \log^{1+\delta/2} n}\right) \\ &< 1.59\Delta + o(\Delta) \\ &< 1.6\Delta. \end{aligned}$$

If $\Delta \leq 16 \log^{1+\delta} n$, then the main algorithm uses Luby's subroutine directly to get a $2\Delta - 1 \leq 32 \log^{1+\delta} n$ edge coloring. Hence the total number of colors to color *any* graph is at most $1.6\,\Delta + 32 \log^{1+\delta} n$ for any fixed $\delta > 0$ w.h.p.

5.1.1. A truly distributed algorithm. We now sketch the modifications needed to handle the case when both Δ and n are unknown. Each node u initially computes the value $\Delta_u = \max_{v \in N(u)} \deg(v)$. The recursion of the Karloff–Shmoys scheme and the loop of Part I of the bipartite subroutine are then repeated for $c \log \Delta_u$ times for a constant $c > 0$ chosen large enough. A vertex u is said to be *active* as long as no more than $c \log \Delta_u$ rounds have elapsed; it is *inactive* otherwise. An edge incident on an inactive node is inactive. It is convenient to think of Luby's algorithm as run directly by the edges. An inactive and yet uncolored edge f will wait until all of its neighboring edges are either colored or inactive, at which point it starts running Luby's algorithm with a palette of $\deg(f) + 1$ fresh colors, where $\deg(f)$ denotes the number of inactive edges incident upon f. There are two main observations to prove the correctness of and the bounds on the number of colors used by this modified algorithm. First, all of the neighbors of a vertex u will stay active for at least $c \log \deg(u)$ rounds. Hence all vertices such that $\deg(u) = \Omega(\log^{1+\delta} n)$ will be able (w.h.p.) to color enough edges to reduce their degree until it drops to $O(\log^{1+\delta} n)$. Second, as discussed in section 2, Luby's algorithm still works correctly when vertices (in our case, edges) are added dynamically.

The high-probability analysis carries through with these modifications. Simple calculations show that with these modifications, the total number of colors used increases to at most $1.6\Delta + 160 \log^{1+\delta} n$. We omit the calculations for this modified algorithm, which are similar to those presented here for the case where n and Δ are known.

We now return to the case where n and Δ are known, and we turn to the task of proving the key claim. We wish to show that given a graph G and Δ such that $\Delta \geq \Delta(G)$ and $\Delta \geq \text{THRESHOLD}$, then after one iteration of Part I of the bipartite algorithm, the maximum degree of the new graph, $\Delta(G_\perp)$, is at most $(1 + \epsilon)\Delta/e$ w.h.p. for any fixed $\epsilon > 0$. It turns out that the analysis is considerably easier for the top vertices than for the bottom vertices. We begin with the easy part.

5.2. Analysis of the top vertices. Let u be a generic top vertex with incident edges $i = (u, v_i)$. Recall that a *loser* is an edge which, after having gotten a tentative color in the random proposal, lost the lottery and got decolored. Therefore, the new degree of u is given by the number of losers incident with it.

From the point of view of a top vertex, the random proposal and the lottery are equivalent to the following random experiment. For each edge i incident on u, we introduce a ball i, and for each color k, we introduce a bin k; the assignment of a

tentative color to an edge by the algorithm is equivalent to throwing each ball into one of the Δ bins independently and uniformly at random since the bottom vertices assign tentative colors with uniform probability and independently of the other bottom vertices. Recalling that we have at most Δ balls and exactly Δ bins,

$$\begin{aligned}\sharp losers &= \sharp balls - \sharp winners \\ &\leq \sharp bins - \sharp nonempty\ bins \\ &= \sharp empty\ bins.\end{aligned}$$

Let X be a random variable denoting the number of losers. To estimate X and its tail distribution, we will study the random variable $B = \sharp empty\ bins$. For this purpose, we introduce Δ many indicator random variables B_i, where $B_i = 1$ if bin i is empty and 0 otherwise; hence $B = \sum_{i\in[\Delta]} B_i$. Notice that $X \leq B$ always. The variable B was studied in section 3, where it was shown that $E[B] \leq \Delta/e$ and that the B_i's are 1-correlated, which implies that $\Pr(B > (1+\epsilon)\Delta/e) \leq F(\Delta/e, \epsilon)$. Since $E[X] \leq E[B]$ and $\Pr(X > (1+\epsilon)\Delta/e) \leq \Pr(B > (1+\epsilon)\Delta/e)$, we get the following result.

THEOREM 5.1. *Let u be a top vertex and X be the random variable denoting the number of losers incident on it. Then $E[X] \leq \Delta/e$ and*

$$\Pr\left(X > \frac{(1+\epsilon)\Delta}{e}\right) \leq F\left(\frac{\Delta}{e}, \epsilon\right).$$

5.3. Analysis of the bottom vertices. In this section, we analyze what happens to the new degree of a generic bottom vertex v_b. This case is considerably harder to handle than the previous one because of the way in which the random variables describing the process are correlated. For a top vertex, the dependency among the variables was playing for us; given that some edges incident on a top vertex are losers, the probability of having another loser decreases. For a bottom vertex, the situation is reversed: having some edges lose the lottery might even make the probability of having another loser increase. The problem can be seen in the following situation. Let $x_1 = v_b$ and x_2 be bottom vertices, and let y_1 and y_2 be top vertices which induce a four-cycle, i.e., there is an edge $e_{i,j} = (x_i, y_j)$ for $i, j = 1, 2$. Suppose we are given that $e_{1,1}$ got tentative color α and lost the lottery and that $e_{1,2}$ got tentative color β; we will argue intuitively that given this, the probability of $e_{1,2}$ losing the lottery has increased. Since $e_{1,1}$ lost, the probability of $e_{2,1}$ getting tentative color α increases, which implies that the probability of $e_{2,2}$ getting tentative color β also increases, and this increases the probability of $e_{1,2}$ losing the lottery.

For the sake of the analysis, we modify the algorithm as follows: instead of performing all random proposals in parallel, suppose that the bottom vertices perform their random proposals sequentially, in some order. This does not modify the probability distributions because the choices are still done independently. We want to focus our attention on the last vertex v_b performing the random proposal. We will use the fact that when v_b performs its random proposal, all edges not incident on v_b already have a tentative color. By symmetry, any upper bound on the probabilities we can find for v_b will hold for all bottom vertices.

Let $i \in [d_{v_b}]$ denote an edge incident with the bottom vertex v_b, with the other endpoint of i being u_i. We introduce the indicator random variables

$$X_i = \begin{cases} 1, & i \text{ loses the lottery,} \\ 0 & \text{otherwise,} \end{cases}$$

and we want to study the expectation and tail probability distribution of $X = \sum_{i\in[d_{v_b}]} X_i$. Computing the expectation is easy.

LEMMA 5.2. $E[X] \le \Delta/e$.

Proof. Let v_b be the bottom vertex. It is sufficient to show that $\Pr(X_i = 1) \le 1/e$ for all $i \in [d_{v_b}]$. From the analysis of the top vertices, we know that the expected number of losers incident with u_i is at most Δ/e and hence that $\sum_{j\in\delta(u_i)} \Pr(j \text{ loses}) \le \Delta/e$. By symmetry, $\Pr(j \text{ loses}) \le 1/e$ for all $j \in \delta(u_i)$, and hence $\Pr(X_i = 1) \le 1/e$. □

We now study the tail probability distribution of X. Our goal is to show that $X \le (1+\epsilon)\Delta/e$ w.h.p. for any fixed $\epsilon > 0$. Establishing this claim will take several lemmas.

We use a method different from the preliminary version of this work [16] to present stronger results. We first invoke a result of Schmidt, Siegel, and Srinivasan [20], which was in fact motivated in part by [16] and in particular by the notion of λ-correlation.

For $z = (z_1, z_2, \ldots, z_n) \in \Re^n$, define a family of symmetric polynomials $q_j(z)$, $0 \le j \le n$, where $q_0(z) \equiv 1$ and for $1 \le j \le n$,

$$q_j(z) \doteq \sum_{1\le i_1<i_2\cdots<i_j\le n} z_{i_1} z_{i_2} \cdots z_{i_j}.$$

THEOREM 5.3 (see [20]). *Let $Y_1, Y_2, \ldots, Y_n$ be arbitrary (not necessarily independent) 0–1 random variables with $Y = \sum_{i=1}^n Y_i$. Then for any $a > 0$ and any positive probability event Z,*

$$\Pr(Y \ge a|Z) \le \min_{\ell=1,\ldots,a} \frac{E[q_\ell(Y_1, Y_2, \ldots, Y_n)|Z]}{\binom{a}{\ell}}.$$

Proof. The actual theorem of [20] is stated unconditionally without reference to Z, but the above conditional extension is easily derivable from its proof as follows. Since the Y_i's are binary, it is easily seen that for any $\ell \le a$, given that Z occured, $(Y \ge a)$ implies $(q_\ell(Y_1, Y_2, \ldots, Y_n) \ge \binom{a}{\ell})$. Thus by Markov's inequality,

$$\Pr(Y \ge a|Z) \le \frac{E[q_\ell(Y_1, Y_2, \ldots, Y_n)|Z]}{\binom{a}{\ell}}. \qquad \square$$

To bound the upper tail of X, we will define an event $\mathcal{A}$ such that $\mathcal{A}$ happens w.h.p. and such that for a suitably chosen k,

$$\frac{E[q_k(X_1, \ldots, X_{d_{v_b}})|\mathcal{A}]}{\binom{\Delta(1+\epsilon)e^{-1}}{k}} = e^{-\Omega(\Delta\epsilon^2)}. \tag{3}$$

In combination with Theorem 5.3, this will show that $\Pr(X \le (1+\epsilon)\Delta/e)$ almost surely because

$$\begin{aligned}\Pr\left(X > \frac{(1+\epsilon)\Delta}{e}\right) &= \Pr\left(X > \frac{(1+\epsilon)\Delta}{e} \mid \mathcal{A}\right)\Pr(\mathcal{A}) \\ &\quad + \Pr\left(X > \frac{(1+\epsilon)\Delta}{e} \mid \mathcal{A}^c\right)\Pr(\mathcal{A}^c)\end{aligned} \tag{4}$$

$$\leq \Pr\left(X > \frac{(1+\epsilon)\Delta}{e} \mid \mathcal{A}\right) + \Pr(\mathcal{A}^c)$$
$$\leq \min_{i\in[d_{v_b}]} \frac{E[q_i(X_1,\ldots,X_{d_{v_b}})|\mathcal{A}]}{\binom{\Delta(1+\epsilon)e^{-1}}{i}} + \Pr(\mathcal{A}^c)$$
$$\leq \frac{E[q_k(X_1,\ldots,X_{d_{v_b}})|\mathcal{A}]}{\binom{\Delta(1+\epsilon)e^{-1}}{k}} + \Pr(\mathcal{A}^c),$$

which is small by assumption. (Note that $\mathcal{A}$ happens w.h.p.) To prove the upper bound (3), we will focus on a generic term $\Pr(\bigwedge_{i\in I} X_i = 1|\mathcal{A})$ in

$$E[q_k(X_1,\ldots,X_{d_{v_b}})|\mathcal{A}] = \sum_{I\subseteq[d_{v_b}],|I|=k} E\left[\prod_{i\in I} X_i|\mathcal{A}\right] = \sum_{I\subseteq[d_{v_b}],|I|=k} \Pr\left(\bigwedge_{i\in I} X_i = 1|\mathcal{A}\right),$$

which will also suggest to us a suitable choice for the event $\mathcal{A}$.

Consider then a generic subset $I = \{w_1, w_2, \ldots, w_k\} \subseteq [d_{v_b}]$ of edges incident on the bottom vertex v_b (corresponding to the neighbors $\{u_{w_i}\}$ of v_b), and let us see how to compute $\Pr(\bigwedge_{i\in I} X_i = 1)$. Without loss of generality, we assume $I = [k]$. Recall that we are analyzing the situation where v_b is the last vertex to perform its random proposal. This means that prior to the assignment of a tentative color to edge $i = (v_b, u_i)$, all other edges incident on u_i already have their tentative color. Using the balls-and-bins language, we can say that prior to throwing ball i at random into one of the bins at vertex u_i, all balls coming from the other neighbors of u_i have been thrown. We will think of i as a red ball and of the other edges at u_i as white balls. Once the red ball is thrown in, say, bin $\ell \in [\Delta]$, a winner is selected uniformly at random among all (i.e., red *and* white) balls in bin ℓ. All other balls, the losers, are discarded. Notice that the probability of discarding the red ball is itself a random variable which depends on the particular placement of the white balls prior to throwing the red ball. (Hence we will study the conditional probability that the red ball loses the lottery, given a placement of white balls.)

Given any placement of white balls at u_i, we construct a vector of probabilities C_i as follows. Let $a_{\ell,i}$ denote the number of white balls in bin $\ell \in [\Delta]$ of vertex u_i, and let $p_{\ell,i} = a_{\ell,i}/(1 + a_{\ell,i})$ denote the probability that the red ball loses the lottery given that it was thrown in bin ℓ. (Equivalently, $p_{\ell,i}$ is the probability that edge i loses given that it got tentative color ℓ.) For each neighbor u_i of our bottom vertex v_b, we construct the corresponding vector $C_i = (p_{1,i}, p_{2,i}, \ldots, p_{\Delta,i})$. We then construct a $\Delta \times k$ matrix M_I whose ith column is the vector C_i. The next lemma explains why this matrix is relevant to us. Henceforth, let $p(m,\ell) \doteq m(m-1)\cdots(m-\ell+1)$.

LEMMA 5.4.

$$\Pr\left(\bigwedge_{i\in I} X_i = 1\right) = \frac{perm(M_I)}{p(\Delta,k)}.$$

Proof. The random proposal of v_b restricted to I is equivalent to choosing a one-to-one function $\pi : I \to [\Delta]$ uniformly at random among the set $\mathcal{P}$ of all such functions. Recall that the entry $M_{i,j}$ of M_I is the probability $p_{i,j}$ that edge w_j loses given that it is given color i. Hence

$$\Pr(\wedge_{i\in I} X_i = 1) = \sum_{\pi\in\mathcal{P}} \Pr(\wedge_{i\in I} X_i = 1 \mid \pi \text{ is selected}) \Pr(\pi \text{ is selected})$$

$$= \sum_{\pi \in \mathcal{P}} \left(M_{\pi(1),1} M_{\pi(2),2} \cdots M_{\pi(k),k} \right) \prod_{i=0}^{k-1} \frac{1}{\Delta - i}$$
$$= \frac{perm(M_I)}{p(\Delta, k)}. \qquad \square$$

We now want to find a good upper bound for $perm(M_I)$. The following lemma gives a simple upper bound that is sufficient for our purposes.

LEMMA 5.5. *Let M be a matrix with c columns and r rows ($c \leq r$) and non-negative entries. Let S_i denote the sum of the entries of the ith column of M. Then* $\text{perm}(M) \leq \prod_{i \in [c]} S_i$.

Proof. Let $\mathcal{P} = \{\pi \mid \pi : [c] \to [r],\ \pi \text{ is one-to-one}\}$. Then

$$\begin{aligned} perm(M) &= \sum_{\pi \in \mathcal{P}} M_{\pi(1),1} M_{\pi(2),2} \cdots M_{\pi(c),c} \\ &\leq (M_{1,1} + \cdots + M_{r,1})(M_{1,2} + \cdots + M_{r,2}) \cdots (M_{1,c} + \cdots + M_{r,c}) \\ &= \prod_{i \in [c]} S_i. \qquad \square \end{aligned}$$

The next lemma relates the value of S_i to that of $1/e \geq \Pr(i \text{ loses})$, $i \in \delta(v_b)$. It is an application of the general definition of λ-correlation. Before the proof of the lemma, we establish the following result.

PROPOSITION 5.6. *If $0 \leq p \leq 1$, $q = 1 - p$, and m is a positive integer, then*

$$\sum_{r=1}^{m} \binom{m}{r} p^r q^{m-r} \frac{r}{r+1} = 1 - \frac{(1 - q^{m+1})}{p(m+1)}.$$

Proof. Let

$$\begin{aligned} f(p) &= \sum_{r=1}^{m} \binom{m}{r} p^r q^{m-r} \frac{k}{k+1} \\ &= 1 - q^m - \sum_{r=1}^{m} \binom{m}{r} p^r q^{m-r} \frac{1}{k+1}. \end{aligned}$$

Integrating both sides of the binomial expansion

$$(x+q)^m = \sum_{r=0}^{m} \binom{m}{r} x^r q^{m-r}$$

between 0 and p, we get

$$\frac{1 - q^{m+1}}{m+1} = p\,(1 - f(p)),$$

from which the proposition follows. $\square$

We now return to our scenario where v_b is the last bottom vertex to pick tentative colors for its edges. Recall that we are focusing on a set $I = \{w_1, w_2, \ldots, w_k\}$ of edges incident on v_b and that we want a good upper bound on $\Pr(\bigwedge_{i \in I} X_i = 1)$; we had also assumed that $I = [k]$ without loss of generality. Combining Lemmas 5.4 and 5.5, we get

$$\Pr\left(\bigwedge_{i \in I} X_i = 1 \right) \leq \frac{perm(M_I)}{p(\Delta, k)} \leq \frac{\Pi_{i=1}^{k} S_i}{p(\Delta, k)},$$

where for each $i \in [d_{v_b}]$, S_i is defined to be the sum of the entries in C_i. Therefore, a good upper bound on S_i for each i will hopefully translate into a good upper bound for $\Pr(\bigwedge_{i\in I} X_i = 1)$. The next lemma says that $S_i \le \Delta(1+\epsilon_1)/e$ w.h.p. for any fixed $\epsilon_1 > 0$ and for each i. Thus a good choice for $\mathcal{A}$ is

$$\mathcal{A} : \text{“}S_i \le \Delta(1+\epsilon_1)/e \text{ for each } i \in [d_{v_b}]\text{”}$$

where ϵ_1 will be fixed later. The next lemma is an application of the general definition of λ-correlation.

LEMMA 5.7. *Let $i = (v_b, u_i)$ be any edge in $[d_{v_b}]$, and let S_i be the sum of the entries of C_i. Then $E[S_i] \le \Delta/e = \mu$ and*

$$\forall \epsilon_1 > 0, \ \Pr(S_i > (1+\epsilon_1)\mu) \le F(\mu, \epsilon_1).$$

Proof. Let Z_ℓ be the random variable denoting the number of white balls in bin ℓ of u_i, and let $Y_\ell = Z_\ell/(Z_\ell + 1)$ be the random variable denoting the probability that the red ball loses the lottery given that it lands in bin ℓ. Then $S_i = Y \doteq \sum_\ell Y_\ell$. Note that the Y_ℓ's are bounded random variables with values in $[0,1]$. We will show that $E[Y] \le \Delta/e$ and that the Y_ℓ's are 1-correlated (under the general definition of λ–correlation), which will give our claim.

We may assume that the total number d of white balls equals $\Delta - 1$ (i.e., that the degree of u_i is Δ): $\Pr(Y > (1+\epsilon_1)\Delta/e)$ is maximized at $d = \Delta - 1$ since d varies from 1 to $\Delta - 1$. (To see this, assume $d = \Delta - 1 - \ell < \Delta - 1$. Add ℓ *yellow* balls to the white balls and run two experiments. In one experiment, throw the white and red balls and compute the probability that the red ball loses the lottery. In the other experiment, throw white, yellow, and red balls and again compute the probability that the red ball loses. In both experiments, let us look at the bin where the red ball fell. The probability that the red ball loses is $b/(b+1)$ for the first experiment and $(b+y)/(b+y+1)$ for the second, where b and y are, respectively, the number of white and yellow balls in the bin. Since $y \ge 0$, $b/(b+1) \le (b+y)/(b+y+1)$. If $Y_i(d)$ indicates the variable Y_i when u_i has degree d, then $Y_i(d) \le Y_i(\Delta)$ for all $i \in [\Delta]$ and $d \in [\Delta]$.)

First, we will show that for all i, $E[Y_i] \le 1/e$, and then we will show that for any set of ℓ indices $J \subseteq [\Delta]$ and strictly positive integers s_i,

$$E\left[\prod_{i\in J} Y_i^{s_i}\right] \le \frac{1}{e^\ell}. \tag{5}$$

Given this we can apply Corollary 3.3 by introducing n independent twin 0–1 random variables $\hat{Y}_i$ such that $E[\hat{Y}_i] = \Pr(\hat{Y}_i = 1) = 1/e$. Since the $\hat{Y}_i$'s are binary, inequality (5) is the same as

$$E\left[\prod_{i\in J} Y_i^{s_i}\right] \le \prod_{i\in J} E[\hat{Y}_i] = \prod_{i\in J} E[\hat{Y}_i^{s_i}],$$

which is to say that the Y_i's are 1-correlated. Noting that $0 \le Y_i \le 1$, it suffices to show that

$$E\left[\prod_{i\in J} Y_i\right] \le \frac{1}{e^\ell}. \tag{6}$$

Without loss of generality, we can assume $J = [\ell]$. We will prove inequality (6) by induction on $\ell \geq 1$; when $\ell = 1$,

$$\begin{aligned} E[Y_1] &= \sum_{r=0}^{\Delta-1} \binom{\Delta-1}{r} \left(\frac{1}{\Delta}\right)^r \left(1-\frac{1}{\Delta}\right)^{\Delta-1-r} \frac{r}{r+1} \\ &= \left(1-\frac{1}{\Delta}\right)^{\Delta} \leq \frac{1}{e}, \end{aligned}$$

where the second equality follows from Proposition 5.6. Notice that for all $j \in [\Delta]$, $E[Y_j] = E[Y_1] \leq 1/e$. When $\ell > 1$, the law of conditional probabilities gives

$$E\left[\prod_{i\in[\ell]} Y_i\right] = E[Y_1 Y_2 \cdots Y_{\ell-1}\, E[Y_\ell \mid Y_1 Y_2 \cdots Y_{\ell-1}]] \tag{7}$$

Suppose we show that for all *nonzero* $c_i \in [0,1]$ with $i \in [\ell-1]$,

$$E\left[Y_\ell \mid \bigwedge_{i=1}^{\ell-1} Y_i = c_i\right] \leq \frac{1}{e}; \tag{8}$$

then since the product $Y_1 Y_2 \cdots Y_{\ell-1}$ in equation (7) is zero when any c_i is zero, we see by induction on ℓ that

$$\begin{aligned} E\left[\prod_{i=1}^{\ell} Y_i\right] &= E[Y_1 Y_2 \cdots Y_{\ell-1}\, E[Y_\ell \mid Y_1 Y_2 \cdots Y_{\ell-1}]] \\ &\leq \frac{1}{e} E\left[\prod_{i=1}^{\ell-1} Y_i\right] \\ &\leq \frac{1}{e^\ell}. \end{aligned}$$

Hence the claim follows if we can show that inequality (8) holds.

If a_i denotes the number of white balls that fell into bin i, then $c_i = a_i/(a_i+1)$. Let $a = \sum_{i=1}^{\ell-1} a_i \geq \ell - 1$, $p = 1/(\Delta - \ell + 1)$, and $q = 1-p$. Then

$$\begin{aligned} E\left[Y_\ell \middle| \bigwedge_{i=1}^{\ell-1} Y_i = c_i\right] &= E\left[Y_\ell \middle| \bigwedge_{i=1}^{\ell-1} Z_i = a_i\right] \\ &= \sum_{r=1}^{\Delta-1-a} t(r,a), \end{aligned}$$

where

$$t(r,a) \doteq \binom{\Delta-1-a}{r} p^r q^{\Delta-1-a-r} \frac{r}{r+1}.$$

It is easy to check that $t(r,a) \geq t(r,a+1)$. As a consequence, the maximum value of $E[Y_\ell \mid \bigwedge_{i=1}^{\ell-1} Y_i = c_i]$ is attained at $a = \ell - 1$, in which case we have

$$\sum_{r=1}^{\Delta-1-a} t(r,a) = \sum_{r=1}^{\Delta-\ell} t(r,\ell-1)$$

$$= \sum_{r=1}^{\Delta-\ell} \left(\begin{array}{c} \Delta-\ell \\ r \end{array} \right) p^r q^{\Delta-\ell-r} \frac{r}{r+1}$$
$$= q^{\Delta-\ell+1} \leq \frac{1}{e}$$

by Proposition 5.6. □

We remark that a short proof of Lemma 5.7 can be derived using the elegant work of [7].

Define $\epsilon_1 \doteq \epsilon/10$. Thus defining the event $\mathcal{A}$ as "$S_i \leq \Delta(1+\epsilon_1)/e$ for each $i \in [d_{v_b}]$", Lemma 5.7 gives the bound

$$\Pr(\mathcal{A}^c) \leq \Delta F\left(\frac{\Delta}{e}, \epsilon_1\right). \tag{9}$$

Now given that $\mathcal{A}$ holds, Lemma 5.5 shows that $perm(M_I) \leq (\Delta(1+\epsilon_1)/e)^k$ and thus from Lemma 5.4,

$$\Pr\left(\bigwedge_{i\in I} X_i = 1 | \mathcal{A}\right) \leq \frac{\left(\frac{\Delta(1+\epsilon_1)}{e}\right)^k}{p(\Delta,k)}. \tag{10}$$

We now turn to defining k suitably to get a good tail bound. Invoking Theorem 5.3 for

$$X = \sum_{i\in[d_{v_b}]} X_i$$

in conjunction with (10), we see that if $a = \Delta(1+\epsilon)/e$, then

$$\begin{aligned}
\Pr(X > a|\mathcal{A}) &\leq \frac{E[q_i(X_1,\ldots,X_{d_{v_b}})|\mathcal{A}]}{\binom{a}{k}} \\
&\leq \frac{\binom{d_{v_b}}{k}\left(\frac{\Delta(1+\epsilon_1)}{e}\right)^k}{p(\Delta,k)\binom{a}{k}} \\
&\leq \frac{\binom{\Delta}{k}\left(\frac{\Delta(1+\epsilon_1)}{e}\right)^k}{p(\Delta,k)\binom{a}{k}} \\
&= \frac{\left(\frac{\Delta(1+\epsilon_1)}{e}\right)^k}{p\left(\frac{\Delta(1+\epsilon)}{e},k\right)}. \qquad (11)
\end{aligned}$$

To lower bound $p(\Delta(1+\epsilon)/e, k)$, we need the following result.

LEMMA 5.8. *For positive integers t and ℓ, $t^\ell/p(t,\ell) \leq e^{\ell^2/t}$ if $\ell \leq t/2$.*

Proof. We first note that $\ln(1-x) \geq -2x$ for $0 \leq x \leq 1/2$. This is true since if we define $f(x) \doteq \ln(1-x) + 2x$, then $f(0) = 0$ and $f'(x) = (1-2x)/(1-x)$, which is nonnegative for $0 \leq x \leq 1/2$. Now

$$\begin{aligned}
\frac{p(t,\ell)}{t^\ell} &= \prod_{i=1}^{\ell-1} \frac{(t-i)}{t} \\
&= \exp\left(\sum_{i=1}^{\ell-1} \ln\left(1 - \frac{i}{t}\right)\right) \\
&\geq \exp\left(-\sum_{i=1}^{\ell-1} \frac{2i}{t}\right) \qquad \left(\text{since } \ell \leq \frac{t}{2}\right) \\
&= \exp\left(-\frac{(\ell-1)\ell}{t}\right) \\
&\geq e^{-\ell^2/t}. \qquad \square
\end{aligned}$$

We now set $k = \lfloor \Delta\epsilon/3e \rfloor$. Using Lemma 5.8 and the facts $\epsilon_1 = \epsilon/10$, $1 + \epsilon \geq e^{\epsilon/2}$, and $1 + \epsilon_1 \leq e^{\epsilon_1}$, we see from (11) that

$$\Pr(X \geq \Delta(1+\epsilon)/e | \mathcal{A}) \leq e^{-\Omega(\Delta\epsilon^2)}. \tag{12}$$

Applying bounds (9) and (12) to (4), we finally arrive at

$$\Pr(X \geq \Delta(1+\epsilon)/e) \leq e^{-\Omega(\Delta\epsilon^2)}. \tag{13}$$

We can now see why the parameter THRESHOLD must be $\Omega(\log^{1+\delta} n)$: the failure probability (13) goes to zero superpolynomially fast if $\Delta = \Omega(\log^{1+\delta} n)$ for any fixed $\delta > 0$. Using (13), we conclude our analysis with the following result.

THEOREM 5.9. *The new degree of the graph after one iteration of Part* I *of the bipartite algorithm is at most* $(1+\epsilon)\Delta/e$ *w.h.p. for any fixed* $\epsilon > 0$.

6. Extensions and applications of the algorithm. Recently, Panconesi and Dubhashi have improved our bounds by presenting a randomized distributed edge-coloring algorithm that runs in polylogarithmic time and uses at most $\Delta(1 + o(1)) + O(\log n)$ colors w.h.p. [6]. However, we feel that this work has independent interest owing to the tools developed to analyze the algorithm. We now describe some recent applications of this work.

Our results on λ-correlation have been used to prove the performance of a randomized rounding technique for multicommodity flow (Young [23]) and to provide an elementary method to bound the upper tail of the number of prime factors of random integers (Srinivasan [21]). As mentioned in section 5.3, the work of [20], which expands the applicability of CH-type bounds to more nonindependent scenarios, was inspired in part by this work. Our results on upper tail bounds for sums of bounded λ-correlated random variables have been generalized in [20].

Our algorithm has also been used and extended in the context of emulating PRAM algorithms using a limited number of processors [5].

Acknowledgments. Our sincere thanks go to David Shmoys for his continued guidance and support. We are grateful to Éva Tardos for an important idea about analyzing the algorithm and to Suresh Chari, Devdatt Dubhashi, David Pearson, Desh Ranjan, Pankaj Rohatgi, and Stephen Vavasis for useful discussions. We also thank the referees for their several valuable comments.

RANDOM DEBATERS AND THE HARDNESS OF APPROXIMATING STOCHASTIC FUNCTIONS*

ANNE CONDON†, JOAN FEIGENBAUM‡, CARSTEN LUND§, AND PETER SHOR¶

Abstract. A *probabilistically checkable debate system* (PCDS) for a language L consists of a probabilistic polynomial-time verifier V and a debate between Player 1, who claims that the input x is in L, and Player 0, who claims that the input x is not in L. It is known that there is a PCDS for L in which V flips $O(\log n)$ coins and reads $O(1)$ bits of the debate if and only if L is in PSPACE [A. Condon, J. Feigenbaum, C. Lund, and P. Shor, *Chicago J. Theoret. Comput. Sci.*, 1995, No. 4]. In this paper, we restrict attention to RPCDSs, which are PCDSs in which Player 0 follows a very simple strategy: On each turn, Player 0 chooses uniformly at random from the set of legal moves. We prove the following result.

THEOREM. *L has an RPCDS in which the verifier flips $O(\log n)$ coins and reads $O(1)$ bits of the debate if and only if L is in* PSPACE.

This new characterization of PSPACE is used to show that certain *stochastic* PSPACE-hard functions are as hard to approximate closely as they are to compute exactly. Examples of such functions include optimization versions of Dynamic Graph Reliability, Stochastic Satisfiability, Mah-Jongg, Stochastic Generalized Geography, and other "games against nature" of the type introduced in [C. Papadimitriou, *J. Comput. System Sci.*, 31 (1985), pp. 288–301].

1. Introduction.

Recently, there has been great progress in understanding the precision with which one can approximate solutions to NP-hard problems efficiently. Feige et al. [13], Arora et al. [2, 3], and others proved strong negative results for several fundamental problems such as Clique and Satisfiability. This progress has led to renewed study of approximation algorithms for PSPACE-hard problems.

Not surprisingly, PSPACE-hard problems also display a wide variation in the precision with which they can be approximated efficiently. The following results in the literature show that, with respect to a particular performance guarantee, some PSPACE-hard problems have efficient approximation algorithms, others have such algorithms if and only if NP = P, and still others have such algorithms if and only if PSPACE = P. One interesting class of results concern problems on hierarchically defined structures, such as graphs. Problems on these structures, and on a related class

of periodic structures, arise in many VLSI and scheduling applications (see, for example, [18] for references to these and other applications). Because such representations can implicitly describe a structure of exponential size, using just polynomial space, the associated problems are often PSPACE-hard. As early as 1981, Orlin [20] claimed a negative result on approximating a PSPACE-hard periodic version of the Knapsack problem, namely that a fully polynomial approximation scheme exists for this problem only if NP = P. Orlin did not address whether in fact it might be PSPACE-hard to approximate this function. On the positive side, Marathe et al. [18] recently developed constant-factor approximation algorithms for PSPACE-hard problems, including the Max Cut and Vertex Cover problems for certain restricted classes of hierarchically represented graphs. In related work, Marathe et al. [19] applied results of Arora et al. [2] to show that these same problems have polynomial-time approximation schemes if and only if NP = P.

In [10], we considered optimization versions of several other problems in PSPACE, including Quantified Satisfiability, Generalized Geography, and Finite Automata Intersection. Building on the techniques of [2, 3, 13], we showed that it is in fact PSPACE-hard to approximate these problems closely (where "closely" depends on the problem). Using direct reduction arguments, Hunt et al. [14] showed that some generalized quantified satisfiability problems (for example, satisfiability of quantified formulas in which "clauses" are not restricted to be disjunctions of literals) are PSPACE-hard to approximate.

An important class of PSPACE-hard problems not previously addressed in this literature is a class of *stochastic* problems that involve decision-making under uncertainty, as in the games against nature of Papadimitriou [21]. In this paper, we develop a new technique for showing that these stochastic PSPACE-hard problems are hard to approximate. Informally, these are problems in which the instances involve probabilities in some essential way. The probabilities may describe failures of arcs in a digraph or moves of one of the players in a game. Examples of functions that we prove are hard to approximate include optimization versions of Stochastic Satisfiability (SSAT) [21], Stochastic Generalized Geography (SGGEOG), Dynamic Graph Reliability (DGR) [21], and Mah-Jongg. We describe two of these problems in more detail below. Precise definitions of all of the functions of interest can be found in section 3.

Our technique for proving that these problems are hard to approximate is based on a new characterization of PSPACE in terms of debates between one powerful and one random player that are checked by a resource-limited verifier. Just as the "games against nature" model is a powerful tool in obtaining hardness results for stochastic problems such as those mentioned above, our new model of PSPACE proves to be a very useful and natural tool in obtaining nonapproximability results for these problems.

We also use the identity IP = PSPACE [16, 23] to derive nonapproximability results for other stochastic PSPACE-hard functions. Examples of the functions that yield to this technique include optimization versions of Dynamic Markov Process (DMP) [21] and Stochastic Coloring, as well as a different optimization version of Stochastic Satisfiability.

We now give two examples that illustrate the kind of problems to which our new technique applies. The first is a variant of Graph Reliability, a #P-complete problem studied by Valiant [25]: Given a directed, acyclic graph G, source and sink vertices s and t, and a failure probability $p(v, w)$ for each arc (v, w), what is the

probability that there is a path from s to t consisting exclusively of arcs that have not failed? Papadimitriou [21] defines Dynamic Graph Reliability as follows: The goal of a strategy is still to traverse the digraph from s to t. Now, however, for each vertex x and arc (v, w), there is a failure probability $p((v, w), x)$; the interpretation is that, if the current vertex is x, the probability that the arc (v, w) will fail before the next move is $p((v, w), x)$. DGR consists of those digraphs for which there exists a strategy for getting from s to t with probability at least $1/2$. A natural optimization problem is MAX-PROB DGR: Given a graph, vertices s and t, and a set $\{p((v, w), x)\}$ of failure probabilities, what is the probability of reaching t from s under an optimal strategy? We show in section 3.3 below that there is a constant $c > 0$ such that it is PSPACE-hard to approximate MAX-PROB DGR within ratio 2^{-n^c}. This implies, for example, that if there is a polynomial-time algorithm that, on input x, outputs a number in the range $[2^{-n^c}\text{MAX-PROB DGR}(x), 2^{n^c}\text{MAX-PROB DGR}(x)]$, then PSPACE = P.

Our second example is a solitaire version of Mah-Jongg that is widely available as a computer game. Mah-Jongg tiles are divided into sets of four matching tiles; we assume that there are an arbitrarily large number of tiles. Initially, the tiles are organized in a preset arrangement of rows, and the rows may be stacked on top of each other. As a result, some tiles are hidden under other tiles. A tile that is not hidden and is at the end of a row is said to be available. In a legal move, any pair of available matching tiles may be removed. The player wins the game if all tiles are removed by a sequence of legal moves. An instance of the Mah-Jongg game describes the arrangement of the rows and, in addition, the tiles that are not hidden. We let MAH-JONGG(x) be the maximum probability of winning the Mah-Jongg game with initial arrangement x of the tiles, assuming that the hidden tiles are randomly and uniformly permuted. We show that approximating the function MAH-JONGG within ratio n^{-c} is PSPACE-hard, where $c < 1$ is some constant. Thus, if there is a polynomial-time algorithm that, on input x, outputs a number in the range $[n^{-c}\text{MAH-JONGG}(x), n^c\text{MAH-JONGG}(x)]$, then PSPACE = P.

Our new characterization of PSPACE, which is used in proving nonapproximability results for these problems, builds on techniques developed in our previous work on *probabilistically checkable debate systems* (PCDSs) [10], which in turn builds on techniques of Arora et al. [2], Lund et al. [16], and Shamir [23]. In a PCDS for L, there are two computationally powerful players, 1 and 0, and a probabilistic polynomial-time verifier V. Players 1 and 0 play a game in which they alternate writing strings on a debate tape π. Player 1's goal is to convince V that an input $x \in L$, and Player 0's goal is to convince V that $x \notin L$. When the debate is over, V looks at x and π and decides whether $x \in L$ (Player 1 wins the debate) or $x \notin L$ (Player 0 wins the debate). Suppose V flips $O(r(n))$ coins and reads $O(q(n))$ bits of π. If, under the best strategies of Players 1 and 0, V's decision is correct with high probability, then we say that L is in $\text{PCD}(r(n), q(n))$. We showed in [10] that $\text{PCD}(\log n, 1) = \text{PSPACE}$. That is, any language in PSPACE can be recognized by a PCDS in which the verifier uses $O(\log n)$ coin flips and queries only a constant number of bits of the debate.

We now restrict attention to PCDSs in which Player 0 follows a very simple strategy—that of tossing coins. Specifically, whenever Player 0 writes a string of length $f(n)$ on the debate tape π, the string is chosen uniformly at random from $\{0, 1\}^{f(n)}$. We call such a debate system an RPCDS and denote by $\text{RPCD}(r(n), q(n))$ the class of languages recognized by RPCDSs in which the verifier flips $O(r(n))$ coins and reads $O(q(n))$ bits of π. We note that an Arthur–Merlin game [4] is an RPCDS

in which the verifier is deterministic and $q(n)$ is an arbitrary polynomial; that is, V reads the entire debate between Arthur (Player 0) and Merlin (Player 1) before deciding whether the input is in the language. Thus the class of languages accepted by Arthur–Merlin games is by definition RPCD$(0, \text{poly}(n))$ and is commonly denoted by IP. It is known that RPCD$(0, \text{poly}(n))$ = PSPACE [16, 23]. In this paper, we prove the following result.

THEOREM. RPCD$(\log n, 1)$ = PSPACE.

This theorem shows that a verifier that tosses $O(\log n)$ coins does not have to read the entire debate between Arthur and Merlin. In fact, only a constant number of bits of the debate are needed. Our result is another in a sequence of results on polynomial-time interactive complexity classes, starting with the result that IP = PSPACE, that show that "universal quantification" can be replaced by "random quantification with bounded error" without changing the complexity class.

In the rest of this section, we first define precisely the PCDS and RPCDS models. We then describe previous work on related complexity classes.

1.1. Preliminaries. In this section, we define both the PCDS model of [10] and the new RPDCS model. We conclude with some definitions relating to the approximability of PSPACE-hard functions.

A *probabilistically checkable debate system*, or PCDS, consists of a *verifier* V and a *debate format* D. The verifier is a probablistic polynomial-time Turing machine that takes as input a pair x, π, where $\pi \in \{0,1\}^*$, and outputs 1 or 0. We interpret these outputs to mean "Player 1 won the debate" and "Player 0 won the debate," respectively.

A debate format is a pair of polynomial-time computable functions $f(n), g(n)$. Informally, for a fixed n, a debate between two players, 0 and 1, consistent with format $f(n), g(n)$, contains $g(n)$ rounds. At round $i \geq 1$, Player i mod 2 chooses a string of length $f(n)$.

For each x of length n, corresponding to the debate format D is a *debate tree*. This is a complete binary tree of depth $f(n)g(n)$ such that, from any vertex, one edge is labeled 0 and the other is labeled 1. A *debate* is any binary string of length $f(n)g(n)$. Thus there is a one-to-one correspondence between debates and the paths in the debate tree. Moreover, a debate is the concatenation of $g(n)$ substrings of length $f(n)$. Each substring is called a *round* of the debate, and each debate of this debate tree has $g(n)$ rounds.

Again for a fixed x of length n, a *debate subtree* is a subtree of the debate tree of depth $f(n)g(n)$ such that each vertex at level i (the root is at level 0) has 1 child if i div $f(n)$ is even, and it has two children if i div $f(n)$ is odd. Informally, the debate subtree corresponds to a list of "responses" of Player 1 against all possible "arguments" of Player 0 in the debate, or, more succinctly, a "strategy" of Player 1.

A language L has a PCDS *with error probability* ϵ if there is a pair $(D = (f(n), g(n)), V)$ with the following properties.

1. For all x in L, there is a debate subtree on which, for all debates π labeling a path of this subtree, V outputs 1 with probability 1 on input x, π. In this case, we say that x is accepted by (D, V).

2. For all x not in L, on all debate subtrees, there exists a debate π labeling some path of the subtree such that V outputs 1 with probability at most ϵ on input x, π. In this case, we say that x is rejected by (D, V).

This definition allows "one-sided error," analogous to the type of errors that are allowed in the complexity class co-RP. (See, for example, Johnson [15] for a definition.)

The main result of [10] also holds for a "zero-sided error" definition, with three possible outputs, 1, 0, and Λ, for "Player 1 won," "Player 0 won," and "I don't know who won," respectively. In this case, the verifier must never declare the losing player to be a winner, but it may, in both the case that $x \in L$ and the case that $x \notin L$, say that it doesn't know who won.

We say that the verifier makes $q(n)$ queries if the number of bits of π read by the verifier is at most $q(n)$ when the input x is of size n. The verifier V in a PCDS is required to be *nonadaptive*, by which we mean that the bits of π read by V depend solely on the input and the coin flips. If L has a PCDS with error probability $1/3$ in which V flips $O(r(n))$ coins and reads $O(q(n))$ bits of π, we say that $L \in \mathrm{PCD}(r(n), q(n))$. The classical result of Chandra et al. [9] that PSPACE is equal to Alternating Polynomial Time can be restated as $\mathrm{PCD}(0, \mathrm{poly}(n)) = \mathrm{PSPACE}$. In [10], we showed that PSPACE is also equal to $\mathrm{PCD}(\log(n), 1)$.

We now focus on PCDSs in which Player 0 follows a very simple strategy—that of tossing coins. Informally, an RPCDS with debate format $D = (f(n), g(n))$ is a PCDS in which, at each even-numbered round, Player 0 moves by choosing a string in $\{0,1\}^{f(n)}$ uniformly at random and writing it on the debate tape. Formally, for a given a debate subtree (i.e., strategy of Player 1), we define the *overall probability* that V outputs 1 to be the average over all debates π in the subtree of the probability that V outputs 1 on debate π. A language L has an RPCDS with error probability ϵ if the following hold.

$1'$. For all x in L, there is a debate subtree for which the overall probability that V outputs 1 is 1. Again, we say that x is accepted by (D, V).

$2'$. For all x not in L, on all debate subtrees, the overall probability that V outputs 1 is at most ϵ. In this case, we say that x is rejected by (D, V).

Note that item $1'$ is equivalent to item 1 above. If L has an RPCDS with error probability $1/3$ in which V flips $O(r(n))$ coins and reads $O(q(n))$ bits of π, we say that $L \in \mathrm{RPCD}(r(n), q(n))$.

To conclude this section, we review some definitions relating to approximability of PSPACE-hard functions. Let f be any real-valued function with domain $D \subseteq \{0,1\}^*$. Let A be an algorithm that, on input $x \in \{0,1\}^*$, produces an output $A(x)$. We say that A *approximates* f *within ratio* $\epsilon(n)$, $0 < \epsilon(n) < 1$, if for all $x \in D$, $\epsilon(|x|) \leq A(x)/f(x) \leq 1/\epsilon(|x|)$. If algorithm A computes the function g, we also say that g approximates f within ratio ϵ.

We say that a function g is PSPACE-*hard* if $\mathrm{PSPACE} \subseteq \mathrm{P}^g$, i.e., if every language in PSPACE is polynomial-time reducible to g. By "approximating f within ratio $\epsilon(n)$ is PSPACE-hard," we mean that, if g approximates f within ratio $\epsilon(n)$, then g is PSPACE-hard.

1.2. Related work. The theory of probabilistically checkable debate systems developed here and in [10] plays the role for PSPACE that the theory of probabilistically checkable proof systems (PCPSs) plays for NP. A PCPS is simply a PCDS with just one player, Player 1, in which case the "debate" corresponds to a "proof." (See Arora et al. [2, 3] or Sudan [24] for an overview of PCPSs.) If the verifier is deterministic and reads all bits of the proof, the model is equivalent in power to a nondeterministic Turing machine, where the proof corresponds to the nondeterministic moves. Thus, by definition, $\mathrm{NP} = \mathrm{PCP}(0, \mathrm{poly}(n))$. Arora et al. [2] showed that $\mathrm{PCP}(\log n, 1) = \mathrm{NP}$. Their result shows that there is a dramatic tradeoff between the number of random bits available to the verifier of such a proof and the number of bits of the proof that the verifier has to read. The techniques used to prove this result are

used heavily in our results on PCDSs and RPCDSs. In the next two paragraphs, we discuss these results and the relationships between the proofs.

In [10], we developed the PCDS in order to extend the work of Arora et al. to PSPACE. The PCDS model is related to the alternating Turing machine model of Chandra et al. [9], just as the PCP model is related to the nondeterministic Turing machine model. Chandra et al. showed that PSPACE is precisely the set of languages recognized by two-player, perfect-information games, in which the referee is a deterministic polynomial-time machine that examines the entire game before deciding who wins. The alternating Turing machine model formalizes their notion of such a game. The PCDS model generalizes this game model of Chandra et al. by allowing the referee to flip coins; this generality allows one to study the tradeoff between the number of coins used and the number of bits of the game, or debate, that are examined by the referee. In current notation, the result of Chandra et al. is that PSPACE $= \mathrm{PCD}(0, \mathrm{poly}(n))$. In [10], we showed that $\mathrm{PCD}(\log n, 1) = \mathrm{PSPACE}$. Thus we get the same tradeoff between random bits and queries as was previously shown for proof systems. The proof that $\mathrm{PSPACE} \subseteq \mathrm{PCD}(\log n, 1)$ is done in two parts. One part shows that PSPACE is contained in the class of languages accepted by PCDSs in which the verifier reads only a constant number of *rounds* of the debate. The second part then shows how the constant number of *rounds* in this result can be replaced by a constant number of *bits*. This second part is proved by extending the work of Arora et al. on PCPSs.

The result IP = PSPACE [16, 23] shows that Chandra et al.'s characterization of PSPACE is true even if one of the two players uses the unsophisticated strategy of simply selecting a move at random. That is, polynomial-time alternating Turing machines and polynomial-round Arthur–Merlin games accept the same class of languages. The main result of this paper shows that this assumption that one player plays randomly does not destroy the tradeoff between the referee's use of randomness and the number of bits of the game that the referee reads. Namely, we prove that $\mathrm{RPCD}(\log n, 1) = \mathrm{PSPACE}$. Again, the proof that $\mathrm{PSPACE} \subseteq \mathrm{RPCD}(\log n, 1)$ is done in two parts. The first shows that PSPACE is contained in the class of languages accepted by PCDS's in which the verifier reads only a constant number of *rounds* of Player 1 and a constant number of *bits* of Player 0. The second part, just as in [10], shows how the constant number of rounds in this result can be replaced by a constant number of bits.

All of these results on PCPSs, PCDSs, and RPCDSs can be used in different ways to prove nonapproximability results for hard problems. The result of Arora et al. that $\mathrm{NP} = \mathrm{PCP}(\log n, 1)$ has been applied to prove that several NP-hard problems are hard to approximate closely. These problems include optimization versions of Satisfiability, Independent Set [2, 3], Clique [13], and Colorability [17]. For example, the MAX SAT function maps a Boolean formula in 3-conjunctive normal form to the maximum number of clauses of that formula that are simultaneously satisfied by some assignment to the variables. Bellare et al. [5] showed that there is no polynomial-time algorithm that can approximate MAX SAT within ratio 112/113, unless NP = P. More recently, Bellare and Sudan [6] improved 112/113 to 64/65, but their assumption is weaker than NP = P.

Similarly, the result that $\mathrm{PCD}(\log n, 1) = \mathrm{PSPACE}$ yields nonapproximability results for optimization versions of PSPACE-hard problems, including Quantified Satisfiability, Generalized Geography, and Finite Automata Intersection [10]. For example, the optimization version of Quantified Satisfiability is defined as follows.

Suppose that the variables of the formula are assigned values, in order of quantification, by two players, 0 and 1. Players 0 and 1 assign values to the universally and existentially quantified variables, respectively. If Player 1 can guarantee that k clauses of the formula will be satisfied, regardless of what Player 0 chooses, we say that k clauses of the formula are simultaneously satisfiable. The function MAX QSAT maps a quantified formula to its maximum number of simultaneously satisfiable clauses. In [10], we show that approximating MAX QSAT within some constant factor $c < 1$ is PSPACE-hard.

The tools developed in [10] are useful in proving nonapproximability results for PSPACE-hard problems that can be cast as two-person games between two powerful players. However, these tools do not seem to lead to similar proofs for the stochastic PSPACE-hard problems that are considered in this paper. Our new results on RPCDSs are used to obtain such proofs in section 3.

There has been other very recent work, both on approximation algorithms and on nonapproximability results for PSPACE-hard problems. Using direct reductions from variations of the Quantified Satisfiability problem, Hunt et al. [14] and Marathe et al. [18] showed that several PSPACE-hard problems are hard to approximate, unless PSPACE = P. These include algebraic problems and graph problems on hierarchically defined graphs. Marathe et al. [19] proved that several graph problems such as vertex cover and independent set, when restricted to planar, hierarchically defined graphs, are PSPACE-hard and yet *do* have polynomial-time approximation schemes. They also developed approximation algorithms for restricted optimization problems on periodically defined graphs. Such problems were proved to be PSPACE-hard by Orlin [20].

The rest of this paper is organized as follows. Our main result that RPCD($\log n, 1$) = PSPACE is proven in section 2. In section 3, we prove several nonapproximability results for stochastic functions, using this characterization of PSPACE. Finally, in section 4, we prove additional nonapproximability results, using the result that IP = PSPACE.

2. Language-recognition power. In this section, we prove our main result, that RPCD($\log n, 1$) = PSPACE. To prove the (harder) direction that PSPACE $\subseteq$ RPCD($\log n, 1$), we build on several techniques of Lund et al. [16], Shamir [23], Arora et al. [3, 2], and Condon et al. [10]. We first describe these results, and, in Lemma 2.3, we put them together to prove PSPACE $\subseteq$ RPCD($\log n, 1$).

The first result we need, Lemma 2.1, shows that in order to prove that PSPACE $\subseteq$ RPCD($\log n, 1$), it is sufficient to show that any language in PSPACE can be recognized by a RPCDS in which the verifier uses $O(\log n)$ random bits, reads a constant number of *rounds* of Player 1, and reads a constant number of bits of Player 0.

LEMMA 2.1. *Suppose L is accepted by an RPCDS (D, V) in which the verifier uses $O(\log n)$ random bits, reads a constant number of rounds of Player* 1*, and reads a constant number of bits of Player* 0*. Then L is accepted by an RPCDS (D', V') in which the verifier uses $O(\log n)$ random bits, reads a constant number of bits of Player* 1*, and reads a constant number of bits of Player* 0*.*

Proof (sketch). We showed in [10, Theorem 3.2] that any language recognized by a PCDS in which V flips $O(\log n)$ coins and reads $O(1)$ *rounds* of the debate is also recognized by a PCDS in which V flips $O(\log n)$ coins and reads $O(1)$ *bits* of the debate. The lemma follows by a straightforward modification of the proof of [10, Theorem 3.2].

Briefly, if D has N rounds on a given input, then D' has $N+1$ rounds. Let the players of (D, V) be 0 and 1 and the players of (D', V') be $0'$ and $1'$. Roughly, the idea is that, in rounds 1 through N, Player $1'$ plays as Player 1 does in debate D, except that each move is encoded using a special encoding function, known as the low-degree polynomial code [2]. The string written by $1'$ in round $N+1$ contains a proof, π_R, for each random string R of V. The proof π_R shows that V outputs 1 given random string R and the decoded debate of rounds $1, \ldots, N$. Moreover, V' can check this proof while examining only a constant number of bits.

The verifier V' chooses a random seed R and computes the indices $i_1, i_2, \ldots, i_q$ of rounds that V queries using the random seed R. Using a protocol of Arora et al. [2, 3], V' need only examine a constant number of bits of each round $i_1, i_2, \ldots, i_q$ and a constant number of bits of round $N+1$ in order to verify that V outputs 1 on random string R and the decoded debate of rounds $1, \ldots, N$.

The correctness of this protocol follows from Arora et al. [2, 3]. For details, see [10]. □

The next lemma is implicit in the proof that IP = PSPACE [16, 23].

LEMMA 2.2. *Let L be a language in* PSPACE *and $x = x_1 x_2 \ldots x_n$ be an input. Then there is a sequence of multivariate polynomials*

$$g_1(y_{1,1}, \ldots, y_{1,n_1}) \text{ (where } n_1 = n), \; g_2(y_{2,1}, \ldots, y_{2,n_2}), \ldots, g_m(y_{m,1}, \ldots, y_{m,n_m})$$

with the following properties.

1. *If $x \in L$, then $g_1(x_1, \ldots, x_n) = 1$, and, if $x \notin L$, then $g_1(x_1, \ldots, x_n) = 0$. (Thus membership in L can be reduced to a g_1-question.)*

2. *There exist polynomial-time computable functions $h_{1,i}$, $h_{2,i}$, and f_i such that $g_i(y) = f_i(g_{i+1}(h_{1,i}(y)), g_{i+1}(h_{2,i}(y)))$ for all y. (That is, one g_i-question reduces to two g_{i+1}-questions.)*

3. *Finally, g_m is a polynomial-time computable function, and the degree of all the polynomials is bounded by $d = \text{poly}(n)$.*

In [16, 23], each g_i is a polynomial that can be explicitly written as a formula of polynomial length in terms of sums and products but may result in a formula of exponential length when these sums and products are expanded.

Finally, we describe a technique, called the *polynomial verification technique*, that was proposed by Babai as a generalization of a technique first used by Lund et al. [16]. Roughly, this method "reduces" a *set* of questions of the form "Is the value of multivariate polynomial g at point a equal to v?" to *one* such question.

To describe this technique precisely, we need the following definitions. Given a (multivariate) polynomial g over a finite field F, a *g-question* is a pair (a, v), where a is an assignment of values in F to the indeterminates in g and v is a value in F. Let $\{(a_1, v_1), (a_2, v_2), \ldots, (a_l, v_l)\}$ be a set of g-questions. Let $L(t)$ be the interpolated polynomial of degree $l-1$ such that $L(j) = a_j$ for every $j = 1, 2, \ldots, l$. (In "$L(j)$," the symbol "j" is used as an abbreviation for "the jth element of the finite field F.") Let p be the (univariate) polynomial $g(L(t))$. Note that $p(j) = g(a_j)$ for $j = 1, 2, \ldots, l$.

The polynomial verification technique receives as input the set of g-questions and a polynomial p'. The technique outputs one g-question $(L(r), p'(r))$, where r is chosen uniformly at random from F. Suppose that $p'(j) = v_j$ for all j. Then the output has the following property. If all input g-questions are *good*, that is, $g(a_j) = v_j, 1 \le j \le l$, and $p' = p$, the output g-question is also good. Otherwise, with probability at least $1 - d(l-1)/|F|$, the output g-question is not good. Correctness in the latter case follows from the fact that two distinct polynomials of degree $d(l-1)$ can agree on

at most $d(l-1)$ points. Note that, since $p'(j) = v_j$ and $p(j) = g(a_j)$ for all j, then $p' \neq p$ because at least one question is not good. Thus the probability that a random point on p' agrees with p is low (at most $d(l-1)/|F|$). This completes the description of the polynomial verification technique.

To motivate our proof that PSPACE $\subseteq$ RPCD($\log n$,1), it is useful to review the proof that PSPACE $\subseteq$ IP. In that proof, an RPCDS for a language L in PSPACE is obtained by combining the polynomial verification technique and Lemma 2.2. Roughly, in each odd-numbered round $2k-1$ of the debate, Player 1 writes a g_k-question, where g_k is defined as in Lemma 2.2. In the first round, the g_1-question should be $((x_1, \ldots, x_n), 1)$, which is equivalent to claiming that $x \in L$. In round $2k+1$, where $k \geq 1$, the g_{k+1}-question written by Player 1 should be obtained from the g_k-question written by Player 1 in round $2k-1$ by first reducing the g_k-question to two g_{k+1}-questions, as in part 2 of Lemma 2.2, and then by randomly reducing these two questions to one g_{k+1}-question, using the polynomial verification technique. The random number r needed in this reduction is provided by Player 0 in round $2k$ and the polynomial p' is provided by Player 1 in round $2k-1$ (in addition to the g_k-question). To verify that x is indeed in L, the verifier does three things. First, the verifier checks that the g_1-question written by Player 1 is $((x_1, \ldots, x_n), 1)$. Second, the verifier checks that, for each $k \geq 1$, the g_{k+1}-question in round $2k+1$ is correctly computed from the g_k-question in round $2k-1$, according to the above description. Finally, the verifier checks that the g_m-question written in the last round of the debate is good; by property 3 of Lemma 2.2, this can be done in polynomial time. If all three checks are passed, the verifier accepts; otherwise, the verifier rejects. For details, see [16, 23].

Unfortunately, this protocol requires that the verifier read all rounds of the debate system. In Lemma 2.3, building on the ideas of the above protocol, we describe a new protocol in which the verifier need only read a constant number of rounds of Player 1 and a constant number of bits of Player 0. The key idea of the new protocol is to add much "redundancy" in the rounds of Player 1 in order to enable the verifier to check correctness while looking at only a constant number of rounds. Roughly, this is achieved by requiring that Player 1 write in each odd-numbered round not just a single g_k-question but also all the questions written in previous rounds.

In each odd-numbered round k and for each $i = 1, 2, \ldots, m$, Player 1 actually writes a (possibly empty) set of g_i-questions, all from some finite field F. In the first round, the only question that Player 1 writes should be $((x_1, \ldots, x_n), 1)$, which is a g_1-question, equivalent to claiming that $x \in L$. Player 1 claims that all g_i-questions written are good. In order to enable the verifier to verify this, Player 1 furthermore writes a univariate polynomial p_i for each i such that the set of g_i-questions is not empty in round k. Player 1 claims that, for every i, the polynomial p_i is the polynomial $g_i(L_i(t))$, where L_i is the polynomial interpolating the domains of the g_i-questions, as in the polynomial verification technique.

Player 0's random move at round $k+1$ supplies the random point $r \in F$ on the curve L to be used in the polynomial verification technique for each i. By first using the polynomial verification technique and then reducing the resulting g_i-question to two g_{i+1}-questions, as in Lemma 2.2, any polynomial number of g_i-questions can be probabilistically reduced to two g_{i+1}-questions in one round. The list of g_{i+1}-questions at round $k+2$ is the list of g_{i+1}-questions at round k, plus these additional two questions. Since at most two new g_i-questions are introduced in each odd round, the total number of g_i-questions in any round is polynomial. The main technical

contribution of our proof shows that the resulting "redundancy" is sufficient to enable the verifier to check the debate while examining $O(1)$ rounds.

Also, in round $4m+1$, Player 1 writes a sequence of strings $(r_2, r_4, \ldots, r_{4m})$. Player 1 claims that these are the random moves of Player 0 in the even-numbered rounds. This enables the verifier to read any of the random strings of Player 0 by examining only one round (of Player 1). The verifier can verify with high probability that Player 1 writes the correct strings by reading just a constant number of bits of the rounds of Player 0.

LEMMA 2.3. PSPACE $\subseteq$ RPCD$(\log n, 1)$.

Proof. Let L be a language in PSPACE. Lemma 2.1 shows that it is sufficient to construct an RPCDS for L in which the verifier uses $O(\log n)$ random bits, reads a constant number of rounds of Player 1, and reads a constant number of bits of Player 0.

The RPCDS is constructed as follows. The debate system has $4m+1$ rounds. In each odd-numbered round, for every $i = 1, 2, \ldots, m$, Player 1 writes a set of g_i-questions

$$\{(a_{i,1}, v_{i,1}), (a_{i,2}, v_{i,2}), \ldots, (a_{i,l_i}, v_{i,l_i})\},$$

where $a_{i,j} \in F^{n_i}$ and $v_{i,j} \in F$ for some finite field F whose size will be determined later. Here $l_1 = 1$; that is, there is only one g_1-question $(a_{1,1}, v_{1,1})$. Also, for $i > 1$, $l_i = 0$ if the round number $k \leq 2i-3$ and otherwise l_i increases by 2 in each subsequent odd-numbered round. That is, if $k > 2i-3$, the number of g_i-questions in odd-numbered round k is 2 more than the number of g_i-questions in round $k-2$. Furthermore, for each i such that $l_i > 0$, Player 1 writes a univariate polynomial $p_i(t)$ of degree at most $d(l_i - 1)$. Finally, in round $4m+1$, Player 1 also writes a sequence of strings $(r_2, r_4, \ldots, r_{4m})$. This completes the description of the debate.

Before describing the verifier, we need one definition. Let $\{(a'_{i,j}, v'_{i,j}),\ 1 \leq i \leq m,\ 1 \leq j \leq l'_i\}$ be the g_i-questions and $\{p'_i\}$ be the polynomials in odd-numbered round $k-2$, and let $\{(a_{i,j}, v_{i,j}), 1 \leq i \leq m, 1 \leq j \leq l_i\}$ be the g_i-questions and $\{p_i\}$ be the polynomials in round k, where $1 < k \leq 4m+1$. Let L'_i be the polynomial interpolating the points $\{a'_{i,j}\}$ in round $k-2$, as in the polynomial verification technique. For odd $k > 1$, we say that round k is *locally consistent with respect to* r if the following holds. First, for all i and j, $1 \leq i \leq m$, $1 \leq j \leq l_i$, $p_i(j) = v_{i,j}$. Also, for all i, $1 \leq i \leq m$, if $l'_{i-1} = 0$ then $l_i = 0$, and if $l'_{i-1} > 0$ then

$$(a_{i,1}, \ldots, a_{i,l_i}) = (a'_{i,1}, \ldots, a'_{i,l'_i}, h_{1,i-1}(L'_{i-1}(r)), h_{2,i-1}(L'_{i-1}(r))),$$

and

$$(v_{i,1}, \ldots, v_{i,l_i}) = (v'_{i,1}, \ldots, v'_{i,l'_i}, w_{i,1}, w_{i,2}),$$

where $p'_{i-1}(r) = f_{i-1}(w_{i,1}, w_{i,2})$. Note that $(L'_{i-1}(r), p'_{i-1}(r))$ is the single g_{i-1}-question obtained by applying the polynomial verification technique to the set of g_{i-1}-questions in round $k-1$. Applying property 2 of Lemma 2.2, one can check whether this single g_{i-1}-question is good by checking that $p'_{i-1}(r) = f_{i-1}(w_{i,1}, w_{i,2})$ and that the two g_i-questions

$$(h_{1,i-1}(L'_{i-1}(r)), w_{i,1}) \quad \text{and} \quad (h_{2,i-1}(L'_{i-1}(r)), w_{i,2})$$

are good. Thus round k is locally consistent with respect to r if, for each $i, 1 \leq i \leq m$, the list of g_i-questions at round k consists of the list of g_i-questions at round $k-2$,

plus two additional questions that can used to verify that the g_{i-1}-questions at round $k-2$ are good.

We now describe the protocol of the verifier V. V first reads the final round $4m+1$. V checks that, for all pairs $(a_{m,j}, v_{m,j})$ in round $4m+1$, $g_m(a_{m,j}) = v_{m,j}$ and also that $(a_{1,1}, v_{1,1}) = ((x_1, \ldots, x_n), 1)$. If not, V rejects. Otherwise, V reads a random odd-numbered round $k > 1$ and checks that (i) round k is *consistent* with the final round $4m+1$—that is, every pair $(a_{i,j}, v_{i,j})$ written in round k is also written in round $4m+1$—and that (ii) round k is locally consistent with respect to the string r_{k-1} written by Player 1 in round $4m+1$. Finally, V reads a random bit of round $k-1$ of Player 0 and checks that it is equal to the corresponding bit of the string r_{k-1} written by Player 1 in round $4m+1$. If all of these checks are satisfied, V accepts; otherwise, V rejects.

It is straightforward to show that if $x \in L$, then Player 1 has a strategy that causes V to accept with probability 1. Hence suppose that $x \notin L$. For a given run of the RPCDS, if, in the final round of the debate, $(a_{1,1}, v_{1,1}) \neq ((x_1, \ldots, x_n), 1)$, then V rejects; hence suppose that, in the final round, $(a_{1,1}, v_{1,1}) = ((x_1, \ldots, x_n), 1)$. Let S be the set of odd-numbered rounds $k > 1$ that are locally consistent with respect to the string r_{k-1} written by Player 1 in the final round, are consistent with the final round, and have $\Delta(r_{k-1}, s_{k-1}) < 1/3$, where s_{k-1} is the move of Player 0 in round $k-1$ and $\Delta(r, s)$ is the fraction of bits that differ in r and s. We say that such a run is *S-consistent*. We will show that, if Player 1 is S-consistent for some S with $|S| \geq m$, then, with very high probability, Player 1's move in round $4m+1$ contains a pair $(a_{m,j}, v_{m,j})$ for which $g_m(a_{m,j}) \neq v_{m,j}$. This follows from the next claim and the fact that the run is S-consistent.

CLAIM. *Let S contain the elements $i_1 < i_2 < \cdots < i_m$. If Player 1 is S-consistent and $g_1(x_1, \ldots, x_n) = 0$, then, for every $k = 1, 2, \ldots, m$, with probability at least $1 - 4mkd/|F|^{1/18}$ (computed over Player 0's coin tosses), there exists some j such that $g_k(a_{k,j}) \neq v_{k,j}$, where $(a_{k,j}, v_{k,j})$ are played in the i_kth round.*

Proof. The claim is proven by induction on k. For $k = 1$, the claim holds: Because Player 1 is S-consistent, the pair $((x_1, \ldots, x_n), 1)$ is written by Player 1, whereas by assumption $g_1(x_1, \ldots, x_n) = 0$.

Thus assume that, for some pair $(a_{k-1,j}, v_{k-1,j})$ in round i_{k-1}, $g_{k-1}(a_{k-1,j}) \neq v_{k-1,j}$. This happens with probability at least $1 - 4m(k-1)d/|F|^{1/18}$ by the inductive hypothesis. Because the run is S-consistent, this pair is also written in round $i_k - 2$. This implies that the polynomial p'_{k-1} played in round $i_k - 2$ is not the polynomial $g_{k-1}(L'_{k-1}(t))$. Thus if $r = r_{i_k - 1}$ is not a root of the polynomial $p'_{k-1}(t) - g_{k-1}(L'_{k-1}(t))$, then $p'_{k-1}(r) \neq g_{k-1}(L'_{k-1}(r))$, implying that either

$$g_k(h_{1,k-1}(L'_{k-1}(r))) \neq w_{k,1} \quad \text{or} \quad g_k(h_{2,k-1}(L'_{k-1}(r))) \neq w_{k,2}.$$

Otherwise, $p'_{k-1}(r) \neq f_{k-1}(w_{k,1}, w_{k,2})$, which contradicts the fact that round i_k is locally consistent with respect to r.

The claim now follows because the polynomial $p'_{k-1}(t) - g_{k-1}(L'_{k-1}(t))$ has at most $4md$ roots (since l'_{k-1} is always at most $4m$), and the number of s's such that $\Delta(s, r) < 1/3$ for some root r is less than $|F|^{17/18}$ (using Chernov bounds). □

The above claim shows that, if Player 1 plays S-consistently for any fixed S with $|S| \geq m$, then with probability at most $\text{poly}(n)/|F|^{1/18}$, the verifier V accepts. Thus to bound the probability that V accepts, on a run in which Player 1 plays S-consistent rounds for some S, where $|S| \geq m$, sum over all possible S to obtain a bound of $2^{2m}\,\text{poly}(n)/|F|^{1/18}$. The error is thus less than $1/3$ for sufficiently large F.

If Player 1 does not play S-consistently for any S of size greater than m, the verifier rejects with probability at least 1/6. This is because, with probability at least 1/2, V checks a round k that is not S-consistent, and then, with probability at least 1/3, V detects that this round is not S-consistent. □

Our main result on the complexity class RPCD($\log n, 1$) now follows easily.

THEOREM 2.4. RPCD($\log n, 1$) = PSPACE.

Proof. Lemma 2.3 proves one direction, that PSPACE $\subseteq$ RPCD($\log n, 1$). In order to prove the other direction, first note that RPCD(poly(n), poly(n)) $\subseteq$ RPCD(0, poly(n)) because, in the last round of the debate, Player 0 can supply the verifier of an RPCDS with random bits; hence the verifier needs no random bits as long as it can read all bits in the debate. Combining this with the result that RPCD(0, poly(n)) = IP = PSPACE [16, 23] gives Theorem 2.4. □

3. Nonapproximability results based on RPCD($\log n, 1$). In this section, we prove that several PSPACE-hard problems are hard to approximate. The PSPACE-complete language SSAT (or "Stochastic Satisfiability"), introduced by Papadimitriou [21], plays an important role in the proofs in this section. In section 3.1, we define the language SSAT and, using our result that PSPACE = RPCD($\log n, 1$), show that the corresponding optimization problem is hard to approximate. In the following three sections, we prove that optimization versions of Stochastic Generalized Geography, Dynamic Graph Reliability, and Mah-Jongg are all hard to approximate.

3.1. Stochastic Satisfiability (SSAT). An SSAT instance is a Boolean formula ϕ over the set of variables $\{x_1, \ldots, x_n\}$ in conjunctive normal form (CNF) with three literals per clause. The instance is in the language if there is a choice of Boolean value for x_1 such that for a random choice (with true and false each chosen with probability 1/2) of x_2, there is a choice for x_3, etc., so the probability that ϕ is satisfied is greater than 1/2. Think of an instance as a game between an existential player and a random player. For each odd value of i, the existential player chooses an optimal Boolean value for x_i, where "optimal" means "maximizes the number of clauses of ϕ that are satisfied." For each even value of i, the random player flips a fair coin to get a Boolean value for x_i. The odd-numbered variables are called existential variables, and the even-numbered variables are called random variables. The players choose boolean values in order, by increasing value of i. We define the function MAX-CLAUSE SSAT, whose value on a given instance ϕ is the expected number of clauses that are satisfied if the existential player follows an optimal strategy.

THEOREM 3.1. *There is a constant* $0 < c < 1$ *such that approximating* MAX-CLAUSE SSAT *within ratio* c *is* PSPACE*-hard.*

Proof. Let L be a language in PSPACE. From section 2, there is an RPCDS (D, V) for L, where V is polynomial-time bounded and uses $r(n) = O(\log n)$ random bits and $O(1)$ queries. Let $D = (f(n), g(n))$. Without loss of generality, we can assume that $f(n)$ is even for all n. We reduce the problem of deciding whether a string x is accepted by (D, V) to the problem of approximating the expected number of simultaneously satisfiable assignments of a quantified 3CNF formula within a constant factor.

To do this, it is sufficient to construct a formula from x and (D, V) such that if $x \in L$, then all clauses are simultaneously satisfiable, but, if $x \notin L$, then the expected number of simultaneously satisfiable clauses is a constant fraction < 1 of the total number of clauses. Let $|x| = n$. The formula has $f(n)g(n)$ variables, corresponding to the bits of a debate between Players 0 and 1, ordered as they appear in the debate. By adding extra variables (which will not appear in the clauses), we can ensure that the

variables corresponding to rounds of Player 1 are existential (odd-numbered) variables and those corresponding to rounds of Player 0 are random (even-numbered) variables.

For each sequence of random bits R of length $r(n)$, there is a subformula with $s = O(1)$ clauses. The subformula is satisfied by a truth assignment to the variables if and only if V outputs 1, when the query bits are as in the truth assignment. Such a subformula can be constructed using those variables corresponding to the bits of a debate that are queried on random sequence R. A constant number of additional existential variables are needed so that the subformula is in 3CNF form; these should be ordered after all variables corresponding to bits of the debate.

If x is accepted by (D, V), then there is a debate subtree for which the overall probability that V outputs 1 is 1. This implies that the expected fraction of simultaneously satisfiable clauses of the formula is 1 if the existential player assigns values to the existential variables according to this debate subtree. If x is not accepted by (D, V), then, for any debate subtree, the overall probability that V outputs 1 is at most 1/3. Thus, no matter how the existential variables are chosen, the expected fraction of subformulas satisfied is at most 1/3. Since each subformula contains $O(1)$ clauses, it follows that the expected fraction of clauses that can be simultaneously satisfied is a constant fraction < 1. □

3.2. Stochastic Generalized Geography (SGGEOG). In this section, we derive a nonapproximability result for a stochastic version of Generalized Geography. Generalized Geography, as defined by Schaefer [22], is a game played on a directed graph G with a distinguished vertex s. A marker is initially placed on s, and two players, 1 and 0, alternately move the marker along arcs of the graph, with the constraints that Player 1 moves first and that each arc can be used at most once. The first player unable to move loses. The language GGEOG is the set of pairs (G, s) on which Player 1 has a winning strategy.

In previous work [10], we defined the function MAX GGEOG that maps a pair (G, s) to the largest integer k such that Player 1 can force the game to be played for k moves. (Note that Player 1's objective is to keep the game going as long as possible, whether or not Player 1 ultimately wins.) Here we consider a variation, Stochastic Generalized Geography, in which Player 0 plays randomly. At each even-numbered move of the game, Player 0 simply chooses an arc uniformly at random among all of the unused arcs out of the vertex at which the marker currently sits. The objective of Player 1 is to maximize the length of the game. The function MAX SGGEOG maps a pair (G, s) to the expected length of the game that is achieved when Player 1 follows an optimal strategy.

THEOREM 3.2. *For any constant $0 < c < 1/2$, it is* PSPACE*-hard to approximate* MAX SGGEOG *within ratio n^{-c}, where n is the number of vertices of the graph.*

Proof. We present an approximability-preserving reduction from MAX-CLAUSE SSAT. A key part of our construction is a gadget (directed graph) with the following properties, where $\epsilon > 0$ is some constant. Let ϕ be an instance of SSAT with n variables and m clauses. The gadget constructed from ϕ has a source vertex and a destination vertex. If $\phi \in$ SSAT, then Player 1 has a strategy that guarantees that the destination is reached from the source, with the last move being by Player 0, if the geography game is played from the source vertex, starting with Player 0. However, if $\phi \notin$ SSAT, then on each strategy of Player 1, one of two facts hold: (i) the destination is reached from the source, with probability at most $1-\epsilon$, with the last move being by Player 0, or (ii) the destination is reached from the source, with probability at most $(1-\epsilon)^n$, with the last move being by Player 1.

Let the size of this gadget be bounded by $p(|\phi|)$ for some polynomial p of degree > 1. Given this gadget, the reduction builds an instance $((V, A), s)$ of MAX SGGEOG as follows. The directed graph (V, A) contains n independent copies of the gadget, say $g_1, \ldots, g_n$. The distinguished vertex s is an additional vertex, with a single arc to the source vertex of g_1. In addition, A contains a directed edge from the destination vertex of of gadget g_i to the source vertex of gadget g_{i+1}, for $1 \leq i < n$. Finally, (V, A) contains a "tail" starting at the destination vertex of g_n. The length of the tail is $(np(|\phi|))^K$, where K is some constant that we will determine later. That is, the tail consists of $(np(|\phi|))^K$ ordered vertices, with an edge between the ith and the $(i+1)$st and one additional edge between the destination vertex of the nth gadget g_n and the first vertex of the tail.

Then if $\phi \in$ SSAT, Player 1 has a strategy that guarantees that the tail is reached from s. Namely, Player 1 first moves to the source vertex of g_1, and then uses the strategy that guarantees that the destination vertex of g_1 is reached on a move of Player 0. From there, Player 1 follows the single arc to the source vertex of g_2, and so on, until the destination vertex of g_n is finally reached. At that point, the tail is traversed, and so the length of the game is at least $(np(|\phi|))^K$, that is, the length of the tail. However, if $\phi \notin$ SSAT, then the properties of the gadgets above guarantee that on all strategies of Player 1, the probability that the tail is reached is at most $(1-\epsilon)^n$. Hence the expected length of the game is at most $np(|\phi|)$ (that is, the size of the graph (V, A), excluding the tail) $+ (1-\epsilon)^n (np(|\phi|))^K$. Thus for sufficiently large ϕ, a multiplicative factor of approximately $(np(|\phi|))^{K-1}/2$ separates the expected length of the game in the cases $\phi \in$ SSAT, and $\phi \notin$ SSAT, respectively. The size (i.e., the number of nodes) of the new instance is $N = np(|\phi|) + (np(|\phi|))^K$. Thus an approximation within a factor of $N^{-(K-2)/2K} = N^{-(1/2-1/K)}$ would distinguish the two cases. This immediately yields the theorem.

It remains to explain how the gadget is constructed. Assume without loss of generality that n (the number of variables of ϕ) is odd and that MAX-CLAUSE SSAT$(\phi) \geq 1$. In the gadget (V_g, A_g), the vertex set V_g consists of V_1, the "variable-assignment vertices," V_2, the "clause vertices," V_3, the "staircase vertices," and in addition, a source vertex s_g and a destination vertex d_g.

$$V_1 = \left(\bigcup_{i=1}^{n} \{u_i, q_i, \overline{q_i}, w_i, \overline{w_i}, z_i, z_i'\} \right) \cup \{u_{n+1}\}.$$

V_2 consists of $\{y_1, \ldots, y_m\}$. V_3 contains $2n$ sets of vertices, each of size $3t$, where t will be chosen later; we denote them by

$$\{w_{i,1}, w_{i,1}', w_{i,1}'', \ldots, w_{i,t}, w_{i,t}', w_{i,t}''\} \quad \text{and} \quad \{\overline{w_{i,1}}, \overline{w_{i,1}'}, \overline{w_{i,1}''}, \ldots, \overline{w_{i,t}}, \overline{w_{i,t}'}, \overline{w_{i,t}''}\},$$

for $1 \leq i \leq n$.

The arc set A_g also consists of four parts, A_1, A_2, A_3, and A_4, that serve the following functions. A_1 connects the vertices of V_1 into a sequence of hexagons: for each odd value of i, $1 \leq i \leq n$, the digraph contains the arcs (u_i, q_i), $(u_i, \overline{q_i})$, (q_i, w_i), $(\overline{q_i}, \overline{w_i})$, (w_i, z_i), $(\overline{w_i}, z_i)$, (z_i, z_i'), (z_i', u_{i+1}); for each even value of i, $1 \leq i \leq n-1$, it contains the arcs (u_i, w_i), $(u_i, \overline{w_i})$, (w_i, q_i), $(\overline{w_i}, \overline{q_i})$, (q_i, z_i), $(\overline{q_i}, z_i)$, (z_i, z_i'), (z_i', u_{i+1}). A_2 connects the vertex u_{n+1} to the clause vertices and the clause vertices back to the hexagons as follows. For $1 \leq j \leq m$, there is an arc (u_{n+1}, y_j). For each literal in the jth clause of ϕ, there is an arc (y_j, v), where v is the "w-vertex" corresponding to this literal. For example, if the 17th clause of ϕ is $x_2 \vee \overline{x_7} \vee x_{12}$, the arcs (y_{17}, w_2), $(y_{17}, \overline{w_7})$,

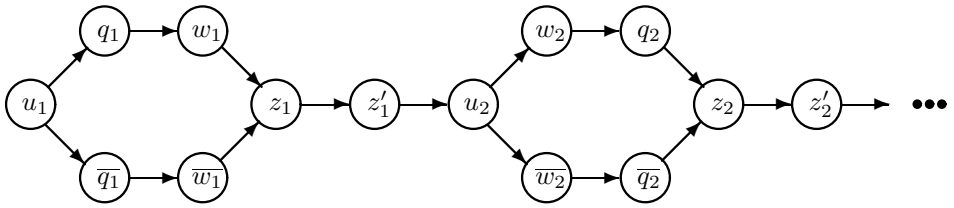

FIG. 1. *The start of the variable assignment (hexagon) section.*

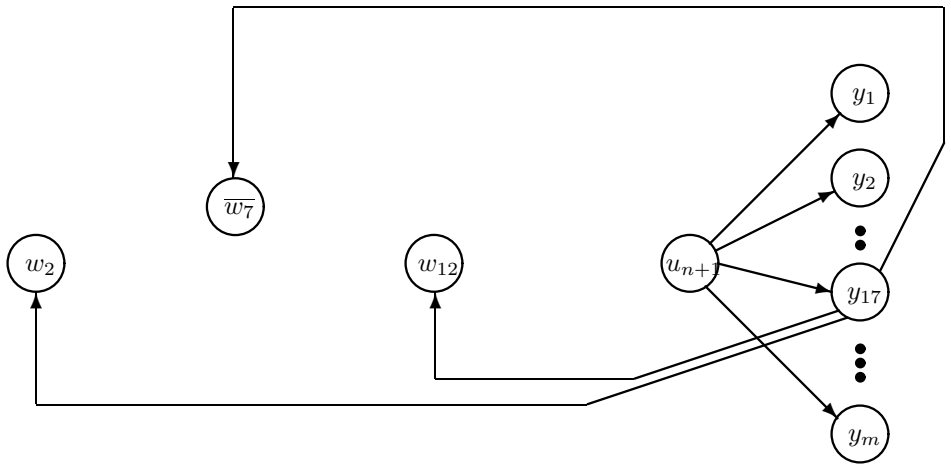

FIG. 2. *The arcs* (u_{n+}, y_j) *and those from* y_{17} *back to the hexagons, where* $c_{17} = x_2 \vee \overline{x_7} \vee x_{12}$.

and (y_{17}, w_{12}) are present. A_3 creates $2n$ "staircases" hanging off the vertices w_i and $\overline{w_i}$: for $1 \le i \le n$, the arcs $(w_i, w_{i,1})$, $(w_{i,1}, w'_{i,1})$, and $(w_{i,1}, w''_{i,1})$ are present, as are the arcs $(w''_{i,j}, w_{i,j+1})$, $(w_{i,j+1}, w'_{i,j+1})$, and $(w_{i,j+1}, w''_{i,j+1})$, for $1 \le j \le t-1$; analogous arcs form staircases emanating from the $\overline{w_i}$'s. Finally, A_4 contains the arc (s_g, u_1), which connects the source vertex s_g to the first variable-assignment vertex u_1, and also arcs $(w''_{i,t}, d_g)$ and $(\overline{w''_{i,t}}, d_g)$, $1 \le i \le n$, which connect the end of each staircase to the destination vertex d_g. Figures 1–3 give examples of hexagons, clause-arcs, and staircases.

Within a gadget (V_g, A_g), the Stochastic Generalized Geography game plays out as follows. We assume that Player 0 initially moves from the source vertex s_g along the single arc to vertex u_1. Player 1 (the existential player) assigns (optimally) either true or false to x_1. If Player 1 assigns true, the next two moves of the game are (u_1, q_1), played by 1, and (q_1, w_1), played by 0. Note that 0 has no choice but to move the marker along (q_1, w_1). Then Player 1 plays (w_1, z_1), 0 plays (z_1, z'_1), and 1 plays (z'_1, u_2). We will consider later the case where Player 1 chooses the arc $(w_1, w_{1,1})$. If Player 1 assigns false to x_1, then the analogous moves are made using the vertices $\overline{w_1}$, $\overline{q_1}$, etc. After (z'_1, u_2) has been traversed, Player 0 (the random player) assigns (with equal probability) true or false to x_2. If Player 0 assigns true, the next move of the game is (u_2, w_2), played by 0. Play continues along the arcs (w_2, q_2), (q_2, z_2), (z_2, z'_2), (z'_2, u_3), played by 1, 0, 1, 0. As before, if Player 0 assigns false to x_2, analogous moves are made using the vertices $\overline{w_2}$, $\overline{q_2}$, etc. From u_3, play continues in this fashion until Player 1 moves along either (z'_n, u_{n+1}) or $(\overline{z'_n}, u_{n+1})$, depending on the Boolean value chosen for x_n. This ends the "variable assignment" phase of the game.

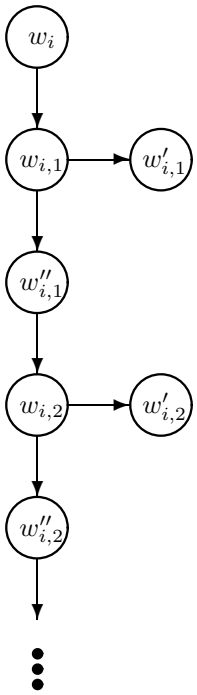

FIG. 3. *The start of the staircase emanating from* w_i.

Player 0 now chooses uniformly at random among the arcs (u_{n+1}, y_1), (u_{n+1}, y_2), $\ldots, (u_{n+1}, y_m)$. Suppose Player 0 chooses (u_{n+1}, y_j). If the jth clause of ϕ is satisfied by the assignment chosen in the first phase of the game, then Player 1 chooses an arc (y_j, w_i) (resp. $(y_j, \overline{w_i})$) corresponding to a true literal x_i (resp. $\overline{x_i}$) that appears in the jth clause. The game then takes $2t$ more steps because it follows the "spine" of the staircase emanating from w_i (resp. $\overline{w_i}$); Player 0 will have no choice but to take a step down the spine, and Player 1 will always choose to go one step further down the spine instead of off onto a "stair" because the game ends as soon as a stair is chosen. The end of the spine is reached on a move of Player 1, and finally Player 0 follows the single arc to the destination d_g. If the jth clause is not satisfied, then Player 1 must choose an arc (y_j, w_i) (resp. $(y_j, \overline{w_i})$) corresponding to a false literal x_i (resp. $\overline{x_i}$). For concreteness, suppose that Player 1 chooses the arc (y_j, w_i). Both of the arcs from w_i are unused in this case; in the previous case, when x_i was a true literal, only the arc $(w_i, w_{i,1})$ was unused. Player 0 chooses each unused arc with probability 1/2. If Player 0 chooses $(w_i, w_{i,1})$, the game continues for $2t$ moves as before to destination d_g; otherwise, the game ends in $O(1)$ moves and d_g is not reached.

The probability of reaching d_g is thus equal to 1 if $\phi \in$ SSAT since in this case Player 1 can guarantee that all clauses are satisfied by the variable assignment. However, if $\phi \notin$ SSAT, then the probability that a given clause is satisfied by the variable assignment chosen in the first phase of the gadget game is at most k/m, where $k =$ MAX-CLAUSE SSAT(ϕ). If in the second phase of the game, Player 0 chooses a clause that is not satisfied, then with probability 1/2, the destination is not reached. Hence the probability of reaching d_g is at most $k/m + (1 - k/m)/2 \leq 1 - \epsilon$, for some $\epsilon > 0$, by Theorem 3.1. Thus, if $\phi \notin$ SSAT, then on a strategy of Player 1 that never goes off into a staircase, fact (i) of the first paragraph of the proof holds. It remains to

consider those strategies of Player 1 that go off into a staircase instead of continuing down the string of hexagons. If Player 1 chooses, say, the arc $(w_i, w_{i,1})$ on the first move from w_i, then Player 0 chooses between the stair arc $(w_{i,1}, w'_{i,1})$ and the spine arc $(w_{i,1}, w''_{i,1})$. With probability 1/2, the stair arc would be chosen, and the game would end after one more step. If the spine arc were chosen, the same choice would confront Player 0 after one more step. Thus the probability of reaching the end of the spine is 2^{-t}, where t is the number of stairs. We choose t so that $2^{-t} < (1-\epsilon)^n$ to ensure that in this case fact (ii) holds. □

We note that the result of Theorem 3.2 could also be proved using a reduction from the MAX-PROB SSAT function, defined in section 4.

3.3. Dynamic Graph Reliability (DGR). Graph Reliability is a #P-complete problem studied by Valiant [25]: Given a directed, acyclic graph G, source and sink vertices s and t, and a failure probability $p(v, w)$ for each arc (v, w), what is the probability that there is a path from s to t consisting exclusively of arcs that have not failed? Papadimitriou [21] defines Dynamic Graph Reliability as follows: The goal of a strategy is still to traverse the digraph from s to t. Now, however, for each vertex x and each arc (v, w), there is a failure probability $p((v, w), x)$; the interpretation is that if the current vertex is x, the probability that the arc (v, w) will fail before the next move is $p((v, w), x)$. The language DGR consists of those digraphs for which there exists a strategy for getting from s to t with probability at least 1/2. A natural optimization problem is MAX-PROB DGR: Given a graph, vertices s and t, and a set $\{p((v, w), x)\}$ of failure probabilities, what is the probability of reaching t from s under an optimal strategy?

To obtain a nonapproximability result for MAX-PROB DGR, we need the following variant of Theorem 3.1.

THEOREM 3.3. *Consider the restriction of* SSAT *to instances in which the random variables appear only nonnegated and there is at most one random variable per clause. There are constants* $0 < c_1 < c_2 < 1$ *such that, given such a restricted instance with* m *clauses, it is* PSPACE*-hard to decide whether on average at least* $c_2 m$ *clauses are satisfiable or whether at most* $c_1 m$ *clauses are satisfiable.*

Proof. From the proof of Theorem 3.1, we can conclude that, given a formula ϕ, it is PSPACE-hard to distinguish between the cases that the expected number of simultaneously satisfiable clauses is at most $c_1 m$ or at least $c_2 m$, for some constants c_1 and c_2 such that $0 < c_1 < c_2 < 1$. It also follows from this proof, together with the proof of Theorem 2.4, that this is true for instances with only one random variable per clause. To see this, note that in the proof of Theorem 2.4, the verifier queries only one of Player 0's bits; thus each clause of any subformula in the construction of Theorem 3.1 has only one random variable.

We now show how to modify that construction so that no random variable is negated in the resulting formula. To do this, we use the identity

$$\bar{x}yz = \bar{x} + yz + xy\bar{z} + x\bar{y}z + x\bar{y}\bar{z} - 3,$$

where concatenation means "or" and "+" and "−" mean addition and subtraction over $\mathbf{Z}$. Suppose ϕ contains n variables and m clauses, of which r contain a negated random variable. We replace any clause $\bar{x}yz$ containing a negated random variable x and literals y and z by the four clauses yz, $xy\bar{z}$, $x\bar{y}z$, and $x\bar{y}\bar{z}$. We now have a formula ϕ' containing n variables and $m + 3r$ clauses. We claim that

$$\text{MAX-CLAUSE SSAT}(\phi') = \text{MAX-CLAUSE SSAT}(\phi) + 5r/2.$$

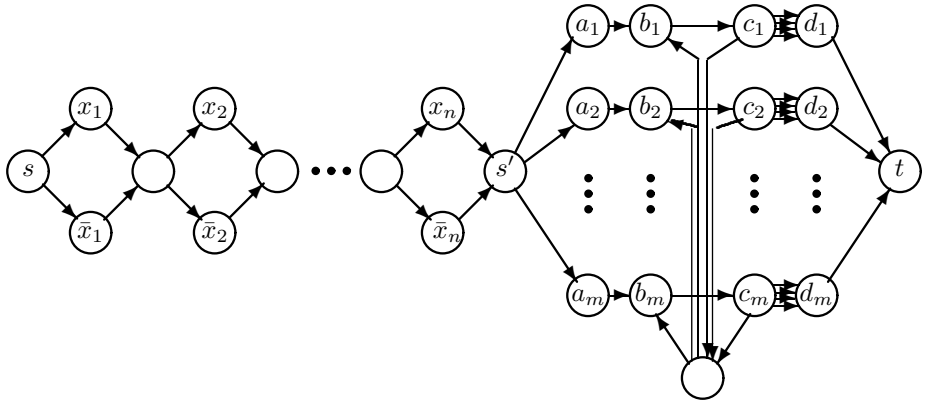

FIG. 4. *The graph constructed in reducing* MAX-CLAUSE SSAT *to* DGR. *Note that all edges are directed from left to right except those incident to r, which go from right to left.*

This formula is derived from the above identity; the term $\bar{x}$ is satisfied exactly half the time, and after subtracting 3, we find that we expect 5/2 additional clauses to be satisfied in ϕ' for each of the r substitutions that we made. □

THEOREM 3.4. *There is a constant $c > 0$ such that approximating* MAX-PROB DGR *within ratio 2^{-n^c} is* PSPACE*-hard.*

Proof. We show how to reduce the problem of approximating the MAX-CLAUSE SSAT function on an instance of the form given in Theorem 3.3 to the problem of approximating the Dynamic Graph Reliability function. The target DGR instance is composed of two parts, a variable-setting component and a set of clause-testing components. The construction is illustrated in Figure 4. The variable-setting component consists of the n "diamonds" in this figure, and the ith clause-testing component lies between vertices a_i and d_i. There are four edges between each pair c_i and d_i. Three of these correspond to the three literals in the clause, and the fourth is a "bypass edge."

Each path from s through the variable-setting component corresponds to an assignment of the variables in order. If x_i is an existential variable, both of the edges into vertices x_i and $\bar{x}_i$ are available, so the strategy determines which vertex is in the path. If the vertex x_i is chosen, all of the edges in the clause-testing components corresponding to $\bar{x}_i$ fail with probability 1, and similarly, if $\bar{x}_i$ is chosen, all of the edges corresponding to x_i in the clause-testing components fail. If x_i is a random variable, upon reaching the vertex immediately before x_i, with probability 1/2 the edge to x_i fails. If it does, the path must go through $\bar{x}_i$, in which case all of the edges corresponding to x_i in the clause-testing components fail. Otherwise, the path may go through $\bar{x}_i$ or x_i. Since $\bar{x}_i$ never appears in any clauses, it can only help to go through the x_i node, so we may assume that the strategy is consistent with this.

From vertex s', the path leaves the variable-setting component and enters one of m clause-testing components. When s' is reached, each edge $(b_i, c_i), 1 \le i \le m$, fails with probability $1 - 1/m$. If all edges (b_i, c_i) fail, clearly t cannot be reached from s'. We next show that if if two or more of these edges survive, t is always reachable, and if exactly one of these edges survives, t is reachable only if the corresponding clause is satisfied. Thus t is reachable with probability approximately $1 - 2/e + k/(me)$, where k is the number of satisfied clauses and e is 2.71828.... From Theorem 3.3, it now follows that for some constants $c_1 < c_2$, it is PSPACE-hard to distinguish between

the cases MAX-PROB DGR(x) $< c_1$ and MAX-PROB DGR(x) $> c_2$.

Recall that three of the four edges between nodes c_i and d_i correspond to the three literals in the clause, and each will be present when s' is reached if the corresponding literal is true. If a_i is visited, then the bypass edge for clause i fails. If exactly one edge (b_i, c_i) survives, clearly t can be reached only if the corresponding clause is satisfied, in which case the path contains $s', a_i, b_i, c_i, d_i, t$. Finally, if two edges (b_i, c_i) and (b_j, c_j) survive, then the path $s', a_i, b_i, c_i, r, b_j, c_j, d_j, t$ reaches t. Note that in this case the bypass edge between c_j and d_j is available because node a_j is never visited.

Finally, we strengthen our result by making several copies of this construction and repeating it in series and in parallel. To show this, we use a result of Ajtai and Ben-Or [1] (see Theorem 3.14 in [8]): For every probabilistic circuit C of size s that accepts a language L with error probability $\epsilon < 1/2$, there is a probabilistic circuit C' of size $s\ \mathrm{poly}(N)$ that accepts L with error probability $< 2^{-N}$. In fact, the circuit C' has the following structure:

$$\bigvee^{2\log N}\left(\bigwedge^{2N^2\log N}\left(\bigvee^{N^3}\left(\bigwedge^{N} C\right)\right)\right).$$

To apply this result to our construction, we replace $\wedge$ by repeating the construction in series (i.e., taking two copies and connecting the sink in the first copy with the source in the second) and replace $\vee$ by repeating the construction in parallel (i.e., taking two copies and connecting s' in the first copy with the source in the second and the sink in the first copy with the sink in the second). The number of edges of the resulting construction is then $O(sN^{6+\epsilon})$ for any $\epsilon > 0$, where s is the size of the construction above. From this, the theorem follows, where c is any constant less than $1/6$ (assuming that the instance is encoded such that the length is $O(sN^{6+\epsilon}\log(sN))$, which can easily be done). □

3.4. A solitaire game using Mah-Jongg tiles (MAH-JONGG). Solitaire Mah-Jongg, widely available as a computer game, is played roughly as follows. The game uses Mah-Jongg tiles, which are divided into sets of two or four matching tiles. We generalize the standard game simply by assuming that there are an arbitrarily large number of tiles. Initially, the tiles are organized in a preset arrangement of rows, and the rows may be stacked on top of each other. As a result, some tiles are hidden under other tiles; it is assumed that each possible arrangement of the hidden tiles is equally likely. A tile that is not hidden and is at the end of a row is said to be available. In a legal move, any pair of available matching tiles may be removed, resulting in a new configuration of the tiles in which up to two previously hidden tiles are uncovered. The player wins the game if all tiles are removed by a sequence of legal moves. MAH-JONGG(x) is defined to be the maximum probability of winning the generalized Mah-Jongg game from initial arrangement x of the tiles, assuming that the hidden tiles are randomly and uniformly permuted.

To define the game precisely, we define a set of Mah-Jongg tiles to be $\mathcal{T} = \cup_i \mathcal{T}_i$, where $\mathcal{T}_1, \ldots, \mathcal{T}_t$ are disjoint sets of tiles, each set being of size 2 or 4. We say tiles T_1 and T_2 *match* if and only if for some i, $T_1, T_2 \in \mathcal{T}_i$. A *configuration* C is a set of positions (i, j, k), where each of i, j, and k is a nonnegative integer, satisfying the following constraints.

1. If $(i, j, k) \in C$ and $(i, j', k) \in C$, where $j < j'$, then for every j'' in the range $[j, j']$, $(i, j'', k) \in C$.
2. If $(i, j, k) \in C$, where $k > 0$, then $(i, j, k-1) \in C$.

Intuitively, this captures the fact that tiles are arranged in three dimensions. Tiles can be stacked on up of each other; all tiles with common k are at the same height. Tiles at the same height with common i index form a row. The first condition ensures that there cannot be "gaps" in a row; the second ensures that a tile at height $k > 0$ must have a tile underneath it.)

With respect to a given configuration, a position (i, j, k) is *hidden* if $(i, j, k + 1)$ is also in the configuration. An *arrangement* consists of a set of Mah-Jongg tiles $\mathcal{T}$, a configuration C of size $|\mathcal{T}|$, and a 1–1 function from the positions of C that are not hidden into $\mathcal{T}$. If this function maps position (i, j, k) to tile T, we say that T is *in position* (i, j, k). With respect to a given arrangement, we say that a position (i, j, k) is *available* if it is not hidden and either position $(i, j - 1, k)$ or $(i, j + 1, k)$ is not in the configuration. An arrangement is *empty* if $\mathcal{T}$ is empty.

Let $x = (\mathcal{T}, C, f)$ be an arrangement. Each pair $\{(i_1, j_1, k_1), (i_2, j_2, k_2)\}$ of available positions at which there are matching tiles T_1 and T_2 defines a *match* of x. We say that arrangement x' is obtainable from x via match $\{(i_1, j_1, k_1), (i_2, j_2, k_2)\}$ if $x' = (\mathcal{T}', C', f')$, where $\mathcal{T}' = \mathcal{T} - \{T_1, T_2\}$, $C' = C - \{(i_1, j_1, k_1), (i_2, j_2, k_2)\}$, and finally, f' and f agree on the set of positions which are not hidden in both C and C'. (Note that f' is not defined on positions (i_1, j_1, k_1) and (i_2, j_2, k_2), and f' is defined on position $(i_1, j_1, k_1 - 1)$ if $k_1 > 0$ and on position $(i_2, j_2, k_2 - 1)$ if $k_2 > 0$ since these are no longer hidden.) Corresponding to each match $\{(i_1, j_1, k_1), (i_2, j_2, k_2)\}$ of x is a *move*, which results in an arrangement x', chosen uniformly and randomly from the set of arrangements obtainable from x via match $\{(i_1, j_1, k_1), (i_2, j_2, k_2)\}$. A sequence of moves from arrangement x leads to a win if it results in the empty arrangement. A *strategy* on x associates a match (if any) with each possible arrangement obtainable from x via any sequence of moves.

An instance of the Mah-Jongg game is an arrangement x. MAH-JONGG(x) is the maximum probability of a win from x, where the maximum is taken over all strategies on x.

In Theorem 3.6, we show that it is PSPACE-hard to approximate the MAH-JONGG function within ratio n^{-c} for some constant $c < 1$. Our result holds for instances x in which tiles are never stacked more than two deep (see Figure 5). We use the following lemma in our reduction.

LEMMA 3.5. *Let $q(n)$ be any polynomial, and let $\epsilon > 0$ be any constant. Let ϕ' be an instance of* SSAT *with no negated random variables. Then there is an instance* SSAT *ϕ with no negated random variables that can be efficiently constructed from ϕ', with the following properties.*

(a) *If the expected fraction of simultaneously satisfiable clauses of ϕ' is at most $c_1 - \epsilon(\geq 0)$, then on any strategy for assigning values to the existential variables of ϕ, with probability at least $1 - 1/q(|\phi'|)$, the fraction of satisfied clauses of ϕ is at most c_1.*

(b) *If the expected fraction of simultaneously satisfiable clauses of ϕ' is at least $c_2 + \epsilon(\leq 1)$, then there is a strategy for assigning values to the existential variables of ϕ such that with probability at least $1 - 1/q(|\phi'|)$, the fraction of satisfied clauses of ϕ is at least c_2.*

Proof. ϕ is simply composed of many independent copies of ϕ', as follows. If

$$\phi' = \exists x_1 \forall x_2 \ldots \exists x_{n'} f(x_1, \ldots, x_{n'}),$$

then for some $p = p(|\phi|)$ to be chosen later,

$$\phi = \exists x_{11} \forall x_{12} \ldots \exists x_{1n'} \ldots \exists x_{p1} \forall x_{p2} \ldots \exists x_{pn'} f(x_{11}, \ldots, x_{1n'}) \wedge \cdots \wedge f(x_{p1}, \ldots, x_{pn'}).$$

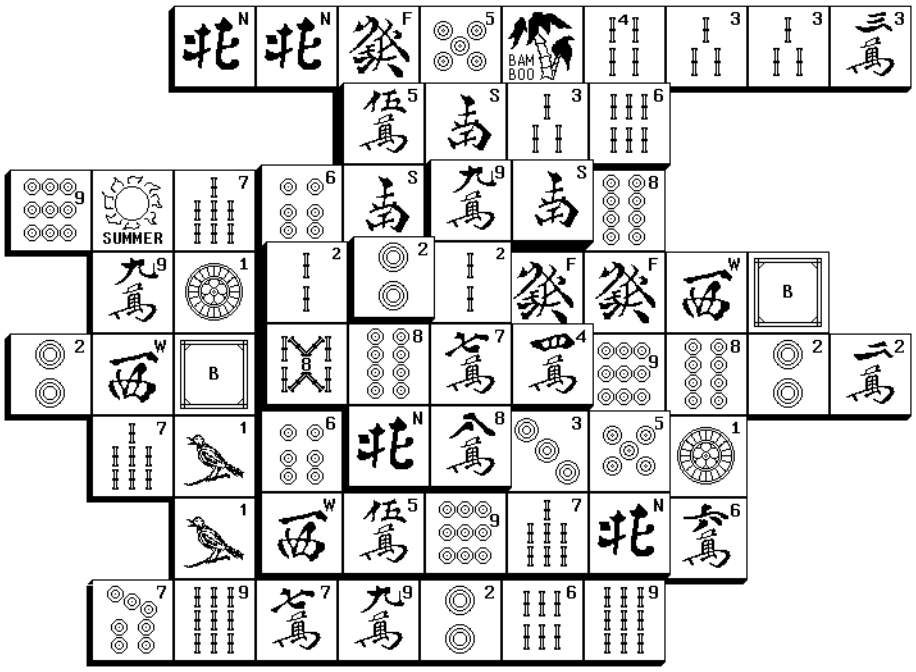

FIG. 5. *The arrangement of tiles part way through a game of Xmahjongg. Possible moves include removing the six of dots in the third row and the six of dots in the sixth row, removing the pair of twos of bamboo in the fourth row, and removing any two of the three available north tiles (in the first, sixth, and seventh rows). Xmahjongg is copyright* 1989 *by Jeff S. Young, and the tile designs are copyright* 1988 *by Mark A. Holm (used with permission).*

Fix any strategy for assigning values to the existential variables of ϕ. Let random variable $X_i, 1 \leq i \leq p$, be the fraction of clauses that are satisfied in the subformula $f(x_{i1}, \ldots, x_{in'})$. Let random variable Y be the fraction of satisfied clauses of ϕ. Then $Y = (1/p)\sum_{i=1}^{p} X_i$. If $\mathrm{Var}(X_i)$ is the variance of X_i, then the variance of Y is

$$\mathrm{Var}(Y) = \sum_{i=1}^{p} \mathrm{Var}(X_i/p) \leq 1/p.$$

To prove part (a), suppose that ϕ' is such that the expected fraction of simultaneously satisfiable clauses is at most $c_1 - \epsilon$. Then the expected value of X_i, and hence of Y, is at most $c_1 - \epsilon$ for all i. Thus, from Chebyshev's inequality, $\mathrm{Prob}[Y \geq c_1] \leq 1/(\epsilon^2 p)$. If $p(|\phi'|) \geq (1/\epsilon^2)q(|\phi'|)$, then with probability at least $1 - 1/q(|\phi|)$, $Y \leq c_1$. The proof of part (b) is similar. □

THEOREM 3.6. *There is a constant* $0 < c < 1$ *such that approximating* MAH-JONGG *within ratio* n^{-c} *is* PSPACE*-hard.*

Proof. To prove this result, we show how to reduce the problem of approximating the MAX-CLAUSE SSAT function on an instance ϕ' of one of the two types given in Theorem 3.3 to the problem of approximating the MAH-JONGG function on some instance. We first convert ϕ' into formula ϕ of Lemma 3.5 and then apply the following reduction to ϕ. We assume without loss of generality that the number of literals in each of the m clauses of ϕ is exactly three and that the number of variables, n, is even. Given such an instance ϕ, the main structures of the corresponding Mah-Jongg

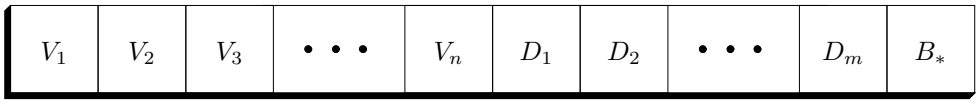

FIG. 6. *The regulating row.*

game are roughly as follows.

Corresponding to each variable is a set of *variable-setting rows*. Removing a particular tile from one of these rows corresponds to "setting" the variable. Corresponding to each clause is a set of *clause rows*. Most of the hidden tiles are in the clause rows. The *treasure chest* consists of a single row. On the left end of this row is a special *treasure-key* tile; the game can be won only by removing this tile. The matching treasure-key tile can only be accessed by uncovering a "good" subset of *guard* tiles, which are initially hidden. Thus the goal of a good strategy is to maximize the number of hidden tiles uncovered so as to maximize the chances of finding a good subset of guard tiles and hence of removing the treasure-key tile. This strategy corresponds to "setting" the existential variables so as to maximize the number of hidden tiles in the clause rows that are uncovered. (We will see that the random variables are "set" randomly.)

A *regulating row* of tiles is used to ensure that variables are set in the correct order and that no tiles can be removed from a clause row until all variables are set. Furthermore, the regulating row, together with the variable-setting rows, ensures that the only tiles in the clause rows that can legally be removed are those tiles in rows of clauses that have been satisfied during the variable-setting phase. Thus the probability of winning the game depends on the number of clauses that are satisfied by the variable assignment chosen in the variable-setting phase.

We now describe the tiles and their arrangement in detail. For each existential variable x_i, there are four tiles labeled V_i (one of which is in the treasure chest), and for each random variable x_i, there are two tiles labeled V_i. For each clause c_j, there are four tiles C_j and two tiles D_j. There are also b pairs of *blocking* tiles; again, b will be specified later. The kth pair of blocking tiles is labeled B_k. One of each pair is in the treasure chest.

Figure 6 describes the regulating row. Here and in what follows, we represent a blocking tile by B_*; the subscript is assumed to be different in each occurrence of B_*, and the position of a particular subscript is arbitrary. If the treasure chest is not open, in order to remove all tiles in regulating row, the V_i must first be matched in order, followed by the D_i in order.

We next describe the variable-setting structures. In addition to the tiles defined above, the variable-setting structures contain for each variable x_i a pair of tiles labeled $M_{i,k}$, where k ranges between 1 and the number of clauses in which either x_i or $\bar{x}_i$ occurs.

If x_i is existential, the ith variable-setting structure is described in Figure 7. If at some point in the game the treasure chest is not open and V_i is the leftmost tile in the regulating row, then this tile must be matched to the V_i in either the first or the second row of this structure. If it is matched to the V_i in the first row, this is equivalent to setting x_i to true. By removing the M-tiles in this row, the player can make available the tiles C_j in this structure for which clause c_j contains literal x_i. Similarly, setting x_i to false makes available the tiles C_j for which c_j contains $\bar{x}_i$.

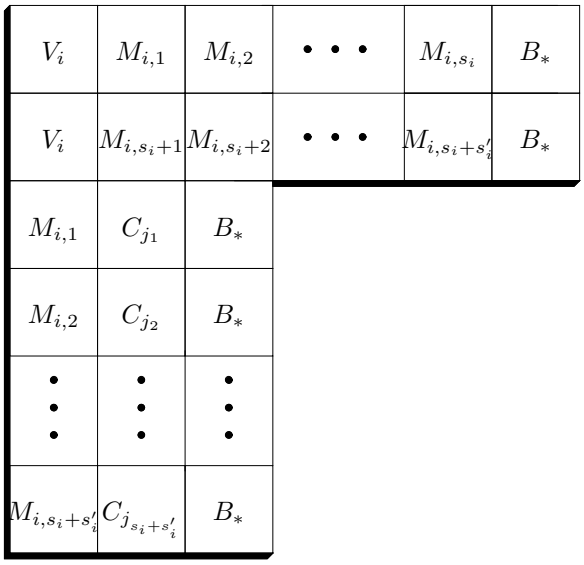

FIG. 7. *The variable-setting structure for existential variable i, where $j_1, j_2, \ldots, j_{s_i}$ are the clauses containing x_i and $j_{s_i+1}, \ldots, j_{s_i+s_i'}$ are the clauses containing $\bar{x}_i$.*

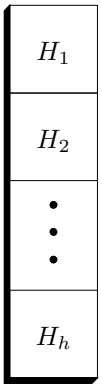

FIG. 8. *The remaining tiles.*

Since the fourth V_i tile is in the treasure chest, the V_i that is not matched cannot be removed until the treasure chest is opened.

If the variable x_i is a random variable, the variable-setting structure is quite similar, except that *hidden* tiles are used to ensure that the setting of x_i is randomly chosen. Each pair of hidden tiles is labeled H_k or H_k', for k in the range 1 to h (where h will be specified later). One tile from each pair is hidden. Each remaining tile H_k' is in the treasure chest and each remaining tile H_k forms a singleton row (see Figure 8). Then if x_i is random, the ith variable-setting structure is described in Figure 9. If the hidden tile under V_i is H_*, then it can be matched to a tile in a singleton row. We will see that this happens with probability approximately 1/2. As before, if x_i is contained in clause c_j, then tile C_j in this structure can be made available. Recall that $\bar{x}_i$ never appears if x_i is a random variable.

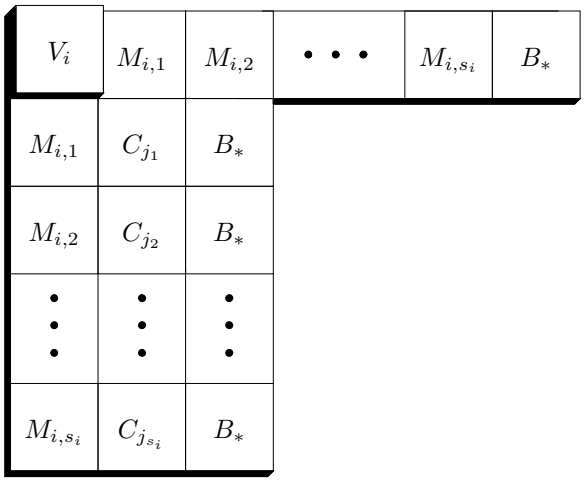

FIG. 9. *The variable-setting structure for random variable i, where $j_1, j_2, \ldots, j_{s_i}$ are the clauses in which x_i appears.*

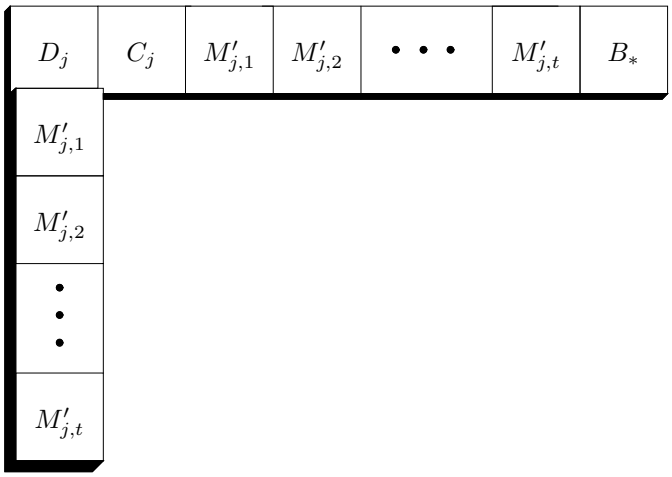

FIG. 10. *The clause row for the ith clause.*

We next describe the clause rows (see Figure 10). Again, we need additional tiles. For each clause j, there is a pair of tiles labeled $M'_{j,k}$, where k ranges between 1 and t (where t will be chosen later). There is a tile hidden under each M'-tile. This arrangement ensures that, if the jth clause is true, then all t of the hidden tiles under all $M'_{j,k}$ can be removed.

Before describing the treasure chest and the arrangement of guard tiles, we state some properties of the game structures constructed so far. In what follows, by "with high probability," we mean with probability at least $1 - 1/p(|\phi'|)$, for some large polynomial p. First, if the number $t = t(|\phi'|)$ of tiles hidden in each clause component is sufficiently large, we can ensure that, with high probability, only tiles of type H_k or H'_k are uncovered in the variable-setting phase. Second, assuming that the random variables are true and false with probability 1/2, it follows from Lemma 3.5 that,

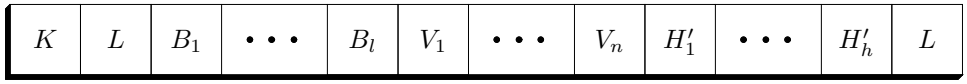

FIG. 11. *The treasure chest, where* $l = 4m + (3n/2) + 1 + (3v - 1)/2$.

if $q(|\phi'|)$ is sufficiently large, then with high probability, the fraction of hidden tiles uncovered in the clause components is either $\geq c_1$ or $\leq c_2$, depending on the type of ϕ'. The difficulty here is that after several hidden tiles have been revealed, the probability of a random variable being true or false is no longer $1/2$ but depends on the relative numbers of H_i and H'_i already revealed. However, if t is sufficiently large, say $t \geq r^k$, the chance of any particular variable being true will change by a factor of at most $1 \pm k!/r^{k-1}$. Thus the probability of any particular assignment of trues and falses to the random variables will be changed by a factor of at most $(1 \pm k!/r^{k-1})^r \approx 1 \pm k!/r^{k-2}$, which won't affect the probabilities enough to change the result. (This is the reason for the tiles D_i: they ensure that the hidden tiles associated with true clauses cannot be revealed, thus changing the probability of a variable being true, until after the variables have been set.)

The treasure chest is described in Figure 11. On the left end is the treasure-key K. Rows called *guard rows* control access to the single key K that matches the treasure-key in the following way. There are v guard rows (where v is a power of 3 and will be chosen later). Associated with the kth guard row are w pairs of guard tiles $G_{kj}, 1 \leq j \leq w$, one of which is initially hidden. The other guard tile from each pair is in the guard row. By finding all guard tiles for one guard row, the treasure-key can be accessed and the treasure chest opened. We describe the structure that enforces this later; we first show how such a structure, with appropriate choice of v and w, can guarantee that the reduction is "approximation preserving."

First, suppose that the expected fraction of simultaneously satisfiable clauses of ϕ' is at most $c_1 - \epsilon$ so that by Lemma 3.5, on any strategy for assigning values to the existential variables of ϕ, with probability at least $1 - 1/q(|\phi'|)$, the fraction of satisfied clauses of ϕ is at most c_1. Then, with high probability (at least $1 - 1/p(|\phi'|)$), on any play of the Mah-Jongg game, at most a fraction c_1 of the hidden tiles in the clause components are uncovered. To remove all guard tiles from a given guard row, all w guard tiles must be uncovered. If at most a fraction c_1 of the hidden tiles in the clause components are uncovered, the probability of finding these tiles in the clause components is at most c_1^w. Hence the probability that the treasure chest is not opened is at least the probability that no guard tiles are found during the variable-setting phase, times the probability that at most a fraction c_1 of the hidden tiles in the clause components are uncovered, times the probability that for all guard rows, it is not the case that all guard-keys in that guard row are uncovered. This is at least $(1 - 1/p(|\phi'|)^2(1 - c_1^w)^v)$.

In the case that the expected fraction of simultaneously satisfiable clauses of ϕ' is at least $c_2 + \epsilon$, a slightly different argument shows that the probability that the treasure chest is opened is at least $(1 - 1/p(|\phi'|)^2(1 - (1 - c_2^w)^v)$. We need to choose w and v so that $(1 - c_1^w)^v$ is large and $(1 - c_2^w)^v$ is small. We let $w = \log_{1/c_1} |\phi'|$ and let $v = |\phi'|$. Then $(1 - c_1^w)^v = (1 - 1/|\phi'|)^{|\phi'|} \approx 1/e$ and $(1 - c_2^w)^v \leq n^{-c}$, for some $c > 0$. This completes the proof that the reduction is approximation preserving.

It remains to describe the structure that ensures that the treasure-key can only be accessed by finding all guard tiles for one guard row. One way to ensure this in

G_{11}	• • •	G_{1w}	K_{01}	B_*
G_{21}	• • •	G_{2w}	K_{01}	B_*

$G_{v-1,1}$	• • •	$G_{v-1,w}$	K_{0i}	B_*
G_{v1}	• • •	G_{vw}	K_{0i}	B_*

FIG. 12. *The guard rows.*

our construction would be to put a key K matching the treasure-key in each guard row, which could be accessed once all the guard tiles of the guard row are removed. However, this requires an unbounded number of treasure-keys. The following scheme achieves the same goal while ensuring that the number of tiles of any one type is at most 4 (see Figures 12 and 13).

The guard rows are arranged in groups of three; each row in the ith group has a tile K_{0i} to the right of all of its guard tiles; this is followed by a blocking tile B_*. For each group i, a fourth tile K_{0i} appears as the leftmost tile in a row with two other tiles. Again, these "first-level" rows are grouped in threes. Each row in the i'th group has a tile $K_{1i'}$ as its middle tile and a blocking B_*-tile as its rightmost tile. Again for each i', the fourth $K_{1i'}$ tile appears as the leftmost tile in a "second-level" row with two other tiles, and these rows are grouped in threes. Each row in the i''th group has a tile $K_{2i''}$ as its middle tile and a blocking B_*-tile as its rightmost tile. Further levels of rows are constructed in this way; the number of rows at each level of this structure decreases by a factor of three until there is only one row left. This row again has three tiles, but the middle one matches the treasure-key K. By opening any one of

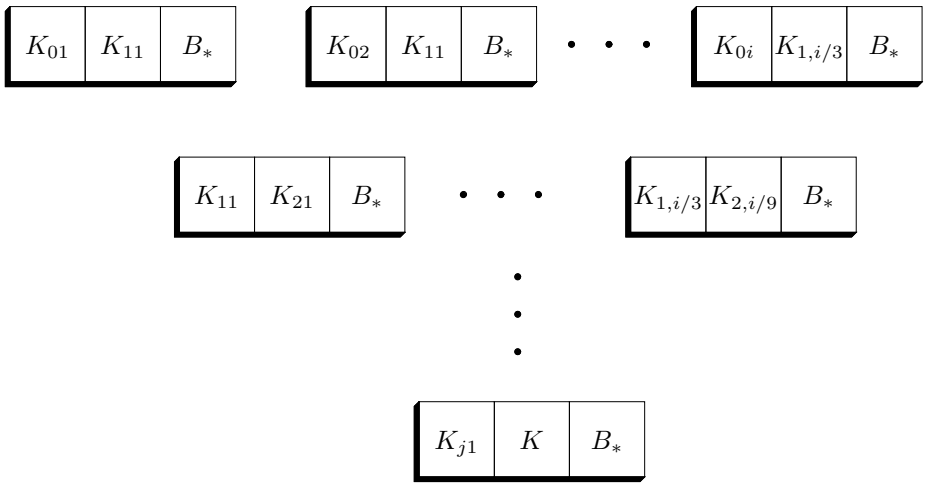

FIG. 13. *Levels of rows which guard access to the treasure chest. If all guard tiles from one guard row are removed, the key K_{0j} in that row can be used to remove keys at successive levels of this structure until the treasure-key K is removed at the last level.*

the guard rows, a row at each level can successively be opened until the treasure-key is finally accessed.

To account for the number of pairs of blocking tiles needed, note that $(3v-1)/2$ are needed for the guard rows, as well as $4m+3n/2$ for the clause and variable-setting rows and 1 for the regulating row. Therefore, the total number of blocking tiles needed is $4m+3n/2+1+(3v-1)/2$. Also, once t, v, and w are selected to ensure correctness of the reduction, h, the number of pairs of initially hidden tiles of the form H_k or H'_k, for some k, can be determined as follows. The total number of hidden tiles is $2h+vw$, that is, one tile from each pair of the form H_k or H'_k, and one of each of the vw pairs of guard tiles. Also, the number of locations in which tiles are hidden initially is $r+mt$, that is, one in each variable-setting structure for the r random variables and t in each of the m clause structures. Hence h is chosen so that $2h+vw = r+mt$. □

4. Nonapproximability results using IP. The proofs of all of the nonapproximability results in the previous section were based on the characterization RPCD$(\log n, 1)$ = PSPACE. In this section, we prove nonapproximability results for different PSPACE-hard functions based on the characterization IP = PSPACE obtained in [16, 22].

The first problem we consider here is also based on the language SSAT. Once again, an instance of SSAT can be thought of as a game between an existential player and a random player, but this time the objective of the existential player is to maximize the probability that ϕ is satisfied. The value of MAX-PROB SSAT on a given instance is the probability that ϕ is satisfied if the existential player follows an optimal strategy. The language SSAT, as defined in [21], consists of all instances ϕ for which MAX-PROB SSAT$(\phi) > 1/2$.

The reductions in this section are based on the following fact, which is a direct consequence of the proof that IP = PSPACE.

FACT 4.1. *For any language* L *in* PSPACE *and any $\epsilon < 1$, there is a polynomial-*

time reduction f from L *to* SSAT *such that*

$$x \in \mathrm{L} \Rightarrow \text{MAX-PROB SSAT}(f(x)) = 1 \quad \textit{and}$$
$$x \notin \mathrm{L} \Rightarrow \text{MAX-PROB SSAT}(f(x)) < 1/2^{n^{\epsilon}},$$

where n is the number of variables in $f(x)$.

The next theorem is a direct consequence of Fact 4.1.

THEOREM 4.2. *There is a constant $c > 0$ such that approximating* MAX-PROB SSAT *within ratio 2^{-n^c} is* PSPACE*-hard.*

Papadimitriou [21] defines the language Dynamic Markov Process (DMP). An instance is a set S of states and an $n \times n$ stochastic matrix P, where $n = |S|$. Associated with each state s_i is a set D_i of decisions, and each $d \in D_i$ is assigned a cost $c(d)$ and a matrix R_d. Each row of R_d must sum to 0, and each entry of $P + R_d$ must be nonnegative. The result of making decision d when the process is in state s_i is that a cost of $c(d)$ is incurred, and the probability of moving to state s_j is the (i, j)th entry of $P + R_d$. A strategy determines which decisions are made over time; an optimal strategy is one that minimizes the expected cost of getting from state s_1 to state s_n. The language DMP consists of tuples $(S, P, \{D_i\}, c, \{R_d\}, B)$ for which there is a strategy with expected cost at most B. A natural optimization problem is MIN DMP, the function that maps $(S, P, \{D_i\}, c, \{R_d\})$ to the expected cost of an optimal strategy. Papadimitriou [21] proves that DMP is PSPACE-complete by providing a reduction from SSAT. In fact, the reduction has the property that if SSAT instance ϕ is mapped to DMP instance $(S, P, \{D_i\}, c, \{R_d\}, B)$ and MAX-PROB SSAT(ϕ) $= p$, then MIN DMP$(S, P, \{D_i\}, c, \{R_d\}) = p/4$. The next result thus follows from Theorem 4.2.

THEOREM 4.3. *There is a constant $c > 0$ such that approximating* MIN DMP *within ratio 2^{-n^c} is* PSPACE*-hard.*

The complexity of coloring games was studied by Bodlaender [7], motivated by scheduling problems. An instance of a coloring game consists of a graph $G = (V, E)$, an ownership function o that specifies which of two players, 0 and 1, owns each vertex, a linear ordering f on the vertices, and a finite set C of colors. This instance specifies a game in which the players color the vertices in the order specified by the linear ordering. When vertex i is colored, its owner chooses a color from the set of *legal* colors, i.e., those in set C that are *not* colors of the colored neighbors of i. The game ends either when all vertices are colored or when a player cannot color the next vertex in the linear ordering f because there are no legal colors. Player 1 wins if and only if all vertices are colored at the end of the game. The length of the game is the number of colored vertices at the end of the game.

We consider a stochastic coloring game (SCG) in which one player, say 0, randomly chooses a color from the set of legal colors at each stage. Two corresponding optimization problems are to maximize the following functions: MAX-PROB SCG(G, o, f, C), which is the maximum probability that Player 1 wins the game (G, o, f, C), and MAX-LENGTH SCG(G, o, f, C), which is the maximum expected length of the game. (Both maxima are taken over all strategies of Player 1.)

We show that MAX-PROB SCG is PSPACE-hard to approximate within ratio 2^{-n^c}, for some constant $c > 0$, and that MAX-LENGTH SCG is PSPACE-hard to approximate within ratio $n^{-c'}$, for some constant $c' > 0$.

THEOREM 4.4. *There is a constant $c > 0$ such that approximating* MAX-PROB SCG *within ratio 2^{-n^c} is* PSPACE*-hard.*

Proof. We describe a reduction from MAX-PROB SSAT to MAX-PROB SCG that adapts the original construction [7]. By Fact 4.1, we can restrict our attention

to instances ϕ such that either MAX-PROB SSAT(ϕ) = 1 or MAX-PROB SSAT(ϕ) $< 1/2^{n^\epsilon}$, for some $\epsilon > 0$. We construct an instance $G = (V, E)$ of MAX-PROB SCG as follows:

$$V = \{\mathit{true}, \mathit{false}, X\} \cup \{x_i, \bar{x}_i \mid 1 \le i \le n\}$$

$$\cup \{c_{j,k} \mid 1 \le j \le m, 1 \le k \le n\} \cup \{d\}.$$

The linear ordering f of the vertices is as follows:

$$\mathit{true}, \mathit{false}, X, x_1, \bar{x}_1, x_2, \bar{x}_2, \ldots, x_n\bar{x}_n, c_{1,1}, c_{1,2}, \ldots, c_{m,n}, d.$$

The ownership function is specified as follows. Player 1 owns the vertices *true*, *false*, and X and also the vertices x_i and $\bar{x}_i$, where x_i is existentially quantified in the formula ϕ. Player 0 owns the remaining vertices. The set of colors C is {*true*, *false*, X}.

It remains to specify the set of edges.

$$E = \{\{\mathit{true}, \mathit{false}\}, \{\mathit{true}, X\}, \{\mathit{false}, X\}\} \tag{1}$$

$$\cup \{\{x_i, \bar{x}_i\}, \{X, x_i\}, \{X, \bar{x}_i\} \mid 1 \le i \le n\} \tag{2}$$

$$\cup \{\{l_i, c_{j,k}\}, \{\mathit{false}, c_{j,k}\} \mid l_i \text{ is a literal in } c_j, 1 \le i \le n, 1 \le j \le m, 1 \le k \le n\} \tag{3}$$

$$\cup \{\{c_{j,k}, d\} \mid 1 \le j \le m, 1 \le k \le n\} \cup \{\{d, \mathit{false}\}, \{d, X\}\}. \tag{4}$$

The set of edges (1) ensures that vertices *true*, *false*, and X are colored with three distinct colors. Without loss of generality, suppose that they are colored *true*, *false*, and X, respectively.

The set of edges (2) ensures that for each pair $x_i, \bar{x}_i$, one is colored *true* and the other *false*. Thus each coloring of these vertices corresponds to a truth assignment of the variables $x_1, \ldots, x_n$.

The set of edges (3) ensures that if clause c_j is true with respect to the truth assignment corresponding to the coloring of vertices $x_1, \ldots, x_n$, then each vertex $c_{j,k}$ is colored X. If c_j is false, then each vertex $c_{j,k}$ is independently colored X or true, each with probability 1/2.

The set of edges (4) ensures that d can be colored only if all the $c_{j,k}$ are colored X.

We claim that deciding whether MAX-PROB SAT(ϕ) is equal to 1 or is at most $1/2^{n^\epsilon}$ can be reduced in polynomial time to approximating MAX-PROB SCG(G, o, f, C) within ratio 2^{-n^c}, where c is a positive constant that depends on ϵ. To see this, note that if MAX-PROB SSAT(ϕ) = 1, then there is a way to choose a truth assignment to the existentially quantified variables that ensures that all clauses of ϕ are true. Hence by definition of the ownership function, Player 1 has a strategy for coloring vertices such that for every choice of colors of Player 0, the corresponding truth assignment to $x_1, \ldots, x_n$ satisfies all clauses. Hence all vertices $c_{j,k}$ are colored X, and so vertex d can be colored. Thus Player 1 has a strategy that wins with probability 1.

On the other hand, if MAX-PROB SSAT(ϕ) $< 1/2^{n^\epsilon}$, then on any strategy of Player 1, d can be colored with only exponentially small probability. This is because, on all strategies of Player 1, with probability at least $1 - 1/2^{n^\epsilon}$, the truth assignment corresponding to the variable coloring fails to satisfy $f(x)$. Suppose that clause c_j is false. Then with probability at least $1 - 1/2^n$, one of the vertices $c_{j,k}, 1 \le k \le n$, is colored *true*. As a result, d can be colored with probability at most $1 - (1 - 1/2^n)(1 - 1/2^{n^\epsilon})$. □

The proof of Theorem 4.4 can easily be modified to show the following.

THEOREM 4.5. *There is a constant $c' > 0$ such that approximating* MAX-LENGTH SCG *within ratio $n^{-c'}$ is* PSPACE*-hard.*

Proof. Simply modify the construction of Theorem 4.4 so that the vertex set is V', consisting of the vertices of V plus $|V|n^{2c'}$ additional vertices $d_1, \ldots, d_{|V|n^{2c'}}$. The ownership of these vertices can be specified arbitrarily, and they are ordered after the vertices in V. No additional edges are needed.

The expected length of the game is now either $|V| - 1 + |V|n^{2c'}$ or $|V| - 1 + (1 - (1 - 1/2^n)(1 - 1/2^{n^\epsilon}))(|V|n^{2c'})$, depending on the two possibilities for the probability that ϕ is satisfied. □

5. Open problems. There are many other two-player games that can be made into stochastic functions by letting Player 0 play randomly. Examples include the following.

1. In the Node Kayles game of Schaefer [22], the input is a graph. A move consists of putting a marker on an unoccupied vertex that is not adjacent to any occupied vertex. The first player unable to move loses. We can define Stochastic Node Kayles (SNK) in the same way, except that Player 0, rather than choosing optimally among all unoccupied vertices that are not adjacent to occupied vertices, instead chooses uniformly at random from the same set. Player 1's objective is to keep the game going as long as possible. MAX SNK is the expected length of the game under an optimal strategy of Player 1.

2. In the Generalized Hex game of Even and Tarjan [12], the input is a graph with two distinguished nodes n_1 and n_2. A move for Player 1 (0) consists of putting a white (black) marker on a vertex; the player is free to choose any unoccupied vertex except n_1 or n_2. After all vertices have been chosen, Player 1 wins if and only if there is a path from n_1 to n_2 along only white-occupied vertices. Stochastic Generalized Hex (SGH) is, as usual, the same game in which Player 0 places a black marker on a random unoccupied vertex rather than an optimal unoccupied vertex. A natural stochastic function is MAX-PROB SGH, which maps a graph to the probability, under an optimal strategy of Player 1, that there will be a white path from n_1 to n_2.

Superficially, these games differ from games like Generalized Geography and Stochastic Coloring in that there is no "locality" requirement on the moves of the random player. In Stochastic Generalized Geography, the random player must choose from among the arcs out of the current vertex, and in SCG the random player must color the vertex specified by the ownership function. The reductions that we use to prove MAX SGGEOG, MAX-PROB SCG, and MAX-LENGTH SCG hard to approximate make essential use of this locality. In Node Kayles, say, the random player may choose to mark a vertex that is very far away from the vertex just marked by the existential player.

We have not proven nonapproximability results for any functions without locality. Are they easy to approximate within some constant ratio? Are they in fact easy to compute exactly? It would be interesting to settle the difficulty of approximating

these functions and, more generally, to characterize precisely those PSPACE-complete languages that give rise to stochastic functions that are hard to approximate.

Acknowledgments. We thank the anonymous referees for their very helpful comments, in particular, for pointing out that our bounds on the nonapproximability of SSGEOG and MAH-JONGG could be improved.

A STRIP-PACKING ALGORITHM WITH ABSOLUTE PERFORMANCE BOUND 2*

A. STEINBERG†

Abstract. This paper proposes a new approximation algorithm M for packing rectangles into a strip with unit width and unbounded height so as to minimize the total height of the packing. It is shown that for any list L of rectangles, $M(L) \leq 2 \cdot \mathrm{OPT}(L)$, where $M(L)$ is the strip height actually used by the algorithm M when applied to L and $\mathrm{OPT}(L)$ is the minimum possible height within which the rectangles in L can be packed.

Key words. two-dimensional bin packing, strip packing, packing rectangles, absolute performance bound

1. Introduction.

We consider the following two-dimensional packing problem first proposed in [1]: Given a vertical strip of width 1, bounded below but not above, and a list L of rectangular pieces $R_1, R_2, \ldots, R_\ell$, pack the pieces into the strip so that the height to which the strip is filled is as small as possible. The pieces are not allowed to overlap. We also assume that each piece R_i in L is defined by its width a_i and height b_i and must be packed in such a way that the edges corresponding to width (i.e., edges of length a_i) are parallel to the horizontal bottom edge of the strip (see Fig. 1). This type of packing is called orthogonal oriented.

Since the problem of finding an optimal packing is NP-hard [1], polynomial-time approximation algorithms which generate near-optimal packings are studied, in particular, from a performance-guarantee point of view [1], [2], [3], [4], [5], [6], [7].

For an arbitrary list $L = \{R_1, R_2, \ldots, R_\ell\}$ of rectangular pieces all having width no more than 1, let $\mathrm{OPT}(L)$ denote the minimum possible strip height within which the pieces $R_1, R_2, \ldots, R_\ell$ can be packed and let $A(L)$ denote the height actually used by a particular packing algorithm A when applied to L. If α is a constant such that for every L,

$$A(L) \leq \alpha \cdot \mathrm{OPT}(L), \tag{1.1}$$

then α is called an absolute performance bound for A. Various algorithms satisfying inequalities of such a type were described in [1], [3], [5] ($\alpha = 3$) and [3] ($\alpha = 2.7$). In [6], an algorithm was found for which (1) holds with $\alpha = 2.5$. In this paper, we present a new algorithm with an absolute performance bound of $\alpha = 2$ which packs the pieces into the strip in an almost linear (up to a logarithmic factor) time.

In fact, this algorithm, denoted by M, is intended for packing pieces $R_1, R_2, \ldots, R_\ell$ from L into a bounded rectangle Q. (We always assume that all rectangles are oriented in such a way that their edges corresponding to width are horizontal).

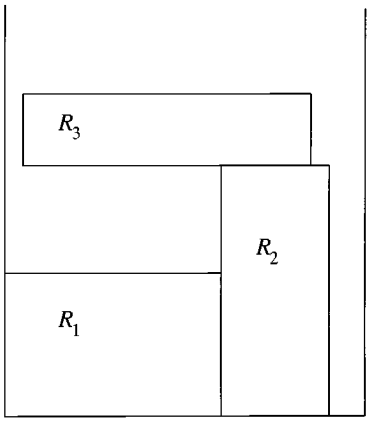

FIG. 1. *An orthogonal oriented strip packing of rectangular pieces* R_1 $(a_1 = 0.6, b_1 = 0.4)$, R_2 $(a_2 = 0.3, b_2 = 0.7)$, *and* R_3 $(a_1 = 0.8, b_1 = 0.2)$.

Denote the width and the height of Q by u and v, respectively, and let

$$a_L = \max_{1\le i\le \ell} a_i, \qquad b_L = \max_{1\le i\le \ell} b_i,$$
$$s_i = a_i b_i \quad (1 \le i \le \ell),$$
$$S_L = \sum_{i=1}^{\ell} s_i.$$

Our main result is the following.

THEOREM 1.1. *If the following inequalities hold,*

$$a_L \le u, \qquad b_L \le v, \qquad 2S_L \le uv - (2a_L - u)_+(2b_L - v)_+ \tag{1.2}$$

then it is possible to pack the rectangles $R_1, R_2, \ldots, R_\ell$ *into the rectangle* Q *by the algorithm* M. (*As usual,* $x_+ = \max(x, 0)$.)

Let us denote the problem of packing all the pieces of L into Q by (Q, L). We will say that (Q, L) is a tractable problem if L is nonempty and (2) is fulfilled.

Our plan is to show how every tractable problem can be reduced to tractable problems with a smaller list of pieces.

2. Reduction procedures. In this section, we define seven reduction procedures P_μ, $-3 \le \mu \le 3$. (For $\mu \ne 0$, the procedure $\mathrm{P}_{-\mu}$ is obtained from the procedure P_μ by interchanging horizontal and vertical directions.) Each P_μ can be applied only to tractable problems satisfying some additional condition C_μ. We combine the description of the procedures P_μ with the proof of the following lemma.

LEMMA 2.1. *Let a tractable problem* (Q, L) *satisfy* C_μ. *If* $|\mu| \le 2$, *then* P_μ *either solves* (Q, L) *or packs a proper part of* L *into* Q, *and for the remaining part* L' *of* L, *it constructs a tractable problem* (Q', L') *with* Q' *lying within the unoccupied area of* Q. *If* $|\mu| = 3$, *then* P_μ *divides* L *into two proper sublists* L' *and* L'' *and divides* Q *into two nonoverlapping rectangles* Q' *and* Q'' *in such a way that the problems* (Q', L') *and* (Q'', L'') *are tractable.*

Of course, we also need the following result.

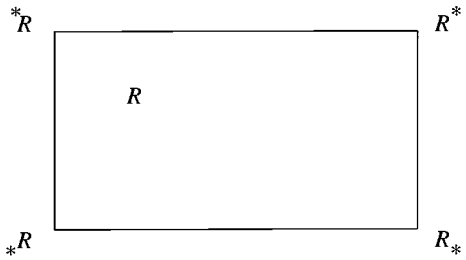

FIG. 2. *Vertices R_*, R^*, ${}^*R$, and ${}_*R$ of a rectangle R.*

LEMMA 2.2. *Every tractable problem satisfies at least one of the conditions* C_μ, $|\mu| \le 3$.

Notation. We will mark the vertices of any rectangle R by R_*, R^*, ${}^*R$, and ${}_*R$ as shown in Fig. 2.

Let (Q, L) be a tractable problem. As before, u and v denote the width and the height of Q. In order to define Procedures P_1 and P_3, it is convenient to assume that the list $L = \{R_1, R_2, \dots, R_\ell\}$ is ordered by decreasing width: $a_1 \ge a_2 \ge \cdots \ge a_\ell$.

PROCEDURE P_1. This procedure can be applied to the problem (Q, L) if the following condition holds:

$$(\mathrm{C}_1) \qquad a_L \ge \frac{1}{2}u.$$

Let m be the maximal index ($1 \le m \le \ell$) such that $a_m \ge \frac{1}{2}u$. Place the pieces $R_1, R_2, \dots, R_m$ so that

$${}_*[R_1] = {}_*Q, \qquad {}_*[R_i] = {}^*[R_{i-1}] \quad (2 \le i \le m)$$

(see Fig. 3). The third inequality in (2) implies that $S_L \le \frac{1}{2}uv$. Hence $\sum_{i=1}^m b_i \le v$ and the pieces $R_1, R_2, \dots, R_m$ lie inside Q. In particular, Procedure P_1 solves the problem (Q, L) if $m = \ell$.

Suppose that $m < \ell$. Denote $v - \sum_{i=1}^m b_i$ by v'. It is clear that $v' > 0$. Let $R_{t_1}, R_{t_2}, \dots, R_{t_{\ell-m}}$ be the list $R_{m+1}, R_{m+2}, \dots, R_\ell$ ordered by decreasing height:

$$b_{t_1} \ge b_{t_2} \ge \cdots \ge b_{t_{\ell-m}}.$$

If $b_{t_1} \le v'$, we form a problem (Q', L'), where

$$L' = \{R_{m+1}, R_{m+2}, \dots, R_\ell\}$$

and the rectangle Q' is defined by

$${}_*[Q'] = {}^*[R_m], \qquad [Q']^* = Q^*.$$

Since

$$2S_{L'} = 2S_L - 2\sum_{i=1}^m s_i \le uv - 2 \cdot \frac{1}{2}u(v - v') = uv'$$

and $a_{L'} < \frac{1}{2}$, we conclude that the new problem (Q', L') is tractable.

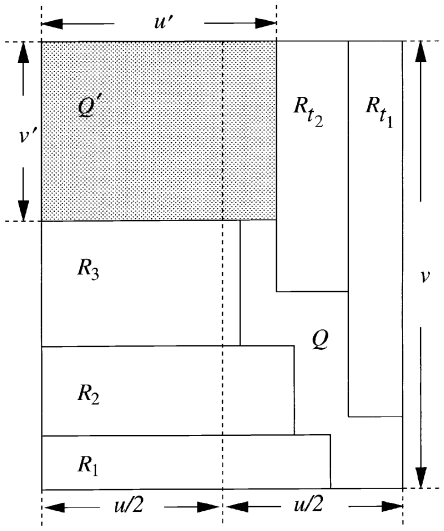

FIG. 3. *Illustration for Procedure* P_1 $(m = 3, n = 2)$.

In the case where $b_{t_1} > v'$, denote by n the maximal index $(1 \le n \le \ell - m)$ for which $b_{t_n} > v'$ and place $R_{t_1}, R_{t_2}, \ldots, R_{t_n}$ in the following way:

$$[R_{t_1}]^* = Q^*, \qquad [R_{t_j}]^* = {}^*[R_{t_{j-1}}] \quad (2 \le j \le n)$$

(see Fig. 3). We claim that the pieces R_i and R_{t_j} do not overlap for $1 \le i \le m$ and $1 \le j \le n$. Indeed if R_i and R_{t_j} overlap, then the pieces $R_1, R_2, \ldots, R_m$ and R_{t_1}, $R_{t_2}, \ldots, R_{t_n}$ cover the rectangles Q_1 and Q_2 defined by

$${}_*[Q_1] = {}_*Q, \qquad [Q_1]^* = [R_i]^* = {}_*[Q_2], \qquad [Q_2]^* = Q^*.$$

Therefore the area of $Q_1 \cup Q_2$ is less than S_L, i.e.,

$$a_i(v - d) + (u - a_i)d < S_L,$$

where $d = v - b_1 - b_2 - \cdots - b_i$. This inequality can be written in the following form:

$$uv - (2a_i - u)(2d - v) < 2S_L.$$

Since $0 \le 2a_i - u \le 2a_L - u = (2a_L - u)_+$ and $d \le b_{t_j} \le b_L$, we obtain

$$uv - (2a_L - u)_+(2b_L - v)_+ < 2S_L,$$

contradicting the fact that (Q, L) is a tractable problem. Note that the inequalities $b_{t_1} \ge b_{t_2} \ge \cdots \ge b_{t_n} > v'$ imply that all of the pieces $R_{t_1}, R_{t_2}, \ldots, R_{t_n}$ lie inside Q. Hence Procedure P_1 solves (Q, L) if $n = \ell - m$.

In the case where $n < \ell - m$, we form a new problem (Q', L'), where

$$L' = \{R_{t_{n+1}}, R_{t_{n+2}}, \ldots, R_{t_{\ell-m}}\}$$

and Q' is the rectangle satisfying

$${}_*[Q'] = {}^*[R_m], \qquad [Q']^* = {}^*[R_{t_n}].$$

Finally, the problem (Q', L') is tractable because $a_{L'} \le a_{m+1} < \frac{1}{2}u \le a_m \le u', b_{L'} = b_{t_{n+1}} \le v'$, and

$$\begin{aligned} 2S_{L'} &= 2S_L - 2\sum_{i=1}^{m} s_i - 2\sum_{j=1}^{n} s_{t_j} \\ &\le uv - 2\cdot\frac{1}{2}u(v-v') - 2(u-u')v' = u'v' - (u-u')v' \\ &\le u'v' - (2a_{L'} - u')_+ (2b_{L'} - v')_+ . \end{aligned}$$

Here u' and v' are the width and the height of Q'.

PROCEDURE P_3. This procedure can be applied to the problem (Q, L) if the following condition holds:

$$(C_3) \qquad a_L \le \frac{1}{2}u, \qquad b_L \le \frac{1}{2}v, \qquad \ell > 1,$$

and

$$S_L - \frac{1}{4}uv \le \sum_{i=1}^{m} s_i \le \frac{3}{8}uv, \qquad a_{m+1} \le \frac{1}{4}u$$

for some index m, $1 \le m < \ell$.

Set

$$Z = \sum_{i=1}^{m} s_i, \qquad u' = \max\left(\frac{1}{2}u, \frac{2Z}{v}\right), \qquad u'' = \min\left(\frac{1}{2}u, u - \frac{2Z}{v}\right).$$

Bearing in mind that $u' + u'' = u$, we cut Q into two rectangles Q' and Q'' with widths u' and u'' and the same height v and we form two problems (Q', L') and (Q'', L'') with $L' = \{R_1, R_2, \dots, R_m\}$ and $L'' = \{R_{m+1}, R_{m+2}, \dots, R_\ell\}$. Since $u' \ge \frac{1}{2}u$, $u'' \ge \frac{1}{4}u$, and $S_L - \frac{1}{2}u''v \le Z \le \frac{1}{2}u'v$, these problems are tractable.

PROCEDURE P_2. This procedure can be applied to the problem (Q, L) if the following condition holds:

$$(C_2) \qquad a_L \le \frac{1}{2}u, \qquad b_L \le \frac{1}{2}v,$$

and there exist two different indices i and $k (1 \le i, k \le \ell)$ such that

$$a_i \ge \frac{1}{4}u, \qquad a_k \ge \frac{1}{4}u, \qquad b_i \ge \frac{1}{4}v, \qquad b_k \ge \frac{1}{4}v,$$

$$2(S_L - s_i - s_k) \le (u - \max(a_i, a_k))v.$$

Assuming that $a_i \ge a_k$, we place R_i and R_k so that

$${}_*[R_i] = {}_*[Q], \qquad {}_*[R_k] = {}^*[R_i].$$

Evidently, R_i and R_k lie inside Q. If $\ell = 2$, the problem (Q, L) is solved. If $\ell > 2$, we form a new problem (Q', L'), where L' is obtained from L by deleting R_i and R_k and Q' is the rectangle such that

$${}_*[Q'] = [R_i]_*, \qquad [Q']^* = Q^*.$$

It is easy to check that (Q', L') is a tractable problem.

In Procedures P_μ ($\mu = 1, 2, 3$), the horizontal and vertical directions play a nonsymmetrical role. Obviously, we can interchange these directions and obtain "transposed" procedures, denoted by $\mathrm{P}_{-\mu}$. Procedure $\mathrm{P}_{-\mu}$ can be applied to tractable problems satisfying condition $(\mathrm{C}_{-\mu})$, "transposed" to (C_μ).

PROCEDURE P_0. This procedure can be applied to the problem (Q, L) if the following condition holds:

$$(\mathrm{C}_0) \qquad a_L \le \frac{1}{2}u, \qquad b_L \le \frac{1}{2}v, \quad \text{and} \quad S_L - \frac{1}{4}uv \le s_i$$

for some i, $1 \le i \le \ell$.

In this case, we place the piece R_i so that

$$_*[R_i] = {}_*Q.$$

If $\ell = 1$, the problem (Q, L) is solved. If $\ell > 1$, we form a new problem (Q', L'), where the rectangle Q' is defined by

$$_*[Q'] = [R_i]_*, \qquad [Q']^* = Q^*$$

and L' is obtained from L by deleting R_i. A trivial verification shows that (Q', L') is a tractable problem.

The proof of Lemma 1 is complete. Our next step is to prove Lemma 2.

Suppose that a tractable problem (Q, L) does not satisfy any of the conditions (C_μ), $|\mu| \le 3$. Since it does not satisfy (C_1) and (C_{-1}), it follows that

$$a_L \le \frac{1}{2}u, \qquad b_L \le \frac{1}{2}v.$$

We retain the assumption that the list L is ordered by decreasing width:

$$a_1 \ge a_2 \ge \cdots \ge a_\ell.$$

Denote by m the minimal index ($1 \le m \le \ell$) such that

$$\sum_{i=1}^{m} s_i > S_L - \frac{1}{8}uv. \tag{2.1}$$

Obviously, $m > 1$ since otherwise (Q, L) satisfies (C_0). Note that

$$\sum_{i=1}^{m-1} s_i \le S_L - \frac{1}{8}uv \le \frac{1}{2}uv - \frac{1}{8}uv = \frac{3}{8}uv.$$

The assumption $a_m \le \frac{1}{4}u$ yields

$$\sum_{i=1}^{m-1} s_i > S_L - \frac{1}{8}uv - s_m \ge S_L - \frac{1}{8}uv - \frac{1}{4}u \cdot \frac{1}{2}v = S_L - \frac{1}{4}uv$$

and hence implies that (Q, L) satisfies (C_3). Therefore, we proved that (3) holds together with

$$a_m > \frac{1}{4}u.$$

Now order list L by decreasing height:

$$L = \{R_{t_1}, R_{t_2}, \ldots, R_{t_\ell}\}, \qquad b_{t_1} \geq b_{t_2} \geq \cdots \geq b_{t_\ell}.$$

By using the "transposed" argument, we see that

$$\sum_{j=1}^{n} s_{t_j} > S_L - \frac{1}{8}uv, \qquad b_{t_n} > \frac{1}{4}v$$

for some n, $1 \leq n \leq \ell$. Let $I = \{1, 2, \ldots, m\}$ and $J = \{t_1, t_2, \ldots, t_n\}$. We have

$$\sum_{k \in I \cap J} s_k = \sum_{i=1}^{m} s_i + \sum_{j=1}^{n} s_{t_j} - \sum_{k \in I \cup J} s_k > 2\left(S_L - \frac{1}{8}uv\right) - S_L = S_L - \frac{1}{4}uv.$$

The intersection $I \cap J$ cannot contain a single index because (Q, L) does not satisfy (C_0). Therefore, there exist two different indices i and k belonging to $I \cap J$. Since

$$a_i, a_k \geq a_m > \frac{1}{4}u, \qquad b_i, b_k \geq b_{t_n} > \frac{1}{4}v,$$

and (Q, L) does not satisfy conditions (C_2) and (C_{-2}), we have

$$2(S_L - s_i - s_k) > (u - \max(a_i, a_k))v,$$
$$2(S_L - s_i - s_k) > u(v - \max(b_i, b_k)).$$

These inequalities together with the inequality $2S_L \leq uv$ imply

$$s_i + s_k < \frac{v}{2}\max(a_i, a_k), \qquad s_i + s_k < \frac{u}{2}\max(b_i, b_k);$$

hence

$$s_i + s_k < \frac{v}{4}\max(a_i, a_k) + \frac{u}{4}\max(b_i, b_k).$$

On the other hand, we have

$$s_i + s_k = a_i b_i + a_k b_k \geq \max(a_i, a_k) \cdot \min(b_i, b_k) + \min(a_i, a_k) \cdot \max(b_i, b_k) > \frac{v}{4}\max(a_i, a_k) + \frac{u}{4}\max(b_i, b_k).$$

This contradiction completes the proof of Lemma 2.

Lemmas 1 and 2 suggest the following recursive algorithm M. For every tractable problem (Q, L), M uses an appropriate Procedure P_μ. The algorithm then stops if (Q, L) is solved; otherwise, M is applied to one or two tractable problems constructed by P_μ.

The algorithm M can be implemented to run in time $O\left((\ell \cdot \log^2 \ell)/\log\log\ell\right)$, where ℓ is the number of pieces in L. To see this, we equip L with the structure of three linked lists corresponding to decreasing order of width, height, and area, and we keep this structure for all sublists of L created by P_μ $(|\mu| \leq 3)$. Since for $|\mu| \leq 2$, the checking of (C_μ) has a constant cost, and since P_μ packs pieces into Q and deletes them from L in linear time, it suffices to show that the total time $T(\ell)$ used by P_3 and P_{-3} when M is applied to (Q, L) has the $O((\ell \cdot \log^2 \ell)/\log\log\ell)$ bound. We may

assume without loss of generality that M uses P_3 and P_{-3} if and only if it cannot use any other reduction procedure. Note that every tractable problem (Q, L) satisfying (C_3) or (C_{-3}) can be decomposed into two subproblems (Q', L') and (Q'', L'') (as in Lemma 1) in $O(\min\{\ell' \log \ell', \ell'' \log \ell'', \ell\})$ time, where ℓ' and ℓ'' are the number of pieces in L' and L'' $(\ell' + \ell'' = \ell, \ell' > 0, \ell'' > 0)$. Therefore,

$$T(\ell) \le T(\ell') + T(\ell'') + O(\min\{\ell' \log \ell', \ell'' \log \ell'', \ell\}).$$

This allows us to prove the desired bound by induction.

Let us consider M as an algorithm for the strip-packing problem. For this purpose, we cut from the strip the rectangle Q_h that has the bottom of the strip as a lowest edge and a minimal height h, for which (Q_h, L) is a tractable problem. This height h is determined by

$$h = \inf\{v : b_L \le v \quad \text{and} \quad 2S_L \le v - (2a_L - 1)_+(2b_L - v)_+\}.$$

It is easy to check that

$$h = \max\left\{b_L, 2S_L + \left(2 - \frac{1}{a_L}\right)_+ (b_L - S_L)_+\right\}.$$

Thus we proved the following result.

THEOREM 2.3. *Let L be a list of rectangular pieces such that $a_L \le 1$. Then*

$$M(L) \le \max\left\{b_L, 2S_L + \left(2 - \frac{1}{a_L}\right)_+ (b_L - S_L)_+\right\}. \tag{2.2}$$

In particular,

$$M(L) \le S_L + \max\{b_L, S_L\} \tag{2.3}$$

and

$$M(L) \le 2 \cdot \mathrm{OPT}(L).$$

The last inequality follows from (5) because $S_L \le \mathrm{OPT}(L)$ and $b_L \le \mathrm{OPT}(L)$.

The examples given in Fig. 4 show that estimate (5) is the best possible in the following sense: for every $b > 0$ and $S > 0$, the optimal packing height $\mathrm{OPT}(L)$ of a list L with $b_L = b$ and $S_L = S$ can be made as close as desired to $S + \max\{b, S\}$. In particular, as a corollary of Theorem 2, we have that

$$\sup\{\mathrm{OPT}(L) : a_L \le 1, \quad b_L = b, \quad S_L = S\} = S + \max\{b, S\}.$$

This suggests the following problem: for every $0 < a \le 1$, $b > 0$, and $S > 0$, find the supremum of $\mathrm{OPT}(L)$ over all lists L of rectangles for which $a_L = a, b_L = b$, and $S_L = S$. One can check that if $\frac{1}{2} < a \le 1$ or $S \le b$, then this supremum coincides with the right side of (4). In general, however, the problem is still open.

Acknowledgments. I would like to thank A. Lipovetsky for many helpful discussions. I also thank the referees for suggestions on the organization of this paper.

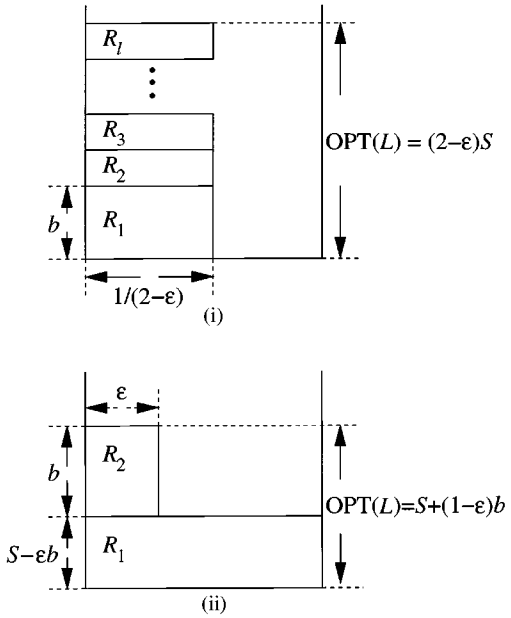

FIG. 4. *Examples of lists L with $b_L = b$, $S_L = S$, and* $\mathrm{OPT}(L) = S + (1-\varepsilon)\max\{b, S\}$ *($\varepsilon > 0$ is sufficiently small).* (i) *The case where $b < S : L = \{R_1, R_2, \ldots, R_\ell\}$, $\ell \geq (2-\varepsilon)S/b$. The pieces $R_2, R_3, \ldots, R_\ell$ have the same height $((2-\varepsilon)S-b)/(\ell-1)$.* (ii) *The case where $b \geq S : L = \{R_1, R_2\}$.*

APPROXIMATING SHORTEST SUPERSTRINGS*

SHANG-HUA TENG† AND FRANCES F. YAO‡

Abstract. The shortest-superstring problem is to find a shortest possible string that contains every string in a given set as substrings. This problem has applications to data compression and DNA sequencing. Since the problem is NP-hard and MAX SNP-hard, approximation algorithms are of interest. We present a new algorithm which always finds a superstring that is at most 2.89 times as long as the shortest superstring. Our result improves the 3-approximation result of Blum et al.

Key words. approximation algorithms, combinatorial optimization, DNA sequencing, data compression, optimal assignments, the shortest-superstring problem

1. Introduction.

Let $S = \{s_1, \ldots, s_n\}$ be a set of strings over an alphabet Σ. A *superstring* of S is a string α which contains each s_i as a *substring*, i.e., there exist u_i and v_i such that α can be written as $u_i s_i v_i$. The *shortest-superstring problem* (SSP) is to find a minimum-length superstring for any given set S.

One obvious application for the shortest-superstring problem is data compression. Storer and Szymanski [14, 15], for example, considered a fairly general model of data compression which includes the SSP as an important special case. See also Mayne and James [9]. Another application is to DNA sequencing. The SSP is one of the simplest models for the problem of recovering DNA sequencing information from experimental data, and some heuristic algorithms have been in routine use for this task [2, 6, 7, 8, 12, 13].

Since the shortest-superstring problem is known to be NP-hard [4, 5], it is of interest to find approximation algorithms with good performance guarantees. Some heuristics have been considered by Tarhio and Ukkonen [16], Turner [18], and Blum et al. [2]. The simplest one is the algorithm Greedy: repeatedly merge a pair of strings with maximum overlap until only one string remains. It was shown that with respect to the *compression* (or *overlap*) measure, that is, the sum of the overlaps between consecutive strings in the candidate superstring, Greedy achieves at least 1/2 the compression of an optimal superstring [16, 18]. However, although a shortest superstring also achieves maximum compression, in general, a performance guarantee with respect to compression implies no performance guarantee with respect to length (see section 2). Indeed, it seemed quite hard to establish any linear approximation in the length measure. The first breakthrough was made by Blum et al. in [2], where they gave an intricate proof that Greedy achieves an approximation ratio of 4. Furthermore, a modified algorithm, called TGreedy, has an approximation ratio of 3. They also showed that the superstring problem is MAX SNP-hard [11]. In conjunction with the recent result of Arora et al. [1] that MAX SNP-hard problems do not have polynomial-time approximation schemes unless P = NP, it implies that

a polynomial-time approximation scheme for this problem is unlikely. It was left as an open question in [2] whether there exist polynomial-time algorithms that achieve approximation ratios better than 3.

In this paper, we present a new polynomial-time approximation algorithm for this problem. The algorithm always finds a superstring whose length is at most 2.89 times the length of the shortest superstring. Thus it affirmatively answers the open question raised in [2].

Our construction makes use of some new structural properties of superstrings. These properties are interesting in their own right and may have other applications to problems on string matching. In section 2, we give an overview of our approach. Section 3 reviews some basic concepts of the superstring problem and the underlying graph representation. In section 4, we describe a new superstring algorithm and prove that it achieves an approximation ratio of 2.89.

2. Overview of our approach. We first give an informal description of the ideas behind our approximation algorithm. These ideas will be worked out analytically in sections 3 and 4. Precise definitions of the terminology used here can be found in the next section.

For any superstring α of S, let length_α and overlap_α denote the length and the overlap (compression) achieved by α, respectively. Then $\text{length}_\alpha + \text{overlap}_\alpha = |S|$, the total length of strings in S. Comparing α with the optimal superstring gives

$$\text{length}_\alpha - \text{length}_{\text{opt}} = \text{overlap}_{\text{opt}} - \text{overlap}_\alpha.$$

In general, $\text{overlap}_{\text{opt}}$ may grow quadratically in $\text{length}_{\text{opt}}$ (in the case that the input strings can be packed densely into a superstring). Hence a guarantee that α achieves, say, 50% of optimal compression does not translate into a constant-factor guarantee for its length. Therefore, a key to designing algorithms with linear length approximation is to construct suitable subproblems for which $\text{overlap}_{\text{opt}}$ is only linear in $\text{length}_{\text{opt}}$ (cf. Lemmas 3.5 and 4.4). We now outline our method below.

Since the shortest-superstring (or maximum-compression) problem corresponds to the maximum-Hamiltonian-path problem in a certain weighted digraph, our approximation scheme starts by computing, as in [2] and [18], an optimal assignment (or cycle cover) C in this graph. The remaining task, then, is to find a suitable linear extension of C, i.e., to merge the cycles into one long path P. Our approach for generating P is to first construct a "backbone" of P by taking one vertex from each cycle of C and finding a suitable path P' for this vertex set V'. We then design a procedure that inserts the remaining parts of C into the backbone structure P' without losing much of their original weights.

To achieve an approximation ratio of 3, one can simply construct P' from an optimal cycle cover C' for V' (or by the Greedy algorithm). To obtain further improvement, we take the above process one step further and build P' via a recursive construction, again making use of optimal cycle covers. However, the key here is to design a different procedure for insertion when it comes to 2-cycles in order to get better performance guarantees.

The complete algorithm, which admits a short description, is given in section 4.3. The design and analysis of our algorithm are accompanied by an investigation of the combinatorial structures of the SSP as well as the periodic properties of strings. Further discussions of our method are given in section 5.

3. Definitions and lemmas. As in previous studies, we may assume without loss of generality that S is *substring free*, i.e., no string $s_i \in S$ is a substring of $s_j \in S$

for $j \neq i$. Let $|s|$ denote the length of a string s, and let $|S| = \sum_{s \in S} |s|$. We use $opt(S)$ to denote the length of the shortest superstring of S.

For two strings s and t, let v be the longest string such that $s = uv$ and $t = vw$ for some nonempty strings u and w. We call $|v|$ the *overlap* between s and t, denoted by $ov(s,t)$. String u is called the *prefix* of s with respect to t and is written as $pref(s,t)$. The value $|pref(s,t)|$ is called the (prefix) *distance* from s to t, denoted by $d(s,t)$. The string $uvw = pref(s,t)t$ of length $d(s,t) + |t| = |s| + |t| - ov(st)$ is the shortest superstring of s and t in which s appears before t, and is called the *merge* of s and t. We will abbreviate $pref(s_i, s_j)$, $d(s_i, s_j)$, and $ov(s_i, s_j)$ to simply $pref(i,j)$, $d(i,j)$, and $ov(i,j)$, respectively.

Given a list of strings $s_1, s_2, \ldots, s_r$, we define the superstring $\langle s_1, s_2, \ldots, s_r \rangle$ to be the string $pref(1,2)pref(2,3)\ldots pref(r-1,r)s_r$. Thus it is the shortest superstring in which $s_1, s_2, \ldots, s_r$ appear in order. For any permutation π of $\{1, 2, \ldots, n\}$, let $S_\pi = \langle s_{\pi(1)}, s_{\pi(2)}, \ldots, s_{\pi(n)} \rangle$. It is easy to see that the shortest superstring α for S must equal S_π for some π.

3.1. Distance graph and overlap graph. The shortest-superstring problem can be formulated either as a minimization problem with respect to prefix distance or as a maximization problem with respect to overlap. We will have occasion to refer to both of these measures in our discussions. First, define a graph G_S for $S = \{s_1, \ldots, s_n\}$ to be the complete digraph on the vertex set $\{1, 2, \ldots, n\}$. The *distance graph* (G_S, d) of S is the weighted digraph where the weight of an edge (i,j) is $d(i,j)$ for $i \neq j$. The *overlap graph* (G_S, ov) of S is also a weighted digraph with edge weights $ov(i,j)$ for $i \neq j$. We use $d(E)$ and $ov(E)$ to denote the total weight of an edge set E in (G_S, d) and in (G_S, ov), respectively. Note that if E is a cycle, then the sum $d(E) + ov(E)$ is equal to the total length of the strings in E.

Notice that $\mathrm{HMP} = |S| - opt(S)$, where HMP is the cost of a maximum Hamiltonian path in (G_S, ov). On the other hand, $\mathrm{TSP}(G_S) \leq opt(S)$, where $\mathrm{TSP}(G_S)$ is the cost of a minimum Hamiltonian cycle in (G_S, d). (See also [2, 18].) Since finding optimal Hamiltonian paths is a hard problem, both Turner and Blum et al. considered approximation schemes that are based on solving the related *assignment* problem, as we will discuss below.

Remark. We have defined G_S to be without self-loops, which is different from the definition adopted in [2]. By doing so, we have sacrificed the "Monge condition" which the graph (G_S, ov) would otherwise satisfy. This slows down the running time of our algorithm, but it enables us to design a more effective approximation.

3.2. Optimal assignment. An *assignment* (or *cycle cover*) of a digraph G is a collection of cycles such that every vertex of G is in exactly one cycle. An *optimal* assignment is an assignment whose total weight is minimized (or maximized). Since $d(C) = |S| - ov(C)$ for any assignment C on G_S, a minimum assignment for (G_S, d) corresponds to a maximum assignment for (G_S, ov). We will use the convention that minimum assignments are for (G_S, d) and maximum assignments are for (G_S, ov). The optimal-assignment problem can be solved in $O(n^3)$ time by the Hungarian method (see, e.g., [10] and [17]).

For a cycle c in an assignment C, we refer to $d(c)$ as the *weight* of c. For a vertex (string) $s_i \in c$, we also say that $d(c)$ is the weight of s_i. The total weight of all cycles in assignment C is $d(C)$, and the total overlap is $ov(C)$.

LEMMA 3.1. *Let C be an optimal assignment for S. Then $d(C) \leq \mathrm{TSP}(G_S) \leq opt(S)$, and $ov(C) \geq |S| - opt(S)$.*

LEMMA 3.2. *Let ov_2, ov_3, and ov_4 denote, respectively, the amount of overlap in all 2-cycles, 3-cycles, and cycles of size 4 or larger in an optimal assignment C for S. Let C' be a subset of C obtained by discarding the minimum-weight edge (with respect to ov) from each cycle in C; then $ov(C') \geq ov_2/2 + 2ov_3/3 + 3ov_4/4$.*

It follows that $ov(C') \geq ov(C)/2$. Thus the superstring corresponding to C' achieves at least half the overlap of an optimal superstring. The same can be said about the superstring produced by the Greedy algorithm, although the proof is not as straightforward (see [18]). We state this result for later use.

LEMMA 3.3. *The total overlap achieved by the Greedy algorithm is at least 1/2 of the overlap achieved by an optimal superstring.*

The structure of the optimal assignment for a string set S is closely related to the periodicity structure of the strings. These relations can be exploited in designing approximate-superstring algorithms. We will look at some of these relations.

3.3. Periodicity of strings. We say a string t is *irreducible* if all cyclic shifts of t yield distinct strings. It is easy to show that (see, e.g., [3]) every string s has a unique prefix t such that t is irreducible and $s = t^k$ for some $k \geq 1$. String t is called the *period* of s. Clearly, in a minimum assignment C for S, the string $t = pref(i_1, i_2)pref(i_2, i_3) \dots pref(i_r, i_1)$ associated with a cycle $c = (i_1, \dots, i_r) \in C$ must be an irreducible string. We refer to t (or any of its cyclic shifts) as the period of c, denoted by $period(c)$; thus $|period(c)| = d(c)$. The next lemma follows immediately from the definition of a cycle.

LEMMA 3.4. *Each string s in c is a substring of $(period(c))^k$ for sufficiently large k.*

The following lemma from [2] is central to the analysis of various superstring algorithms based on minimum assignments. (A strengthened version, given in Lemma 4.4, will be used to analyze our algorithm.)

LEMMA 3.5. *Let c_1 and c_2 be two cycles in a minimum-weight assignment C with $s_1 \in c_1$ and $s_2 \in c_2$. Then the overlap between s_1 and s_2 is less than $d(c_1) + d(c_2)$.*

We use the shorthand $\langle s_j, c \rangle$ for the superstring $\langle s_j, s_{j+1}, \dots, s_r, s_1 \dots, s_j \rangle$. That is, $\langle s_j, c \rangle$ is the result of merging the strings in order around cycle c, beginning and ending with s_j. Let C be an assignment for G_S. Suppose we pick an arbitrary string r_i from each cycle c_i to form a representative set R and construct a superstring α for R, say $\alpha = \langle r_1, \dots, r_t \rangle$. Now let $\bar{\alpha}$ be the string derived from α by "extending" each r_i by its period, i.e., by letting $\bar{\alpha} = \langle \langle r_1, c_1 \rangle, \dots, \langle r_t, c_t \rangle \rangle$. Note that $\bar{\alpha}$ is a superstring of S, and we will call $\bar{\alpha}$ the *extended string* of α (with respect to C).

LEMMA 3.6. *Let R be a representative set of an assignment C, and let α be a superstring of R. Then the extended string $\bar{\alpha}$ of α is a superstring of S and $|\bar{\alpha}| = |\alpha| + d(C)$.*

4. A new approximation algorithm. In this section, we present an algorithm for the superstring problem that has an approximation ratio of 2.89. There are several new ingredients in this approximation scheme. The first idea is to select, among all optimal assignments of G_S, a *canonical* one, as we shall define. This enables us to prove a strengthened version of Lemma 3.5. Another crucial step in our algorithm is to find an economical way to merge the 2-cycles in an optimal assignment. In this case, our method gives a better guarantee than retaining only half of the overlap, as stated in Lemmas 3.2 and 3.3.

4.1. Canonical optimal assignments. Let C be an minimum assignment of a string set S. For a string $s \in S$ and a cycle $c \in C$, if there exists a (sufficiently large)

positive integer k such that s is a substring of $(period(c))^k$, then we say that s *fits* c. Clearly, if $s \in c$, then s fits c (Lemma 3.4). We can restate Lemma 3.5 as follows.

LEMMA 4.1. *Let c_1 and c_2 be two cycles in C. If $s \in S$ fits both c_1 and c_2, then $|s| \leq d(c_1) + d(c_2)$.*

We say that s fits c *uniquely* if s fits c and any two occurrences of s as substrings in $(period(c))^k$ must be offset by one or more periods.

LEMMA 4.2. *Let c be a cycle in a minimum assignment of S. If $s \in S$ fits c and $|s| \geq d(c)$, then s fits c uniquely.*

Proof. The result follows immediately from the fact that $period(c)$ is an irreducible string. □

Let c and c' be two cycles of C. Suppose that string s belongs to c and that s also fits c'. Since removing s from c and reassigning s to c' does not increase the overall weight, it still yields a minimum assignment. We call a minimum assignment *canonical* if each string s is assigned to a cycle whose weight is the smallest among all cycles that s fits.

LEMMA 4.3 (canonical assignment). *Given a minimum assignment C for S, we can transform C into a canonical minimum assignment C' for S in $O(n|S|)$ time.*

Proof. Note that s fits c if and only if s is a prefix of $(period(c))^k$ for $k = \lceil |s|/|d(c)| \rceil + 1$. Thus in $O(n|S|)$ time, we can find for each $s \in S$ the set of all cycles that s fits and assign s to the one with the smallest weight. □

Thus a canonical minimum assignment of a string set can be found in polynomial time. For canonical minimum assignments, we can establish an extension of Lemma 3.5 by bounding the sum of a pair of symmetric overlaps $ov(r_1, r_2)$ and $ov(r_2, r_1)$. This lemma is useful for designing linear embeddings of 2-cycles.

LEMMA 4.4. *Let c_1 and c_2 be two cycles in a canonical minimum assignment C with $r_1 \in c_1$ and $r_2 \in c_2$. Then $ov(r_1, r_2) + ov(r_2, r_1) < \max(|r_1|, |r_2|) + \min(d(c_1), d(c_2))$.*

Proof. Denote the sum $ov(r_1, r_2) + ov(r_2, r_1)$ by L. Let h_1 be the amount of overlap between the two copies of r_1 in $\langle r_1, r_2, r_1 \rangle$. Similarly, let h_2 be the amount of overlap between the two copies of r_2 in $\langle r_2, r_1, r_2 \rangle$.

We have the following two cases:

1. Suppose that $h_1 < d(c_1)$ and $h_2 < d(c_2)$. Then we have $L = |r_1| + h_2 < |r_1| + d(c_2)$, and similarly $L = |r_2| + h_1 < |r_2| + d(c_1)$; the lemma is true.

2. Suppose that either $h_1 \geq d(c_1)$ or $h_2 \geq d(c_2)$. Without loss of generality, assume that $h_1 \geq d(c_1)$. By Lemma 4.2, in the superstring $\langle r_1, r_2, r_1 \rangle$, the two occurrences of r_1 must be offset by a multiple of $d(c_1)$; hence $h_1 \leq |r_1| - d(c_1)$. It also follows that r_2, being sandwiched between these r_1's, must fit c_1. Hence $d(c_1) \geq d(c_2)$ since C is a canonical optimal assignment. Also, $|r_2| < d(c_1) + d(c_2)$ by Lemma 3.5. Therefore, $L = |r_2| + h_1 < (d(c_1) + d(c_2)) + (|r_1| - d(c_1)) \leq |r_1| + d(c_2) \leq \max(|r_1|, |r_2|) + \min(d(c_1), d(c_2))$. □

Remark. It is worthwhile to point out that the notion of canonical optimal assignment is essential in the sense that Lemma 4.4 does not hold for all optimal assignments. In fact, the left-hand side of the inequality can be much larger than the right-hand side in general.

4.2. Long paths through 2-cycles. Let $F = \{f_1, \ldots, f_m\}$ and $G = \{g_1, \ldots, g_m\}$ be two lists of m strings. Form m 2-cycles $C_{F,G}$ by matching f_i with g_i, that is, let $C_{F,G} = \{\langle f_i, g_i, f_i \rangle, 1 \leq i \leq m\}$. Let $ov(F, G)$ be the total overlap in the resulting 2-cycles $\langle f_i, g_i, f_i \rangle$. Let η be a superstring of G; without loss of generality, assume that $\eta = \langle g_1, g_2, \ldots, g_m \rangle$. Let $ov(\eta)$ be the total overlap in η.

We now describe an algorithm Insert(F, η) which generates a superstring of $F \cup G$ by inserting F into η. This is the process we alluded to in section 2 for building a path on $F \cup G$ from a backbone structure η on G.

ALGORITHM Insert(F, η)

1. Define

$$Q_O = \{\langle f_i, g_i, g_{i+1}, f_{i+1}\rangle : i \text{ is odd}\},$$
$$Q_E = \{\langle f_i, g_i, g_{i+1}, f_{i+1}\rangle : i \text{ is even}\}.$$

2. Let q_O and q_E be the concatenation of strings from Q_O and Q_E, respectively.
3. Let q be the shorter of q_O and q_E; output q.

Clearly, q is a superstring of $F \cup G$. Moreover, we have the following lemma.

LEMMA 4.5. *The amount of overlap in q constructed above is at least $ov(F, G)/2 + ov(\eta)/2$.*

Proof. It follows from the fact that $Q_O \cup Q_E$ and $C_{F,G} \cup \eta$ correspond to two decompositions of the same edge set in G_S (see Figure 1). □

Given F and G, we will apply the above procedure Insert(F, η) to the string η obtained by first running the Greedy algorithm on G. (It would work equally well if we obtained η via an optimal assignment, as described in Lemma 3.2.) Call the combined procedure Greedy-Insert(F, G). It produces a superstring of $F \cup G$ with guaranteed overlap because of Lemmas 3.3 and 4.5.

LEMMA 4.6 (Greedy-Insert). *The amount of overlap in the superstring generated by* Greedy-Insert(F, G) *is at least $ov(F, G)/2 + \max\{0, (|G| - opt(G))/4\}$.*

4.3. The algorithm. We now present our new approximation algorithm.

ALGORITHM (superstring approximation)
Input: $S = \{s_1, \ldots, s_n\}$.

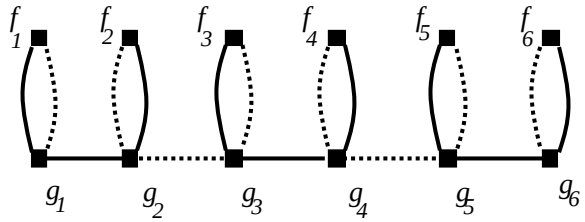
1. Find an optimal assignment C of S, and make C canonical.
2. Take an arbitrary string from each cycle of C to form a set R, and find an optimal assignment CC for R.
3. Let F be the set that contains the shorter string from each 2-cycle in CC, and let G be the set containing the longer string from each 2-cycle in CC; run Greedy-Insert(F, G) to obtain q.
4. Open each non-2-cycle in CC by deleting the edge with the smallest overlap; concatenate the resulting strings together with q to obtain α; let $\bar{\alpha}$ be the extended string of α and return $\bar{\alpha}$.

4.4. Analysis. Clearly, the algorithm runs in polynomial time. To analyze its performance ratio, we first introduce some notation.

• Let d_2, d_3, and d_4 be, respectively, the total weight (in C) of the strings that appear in 2-cycles, 3-cycles, and all i-cycles for $i \geq 4$ in assignment CC. Thus $d_2 + d_3 + d_4 = d(C)$.

• Let ov_2, ov_3, and ov_4 be, respectively, the total overlap present in the 2-cycles, 3-cycles, and all i-cycles for $i \geq 4$ in assignment CC. Thus $ov_2 + ov_3 + ov_4 = ov(CC)$. Also from Lemma 3.1, we have $d(C) \leq opt(S)$ and $|R| - ov(CC) \leq opt(R) \leq opt(S)$.

Recall that G is the set containing the longer string from each 2-cycle in CC. Summing over all 2-cycles (using Lemma 4.4), we obtain the following lemma.



$$Q_O = \langle f_1, g_1, g_2, f_2, f_3, g_3, g_4, f_4, f_5, g_5, g_6, f_6 \rangle,$$
$$Q_E = \langle g_1, f_1, f_2, g_2, g_3, f_3, f_4, g_4, g_5, f_5, f_6, g_6 \rangle.$$

FIG. 1. *The decompositions induced by Q_O and Q_E are indicated by bold and dashed edges, respectively.*

LEMMA 4.7. $ov_2 \leq |G| + d_2/2$.

LEMMA 4.8. $|\alpha| \leq (1 + 8/9)opt(S)$.

Proof. By Lemmas 3.2 and 4.6, the amount of overlap in α, $ov(\alpha)$, is at least max(a,b), where

$$a = ov_2/2 + 2ov_3/3 + 3ov_4/4,$$
$$b = ov_2/2 + (|G| - opt(G))/4 + 2ov_3/3 + 3ov_4/4.$$

Recall that $ov_i \leq 2d_i$ for $i = 2, 3, 4$ by Lemma 3.5. Therefore,

$$\begin{aligned} |\alpha| &\leq |R| - a \\ &\leq opt(S) + ov_2/2 + ov_3/3 + ov_4/4 \\ &\leq opt(S) + d_2 + (2/3)d_3 + (1/2)d_4, \end{aligned} \tag{1}$$

where we have made use of the fact that $|R| \leq opt(S) + ov(CC)$.

Since $|G| \geq ov_2 - d_2/2$ by Lemma 4.7 and since $opt(G) \leq opt(S)$, we have $b \geq ov_2/2 + (ov_2 - d_2/2 - opt(S))/4 + 2ov_3/3 + 3ov_4/4 = 3ov_2/4 + 2ov_3/3 + 3ov_4/4 - d_2/8 - opt(S)/4$. Therefore,

$$\begin{aligned} |\alpha| &\leq |R| - b \\ &\leq 5opt(S)/4 + ov_2/4 + ov_3/3 + ov_4/4 + d_2/8 \\ &= 5opt(S)/4 + ov(CC)/4 + ov_3/12 + d_2/8 \\ &\leq (2 - 1/4)opt(S) + d_3/6 + d_2/8. \end{aligned} \tag{2}$$

We complete the analysis by considering two cases.

Case 1. If $d_2 \leq (2/3)d(C)$, then the right-hand side of (1) is maximized when $d_2 = (2/3)d(C)$ and $d_3 = (1/3)d(C)$, giving

$$\begin{aligned} |\alpha| &\leq opt(S) + (2/3)d(C) + (2/3)(1/3)d(C) \\ &\leq (1 + 8/9)opt(S). \end{aligned}$$

Case 2. If $d_2 > (2/3)d(C)$, then $d_3 \leq d(C)/3$. By inequality (2),

$$\begin{aligned} |\alpha| &= (2 - 1/4)opt(S) + (d_2 + d_3)/8 + d_3/24 \\ &\leq (2 - 1/4)opt(S) + d(C)/8 + d(C)/72 \\ &\leq (1 + 8/9)opt(S). \end{aligned}$$

Now the result follows immediately from Lemma 3.6. □

THEOREM 4.9. *There exists an $O(n^3 + n|S|)$-time algorithm for constructing superstrings that achieves an approximation ratio of* 2.89.

5. Conclusion. The shortest-superstring problem is a fundamental problem about strings with some natural applications. We have established a better approximation bound than what was previously available. Given the possible large sizes of $|S|$ and $opt(S)$, a small percentage improvement in superstring approximation might still be viewed as significant. We do not know any examples for which our algorithm's approximation ratio is worse than 2; thus it is possible that the analysis can be further improved. We close by raising two open problems:

- Give further improvement to the 2.89 upper bound or the $1+\epsilon$ lower bound (as provided by [1]) for superstring approximation.
- Find an algorithm that achieves better than 50% of the optimal compression. Such an algorithm, when used as a subroutine, will immediately lead to improvement in length approximation as well.

BOUNDED CONCURRENT TIME-STAMPING*

DANNY DOLEV† AND NIR SHAVIT‡

Abstract. We introduce concurrent time-stamping, a paradigm that allows processes to temporally order concurrent events in an asynchronous shared-memory system. *Concurrent time-stamp systems* are powerful tools for concurrency control, serving as the basis for solutions to coordination problems such as mutual exclusion, ℓ-exclusion, randomized consensus, and multiwriter multireader atomic registers. Unfortunately, all previously known methods for implementing concurrent time-stamp systems have been theoretically unsatisfying since they require unbounded-size time-stamps—in other words, unbounded-size memory.

This work presents the first bounded implementation of a concurrent time-stamp system, providing a modular unbounded-to-bounded transformation of the simple unbounded solutions to problems such as those mentioned above. It allows solutions to two formerly open problems, the bounded-probabilistic-consensus problem of Abrahamson and the *fifo-ℓ*-exclusion problem of Fischer, Lynch, Burns and Borodin, and a more efficient construction of *multireader multiwriter* atomic registers.

Key words. atomic registers, serialization, concurrency, time-stamping, distributed computing, parallel computing

1. Introduction.

A *time-stamp system* is like a ticket machine at an ice cream parlor. People's requests to buy the ice cream are time-stamped based on a numbered ticket (label) taken from the machine. In order to know the order in which requests will be served, a person need only scan through all the numbers and observe the order among them. A *concurrent* time-stamp system (CTSS) is a time-stamp system in which any process can either take a new ticket or scan the existing tickets simultaneously with other processes. A CTSS is required to be *wait-free*, which means that a process is guaranteed to finish any of the two above-mentioned label-taking or scanning tasks in a finite number of steps, even if other processes experience stopping failures. Wait-free algorithms are highly suited for fault-tolerant and real-time applications (see Herlihy [Her91]).

Concurrent time-stamping is the basis for simple solutions to a wide variety of problems in concurrency control. Examples of such algorithms include Lamport's *first-come first-served* mutual exclusion [Lam74], Vitanyi and Awerbuch's construction of a multireader multiwriter (MRMW) atomic register [VA86], Abrahamson's randomized consensus [Abr88], and Fischer, Lynch, Burns, and Borodin's *fifo-ℓ*-exclusion problem [FLBB79, FLBB89] (also see [AD*94]).

The research of this author was supported by a Libnitz Foundation Scholarship, the Israeli Communications Ministry Award, NSF contract CCR-8611442, ONR contract N0014-85-K-0168, DARPA contract N00014-83-K-0125, and a special grant from IBM. Parts of this research were also conducted while this author was visiting the Theory of Distributed Systems group at MIT, AT&T Bell Laboratories, and the IBM Almaden Research Center.

Unfortunately, the only formerly known implementation of the CTSS paradigm using read/write registers was a version of Lamport's "bakery algorithm," which uses labels of unbounded size [Lam74]. Researchers were thus led to devise complicated problem-specific solutions to show that the above problems are solvable in a bounded way.[1]

In [IL93], Israeli and Li were the first to isolate the notion of bounded time-stamping (time-stamping using bounded-size memory) as an independent concept, developing an elegant theory of bounded *sequential* time-stamp systems. Sequential time-stamp systems prohibit concurrent operations. This work was continued in several interesting papers on sequential systems with weaker ordering requirements by Li and Vitanyi [LV87], Cori and Sopena [CS93], and Saks and Zaharoglou [SZ91].

This paper introduces the *concurrent time-stamping* paradigm and provides the first bounded construction of a concurrent time-stamp system. It provides a modular unbounded-to-bounded transformation, enabling the design of simple unbounded concurrent-time-stamp-based algorithms to problems such as those mentioned above, with the knowledge that each unbounded solution immediately implies a bounded one. Our work allows solutions of the above flavor to two formerly open problems, the bounded-randomized-consensus problem of [Abr88] (which requires one to solve the randomized-consensus problem of [CIL87] without using an atomic coin-flip operation) and the *fifo*-ℓ-exclusion problem of [FLBB79, FLBB89] (see [AD*94] for details). A bounded CTSS solution to the former problem is given in [Sha90], and in [AD*94], Afek et al. use a CTSS to provide the first bounded solution to the latter problem.[2]

Though one might think that the price of introducing a modular unbounded-to-bounded transformation would be a blowup in memory size or number of operations, this is hardly the case. For an n-process system, the construction presented in this paper requires only n registers of $O(n)$ bits each, meeting the lower bound of [IL93] for sequential-time-stamp-system construction. The time complexity is $O(n)$ operations for an update and $O(n^2 \log n)$ for a scan. (Like the unbounded algorithm, the scan consists only of read operations, i.e., no writes.)

One example of the efficiency of the CTSS solutions is given by the famous problem of multireader multiwriter atomic register construction. A simple solution based on transforming the unbounded protocol of Vitanyi and Awerbuch [VA86] using our construction (see [Sha90, G92]) has the same space complexity of the [PB87, Sch88] algorithm, yet it has a better time complexity—$O(n)$ memory accesses for a write, $O(n \log n)$ for a read, as compared with $O(n^2)$ for either in the former solutions. Our implementation is the only known bounded construction of an MRMW atomic register from single-writer multireader (SWMR) atomic registers where the implementation of the MRMW read operation does not require a process to perform an SWMR write. The importance of the readers-do-not-write property was first raised by Lamport in [Lam86a], where he showed the impossibility of a bounded construction where readers do not write of a single-writer single-reader (SWSR) atomic register from SWSR regular ones. Moreover, as explained in [AD*94], this property is important when defining liveness conditions such as *first-come first-enabled* for problems like ℓ-exclusion.

The structure of our presentation is as follows. We begin by describing concurrent time-stamping (sections 2 and 3), first formally using Lamport's axiomatic approach

[1] See [And89a, Blo88, BP87, CIL87, Dij65, DGS88, FLBB79, FLBB89, Kat78, Lam74, Lam77, Lam86b, LH89, LV87, **?**, Ray86, Pet81, Pet83, PB87, VA86].

[2] The only prior known solutions to the *fifo*-ℓ-exclusion problem [DGS88, Pet88] achieve weaker forms of fairness than the original *test-and-set*-based solution of [FLBB79].

[Lam86c, Lam86a] and then informally through a simple unbounded-memory implementation. In sections 4.3 and 4.4, the bounded wait-free CTSS implementation is described. Section 5 provides the final details of the formal specification and the main parts of the proof of the bounded CTSS implementation are presented. Section 6 describes the implications of a bounded CTSS construction on various interprocess-communication problems and gives a summary of research following our work. For berevity, some of the more tedious parts of the correctness proof have been omitted and can be found in [Sha90].

2. A concurrent time-stamp system. The following is a formal definition of a CTSS for a system of processes numbered $1, \ldots, n$. It uses the axiomatic specification formalism of Lamport [Lam86c, Lam86a]. The reader may benefit by checking how the formal properties described below are met by the unbounded implementation described in the next section.

A CTSS is a problem specification with an operational interface. A CTSS that permits n concurrent operations has $2n$ operation types, specifically, $\mathit{labeling}_i(\ell_i)$ and $\mathit{scan}_i(\bar{\ell}, \prec)$ for $i \in \{1, \ldots, n\}$. A $\mathit{labeling}_i$ operation associates an input *value*, ℓ_i, taken from any domain $\mathcal{D}$ with a label.[3] We call ℓ_i the *labeled-value* of operation $\mathit{labeling}_i$. In an application such as an atomic-register construction, the labeled-value would be the value written to the register, while in a mutual-exclusion-type application, where the input values are unimportant, it would be null. A scan_i operation returns as output a pair $(\bar{\ell}, \prec)$, where the *view* $\bar{\ell} = \{\ell_1, \ldots, \ell_n\}$ is an indexed set of labeled-values (one per process) and $\prec$ is a *total order* on these indexes.

Assume that each process' program consists of these two operations, whose execution generates a sequence of *elementary operation executions*, totally ordered by the *precedes* relation (of [Lam86c, Lam86a], denoted "$\longrightarrow$") and where any number of scan operation executions are allowed between any two labeling operation executions. The following,

$$L_i^{[1]} \longrightarrow S_i^{[1]} \longrightarrow L_i^{[2]} \longrightarrow L_i^{[3]} \longrightarrow S_i^{[2]} \longrightarrow S_i^{[3]} \longrightarrow S_i^{[4]} \longrightarrow \cdots,$$

is an example of such a sequence by process i, where $L_i^{[k]}$ denotes process i's kth execution of a labeling operation and $S_i^{[k]}$ is the kth execution of a scan operation. (The superscript $[k]$ is used for notation and is not visible to the processes.) The labeled-value input in each labeling operation execution $L_i^{[k]}$ is denoted by $\ell_i^{[k]}$.[4] A *global-time model* of operation executions is assumed, implying that for any two operation executions, $a \longrightarrow b$ or $b \dashrightarrow a$. (For more details, see section 5.1.)

The elementary operation executions of a CTSS must have following set of properties.

P1: *ordering.* There exists an irreflexive total order $\Longrightarrow$ on the set of all labeling operation executions such that we have the following:

a: *precedence.* For any pair of labeling operation executions $L_p^{[a]}$ and $L_q^{[b]}$ (where p and q are possibly the same process), if $L_p^{[a]} \longrightarrow L_q^{[b]}$, then $L_p^{[a]} \Longrightarrow L_q^{[b]}$.

b: *consistency.* For any scan operation execution $S_i^{[k]}$ that returns $(\bar{\ell}, \prec)$, $p \prec q$ if and only if $L_p^{[a]} \Longrightarrow L_q^{[b]}$.

[3] In order correctly handle initial conditions, the value domain $\mathcal{D}$ must specify some initial value.

[4] In order for a unique labeled-value $\ell_i^{[k]}$ to be associated with each label operation execution $L_i^{[k]}$, the reader can think of $\ell_i^{[k]}$ as a triplet $\langle \ell_i^{[k]}, i, k \rangle$, where the second and third fields are dummy indexes used only for purposes of the specification.

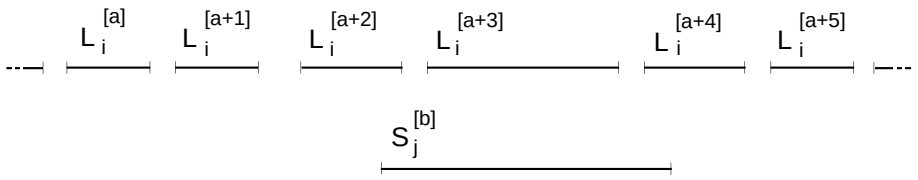

FIG. 1. *Regularity.*

Property P1 formalizes the idea that a CTSS can be envisioned as a black box, inside of which hides a mechanism (a logical clock) associating causally ordered time stamps—from an infinite totally ordered range—with each of the labeled-values entered in labeling operations, and where scanning is like peeping into this black box, each scan returning a view of a part of this hidden ordering.[5] The black box metaphor is used to stress that it suffices to know of the existence of such a total ordering $\Longrightarrow$, while the ordering itself need not be known.

One should bear in mind that the asynchronous nature of the operations allows situations where a scan operation execution overlaps many consecutive labeling operation executions of other processes. Also, several consecutive scans could possibly be overlapped by a single labeling operation execution. It is therefore important that a requirement be made that the view $\bar{\ell}$ returned by $S_i^{[k]}$ be a meaningful one, namely, that it reflect the ordering among labeling operation executions immediately before or concurrent with the scan, and not just any possible set of labeled-values. (In the example of Figure 1, any of the labeled-values $\ell_x^{[a+1]}$ through $\ell_x^{[a+4]}$ can be returned by $S_i^{[k]}$, but not those preceding or following them.) This will eliminate uninteresting trivial solutions and introduce a measure of liveness into the system. This requirement is formalized in the following definition, where $\dashrightarrow$ is the *can affect* relation of [Lam86c, Lam86a].

P2: *regularity.* For any labeled-value $\ell_p^{[a]}$ in $\bar{\ell}$ of $S_i^{[k]}$, $L_p^{[a]} \dashrightarrow S_i^{[k]}$, and there is no $L_p^{[b]}$ such that $L_p^{[a]} \longrightarrow L_p^{[b]} \longrightarrow S_i^{[k]}$.

Although such a *regular* concurrent time-stamp system as P1–P2 would suffice for some applications (as in Lamport's "bakery algorithm" [Lam74]), a more powerful *monotonic* concurrent time-stamp system will be needed in applications such as the *multireader multiwriter* atomic register construction (as in [LV87, VA86]). zTo this end, the following third property is added.

P3: *monotonicity.* For any labeled-value $\ell_p^{[a]}$ in $\bar{\ell}$ of $S_i^{[k]}$, there does not exist an $S_j^{[k']}$ with a labeled-value $\ell_p^{[b]}$ in its view $\bar{\ell}'$, such that $S_i^{[k]} \longrightarrow S_j^{[k']}$ and $L_p^{[b]} \longrightarrow L_p^{[a]}$ (possibly $i = j$).

Monotonicity is the property that in the unbounded natural-number CTSS can be described by saying that the labels of any one process, as read by increasingly later scans, are "monotonically nondecreasing." In other words, later scans cannot read labels smaller than those read by earlier ones. It is important to note, however, that P3 does not imply that labeling and scan operation executions of all processes are serializable, that is, appear to happen atomically. (Figure 2 shows two scan operations that meet property P3 that cannot be serialized.) It does, however, imply the serializability of the scan operation executions of all processes relative to the labeling operation executions of any *one* process.

[5] Notice that there is no requirement that labeled-values returned by different scans must be comparable.

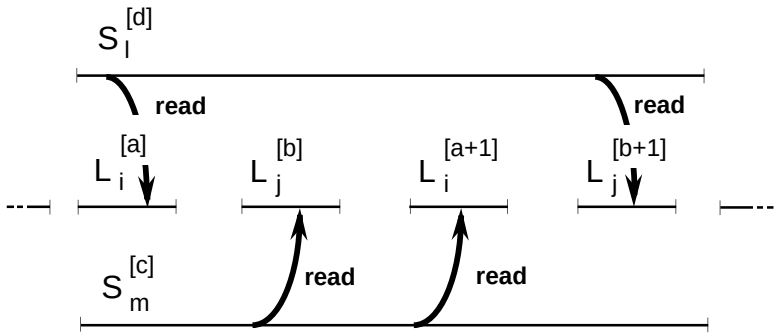

FIG. 2. *Monotonicity does not imply atomicity.*

Property P4 is an extension of part of the regularity property to the $\Longrightarrow$ order.[6] Properties P3 and P4 together imply that all *scan* operations that consider only the "largest" value, where "largest" is based on the $\prec$ ordering, can be serialized with respect to all labeling operations.

P4: *order regularity.* For any labeled-value $\ell_p^{[a]}$ in $\bar{\ell}$ of $S_i^{[k]}$, $S_i^{[k]} \longrightarrow L_q^{[b]}$ implies that $L_p^{[a]} \Longrightarrow L_q^{[b]}$.

3. Unbounded concurrent time-stamping. The basic communication primitive used in our implementations is a single writer multireader atomic register. Our goal is to design an implementation that is *wait-free* [Her91, AG90]: each process' *scan* or *label* operation execution consists of a bounded number of SWMR register operations independently of the pace or type of operations carried out by other processes. Wait-free constructions of SWMR atomic registers from weaker primitives have been shown in [BP87, IL93, Lam86d, SAG94, New87].

We begin with the following simple implementation of a CTSS using SWMR registers of unbounded size. The concurrent time stamp system will consist of n SWMR atomic registers v_i, $i \in \{1..n\}$. Each v_i is written by process i and read by all. Each $labeling_i$ operation writes ℓ_i to register v_i. In our implementation, ℓ_i is a data type consisting of two fields, a labeled-value, denoted $value(\ell_i)$, and its associated label, denoted $label(\ell_i)$. Each $label(\ell_i)$ is a pair of the form $(number_i, i)$, where $number_i$ is a natural number and $i \in \{1..n\}$ is the id of the process writing ℓ_i.

A process i collects the labels and values of other processes by performing a *collect* operation, a reading of all the registers v_j, $j \in \{1..n\}$, once each, in some arbitrary order. The collect operation returns an indexed set $\ell = \{\ell_1, \ldots, \ell_n\}$, that is, one value and associated label per process. The collected elements in ℓ are ordered by $ord(\ell)$, an ordering on their indexes in $\{1..n\}$, such that i is smaller than j if and only if the label $(number_i, i)$ is lexicographically smaller than the label $(number_j, j)$. Figure 3 provides the pseudocode of the *labeling* and *scan* operations for a process i.

To understand how property P1 is met, consider that if the labeling operation execution of ℓ_i by a process i completely preceded the labeling operation execution of ℓ_j by j, then it must be that j chose a label with $number_j > number_i$ since j collected ℓ_i. If they are concurrent, at worst they might both collect the same maximal label and choose $number_i = number_j$, in which case they are ordered by their ids. Thus

[6] The need for property P4 in applications such as the multireader multiwriter atomic register construction of [LV87, VA86] was discovered by Gawlick [G92].

```
procedure labeling(val);
  begin
    ℓ := collect;
    v_i := (val, (max_{j∈{1..n}} number_j + 1, i));
  end;
function scan;
  begin
    ℓ := collect;
    return ({value(ℓ_1) ... value(ℓ_n)}, ord(ℓ));
  end;
```

FIG. 3. *The unbounded* natural-number-*based implementation.*

the lexicographic order on the labels defines a linearization order [HW88] on the concurrent labeling operation executions, that is, an order $\Longrightarrow$ by which they can be thought of as happening sequentially in time. The reader can convince herself that properties P2–P4 follow directly from the use of SWMR atomic registers in the implementation.

It is important to note that the actual $label(\ell_1) \ldots label(\ell_n)$ used in computing $ord(\ell)$ are hidden from the user (scan operations do not return them), and there is thus no way to compare the order among a pair of values returned by different scans.

4. A bounded concurrent time-stamp system.

4.1. Labels and precedence. The bounded implementation presented will be of the exact same form as the unbounded natural-number-based one. The concurrent time-stamp system will consist of n SWMR atomic registers v_i, $i \in \{1..n\}$, each v_i written by process i and read by all. Each value ℓ_i written to register v_i consists, just as in the unbounded case, of two fields, a *labeled-value*, to which the input of a labeling operation is written, and an associated *label*.

Note. In what follows, almost all of the discussion involves only the label field of v_i and not its labeled-value field. In order to simplify the exposition, we choose, with few exceptions, to ignore the existence of the labeled-value field and deal only with the associated label field. Thus, for example, the notation $\ell_i^{[k]}$ will represent only the label field written in a labeling operation execution $L_i^{[k]}$. We trust that the interested reader will be able to add the relevant operations regarding the labeled-value, as in the unbounded implementation in section 3.

Let V denote the range of possible labels and $\stackrel{\nu}{\prec}$ denote an irreflexive and anti-symmetric relation among them. In the unbounded natural-number implementation of a CTSS, V is just the unbounded size set of pairs of natural numbers and integers in $\{1..n\}$ and $\stackrel{\nu}{\prec}$ is the lexicographic total ordering among them. In the following sections, the set of possible label values V of the implementation, together with a relation $\stackrel{\nu}{\prec}$ among them, are defined in terms of a *precedence graph*[7] $(V, \stackrel{\nu}{\prec})$. Each possible label is a node in this graph. The order among the labels in any two registers is the order $\stackrel{\nu}{\prec}$ established by the edges of the precedence graph. A tournament is a complete directed graph. The precedence graph representing labels of the natural-number-based implementation is an acyclic tournament of unbounded size, i.e., a total

[7] The elegant idea of defining the labels and ordering as a tournament graph was introduced by Israeli and Li in [IL93].

order. The definition of the precedence graph will provide the basis for describing the implementation of the labeling and scan operations.

4.2. A bounded precedence graph. The following is the description of the *precedence graph* T^n (see Figure 4). Unlike the unbounded precedence graph defined by the natural numbers, T^n contains cycles.

Define "*A dominates B* in *G*," where A and B are two subgraphs of a graph G (possibly single nodes), to mean that every node of A has edges directed to every node of B. Define the following generalization of the composition operator of [IL93]. The *α-composition*, $G \circ_\alpha H$, of two graphs G and H, where α is a subset of the nodes of G, is the following noncommutative operation:

> Replace every node $v \in \alpha$ of G by a copy of H (denoted H_v), and let H_v (or v) dominate H_u in $G \circ_\alpha H$ if v dominates u in G.

Define the graph T^2 to be the following graph of five nodes: a cycle of three nodes $\{3, 4, 5\}$, where 3 dominates 5, which dominates 4, which in turn dominates 3, all dominating the nodes $\{2, 1\}$, and where node 2, in turn, dominates node 1.

Define the graph T^k (a tournament) inductively as follows:

1. T^1 is a single node.
2. $T^k = T^2 \circ_\alpha T^{k-1}$, where $\alpha = \{5, 4, 3, 1\}$ and $k > 1$.

The graph $T^n = (V, \overset{\vee}{\prec})$ is the precedence graph to be used in the implementation of the labeling and scan algorithms of a concurrent time-stamp system for n processes. For any process i, each node in T^n corresponds to a uniquely defined label value ℓ_i. The label can be viewed as a string $\ell_i[n..1]$ of n digits, where each $\ell_i[k] \in \{1, \ldots, 5\}$ is the digit of the corresponding node in T^2, replaced by a T^k subgraph during the kth step of the inductive construction above. The digit $\ell_i[n]$ is always 1, representing the complete T^n graph, and if in ℓ_i, $\ell_i[k] = 2$, then $\ell_i[j] = 1$ for all $j \in \{k-1..1\}$ (since node 2 is never expanded in the induction step). Therefore, given any label ℓ_i, the T^k subgraph of T^n in which its corresponding node is located is identified by the corresponding prefix $\ell_i[n..k]$.

To assure that based on the graph T^n a total ordering among the label values returned by a scan can be established, we need to break symmetry among processes having the same label. Thus the label ℓ_i is assumed to be concatenated with the id of process i, where label and id are lexicographically ordered. (In terms of the graph T^n, this amounts to no more than assuming that each T^1 graph consists of a total order tournament of n nodes, each process i always choosing the ith node in the order. For simplicity, this point is not further elaborated upon in what follows.)

4.3. The labeling operation. Recall that the *collect* operation by any process i is a reading of all the registers v_j, $j \in \{1..n\}$, once each, in an arbitrary order, returning a set ℓ of labels. The *labeling* operation of a process i is of the form described in Figure 5, where $\mathcal{L} : V^n \times \{1..n\} \mapsto V$ is a *labeling function*, returning a label value ℓ_i "greater than" all other label values.[8] This is the same form as the natural number CTSS, where the labeling function $\mathcal{L}$ returns $(\max_{j \in \{1..n\}} number_j + 1, i)$. However, the interpretation of being "greater than" is not as straightforward as in the natural-number case.

The definition of the labeling function $\mathcal{L}(\ell, i)$ presented below is based on a recursively defined function $\mathcal{L}^k(G, \ell, \ell_{\max})$, which, given a T^k subgraph G of T^n, a set of labels ℓ, and a "maximal" label $\ell_{\max} \in \ell$ in T^k, returns the label of a node in G

[8] Initially, all labels are on node 111..11, the node dominated by all others in T^n.

  end;

FIG. 5. *The labeling operation.*

that is "greater than" the other labels. The reader may benefit by going through Examples 4.1, 4.2, and 4.3 before or during the reading of the code in Figure 6. For simplicity, and since the collected set of labels ℓ remains unchanged in $\mathcal{L}(\ell, i)$ once it is collected (similarly for the variable $\ell_{\max}$ once it is computed), it is treated as a global variable and is not passed as a parameter in all of the utility functions used by $\mathcal{L}(\ell, i)$. The following functions are used in defining $\mathcal{L}$:

num_labels(G)—a function that, for the given label set ℓ, returns how many of the labels are in subgraph G;

```
function L(ℓ, i);
    function L^k(G);
    begin
     1: if k= 1 then return G;
     2: if ℓ_max[n..k] ≠ G
          then return L^{k-1}(G.1);
     3: if ℓ_max[n..k-1] = G.2
          then return L^{k-1}(G.3);
     4: if k > 2 then
          if ℓ_max[k-2] ∈ {2,3,4,5} and
            (ℓ_i[n..k-1] ≠ ℓ_max[n..k-1])
          then return L^{k-1}(G.dom(ℓ_max[k-1]));
     5: if (num_labels(ℓ_max[n..k-1]) < k-1) or
          ((num_labels(ℓ_max[n..k-1]) = k-1) and
          (ℓ_i[n..k-1] = ℓ_max[n..k-1]))
          then return L^{k-1}(G.ℓ_max[k-1])
          else return L^{k-1}(G.dom(ℓ_max[k-1]));
    end L^k;
begin
    ℓ_max := max(dominating_set(ℓ, ℓ_i));
    return L^n(T^n);
end L;
```

FIG. 6. *The labeling function.*

$dom(x)$—a function that, for a given digit $x \in \{1..5\}$ representing a node in the graph T^2, returns the next dominating node, namely, $dom(1) = 2$, $dom(2) = 3$, $dom(3) = 4$, $dom(4) = 5$, and $dom(5) = 3$;

$dominating\_set(\hat{\ell}, \ell_i)$—a function that, for a set of labels $\hat{\ell} \subseteq \ell$ and a label $\ell_i \in \hat{\ell}$, returns a subset of labels $\{\ell_j \in \hat{\ell} \,|\, \ell_i \overset{V}{\prec} \ell_j\} \cup \{\ell_i\}$; and

$max(\hat{\ell})$—a function that, for a set of labels $\hat{\ell} \subseteq \ell$, returns a label

$$(\ell_x \in \hat{\ell} \,:\, |dominating\_set(\hat{\ell}, \ell_x)| \leq |dominating\_set(\hat{\ell}, \ell_j)|, \forall \ell_j \in \hat{\ell}\,),$$

the maximal label, i.e., the one least dominated within this set.

Define $G.x$ to be the *concatenation* of string G and digit x. Figure 6 is thus the definition of the labeling function $\mathcal{L}(\ell, i)$, where the parameter subgraphs G are identified with the relative label prefixes and T^n is identified with the label 1. To give the reader some intuition about the properties of the labeling operation, let it be assumed that one can talk about the values of the labels of all processes at "points in time." To show how the labeling operation executions allow us to define the order $\Longrightarrow$, we will first argue informally that they meet a much simpler requirement, namely, that at any point in time, the following hold:

R1. The labels reflect the precedence among nonconcurrent labeling operation executions.

R2. The subgraph of the precedence graph T^n induced by the labeled nodes (those whose corresponding label is written in some v_i) contains no cycle.

Since T^n is a tournament, R2 implies that at any point in time, all labels are totally ordered. One should notice that these two requirements are easily met by the unbounded implementation since for any $n - 1$ nodes, one can always choose a

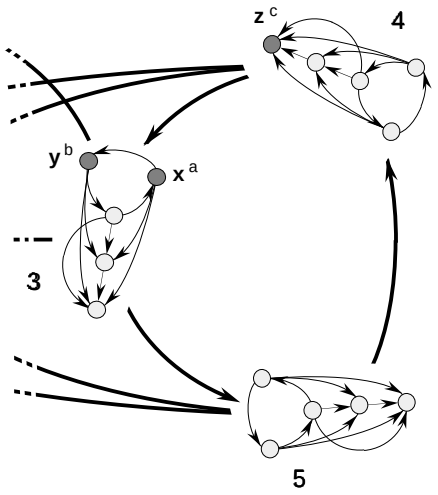

FIG. 7. *Starting state for the examples.*

dominating node in an unbounded total order graph in order to maintain R1, and this will never impair R2 because the graph does not contain cycles.

Let us begin by showing that the labeling operation executions maintain the following two "invariants" at any point in time:

(1) There are labels on at most two of the three nodes in any cycle of any subgraph T^k. (The cycle consists of "supernodes" $\{3, 4, 5\}$, called supernodes since they are actually T^{k-1} subgraphs.)

(2) There are no more than k labels in the cycle of any subgraph T^k.

Maintaining the second invariant is the key to maintaining the first, and the first implies R2.

The manner by which the invariance of (1) and (2) is preserved is explained via several examples. In these examples, T^3 is a precedence graph for a system of three processes x, y, and z. As shown in Figure 7, all of the examples start at a point in time where $\ell_y^{[b]} = 134$, $\ell_x^{[a]} = 135$, and $\ell_z^{[c]} = 141$, that is, all labels are totally ordered by $\precdot$. In the figure, a label such as $\ell_x^{[a]} = 135$ is denoted by shading node 135 and denoting it with the mark x^a.

Example 4.1. Assume that the following sequence of labeling operation executions occur sequentially. Process y performs $L_y^{[b+1]}$, reading $\ell_x^{[a]}$, $\ell_y^{[b]}$, and $\ell_z^{[c]}$ and moving based on $\mathcal{L}(\ell, y)$ to $\ell_y^{[b+1]} = 142$. Process z performs $L_z^{[c+1]}$, reading the new label $\ell_y^{[b+1]}$. It thus moves to the T^2 subgraph 14, following the rule that the node chosen should be the "lowest node dominating all other nodes with labels." This is actually the most basic rule implied by the definition of $\mathcal{L}$. The move to a dominating node is intended to meet R1.

Processes y and z can continue forever to choose $\ell_y^{[b+2]} = 144$, $\ell_z^{[c+2]} = 145$, $\ell_y^{[b+3]} = 143, \ldots$ (that is, move in the cycle of 14), maintaining the above invariants, because the T^2 graph is a precedence graph for two processes. If at some point x moves, in $L_x^{[a+1]}$ it will read the labels of both z and y as being in the T^2 subgraph 14. A T^2 subgraph is a precedence graph able to accommodate two labels and no more.

Since *num_labels*$('14') = 2$ in $L_x^{[a+1]}$, that is, there are already two labels in the T^2 subgraph, by line 5 of $\mathcal{L}(\ell, i)$, x will move to $\ell_x^{[a+1]} = 151$, and so on. □

The reader can convince herself that following any labeling operation execution $L_z^{[c]}$ by some process z, the above invariants hold. Furthermore, for the set of labels of processes y ($y \neq z$) that were read in $L_z^{[c]}$'s collect operation (denoted $read(L_z^{[c]})$), it is the case that

$$(\forall \ell_y^{[b]} \in read(L_z^{[c]}))\,(\ell_y^{[b]} \preceq \ell_z^{[c]}). \tag{3}$$

This invariant—that the new label chosen is greater than all those read—is the basis for meeting requirement R1.

As seen in the following example, in the concurrent case, more than k labels may move into the same T^k subgraph at the same time. It is thus not immediately clear why the second invariant holds.

Example 4.2. Assume that the following sequence of labeling operation executions occur concurrently. Processes x and y begin performing $L_x^{[a+1]}$ and $L_y^{[b+1]}$ concurrently, reading $\ell_x^{[a]}$, $\ell_y^{[b]}$, and $\ell_z^{[c]}$ and computing $\mathcal{L}$ such that $\ell_x^{[a+1]} = \ell_y^{[b+1]} = 142$. If they then continue to complete their operations by writing their labels, though they choose the same node, they were concurrent and can be ordered by relative id. If any of them were to continue to perform a new labeling operation, since *num_labels*$('14') > 2$, it would choose label 151, not entering the cycle. However, let us suppose that they do not both complete writing their labels, that is, x stops just before writing $\ell_x^{[a+1]}$ to v_x, while y writes $\ell_y^{[b+1]} = 142$. Process z then performs $L_z^{[c+1]}$, reading the new label $\ell_y^{[b+1]}$ and the old label $\ell_x^{[a]}$, thus moving to $\ell_z^{[c+1]} = 143$. Processes y and z continue to move into and in the cycle of the T^2 subgraph 14 since they continue to read x's old label. Then at some point, x completes $L_x^{[a+1]}$, and there are three labels in 14 (two of them in the cycle). However, if x now performs a new labeling $L_x^{[a+2]}$, it will read the labels of both x and y as being in 14. Since *num_labels*$('14') > 2$, by line 5 of $\mathcal{L}(\ell, i)$, x will move to $\ell_x^{[a+2]} = 151$, not entering the cycle. □

If nodes 1 and 2 did not exist in a T^2 subgraph (that is, each T^2 subgraph was a cycle of three nodes), a process' first move into T^k would be onto a node of the cycle. The reader can verify that the sequence of operations in Example 4.2, given that T^2 is just a cycle, would cause the labels of x, y, and z to end up each on a different node of the cycle, contradicting the first invariant. Based on the existence of nodes 1 and 2, this does not occur.

The following is intended to explain to the reader why for a given level k ($k = 2$ in the example), even if more than k processes move into a T^k subgraph *without* reading one another's labels, at most k of them will enter the cycle in T^k. The reason is the following well-known *flag principle*[9]:

> If there are $k + 1$ people, each of which first raises a flag and then counts the number of raised flags, at least one person must see $k + 1$ flags raised.

By the definition of the labeling function $\mathcal{L}$, each process moving into the cycle of a T^k subgraph must first move to either supernode 1 or 2 in T^k, and only then can it perform a labeling into the cycle. The move to 1 or 2 is the raising of the flag, and the move into the cycle is the counting of all flags.

[9] The proof follows since the last person to start counting flags must have seen $k + 1$ flags raised.

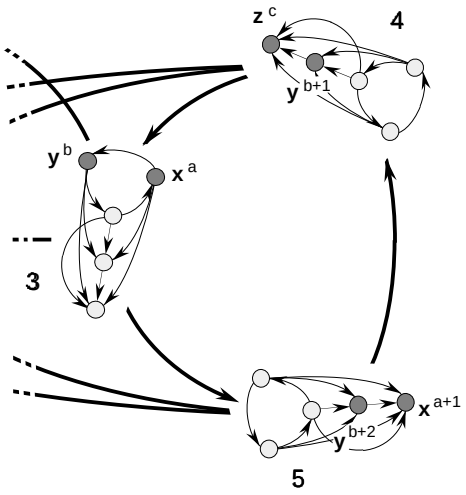

FIG. 8. *A collect returning a cycle.*

Example 4.3 below, which is depicted in Figure 8, shows that even though by the above there are at most k labels at a time in any T^k subgraph, the sets of labels *read* in a labeling operation execution may contain cycles.

Example 4.3. Process z begins performing $L_z^{[c+1]}$, reading $\ell_x^{[a]} = 135$. Process y then performs $L_y^{[b+1]}$, reading $\ell_x^{[a]}$, $\ell_y^{[b]}$, and $\ell_z^{[c]}$ and moving to $\ell_y^{[b+1]} = 142$. Process x performs $L_x^{[a+1]}$, reading the new label $\ell_y^{[b+1]}$ and $\ell_z^{[c]}$ and thus, by line 5 of $\mathcal{L}$, moving to $\ell_x^{[a+1]} = 151$. Process y then performs $L_y^{[b+2]}$, reading $\ell_x^{[a+1]}$ and moving to $\ell_y^{[b+2]} = 152$. Finally, process z reads $\ell_y^{[b+2]}$. It thus read $\ell_x^{[a]} = 135$, $\ell_y^{[b+2]} = 152$, and $\ell_z^{[c]} = 141$, three labels on a cycle. □

In order to select a label that dominates all others, z must establish where the "maximal label" among them is. To overcome the problem that the labels read form cycles (as in the example above), the labeling function $\mathcal{L}(\ell, z)$ does not take into account "old values" such as $\ell_x^{[a]}$; it considers only the labels that dominate the current label $\ell_z^{[c]}$.

In order to maintain the first invariant, z should move to $\ell_z^{[c+1]} = 131$ to dominate the current labels of both x and y without moving directly into the cycle. However, there is seemingly a problem since z did not read the label $\ell_x^{[a+1]} = 151$; so how can it know that there are already two labels in the T^2 subgraph 15? The solution is based on the fact that z can indirectly deduce the existence of $\ell_x^{[a+1]} = 151$. By the first invariant, in all of the cycle of T^3, there are at most three labels. In order to move to $\ell_y^{[b+1]} = 152$, y must have read some label in node 151 of the T^2 subgraph 15. By simple elimination, this must be a label of x. This rule is maintained by the application of line 4 in $\mathcal{L}^k$.

If the above scenario had occurred in the cycle of a T^k graph, where $k > 3$, then in order to allow the same reasoning as above, it would have to be that z's reading $\ell_y^{[b+2]} = 152$ (or $\ell_y^{[b+2]} \in \{153, 154, 155\}$) would imply that there are $k-2$ labels apart from that of y in the T^{k-1} subgraph 15. It would thus have to be that if $\ell_y^{[b+2]}$ is

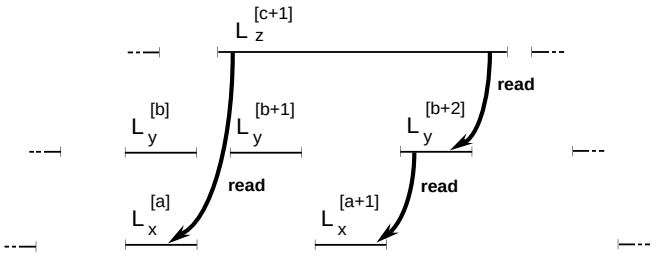

FIG. 9. *The observed relation.*

on supernode 2 in 15, it already established the existence of $k-2$ (and not just one) other labels in supernode 1.

It is for this purpose that supernode 1 of any T^k graph, where $k > 2$, is *not* a single node but a T^{k-1} subgraph. This creates a situation whereby as long as there are $k-1$ or fewer labels in T^k, all labels enter and move around in supernode 1. Supernode 2 can be chosen in $L_y^{[b+2]}$ only if $k-1$ labels were established by it as being in supernode 1 (i.e., supernode 1 is full). Since supernode 2 is a "bridge" that some process must "cross" (choose) before any process can move into the cycle, the above reasoning for z holds in case it read $\ell_y^{[b+2]} \in \{152, 153, 154, 155\}$.

Although the above invariants hold, it follows from Example 4.3 that the property that the chosen new label is greater than all those read, true for sequential labeling operation executions, does not hold in the concurrent case. Fortunately, there is a similar property that does hold, a property that will prove important in the implementation of the scan. Recall that $read(L_y^{[b]})$ denotes the set of label values read in the collect of $L_y^{[b]}$. Let us define the following *observed* relation among labeling operation executions to be the transitive closure of the *read* relation.

DEFINITION 4.1. *A labeling operation execution* $L_x^{[a]}$ *is* observed *by* $L_y^{[b]}$ (*denoted* $L_x^{[a]} \xrightarrow{\text{obs}} L_y^{[b]}$) *if* $\ell_x^{[a]} \in read(L_y^{[b]})$ *or there exists an* $L_z^{[c]}$ *such that* $\ell_z^{[c]} \in read(L_y^{[b]})$ *and* $L_x^{[a]} \xrightarrow{\text{obs}} L_z^{[c]}$.

DEFINITION 4.2. *Let the* maximal observed *set* $max\_obs(L_x^{[a]})$ *be defined as*

$$\{L_y^{[b]} \mid y \in \{1..n\},\ y \neq x,\ L_y^{[b]} \xrightarrow{\text{obs}} L_x^{[a]} \text{ and}$$
$$(\forall L_y^{[b']})\ (\text{if } L_y^{[b]} \longrightarrow L_y^{[b']}, \text{ then } L_y^{[b']} \not\xrightarrow{\text{obs}} L_x^{[a]})\}.$$

It thus consists of the "latest" of labeling operation executions observed for each process. In a concurrent execution, instead of invariant (3) stating that the new label chosen is greater than all the labels read, it is the case that

$$(\forall \ell_y^{[b]} \in max\_obs(L_x^{[a]}))\,(\ell_y^{[b]} \not\prec \ell_x^{[a]}). \tag{3'}$$

The new label chosen is greater than the latest of those observed for each process. As shown in Figure 9, for the labeling $L_z^{[c+1]}$ of Example 4.3, although z read $\ell_x^{[a]} = 143$ and $\ell_z^{[c+1]} \not\prec \ell_x^{[a]}$, it is the case that its maximal observed label is $\ell_x^{[a+1]}$, and $\ell_x^{[a+1]} \not\prec \ell_z^{[c+1]}$.

Finally, the following is the irreflexive total order $\Longrightarrow$ on the labeling operation executions as required by property P1.

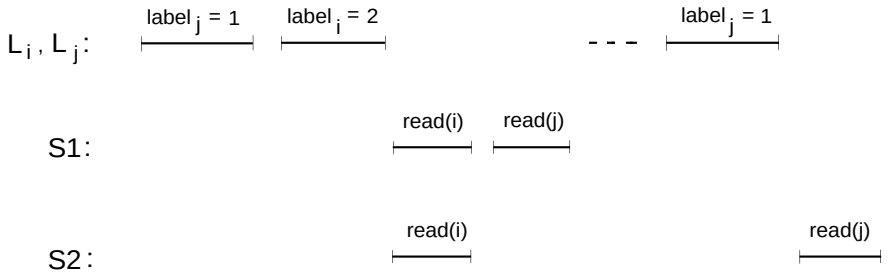

FIG. 10. *Ambiguity given bounded labels.*

DEFINITION 4.3. *Given any two distinct labeling operation executions* $L_x^{[a]}$ *and* $L_y^{[b]}$, $L_x^{[a]} \Longrightarrow L_y^{[b]}$ *if either*

1. $L_x^{[a]} \xrightarrow{\text{obs}} L_y^{[b]}$ *or*
2. $L_x^{[a]} \not\xrightarrow{\text{obs}} L_y^{[b]}$, $L_y^{[b]} \not\xrightarrow{\text{obs}} L_x^{[a]}$, *and* $\ell_x^{[a]} \precdot \ell_y^{[b]}$.

Since with every $L_x^{[a]}$ there is an associated label $\ell_x^{[a]}$, $\Longrightarrow$ can be seen as a "lexicographical" order on pairs $(L_x^{[a]}, \ell_x^{[a]})$. The first element in the pair is ordered by $\xrightarrow{\text{obs}}$, a partial order that is consistent with the ordering $\longrightarrow$. (If $L_x^{[a]} \longrightarrow L_y^{[b]}$, then in $L_y^{[b]}$, y read $\ell_x^{[a]}$ or a later label.) The second element is ordered by $\precdot$, an irreflexive and antisymmetric relation. Parts of the rather involved reasoning as to why the "static" relation $\precdot$ on the labels completes the "dynamic" partial order $\xrightarrow{\text{obs}}$ to a total order on all labeling operation executions are provided in section 5.9. The main difficulty is in establishing transitivity. The intuition as to why $\Longrightarrow$ is transitive is based on the fact that "at any point in time," the current labels of all processes are totally ordered, that is, no three labels are on three different supernodes of a cycle in any T^k subgraph. The reader is encouraged to try to bring about a scenario where there are three labeling operation executions such that

$$L_x^{[a]} \Longrightarrow L_y^{[b]} \Longrightarrow L_z^{[c]} \Longrightarrow L_x^{[a]}$$

while keeping in mind that $\xrightarrow{\text{obs}}$ is transitive. It will become clear that this requires that at some point in time, there will be three labels of x, y, and z on three different supernodes of a cycle in some T^k subgraph, a contradiction.

4.4. The scan operation. The scan operation returns a pair $(\bar{\ell}, \prec)$. In the scan operation of the unbounded label implementation, the linearization order among the labeling operation executions can be determined just by reading the labels since the order among any two operations is just the order among their associated labels. However, as Example 4.4 shows, if labels are taken from a bounded range (and therefore the same labels are repeatedly used), a process scanning the labels concurrently with ongoing labeling operations cannot deduce the order $\Longrightarrow$ from the order of the labels alone.

Example 4.4. In Figure 10, segments represent operation-execution intervals, where time runs from left to right. Two processes i and j perform labeling operations sequentially, j followed by i, followed by many labelings, until eventually the labels are used, and j, for example, uses the same label as before. A third process z performs a scan concurrently with the labelings, reading $label_i$ and then $label_j$. $S1$ and $S2$

represent possible executions of this same scan, the only difference being that many labeling operations of other processes occurred between the reads in $S2$. In both the case where the scan is of the form $S1$ and the case where it is of the form $S2$, the values collected are $label_i = 2$ and $label_j = 1$, where the order among the labels is, say, $1 < 2$. However, in the case of $S1$, j's labeling preceded i's, while in $S2$, i's labeling preceded j's. Thus the order of the labels is not the order among the labeling operations. □

However, we do wish to provide the exact form of solution as in the unbounded case, where just by reading the labels, the scanning process can return a set of labels and the order among them. From Example 4.4, it should be clear that the order $\prec$ returned by the scan cannot be the order $\Longrightarrow$ among the associated labels of labeled-values in $\bar{\ell}$. Nevertheless, the requirement of property P1b is that $\prec$ be consistent with $\Longrightarrow$ for the set of labeling operation executions of labeled-values in $\bar{\ell}$. The key to the solution is to perform many collections of labels and then, based on the properties proven in what follows, return n of them for which $\prec$ can be determined.

The scan algorithm thus consists of two main steps, a sequence of $8n \log n$ *collect* operations[10] and an analysis phase of the collected labels to select a set $\bar{\ell}$ and an order $\prec$.

The $8n \log n$ *collect* operations are logically divided into n phases, where each phase consists of $\log n$ levels, each of eight collects. We use the notation $\ell^{c,m,k}, c \in \{1..8\}$, $m \in \{1..\lceil \log n \rceil\}$, and $k \in \{1..n\}$, to denote variables, each holding a set of labels $\{\ell_1^{c,m,k}, \ldots, \ell_n^{c,m,k}\}$ collected in the cth *collect* operation execution of the mth *level* of the kth *phase*. Let $half(r)$ and $other\_half(r)$ be complementary functions that, for a given set r, return two disjoint subsets $r1$ and $r2$ such that $r1 \cup r2 = r$ and $-1 \leq ||r1|| - ||r2|| \leq 1$.

The scan algorithm, presented in Figure 11, returns the indexed set of labeled-values $\bar{\ell}$, one of each process, and an ordering $\prec$ on their indexes. This order is represented by the vector $O[1..n]$, holding a *permutation* of the indexes in $\{1..n\}$, the number in the ith position representing the ith largest element in the order. The scan algorithm begins with a sequence of $8n\lceil \log n \rceil$ collect operation executions, for which the returned labels are all saved in the variables $\ell^{c,m,k}, c \in \{1..8\}$, $m \in \{1..\lceil \log n \rceil\}$, and $k \in \{1..n\}$. The remainder of the algorithm defines how to choose n of these labels, one per process, for which $\prec$ (i.e., $\Longrightarrow$) can be established. The following is an outline of how this selection process is performed. A formal proof of its correctness can be found in section 5.

By the order of label collection, the labels read in phase $k = 1$ are the earliest to have been collected and those for $k = n$ the last. Notice that from the $8\lceil \log n \rceil$ collected label sets of each phase, the algorithm selects one label. The selected label in the kth phase will be the k largest in the order $\prec$. As it turns out, in order to be able to show that it is the kth largest, it suffices that the following condition holds (slightly abusing notation in the definition).

Condition 1. For the label $\ell_s^{8,\lceil \log n \rceil,k}$, collected in the $\lceil \log n \rceil$th level of the kth phase, and any label $\ell_y^{8,1,k}$ of a process $y \in R$, collected in the first level of the kth phase, it is the case that $L_y^{8,1,k} \Longrightarrow L_s^{8,\lceil \log n \rceil,k}$.

To prove that this condition suffices, let it be shown that if it is maintained, the labeling operation execution of a label returned in a phase $k' < k$ precedes (in the

[10] Note that, as mentioned in section 1, the *scan* algorithm requires a scanning process *only to read* other's labels and does not require it to write.

```

FIG. 11. *The scan algorithm.*

ordering $\Longrightarrow$) that of the label returned in phase k. The following shows that this is the case for the labels $\ell_x^{8,\lceil \log n\rceil,k}$, $\ell_y^{8,\lceil \log n\rceil,k-1}$, and $\ell_z^{8,\lceil \log n\rceil,k-2}$ returned in phases k, $k-1$, and $k-2$, respectively. The same line of proof can be extended inductively to all $k' < k$.

By Condition 1, $L_y^{8,1,k} \Longrightarrow L_x^{8,\lceil \log n\rceil,k}$. Since the read of $\ell_y^{8,1,k}$ was performed after that of $\ell_y^{8,\lceil \log n\rceil,k-1}$, either the label of the same labeling operation execution was read in both cases or $L_y^{8,\lceil \log n\rceil,k-1} \Longrightarrow L_x^{8,\lceil \log n\rceil,k}$. By similar reasoning, $L_z^{8,\lceil \log n\rceil,k-2} \Longrightarrow L_y^{8,\lceil \log n\rceil,k-1}$, which by the transitivity of $\Longrightarrow$ establishes $L_z^{8,\lceil \log n\rceil,k-2} \Longrightarrow L_x^{8,\lceil \log n\rceil,k}$.

It remains to be shown that the label returned in any phase, determined by the *select* function, meets Condition 1. The *select* function is a recursively defined "winner-take-all"-type algorithm among the processes in R. In any given phase, R is the set of processes for which a label has not been selected in earlier phases. The *select* function returns the id of the "winner," a process s that meets Condition 1. At any level m of the application of $select(m, k, r)$, the winners of the selections at level $m-1$ are paired up, and from each pair one "winner" process is selected to be passed

on to the $(m+1)$th level of selection. After at most $\lceil \log ||R|| \rceil$ levels, s, the winner of all selections, is returned.

Based on the definition of the *select* function, maintaining the following condition two suffices to assure that the label of the process s returned by $select(m, k, r)$ meets Condition 1.

Condition 2. Of the two processes x and y in the application of *select* at level m of phase k, the one returned, say x, is such that $L_y^{1,m,k} \Longrightarrow L_x^{8,m,k}$, where $\ell_y^{1,m,k}$ and $\ell_x^{8,m,k}$, respectively, are the labels associated with these labeling operation executions.

Maintaining Condition 2 suffices for the following reason. If at level m process x was selected between x and y and at level $m-1$ process y was selected between y and z, by the same line of proof as above, from $L_y^{1,m,k} \Longrightarrow L_x^{8,m,k}$ and $L_z^{1,m-1,k} \Longrightarrow L_y^{8,m-1,k}$, it follows that $L_z^{8,m-2,k} \Longrightarrow L_x^{8,m,k}$. By induction, this implies Condition 1.

It remains to be shown that Condition 2 can be met. Recall Example 4.4, which implies that it is impossible to establish the order $\Longrightarrow$ among two labeling operation executions from the order among their associated labels alone. To overcome this problem, instead of attempting to decide the order between two given labeling operation executions, the algorithm will choose a pair out of several given labeling operation executions for which the order $\Longrightarrow$ can be determined. Thus to allow the *select* operation at level m of phase k to choose a "winner" process, say x, for which $L_y^{1,m,k} \Longrightarrow L_x^{8,m,k}$, labels of x and y from eight consecutive collects will be analyzed.

Let it first be shown that if the following condition holds for y, namely, if it is the case that

$$[Condition\ 3.] \qquad (\exists c1, c2 \in \{1..8\})\,(c1 < c2) \wedge (\ell_x^{c1,m,k} \not\preceq \ell_y^{c2,m,k}),$$

then $L_x^{c1,m,k} \Longrightarrow L_y^{c2,m,k}$. (Because of the order of label collecting, this will imply $L_x^{1,m,k} \Longrightarrow L_y^{8,m,k}$.) Assume by way of contradiction that $L_x^{c1,m,k} \Longrightarrow L_y^{c2,m,k}$. Since $\ell_x^{c1,m,k} \not\preceq \ell_y^{c2,m,k}$, it must be by the definition of $\Longrightarrow$ that $L_y^{c2,m,k} \xrightarrow{obs} L_x^{c1,m,k}$. It cannot be that $\ell_y^{c2,m,k} \in max\_obs(L_x^{c1,m,k})$ since by the properties of the labeling scheme, for the label $\ell_y^{[b]} \in max\_obs(L_x^{c1,m,k})$, $\ell_y^{[b]} \not\preceq \ell_x^{c1,m,k}$. Thus there must be a different labeling operation execution $\ell_y^{[b]} \in max\_obs(L_x^{c1,m,k})$, $L_y^{c2,m,k} \longrightarrow L_y^{[b]}$. This label $\ell_y^{[b]}$ was already observed (i.e., must have been written) before the end of the read of $\ell_x^{c1,m,k}$. Thus $\ell_y^{[b]}$ or a label later than it must have been read instead of $\ell_y^{c2,m,k}$ in the *collect* $c2$ of level m in phase k, a contradiction.

It remains to be shown that if Condition 3 does not hold for y, it is the case that $L_y^{1,m,k} \Longrightarrow L_x^{8,m,k}$, and x can be correctly returned. Assume by way of contradiction that Condition 3 does not hold for y. By the same arguments as above, it cannot be that Condition 3 holds for x, that is, $(\exists c1, c2 \in \{1..8\})\ (c1 < c2) \wedge (\ell_y^{c1,m,k} \not\preceq \ell_x^{c2,m,k})$. Therefore, it must be that there are four nonconsecutive collects of $\ell^{\,c1,m,k}$, $c1 \in \{1,3,5,7\}$, and four nonconsecutive collects of $\ell^{\,c2,m,k}$, $c2 \in \{2,4,6,8\}$, such that the labels $\ell_y^{c1,m,k}$, $c1 \in \{1,3,5,7\}$, are all different from one another and the labels $\ell_x^{c2,m,k}$, $c2 \in \{2,4,6,8\}$, are all different from one another. The reason is that if any two of them, say $\ell_y^{3,m,k}$ and $\ell_y^{5,m,k}$, are the same, then in order for Condition 3 not to hold for x $c1 = 4$ and $c2 = 3$, it must be that $\ell_x^{4,m,k} \not\preceq \ell_y^{3,m,k}$. However, since $\ell_y^{3,m,k}$ and $\ell_y^{5,m,k}$ are the same, it would follow that $\ell_x^{4,m,k} \not\preceq \ell_y^{5,m,k}$, and Condition 3 would hold for y, a contradiction.

To complete the proof, it remains to be shown that if the labels $\ell_y^{c1,m,k}$, $c1 \in \{1,3,5,7\}$, are all different from one another and the labels $\ell_x^{c2,m,k}$, $c2 \in \{2,4,6,8\}$,

are all different from one another, then $L_y^{1,m,k} \Longrightarrow L_x^{8,m,k}$. The situation above is such that during the eight collect operations, each of the processes x and y executed a new labeling operation at least three times. It can be formally shown[11] that after x and y moved at least three times, the third new labeling operation execution $L_x^{8,m,k}$ occurred completely after the initial labeling of y, that is, after $L_y^{1,m,k} \longrightarrow L_x^{8,m,k}$ (see Figure 13 in section 5.8). The scan thus takes $O(n^2 \log n)$ read operations.

As a final comment, note that for algorithms where only the maximum label is required and not a complete order among all returned labels (as in the construction of an MRMW atomic register or solutions to the *mutual exclusion* problem), only one phase of label collection is required, that is, only $8 \log n$ collects.[12]

5. Correctness proof.

5.1. A short review of Lamport's formal theory. This is a minimal outline (due to Ben-David [Ben88]) of Lamport's formalism, on which the correctness proof in this chapter is based. The reader is encouraged to consult [Lam86c, Lam86d, Lam86a, Lam86b] for an elaborate presentation and discussion.

Lamport bases his formal theory on two abstract relations over operation executions. For operation executions A and B, "$A \longrightarrow B$" stands for "A precedes B" and "$A \dashrightarrow B$" stands for "A can causally affect B."

A *system execution* is a triple $\langle \varphi, \longrightarrow, \dashrightarrow \rangle$, where φ is a set of *operation executions* and $\longrightarrow$ and $\dashrightarrow$ are binary relations over φ. Lamport offers the following axioms:

A1. $\longrightarrow$ is an irreflexive transitive relation.

A2. If $A \longrightarrow B$, then $A \dashrightarrow B$ and $B \not\dashrightarrow A$.

A3. If ($A \longrightarrow B$ and $B \dashrightarrow C$) or ($A \dashrightarrow B$ and $B \longrightarrow C$), then $A \dashrightarrow C$.

A4. If $A \longrightarrow B \dashrightarrow C \longrightarrow D$, then $A \longrightarrow D$.

A5. For any A, the set of B such that $A \not\longrightarrow B$ is finite.

An intuition for these axioms can be gained by considering the following model for it. Let $\mathcal{E}$ be a partially ordered set of events and let φ be a collection of nonempty subsets of $\mathcal{E}$. For A and B in φ, define $A \longrightarrow B$ if and only if $(\forall a \in A)\ (\forall b \in B)\ (a < b)$ (in the sense of $\mathcal{E}$) and $A \dashrightarrow B$ if and only if $(\exists a \in A)\ (\exists b \in B)\ (a < b)$. A straightforward checking shows that such models satisfy axioms A1–A4 and also the following axiom:

A4*. If $A \dashrightarrow B \longrightarrow C \dashrightarrow D$, then $A \dashrightarrow D$.

This last axiom was suggested by Abraham[13] in [AB87], where a completeness theorem was proven for the above-mentioned class of models with respect to axioms {A1, A2, A3, A4, A4*}. An important class of models is obtained when $\mathcal{E}$ is a linear (total) ordering. In such a case, the system satisfies an additional axiom:

Global time. For all A and B, it is the case that either $A \dashrightarrow B$ or $B \longrightarrow A$ but not both.

The above axioms can be extended to nonterminating operation executions as described in [Lam86c]. Added on top of these axioms are the communication axioms, in our case axioms B0–B5 of [Lam86d], for communication via shared registers. These axioms formalize the behavior of a single-writer multireader atomic register. In a few words, axioms B0–B4 define what constitutes *regular* register behavior, namely, that reads can return only values that

[11] This claim is *not* true if fewer than three new labelings took place.

[12] The number of collects in each phase can be lowered to $5 \log n$ if one gives up the property that the order of reads in a collect be arbitrary.

[13] Ben-David was later informed that this result was obtained independently by Anger.

- were actually written,
- were written before the end of the read, and
- were not overwritten before the beginning of read.

Axiom B5 is added to these, which restricts the allowed behavior of the register by requiring that reads and writes be linearizable. Such a register that abides by axioms B0–B5 is called *atomic* since, in effect, its behavior is equivalent to one in which all reads and writes are "atomic," that is, occur in nonoverlapping intervals of time.

5.2. Proof outline. The proof will follow Definition 8 of [Lam86a], namely, that a system **S** *implements* a system **H** if there is a mapping $m : \mathbf{S} \mapsto \mathbf{H}$ such that for every system execution $\langle \varphi, \longrightarrow, \dashrightarrow \rangle$ in **S**, $\langle \varphi, \longrightarrow, \dashrightarrow \rangle$ implements $m(\langle \varphi, \longrightarrow, \dashrightarrow \rangle)$. The definition of a system execution used in what follows is that of [Lam86a] under the assumption of global time. Theorem 5.1 below establishes the correctness of the implementation.

THEOREM 5.1. *The system defined by the labeling and scan procedures implements a concurrent time-stamp system.*

In order to prove the theorem correct, the systems involved need to be formally defined and a mapping between them must be established.

5.3. System definitions. The labeling and scan procedures of the previous sections define a system **S**, the set of all system executions that consist of reads and writes of the single-writer multireader atomic registers $v_1, \ldots, v_n$, such that the only operations on these registers are the ones indicated by the scan and labeling algorithms. Formally, **S** contains all system executions $\langle \varphi, \longrightarrow, \dashrightarrow \rangle$ such that we have the following:

1. φ consists of reads and writes of single-writer multireader atomic registers $v_1, \ldots, v_n$ (with register axioms B0–B5 restricting such read and write operations [Lam86b]).

2. Each v_x is written by process x and read by all processes in $\{1..n\}$, where $r_x^{[k]}(y)$ ($w_x^{[k]}(x)$) denote the kth read (respectively, write) of v_x by process y (respectively, x).

3. The read and write operation executions of a process x are totally ordered by $\longrightarrow$.

4. For any process z and any x and y:

(a) If the read operation $r_x^{[k]}(z)$ occurs, then $r_y^{[k]}(z)$ occurs, $r_x^{[k-1]}(z) \longrightarrow r_y^{[k]}(z)$, and if for some $w_z^{[k']}(z)$, $r_x^{[k]}(z) \longrightarrow w_z^{[k']}(z)$, then $r_y^{[k]}(z) \longrightarrow w_z^{[k']}(z)$.

(b) For any two writes $w_z^{[k]}(z)$ and $w_z^{[k+1]}(z)$, there exists a set of read operation executions

$$\mathcal{R}_{k+1} = \{r_x^{[\alpha]}(z) \,|\, w_z^{[k]}(z) \longrightarrow r_x^{[\alpha]}(z) \longrightarrow w_z^{[k+1]}(z),\ \alpha \in \{0, 1, \ldots\}\},$$

of reads of v_x such that $||\mathcal{R}_{k+1}|| \bmod (8n\lceil \log n \rceil) = 1$.

(c) For every $r_x^{[k]}(z)$, $r_x^{[k]}(z) \in \mathcal{R}_r$, for some r.

This fourth condition formalizes some of the semantics of labeling and scan procedures. It states that every read is part of a *collect* operation consisting of a sequence of reads, one of each register, each collection ending before the next begins, and that reads and writes are bunched in groups of either $8n \log n$ collects or a collect followed immediately by a write.

The following is a formal definition of **H**, a concurrent time-stamp system.

DEFINITION 5.1. *A* concurrent time-stamp system *is a set of system executions* $\langle \psi, \longrightarrow, \dashrightarrow \rangle$ *that have properties* P0–P4.

Properties P1–P4 are as defined earlier, and the following is the definition of P0.

P0. The set of operation executions on the CTSS is the set $\psi = \bigcup_i \psi_i$, where each ψ_i, the set of operation executions by process i, is as follows:

- *A finite or infinite set of labeling operation executions* $\{L_i^{[1]}, L_i^{[2]}, \ldots\}$: A unique *labeled-value* $\ell_i^{[k]}$ is associated with each $L_i^{[k]}$. The set of possible labeled-values can be from any range. For example, if an atomic register is to be implemented, the labeled-value can be the value written to the register. Given that the value $\ell_i^{[k]}$ may repeatedly appear, in order that a unique labeled-value be associated with each $L_i^{[k]}$, let $\ell_i^{[k]}$ be the triplet $\langle \ell_i^{[k]}, i, k\rangle$, where i and k are dummy fields and only $\ell_i^{[k]}$ is visible to the user. There is thus a one-to-one mapping from labeled-values to labeling operations.
- *A finite or infinite set of scan operation executions* $\{S_i^{[1]}, S_i^{[2]}, \ldots\}$: A *view* $\bar{\ell} = \{\ell_1^{[k_1]}, \ldots, \ell_n^{[k_n]}\}$ is returned by each scan, with different labeled-values associated with labeling operation executions of different processes.
- *An initial labeling operation execution* $L_i^{[0]}$ *with labeled-value* $\ell_i^{[0]}$.

The initial labeling $L_i^{[0]} \longrightarrow S_j^{[k]}$ for any i, j, and k. (This is the same as assuming that there is some initial labeled-value for any process i that a scan will obtain if it preceded any labeling operation of i.) All operation executions in ψ_i are totally ordered by $\longrightarrow$, that is, they occur sequentially.

5.4. The mapping. By Definition 8 of [Lam86a], to show that the labeling and scan procedures implement a CTSS, a mapping m from **S** to **H** must be defined. In the definition of the labeling and scan procedures, for each system execution $\langle \varphi, \longrightarrow, \dashrightarrow\rangle$ of **S**, the set of operation executions $m(\varphi)$ of $m(\langle \varphi, \longrightarrow, \dashrightarrow\rangle)$ is the following *higher-level view* of $\langle \varphi, \longrightarrow, \dashrightarrow\rangle$:

1. Each *labeling* operation execution $L_i^{[k]}$ consists of a set $r_1^{[k']}(i), \ldots, r_n^{[k']}(i)$ of reads followed by a write $w_i^{[k]}(i)$, where $k' = \max\{\alpha \mid r_j^{[\alpha]}(i) \longrightarrow w_i^{[k]}(i)\}$.
2. Each *scan* operation execution by process i is a set of reads

$$\{r_j^{[\alpha]}(i) \mid j = 1..n,\ \alpha = k..k + 8n\lceil \log n\rceil \text{ and}$$
$$(\neg\exists w_i^{[k']}(i),\ r_j^{[\alpha]}(i) \longrightarrow w_i^{[k']}(i) \longrightarrow r_j^{[\alpha+1]}(i))\},$$

all in φ and no element of which is part of another *scan* or *labeling*.

The set $m(\varphi)$ meets conditions H1 and H2 of Definition 4 of [Lam86a], that is, each of its elements is a finite and nonempty set of elements of φ and each element of φ belongs to a finite, nonzero number of elements of $m(\varphi)$. It is thus a higher-level view of φ. (In fact, this implies that the labeling and scan operations as implemented are wait-free since waiting means that a higher-level operation takes an infinite number of lower-level ones.) To complete the description of the mapping m, the precedence relations $\xrightarrow{H}$ and $\dashrightarrow^{H}$ must be defined so that $m(\langle \varphi, \longrightarrow, \dashrightarrow\rangle)$ is defined as $\langle m(\varphi), \xrightarrow{H}, \dashrightarrow^{H}\rangle$.

By choosing $\xrightarrow{H}$ and $\dashrightarrow^{H}$ to be the induced relations $\xrightarrow{*}$ and $\dashrightarrow^{*}$ as defined by equation 2 of [Lam86a] (by equation 2, choosing the induced precedence relations $\xrightarrow{*}$ and $\dashrightarrow^{*}$ for $\xrightarrow{H}$ and $\dashrightarrow^{H}$ simply means that the ordering among the higher-level *scan* and *labeling* operation executions is that of the reads and writes implementing them), axioms A1–A5 are met, implying that $\langle m(\varphi), \xrightarrow{H}, \dashrightarrow^{H}\rangle$ is indeed a system execution. Since condition H3 of Definition 5 of [Lam86a] is satisfied by the induced precedence

relations,[14] $\langle \varphi, \longrightarrow, \dashrightarrow \rangle$ implements $\langle m(\varphi), \xrightarrow{H}, \dashrightarrow^{H} \rangle$.

Having defined the system $\langle m(\varphi), \xrightarrow{H}, \dashrightarrow^{H} \rangle$, it remains to be shown that it is indeed a CTSS, that is, is in **H**. This amounts to showing that $\langle m(\varphi), \xrightarrow{*}, \dashrightarrow^{*} \rangle$ satisfies properties P0–P4.

5.5. Properties P0 and P2–P4. The proof that $\langle m(\varphi), \xrightarrow{*}, \dashrightarrow^{*} \rangle$ meets property P0 follows by applying equation 2 of [Lam86a] to $\langle \varphi, \longrightarrow, \dashrightarrow \rangle$ (again, this amounts to defining the high-level order among *scan* and *labeling* operation executions to be that among the reads and writes implementing them) and observing the following:

1. The labeled-value $\ell_i^{[k]}$ associated with each labeling operation $L_i^{[k]}$ is just the labeled-value part written to v_i by the write $w_i^{[k]}(i)$ of process i. (Recall that there is also a label part of v_i.)

2. Any labeled-value returned by a scan is the result of some write $w_i^{[k]}(i)$.

3. The initial labeling $L_i^{[0]}$ is the write of some initial labeled-value and label 11..1 to register v_i.

The proof that $\bar{\ell}$ and $\succ$ are a *view* and an *irreflexive total order* on its elements follows from the definition of the *scan procedure*. Since v_i, $i \in \{1..n\}$ are SWMR atomic registers, applying equation 2 of [Lam86a] together with register axioms B0–B5 to $\langle \varphi, \longrightarrow, \dashrightarrow \rangle$ yields the proof that $\langle m(\varphi), \xrightarrow{*}, \dashrightarrow^{*} \rangle$ satisfies properties P2, P3, and P4. The details are left to the reader.

To simplify the presentation, for the remainder of this section, we use the notation $\ell_i^{[k]}$ to denote the label part of the value written to register v_i in the labeling operation execution $L_i^{[k]}$. We will use the notation $value(\ell_i^{[k]})$ to refer to the labeled-value part.

5.6. Properties of the observed relation. As part of the notation used in what follows, $r_j(L_i^{[k]})$ and $w(L_i^{[k]})$ will denote, respectively, the reading of v_j and writing of v_i during a labeling operation execution $L_i^{[k]}$. Also, let $m(\varphi)^L \subseteq m(\varphi)$ denote the set of all labeling operation executions in $m(\varphi)$. To prove that $\langle m(\varphi), \xrightarrow{*}, \dashrightarrow^{*} \rangle$ meets property P1, the relation $\Longrightarrow$ on the labeling operation executions in $m(\varphi)$ should be shown to be an irreflexive total order. The definition of this relation (Definition 4.3) is based on that of the relation $\dashrightarrow^{obs}$ (Definition 4.1).

The following lemma establishes the properties of $\dashrightarrow^{obs}$, later used to establish the properties of $\Longrightarrow$.

LEMMA 5.1. *The relation $\dashrightarrow^{obs}$ is an irreflexive partial order on the labeling operation executions in $m(\varphi)$, such that for any two labeling operations $L_i^{[a]}$ and $L_j^{[b]}$, if $L_i^{[a]} \xrightarrow{*} L_j^{[b]}$, then $L_i^{[a]} \dashrightarrow^{obs} L_j^{[b]}$.*

Proof. Since $r_j(L_i^{[a]}) \longrightarrow w_i(L_i^{[a]})$ for any j, it follows that $\dashrightarrow^{obs}$ is irreflexive. The rest of the proof is based on the three claims below.

CLAIM 5.1.1 (transitive). *For any three labeling operation executions $L_i^{[a]}$, $L_j^{[b]}$, and $L_k^{[c]}$, if $L_i^{[a]} \dashrightarrow^{obs} L_j^{[b]} \dashrightarrow^{obs} L_k^{[c]}$, then $L_i^{[a]} \dashrightarrow^{obs} L_k^{[c]}$.*

Proof. The proof is by induction on the length of the minimal production sequence of the production of $L_j^{[b]} \dashrightarrow^{obs} L_k^{[c]}$. If $||L_j^{[b]} \dashrightarrow^{obs} L_k^{[c]}|| = 1$, then by definition $r_j(L_k^{[c]}) = \ell_j^{[b]}$ and $L_i^{[a]} \dashrightarrow^{obs} L_j^{[b]}$, which by the definition of $\dashrightarrow^{obs}$ implies that

[14] Definition 5 of [Lam86a] states that a lower-level system execution $\langle \varphi, \longrightarrow, \dashrightarrow \rangle$ implements a higher-level one $\langle \psi, \xrightarrow{H}, \dashrightarrow^{H} \rangle$ if ψ is a higher-level view of φ and condition H3 holds, that is, for any G, $H \in \psi$, if $G \xrightarrow{*} H$, then $G \xrightarrow{H} H$.

$L_i^{[a]} \overset{\text{obs}}{\dashrightarrow} L_k^{[c]}$. Assume that the induction hypothesis holds for every $r' < r$. Let $||L_j^{[b]} \overset{\text{obs}}{\dashrightarrow} L_k^{[c]}|| = r$. By definition, there exists an $L_j^{[b']}$ such that $L_i^{[a]} \overset{\text{obs}}{\dashrightarrow} L_j^{[b]} \overset{\text{obs}}{\dashrightarrow} L_j^{[b']}$, where $||L_j^{[b]} \overset{\text{obs}}{\dashrightarrow} L_j^{[b']}|| = r-1$ and $r_j(L_k^{[c]}) = \ell_j^{[b']}$. By the induction hypothesis, $L_i^{[a]} \overset{\text{obs}}{\dashrightarrow} L_j^{[b']}$, which by definition implies that $L_i^{[a]} \overset{\text{obs}}{\dashrightarrow} L_k^{[c]}$. □

COROLLARY 5.1. *If $L_i^{[a]} \overset{\text{obs}}{\dashrightarrow} L_j^{[b]}$, then there exists a read $r_i(L_\alpha^{[\beta]}) = \ell_i^{[a]}$ such that $w(L_i^{[a]}) \dashrightarrow r_i(L_\alpha^{[\beta]}) \longrightarrow w(L_j^{[b]})$ for some α and β (possibly $\alpha = j$ and $\beta = b$).*

Proof. The proof is by induction on the length of the minimal production of the observation sequence, as in the previous claim. If $||L_i^{[a]} \overset{\text{obs}}{\dashrightarrow} L_j^{[b]}|| = 1$, then by definition $\alpha = j$ and $\beta = b$. Assume that the induction hypothesis holds for every $r' < r$. By the minimality of the production sequence, there must exist an $L_\alpha^{[\beta]}$, $r_i(L_\alpha^{[\beta]}) = \ell_i^{[a]}$, such that $||L_\alpha^{[\beta]} \overset{\text{obs}}{\dashrightarrow} L_j^{[b]}|| = r-1$. By the induction hypothesis, there exist α' and β' such that

$$w(L_\alpha^{[\beta]}) \dashrightarrow r_\alpha(L_{\alpha'}^{[\beta']}) \longrightarrow w(L_j^{[b]}),$$

where possibly $\alpha' = j$ and $\beta' = b$. By the definition of the labeling operation, $r_i(L_\alpha^{[\beta]}) \longrightarrow w(L_\alpha^{[\beta]})$, and so

$$r_i(L_\alpha^{[\beta]}) \longrightarrow w(L_\alpha^{[\beta]}) \dashrightarrow r_\alpha(L_{\alpha'}^{[\beta']}) \longrightarrow w(L_j^{[b]}),$$

which by axiom A4 implies $r_i(L_\alpha^{[\beta]}) \longrightarrow w(L_j^{[b]})$. Since $r_i(L_\alpha^{[\beta]}) = \ell_i^{[a]}$, it follows by atomic register axiom B5 that $w(L_i^{[a]}) \dashrightarrow r_i(L_\alpha^{[\beta]}) \longrightarrow w(L_j^{[b]})$. □

CLAIM 5.1.2 (antisymmetric). *For any two distinct labeling operation executions $L_i^{[a]}$ and $L_j^{[b]}$, if $L_i^{[a]} \overset{\text{obs}}{\dashrightarrow} L_j^{[b]}$, then $L_j^{[b]} \overset{\text{obs}}{\not\dashrightarrow} L_i^{[a]}$.*

Proof. Assume by way of contradiction that $L_i^{[a]} \overset{\text{obs}}{\dashrightarrow} L_j^{[b]}$ and $L_j^{[b]} \overset{\text{obs}}{\dashrightarrow} L_i^{[a]}$. Thus by Corollary 5.1, for some α, β, γ, and δ (possibly $\alpha = j$, $\beta = b$, $\gamma = i$, or $\delta = a$),

$$w(L_i^{[a]}) \dashrightarrow r_i(L_\alpha^{[\beta]}) \longrightarrow w(L_j^{[b]}) \text{ and}$$
$$w(L_j^{[b]}) \dashrightarrow r_j(L_\gamma^{[\delta]}) \longrightarrow w(L_i^{[a]}).$$

Since this implies

$$w(L_i^{[a]}) \dashrightarrow r_i(L_\alpha^{[\beta]}) \longrightarrow w(L_j^{[b]}) \dashrightarrow r_j(L_\gamma^{[\delta]}),$$

by axiom A4*, $w(L_i^{[a]}) \dashrightarrow r_j(L_\gamma^{[\delta]})$. By $w(L_i^{[a]}) \dashrightarrow r_j(L_\gamma^{[\delta]})$ and $r_j(L_\gamma^{[\delta]}) \longrightarrow w(L_i^{[a]})$, a contradiction to the axiom of global time is derived. □

CLAIM 5.1.3 (consistent). *If $L_x^{[a]} \overset{*}{\longrightarrow} L_y^{[b]}$, then $L_x^{[a]} \overset{\text{obs}}{\dashrightarrow} L_y^{[b]}$.*

Proof. If $x = y$, then $r_x(L_y^{[a+1]}) = \ell_x^{[a]}$, and by induction, for $b > a$, $L_x^{[a]} \overset{\text{obs}}{\dashrightarrow} L_y^{[b]}$. If $x \neq y$, then by register axioms B0–B4, since $w(L_x^{[a]}) \longrightarrow r_x(L_y^{[b]})$, either $r_x(L_y^{[b]}) = \ell_x^{[a]}$ (implying $L_x^{[a]} \overset{\text{obs}}{\dashrightarrow} L_y^{[b]}$) or there exists an $L_x^{[a']}$, $L_x^{[a]} \overset{*}{\longrightarrow} L_x^{[a']}$, where $r_x(L_y^{[b]}) = \ell_x^{[a']}$, which by the transitivity of $\overset{\text{obs}}{\dashrightarrow}$ (Claim 5.1.1) implies $L_x^{[a]} \overset{\text{obs}}{\dashrightarrow} L_y^{[b]}$. This completes the proof of Lemma 5.1. □

The following lemma formalizes the property that whenever a new label $\ell_x^{[a]}$ is selected, it is greater (by the ordering $\not\prec$) then the latest label observed in $L_x^{[a]}$ for any process $y \neq x$.

LEMMA 5.2. *For any labeling operation execution $L_x^{[a]}$, it is the case that*

$$(\forall \ell_y^{[b]} \in max\_obs(L_x^{[a]}))\,(\ell_y^{[b]} \not\prec \ell_x^{[a]}).$$

To simplify the exposition, the the proof is differed to section 5.9, where it is joined with the proof of Claim 5.3.2.

5.7. Property P1a. The following lemma asserts that $\Longrightarrow$ meets part a of property P1.

LEMMA 5.3. *The relation $\Longrightarrow$ is an irreflexive total order on the labeling operation executions in $m(\varphi)$ such that for any two labeling operations $L_i^{[a]}$ and $L_j^{[b]}$, if $L_i^{[a]} \xrightarrow{*} L_j^{[b]}$, then $L_i^{[a]} \Longrightarrow L_j^{[b]}$.*

Proof. By Definition 4.3, the relation $\Longrightarrow$ is irreflexive and total, and is consistent with the ordering $\xrightarrow{*}$ among the labeling operation executions in $m(\varphi)$. The following two claims complete the proof by showing that it is also antisymmetric and transitive.

CLAIM 5.3.1 (antisymmetric). *For any two distinct labeling operation executions $L_i^{[a]}$ and $L_j^{[b]}$, if $L_i^{[a]} \Longrightarrow L_j^{[b]}$, then $L_i^{[a]} \not\Longleftarrow L_j^{[b]}$.*

Proof. Assume by way of contradiction that for two distinct labeling operation executions, $L_i^{[a]} \Longrightarrow L_j^{[b]}$ and $L_i^{[a]} \Longleftarrow L_j^{[b]}$. Since $\xrightarrow{obs}$ is antisymmetric, it is not the case that both $L_i^{[a]} \xrightarrow{obs} L_j^{[b]}$ and $L_j^{[b]} \xrightarrow{obs} L_i^{[a]}$ hold. Thus if $L_i^{[a]} \xrightarrow{obs} L_j^{[b]}$, $L_j^{[b]} \not\Longrightarrow L_i^{[a]}$ even if $\ell_j^{[b]} \not\prec \ell_i^{[a]}$, a contradiction. Thus it must be the case that $\ell_j^{[b]} \not\prec \ell_i^{[a]}$ and $\ell_i^{[a]} \not\prec \ell_j^{[b]}$, which contradicts the definition of the ordering $\not\prec$ of the labels. □

CLAIM 5.3.2 (transitive). *For any three labeling operation executions $L_i^{[a]}$, $L_j^{[b]}$, and $L_k^{[c]}$, $L_i^{[a]} \Longrightarrow L_j^{[b]} \Longrightarrow L_k^{[c]}$ implies $L_i^{[a]} \Longrightarrow L_k^{[c]}$.*

Due to its extreme length and to simplify the presentation, the proof is deferred to section 5.9.

This completes the proof of Lemma 5.3. □

5.8. Property P1b. It remains to be proven that $\langle m(\varphi), \xrightarrow{*}, \dashrightarrow^{*} \rangle$ meets part b of property P1, that is, for any scan operation execution $S_i^{[k]}$ that returns $(\bar{\ell}, \prec)$, where

$$value(\ell_x^{[a]}),\ value(\ell_y^{[b]}) \in \bar{\ell},$$

it is the case that $x \prec y$ if and only if $L_x^{[a]} \Longrightarrow L_y^{[b]}$. Since both $\prec$ and $\Longrightarrow$ are irreflexive total orders, it suffices to show the "only if" direction. By the definition of the scan implementation, the returned order $\prec$ among the indexes of labeled-values in $\bar{\ell}$ is just the ordering among the collection phases in which they were selected. Thus it suffices to prove that in any scan operation execution $S_i^{[k]}$ that returns $(\bar{\ell}, \prec)$, if $value(\ell_x^{[a]})$ was returned in phase k' and $value(\ell_y^{[b]})$ was returned in phase k, where $k' < k$, then $L_x^{[a]} \Longrightarrow L_y^{[b]}$. This is captured by the following lemma (slightly abusing notation).

LEMMA 5.4. *In any scan operation execution, for any i such that $O[i] < O[j]$, where $value(\ell_i^{8,\lceil \log n \rceil, O[i]}), value(\ell_j^{8,\lceil \log n \rceil, O[j]}) \in \bar{\ell}$, it is the case that $L_i^{8,\lceil \log n \rceil, O[i]} \Longrightarrow L_j^{8,\lceil \log n \rceil, O[j]}$.*

Proof. The general outline of the proof is as follows. Recall that a phase of the scan execution consists of $8 \log n$ collect operation executions, where each consecutive

eight of them are called a *level* in the phase. The "first" level is the earliest collected and the "$\log n$th" is the latest. The proof begins with Claim 5.4.1, which states that the relation between two labels in any two collects can be extended to the collects preceding and following them. Then in Claims 5.4.3, 5.4.4, and 5.4.5, it is shown that among the labels of any eight collects in a level of the scan, two labels can be chosen for which the order $\Longrightarrow$ is known. Based on Claim 5.4.1 and the transitivity of $\Longrightarrow$, the results of comparing labels of x and y in one level and y and z in a lower level are extended to relate those of x and z, allowing us to show (Claim 5.4.6) that for any k and R, if s is returned by $select(\lceil \log n \rceil, k, R)$, then $L_i^{1,1,k} \Longrightarrow L_s^{8,\lceil \log n \rceil,k}$ for all $i \in R - \{s\}$. Finally, transitivity is used again to prove Lemma 5.4, that is, that the results of different phases (*select* executions) are comparable and that the order $\Longrightarrow$ among the labels returned is the order of the phases.

To simplify the presentation, in what follows, indexes will be dropped when it is clear from the context what they should be. This will include the index of the process i performing the *scan* or *collect* operation. The notation C_w will denote $C_i^{[w]}$, the wth collect operation execution performed during a given scan. A label associated with $L_x^{[a]}$, read in any C_w, will be denoted by $\ell_{x,w}^{[a]}$ or ℓ_x^w, and the labeling operation execution $L_x^{[a]}$ itself will be similarly denoted by $L_{x,w}^{[a]}$ or L_x^w.

The following claim will be used to assert that the relation between two labels in any two collects can be extended to the collects preceding and following them. More specifically, this claim asserts that if the label of x is ordered before that of y, where x's label was collected in a collect C_{w+1}, earlier than C_{w+2} in which y's was collected, then any label of x collected in collect C_w that precedes collect C_{w+1} must be ordered before that of y and, similarly, any label of y from collect C_{w+3} must be ordered after that of x.

CLAIM 5.4.1. *If* $C_w \xrightarrow{*} C_{w+1} \xrightarrow{*} C_{w+2}$ (*or* $C_{w+1} \xrightarrow{*} C_{w+2} \xrightarrow{*} C_{w+3}$) *and if for some* $\ell_{x,w+1}^{[a]}$ *and* $\ell_{y,w+2}^{[b]}$, $L_x^{[a]} \Longrightarrow L_y^{[b]}$, *then for any* $\ell_{x,w}^{[c]}$ (*similarly,* $\ell_{y,w+3}^{[d]}$), *it is the case that* $L_x^{[c]} \Longrightarrow L_y^{[b]}$ (*similarly,* $L_x^{[a]} \Longrightarrow L_y^{[d]}$).

Proof. For any x, if $a \neq c$, that is, if they are of different labeling operations, then it must be the case that $L_x^{[c]} \xrightarrow{*} L_x^{[a]}$. The reason is that if this were not the case, then since $\ell_{x,w}^{[c]}$ was read in C_w and $L_x^{[a]} \xrightarrow{*} L_x^{[c]}$, by atomic register axiom B5, it could not be the case that $\ell_{x,w+1}^{[a]}$ was read in the later collect C_{w+1}, a contradiction. By Definition 4.3, it is thus the case that $L_x^{[c]} \Longrightarrow L_x^{[a]} \Longrightarrow L_y^{[b]}$, which by transitivity (Claim 5.3.2) implies $L_x^{[c]} \Longrightarrow L_y^{[b]}$. By a similar proof, $L_x^{[a]} \Longrightarrow L_y^{[d]}$. □

CLAIM 5.4.2. *For any eight collect operation executions of level* m *of phase* k *in a given scan operation execution, if the condition*

$$(\exists c1, c2 \in \{1..8\})\ (c1 < c2) \wedge (\ell_x^{c1,m,k} \overset{V}{\prec} \ell_y^{c2,m,k}),$$

holds, then $L_x^{1,m,k} \Longrightarrow L_y^{8,m,k}$, *and otherwise* $L_y^{1,m,k} \Longrightarrow L_x^{8,m,k}$.

Proof. The following claim (Claim 5.4.3) establishes that there are three complementary conditions (one of the three must always hold) on the labels in the eight collects:

1. There are a label of y and a label of x where the label of y was collected in a later collect than that in which x was collected and where the label of y is greater (by $\prec$) than the label of x.

2. This is the first condition with the roles of x and y reversed.

3. The labels of x and y have each changed at least three times during these eight collect operation executions.

The claims that follow show that if the first condition holds, $L_x^{1,m,k} \Longrightarrow L_y^{8,m,k}$, and if one of the other two holds, then $L_y^{1,m,k} \Longrightarrow L_x^{8,m,k}$. More formally, we have the following.

CLAIM 5.4.3. *For the* 16 *labels* $\ell_x^{c1,m,k}$ *and* $\ell_y^{c2,m,k}$, $c1, c2 \in \{1..8\}$, *collected in level* m *of phase* k *of a scan operation execution, one of the following three conditions must hold:*

1. $(\exists c1, c2 \in \{1..8\})\ (c1 < c2) \wedge (\ell_x^{c1,m,k} \not\prec \ell_y^{c2,m,k})$.
2. $(\exists c1, c2 \in \{1..8\})\ (c1 < c2) \wedge (\ell_y^{c1,m,k} \not\prec \ell_x^{c2,m,k})$.
3. *The four labels* $\ell_x^{2,m,k}$, $\ell_x^{4,m,k}$, $\ell_x^{6,m,k}$, *and* $\ell_x^{8,m,k}$ *differ from one another according to* $\prec$, *and the four labels* $\ell_y^{1,m,k}$, $\ell_y^{3,m,k}$, $\ell_y^{5,m,k}$, *and* $\ell_y^{7,m,k}$ *also differ from one another according to* $\prec$.

Proof. Let it be shown that if condition 3 does not hold, then either condition 1 or 2 holds. If condition 3 does not hold, then either

$$(\exists c1, c2 \in \{1..8\})\ (c1 + 1 < c2) \wedge (\ell_x^{c1,m,k} = \ell_x^{c2,m,k})$$

or

$$(\exists c1, c2 \in \{1..8\})\ (c1 + 1 < c2) \wedge (\ell_y^{c1,m,k} = \ell_y^{c2,m,k})$$

Note that labels of the same process can be the same, as denoted by the equivalence sign, though by definition those of different processes always differ by $\not\prec$. Without loss of generality, assume that the first condition holds. Then by definition, there must exist a label $\ell_y^{c,m,k}$, $c1 < c < c2$. If $\ell_x^{c1,m,k} \not\prec \ell_y^{c,m,k}$, then condition 1 holds and the claim is proven. Thus it must be the case that $\ell_y^{c,m,k} \not\prec \ell_x^{c1,m,k}$. However, since $\ell_x^{c1,m,k} = \ell_x^{c2,m,k}$, it is the case that $\ell_y^{c,m,k} \not\prec \ell_x^{c2,m,k}$, and condition 2 holds. ∎

By direct application of Claim 5.4.1, the following claim (Claim 5.4.4) implies that if condition 1 of Claim 5.4.3 holds, then $L_x^{1,m,k} \not\prec L_y^{8,m,k}$, and similarly, if condition 2 holds, then $L_y^{1,m,k} \not\prec L_x^{8,m,k}$. (This follows by exchanging the roles of x and y in Claim 5.4.4 below.)

CLAIM 5.4.4. *If* $\ell_x^{c1,m,k} \not\prec \ell_y^{c2,m,k}$, *then* $L_x^{c1,m,k} \Longrightarrow L_y^{c2,m,k}$.

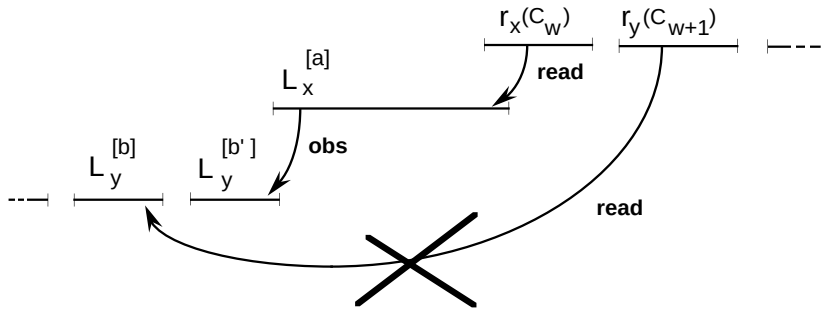

FIG. 12. *Greater and later implies precedence.*

Proof. For simplicity, let $(c1, m, k) = w$ (the label $\ell_x^{c1,m,k}$ read is $\ell_{x,w}^{[a]}$, that is, of labeling operation execution $L_x^{[a]}$) and $(c2, m, k) = w+1$ (similarly, $\ell_y^{c2,m,k}$ is $\ell_{y,w+1}^{[b]}$). The outline of the proof appears in Figure 12. Assume by way of contradiction that $\ell_{x,w}^{[a]} \not\prec \ell_{y,w+1}^{[b]}$ and $L_y^{[b]} \Longrightarrow L_x^{[a]}$. By Definition 4.3, it must be that $L_y^{[b]} \xrightarrow{\text{obs}} L_x^{[a]}$. By

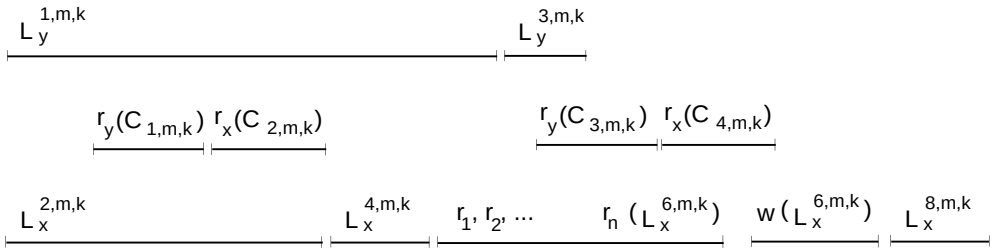

FIG. 13. *Three labeling "moves" are necessary.*

Lemma 5.2, it cannot be that $L_y^{[b]} \in max\_obs(L_x^{[a]})$. Thus there must exist an $L_y^{[b']}$, $b < b'$, such that $L_y^{[b']} \in max\_obs(L_x^{[a]})$. By Corollary 5.1, since $L_y^{[b']} \xrightarrow{obs} L_x^{[a]}$, there must exist some $r_y(L_\alpha^{[\beta]}) = \ell_y^{[b']}$ such that

$$w(L_y^{[b']}) \dashrightarrow r_y(L_\alpha^{[\beta]}) \longrightarrow w(L_x^{[a]}),$$

where possibly $\alpha = x$ and $\beta = a$. Since $r_y(C_{w+1}) = \ell_y^{[b]}$ and $r_y(L_\alpha^{[\beta]}) = \ell_y^{[b']}$, $b < b'$, by atomic register axiom B5, it must be that $r_y(C_{w+1}) \dashrightarrow r_y(L_\alpha^{[\beta]})$. Similarly, since $\ell_x^{[a]}$ was read in C_w, it must be by axiom B5 that $w(L_x^{[a]}) \dashrightarrow r_x(C_w)$. Thus

$$r_y(C_{w+1}) \dashrightarrow r_y(L_\alpha^{[\beta]}) \longrightarrow w(L_x^{[a]}) \dashrightarrow r_x(C_w),$$

which by axiom A4* of [AB87] implies that $r_y(C_{w+1}) \dashrightarrow r_x(C_w)$, a contradiction to $C_w \xrightarrow{*} C_{w+1}$. □

To complete the proof, it remains to be shown that if the first two conditions of Claim 5.4.3 do not hold (in which case the third one does), it is the case that $L_y^{1,m,k} \Longrightarrow L_x^{8,m,k}$. One can intuitively think of this claim as stating that if each of the processes x and y "moved" (chose a new label) three times, the original labeling operation of y—before the three new ones—must have been completely before the latest labeling operation of x and so precedes it by $\Longrightarrow$. The reason that one needs three "moves" to assure this property becomes clear from the proof. The example in Figure 13 shows why if fewer "moves" are made by each, the property does not hold.

CLAIM 5.4.5. *If the four labels $\ell_x^{2,m,k}$, $\ell_x^{4,m,k}$, $\ell_x^{6,m,k}$, and $\ell_x^{8,m,k}$ differ from one another according to $\prec$ and the four labels $\ell_y^{1,m,k}$, $\ell_y^{3,m,k}$, $\ell_y^{5,m,k}$, and $\ell_y^{7,m,k}$ also differ from one another according to $\prec$, then $L_y^{1,m,k} \Longrightarrow L_x^{8,m,k}$.*

Proof. By serialization axiom B5 of reads and writes from the atomic registers v_x and v_y, it must be the case that

$$L_y^{1,m,k} \xrightarrow{*} w(L_y^{3,m,k}) \dashrightarrow r_y(C_{3,m,k}) \longrightarrow r_x(C_{4,m,k}) \dashrightarrow w(L_x^{6,m,k}) \xrightarrow{*} L_x^{8,m,k}.$$

By applying axiom A4 twice, it follows that $L_y^{1,m,k} \xrightarrow{*} L_x^{8.m,k}$, which by Definition 4.3 implies that $L_y^{1,m,k} \Longrightarrow L_x^{8.m,k}$. □

This completes the proof of Claim 5.4.2. □

The following claim proves the correctness of the recursive procedure *select*.

CLAIM 5.4.6. *For any k and R, if s is returned by select$(\lceil \log n \rceil, k, R)$, then $L_i^{1,1,k} \Longrightarrow L_s^{8,\lceil \log n \rceil,k}$ for all $i \in R - \{s\}$.*

Proof. First, observe that for $||r||$, the size of the input set of $select(m, k, r)$, it follows by simple induction (given that initially $||r|| \leq n$) that $m \geq \lceil \log ||r|| \rceil$. The proof of the claim will thus be by induction on $||r|| \in \{1..\lceil R \rceil\}$.

For $||r|| = 1$, the claim follows vacuously. For $||r|| = 2$, since $m \geq \lceil \log ||r|| \rceil = 1$, the claim follows from Claim 5.4.2. Assume that the claim holds for $||r|| < t$, and let the claim be proven for $||r|| = t$. Since $||half(r)||, ||other\_half(r)|| \leq t/2$, by the induction hypothesis applied to $select(\lceil \log t \rceil - 1, k, half(r))$ and $select(\lceil \log t \rceil - 1, k, other\_half(r))$, it follows that

$$(\forall i \in half(r))\ (L_i^{1,1,k} \Longrightarrow L_x^{8,\lceil \log t \rceil - 1,k}) \quad \text{and}$$
$$(\forall i \in other\_half(r))\ (L_i^{1,1,k} \Longrightarrow L_y^{8,\lceil \log t \rceil - 1,k}).$$

By Claim 5.4.2, without loss of generality, it can be assumed that $L_y^{1,\lceil \log t \rceil,k} \Longrightarrow L_x^{8,\lceil \log t \rceil,k}$ in $select(\lceil \log t \rceil, k, r)$. Thus since $C_{8,\lceil \log t \rceil - 1,k} \xrightarrow{*} C_{1,\lceil \log t \rceil,k}$, by Claim 5.4.1 and the above,

$$L_i^{1,1,k} \Longrightarrow L_y^{8,\lceil \log t \rceil - 1,k} \Longrightarrow L_y^{1,\lceil \log t \rceil,k} \Longrightarrow L_x^{8,\lceil \log t \rceil,k}$$

for every $i \in other\_half(r)$. By transitivity (Claim 5.3.2), it is the case that $L_i^{1,1,k} \Longrightarrow L_x^{8,\lceil \log t \rceil,k}$ for every $i \in other\_half(r)$. Similarly, by Claim 5.4.1 and the above, given that $C_{8,\lceil \log t \rceil - 1,k} \xrightarrow{*} C_{1,\lceil \log t \rceil,k}$, it follows that

$$L_i^{1,1,k} \Longrightarrow L_x^{8,\lceil \log t \rceil - 1,k} \Longrightarrow L_x^{8,\lceil \log t \rceil,k}$$

for every $i \in half(r)$. Again by transitivity, it is the case that $L_i^{1,1,k} \Longrightarrow L_x^{8,\lceil \log t \rceil,k}$ for every $i \in half(r)$, and the claim follows. □

Based on the above claims, the proof can be completed by showing that in any scan operation execution, for any i such that $O[i] < O[j]$, where $value(\ell_i^{8,\lceil \log n \rceil,O[i]}), value(\ell_j^{8,\lceil \log n \rceil,O[j]}) \in \bar{\ell}$, it is the case that $L_i^{8,\lceil \log n \rceil,O[i]} \Longrightarrow L_j^{8,\lceil \log n \rceil,O[j]}$. The proof is by induction on k, where $O[i] := k$ in phase k of a scan operation execution. For $k = n$, since there exists no $k', k < k'$, there is no $O[i] < O[j]$, and the claim holds vacuously. Assume that for some $k < n$, the claim holds for all $k', k < k' \leq n$. Let it be proven for k.

Since $k < n$, there is an $O[\alpha] = k + 1$ for some $\alpha \in \{1..n\} - \{i\}$ (possibly $\alpha = j$), where $value(\ell_\alpha^{8,\lceil \log n \rceil,k+1}) \in \bar{\ell}$ of the scan operation execution, that is, the returned labeled-value for process α. By Claim 5.4.6,

$$L_i^{1,1,k+1} \Longrightarrow L_\alpha^{8,\lceil \log n \rceil,k+1}$$

for $i \in R$. By Claim 5.4.1, since $C_{8,\lceil \log n \rceil,k} \xrightarrow{*} C_{1,1,k+1}$, it is the case that

$$L_i^{8,\lceil \log n \rceil,k} \Longrightarrow L_\alpha^{8,\lceil \log n \rceil,k+1}.$$

If $\alpha = j$ the lemma follows. If not, by the induction hypothesis, it follows that for any $O[j]$, $k+1 < O[j]$,

$$L_i^{8,\lceil \log n \rceil,k} \Longrightarrow L_\alpha^{8,\lceil \log n \rceil,k+1} \Longrightarrow L_\alpha^{8,\lceil \log n \rceil,O[j]}.$$

By the transitivity of $\Longrightarrow$ (Claim 5.3.2), it then follows that $L_i^{8,\lceil \log n \rceil,O[i]} \Longrightarrow L_j^{8,\lceil \log n \rceil,O[j]}$. □

5.9. Proof of precedence and transitivity. To complete the proof of Theorem 5.1, it remains to be proven that Lemma 5.2 and Claim 5.3.2 hold.

5.9.1. Preliminaries. Given that the definitions of both the graph T^n and the labeling function $\mathcal{L}$ are inductive on k, the first two parts of the following definition simply define the notation to be used in relating labels. The third part is the notion of *inside*(X). X identifies a specific labeling operation execution. In this labeling operation execution, the label chosen was in a certain T^k subgraph on level k. X also identifies this T^k subgraph. The set of labeling operation executions in *inside* are those performed inside T^k from the latest time the process moved into T^k and up to its labeling operation execution X. The *min* is simply the earliest in a sequence of labeling operation executions. For example, *min*(*inside*(X)) is the first among the moves since the process performing X entered T^k.

DEFINITION 5.2. *For $k \in \{1..n\}$ and $\xrightarrow{*}$, the ordering on labeling operation execution, we have the following notation:*

- *Let $\ell_y^{[b]} \overset{k}{=} \ell_x^{[a]}$ denote that $\ell_y^{[b]}[n..k-1] = \ell_x^{[a]}[n..k-1]$ for $k \geq 2$.*
- *Let $\ell_y^{[b]} \overset{k}{\neq} \ell_x^{[a]}$ (similarly, $\ell_y^{[b]} \overset{k}{\prec} \ell_x^{[a]}$) denote that $\ell_y^{[b]}[n..k] \overset{k+1}{=} \ell_x^{[a]}[n..k]$ and $\ell_y^{[b]}[k-1] \neq \ell_x^{[a]}[k-1]$ (similarly, $\ell_y^{[b]}[k-1]$ is dominated by $\ell_x^{[a]}[k-1]$).*
- *Let inside$(\ell_x^{[a]}[n..k])$ be a set of operation executions*

$$\{L_x^{[\alpha]} \mid \alpha = \text{ a or } L_x^{[\alpha]} \xrightarrow{*} L_x^{[a]} \text{ and } \ell_x^{[\alpha]} \overset{k+1}{=} \ell_x^{[a]} \text{ and } (\forall L_x^{[a']})\ (\text{if } L_x^{[\alpha]} \xrightarrow{*} L_x^{[a']} \xrightarrow{*} L_x^{[a]}, \text{ then } \ell_x^{[a']} \overset{k+1}{=} \ell_x^{[a]})\}.$$

- *Let the min of a set of labeling operation executions totally ordered by $\xrightarrow{*}$ be the least element in the ordering.*

If $\ell_x^{[a-1]} \overset{k}{=} \ell_x^{[a]}$, $k = 2$ (the same label by the same process), then let the convention be that $\ell_x^{[a-1]} \overset{k}{\neq} \ell_x^{[a]}$, where $k = 1$ (and similarly for any two equal labels of different labelings by the same process).

5.9.2. The order of induction. The proof of Claim 5.3.2 and Lemma 5.2 will proceed by induction on the system execution $\langle m(\varphi)^L, \xrightarrow{*}, \dashrightarrow^{*} \rangle$ consisting of all labeling operation executions in $m(\varphi)^L$. (Recall that $m(\varphi)^L$ is the set of labeling operation executions in $m(\varphi)$.) The induction base will be the subexecution $m(\varphi)^{L'} = \{L_1^{[0]}, \ldots, L_n^{[0]}\}$ of $m(\varphi)^L$. The induction will proceed to larger subexecutions $m(\varphi)^{L'}$, where $m(\varphi)^{L'} \subseteq m(\varphi)^L$. The subexecution in each step of the induction will include one $L_i^{[a]} \in m(\varphi)^L$ more than its preceding one. The induction order on $\langle m(\varphi)^L, \xrightarrow{*}, \dashrightarrow^{*} \rangle$ is thus that $m(\varphi)^{L'} \cup \{L_i^{[a]}\}$ follows $m(\varphi)^{L'}$, where $L_i^{[a]} \in m(\varphi)^L - m(\varphi)^{L'}$, if for any $L_j^{[b]} \in m(\varphi)^L - m(\varphi)^{L'}$, it is the case that either

- $L_i^{[a]} \dashrightarrow^{\text{obs}} L_j^{[b]}$ or
- $L_j^{[b]} \not\dashrightarrow^{\text{obs}} L_i^{[a]}$ and for $\ell_i^{[a-1]} \overset{k}{\prec} \ell_i^{[a]}$ and $\ell_j^{[b-1]} \overset{k'}{\prec} \ell_j^{[b]}$, it is the case that $k' > k$ or that $k' = k$ and $j > i$.

The order is thus to add the labeling operation executions that observed a greater part of the execution later, and if no such labeling operation execution can be identified, settle on choosing the one that was a move (a change in the label) on the lowest-level k.

To see that the above defines a total order of induction, note that $\dashrightarrow^{\text{obs}}$ is a partial order, and if two labels are not related by $\dashrightarrow^{\text{obs}}$, they are ordered by the order $<$ on the level in the graph in which they made their last move and by the id if they have

the same level. Since $<$ together with the id forms a total order that is independent of the partial order $\xrightarrow{\text{obs}}$, the above order of induction is total.

5.9.3. The induction hypothesis. The induction hypothesis consists of I1 $\wedge$ I2 $\wedge$ I3 $\wedge$ I4, where I1–I4 are as follows:

I1. For any $L_y^{[b]} \in max\_obs(L_x^{[a]})$, it is the case that $\ell_y^{[b]} \not\preccurlyeq \ell_x^{[a]}$.

I2. The relation $\Longrightarrow$ is transitive.

I3. For any $L_x^{[a]}$ and $L_y^{[b]}$, where

- $\ell_y^{[b]}[k-1]$, $\ell_x^{[a]}[k-1] \in \{3,4,5\}$ and
- $\ell_y^{[b]} \overset{k}{\neq} \ell_x^{[a]}$, $k \geq 2$,

if there exist labeling operation executions $\ell_x^{[a-1]}$ and $\ell_y^{[b-1]}$, where

- $\ell_x^{[a-1]} \overset{k}{\neq} \ell_x^{[a]}$ and
- $\ell_y^{[b-1]} \overset{k}{\neq} \ell_y^{[b]}$,

then either $L_x^{[a]} \xrightarrow{\text{obs}} L_y^{[b]}$ or $L_y^{[b]} \xrightarrow{\text{obs}} L_x^{[a]}$.

I4. 1. If $\ell_x^{[a]}[k-1] \in \{2,3,4,5\}$, $k > 2$, then there are at least $k-1$ labels $L_y^{[b]} \in max\_obs(L_x^{[a]})$ such that $\ell_y^{[b]} \overset{k+1}{=} \ell_x^{[a]}$;

2. if there exists an $L_x^{[a1]} \in inside(\ell_x^{[a]}[n..k])$, $\ell_x^{[a1]}[k-1] \in \{4,5\}$ (possibly $a = a1$), then there are exactly $k-1$ labels $L_y^{[b]} \in max\_obs(L_x^{[a]})$ such that $\ell_y^{[b]} \overset{k+1}{=} \ell_x^{[a]}$ and $\ell_y^{[b]}[k-1] \in \{3,4,5\}$; and

3. if $\ell_x^{[a]} \not\preccurlyeq \ell_x^{[a-1]}$ ($\ell_x^{[a]}[k-1]$, $\ell_x^{[a-1]}[k-1] \in \{3,4,5\}$), then for any $L_y^{[b]} \in max\_obs(L_x^{[a]})$, where $\ell_y^{[b]} \overset{k+1}{\neq} \ell_x^{[a-1]}$ and $\ell_y^{[b]}[k-1] \in \{3,4,5\}$, it is the case that $\ell_x^{[a-1]} \not\preccurlyeq \ell_y^{[b]} \not\preccurlyeq \ell_x^{[a]}$.

The induction hypothesis includes four main parts. I1 and I2 are simply Lemma 5.2 and Claim 5.3.2, which are to be proven. However, the proof of these properties is based on several "structural" properties of the labeling operation executions, and these are added in order to strengthen the induction hypothesis.

Property I3 is a weak formulation for the case of any T^k subgraph, $k \geq 2$, of a powerful property that holds in the case of a T^2 subgraph. For $k = 2$, that is, two labels in the cycle of a T^2 subgraph, it is the case that

> among any two labeling operation executions in the cycle, there must be one that observed the other.

Unfortunately, this is not true for any pair of labeling operation executions in a cycle on level $k > 2$. For example, the reader can verify that it is possible that while one process x moves among supernodes 3 and 4 on level k, another process y can concurrently move many times inside supernode 3 (that is, on a level lower than k) with neither x nor y observing a labeling operation execution of the other. However, the property that does hold is that the process x must have observed at least one labeling operation execution by y among those that y executed since it last started choosing labels in supernode 3. (Thus the first move into 3 was definitely observed.) The generalization of this example is formalized by property I3 of the inductive hypothesis.

Property I4 is a collection of three properties that were informally mentioned in section 4.3:

- I4.1 is based on the fact that supernode 1 in any T^k subgraph is a sink in which at least $k-1$ labels must accumulate before a label may be placed on the bridge supernode 2. Because of this accumulation property, any process that performs a

labeling operation execution on supernodes $\{2,3,4,5\}$ must have maximally observed at least $k-1$ other labels in the subgraph with him. The maximally observed set of operations of a labeling operation execution $L_x^{[a]}$ ($max\_obs(L_x^{[a]})$) is actually the set of labeling operation executions whose labels, in a sequential execution, could have existed together with $L_x^{[a]}$ at some point in time. Thus I4.1 can be thought of as establishing that if a process completes a labeling operation execution on one of the supernodes $\{2,3,4,5\}$, there are at that point in time at least $k-1$ other labels in the subgraph with him.

• I4.2 is a continuation of the behavior described in I4.1. Again, given that the maximally observed set of operations of a labeling operation execution $L_x^{[a]}$ represents the set of labeling operation executions whose labels, in a sequential execution, could have existed together with $L_x^{[a]}$ at some point in time, I4.2 formalizes the "invariant" that

> at any given time, there cannot be more than k labels in a cycle of a T^k structure.

In addition, not only is it true that there are not more than k, but if any one of these k labels moves inside the cycle, it must maximally observe exactly $k-1$ other labels in the cycle with it.

• Finally, I4.3 strengthens I1 for the particular case in which the new label chosen is dominated by the older label (such as a move from supernode 3 to 5 in the cycle). Based on I1, it could still be that some of the labels maximally observed by the process, though dominated by the new label, are on node 5 together with it. I4.3 establishes that this cannot be the case, that is, all other labels maximally observed in the cycle must be on supernode 4. Property I1 together with I4.3 capture the the "invariant" that

> at any given time, there are never labels on three different nodes of a cycle of a T^k subgraph.

In the next two sections, the induction base and the inductive step are presented.

5.9.4. The induction base.

LEMMA 5.5. *The hypothesis* $\mathrm{I1} \wedge \mathrm{I2} \wedge \mathrm{I3} \wedge \mathrm{I4}$ *holds for* $m(\varphi)^{L'} = \{L_1^{[0]}, \ldots, L_n^{[0]}\}$.

Proof. By definition, initially $max\_obs(L_x^{[a]}) = \emptyset$, and I1 and I4 hold vacuously. Since for any $L_x^{[a]}$, $a = 0$, there does not by definition exist an $L_x^{[a-1]}$, I3 holds vacuously. Also, by definition, for any two labels $\ell_x^{[0]}$ and $\ell_y^{[0]}$, $\ell_x^{[0]} \overset{k1}{\neq} \ell_y^{[0]}$, where $k1 = 1$, and $L_x^{[0]} \overset{obs}{\not\longleftrightarrow} L_y^{[0]}$. Since $\overset{k1}{\prec}$ is a total order for level $k1 = 1$, it follows that $\Longrightarrow$ is transitive in $m(\varphi)^{L'}$. □

5.9.5. The induction step.

LEMMA 5.6. *Given that the induction hypothesis* $\mathrm{I1} \wedge \mathrm{I2} \wedge \mathrm{I3} \wedge \mathrm{I4}$ *holds for the system execution* $\langle m(\varphi)^{L'}, \overset{*}{\longrightarrow}, \overset{*}{\dashrightarrow} \rangle$, $m(\varphi)^{L'} \subseteq m(\varphi)^{L}$, *it holds also for* $\langle m(\varphi)^{L'} \cup \{L_x^{[a]}\}, \overset{*}{\longrightarrow}, \overset{*}{\dashrightarrow} \rangle$, *where* $L_i^{[a]} \in m(\varphi)^{L} - m(\varphi)^{L'}$ *is such that for any* $L_j^{[b]} \in m(\varphi)^{L} - m(\varphi)^{L'}$, *either*

• $L_i^{[a]} \overset{obs}{\dashrightarrow} L_j^{[b]}$ *or*

• $L_j^{[b]} \overset{obs}{\not\longleftrightarrow} L_i^{[a]}$ *and for* $\ell_i^{[a-1]} \overset{k}{\prec} \ell_i^{[a]}$ *and* $\ell_j^{[b-1]} \overset{k'}{\prec} \ell_j^{[b]}$, *it is the case that* $k' > k$ *or that* $k' = k$ *and* $j > i$.

The proof of Lemma 5.6 will be separated into several sections. In the following section, several lemmas that will become useful in later sections of the proof are

presented and proven. The proof will then proceed by showing that the *maximally observed* set of labeling operation executions by a process x is a good representation of the possible label values that other processes can have given the location of x. In other words, later unobserved labeling operation executions cannot be "far away" from the maximally observed labels, and could definitely not have "cycled around" the current location of x. Based on these established properties, I1, I4, I3, and finally I2 will be proven for the inductive case. The order of presentation of the different lemmas will follow the order of dependency among them.

We make a final important comment: Throughout the proof, unless specifically stated otherwise, $L_x^{[a]}$ will denote the labeling operation execution added in the induction step to form $\langle m(\varphi)^{L'} \cup \{L_x^{[a]}\}, \xrightarrow{*}, \dashrightarrow^{*} \rangle$,

5.9.6. At most k labels in the cycle of a T^k subgraph. In this section, several lemmas are presented, proving a lemma that captures the informal invariant that at any point in time, there can be at most k different labels in the cycle of a T^k subgraph (supernodes $\{3,4,5\}$. The following lemma formalizes the notion that "before it can choose a label in the cycle of any T^k subgraph, a process must first raise a flag, that is, choose a label on supernodes 1 or 2 on level k in T^k."

LEMMA 5.7. *For any labeling operation execution $L_x^{[a]}$, if $\ell_x^{[a]}[k-1] \in \{3,4,5\}$, $k \geq 2$, then there exists an $L_x^{[a1]} \in inside(\ell_x^{[a]}[n..k])$ such that $L_x^{[a1]}[k-1] \in \{1,2\}$.*

Proof. Assume by way of contradiction that the claim does not hold. It must thus be that for $L_x^{[a2]} = min(inside(\ell_x^{[a]}[n..k]))$, $\ell_x^{[a2]}[k-1] \in \{3,4,5\}$. This implies that there is a labeling operation execution $\ell_x^{[a2-1]} \overset{k+1}{\neq} \ell_x^{[a2]}$. By the definition of $\mathcal{L}$, in order for $\ell_x^{[a2]}[k-1]$ to be in $\{3,4,5\}$, it must be that for $\ell_{\max}$, the maximal label in the dominating set read by $L_x^{[a2]}$, we have the following:

- $\ell_{\max} \overset{k+1}{=} \ell_x^{[a2]}$ (as a reminder, this means $\ell_{\max}[n..k] = \ell_x^{[a2]}[n..k]$),
- $\ell_{\max}[k-1] \in \{2,3,4,5\}$, and
- $\mathcal{L}^k(G)$ (the kth level of the recursion in $\mathcal{L}$) was executed for $G = \ell_{\max}[n..k]$ and returned the value $\ell_x^{[a2]}[k-1] = 3$ (as in line 3) or $\ell_x^{[a2]}[k-1] = dom(\ell_{\max}[k-1])$ (as in line 4 or 5).

But this implies that when executing $\mathcal{L}^{k+1}$, it must have been line 4 that was executed because from the above the conditions of lines 1–3 are not met and because

- $\ell_{\max}[k-1] \in \{2,3,4,5\}$, $k \geq 2$, and
- $\ell_{\max}[n..k] = \ell_x^{[a2]}[n..k] \neq \ell_x^{[a2-1]}[n..k]$ ($\ell_x^{[a2-1]}$ is ℓ_i in line 4).

But this implies that $\ell_x^{[a2]}[k] = dom(\ell_{\max}[k])$, that is, x would not execute $\mathcal{L}^k(G)$ for $G = \ell_{\max}[n..k]$ in the first place, a contradiction. □

The following lemma establishes that if in an earlier labeling operation execution a label $\ell_y^{[b]}$ was observed, the current labeling operation execution must read that label for y or a label later than it.

LEMMA 5.8. *If $L_y^{[b]} \overset{\text{obs}}{\dashrightarrow} L_x^{[a-1]}$, it cannot be that $r_y(L_x^{[a]}) = \ell_y^{[b1]}$, where $b1 < b$.*

Proof. By Corollary 5.1, it follows that if $L_y^{[b]} \overset{\text{obs}}{\dashrightarrow} L_x^{[a-1]}$, then there exists a read $r_y(L_\alpha^{[\beta]}) = \ell_y^{[b]}$ such that

$$w(L_y^{[b]}) \dashrightarrow r_y(L_\alpha^{[\beta]}) \longrightarrow w(L_x^{[a-1]}),$$

where possibly $\alpha = x$ and $\beta = a-1$. Since $w(L_x^{[a-1]}) \longrightarrow r_y(L_x^{[a]})$, it follows that $r_y(L_\alpha^{[\beta]}) \longrightarrow r_y(L_x^{[a]})$. Since, in addition, $w(L_y^{[b1]}) \longrightarrow w(L_y^{[b]})$, by register axiom B5, it cannot be that $r_y(L_x^{[a]}) = \ell_y^{[b]}$. □

The following lemma states that there cannot be a label read by $L_x^{[a]}$ that dominates $\ell_x^{[a-1]}$ on level $k1 > k$, where k is the level such that $\ell_x^{[a-1]} \overset{k}{\neq} \ell_x^{[a]}$.

LEMMA 5.9. *For $\ell_x^{[a]} \overset{k}{\neq} \ell_x^{[a-1]}$, it cannot be that there is an $L_y^{[b]}$ such that*

- $r_y(L_x^{[a]}) = \ell_y^{[b]}$ *and*
- $\ell_x^{[a-1]} \overset{k1}{\prec} \ell_y^{[b]}$, *where* $k1 > k$.

Proof. By the definition of $\overset{k}{\prec}$, it must be that $\ell_x^{[a]} \overset{k1}{\prec} \ell_y^{[b]}$, where $k1 \geq k$. By the definition of $\mathcal{L}$, either $\ell_{\max} \overset{k}{\prec} \ell_x^{[a]}$ or $\ell_{\max}$ is equal to $\ell_x^{[a]}$ (in which case by definition $\ell_{\max}$ is just $\ell_x^{[a-1]}$). The reason is that when executing $\mathcal{L}^{k3}$ for some level $k3$, $\ell_{\max}[k3] = \ell_x^{[a]}[k3]$ or $\ell_{\max}[k3] = dom(\ell_x^{[a]}[k3])$. It thus must be that $max \neq y$. It can either be the case that $\ell_y^{[b]} \overset{k}{\prec} \ell_{\max}$ or not.

If indeed $\ell_y^{[b]} \overset{k}{\prec} \ell_{\max}$, by the definition of $\overset{k}{\prec}$, in order for $\ell_x^{[a]} \overset{k}{\prec} \ell_y^{[b]}$, $\ell_y^{[b]} \overset{k}{\prec} \ell_{\max}$, and either $\ell_{\max} \overset{k}{\prec} \ell_x^{[a]}$ or $\ell_{\max} = \ell_x^{[a]}$, it must be that

$$\ell_x^{[a]} \overset{k}{\prec} \ell_y^{[b]} \overset{k}{\prec} \ell_{\max} \overset{k}{\prec} \ell_x^{[a]},$$

that is, the three labels are also on a cycle. Since by the definition of

$$max(dominating\_set(\ell, \ell_x^{[a-1]})),$$

either $\ell_x^{[a-1]} \overset{k}{\prec} \ell_{\max}$ or $\ell_{\max} = \ell_x^{[a-1]}$, it follows that $k \geq k1$, a contradiction.

However, if $\ell_{\max} \overset{k}{\prec} \ell_y^{[b]}$, by the definition of $max(dominating\_set(\ell, \ell_x^{[a-1]}))$, it could be only if the labels of y and max were on a cycle on a level $k2$, where $2 \leq k2 \leq k1$ ($k1$ is the level such that $\ell_x^{[a-1]} \overset{k1}{\prec} \ell_y^{[b]}$).[15] In order for $\ell_{\max} \overset{k}{\prec} \ell_x^{[a]}$ or $\ell_{\max} = \ell_x^{[a]}$, together with $\ell_x^{[a]} \overset{k}{\prec} \ell_y^{[b]}$, it must be that $\ell_x^{[a]}$ is in the cycle with these two labels. However, this implies $k \geq k1$, a contradiction. □

The following lemma captures the informal invariant that at any point in time, there can be at most k different labels in the cycle of any T^k subgraph. More precisely, it states that for any set of more than k labeling operation executions whose labels are in the cycle of the same T^k subgraph, all could not have been there at the same point in time since at least one of them must have already been observed by the others in a later location outside the cycle.

LEMMA 5.10. *Let $\mathcal{S}^k = \{L_{i_1}^{[a_1]}, L_{i_2}^{[a_2]}, \ldots, L_{i_m}^{[a_m]}\}$, $i_1, \ldots, i_m \in \{1..n\}$, and $i_\alpha \neq i_\beta$ for any $\alpha, \beta \in \{1..m\}$ be the set of labeling operation executions such that for any $L_i^{[a]}, L_j^{[b]} \in \mathcal{S}^k$,*

- $\ell_i^{[a]} \overset{k+1}{=} \ell_j^{[b]}$ *and* $\ell_i^{[a]}[k-1], \ell_j^{[b]}[k-1] \in \{3,4,5\}$, *and*
- *for $L_j^{[b1]} \in max\_obs(L_i^{[a]})$ and $L_i^{[a1]} \in max\_obs(L_j^{[b]})$, it is the case that $b1 \leq b$ and $a1 \leq a$.*

It must be that $||\mathcal{S}^k|| \leq k$.

Proof. Assume by way of contradiction that $||\mathcal{S}^k|| > k$. By Lemma 5.7, for each $L_i^{[a]} \in \mathcal{S}^k$, $||inside(L_i^{[a]}[n..k])|| \geq 2$, that is, it is included at least two labeling operation executions inside the T^k subgraph that $L_i^{[a]}$ is in. Let us define the relation *not_read_by* between labeling operation executions $L_i^{[a]}, L_j^{[b]} \in \mathcal{S}^k$ to be as follows.

DEFINITION 5.3. *$L_i^{[a]}$ not_read_by $L_j^{[b]}$ if $r_i(L_j^{[b]}) \neq \ell_i^{[a1]}$, $a1 \in \{a-1, a\}$.*

[15] The reason for this is that if the two labels are on different supernodes of a cycle, there could be a third label on the other supernode of the cycle, and any one of them could be selected as $\ell_{\max}$.

That is, $L_j^{[b]}$ did not read a label of a labeling operation execution $L_i^{[a]}$ or its preceding operation execution in the T^k that it is in. The contradiction will be derived by showing that there must be at least one labeling operation execution $L_i^{[a]} \in \mathcal{S}^k$ that read at least $k+1$ labels (including its own) in the T^k subgraph that $L_i^{[a]}$ and $L_i^{[a-1]}$ are in. This is the *flag principal* mentioned in section 4.3. Since for each $L_i^{[a]} \in \mathcal{S}^k$, $\ell_i^{[a]_k} = \ell_i^{[a-1]}$, that is, a move at level k, it must be that when executing $\mathcal{L}^{k+1}$ in $L_i^{[a]}$, line 5 was executed and that $num\_labels < (k+1) - 1$ (at most $k-1$ labels not including its own, or k including it, were read in the T^k subgraph $\ell_i^{[a]}[n..k]$), a contradiction.

Since it was assumed by way of contradiction that there are more than k labeling operation executions in $\mathcal{S}^k$, it must be that each labeling operation execution did not read (*not_read_by*) at least one of the others. Let it first be shown that the relation *not_read_by* is antisymmetric.

CLAIM 5.10.1. *For any $L_i^{[a]}$ and $L_j^{[b]}$ in $\mathcal{S}^k$, if $L_i^{[a]}$ not_read_by $L_j^{[b]}$, then it cannot be that $L_j^{[b]}$ not_read_by $L_i^{[a]}$.*

Proof. For any two labeling operation executions $L_i^{[a]}$ and $L_j^{[b]}$ in $\mathcal{S}^k$, by definition (for $L_j^{[b1]} \in max\_obs(L_i^{[a]})$ and $L_i^{[a1]} \in max\_obs(L_j^{[b]})$, it is the case that $b1 \leq b$ and $a1 \leq a$,) neither $r_i(L_j^{[b]}) = \ell_i^{[a1]}$, $a1 > a$, nor $r_j(L_i^{[a]}) = \ell_j^{[b1]}$, $b1 > b$. Given $L_i^{[a]}$ *not_read_by* $L_j^{[b]}$, it thus follows by atomic register axiom B5 that $r_i(L_j^{[b]}) \dashrightarrow w(L_i^{[a-1]})$. However, this implies

$$w(L_j^{[b-1]}) \longrightarrow r_i(L_j^{[b]}) \dashrightarrow w(L_i^{[a-1]}) \longrightarrow r_j(L_i^{[a]}).$$

By axiom A4, it follows that $w(L_j^{[b-1]}) \longrightarrow r_j(L_i^{[a]})$, implying that it cannot be that $L_j^{[b]}$ *not_read_by* $L_i^{[a]}$. □

Think of the relation *not_read_by* as the set of edges of a directed graph whose nodes are labeling operation executions, where an edge is directed from $L_i^{[a]}$ to $L_j^{[b]}$ if $L_i^{[a]}$ *not_read_by* $L_j^{[b]}$. Each labeling operation execution in $\mathcal{S} \cup \{L_x^{[a]}\}$ did not read at least one of the others; each node has at least one incoming edge. By known graph-theoretic arguments, this implies that

- there are two nodes that have edges directed one at the other or
- there is at least one node $L_s^{[c]}$ that has a directed path leading from it to every other node in the graph.

By Claim 5.10.1 (antisymmetry of *not_read_by*), the former is impossible.[16] The following claim establishes that the labeling operation execution associated with the node $L_s^{[c]}$ from which all other nodes are reachable (note that by assumption, this node has at least one incoming edge and is not a "root") must have read all of them.

CLAIM 5.10.2. *For any subset $\{L_{i_1}^{[a_1]}, L_{i_2}^{[a_2]}, \ldots, L_{i_m}^{[a_m]}\}$ of m labeling operation executions in $\mathcal{S}^k$, where*

$$L_{i_1}^{[a_1]} \text{ not\_read\_by } L_{i_2}^{[a_2]} \text{ not\_read\_by} \cdots \text{ not\_read\_by } L_{i_m}^{[a_m]},$$

it is the case that $r_{i_m}(L_{i_1}^{[a_1]}) = L_{i_m}^{[a_m]}$.

[16] Note that if the former does not hold, there is a cycle in the graph. If the relation *not_read_by* were transitive, a cycle would be impossible, and the proof would be complete. However, the reader can verify that this is not the case.

Proof. For any two labeling operation executions $L_i^{[a]}$, $L_j^{[b]} \in \mathcal{S}^k$, it follows by definition that neither $r_i(L_j^{[b]}) = \ell_i^{[a1]}$, $a1 > a$, nor $r_j(L_i^{[a]}) = \ell_j^{[b1]}$, $b1 > b$.

Let it be proven by induction that $r_{i_{m-1}}(L_{i_m}^{[a_m]}) \dashrightarrow w(L_{i_1}^{[a_1-1]})$. This will imply

$$w(L_{i_m}^{[a_m-1]}) \longrightarrow r_{i_{m-1}}(L_{i_m}^{[a_m]}) \dashrightarrow w(L_{i_1}^{[a_1-1]}) \longrightarrow r_{i_m}(L_{i_1}^{[a_1]}),$$

from which by axiom A4 follows $w(L_{i_m}^{[a_m-1]}) \longrightarrow r_{i_m}(L_{i_1}^{[a_1]})$, implying, $r_{i_m}(L_{i_1}^{[a_1]}) = L_{i_m}^{[a_m]}$, as desired.

The proof that $r_{i_{m-1}}(L_{i_m}^{[a_m]}) \dashrightarrow w(L_{i_1}^{[a_1-1]})$ is by induction on m, the size of the subset of labeling operation executions. For $m = 2$, it follows by definition. Assume it holds for sequences of length $m-1$, that is,

$$r_{i_{m-2}}(L_{i_{m-1}}^{[a_{m-1}]}) \dashrightarrow w(L_{i_1}^{[a_1-1]}).$$

Since $r_{i_{m-1}}(L_{i_m}^{[a_m]}) \neq \ell_{i_{m-1}}^{[a_{m-1}]}$, it follows that

$$r_{i_{m-1}}(L_{i_m}^{[a_m]}) \dashrightarrow w(L_{i_{m-1}}^{[a_{m-1}-1]}) \longrightarrow r_{i_{m-2}}(L_{i_{m-1}}^{[a_{m-1}]}) \dashrightarrow w(L_{i_1}^{[a_1-1]}).$$

By axiom A4*, it follows that $r_{i_{m-1}}(L_{i_m}^{[a_m]}) \dashrightarrow w(L_{i_1}^{[a_1-1]})$, implying the claim. □

Thus the node $L_s^{[c]}$ read at least k labels apart from its own in the T^k subgraph $L_s^{[c]}[n..k]$, providing the desired contradiction. □

Based on the above, the following lemma, which is part of the proof of I4.2 for the inductive case, can be shown. As mentioned before, the maximally observed set *max_obs*$(L_x^{[a]})$ is actually the set of labeling operation executions whose labels, in a sequential execution, could have existed together with $L_x^{[a]}$ at some point in time. The lemma thus captures the informal notion that if one could look at the cycle of a T^k subgraph at a given point in time in which x had a label $\ell_x^{[a]}$ in it, there would be at most $k-1$ other labels in the cycle together with it.

LEMMA 5.11. *For $\ell_x^{[a]}[k] \in \{3,4,5\}$, there are at most $k-1$ labels $L_y^{[b]}$, where $L_y^{[b]} \in$ max_obs$(L_x^{[a]})$, such that $\ell_y^{[b]} \overset{k+1}{=} \ell_x^{[a]}$ and $\ell_y^{[b]}[k-1] \in \{3,4,5\}$.*

Proof. For any two labeling operation executions $L_y^{[b]}$, $L_z^{[c]} \in$ *max_obs*$(L_x^{[a]})$, by the definition of *max_obs*$(L_x^{[a]})$, neither $r_y(L_z^{[c]}) = \ell_y^{[b1]}$, $b1 > b$, nor $r_z(L_y^{[b]}) = \ell_z^{[c1]}$, $c1 > c$. Also, by definition, for $L_y^{[b]} \in$ *max_obs*$(L_x^{[a]})$, neither $r_y(L_x^{[a]}) = \ell_y^{[b1]}$, $b1 > b$, nor $r_x(L_y^{[b]}) = \ell_x^{[a1]}$, $a1 \geq a$. The claim follows from Lemma 5.10 by defining $\mathcal{S}^k$ to be the set of labeling operation executions maximally observed by $L_x^{[a]}$ together with $L_x^{[a]}$ itself. □

The completion of the inductive argument involves a proof of properties I1–I4 through rather tedious case analysis. It is ommitted from this manuscript and can be found in [Sha90].

6. Discussion. There are three main types of problems defined in the shared-memory model:

- *waiting problems*, whose solution allows a process to take an infinite number of steps to complete an operation—that is, it could "busy-wait" for some other processes indefinitely;
- *wait-free problems*, whose solution is such that each process is *guaranteed* to complete an operation within a finite number of steps, independently of the pace of other processes; and

• *expected-wait-free problems*, whose solution is such that each process is *expected* (rather than guaranteed) to complete an operation within a finite number of steps, independently of the pace of other processes.

These classes of problems are fundamentally different from one another. However, they have the unifying theme that

> if the requirement that memory size be bounded is dropped, the problems have elegant and simple unbounded solutions based on the use of a CTSS.

The main implication of bounded concurrent time-stamping is that this unifying theme, true under the assumption that memory size can be unbounded, holds true for the bounded-memory case as well.

Based on the use of a bounded CTSS implementation, simple unbounded solutions can be given for what are considered to be core problems in each category and then directly transformed into bounded ones. Examples of problems and algorithms in the first category are the famous first-come first-served mutual-exclusion problem of Lamport [Lam74] (see [Lam86b, Ray86] for complete details) and the *fifo*-ℓ-exclusion problem of [AD*94, FLBB79, FLBB89]. As mentioned earlier, a CTSS-based solution due to Afek et al. can be found in [AD*94].

In the second category, we have Li and Vitanyi's simple version [LV87] of the elegant unbounded Vitanyi–Awerbuch algorithm [VA86] for solving the problem of providing a wait-free construction of an MRMW atomic register from SWMR atomic registers (see also [PB87, IL93, Sch88, **?**]). This algorithm can be immediately transformed into a bounded solution (see [G92]).

In the third category, a version (see [Sha90]) of the algorithm of Abrahamson [Abr88] based on the use of a CTSS can be modularly transformed into a bounded solution to the randomized consensus problem of [CIL87].

6.1. Further related research. The introduction of the concurrent time-stamping paradigm in the conference version of this paper [DS89] has led researchers to devising a series of alternative bounded CTSS algorithms. Israeli and Pinchasov [IP91] have provided a linear-complexity version of our algorithm by dropping the requirement that scan operations do not perform writes. In [DW92], Dwork and Waarts present the most efficient read/write-register-based CTSS construction to date, taking only $O(n)$ time for either a scan or update. They model their bounded construction after a new type of unbounded CTSS construction, where processes choose from "local pools" of label values instead of the simple "global-pool"-based CTSS as in the bakery algorithm [Lam74]. In order to bound the number of possible label values in the local pool of the bounded implementation, they introduce a form of garbage collection on "old" labels. They then prove that the linear-time bounded implementation meets the CTSS axioms of section 2. In [DPHW92], Dwork, Herlihy, Plotkin, and Waarts introduce an alternative linear-complexity bounded CTSS construction that combines a time-lapse snapshot with our bounded CTSS algorithm. The proof of their algorithm leverages the axiomatic proof in this paper by arguing that the executions of their algorithm are a subset of the executions of our algorithm. In [GLS92], Gawlick, Lynch, and Shavit introduce a streamlined version of our CTSS algorithm based on the use of an atomic snapshot primitive [AAD*89, And89a]. A snapshot primitive allows a process P_i to *update* the ith memory location, or *snap* the memory, that is, collect an "instantaneous" view of all n shared-memory locations. By using a snapshot primitive, they limit the number of interleavings that can occur and are able to introduce a considerably simplified version of our labeling algorithm (though

a logarithmic factor less efficient) that is tailored to allow a forward-simulation proof [LT87]. An advantage of their algorithm over other solutions is that it is no longer limited to read/write memory, providing a CTSS construction in any computation model whose basic operations suffice to provide a wait-free snapshot implementation, be it single-writer multireader registers [A93], multireader multiwriter registers [ICMT94], consensus objects [CD93], or memory with hardware supported *compare-and-swap* and *fetch-and-add* primitives.

Acknowledgments. We would like to thank Yehuda Afek, Hagit Attiya, Eli Gafni, Rainer Gawlick, Maurice Herlihy, Nancy Lynch, and Mike Merritt for many important conversations and comments. It was a subtle observation of Mike's regarding pairwise consistency among scans that led us to the current CTSS definitions. A subsequent observation by Rainer led us to add property P4 to the CTSS specification.

Finally, the second author would like to thank Nancy Lynch, Baruch Awerbuch, and the members of MIT's Theory of Distributed Systems group for their warm hospitality throughout the writing of this paper.

PROBE ORDER BACKTRACKING*

PAUL WALTON PURDOM, JR.† AND G. NEIL HAVEN‡

Abstract. The algorithm for constraint-satisfaction problems, Probe Order Backtracking, has an average running time much faster than any previously analyzed algorithm under conditions where solutions are common. The algorithm uses a probing assignment (a preselected test assignment to unset variables) to help guide the search for a solution. If the problem is not satisfied when the unset variables are temporarily set to the probing assignment, the algorithm selects one of the relations which is not satisfied by the probing assignment and selects an unset variable which affects the value of that relation. It then does a backtracking (splitting) step, where it generates subproblems by setting the selected variable each possible way. Each subproblem is simplified and then solved recursively. For random problems with v variables, t clauses, and probability p that a literal appears in a clause, the average time for Probe Order Backtracking is no more than v^n when $p \geq (\ln t)/v$ plus lower-order terms. The best previous result was $p \geq \sqrt{(\ln t)/v}$. When the algorithm is combined with an algorithm of Franco that makes selective use of resolution, the average time for solving random problems is no more than v^n for all values of p when $t \leq O(n^{1/3}(v/\ln v)^{2/3})$. The best previous result was $t \leq O(n^{1/3}(v/\ln v)^{1/6})$. Probe Order Backtracking also runs in polynomial average time when $p \leq 1/v$, compared with the best previous result of $p \leq 1/(2v)$. With Probe Order Backtracking, the range of p that leads to more than polynomial time is much smaller than that for previously analyzed algorithms.

Key words. average time, backtracking, combinatorial search, NP-complete, satisfiability, searching

1. Backtracking.

The constraint-satisfaction problem is to determine whether a set of constraints over discrete variables can be satisfied. Each constraint must have a form that is easy to evaluate, so any difficulty in solving such a problem comes from the interaction between the constraints and the need to find a setting for the variables that simultaneously satisfies all of the constraints.

Constraint-satisfaction problems are extremely common. Indeed, the proof that a problem is NP-complete implies an efficient way to transform the problem into a constraint-satisfaction problem. Most NP-complete problems are initially stated as constraint-satisfaction problems. A few special forms of constraint-satisfaction problems have known algorithms that solve problem instances in polynomial worst-case time. However, for the general constraint-satisfaction problem, no known algorithm is fast for the worst case. Nonetheless, many instances of the problem can be solved rapidly.

When no polynomial-time algorithm is known for a particular form of constraint-satisfaction problem, it is common practice to solve problem instances with a search algorithm. The basic idea of searching is to choose a variable and generate subproblems by assigning each possible value to the variable. In each subproblem, the relations are simplified by plugging in the value of the selected variable. This step of generating simplified subproblems is called *splitting*. If any subproblem has a solution, then the original problem has a solution. Otherwise, the original problem has no

solution. Subproblems that are simple enough (such as those with no unset variables) are solved directly. More complex subproblems are solved by applying the technique recursively.

If a problem contains the always *false* relation, then the problem has no solution. *Simple Backtracking* improves over plain search by immediately reporting no solution for such problems. Backtracking often saves a huge amount of time.

2. Probe Order Backtracking. This research is concerned with an algorithm that is an improvement over Simple Backtracking. A key idea in the algorithm is *probing*: if a fixed assignment to the unset variables solves the problem, no additional investigation is needed. An algorithm probes by setting each unset variable to some preselected value and testing to see whether all relations simplify to *true*. For random problems, one may as well use the value *false* for all variables. For practical problems, one could use a randomly selected probe sequence.

The algorithm *Backtracking with Probing* uses backtracking, probing, and no additional techniques. In particular, during splitting, it always picks the first unset variable from a fixed ordering on the variables. This algorithm is only a slight improvement over Simple Backtracking, and so it is not discussed further in this paper. The reader is referred to [19] for a detailed analysis.

A better algorithm, *Probe Order Backtracking*, is more sophisticated in its variable selection. It has a fixed ordering on the variables and a fixed ordering on the relations. First, it checks that there are no always *false* relations. If an always *false* relation is encountered, the problem is not satisfiable and the algorithm backtracks. Next, it checks to see if there is a currently selected relation. If there is no currently selected relation, it selects the first relation that evaluates to *false* under the probing assignment. (If all clauses evaluate to *true*, then the probing assignment solves the problem.) Finally, the algorithm does splitting using the first unset variable of the selected relation. The algorithm always finds a solution if there is one, it may find several solutions, but it normally does not find all solutions.

This paper shows that Probe Order Backtracking is fast for random problems drawn from the region of parameter space where solutions are common. It is also fast for random problems drawn from the region where solutions are uncommon. The algorithm probably uses exponential average time in a narrow region between those two regions, but this paper has only an upper-bound analysis, so it does not address that question.

3. Probability model. To measure the quality of a search algorithm, we use the average number of nodes in the backtrack tree that is generated when the algorithm solves a randomly generated problem. Our random problems are formed by the conjunction of independently generated random *clauses* (the logical *or* of literals, where a literal is a binary variable or the negation of a binary variable). A random clause is generated by independently selecting each literal with a fixed probability p. We use v for the number of variables and t for the number of clauses. (Some of the clauses may happen to be tautological.) For the asymptotic analysis, both p and t are functions of v.

Many algorithms have been analyzed with this random-clause-length model [3, 4, 7, 8, 9, 13, 15, 17, 18]. Most of these analyses and a few unpublished ones are summarized in [14].

A second probability model that is in common use is the fixed-clause model, where the significant difference is that all clauses have the same length. Much research has been done with the fixed-clause model, but only a few authors have done average

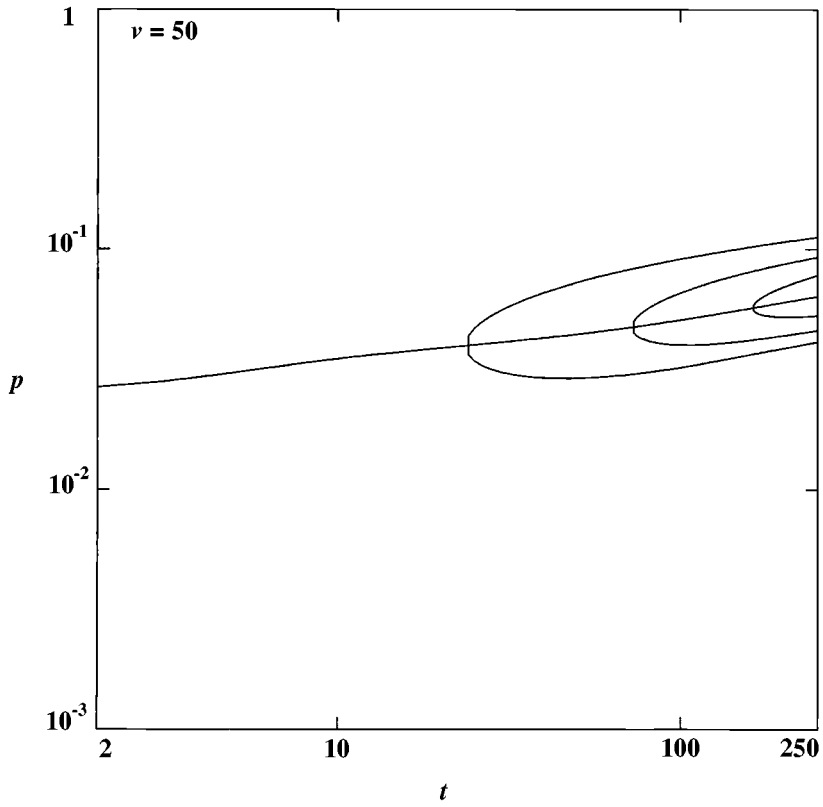

FIG. 1. *Probe Order Backtracking.*

time analyses for algorithms using this model [1, 2, 11, 16]. This second model generates problems that are more difficult to satisfy but perhaps more like the problems encountered in practice. It also leads to much more difficult analyses.

4. Summary of results. This section summarizes the performance of Probe Order Backtracking and gives some intuition as to why Probe Order Backtracking is fast.

Figure 1 is a contour plot showing the performance of Probe Order Backtracking for random problems with 50 variables. The vertical axis shows p, the probability that a given literal appears in a clause, running from 0.001 to 1 with ticks at 0.01 and 0.1. At $p = 0.01$, the average clause length for problems is 1. At $p = 0.1$, the average clause length is 10 literals. The horizontal axis shows t, the number of clauses, running from 2 to 250 with ticks at 10 and 100. When p is near 0 or 1, most problems are trivial. When p is low, most problems are easy because they contain an empty clause; empty clauses are trivially unsatisfiable. When p is high, most problems are easy because any assignment of values to variables is a solution to most problems. The region of hard problems lies in the middle.

The contours are shaped like elongated horseshoes. The area within a horseshoe contour represents problems that are more difficult than the problems outside the contour. The outermost contour shows where the average number of nodes required to solve a problem is 50, the next inner one 50^2, and finally 50^3. Running near the

centerline of the horseshoes is a line that shows for each t that value of p that results in the hardest problems (those with the largest number of nodes).

Except for the small t region, these contours are much better than those of any other algorithm for which such contours have been published. The improvement is particularly noticeable along the upper contour.

The asymptotic analysis of Probe Order Backtracking shows that the average number of nodes is no more than v^n, for large v and $n > 1$, when any of the following conditions hold:

$$(1) \quad p \geq \frac{\ln t + 2\ln\ln t - \ln\ln v - \ln(n-1) - \ln 2}{v} + \Theta\left(\frac{\ln\ln t}{v \ln t}\right),$$

$$(2) \quad p \leq \left\lceil \frac{\ln(t/v) + \ln\ln(t/v) + 1 - \ln 2 - \ln\ln 2}{2v} \right\rceil \times \left\lceil 1 + \frac{2(n-1)\ln v - (\ln 2)[\ln(t/v) + \ln\ln(t/v) + 3 - \ln 2 - \ln\ln 2]}{4v \ln 2} - \Theta\left(\frac{(\ln v)\ln(t/v)}{v^2}\right) - \Theta\left(\frac{\ln\ln(t/v)}{v\ln(t/v)}\right) \right\rceil,$$

$$(3) \quad p \leq \frac{1}{v} + \frac{e[(n-1)\ln v - \ln 2]}{tv},$$

$$(4) \quad t \leq \frac{(n-1)\ln v - \ln 2}{\ln\{1 + [(pv)^2 - 1]e^{-pv}/2\}}.$$

The Θ term in bound (1) is valid only when t increases more rapidly than $\ln v$. Bound (4) is valid when the limit of pv is greater than 1 and finite.

By setting p to minimize the right side of (4), we see that for all p and large v, the average number of nodes is no more than v^n when

$$(5) \quad t \leq 5.1150(n-1)\ln v - \Theta(1)$$

because in bound (4), the minimum value of the right side (when considered as a function of pv) occurs at $pv = 1 + \sqrt{2}$.

The bound for large p, bound (1), is much better than that for any previously analyzed algorithm. The best previous result was

$$(6) \quad p \geq \sqrt{\frac{\ln t - \ln n}{v}}$$

for Iwama's inclusion–exclusion algorithm [9]. In the region between bounds (1) and (6), Probe Order Backtracking is the fastest algorithm with proven results on its running time (as long as t is not small compared to v). Algorithms that repeatedly adjust variable settings to satisfy as many clauses as possible [20] are even faster on many problems. Those algorithms, however, have difficulty with problems which have no solution. They have been difficult to correctly analyze, and it is not clear at this time what their average running time is.

For the best previously analyzed algorithms, there was a large range of p where the algorithms apparently required more than polynomial time. (The word "apparently" is used because the analyses are all upper-bound analyses.) The ratio of the large p boundary to the small p boundary was $v^{1/2}$ times logarithmic factors. For Probe Order Backtracking, only the logarithmic factors are left. In some cases, even the logarithmic factors are gone and the ratio is constant (in the limit of large v). Bound (2) for small p results from the fact that the average number of nodes for Probe Order Backtracking is no larger than the average for Simple Backtracking. When $t = v^\alpha$ with $\alpha > 1$, the ratio of the upper boundary (1) to the lower boundary (2) is $2\alpha/(\alpha - 1)$ plus lower-order terms. Thus, for large α only a very limited range of p leads to problems with a large average time.

Perhaps the region of greatest interest is the one where t is proportional to v. When t is below $3.22135v$, bound (3) is better than (2). When $t = \beta v$, the ratio of the upper bound (1) to the first lower bound (2) is $(2 \ln v)/(\ln \beta + \ln \ln \beta + 1 - \ln 2 - \ln \ln 2)$ plus lower-order terms. When $t = \beta v$, the ratio of the upper bound to the second lower bound (3) is $\ln v$ plus lower-order terms.

Previously, for small t, the best algorithm was a combination of Franco's limited-resolution algorithm [8] for small p and Iwama's inclusion–exclusion algorithm [9] for large p. When p is unknown, the two algorithms can be run in parallel and stopped as soon as an answer is found. This combined algorithm generates no more than than v^n nodes (regardless of p) when $t = O(n^{1/3}(v/\ln v)^{1/6})$. Combining Franco's algorithm with Probe Order Backtracking improves the bound to $O(n^{1/3}(v/\ln v)^{2/3})$. The techniques of Franco's algorithm can be combined with Probe Order Backtracking, so there is no need to have two algorithms running in parallel. This is helpful when designing practical algorithms.

4.1. Informal discussion. The basic idea behind probing is old. The idea resembles that used by Newell and Simon in GPS [12]. Just as their program concentrates on differences between its current state and its goal state, Probe Order Backtracking focuses on a set of troublesome relations that are standing in the way of finding a solution. It is our impression that people who are good at solving puzzles use related ideas all the time.

Franco observed that two extremely simple algorithms could quickly solve most problems outside of a small range of p [6]. His algorithm for the region of high p does a single probe and gives up if no solution is found. His algorithm for the region of low p looks for an empty clause and gives up if there is none. Since Franco's algorithms sometimes give up, their average time is not well defined.

At the time of Franco's work, it was already known that Simple Backtracking was fast along the lower boundary (2), but it was not clear how to obtain an algorithm with a fast average time along the upper boundary (1). Simple uses of probing did not seem to lead to a good average time. Probe Order Backtracking was discovered while considering Franco's results [6] and considering the measurements of Sosič and Gu [20] for algorithms that concentrate on adjusting values until a solution is found. Both of those algorithms have difficulty with problems that have no solution.

Simple Backtracking improves over plain search by noticing when a problem has no solution due to the presence of an empty clause. However, Simple Backtracking is unfocused in its variable selection. As long as a problem does not have an empty clause, Simple Backtracking always proceeds by selecting the next splitting variable from a fixed ordering. The Clause Order Backtracking algorithm [3] improves over Simple Backtracking by focusing on the variables in one clause of the problem at a

time. This method of searching has the advantage that it performs splitting on just those variables that actually appear in a problem.

The Clause Order Backtracking algorithm provides a framework for the construction of a probing algorithm that has good performance for a wide range of problems, including those with no solution. Probe Order Backtracking, like Clause Order Backtracking, focuses on the variables in one clause at a time. However, Probe Order Backtracking improves over Clause Order Backtracking by only selecting variables from clauses which are not satisfied by the probing assignment. These are the clauses standing in the way of finding a solution: the *troublesome* clauses. Because Probe Order Backtracking probes by setting all unset variables to *false*, the troublesome clauses for Probe Order Backtracking are the clauses containing no negated variables.

When solutions are common, the informal explanation of why the algorithm is fast is that there will be only a few relations that are not satisfied by the probing assignment. Indeed, for $pv > \ln t$, the expected number of troublesome clauses for any given probing sequence is less than $1 - 1/t$. (See section 7.1.1 below.) By setting a variable so as to satisfy a troublesome clause, you definitely eliminate that clause. If luck is with you, you do not create any new troublesome clauses. The analysis at the end of the paper shows that, when solutions are common, setting variables so as to satisfy troublesome clauses creates new troublesome clauses at a rate slow enough that the algorithm is fast.

When solutions are uncommon, the algorithm is fast because it usually works on clauses that are shorter than average. First, the algorithm keeps working on the selected clause until it is satisfied—once the first variable has been set, the average length of the selected clause is less than that of a random clause. Second, troublesome clauses are smaller than average. The first reason is the same reason that Clause Order Backtracking is fast when solutions are uncommon [3]. (That algorithm is essentially Probe Order Backtracking without the probing.)

In the worst case, Probe Order Backtracking may need to try almost every combination of values for the variables. Thus the average-case performance of the algorithm is extremely good, but its worst-case performance is probably not a significant improvement over previous algorithms.

The analysis of the simpler Backtracking with Probing algorithm, which uses probing to test for a solution but not to select the variables to set [19], shows that a naïve application of probing does not lead to fast average time for the region of high p or for the region of low t. For good performance, it appears to be essential that an algorithm use probing both to notice when there is a solution and to focus its effort on the clauses which are interfering with solving the problem.

5. Practical algorithms. Probe Order Backtracking was studied in part because it is simple enough to analyze. In practice, one wants an algorithm that is fast whether or not it is possible to analyze its running time. There are several improvements that would clearly improve Probe Order Backtracking's average speed even though it is difficult to analyze their precise effectiveness:

1. Stop the search as soon as one solution is found. The analysis suggests that this would greatly improve the speed near the upper boundary (1), but stopping at the first solution leads to statistical dependencies that are difficult to analyze.

2. Carefully choose the probing sequence instead of just setting all variables to a fixed value. Various greedy approaches where variables are set to satisfy as many clauses as possible should be considered (see [10, 20]). This is particularly important near the upper boundary (1).

3. Probe with several sequences at one time. See [5, p. 151] for an algorithm that used two sequences. This is helpful along the upper boundary.

4. Carefully select which variable to set. The analysis suggests that this is particularly important along the lower boundary. Variables in hard-to-satisfy relations (short clauses) are more important than those in easy-to-satisfy relations. Variables that appear in lots of relations are more important than those that appear in a few relations. Apparently, when the relations are clauses, it is helpful to consider the number of clauses containing a particular variable positively and the number containing it negatively [5]. It appears that variable selection was a major factor in determining the order of placement of winning entries in a recent SAT competition [5].

5. Use resolution when it does not increase the problem size [8].

6. Algorithm statement. The precise form of Probe Order Backtracking that is analyzed and the rules for charging time are given below. The algorithm is specialized to work on satisfiability problems presented in conjunctive normal form (CNF). This version of the algorithm is specially tailored to accord with the mathematics of the equations in section 7 below.

A literal is *positive* if it is not in the scope of a *not* sign. It is *negative* if it is in the scope of a *not* sign. In the following algorithm, a variable can have the value *true*, *false*, or *unset*. The *positively augmented* current assignment is the current assignment of values to variables with the *unset* values changed to *true*. The *negatively augmented* current assignment is the current assignment of values to variables with the *unset* values changed to *false*.

The algorithm simplifies clauses by plugging in the values of the set variables so that (except when simplifying) it is concerned with only those variables that have the value *unset*. In this algorithm, the set of solutions is a global variable that is initially the empty set. Any solutions that are found are added to the set. If the problem has any solutions, at least one solution will be added to the set before the algorithm terminates. The algorithm may find more than one solution, but it does not in general find all solutions. If the problem has no solution, then the algorithm will terminate with an empty set of solutions.

Probe Order Backtracking for CNF Problems. Given a CNF predicate, perform a preprocessing step by determining whether the predicate has an empty clause. If it does, charge one time unit and return with an empty solution set. The following algorithm is never called on a predicate with an empty clause. Also, remove all tautological clauses from the problem.

1. (probe) If there are no all-positive clauses (that is, every clause has at least one negative literal), then return with the negatively augmented current assignment added to the set of solutions and charge one time unit.

2. (partial probe) If every clause of the CNF problem has only positive literals, then return with the positively augmented current assignment added to the set of solutions and charge one unit of time.

3. (select) Choose the first clause that is all-positive. Step 1 ensures that there is at least one such clause.

4. (splitting) Let k be the number of variables in the selected clause. (The lack of empty clauses ensures that $k \geq 1$, and step 3 ensures that each variable occurs in at most one literal of the clause.) For j starting at 1 and increasing to at most $k+1$, set the first $j-1$ variables of the clause so that their literals are *false* and charge one time unit. Use the assigned values to simplify the problem (remove each false

literal from its clause and remove from the problem each clause with a true literal). If setting the first $j-1$ literals of the selected clause to *false* results in some clause being empty, then stop the loop. If setting the first $j-1$ literals of the selected clause to *false* results in all clauses of the CNF problem having only positive literals, then add the positively augmented current assignment to the set of solutions and stop the loop. Generate a new subproblem by taking the simplified predicate obtained by setting the first $j-1$ literals of the selected clause to *false* and also setting the jth variable to *true* and simplifying. (This assignment satisfies the selected clause.) If this subproblem has an empty clause, charge one additional time unit. Otherwise, apply the algorithm recursively to the subproblem.

The cost in time units has been defined to be the same as the number of nodes in the backtrack tree generated by the algorithm. The actual running time of the algorithm depends on how cleverly it is implemented, but a good implementation will result in a time that is proportional to the number of nodes multiplied by a factor that is between 1 and tv, where v is the number of variables and t is the number of clauses.

The backtrack tree includes nodes for determining that the selected clause is empty. The computation associated with those nodes can be done quickly, so one might wish to have an upper limit of k on the time units for step 4. This would lead to small, unimportant changes in the analysis.

7. Exact analysis. The remainder of this paper consists of the analysis of the Probe Order Backtracking algorithm. The same analysis is presented in greater detail in [19]. An exact analysis of the Backtracking with Probing algorithm is also contained in [19].

We now derive recurrence equations which give exact values of the average number of nodes generated by Probe Order Backtracking.

7.1. Basic probabilities. For the analysis of probing algorithms it is useful to divide clauses into the following categories: *empty* (no literals), *all-positive* (1 or more positive literals and no negative ones), *tautological* (a positive and negative literal for the same variable, possibly with additional literals), and *mixed* (any clause that does not fall into one of the preceding categories). The mixed clauses have at least one negative literal and zero or more positive literals. Assigning values to some variables and then simplifying the clause may change the category of a clause, or it may result in the clause becoming *satisfied*. (Note that empty clauses remain empty and all-positive clauses never become mixed clauses.)

The probability that a random clause formed from v variables is nontautological, contains j positive literals, and contains k negative literals is

$$P(v,j,k) = \binom{v}{j,k,v-j-k} p^{j+k}(1-p)^{2v-j-k}. \tag{7}$$

The probability that a random clause has no literals is

$$P(v,0,0) = (1-p)^{2v}. \tag{8}$$

Note that

$$\sum_{j,k} P(v,j,k) = (1-p^2)^v \le 1 \tag{9}$$

because tautological clauses are not counted in the double sum.

Suppose a random clause is formed from v variables and then one of the variables is selected at random. The probability that the clause has a particular value of j and k (implying that it is not a tautology) and that the selected variable appears in the indicated way is

$$\text{positive: } \frac{j}{v}P(v,j,k), \quad \text{negative: } \frac{k}{v}P(v,j,k), \quad \text{neither: } \frac{v-j-k}{v}P(v,j,k). \tag{10}$$

7.1.1. All-positive clauses. The probability that a random clause is all-positive is

$$\sum_{j\geq 1} P(v,j,0) = (1-p)^v[1-(1-p)^v]. \tag{11}$$

As p becomes large, all-positive clauses become rare. In particular, for $pv > \ln t$, the average number of all-positive clauses in a predicate is bounded by

$$t(1-p)^v[1-(1-p)^v] < t\left(1-\frac{\ln t}{v}\right)^v\left[1-\left(1-\frac{\ln t}{v}\right)^v\right] < 1-\frac{1}{t}.$$

Suppose clauses are generated at random until an all-positive clause is produced. The probability that the all-positive clause contains j literals is

$$A(v,j) = \frac{P(v,j,0)}{\sum_{j\geq 1}P(v,j,0)} = \binom{v}{j}\frac{p^j(1-p)^{v-j}}{1-(1-p)^v}. \tag{12}$$

If a random variable is assigned the value *true*, then an all-positive clause will either become satisfied or remain all-positive. The probability that the clause becomes satisfied is

$$\sum_j \frac{j}{v}A(v,j) = \frac{p}{1-(1-p)^v}. \tag{13}$$

The probability that the clause has length j and that it remains all-positive is

$$\frac{v-j}{v}A(v,j) = \binom{v-1}{j}\frac{p^j(1-p)^{v-j}}{1-(1-p)^v} = \frac{P(v-1,j,0)}{(1-p)^{v-2}[1-(1-p)^v]}. \tag{14}$$

If a random variable is assigned the value *false*, then an all-positive clause will either become empty or remain all-positive. The probability that the resulting clause becomes empty is

$$\frac{1}{v}A(v,1) = \frac{p(1-p)^{v-1}}{1-(1-p)^v}. \tag{15}$$

The probability that the resulting clause remains all-positive and that it has length $j \geq 1$ is

$$\frac{j+1}{v}A(v,j+1) + \frac{v-j}{v}A(v,j) = \frac{P(v-1,j,0)}{(1-p)^{v-1}[1-(1-p)^v]}. \tag{16}$$

The average length of a random all-positive clause is

$$\sum_j jA(v,j) = \frac{pv}{1-(1-p)^v}. \tag{17}$$

7.1.2. Mixed clauses. The probability that a random clause is a mixed clause is

$$\sum_{\substack{j\geq 0\\ k\geq 1}} P(v,j,k) = (1-p)^v[(1+p)^v - 1]. \tag{18}$$

Suppose clauses are generated at random until a mixed clause is produced. The probability that the mixed clause contains j positive literals and $k \geq 1$ negative literals is

$$M(v,j,k) = \frac{P(v,j,k)}{\sum_j \sum_{k\geq 1} P(v,j,k)} = \binom{v}{j,k,v-j-k} \frac{p^{j+k}(1-p)^{v-j-k}}{(1+p)^v - 1}. \tag{19}$$

If a random variable is assigned the value *true*, a mixed clause may become empty, become all-positive, become satisfied, or remain a mixed clause. The probability that a mixed clause becomes an empty clause is

$$\frac{1}{v} M(v,0,1) = \frac{p(1-p)^{v-1}}{(1+p)^v - 1}. \tag{20}$$

The probability that it becomes an all-positive clause with length j is

$$\frac{1}{v} M(v,j,1) = \binom{v-1}{j} \frac{p^{j+1}(1-p)^{v-j-1}}{(1+p)^v - 1} = \frac{pP(v-1,j,0)}{(1-p)^{v-1}[(1+p)^v - 1]}. \tag{21}$$

The probability that it is satisfied is

$$\sum_j \sum_{k\geq 1} \frac{j}{v} M(v,j,k) = \frac{p[(1+p)^{v-1} - 1]}{(1+p)^v - 1}. \tag{22}$$

The probability that the mixed clause remains a mixed clause and that it has j positive literals and $k \geq 1$ negative literals is

$$\frac{k+1}{v} M(v,j,k+1) + \frac{v-j-k}{v} M(v,j,k) = \frac{P(v-1,j,k)}{(1-p)^{v-1}[(1+p)^v - 1]}. \tag{23}$$

If a random variable is assigned the value *false*, a mixed clause may become satisfied or remain a mixed clause. The probability that a mixed clause is satisfied is

$$\sum_j \sum_{k\geq 1} \frac{k}{v} M(v,j,k) = \frac{p(1+p)^{v-1}}{(1+p)^v - 1}. \tag{24}$$

The probability that the mixed clause becomes a mixed clause with j positive literals and $k \geq 1$ negative literals is

$$\frac{j+1}{v} M(v,j+1,k) + \frac{v-j-k}{v} M(v,j,k) = \frac{P(v-1,j,k)}{(1-p)^{v-1}[(1+p)^v - 1]}. \tag{25}$$

Equations (14), (16), (21), (23), and (25) show that in all cases where a nonempty clause results from setting a variable associated with a random nonempty clause generated from v variables, the resulting clause either is satisfied or has the same length distribution as random clauses generated from $v-1$ variables. Thus it is possible to base an analysis on the number of all-positive clauses, the number of mixed clauses, and the number of variables without having to contend with statistical dependencies.

7.1.3. Total number of nodes. Equation (8) implies that a random predicate with t clauses contains an empty clause (and is therefore solved with one node) with probability

$$1-[1-(1-p)^{2v}]^t. \tag{26}$$

Equations (8), (11), and (18) imply that the probability that a random predicate contains zero empty clauses, m all-positive clauses, n mixed clauses, and $t-m-n$ tautological clauses is

$$\binom{t}{m,n,t-m-n}(1-p)^{(n+m)v}[1-(1-p)^v]^m[(1+p)^v-1]^n[1-(1-p)^v(1+p)^v]^{t-m-n}. \tag{27}$$

If we let $T(v,m,n)$ be the average time required to solve a random problem with v variables, m all-positive clauses, n mixed clauses, and no empty clauses then by summing all of the cases we see that the expected number of nodes is

$$\begin{aligned} 1\ &-[1-(1-p)^{2v}]^t+\sum_{m,n}\binom{t}{m,n,t-m-n}(1-p)^{(n+m)v} \\ &\times[1-(1-p)^v]^m[(1+p)^v-1]^n[1-(1-p)^v(1+p)^v]^{t-m-n}T(v,m,n). \end{aligned} \tag{28}$$

7.1.4. Heuristic analysis. Before continuing with the exact analysis, we give a brief heuristic analysis, for the average time used by Probe Order Backtracking.

Ignore the fact that setting variables has an effect on clauses other than the selected clause. In particular, ignore the fact that the nonselected clauses can become empty or satisfied and ignore the fact that once the variables of one clause are set, there could be fewer variables waiting to be set in the remaining clauses. Under this radical assumption, the number of subproblems produced by splitting on the variables of the selected clause is the same as the length of the selected clause. If each of m clauses contains w variables, the total number of nonroot nodes in the implied search tree satisfies the recurrence

$$N(m)=wN(m-1)+2w.$$

"$2w$" is the number of nodes arising from setting each variable in the clause (one node for *true* and one for *false*) as specified in the Probe Order Backtracking algorithm. There are w subproblems produced by splitting. Each subproblem has $m-1$ clauses. The solution to this recurrence is

$$2\left[\frac{w^{m+1}-1}{w-1}\right]-2.$$

Add 1 for the root node and use equation (17) for w. Under these assumptions, $T(v,m,n)$ is given by

$$2\left\{\left[\left(\frac{pv}{1-(1-p)^v}\right)^{m+1}-1\right]\Big/\left[\left(\frac{pv}{1-(1-p)^v}\right)-1\right]\right\}-1. \tag{29}$$

Plugging into (28) and summing over m and n gives an average number of nodes of

$$1+\left(\frac{2pv}{pv-1+(1-p)^v}\right)\{[1+(pv-1)(1-p)^v]^t-[1-(1-p)^{2v}]^t\}. \tag{30}$$

The heuristic analysis ignores three aspects of setting variables: 1. a clause other than the selected clause can become empty, 2. a clause other than the selected clause can be satisfied, and 3. a mixed clause can become an all-positive clause. The first leads to a predicted answer that is too large—particularly for small p. The last two effects come close to canceling, but for large p they can lead to the predicted value being either too large or too small depending on the exact value of the parameters. Curves for the heuristic analysis are given in [19].

This rough and not quite correct analysis is useful for obtaining a general understanding of the performance of the algorithm before completing a correct analysis. In particular, the heuristic analysis given here is useful in guessing the form of the dependence of the exact analysis on m, the number of all-positive clauses. See the value selected for $x(v)$ in section 8.3.

7.1.5. Transition probabilities. Suppose a predicate is produced by repeatedly generating random clauses from v variables. Suppose the resulting predicate contains m all-positive clauses, n mixed clauses, and no empty clauses.

Let $G(v,n)$ be the probability that setting a random variable to *true* results in the predicate having one or more empty clauses. When a variable is set to *true*, mixed clauses become empty with the probability given in equation (20) while all-positive clauses do not become empty. Therefore,

$$G(v,n) = 1 - \left(1 - \frac{p(1-p)^{v-1}}{(1+p)^v - 1}\right)^n. \tag{31}$$

Let $F(v,m)$ be the probability that setting a random variable to *false* results in a predicate with one or more empty clauses. Equation (15) implies

$$F(v,m) = 1 - \left(1 - \frac{p(1-p)^{v-1}}{1-(1-p)^v}\right)^m. \tag{32}$$

Let $D(v,i,k,m,n)$ be the probability that setting i random variables to *false* results in no clauses becoming empty and k mixed clauses becoming satisfied. If $i = 0$, nothing happens, so

$$D(v,0,k,m,n) = \delta_{k0}. \tag{33}$$

For $i = 1$, equations (15) and (24) imply

$$D(v,1,k,m,n) = \binom{n}{k}\left(1 - \frac{p(1-p)^{v-1}}{1-(1-p)^v}\right)^m \left(\frac{p(1+p)^{v-1}}{(1+p)^v - 1}\right)^k \left(1 - \frac{p(1+p)^{v-1}}{(1+p)^v - 1}\right)^{n-k}. \tag{34}$$

For $i > 1$, some of the mixed clauses (x of them) must be satisfied when the first $i-1$ variables are set and then the rest ($k-x$) must be satisfied when the last variable is set, so D can be calculated from

$$D(v,i,k,m,n) = \sum_x D(v,i-1,x,m,n) D(v-i+1,1,k-x,m,n-x). \tag{35}$$

Since the m index is constant in this recurrence and

$$\prod_{0 \le j < i}\left(1 - \frac{p(1-p)^{v-j-1}}{1-(1-p)^{v-j}}\right) = \frac{1-(1-p)^{v-i}}{1-(1-p)^v}, \tag{36}$$

we have

$$D(v,i,k,m,n) = \left(\frac{1-(1-p)^{v-i}}{1-(1-p)^v}\right)^m D(v,i,k,n), \tag{37}$$

where

$$D(v,1,k,n) = \binom{n}{k}\left(\frac{p(1+p)^{v-1}}{(1+p)^v-1}\right)^k\left(1-\frac{p(1+p)^{v-1}}{(1+p)^v-1}\right)^{n-k} \tag{38}$$

and

$$D(v,i,k,n) = \sum_x D(v,i-1,x,n)D(v-i+1,1,k-x,n-x). \tag{39}$$

The solution to this recurrence is

$$D(v,i,k,n) = \binom{n}{k}\frac{[(1+p)^v-(1+p)^{v-i}]^k[(1+p)^{v-i}-1]^{n-k}}{[(1+p)^v-1]^n}. \tag{40}$$

Let $E(v,j,k,l,m,n)$ be the probability that setting one random variable to *true* results in no clauses becoming empty, j mixed clauses becoming all-positive clauses, k mixed clauses becoming satisfied, and l all-positive clauses becoming satisfied. (Notice that no other changes of clause category can occur.) From equation (21), the probability that a mixed clause will become all-positive is

$$\sum_{j\geq 1}\binom{v-1}{j}\frac{p^{j+1}(1-p)^{v-j-1}}{(1+p)^v-1} = \frac{p[1-(1-p)^{v-1}]}{(1+p)^v-1}. \tag{41}$$

Using this with Equations (13), (20), and (22) gives

(42)

$$\begin{aligned}
&E(v,j,k,l,m,n)\\
&= \binom{m}{l}\binom{n}{j,k,n-j-k}\left(\frac{p}{1-(1-p)^v}\right)^l\left(1-\frac{p}{1-(1-p)^v}\right)^{m-l}\\
&\quad\times\left(\frac{p[1-(1-p)^{v-1}]}{(1+p)^v-1}\right)^j\left(\frac{p[(1+p)^{v-1}-1]}{(1+p)^v-1}\right)^k\\
&\quad\times\left(1-\frac{p(1-p)^{v-1}}{(1+p)^v-1}-\frac{p[1-(1-p)^{v-1}]}{(1+p)^v-1}-\frac{p[(1+p)^{v-1}-1]}{(1+p)^v-1}\right)^{n-j-k}\\
&= \binom{m}{l}\binom{n}{j,k,n-j-k}\left(\frac{p}{1-(1-p)^v}\right)^l\left(1-\frac{p}{1-(1-p)^v}\right)^{m-l}\\
&\quad\times\left(\frac{p[1-(1-p)^{v-1}]}{(1+p)^v-1}\right)^j\left(\frac{p[(1+p)^{v-1}-1]}{(1+p)^v-1}\right)^k\left(1-\frac{p(1+p)^{v-1}}{(1+p)^v-1}\right)^{n-j-k}.
\end{aligned}$$

7.2. Recurrence. Probe Order Backtracking selects a clause and then sets the variables that occur in the clause. If the selected clause has h variables, then there is a root, a node from setting the first variable to *false*, a potential node from setting the first two variables to *false*, and so on. This gives a root plus up to h additional

nodes. In addition, there is a subtree for setting the first variable to *true*, potentially a subtree for setting the first variable to *false* and the second to *true*, and so on. When setting the first few variables, some of the mixed clauses may evaluate to *false*. Also, setting the first few variables may result in the number of mixed clauses dropping to zero. Either of these effects may prevent a potential node from occurring in the tree.

Define $a(v,i)$ as the probability that the selected clause contains i or more literals (thus potentially contributing an ith node to the backtrack tree). Then from equation (12), we obtain

$$a(v,i) = \sum_{j \geq i} A(v,j) = \sum_{j \geq i} \binom{v}{j} \frac{p^j (1-p)^{v-j}}{1-(1-p)^v}. \tag{43}$$

Let $T(v,m,n)$ be the average number of nodes for a problem that has v variables, m all-positive clauses, n mixed clauses, and no empty clauses. Then

(44)

$$\begin{aligned} T(v,m,n) &= 1 \\ &\quad + \sum_{1 \leq i \leq v} a(v,i) \sum_{x<n} D(v,i-1,x,m-1,n) \Big[1 + G(v-i+1,n-x) \\ &\quad + \sum_{j,k,l} E(v-i+1,j,k,l,m-1,n-x) T(v-i,m+j-l-1,n-j-k-x) \Big]. \end{aligned}$$

The initial 1 is for the root of the tree. The i index is for those nodes that occur as a result of setting the first i variables from the clause. The factor $a(v,i)$ gives the probability that the selected clause has at least i variables. The index x is for the number of mixed clauses that are satisfied when setting the first $i-1$ variables to *false*. The sum does not include $x = n$ because no subproblems are generated when the number of mixed clauses is reduced to zero. The factor $D(v,i-1,x,m-1,n)$ is the probability that x of the n mixed clauses become satisfied and no clauses become empty as a result of setting the first $i-1$ variables. The D factor multiplies the sum of terms that relate to the various kinds of nodes that can result when the ith variable is set. The 1 following the square bracket is for the node that results from setting the ith variable to *false*. The $G(v-i+1,n-x)$ term gives the probability that setting the ith variable to *true* produces an empty clause. When setting the ith variable to *true*, the j index counts the number of mixed clauses that become all-positive, the k index counts the number of mixed clauses that become satisfied, and the l index counts the number of all-positive clauses that are satisfied. (The selected clause is not included in this count.) The factor $E(v-i+1,j,k,l,m-1,n-x)$ is the probability that setting the ith variable results in the values j, k, and l. The factor $T(v-i,m+j-l-1,n-j-k-x)$ is the expected number of nodes in the subtree that results from setting the first $i-1$ variables to *false* and the ith variable to *true*.

If m or n is zero, then the algorithm stops immediately, so there is only one node. Thus

$$T(v,0,n) = T(v,m,0) = 1. \tag{45}$$

We now do a number of transformations to convert equation (44) into a more convenient form. Define

$$Y(v,i) = \frac{1-(1-p)^{v-i}}{1-(1-p)^v}. \tag{46}$$

Then equations (37) and (44) imply

$$\begin{aligned}T(v,m,n) = 1 + \sum_{1\le i\le v} a(v,i) \sum_{x<n} [Y(v,i-1)]^{m-1} D(v,i-1,x,n) \\ \times \Bigg[1 + G(v-i+1,1,n-x) \\ + \sum_{j,k,l} E(v-i+1,j,k,l,m-1,n-x) \\ \times T(v-i,m+j-l-1,n-j-k-x) \Bigg].\end{aligned}$$

Change indices with $j' = m+j-l-1$ and $k' = n-j-k-x$ ($j = l+j'-m+1$, $k = n+m-l-x-j'-k'-1$) and drop primes to obtain

(47)
$$\begin{aligned}T(v,m,n) = 1 + \sum_{1\le i\le v} a(v,i) \sum_{x<n} [Y(v,i-1)]^{m-1} D(v,i-1,x,n) \\ \times \Bigg[1 + G(v-i+1,1,n-x) \\ + \sum_{j,k,l} E(v-i+1,l+j-m+1,n+m-l-x-j-k-1,l,m-1,n-x) T(v-i,j,k) \Bigg].\end{aligned}$$

Define

(48)
$$\begin{aligned}Z(v,i,m,n) &= \sum_{x<n} [Y(v,i-1)]^{m-1} D(v,i-1,x,n)[1+G(v-i+1,1,n-x)] \\ &= [Y(v,i-1)]^{m-1} \\ &\quad \times \left[2 - \left(\frac{(1+p)^v - (1+p)^{v-i+1}}{(1+p)^v - 1} \right)^n - \left(\frac{(1+p)^v - 1 - p(1-p)^{v-i}}{(1+p)^v - 1} \right)^n \right]\end{aligned}$$

and

$$\begin{aligned}&H(v,i,j,k,m,n) \\ &\quad = \sum_{x<n} [Y(v,i-1)]^{m-1} D(v,i-1,x,n) \\ &\qquad \times \sum_{l} E(v-i+1,l+j-m+1,n+m-l-x-j-k-1,l,m-1,n-x).\end{aligned}$$

After doing the sum over x and canceling some factors (one page of algebra), one has

(49)
$$\begin{aligned}H(v,i,j,k,m,n) = \left(\frac{(1+p)^{v-i}-1}{(1+p)^v - 1} \right)^k \sum_l \binom{m-1}{l} \binom{n}{l+j-m+1} \\ \times \binom{n+m-l-j-1}{k} \left(\frac{p}{1-(1-p)^v} \right)^l \\ \times \left(\frac{1-(1-p)^{v-i+1}-p}{1-(1-p)^v} \right)^{m-l-1} \left(\frac{p[1-(1-p)^{v-i}]}{(1+p)^v - 1} \right)^{l+j-m+1}\end{aligned}$$

$$\times \left(\frac{(1+p)^v - (1+p)^{v-i} - p}{(1+p)^v - 1} \right)^{n+m-l-j-k-1}$$
$$- \delta_{k0} \left(\frac{(1+p)^v - (1+p)^{v-i+1}}{(1+p)^v - 1} \right)^n$$
$$\times \binom{m-1}{j} \left(\frac{1-(1-p)^{v-i+1} - p}{1-(1-p)^v} \right)^j \left(\frac{p}{1-(1-p)^v} \right)^{m-1-j}.$$

With these definitions, equation (47) can be written as

$$T(v,m,n) = 1 + \sum_{1 \le i \le v} a(v,i) \left(Z(v,i,m,n) + \sum_{j,k} H(v,i,j,k,m,n) T(v-i,j,k) \right). \tag{50}$$

Equation (50) is suitable for the derivation of the asymptotic number of nodes, but it requires time $O(v^2t^4)$ to evaluate. In [19], an alternate four-index recurrence is given which can be evaluated in time $O(vt^4 + v^2t^3)$.

7.3. Verification of the recurrences. Aside from being careful with the mathematics, we performed measurements to help insure the correctness of the analysis of Probe Order Backtracking.

For t and v in the range $1 \le v \le 6$, $1 \le t \le 6$, $1 \le tv \le 12$, we generated each of the 2^{2tv} SAT problems and counted the number of nodes produced. A problem with i literals has probability $p^i(1-p)^{2tv-i}$. Multiplying the node counts for each i by this probability gives a polynomial in p with integer coefficients [3]. We used Maple V to solve (50) algebraically and verified that the polynomials from the recurrence were identical with the polynomials generated from the corresponding node counts.

8. Bounds. We are interested in values for t and p for which the running time is polynomial in v. Thus we now compute a simple upper bound on the number of nodes and compare this bound with v^n as v becomes large.

Our approach is to eliminate indices from the recurrence until we obtain a linear first-order recurrence. To eliminate an index, we assume that the unknown function (T) has a particular dependence on the index being eliminated times a new unknown function of the remaining indices. By plugging the assumed form into the initial recurrence (and performing one or two summations), we obtain a bounding recurrence for the new function.

To simplify the algebra, we now drop the term that starts with δ_{k0} from the definition of H (in equation (49)) and drop the first negative term from the definition of Z (in equation (48)). These changes lead to a new $T(v,m,n)$, which is an upper bound on the number of nodes. The terms have no significant effect when v is large. Dropping them now saves a lot of ink.

It is convenient to first shift the recurrence by using $T'(v,m,n) = T(v,m,n) - 1$. From equation (50), we obtain

(51)
$$\begin{aligned} & T'(v,m,n) \\ &= \sum_{1 \le i \le v} a(v,i) \left(Z(v,i,m,n) + \sum_j \sum_k H(v,i,j,k,m,n)[T'(v-i,j,k)+1] \right) \\ &= \sum_{1 \le i \le v} a(v,i) \left[Z(v,i,m,n) + \left(\frac{1-(1-p)^{v-i+1}}{1-(1-p)^v} \right)^{m-1} \left(\frac{(1+p)^v - 1 - p(1+p)^{v-i}}{(1+p)^v - 1} \right)^n \right. \\ &\qquad \left. + \sum_j \sum_k H(v,i,j,k,m,n) T'(v-i,j,k) \right], \end{aligned}$$

which can be written as

(52)
$$T'(v,m,n) = \sum_{1\le i\le v} a(v,i)\biggl(Z'(v,i,m,n) + \sum_j \sum_k H(v,i,j,k,m,n)T'(v-i,j,k)\biggr),$$

where

$$Z'(v,i,m,n) = 2\left(\frac{1-(1-p)^{v-i+1}}{1-(1-p)^v}\right)^{m-1}. \tag{53}$$

The boundary conditions for the shifted recurrence are

$$T'(v,0,n) = T'(v,m,0) = 0, \tag{54}$$

and the average number of nodes is

$$\begin{aligned} &1 + \sum_{m,n} \binom{t}{m,n,t-m-n}(1-p)^{(n+m)v} \\ &\quad\times [1-(1-p)^v]^m[(1+p)^v-1]^n[1-(1-p)^v(1+p)^v]^{t-m-n}T'(v,m,n). \end{aligned} \tag{55}$$

8.1. Two-index recurrence. For any $x(v)$, define $T(v,n)$ so that $T'(v,m,n) \le x(v)^m T(v,n)$ for all m. (We could include an n dependence in x, but that does not appear to be useful.) Rearrange the binomials to obtain

$$\begin{aligned} H(v,i,j,k,m,n) = \binom{n}{k}&\left(\frac{(1+p)^{v-i}-1}{(1+p)^v-1}\right)^k \sum_l \binom{m-1}{l}\binom{n-k}{l+j-m+1} \\ &\times \left(\frac{p}{1-(1-p)^v}\right)^l \left(\frac{1-(1-p)^{v-i+1}-p}{1-(1-p)^v}\right)^{m-l-1} \\ &\times \left(\frac{p[1-(1-p)^{v-i}]}{(1+p)^v-1}\right)^{l+j-m+1} \\ &\times \left(\frac{(1+p)^v-(1+p)^{v-i}-p}{(1+p)^v-1}\right)^{n+m-l-j-k-1}. \end{aligned} \tag{56}$$

Equation (52) implies that we can obtain our bound by requiring

$$\begin{aligned} &x(v)^m T(v,n) \\ &\quad\ge \sum_{1\le i\le v} a(v,i)\biggl(Z'(v,i,m,n) + \sum_j \sum_k x(v-i)^j H(v,i,j,k,m,n)T(v-i,k)\biggr), \end{aligned}$$

$$T(v,0) = 0, \qquad T(v,n) \ge 0,$$

where the bounds must hold for all m of interest. Thus

$$\begin{aligned} T(v,n) = \max_m \biggl\{ \frac{1}{x(v)^m}\biggl[\sum_{1\le i\le v} a(v,i)\biggl(&Z'(v,i,m,n) \\ &+ \sum_j \sum_k x(v-i)^j H(v,i,j,k,m,n)T(v-i,k)\biggr)\biggr]\biggr\}, \end{aligned} \tag{57}$$

$$T(v,0)=0.$$

Summing x^jH over j gives

$$\begin{aligned}\sum_j x^jH(v,i,j,k,m,n)&\\ =\left(\frac{x[1-(1-p)^{v-i+1}]+(1-x)p}{1-(1-p)^v}\right)^{m-1}&\binom{n}{k}\left(\frac{(1+p)^{v-i}-1}{(1+p)^v-1}\right)^k\\ \times\left(\frac{(1+p)^v-(1+p)^{v-i}-(1-x)p-xp(1-p)^{v-i}}{(1+p)^v-1}\right)^{n-k}&.\end{aligned}\tag{58}$$

Using this sum and the definition of Z' in equation (57) gives

$$\begin{aligned}T(v,n)&\\ =\frac{1}{x(v)}\max_m\Bigg\{\sum_{1\le i\le v}a(v,i)\Bigg[&2\left(\frac{1-(1-p)^{v-i+1}}{x(v)[1-(1-p)^v]}\right)^{m-1}\\ &+\left(\frac{x(v-i)[1-(1-p)^{v-i+1}]+[1-x(v-i)]p}{x(v)[1-(1-p)^v]}\right)^{m-1}\\ &\times\sum_k\binom{n}{k}\left(\frac{(1+p)^{v-i}-1}{(1+p)^v-1}\right)^k\\ &\times\left(\frac{(1+p)^v-(1+p)^{v-i}-[1-x(v-i)]p-x(v-i)p(1-p)^{v-i}}{(1+p)^v-1}\right)^{n-k}\\ &\times T(v-i,k)\Bigg]\Bigg\},\end{aligned}\tag{59}$$

$$T(v,0)=0,\qquad T(v,n)\ge 0.\tag{60}$$

So that this recurrence will be favorable, we wish to avoid raising quantities that are above 1 to the mth power. Thus we require

$$[1-(1-p)^v]x(v)\ge 1-(1-p)^{v-i+1}\tag{61}$$

and

$$[1-(1-p)^v]x(v)\ge[1-(1-p)^{v-i+1}]x(v-i)+[1-x(v-i)]p.\tag{62}$$

As long as $x(v)$ is above 1, any increasing function of v can be chosen for $[1-(1-p)^v]x(v)$.

If $x(v)$ obeys the bounds (61) and (62), then we have

$$\begin{aligned}T(v,n)=\frac{1}{x(v)}\Bigg[\sum_{1\le i\le v}a(v,i)\Bigg(&2+\sum_k\binom{n}{k}\left(\frac{(1+p)^{v-i}-1}{(1+p)^v-1}\right)^k\\ \times\left(\frac{(1+p)^v-(1+p)^{v-i}-[1-x(v-i)]p-x(v-i)p(1-p)^{v-i}}{(1+p)^v-1}\right)^{n-k}&T(v-i,k)\Bigg)\Bigg].\end{aligned}\tag{63}$$

(55) implies that the average number of nodes is bounded by

(64)
$$1+\sum_{m,n}\binom{t}{m,n,t-m-n}(1-p)^{(n+m)v}x(v)^m[1-(1-p)^v]^m \times[(1+p)^v-1]^n[1-(1-p)^v(1+p)^v]^{t-m-n}T(v,n)$$
$$=1+\sum_n\binom{t}{n}(1-p)^{nv}[(1+p)^v-1]^n \times\{1-(1-p)^v(1+p)^v+x(v)(1-p)^v[1-(1-p)^v]\}^{t-n}T(v,n).$$

Equation (64) gives a good bound when $x(v)$ is set to the average length of an all-positive clause, equation (17). (See Figure 5 in [19].)

Note the division by $x(v)$ in equation (63). This is critical to obtaining an analytical understanding of why Probe Order Backtracking is fast. We are free to set $x(v)$ large enough to cancel out the effect of summing over i (which is where the growth in $T(v,n)$ comes from) as long as the factor in equation (64) which is raised to the power $t-n$ is not above 1. This division by $x(v)$ is related to the fact that selecting an all-positive clause results in a reduction of one in the number of all-positive clauses. (The setting of variables can augment or counteract this reduction.)

8.2. One-index recurrence. For any $x(v)$ and $y(v)$, define $T(v)$ so that $T'(v,m,n)\le x(v)^m y(v)^n T(v)$ for all m and n. Summing x^jy^kH over j and k gives

$$\begin{aligned}&\sum_{j,k}x^jy^kH(v,i,j,k,m,n)\\ &\quad=\sum_k y^k\left(\frac{x[1-(1-p)^{v-i+1}]+(1-x)p}{1-(1-p)^v}\right)^{m-1}\binom{n}{k}\left(\frac{(1+p)^{v-i}-1}{(1+p)^v-1}\right)^k\\ &\qquad\times\left(\frac{(1+p)^v-(1+p)^{v-i}-(1-x)p-xp(1-p)^{v-i}}{(1+p)^v-1}\right)^{n-k}\\ &\quad=\left(\frac{x[1-(1-p)^{v-i+1}]+(1-x)p}{1-(1-p)^v}\right)^{m-1}\\ &\qquad\times\left(\frac{(1+p)^v+(y-1)(1+p)^{v-i}-y-(1-x)p-xp(1-p)^{v-i}}{(1+p)^v-1}\right)^n.\end{aligned}\tag{65}$$

Using this result in equation (59) implies that a suitable $T(v)$ is any function at least as large as the solution to

(66)
$$\begin{aligned}T(v)=\frac{1}{x(v)}\max_{m,n}\Bigg\{\sum_{1\le i\le v}a(v,i)\Bigg[&\frac{2}{y(v)^n}\left(\frac{1-(1-p)^{v-i+1}}{x(v)[1-(1-p)^v]}\right)^{m-1}\\ &+\left(\frac{x(v-i)[1-(1-p)^{v-i+1}]+[1-x(v-i)]p}{x(v)[1-(1-p)^v]}\right)^{m-1}\\ &\times\Bigg(\frac{(1+p)^v+[y(v-i)-1](1+p)^{v-i}}{y(v)[(1+p)^v-1]}\\ &-\frac{y(v-i)-[1-x(v-i)]p-x(v-i)p(1-p)^{v-i}}{y(v)[(1+p)^v-1]}\Bigg)^n T(v-i)\Bigg]\Bigg\}.\end{aligned}$$

Again, we wish to avoid raising quantities above 1 to high powers. Thus we still have the bounds (61) and (62) for $x(v)$. In addition, we have

$$y(v) \geq 1 \tag{67}$$

and

$$[y(v)-1][(1+p)^v-1]-[y(v-i)-1][(1+p)^{v-i}-1] \geq p\{x(v-i)[1-(1-p)^{v-i}]-1\}. \tag{68}$$

These bounds for y are satisfied by

$$[y(v)-1][(1+p)^v-1] = p \sum_{1\leq j\leq v-1} \max\{0, \{x(j)[1-(1-p)^j]-1\}\}. \tag{69}$$

If $x(v)$ and $y(v)$ obey the bounds, we have

$$T(v) = \frac{1}{x(v)} \sum_{1\leq i\leq v} a(v,i)[2+T(v-i)]. \tag{70}$$

Equation (64) implies that the average number of nodes is bounded by

$$\begin{aligned} &1+\sum_n \binom{t}{n} y(v)^n (1-p)^{nv}[(1+p)^v-1]^n \\ &\quad \times \{1-(1-p)^v(1+p)^v + x(v)(1-p)^v[1-(1-p)^v]\}^{t-n} T(v) \\ &= 1 + \\ &\{1-(1-p)^v(1+p)^v + y(v)(1-p)^v[(1+p)^v-1] + x(v)(1-p)^v[1-(1-p)^v]\}^t T(v). \end{aligned} \tag{71}$$

If the value of $y(v)$ is set by equation (69), then the number of nodes is bounded by

$$1+\left[1+(1-p)^v\left(x(v)[1-(1-p)^v]-1+p\sum_{1\leq j\leq v-1}\max\{0,(x(j)[1-(1-p)^j]-1)\}\right)\right]^t T(v). \tag{72}$$

(72) gives a good bound when $x(v)$ is set to the average length of an all-positive clause, equation (17). (See Figure 2 in [19].)

If one sets $x(v)$ to the average clause size and $y(v) = 1$ (ignoring the requirement that $y(v)$ satisfy bounds (67, 68)), one obtains a result that is essentially the same as that given by the heuristic analysis, eq. (30).

8.3. A simplification. Equation (70) has only one index, but it is still rather complex due to the summation on the right side. Define $U(0) = T(0)$ and

$$U(v) = \frac{2+U(v-1)}{x(v)} \sum_{1\leq i\leq v} a(v,i). \tag{73}$$

When $U(v)$ is nondecreasing, $T(v) \leq U(v)$. (In equation (70), we can obtain an upper bound by replacing $T(v-i)$ with an upper bound, i.e., with $U(v-1)$.) A good choice for $x(v)$ is one that cancels the effect of the summation. For

$$x(v) = \sum_{1\leq i\leq v} a(v,i) = \frac{pv}{1-(1-p)^v}, \tag{74}$$

we have

$$U(v) = 2 + U(v-1), \qquad U(0) = 0. \tag{75}$$

Thus

$$T(v) \le 2v. \tag{76}$$

When $x(v)$ is given by equation (74), we have

$$\begin{aligned}\sum_{1\le j\le v-1} \max\{x(j)[1-(1-p)^j]-1,0\} &= \sum_{1/p\le j\le v-1} (pj-1)\\ &\le \frac{pv(v-1)}{2} - \frac{(1/p-1)}{2} - \left(v-\frac{1}{p}\right).\end{aligned} \tag{77}$$

(The less than or equal comes from the fact that $1/p$ may be a noninteger.) Thus equations (72) and (77) imply that the number of nodes is bounded by

$$1 + 2v\left[1 + (1-p)^v\left(\frac{p^2v(v-1)}{2} - \frac{1-p}{2}\right)\right]^t. \tag{78}$$

Figure 2 shows the bounds that result from (78). The contour for v^1 nodes has two branches, the upper one along the $p = 1$ axis and the lower one shown on the figure. The remaining contours have about the same shape as the contours from the exact analysis (Figure 1), but they are fatter. Also, the v^4 contour is shown in Figure 2, whereas it occurs at too large of a t value to be shown in Figure 1.

In [19], we show that

$$x(v) = \frac{apv}{1-(1-p)^v} \tag{79}$$

with

$$a = \frac{2 + (1-p)^v[-1+p+2(t-1)pv + p^2tv(v-1)]}{p(t-1)v(1-p)^v[p(v-1)+2]} \tag{80}$$

gives a better bound, but we do not use that result here.

9. Asymptotics. For the asymptotic analysis, we require that the bound on the number of nodes be no more than v^n. That is,

$$v^n \ge 1 + 2v\left[1 + (1-p)^v\left(\frac{p^2v(v-1)}{2} - \frac{1-p}{2}\right)\right]^t \tag{81}$$

or

$$\frac{v^{n-1}}{2}\left(1 - \frac{1}{v^n}\right) \ge \left[1 + (1-p)^v\left(\frac{p^2v(v-1)}{2} - \frac{1-p}{2}\right)\right]^t. \tag{82}$$

9.1. Small *t*. From (82), we have

$$\ln\left[\frac{v^{n-1}}{2}\left(1 - \frac{1}{v^n}\right)\right] \ge t\ln\left[1 + (1-p)^v\left(\frac{p^2v(v-1)}{2} - \frac{1-p}{2}\right)\right]. \tag{83}$$

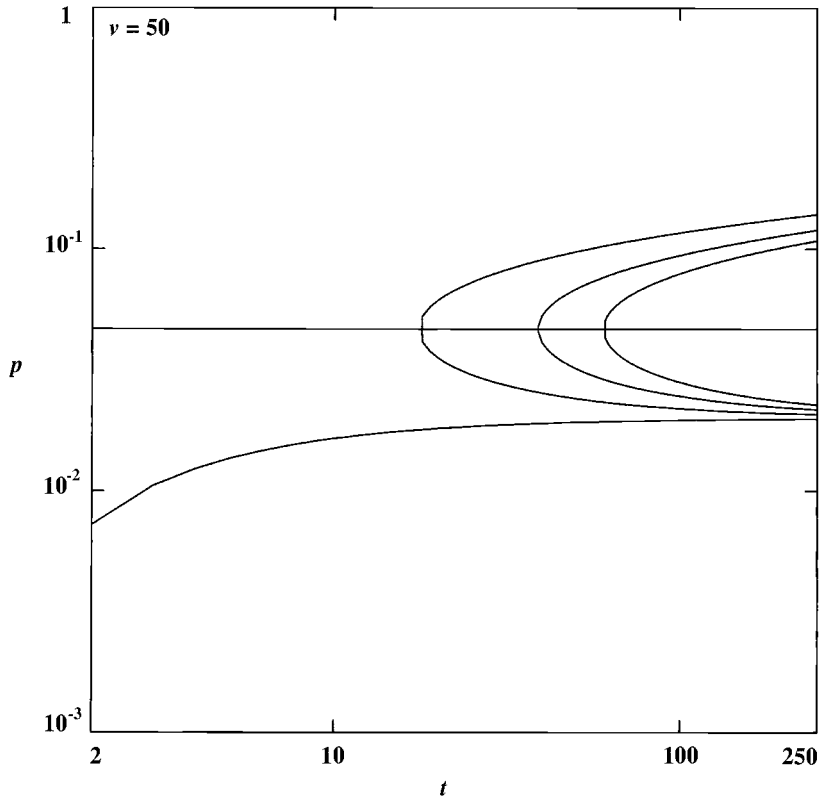

FIG. 2. *Upper limit.*

Simplifying and solving for t gives

$$t \le \frac{(n-1)\ln v - \ln 2 - \Theta(1/v^n)}{\ln\{1 + [p^2 v(v-1) - 1 + p](1-p)^v/2\}}. \tag{84}$$

For $n > 1$ and $1 < a \le pv \le b < \infty$, (84) can be simplified to

$$t \le \frac{(n-1)\ln v - \ln 2}{\ln\{1 + [(pv)^2 - 1]e^{-pv}/2\}}, \tag{85}$$

which is bound (4). (Since this is an upper bound, positive Θ terms were dropped.)

9.2. Small *p*. When p is small, it is useful to simplify (82) by taking the tth root and using $x = e^{\ln x}$:

$$1 + (1-p)^v \left(\frac{p^2 v(v-1)}{2} - \frac{1-p}{2}\right) \le \frac{v^{(n-1)/t}}{2^{1/t}} \left[1 - \Theta\left(\frac{1}{v^n t}\right)\right]. \tag{86}$$

Expanding in power series and multiplying by 2 gives

$$(1-p)^v [p^2 v(v-1) - 1 + p] \le \frac{2[(n-1)\ln v - \ln 2]}{t} \left[1 + \Theta\left(\frac{\ln v}{t}\right)\right]. \tag{87}$$

When $pv > 1$ and p^2v is bounded, bound (87) can be written as

$$[(pv)^2 - 1]e^{-pv} \leq \frac{2[(n-1)\ln v - \ln 2]}{t}\left[1 + \Theta\left(\frac{1}{v}\right) + \Theta(p^2 v) + \Theta\left(\frac{\ln v}{t}\right)\right]. \tag{88}$$

This can be written as

$$p^2v^2 \leq 1 + 2e^{pv}\frac{(n-1)\ln v - \ln 2}{t}\left[1 + \Theta\left(\frac{1}{v}\right) + \Theta\left(\frac{\ln v}{t}\right)\right]. \tag{89}$$

To find the solution near $pv = 1$, let $pv = 1 + y$, giving

$$2y + y^2 \leq 2e[1 + y + \Theta(y^2)]\frac{(n-1)\ln v - \ln 2}{t}\left[1 + \Theta\left(\frac{1}{v}\right) + \Theta\left(\frac{\ln v}{t}\right)\right]. \tag{90}$$

Thus

$$y \leq \frac{e[(n-1)\ln v - \ln 2]}{t}\left[1 + \Theta\left(\frac{1}{v}\right) + \Theta\left(\frac{\ln v}{t}\right)\right]. \tag{91}$$

Drop positive Θ terms to obtain

$$pv \leq 1 + \frac{e[(n-1)\ln v - \ln 2]}{t}, \tag{92}$$

which is equivalent to bound (3).

9.3. Large *p*. In the previous section, we found a solution to bound (82) that has pv near 1. For large pv, $(1-p)^v$ decreases much more rapidly than $(pv)^2$ increases. Bound (88) has the form $(x^2-1)e^{-x} \leq y$ with small y. Define z by $x = -\ln y + 2\ln(-\ln y) + z\ln(-\ln y)/(-\ln y)$. Plugging into $(x^2-1)e^{-x} \leq y$ gives

$$\frac{[-\ln y + 2\ln(-\ln y) + z\ln(-\ln y)/(-\ln y)]^2 - 1}{(-\ln y)^{2+z/(-\ln y)}}y = y. \tag{93}$$

Dividing both sides by y and clearing fractions gives

$$\left(1 + \frac{2\ln(-\ln y)}{-\ln y} + \frac{z\ln(-\ln y)}{(-\ln y)^2}\right)^2 - \frac{1}{(-\ln y)^2} = (-\ln y)^{z/(-\ln y)}.$$

Taking logarithms, expanding the logarithms, and retaining the important terms gives

$$\frac{4\ln(-\ln y)}{-\ln y}\left[1 + \Theta\left(\frac{\ln(-\ln y)}{-\ln y}\right)\right] = \frac{z\ln(-\ln y)}{-\ln y}.$$

In the limit, the right side is bigger for $z > 4$ and the left side is bigger for $z \leq 4$. Thus

$$x = -\ln y + 2\ln(-\ln y) + \Theta\left(\frac{\ln(-\ln y)}{-\ln y}\right)$$

is a solution to the bound $(x^2-1)e^{-x} \leq y$. (Also, there is no solution with larger x.)

When t increases more rapidly than $\ln v$, the solution to (88) is

$$pv \geq \ln t + 2\ln\ln t - \ln\ln v - \ln(n-1) - \ln 2 + \Theta\left(\frac{\ln\ln t}{\ln t}\right). \tag{94}$$

This is bound (1).

9.4. Comparison with Simple Backtracking. When t/v is large, the results of the small-p analysis are not very good. A better result can be obtained by observing that the average running time for Probe Order Backtracking is no larger than that of Simple Backtracking. (The proof that the average running time of Clause Order Backtracking is no larger than that of Simple Backtracking [3, Theorem 1] also applies to Probe Order Backtracking.)

We require that A.18 from [18], the bound for Simple Backtracking, be no more than v^n. For this bound, we use $M(v) = v$ and $\delta = 0$ and let $q = -\ln(1-p)$ to obtain

$$v^n \geq 1 + v \exp\left[2(\ln 2)v + \ln 2 - \frac{\ln 2}{q} \ln\left(1 + \frac{qt}{\ln 2}\right) + t \ln\left(1 - \frac{\ln 2}{\ln 2 + qt}\right)\right]. \tag{95}$$

This can be written as

$$qv - \frac{1}{2}\ln(qv) \leq \frac{1}{2}\ln\left(\frac{t}{v}\right) + \frac{1 - \ln\ln 2}{2} + \frac{q}{2\ln 2}[(n-1)\ln v - \ln 2] - \Theta\left(\frac{q}{v^n}\right) + \Theta\left(\frac{1}{qt}\right). \tag{96}$$

When $t/v > e$, the solution to bound (96) is

$$\begin{aligned} qv \leq \frac{1}{2}\ln\left(\frac{t}{v}\right) + \frac{1}{2}\ln\ln\left(\frac{t}{v}\right) + \frac{1 - \ln 2 - \ln\ln 2}{2} + \frac{q}{2\ln 2}[(n-1)\ln v - \ln 2] \\ + \Theta\left(\frac{\ln\ln(t/v)}{\ln(t/v)}\right) - \Theta\left(\frac{q}{v^n}\right). \end{aligned} \tag{97}$$

Replacing q with its value in terms of p and solving for p in bound (97) gives

$$\begin{aligned} p \leq \left[\frac{\ln(t/v) + \ln\ln(t/v) + 1 - \ln 2 - \ln\ln 2}{2v}\right] \\ \times\left[1 + \frac{2(n-1)\ln v - (\ln 2)[\ln(t/v) + \ln\ln(t/v) + 3 - \ln 2 - \ln\ln 2]}{4v\ln 2}\right. \\ \left. - \Theta\left(\frac{(\ln v)\ln(t/v)}{v^2}\right) - \Theta\left(\frac{\ln\ln(t/v)}{v\ln(t/v)}\right)\right], \end{aligned} \tag{98}$$

which is bound (2). For large v, this is an improvement over the small-p analysis when $t = \beta v$ and $\beta > 3.22136$. Note that $\beta > e$.

9.5. Comparison with solution boundary. The average number of solutions to a random CNF satisfiability problem is

$$2^v[1 - (1-p)^v]^t \tag{99}$$

[18, equation A.1]. This is v^n when

$$p = \frac{1}{v}\left[-\ln\left(1 - \frac{1 + \Theta(n(\ln v)/t)}{e^{(\ln 2)v/t}}\right)\right][1 - \Theta(p)]. \tag{100}$$

(Note that $n = 0$ corresponds to an average of one solution per problem.) When t/v is large, this can be simplified to

$$\begin{aligned} pv = (\ln t - \ln v - \ln\ln 2)\left[1 - \Theta\left(\frac{\ln t - \ln v}{v}\right)\right] \\ + \Theta\left(\frac{v}{t}\right) + \Theta\left(\frac{n\ln v}{v}\right). \end{aligned} \tag{101}$$

Note that for large t/v, the large-p boundary for Probe Order Backtracking being fast (based on the upper bound analysis) is only slightly above the boundary for the number of solutions per problem being above 1. That is, the leading terms in (94) are bigger than those in (101) by only the amount $\ln v$. When t/v is not large, the relative distance between the two curves increases.

9.6. Intersection with Franco's analysis. Franco gives an algorithm [8] which makes selective use of resolution. This algorithm has the fastest proven average time for small t as long as p is not too large. Combining Franco's algorithm with Iwama's algorithm [9] gives an algorithm that is fast for all p when

$$t \le O(n^{1/3}(v/\ln v)^{1/6}). \tag{102}$$

The number of nodes for Franco's algorithm is no more than

$$3 + v + e^{-te^{-2p(1+p)v} + (\ln 2)[8(pt)^3 v + 1]} \tag{103}$$

[8, pp. 1123–1124]. To find the intersection of this bound with the bound for Probe Order Backtracking, it is useful to write (94) as

$$pv \ge \ln t + 2\ln\ln t - \ln\ln v - \Theta(\ln(n-1)) = \ln\left[\frac{t(\ln t)^2}{\Theta(n-1)\ln v}\right].$$

When pv is equal to this bound,

$$e^{-2p(1+p)v} = e^{-(2+2p)pv} = \left[\frac{(n-1)^{\Theta(1)}\ln v}{t(\ln t)^2}\right]^{2+\Theta(p)}.$$

When v and t are polynomially related ($\ln t = \Theta(\ln v)$), we may write this as

$$e^{-2p(1+p)v} = \frac{1}{t^{2+\Theta(p)}}\left[\frac{(n-1)^{\Theta(1)}}{\Theta(1)\ln t}\right]^{2+\Theta(p)} = \frac{1}{t^{2+\Theta(1)}}\left(\frac{n-1}{\ln t}\right)^{\Theta(1)}.$$

Plugging these results into (103) gives a number of nodes (at the intersection of the curves for the two algorithms) of

$$\begin{aligned} &3 + v + \exp\Bigg\{-\left(\frac{n-1}{t\ln t}\right)^{\Theta(1)} \\ &\quad + \frac{(8\ln 2)t^3(\ln t)^3}{v^2}\left[1 + \frac{2\ln\ln t}{\ln t} - \frac{\ln\ln v}{\ln t} - \Theta\left(\frac{\ln(n-1)}{\ln t}\right)\right]^3 + \ln 2\Bigg\}. \end{aligned} \tag{104}$$

If we set this equal to v^n and take logarithms, we have

$$\begin{aligned} &n\ln v - \Theta\left(\frac{1}{v^{n-1}}\right) \\ &= -\left(\frac{n-1}{t\ln t}\right)^{\Theta(1)} + \frac{(8\ln 2)t^3(\ln t)^3}{v^2}\left[1 + \frac{2\ln\ln t}{\ln t} - \frac{\ln\ln v}{\ln t} - \Theta\left(\frac{\ln(n-1)}{\ln t}\right)\right]^3 + \ln 2, \\ &\frac{8(\ln 2)t^3(\ln t)^3}{v^2}\left[1 + \frac{2\ln\ln t}{\ln t} - \frac{\ln\ln v}{\ln t} - \Theta\left(\frac{\ln(n-1)}{\ln t}\right)\right]^3 = n\ln v - \Theta(1), \end{aligned}$$

$$t^3(\ln t)^3 = \frac{nv^2 \ln v}{8 \ln 2} \left[1 - \Theta\left(\frac{1}{\ln v}\right)\right] \left[1 + \frac{2 \ln \ln t}{\ln t} - \frac{\ln \ln v}{\ln t} - \Theta\left(\frac{\ln(n-1)}{\ln t}\right)\right]^{-3}.$$

We may write

$$\begin{aligned} t \ln t &= \frac{(n \ln v)^{1/3} v^{2/3}}{2(\ln 2)^{1/3}} \left[1 - \Theta\left(\frac{1}{\ln v}\right)\right] \left[1 + \frac{2 \ln \ln t}{\ln t} - \frac{\ln \ln v}{\ln t} - \Theta\left(\frac{1}{\ln t}\right)\right]^{-1} \\ &= \frac{(n \ln v)^{1/3} v^{2/3}}{2(\ln 2)^{1/3}} \left[1 - \Theta\left(\frac{1}{\ln v}\right)\right] \left[1 - \frac{2 \ln \ln t}{\ln t} + \frac{\ln \ln v}{\ln t} + \Theta\left(\frac{1}{\ln t}\right)\right] \\ &= \frac{(n \ln v)^{1/3} v^{2/3}}{2(\ln 2)^{1/3}} \left[1 - \frac{2 \ln \ln t}{\ln t} + \frac{\ln \ln v}{\ln t} + \Theta\left(\frac{1}{\ln t}\right) - \Theta\left(\frac{1}{\ln v}\right)\right]. \end{aligned}$$

Define

$$y = \frac{(n \ln v)^{1/3} v^{2/3}}{2(\ln 2)^{1/3}} \left[1 - \frac{2 \ln \ln t}{\ln t} + \frac{\ln \ln v}{\ln t} + \Theta\left(\frac{1}{\ln t}\right) - \Theta\left(\frac{1}{\ln v}\right)\right]$$

and solve $y = t \ln t$ for t. Consider the test solution

$$t = \frac{y}{\ln y} \left[1 + \frac{\ln \ln y}{\ln y} + a \left(\frac{\ln \ln y}{\ln y}\right)^2\right].$$

Plugging this in gives

$$\begin{aligned} y &= \frac{y}{\ln y} \left[1 + \frac{\ln \ln y}{\ln y} + a \left(\frac{\ln \ln y}{\ln y}\right)^2\right] \ln \left\{\frac{y}{\ln y} \left[1 + \frac{\ln \ln y}{\ln y} + a \left(\frac{\ln \ln y}{\ln y}\right)^2\right]\right\} \\ &= y \left[1 + \frac{\ln \ln y}{\ln y} + a \left(\frac{\ln \ln y}{\ln y}\right)^2\right] \\ &\quad \times \left[1 - \frac{\ln \ln y}{\ln y} + \frac{\ln \ln y}{(\ln y)^2} + \Theta\left(\frac{(a - 1/2)(\ln \ln y)^2}{(\ln y)^3}\right)\right] \\ &= y \left[1 + (a-1) \left(\frac{\ln \ln y}{\ln y}\right)^2 + \Theta\left(\frac{\ln \ln y}{(\ln y)^2}\right)\right]. \end{aligned}$$

In the limit, the left side is larger for $a < 1$ and the right side is larger for $a > 1$, so a solution is

$$t = \frac{y}{\ln y} \left[1 + \frac{\ln \ln y}{\ln y} + \Theta\left(\frac{(\ln \ln y)^2}{(\ln y)^2}\right)\right].$$

We have

$$\ln y = \frac{2 \ln v}{3} + \frac{\ln \ln v}{3} + \Theta(\ln n) = \frac{2 \ln v}{3} \left[1 + \frac{\ln \ln v}{2 \ln v} + \Theta\left(\frac{\ln n}{\ln v}\right)\right]$$

and

$$\ln \ln y = \ln \ln v + \Theta(1),$$

so

$$t = \frac{3(n\ln v)^{1/3}v^{2/3}}{4(\ln 2)^{1/3}\ln v}\,\frac{1-(2\ln\ln t)/\ln t+(\ln\ln v)/\ln t+\Theta(1/\ln t)-\Theta(1/\ln v)}{1+(\ln\ln v)/(2\ln v)+\Theta((\ln n)/\ln v)}$$
$$\times\left[1+\frac{3\ln\ln v+\Theta(1)}{2\ln v+\Theta(\ln\ln v)}+\Theta\left(\frac{(\ln\ln v)^2}{(\ln v)^2}\right)\right]$$
$$= \frac{3(n\ln v)^{1/3}v^{2/3}}{4(\ln 2)^{1/3}\ln v}\left[1-\frac{2\ln\ln t}{\ln t}+\frac{\ln\ln v}{2\ln t}+\Theta\left(\frac{1}{\ln t}\right)-\Theta\left(\frac{1+\ln n}{\ln v}\right)\right]$$
$$\times\left[1+\frac{3\ln\ln v}{2\ln v}+\Theta\left(\frac{1}{\ln v}\right)\right]$$
$$= \frac{3(n\ln v)^{1/3}v^{2/3}}{4(\ln 2)^{1/3}\ln v}\left[1-\frac{2\ln\ln t}{\ln t}+\frac{\ln\ln v}{2\ln t}+\frac{3\ln\ln v}{2\ln v}+\Theta\left(\frac{1}{\ln t}\right)-\Theta\left(\frac{1+\ln n}{\ln v}\right)\right].$$

Since t is approximately $v^{2/3}$,

$$\frac{-2\ln\ln t}{\ln t}+\frac{\ln\ln v}{2\ln t}+\frac{3\ln\ln v}{2\ln v}$$

is approximately $-(3/4)(\ln\ln v)/\ln v$. Thus bound (104) is no more than v^n when

$$t = \frac{3n^{1/3}v^{2/3}}{4(\ln 2)^{1/3}(\ln v)^{2/3}}\left[1-\Theta\left(\frac{\ln\ln v}{\ln v}\right)\right]. \tag{105}$$

Note added in proof. The idea of selecting from all positive clauses has been used with good effect on quasigroup problems; see p. 546 of [H. Zhang, M. P. Bonacina, and J. Hsiang, "PSATO: A distributed propositional prover and its application to quasigroup problems," *J. Symbolic Comput.*, 21 (1996), pp. 543–560].

AMBIVALENT DATA STRUCTURES FOR DYNAMIC 2-EDGE-CONNECTIVITY AND k SMALLEST SPANNING TREES*

GREG N. FREDERICKSON†

Abstract. Ambivalent data structures are presented for several problems on undirected graphs. These data structures are used in finding the k smallest spanning trees of a weighted undirected graph in $O(m \log \beta(m,n) + \min\{k^{3/2}, km^{1/2}\})$ time, where m is the number of edges and n the number of vertices in the graph. The techniques are extended to find the k smallest spanning trees in an embedded planar graph in $O(n + k(\log n)^3)$ time. Ambivalent data structures are also used to dynamically maintain 2-edge-connectivity information. Edges and vertices can be inserted or deleted in $O(m^{1/2})$ time, and a query as to whether two vertices are in the same 2-edge-connected component can be answered in $O(\log n)$ time, where m and n are understood to be the current number of edges and vertices, respectively.

Key words. analysis of algorithms, data structures, embedded planar graph, fully persistent data structures, k smallest spanning trees, minimum spanning tree, on-line updating, topology tree, 2-edge-connectivity

1. Introduction.

Efficient handling of on-line requests requires that data be stored flexibly. At each location in a data structure, it can be advantageous to keep track of a small number of alternatives, only one of which can in fact be valid. An example of such alternatives might be whether a path between vertices x and y in a spanning tree of a graph goes through a vertex w or through a vertex w'. We say that a data structure possesses *ambivalence* if at each of many locations in the structure it keeps track of several alternatives, even when a global examination of the data structure would identify for each location the alternative (or valence) that is in fact valid. (A more formal definition of this property is given at the beginning of section 7.) The structure necessarily organizes the data in such a way that the correct alternative is known for some crucial case. We apply this technique in the design of data structures for several graph problems related to connectivity. Our data structures are ambivalent with regard to the structure of a spanning tree as that spanning tree is being updated, and they yield algorithms faster than any previously known.

Our first problem is that of finding the k smallest spanning trees of a weighted undirected graph. Using data structures that are both ambivalent and fully persistent [DSST], we give an algorithm that uses $O(m \log \beta(m,n) + \min\{k^{3/2}, km^{1/2}\})$ time, where m is the number of edges and n is the number of vertices. Here $\beta(\cdot,\cdot)$ is a very slowly growing function, as defined by Fredman and Tarjan [FT], and the first term in our running time represents the best known time to find a minimum spanning tree [GGST]. Where appropriate, we shall substitute this time when quoting previous results. The amount of space used by our algorithm is $O(m + \min\{k^{3/2}, km^{1/2}\})$. For

the case of a planar graph, we give fully persistent data structures that are then used in an algorithm that takes $O(n + k(\log n)^3)$ time and $O(n + k(\log n)^2)$ space.

Our results compare with previous results on this problem as follows. The problem of enumerating the k smallest combinatorial objects of some particular type has been studied in a number of contexts, including the assignment problem [M], the shortest-path problem [Y], [L1], and the minimum-spanning-tree problem [BH], [CFM], [G], [KIM], [F1], [E]. Early algorithms for finding the k smallest minimum spanning trees can be found in [BH] and [CFM]. Gabow has given an $O(m \log m + km\alpha(m, n))$-time algorithm [G], Katoh, Ibaraki, and Mine have given an $O(m \log \beta(m, n) + km)$-time algorithm [KIM], Frederickson gave an $O(m \log \beta(m, n)+k^2 m^{1/2})$-time algorithm [F1], and Harel claimed an $O(m \log n + kn(\log n)^2)$-time algorithm [Hl2]. Most recently, in [E], Eppstein has given an elegant preprocessing step that allows him to achieve, in conjunction with the algorithm of [KIM], a running time of $O(m \log \beta(m, n) + \min\{k^2, km\})$, using $O(m + k)$ space. Our algorithm matches the running time of Eppstein's for $k \leq (m \log \beta(m, n))^{1/2}$ and is faster for larger values of k. While our algorithm uses more space than Eppstein's for sufficiently large k, the space used by our algorithm is $O(k + m)$ whenever $k \leq m^{2/3}$.

For the case of a planar graph, there are two previous results. In [F1], Frederickson gave an $O(n+k^2(\log n)^3)$-time algorithm, and in [E], Eppstein has given an $O(n+k^2)$-time algorithm. Thus the time for our algorithm is never worse than that in [E], and it is strictly better whenever $k > n^{1/2}$. The space of our algorithm is $O(n)$ whenever $k \leq n/(\log n)^3$.

Our second problem is that of maintaining a data structure for an undirected graph under the operations of inserting and deleting edges and vertices, so as to be able to answer queries about whether two given vertices are in the same 2-edge-connected component. Using ambivalent data structures, we achieve an update time of $O(m^{1/2})$ and a query time of $O(\log n)$, where m and n are understood to be the current number of edges and vertices, respectively.

The question of whether there are data structures with sublinear-time algorithms for maintaining 2-edge-connectivity information under the operations of both insertion and deletion of edges was posed by Westbrook and Tarjan [WT]. Galil and Italiano [GI] describe a data structure that achieves $O(m^{2/3})$ update and query times.

Recently, Eppstein, Galil, Italiano, and Nissenzweig [EGIN] and Eppstein, Galil, and Italiano [EGI] have introduced a sparsification technique that creates a data structure using multiple copies of other data structures. Their technique allows them to use the data structures in this paper and thus replace the m by an n in the times for updating 2-edge-connectivity information and for finding the k smallest spanning trees in a general graph.

Our approach is based on variants of the topology tree and the 2-dimensional topology tree structures presented in [F1]. To make the approach work, we present a different, and in some sense simpler, multilevel partition of the vertices, on which the topology tree and 2-dimensional topology tree are based. A version of our variant of the topology tree that is designed for rooted trees [F3] is appropriate for implementing dynamic trees. In addition to ambivalence, we introduce other novel ideas in our solutions. These include an encoding scheme for vertex names, with the encoded names changing as the topology of a spanning tree changes, and also a partition of the spanning tree into paths based on the multilevel partition.

Our paper is organized as follows. In section 2, we describe the new multilevel partition, and in section 3, we describe the data structures, including fully persistent

data structures, used for updating spanning trees. In section 4, we characterize the adjacency of clusters in embedded planar graphs. In section 5, we describe the data structures, including fully persistent data structures, that are use for updating spanning trees in embedded planar graphs. In section 6, we describe the basic algorithm for finding the k smallest spanning trees, omitting the description of the key data structure. In section 7, we define ambivalence formally and then describe this key data structure for general graphs. In section 8, we describe this key data structure for planar graphs. In section 9, we give a data structure to maintain 2-edge-connectivity in general graphs.

2. Clustering vertices in spanning trees. In this section, we define basic data structures similar to but simpler than those in [F1]. The main contribution of the section is a new way to partition the vertices based on the topology of a spanning tree. We first describe a graph transformation that we use throughout. We then define vertex clusters and our new partition and discuss how the clusters change when an edge is inserted or deleted. We then show that the partition can be applied recursively for only $\Theta(\log n)$ levels.

Throughout this paper, we shall wish to deal with graphs that have maximum vertex degree 3. We first describe how to transform our graph into a graph in which every vertex has degree no greater than three. A well-known transformation in graph theory [Hy, p. 132] is used. By ∞ we designate a sufficiently large value, say equal to the largest value that can be represented in a single word of memory. For each vertex v of degree $d > 3$ and neighbors $w_0, w_1, \ldots, w_{d-1}$, replace v with new vertices $v_0, v_1, \ldots, v_{d-1}$. Add edges $\{(v_i, v_{i+1}) | i = 0, \ldots, d-2\}$, each of cost $-\infty$, and edge (v_{d-1}, v_0) of cost ∞, and replace edges $\{(w_i, v) | i = 0, 1, \ldots, d-1\}$ with $\{(w_i, v_i) | i = 0, \ldots, d-1\}$, of corresponding costs. Note that a minimum spanning tree for the transformed graph will be a minimum spanning tree for the original graph with every edge of cost $-\infty$ added. (The value $-\infty$ is used to ensure that these edges are not swapped out when identifying a best swap in section 6. For the purpose of identifying the cost of the minimum spanning tree in the original graph, treat the $-\infty$ as 0.)

We next define some terms that serve as the foundation for data structures from [F1] that we wish to use. Let $G = (V, E)$ be a connected undirected graph with maximum vertex degree at most 3, and let T be a subgraph of G that is a tree. A *vertex cluster* with respect to T is a set of vertices such that the subgraph of T induced on the cluster is connected. A *boundary vertex* of a cluster is a vertex that is adjacent in T to some vertex not in the cluster. The *tree degree* of a vertex cluster is the number of tree edges with precisely one endpoint in the cluster. Two disjoint vertex clusters are *adjacent* if there is a tree edge that contains one endpoint in each of the clusters. We illustrate the above definitions using Fig. 1, in which a spanning tree is shown with bold edges. The set of vertices $\{6, 7, 13\}$ is not a cluster, since the subset of edges of T incident on it is just $\{(6, 7)\}$ so that the subgraph of T induced on it is not connected. The set of vertices $\{4, 10\}$ is a cluster since the subset of edges of T incident on it is $\{(4, 10)\}$, which connects the vertices. The tree degree of cluster $\{4, 10\}$ is 4. Clusters $\{8, 9, 10, 11\}$ and $\{12, 13, 14\}$ are adjacent because there is a tree edge $(11, 12)$.

We define a partition of a set of vertices so that the resulting vertex clusters possess certain nice properties. Let z be a positive integer. A *restricted partition of order* z with respect to T is a partition of V such that:

1. Each set in the partition is a vertex cluster of tree degree at most 3.
2. Each cluster of tree degree 3 is of cardinality 1.

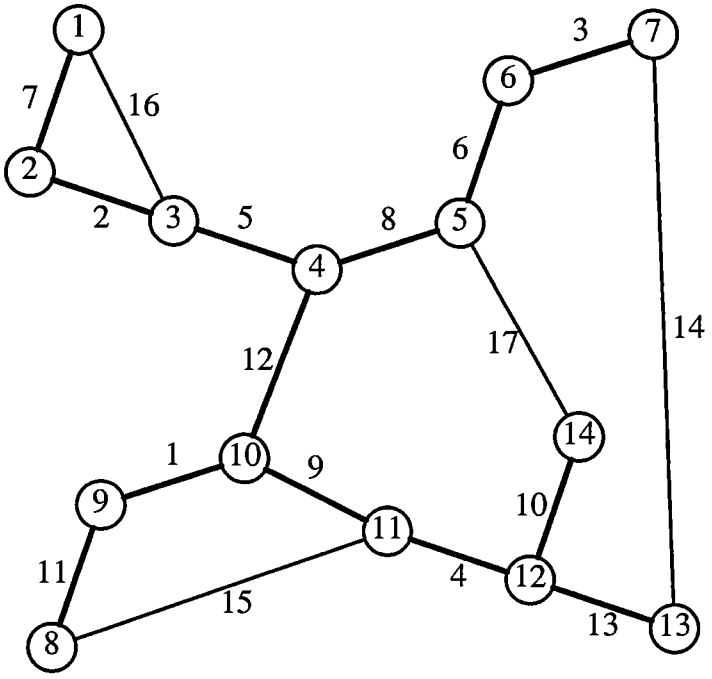

FIG. 1. *A weighted undirected graph with its minimum spanning tree in bold.*

3. Each cluster of tree degree less than 3 is of cardinality at most z.
4. No two adjacent clusters can be combined and still satisfy the above.

As an example, consider the spanning tree from the graph in Fig. 1. A restricted partition of order 2 is shown for this tree in Fig. 2. Note that vertices 10 and 11 cannot be clustered together due to the constraint on the cardinality of a cluster of tree degree 3. Also note that vertex 2 could have been clustered with vertex 1 rather than with vertex 3. In general, there are many different restricted partitions for a given tree and parameter z.

It is not hard to show that the number of clusters in a restricted partition of order z is $\Theta(m/z)$. We do this after the proof of the upcoming Lemma 2.2.

Given a tree described by adjacency lists, a restricted partition can be found as follows. Root the tree at a vertex of tree degree 1. Call the procedure *cluster* with the root as argument. Procedure *cluster*(v), defined below, does the following. It finds all clusters of the subtree rooted at v and outputs all except the partial cluster containing v, which it leaves as $C(v)$. It also finds $tdeg(v)$, the tree degree of $C(v)$, and $size(v)$, the number of vertices in $C(v)$. Upon the return of the call to *cluster*(*root*), print out the set $C(root)$ as the final cluster. Function *cluster*(v) is defined as follows. It initializes $C(v)$ to $\{v\}$, $size(v)$ to 1, and $tdeg(v)$ to the tree degree of v. Then for each child w of v, it calls *cluster*(w) and then does the following. If $tdeg(v) + tdeg(w) - 2 \leq 2$ and $size(v) + size(w) \leq z$, then it resets $C(v)$ to be $C(v) \cup C(w)$, $tdeg(v)$ to be $tdeg(v) + tdeg(w) - 2$, and $size(v)$ to be $size(v) + size(w)$. Otherwise, $C(w)$ is output as a cluster. This completes the description of how each child is handled, and with it the description of procedure *cluster*. Note that the tree degree of any resulting partial cluster will be correctly computed since the tree degree of two unioned partial clusters will be 2 less than the sum of their tree degrees.

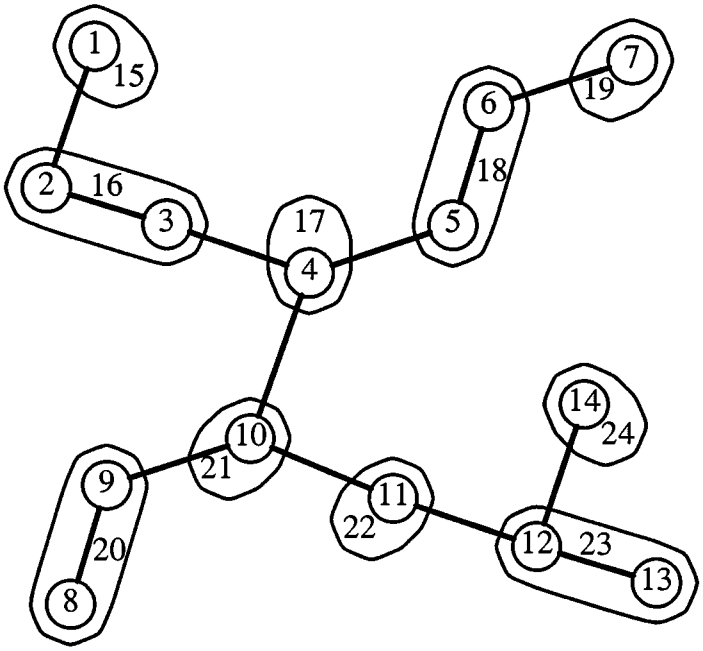

FIG. 2. *A restricted partition of the vertices of the spanning tree in Fig.* 1.

Furthermore, the resulting tree degree will always be less than 3.

The above procedure takes $O(n)$ time for a tree of n vertices. The procedure can be modified in a straightforward fashion to identify the boundary vertices for each cluster and for each vertex identify whether it is a boundary vertex and, if so, for which cluster. Using this representation, the neighboring clusters of any given cluster can be identified in constant time.

An operation that changes the structure of T may force a change in the clusters of a restricted partition. Consider the operation of removing an edge from T, which leaves two trees, T_1 and T_2. Given a restricted partition of order z with respect to T and given an edge in T that is deleted, we discuss how to efficiently generate restricted partitions with respect to the resulting trees T_1 and T_2. Trees T_1 and T_2 inherit the clusters of T, with the following exceptions. Either the edge to be removed has both endpoints contained in one cluster C, or it has one endpoint in a cluster C' and the other in a cluster C''. If the edge to be removed has both endpoints contained in one cluster C, then split C into two clusters, calling them C' and C'', so that the edge has one endpoint in C' and the other in C''. Deleting the edge now causes the tree degree of C' and C'' to change. We need to check if either cluster needs to be combined with other clusters. We discuss how to handle C', with handling C'' being completely analogous. Initialize vertex cluster A to be C'. Repeat the following until no change occurs to A on an iteration. If A has tree degree 1, then check to see if the combined size of it and its neighboring cluster is no greater than z and, if so, combine the neighboring cluster into A. If A has tree degree 2, check to see if there is a neighboring cluster of tree degree no greater than 2 such that the combined size of A and that neighboring cluster is no greater than z and, if so, combine that neighboring cluster into A. This completes the description of how to handle C'.

Next consider the inverse operation of combining two vertex disjoint trees T_1 and

T_2 into one tree T by adding an edge with one endpoint in each of the trees. (Here we assume that the edge was already in the graph, but just not in T.) Given restricted partitions of order z with respect to T_1 and T_2 and given an edge to be inserted that links the trees, we discuss how to efficiently generate a restricted partition with respect to the resulting tree T. Tree T will inherit the clusters of the trees T_1 and T_2, with the following exceptions. If the addition of the edge causes the tree degree of a cluster containing more than 1 vertex to increase from 2 to 3, we must do the following. Consider the three tree edges with exactly one endpoint in the cluster, and let w, w', and w'' denote these endpoints, which are boundary vertices. (Note that two or three of w, w', and w'' may be identical if two or all three of the edges share an endpoint.) Identify the common vertex x on paths in the tree between w and w', between w' and w'', and between w'' and w. Split the cluster by making the vertex x into a cluster by itself and taking the remaining parts of the cluster as clusters. For each cluster so formed, check if another cluster that is adjacent to it is of tree degree at most 2 and if these two clusters together have at most z vertices. If so, combine these clusters. This completes the description of how to handle a cluster when its tree degree increases to 3. Note that these operations can be performed in time proportional to the size of the cluster. If the addition of the edge causes the tree degree of a cluster to increase from 0 to 1 or from 1 to 2, we must do the following. Check to see if the cluster can be combined with the cluster newly adjacent to it. If so, combine these clusters. This completes the description of how to handle a cluster when its tree degree increases from 0 to 1 or from 1 to 2.

LEMMA 2.1. *At most a constant number of clusters are deleted or created when an edge insertion or deletion is performed with respect to restricted partitions of z. The time to perform the changes is $O(z)$.*

Proof. We first observe that only a constant number of clusters are deleted or created when an edge insertion is performed. In the case that a cluster has its tree degree increase from 2 to 3, each part of the split cluster except the part containing only vertex x has tree degree 2. It can be combined with a neighbor B_1 of tree degree 2 but not also combined with the other neighbor B_2 of B_1 since otherwise B_1 and B_2 would have already been combined. In the case of adding an edge that causes the tree degree of a cluster to increase from 0 to 1 or from 1 to 2, a similar argument ensures that only the two clusters containing the endpoints of the edge need to be considered for merging.

We next consider how many clusters are deleted or created when an edge deletion is performed. We perform a case analysis below for how C' can be combined with other clusters. The analysis for C'' is essentially the same. We consider size constraints only when they definitely rule out a case. Subcases are meant to inherit the conditions satisfied by parent cases. *Case* 1: (C' is of tree degree 1.) Then C' can be combined with a neighboring cluster B_1 of tree degree 1, 2, or 3. Let the resulting cluster be B_2. *Case* 1.1: (B_1 is of tree degree 1.) Then B_2 has tree degree 0 and we are done. *Case* 1.2: (B_1 is of tree degree 2.) Then B_2 is of tree degree 1. Let the other neighbor of B_1 be B_3. *Case* 1.2.1: (B_3 is of tree degree 1 or 2.) Then B_2 cannot be combined with B_3 since otherwise B_1 and B_3 would have already been combined. *Case* 1.2.2: (B_3 is of tree degree 3.) Then B_2 and B_3 may be combined, and the resulting cluster B_4 is of tree degree 2. Let the neighbors of B_3, besides B_1, be B_5 and B_6. *Case* 1.2.2.1: (B_5 is of tree degree 1.) Then B_5 cannot be combined with B_4 since it would already have been combined with B_3. *Case* 1.2.2.2: (B_5 is of tree degree 3.) Then B_5 cannot be combined with B_4 because the resulting cluster would have tree degree 3. *Case*

1.2.2.3: (B_5 is of tree degree 2.) Then B_5 can be combined with B_4, but the resulting cluster B_7 cannot be combined with the other neighbor B_8 of B_5 since otherwise B_5 would already have been combined with B_8. A similar discussion holds for cluster B_6, allowing that B_7 could be used in place of B_4 in the arguments. *Case* 1.3: (B_1 is of tree degree 3.) The argument mimics that in Case 1.2.2 and its subcases, but with B_1 in the role of B_3 and C' in the role of B_2. *Case* 2: (C' is of tree degree 2.) The argument mimics those in Cases 1.2.2.1, 1.2.2.2, and 1.2.2.3, with C' in the role of B_4 and with B_5 and B_6 being the neighbors of C'. This completes an analysis of the cases. It is clear that the above operation will examine just a constant number of clusters.

We next consider the time to perform an edge insertion. In the case that a cluster has its tree degree increase from 2 to 3, identifying w, w', and w'' takes constant time, and finding x takes time proportional to the size of the cluster, which is $O(z)$. Splitting the cluster will take $O(z)$ time. Checking neighboring clusters and merging as necessary will take constant time. In the case that a cluster has its tree degree increase to 1 or 2, the time to perform checking and merging is constant.

We next consider the time to perform an edge deletion. If the edge to be deleted has both endpoints contained in one cluster, then the time to split the list of vertices of the cluster into two lists is $O(z)$. All checking and combining will then take constant time. □

We next define our restricted multilevel partition. A *restricted multilevel partition* is a set of partitions of V that satisfy the following:

1. For each level $l = 0, 1, \ldots, q$, the vertex clusters at level l form a partition of V.
2. The clusters at level 0 form a restricted partition of order z.
3. The clusters at any level $l > 0$ constitute a restricted partition of order 2 with respect to the tree resulting from viewing each cluster at level $l-1$ as a vertex.
4. There is precisely one vertex cluster at level q, which contains all vertices.

As an example, consider the spanning tree from the graph in Fig. 1. A restricted multilevel partition for this tree is shown in Fig. 3. Here we assume that $z = 1$ so that each basic vertex cluster contains precisely one vertex. The second level corresponds to the restricted partition in Fig. 2. There are six levels in this multilevel partition.

We note that the restricted multilevel partition is somewhat similar to a structure that may be inferred from applying the rake-and-compress paradigm to a rooted binary tree [MR], [CV], [ADKP].

A vertex cluster at level 0 of a restricted multilevel partition is called a *basic vertex cluster*. Since any basic vertex cluster of tree degree 3 consists of a single vertex and any cluster resulting from the union of two clusters will have tree degree at most 2, any nonbasic cluster of tree degree 3 will also consist of a single vertex. All three of its incident edges will be tree edges. Note that there are no nontree edges with an endpoint in a cluster of tree degree 3.

We next show that the restricted multilevel partition has other nice properties. Consider any level $l > 0$ of a restricted multilevel partition. Call any vertex cluster of level $l-1$ *matched* if it is unioned with another another cluster to give a vertex cluster at level l. Call all other vertex clusters at level $l-1$ *unmatched*. Since a cluster of tree degree 1 can be matched with a cluster of tree degree 1, 2, or 3, the only reason that a cluster of tree degree 1 is not matched is that its adjacent cluster is already matched with some other cluster. Since a cluster of tree degree 2 can be matched

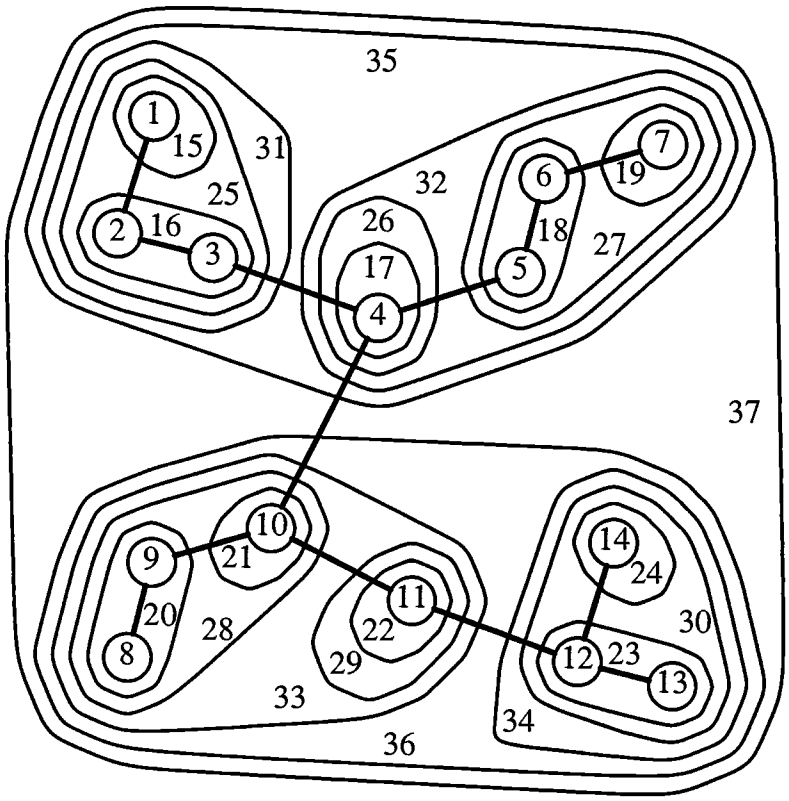

FIG. 3. *A restricted multilevel partition of the vertices of the spanning tree in Fig.* 1.

with an adjacent cluster of tree degree 2, the only reason that a cluster of tree degree 2 is not matched with an adjacent cluster of tree degree 2 is that that adjacent cluster is already matched with another cluster.

LEMMA 2.2. *For any level* $l > 0$ *of a restricted multilevel partition, the number of matched vertex clusters at level* $l-1$ *is at least* $1/3$ *of the total number of vertex clusters at level* $l-1$.

Proof. Consider any level $l > 0$ of a restricted multilevel partition. Contract the graph by contracting all tree edges both of whose endpoints are in the same cluster at level $l-1$. Let each vertex resulting from a matched cluster by such a contraction be called a *matched* vertex. Let the tree degree of a resulting vertex be the tree degree of the corresponding cluster. If all vertices are matched, then clearly the lemma follows. Otherwise, root the tree at an unmatched vertex of largest tree degree. We shall give 6 credits to each pair of vertices that have been matched together, and we will show that these credits can be spread around so that, in the end, each vertex will receive at least 1 credit. The lemma will then follow.

Consider any pair of vertices that have been matched together, and assume that the pair has been allocated 6 credits. Since neither is the root, and since the number of unmatched neighbors of the pair is at most 2, the higher of the two has a parent, which may be unmatched, and the second neighbor (if any) is a child, which may be unmatched. If the higher vertex of the pair has an unmatched parent, let the matched pair send 3 credits to this parent. If there is a second neighbor, let

the matched pair send 1 credit to this child. Let each matched vertex in the pair retain at least 1 credit. Call any unmatched vertex of tree degree 2 that is the root or has an unmatched parent of tree degree 3 *sheltered*. From the properties of unmatched clusters discussed prior to the statement of this lemma, every unmatched vertex of tree degree 1 and every unsheltered unmatched vertex of tree degree 2 must have a neighbor that is matched. In particular, the parent of every such vertex will be matched so that the vertex will receive from its parent 1 credit, which it will retain.

The above credit-sharing rule guarantees that if an unmatched vertex has not received a credit from either its children or its parent, then it must be either a vertex of tree degree 3 or a sheltered vertex. We add the following two rules to handle these cases. For any sheltered nonroot vertex, if it receives 3 credits from its child, it should pass 2 credits to its parent and retain the other 1. For any unmatched nonroot vertex of tree degree 3, if it receives at least 2 credits from each of its two children, it should pass 3 credits to its parent and retain the other at least 1 credit. By a simple induction, it can be shown that every sheltered nonroot vertex will receive 3 credits from its child and retain 1 of them, and every unmatched nonroot vertex of tree degree 3 will receive at least 4 credits from its children and retain at least 1 of them. It follows that at the end of all credit passing, each vertex will retain (at least) 1 credit. A root of tree degree 3 will receive at least 2 credits from each of its 3 children, and a root of tree degree 2 will receive 3 credits from each of its 2 children. Since an unmatched vertex of tree degree 1 must have a matched neighbor, an unmatched tree root will receive 3 credits from its child. □

We now show that the number of clusters in a restricted partition of order z is $\Theta(m/z)$. Consider a restricted multilevel partition of order z. Level 0 of the multilevel partition is a restricted partition of order z. Consider the vertex clusters at level 0 that are matched together to form vertex clusters at level 1. The total number of vertices in a pair of matched vertex clusters must be greater than z since otherwise the pair could have been merged in the partition at level 0. Thus there are fewer than m/z such pairs of matched vertex clusters. By Lemma 2.2, the total number of these pairs is at least 1/3 of the total number of vertex clusters at level 0. Thus there are fewer than $3m/z$ clusters at level 0, i.e., in the restricted partition.

There is an infinite family of examples that match the bound of Lemma 2.2 in the following way. Let n_{l-1} be the number of clusters at level $l-1$. For $n_{l-1} \geq 13$ and $n_{l-1}+5$ a multiple of 6, the number of matched vertex clusters is at least $(n_{l-1}+5)/3$. It has not escaped our attention that we could match more vertex clusters if rule 3 in the restricted multilevel partition allowed unions whose resulting vertex cluster had tree degree 3. However, it appears difficult and inefficient to update the corresponding topology tree structures when changes occur. (Indeed, the difficulty encountered when trying to make things work with tree degree 3 rather than tree degree 2 in rule 3 was the reason that the multilevel partition was defined as it was in [F1].)

THEOREM 2.3. *The number of levels in a restricted multilevel partition is* $\Theta(\log n)$.

Proof. The number of vertex clusters at level 0 is $O(n)$. By Lemma 2.2, for any level $l > 0$, the number of matched vertex clusters at level $l-1$ is at least 1/3 of the total number of vertex clusters at level $l-1$. Since each pair of matched vertex clusters at level $l-1$ that are paired together are replaced by the union at level l, the number of vertex clusters at level l is at most 5/6 the number of vertex clusters at level $l-1$. Since the number of vertex clusters at level l is at least 1/2 the number of vertex clusters at level $l-1$, it follows that the number of levels is $\Theta(\log n)$. □

3. Data structures for maintaining spanning trees.

In this section, we define basic data structures similar to but simpler than those in [F1]. Following [F1], we define a "topology tree" based on the partition and show how to update the topology tree when an edge not in the spanning tree is swapped for an edge in the spanning tree. We then define a "2-dimensional topology tree," again following [F1]. We show how to make 2-dimensional topology trees fully persistent. Finally, we show how to update a 2-dimensional topology tree when edges and vertices are inserted into or deleted from the underlying graph.

As in [F1],we define data structures that describe our partitions. Given a restricted multilevel partition for a spanning tree T, a *topology tree* for T is a tree in which each nonleaf node has at most two children and all leaves are at the same depth, such that:

1. A node at level l in the topology tree represents a vertex cluster at level l in the restricted multilevel partition.
2. A node at level $l > 0$ has children that represent the vertex clusters at level $l-1$ whose union is the vertex cluster it represents.

We label a node in the topology tree by the indexed name of the vertex cluster that the node represents.

A topology tree for the restricted multilevel partition of Fig. 3 is given in Fig. 4. Each node in the topology tree is labeled with the index of the vertex cluster that it represents. The children and parent pointers are represented by the straight, bold edges. The adjacency between clusters is represented by the thin, curved edges.

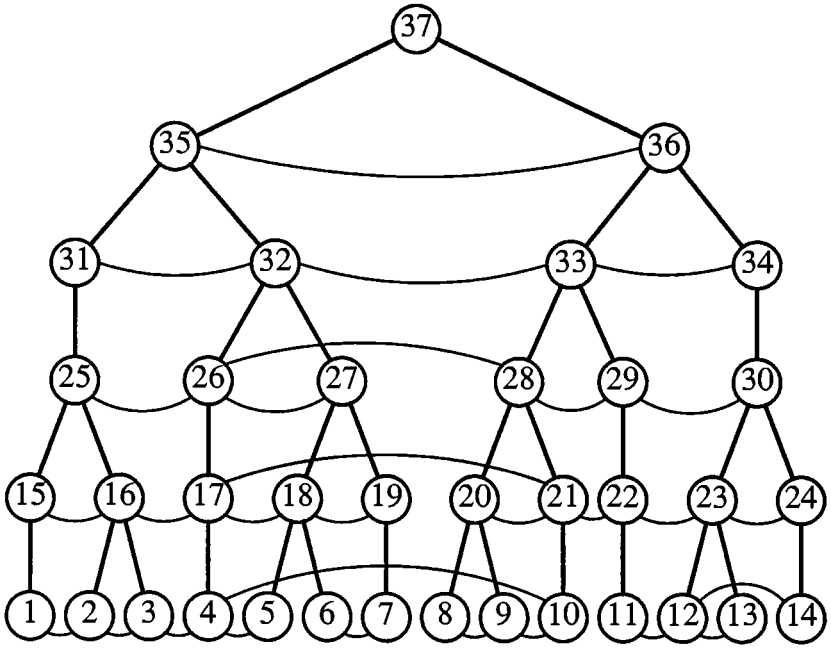

FIG. 4. *The topology tree corresponding to the restricted multilevel partition in Fig.* 3.

A topology tree based on a restricted multilevel partition has the same nice properties as a topology tree based on the multilevel partition of [F1]. In particular, it can be modified efficiently to show the result of inserting or deleting an edge or performing a swap. A *swap* (e, f) in a spanning tree T replaces a tree edge e by a nontree edge

f, yielding another spanning tree. We next discuss how to modify the topology tree when a swap is performed. First, reform the basic clusters to reflect the insertion and deletion of edges, as discussed previously. The number of basic vertex clusters that are changed, created, or deleted will be at most some constant. Then starting with the lists of basic vertex clusters that are changed, created, or deleted, we rebuild portions of the topology tree from the bottom up.

We describe this rebuilding carefully. We shall use three lists of nodes that need to be examined: Let L_D be a list of nodes that represent clusters that should be deleted, L_C a list of nodes that have parents and that represent clusters that have been changed, and L_A a list of nodes that represent clusters that have no parent, either because they are new or because their parent is on a list of nodes to be deleted. Note that we view a cluster as changing not only if its set of vertices changes, but also if its set of tree edges to other clusters changes. (Here we assume that a tree edge to another cluster has not changed if it is the same tree edge as before the swap, i.e., that it has the same vertices as endpoints in the underlying graph even though one of the endpoints may be in a different cluster than before.)

We initialize L_D, L_C, and L_A as follows. Insert into L_D each node representing a basic cluster that has been split or combined to form new basic clusters, and insert into L_A each node representing a new basic cluster. Let the adjacency information of neighboring nodes refer to the nodes inserted into L_A rather than L_D, and let the nodes on L_D retain their parent information but have their adjacency information set to null. For each node x representing a basic cluster whose set of vertices has not changed but whose set of edges incident on it has changed, update its adjacency information and insert it into L_C.

While we have not reached the root of the resulting topology tree, we will recluster the clusters represented by the nodes on these lists and reset the lists to contain the nodes representing the corresponding parents. We perform this activity in such a way that at any point in time, the total size of these lists does not exceed a fixed constant. At each level in the topology tree, we do the following. Assume that the adjacency information of the nodes on L_D, L_C, and L_A reflects the result of the swap but that the adjacency information of the parents of these nodes does not yet. We shall create lists L'_D, L'_C, and L'_A to hold the corresponding nodes at the next higher level. Initialize lists L'_D, L'_C, and L'_A to be empty.

First, we handle list L_D. For every node x in L_D, remove x from L_D (and return it to the available storage pool), remove x as a child from its parent y (if any), and if y then has no children, insert y into L'_D. If y had another child x' and this child is not already on L_C or L_D, then insert x' into L_C. Next, we scan L_C for nodes that have siblings. Let x be such a node on L_C, with parent y and sibling x'. If the cluster corresponding to node y remains a valid cluster, then remove x from L_C (and x' too if it resides on L_C) and insert y into L'_C. By a cluster remaining valid, we mean that there is actually an edge between the cluster representing x and the one representing x', and the tree degree of the cluster for y does not now exceed 2. If the cluster corresponding to y does not remain a valid cluster, then remove x and x' as children of y, remove x from L_C (and also x' if it resides on it), insert x' and x into L_A, and insert y into L'_D.

Finally, we handle nodes on L_A and the remaining nodes on L_C. Let x be such a node. Remove x from the appropriate list. We consider three cases. First, suppose that node x represents a cluster of tree degree 3. If x is adjacent to a node x' representing a cluster of tree degree 1, then do the following. Cluster x and x' together,

removing one or both from lists L_A and L_C as necessary. If neither had a parent, then create a parent and insert it into L'_A. If both had a parent, then use the parent y of x, inserting y into L'_C and inserting the old parent y' of x' into L'_D. If just one of x and x' had a parent, use it and insert it into L'_C. This completes the description of how to handle x when it is adjacent to such a node x'. If x is not adjacent to such a node x', then do the following. Cluster node x by itself. If x has a parent, then insert this parent onto L'_C. If x has no parent, then create a parent and insert it onto L'_A. This completes the description of the first case.

The second and third cases are similar. Second, suppose node x represents a cluster of tree degree 2. If x is adjacent to a node x' representing a cluster of tree degree 1 or 2 such that or x' has no sibling (either because it is an only child or because it has no parent), then cluster x and x' together as discussed in the case above in which x represents a cluster of tree degree 3. If node x is not adjacent to such a node x', then cluster x with itself and handle the parent (or lack of one) as discussed in the case above for tree degree 3. Third, suppose node x represents a cluster of tree degree 1. If x is adjacent to a node x' such that x' has no sibling (either because it is an only child or because it has no parent), then cluster x and x' together as discussed in the case above for tree degree 3. Note that if x' represents a cluster of tree degree 1, the resulting cluster must have tree degree 0 so that the corresponding node will be the root of the topology tree. If node x is not adjacent to such a node x', then cluster x with itself and handle the parent (or lack of one) as discussed in the case above for tree degree 3. Fourth, if x represents a node of tree degree 0, then it is the root of a topology tree, and a pointer to it should be saved. This completes the discussion of how to handle a node x on L_A or on L_C.

When all nodes have been removed from L_D, L_C, and L_A, determine and adjust the adjacency information for all nodes on L'_D, L'_C, and L'_A and then reset L_D to be L'_D, L_C to be L'_C, and L_A to be L'_A. This completes the description of how to handle the lists L_D, L_C, and L_A. When L_C and L_A together contain only one node, then this node corresponds to the root of the topology tree. Any additional nodes in L_D should be removed. (These nodes and their ancestors should be returned to the available storage pool.) This completes the description of the algorithm to handle a swap, which we call algorithm *basic_swap*.

LEMMA 3.1. *Consider a topology tree based on a restricted multilevel partition. Algorithm basic_swap performs a swap in* $O(z + \log n)$ *time.*

Proof. We first consider the correctness of *basic_swap*. The algorithm processes the topology tree level by level in rounds. Before each round, we claim that the only nodes that need to be considered are on L_D, L_A, and L_C and that the adjacency information is valid for the nodes on the level being processed. Furthermore, we claim that for any level after the first that is being processed, clusters for all nodes on that level except for the ones on L_D correspond to a valid restricted partition of the clusters on the next lower level. We prove the above claims by induction on the number of rounds, with the final result being that the structure created is a valid topology tree.

For the basis, note that before the first round, the lists L_D, L_A, and L_C contain precisely those nodes whose corresponding clusters are undergoing some change. Also, the adjacency information for the nodes corresponding to basic clusters has been changed to accurately reflect the changes in basic clusters caused by replacing one edge by another. For the induction step, we consider the point in the execution of the algorithm just before the rth round, $r > 1$. We assume that the claims are true at the

point in the execution of the algorithm just before the $(r-1)$st round. The algorithm deletes each node x from L_D and adjusts the information at its parent correctly. The algorithm also examines nodes on L_C that have siblings and splits any node from its sibling if they do not now form a valid cluster. Finally, any nodes that are only children and can be clustered together are clustered together. Any resulting node is put on L'_A if it is a new node and on L'_C if it represents a changed cluster. Thus at this point, the nodes at the next level minus those nodes on L'_D represent the clusters of a valid restricted partition. Nodes on L'_D are those nodes at the next level that should be deleted. Thus the only nodes that need to be considered at the next level are on L'_D, L'_A, and L'_C. Just before the end of the round, the adjacency information is adjusted for all nodes on L'_D, L'_A, and L'_C, and L'_D, L'_A, and L'_C are reassigned to be L_D, L_A, and L_C, respectively. Thus at the beginning of the rth round, all three claims hold.

We next consider the time complexity of *basic_swap*. Since a constant number of basic vertex clusters are changed, deleted, and created and each basic cluster that is altered in some way can be handled in $O(z)$ time, the total cost of handling the basic vertex clusters is $O(z)$. The time to perform this algorithm exclusive of changing the basic clusters will be proportional to the number of nodes in the topology tree that are deleted, examined, and created. We analyze how many nodes can be on the lists L_A, L_C, and L_D at the beginning of any round, and we show this to be bounded by a constant. For a *link*, there are no more than some constant number of nodes on L_A and L_C before the first round. A simple case analysis indicates that this number of nodes can be at most eight before the first round begins. This is realized when two vertices in clusters previously of tree degree 2 are linked together. Each of these may be split into at most four clusters. For a *cut*, there are also no more than some constant number of nodes on L_A and L_C before the first round.

Our analysis depends on the way in which the nodes on L_A and L_C relate to each other within the structure of the tree induced on the level corresponding to a round. If the operation is *link*, then the nodes on lists L_A and L_C form a subtree of the resulting tree induced on that level. If the operation is *cut*, then the nodes on lists L_A and L_C form a subtree of each of the two resulting trees induced on that level.

We first analyze the *link* operation. Before the first round, the subtree induced on nodes in L_A and L_C consists of no more than eight nodes and seven edges. Let a *border edge* be an edge in the tree but not in the subtree that is incident to a node of the subtree. We claim that at any point while the topology tree is being rebuilt, there are at most two border edges on each side of the linking edge in the tree. This is true initially since each of the linked clusters previously had tree degree at most 2. During a round, the subtree can be extended to include a larger portion of the tree in two ways. First, a cluster represented by node y can be recognized to be invalid, where the constituent clusters are represented by x and x', x is on L_C, and x' is not on any list. If the cluster is invalid because the tree degree would now be 3, then either of two cases holds. If x now has tree degree 3 and x' has tree degree 2, then including x' in the subtree does not increase the number of border edges. If x now has tree degree 2 and x' has tree degree 3, then including x' in the subtree increases by one the number of border edges. But in this case x must have previously had tree degree 1. It follows that the linking edge is incident on a vertex in the cluster represented by x and that this node was the only one in the subtree on its side of the linking edge. Thus there was just one border edge (the one incident on x) on its side of the linking edge, and we are now increasing the number to two.

If the cluster is invalid because the two constituent clusters are not adjacent, then before the previous round, the cluster corresponding to node x included a cluster adjacent to a constituent cluster of x'. If x' has tree degree 2, then including x' does not increase the number of border edges. If x' has tree degree 3, then including x' increases the number of border edges by one. But in this case, the old version of x previously had tree degree 1, and its cluster contained one endpoint of the linking edge and thus was the only node in the subtree on one side of the linking edge. So prior to including x' in the subtree, the portion of the subtree on that side of the linking edge had just one border edge. Thus that number is now increased to two.

The second way to extend the subtree is to union a cluster represented by a node x on L_A with a cluster represented by a node x' not on L_A or L_C. If x' has tree degree 2, then including x' does not increase the number of border edges. If x' has tree degree 3, then x must have tree degree 1. This means that the subtree consists only of x. On all subsequent rounds, the subtree will consist of only a single node, and the number of edges incident on it will be at most two. This completes our case analysis. In all cases, the number of border edges will never exceed four.

We next consider how many nodes will be in the subtree at the end of a round, when there are s nodes in the subtree at the beginning of the round. The only clusters that can be determined to be invalid must contain the endpoints of the original *link* operation. Thus at most two clusters will be determined to be invalid, yielding two more nodes for the subtree. Other clusters may enter the subtree by unioning a cluster in the subtree with one not in the subtree, but this results in no net gain in the number of nodes. In the worst case, each node in the subtree that has a border edge incident on it will not have its cluster unioned with one whose node is in the subtree. Of the remaining $s + 2 - 4$ nodes, Lemma 2.2 establishes that at most $5/6$ of that number, or $5(s-2)/6$, will remain. An upper bound on the largest value possible for s is thus determined by the inequality $s \leq 5(s-2)/6 + 4$. This implies that the total size of L_A and L_C will never exceed 14. (A more careful analysis of the proof of Lemma 2.2, considering the constant additive term, will reduce the bound substantially.)

To bound the number of nodes in L_D, consider the original two topology trees representing the two trees linked together. For each round, we consider the minimal subtrees of the induced trees that connect nodes on L_D. These subtrees are of the same form as the subtree induced on nodes of L_A and L_C. By similar arguments, it can be shown that the subtrees, and hence the length of L_D, are bounded by a constant. Thus the total size of lists L_A, L_C, and L_D is bounded by a constant on any round. Since the amount of work per list entry is constant, and by Theorem 2.3 the number of rounds is $O(\log n)$, the total time for a *link* is $O(\log n)$.

The analysis for a *cut* is similar. In each of the two subtrees, there will be at most two border edges. The subtrees can be extended in a fashion similar to that for a *link*. The analysis is essentially the same, yielding equivalent bounds for the lengths of lists L_A, L_C, and L_D. Thus the total time for a *cut* is also $O(\log n)$. □

We trace through an example to illustrate algorithm *basic_swap*. Consider the graph in Fig. 2 and the spanning tree and multilevel partition in Fig. 3. We assume that each node in Fig. 2 represents a basic cluster. Suppose that the edge between V_7 and V_{13} is swapped in to replace the edge between V_4 and V_{10}. For simplicity, we shall assume that no basic cluster is changed as far as the set of vertices it contains. (This would be true if clusters V_3, V_4, V_9, and V_{11} have size exactly z, so V_4 or V_{10} cannot be combined with their neighboring clusters, and the size of V_7 plus the size of V_{13} is greater than z and the size of V_6 plus the size of V_7 is greater than z, so that

neither V_7 nor V_{13} can be combined with a neighboring cluster.) For convenience, we use as the name of the node the index of its cluster. Initially, L_D and L_A are empty, and L_C comprises $4, 10, 7$, and 13. When L_C is examined on the first phase, node 13 and its sibling 12 no longer form a valid cluster. Thus node 12 is placed on L_C and node 23 is placed on L'_D. We then proceed to handling the remainder of L_C and L_A. Node 4 cannot be clustered with a neighbor, so its parent 17 is placed on L'_C. Node 10 is clustered with 11, and the resulting parent 21 is placed on L'_C, while the previous parent 22 of 11 is placed on L'_D. Nodes 7 and 13 get clustered, and the parent 19 is placed on L'_C. Node 12 can be clustered with 14, putting resulting parent 24 on L'_C. At this point, L_D, L_A, and L_C are empty, and the next phase begins with setting L_D, L_A, and L_C to L'_D, L'_A, and L'_C.

When L_D is handled on the second phase, nodes 22 and 23 are deleted. Since node 22 is an only child, its parent 29 is put on L'_D. Node 24, the sibling of 23, is already on L_C. Node 28, the parent of 21, remains a valid cluster and is put on L'_C. Similarly, node 27, the parent of 19, remains a valid cluster and is put on L'_C. We then proceed to handling the remainder of L_C and L_A. Node 17 cannot be clustered with a neighbor, so its parent 26 is placed on L'_C. Node 24 cannot be clustered with a neighbor, so its parent 30 is placed on L'_C.

At this point, the second phase ends, and the third phase begins with recopying the lists. Node 29 is removed from L_D, and its sibling 28 is already on L_C. Node 32, the parent of nodes 26 and 27, remains a valid cluster and is put on L'_C. We then proceed to handling the remainder of L_C and L_A. Node 28 is clustered with 30, and the resulting parent 33 is placed on L'_C, while the previous parent 34 of 30 is placed on L'_D. At this point, the third phase ends, and the fourth phase begins. Node 34 is removed from L_D, and its sibling 33 is already on L_C. Node 32 on L_C has a sibling, and its parent cluster 35 is still valid, so that 35 is placed on L'_C. Node 33 cannot be clustered with a neighbor, so its parent 36 is placed on L'_C. At this point, the fourth phase ends, and the fifth phase begins. List L_D is empty. Nodes 35 and 36 each have siblings (each other), and their parent 37 represents a valid cluster, so 37 is placed on L'_C. In the sixth phase, 37 is identified as having tree degree 0, so that it is the root of the new topology tree. The algorithm then terminates. The resulting topology tree, with the old vertices crossed out and the old edges dashed, is shown in Fig. 5. To minimize the clutter in Fig. 5, the edges representing adjacency between clusters are not shown.

A 2-*dimensional topology tree* for a given topology tree is a tree in which for every ordered pair of nodes labeled V_j and V_r at the same level in the topology tree, there is a node labeled $V_j \times V_r$, and there is a child of node $V_j \times V_r$, labeled $V_{j'} \times V_{r'}$, for each pair consisting of a child $V_{j'}$ of V_j and a child $V_{r'}$ of V_r in the topology tree.

A portion of the 2-dimensional topology tree for the topology tree of Fig. 4 is given in Fig. 6. Specifically, all nodes and children of nodes on the path from the root to the leaf 5×14 are shown. For any node that is shown in the figure but whose children are not shown, there is an edge for each child coming from the bottom of that node.

For the size bound z on the number of vertices in a basic cluster, we choose $z = \lceil m^{1/2} \rceil$. When one modifies a topology tree as the result of performing a swap, the 2-dimensional topology tree must be modified. This modification is essentially the same as that discussed in [F1].

LEMMA 3.2. *Consider a 2-dimensional topology tree for a topology tree that is based on a restricted multilevel partition. The space is $O(m)$, the time to set up the*

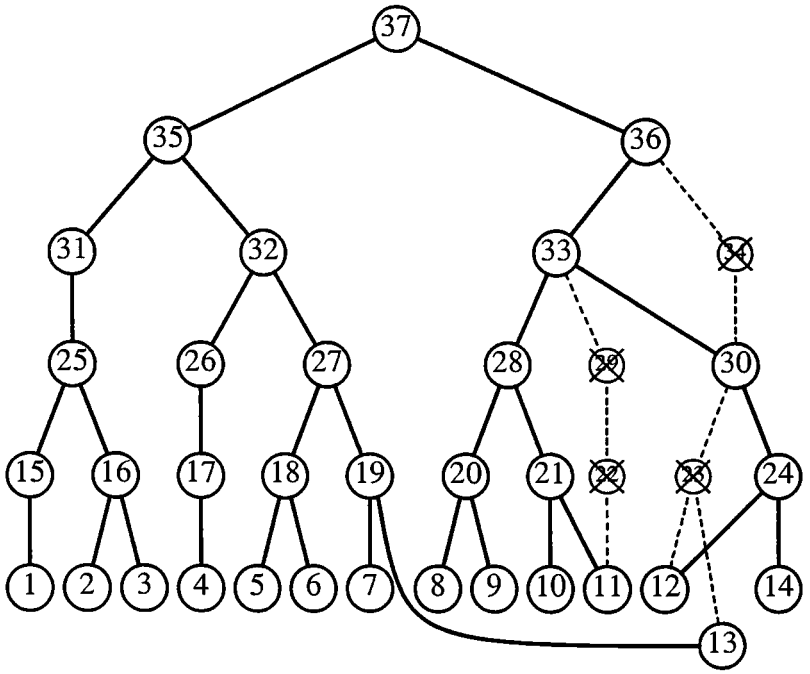

FIG. 5. *The changes to the topology tree in Fig.* 4 *after edge* $(7, 13)$ *replaces edge* $(4, 10)$ *in the spanning tree.*

2-*dimensional topology tree given its topology tree is* $O(m)$*, and the time required to modify the* 2-*dimensional topology tree to show the result of performing a swap is* $O(m^{1/2})$.

Proof. The space and times are derived in a fashion similar to that in [F1]. □

In section 7, we use a version of 2-dimensional topology trees that is fully persistent [DSST]. Thus when we perform a swap, we want to retain the old version of the 2-dimensional topology tree before the swap and also create a version of the 2-dimensional topology tree after the swap. This can be done efficiently by creating new nodes when they are needed and by allowing a new node in the 2-dimensional topology tree to have one or more children in the old 2-dimensional topology tree. Thus certain subtrees of the old 2-dimensional topology tree are shared by both old and new trees by virtue of having two pointers pointing at the root of any such subtree. (After creating a number of versions via swaps, a node could have any number of pointers less than or equal to the number of versions pointing to it.) To make such a scheme work, the version of 2-dimensional topology tree that is made fully persistent is not allowed to have any parent pointers in the nodes.

The discussion in [F1] regarding modifying a 2-dimensional topology tree implicitly supposes that there are parent pointers in the tree. We thus discuss how to perform a swap when the 2-dimensional topology tree does not have these pointers. We maintain a copy of the topology tree for each version of the 2-dimensional topology tree, and since the nodes of these topology trees will not be shared, we allow the nodes of the topology tree to have parent pointers. When we want to perform a swap (e, f) in tree T with topology tree $T1D(T)$ and a pointer to the 2-dimensional topology tree $T2D(T)$, we do the following. First, we make a copy of $T1D(T)$ and run *basic_swap*

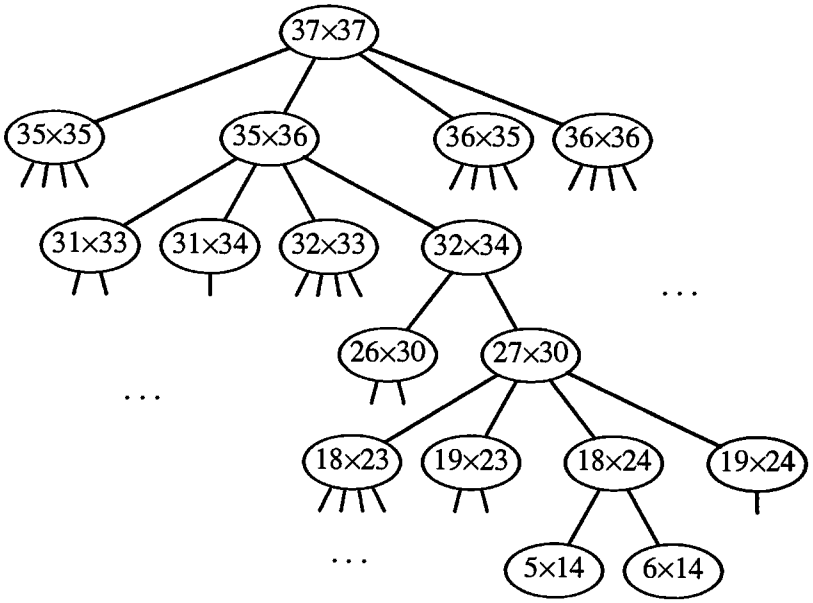

FIG. 6. *A portion of the* 2*-dimensional topology tree for the topology tree shown in Fig.* 4.

on this copy, generating $T1D(T')$. We actually use a modified version of *basic_swap* that marks each node in $T1D(T)$ that has been deleted or whose corresponding node in $T1D(T')$ represents a cluster that has changed. These nodes are all the nodes that have been inserted into L_D, L'_D, or L'_C.

For example, consider the graph and spanning tree in Fig. 1, whose topology tree is shown in Fig. 4, with edge $(7, 13)$ swapped in to replace edge $(4, 10)$, as shown shown in Fig. 5. The vertices in the topology tree in Fig. 4 that should be marked are $4, 7, 10, 13, 17, 19, 21, 22, 23, 24, 26, 27, 28, 29, 30, 32, 33, 34, 35,$ and 36. The subtrees shared by both the old 2-dimensional topology tree, as shown in Fig. 6, and the new 2-dimensional topology tree are those rooted at the nodes $V_{31} \times V_{31}$, $V_{18} \times V_{18}$, $V_{20} \times V_{20}$, $V_{15} \times V_{18}$, $V_{18} \times V_{15}$, $V_{15} \times V_{20}$, $V_{20} \times V_{15}$, $V_{16} \times V_{18}$, $V_{18} \times V_{16}$, $V_{16} \times V_{20}$, $V_{20} \times V_{16}$, $V_{18} \times V_{20}$, and $V_{20} \times V_{18}$ and leaves $V_j \times V_r$ and $V_r \times V_j$, for $j \in \{1, 2, 3, 5, 6, 8, 9\}$ and $r \in \{11, 12, 14\}$ or for $j, r \in \{11, 12, 14\}$.

Having marked those nodes in $T1D(T)$ whose corresponding nodes in the copy are involved in the restructuring that generates $T1D(T')$, we then set temporary parent pointers in a portion of the shared data structure that represents $T2D(T)$. The temporary pointers, as well as the marks in the nodes of $T1D(T)$, will be reset to a null value once $T2D(T')$ has been generated. The temporary pointers will be set for any node $V_j \times V_r$ such that either V_j or V_r or both are marked in $T1D(T)$. The procedure *set_tpp*$(p1, p2)$ will do this, where $p1$ points to a marked node in $T1D(T)$ representing some cluster V_j and $p2$ points to a node in $T2D(T)$ representing an ordered pair of clusters $V_j \times V_r$ or $V_r \times V_j$.

proc *set_tpp*$(p1, p2)$
    if $p1$ is a leaf
    then Save $(p1, p2)$ on a list.
    else

```
if p1 has just one child p1c
then
    if p1c is marked
    then
        for each child p2c of p2 do
            temp_par(p2c) ← p2
            Call set_tpp(p1c, p2c).
        endfor
    endif
else
    if the left child p1L of p1 is marked
    then
        for each child p2L of p2 that corresponds to V_j × V_r
                where V_j is a left child do
            temp_par(p2L) ← p2
            Call set_tpp(p1L, p2L).
        endfor
    endif
    if the right child p1R of p1 is marked
    then
        for each child p2R of p2 that corresponds to V_j × V_r
                where V_j is a right child do
            temp_par(p2R) ← p2
            Call set_tpp(p1R, p2R).
        endfor
    endif
endif
endif
```

Consider the list of pairs $(p1, p2)$ corresponding to certain leaves that is created by procedure *set_tpp*. This list is then used to initialize a simultaneous bottom-up traversal of the portion of $T1D(T)$ whose nodes are marked and the portion of $T2D(T)$ whose nodes have temporary parent pointers. During the traversal, actions are performed in $T2D(T)$ that are analogous to those of *basic_swap* on $T1D(T)$, except that no nodes in $T2D(T)$ are deleted. Instead, new nodes are created and the child pointers of these nodes are set to both new nodes and nodes in $T2D(T)$. The new nodes and their pointers are set up to be consistent with the structure of $T1D(T')$. A pointer to the root of the resulting 2-dimensional topology tree $T2D(T')$ is returned. Let the above approach be called algorithm *persist_swap*.

THEOREM 3.3. *Algorithm persist_swap maintains a fully persistent version of 2-dimensional topology trees, using $O(m + km^{1/2})$ space to store k versions and generating a new version reflecting the result of a swap in $O(m^{1/2})$ time.*

Proof. We first consider the correctness of algorithm *persist_swap*. Algorithm *basic_swap* correctly marks each node in $T1D(T)$ that has been deleted or whose corresponding node in $T1D(T')$ represents a cluster that has changed. Next, a proof by induction can be used to establish that if a node in $T1D(T)$ is marked, then all ancestors of that node are marked. Now any subtree rooted at a node $V_j \times V_r$ in $T2D(T)$ such that V_j and V_r are not marked will remain the same in $T2D(T')$. Thus the only nodes that may get deleted or changed in modifying $T2D(T)$ to get $T2D(T')$

are nodes $V_j \times V_r$ such that at least one of V_j and V_r are marked. A proof by induction establishes that procedure *set_tpp* correctly sets temporary parent pointers for all such nodes. A bottom-up procedure for deleting and changing all such nodes then can then simulate the effect of *basic_swap* in $T2T$ by following the temporary parent pointers.

We next consider the resource usage of *persist_swap*. Given the choice of z, there are $\Theta(m^{1/2})$ basic clusters, and each is of size $O(m^{1/2})$. It follows from Lemma 2.2 that there are $\Theta(m^{1/2})$ vertices in the topology tree $T1D(T)$. Thus a copy can be made in $O(m^{1/2})$ time. By Lemma 3.1 the modified version of *basic_swap* will take $O(m^{1/2})$ time. By Lemma 3.2, the time used in modifying the 2-dimensional topology tree $T2D(T)$ is $O(m^{1/2})$, and this is a bound also on the number of nodes examined. The time of *set_tpp* is proportional to the number of nodes examined, so that this time is also $O(m^{1/2})$. It follows that the total time to perform a swap is $O(m^{1/2})$. Since the number of new nodes is bounded by the time, each of $k-1$ versions after the first will use $O(m^{1/2})$ additional space. □

In section 9, we consider a problem in which the underlying graph can change by inserting or deleting edges or vertices. Inserting edges into or deleting edges from the original graph can be handled similarly to that discussed at the beginning of section 8 of [F1]. We supply some additional explanation since the discussion in [F1] is brief. In particular, we discuss what happens when the insertion of an edge increases the degree of a vertex above 3 or decreases the degree of a vertex that is above 3. In the either case, the transformation that replaces a vertex by a ring of vertices of degree 3 must be modified. For simplicity of discussion, we assume that every vertex of degree at least 2 is converted into a ring of degree-3 vertices. In the case of edge insertion, we define an *inflate* operation as follows. For each endpoint v of the inserted edge, do the following. If the degree of v was previously 1, then treat the existing v as v_0 and treat the endpoint of the new edge as v_1. Generate the topology tree data structures for the single edge. Then insert edges (v_0, v_1) and (v_1, v_0), rebuilding the data structures in a fashion similar to that done in *basic_swap*. If the previous degree d of v was greater than 1, then treat the endpoint of the new edge as v_d. Generate the topology tree data structures for the single edge. If edge (v_0, v_{d-1}) is a tree edge, then identify a nontree edge with which it can swap and perform the swap. Then delete edge (v_0, v_{d-1}) and insert edges (v_{d-1}, v_d) and (v_d, v_0), rebuilding the data structures in a fashion similar to that done in *basic_swap*. Note that the vertices v_0 through v_{d-1} are identified by position rather than labeled as such. Identifying a nontree edge which can participate in a swap can be accomplished by organizing the data structure for maintaining a minimum spanning tree and changing the cost of the edge to be deleted to ∞.

An operation *deflate* can be defined to perform essentially the reverse of *inflate*. If an edge to be deleted is a tree edge, first determine if there is a nontree edge that can be swapped for the edge to be deleted and, if so, then perform the swap.

It is not hard to cast the problems of edge and vertex insertion and deletion as edge insertion or deletion. We allow a vertex to be inserted whenever it is an endpoint of an edge that is being inserted and the other endpoint of the edge is already in the graph. A vertex is deleted whenever it is an endpoint of degree 1 and its incident edge is being deleted. (We thus force our graph to always be connected.)

THEOREM 3.4. *Consider a structure based on a restricted multilevel partition. The time required to insert or delete an edge or vertex is $O(m^{1/2})$, where m is the current number of edges.*

Proof. As in [F1], splitting and merging basic vertex sets will use $O(z)$ time. The

time to modify all affected nodes in the topology and 2-dimensional topology tree will be $O(m/z)$. □

4. Adjacency in embedded planar graphs. For embedded planar graphs, we characterize the adjacency relationships between clusters in the multilevel partition presented in section 3. Nontree edges with precisely one endpoint in any given vertex cluster will be grouped together and ordered according to the embedding. Our work will follow the general idea in [F1] but will elaborate the details with more care than in [F1].

We shall first choose a size for basic vertex clusters and then make a number of simple observations about the consequences of this choice. We then define sets of nontree edges, called "boundary sets," with precisely one endpoint in any given vertex cluster. We show how to generate a boundary set of a cluster that is the union of two other clusters from their boundary sets. The situation is complicated by what we call "separating edges," which are not always easy to identify efficiently. Our approach will first generate "pseudoboundary sets," which can contain the separating edges, and then later at opportune times it will remove the separating edges to give the boundary sets.

First, we choose $z = 1$ in our restricted multilevel partition so that each basic vertex cluster will be a vertex by itself. We carefully examine how to represent the nontree edges. Recall that a cluster of tree degree 3 will consist of a single vertex and will have no nontree edges incident on it. Next, consider a cluster V_j of tree degree 1. All nontree edges with exactly one endpoint in V_j can be ordered in clockwise order around V_j, starting with the first edge in a clockwise direction from the tree edge with one endpoint in V_j. This ordering will be entirely consistent with the embedding. Next, consider a cluster V_j of tree degree 2. There will be a unique path of tree edges between the two boundary vertices of V_j. We partition all nontree edges with precisely one endpoint in V_j into two sets, depending on which "side" of the path an edge is incident on. Each set can be ordered in a natural way corresponding to the embedding and represented by a balanced tree. Call each such ordered set of edges a *boundary set*. It is easy to identify the zero, one, or two boundary sets of a basic cluster in constant time, given a list of edges incident on the single vertex in the cluster, as well as an indication of which edges are tree edges.

Consider the embedded planar graph in Fig. 7. The spanning tree edges are in bold, the nontree edges are dashed, and a multilevel partition is shown by the closed curves. The vertex cluster $\{10, 11\}$ has an associated path from vertex 10 to vertex 11. Cluster $\{10, 11\}$ has edges $(10, 9)$ and $(11, 7)$ in the boundary set to the left of the path and no edges in the boundary set to the right of the path. Cluster $\{4, 5, 6, 7\}$ has an associated path from vertex 4 to vertex 7. It has edge $(5, 3)$ in one boundary set and edge $(7, 11)$ in the other boundary set. Note that edge $(6, 4)$ has both endpoints in this cluster and thus is not in either boundary set.

We next discuss how to determine the boundary sets of the clusters. Clearly, a cluster that has just one cluster as its child has the same boundary sets as its child. Given cluster V_j that is the result of the union of two clusters $V_{j'}$ and $V_{j''}$, we show how to generate the boundary set of V_j from the boundary sets of $V_{j'}$ and $V_{j''}$. We first discuss two simple cases. The first case is that $V_{j'}$ and $V_{j''}$ are both of tree degree 1. Then V_j is the set of all vertices, and all edges in the boundary sets of $V_{j'}$ and $V_{j''}$ will be interior with respect to V_j. Thus there will be no boundary set for V_j. The second case is that $V_{j'}$ is of tree degree 1 and $V_{j''}$ is of tree degree 3. In this case, V_j will be of tree degree 2. Make the boundary set of $V_{j'}$ one of the two boundary sets

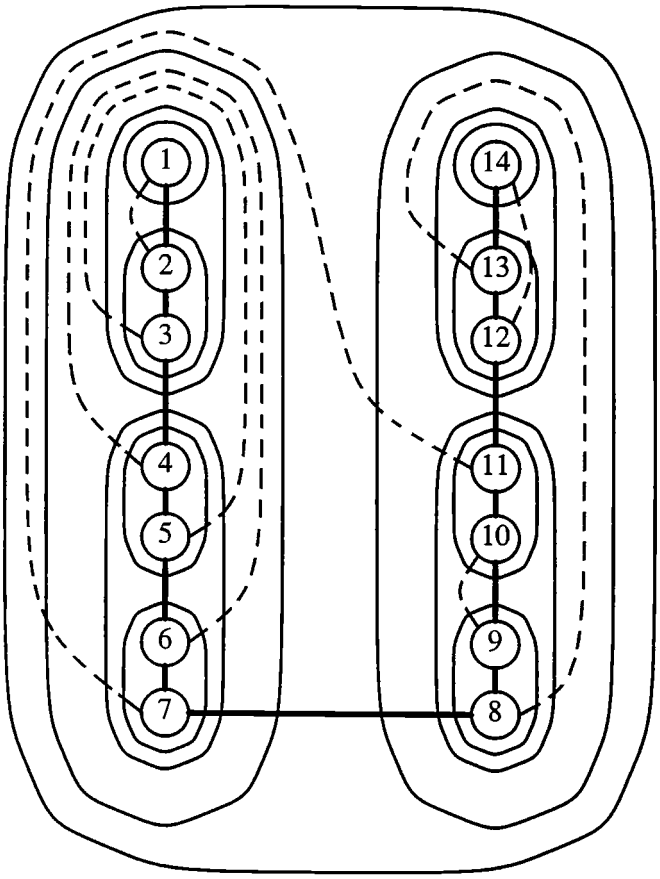

FIG. 7. *An embedded planar graph, its spanning tree, and a multilevel partition.*

of V_j. The other boundary set of V_j is empty.

The third case is that $V_{j'}$ and $V_{j''}$ are both of tree degree 2. Each of $V_{j'}$ and $V_{j''}$ will have two boundary sets, one on each side of the path between the boundary vertices of V_j. Consider a nontree edge with one endpoint in each of $V_{j'}$ and $V_{j''}$. If every such edge is a member of two boundary sets that are on the same side of the path, then things are easy: we shall describe in due course a simultaneous search of two boundary sets to identify the subset of edges contained in both boundary sets. However, suppose that there are nontree edges that are members of the boundary set of $V_{j'}$ on one side of the path and are also members of the boundary set of $V_{j''}$ on the other side of the path. We call any such edge e a *separating edge for* V_j since the cycle induced by e in the tree separates some pair of clusters that are different from V_j. Let the *separating set* of edges for V_j be the separating edges with one endpoint in $V_{j'}$ and the other endpoint in $V_{j''}$. Consider, for example, Fig. 7. The cluster containing vertices 4 and 5 has a separating edge $(4, 5)$. It separates the cluster containing vertices 2 and 3 from the cluster containing vertices 6 and 7. The presence of separating edges complicates matters considerably since there appears to be no efficient way to identify this set by merely examining the boundary sets for $V_{j'}$ and $V_{j''}$. Our solution will be to avoid identifying these edges when initially examining

the union of two clusters of tree degree 2 and to identify only "pseudoboundary sets" at that time.

A *pseudoboundary set* of a cluster V_j of tree degree 2 is defined as follows. If V_j is a basic vertex cluster, then the pseudoboundary sets of V_j are identically the boundary sets of V_j. If V_j has just one child cluster, then the pseudoboundary sets of V_j are identically the pseudoboundary sets of the child cluster. If V_j is the union of two clusters of tree degree 1 and 3, then the pseudoboundary sets of V_j are identically the boundary sets of V_j. Otherwise, V_j is the union of two clusters $V_{j'}$ and $V_{j''}$ of tree degree 2. A simultaneous search of each pseudoboundary set of $V_{j''}$ and the pseudoboundary set of $V_{j'}$ that is on the same side of the path can be performed to identify the subset of edges common to both sets. Split these subsets off from the pseudoboundary sets of $V_{j'}$ and $V_{j''}$ and concatenate the remaining portions to get the two pseudoboundary sets of V_j. It follows that the edges in the pseudoboundary sets of V_j that are not in the boundary sets of V_j are separating edges of either V_j or certain clusters that are descendants of V_j. (In a multilevel partition, one cluster is a descendant of another cluster if the former is contained in the latter.)

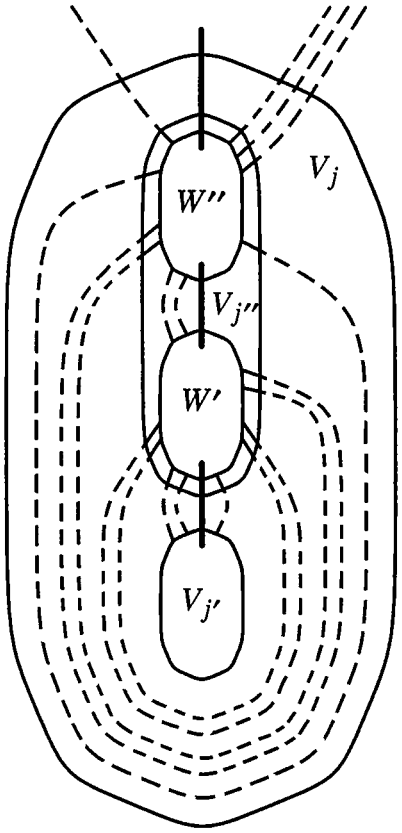

FIG. 8. *An example that illustrates finding sets of separating edges.*

Consider Fig. 8, in which the spanning tree edges are in bold, the nontree edges are dashed, and a portion of a multilevel partition is shown by the closed curves. There are two separating edges for cluster W', one seperating edge for cluster W'', and two separating edges for cluster $V_{j''}$. Looking just at $V_{j''}$, there is no efficient way

to find the separating edges for $V_{j''}$ because they are sandwiched between edges to clusters that are not unioned yet (at this level) to $V_{j''}$. The left pseudoboundary set of W'' contains six edges, and the right contains four edges. The left pseudoboundary set of W' contains six edges, and the right contains five edges. The left pseudoboundary set of $V_{j''}$ contains eight edges, and the right contains nine edges.

The fourth and final case is that $V_{j'}$ is of tree degree 1 and $V_{j''}$ is of tree degree 2. Let the sides of the path between the boundary vertices of $V_{j''}$ be designated as L for left and R for right. We differentiate the directions "down" and "up," with down being closer to $V_{j'}$ and up being farther away from $V_{j'}$. Perform a simultaneous search from either end of the boundary set of $V_{j'}$ with the appropriate pseudoboundary set of $V_{j''}$ to identify the two subsets of edges of set $V_{j'}$ that are in either of the pseudoboundary sets of $V_{j''}$. Split these two subsets off from the boundary set of $V_{j'}$ and from the pseudoboundary sets of $V_{j''}$. If any edges remain in the boundary set of $V_{j'}$, then there are no separating edges for $V_{j''}$. In this case, take the remaining portions of the two pseudoboundary sets of $V_{j''}$ and concatenate them with the remaining portion of the boundary set of $V_{j'}$ to give the boundary set of V_j. If no edges remain in the boundary set of $V_{j'}$, then one can identify all separating edges of V_j (and also of certain of its descendants) that are in the pseudoboundary set of $V_{j''}$. Perform a simultaneous search from the lower end of the remaining portions of the two pseudoboundary sets of $V_{j''}$ to identify all edges that are in the remaining portions of both pseudoboundary sets. Then split this subset off from the remaining pseudoboundary sets of $V_{j''}$. Take the remaining portions of the two pseudoboundary sets of $V_{j''}$ and concatenate them together to give the boundary set of V_j.

We return to our example in Fig. 7. When clusters $\{8, 9\}$ and $\{10, 11\}$ are unioned together, the edge $(9, 10)$ is identified as staying on the same side of the path (from vertex 8 to vertex 11). Thus it is not in the pseudoboundary sets for $\{8, 9, 10, 11\}$. When clusters $\{4, 5\}$ and $\{6, 7\}$ are unioned together, edge $(6, 4)$ is a separating edge, though it would not in general be determined as such at that time. The pseudoboundary sets of cluster $\{4, 5, 6, 7\}$ are $\{(5, 3), (6, 4)\}$ and $\{(4, 6), (7, 11)\}$. When cluster $\{1, 2, 3\}$ of tree degree 1 and cluster $\{4, 5, 6, 7\}$ of tree degree 2 are unioned together, we detect the separating edges as follows. First, cluster $\{1, 2, 3\}$ has a boundary set containing edge $(3, 5)$, which is deleted from that set as well as from a pseudoboundary set for $\{4, 5, 6, 7\}$. The separating edge $(6, 4)$ is uncovered from each pseudoboundary set of $\{4, 5, 6, 7\}$. Note that there are no separating edges to be discovered within either cluster $\{4, 5\}$ or $\{6, 7\}$. The boundary set for cluster $\{1, 2, \ldots, 7\}$ will then just contain edge $(7, 11)$.

Note that we have not yet completed our discussion of how to determine the boundary sets of all clusters since the above only determines pseudoboundary sets for the case of a cluster that is the union of tree degree 2. First, we make some additional remarks about how to represent and manipulate these sets of edges. For each cluster, keep track of the portions of pseudoboundary sets of the children that are not used in building the pseudoboundary set of the cluster. We call the set of such edges on each side to be the *newly interior set* of edges.

We next describe how to take the separating edges determined when clusters $V_{j'}$ of tree degree 1 and $V_{j''}$ of tree degree 2 are unioned together, and we determine the boundary sets and separating sets for the descendant clusters for which only pseudoboundary sets were previously known. Let W be any descendant cluster of $V_{j''}$ such that all ancestors of W that are also descendants of $V_{j''}$ have tree degree 2. Call such a cluster W a *relevant descendant* for $V_{j''}$. We introduce the following notation.

Let $pbs_L(W)$ be the pseudoboundary set of W on the left side of the path, and let $pbs_R(W)$ be the pseudoboundary set of W on the right side of the path. Let $s_T(W)$ be the number of separating edges with both endpoints in W. Let $d_L(W)$ be the number of edges in $pbs_L(W)$ with the other endpoint down from W, and let $u_L(W)$ be the number of edges in $pbs_L(W)$ with the other endpoint up from W. Similarly, let $d_R(W)$ be the number of edges in $pbs_R(W)$ with the other endpoint down from W, and let $u_R(W)$ be the number of edges in $pbs_R(W)$ with the other endpoint up from W.

To determine the boundary sets and separating sets for all relevant descendants of $V_{j''}$, call the recursive procedure *sep_edge* with arguments $V_{j''}$, $s_T(V_{j''})$, $u_L(V_{j''})$, $u_R(V_{j''})$, $d_L(V_{j''})$, and $d_R(V_{j''})$. Procedure *sep_edge*$(W, s_T(W), u_L(W), u_R(W), d_L(W), d_R(W))$ will take a relevant descendant W of tree degree 2 and construct representations of the boundary sets and separating sets of W and all of its relevant descendants. We make the following notational simplifications. The argument (W) will be omitted, using, for example, u_L rather than $u_L(W)$. In the case that W has two children, W' will be down from W''. An argument such as (W'') will be replaced by a double prime, so that u''_L represents $u_L(W'')$ and similarly for (W'). The number of separating edges of W, i.e., separating edges with one endpoint in W' and the other in W'', will be s. The number of such separating edges with the left endpoint higher than the right will be s_L, and the number of such separating edges with the right endpoint higher than the left will be s_R. The number of edges that are in both $pbs_L(W'')$ and $pbs_L(W')$ will be c_L, and the number of edges that are in both $pbs_R(W'')$ and $pbs_R(W')$ will be c_R. Let $bs_L(W)$ and $bs_R(W)$ represent the left and right boundary sets, respectively, of W, and let $ss(W)$ represent the separating set of W.

proc *sep_edge*$(W, s_T, u_L, u_R, d_L, d_R)$
  if the boundary sets of W are not defined
  then
    if W has a single child W'
    then
      Call *sep_edge*$(W', s_T, u_L, u_R, d_L, d_R)$.
      $bs_L(W) \leftarrow bs_L(W')$; $bs_R(W) \leftarrow bs_R(W')$; $ss(W) \leftarrow \emptyset$
    else
      Let W' and W'' be the children of W.

As an example, consider the portion of an embedded planar graph in Fig. 8. The spanning tree edges are in bold, the nontree edges are dashed, and a portion of a multilevel partition is shown by the closed curves. In particular, a cluster V_j is shown that is the union of a cluster $V_{j'}$ of tree degree 1 and a cluster $V_{j''}$ of tree degree 2. As discussed above, the set of separating edges of $V_{j''}$, as well as the set of separating edges of certain descendants of $V_{j''}$, can be determined. There are three edges in the boundary set of $V_{j'}$ and eight and nine edges, respectively, in the left and right pseudoboundary sets of $V_{j''}$. There are two edges in the newly interior set

to the left of the path in Fig. 8 and none in the newly interior set to the right of the path. There are one edge from the left pseudoboundary set and three from the right pseudoboundary set that will be in the boundary set of V_j. For the sake of discussion, let W be $V_{j''}$. Then $s_T = 5$, $u_L = 1$, $u_R = 3$, $d_L = 2$, and $d_R = 1$. On the recursive call *sep_edge*$(V_{j''}, 5, 1, 3, 2, 1)$, it is determined that W has two children W' and W''. It would then be determined that $c_L = 2$, $c_R = 0$, $s''_T = 1$, $d''_L = 2$, $d''_R = 1$, $s'_T = 2$, $u'_L = 2$, $u'_R = 0$, $s = 2$, $s_L = 2$, and $s_R = 0$. By initialization, $u''_L = 1$, $d'_L = 2$, $u''_R = 3$, and $d'_R = 1$. Note that $size(pbs_L(W'')) = 6$, $size(pbs_L(W')) = 6$, $size(pbs_R(W'')) = 4$, and $size(pbs_R(W')) = 5$. We have not shown the internal structure of W' and W'', and so we will not discuss what happens during the recursive calls *sep_edge*$(W', 2, 2, 0, 2, 1)$ and *sep_edge*$(W'', 1, 1, 3, 2, 0)$. Upon the returns, $bs_L(W)$ would be created, containing three edges, and $bs_R(W)$ would be created, containing four edges.

We designate as algorithm *build_sets* the algorithm presented above to compute the boundary sets, newly interior sets, and separating sets for the clusters in a multilevel partition of a planar graph.

LEMMA 4.1. *Algorithm build_sets correctly computes the boundary sets, newly interior sets, and separating set for the clusters in a multilevel partition of a planar graph.*

Proof. We shall prove by induction that for any level $l \leq q$, *build_sets* correctly computes pseudoboundary sets and newly interior sets for all clusters of tree degree 2 whose level is at most l and that have no ancestor of tree degree 1 whose level is at most l, and it correctly computes boundary sets, newly interior sets, and separating set for all other clusters whose level is at most l. Since every cluster except the one containing all vertices has an ancestor of tree degree 1, the lemma will then follow.

The proof is by induction on level number. For the basis, $l = 0$. Any cluster at level at most 0 is a basic cluster, and the identification of boundary sets is clearly correct, as is the identification of pseudoboundary sets for clusters of tree degree 2. For the induction step, $l > 0$. We assume as the induction hypothesis that the above claim holds for clusters at any levels $l' < l$. For the newly interior sets of a cluster V_j, an examination of cases indicates that these are correctly computed from the boundary or pseudoboundary sets of the children of V_j.

For the sets other than newly interior, we consider cases for a cluster V_j at level l. Suppose cluster V_j at level l is of tree degree 0. It will have no boundary set since all vertices are contained within it. Suppose cluster V_j at level l is of tree degree 2. If V_j has just one child cluster, then by the induction hypothesis, that child's pseudoboundary set is correct. Clearly, the pseudoboundary set of V_j will be the same set. If V_j is the union of two clusters of tree degree 1 and 3, then its boundary sets and pseudoboundary sets are formed from the boundary set for its child of tree degree 1, which is correctly generated, by the induction hypothesis. Otherwise, V_j is the union of two clusters of tree degree 2. By the induction hypothesis, the pseudoboundary sets of the children are correctly computed. The only edges in those sets that are not in the pseudoboundary set of V_j are the edges from one child to the other that stay on the same side of the path between the boundary vertices of V_j. Algorithm *build_sets* correctly identifies these and removes them before concatenating the remaining lists of edges.

Next, suppose cluster V_j at level l is of tree degree 1. If V_j has just one child cluster, then by the induction hypothesis, that child's boundary set is correct. Clearly, the boundary set of V_j will be the same set. Otherwise, V_j is the union of two clusters

$V_{j'}$ and $V_{j''}$ of tree degree 1 and 2, respectively. By the induction hypothesis, the boundary set of $V_{j'}$ and the pseudoboundary set of $V_{j''}$ are computed correctly. If any edges in the boundary set of $V_{j'}$ have their other endpoint in a cluster up from $V_{j''}$, then no edge in the pseudoboundary set of $V_{j''}$ can be a separating edge. Thus removing those edges from the pseudoboundary sets of $V_{j''}$ that are in the boundary set of $V_{j'}$ and then concatenating the remainder will give the boundary set of V_j. Otherwise, there can be separating edges in the pseudoboundary sets of $V_{j''}$. A pseudoboundary set will contain first the edges with the other endpoint down from $V_{j''}$, then the separating edges for $V_{j''}$ and its relevant descendants, and finally the edges with the other endpoint up from $V_{j''}$. Thus, after removing edges from the boundary set of $V_{j'}$, the separating edges come next, in order, starting with the lowest edge in the remaining portions of the pseudoboundary sets of $V_{j''}$. Once these are identified and removed, the remaining portions of the pseudoboundary sets of $V_{j''}$ will comprise the boundary set of V_j.

Finally, consider the relevant descendants of cluster $V_{j''}$. We argue that *sep_edge* correctly computes the boundary sets and separating sets of all such clusters that have their boundary sets undefined. By the induction hypothesis, the pseudoboundary sets have been computed correctly. The proof that *sep_edge* correctly computes the boundary sets and separating sets is by induction on the distance to the deepest relevant descendant. For the basis, the distance is zero, and the cluster W has no proper relevant descendant. Then W is either a basic cluster or the union of clusters of tree degree 1 and 3. In both cases, the boundary sets of W will already be defined. For the induction step, we have the following. If the boundary set of W is already defined, then nothing need be done since all relevant descendants of W will have their boundary sets defined. Otherwise, if W has a single child W', then the recursive call for W' will, by the induction hypothesis for *sep_edge*, correctly compute the boundary sets of all relevant descendants of W'. Then the boundary set of W will be the boundary set of W', and there will be no separating set for W. Finally, if W has two children, then we have the following. If there are no separating edges with endpoints in W, then the boundary sets of W are the same as the pseudoboundary sets of W. In this case, there will be no separating edges with endpoints in either W' or W'', so that it does not matter what the u_L, u_R, d_L, and d_R parameters are in the recursive calls on W' and W''. Clearly, the number s of actual separating edges for W will equal the total number of separating edges with both endpoints in W minus the total number of separating edges with both endpoints in W' minus the total number of separating edges with both endpoints in W''. If $s > 0$, then one of s_L and s_R is 0 and the other is s. For $s_L > 0$, we must have one of the following cases. If $s''_T > 0$, then there are no edges from W' to a cluster up from W'', and thus the topmost separating edge out of the right side of W' is the $(c_R + 1)$st edge from the top in $pbs_R(W')$. If $s'_T > 0$, then there are no edges from W'' to a cluster down from W', and thus the bottommost separating edge out of the left side of W'' is the $(c_L + 1)$st edge from the bottom in $pbs_L(W'')$. If $s'_T = 0$ and $s''_T = 0$, then the $(u_L + 1)$st edge down in $pbs_L(W'')$ is the topmost separating edge for W, as is the $(d_R + s)$th edge up in $pbs_R(W')$. Upon the return from the recursive calls, the separating and nonseparating edges between W' and W'' are located and removed from the boundary sets of W' and W'', and the results are concatenated to give the boundary sets of W. Note that if $s_L > 0$, then edges up from the left of W are necessarily precisely the edges up from the left of W'', and if $s_L = 0$, it does not matter whether u''_L is set correctly or not. Similar remarks apply to the other cases. □

5. Data structures for embedded planar graphs. We describe the data structures for representing embedded planar graphs and show how to update them quickly when an update occurs. We use the topology tree of section 3 as a basis for our update data structure. Edges in any boundary, pseudoboundary, or newly interior set of a vertex cluster will be ordered according to the embedding and then represented by a balanced tree structure called an "edge-ordering tree." Next we define an "edge-ordered topology tree," which is a topology tree augmented by the edge-ordering information. We discuss how to update the edge-ordered topology tree to show the result of a swap. We then discuss how to update the edge-ordered topology tree to show the effect of the insertion or deletion of an edge or vertex. Finally, we show how to make edge-ordered topology trees fully persistent by introducing "internal names" of vertices, which are based on a vertex's position in the topology tree, and by showing how to keep track of internal indices while performing operations that change the structure of edge-ordering trees.

Let each set of nontree edges associated with a cluster, either a boundary, pseudoboundary, or newly interior set, be represented by a balanced tree called an *edge-ordering tree*. Each leaf in the edge-ordering tree will represent an edge in the corresponding set. When the pseudoboundary set of a cluster V_j is formed from the pseudoboundary sets of the children, do not change the edge-ordering trees for the pseudoboundary sets of the children, but rather build a new edge-ordering tree by introducing some new nodes and sharing subtrees with the already existing edge-ordering trees. The same idea applies for generating a representation of the boundary sets and the newly interior sets.

We define an *edge-ordered topology tree* for an embedded planar graph of maximum degree 3 to be the topology tree, along with pointers from each node in the topology tree to the edge-ordering trees for its one or two boundary sets, and its one or two newly interior sets. It is understood that the root of the tree has a pointer to an empty boundary set. We then note that the algorithm *build_sets* from the last section can be adapted to build an edge-ordered topology tree.

We now consider how to swap a nontree edge into the tree, replacing a tree edge. We will perform an operation similar to *basic_swap* of section 3, with the following additional work. When a node in the topology tree is removed, its boundary, pseudoboundary, and newly interior sets should be removed. Since subtrees are being shared in the edge-ordering trees, we keep a reference count in each node in a balanced tree indicating how many pointers have been set to point at it. When a node in an edge-ordering tree is removed, the reference count in each of its two children should be decremented. If a reference count goes to zero, then its node should be deleted. (In the case that we wish to enforce a particular bound on the time per operation, if some operation would cause a very large number of nodes to have their reference counts go to zero, then these nodes are saved in a list that can be reduced in size of the subsequent operations.) Thus edge-ordering trees will be removed as nodes are removed from the topology tree. In rebuilding the topology tree, whenever a parent for two nodes is created or changed, the boundary, pseudoboundary, and newly interior sets are recomputed in the fashion discussed in algorithm *build_sets*.

This approach is related to that in [F1], but we are specifying it carefully since we believe there is an error in [F1] with regard to the analysis of the running time. In particular, we believe that the time to search for the correct point to split boundary sets is underestimated in [F1]. The reason is the following. Consider a cluster V_j created by the union of two clusters $V_{j'}$ and $V_{j''}$, each of tree degree 2. We wish

to perform a simultaneous search in edge-ordering trees representing a boundary (or pseudoboundary) set for $V_{j'}$ and a boundary (or pseudoboundary) set for $V_{j''}$ to identify the edges common to both sets. It is easy to produce in constant time a suitable edge in one boundary set to test. The problem is determining whether that edge is also in the other boundary set. It is easy to keep a pointer from the leaf of one edge-ordering tree to the leaf in another edge-ordering tree representing the same edge but with respect to its other endpoint. However, it does not seem possible to deduce the name of the corresponding boundary set in constant time unless an excessive amount of work is performed on each update.

Since subtrees of the edge-ordering trees are shared, we give a top-down procedure to search within $V_{j'}$ and $V_{j''}$ simultaneously. To make the above searches efficient, we keep in each node of every edge-ordering tree the number of edges represented by the subtree rooted at that node. Then the position of the edges to be deleted can be computed quickly by keeping track of the positions of edges already deleted from the boundary sets. We then binary search to find the number of shared edges. For any test value, we search down through both trees to find the corresponding leaf in each tree. If the pointers in the leaves point at each other, then there are at least that many common edges; otherwise, there are fewer. Clearly, such a search will also involve $O(\log n)$ tests at $O(\log n)$ time per test, or $O((\log n)^2)$ time in total. Call the above procedure *plane_swap*.

LEMMA 5.1. *Procedure plane_swap correctly rebuilds an edge-ordered topology tree after a swap.*

Proof. Lemma 3.1 establishes that the topology tree is rebuilt correctly after a swap is performed. The simultaneous search of two boundary (or pseudoboundary) sets determines for any given size whether there is a common subset of that size, and it thus finds the size of the subset by binary search. Note that the search is indeed top-down, so that it works when subtrees of the edge-ordering trees are shared. Finally, the recomputing of the boundary, pseudoboundary, and newly interior sets is correct by arguments similar to those in the proof of Lemma 4.1. □

LEMMA 5.2. *The edge-ordered topology tree for an n-vertex embedded planar graph of maximum degree 3 uses $O(n)$ space, can be set up in $O(n)$ time, and can be updated to show the result of a swap in $O((\log n)^3)$ time.*

Proof. The topology tree itself uses $O(n)$ space. Each nontree edge will appear in two boundary sets (one for each endpoint) at the lowest level in the partition. Thus edge-ordering trees at level 0 use $O(n)$ space. We count the additional space used by the edge-ordering trees as follows. It follows from Lemma 2.2 that at level i, $i = 0, 1, \ldots, q$, there are at most $(5/6)^i n$ clusters. For a cluster V_j of size n_j, there are at most $c \log(2n_j)$ new nodes created in building additional boundary trees, where c is a constant. The sum of $c \log(2n_j)$ over all clusters V_j at level i is maximized when there are as many clusters as possible and each cluster is of roughly equal size. Thus we bound the total additional space used by edge-ordering trees by $\sum_{i=0}^{q} (5/6)^i n(1 + i \log(6/5))$. This quantity is clearly $O(n)$. It follows that the total space is $O(n)$.

We next discuss the setup time. Let V_j be a cluster of size n_j, with V_j being the union of clusters $V_{j'}$ and $V_{j''}$. If $V_{j'}$ is of tree degree 1 and $V_{j''}$ is of tree degree 2, then charge the work of identifying each separating set to the parent W of the pair of clusters W' and W'' for which the separating set arose. This amounts to a charge of the cost of one search in the pseudoboundary sets of W, which is proportional to the square of the logarithm of the size of W. The time to remove the separating sets from the affected clusters should be apportioned similarly and will be of cost proportional

to the logarithm of the cluster size. Then the charge to generate the edge-ordering tree for cluster V_j will be at most $c(\log(2n_j))^2$, where c is a constant. The sum of $c(\log(2n_j))^2$ over all clusters V_j at level i is within a constant multiplicative factor of maximum when there are as many clusters as possible and each cluster is of roughly equal size. Thus we bound the setup time by $\sum_{i=0}^{q}(5/6)^i n(1 + i\log(6/5))^2$. This quantity is clearly $O(n)$.

By Lemma 3.1, a topology tree can be updated in $O(\log n)$ time to show the result of a swap, and thus $O(\log n)$ nodes are affected. As in setting up the edge-ordered topology tree, first find the pseudoboundary sets, then identify separating edges at higher nodes, and then correct the pseudoboundary sets to be boundary sets. As in the analysis of the setup time, charge the time to identify the separating edges to the lowest cluster to which both endpoints belong. Since there are $O(\log n)$ nodes that will be created, there will be $O(\log n)$ separating sets created, at most 1 per node created. Since each such node gets charged $O((\log n)^2)$, the total charge is $O((\log n)^3)$. In addition, there are a constant number of concatenations or splits per node, and there are at most $O(\log n)$ concatenations and splits that must be performed. Each such concatenation or split uses at most one search, at $O((\log n)^2)$ per search. □

The edge-ordered topology tree for the embedded planar graph can also be updated to reflect the insertion or deletion of an edge, as long as the insertion is consistent with the current embedding. The approach is similar to what is described in the discussion preceding Lemma 3.2, except that there is no need to adjust the value of z since $z = 1$ is independent of the number of vertices in the graph.

LEMMA 5.3. *The edge-ordered topology tree for an embedded planar graph of maximum degree* 3 *can be updated to show the result of an edge or vertex insertion or deletion that is consistent with the embedding in* $O((\log n)^3)$ *time, where* n *is the current number of vertices.*

Proof. The number of inserted and deleted vertices and edges will be a small constant. Thus by reasoning similar to that in the proof of Lemma 3.1, the number of nodes in the topology tree that are changed will be $O(\log n)$. The time bound then follows by the same argument as in Lemma 5.2. □

As shown in Lemma 5.2, an edge-ordered topology tree can be updated to show the result of a swap in $O((\log n)^3)$ time. It would at first appear easy to modify this representation in the same fashion as we did to the 2-dimensional topology tree in section 2 to give a persistent data structure. The difficulty is that on each update in the persistent structure, we made an unshared copy of a topology tree, at a cost of $O(m^{1/2})$ time. This was done because there appears to be no good way to both share subtrees and still have a pointer from each node to its parent. If we wish to achieve $O((\log n)^3)$ time per update in a persistent structure for planar graphs, we must do it without making complete copies of objects such as topology trees. Instead, we shall present a scheme for encoding new *internal* names of vertices. These names will be generated bottom-up and read top-down.

The names will be based on the structure of the topology tree and will thus change as the topology of the tree it is representing changes. We first note that the topology tree is a binary tree of height $O(\log n)$. We shall assume that any child of a node with exactly one child will be designated as a left child. We shall also assume that a node with two children will have the children designated as left or right in an arbitrary but fixed fashion. We encode the *level-l internal index* of a vertex, for $l = 0, 1, \ldots, q$, as follows. Let $a_l(v)$ be the ancestor at level l of the leaf in the topology tree that represents the vertex v. The level-0 internal index of any vertex v is the empty string.

For any l, $0 < l \leq q$, the level-l internal index of v is formed as follows. Take the level-$l-1$ internal index of v and concatenate onto its left a 0 if $a_{l-1}(v)$ is a left child of $a_l(v)$ and a 1 otherwise. To differentiate the original names from these new names, the original index of a vertex or vertex cluster will be called its *external index*.

Consider the graph in Fig. 1 along with the restricted multilevel partition of Fig. 3. We give the internal indices of vertex 13, using the topology tree as shown in Fig. 4. The level-l indices of vertex 13, for $l = 1, 2, 3, 4, 5$, respectively, are 1, 01, 001, 1001, and 11001.

Each node V_j at level l in the topology tree will have its (at most two) boundary vertices specified by both external index and level-l internal index and the (at most three) tree edges with precisely one endpoint in the cluster specified by external indices of the endpoints. In addition, each leaf in the topology tree will have the external name of its only vertex. If node V_j has two children, then it will have the level-l internal index for each endpoint of the tree edge that connects the two clusters corresponding to the children.

To represent the internal names of the endpoints of edges referred to in an edge-ordering tree, an additional mechanism is needed. Each value in an edge-ordering tree associated with node V_j will have the endpoints of its corresponding edge or pair of edges specified by a level-l' internal index for some $l' \leq l$. There will be an additional field *substr* in each node of the edge-ordering tree. The concatenation of the *substr* fields on a path from the root down to any node in the edge-ordering tree, when concatenated with a level-l' index there, will give a level-l internal index for the corresponding vertex. When two clusters are unioned, the *substr* fields at the roots of the corresponding edge-ordering trees are appended with either a 0 or 1 before the trees are concatenated. Clearly, these fields can be maintained as the trees are split and concatenated. Indeed, we note that the edge-ordering trees will be balanced naturally if every time we concatenate, we just add a new root above the current two (or three) roots, rather than performing some complicated rebalancing. This follows since there are only $O(\log n)$ levels in the topology tree.

We next discuss updating a persistent structure when it has been determined that a swap should be performed. We assume that the external and internal indices of the endpoints of the edges in the swap pair (e, f) will be provided. Using the internal indices of these endpoints, we can search down in the topology tree to the leaves, using constant time per level and setting temporary pointers as follows. For each node v on a path from the root down to an endpoint of e or f, set the parent pointer of v, the pointers between v and the nodes representing clusters adjacent to the cluster for v, and the parent pointer for each node representing an adjacent cluster.

Then proceed as in algorithm *plane_swap*, but doing the necessary work to maintain the following invariant with respect to nodes on the lists L_D, L_A, and L_C:

1. For the ancestor of any node in the lists L_D and L_C, there are temporary pointers to its parent.
2. For the ancestor of any node in the lists L_D, L_A, and L_C, there are temporary pointers to nodes representing adjacent clusters.
3. For any node representing a cluster adjacent to an ancestor of any node in the lists L_D, L_A, and L_C, there is a temporary parent pointer.

Whenever we insert a node y onto a list, where y was not previously an ancestor of a member of some list, we do the following. Either node y is put on list L_A and thus has no parent, or it is put on list L_C and it or a child of it must have been adjacent to a node on a list. In the latter case, the temporary pointer to the parent of y is

already set, as well as temporary parent pointers for all of its ancestors. We also know the external names of the endpoints of tree edges with precisely one endpoint in the cluster represented by node y. If such a tree edge does not have a temporary pointer associated with it, search up through the ancestors of y until we find an ancestor node x such that that edge is internal to x. We then use the internal indices for the endpoint of that edge to search down to a node z that represents a cluster that is adjacent to the cluster represented by node y. As the search goes back down, set temporary parent pointers along this path, as well as pointers from each ancestor of y to the node representing an adjacent cluster on the path up from z. When all such tree edges from the cluster represented by node y have been handled, the invariant is once again satisfied. We call this search from y an *invariant-enforcing search.*

Let the above approach be called algorithm *plane_persist_swap.*

THEOREM 5.4. *Algorithm plane_persist_swap maintains a fully persistent version of edge-ordered topology trees, using $O(n + k(\log n)^2)$ space to store k versions and generating a new version reflecting the result of a swap in $O((\log n)^3)$ time.*

Proof. By Lemma 5.1, algorithm *plane_swap* correctly updates an edge-ordered topology tree when a swap is performed. We verify that *plane_persist_swap* maintains the invariant stated above. The proof is by induction on the number of nodes that have been placed on L_D, L_A, and L_C. Initially, four nodes are placed on L_D and four nodes are placed on L_A. The nodes on L_D are the endpoints of edges e and f, and the ancestors of these nodes constitute the search paths along which temporary pointers are set. The four nodes on L_A are the replacements for the nodes on L_D, and copying the adjacency information of those nodes ensures that the ancestors of all adjacent nodes have the appropriate temporary pointers set. Subsequently, the following cases describe nodes placed on lists. These cases result from a close examination of *basic_swap.* For a node to be placed on L_D, a child of it must have been on L_D or L_C, or a child of it must have been adjacent to a node on L_C or L_A. The invariant is satisfied in all but the latter case, in which the invariant-enforcing search restores the invariant. For a node to be placed on L_C, either it had a sibling on L_D, or it had a child on L_C or L_A, or a child of it must have been adjacent to a node on L_C or L_A. The invariant is satisfied in all but the latter case, in which the invariant-enforcing search restores the invariant. For a node to be placed on L_A, either it or an adjacent node is on L_C, or a child is on L_C or L_A. The invariant-enforcing search restores the invariant in the former case. Thus the invariant is maintained. Given that the invariant is maintained, the algorithm is then able to access nodes to test whether or not to combine clusters.

Furthermore, we assert that for any quantity in an edge-ordering tree that is associated with an endpoint expressed by a level-l internal index, its level-l internal index can be maintained and manipulated as the edge-ordering trees are split and concatenated.

Finally, we establish the claimed resource bounds. From Lemma 5.1, the time used by *plane_swap* is $O((\log n)^3)$. In setting up temporary parent and adjacency pointers, the number of additional nodes examined is just a constant times the number of nodes examined in *plane_swap.* Furthermore, each node that is examined is examined just a constant number of times. Thus setting up temporary parent and adjacency pointers will take $O((\log n)^3)$ time. Each operation using level-l internal indices will take just constant time, so that the time to split and concatenate edge-ordering trees will be proportional to what it was in *plane_swap.* Thus the total time for one swap in a fully persistent version of edge-ordered topology trees will be $O((\log n)^3)$ time. By

Lemma 3.1, a topology tree can be updated in $O(\log n)$ time to show the result of a swap, and thus $O(\log n)$ nodes in the topology tree are affected. Since a constant number of boundary sets, newly interior sets, and separating sets are created for each node, and each split or concatenation of edge-ordering trees will create $O(\log n)$ nodes, $O((\log n)^2)$ additional space is used whenever a swap is performed. □

6. Basic approach for finding the *k* smallest spanning trees. In this section, we discuss the overall structure of our algorithm for finding the k smallest spanning trees, leaving out the description of the particular data structure that we employ. We shall assume that there are at least k distinct spanning trees of the graph. (It is easy to modify the algorithm to detect the case in which there are fewer than k distinct spanning trees.) We shall also assume that all edge weights are nonnegative. (If not, we can add a positive value to each edge weight to give an equivalent problem with all edge weights nonnegative.)

We first find a minimum spanning tree of our graph using the fast algorithm of [GGST] for general graphs or [CT] for planar graphs. Then we use Eppstein's technique to reduce the problem to one in which there are $O(k)$ vertices and edges [E]. If $k < m - n$, this technique identifies and deletes $m - n - k$ edges that will be in none of the k smallest spanning trees, and if $k < n$, it identifies and contracts $n - k$ edges that will be in all of these trees. Identifying these edges uses an algorithm for the sensitivity analysis of minimum spanning trees, either Tarjan's algorithm [T1], [T2] for general graphs or the algorithm of Booth and Westbrook [BW] for planar graphs. Also used is the linear-time selection algorithm [BFPRT]. We call the resulting graph the *contracted graph*. Note that the k smallest spanning trees of the contracted graph are in one-to-one correspondence with the k smallest spanning trees of our original graph.

Next, we transform the contracted graph into a graph in which every vertex has degree no greater than 3 using the transformation discussed in section 2. Note that each edge of cost $-\infty$ will be in all of the k smallest spanning trees, and each edge of cost ∞ will be in none. It follows that the k smallest spanning trees of the transformed graph are in one-to-one correspondence with the k smallest spanning trees of the contracted graph.

Let T_i denote the ith smallest spanning tree of the transformed graph. Thus T_1 denotes the minimum spanning tree. Having already found T_1, our algorithm will generate the $k - 1$ spanning trees $T_2, \ldots, T_k$ one at a time. Each tree T_i with $i > 1$ will be derived from some tree T_j, $j < i$, by a swap (e_i, f_i), in which a tree edge e_i is replaced by a nontree edge f_i. To guarantee that no tree is derived more than once, the trees will have certain restrictions placed on them of the form that any tree derived from T_j must include certain edges and exclude certain other edges. This inclusion–exclusion approach was presented by Lawler in [L1] and [L2, pp. 100–104].

Associated with each spanning tree T_i that is generated will be a *best-swap structure* R_i. We shall discuss the best-swap structure in greater detail later but mention a few properties now. Structure R_i will represent all spanning trees derivable from T_i by a sequence of swaps and will identify a swap for T_i of minimum cost. The algorithm will maintain a heap on the costs of the trees obtainable via these minimum-cost swaps. (When k is very large, our final version of the algorithm will manage the heap somewhat differently; see the discussion at the end of this section.)

We now proceed with a description of the rest of the algorithm. Given the minimum spanning tree T_1, we generate a best-swap structure for T_1. We initialize the heap with the value representing the cost of the spanning tree derived from T_1 by

applying the swap of minimum cost. We then repeat the following $k-1$ times. Extract the minimum from the heap. The extracted value represents the cost of a tree T_i produced by applying a swap (e_i, f_i) to spanning tree T_j. Generate a best-swap structure R_i from R_j using the fully persistent versions of the data structures discussed in sections 3 and 5. The changes in generating R_i from R_j should reflect the effect of two changes: replacing e_i by f_i in the spanning tree and resetting the cost of edge e_i to be the value ∞ for the purpose of determining the best swap. Resetting the cost of edge e_i effectively keeps edge e_i out of any of the spanning trees that are subsequently derived (transitively) from T_i. Finally, modify R_j to reflect the resetting of the cost of e_i to be $-\infty$ for the purpose of determining the best swap. Resetting the cost of edge e_i in this manner effectively forces edge e_i to be in all of the spanning trees that are subsequently derived (transitively) from T_j. The minimum costs identified by each of R_i and R_j correspond to swaps to be applied to T_i and T_j, respectively. Compute the costs of the trees generated by these trees and insert them into the heap. Note that the original costs of edges should be used in computing these costs. This completes the description of the repeat loop.

As we have described the algorithm, its output will be in the form of a minimum spanning tree plus a sequence of triples (e_i, f_i, j_i), $i = 2, 3, \ldots, k$. Note that it is easy to include the cost of tree T_i with the triple.

We can visualize the inclusion–exclusion using a binary tree B. Each node x in B represents a modified version $G(x)$ of the original graph G based on the inclusion and exclusion conditions. Associated with each node is the minimum spanning tree $T(x)$ for $G(x)$, along with a value that is the cost of $T(x)$ with respect to the edge weights in G. The root of B represents G, $T(root)$ is the minimum spanning tree T_1 of G, and the value associated with the root is the cost of T_1. For any node x in B, we determine the children of x as follows. If there is a swap of finite cost that can be applied to $T(x)$, let $(e(x), f(x))$ be the minimum-cost such swap. Then x will have right and left children. Graph $G(right(x))$ will be graph $G(x)$ with the cost of $e(x)$ reset to ∞, and spanning tree $T(right(x))$ will be $T(x) - e(x) + f(x)$. Graph $G(left(x))$ will be graph $G(x)$ with the cost of $e(x)$ reset to $-\infty$, and spanning tree $T(left(x))$ will be $T(x)$. This completes the definition of binary tree B.

As an example, we consider the spanning trees for the graph in Fig. 1. We shall name edges by their weights. In Fig. 9, we give binary tree B for this graph. The minimum spanning tree, as shown in Fig. 1, has a cost of 91 and is represented by the root of the tree in Fig. 9. The best swap for this tree is $(13, 14)$. The right child of the root represents the resulting tree, with cost 92. Note that edge 13 is excluded from being a member of any of the spanning trees represented by this node or any of its descendants. Conversely, edge 13 is required to be included in any tree represented by the left child of the root or any of its descendants. The minimum-cost swap given that edge 13 must be included is $(12, 14)$, yielding a tree with cost of 93. In our representation, the edge to the right child is labeled with a tree edge that is excluded, and the edge to the left child is labeled with a tree edge (the same edge) that must be included. To make the representation less cluttered, we subsequently put the included/excluded tree edge between the edges to the right and left children. Note that we label a nonroot node with its cost only if its spanning tree differs from that of its parent. Also, we do not draw the complete representation but only the first four levels, noting that all nodes shown have children except the lower rightmost one.

The time required by the algorithm will be the following. From [GGST], [E], [T1],

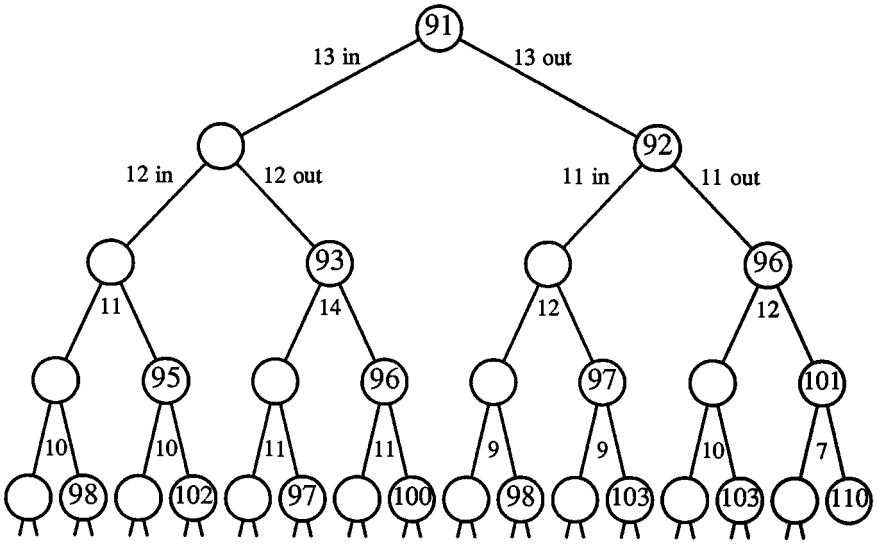

FIG. 9. *The first four levels of inclusion/exclusion for Fig.* 1, *with spanning tree costs indicated.*

[T2], [BFPRT], and [F1], finding the contracted graph and transforming it into one with maximum degree 3 will take $O(m \log \beta(m, n))$ time and $O(m)$ space. From [CT], [E], [BW], [BFPRT], and [F1], finding the contracted graph of a planar graph and transforming it into one with maximum degree 3 will take $O(n)$ time and space. In addition to setting up R_1, the algorithm will perform $2(k-1)$ updates of best-swap structures. With regard to the heap, $k-1$ *extractmin*s and $2(k-1)$ *insert*s will be performed. Thus the total time for all heap operations is $O(k \log k)$.

For very large values of k, the total time for maintaining the heap on the costs of trees may dominate the total time for updating the best-swap structures. In such a case, we may reduce the $O(k \log k)$ charge for maintaining the heap to $O(k)$ as follows. Note that when a best-swap structure is modified, the cost of the new spanning tree induced by the new best swap is never smaller than the spanning tree from which it was derived.

Suppose that these costs can be viewed as forming a min-heap. From [F4] it is known that the kth smallest value in a min-heap can be selected in $O(k)$ time. This algorithm is then used in place of the simple heap mechanism. Given $O(k)$ values that include the costs of all k smallest spanning trees, it is then straightforward to identify the costs of the k smallest spanning trees. Note, however, that these costs will not necessarily be output in sorted order.

It remains to show that the costs in binary tree B can be viewed as forming a min-heap. Since the spanning tree for each left child is the same as that of its parent, we need to compress B to get our min-heap. Note that for any node x such that $right(left(x))$ is defined, the value labeling $right(x)$ is no larger than the value labeling $right(left(x))$. This follows since a swap of smallest cost relative to $T(x)$ in $G(x)$ is of cost no larger than a swap of smallest cost relative to $T(left(x))$ in $G(left(x))$. Thus we generate our min-heap to contain nodes that correspond to a subset of the nodes in B in the following way. The root of the min-heap corresponds to the root of B. For any node y in the min-heap corresponding to node x in B, we determine the children of y as follows. If $right(x)$ is defined, then $right(y)$ is defined

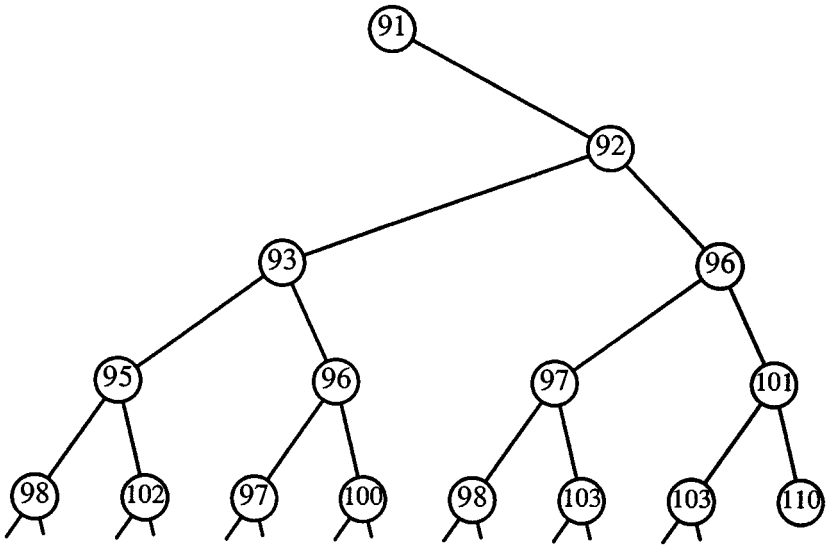

FIG. 10. *The min-heap induced by inclusion/exclusion on Fig.* 1.

to be a node that corresponds to $right(x)$. If node x has a parent, $parent(x)$, and if $right(left(parent(x)))$ is defined, then $left(y)$ is defined to be a node that corresponds to $right(left(parent(x)))$. Since the algorithm in [F4] first accesses an element in the min-heap only after having accessed its parent, the portion of the min-heap actually accessed by that algorithm can be constructed on the fly as we create and access our replacement data structures. Thus only $O(k)$ nodes in the min-heap need to be created. The binary min-heap corresponding to binary tree B in Fig. 9 is shown in Fig. 10.

7. Ambivalent data structures I: Best-swap structures. In this section, we adapt the data structures from section 3 to give an efficient best-swap structure for the case of general graphs. This will lead to an efficient algorithm for finding the k smallest spanning trees of a graph. We first give a more formal definition of an ambivalent data structure. Then we define what we call a "pseudoswap," which will allow us to design an ambivalent data structure. Using pseudoswaps, we next describe the information maintained in the nodes of the 2-dimensional topology tree and show how to generate this information for a node, given the information for its children. We then specify the best-swap data structure and discuss how to update this structure. We conclude with a claim of the time and space bounds on our algorithm for finding the k smallest spanning trees.

We now give a more formal definition of an ambivalent data structure. An item or set of items of data is said to be *substantiated* if that item or set of items represents an actual state of affairs. If that item or set of items does not represent an actual state of affairs but rather a hypothetical state of affairs that does not actually hold, then it is said to be *nonsubstantiated*. Let an item or set of items be called an *alternative* if examination of that item or set of items in isolation cannot determine whether it is substantiated or nonsubstantiated, but examination of a larger context of data will determine whether it is substantiated or nonsubstantiated. A *substantiated set of alternatives* is a set of two or more alternatives, one of which will be substantiated and

the rest of which will be nonsubstantiated. A data structure is said to be *ambivalent* if at many locations within itself it maintains substantiated sets of alternatives, and the data structure as a whole contains sufficient data to determine which alternative in every substantiated set of alternatives is substantiated. The ambivalence in our particular data structures comes from considering two clusters of vertices in a spanning tree and then attempting to represent how a nontree edge with one endpoint in each cluster relates to tree edges in these clusters. Such a relation might be whether a tree edge is in the cycle induced by the nontree edge. Determining whether a tree edge is in the cycle induced by the nontree edge may require information not stored with either cluster, i.e., it is information about the topology of the spanning tree. However, this information will always be available in our data structure as a whole.

We seek to build a data structure in which we can maintain a large set of swaps in a heap-like fashion so that a best swap can be identified quickly. We do this by considering nontree edges that have both endpoints in the same cluster and nontree edges that have their endpoints in different clusters. It is not hard to compute the most advantageous swap involving edges both of whose endpoints are in the same basic cluster. Thus the more challenging task is handling nontree edges that have their endpoints in different clusters. We set up ambivalent information for each cluster V_j of tree degree 2 as follows. Let V_r be a cluster at the same level as V_j. For any boundary vertex w of V_j, a *pseudoswap* is a pair (e, f) of edges, where f is a nontree edge having one endpoint in each of V_j and V_r and e is an edge on the path in the tree from w to the endpoint of f in V_j. Let w and w' be the boundary vertices of V_j. Suppose (e, f) is a pseudoswap for w and (e', f) is a pseudoswap for w'. Then one of those pseudoswaps is actually a swap, depending on whether w or w' is nearer V_r in tree T. Thus the set of pseudoswaps $\{(e, f), (e', f)\}$ is a substantiated set of alternatives.

Consider clusters V_j and V_r shown in Fig. 11. The spanning tree edges within these clusters are shown in bold, and the only nontree edge with an endpoint in each cluster is indicated by a dashed line. Some of the edges are labeled with their costs. Since the whole spanning tree is not shown, it is not clear whether the path in the tree between the endpoints of edge 18 goes through vertex w or vertex w'. Pseudoswap $(16, 18)$ is the best for clusters V_j and V_r and boundary vertex w. Pseudoswap $(17, 18)$ is the best for clusters V_j and V_r and boundary vertex w'.

We next discuss carefully the additional information that will be maintained in the nodes of the 2-dimensional topology tree. This includes the cost of a maximum-weight edge on the path between certain pairs of boundary vertices, the cost of a minimum-cost nontree edge between given pairs of clusters, the cost of a minimum-cost pseudoswap from a certain class of pseudoswaps, and the cost of a minimum-cost swap from a certain class of swaps.

We first discuss the cost of a maximum-weight edge on the path between certain pairs of boundary vertices. Let V_j be a vertex cluster with tree degree 2, and let $treemax(j)$ be the cost of a tree edge of maximum weight on the path between the two boundary vertices. We store $treemax(j)$ for a given j in node $V_j \times V_j$ in the 2-dimensional topology tree. If V_j is a basic vertex cluster, then $treemax(j)$ can be determined by inspection of V_j. If V_j is not a basic vertex cluster, then $treemax(j)$ can be computed in constant time given the $treemax$ values of the children in the topology tree and the cost of the tree edge between the children's corresponding clusters. Note that it is easy to keep track of the edge that yields the $treemax(j)$ value.

We next discuss the cost of a minimum-cost nontree edge between a given pair of

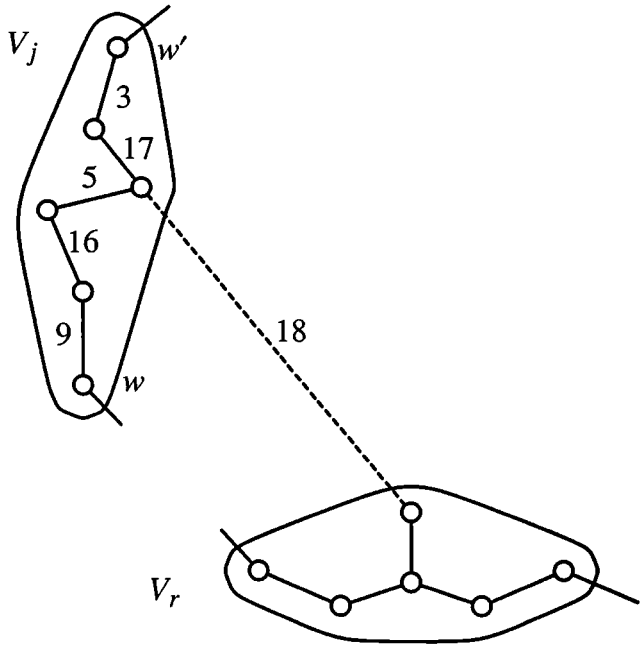

FIG. 11. *Example for illustrating best pseudoswaps.*

clusters. Let V_j and V_r be two distinct clusters at the same level. Let $nontreemin(j, r)$ be the cost of a nontree edge of minimum cost with an endpoint in each of V_j and V_r. Store $nontreemin(j, r)$ at node $V_j \times V_r$. If V_j and V_r are basic vertex clusters, then $nontreemin(j, r)$ can be computed for any particular j and all r by inspection of V_j. If V_j and V_r are not basic vertex clusters, then $nontreemin(j, r)$ is the minimum of the values $nontreemin(j', r')$, where $V_{j'} \times V_{r'}$ is a child of $V_j \times V_r$ in the 2-dimensional topology tree. Note that it is easy to keep track of the edge that yields each $nontreemin(j, r)$ value.

We next discuss the cost of a minimum-cost pseudoswap from a certain class of pseudoswaps. Let V_j and V_r be two distinct clusters at the same level. For each boundary vertex w of V_j, let $pswapmin(j, r, w)$ be the minimum value from the set of differences consisting of the cost of a nontree edge f with an endpoint in each of V_j and V_r, minus the cost of an edge e of maximum cost on the path in T from w to the endpoint of edge f that is in V_j. The values $pswapmin(j, r, w)$ for any particular value of j and r are stored in the node labeled $V_j \times V_r$. If V_j and V_r are basic vertex clusters, then $pswapmin(j, r, w)$ can be computed for any particular j, all boundary vertices w of V_j, and all r by inspection of V_j.

If V_j and V_r are not basic vertex clusters, then $pswapmin(j, r, w)$ can be computed in constant time given the *treemax* values for all children of V_j, and the *nontreemin* and *pswapmin* values for all children of $V_j \times V_r$ in the 2-dimensional topology tree. We specify this computation in detail. If the node for V_j in the topology tree has a single child $V_{j'}$, then $pswapmin(j, r, w)$ is the minimum of $pswapmin(j', r', w)$ taken over the one or two clusters $V_{r'}$ that form V_r. Otherwise, V_j is formed from two clusters $V_{j'}$ and $V_{j''}$, and we assume without loss of generality that w is contained in $V_{j'}$. Let w' be the boundary vertex of $V_{j'}$ adjacent to $V_{j''}$, and let w'' be the boundary vertex of $V_{j''}$ adjacent to $V_{j'}$. Then $pswapmin(j, r, w)$ is the minimum taken over the

one or two clusters $V_{r'}$ that form V_r of $pswapmin(j', r', w)$, $pswapmin(j'', r', w'')$, $nontreemin(j'', r') - c(w', w'')$, and $nontreemin(j'', r') - treemax(j')$. Once again, it is easy to keep track of the pair of edges that yield each $pswapmin(j, r, w)$ value.

We finally discuss the cost of a minimum-cost swap from a certain class of swaps Let V_j be a vertex cluster. Let $swapmin(j)$ be the cost of the minimum-cost swap such that the nontree edge has both endpoints in V_j. This value can be maintained in node $V_j \times V_j$ of the 2-dimensional topology tree. If V_j is a basic vertex cluster, then $swapmin(j)$ can be computed by inspection of V_j. If V_j is not a basic vertex cluster, then $swapmin(j)$ can be computed in constant time given the *swapmin*, *nontreemin*, and *pswapmin* values for children of $V_j \times V_j$ in the 2-dimensional topology tree. We specify this computation in detail. If the node for V_j in the topology tree has a single child $V_{j'}$, then $swapmin(j) = swapmin(j')$. Otherwise, V_j is formed from two clusters $V_{j'}$ and $V_{j''}$. Let w' be the boundary vertex of $V_{j'}$ adjacent to $V_{j''}$, and let w'' be the boundary vertex of $V_{j''}$ adjacent to $V_{j'}$. Then $swapmin(j)$ is the minimum of $pswapmin(j', j'', w')$, $pswapmin(j'', j', w'')$, and $nontreemin(j', j'') - c(w', w'')$. Once again, it is easy to keep track of the pair of edges that yield each $swapmin(j)$ value.

Our best-swap structure will be based on the fully persistent data structure described in section 3. A best-swap structure R_i will consist of a topology tree for tree T_i, a pointer to a 2-dimensional topology tree, many of whose subtrees are shared with other 2-dimensional topology trees, and pointers to representations of basic vertex clusters, most of which are shared. Each node in the topology tree will have the index of the corresponding cluster and a pointer to the node's parent. Each node in the 2-dimensional topology tree will have the indices of the corresponding clusters, along with the following. If the node is of type $V_j \times V_j$, it will have a *treemax* value and a *swapmin* value, while if it is of type $V_j \times V_r$, for $r \neq j$, it will have a *nontreemin* value and *pswapmin* values. Note that each such *treemax*, *nontreemin*, *pswapmin*, and *swapmin* value should also carry with it the index of the edge or edges involved and the indices of its basic vertex clusters. The representation of a basic vertex cluster V_j will consist of a list of vertices, a list of edges with both endpoints in the cluster (both tree and nontree edges), and, for every other basic cluster V_r, a pointer to a list of nontree edges with one endpoint in each of V_j and V_r. In addition, for each nontree edge with both endpoints in the same basic cluster, there will be the largest-cost tree edge with which it can swap.

We now discuss how to update a best-swap structure. If the swap causes a basic vertex cluster to be split or combined, generate a description of each new basic cluster V_j consisting of a list of vertices, a list of edges with both endpoints in V_j, and, for every other basic cluster V_r, a list of nontree edges with one endpoint in each of V_j and V_r. If the new basic cluster V_j is merged from old basic clusters V_j' and V_j'', determine the best swap for each nontree edge with one endpoint in each of V_j' and V_j'' as follows. Let tree edge (w', w'') connect V_j' to V_j'' with w' in V_j' and w'' in V_j''. Find the maximum-cost edge from each vertex in V_j' to w' and from each vertex in V_j'' to w''. Given nontree edge (v', v'') with v' in V_j' and v'' in V_j'', the best tree edge that can swap with (v', v'') can then be found in constant time. A similar approach can be used if a tree edge (w', w'') with both endpoints in basic cluster V_j has its cost set to $-\infty$ to find the new swaps that replace those involving edge (w', w'').

We next generate the new topology tree and the new 2-dimensional topology tree. For each basic vertex cluster V_j that has changed, do the following. For each pair of boundary vertices w and w' in V_j, determine the value $treemax(j, w, w')$. Next, determine the value $swapmin(j)$ by finding the minimum-cost swap over all best

swaps for nontree edges with both endpoints in V_j. For each set of nontree edges with one endpoint in each of V_j and V_r, set the appropriate pointers in the descriptions of V_j and V_r. Also, find the minimum-cost edge in the set, giving the $nontreemin(j, r)$ value. For each vertex v in V_j and each boundary vertex w of V_j, determine the maximum-cost tree edge on the path from v to w. For every other basic cluster V_r, examine every edge with one endpoint in each of V_j and V_r to find the best pseudo-swap for each boundary vertex w of V_j. Thus we can determine the $pswapmin(j, r, w)$ values. Create a new copy of the topology tree, and then modify the structure of the new topology tree and the 2-dimensional topology tree. As selected portions of the 2-dimensional topology tree are being rebuilt bottom-up, modify the information in the *treemax*, *nontreemin*, *pswapmin*, and *swapmin* fields.

THEOREM 7.1. *Let G be a graph with m edges and n vertices for which we know the minimum spanning tree T_1 and the best swap for each nontree edge. The best-swap structure R_1 can be set up in $O(m)$ time and space. A best-swap structure R_i can be updated in $O(m^{1/2})$ time, using $O(m^{1/2})$ additional space.*

Proof. The above algorithm indicates how to update basic clusters as a result of a swap or resetting the cost of a tree edge to $-\infty$. Once basic clusters have been updated, for any basic cluster V_j that has changed, the fields associated with nodes $V_j \times V_r$ must be recomputed. Then the fields for all ancestors of such nodes must be recomputed. The above algorithm does this.

Basic vertex clusters can be found in $O(m)$ time using procedure *cluster* from section 2. Similar to that in [F1], a restricted multilevel partition, a topology tree, and a 2-dimensional topology tree can be found in $O(m)$ time. Generating all other values can be done in time proportional to the number of them.

We next discuss the resources needed to update R_i. By Theorem 3.3, the time and space to perform the structural changes to the data structure is $O(m^{1/2})$. The time to compute each value in a newly created node is constant if these values are computed bottom-up. Thus the total time to update R_i is $O(m^{1/2})$. □

THEOREM 7.2. *The k smallest spanning trees of a weighted undirected graph can be found in $O(m \log \beta(m, n) + \min\{k^{3/2}, km^{1/2}\})$ time and $O(m + \min\{k^{3/2}, km^{1/2}\})$ space.*

Proof. The algorithm used is that described in section 6, with the best-swap structure R_1 just described. The algorithm uses the algorithm for finding the kth smallest element in a min-heap, as discussed at the end of section 6. Correctness follows from the discussion in section 6, plus Theorem 7.1.

As discussed in section 6, the time to find the minimum spanning tree and also find a transformed graph with $O(\min\{k, m\})$ edges will be $O(m \log \beta(m, n))$. By the discussion in section 6, there will be $O(k)$ such updates. By the discussion at the end of section 6, the cost of the kth smallest spanning tree can be found by performing $O(k)$ updates which produce $O(k)$ values, from which one selects the kth smallest in $O(k)$ time. By Theorem 7.1, updating a best-swap structure for a graph with $O(\min\{k, m\})$ edges will take $O((\min\{k, m\})^{1/2})$ time. The time bound then follows. By Theorem 7.1, each update will introduce $O(\min\{k^{3/2}, km^{1/2}\})$ additional space. The space bound then follows. □

8. Best-swap data structures for embedded planar graphs. In this section, we describe our ambivalent data structure to find a best swap for a spanning tree of an embedded planar graph. We first discuss how to store in fully persistent edge-ordering trees ambivalent information with respect to boundary sets, pseudoboundary sets, newly interior sets, and separating sets. We then describe how to compute the

minimum-cost swap for a vertex cluster, given the appropriate information about the cluster's children. We next describe the best-swap structure and its updating. Finally, we claim the time and space bounds for our algorithm that finds the k smallest spanning trees in a planar graph.

We first describe how to maintain ambivalent information in the edge-ordering tree for each set of edges. Consider a cluster V_j of tree degree 2. Consider the path P_j between the two boundary vertices of V_j. For any vertex u in V_j, we define $proj(j, u)$, the *projection* of u onto P_j, to be the vertex on P_j that is closest to u in the tree. First, consider the left boundary set $bs_L(V_j)$. For each edge (u, v) in $bs_L(V_j)$ with u in V_j, consider $proj(j, u)$. For edges (u, v) in $bs_L(V_j)$, there may be some vertex on P_j that has several vertices u projected onto it, and there may be some vertex that has no vertices projected onto it. We consider the *left modified path* $m_L(P_j)$ in which every vertex of $m_L(P_j)$ has exactly one vertex projected onto it except for the endpoints, which have none. Between two consecutive vertices x and y of $m_L(P_j)$, we shall have an edge whose cost is the cost of a maximum-cost edge on the subpath between x and y in P_j. In the case that x and y represent the same vertex in P_j, this cost will be $-\infty$. Note that $m_L(P_j)$ should be set up so as to be consistent with the planar embedding. We define and represent the *right modified path* $m_R(P_j)$ in a similar way. It is clear that a modified path is a generalization of a boundary set and can be represented by an edge-ordering tree.

We represent information about a modified path within the edge-ordering tree as follows.

- For each leaf, we keep
  1. the cost of the edge in the boundary set,
  2. the cost of the next edge in a given direction on the modified path,
  3. the cost of the swap using this next edge,
  4. the cost of the next edge in the other direction on the modified path,
  5. the cost of the swap using that next edge.
- For each nonleaf node in the edge-ordering tree, we keep
  1. the cost of the minimum-cost edge in the portion of the boundary set represented in the subtree rooted at the nonleaf node,
  2. the maximum of the costs of next edges in the given direction on the modified path in the subtree,
  3. the cost of the best swap if all edges in the portion of the boundary set for the subtree were able to swap with their next edges in this given direction,
  4. the maximum of the costs of next edges in the other direction on the modified path in the subtree,
  5. the cost of the best swap if all edges in the portion of the boundary set for the subtree can swap with their next edges in that other direction.

Given these values for any two siblings in the edge-ordering tree, the values for the parent can be computed in constant time.

If cluster V_j has tree degree 1, then the information is represented in an especially simple form. Since we know in which direction any nontree edge goes, we consider in computing *pswapmin* the swap of any nontree edge with a tree edge in V_j. We let P_j be the trivial path (of no edges) whose endpoints are both the single boundary vertex of V_j. The endpoints of all edges in the boundary set of V_j then project onto this single point in P_j, and all edges in $m(P_j)$ will have cost $-\infty$. For a cluster V_j of tree degree 2, the information corresponding to *treemax*, *nontreemin*, and *pswapmin* which we

maintained in section 7 is now held within the edge-ordering trees for the modified paths corresponding to the boundary sets, pseudoboundary sets, newly interior sets, and separating set. For a cluster V_j of tree degree 1, the same is true, except that no *treemax* is maintained.

As in section 7, we shall keep for each cluster V_j the cost $swapmin(j)$ of the best swap found within V_j. We discuss the additional changes that are necessary in the handling of edge-ordering trees when two clusters $V_{j'}$ and $V_{j''}$ are unioned to give cluster V_j. This involves examining four cases. Suppose $V_{j'}$ is of tree degree 1 and $V_{j''}$ is of tree degree 3. We take $swapmin(j)$ to be the minimum of $swapmin(j')$ and $c(f) - c(e)$, where e is the tree edge between $V_{j'}$ and $V_{j''}$ and f is the edge of smallest cost in the boundary set of $V_{j'}$. In a fashion similar to that discussed before, the now modified edge-ordering tree for the boundary set of $V_{j'}$ will represent the modified edge-ordering tree for one of the two boundary sets of V_j.

Suppose $V_{j'}$ is of tree degree 1 and $V_{j''}$ is of tree degree 2. We split and concatenate boundary sets as in sections 4 and 5. For any remaining portions of these sets, we now know in which direction the connection lies. For each newly interior set, we query the corresponding edge-ordering tree to get the minimum swap in the appropriate direction. (In particular, suppose $V_{j'}$ is "down" from $V_{j''}$. Then for the edge-ordering tree that represents the portion of the left boundary set of $V_{j''}$ that is newly interior, identify the minimum-cost swap in a downward direction. Do the same for the portion of the right boundary set of $V_{j''}$ that is newly interior.) Also, we query the edge-ordering tree for the remaining portion of each boundary set of $V_{j''}$ to identify the minimum-cost swap in an upward direction. We then take the minimum of the costs of these swaps, along with the values $swapmin(j')$, $swapmin(j'')$, and $c(f) - c(e)$, where e is a maximum-weight tree edge on the path between the top of $V_{j'}$ and the top of $V_{j''}$ and f is the edge of smallest cost in the boundary set of $V_{j'}$. Since V_j is of tree degree 1, we must reset the cost of tree edges in the modified path to be $-\infty$. We do this symbolically by letting the cost of the maximum-cost edge in this be set to $-\infty$. In any subsequent splits that affect this node, we propagate this value down as necessary in the edge-ordering tree. (This can be done by creating new nodes.)

When two boundary sets are concatenated together, values in the edge-ordering trees must be changed. One important change is that on each side of the modified path, we must find the maximum cost of a tree edge on the path between the nearest pair of edges, one in the boundary set of $V_{j'}$ and the other in the boundary set of $V_{j''}$, that will be in boundary sets for V_j. This can be done by taking the maximum over the tree edges in the edge-ordering trees representing newly interior edges on that side, along with the tree edge between $V_{j'}$ and $V_{j''}$.

Suppose $V_{j'}$ and $V_{j''}$ are both of tree degree 2. As discussed in sections 4 and 5, we split and concatenate pseudoboundary and boundary sets and form newly interior sets and a separating set. For each newly interior set, we query the corresponding edge-ordering tree to find the minimum swap in the appropriate direction. (Suppose $V_{j'}$ is "down" from $V_{j''}$. Then for the edge-ordering tree that represents the portion of the left boundary set of $V_{j''}$ that is newly interior, identify the minimum-cost swap in a downward direction. Do the same for the portion of the right boundary set of $V_{j''}$ that is newly interior. Then for the edge-ordering tree that represents the portion of the left boundary set of $V_{j'}$ that is newly interior, identify the minimum-cost swap in an upward direction. Do the same for the portion of the right boundary set of $V_{j''}$ that is newly interior.) For the separating set, we query the corresponding portions of the edge-ordering trees for the boundary sets of $V_{j'}$ and $V_{j''}$ to find the minimum swap in

the appropriate direction. (If the edges go from the left of $V_{j''}$ to the right of $V_{j'}$, then for the edge-ordering tree that represents the portion of the separating set incident on the left of $V_{j''}$, identify the minimum-cost swap in a downward direction, and for the edge-ordering tree that represents the portion of the separating set incident on the right of $V_{j'}$, identify the minimum-cost swap in an upward direction. The mirror-image case is similarly handled.) We then take the minimum of the cost of these swaps, along with $swapmin(j')$, $swapmin(j'')$, and $c(f) - c(e)$, where e is as before and f is the minimum-cost edge over all the newly interior sets and the separating set of V_j.

Finally, suppose $V_{j'}$ and $V_{j''}$ are both of tree degree 1. We take the minimum of $swapmin(j')$, $swapmin(j'')$, and $c(f) - c(e)$, where e is as before and f is the minimum-cost edge over all the newly interior sets of V_j. This concludes the examination of the four cases when two vertex clusters are unioned.

We next specify the swap structure. The best-swap structure R_i will consist of a pointer to a persistent edge-ordered topology tree for tree T_i. Shared by all R_i will be descriptions of the basic vertex clusters. The description of each basic vertex cluster will be in the form of the original name of the vertex contained in it, along with each edge incident on it, specified by the original names of the endpoints and the cost. Each node V_j at level l in the topology tree will have the cost of the pair of edges realizing its *swapmin* value, along with the level-l internal indices of the endpoints of the edges. As discussed in section 5, each value in an edge-ordering tree associated with node V_j will have its corresponding edge or pair of edges specified by a level-l' internal index for some $l' \leq l$.

We discuss how to update a best-swap structure when a swap occurs. Perform the procedure *plane_persist_swap* from section 5. Note that this procedure swaps nontree edge f in for tree edge e. We also wish to reset edge e to have cost ∞, so we reset the cost of this edge before rebuilding the edge-ordered topology tree. As we rebuild these structures, we update the *swapmin* value and the values in the edge-ordering trees of the affected nodes. As in section 7, a similar but simpler approach is used to handle an update when no swap is performed but the cost of a tree edge is reset to $-\infty$.

The full algorithm for generating the k smallest spanning trees uses the algorithm in section 6 and the persistent best-swap structure R_i.

THEOREM 8.1. *The k smallest spanning trees of a weighted undirected planar graph can be found in $O(n + k(\log n)^3)$ time and $O(n + k(\log n)^2)$ space.*

Proof. The algorithm used is that described in section 6, with the best-swap structure R_1 just described. The algorithm uses the algorithm for finding the kth smallest element in a min-heap, as discussed at the end of section 6. Correctness follows from the discussion in section 6, Theorem 5.4, plus the following. We first verify that $swapmin(j)$ is correctly computed when two clusters $V_{j'}$ and $V_{j''}$ are unioned to give cluster V_j. When $V_{j'}$ is of tree degree 1 and $V_{j''}$ is of tree degree 3, then no nontree edges are incident on $V_{j''}$, and $swapmin(j)$ results either from within $V_{j'}$ or from swapping the edge between $V_{j'}$ and $V_{j''}$ with an edge in the boundary set of $V_{j'}$. When $V_{j'}$ is of tree degree 1 and $V_{j''}$ is of tree degree 2, then $swapmin(j)$ results either from within $V_{j'}$ or within $V_{j''}$, or from swapping a tree edge between the top of $V_{j'}$ and the top of $V_{j''}$ with an edge contained in the boundary sets of both $V_{j'}$ and V_j, or from swapping a tree edge in $V_{j''}$ with an edge in the boundary sets of both $V_{j''}$ and V_j, or from swapping an edge in a newly interior set with a tree edge. When both $V_{j'}$ and $V_{j''}$ are of tree degree 2, then $swapmin(j)$ results either from within $V_{j'}$

or within $V_{j''}$, or from swapping an edge in a newly interior set with a tree edge, or from swapping an edge in the separating set with a tree edge. When both $V_{j'}$ and $V_{j''}$ are of tree degree 1, the effect of all nontree edges in the boundary sets has already been accounted for, except for swapping with the tree edge connecting $V_{j'}$ and $V_{j''}$.

The time claim in the theorem follows from Theorem 5.4, the discussion at the end of section 6, and the following. We first consider setting up the trees for R_1. Clearly, the structure of the topology tree can be determined and set up in $O(n)$ time. The information in each leaf can be set up in constant time. Then the information in nonleaf nodes can be determined in a bottom-up fashion, at a constant cost per operation in setting up an edge-ordered topology tree as in section 5. To form the value $swapmin(j)$ for a cluster V_j, a constant number of operations must be performed on edge-ordering trees. As discussed in Lemma 5.2 and Theorem 5.4, these operations will take $O((\log n)^2)$ time. The space follows from Theorem 5.4 and the observation that a constant number of nodes per level are changed in the edge-ordered topology tree for each update and that the edge-ordering trees at a node can be updated by introducing $O(\log n)$ new nodes. □

Note that for values of $k < n$, $n + k(\log k)^3$ would seem to be better than $n + k(\log n)^3$. However, $k(\log n)^3 < n$ for $k < n/(\log n)^3$, and for $n/(\log n)^3 \leq k \leq n$, $\log k$ is $\Theta(\log n)$.

9. Ambivalent data structures II: 2-edge-connectivity information. In this section, we adapt the data structure from section 3 to give a data structure for updating and querying 2-edge-connectivity information in the case of general graphs. We first give two simple characterizations of 2-edge-connectivity and 2-edge-connected components. We then discuss the set of "complete paths," which are a partition of a subset of the spanning tree, and "partial paths," from which the complete paths are formed. We show how to generate these paths for a cluster when the paths of the children are known. We motivate how complete paths are used in answering a query. We next define "pseudocovering edges," which allow us to define an ambivalent data structure. We discuss the additional information stored at a node in the 2-dimensional topology tree and show how to generate it given the information of the children. We then give a summary of the update structure, including the specification of information associated with a basic cluster. We then describe how to perform queries and updates. Finally, we establish the resource bounds of our approach.

Let G be an undirected graph. Graph G is 2-*edge-connected* if there is no edge whose removal disconnects G. An edge whose removal disconnects G is called a *bridge*. The 2-*edge-connected components* of G are the subgraphs that result when all bridges are removed. We first present two propositions that characterize 2-edge-connectivity and 2-edge-connected components. Let T be a spanning tree of graph G. For each edge e in T, let $cover(e) = 1$ if there is a nontree edge f such that e is on the path in T between the endpoints of f, and let $cover(e) = 0$ otherwise.

PROPOSITION 9.1. *Graph G is 2-edge-connected if and only if $cover(e) = 1$ for each edge e in T.*

PROPOSITION 9.2. *Vertices v' and v'' are in the same 2-edge-connected component if and only if there is no edge e on the path from v' to v'' in T with $cover(e) = 0$.*

We seek to build a data structure in which we can maintain *cover* values easily. We partition the edges of the tree into two sets and maintain the *cover* information about each set differently. We use the topology tree and 2-dimensional topology tree to organize this information. Let the *boundary tree* be the set of all tree edges that are on a path in the tree between any two boundary vertices. The first set of edges

consists of tree edges that are not in the boundary tree, and the second set consists of all edges that are in the boundary tree. It is relatively easy to maintain information about the first set, so we shall concentrate for the moment on the second set of tree edges.

We next define partial and complete paths. We define a partition of the edges in the boundary tree into paths, which we call *complete paths*. This partition is based on the multilevel partition. The complete paths are built up from what we call *partial paths* in a manner that we now describe. There will be a partial path associated with each cluster, and there will be a complete path associated with each cluster that is the union of two clusters of odd tree degree. For any multilevel partition with more than one level, we have the following. No basic vertex cluster will have a complete path associated with it. A basic vertex cluster of tree degree 1 will have a partial path containing the path of zero length beginning and ending at its single boundary vertex. A basic vertex cluster of tree degree 2 will have a partial path consisting of the path in the tree between its two boundary vertices. A basic vertex cluster of tree degree 3 will have the partial path consisting of no edges and the single vertex contained in the cluster.

Let PP_j and CP_j designate the partial path and complete path (if any) of vertex cluster V_j. If the node in the topology tree for vertex cluster V_j has a single child $V_{j'}$, then $PP_j = PP_{j'}$. When two vertex sets $V_{j'}$ and $V_{j''}$ are unioned to form V_j, the partial paths are handled as follows. If $V_{j'}$ is of tree degree 1 or 2 and $V_{j''}$ is of tree degree 2, then the resulting vertex cluster will have a partial path that is the concatenation of $PP_{j'}$ and $PP_{j''}$ and the tree edge between them. If $V_{j'}$ is of tree degree 1 and $V_{j''}$ is of tree degree 3, then the resulting vertex cluster will have the following two paths associated with it. First, it will have a complete path that is the concatenation of $PP_{j'}$ and the tree edge between the two clusters. Second, it will have a partial path consisting of the single vertex of $V_{j''}$. If $V_{j'}$ is of tree degree 1 and $V_{j''}$ is of tree degree 1, then the resulting vertex cluster will have a complete path that is the concatenation of $PP_{j'}$ and $PP_{j''}$ and the tree edge between them.

Three of the four cases discussed above are shown in Fig. 12. Each small circle represents a single vertex. The top part of Fig. 12 shows two vertex clusters of tree degree 2 being unioned together. Their partial paths are shown in bold, and the new partial path for the unioned cluster is the path containing the bold edges and the dashed edge. The middle part of Fig. 12 shows vertex clusters of tree degree 1 and 3 being unioned together. The partial path of the cluster of tree degree 1 is shown in bold, and the new complete path for the unioned cluster is the path containing the bold edges and the dashed edge. The bottom part of Fig. 12 shows two vertex clusters of tree degree 1 being unioned together. Their partial paths are shown in bold, and the new complete path for the unioned cluster is the path containing the bold edges and the dashed edge. Note that the clusters shown are not basic clusters, which is why the partial paths of clusters of tree degree 1 appear to start in the "middle" of those clusters.

Note that a vertex cluster will have a complete path if and only if it is the union of two clusters of odd tree degree. For any complete path generated when clusters of tree degree 1 and 3 are unioned together, let the single vertex in the cluster of tree degree 3 be called the *top* of the path. We say that complete path P' *dominates* complete path P if and only if the top of path P is contained in P'.

Consider the restricted multilevel partition shown in Fig. 3. The complete paths are shown in Fig. 13. The complete path between vertices 12 and 13 will be associated

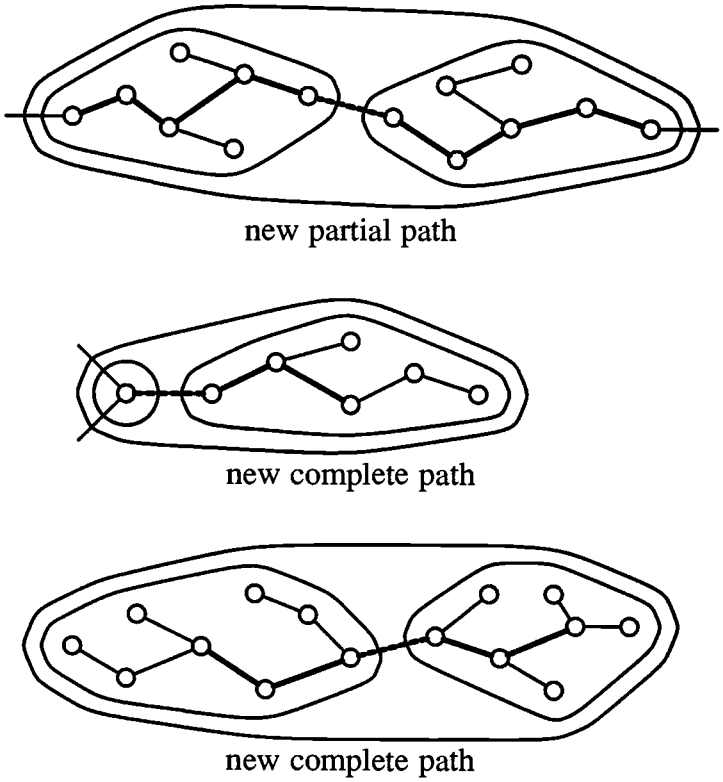

FIG. 12. *Combining partial paths.*

with V_{23} of Fig. 3, the complete path between 8 and 10 will be associated with V_{28}, the complete path between 4 and 7 will be associated with V_{32}, and the complete path between 1 and 14 will be associated with V_{37}. Each of the complete paths except the last has a top, and these are 12, 10, and 4, respectively. The complete path from 1 to 14 dominates each of the other paths. Examples of partial paths are the following. The partial path PP_{15} consists of the single vertex 11, PP_{16} is the path from 2 to 3, PP_{25} and PP_{31} are both the path from 1 to 3, PP_{32} consists of the single vertex 4, PP_{35} is the path from 1 to 4.

We describe how complete paths are used in answering a *same-2-edge-component* query. When a *same-2-edge-component* query on vertices v' and v'' is made, the path in the spanning tree T between v' and v'' is considered in the following way. Either the path contains no edges in the boundary tree, or it contains at least one edge in the boundary tree. In the former case, the path will be wholly contained in one basic cluster, and information associated with the basic cluster will be examined to see if there is a bridge between v' and v''. In the latter case, the path between v' and v'' will consist of three subpaths: the first and third subpaths will contain only edges not in the boundary tree, while second subpath will contain only edges in the boundary tree. First, information associated with the basic clusters containing v' and v'' will be examined to see if there is a bridge on the first or third subpath. If no bridge is found on these subpaths, then information associated with the complete paths containing edges on the path from v' to v'' will be examined.

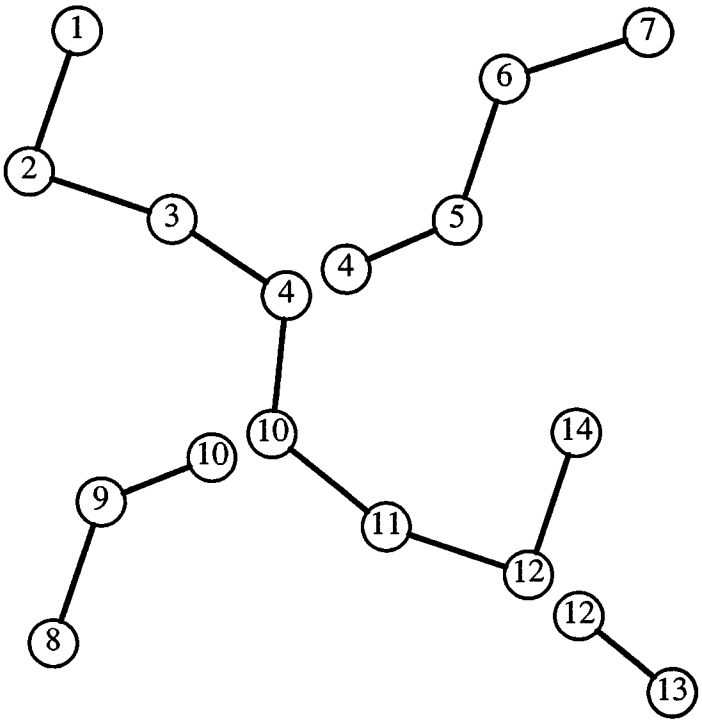

FIG. 13. *Complete paths for the restricted multilevel partition in Fig.* 3.

We maintain ambivalent information for V_j as follows. For boundary vertex w of V_j and cluster V_r at the same level, a nontree edge f with one endpoint in each of V_j and V_r is a *pseudocovering edge* for tree edge e if e is in PP_j and e is on the path in T from w to the endpoint of f in V_j. Pseudocovering edge f actually covers e if w is on the path in T between the endpoints of f. For each boundary vertex w of V_j and cluster V_r at the same level, we shall maintain a best pseudocovering edge in the following sense. A *best pseudocovering edge* for V_j, V_r, and w is a pseudocovering edge with respect to V_j, V_r, and w for the most tree edges in PP_j. This set of tree edges constitutes a subpath of PP_j with one endpoint at w.

Consider the graph in Fig. 1, with a restricted multilevel partition in Fig. 3. For cluster V_{18} and boundary vertex 6, edge 17 is a pseudocovering edge and also a best pseudocovering edge (since it is the only one). However, edge 17 does not actually cover any edges in V_{18}. For cluster V_{27} and boundary vertex 5, edge 17 is a pseudocovering edge. However, edge 17 is not a best pseudocovering edge for V_{27} and boundary vertex 5 since it covers zero edges in the partial path of V_{27} up to vertex 5, while edge 14 is a pseudocovering edge for V_{27} and vertex 5 that covers two edges in the partial path of V_{27} up to vertex 5.

We next discuss carefully the additional information that will be maintained in the nodes of the 2-dimensional topology tree. This includes pointers to partial and complete paths associated with the node, the number of edges in the partial paths, the number of edges from the top of a complete path to the first bridge (if any) in that path, and the best pseudocovering edges.

We first discuss the length of various paths. Note that by *distance* we mean the

number of edges in a path in the spanning tree. For the remainder of this section, we shall use the term distance in this way. Let V_j be a vertex cluster of tree degree 1 or 2. Let $length(j)$ be the length of the partial path in V_j. We store $length(j)$ at the node $V_j \times V_j$ in the 2-dimensional topology tree. If V_j is a basic vertex cluster, then any value $length(j)$ can be determined by inspection of V_j. If V_j is not a basic vertex cluster, then any value $length(j)$ can be computed in constant time given the lengths of the partial paths of the children in the topology tree.

We next discuss the pseudocovering edges. Let V_j and V_r be two distinct clusters at the same level, with V_j of tree degree 1 or 2. Let w be a boundary vertex of V_j, and let PP_j be a partial path that contains w as an endpoint. For any vertex u in V_j, recall from the previous section the definition of $proj(j, u)$, which is the vertex on PP_j that is nearest to u in the tree. (Here we use a slight extension of the definition from the last section, in that now we allow V_j to be also of tree degree 1.) For each boundary vertex w of V_j, let $maxcover(j, r, w)$ be the maximum of the distances from w to $proj(j, u)$ taken over the set of nontree edges (u, v) with u in V_j and v in V_r. (If there is no edge with one endpoint in each of V_j and V_r, let $maxcover(j, r, w)$ be $-\infty$.) A *best pseudocovering edge* is a pseudocovering edge that realizes a particular $maxcover(j, r, w)$ value. The values $maxcover(j, r, w)$ for any particular value of j and r are stored in node $V_j \times V_r$ of the 2-dimensional topology tree.

If V_j and V_r are basic vertex clusters, then $maxcover(j, r, w)$ can be computed for any particular j, all boundary vertices w of V_j, and all r by inspection of V_j. Then $maxcover(j, r, w)$ is the maximum distance $d(w, proj(j, u))$ taken over all edges (u, v) with u in V_j and v in V_r. If V_j and V_r are not basic vertex clusters, then $maxcover(j, r, w)$ can be computed in constant time given the *length* values for all children of V_j in the topology tree and the *maxcover* values for all children of $V_j \times V_r$ in the 2-dimensional topology tree. We specify this computation in detail. If the node for V_j in the topology tree has a single child $V_{j'}$, then $maxcover(j, r, w)$ is the maximum of $maxcover(j', r', w)$ taken over the one or two clusters $V_{r'}$ that form V_r. Otherwise, V_j is formed from two clusters $V_{j'}$ and $V_{j''}$, and we assume without loss of generality that w is in $V_{j'}$. If $V_{j''}$ is of tree degree 3, then the partial path of V_j is trivial and thus for the single vertex w in $V_{j''}$, $maxcover(j, r, w)$ is 0 if there is some nontree edge with one endpoint in each of V_j and V_r and is $-\infty$ otherwise. Such a nontree edge exists if $maxcover(j', r', w') > -\infty$ for $V_{r'}$ a child of V_r and w' the single boundary vertex of $V_{j'}$. Suppose that neither $V_{j'}$ nor $V_{j''}$ are of tree degree 3. Let w' be the boundary vertex of $V_{j'}$ adjacent to $V_{j''}$, and let w'' be the boundary vertex of $V_{j''}$ adjacent to $V_{j'}$. Then $maxcover(j, r, w)$ is the maximum taken over the one or two clusters $V_{r'}$ that form V_r of $maxcover(j', r', w)$ and $maxcover(j'', r', w'') + 1 + length(j')$. Note that it is easy to keep track of an edge that yields each particular $maxcover(j, r, w)$ value. (This is needed when we consider deleting a tree edge.)

We next discuss partial and complete paths. Let V_j be a vertex cluster. We maintain partial and complete paths in the following form. Each such path is represented by a balanced tree in which the leaves from left to right represent consecutive edges on the path. Associated with each node in the tree is a value *somecov* such that $cover(e) = 1$ for edge e on the path between boundary vertices if and only if $somecov(x) = 1$ for some node x on the path from the root to the leaf representing edge e. In addition, there is a value *allcov* such that $allcov(x)$ is 1 if and only if $somecov(x) = 1$ or $allcov(y) = 1$ for each child y of x. We assume that partial path PP_j and complete path CP_j (if it exists) are specified as a pointer to a structure of the above type.

We describe how to set up partial paths. If V_j is a basic vertex cluster, then the partial path can be set up by inspection of V_j. If V_j is not a basic vertex cluster and has just one child in the topology tree, then its partial path is the same as its child. If V_j is the union of two clusters $V_{j'}$ and $V_{j''}$ and is also not the set of all vertices, then its partial path is formed by concatenating the relevant partial paths of children, as discussed previously. The tree edge between $V_{j'}$ and $V_{j''}$ is initially assumed to have a *cover* value of 0. Certain *somecov* values are adjusted to reflect the effect of the best pseudocovering edges between $V_{j'}$ and $V_{j''}$. For example, suppose V_j, $V_{j'}$, and $V_{j''}$ are all of tree degree 2. Let w' be the boundary vertex of $V_{j'}$ adjacent to a vertex in $V_{j''}$, let w'' the boundary vertex of $V_{j''}$ adjacent to w', and suppose $maxcover(j', j'', w') \neq -\infty$. Then we modify the *somecov* values to reflect the fact that a subpath of length $maxcover(j', j'', w') + 1$, starting in $V_{j'}$ and ending at w'', is covered. This can be done by searching in the tree structure for the partial path to find the extreme edges in the subpath. A set of $O(\log n)$ nodes in the tree cover all and only the edges in the subpath, and the *somecov* values of these nodes should be set to 1. The *allcov* values of these nodes and their ancestors should also be adjusted. A similar operation would be performed with respect to $maxcover(j'', j', w'')$. Other cases, in which V_j is of tree degree less than 2 (meaning that the sum of the tree degrees of $V_{j'}$ and $V_{j''}$ is less than 4), are handled similarly.

We next discuss complete paths. Let V_j be a vertex cluster. Suppose V_j is a cluster that is the union of a cluster $V_{j'}$ of tree degree 1 and a cluster $V_{j''}$ of tree degree 3. Then the single vertex of $V_{j''}$ is the top of the complete path at V_j. Complete path CP_j is the result of concatenating the edge between $V_{j'}$ and $V_{j''}$ onto $PP_{j'}$. In addition, the *somecov* and *allcov* values must be modified to show the effect of nontree edges with precisely one endpoint in $V_{j'}$. Let $mcov(j)$ be one plus the maximum of the values $maxcover(j', r, w)$, where $r \neq j'$ and w is the single boundary vertex in $V_{j'}$. Then modify the *somecov* values to reflect the fact that the first $mcov(j)$ edges of CP_j from the top are covered. Let $toptobr(j)$ be the distance from the top of the complete path to the first bridge (if any) in the complete path. This can be found by searching in the tree structure for the complete path. There will be a bridge in the complete path if and only if the *allcov* value of the root of the tree structure is 0. Search down from the root, always taking the child representing a subpath closer to the top of the complete path when there are two children and both have *allcov* value equal to 0. Note that if both $V_{j'}$ and $V_{j''}$ are of tree degree 1, then V_j is the set of all vertices, and there is no top of the complete path.

The operations performed on partial and complete paths are concatenation and the update of *allcov* and *somecov* values. To make these operations efficient, we share common subtrees in the tree representations of partial and complete paths. When two paths are concatenated together, no nodes in the existing structures are changed or deleted. Rather, new nodes are allocated to handle structural changes. When an *allcov* or *somecov* value is changed, new copies are made of any node that has a value change or has a descendant that has a value that changes. To prevent the space from increasing without bound, a reference-count system should be used. The appropriate pointers PP_j and/or CP_j are maintained in node $V_j \times V_j$ of the 2-dimensional topology tree. Whenever a node V_j is identified as changing during an update, the appropriate pointers PP_j and/or CP_j are set to null, and then any nodes whose reference counts go to zero are deleted.

An update data structure Q will consist of a topology tree for a spanning tree T, a 2-dimensional topology tree, and representations of basic vertex clusters. Each node

in the topology tree will have the index of the corresponding cluster and a pointer to the node's parent. Each node in the 2-dimensional topology tree will have the indices of the corresponding clusters, along with the following. If the node is of type $V_j \times V_j$, it will have *length*, *PP*, *CP*, and *toptobr* values. If the node is of type $V_j \times V_r$, it will have *maxcover* values. The representation of a basic vertex cluster V_j will consist of a list of vertices, a list of edges with both endpoints in the cluster (both tree and nontree edges), and, for every other cluster V_r, a list of nontree edges with one endpoint in each of V_j and V_r and the associated $maxcover(j, r, w)$ values. In addition, we keep information that will help to determine if there is a bridge between two vertices in V_j, as discussed below.

We can find the *cover* values for edges not in the boundary tree as follows. Generate a *reduced cluster* for the basic cluster V_j as follows. The vertex set will be the same in the reduced cluster as in the basic cluster. Any edge (tree or nontree) with both endpoints in the basic cluster will be in the reduced cluster. For any nontree edge (u, v) with u in the basic cluster, v not in it, and $proj(j, u) \neq u$, edge $(u, proj(j, u))$ will be in the reduced cluster. We then find the biconnected components of the reduced cluster. Any tree edge that is in a biconnected component consisting of more than one edge will have nonzero *cover* value. To represent this information, we maintain the following. For each vertex u, keep the distance $d(u, proj(j, u))$, and also keep the distance $disttobr(u)$ to the bridge nearest to u on the path from u to $proj(j, u)$. (Let $disttobr(u)$ be ∞ if there is no bridge between u and $proj(j, u)$.) For each y on a partial path in a basic cluster, keep the distance to both endpoints of the partial path, and keep a data structure to find the lowest common ancestor [HT], [SV] with respect to the tree rooted at y and induced on all vertices u such that $proj(j, u) = y$.

We are now ready to discuss how a *same-2-edge-component*(v', v'') query is handled. Let v' and v'' be in basic clusters $V_{j'}$ and $V_{j''}$, respectively. If $j' = j''$ and $proj(j', v') = proj(j', v'')$, we do the following. Let $y = proj(j', v') = proj(j', v'')$. Find the lowest common ancestor z of v' and v'' in the tree rooted at y. It follows that v' and v'' are in the same bridge-component if and only if $disttobr(v') \geq d(v', y) - d(z, y)$ and $disttobr(v'') \geq d(v'', y) - d(z, y)$.

Suppose $j' \neq j''$ or $proj(j', v') \neq proj(j'', v'')$. If $disttobr(v') < d(v', proj(j', v'))$ or $disttobr(v'') < d(v'', proj(j'', v''))$, then v' and v'' are not in the same bridge-component. Otherwise, we examine the set of complete paths containing edges in the path from $proj(j', v')$ to $proj(j'', v'')$. We examine these paths as we search up through the topology tree. At the top of each complete path in the sequence except the highest one, we shall use the *toptobr* value to test if a bridge comes in the relevant portion of the complete path. At the highest complete path, we examine the appropriate *allcov* values to see if a bridge appears in the relevant portion.

We present the identification and the search of the complete paths in our algorithm *search_cps*. As input to our algorithm are the vertices v' and v'' and pointers to the nodes representing $V_{j'} \times V_{j'}$ and $V_{j''} \times V_{j''}$ in the 2-dimensional topology tree, where $V_{j'}$ and $V_{j''}$ are the basic clusters containing v' and v'', respectively. The algorithm sets variable *isbridge* to **true** if there is a bridge between $proj(j', v')$ and $proj(j'', v'')$. The algorithm maintains two variables $vert'$ and $vert''$, representing vertices on the path from $proj(j', v')$ to $proj(j'', v'')$, to indicate that it has checked for bridges between $proj(j', v')$ and $vert'$ and between $vert'$ and $proj(j', v')$. For the partial path of a cluster containing v' that it is examining, it maintains the distances $dist1'$ and $dist2'$ from $vert'$ to the endpoints of the partial path, and similarly for v'' and $vert''$. It uses these distances when checking a complete path for a bridge in the

relevant portion of the complete path, then resets $vert'$ and $vert''$ to reflect the additional portions of the path from $proj(j', v')$ to $proj(j'', v'')$ that have been checked. Note that it is not necessary to maintain both $dist1'$ and $dist2'$ if a preliminary search is used to determine which direction to search in on a cluster of tree degree 2. We have chosen not to employ such a preliminary search.

```
proc search_cps(v', v'', j', j'')
    isbridge ← false
    /* Initialize vert', w1', w2', dist1', dist2', and r' as follows: */
    vert' ← proj(j', v')
    w1' ← one endpoint of PP_j'
    w2' ← other endpoint of PP_j'
    dist1' ← distance from vert' to w1'
    dist2' ← distance from vert' to w2'
    r' ← j'
    /* Initialize vert'', w1'', w2'', dist1'', dist2'', and r'' similarly. */
    while V_r' has tree degree greater than 0 and vert' ≠ vert'' do
        /* Handle V_r' as follows: */
        if V_r' is of tree degree at most 2 and has a sibling
        then
            V_s' ← sibling of V_r'
            Let ws1' and ws2' be the endpoints of the PP_s'
            Without loss of generality, assume w2' is adjacent to ws1'.
            dist2' ← dist2' + 1 + length(s')
            w2' ← ws2'
            if V_s' is of tree degree 3
            then
                if the toptobr value at the parent of V_r' is less than dist2'
                then isbridge ← true
                endif
            endif
        endif
        V_r' ← parent of V_r'
        /* Handle V_r'' similarly. */
    endwhile
    if vert' ≠ vert''
    then
        Check the portion of CP(r') between vert' and vert''.
        if an allcov value along this portion of CP(r') equals 0
        then isbridge ← true
        endif
    endif
```

This concludes the discussion of how to handle a *same-2-edge-component* query. Let the above algorithm be called *2ec_query*.

LEMMA 9.3. *Algorithm 2ec_query identifies a bridge between two given vertices in* $O(\log n)$ *time.*

Proof. We first consider correctness. If $j' = j''$ and $proj(j', v') = proj(j', v'')$, then no edge of the boundary tree is in the path in T from v' to v''. The path from

v' to v'' will go from v' to z to v'', where z is the lowest common ancestor of v' and v'' in the tree rooted at $proj(j', v')$. Checking for a bridge in the two portions of this path yields the correct result.

If $j' \neq j''$ or $proj(j', v') \neq proj(j', v'')$, then the path from v' to v'' in T consists of a subpath from v' to $proj(j', v')$ that is not in the boundary tree, followed by a subpath from $proj(j', v')$ to $proj(j'', v'')$ in the boundary tree, followed by a subpath from $proj(j'', v'')$ to v'' that is not in the boundary tree. A bridge in the first or third subpath is identified by checking $disttobr(v')$ and $disttobr(v'')$. The second subpath is checked correctly by *search_cps*, as we now argue. Algorithm *search_cps* simultaneously searches up through the 2-dimensional topology tree from $V_{j'}$ and $V_{j''}$. For each pair of ancestors $V_{r'}$ and $V_{r''}$ of $V_{j'}$ and $V_{j''}$, respectively, the algorithm maintains the distance of $vert'$ and $vert''$ to the endpoints of the partial paths. In particular (referring to $V_{r'}$, with a similar argument for $V_{r''}$), if $V_{r'}$ has no sibling, then the same information will be maintained at its parent. If $V_{r'}$ is of tree degree 3, then it consists of a single vertex, which is necessarily $vert'$, so that the distances to the endpoints of the partial path of the parent, even when $V_{r'}$ is unioned with a sibling (of tree degree 1), will both remain 0. If $V_{r'}$ is of tree degree at most 2 and has a sibling, then one of the two distances to endpoints of the partial path must be updated. If the sibling is of tree degree 3, then the parent will contain a complete path, in which case the portion of the complete path from $vert'$ to the vertex of $V_{s'}$ must be checked and $vert'$, $dist1$, and $dist2'$ must be reset. When the tree degree of $V_{r'}$ is 0, then the complete path of $V_{r'}$ should be checked between $vert'$ and $vert''$ in the case that $vert' \neq vert''$.

We next consider the time. If v' and v'' are presented in terms of pointers, then clusters $V_{j'}$ and $V_{j''}$ can be identified in constant time; otherwise, $O(\log n)$ time can be used to search a dictionary. The values $proj(j', v')$ and $proj(j', v'')$ can be looked up in constant time. If $j' = j''$ and $proj(j', v') = proj(j', v'')$, then the lowest common ancestor z of v' and v'' can be found in constant time, and the values *disttobr* can be accessed in constant time as well. If $j' \neq j''$ or $proj(j', v') \neq proj(j', v'')$, then checking the first and third subpaths takes constant time to access and compare *disttobr* values. The second subpath can be checked in $O(\log n)$ time, as we now argue. Each iteration of the while loop of *search_cps* takes constant time. Searching the complete path for the cluster of tree degree 0 will take $O(\log n)$ time since there are $O(\log n)$ nodes in the complete path that cover exactly the portion of the path between $vert'$ and $vert''$, and it takes constant time to check the *allcov* value of each node. □

We consider our graph in Fig. 1, using the restricted multilevel partition of Fig. 3, with its associated complete paths, as shown in Fig. 13. There is only one bridge in the graph, edge $(3, 4)$. The value *toptobr* value is 0 for each of the complete paths from 4 to 7, 8 to 10, and 12 to 14. Recall that each basic vertex cluster is a single vertex. The query *same-2-edge-component*$(6, 8)$ will determine that there are no bridges from 8 to 10 on that complete path, that there are no bridges from 6 to 4 on the corresponding complete path, and that there are no bridges from 4 to 10 on the topmost complete path. Thus 6 and 8 are in the same 2-edge-connected component. The query *same-2-edge-component*$(2, 7)$ would examine the complete path from 7 to 4 and then the portion of the topmost complete path from 4 to 2, identifying a bridge, namely edge $(3, 4)$.

We next discuss how to insert or delete an edge. The approach builds on the way an edge was inserted or deleted in section 3. If a tree edge is to be deleted, then we

first attempt to swap a nontree edge in to replace it. If there is no edge with which it can swap, then deleting the edge splits the spanning tree and thus also the topology-tree-based data structures. On each of the swap, insert, or delete operations specified by the appropriate *inflate* or *deflate*, the following is done. First, all necessary changes are made to the basic clusters, and all information local to the changed or new basic clusters is computed. For a basic cluster, this information includes a description of each new cluster V_j, consisting of a list of vertices, a list of edges with both endpoints in V_j, and, for every other cluster V_r, a list of nontree edges with one endpoint in each of V_j and V_r, as well as the partial path PP_j, the values $proj(j,u)$, $length(j)$, $maxcover(j,r,w)$, and $disttobr(u)$, and the lowest common ancestor structures for each subtree of T rooted at a vertex on PP_j. For any basic cluster V_r, regroup edges with one endpoint in V_r and the other in a basic cluster V_j that has changed or is new, and recompute $maxcover(r,j,w)$ values.

After rebuilding certain basic clusters, rebuild portions of the 2-dimensional topology tree bottom-up. At nodes that are examined, recompute the information in the *maxcover*, *PP*, *CP*, *length*, and *toptobr* fields. Recall that rules were given earlier on how to generate a partial path from the partial paths of the children, including the *maxcover* values with an endpoint in each of two children. Also discussed is how to generate the complete path, computing and using the *mcov* value.

We discuss a little more how partial and complete paths are handled, since subtrees in the tree structures representing these paths are shared, and there are thus no parent pointers. Each vertex in a partial path will be identified by its distance from the end of the path. Each internal node of the balanced tree representing the path will contain a count of the number of edges in the subpath represented by that node. Thus a vertex in a path can be located in the tree using this positional information.

THEOREM 9.4. *Let G be a graph with n vertices and m edges at the current time. The update data structure Q can be set up in $O(m)$ time and space. Structure Q can be updated in $O(m^{1/2})$ time, while still using $O(m)$ space, and accommodates same-2-edge-component queries in $O(\log n)$ time.*

Proof. Given a spanning tree T for G, basic vertex clusters can be found in $O(m)$ using procedure *cluster* in section 2. Similar to that in [F1], a restricted multilevel partition, a topology tree, and a 2-dimensional topology tree can be found in $O(m)$ time. Since there are $O(m^{1/2})$ basic clusters, it follows from Lemma 2.2 that the number of nodes in the topology tree is $O(m^{1/2})$. Creating a partial path by concatenating the partial paths of the children will cost $O(\log n)$ for each node in the topology tree, or $O(m^{1/2}\log n)$ overall. Generating all other values can be done in time proportional to the number of them.

An edge insertion or edge deletion is handled by *inflate* or *deflate*, respectively. Since all data regarding clusters that change is recomputed, the updating is performed correctly. We next discuss the resources needed to update Q. The size of a description of a basic vertex cluster is $O(m^{1/2})$, and at most a constant number of basic vertex clusters are changed by any update operation. The time to generate the new information associated with a new basic cluster is $O(m^{1/2})$ if we are given the description of the basic cluster(s) from which it is formed. The number of nodes examined and created in generating the new 2-dimensional topology tree is $O(m^{1/2})$ by an argument similar to one in [F1]. The time to compute each value except $mcov(j)$ in a newly created node of the 2-dimensional topology tree is constant if these values are computed bottom-up. For $mcov(j)$ values, these can be found by scanning $maxcover(j',r,w)$ values. Each such *maxcover* value is from a node $V_{j'} \times V_r$ that is

examined as the 2-dimensional topology tree is rebuilt, so that each of $O(m^{1/2})$ nodes in the 2-dimensional topology tree can be charged a constant. There are $O(\log n)$ nodes of the form $V_j \times V_j$ that change, so that $O(\log n)$ complete or partial paths must be recomputed, at $O(\log n)$ time each. For the nearest bridge values, $O(\log n)$ complete or partial paths can have their nearest bridges change. The new values can be found in $O(\log n)$ time each. Thus the total time to update Q is $O(m^{1/2})$. By using a reference-count scheme, the form in the updated structure will be the same as if the structure were recomputed from scratch. Thus the space usage will remain $O(m)$.

The correctness and time for queries are established by Lemma 9.3. □

TIME-ADAPTIVE ALGORITHMS FOR SYNCHRONIZATION*

RAJEEV ALUR†, HAGIT ATTIYA‡, AND GADI TAUBENFELD§

Abstract. We consider concurrent systems in which there is an unknown upper bound on memory access time. Such a model is inherently different from the asynchronous model, where no such bound exists, and also from timing-based models, where such a bound exists and is known a priori. The appeal of our model lies in the fact that while it abstracts from implementation details, it is a better approximation of real concurrent systems than the asynchronous model. Furthermore, it is stronger than the asynchronous model, enabling us to design algorithms for problems that are unsolvable in the asynchronous model.

Two basic synchronization problems, consensus and mutual exclusion, are investigated in a shared-memory environment that supports atomic read/write registers. We show that $\Theta(\Delta \frac{\log \Delta}{\log \log \Delta})$ is an upper and lower bound on the time complexity of consensus, where Δ is the (unknown) upper bound on memory access time. For the mutual exclusion problem, we design an efficient algorithm that takes advantage of the fact that some upper bound on memory access time exists. The solutions for both problems are even more efficient in the absence of contention, in which case their time complexity is a constant.

Key words. distributed computing, consensus, mutual exclusion, timing-based algorithms

1. Introduction.

The possibility and complexity of synchronization in a distributed environment depends heavily on timing assumptions. In the asynchronous model, no timing assumptions are made about the relative speeds of the processes, while a timing-based model assumes known bounds on the speeds of the processes. Although the asynchronous model is weaker than the timing-based model, it provides a useful abstraction of the timing constraints, and algorithms designed for the asynchronous model work correctly in all possible environments. However, sometimes the assumption of asynchrony is too weak, and many problems have been shown to be unsolvable in the asynchronous model. These impossibility results never seem to bother practitioners, which brings up the question of whether such a model is the correct abstraction for modeling real systems.

We focus on an intermediate model which provides an alternative abstraction of the timing details of concurrent systems. We assume that there is an unknown upper bound on memory access time. This assumption is inherently different from the asynchronous model, where no such bound exists, and from timing-based systems, where such a bound exists and is known a priori. The appeal of the model lies in the fact that while it abstracts from implementation details, it is a better approximation of the real concurrent systems than the asynchronous model. Furthermore, it is stronger than the asynchronous model, enabling us to design algorithms for problems that are

unsolvable in the asynchronous model. The importance of a timing-based model with unknown bounds is also supported by an earlier work of Dwork et al. in the context of message-passing systems [DLS88] (see also [ADLS91]).

We use a shared-memory model where processes communicate with each other by reading and writing to shared registers. We assume that there is an upper bound, denoted by Δ, on the time required for a single access to shared memory. There is no lower bound on time needed to execute a step, but a process can delay itself explicitly by executing a statement $delay(d)$, for some constant d. The resulting model is called the *known-delay* model or the *unknown-delay* model depending on whether or not the bound Δ is known a priori. An algorithm in the unknown-delay model is required to be correct for all possible choices of Δ and hence cannot refer to Δ directly. We show that the unknown-delay model is inherently different from both the known-delay model and the asynchronous model by investigating two basic synchronization problems, consensus and mutual exclusion.

In the *consensus* problem, processes need to agree on a common output in the presence of possible failures [PSL80]. It has been proven that when even one process can fail, the consensus problem is not solvable in asynchronous systems [DDS87, FLP85, LA87]. In the known-delay model, there is an algorithm which tolerates any number of failures and terminates within time $O(\Delta)$ [AT96].

Our first result is a consensus algorithm that works in the unknown-delay model. The algorithm guarantees that in every possible execution, processes never decide on conflicting values and the decision value is an input value of some process. If every step finishes within time Δ, then a process decides within time $O(\Delta \cdot fac^{-1}(\Delta))$ irrespective of the failures of other processes, where fac^{-1} is the inverse of the factorial function;[1] note that $fac^{-1}(d) = \Theta(\frac{\log d}{\log \log d})$. Furthermore, the algorithm is *fast*: in absence of contention, a process decides after a constant number of its own steps.

Our second result shows that the worst-case time complexity of any two-process algorithm for consensus in the unknown-delay model is $\Omega(\Delta \cdot fac^{-1}(\Delta))$; this implies that our algorithm is time-optimal. The lower bound implies that not knowing Δ multiplies the time complexity by a factor of $fac^{-1}(\Delta)$.

The *mutual exclusion* problem is to design a protocol that guarantees mutually exclusive access to a critical section among a number of competing processes [Dij65]. A mutual exclusion algorithm satisfies the *fast access property* if in the absence of contention, a process needs to execute only a constant number of steps in order to enter or exit its critical section. In [Lam87], Lamport presented a fast mutual exclusion algorithm that satisfies the fast-access property. In the presence of contention, however small, the winning process in Lamport's algorithm may have to check the status of all of the other n processes before it is allowed to enter its critical section. In the known-delay model, there is an algorithm that satisfies the fast-access property without requiring the winning process to check the status of all of the other n processes in the presence of contention [AT96]. Other algorithms which satisfy the fast access property can be found in [CS93, MS93, Sty92, YA93].

Our third result is a mutual exclusion algorithm for the unknown-delay model where in the presence of contention, a process needs to delay itself for $2 \cdot \Delta$ time units before entering its critical section. The algorithm has a "warm-up" period during which the processes might have to access n registers before entering the critical section. The algorithm always provides fast access in the absence of contention.

[1] For a real number $d > 0$, $fac^{-1}(d)$ is the smallest natural number r such that $r! \geq d$.

For both problems, the knowledge of Δ is beneficial: in the case of consensus, the problem becomes solvable, and in the case of mutual exclusion, more efficient solutions can be obtained. Our results imply that these benefits can be achieved even when Δ is unknown.

Dwork et al. have studied the consensus problem in message-passing systems where there are unknown bounds on the time to deliver a message and on processes' speed [DLS88]. Their work concentrates on the percentage of faulty processes (compared to the total number of processes) that can be tolerated. Our consensus algorithm is wait-free, that is, it can tolerate any number of crash failures.

Herzberg and Kutten [HK89] have studied a message-passing model where an a priori upper bound on message delivery time is known but is much larger than the actual message delay; this encourages the use of the (unknown) message delivery time in the algorithm. They considered the problem of detecting faulty processes.

In section 2, a formal model is introduced and the issue of how to measure the time complexity is discussed. Section 3 is dedicated to the consensus problem; matching upper and lower bounds are presented for the worst-case time of a consensus algorithm. The fast algorithm for mutual exclusion appears in section 4. We conclude with a discussion of our results and directions for future work.

2. A timing-based model. In this section, we outline our model of distributed systems. Processes are modeled as (possibly infinite) state machines communicating via shared memory consisting of registers that support atomic reads and writes.

A *configuration* of the system includes the state of each process and the values of all shared registers. An *event* is a single step of some process and is either a read of a shared register, or a write to a shared register, or simply an update of the internal state of a process. Processes can also execute a delay statement $delay(d)$, for a positive integer d, and its effect on a configuration is the same as a skip statement.

As in the standard interleaving semantics, an *execution* α of the system is an alternating sequence $s_0 \stackrel{e_0}{\rightarrow} s_1 \stackrel{e_1}{\rightarrow} \cdots$ of configurations s_i and events e_i such that (1) the initial configuration s_0 satisfies some initial conditions and (2) every configuration s_{i+1} is derived from the previous configuration s_i by executing the event e_i.

We allow only crash failures: a failed process simply ceases to participate. Formally, a process p is *nonfaulty* in an execution α if and only if either α is finite or p takes infinitely many steps in α.

The notion of an execution captures only the asynchronous part of the system and not its timing requirements. Define the *explicit delay* of an event e, denoted by $d(e)$, to be n if e is the delay statement $delay(n)$ and 0 otherwise. A *time assignment* τ for an execution α is a mapping that assigns a real-valued occurrence time τ_i to each event e_i in α such that

1. the occurrence times are nondecreasing,
2. if α is infinite, then the sequence of occurrence times is unbounded,[2] and
3. whenever two events e_i and e_j are consecutive steps of the same process, then difference $\tau_j - \tau_i$ is greater than $d(e_i)$.

The last requirement captures the assumption regarding the lower bounds on execution speeds. A delay statement $delay(d)$ by a process p delays p for at least d time units before it can continue. For other statements, we simply require that a step of a process takes nonzero time.[3] Note that adjacent events belonging to different processes can be assigned the same time. As an example, consider the following

[2] Our results do not depend on this second requirement.

[3] Our definition allows delays of read or write steps to be as small as we want. In a context

execution, where each event is labeled with the process it belongs to:

$$\alpha_{\text{sample}}: \; s_0 \overset{p:read(x)}{\longrightarrow} s_1 \overset{q:write(y)}{\longrightarrow} s_2 \overset{p:delay(4)}{\longrightarrow} s_3 \overset{p:read(y)}{\longrightarrow} s_4 \overset{q:read(x)}{\longrightarrow} s_5.$$

A time assignment τ for the above execution α_{sample} is a sequence $\tau_0 \leq \tau_1 \leq \cdots \leq \tau_4$ such that

$$\tau_2 - \tau_0 > 0, \qquad \tau_3 - \tau_2 > 4, \qquad \tau_4 - \tau_1 > 0.$$

Thus a possible time assignment is

$$\tau_{\text{sample}}: \; \tau_0 = 0, \quad \tau_1 = 0, \quad \tau_2 = 0.1, \quad \tau_3 = 4.5, \quad \tau_4 = 5.$$

The definition of the explicit delay of an event is also extended to finite executions: for a finite execution $\alpha = s_0 \overset{e_0}{\rightarrow} \cdots s_n$, let $d(\alpha)$ denote the sum $\sum_{0 \leq i < n} d(e_i)$ of explicit delays of all the events in α. For instance, $d(\alpha_{\text{sample}})$ equals 4.

The assumption about the time needed to access shared memory is reflected in the following notion of admissibility. Let Δ be a positive real number.

> A timing assignment τ for an execution α is said to be Δ-*admissible* if and only if whenever two events e_i and e_j are consecutive steps of the same process, $\tau_j - \tau_i \leq \Delta + d(e_i)$.

Thus if the ith step in an execution is a read or a write by process p, then the next step by process p must be within time Δ; if it is the delay statement $delay(d)$, then p's next step must be within time $\Delta + d$. If a process does not take the next step within this bounded time period, then it can never take a step, implying a crash failure.

Every execution has several time assignments but may not have a Δ-admissible time assignment for a given Δ; this is because delay statements restrict the possible time assignments. An execution α is Δ-*admissible* if there exists a Δ-admissible time assignment for α. For our sample execution α_{sample}, the timing assignment τ_{sample} is 5-admissible (in fact, it is Δ-admissible if and only if $\Delta \geq 5$). The execution α_{sample} itself is Δ-admissible for every $\Delta > 4$.

A problem such as consensus or mutual exclusion is usually specified by listing the properties to be satisfied by all the executions. An algorithm A satisfies a property ϕ in the asynchronous model if and only if all of its executions satisfy ϕ. While solving a problem in the timing-based model with an upper bound of Δ on the step time, a key issue is whether the processes know the upper bound Δ.

In the *known-delay* model, we assume that individual processes know the upper bound Δ. Consequently, delay statements can refer directly to this value, and a process can enforce every other (nonfaulty) process to take at least one step by executing the statement $delay(\Delta)$. To solve a problem in this model, we want a family of algorithms $A(\Delta)$, parameterized by the upper bound Δ, such that for each Δ, all Δ-admissible executions of $A(\Delta)$ satisfy all the requirements of the problem.

In the *unknown-delay* model, we assume that some upper bound exists, but it is not known to individual processes a priori. In this model, we want a single algorithm A that works for all possible values of Δ without referring to its actual value. We will say that an algorithm A satisfies a property ϕ in the unknown-delay model if for every Δ, all Δ-admissible executions of A satisfy ϕ.

Before we consider specific problems, let us observe one property of algorithms in the unknown-delay model. A property ϕ is a *safety* property if the following holds:

---

where a nonnegligible lower bound, say ϵ, on these steps is more appropriate, we can simply insert the statement $delay(\epsilon)$ after every step.

An infinite execution α satisfies ϕ if and only if all finite prefixes of α satisfy ϕ; that is, a safety property has to be *prefix-closed*. The unknown-delay model is the same as the asynchronous model as far as safety properties are concerned.

LEMMA 2.1. *An algorithm A satisfies a safety property ϕ in the asynchronous model if and only if it satisfies ϕ in the unknown-delay model.*

Proof. Clearly, if A satisfies a property ϕ in the asynchronous model, then it satisfies ϕ in the unknown-delay model. Suppose A does not satisfy ϕ in the asynchronous model. Then there is an execution α of A which violates ϕ. If ϕ is a safety property, then there is a finite prefix α' of α such that α' violates ϕ. The finite execution α' is Δ-admissible for every $\Delta \geq d(\alpha')$. This implies the lemma. ∎

Lemma 2.1 does not hold for liveness properties such as termination.

We now define our time complexity measures. Given an execution α and a time assignment τ for it, suppose $time(\alpha, \tau)$ is a measure of time taken according to τ. The exact definition of *time* depends on the problem and on whether we are computing the worst-case complexity or the contention-free complexity. For instance, in consensus, *time* may denote the maximum time spent by a process between its first step and its decision step in α. We denote by $time_\Delta(\alpha)$ the maximum of $time(\alpha, \tau)$ over all Δ-admissible time assignments τ for α. For an algorithm A, $time_\Delta(A)$ denotes the maximum of $time_\Delta(\alpha)$ over all Δ-admissible executions α of A.

Sometimes we will also need an estimate of how much time is spent due to explicit delay statements. For an execution α, let $min\text{-}time_\Delta(\alpha)$ denote the greatest lower bound on $time(\alpha, \tau)$ over all Δ-admissible time assignments τ for α; it gives the minimum time spent by a process in α. For instance, if we define $time(\alpha_{\text{sample}}, \tau)$ as $\tau_4 - \tau_0$, then for $\Delta > 4$, $time_\Delta(\alpha_{\text{sample}})$ is $2\Delta + 4$ and $min\text{-}time_\Delta(\alpha_{\text{sample}})$ is 4.

If *time* measures the *contention-free* complexity, which is the time spent by a process when it executes by itself, then according to [Lam87, AT96], an algorithm is *fast* if and only if $time_\Delta(A)$ is $O(\Delta)$ and $min\text{-}time_\Delta(A)$ is zero. This implies that in absence of contention, a process executes only a constant number of steps and no explicit delay statements.

3. Time-adaptive consensus. In this section, we consider the problem of (binary) consensus in the unknown-delay model and provide tight bounds for its worst-case time complexity.

The *consensus problem* is to design an algorithm in which all correct processes reach a common decision based on their initial inputs [PSL80]. Formally, the problem is defined as follows. There are n processes, and each process p_i has an input value $in_i \in \{0, 1\}$. A process p_i *decides* on a value $v \in \{0, 1\}$ by executing the statement $decide(v)$. It may decide at most once. The consensus problem requires the following:

- *Agreement:* There exists a *decision value* $out \in \{0, 1\}$ such that if a process p_i decides on the value v, then $v = out$.
- *Validity:* If a process p_i decides on the value v, then v equals the input value in_j for some process p_j.

Thus no two processes decide on conflicting values, and if all input values are the same, then that value must be the decision value. Apart from the above safety requirements, we want the correct processes to eventually decide the following:

- *Wait freedom:* Each process p_i either takes only finitely many steps or decides on some value.

The requirement of wait freedom means that one process cannot prevent another process from reaching a decision, and thus the algorithm must tolerate arbitrary number of process failures.

3.1. The algorithm. In this section, we present a consensus algorithm. The algorithm always guarantees the safety requirements of agreement and validity. The liveness requirement is ensured using timing assumptions. If every step finishes within time Δ, then a process decides within time $O(\Delta \cdot fac^{-1}(\Delta))$ irrespective of the failures of other processes, where fac^{-1} is the inverse of the factorial function. Thus the algorithm satisfies wait freedom in the unknown-delay model. Furthermore, the algorithm is fast: in the absence of contention, a process decides after a constant number of steps without explicitly delaying itself.

Recall that there is no wait-free algorithm for consensus in the asynchronous model. In the known-delay model, a process can use its knowledge about the speeds of other processes by executing the statement $delay(\Delta)$, and it is possible to design a wait-free solution [AT96]. Let us see how such an algorithm can be constructed when the upper bound is not known.

Initially, each process starts with some estimate, say 1, for Δ. The algorithm proceeds in rounds. Each process has a preference for the decision value in each round; initially, this preference is the input value of the process. In each round r, processes execute a timing-based consensus algorithm with their current estimate of Δ, using their preferences for this round as inputs.[4] The algorithm guarantees that once processes have the same preference in some round, they will remain in agreement and will eventually decide. The timing-based algorithm used in each round avoids conflicting decisions even if the current estimate for Δ is wrong. If no decision is made in a round, then the processes advance to the next round, using a larger estimate for the time bound Δ. Eventually, processes either decide or end up using the correct estimate, in which case the timing-based algorithm guarantees that they will decide.

The code for the algorithm appears in Figure 1. The algorithm uses the following shared data structures: an infinite array $x[*, 0..1]$ of bits, and an infinite array $y[*]$; the possible values of each $y[i]$ are $\{\perp, 0, 1\}$. The decision value is written to the shared bit *out*. We use only atomic reads and writes to the shared registers. In addition, each process p_i has a local register v_i containing its current preference and a local register r_i containing its current round number. The estimate d_r used in round r is $r!$.

In round r, process p_i first flags its preference v by writing 1 to $x[r, v]$. Then the process checks the lock on this round by reading $y[r]$ and writes its preference to $y[r]$ if $y[r]$ has still its initial value $\perp$. Process p_i then reads the flag for the other preference (denoted by $\bar{v}$). If $x[r, \bar{v}]$ is not set, then every process that reaches round r with the conflicting preference $\bar{v}$ will find $y[r]$ set to v. Consequently, process p_i can safely decide on v, and it writes the decision value to *out*. Otherwise, it waits for d_r (the estimate of Δ for the current round) and then sets its preference for the next round by reading $y[r]$.

Two processes with conflicting preferences for round r will not resolve the conflict only if both of them find $y[r] = \perp$ first and one of them proceeds and chooses its preference for the next round before the other one finishes the assignment to $y[r]$. However, if each process is required to finish the assignment within time Δ, and the value of d_r exceeds Δ, then this cannot happen. Also, notice that if all processes in a round have the same preference, then a decision is reached in that round. These observations, together with the fact that the sequence $d_1, d_2, \ldots$ increases without a bound, ensure termination. The next section includes a complete proof of correctness for this algorithm.

[4] The idea of using preferences for consensus was used previously, e.g., in [AH90].

```
Shared registers: initially: out = ⊥, y[∗] = ⊥, x[∗, ∗] = 0.
Local registers: initially: r_i = 1, v_i = in_i.
Constants: d_r = r! for all r.

1 while out = ⊥ do
2       x[r_i, v_i] := 1;
3       if y[r_i] = ⊥ then y[r_i] := v_i fi;
4       if x[r_i, v̄_i] = 0 then out := v_i
5                          else delay(d_{r_i});
6                               v_i := y[r_i];
7                               r_i := r_i + 1 fi
8 od;
9 decide(out).
```

FIG. 1. *Time-adaptive consensus: the program for process p_i with input in_i.*

3.2. Correctness. We now present the correctness proof of the algorithm. We assume that a process keeps taking idling steps after it has decided. Thus an infinite execution contains infinitely many steps of every nonfaulty process.

LEMMA 3.1. *If process p_i decides on a value v, then $in_j = v$ for some process p_j.*

Proof. If there are two processes that have different inputs, then the lemma holds trivially. Suppose all processes start with the same input in. Consider the following formula ϕ:

$$\forall i.\, v_i \;=\; in \;\wedge\; \forall r.\, y[r] \in \{\bot, in\} \;\wedge\; out \in \{\bot, in\}.$$

Initially, ϕ holds. It is easy to check that each transition of the algorithm preserves ϕ. Thus ϕ is an invariant of the algorithm. The lemma follows immediately. □

Let $r \geq 1$ and $v \in \{0, 1\}$. Formally, a process p_i *reaches* round r if it executes statement 2 (see Figure 1) with $r_i = r$. A process p_i *prefers* the value v in round r if $v_i = v$ when p_i reaches round r. A process p_i *commits* to the value v in round r if it executes the assignment $out := v$ with $r_i = r$.

LEMMA 3.2. *If all processes reaching round r have the same preference v for round r, then all nonfaulty processes reaching round r commit to v in round r.*

Proof. Suppose all processes reaching round r have the same preference v for round r. Thus whenever some process p_i sets the bit $x[r, v_i]$ to 1, v_i equals v. Consequently, $x[r, \bar{v}] = 0$ is an invariant. Now consider a process p reaching round r. Assuming that p continues to take steps in round r, p will find $x[r, \bar{v}]$ unset at statement 4 and commit to the value v. □

LEMMA 3.3. *If some process commits to v in round r, then all processes reaching round $r + 1$ prefer v in round $r + 1$.*

Proof. Suppose some process p commits to v in round r. Since p finds $x[r, \bar{v}]$ unset at statement 4, it follows that every process with preference $\bar{v}$ for round r finds $y[r] \neq \bot$ at statement 3. This implies that for a committed value v, $y[r] \neq \bar{v}$ is an invariant of the program. Since a process decides on its preference for round $r + 1$ by reading $y[r]$, the lemma follows. □

LEMMA 3.4. *No two processes decide on conflicting values.*

Proof. Suppose two processes decide on conflicting values. This means that there

exist nonfaulty processes p_0 and p_1 such that p_0 commits to 0 in round r and p_1 commits to 1 in round r'. We will obtain a contradiction.

First, suppose that $r \neq r'$. Without loss of generality, let $r < r'$. Since p_0 commits to 0 in round r, by Lemma 3.3, all processes reaching round $r+1$ prefer 0 in round $r+1$, and consequently, by Lemma 3.2, if nonfaulty, commit to 0 in round $r+1$. Since p_1 reaches round $r+1$ and is nonfaulty, it follows that p_1 commits to 0 in round $r+1$, a contradiction.

Now suppose that $r = r'$. In round r, process p_0 prefers 0 and process p_1 prefers 1. If process p_0 finds $x[r,1]$ unset at statement 4, then process p_1 must find $x[r,0]$ set at statement 4, and vice versa. Consequently, it is not possible that both commit in round r. □

The proof of termination relies only on the fact that the sequence of delays, $d_1, d_2, \ldots$ is unbounded. The termination is guaranteed by the following lemma.

LEMMA 3.5. *In a Δ-admissible execution, if $d_r \geq \Delta$, then all processes reaching round $r+1$ have the same preference in round $r+1$.*

Proof. Assume $d_r \geq \Delta$. Consider a Δ-admissible execution α and a Δ-admissible time assignment τ for it. Let k be the smallest index such that the event e_k is the assignment $v_i := y[r]$ (at statement 6) by some process p_i that reaches round $r+1$. Let the event e_l correspond to the delay statement $delay(d_r)$ (at statement 5) by process p_i. We know that $\tau_k - \tau_l > d_r$ and hence $\tau_k - \tau_l > \Delta$.

Before it reaches the delay statement, process p_i either finds $y[r] \neq \perp$ or assigns its preference for round r to $y[r]$. Hence in states s_m, for $m \geq l$, $y[r] \neq \perp$. Let $y[r] = v$ in state s_k. We want to prove that $y[r] = v$ in all states s_m for $m \geq k$. Suppose not. Let p_j, $j \neq i$, be a process that writes to $y[r]$ (at statement 3) at step $k' > k$. Let $e_{l'}$ be the event that p_j tests the condition $y[r] = \perp$ (at statement 3). Since $y[r] \neq \perp$ in all states s_m for $m \geq l$, we have $l' < l$. This implies $\tau_{k'} - \tau_{l'} \geq \tau_k - \tau_l > \Delta$. Since l' and k' are consecutive steps of p_j, this contradicts the Δ-admissibility of τ. Thus $y[r] = v$ in all states s_m for $m \geq k$.

Since every process reaching round $r+1$ chooses its preference for round $r+1$ by reading $y[r]$ at some step $m \geq k$, the lemma follows. □

If $d_r \geq \Delta$, then Lemmas 3.5 and 3.2 imply that in a Δ-admissible execution, no process can reach round $r+2$, and every nonfaulty process decides in round $r+1$ or lower. If the sequence $d_1, d_2, \ldots$ is unbounded, then for every Δ, there is some r such that $d_r \geq \Delta$. Consequently, we get termination in each Δ-admissible execution. This implies the following theorem.

THEOREM 3.6 (correctness). *The algorithm in Figure 1 is a correct solution to wait-free consensus in the unknown-delay model.*

3.3. Time complexity. Now let us analyze the time complexity of the algorithm. Recall that the worst-case time complexity of the algorithm is the maximum time after which a nonfaulty process decides.

Formally, given an execution α and a time assignment τ, let $time(\alpha, \tau)$ be the maximum difference $\tau_k - \tau_l$ such that both the events e_l and e_k are nonidling steps of the same process. Recall that a process takes idling steps only after it has decided. The worst-case time complexity of an algorithm A when the upper bound is Δ is then $time_\Delta(A)$ as defined in section 2.

LEMMA 3.7. *Let R be the smallest index such that $d_R \geq \Delta$. Then the worst-case time complexity $time_\Delta(A)$ is at most $9(R+1)\Delta + d_R$.*

Proof. Let $d_R \geq \Delta$ and $d_{R-1} < \Delta$. Consider an execution α and a Δ-admissible time assignment τ. Let p be a process. Since $d_R \geq \Delta$, by Lemmas 3.5 and 3.2, either

p fails or p decides in round $R+1$ or lower. For the worst-case analysis, we assume that p decides in round $R+1$. For each round r, suppose p enters round r at the i_rth step in α.

Let e_k be the last nonidling step of process p. The time taken by p is $\tau_k - \tau_{i_1}$. In each round r, p executes only a constant, at most 8, number of steps, possibly including a delay statement. By Δ-admissibility, we have $\tau_{i_{r+1}} - \tau_{i_r} \leq 8\Delta + d_r$, for any round r. For $r < R$, $d_r < \Delta$. Hence $\tau_{i_{R+1}} - \tau_{i_1} \leq 9R\Delta + d_R$. In round $R+1$, p_i takes only a constant, at most 7, number of steps without executing the delay statement. Hence $\tau_k - \tau_{i_{R+1}} \leq 7\Delta$. Hence $\tau_k - \tau_{i_1} \leq 9(R+1)\Delta + d_R$. The lemma follows. □

The time complexity of the algorithm depends on the choice of the sequence d_r. If the sequence is fast growing, then the value of R will be small. However, if the sequence grows too fast, then the value of d_R can be much larger than Δ itself. For instance, if we let $d_r = r$, then $R = \Delta = d_R$, and the time complexity is $O(\Delta^2)$. For $d_r = 2^r$, $R = O(\log \Delta)$, $d_R \leq 2 \cdot \Delta$, and the time complexity is $O(\Delta \cdot \log \Delta)$. For $d_r = 2^{2^r}$, $R = O(\log \log \Delta)$, but $d_R \leq 2^\Delta$, giving time complexity $O(2^\Delta)$. As we shall see (as part of the lower-bound proof in the next section), the best sequence is $d_r = r!$.

Let fac^{-1} be the inverse of the factorial function, that is, $fac^{-1}(d)$ is the smallest integer r such that $r! \geq d$, for any real $d > 0$; note that $fac^{-1}(d) = \Theta(\frac{\log d}{\log \log d})$. In the case where $d_r = r!$ for all r, $R = fac^{-1}(\Delta)$, and $d_R = (fac^{-1}(\Delta))!$. Hence $d_R \leq \Delta \cdot fac^{-1}(\Delta)$. This gives the overall complexity of $O(\Delta \cdot fac^{-1}(\Delta))$.

THEOREM 3.8 (time complexity). *For the algorithm in Figure* 1 *with the sequence of delays $d_r = r!$, for every Δ, the worst-case time complexity $time_\Delta(A)$ is bounded by $10 \cdot \Delta \cdot (fac^{-1}(\Delta) + 1)$.*

Note that our algorithm uses unbounded space. In a Δ-admissible execution, only the first $(fac^{-1}(\Delta) + 1)$ elements of the arrays x and y are used. Since $fac^{-1}(\Delta)$ is small for any reasonable value of Δ, space is not a real problem. For instance, if our time unit is a second and the upper bound Δ is 1000 years, then $fac^{-1}(\Delta)$ is 14.

Finally, let us consider the contention-free complexity of the algorithm. Informally, we want the contention-free complexity to indicate the time taken by a process when it executes by itself without interference from other processes. Formally, given an execution α and a time assignment τ, let *cf-time*(τ, α) be the maximum difference $\tau_j - \tau_i$ such that both events e_j and e_i are nonidling events of the same process p, and every other process q either has decided before step i or has not taken any step before step j.

The contention-free time complexity of algorithm A for the upper bound Δ is then given by *cf-time*$_\Delta(A)$ and *min-cf-time*$_\Delta(A)$. Our algorithm has low contention-free complexity.

THEOREM 3.9 (fast decision in the absence of contention). *For the algorithm in Figure* 1, *for every Δ, cf-time$_\Delta(A) = 7 \cdot \Delta$, and min-cf-time$_\Delta(A) = 0$.*

Proof. Consider an execution α and indices i and j such that event e_i is the first event of process p, event e_j is the decision event of p, and every other process q either has decided before step i or has not taken any step before step j. There are two cases to consider.

If some process q has decided before process p starts, then the value of *out* is different from $\perp$ in state s_i, and p takes at most two steps before deciding, both of which have zero explicit delay. This implies that if τ is a Δ-admissible assignment for α, then $\tau_j - \tau_i \leq 2\Delta$. Furthermore, since p does not execute any delay statement,

the difference $\tau_j - \tau_i$ can be made as small as possible, implying that the infimum of $\tau_j - \tau_i$ over all Δ-admissible time assignments for α is 0.

If no process q has taken a step before event e_i, then p is the first process to start, and no process starts before p decides. In this case, p decides in the first round after taking at most seven steps, again without executing any delay statement. In this case, the maximum of $\tau_j - \tau_i$ over all Δ-admissible time assignments for α is 7Δ, and the infimum is 0. □

We point out that if some processes fail without deciding before a process p starts, then even if p runs by itself, it may execute for $O(\Delta \cdot fac^{-1}(\Delta))$ time. Thus failures of processes can lead to the worst-case time complexity.

3.4. Lower bound on time complexity. For the algorithm of section 3, if Δ is the upper bound on step time, then a process decides within time $O(\Delta \cdot fac^{-1}(\Delta))$. If a process knew the value of Δ in advance, then it can execute the algorithm with $d_1 = \Delta$, ensuring termination in the second round, within time $O(\Delta)$. Thus the lack of knowledge of the value of Δ multiplies the time complexity by a factor of $fac^{-1}(\Delta)$. In this section, we prove this increase in cost to be inherent: we prove that any algorithm for solving two-process consensus in the unknown-delay model has worst-case time complexity of $O(\Delta \cdot fac^{-1}(\Delta))$.

To prove the lower bound, we restrict our attention to a system with two processes, p_1 and p_2. Let A be an algorithm for wait-free consensus in the unknown-delay model. Consider an execution $\alpha = s_0 \stackrel{e_0}{\to} s_1 \stackrel{e_1}{\to} \cdots$. The execution can be partitioned into *blocks*, each containing a sequence of events by the same process. Formally, let $b_0, b_1, \ldots$ be an increasing sequence of integers with $b_0 = 0$ such that for each i, all of the steps indexed from b_i to $b_{i+1} - 1$ are of the same process, and the step indexed b_{i+1} is of a different process. Thus the ith block is the execution fragment $s_{b_i} \stackrel{e_{b_i}}{\to} s_{b_i+1} \cdots \stackrel{e_{b_{i+1}-1}}{\to} s_{b_{i+1}}$ consisting of steps of a single process.

By Lemma 2.1, A must also guarantee safety in the asynchronous shared-memory model. Therefore, from the proof of the impossibility of solving consensus in the shared-memory asynchronous model (e.g., [LA87, Theorem 4.1]), we can deduce the following.

LEMMA 3.10. *There exists an infinite sequence of executions $\alpha_0, \alpha_1, \ldots$ such that for all $k \geq 0$, (1) α_k is a finite execution with $k+1$ blocks, (2) α_{k+1} is an extension of α_k, and (3) no process has decided at the end of α_k.*

Let us recall the definition of the time complexity of consensus. Given an execution α of A and a Δ-admissible time assignment τ for α, whenever e_i and e_j are the (nonidling) steps of the same process, we have $time_\Delta(A) \geq \tau_j - \tau_i$. Now we consider another definition needed for the proof. Given an execution α, define d_i to be the total sum of the delays in delay statements appearing in the ith block. With each execution we can associate a sequence $d_0, d_1, \ldots$, called the *sequence of block delays*.

LEMMA 3.11. *Let α be a finite execution with $k+1$ blocks with $k \geq 1$ such that no process has decided at the end of α. Let $d_0, d_1, \ldots, d_k$ be the associated sequence of block delays, and let $\Delta \geq 1 + \sum_{i=0}^{k-1} d_i$. Then $time_{2\Delta}(A) \geq k \cdot \Delta + d_k$.*

Proof. Let α be $s_0 \stackrel{e_0}{\to} \cdots s_{n-1} \stackrel{e_n}{\to} s_n$ consisting of $k+1$ blocks starting at indices $b_0, \ldots, b_k$. Without loss of generality, assume that the last block corresponds to steps of process p_1.

Since no process has decided and A satisfies wait freedom, we know that p_1 can take an additional step, e_{n+1}; let α' denote the extended execution. Now we construct a time assignment τ for α' as follows. Let $\Delta \geq 1 + \sum_{i=0}^{k-1} d_i$.

We want each block, except the last one, to take Δ time. For every $0 \le j \le n$,

- if e_j is the first step of the ith block (i.e., $j = b_i$), for $i = 0, \ldots, k$, then let τ_j be $i \cdot \Delta$; otherwise,
- if e_j is the last step of the ith block (i.e., $j = b_{i+1} - 1$), for $i = 0, \ldots, (k-1)$, then let τ_j be $(i+1) \cdot \Delta$; otherwise,
- let τ_j be $\tau_{j-1} + d(e_{j-1}) + 1/n$.

For each block i, the sum of the explicit delays of events in the block i is d_i, and the number of events in the block i is bounded by n. By the choice of Δ, it is clear that the sequence of values defined above is nondecreasing. Furthermore, let the time τ_{n+1} of the last step be $\tau_n + d(e_n) + \Delta$.

Now consider events e_j and $e_{j'}$ that are consecutive steps of the same process. There are two cases to consider.

1. Both e_j and $e_{j'}$ belong to the same block (i.e., $j' = j + 1$). Then $\tau_{j'} - \tau_j > d(e_j)$. In each block, except possibly the last one, the difference between the time of the last step and the first step is Δ. In the last block, the time of the first step is $k \cdot \Delta$, and the times of the remaining steps are increased only when p_1 executes delay statements. Hence $\tau_{j'} - \tau_j \le \Delta + d(e_j)$.

2. The event e_j is the last event of a block, say the ith block, and $e_{j'}$ is the first event of the $(i+2)$th block. In this case, $\tau_{j'} = (i+2) \cdot \Delta$. If the ith block has only one event, then $\tau_j = i \cdot \Delta$; otherwise, $\tau_j = (i+1) \cdot \Delta$. Thus $\Delta \le \tau_{j'} - \tau_j \le 2\Delta$.

This implies that τ is a legal time assignment for α, and furthermore, it is 2Δ-admissible (i.e., we can choose 2Δ as the upper bound). Note that the total delay in the last block may be larger than 2Δ. Since only p_1 takes steps in the last block, this means that p_2 has failed if we put an upper bound of 2Δ on the step times.

Finally, observe that the time of the last step τ_{n+1} is $(k+1) \cdot \Delta + d_k$. The time of the first step of p_1 is either 0 or Δ depending on whether the first or the second block corresponds to steps of p_1. This means that p_1 has executed for at least $k \cdot \Delta + d_k$ time without deciding. Hence $time_{2\Delta}(A) \ge k \cdot \Delta + d_k$. □

LEMMA 3.12. *There exists an infinite nondecreasing sequence of values $\Delta_1, \Delta_2, \ldots$ such that for all $k \ge 1$, for all $\Delta \ge \Delta_k$, $2time_\Delta(A) \ge k \cdot \Delta + (\Delta_{k+1} - \Delta_k)$.*

Proof. Consider the infinite sequence of executions $\alpha_0, \alpha_1, \ldots$ of Lemma 3.10. Note that the lemma implies that α_{k+1} is obtained from α_k by adding one block. Let d_k be the delay of the last block of α_k. Let $\Delta_k = 2(1 + \sum_{i=0}^{k-1} d_i)$. For each $k \ge 1$, by applying Lemma 3.11 to α_k, we get that for all $\Delta \ge \Delta_k$, $time_\Delta(A) \ge k \cdot \Delta/2 + d_k$. The lemma follows since $d_k = (\Delta_{k+1} - \Delta_k)/2$. □

To complete the proof of the lower bound, we present the following technical lemma.

LEMMA 3.13. *For any nondecreasing sequence $\Delta_1, \Delta_2, \ldots$ of real numbers, for infinitely many indices k, $k \cdot \Delta_k + (\Delta_{k+1} - \Delta_k) \ge \Delta_k \cdot fac^{-1}(\Delta_k)$.*

Proof. The proof is by contradiction. Suppose there exists a nondecreasing sequence $\Delta_1, \Delta_2, \ldots$ and an index i such that for all $k \ge i$, $k \cdot \Delta_k + (\Delta_{k+1} - \Delta_k) < \Delta_k \cdot fac^{-1}(\Delta_k)$. Define $m_k = fac^{-1}(\Delta_k)$. By definition, for all k,

$$(m_k - 1)! < \Delta_k \le m_k!.$$

The proof follows the following steps:

(1) For all $k \ge i$, we have $k \cdot \Delta_k + (\Delta_{k+1} - \Delta_k) < \Delta_k \cdot m_k$. Also, $\Delta_{k+1} - \Delta_k \ge 0$ for all k. Hence $m_k > k$ for all $k \ge i$.

(2) Let $k \ge i$. We have

$$\Delta_{k+1} < (m_k - k + 1) \cdot \Delta_k \le (m_k - k + 1) \cdot m_k! < (m_k + 1)!.$$

Hence $m_{k+1} \leq m_k + 1$. Thus the sequence of values $(m_k - k)$, for $k \geq i$, is nonincreasing. From (1), $(m_k - k)$ is positive for all $k \geq i$. That is, $(m_k - k)$, $k \geq i$, forms a nonincreasing infinite sequence of positive numbers. Hence there exists a positive integer a and an index j such that $m_k - k = a$ for all $k \geq j$.

(3) Choose $k \geq j$ such that $k > (a+1)^2$. We have $\Delta_{k+1} < (a+1) \cdot \Delta_k$, and $\Delta_{k+2} < (a+1) \cdot \Delta_{k+1}$. Hence

$$\Delta_{k+2} < (a+1)^2 \cdot \Delta_k \leq (a+1)^2 \cdot m_k! < k \cdot (a+k)! < (a+k+1)!.$$

This implies $m_{k+2} \leq a + k + 1$. This contradicts the assertion $m_{k+2} = a + k + 2$ of (2), which completes the proof. □

Lemma 3.13, together with Lemma 3.12, implies the following.

THEOREM 3.14 (lower bound on time complexity). *For any algorithm A for solving two-process wait-free consensus in the unknown-delay model, for every real number d, there exists $\Delta > d$ such that the worst-case time complexity $time_\Delta(A)$ is at least $(\Delta \cdot fac^{-1}(\Delta))/2$.*

Proof. Lemma 3.12 gives a nondecreasing sequence $\Delta_1, \Delta_2, \ldots$ such that for all $k \geq 1$, for all $\Delta \geq \Delta_k$, $2time_\Delta(A) \geq k \cdot \Delta + (\Delta_{k+1} - \Delta_k)$. There are two cases to consider:

1. The sequence $\Delta_1, \Delta_2 \ldots$ is unbounded: For every real value d, there is an index i such that for all $k \geq i$, $\Delta_k > d$. Using Lemma 3.13, there is an index $k \geq i$ such that $\Delta_k > d$ and $k \cdot \Delta_k + (\Delta_{k+1} - \Delta_k) \geq \Delta_k \cdot fac^{-1}(\Delta_k)$, and hence $2time_{\Delta_k}(A) \geq \Delta_k \cdot fac^{-1}(\Delta_k)$.

2. The sequence $\Delta_1, \Delta_2 \ldots$ is bounded: There is a value d^* such that $\Delta_k < d^*$ for all k. Let $\Delta \geq d^*$. Then by Lemma 3.12, for all k, $2time_\Delta(A) \geq k \cdot \Delta$. Choosing $k > fac^{-1}(\Delta)$ gives $2time_\Delta(A) > \Delta \cdot fac^{-1}(\Delta)$. □

Notice that our lower bound implies that for every algorithm, there is an unbounded sequence of values Δ for which the worst-case time complexity is at least $(\Delta \cdot fac^{-1}(\Delta))/2$. This does not rule out the existence of a (different) unbounded sequence of values Δ for which the worst-case time complexity is less than $(\Delta \cdot fac^{-1}(\Delta))/2$. For the algorithm of Figure 1, if we choose the sequence $d_r = 2^{2^r}$, then setting $\Delta = d_r$ implies termination in $O(\log \log r)$ rounds, giving the worst-case time complexity of $O(\Delta \cdot \log \log \Delta)$; however, if we set $\Delta = d_r + 1$, the worst-case time complexity is $O(2^\Delta)$.

4. Time-adaptive mutual exclusion. The mutual exclusion problem is to design a protocol that guarantees mutually exclusive access to a critical section among a number of competing processes [Dij65]. A solution to the problem should satisfy the following two properties:

- *Mutual exclusion:* No two processes are in their critical section at the same time.
- *Deadlock freedom:* If some process p starts executing its algorithm, then eventually some process (possibly different from p) is in its critical section.

We assume that each of the potentially n contending processes has a unique identifier taken from the set $\{1, \ldots, n\}$. While deadlock freedom is essential, starvation freedom—any process that is trying to enter its critical section eventually does enter its critical section—is less important in systems where contention is rare. When contention is rare, it is important to design algorithms satisfying the fast-access property:

- *Fast access:* In the absence of contention, a process executes only a constant number of steps in order to enter its critical section and only a constant number of steps in order to execute the exit code.

In [Lam87], Lamport presented a mutual exclusion algorithm that satisfies the fast-access property. However, in the presence of contention, however small, the winning process may have to check the status of all of the other n processes before it is allowed to enter its critical section. Alur and Taubenfeld overcome this limitation in the known-delay model [AT96] (see also [AT93]). Their algorithm satisfies the fast access property, and furthermore, in the presence of contention, a process does not have to check the status of all of the other n processes before it can enter its critical section, but it may need to delay itself for $2 \cdot \Delta$ time units. In the next section, we describe an algorithm with similar properties for the unknown-delay model. Other algorithms which satisfy the fast-access property can be found in [CS93, MS93, Sty92, YA93].

4.1. The algorithm. We now present a fast mutual exclusion algorithm for the unknown-delay model. Since in this model a time bound on the speed exists but is not known, the processes keep an estimate of this time (stored in a shared register) and update it when it is noticed that the estimate is not accurate. An entry to the critical section which involves an update (of the estimate) is going to be much slower than an entry without an update. However, the algorithm has the property that at most Δ updates are necessary. As we show, the algorithm is also time efficient when there is contention. As is usually assumed when designing a mutual exclusion algorithm, we also assume that process failures do not occur.

The precise code for the algorithm is given in Figure 2. Notice that the statement **await** *condition* is an abbreviation for **while** $\neg$*condition* **do** *skip* (and hence may involve many accesses to the shared memory). The algorithm is composed of two basic algorithms. The first is Alur and Taubenfeld's algorithm (abbreviated AT) for fast mutual exclusion using a timing assumption [AT96]. Statements 1–10 are the entry code of AT and statements 29–31 are its exit code. We point out that in the original AT, the register *bound* is initially set to Δ (which is assumed to be known). Furthermore, while AT satisfies mutual exclusion only when $bound \geq \Delta$, the proof of deadlock freedom does not depend on the value of *bound*. We will exploit this property in our construction. The critical section of AT is now replaced by Lamport's fast mutual exclusion algorithm, statements 11–28. These two algorithms are combined along with a mechanism for estimating and updating the current bound. All references to the register *update* and the array *trying* belong to this mechanism and are not part of the original AT and Lamport's algorithms.

Intuitively, the algorithm works as follows. First, each process executes AT, using the current estimate *bound*. If the estimate is correct, or if there is no contention, only one process will proceed to the next stage (i.e., get to statement 11). However, it is possible that the current estimate used by the processes is incorrect. In this case, more than one process may proceed to the next stage, and therefore, to guarantee mutual exclusion, we embed Lamport's fast algorithm at this point. If a process discovers contention while executing Lamport algorithm, it "knows" that the current estimate used is incorrect and has to be increased. Contention is discovered when either of the conditions in statements 14 and 18 evaluates *true*.

To avoid complications, only a process that enters its critical section (statement 23) is allowed to update the register *bound*. This guarantees that no two processes try to update the estimate at the same time, and thus the value of *bound* never decreases.

The update is done as follows. First, the process sets *update* to 1, signaling that it wants to make an update (statement 22). Then it waits until each active process returns to the beginning of its trying code and waits for *update* to become 0 (statement 2). It is easy to check that once *update* is 1, eventually every process will

```
Initially: y = 0, yy = 0, z = 0, bound = 1, update = 0, trying[i] = 0, and b[i] = 0 for all i.

1   start1: repeat
2             if update = 1 then trying[i] := 0; await update = 0 fi;
3             trying[i] := 1;
4             x := i;
5           until (y = 0);
6           y := i;
7           if x ≠ i then delay(2 · bound);
8                         if y ≠ i then goto start1 fi;
9                         await (z = 0) or (update = 1)
10          else z := 1;
11  start2: if update = 1 then goto start1 fi;
12          b[i] := 1;
13          xx := i;
14          if yy ≠ 0 then b[i] := 0;
15                        await (yy = 0) or (update = 1);
16                        goto start2 fi;
17          yy := i;
18          if xx ≠ i then b[i] := 0;
19                        for j := 1 to n do await (b[j] = 0) or (update = 1) od;
20                        if yy ≠ i then await (yy = 0) or (update = 1);
21                                       goto start2
22                        else update := 1 fi fi;                    (* set lock *)
23          critical section;
24          trying[i] := 0;
25          if update = 1 then for j := 1 to n do await trying[j] = 0 od;     (* wait *)
26                        bound := bound + 1 fi;                     (* increment bound *)
27          yy := 0;
28          b[i] := 0;
29          z := 0;
30          if update = 1 then y := 0; update := 0
31                        else if  y = i then y := 0 fi fi
```

FIG. 2. *Fast time-adaptive algorithm: process i's program.*

test it. Once process i finds that *update* is 1, it returns to the beginning of its code, signals to the updating process that it is at the beginning by setting $trying[i]$ to 0, and waits (statement 2). Once the updating process gets acknowledgments from all active processes, it safely increments *bound* (statement 26), executes the exit code of both the algorithms, and releases the lock (statement 30), which leaves the system in its initial configuration (except for the value of *bound*).

The fact that the processes return to the beginning of their code before *bound* is incremented guarantees that the value of the *bound* will never be greater than Δ.

Once *bound* equals Δ, the entry code of AT (statements 1–10) ensures that no two processes execute Lamport's algorithm (statements 11–28) at the same time. Hence from that point on, processes will always enter their critical section along the fast path of Lamport's algorithm.

In summary, each process starts by checking if an update of *bound* is taking place, in which case it waits until the update is finished. Then the process performs the entry code for the timing-based mutual exclusion algorithm using the current estimate. If it gains access to the critical section (of AT), the process executes Lamport's fast mutual exclusion algorithm. However, in the algorithm, if a process enters its critical section via the slow path, it "knows" that the current estimate in use is incorrect and should be increased. It does so by first signaling other processes to go to the beginning of

their code and, after they all do so, incrementing the register *bound*.

4.2. Correctness. The design of the algorithm and its correctness proof are based on the following straightforward general observation.

LEMMA 4.1. *Let A and B be mutual exclusion algorithms (with disjoint sets of shared registers), and let C be the algorithm obtained by replacing the critical section of A with algorithm B.*[5]

1. *If both A and B are deadlock-free, then C is deadlock-free.*
2. *If either A or B satisfies mutual exclusion, then C satisfies mutual exclusion.*

Proof. The entry code of C is composed of the entry code of A, denoted by C_A, followed by that of B, denoted by C_B. Assume that both A and B are deadlock-free. If some process starts executing algorithm C, then since A is deadlock-free, eventually some process will finish C_A and proceed to C_B. Since B is deadlock-free, eventually some process will finish C_B and enter its critical section. Thus C is deadlock-free.

If A satisfies mutual exclusion, then no two processes can be at their C_B code at the same time. If B satisfies mutual exclusion, then no two processes can finish their C_B code at the same time. In either case, it implies that no two processes are in their critical section at the same time. □

The correctness of the algorithm is based on Lemma 4.1 and the properties of Lamport's algorithm and AT. Note that the algorithm also satisfies the correctness requirements in the asynchronous model.

As already explained, the algorithm is obtained by replacing the critical section of Alur and Taubenfeld's algorithm with Lamport's algorithm (statements 11–28). These two algorithms are combined along with a mechanism for estimating and updating the current time bound. All references to the register *update* and the array *trying* belong to this mechanism and are not part of the original AT and Lamport's algorithm.

It is known that Lamport's algorithm satisfies mutual exclusion and deadlock freedom and that AT satisfies deadlock freedom regardless of the value of *bound*.

THEOREM 4.2. *The algorithm in Figure* 2 *satisfies deadlock freedom in the asynchronous model.*

Proof. As long as the value of *update* is 0, executing statements 1–10 or 11–22 is the same as executing the entry code of AT or the entry code of Lamport's algorithm, respectively. Since both AT and Lamport's algorithm are deadlock-free (regardless of the value of *bound*), Lemma 4.1 implies that the algorithm cannot be deadlocked while the value of *update* is continuously 0.

We observe that if the value of *update* is 1, then there must be some process (called the *winner*) which is either in its critical section or in its exit code. Once *update* is 1, eventually every process (other than the winner) will test it. Once process i finds that *update* is 1, it returns to the beginning of its code and signals to the winner that it is at the beginning by setting $trying[i]$ to 0. Thus eventually the winner gets acknowledgments from all active processes, which implies that the winner cannot be blocked forever in the *for* loop of statement 25, and will eventually set *update* back to 0. This implies that the system cannot be deadlocked while the value of *update* is continuously 1.

Thus a deadlock can occur in an infinite execution only if *update* changes values an infinite number of times. However, each time *update* changes its value, some process

[5] If the critical section of A has a label, then in C this label is associated with the first statement of B.

either enters or exits its critical section. Therefore, in an execution where *update* changes values an infinite number of times, no deadlock can occur. □

THEOREM 4.3. *The algorithm in Figure* 2 *satisfies mutual exclusion in the asynchronous model.*

Proof. As long as the value of *update* is 0, executing statements 11–28 is the same as executing Lamport's algorithm. Since Lamport's algorithm satisfies mutual exclusion, by Lemma 4.1, the new algorithm must also satisfy mutual exclusion when the value of *update* is 0.

If the value of *update* is 1, then there must be some process (the *winner*) which is either in its critical section or in its exit code.

If some process has tested *update* before it was set to 1, then the value of *update* was 0 at this time, and (as already explained above) since Lamport's algorithm satisfies mutual exclusion, this process will not enter its critical section, and eventually it will have to test *update* again.

Once the winner sets *update* to 1, no other process can enter the critical section until *update* is set back to 0. To see this, observe that once *update* is 1, eventually every process will test it, and once a process finds that *update* is 1, it returns to the beginning of its code, signals to the updating process that it is at the beginning by setting *trying*[*i*] to 0, and waits (statement 2) until *update* is set to 0. The winner sets *update* to 0 in its exit code only after it gets acknowledgments from all active processes. Because the processes retreat to *start*1 at the beginning of their code before *update* is reset, no process executes Lamport's (embedded) algorithm, which in turn guarantees that no two processes can enter their critical section as long as the value of *update* is not changed. □

4.3. Time complexity. Next, we show that the register *bound* is updated at most Δ times.

LEMMA 4.4. *bound* $\leq \Delta$ *is an invariant of the algorithm.*

Proof. Once *bound* reaches the correct Δ, the delay in statement 7 is $2 \cdot \Delta$. At this point, all the processes that participate in the algorithm, except the one that is updating the value of *bound*, are at the beginning of their code, waiting for *update* to become 0. Thus from that point on, this code (statements 1–10) behaves exactly like the original AT.

This means that from now on, only one process can be in Lamport's algorithm (statements 11–28). When only one process is in Lamport's algorithm, the test in line 18 is always evaluated to false, and hence statement 22 will not be reached, the value of *update* will remain at 0, and no more updates to *bound* will occur. (Statement 22 is the only place where the value of *update* is changed from 0 to 1.) Thus the number of times a winning process has to update *bound* after executing its critical section is bounded by Δ. □

The next theorem shows that the algorithm is time efficient. In the theorem, the time it takes for a process to enter its critical section is measured from the last time some process exited its critical section.

THEOREM 4.5. *The algorithm has the following properties:*

1. *Fast access: In the absence of contention, a process executes only a constant number of steps* (13) *from the location start*1 *to its critical section and only a constant number of steps* (8) *to execute the exit code. No delays are necessary.*

2. *In the presence of contention, a winning process which does not update the register bound executes a constant number of steps* (14) *and may need to delay itself for at most* $2 \cdot \Delta$ *time units before entering its critical section.*

3. *In the presence of contention, a winning process which needs to update the register bound may execute $O(n)$ steps and may need to delay itself for at most $2\cdot\Delta$ time units before entering its critical section. This may happen at most Δ times.*

Proof. The first part is straightforward.

By Lemma 4.4, *bound* $\leq \Delta$. Thus executing the delay in statement 7 takes at most $2\cdot\Delta$ time units. Note that a winning process updates *bound* if and only if it finds the condition in statement 18 (i.e., $xx \neq i$) to be true. The second part of the theorem is easily verified by counting steps in the algorithm.

Only when a process finds the condition in statement 18 to be true does it execute the *for* statement at statement 19, in which it may need to execute $O(n)$ steps. This implies the third part of the theorem and explains why the term $O(n)$ is added. □

Observe that there is a tradeoff between the number of updates of the register *bound* and its maximum value. For example, if instead of incrementing it by 1, we double its value when it is updated, then we can show that *bound* is updated at most $\log\Delta$ times and *bound* $\leq 2\cdot\Delta - 1$. Incrementing by 1 is the best strategy since it gives the best amortized time complexity when the number of entries to the critical section is much bigger than Δ.

Notice that our algorithm uses $2n + 5$ shared registers. It is possible to replace the arrays b and *trying*, each of n bits, with one array of n 3-valued registers. Lynch and Shavit proved that when the timing bounds are not known, n is a lower bound on the number of shared registers [LS92]. (The model they used for their algorithm design is the known-delay model, but their lower bound proof continues to hold for the unknown-delay model as well.) In contrast, the algorithms for mutual exclusion in the known-delay model use only a constant number of registers [Lam87, AT96, LS92].

In our algorithm, the value of the register *bound* can only be increased, and after it is updated Δ times, it will reach its maximum value Δ. In a dynamic system where processes are created and destroyed, the upper bound on the speed of the processes may change over time. Our algorithm adapts to an increase in Δ (that may be caused by adding slow processes). However, when Δ decreases (a slow process is destroyed), the value of *bound* may be too high, leading to inefficient utilization. This may be resolved by periodically resetting *bound* to zero and letting it adjust to reflect the current speed.

5. Discussion. We have defined the unknown-delay model, which formalizes systems in which there is an upper bound on memory access time, but this bound is not known. For the consensus problem, we have shown that $\Theta(\Delta\cdot fac^{-1}(\Delta))$ is an upper and lower bound on the time complexity of any algorithm, where fac^{-1} is the inverse of the factorial function. The algorithm that achieves this bound is fast in the absence of contention. Since consensus is universal [He91], our results imply that atomic reads and writes are universal in the unknown-delay model. For the mutual exclusion problem, we have presented an algorithm in which, in the presence of contention, a process needs only delay itself for $2\cdot\Delta$ time units before entering the critical section, when no update of the time estimate is needed. This algorithm is also fast in the absence of contention.

The standard definitions of the consensus problem and the mutual exclusion problem differ in two ways. First, a mutual exclusion algorithm is invoked repeatedly, while a consensus algorithm is invoked only once. Second, in the consensus problem, processes may fail, while in the mutual exclusion problem, it is assumed that processes do not fail. Note however, that our algorithms for both problems are constructed in

a similar manner, by combining an asynchronous algorithm that guarantees safety, a timing-based algorithm that converges when used with a correct estimate for Δ, and a mechanism for estimating Δ.

Acknowledgments. We wish to thank Yehuda Afek, Eli Gafni, Eyal Kushilevitz, and Michael Merritt for helpful discussions and the anonymous referees for a thorough review of the manuscript.

A FIRST-ORDER ISOMORPHISM THEOREM*

ERIC ALLENDER†, JOSÉ BALCÁZAR‡, AND NEIL IMMERMAN§

Abstract. We show that for most complexity classes of interest, all sets complete under first-order projections (fops) are isomorphic under first-order isomorphisms. That is, a very restricted version of the Berman–Hartmanis conjecture holds. Since "natural" complete problems seem to stay complete via fops, this indicates that up to first-order isomorphism there is only one "natural" complete problem for each "nice" complexity class.

Key words. complexity classes, descriptive complexity, reduction, first-order projection

1. Introduction.

In 1977, Berman and Hartmanis noticed that all NP-complete sets that they knew of were polynomial-time isomorphic [BH77]. They made their now-famous isomorphism conjecture, namely that all NP-complete sets are polynomial-time isomorphic. This conjecture has engendered a large amount of work (cf. [KMR90, You] for surveys).

The isomorphism conjecture was made using the notion of NP-completeness via polynomial-time many–one reductions because that was the standard definition at the time. In [Coo], Cook proved that the Boolean satisfiability problem (SAT) is NP-complete via polynomial-time Turing reductions. Over the years SAT has been shown to be complete via weaker and weaker reductions, e.g., polynomial-time many–one [Kar], logspace many–one [Jon], one-way logspace many–one [HIM], and first-order projections (fops) [Dah]. These last reductions, defined in section 3, are provably weaker than logspace reductions. It has been observed that *natural* complete problems for various complexity classes including NC^1, L, NL, P, NP, and PSPACE remain complete via fops; cf. [I87, IL, SV, Ste, MI].

On the other hand, Joseph and Young, [JY] have pointed out that polynomial-time many–one reductions may be so powerful that they allow *unnatural* NP-complete sets. Most researchers now believe that the isomorphism conjecture as originally stated by Berman and Hartmanis is false.[1]

We feel that the choice of polynomial-time many–one reductions in the statement of the isomorphism conjecture was made in part for historical rather than purely scientific reasons. To elaborate on this claim, note that the class NP arises naturally

[1] One way of quantifying this observation is that since Joseph and Young produced their unnatural NP-complete sets, Hartmanis has been referring to the isomorphism conjecture as the "Berman" conjecture.

in the study of logic and can be defined entirely in terms of logic, without any mention of computation [Fa]. Thus it is natural to have a notion of NP-completeness that is formulated entirely in terms of logic. On another front, Valiant [Val] noticed that reducibility can be formulated in algebra using the natural notion of a projection, again with no mention of computation. The sets that are complete under fops are complete in *all* of these different ways of formulating the notion of NP-completeness.

Since natural complete problems turn out to be complete via very low-level reductions such as fops, it is natural to modify the isomorphism conjecture to consider NP-complete reductions via fops. Motivating this in another way, one could propose as a slightly more general form of the isomorphism conjecture the following question: Is completeness a sufficient structural condition for isomorphism? Our work answers this question by presenting a notion of completeness for which the answer is yes. Namely, for every nice complexity class including P, NP, etc., any two sets complete via fops are not only polynomial-time isomorphic but first-order isomorphic.

There are additional reasons to be interested in first-order computation. It was shown in [BIS] that first-order computation corresponds exactly to computation by uniform AC^0 circuits under a natural notion of uniformity. Although it is known that AC^0 is properly contained in NP, knowing that a set A is complete for NP under polynomial-time (or logspace) reductions does not currently allow us to conclude that A is not in AC^0; however, knowing that A is complete for NP under first-order reductions does allow us to make that conclusion.

First-order reducibility is a uniform version of the constant-depth reducibility studied in [FSS, CSV]; sometimes this uniformity is important. For a concrete example where first-order reducibility is used to provide a circuit lower bound, see [AG92].

Preliminary results and background on isomorphisms follow in section 2. Definitions and background on descriptive complexity are found in section 3. The main result is stated and proved in section 4, and then we conclude with some related results and remarks about the structure of NP under first-order reducibilities.

2. Short history of the isomorphism conjecture. The isomorphism conjecture is analogous to Myhill's Theorem that all recursively enumerable (r.e.) complete sets are recursively isomorphic, [Myh]. In this section, we summarize some of the relevant background material. In the following, FP is the set of functions computable in polynomial time.

DEFINITION 2.1. *For $A, B \subseteq \Sigma^*$, we say that A and B are* p-isomorphic ($A \stackrel{\mathrm{p}}{\cong} B$) *iff there exists a bijection $f \in \mathrm{FP}$ with inverse $f^{-1} \in \mathrm{FP}$ such that A is many–one reducible to B ($A \leq_{\mathrm{m}} B$) via f (and therefore $B \leq_{\mathrm{m}} A$ via f^{-1}).*

OBSERVATION 2.2 ([BH77]). *All the* NP*-complete sets in* [GJ] *are* p*-isomorphic.*

How did Berman and Hartmanis make their observation? They did it by proving a polynomial-time version of the Schröder–Bernstein theorem. Recall the following.

THEOREM 2.3 ([Kel, Theorem 20]). *Let A and B be any two sets. Suppose that there are* 1:1 *maps from A to B and from B to A. Then there is a* 1:1 *and onto map from A to B.*

Proof. Let $f : A \to B$ and $g : B \to A$ be the given 1:1 maps. For simplicity, assume that A and B are disjoint. For $a, c \in A \cup B$, we say that c is an *ancestor* of a iff we can reach a from c by a finite (nonzero) number of applications of the functions f and/or g. Now we can define a bijection $h : A \to B$ which applies either f or g^{-1}

according to whether a point has an odd number of ancestors or not:

$$h(a) = \begin{cases} g^{-1}(a) & \text{if } a \text{ has an odd number of ancestors,} \\ f(a) & \text{if } a \text{ has an even or infinite number of ancestors.} \end{cases} \quad \square$$

The feasible version of the Schröder–Bernstein theorem is as follows.

THEOREM 2.4 ([BH77]). *Let $f : A \leq_{\mathrm{m}} B$ and $g : B \leq_{\mathrm{m}} A$, where f and g are* 1:1*, length-increasing functions. Assume that $f, f^{-1}, g, g^{-1} \in \mathrm{FP}$, where f^{-1} and g^{-1} are the inverses of f and g. Then $A \overset{\mathrm{p}}{\cong} B$.*

Proof. Let the ancestor chain of a string w be the path from w to w's parent, to w's grandparent, and so on. Ancestor chains are at most linear in length because f and g are length-increasing. Thus they can be computed in polynomial time. The theorem now follows as in the proof of Theorem 2.3. $\square$

Consider the following definition.

DEFINITION 2.5 ([BH77]). *We say that the language $A \subseteq \Sigma^*$ has* p-time padding functions *iff there exist $e, d \in \mathrm{FP}$ such that the following hold:*

1. *For all $w, x \in \Sigma^*$, $w \in A \Leftrightarrow e(w, x) \in A$.*
2. *For all $w, x \in \Sigma^*$, $d(e(w, x)) = x$.*
3. *For all $w, x \in \Sigma^*$, $|e(w, x)| \geq |w| + |x|$.*

As a simple example, the following is a padding function for SAT:

$$e(w, x) = (w) \wedge c_1 \wedge c_2 \wedge \cdots \wedge c_{|x|},$$

where c_i is $(y \vee \bar{y})$ if the ith bit of x is 1 and $(\bar{y} \vee y)$ otherwise, where y is a Boolean variable numbered higher than all of the Boolean variables occurring in w.

Then the following theorem follows from Theorem 2.4.

THEOREM 2.6 ([BH77]). *If A and B are* NP*-complete and have* p*-time padding functions, then $A \overset{\mathrm{p}}{\cong} B$.*

Finally, Observation 2.2 now follows from the following.

OBSERVATION 2.7 ([BH77]). *All of the* NP*-complete problems in* [GJ] *have* p*-time padding functions.*

Hartmanis also extended the above work as follows: Say that A has *logspace padding functions* if there are logspace-computable functions as in Definition 2.5.

THEOREM 2.8 ([Har]). *If A and B are* NP*-complete via logspace reductions and have logspace padding functions, then A and B are logspace isomorphic.*

Proof. Since A and B have logspace padding functions, we can create functions f and g as in Theorem 2.4 that are length-squaring and computable in logspace. Then the whole ancestor chain can be computed in logspace because each successive iteration requires half of the previous space. $\square$

Here we show that sets complete under a very restrictive notion of reducibility are isomorphic under a very restricted class of isomorphisms. This result is incomparable to a recent result of [AB], which showed that all sets complete under one-way logspace reductions (1-L reductions) are isomorphic under polynomial-time-computable-isomorphisms. (This work of [AB] improves an earlier result of [A88].) Note that it is easy to prove that the class of 1-L reductions is incomparable with the class of first-order projections. Other interesting results concerning 1-L reductions may be found in [BH90, HH].

3. Descriptive complexity. In this section, we recall the notation of descriptive complexity, which we will need to state and prove our main results. See [I89] for a

survey and [IL] for an extensive discussion of the reductions we use here, including first-order projections.

We will code all inputs as finite logical structures. The most basic example is a binary string w of length $n = |w|$. We will represent w as a logical structure:

$$\mathcal{A}(w) = \langle \{0, 1, \ldots, n-1\}, R \rangle,$$

where the unary relation $R(x)$ holds in $\mathcal{A}(w)$ (in symbols, $\mathcal{A}(w) \models R(x)$) just if bit x of w is a 1). As is customary, the notation $|\mathcal{A}|$ will be used to denote the universe $\{0, 1, \ldots, n-1\}$ of the structure $\mathcal{A}$. We will write $\|\mathcal{A}\|$ to denote n, the cardinality of $|\mathcal{A}|$.

A *vocabulary* $\tau = \langle R_1^{a_1} \ldots R_r^{a_r}, c_1, \ldots, c_s \rangle$ is a tuple of an input relation and constant symbols. We call the R_i's "input relations" because they correspond to the input bits to a Boolean circuit. In the case of binary strings, the input relation tells us which bits are 0 and which are 1. In the case of graphs, the input relation E tells us which edges are present.

Let STRUC$[\tau]$ denote the set of all finite structures of vocabulary τ. We define a complexity-theoretic *problem* to be any subset of STRUC$[\tau]$ for some τ.

For any vocabulary τ, there is a corresponding first-order language $\mathcal{L}(\tau)$ built up from the symbols of τ and the numeric relation symbols and constant symbols:[2] $=$, $\leq$, BIT, 0, $\mathbf{m}$, using logical connectives: $\wedge, \vee, \neg$, variables: $x, y, z, \ldots$, and quantifiers: $\forall$, $\exists$.

3.1. First-order interpretations and projections. In [Val], Valiant defined the *projection,* an extremely low-level many–one reduction.

DEFINITION 3.1. *Let $S, T \subseteq \{0,1\}^\star$. A k-ary* projection *from S to T is a sequence of maps $\{p_n\}$, $n = 1, 2, \ldots$, that satisfy the following properties. First, for all n and for all binary strings s of length n, $p_n(s)$ is a binary string of length n^k and*

$$s \in S \quad \Leftrightarrow \quad p_n(s) \in T.$$

Second, let $s = s_0 s_1 \ldots s_{n-1}$. Then each map p_n is defined by a sequence of n^k literals $\langle l_0, l_1, \ldots, l_{n^k-1} \rangle$, where

$$l_i \in \{0, 1\} \cup \{s_j, \bar{s}_j \mid 0 \leq j \leq n-1\}.$$

Thus as s ranges over strings of length n, each bit of $p_n(s)$ depends on at most one bit of s:

$$p_n(s)[[i]] = l_i(s).$$

Projections were originally defined as a nonuniform sequence of reductions—one for each value of n. That is, a projection can be viewed as a many–one reduction produced by a family $\{C_n\}$ of circuits of depth one. The circuits consist entirely of wires connecting input bits or negated input bits to outputs. If the circuit family $\{C_n\}$ is sufficiently *uniform*, we arrive at the class of *first-order projections.* (Recall that first-order corresponds to uniform AC^0 [BIS].) We find it useful to work in the

[2] Here $\leq$ refers to the usual ordering on $\{0, \ldots, n-1\}$, "BIT(i, j)" means that the ith bit of the binary representation of j is 1, and 0 and $\mathbf{m}$ refer to 0 and $n-1$, respectively. For simplicity, we will assume throughout that $n > 1$ and thus $0 \neq \mathbf{m}$. These relations are called "numeric" as opposed to the input relations because, for example, "BIT(i, j)" and "$i \leq j$" depend only on the numeric values of i and j and do not refer to the input.

framework of first-order logic rather than in the circuit model. The rest of this section presents the necessary definitions of first-order reductions.

The idea of the definition is that the choice of the literals $\langle l_0, l_1, \ldots, l_{n^k-1}\rangle$ in Definition 3.1 is given by a first-order formula in which no input relation occurs. Thus the formula can only talk about bit positions and not bit values. The choice of literals depends only on n. In order to make this definition, we must first define first-order interpretations. These are a standard notion from logic for translating one theory into another (cf. [End]), modified so that the transformation is also a many–one reduction [I87]. (For readers familiar with databases, a first-order interpretation is exactly a many–one reduction that is definable as a first-order query.)

DEFINITION 3.2 (first-order interpretations). *Let σ and τ be two vocabularies, with $\tau = \langle R_1^{a_1}, \ldots, R_r^{a_r}, c_1, \ldots, c_s\rangle$. Let $S \subseteq \mathrm{STRUC}[\sigma]$ and $T \subseteq \mathrm{STRUC}[\tau]$ be two problems. Let k be a positive integer. Suppose we are given an r-tuple of formulas $\varphi_i \in \mathcal{L}(\sigma)$, $i = 1, \ldots, r$, where the free variables of φ_i are a subset of $\{x_1, \ldots, x_{k\cdot a_i}\}$. Finally, suppose we are given an s-tuple of constant symbols[3] $t_1, \ldots, t_s$ from $\mathcal{L}(\sigma)$. Let $I = \lambda_{x_1 \ldots x_d}\langle \varphi_1, \ldots, \varphi_r, t_1, \ldots, t_s\rangle$ be a tuple of these formulas and constants. (Here $d = \max_i(ka_i)$.)*

Then I induces a mapping also called I from $\mathrm{STRUC}[\sigma]$ to $\mathrm{STRUC}[\tau]$ as follows. Let $\mathcal{A} \in \mathrm{STRUC}[\sigma]$ be any structure of vocabulary σ, and let $n = ||\mathcal{A}||$. Then the structure $I(\mathcal{A})$ is defined to be

$$I(\mathcal{A}) \;=\; \langle \{0, \ldots, n^k - 1\}, R_1, \ldots, R_r, t_1, \ldots, t_s\rangle,$$

where the relation R_i is determined by the formula φ_i for $i = 1, \ldots, r$ as follows. Let the function $\langle \cdot, \cdots, \cdot\rangle : |\mathcal{A}|^k \to |I(\mathcal{A})|$ be given by

$$\langle u_1, u_2, \ldots, u_k\rangle \;=\; u_k + u_{k-1}n + \cdots + u_1 n^{k-1}.$$

Then

$$R_i \;=\; \big\{(\langle u_1, \ldots, u_k\rangle, \ldots, \langle u_{1+k(a_i-1)}, \ldots, u_{ka_i}\rangle) \;\big|\; \mathcal{A} \models \varphi_i(u_1, \ldots, u_{ka_i})\big\}.$$

If the structure $\mathcal{A}$ interprets some variables $\bar{u}$, then these may appear freely in the the φ_i's and t_j's of I, and the definition of $I(\mathcal{A})$ still makes sense.

Suppose that I is a many–one reduction from S to T, i.e., for all $\mathcal{A}$ in $\mathrm{STRUC}[\sigma]$,

$$\mathcal{A} \in S \quad \Leftrightarrow \quad I(\mathcal{A}) \in T$$

Then we say that I is a k-ary first-order interpretation *of S to T.*

We are now ready to define first-order projections, a syntactic restriction of first-order interpretations. If each formula in the first-order interpretation I satisfies this syntactic condition, then it follows that I is also a projection in the sense of Valiant. In this case, we call I a first-order projection.

DEFINITION 3.3 (first-order projections). *Let $I = \langle \varphi_1, \ldots, \varphi_r, t_1, \ldots, t_s\rangle$ be a k-ary first-order interpretation from S to T as in Definition* 3.2. *Suppose further that the φ_i's all satisfy the following* projection condition:

$$\varphi_i \equiv \alpha_1 \vee (\alpha_2 \wedge \lambda_2) \vee \cdots \vee (\alpha_e \wedge \lambda_e), \tag{3.1}$$

[3] More generally, we could use closed terms, which are expressions involving constants and function symbols. An even more general way to interpret constants and functions is via a formula φ such that $\vdash (\forall \bar{x})(\exists! y)\varphi(\bar{x}, y)$. However, in this paper, the simpler definition involving constant symbols suffices.

where the α_j's are mutually exclusive formulas in which no input relations occur and where each λ_j is a literal, i.e., an atomic formula $P(x_{j_1}, \ldots, x_{j_a})$ or its negation.

In this case, the predicate $R_i(\langle u_1, \ldots, u_k\rangle, \ldots, \langle \ldots, u_{ka_i}\rangle)$ holds in $I(\mathcal{A})$ if $\alpha_1(\bar{u})$ is true, or if $\alpha_j(\bar{u})$ is true for some $1 < j \leq e$ and the corresponding literal $\lambda_j(\bar{u})$ holds in $\mathcal{A}$. Thus each bit in the binary representation of $I(\mathcal{A})$ is determined by at most one bit in the binary representation of $\mathcal{A}$. We say that I is a first-order projection. *We write rite $S \leq_{\text{fop}} T$ to mean that S is reducible to T via a first-order projection.*

Example 3.4. To help the reader grasp an intuition of the way an fop reduction behaves, let us describe an example. We present here the reduction from 3-SAT, satisfiability of CNF Boolean expressions with exactly three literals per clause, to 3-COL, the problem of coloring the vertices of a graph with three colors under the constraint that the endpoints of all edges get different colors. We use the same reduction as described in [Man, section 11.4.5] so that the reader in need of additional help can consult it there.

The respective vocabularies for the input and output structures are as follows. To describe instances of 3-SAT, clauses and Boolean variables are each numbered from 0 through $n-1$. There are six predicates: $P_i(x,c), N_i(x,c)$, $i = 1,2,3$, indicating that variable x occurs positively or negatively in the ith position of the clause c. The vocabulary for the output structures is simply a binary predicate E that stands for the Boolean adjacency matrix of the output graph. Thus $E(u,v)$ is true exactly when the edge (u,v) is present in the output graph.

The output graph consists of six vertices per clause and two vertices per Boolean variable, plus three additional vertices usually named T, F, and R (standing for true, false, and red). Let an arbitrary 3CNF formula be coded by an input structure,

$$\mathcal{A} = \langle \{0, 1, \ldots, n-1\}, P_1, P_2, P_3, N_1, N_2, N_3 \rangle.$$

The output structure will be a graph with $8n + 3$ relevant vertices. The easiest way for us to code this is to use an fop of arity 2. We will assume for simplicity that n is always greater than or equal to 9.

$$I(\mathcal{A}) \;=\; \langle \{\langle a, b\rangle \,:\, 0 \leq a, b < n\}, E\rangle \;=\; \langle \{0, \ldots, n^2 - 1\}, E\rangle,$$

where

$$E \;=\; \big\{(\langle x_1, x_2\rangle, \langle y_1, y_2\rangle) \;\big|\; \mathcal{A} \models \varphi(x_1, x_2, y_1, y_2)\big\}.$$

It remains to write down the first-order projection, φ. To do this, we need some nitty gritty coding. We will let the vertices T, F, and R be the elements $\langle 0,0\rangle, \langle 1,0\rangle$, and $\langle 2,0\rangle$ of $I(\mathcal{A})$, respectively. The formula φ will have three pieces:

$$\begin{aligned}\varphi(x_1, x_2, y_1, y_2) \;=\; \alpha(x_1, x_2, y_1, y_2) \vee \beta(x_1, x_2, y_1, y_2) \;\vee\; \beta(y_1, y_2, x_1, x_2) \\ \vee\, \gamma(x_1, x_2, y_1, y_2) \;\vee\; \gamma(y_1, y_2, x_1, x_2),\end{aligned}$$

where α says that there are edges between T, F, and R; β says that vertices $\langle x, 1\rangle$ and $\langle x, 2\rangle$ representing the variable x and its negation are connected to each other and to R; and γ says that for clause $C = (a \vee b \vee d)$, vertices $\langle C, 6\rangle, \langle C, 7\rangle$, and $\langle C, 8\rangle$ are connected to each other, and the following edges exist: $(\langle C, 3\rangle, \langle C, 6\rangle)$, $(\langle C, 4\rangle, \langle C, 7\rangle)$, $(\langle C, 5\rangle, \langle C, 8\rangle)$, as well as the edges $(a, \langle C, 3\rangle), (T, \langle C, 3\rangle), (b, \langle C, 4\rangle), (T, \langle C, 4\rangle)$, and $(d, \langle C, 5\rangle), (T, \langle C, 5\rangle)$.

In case anyone really wants to see them, here are the formulas written out:

$$\alpha(x_1,x_2,y_1,y_2) \equiv (x_2 = y_2 = 0) \wedge (x_1 \neq y_1) \wedge (x_1 \leq 2) \wedge (y_1 \leq 2),$$
$$\beta(x_1,x_2,y_1,y_2) \equiv (x_2 = 1 \wedge y_2 = 2 \wedge x_1 = y_1) \vee (x_1 = 2 \wedge x_2 = 0 \wedge (1 \leq y_2 \leq 2)),$$
$$\begin{aligned}\gamma(x_1,x_2,y_1,y_2) \equiv\ & (x_1 = x_2 = 0 \wedge (3 \leq y_1 \leq 5) \wedge (3 \leq y_2 \leq 5)\\ & \vee (x_1 = y_1 \wedge (3 \leq x_2 \leq 5) \wedge (y_2 = x_2 + 3))\\ & \vee [(x_2 = 1 \wedge y_2 = 3) \wedge P_1(x_1,y_1)] \vee [(x_2 = 2 \wedge y_2 = 3) \wedge N_1(x_1,y_1)]\\ & \vee [(x_2 = 1 \wedge y_2 = 4) \wedge P_2(x_1,y_1)] \vee [(x_2 = 2 \wedge y_2 = 4) \wedge N_2(x_1,y_1)]\\ & \vee [(x_2 = 1 \wedge y_2 = 5) \wedge P_3(x_1,y_1)] \vee [(x_2 = 2 \wedge y_2 = 5) \wedge N_3(x_1,y_1)]\\ & \vee (x_1 = y_1 \wedge x_2 \neq y_2 \wedge (6 \leq x_2 \leq 8) \wedge (6 \leq y_2 \leq 8)).\end{aligned}$$

4. Main theorem and proof.

THEOREM 4.1. *Let $\mathcal{C}$ be a nice complexity class, e.g.,* L, NL, P, NP, *etc. Let S and T be complete for $\mathcal{C}$ via first-order projections. Then S and T are isomorphic via a first-order isomorphism.*

To prove Theorem 4.1, we begin with the following lemma. Note the similarity between Lemma 4.2 and the proofs of Theorems 2.4 and 2.8. For simplicity, in this lemma we are assuming that I is a single fop that maps STRUC$[\sigma]$ to itself. The proof for the case with two fops and two vocabularies as in Lemma 4.3 is similar.

LEMMA 4.2. *Let I be an fop that is* 1:1 *and of arity greater than or equal to* 2 *(i.e., it at least squares the size). Then the following two predicates are first-order expressible concerning a structure $\mathcal{A}$:*

a. IE($\mathcal{A}$), *which means that $I^{-1}(\mathcal{A})$ exists*;

b. *#Ancestors*($\mathcal{A}, r$), *which means that the length of $\mathcal{A}$'s maximal ancestor chain is r.*

Proof. Let $I = \lambda_{x_1 \ldots x_d}\langle \varphi_1, \ldots, \varphi_r, t_1, \ldots, t_s\rangle$, where each φ_i is in the form of equation (3.1). To prove a, just observe that each bit of the relation R_i of $\mathcal{A}$ either (1) depends on exactly one bit of some preimage $\mathcal{B}$ (specified by an occurrence of a literal λ_{ij} in φ_i) or (2) does not depend on any bit of a preimage. In case (2), a given bit of $\mathcal{A}$ is either "right" or "wrong." Thus $\mathcal{A}$ has an inverse iff no bit of $\mathcal{A}$ is wrong, and no pair of bits from $\mathcal{A}$ are determined by the same bit of $\mathcal{A}$'s preimage in conflicting ways. We can check this in a first-order way by checking that for all pairs of bits from $\mathcal{A}$, $R_i(\bar{a})$ and $R_{i'}(\bar{b})$, either they do not depend on the same bit from $\mathcal{B}$, or the same value of that bit gives the correct answer for $R_i(\bar{a})$ and $R_{i'}(\bar{b})$. Furthermore, the preimage $\mathcal{B}$ if it exists can be described uniquely by a first-order formula that chooses the correct bits determined by entries of $\mathcal{A}$. *N.B.* Since we have assumed that I is 1:1, every bit of $I^{-1}(\mathcal{A})$ is determined by some bit of $\mathcal{A}$.

b. To express *#Ancestors*($\mathcal{A}, r$), we want to describe the existence of an ancestor chain:

$$\mathcal{A}_r \xrightarrow{I} \mathcal{A}_{r-1} \xrightarrow{I} \cdots \xrightarrow{I} \mathcal{A}_1 \xrightarrow{I} \mathcal{A}_0 = \mathcal{A}. \tag{4.1}$$

We will then assert that this is the maximal-length such chain, i.e.,

$$\neg\mathrm{IE}(\mathcal{A}_r) \wedge (\forall k < r)\mathrm{IE}(\mathcal{A}_k) \tag{4.2}$$

Equation (4.2) expresses the existence of the ancestor chain (4.1) inductively in the following sense. Once we know that $\mathcal{A}_k$ exists, we can ascertain the value $\mathcal{A}_k[[p_k]]$ of the bit at position p_k of $\mathcal{A}_k$ by exhibiting a certificate:

$$C(k,p_k) = \langle(\mathcal{A}_k[[p_k]],p_k),(\mathcal{A}_{k-1}[[p_{k-1}]],p_{k-1}),\ldots,(\mathcal{A}_0[[p_0]],p_0)\rangle.$$

We can say in a first-order sentence that $C(k, p_k)$ is internally consistent. That is, for all i with $k > i \geq 0$, bit p_{i+1} of $\mathcal{A}_{i+1}$ is determined correctly via I by bit p_i of $\mathcal{A}_i$.[4] Note that because each structure $\mathcal{A}_{i+1}$ is of size at most the square root of the size of $\mathcal{A}_i$, the certificate requires only $O(\log n)$ bits, i.e., a constant number of variables, to express.

Thus in equation (4.2), we refer to bit p_k of the structure $\mathcal{A}_k$ by existentially quantifying an internally consistent certificate $C(k, p_k)$. We know inductively that since $\mathrm{IE}(\mathcal{A}_{k-1})$, the bit value determined by $C(k, p_k)$ is unique and correct. □

LEMMA 4.3. *If S and T are interreducible via* 1:1 *fops I and J each of arity at least* 2*, then S and T are isomorphic via first-order isomorphisms.*

Proof. Let $\mathcal{A}$ be a structure in the vocabulary of S, and, as in the proof of Theorem 2.3, define the length of the ancestor chain of $\mathcal{A}$ to be the length of the longest sequence of the form $J^{-1}(\mathcal{A})$, $I^{-1}(J^{-1}(\mathcal{A}))$, $J^{-1}(I^{-1}(J^{-1}(\mathcal{A}))), \ldots$. The argument given in Lemma 4.2 shows that there is a formula $\#Ancestors(\mathcal{A}, r)$ that evaluates to true iff $\mathcal{A}$'s ancestor chain has length r. Lemma 4.2 also shows that there is a formula computing J^{-1}. The desired isomorphism is now the function b such that the ith bit of $b(\mathcal{A})$ is 1 iff the following first-order formula is true:

$$(\exists r)\left(\#Ancestors(\mathcal{A}, r) \wedge (\mathrm{BIT}(0, r) \wedge I(i)) \vee (\neg \mathrm{BIT}(0, r) \wedge J^{-1}(i))\right)$$

(Note that this first-order isomorphism b is not, strictly speaking, a first-order interpretation since it maps some inputs to strictly shorter outputs, which is impossible for an interpretation.) □

It now remains to show the following.

LEMMA 4.4. *Suppose that a problem S is complete via fops for a nice complexity class $\mathcal{C}$. Then S is complete for $\mathcal{C}$ via fops that are* 1:1 *and of arity at least* 2.

Proof. Of course, it remains to define "nice," but here is the proof. Every nice complexity class has a universal complete problem:

$$U_{\mathcal{C}} = \left\{M\$w\#^r \;\middle|\; M(w)\downarrow \text{ using resources } f_{\mathcal{C}}(r)\right\}. \tag{4.3}$$

Here $f_{\mathcal{C}}(r)$ defines the appropriate complexity measure, e.g., r nondeterministic steps for NP, deterministic space $\log r$ for L, space 2^r for EXPSPACE, etc.

We claim that $U_{\mathcal{C}}$ is complete for $\mathcal{C}$ via fops that are 1:1 and of arity at least 2. In order to make this claim, we need to agree on an encoding of inputs to $U_{\mathcal{C}}$ that allows us to interpret them as structures over some vocabulary. Since all of our structures are encoded in binary, we will encode \$ and # by 10 and 11, respectively, and the binary bits 0 and 1 constituting M and w will be encoded by 00 and 01, respectively. Now, as in, for example, [I87], we consider a binary string of length n to be a structure with a single unary predicate over a universe of size n. Now for any given problem $T \in \mathcal{C}$ accepted by machine M, we show that T is reducible to $U_{\mathcal{C}}$ via a fop that is 1:1 and of arity at least 2. The fop simply maps input w to the string $M\$w\#^r$, for an appropriate r which we can always take to be at least $|w|^2$. The fop checks that if $i \leq 2|M|$, then the odd-numbered bits are 0 and if i is even, then the ith bit is 1 iff the $i/2$nd bit of M is 1. Similarly, if $2|M| + 2 < i \leq 2(|M| + |w| + 1)$, then the odd-numbered bits are 0 and the even numbered bits are the corresponding bit of w, etc.

[4] The reader who is more familiar with bit hacking on Turing machines than with first-order formulas could instead convince herself that this can be done by an alternating Turing machine running in logarithmic time and making $O(1)$ alternations; first-order expressibility follows by [BIS].

To complete the proof of the lemma, let T be any problem in $\mathcal{C}$ and let S be as above. Then we reduce T to S via a 1:1 length-squaring fop as follows. First, reduce T to $U_{\mathcal{C}}$ as above. Next, reduce $U_{\mathcal{C}}$ to S via the fop promised in the statement of the lemma.

It is easy to verify that, using the encoding that we have chosen for $U_{\mathcal{C}}$, it holds that for every length n, for all $i \leq n$, there are two strings x and y of length n, differing only in position i, such that $x \in U_{\mathcal{C}}$ and $y \notin U_{\mathcal{C}}$.

Thus the fop from $U_{\mathcal{C}}$ cannot possibly ignore any of the bits in its input. However, an fop cannot process several bits into one; it can only either ignore a bit or copy it, or negate it, and this choice is made independently of the values of any of the bits.

It follows that the composition of these two fops is the 1:1 length-squaring fop that we desire. (Note that an fop by definition must have arity at least 1 and thus cannot be length-decreasing on Boolean strings.) □

From the above three lemmas, we have a first-order version of Theorem 2.3, and thus Theorem 4.1 follows.

We can inspect the proof of Lemma 4.4 to get a definition of "nice." A complexity class is "nice" if it has a universal complete problem via fops as in equation (4.3). It is easy to check that the following complexity classes, among many others, are nice and thus meet the conditions of Theorem 4.1.

PROPOSITION 4.5. *The following complexity classes are nice:* NC^1, L, NL, LOG(CFL), NC^2, P, NP, PSPACE, EXPTIME, and EXPSPACE.

Proof. This is immediate for the Turing-machine-based classes: L, NL, P, NP, PSPACE, EXPTIME, and EXPSPACE. It similarly follows for the other three classes using the definitions $\mathrm{NC}^i = \mathrm{ASPACE}[\log n] - \mathrm{TIME}[(\log n)^i]$ and $\mathrm{LOG(CFL)} = \mathrm{ASPACE}[\log n] - \forall\mathrm{TIME}[\log n]$. □

5. More on the relationship between isomorphisms and projections. There are several questions about isomorphisms among complete sets that can be answered in the setting of first-order computation but are open for general polynomial-time computation. It is not known whether one-way functions exist since their existence would imply that P $\neq$ NP. However, if one-way functions exist (i.e., if P $\neq$ UP), then there exists a one-way function f such that f(SAT) is polynomial-time isomorphic to SAT [Ga].

Here we can be more definitive: the bijection $f(x) = 3x \pmod{2^{|x|}}$ was shown in [BL] to be one-way for first-order computation, in the sense that f is first-order expressible but f^{-1} is not. (See also [Hås] for other examples.) However, it is not too hard to show that for this choice of f, f(SAT) is complete for NP under first-order projections, and thus it is first-order isomorphic to SAT.

The next result shows that the class of sets that are complete under first-order projections is not closed under first-order isomorphisms. (This also seems to be the first construction of a set that is complete for NP under first-order (or even poly-time) many–one reductions that is not complete under first-order projections.)

THEOREM 5.1. *There is a set first-order isomorphic to* SAT *that is not complete for* NP *under first-order projections.*

Proof. Let $g(x)$ be a string of $|x|^2$ bits, with bit $x_{i,j}$ representing the logical AND of bits i and j of x. Let $A = \{\langle x, g(x)\rangle : x \in \mathrm{SAT}\}$. By an extension of the techniques used in proving Theorem 4.1, it can be shown that A is first-order isomorphic to SAT. However, a direct argument shows that there cannot be any projection (even a nonuniform projection) from SAT to A. (*Sketch*: For all n, one can find bit positions i and j that are independent of each other and independent of every other bit position,

in the sense that for any setting b of bit j, there are two words that differ only in bit i, having b in position j, such that one of the words is in SAT and one is not. No projection reducing SAT to another language can "ignore" either i or j. However, since i and j are independent of all other bit positions, no projection can encode the AND of bits i and j.) □

A natural question that remains open is the question of whether every set that is complete for NP under first-order many–one reductions is first-order isomorphic to SAT. A related question is whether one can construct a set that is complete for NP under poly-time many–one reductions that is not first-order isomorphic to SAT. Since so many tools are available for proving the limitations of first-order computation, we are optimistic that this and related questions about sets that are complete under first-order reductions should be tractable.[5] Furthermore, we hope that insights gleaned in answering these questions will be useful in guiding investigations of the polynomial-time degrees.

GENERAL TECHNIQUES FOR ANALYZING RECURSIVE ALGORITHMS WITH APPLICATIONS*

RAKESH M. VERMA†

Abstract. The complexity of divide-and-conquer algorithms is often described by recurrences of various forms. In this paper, we develop general techniques and master theorems for solving several kinds of recurrences, and we give several applications of our results. In particular, almost all of the earlier work on solving the recurrences considered here is subsumed by our work. In the process of solving such recurrences, we establish interesting connections between some elegant mathematics and analysis of recurrences. Using our results and improved bipartite matching algorithms, we also improve existing bounds in the literature for several problems, viz, associative-commutative (AC) matching of linear terms, associative matching of linear terms, rooted subtree isomorphism, and rooted subgraph homeomorphism for trees.

Key words. analysis of algorithms, divide-and-conquer, recurrences, problem complexity, subtree isomorphism, associative-commutative (AC) matching, graph algorithms

1. Introduction.

This paper investigates recurrences that arise frequently in the analysis of divide-and-conquer algorithms. Divide-and-conquer is an important and useful technique in the design of efficient sequential and parallel algorithms with innumerable applications. For example, much of the book by Aho et al. [1] consists of divide-and-conquer algorithms. The recurrences considered here are of three basic forms (with appropriate initial conditions):

$$T(n,m) = \sum_{i=1}^{k}\sum_{j=1}^{l} T(n_i, m_j) + h(k,l), \tag{1}$$

$$T(n,m) = \sum_{i=1}^{k}\sum_{j=1}^{l} T(n_i, m_j) + h(n,m), \tag{2}$$

$$T(n) = \sum_{i=1}^{k} a_i T(n/c_i) + f(n), \quad k \geq 2. \tag{3}$$

Our choice of the forms and dimensions (a recurrence in k variables, integer $k > 0$, will be called *k-dimensional*) in this paper is motivated by both the applications and the desire to minimize redundancy. If necessary, our results can be extended from the one-dimensional case to the two-dimensional case, or specialized in the opposite direction, for recurrences of the same form. In an earlier paper [22], we considered the recurrence $T(n) = aT(n/c)+f(n)$ and proved a general theorem on its analysis. These recurrences typically arise in connection with recursive algorithms described as follows: "To process an input of size n (or (n,m), etc.), spend an amount of computational effort $f(n)$ (or $h(n,m)$, etc.) and recursively solve derived instances of the same pro-

† Department of Computer Science, University of Houston, Houston, TX 77004 (rmverma@cs.uh.edu).

blem having size $c(n)$ (or n/c_i, (n_i, m_j), etc.)." Such recurrences also arise in other situations, e.g., as deterministic counterparts of probabilistic recurrences.

Earlier systematic efforts on solving recurrences have emphasized linear one-dimensional recurrences. Methods developed for them include differential-equation methods, operator methods, the generating-function approach, etc. Some effort has been given to nonlinear recurrences, but here the path is full of difficulties (see [11, 14] for a detailed discussion on linear and some nonlinear recurrences). Recently, some pioneering work has been done by Karp [15] on probabilistic recurrences. Much of this work, however, is difficult to apply to the recurrences considered here.[1] Earlier work known to us that has a direct bearing on our investigations in this and the earlier paper is as follows: a theorem on divide-and-conquer with equal parts (see [1, 3, 5] and [7, p. 62]) and the two theorems given below.

Let $G = (V_1, V_2, E)$ be a bipartite graph with $r = |V_1|$, $s = |V_2|$, and $r \leq s$. Let p and q be the two trees for rooted subtree isomorphism with sizes n and m, $n \leq m$ (p is to be mapped into q). In 1977 Reyner claimed and in 1988 Verma and Reyner [21, 25] proved the following.

THEOREM 1.1 ([25]). *Given an algorithm for bipartite matching that requires at most $O(rs^u)$ operations, where $u > 1$, the subtree algorithm requires at most $O(nm^u)$ operations.*

THEOREM 1.2 ([20]). *Given an algorithm for bipartite matching that requires at most $O(rs)$ operations, the subtree algorithm will require at most $O(nm \ln n)$ operations.*

In this paper, we present some techniques and several "master theorems" that can be used to obtain fairly tight upper bounds on the functions $T(n)$ and $T(n, m)$ of the above recurrences. In the process, we establish connections between some elegant mathematics (viz, theory of convex functions and inequalities) and analysis of recurrences, which appears to have been missed so far. An immediate motivation for analyzing these recurrences must also be mentioned. With progress in computer science, the computational expenditure f keeps decreasing, which forces us to reconsider the analysis and rederive the bounds on $T(n)$. For example, the complexity of bipartite matching was improved from $O(rs^{1.5})$ (see Hopcroft and Karp [13]) to $O((r+s)^{1.5}\sqrt{rs/\log s})$ in 1990 by Alt et al. [2] and further to $O(rs^{1.5}/\log s)$ in 1991 by Feder and Motwani [8] ($r \leq s$ are the sizes of the two vertex sets). Since these new bounds do not satisfy the hypotheses of Theorems 1.1 and 1.2, one is forced to reanalyze the rooted subtree isomorphism algorithms from scratch. This rework can be avoided if we can prove powerful theorems that can be applied to large classes of functions representing the computational expenditure for dividing the problem and merging the solutions.

1.1. Overview of our approach and results. To enhance the applicability of our results, we extract the salient features of a variety of situations as follows. We consider a homogeneous collection $\mathcal{C}$ of finite data structures partially ordered by inclusion and for which a suitable *size* function has been defined (see section 3). We then consider divide-and-conquer algorithms of a very general form with inputs from $\mathcal{C}$ in two kinds of situations. The first is the more general one in which the sizes of the

[1] Recurrence (3) can be transformed into a linear, nonhomogeneous, k-dimensional, $k \geq 1$, recurrence by the substitution $U(n_1, n_2, \ldots, n_k) = T(c_1^{n_1} \ldots c_k^{n_k})$. However, there are two problems in applying existing work to the resulting recurrence: nonhomogeneity and dimensions. Techniques are scarce and hard to apply for $k > 2$, and for $k \leq 2$ complicated summations must still be evaluated to obtain solutions by existing methods (see [14, 19]). This approach cannot be applied to recurrences (1) and (2).

derived problem instances may depend not just on the size of the original instance but on the instance itself, e.g., $T(n,m) = \sum\sum T(n_i, m_j) + h(k,l)$. In the second, the dependence is only on the size of the original instance and takes a certain known form, e.g., $T(n) = \sum a_i T(n/c_i) + f(n)$. We then prove the following general results.

Recurrence (1). Here we study the general situation in which the sizes of the derived instances depend on both the original instance and its size. In such situations, we assume that the *sum* of the sizes of the derived instances is less than the size of the original instance, which holds in a number of practical examples. We extend the definition of additivity (see section 2) (called superadditivity in the mathematics literature) of a univariate function to multivariate functions in a natural way. Then, under fairly weak assumptions, we obtain upper bounds for T when (i) h is biadditive, (ii) h is additive in one argument only, say the first, and there is a function f such that $h(\_, f(\_))$ is biadditive, (iii) h is additive in neither argument but there are f and g such that $h(f(\_), g(\_))$ is biadditive, and (iv) h is a continuous pseudoconvex function (section 3).

Recurrence (2). As in the previous paragraph, this is the general situation and we make the same assumption on the sum of the sizes of the derived instances. Then, under weak assumptions, we obtain upper bounds for T when h is biadditive and when h is continuous and pseudoconvex.

Recurrence (3). For simplicity and rigor, we consider recurrences over a real variable x instead of an integer variable n. We identify two crucial properties of a function, which we call g-star-shaped (this extends the definition of a star-shaped function in the mathematics literature) and g-co-star-shaped, and then prove master theorems, using the powerful principle of noetherian induction, under a variety of hypotheses (see section 5).

Our proofs make use of the basic properties of convex, pseudoconvex, and biadditive functions. These are included in section 2.1. We also give some conditions which imply that a function is biadditive, pseudoconvex, or convex, which we use in applying our results. These are (mostly) known and are included in section 4 to make the paper self-contained and to demonstrate the richness of these classes of functions.

Applications. In section 6, we present some of the applications of our theorems. Specifically, in the two-dimensional case, we prove that all three problems, rooted subtree isomorphism, associative-commutative (AC) matching of linear terms, and rooted subgraph homeomorphism on trees, have tight upper bounds of $O(nm^{1.5}/\log m)$. Our approach unifies the analysis of these problems and improves the existing upper bounds (given by Verma and Reyner [25], Verma and Ramakrishnan [24, 23], and Chung [6]) for these problems by a factor of $\log m$ in each case. In the process, we demonstrate the existence of a much tighter relationship between these three problems and bipartite matching than previously known. We also prove that all three problems above require time $O(nm)$ if there is a bipartite matching of time complexity $O(rs)$ and that associative matching of linear terms can be done in $O(nm)$ time. First, this improves by a factor of $\log n$ the existing upper bounds for (a) rooted subtree isomorphism (see Theorem 1.2 above) and (b) associative matching of linear terms, given by Verma and Ramakrishnan [24, 23]. Second, it implies that there are parallel algorithms for all three problems of time complexity $O(mn)$ using the parallel algorithms for bipartite matching [9, 10]. Finally, solutions of recurrences arising in [4] and [17] are corollaries of our theorems for the one-dimensional case.

Some implications of this work are as follows. First, much of the existing work on these recurrences, e.g., the popular theorem on analyzing divide-and-conquer algorithms with equal parts [1, 3, 5, 7, 14] (see Corollary 5.7) and the two theorems

given above, is subsumed by our results. Second, we establish interesting connections between some elegant mathematics and analysis of recursive algorithms. The power of our results means that considerable reworking may be avoided with future progress in computer science and upper bounds for new algorithms that fit our framework could be painlessly obtained. Finally, our work opens up an interesting area of research.

2. Preliminaries.

Notation. 1. All functions are defined on the nonnegative reals and take only nonnegative real values unless explicitly stated otherwise. 2. All variables p, q, x, and y and their subscripted versions take only nonnegative real values unless explicitly stated otherwise. Thus the phrase "for all x" means "for all nonnegative real values of x." 3. All variables m and n and their subscripted versions take only nonnegative integral values unless explicitly stated otherwise. 4. The restriction of a function f on the nonnegative reals to nonnegative integers is indicated by changing the arguments of f from real valued, e.g., x, to integer valued, e.g., n.

DEFINITION 2.1. *We say that a unary function f is* additive *iff $f(x) + f(y) \leq f(x+y)$ for all x and y. We say that a binary function h is* biadditive *iff $h(x_1, y) + h(x_2, y) \leq h(x_1 + x_2, y)$ and $h(x, y_1) + h(x, y_2) \leq h(x, y_1 + y_2)$ for all values of the arguments to h. Similarly, we say that a function is additive for $x > a$ if the additivity requirement is satisfied for all values of x greater than a. Analogously, we define biadditivity for $x > a$ and $y > b$.*

Remarks. An additive nonnegative function must be nondecreasing since by the additivity of f, $f(x_1) + f(x_2 - x_1) \leq f(x_2)$ for $x_1 \leq x_2$, which by the nonnegativity of f implies $f(x_1) \leq f(x_2)$ for $x_1 \leq x_2$. Similarly, a biadditive nonnegative function must be nondecreasing in x for each y and in y for each x. An easy induction shows that the biadditivity requirement on h implies that $\sum_{i=1}^{n} \sum_{j=1}^{m} h(a_i, b_j) \leq h(\sum_{i=1}^{n} a_i, \sum_{j=1}^{n} b_j)$.

DEFINITION 2.2. *A unary function f is* convex *iff $f((x+y)/2) \leq (f(x)+f(y))/2$ for all x and y. A binary function f on the nonnegative reals is* convex *iff $f((x_1 + x_2)/2, (y_1 + y_2)/2) \leq (f(x_1, y_1) + f(x_2, y_2))/2$ for all x_1, x_2, y_1, and y_2.* Notice that the definition of convexity for binary functions requires more than convexity in x and y separately. Functions that are convex in x for every y and in y for every x will be called pseudoconvex.

DEFINITION 2.3. *A binary function f is* pseudoconvex *iff $f((x_1 + x_2)/2, y) \leq (f(x_1, y) + f(x_2, y))/2$ for all x_1, x_2, and y and $f(x, (y_1 + y_2)/2) \leq (f(x, y_1) + f(x, y_2))/2$ for all x, y_1, and y_2.*

2.1. Properties of convex and pseudoconvex functions. We need some basic properties of convex and pseudoconvex functions to prove our theorems in the following sections.

LEMMA 2.4 ([12]). *Let f be a continuous convex function on the nonnegative reals. Then $f((px + qy)/(p + q)) \leq (pf(x) + qf(y))/(p + q)$.*

LEMMA 2.5. *Let f be a binary, continuous, pseudoconvex function on the nonnegative reals. We have the following:*

1. $f((px_1 + qx_2)/(p + q), y) \leq (pf(x_1, y) + qf(x_2, y))/(p + q)$.
2. $f(x, (py_1 + qy_2)/(p + q)) \leq (pf(x, y_1) + qf(x, y_2))/(p + q)$.
3. $f(x_1, y_1)+f(x_2, y_2) \leq f(x_1+x_2, y_1+y_2)+f(x_1+x_2, 0)+f(0, y_1+y_2)+f(0, 0)$.

$$\sum_{i=1}^{n} f(x_i, y_i) \leq f\left(\sum_{i=1}^{n} x_i, \sum_{i=1}^{n} y_i\right) + \sum_{j=1}^{n-1} \left(f\left(\sum_{i=1}^{j+1} x_i, 0\right) + f\left(0, \sum_{i=1}^{j+1} y_i\right)\right) + (n-1) f(0, 0).$$

4. $\sum_{i=1}^{n} f(x_i, y) \leq f(\sum_{i=1}^{n} x_i, y) + (n-1)f(0, y)$. *Similarly,* $\sum_{j=1}^{m} f(x, y_j) \leq f(x, \sum_{j=1}^{m} y_j) + (m-1)f(x, 0)$.

5. *Finally,* $\sum_{i=1}^{n} \sum_{j=1}^{m} f(x_i, y_j) \leq f(\sum_{i=1}^{n} x_i, \sum_{j=1}^{m} y_j) + (n-1)f(0, \sum_{j=1}^{m} y_j) + (m-1)f(\sum_{i=1}^{n} x_i, 0) + (m-1)(n-1)f(0, 0)$.

Proof.

1. For every y, we can apply Lemma 2.4 since f is convex in x for each y.

2. This is proved by the same reason as 1.

3. We first prove that $f(x_1, y) + f(x_2, y) \leq f(x_1 + x_2, y) + f(0, y)$, a very useful inequality. We will call this and the corresponding inequality in y the *addition inequalities* for pseudoconvex functions. Let $p = t_1$, $x_1 = t_1 + t_2$, $q = t_2$, and $x_2 = 0$ in property 1 of this lemma. Then

$$f(t_1, y) \leq t_1 f(t_1 + t_2, y)/(t_1 + t_2) + t_2 f(0, y)/(t_1 + t_2).$$

Now let $p = t_2$, $x_1 = 0$, $q = t_1$, and $x_2 = t_1 + t_2$. Then

$$f(t_2, y) \leq t_2 f(t_1 + t_2, y)/(t_1 + t_2) + t_1 f(0, y)/(t_1 + t_2)$$

Adding the two inequalities for f above, we have $f(t_1, y) + f(t_2, y) \leq f(t_1 + t_2, y) + f(0, y)$. Similarly, we have $f(x, t_1) + f(x, t_2) \leq f(x, t_1 + t_2) + f(x, 0)$. This proof of the addition inequalities is from [18].

Now we have $f(x_1, y_1) + f(x_2, y_1) \leq f(x_1 + x_2, y_1) + f(0, y_1)$. Since f is nonnegative, this implies $f(x_1, y_1) \leq f(x_1 + x_2, y_1) + f(0, y_1)$. Similarly, $f(x_2, y_2) \leq f(x_1 + x_2, y_2) + f(0, y_2)$. Adding the last two inequalities, we have $f(x_1, y_1) + f(x_2, y_2) \leq f(x_1 + x_2, y_1) + f(x_1 + x_2, y_2) + f(0, y_1) + f(0, y_2) \leq f(x_1 + x_2, y_1 + y_2) + f(x_1 + x_2, 0) + f(0, y_1 + y_2) + f(0, 0)$, which was what we wanted to prove.

For the generalization, use induction and the first part.

4. This is proved by induction on n using the addition inequalities.

5. This is proved by application of 4. □

3. Two-dimensional recurrences. Let $\mathcal{C}$ be any homogeneous class of finite data structures, partially ordered by inclusion. For example, $\mathcal{C}$ may be the class of all finite graphs partially ordered by the subgraph relation, or $\mathcal{C}$ may be the class of all finite rooted trees partially ordered by the subtree relation, etc. Further, let a *size* be defined for each member of $\mathcal{C}$ by a positive monotonic *size function* s.

DEFINITION 3.1. *$s : \mathcal{C} \to N$ is a size function if* (i) *$s(D) \geq 1$ for every $D \in \mathcal{C}$ and* (ii) *D included in E implies $s(D) \leq s(E)$ (the inequality being strict when the inclusion is proper).*

We wish to analyze the following type of recursive algorithms A, which return a yes/no answer represented by 1/0. The algorithm divides the input data structures D and E into n and m parts, respectively, where each part is also from the same class of data structures as D and E.

```
ALGORITHM A(D, E) /* D, E ∈ C. */
if s(D) ≤ threshold or s(E) ≤ threshold then /* threshold ≥ 2 is a constant. */
  B(D, E)
else
  begin
    for each pair (D_i, E_j), i ∈ [n], j ∈ [m] do A(D_i, E_j);
    /* The D_i's are included in D, and the E_j's are included in E. */
    Form an n × m matrix M with M_ij = A(D_i, E_j)
    return C(M)
  end
```

Let the time complexity of algorithm C be $O(h(n,m))$ when an $n \times m$ matrix is the input to C. We first consider the case where h is a biadditive function on the nonnegative reals. Suppose that $\sum_{i=1}^{n} s(D_i) \leq s(D) - 1$, $\sum_{j=1}^{m} s(E_j) \leq s(E) - 1$, and algorithm B takes a constant amount of time when the size of one of its inputs is at most a constant called *threshold*. Then we can show that the time complexity of algorithm A is $O(h(s(D), s(E)) + s(D)s(E))$.

Note that algorithm A needs the size of D, E, and their substructures on recursive calls. The determination of these sizes is the preprocessing cost of algorithm A. We will assume throughout this section that the preprocessing cost of the algorithm denoted T_{pre}, is bounded from above by the cost of the algorithm itself, denoted T, i.e., $T_{\text{pre}}(s(D), s(E)) \leq T(s(D), s(E))$, which holds in all of the applications that we discuss in this paper. Thus the total cost $T_{\text{pre}} + T \leq 2T$, so T will also stand for the total cost. This assumption will not be stated in our theorems.

3.1. Biadditive *h*. The following theorem essentially states that if the complexity of algorithm C is a biadditive function h of the input sizes, then the complexity of algorithm A is also the same function h.

THEOREM 3.2. *If*

1. *identification of each pair* (D_i, E_j) *takes* $O(1)$ *time,*

2. *algorithm* B *takes* $O(1)$ *time when the size of one of its inputs does not exceed the threshold,*

3. *the time complexity of algorithm* C *is* $O(h(n,m))$ *for an* $n \times m$ *input matrix, where* h *is biadditive,*

4. s *is a size function, and the sum of the substructure sizes on the recursive calls is less than the parent structure size,*

then the time complexity of algorithm $A(D,E)$ *is* $O(h(s(D), s(E)) + s(D)s(E))$.

Proof. We assume that comparing a number with a constant takes a constant of time. A simple proof by induction shows that the total number of recursive calls is less than $s(D)s(E)$. Therefore, by our assumption and hypothesis 1, the cost of all comparisons and identification of the substructure pairs for the recursive calls over all the recursive calls is $O(s(D)s(E))$. We now show that the cost of the remaining steps is as claimed above, thus completing the proof. The proof is by induction on $s(D)$ and $s(E)$. For the induction to succeed, we need to prove something slightly stronger, viz, the complexity of $A(D,E)$ is $O(h((s(D)-1),(s(E)-1)) + (s(D)-1)(s(E)-1))$.

Basis. If either $s(D)$ or $s(E)$ is equal to *threshold* and both are at least two, then the statement is trivially true by choosing the constant, say c, in the O notation large enough and at least equal to $\max(c_1, c_2)$, where c_1 is the positive constant in the time complexity for setting up matrix M and c_2 is the constant in the time complexity of algorithm C.

Induction step. The time complexity of $A(D,E)$ is bounded above by the time for the recursive calls, plus the time c_1nm for setting up the matrix M, and the time taken by algorithm C on an $n \times m$ input matrix. Therefore, by the inductive hypothesis, the complexity of $A(D,E)$ is bounded by

$$B = \sum_{i=1}^{n} \sum_{j=1}^{m} c[h((s(D_i)-1),(s(E_j)-1)) + (s(D_i)-1)(s(E_j)-1)] + ch(n,m) + c_1nm,$$

where c is the positive constant chosen above such that $c \geq c_1$ and $c \geq c_2$. Since h is biadditive,

$$\begin{aligned} B &\leq ch\left(\sum_{i=1}^{n}(s(D_i)-1), \sum_{j=1}^{m}(s(E_j)-1)\right) + c(s(D)-n-1)(s(E)-m-1) \\ &\quad + ch(n,m) + c_1 nm \\ &= ch\left(\sum_{i=1}^{n}(s(D_i)-1), \sum_{j=1}^{m}(s(E_j)-1)\right) + ch(n,m) + c(s(D)-1)(s(E)-1) \\ &\quad - cns(E) - cms(D) + (c+c_1)nm + c(n+m). \end{aligned}$$

Further, since $\sum_{i=1}^{n} s(D_i) \leq s(D) - 1$ and all of the $s(D_i)$'s are at least one (s is a size function), it follows that $s(D) > n$. Similarly, $s(E) > m$. Also, since $c \geq c_1$, we have $(c+c_1)nm + c(n+m) \leq cns(E) + cms(D)$. Therefore,

$$B \leq ch(s(D)-n-1, s(E)-m-1) + ch(n,m) + c(s(D)-1)(s(E)-1)$$

Again, by the additivity of h, we have

$$B \leq ch(s(D)-1, s(E)-1) + c(s(D)-1)(s(E)-1).$$

This completes the induction step. Now since h is nondecreasing in both arguments, $h(s(D)-1, s(E)-1) \leq h(s(D), s(E))$ and therefore $T(s(D), s(E)) = O(h(s(D), s(E)) + s(D)s(E))$. □

Remark 3.3. Note that it is sufficient for h to be biadditive over the positive integers. Furthermore, it is not necessary that h be biadditive for all positive n and m. It is sufficient that h be biadditive almost everywhere, i.e., with at most a finite number of (positive integral) exceptions. Also, it is possible to weaken the first two hypotheses by requiring that the time taken in each is $O(h(s(D), s(E))/(s(D)s(E)))$ instead of $O(1)$.

The following proposition merely states that the complexity of algorithm A cannot be reduced by using a more time consuming algorithm C.

PROPOSITION 3.4. *Let T and T' denote the time complexities of algorithm A when the time complexities of algorithm C are $ch(m,n)$ and $ch'(m,n)$ $(c > 0)$, respectively, and suppose that $h(m,n) \leq h'(m,n)$ for all m and n. Then for all values of $s(D)$ and $s(E)$, $T(s(D), s(E)) \leq T'(s(D), s(E))$.*

Proof. The proof is by induction on $s(D)$ and $s(E)$. □

3.2. h is additive in one argument only. We now consider the case when h is not biadditive, but $h(x,y)$ is additive in only one argument, say x. Additivity on the second argument, y, is handled similarly. Other things being equal, we prove that the time complexity of algorithm $A(D,E)$ is $O(h(s(D), f(s(E))) + s(D)s(E))$ if there is an additive function f such that $h(x, f(y))$ is biadditive and $h(x,y) \leq h(x, f(y))$ for all x and y.

THEOREM 3.5. *If all assumptions of Theorem* 3.2 *hold except that the time complexity of algorithm C for an $n \times m$ input matrix is $O(h(n,m))$, where h is additive in one argument only, say m, then the time complexity of algorithm $A(D,E)$ is $O(h(f(s(D)), s(E)) + s(D)s(E))$ provided there exists additive function f such that $h(f(x), y)$ is biadditive and $h(x,y) \leq h(f(x), y)$ for all x and y.*

Proof. The proof is similar to that of Theorem 3.2, except for minor changes and one extra step, where, using the additivity of f, we push the summation from outside f to inside, i.e., $\ldots \sum_{i=1}^{n} f(s(D_i)) \ldots$ to $\ldots f(\sum_{i=1}^{n} s(D_i)) \ldots$. □

3.3. h is additive in neither argument. Next, suppose that h is not additive in either argument. In this case, we prove that the time complexity of algorithm $A(D, E)$ is $O(h(f(s(D)), g(s(E))) + s(D)s(E))$ if there are additive functions f and g such that $h(f(x), g(y))$ is biadditive and $h(x, y) \leq h(f(x), g(y))$ for all x, y.

THEOREM 3.6. *If all assumptions of Theorem* 3.2 *hold except that the time complexity of algorithm C for an $n \times m$ input matrix is $O(h(n, m))$, where h is additive in neither argument, then the time complexity of algorithm $A(D, E)$ is $O(h(f(s(D)), g(s(E))) + s(D)s(E))$, provided there exist additive functions f and g such that $h(f(x), g(y))$ is additive and $h(x, y) \leq h(f(x), g(y))$ for all x and y.*

Proof. The proof is similar to that of Theorem 3.5 except for minor changes. □

Clearly the time complexity of algorithm $A(D, E)$ is $O(s(D)s(E))$ if $h(n, m) = O(nm)$. Also, if $h(n, m) \leq h'(n, m)$ and $h'(n, m)$ is biadditive, then algorithm A takes $O(h'(s(D), s(E)) + s(D)s(E))$ time by Proposition 3.4 and Theorem 3.2. With these results, we can often handle functions that are not biadditive and do not become biadditive for any additive functions f and g applied to n and m. Another useful generalization is the following theorem, which gives a biadditive bound on the complexity of algorithm A when the complexity of algorithm C is a pseudoconvex function.

THEOREM 3.7. *If all assumptions of Theorem* 3.2 *hold except that the time complexity of algorithm C for an $n \times m$ input matrix is $O(h(n, m))$, where h is a continuous pseudoconvex function, then the time complexity of algorithm $A(D, E)$ is $O(h(s(D), s(E)) + s(D)s(E)(1 + h(0, 0)) + s(D)h(0, s(E)) + s(E)h(s(D), 0))$.*

Proof. For $n \geq 1$ and $m \geq 1$, define $\phi(n, m) = h(m, n) + (n - 1)h(m, 0) + (m - 1)h(0, n) + (n - 1)(m - 1)h(0, 0)$. A simple computation using the properties of pseudoconvex functions given in Lemma 2.5 shows that ϕ is biadditive for all $n \geq 1$ and $m \geq 1$. Clearly, $\phi(n, m) \geq h(n, m)$ for all $n \geq 1$ and $m \geq 1$ since h is nonnegative. Now apply Proposition 3.4 and Theorem 3.2. Note that the theorem can also be proved from scratch by an induction similar to that of Theorem 3.2 using only the properties of pseudoconvex functions, but the proof is longer and involves more computations. □

3.4. Recurrence (2). Now we examine the case when the merging process requires more time. Specifically, we consider the case when the merging process takes time that depends on the sizes of D and E as well, i.e., $O(h(s(D), s(E)) + mn)$ time instead of $O(h(m, n) + mn)$ time.

THEOREM 3.8. *If all assumptions of Theorem* 3.2 *hold except that the time complexity of merging solutions is $O(h(s(D), s(E)) + mn)$, where h is biadditive, then the time complexity of algorithm $A(D, E)$ is $O((s(D) + s(E))h(s(D), s(E)) + s(D)s(E))$.*

Proof. The proof is similar to that of Theorem 3.2. □

If h is pseudoconvex, then the time complexity of algorithm A is $T(s(D), s(E)) = O((s(D) + s(E))\phi(s(D), s(E)) + s(D)s(E))$, where ϕ is given in the proof of Theorem 3.7.

4. Necessary and sufficient conditions. We now give relevant (some sufficient and some necessary and sufficient) conditions that ensure the additivity of a unary function, the biadditivity of a binary function, and pseudoconvexity.

LEMMA 4.1. *A unary function f is additive on the nonnegative reals if it satisfies one of the following conditions:* 1. *$f(x) = xg(x)$, where g is a monotonically increasing function.* 2. *f is twice differentiable, $f'' \geq 0$, and $f(0) = 0$.*

Proof. 1. A simple computation suffices for 1.

2. Note that if f'' is nonnegative, f' is nondecreasing. Therefore, $f'(t) \leq f'(t+y)$ for all $t, y \geq 0$. Integrating both sides, we have $\int_0^x f'(t)dt \leq \int_0^x f'(t+y)dt$, or $f(x) - f(0) \leq f(x+y) - f(y)$. Since $f(0) = 0$, we have $f(x) + f(y) \leq f(x+y)$. Since $f(0) + f(x) \leq f(0+x) = f(x)$, the requirement $f(0) = 0$ is also necessary for nonnegative f. If f is twice differentiable, then the requirement $f'' \geq 0$ is also necessary. □

Examples. Some examples of additive functions are as follows: for any $c \geq 0$, $cx(\log(x+1))^k$ $(k \geq 0)$, cx^u for all $u \geq 1$, etc.

LEMMA 4.2 ([12]). *A twice-differentiable unary function f is convex on the nonnegative reals iff $f'' \geq 0$.*

THEOREM 4.3. *A twice-differentiable binary function f is pseudoconvex iff $f''_{xx} \geq 0$ and $f''_{yy} \geq 0$ (the second partial derivatives of f with respect to x and y, respectively).*

Proof. The proof follows from the definition of a pseudoconvex function and the above lemma. □

Examples. $x + y$, xy, and $(x-y)^2$ are some examples of pseudoconvex functions.

THEOREM 4.4.

1. *$h(x,y) = f(x)g(y)$ is biadditive (pseudoconvex) if f and g are additive (convex) functions.*
2. *$h(x) = (f(x))^u$ is additive for $u \geq 1$ if f is additive.*
3. *For $p \geq 2$, $h(x,y) = p^{f(x)+g(y)}$ is biadditive for $x \geq 2$ and $y \geq 2$ if f and g are additive and $f(x) \geq 1$ and $g(y) \geq 1$ for all x and y.*
4. *$h(x,y) = xyg(x,y)$ is biadditive if $g(x,y)$ is a nondecreasing function of x for every y and of y for every x.*
5. *$h(x,y)$ is biadditive if $h(x,y)$ is pseudoconvex and $h(x,0) = 0$ for all x and $h(0,y) = 0$ for all y.*

Proof. 1. We verify only the biadditivity part. $h(u,x) + h(v,x) = f(u)g(x) + f(v)g(x) = (f(u) + f(v))g(x) \leq f(u+v)g(x) = h(u+v,x)$ by the additivity of f. Similarly, $h(x,u) + h(x,v) \leq h(x,u+v)$.

2. $h(x) + h(y) = (f(x))^u + (f(y))^u \leq (f(x) + f(y))^u$ since $u \geq 1$. Also, $(f(x) + f(y))^u \leq (f(x+y))^u = h(x+y)$ since f is additive and u is positive.

3. The proof follows from $x + y \leq xy$ for $x \geq 2$ and $y \geq 2$. $h(u,x) + h(v,x) = p^{f(u)+g(x)} + p^{f(v)+g(x)} = (p^{f(u)} + p^{f(v)})p^{g(x)} \leq p^{f(u)}p^{f(v)}p^{g(x)} = p^{f(u)+f(v)}p^{g(x)} \leq p^{f(u+v)+g(x)} = h(u+v,x)$. Similarly, $h(x,u) + h(x,v) \leq h(x,u+v)$.

4. A simple computation suffices.

5. The proof follows from the addition inequalities of a pseudoconvex function. □

5. One-dimensional recurrences. Let $T(x) = \sum_{i=1}^{k} a_i T(x/c_i) + f(x)$ for all reals $x > K$, $T(x) = b$ for all reals $1 \leq x \leq K$ for some real constants $a_i \geq 1$, $c_i > 1$ for $1 \leq i \leq k$, and $b > 0$, and function f be defined on the nonnegative reals. Also, let $K \geq \max_i\{c_i\}$ be an integer. In many applications, T is defined only for integral values using flooring and ceiling operations. The reason for defining T for all real values is that our analysis can easily be extended to the integral case. These details can be filled in easily.

We need the principle of noetherian induction for our proofs. Let $Q = \{x \in R \mid x \geq 1\}$. We define the relation R on Q by xRy iff $y > K$ and $x = y/c_i$ for some c_i in the recurrence given above (i.e., $T(x)$ appears on the right-hand side of the recurrence for $T(y)$). Let R^+ denote the transitive closure of R. Clearly, R is noetherian, i.e., there are no infinite descending chains in R. Let P be any predicate

on Q. We say that P is *R-complete* iff $\forall y \in Q[\forall x$ such that $xR^+yP(x)] \Rightarrow P(y)$. Our interest in noetherian relations is because of the following *principle of noetherian induction*. Let R be a noetherian relation and P be a R-complete predicate; then $\forall x \in Q\ P(x)$.

DEFINITION 5.1. *Let function g be given. We say that a function f is g-*star-shaped *iff for all $x \geq 1$ and $0 < t < 1$, $f(tx) \leq g(t)f(x)$. We say that f is g-co-star-shaped iff for all x and $0 < t < 1$, $f(tx) \geq g(t)f(x)$.*

The following theorem gives a tight bound on $T(x) = \Theta(f(x))$ if f is g-star-shaped and a certain sum of the subproblem sizes is smaller than 1 (which, for lack of a better term, we call the g weighted sum of the suproblem-size fractions). For convenience, we introduce the following notation.

Notation. Given function g, let $S(g,T)$ denote $\sum_{i=1}^{k} a_i g(1/c_i)$, where the a_i's and c_i's are as in the recurrence for T.

THEOREM 5.2. *If $f(x) \geq d$ over $[1,K]$ for some $d > 0$, there exists g such that f is g-star-shaped, and $S(g,T) < 1$, then $T(x) = \Theta(f(x))$.*

Proof. Clearly, $T(x) = \Omega(f(x))$. Therefore, it suffices to show that $T(x) = O(f(x))$. The proof is by noetherian induction. Choose $C = \max\{b/d, 1/(1 - S(g,T))\}$.

Basis. All the reals in $[1,K]$ are minimal with respect to R. The statement of the theorem is trivially true for all of these minimal elements since by our choice of C, $b \leq (b/d)d \leq Cf(x)$.

Induction step. Suppose $y > K$. By definition, $T(y) = \sum_{i=1}^{k} a_i T(y/c_i) + f(n)$. By definition of R, $(y/c_i)\ R\ y$. Therefore, combining the recurrence for $T(y)$ with our induction hypothesis for the $T(y/c_i)$'s, we have

$$\begin{aligned} T(y) &\leq \sum_{i=1}^{k} a_i C f(y/c_i) + f(y) \\ &\leq C \sum_{i=1}^{k} a_i g(1/c_i) f(y) + f(y) \\ &\leq Cf(y) \left(1/C + \sum_{i=1}^{k} a_i g(1/c_i) \right), \end{aligned}$$

which is at most $Cf(y)$ by our choice of C. □

Next, we consider the case when f is of the form $h(x)(\log x)^l$ for some h and $l \geq 0$. Here we give (i) an upper bound on $T(x)$ of $O(f(x)\log x)$ when h is g-star-shaped and the g weighted sum of the subproblem-size fractions is equal to 1 and (ii) a lower bound of $\Omega(f(x)\log x)$ when h is g-co-star-shaped and the g weighted sum of the subproblem-size fractions is at least 1.

THEOREM 5.3.

1. *If $f(x) = h(x)(\log x)^l + d$ $(x \geq 1)$ for some $l \geq 0$, $d > 0$, there is a g such that h is g-star-shaped, and $S(g,T) = 1$, then $T(x) = O(f(x)\log x)$.*

2. *If $f(x) = h(x)(\log x)^l$ $(x \geq 1,\ l \geq 0)$, there exists g such that h is g-co-star-shaped, and $S(g,T) \geq 1$, then $T(x) = \Omega(f(x)\log x)$.*

Proof.

1. First, we prove that $T(x) \leq Cf(x)(1 + \log_m x)$ for every $x \geq 1$. Here $m = \min_i\{c_i\}$, which is clearly greater than 1. Again, we use noetherian induction. Without loss of generality, we may assume that $f(x) = h(x)(\log_m x)^l + d$. Choose $C = \max\{1, b/d\}$.

Basis. The upper bound on $T(x)$ holds trivially for all reals in $[1, K]$ by our choice of C.

Induction step. Let $y > K$. Then $T(y) = \sum_{i=1}^{k} a_i T(y/c_i) + f(y)$. By our induction hypothesis for the $T(y/c_i)$'s, we have

$$\begin{aligned}
T(y) &\le \sum_{i=1}^{k} a_i C f(y/c_i)(1 + \log_m(y/c_i)) + f(y) \\
&= \sum_{i=1}^{k} a_i C(h(y/c_i)(\log_m(y/c_i))^l + d)(1 + \log_m(y/c_i)) + f(y) \\
&\le C \sum_{i=1}^{k} a_i g(1/c_i)(h(y)(\log_m y)^l + d)(1 + \log_m(y/c_i)) + f(y) \\
&\le C f(y) \sum_{i=1}^{k} a_i g(1/c_i)(1 + \log_m(y/m)) + f(y) \\
&\le C f(y)(1 + \log_m y)
\end{aligned}$$

since $S(g, T) = 1$ and $C \ge 1$. Now $Cf(x) \log_m x \ge Cf(x)$ for $x > m$, so $T(x) = O(f(x) \log_m x) = O(f(x) \log\ x)$.

2. Let $f(x) = h(x)(\log_p x)^l$ and let D be any constant such that $f(x) \le D$ over $[1, K]$. A similar proof by induction shows that $T(x) \ge Cf(x) \log_M x$, where $M = p(\max_i\{c_i\})$ and $C = \min\{1/S(g, T), b/(D \log_M K)\}$. □

By combining the two conditions of the above theorem, we have the following corollary, which gives a $\Theta(f(x) \log x)$ bound for T.

COROLLARY 5.4. *If $d \le f(x)$ over $[1, K]$ for some $d > 0$, $f(x) = \Theta(h(x)(\log\ x)^l)$ $(l \ge 0)$, there exists g such that $h(tx) = g(t)h(x)$ for all x and $0 < t < 1$, and $S(g, T) = 1$, then $T(x) = \Theta(f(x) \log\ x)$.*

The following useful proposition is easy to prove by noetherian induction.

PROPOSITION 5.5. *Let $f_1(x) \le f(x) \le f_2(x)$ for all $x \ge 1$ and let T_1, T, and T_2 denote the solutions to recurrences of form 3 corresponding to f_1, f, and f_2, respectively (initial conditions remain the same). Then for all $x \ge 1$, $T_1(x) \le T(x) \le T_2(x)$.*

The following theorem is useful when for every function g such that f is g-star-shaped, the g weighted sum of the subproblem-size fractions exceeds 1. Roughly speaking, we try to find a function F that dominates f and satisfies conditions similar to the ones imposed on f in the above theorems.

THEOREM 5.6. *Let F be any function such that $f(x) \le F(x)$ for all $x \ge 1$ and for some d $F(x) \ge d > 0$ over $[1, K]$.*

1. *$T(x) = O(F(x))$ if there exists G such that F is G-star-shaped and $S(G, T) < 1$.*

2. *$T(x) = O(F(x))$ if there is a $c > 0$ such that $f(x) + c \le F(x)$ for all $x \ge 1$, there exists G such that F is G-star-shaped, $S(G, T) \le 1$ (note the $\le$ sign as opposed to $<$), and there is a g such that f is g-co-star-shaped with $S(g, T) > 1$.*

3. *$T(x) = \Omega(F(x))$ if there exists G such that F is G-co-star-shaped and $S(G, T) \ge 1$.*

Proof.

1. Let $T'(x) = \sum_{i=1}^{k} a_i T'(x/c_i) + F(x)$ and apply Theorem 5.2 to T' and then Proposition 5.5 to get $T(x) = O(F(x))$.

2. Choose $C = \max\{b/c, 1/(S(g,T)-1)\}$. We need to prove something stronger, viz, $T(x) \le C(F(x) - f(x))$.

Basis. For $x \in [1, K]$, we have $T(x) = b \le Cc \le C(F(x) - f(x))$.

Induction step. By our induction hypotheses for the $T(y/c_i)$'s, we have

$$T(y) \le \sum_{i=1}^{k} a_i C(F(y/c_i) - f(y/c_i)) + f(y).$$

Since F is G-star-shaped and f is g-co-star-shaped, we have

$$\begin{aligned} T(y) &\le CF(y) \sum_{i=1}^{k} a_i G(1/c_i) - f(y) \left(C \sum_{i=1}^{k} a_i g(1/c_i) - 1 \right) \\ &\le C(F(y) - f(y)) \end{aligned}$$

by our choice of C and the assumption that $S(G,T) = \sum_{i=1}^{k} a_i G(1/c_i) \le 1$.

3. The proof is straightforward and follows by noetherian induction. □

We now show that the popular theorem on the analysis of divide-and-conquer algorithms with equal parts [1, 3, 5, 14], [7, p. 62] emerges as a special case of our theorems above.

COROLLARY 5.7. *Let $\epsilon > 0$ and $q = \log_c a$. The solution to $T(x) = aT(x/c) + f(x)$ $(a, b > 0,\ c > 1,\ T(x) = b$ for $x \le c)$ is* (i) $T(x) = \Theta(x^q)$ *if* $f(x) = O(x^{q-\epsilon})$, (ii) $T(x) = \Theta(f(x) \log_c x)$ *if* $f(x) = \Theta(x^q (\log_c x)^l)$, *and* (iii) $T(x) = \Theta(f(x))$ *if* $f(x) = \Omega(x^{q+\epsilon})$.

Proof. (iii) By Proposition 5.5, it suffices to consider $f(x) = dx^p$ $(d > 0,\ p \ge 0)$ and $g(t) = t^p$. Then $f(tx) = d(tx)^p = g(t)f(x)$. If $q < p$, then $ag(1/c) = a(1/c)^p = c^{q-p} < 1$. Therefore, by Theorem 5.2, we have $T(x) = \Theta(x^p)$. (i) Again, it is sufficient to let f be as in part (iii). If $p < q$, then $ag(1/c) > 1$. Let $F(x) = (d+1)x^q$ so that there is an $e > 0$ such that $f(x) + e \le F(x)$. F is G-star-shaped, where $G(t) = t^q$, and $aG(1/c) = 1$. Since f is g-co-star-shaped and $ag(1/c) > 1$, by Theorem 5.6, we have $T(x) = \Theta(x^q)$. (ii) The proof follows from Theorem 5.3. □

Note that Brassard and Bratley [5] have a slight generalization of the above corollary, which is a consequence of our work reported in [22].

6. Applications. We present some applications of the above theorems.

COROLLARY 6.1. *Let n and m denote the sizes of the two rooted trees, $n \le m$. The following problems can be solved in $O(nm^{1.5}/\log\ m)$ time:*

1. *rooted subtree isomorphism* [25];
2. *AC matching of linear terms* [23];
3. *rooted subgraph homeomorphism on trees* [6].

Proof. The function $h(x,y) = cxy^{1.5}/\log\ y$ is biadditive for every constant $c \ge 0$ (part 1 of Theorem 4.4). Since the algorithms for all of these problems are of the form given above with an algorithm for bipartite maximum matching in place of C, and since there is a bipartite matching algorithm of complexity $O(rs^{1.5}/\log\ s)$ [8], where $r \le s$ are the sizes of the vertex sets, by Theorem 3.2 we have the stated result. In each case, all of the assumptions of the theorem are satisfied. □

Remarks. Clearly, this corollary does not follow from Theorem 1.1 given above. Moreover, Theorem 1.1 is a corollary of Theorem 3.2.

COROLLARY 6.2. *Associative matching of linear terms can be done in $O(nm)$ time, where n and m are the sizes of the input trees representing the terms.*

Proof. The function $h(x, y) = cxy$ is biadditive for every constant $c \geq 0$. Since there is an ordered bipartite matching (see [23] for the definition of ordered bipartite matching) algorithm of time complexity $O(rs)$, where $r < s$ are the sizes of the vertex sets, and since the algorithm for associative matching of linear terms is of the form given above [23], by Theorem 3.2 we have the stated result. □

Remark. This improves the bound given by Verma and Ramakrishnan [23] by a factor of log n, and the corollary below improves Theorem 1.2 proved by Reyner in [20] by a factor of $\ln n$.

COROLLARY 6.3. *If there is a bipartite matching algorithm of time complexity $O(rs)$, where $r < s$ are the sizes of the vertex sets, then the algorithms for rooted subtree isomorphism, AC matching of linear terms, and rooted subgraph homeomorphism on trees are of time complexity $O(nm)$.*

COROLLARY 6.4. *There are* parallel *algorithms for rooted subtree isomorphism, AC matching of linear terms, and rooted subgraph homeomorphism on trees of time complexity $O(nm)$.*

Proof. The proof follows from Corollary 6.3 and the parallel bipartite matching algorithms of time complexity better than $O(rs)$ [9, 10]. Note that everything else in algorithm A is being done sequentially except for a parallel algorithm for C. (This means that faster algorithms using more processors can be designed.) □

COROLLARY 6.5.

1. *The Select algorithm of Blum et al.* [4] *is of time complexity $O(n)$, where n is the input size.*

2. *The solution to $T(n) \leq T(n/2) + T(n/4) + cn^a$, $c > 0$ [17], where $a < b = \log_2(1 + \sqrt{5}) - 1$, is $O(n^b)$.*

Proof.

1. The recurrence for the algorithm is $T(x) = T(x/5) + T(3x/4) + cx$ for some $c > 0$. Here $f(x) = cx$. Let $g(t) = t$; then $f(tx) = ctx \leq g(t)f(x)$ and $S(g, T) = \sum_i a_i g(1/c_i) = 1(1/5) + 1(3/4) < 1$. Therefore, by Theorem 5.2, we have the stated result.

2. The proof follows from part 2 of Theorem 5.6. □

7. Conclusion. In this paper, we have presented some general techniques and master theorems for three kinds of recurrences frequently occurring in the analysis of divide-and-conquer algorithms. Much of the existing work on the recurrences considered here is subsumed by our results. In the process, we established interesting connections between some elegant mathematics and the analysis of recurrences. We then gave several applications of our theorems, thus improving existing bounds in the literature for several problems. This paper is an invitation to an exciting area for further research, viz, general techniques and theorems for other frequently occurring recurrences, which is obviously of considerable importance.

Acknowledgments. The author thanks the referees for their constructive comments and suggestions. After this paper was submitted for publication, P. Kilpelainen sent me a copy of his thesis [16], which contains a weaker form of Theorem 3.2. Subsequently, we also received a paper [26] from E. Reingold which analyzes a different (min-max) recurrence. Thanks also go to both of them.

POTENTIALS IN UNDIRECTED GRAPHS AND PLANAR MULTIFLOWS*

ANDRÁS SEBŐ†

Abstract. The duality relation between shortest paths and potentials in *directed graphs* and the significance of both of these in the theory of network flows is well known. In this paper, we work out the analogous *undirected* notions, which neither are contained in nor contain their directed counterpart. They are more related to matching theory than to network flows: the corresponding min-path-max-potential theorem can be considered a weighted generalization of the Gallai–Edmonds structure theorem for matchings.

In our earlier work [*J. Combin. Theory Ser. B*, 49 (1990), pp. 10–39], the corresponding theorems are proved in the special case of ±1 bipartite weightings, and this special case already contains the main points of the general proof. The goal of the present paper is to extrapolate from this ±1-weighted bipartite special case the arbitrarily weighted general min-path-max-potential theorem and to show some algorithmic consequences related to planar multiflows, the Chinese postman problem, the weighted and unweighted matching structure, etc. In order to make this paper self-contained, we also include a compact, revised variant of earlier proofs, adapted to the present context. In addition to good characterization theorems and polynomial algorithms, efficient (logarithmic polynomial) parallel algorithms follow for some of these problems.

Key words. T-joins, T-cuts, multicommodity flows, Chinese postman, matching, structure, parallel algorithm

1. Introduction.

In this section, we explain the background of the paper and introduce the main tools that we will use. In particular, we present potentials in the ±1-weighted bipartite special case, which was developed in Sebő [1990]. Since this constitutes the kernel of our results, we fully include a compact proof of the main theorem concerning this case.

Then in section 2, we define potentials in arbitrary weighted undirected graphs and prove (extrapolate from the bipartite special case) a minimax theorem on minimum weight paths and maximum potentials. In section 3, we point out the algorithmic consequences of our results and apply them to, for example, planar multiflows.

If G is a graph and $w : E(G) \to \mathbb{R}$, define the *distance* of $x, y \in V(G)$ as

$$\lambda_{G,w}(x,y) = \lambda_w(x,y) = \lambda(x,y) = \min\{w(P) : P \text{ is an } (x,y) \text{ path}\}.$$

In this paper, *paths* are considered to be sets of edges, or subgraphs. (For instance, $V(P)$ will denote the set of vertices of the path P.) They can have a repetition of vertices, but no repetition of edges is allowed. An (x,y) path is a path whose endpoints are $x, y \in V(G)$. The definition of $\lambda_{G,w}(x,y)$ is meant to be ∞ if x and y are not in the same component of G.

A path without repetition of vertices will be called *simple*. If the two endpoints of a (simple) path coincide, it is a *cycle* (*circuit*). $w(P)$ denotes the sum $\sum_{e\in P} w(e)$. A *shortest* (*w-shortest*) *path* is an (a,b) path P with $w(P) = \lambda_w(a,b)$. If $a, b \in V(P)$,

$P(a,b)$ denotes a simple subpath of P joining a and b. (If P is simple, $P(a,b)$ is uniquely determined.) For $X \subseteq V(G)$, $\delta(X)$ will denote the set of edges with exactly one endpoint in X. We will also use the notation $E^- := \{e \in E(G) : w(e) < 0\}$, $E^+ := \{e \in E(G) : w(e) > 0\}$.

A graph G with a weighting $w : E(G) \to \mathbb{R}$ is called *conservative* if $w(C) \geq 0$ for every circuit $C \subseteq E(G)$. Conservative graphs are characterized as follows.

(1.1) *(G,w) is conservative if and only if for all $x, y \in V(G)$, $\lambda_w(x,y) = \min\{w(P) :$ P is a simple (x,y) path$\}$.*

In particular, for connected graphs, $\lambda_w(x,y)$ is finite for all $x, y \in V(G)$.

Recall that $\lambda_w(x,y)$ can be computed via matching techniques in various well-known ways (see Edmonds [1965a] or Lawler [1976]); one of these will be explained in section 3. On the other hand *it cannot be reduced to the well-known shortest-path algorithms* because the two directed edges corresponding to an undirected edge of negative weight constitute a negative directed cycle; moreover, subpaths of shortest paths are not necessarily shortest and distances do not satisfy the triangle inequality. Thus the notion of potentials and the related theory are also different in the undirected case.

The behavior of undirected potentials is determined by the following theorem, as will be explained in section 2:

If (G,w) is conservative and $x_0 \in V(G)$, we call each set $V^i = V^i(\lambda) := \{x \in V(G) : \lambda_w(x_0,x) \leq i\}$ $(i = 0, \pm 1, \pm 2, \ldots)$ a *level set* of (G,w,x_0); we denote by G^i the graph induced by V^i, and we call it the *level graph*. If the weights are ± 1, then edges go between neighboring levels; that is, we have the following.

(1.2) *If $w : E(G) \to \{-1,1\}$ is conservative, then for all $xy \in E(G)$, $|\lambda(x_0,x) - \lambda(x_0,y)| \leq 1$. If, in addition, G is bipartite, then this inequality is satisfied with equality for every edge.*

Indeed, we can assume without loss of generality that $\lambda(x_0,x) \geq \lambda(x_0,y)$. Let P be a simple shortest (x_0,y) path. If $xy \in P$, then $xy \in E^-$ follows, and $\lambda(x_0,x) \leq w(P \setminus \{xy\}) = w(P) + 1$; if $xy \notin P$, then $xy \in E^+$, and $\lambda(x_0,x) \leq w(P \cup \{xy\}) = w(P) + 1$. Thus $\lambda(x_0,y) \leq \lambda(x_0,x) \leq \lambda(x_0,y) + 1$. If G is bipartite, then in addition $\lambda(x_0,x) \neq \lambda(x_0,y)$, whence $\lambda(x_0,x) = \lambda(x_0,y) + 1$, and (1.2) is proved.

For an arbitrary conservative weighting, the inequality $|\lambda(x_0,x) - \lambda(x_0,y)| \leq |w(xy)|$ can be checked in the same way (and also follows easily from (1.2); see the proof of Lemma 2.1(a)).

THEOREM 1.1. *Let G be a bipartite graph and $w : E(G) \to \{-1,1\}$ such that (G,w) is conservative. Furthermore, let $x_0 \in V(G)$ be arbitrary and D be the vertex set of a component of G^i $(i \in \{0, \pm 1, \pm 2, \ldots\}$, $V^i \neq \emptyset)$. Then $|\delta(D) \cap E^-| = 1$ provided that $x_0 \notin D$ and $|\delta(D) \cap E^-| = 0$ provided that $x_0 \in D$.*

If $\mathcal{D}$ denotes the family of sets occurring as the vertex set of a component of a G^i (as a D in the theorem), where G is bipartite, then because of (1.2), $\{\delta(D) : D \in \mathcal{D}\}$ partitions $E(G)$; the theorem states that the $D \in \mathcal{D}$ with $x_0 \notin D$ partition E^- into singletons.

Theorem 1 contains Seymour's minimax theorem on T-joins and T-cut packings, the Berge–Tutte theorem, and the Gallai–Edmonds structure theorem. It actually implies the generalization of this structure theorem to T-joins and weighted matchings (see Sebő [1990] and section 3 below).

Figure 1 illustrates the components of the level sets of a ± 1-weighted conservative graph. The thick edges are those of weight -1.

Proof of Theorem 1.1. Let (G,w) be conservative. We prove the theorem by

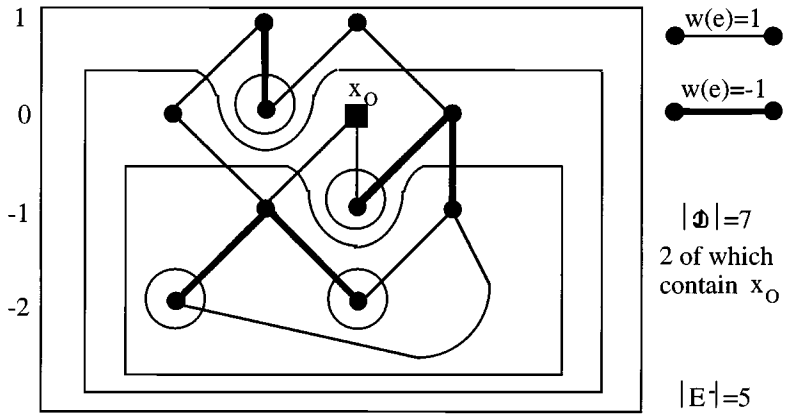

FIG. 1.

induction on $|V(G)|$. Let b be a vertex that satisfies

$$\lambda_w(x_0, b) = m := \min\{\lambda_w(x_0, x) : x \in V(G)\}$$

and let P be a simple (x_0, b) path, with $w(P) = m$. (P exists because of (1.1).) In addition, we assume that b is chosen among all possible choices so that $|P|$ is minimum. (This last assumption is not really essential; the claims that we will prove for b are true without it. However, it will be useful for technical simplicity.)

Let us first check the statement for $\{b\}$: since G is bipartite, V^m does not induce edges, whence $\{b\}$ is one of its components. The statement to check is the following.

CLAIM 1.

$$|\delta(b) \cap E^-| = 1 \quad \textit{provided } b \neq x_0,$$

$$|\delta(b) \cap E^-| = 0 \quad \textit{provided } b = x_0;$$

Moreover, if $b \neq x_0$, then P contains the unique negative edge adjacent to b.

If $b = x_0$, then because of $m = \lambda_w(x_0, b) = 0$, there cannot be a negative edge adjacent to $x_0 = b$. Now suppose that $b \neq x_0$.

Since P is simple, it has exactly one edge adjacent to b. That edge is negative because otherwise, if we delete it from P, we get a path which is shorter than $w(P) = m$. Suppose indirectly that there exists a negative edge $e \in \delta(b) \setminus P$: $P \cup e$ is also a path and $w(P \cup e) < w(P) = m$, and this contradiction proves Claim 1.

Let G^* be the graph that we obtain after contracting $\delta(b)$ or, equivalently, after identifying the vertices adjacent to b and deleting b. (By the choice of b and because of (1.2), all neighbors of b are at level $m - 1$.) We consider that the vertices and edges of G^* are the same as those of $G - b$; w^* is defined as the restriction of w to $E(G - b) = E(G^*)$. (Parallel edges can be replaced by one edge whose weight is the minimum of the weights.)

CLAIM 2. *Suppose $b \neq x_0$. Then (G^*, w^*) is conservative, and for every $x \in V(G^*)$, $x \neq b$, $\lambda_{G^*,w^*}(x_0, x) = \lambda_{G,w}(x_0, x)$.*

A circuit or (x_0, x) path ($x \in V(G)$, $x \neq b$) K^* of G^* is a circuit or (x_0, x) path of G or can be made into one by adding two edges of $\delta(b)$. Denote this corresponding circuit or path of G by K. Since $|\delta(b) \cap E^-| = 1$, $w(K^*) = w(K) - 2$ or $w(K^*) = w(K)$.

If K is not a zero-weight circuit or shortest (x_0, x) path, then since G is bipartite, $w(K) \geq 2$ or $w(K) \geq \lambda_w(x_0, x)+2$, respectively, and $w(K^*) \geq 0$ or $w(K^*) \geq \lambda_w(x_0, x)$ follow.

Therefore, let $w(K) = 0$ or $w(K) = \lambda_w(x_0, x)$, respectively. Claim 2 clearly follows now from the following: either $K \cap \delta(b) = \emptyset$ or $K \cap \delta(b) = \{e_1, e_2\}$, $e_1 \in E^-$, $e_2 \in E^+$.

Suppose indirectly that $K \cap \delta(b) = \{e_1, e_2\}$, $e_1, e_2 \in E^+$.

Case 1. $K \cap P = \emptyset$. If K is a zero-weight circuit, then $P' := (P \cup K) \setminus e_1$ is a path, with $w(P') = w(P) + w(K) - 1 = w(P) + 0 - 1 < m$, a contradiction. Therefore, suppose that K is a w-shortest (x_0, x) path. By (1.1), we can suppose that K is simple. Since the only edge of $K(x_0, b)$ adjacent to b is positive, by Claim 1, $K(x_0, b)$ is not a w-shortest path, that is, $w(K(x_0, b)) > w(P(x_0, b))$. Then, however, $w(P(x_0, b) \cup K(b, x)) = w(P(x_0, b)) + w(K(b, x)) < w(K(x_0, b)) + w(K(b, x)) = \lambda_w(x_0, x)$, a contradiction because $P(x_0, b) \cup K(b, x)$ contains an (x_0, x) path.

Case 2. $K \cap P \neq \emptyset$. Then $b \neq x_0$ (otherwise $P = \emptyset$), and by the last part of Claim 1, the edge of P adjacent to b is negative, so it is different from the edges of K adjacent to b. Thus $V(K) \cap V(P)$ cannot consist of b only. Walking on P from b towards x_0, let $a \neq b$ be the first vertex of K we meet. $K(a, b) \cap P(a, b) = \emptyset$. $K' := (K \setminus K(a, b)) \cup P(a, b)$ is also a circuit (if K is a circuit) or an (x_0, x) path (if K is so), whence $w(K(a, b)) \leq w(P(a, b))$; otherwise, K' would be shorter than K. Moreover, $w(P(a, b)) \leq 0$ because otherwise $w(P(x_0, a)) = w(P(x_0, b)) - w(P(a, b)) < m$. On the other hand, by the conservativeness of (G, w), $w(K(a, b) \cup P(a, b)) \geq 0$, whence we have equality throughout; in particular, $w(K(a, b)) = w(P(a, b)) = 0$ and $w(P(x_0, a)) = m$. $|P(x_0, a)| < |P(x_0, b)|$, contradicting the choice of b. Claim 2 is proved.

Theorem 1.1 now follows by induction in a straightforward way:

• If b can be chosen to be different from x_0, then the level sets of G^* are the same as those of G by Claim 2, except that $\{b\}$ is no longer a level set and its neighbors are identified.

• If $b = x_0$ is the only possible choice for b, then all distances are positive from x_0. In particular, there is no negative edge adjacent to x_0, and in contracting $\delta(x_0)$, all distances from x_0 decrease exactly by one; again, the level sets of G^* are the same as those of G, except that $\{x_0\}$ is no longer more a level set and its neighbors are identified.

In both cases, the components of the level graphs of G that are different from $\{b\}$ are exactly the components of the level graphs of G^*. We apply Claim 1 to $\{b\}$ and apply the induction hypothesis to G^*, and the theorem follows. □

In the remaining part of this section, we explore some applications of our results. For the moment, we restrict ourselves to the ± 1-weighted special case.

If $T \subseteq V(G)$, then $F \subseteq E(G)$ is called a *T-join* if T is the set of odd-degree vertices of F. $X \subseteq V(G)$ is said to be T-odd if $|X \cap T|$ is odd. $C \subseteq E(G)$ is a T-cut if $C = \delta(X)$ for some $X \subseteq V(G)$ and X is T-odd. It is an easy exercise to show that a T-join F and a T-cut C have an odd and, in particular, nonempty intersection, and it follows that the minimum cardinality of a T-join is at least as much as the maximum cardinality of a family of pairwise-disjoint T-cuts.

To give a first, typical example of how Theorem 1 relates T-joins and T-cuts, let us show how Theorem 1.1 implies Seymour's [1981] following well-known theorem.

(1.3) *If G is bipartite, then the minimum cardinality of a T-join is equal to the maximum cardinality of a family of pairwise-disjoint T-cuts.*

It is an easy exercise to show that a T-join F has minimum cardinality if and only if, upon defining the weight of the edges in F to be -1 and the weight of the other edges to be 1, we get a conservative weighting (a remark of Guan [1962]). Apply Theorem 1.1 to this conservative weighting and to an arbitrary $x_0 \in V(G)$. If D is a component of a level graph for which $x_0 \notin D$, then $|\delta(D) \cap F| = 1$; it follows that $\delta(D)$ is a T-cut. According to (1.2) applied to the bipartite graph G, every edge leaves some level graph, whence by Theorem 1.1, the number of T-cuts $\delta(D)$, $x_0 \notin D$, is $|F|$, and these are pairwise disjoint. We have thus found a family of pairwise-disjoint T-cuts which has the same cardinality as the minimum T-join, and Seymour's theorem is proved. In fact, the constructed set of disjoint T-cuts has the particular form of the packings presented by the following theorem of Frank, Sebő, and Tardos [1984].

(1.4) *Given a bipartite graph with a* ± 1 *conservative weighting, both classes of the bipartition can be partitioned into classes* $X_1, \dots, X_k$ *so that* $\delta(C)$*, where* C *is a component of* $G - X_i$ $(i = 1, \dots, k)$*, contains at most one negative edge.*

Indeed, according to Theorem 1.1, the vertices x, $\lambda_w(x_0, x) = i$, in the components of G^i with i odd, $i = \pm 1, \pm 3, \dots$ (or of G^i with i even), constitute the classes of a partition which has the claimed property.

(1.3) and (1.4) easily imply half-integer minimax theorems valid for arbitrary graphs. (The half-integer version of (1.3) is a result of Lovász [1975].)

The generalization of theorems on T-joins or conservative weightings to the weighted case is straighforward via subdivision of edges. For instance, given a weight function $w : E(G) \to \mathbb{N}$, the minimum weight of a T-join is at least as much as the maximum cardinality of a w-packing of T-cuts, where a *w-packing* is a multiset which covers edge $e \in E(G)$ at most $w(e)$ times; Seymour's theorem ((1.3)) states that there is equality here for bipartite weightings. (For the sharpening series of integer minimax theorems that have been developed (including weighted variants) and the blocking pair of T-join and T-cut polyhedra, see Lovász and Plummer [1986b]; for a survey of more recent results, see, for instance, Frank [1990] or other recent publications on T-joins mentioned in the reference list. We will state some of these in section 3.) The weighting $w: E(G) \to \mathbb{Z}$ is called *Eulerian* if $w(C)$ is even for every cut C, and it is *bipartite* if it is even for every circuit C. A graph is Eulerian or bipartite if the identically 1 function on its edges is Eulerian or bipartite.

Let us also note that the distances *do not depend on the choice of the minimum T-join F*. (For an easy exercise, see, for example, Sebő [1990].)

The weighted generalization of (1.4) is somewhat artificial. On the other hand, Theorem 1.1 itself can be straightforwardly generalized to the weighted case, and this can be used for various purposes, as we will show in the following sections.

We finish this introduction by showing how Theorem 1.1 already applies to unweighted multiflows, that is, edge-disjoint path problems. We assume that the reader is familiar with the (easy) relation between some notions in planar graphs and those in the planar dual: the dual of the dual of a graph G is equal to G; Eulerian and bipartite graphs or weight functions correspond to each other; disjoint unions of circuits correspond to sets of the form $\delta(X)$ $(X \subseteq V(G))$; etc.

If G is planar, in the dual graph, Theorem 1.1 has the following more apparent meaning.

We are given an Eulerian graph (dual of "bipartite") G embedded in the plane and $R \subseteq E(G)$ so that the *cut condition*

$$|C \cap R| \leq |C \setminus R| \quad \text{for every cut } C$$

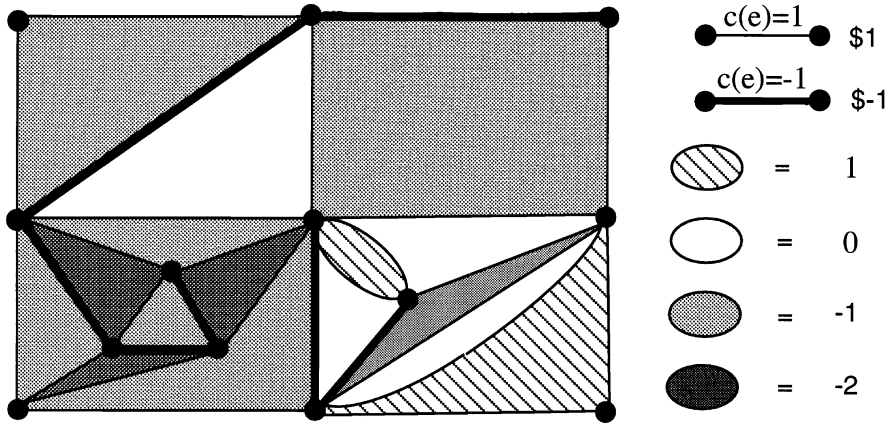

FIG. 2.

is satisfied for (G, R). (This condition is equivalent to the conservativeness of the dual graph. Set weights -1 on (duals of) edges in R.) Assign to every face φ of G the following *magic numbers*:

$$\lambda(\varphi) := \min\{|P \setminus R| - |P \cap R| : P \text{ dual path from the infinite face to } \varphi\}.$$

A "dual" path is a path of the dual graph and can be imagined as going from face to face, crossing edges. $\lambda(\varphi)$ can be interpreted as the minimum cost of reaching face φ if we must pay 1\$ for crossing an edge in $|E(G) \setminus R|$ and -1\$ for crossing an edge of R. (Negative costs correspond to incomes.)

This definition of $\lambda(\varphi)$ corresponds to a natural choice of x_0 in Theorem 1.1. Let x_0 be the vertex corresponding to the infinite face of the dual graph. Let us apply Theorem 1.1 to the dual of G with this choice of x_0.

The union of any set of faces of a planar graph can be partitioned into (topologically) connected regions, where each region is the union of faces corresponding to the components of the dual graph. Consider the regions determined by the faces φ with $\lambda(\varphi) \leq i$ (Figure 2). Among these, those whose territory is bounded (equivalently, which do not contain the infinite face) will be called *patches* (see Figure 2).

THEOREM 1.2. *Let G be an Eulerian graph embedded in the plane, and let $R \subseteq E(G)$ be such that (G, R) satisfies the cut condition. Then the boundaries of patches contain exactly one edge of R each, they are pairwise disjoint, and every $e \in R$ is contained in one of them.*

Proof. Apply Theorem 1.1 to the dual of G, where the edge weights are -1 for the duals of edges in R and 1 otherwise; note that the dual of G is bipartite; define x_0 to be the vertex of the dual graph corresponding to the infinite face of G. Clearly, there is a one-to-one correspondence between the patches of G and those components of the level graphs of the dual graph which do not contain x_0. Because of (1.2), the boundaries of these patches are disjoint; the rest of the statement can be extrapolated from Theorem 1.1. □

In other words, if G is a planar Eulerian graph and $R \subseteq E(G)$ is such that (G, R) satisfies the cut condition, then Theorem 1.2 provides a uniquely determined integer "multiflow" (see the definition below), which will be called a *patch flow*. Similarly, the packing of odd cuts defined after Theorem 1.1 will be called a *patch packing* for (G, T, x_0).

The reader may find it amusing to translate the proof of Theorem 1.1 to give a direct proof of Theorem 1.2 and, in fact, of the following sharpening.

The necessity of the cut condition for the existence of paths in $G - R$ between the endpoints of the edges in R is trivial. The sufficiency is just the "planar dual" of (1.3). That is, we have shown a constructive proof (see the corresponding polynomial algorithm in section 3) of the following theorem of Seymour [1981].

(1.5) *Let G be a planar Eulerian graph and $R \subseteq E(G)$. Then there exist edge-disjoint paths in $G - R$ between the endpoints of the edges of R if and only if the cut condition is satisfied for (G, R).*

We conclude this section by defining multiflows precisely and listing a sequence of known results about them. Let G be a graph and $c: E(G) \to \mathbb{R}$. c will mean capacity on the positive edges and demand on the negative edges. We define the *demand* of $e \in E(G)$, $c(e) < 0$, to be $-c(e)$. If $c(e) < 0$, e is called a demand edge.

Given a weight function in a graph, let us denote the set of negative edges by E^- and the set of nonnegative edges by E^+. A *multiflow* for (G, c) is a set of circuits $\mathcal{C}$ with "multiplicities" $f: \mathcal{C} \to \mathbb{R}$ such that

$$|C \cap E^-| = 1 \quad \text{for all } C \in \mathcal{C},$$

$$\sum_{e \in C} f(C) \leq c(e) \quad \text{if } e \in E^+, \quad \text{and}$$
$$\sum_{e \in C} f(C) = -c(e) \quad \text{if } e \in E^-.$$

If $f(e)$ is (half-) integer for every $e \in E(G)$, we say that the flow is (*half-*) *integer*. If in this definition we replace "circuit" by "cut," we say that $(\mathcal{C}, f)$ is a *dual multiflow*. The planar special case of dual multiflows is the panar multiflow problem, but dual multiflows have the advantage that the theorems concerning them are valid for arbitrary graphs.

The (*integer*) *multiflow problem* is the problem whose instances are (G, c) pairs, where G is a graph and $c: E(G) \to \mathbb{R}$, and the question is to decide the existence of an (integer) multiflow. In the *planar multiflow problem*, we consider only instances where G is planar.

Statements about capacitated multiflow problems can be reduced to uncapacitated ones by replacing e by $|c(e)|$ parallel copies of e. For instance, the cut condition becomes

$$c(\delta(X)) \geq 0 \quad \text{for every } X \subseteq V(G).$$

The results of Edmonds and Johnson [1973], Lovász [1975], Barahona [1980], and Korach [1982] proved that in a planar graph, a half-integer flow or a violating cut can be found in polynomial time. The best complexity was attained by Barahona [1989]. The closest predecessor to our approach is in the work of Matsumoto, Nishizeki, and Saito [1986]. They decreased c along a face for all possible choices of faces and checked the cut condition for each choice. The proof of Theorem 1.1 indicates explicitly that the face to be chosen is φ with $\lambda(\varphi)$ minimum; moreover, Theorem 1.1 foresees the entire multiflow, the same one which would be the result of alternatively determining φ and deleting its boundary.

Various results about integral (dual) multiflows have been obtained by Seymour [1977, 1981], Korach and Penn [1992], Frank [1990], Sebő [1987a, b], and, more recently, Frank and Szigeti [1995] and Ageev, Kostochka, and Szigeti [1995]. These

integer multiflows can also be obtained with the help of the "magic numbers"—some of them with considerable additional work, but also with the algorithmic advantages that this represents (see section 3).

The planar multiflow problem in general was proved by Middendorf and Pfeiffer [1989] to be NP-complete.

In section 2, we will extrapolate the weighted generalization of the results in this section, and in section 3, we will apply the results that we obtain.

2. Potentials. Potentials in directed graphs are defined in the following way:

Let G be a directed graph, $w: E(G) \to \mathbb{R}$, and $x_0 \in V(G)$. (G, w) is said to be *conservative* if $w(C) \geq 0$ for every directed circuit C. $\pi : V(G) \to \mathbb{R}$ is called a *potential* (centered at x_0) if

$$\pi(x_0) = 0 \quad \text{and}$$

$$\pi(y) - \pi(x) \leq w(x, y) \quad \text{for every directed edge } xy.$$

The role of potentials is apparent from, for instance, the following well-known proposition.

(2.1)

(a) (G, w) *is conservative if and only if there exists a potential.*

(b) *If* π *is a potential centered at* x_0, *then for all* $x \in V(G)$,

$$\lambda_w(x_0, x) \geq \pi(x).$$

(c) *If* (G, w) *is conservative, the function defined by* $\pi(x) := \lambda_w(x_0, x)$ *is a potential centered at* x_0.

(b) and the *if* part of (a) are trivial; (c) is also easy and proves the *only if* part of (a). In other words, potentials centered at x_0 give an apparent proof of conservativeness and a lower bound for the distances from x_0. (c) claims the a priori surprising fact that $\max\{\pi(x) : \pi \text{ is a potential centered at } x_0\}$ is attained by one and the same potential for every $x \in V(G)$, that is, by the distance function λ, $\lambda(x) := \lambda_w(x_0, x)$ $(x \in V(G))$.

Now let G be undirected. Suppose first that G is bipartite, $w: E(G) \to \{-1, 1\}$, and $x_0 \in V(G)$. $\pi: V(G) \to \mathbb{Z}$ will be called a *potential* centered at x_0 if

(i) $\pi(x_0) = 0$ and

(ii) $|\pi(y) - \pi(x)| = 1$ for every $xy \in E(G)$.

If D is a component of the graph $G^i = G^i(\pi)$ induced by the level set $V^i = V^i(\pi)$ $:= \{x \in V(G) : \pi(x) \leq i\}$ $(i = 0, \pm 1, \pm 2, \ldots)$, then

(iii)

$$|\delta(D) \cap E^-| = 1 \quad \text{provided that } x_0 \notin D,$$

$$|\delta(D) \cap E^-| = 0 \quad \text{provided that } x_0 \in D.$$

Theorem 1.1 can now be restated in the following way.

(2.2) *If* G *is* ± 1*-weighted and bipartite, then* (2.1) *holds.*

The *if* part of (2.1a) and all of (2.1b) can be proved in a straightforward way. (For details, see Sebő [1990].) To prove (2.1c), which also implies the *only if* part of (2.1a), we have to check (i), (ii), and (iii): (i) is trivial, (ii) is easy (we have already proved it; see (1.2)), and (iii) is Theorem 1.1.

We have arrived at the main purpose of this section: we will generalize potentials for arbitrary undirected graphs with arbitrary weights. Of course, we have to satisfy two constraints: it should be easy to check whether a given function is a potential (like the inequality for directed graphs or (i), (ii), and (iii) for bipartite ±1-weighted graphs); (2.1) should be true.

For the sake of simplicity, we first do this work only for integer weights, and then we will observe that the theorems hold for arbitrary real weights almost without change and that the extension is straightforward.

If w is not bipartite, we associate with the pair (G,w) a bipartite graph $\hat{G}$ and a weight function $\hat{w}\colon E(\hat{G}) \to \{-1,1\}$ in the following way:

Contract the zero-weight edges of G and replace each edge $e \in E(G), w(e) \neq 0$, by $2|w(e)|$ edges in series. (Divide e into $2|w(e)|$ edges by $2|w(e)|-1$ new points.) We think of $V(G)$ as a subset of $V(\hat{G})$. If $\hat{e} \in E(\hat{G})$ is an element of the subdivision of $e \in E(G)$, let $\hat{w}(\hat{e}) = -1$ if $w(e) < 0$ and let $\hat{w}(\hat{e}) = +1$ if $w(e) > 0$.

Clearly, the natural correspondence between paths of G and paths of $\hat{G}$ simply doubles the weights. Thus

$$\forall x, y \in V(G), \quad \lambda_{\hat{G},\hat{w}}(x,y) = 2\lambda_{G,w}(x,y).$$

This shows that we shall have an easy task. We know that the potentials in $(\hat{G},\hat{w})$ are the functions for which (i), (ii), and (iii) hold. On the other hand (e.g., for applications), we need theorems that consider only (G,w) directly; potentials should be defined in terms of (G,w). We will face no obstacles in obtaining this direct definition because it turns out that a potential $\hat{\pi} : V(\hat{G}) \to \mathbb{Z}$ is *already determined by its restriction to* $V(G)$.

LEMMA 2.1. *Suppose $\hat{\pi} : V(\hat{G}) \to \mathbb{Z}$ is a potential in $(\hat{G},\hat{w})$. Then $\hat{\pi}$ is even on $V(G)$, and if $\pi : V(G) \to \mathbb{Z}$ denotes the restriction of $\hat{\pi}/2$ to $V(G)$, then for every $ab \in E(G)$,*

(a) $|\pi(a) - \pi(b)| \leq |w(ab)|$.

Denote the path of $\hat{G}$, replacing $ab \in E(G)$ by $Q = \{p_0,\ p_1, \dots, p_{t-1},\ p_t\}$ ($p_0 = a,\ p_t = b,\ t = 2|w(ab)|$).

(b) *π uniquely determines $\hat{\pi}$, namely, if $w(ab) \neq 0$, then in $(\hat{G},\hat{w})$,*

$$\hat{\pi}(p_i) := \begin{cases} 2\pi(a) + i & \text{provided that } 0 \leq i \leq i_0, \\ 2\pi(b) + |2w(ab)| - i & \text{provided that } i_0 \leq i \leq t, \end{cases}$$

where $i_0 = \pi(b) - \pi(a) + |w(ab)|$.

(c) $\max_{0\leq i\leq t}\ \hat{\pi}(p_i) = \hat{\pi}(p_{i_0}) = \pi(a) + \pi(b) + |w(ab)|$.

Remark. Lemma 2.1 gives the value of $\hat{\pi}(p_i)\,(0 \leq i \leq t)$; it even gives two definitions for $\hat{\pi}(p_{i_0})$, but both of them define the value $\hat{\pi}(p_{i_0}) = \hat{\pi}(a) + \hat{\pi}(b) + |\hat{w}(ab)|$.

Lemma 2.1 is illustrated in Figure 3.

Proof of Lemma 2.1. First, we prove that $\hat{\pi}$ is even on $V(G)$. Indeed, it follows from (ii) that $\hat{\pi}$ has different parity on the two endpoints of every edge, and hence its parity is fixed on each class of the bipartition of $\hat{G}$. Since one of these classes contains $V(G)$, and since $\hat{\pi}(x_0) = 0$, we get that $\hat{\pi}$ is even on $V(G)$.

We now prove (a). If $w(ab) = 0$, then $\hat{\pi}(a) = \hat{\pi}(b)$, and (a) is trivial.

Suppose that $w(ab) \neq 0$. According to (ii), $|\hat{\pi}(p_i) - \hat{\pi}(p_{i-1})| = 1$, whence

$$2|\pi(a) - \pi(b)| = |\hat{\pi}(a) - \hat{\pi}(b)| = \left|\sum_{i=1}^{t} \hat{\pi}(p_i) - \hat{\pi}(p_{i-1})\right| \leq e\sum_{i=1}^{t} |\hat{\pi}(p_i) - \hat{\pi}(p_{i-1})|$$

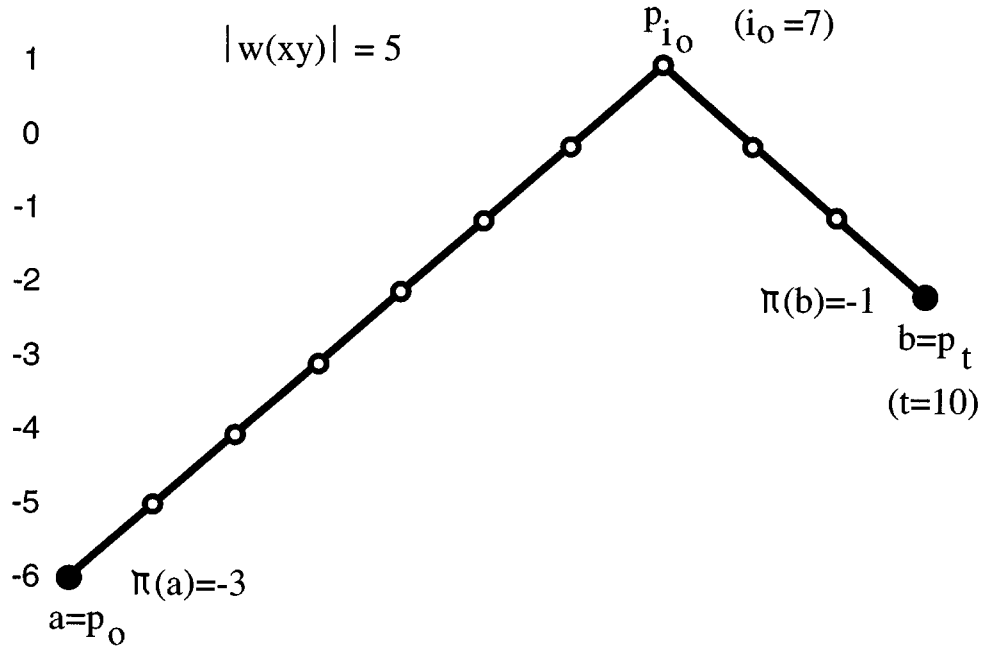

FIG. 3.

$$= t = |2w(ab)|,$$

and (a) is proved.

If $\hat{\pi}(p_i) = \hat{\pi}(p_{i-1}) - 1$, then we call the edge $p_{i-1}p_i$ *descending*, and if $\hat{\pi}(p_i) = \hat{\pi}(p_{i-1}) + 1$, then we call it *ascending*. By (ii), every edge is either descending or ascending. If $p_{i-1}p_i$ is descending, $i < t$, then p_ip_{i+1} cannot be ascending; otherwise, $\{p_i\} \in D$, which contradicts (iii) because $\delta(p_i)$ consists of two positive or two negative edges. From this it follows that there exists an $i_0 \in \mathbb{N}$ such that $p_{i-1}p_i$ is ascending if $1 \le i \le i_0$ and descending if $i_0 < i \le t$. Consequently, with this i_0, $\hat{\pi}(p_i) = \hat{\pi}(p_0) + i$ if $0 \le i \le i_0$ and $\hat{\pi}(p_i) = \hat{\pi}(p_t) + (t - i)$ if $i_0 \le i \le t$. Hence $\hat{\pi}(p_0) + i_0 = \hat{\pi}(p_{i_0}) = \hat{\pi}(p_t) + (t - i_0)$, that is, $i_0 = (\hat{\pi}(b) - \hat{\pi}(a) + 2|w(ab)|)/2$. Thus we have proved (b). (c) is the immediate consequence of (b). □

We call a function $\pi : V(G) \to \mathbb{Z}$ a *potential centered at* $x_0 \in V(G)$ if the function 2π is the restriction to $V(G)$ of a potential in $\hat{G}$ centered at $x_0 \in V(\hat{G})$. Given G, w, and a potential π, we will keep the notation $\hat{G}$, $\hat{w}$, $\hat{\pi}$; these are uniquely determined (see Lemma 2.1(b)). The properties of $\hat{\pi}$ can be "translated" into properties of π:

Let $\pi : V(G) \to \mathbb{Z}$ and define $G^i_w = G^i_w(\pi)$ by $V(G^i_w) := \{x \in V(G) : \pi(x) \le i\}$ and $E(G^i_w) := \{xy \in E(G) : (\pi(x) + \pi(y) + |w(xy)|)/2 \le i\}$ ($i = 0, \pm 1/2, \pm 1, \pm 3/2, \ldots$). We also introduce the notation

$$\mathcal{D} := \{D \subseteq V(G)\text{: } D \text{ is a component of } G^i_w \text{ for some } i\}.$$

LEMMA 2.2. *Let G be an arbitrary undirected graph, $w : E(G) \to \mathbb{Z}$, $x_0 \in V(G)$. $\pi : V(G) \to \mathbb{Z}$ is a potential centered at x_0 if and only if the following hold:*

(i) $\pi(x_0) = 0$.

(ii) $|\pi(y) - \pi(x)| \le |w(x, y)|$ *for all* $xy \in E(G)$.

(iii) *If D is a component of $G^i_w(\pi)$, then*

- *all negative edges induced by D in G are in $E(G^i_w)$ and*
- (iii) *holds for D.*

Proof. To prove the *only if* part, suppose that $\pi : V(G) \to \mathbb{Z}$ is a potential centered at x_0, that is, 2π is the restriction to $V(G)$ of a potential $\hat{\pi}$ of $(\hat{G}, \hat{w})$ centered at x_0. We must prove that (î), (îî), and (îîî) hold for π provided that (i), (ii), and (iii) hold for $\hat{\pi}$. (î) is obvious and (îî) is just Lemma 2.1(a).

To prove (îîî), let $\hat{\imath} \in \mathbb{Z}$ and note the following: the level graph $\hat{G}^{\hat{\imath}}(\hat{\pi})$ of $\hat{G}$ contains exactly those vertices $v \in V(G)$ for which $\hat{\pi}(v) = 2\pi(v) \leq \hat{\imath}$; by Lemma 2.1(c), it entirely contains the subdivision of exactly those edges $ab \in E(G)$ for which $\pi(a) + \pi(b) + |w(ab)| \leq \hat{\imath}$. That is, the components of $\hat{G}^{\hat{\imath}}$ are determined by those vertices $v \in V(G)$ for which $\pi(v) \leq \hat{\imath}/2$ and those edges $ab \in E(G)$ for which $(\pi(a) + \pi(b) + w(ab))/2 \leq \hat{\imath}/2$ ($\hat{\imath} = 0, \pm 1, \pm 2, \ldots$). Defining $i := \hat{\imath}/2$, we see that these vertices and edges are exactly those of $E(G^i_w(\pi))$. Thus there is a one-to-one correspondence between the components of $\hat{G}^{\hat{\imath}}(\hat{\pi})$ and those of $G^i_w(\pi)$. If D is a component of the latter, we will denote the corresponding component of the former by $\hat{D}$.

(îîî) now follows easily. If a negative edge ab induced by D is not in $E(G^i_w)$, then $(\pi(a) + \pi(b) + |w(ab)|)/2 > i$, and it follows from Lemma 2.1 that there are two negative edges in $\delta(\hat{D})$. (Follow on Figure 3: since $p_{i_0} \notin \hat{D}$ but $a, b \in \hat{D}$, $\delta(\hat{D})$ contains one negative edge from each of the paths (a, p_{i_0}) and (p_{i_0}, b).) Therefore, since by assumption $\hat{\pi}$ satisfies (ii), such an edge ab does not exist, and the first part of (îîî) is proved. Furthermore, it now follows that the negative edges of $\hat{D}$ are in one-to-one correspondence with those entering D, so the second part of (îîî) holds as well.

To prove the *if* part, suppose that (î), (îî), and (îîî) hold for π. Define $\hat{\pi}$ to be equal to 2π on $V(\hat{G}) \cap V(G)$, and extend it to the entire $V(\hat{G})$ in the unique way dictated by Lemma 2.1 (b). By definition, $\hat{\pi}$ satisfies (i) and (ii). If D is as in (îîî), then by the same correspondence as in the proof of the *only if* part, D correponds to a component $\hat{D}$ of $\hat{G}^{\hat{\imath}}(\hat{\pi})$, and because of the first part of (îîî), there is a one-to-one correspondence between the negative edges of $\delta(\hat{D})$ and those of $\delta(D)$. Now the second part of (îîî) implies that (iii) holds for $\hat{D}$. □

The following theorem is a straightforward reformulation of Theorem 1.1 (that is, of (2.2)) for the weighted case.

THEOREM 2.1 *Let G be an arbitrary undirected graph, and let $w : E(G) \to \mathbb{Z}$ such that (G, w) is conservative*; *furthermore, $x_0 \in V(G)$. Then $\lambda : V(G) \to \mathbb{Z}$, where $\lambda(x) := \lambda_{G,w}(x_0, x)$ $(x \in V(G))$ is a potential centered at x_0. Furthermore,* (2.1) *holds.*

Proof. Apply Theorem 1.1 and then (2.2) to the conservative bipartite $(\hat{G}, \hat{w})$. Then apply Lemma 2.2 to obtain the result for (G, w). □

The reader may find it to be a useful exercise to give a direct proof of the trivial *if* part of (2.1a) and all of (2.1b), where the definition of potentials is given in (î), (îî), and (îîî).

The main point of Theorem 2.1 is that (îîî) holds for the distances from x_0. Since this statement will be often used in what follows, let us restate it separately in a slightly different form for later convenience.

(2.3) *Let G be a undirected graph, $w : E(G) \to \mathbb{Z}$ such that (G, w) is conservative, and $x_0 \in V(G), \lambda(x) := \lambda_{G,w}(x_0, x)$, $G^i_w := G^i_w(\lambda)$.*

(a) *If D is a component of G^i_w,*

$$|\delta(D) \cap E^-| = 1 \quad \textit{provided that } x_0 \notin D,$$

$$|\delta(D) \cap E^-| = 0 \quad \textit{provided that } x_0 \in D.$$

(b) *Let $y(D) := \max\{i : D \text{ is a component of } G^i\} - \min\{i : D \text{ is a component of } G^i\}$. Then for all $e \in E^-$, $\sum_{D\in\mathcal{D}, e\in\delta(D)} y(D) = |w(e)|$, and for all $e \in E(G)$, $\sum_{D\in\mathcal{D}, e\in\delta(D)} y(D) \le |w(e)|$.*

(2.3) shows how the magic numbers $\lambda(x_0, x)$ generate a special dual flow (packing of T-cuts). This will be the basis of the applications in the following section.

In the rest of the paper, G^i will denote the graph defined in (2.3) (given that (G, w) is conservative and $x_0 \in V(G)$). The family $\mathcal{D}$ can be split into the union of $\mathcal{D}'$ and $\mathcal{D}''$, where $\mathcal{D}'$ is the family of all components of G^i with i as an integer and $\mathcal{D}''$ is the family of all components of G^i with i as a noninteger (but, of course, as a half-integer). Each element of $\mathcal{D}''$ is partitioned by some elements of $\mathcal{D}'$ because $V(G^i) = V(G^{i+1/2})$, and $E(G^i) \subseteq E(G^{i+1/2})$. The following remark will be useful in the construction of integer (dual) flows or packings.

(2.4) *Let G be an undirected graph, and let $w : E(G) \to \{-1, 1\}$ so that (G, w) is conservative. Then $\{\delta(D) : D \in \mathcal{D}'', x_0 \notin D\}$ is a set of disjoint cuts each of which contains one negative edge, and $xy \in E(G)$ is in none of these cuts if and only if $\lambda(x) = \lambda(y)$.*

Indeed, let $xy \in E(G)$, and suppose without loss of generality that $\lambda(x) \le \lambda(y)$. Then either $\lambda(x) = \lambda(y)$ or $\lambda(x) = \lambda(y) - 1$. In the latter case, xy is in $\delta(D)$, where D is the component of $G^{\lambda(x)+1/2}$ containing x; xy is in none of the other sets of the form $\delta(X)$, $X \in \mathcal{D}''$. In the former case, $(\lambda(x)+\lambda(y)+w(xy))/2 = \lambda(x)+1/2$, that is, $xy \in E(G^{\lambda(x)+1/2}$. It follows that x and y are in the same component of $G^{\lambda(x)+1/2})$, whence none of the sets $\delta(D)$ $(D \in \mathcal{D}'')$ contains it, and (2.4) is proved.

The dual flow defined by

$$\mathcal{V} := \{\delta(D) : D \in \mathcal{D},\, x_0 \notin D\}$$

with multiplicities $y(D)$ will be called the *patch dual flow* of (G, w, x_0). It is, in fact, a dual multiflow. A patch dual flow becomes a multiflow in the dual of a planar graph (and if we dualize so that x_0 is the infinite face, this is the uniquely determined patch flow); applying it to the conservative graph corresponding to a minimum T-join, we get a *patch packing* of T-cuts (see section 1 for the unweighted case), which is a maximum packing of T-cuts.
