Note that the results can be *generalized to arbitrary $w: E(G) \to \mathbb{R}$*, where the potentials can be defined by (î), (ĩî), and (ĩĩî). *The distances still form a potential*; *furthermore,* (2.1) *still holds.*

Indeed, let $\varepsilon \le (1/2n^2)\mu$, where μ is the minimum difference between *different* path lengths. The function $w_\varepsilon(e) := \lceil w(e)/\varepsilon \rceil$ $w_\varepsilon: E(G) \to \mathbb{N}$ has the property that for two paths P and Q (not necessarily between the same pair of vertices), $w(P) < w(Q)$ implies $w_\varepsilon(P) < w_\varepsilon(Q)$, whence the w_ε-shortest paths are also w-shortest paths.

Since $w(e)/\varepsilon \le w_\varepsilon \le 1 + w(e)/\varepsilon$, we have $w(e) \le \varepsilon w_\varepsilon \le \varepsilon + w(e)$. Thus, choosing an arbitrary series $\varepsilon_n \to 0$, $\varepsilon_n w_{\varepsilon_n} \to w$ holds (uniformly on the paths). It follows that, applying (2.1) to w_{ε_n}, the same follows for $\varepsilon_n w_{\varepsilon_n}$. Since, as we noticed, the w_{ε_n}-shortest paths are also w-shortest, the distances according to the weight function $\varepsilon_n w_{\varepsilon_n}$ converge to λ_w. Now since in (î), (ĩî), and (ĩĩî) we only have linear functions

of convergent series, these linear functions also converge to the same linear function of the limits, and (2.1) follows for arbitrary real weights in a straightforward way.

Patch flows and patch packings (without using this term) have been applied to prove integer-path or cut-packing theorems. See, for instance, Sebő [1990], Frank and Szigeti [1995], or Ageev, Kostochka, and Szigeti [1995].

3. Algorithms and applications. It is well known that an algorithm for minimum-weight T-joins has been deduced from weighted matching algorithms in various ways (see Edmonds [1965b] and Lawler [1976]). The same sources reduce the shortest-undirected-path problem of conservative graphs to matching problems with similar gadget-type reductions. However, these and other "Waterloo folklore solutions" do not give a satisfactory answer to the dual of the minimum-weight T-join problem (though it is often needed in applications; see below). That is why there were later several attempts at the solution of the primal and dual problem at the same time; see Barahona [1980, 1989], Edmonds and Johnson [1973], and Korach [1982]. Barahona [1989] gave a clear presentation; Barahona and Cunningham [1989] showed an elegant way to provide an integer dual solution in the bipartite case.

Let n stand for $|V(G)|$ and m stand for $|E(G)|$ in the rest of the paper. In this section, we will show that a dual flow or a maximum w-packing of T-cuts can be found by solving n independent matching problems (which can also be carried out in parallel). Furthermore, we always get a half-integer solution, and if for all circuits $w(C)$ is even, then we automatically get an integer solution. Then we collect applications of weighted and unweighted potentials, the complexity of which is determined by our algorithm.

In the following, we shall need a subroutine that determines a minimum-weight T-join. For this we shall use Edmonds and Johnson's [1973] reduction to matchings, which we shall describe now. It is the following obvious fact that makes possible the use of this method.

LEMMA 3.1. *Suppose that (G,w) is conservative, $a,b \in V(G)$, and $T := \{x \in V(G) : d_{E^-}(x)$ is odd$\}$. If F is a $|w|$-minimum $T\triangle\{a,b\}$-join, then in $F\triangle E^-$, any (a,b)-path is w-shortest.*

Remark. Since $F\triangle E^-$ is an $\{a,b\}$-join, an (a,b)-path contained in it is trivial to find. Thus Lemma 3.1 reduces the shortest-path problem to finding a minimum T-join for nonnegative weights. Since, moreover, the zero-weight edges can be contracted, in the following, we can concentrate on T-joins in graphs with positive weights.

We also remark that the converse of Lemma 3.1 is also true (but irrelevant here): if P is a w-shortest (a,b)-path, then $P\triangle E^-$ is a $|w|$-minimum $T\triangle\{a,b\}$-join.

Proof of Lemma 3.1. Clearly, $F\triangle E^-$ is an $\{a,b\}$-join, and

$$\begin{aligned} w(F\triangle E^-) &= w(F \setminus E^-) + w(E^- \setminus F) \\ &= |w|(F \setminus E^-) + |w|(F \cap E^-) - |w|(E^- \cap F) + w(E^- \setminus F) \\ &= |w|(F) + w(E^-). \end{aligned}$$

Thus $|w|(F)$ and $w(F\triangle E^-)$ differ only in a constant independent of F. F is a $|w|$-minimum $T\triangle\{a,b\}$-join $\Leftrightarrow$ $F\triangle E^-$ is a w-minimum (a,b)-path $\Leftrightarrow$ in $F\triangle E^-$, an arbitrary circuit has weight 0. □

Now let $w : E(G) \to \mathbb{N}$, and on the edges of the complete graph on H with $V(H) := T$, define the weighting $c(x,y) := \min\{w(P) : P \subseteq E(G),\ P$ is an (x,y) path$\}$

> 0. ($c(x, y)$ can, for instance, be computed by Dijkstra's algorithm; see, for example, Lawler [1976].) The following lemma of Edmonds and Johnson [1973] relates the w-minimum T-joins of G to the c-minimum matchings of H.

LEMMA 3.2. *Let G be a connected graph, $T \subseteq V(G)$, where $|T|$ is even, and $w : E(G) \to \mathbb{N}$, and from these let us define H and c in the above way. Furthermore, let $k := |V(H)|/2$. If $\{x_i y_i : i = 1, \dots, k\}$ is a c-minimum perfect matching in H and P_i is a shortest (x_i, y_i)-path $(i = 1, \dots, k)$, then $P_i \cap P_j = \emptyset$ $(i \neq j)$ and $\bigcup_{i=1}^{k} P_i$ is a w-minimum T-join in G.*

Remark. Applying both Lemmas 3.1 and 3.2, the shortest paths of conservative graphs can be determined using any matching algorithm (see Algorithm 1 below).

Proof of Lemma 3.2. Let $M := \{x_i y_i : i = 1, \dots, |V(H)|/2\}$ be a c-minimum perfect matching and P_i be a w-minimum (x_i, y_i) path $(i = 1, \dots, k)$. Thus $P_i \cap P_j = \emptyset$ since if $P_i \cap P_j \neq \emptyset$, then $w(P_i \triangle P_j) < w(P_i) + w(P_j)$, and $P_i \triangle P_j$ contains two (edge-) disjoint paths between two disjoint pairs of points in $\{x_1, y_1, x_2, y_2\}$, which contradicts the minimality of M. □

The converse of this lemma is also easy. Given nonnegative weights, a minimum-weight T-join (which is a forest) is easy to split into edge-disjoint paths between pairs in $V(H)$, and no matter how we carry this out, the pairs will create a c-minimum matching of H.

We now have the means at our disposal to describe the algorithm based on Theorem 2.1 (section 2).

ALGORITHM 1.

Input: graph G, $x_0 \in V(G)$, and $w : E(G) \to \mathbb{Z}$.

Output: either a negative circuit in (G, w) or a feasible w-packing which is furthermore the uniquely existing patch dual flow belonging to (G, w, x_0).

0. Contract the zero-weight edges and with the help of Lemma 3.2 above, determine a $|w|$-minimum T-join F, $T := \{x \in V(G) \ : \ d_{E^-}(x) \text{ is odd}\}$.

• If $|w|(F) < |w|(E^-)$, then a negative circuit can easily be found in $F \triangle E_-$. STOP.

• If $|w|(F) = |w|(E_-)$, then GOTO 1.

1. With the help of Lemmas 3.1 and 3.2, determine the weight of a w-shortest (x_0, x) path for every $x \in V(G), x \neq x_0$. Let this number be denoted by $\lambda(x)$. GOTO 2.

2. Let the function $\lambda : V(G) \cup E(G) \to \mathbb{Z}$ be the following:

$$\lambda(x) := \begin{cases} \lambda(x) & \text{if } x \in V(G), \\ \dfrac{\lambda(u) + \lambda(v) + w(uv)}{2} & \text{if } x = uv \in E(G). \end{cases}$$

• For the value of $\lambda(x)$ $(x \in V(G))$ and $\lambda(xy)$ $(xy \in E(G))$, define the components of the graph G^i, that is, the set system $\mathcal{D}$. (In the case of bipartite weightings, λ takes only integer values because $\lambda(x)$ and $\lambda(y)$ have the same parity if $w(xy)$ is even and have different parities if it is odd.) The multiplicities $y(D)$ $(D \in \mathcal{D})$ are easily seen to be computable in the following way:

$$y(D) \leftarrow \max_{e \in E^- \cap \delta(D)} \lambda(e) - \min_{e \in E^- \cap E(D)} \lambda(e).$$

(See (2.3b); for a proof, use (îîî).)

$$\mathcal{V} \leftarrow \{\delta(D) : D \in \mathcal{D}, x_0 \notin D\},$$

where we mean the multiplicity of $C \in \mathcal{V}, C = \delta(D)$ $(D \in \mathcal{D})$, to be $y(C) := y(D)$.

Comments.

• The first step of Algorithm 1 associates the execution of a matching algorithm with each point $x \neq x_0$ (see Lemma 3.1) of step 0. The matching subroutine carried out in step 0 can be associated with x_0, so a matching algorithm has been associated with each $x \in V(G)$.

In fact, there is no real assymmetry between steps 0 and 1, in other words, between x_0 and the other vertices of G. The assymetry disappears as soon as we consider a somewhat more general object than graphs (see "towers" in Sebő [1990]).

• For arbitrary real weights, Algorithm 1 works without any change; the only difference is that the function λ defined in step 2 will not be an integer function. We prefer to assume that the weights are integer and often that they are bipartite because then λ is also an integer function and the integrality results that we obtain are included in a natural way.

THEOREM 3.1.

(a) *$\mathcal{V}$ with multiplicities $y(V)$ $(V \in \mathcal{V})$ is a dual flow.*

(b) *$\mathcal{V}$ and $y(V)$ $(V \in \mathcal{V})$ can be determined by first computing the distances in $(G, |w|)$, then using n parallel running and noncommunicating matching subroutines, and then executing at most $n + m$ subroutines that find the connected components of a graph. (These can also be executed in parallel and without communication.) The inputs of the subroutines are graphs on at most n points, and in the input of the matching algorithm, every weight is the sum of the weights $w(e)$ of at most n edges $e \in E(G)$.*

We will assume throughout the paper that the complexity of computing the distances (in parallel or nonparallel) in a graph with nonnegative weights does not exceed that of the (parallel or nonparallel) matching algorithms, whence it can be neglected.

Proof of Theorem 3.1. (a) can immediately be seen from (2.3) (that is, Theorem 2.1), and it is an immediate consequence of Lemma 3.1 and 3.2 that Algorithm 1 satisfies the properties described in (b). □

COROLLARY 1. *Suppose that we have a weighted matching algorithm whose running time is $t(n)$ for an input of n points, and suppose that it uses $p(n)$ processors. Then either a dual multiflow or a negative circuit can also be determined in $t(n)$ time and with $np(n)$ processors.*

According to the results of Mulmuley, Vazirani, and Vazirani [1986], a maximum matching can be determined in $O(\log^2 n)$ time with a random parallel algorithm. The same article solves weighted matching problems for particular weights, but we do not know of any general efficient parallel algorithm that solves this problem. However, Mulmuley, Vazirani, and Vazirani note that the general weighted problem is also in RNC^2 if the encoding of the weights is unary. Wein [1991] developed a Las Vegas RNC algorithm for minimum-weight perfect matchings which is logarithmic polynomial if the encoding of the weights is unary. Through Theorem 2.1, we get the same results for dual multiflows and all of their applications. (Wein's [1991] result itself uses Theorem 2.1.)

In Algorithm 1, Theorem 3.1, and Corollary 1, instead of "dual flow," we could of course have written "maximum T-cut packing" for a (G, T) and a weighting $w : E(G) \to \mathbb{Z}_+$. Furthermore, Algorithm 1 always defines *the uniquely existing patch packing.* Thus for every application of patch packings, we have the following corollary:

In planar networks, with the "dualization" described in section 1 and within the time limits in Corollary 1, Algorithm 1 either finds a cut that violates the cut condition

or finds a feasible flow. The "dual distances" (see section 1) taken from the infinite face can be determined by Algorithm 1, and in this way our result will be the uniquely existing patch flow. The same holds for the Ising model (see Barahona [1980]). Thus for these problems as well, a structural decomposition is implied. In the case of an Eulerian graph, this will automatically be an integer flow.

Of course, to get the best complexity results, one should substitute into Corollary 1 the best possible complexity results that exploit planarity. Finding a logarithmic polynomial parallel matching algorithm is still an open problem. The best known complexity for matchings in planar graphs is by Lipton and Tarjan [1980]: $O(n^{3/2}\log n)$. It follows that the sequential complexity of finding a patch flow in planar graphs—and of all the planar problems mentioned above—is $O(n^{5/2}\log n)$.

Nishizeki, Matsumoto, and Saito [1986] also solved planar flow problems within this time limit via n matching algorithms; however, these must be successive. In their algorithm, the input of every matching subroutine depends on the output of all subroutines carried out previously, and the output of the whole algorithm depends on the choices made during the running of the algorithm.

Note that the best sequential complexity for the planar Chinese postman problem has thus far been reached by Barahona [1989] with a direct algorithm that has the same complexity as the best planar matching algorithm at present, $O(n^{3/2}\log n)$.

We now mention some applications that require more than a simple use of Theorems 2.1 and 3.1.

3.1. Integer packings in graphs without odd K_4.

(3.1) (Seymour [1977]) *Let G be a graph and suppose that $T \subseteq V(G)$, where $|T|$ is even. If $V(G)$ cannot be partitioned into four T-odd parts so that each induces a connected graph, and if there exists an edge between any two of the four parts, then the maximum cardinality of a family of disjoint T-cuts is equal to the minimum cardinality of a T-join.*

Since the constraint of (3.1) remains true after the usual subdivision (or contraction) of edges, the weighted generalization can be straightforwardly deduced. The condition of (3.1) is not only sufficient but also necessary to have a maximum w-packing of T-cuts that is integer for an arbitrary nonnegative integer weight function w.

(3.1) is an important special case of Seymour's general characterization of binary clutters with the strong max-flow min-cut property. It is closely related to the following result. (Again, for the sake of simplicity, we state only the cardinality case, which implies the general case through the usual subdivision of edges.)

If $\mathcal{P}$ is a partition of $V(G)$ into T-odd parts each of which induces a connected graph, then the set of edges whose endpoints are in different parts of $\mathcal{P}$ is called a *T-border*. The *value* of this T-border is $|\mathcal{P}|/2$. A T-border B is called *bicritical* if, upon contracting all the edges of $E(G) \setminus B$ (that is, shrinking all the classes of $\mathcal{P}$), we get a bicritical graph, that is, a graph that has a perfect matching, and according to the weight function that is -1 on a perfect matching and 1 everywhere else, the distance between any two points is -1. (It is an easy exercise to show that this definition does not depend on the chosen matching.)

(3.2) (Sebő [1988]) *Let G be a graph and $T \subseteq V(G)$, where $|T|$ is even. The minimum cardinality of a T-join of G is equal to the maximum sum of the values of a set of edge-disjoint bicritical T-borders.*

Again, (3.2) implies its own weighted generalization in the usual way. (3.2) implies (3.1) using the following.

(3.3) (Sebő [1988]) *The vertices of a bicritical graph can be partitioned into four classes of odd cardinality so that, upon contracting all edges with both endpoints in the same class, we get* K_4.

The original proof of (3.3) reduces the statement to Seymour's theorem and points out that an elementary proof would generate a simple proof of Seymour's theorem via (3.2). A simple proof of (3.3) was given by Lovász through the ear decomposition of nonbipartite matching-covered graphs and by Gerards [1987] in an elementary way. For an elegant, elementary proof of (3.3), see Frank and Szigeti [1994].

The original proof (see Sebő [1987a]) of (3.2) used Theorem 1.1, and for the sake of the algorithmic consequences, this is what we must follow here. (In Sebő [1988], the same proof was described in a self-contained way by substituting the proof of Theorem 1.1 instead of using it. Frank and Szigeti [1994] replaced Theorem 1.1 by using (1.4), which combined with their proof of (3.3) is the shortest variant.)

Proof of (3.2). It is trivial that the minimum is greater than or equal to the maximum. To prove equality, let F be a minimum T-join and define $w(e) := -1$ if $e \in F$ and $w(e) := 1$ if $e \in E(G) \setminus F$. By Guan's remark (see section 1), (G, w) is conservative. We can suppose without loss of generality that G is connected. Let $x_0 \in V(G)$ be arbitrary. Define $\mathcal{D}$, $\mathcal{D}'$, and $\mathcal{D}''$ as we did immediately after (2.3), and apply (2.3).

As we noticed after (2.3), each $D \in \mathcal{D}''$ is partitioned by some elements $D_1, \dots, D_k$ of $\mathcal{D}'$. If $x_0 \notin D$, then $x_0 \notin D_1 \in \mathcal{D}, \dots, x_0 \notin D_k \in \mathcal{D}$, and by (2.3a), $\delta(D_i)$ contains exactly one negative edge for $i = 1, \dots, k$, and since $\delta(V(G) \setminus D) = \delta(D)$, so does $\delta(V(G) \setminus D)$. $G - D$ may be disconnected, but for one of its components—denote it by D_0—$\delta(D_0)$ contains the unique negative edge of $\delta(D)$. Add each component of $G - D$ except D_0 to one of the D_i's ($i = 1, \dots, k$) adjacent to it. (Since G is connected, there exists at least one such D_i for every component of $G - D$.) In this way, we get a partition $\mathcal{P}(D) := \{D_0, D'_1, \dots, D'_k\}$ whose classes are matched by $(k+1)/2$ edges of F, and there is no other edge of F in the set $B(D)$ of edges joining different classes of $\mathcal{P}(D)$. Thus B(D) is a T-border.

Moreover, $\mathcal{B} := \{B(D) : D \in \mathcal{D}'', x_0 \notin D\}$ is a set of disjoint T-borders whose sum of values is equal to $|F|$. This proves (3.2) without proving that these T-borders are bicritical. If some of the T-borders $B \in \mathcal{B}$ are not bicritical, we will *find a larger number of disjoint* T*-borders with the same value.* This will complete the proof of (3.2) because the number of disjoint T-borders is bounded by the number of edges, so it has a maximum, and then all T-borders are bicritical.

Let B^* be the graph that we obtain by contracting $E(G) \setminus B$ (that is, by shrinking the classes of the underlying partition). $F \cap B$ is a perfect matching of B^*, and the weighting w becomes w^*: -1 on F and 1 elsewhere. (B^*, w^*) is conservative. Suppose that B^* is not bicritical; let $x_0^* \neq x^* \in V(B^*)$ and $\lambda_{B^*,w^*}(x_0^*, x^*) \geq 0$.

Apply to (B^*, w^*) the argument that we used for (G, w) to find a set of disjoint $V(B^*)$-borders of maximum sum of values. We get a set $\mathcal{B}^*$ of disjoint T-borders of total value $|B \cap F|$, the same as the value of B. The T-border in $\mathcal{B}^*$ containing the negative edge e adjacent to x_0^* contains only edges adjacent to vertices at distance -1, whence it does not contain the negative edge adjacent to x^*. Thus $|\mathcal{B}^*| \geq 2$, as claimed. □

The algorithm that follows from this proof for finding the integer packing of (3.2) is the following.

ALGORITHM 2.

Input: a graph G and $w : E(G) \to \mathbb{N}$.

Output: a w-packing of T-borders (T-cuts if the condition of (3.1) is satisfied).

1. Find a patch dual flow (see Algorithm 1).

2. Find a w-packing of T-borders using the guidelines of the first part of the proof of (3.2).

Comment. Of course, the proof must be applied to the graph where each $e \in E(G)$ is subdivided into a path of $w(e)$ edges, and if the algorithm really does the subdivision, the polynomial bound is lost. However, from the multiplicities of the cuts in the dual flow provided by Algorithm 1, it is straightforward to compute the multiplicities of the T-borders in the packing without actually doing the subdivision.

3. Decompose each T-border B of the constructed packing into disjoint bicritical T-borders using the guidelines of the second part of the proof of (3.2), and replace B with the elements of the decomposition, assigning its multiplicity to each. Continue this procedure with each of the newly constructed T-borders until there is no more proper decomposition, that is, until the distance between any two vertices in all of the T-borders is -1 (according to the weight function defined in the proof of (3.2)), i.e., until they are all bicritical.

Comment. This step is the same in the weighted and unweighted cases. The decomposition of a T-border into bicritical T-borders is an *unweighted* problem.

THEOREM 3.2. *The integer packing of odd cuts in* (3.2) *and* (3.1) *can be found by solving* $O(mn^2)$ *matching algorithms on minors of* G (*graphs that arise with the contraction and deletion of some edges from* G) *and performing some additional steps whose order of magnitude is smaller.*

Proof. To execute steps 1 and 2, the number of matching algorithms to be solved is n. After the execution of step 3, the number of bicritical T-borders that decompose a bicritical T-border is at most the number of edges of the latter. Thus m is an upper bound for the number of times Algorithm 1 must be applied to the subsequent T-borders. On each of these T-borders, we have to execute n^2 matching algorithms to prove that they are bicritical or decompose them. □

It follows that the maximum integral dual solution to the minimization problem on a T-join polyhedron described with a minimal totally dual integral (TDI) description (see Sebő [1988]) can also be computed within the same time limit.

However, note that the bounds in Theorem 3.2 are weaker than those in Corollary 1. We do not see how our parallel complexity estimates could be saved for this case.

3.2. Integer flows—almost. Let (G, w) be ± 1-weighted and conservative. Of course, E^- forms a forest. Korach and Penn [1992] proved that there exist pairwise-disjoint cuts, each of which contains one negative edge, so that every negative edge is in some of the cuts except perhaps at most one edge of each component of E^-; in fact, for one component of E^-, one can require every edge to be in some of the cuts. Equivalently, for arbitrary weights, Korach and Penn proved the following theorem.

(3.4) *If* (G, w) *is conservative, then there exists* $F \subseteq E^-$ *with* $|F \cap C| \leq 1$ *for every connected component* C *of* E^- *such that for the weight function* w'*, there exists an integer dual flow, where* $w'(e) := w(e)$ *if* $e \in E \setminus F$ *and* $w'(e) := w(e) - 1$ *if* $e \in F$.

We give the proof of Sebő [1990], which provides an algorithm for finding this dual flow and the multiflow of Corollary 2 below via Theorem 2.1, with the time limits of Theorem 3.1.

Proof of (3.4). The usual subdivision of edges leads to a ± 1-weighted conservative graph, so suppose that (G, w) is already one. Let $x_0 \in V(G)$ be arbitrary and $\lambda(x) := \lambda_w(x_0, x)$ $(x \in V(G))$. Denote the components of E^- by $E_0, \ldots, E_k$.

CLAIM 3. *For every $x \in V(E_i)$, there exists at most one $y \in V(E_i)$ with $xy \in E_i$ such that $\lambda(y) \geq \lambda(x)$ $(i = 1, \ldots, k)$.*

Indeed, let $xy_1, xy_2 \in E_i$, $y_1 \neq y_2$. A shortest simple (x_0, x) path P contains at most one of these edges—say, it does not contain the edge xy_2. Then, however, $P \cup xy_2$ is an (x_0, y_2) path and $\lambda(y_2) \leq w(P \cup xy_2) = w(P) - 1 = \lambda(x) - 1$.

CLAIM 4. *The maximum of $\lambda(x)$ on $V(E_i)$ is reached on one vertex or the two endpoints of an edge $(i = 1, \ldots, k)$. For every edge $uv \in E_i$ but this one, $|\lambda(u) - \lambda(v)| = 1$.*

Indeed, if there are two nonadjacent vertices of E_i with $\lambda(x)$ maximum, then these two vertices are joined by a subpath of E_i, which, if it consists of at least two edges, must contain a vertex, contradicting the claim. If $|\lambda(u) - \lambda(v)| = 0$, then in exactly the same way, we get from Claim 3 that $\lambda(u) = \lambda(v)$ are the only maxima of $\lambda(x)$, $x \in V(E_i)$.

Thus each E_i $(i = 1, \ldots, k)$ contains at most one edge xy with $\lambda(x) = \lambda(y)$. According to (2.4), $\{\delta(D) : D \in \mathcal{D}'', x_0 \notin D\}$ is a set of disjoint cuts which contains every negative edge except those with $\lambda(x) = \lambda(y)$, that is, there is at most one exception in each E_i $(i = 1, \ldots, k)$ (see Claim 4). □

The following statement of Korach and Penn [1992] is an immediate corollary.

COROLLARY 2. *If (G, c) is an instance of the planar multiflow problem and the cut condition is satisfied, then upon decreasing all but one of the demands by 1 (that is, increasing all the negative capacities by 1), there exists an integer multiflow.*

Korach and Penn also noticed that one can, in fact, require $F \cap E_0 = \emptyset$ for any given component E_0 of E^-. Indeed, in the above proof as well, the choice $x_0 \in V(E_0)$ makes sure that in Claim 4, $\lambda(x_0) = 0$, and for every other vertex of E_0, $\lambda(x) < 0$. In E_0 there is no edge xy with $\lambda(x) = \lambda(y)$.

Frank and Szigeti [1995] generalized (3.4) in the following way.

(3.5) *Let G be a graph, $w : E(G) \to \mathbb{Z}$, and $E_0, E_1, \ldots, E_k, E_{k+1}, \ldots, E_{k+l}$ be the components of E^-. Suppose that $w(C) \geq s(C)$ holds for every circuit C of G, where $s(C) := |\{i \in \{1, \ldots, k\} : E_i \cap C \neq \emptyset\}|$.*

Then there exists a set $F \subseteq E_{k+1} \cup \cdots \cup E_{k+l}$ such that $|F \cap E_i| \leq 1$ if $i = k+1, \ldots, k+l$, with the property that, upon decreasing the demand of $e \in E_i \cap F$ by 1 $(i = k+1, \ldots, k+l)$, there exists a dual multiflow.

The proof of Frank and Szigeti consists of splitting every vertex $v \in E_1 \cup \cdots \cup E_k$ into two vertices v_1 and v_2, where v_1 is incident to the positive edges and v_2 is incident to the negative edges of $\delta(v)$. v_1 and v_2 are joined by an edge of weight $-1/2$. If the condition of (3.5) is satisfied, then the constructed graph with the constructed weighting is conservative, and applying the proof of (3.4) to this graph with this weight, we can obtain the dual multiflow stated in (3.5).

Frank and Szigeti [1995] also observed the following immediate corollary.

COROLLARY 3. *If (G, w) is conservative and $w(\delta(X)) + w(\delta(X) \cap E^-) \geq 0$, then there exists an integer dual multiflow.*

Theorem 3.1 then implies the following:

The integer (dual) multiflow in (3.4), (3.5), and Corollary 3 can be found within the same time limits as those in Corollary 1. Of course, the same holds for integer multiflows in planar graphs.

3.3. Packing cuts exactly. Finally, let us comment on the complexity of integer odd cut packings. Let G be a graph and $T \subseteq V(G)$, where the number of vertices of T in each component of G is even. (G, T) is said to have the *Seymour property* if the minimum cardinality of a T-join is equal to the maximum cardinality of a set

of disjoint T-cuts. Accordingly, (G, w) $(w : E(G) \to \mathbb{Z})$ has the Seymour property if there exists an integer dual flow. Middendorf and Pfeiffer [1989] proved that it is NP-complete to test the Seymour property, even in planar graphs.

Therefore, instead of the Seymour property, our interest turns towards Seymour graphs. G is called a Seymour graph if for arbitrary $w : E(G) \to \{-1, 1\}$ for which the cut condition holds, there exists an integer dual multiflow. Through the subdivision of edges, the weighted generalization is the following: G is a Seymour graph with respect to the weight function $w : E(G) \to \mathbb{N}$ if for an arbitrary $w' : E(G) \to [-|w(e)|, w(e)]$ such that $w'(e) \equiv w(e) \bmod 2$ and the cut condition holds, there exists an integer dual multiflow. (This is the class of weight functions that one gets by independently signing the parts of a subdivided edge. In the following, we will restrict ourselves to unweighted Seymour graphs since the generalization is trivial and somewhat artificial.) It is not known whether the problem of deciding whether a graph G is a Seymour graph is polynomially solvable or coNP-complete. (It is not trivial but true that it is in coNP, as we shall see later.) However, the following somewhat weaker results are known:

As Seymour's result (1.3) implies that bipartite graphs are Seymour graphs, so does (3.1) imply that series-parallel graphs are Seymour graphs. (The latter statement can also be easily proved directly without using (3.1).) Gerards [1992] proved a common generalization of these two results. A sharpening of this that provides a coNP characterization of Seymour graphs was conjectured by Sebő [1991] and proved by Ageev, Kostochka, and Szigeti [1995]. The following simplified version still provides a polynomially checkable obstacle, and it suffices for our purposes.

(3.6) *G is not a Seymour graph if and only if there exists a signing of the edges such that the union of zero-weight circuits* (*in fact, of only two zero-weight circuits*) *is nonbipartite.*

The proof of the *if* part of this conjecture is a straightforward exercise.

The proof of the *only if* part given by Ageev, Kostochka, and Szigeti is based on Theorem 1.1 in such a way that Algorithm 1 can be straightforwardly substituted in it, and the corresponding polynomial bounds follow easily:

Given the graph G and $w : E(G) \to \{-1, 1\}$, there is a polynomial algorithm which either (a) finds an integer dual multiflow in (G, w) or a negative circuit or (b) exhibits a weight function $w' : E(G) \to \{-1, 1\}$ for which (G, w') is conservative but no integer dual multiflow exists. In the latter case, a "good certificate" (a nonbipartite graph and two zero-weight circuits covering all the edges) is provided.

As a consequence, *the unweighted dual multiflow problem is polynomially solvable in Seymour graphs*, and all of the consequences provided by the Corollary 1 also hold. Let us finally state the specialization to planar graphs (after dualization):

Given the graph $G = (V, E)$ and $R \subseteq E$, there is a polynomial algorithm which either (a) finds an integer multiflow in (G, R) or a violated cut or (b) exhibits $R' \subseteq E$ for which the cut condition is satisfied (certificate: a half-integer multiflow) but no integer multiflow exists (certificate: two zero-weight cuts whose union is odd).

As a consequence, *the edge-disjoint paths problem is polynomially solvable in dual Seymour planar graphs.* The main open problem of whether Seymour graphs are in NP and whether they can be recognized in polynomial time remains.

3.4. Weighted and canonical matching and T-join structure. If $V(G)$ is odd, a matching M will be called *perfect* if it leaves exactly one vertex uncovered. The maximum- (or minimum-) weight matching problem can be easily reduced to the problem of finding minimum-weight perfect matchings. If $w : E(G) \to \mathbb{R}$, we will

denote by $\tau(G, w)$ the minimum weight of a perfect matching in G.

It is now easy to deduce the consequences of Theorems 2.1 and 3.1 to weighted matchings:

Add a large number N (say, N is the sum of the absolute values of the weights) to the weight of every edge. Add a new vertex x_0 to G, and join it to every vertex with an edge of weight N. Let G' denote this new graph and w' denote the weight function that we defined on its edges. It is easy to see that the w'-minimum $T := V(G')$-joins (or $T := V(G') \setminus \{x_0\}$-joins, depending on which of the two is even) of G' are exactly the w-minimum perfect matchings of G (after deleting the edge adjacent to x_0 if $|V(G)|$ is odd).

Choose a minimum-weight perfect matching of G or G' (depending on whether $|V(G)|$ or $|V(G')|$ is even), and change the sign of the weights of the edges in it.

It is now easy to see that the distance of the vertex $x \in V(G)$ from x_0 is the number $\tau(G - x, w) - \tau(G, w)$. Note that it is independent of the particular w-minimum matching chosen.

From a maximum 2-packing of T-cuts in G', a maximum odd cut packing of G can also be reconstructed. That is, Theorem 1.1 can be adapted to weighted matchings. The "magic" numbers should be defined to be $\tau(G - x, w) - \tau(G, w)$. These numbers will be equal to the distances with the chosen weights; these independently computable numbers determine a packing of odd cuts, which could be called a "patch packing" and which generalizes the Gallai–Edmonds structure of maximum matchings. (See more about the relation of Theorem 1.1 and the Gallai–Edmonds structure theorem in Sebő [1990].)

Algorithm 1 and Lemmas 3.1 and 3.2 can be applied to other problems involving integer packings in a similar way. We mention some results whose proofs involve Theorem 1.1 (or 2.1) so that they can be accompanied by a polynomial algorithm that combines Lemmas 3.1 and 3.2 and Algorithm 1.

A generalization of the Kotzig–Lovász theorem (Sebő [1987a, b]) provides a "canonical partition" (implying new results on integer feasible flows or the computation of the dimension of T-join polyhedra or multiflows). This canonical partition can be computed via the distances, that is, with Lemmas 3.1 and 3.2. Thus the integer packings and flows of Sebő [1990], or perhaps a negative cut or an odd circuit consisting of tight edges, or a set violating the cut condition or some stronger condition (see Sebő [1987b]) can also be found in polynomial time.

Acknowledgments. I am thankful to András Frank for his encouragement and to Zoltán Szigeti and an anonymous referee for a lot of helpful advice.

BOOLEAN CIRCUITS, TENSOR RANKS, AND COMMUNICATION COMPLEXITY *

PAVEL PUDLÁK†, VOJTĚCH RÖDL‡, AND JIŘÍ SGALL§

Abstract. We investigate two methods for proving lower bounds on the size of small-depth circuits, namely the approaches based on multiparty communication games and algebraic characterizations extending the concepts of the tensor rank and rigidity of matrices. Our methods are combinatorial, but we think that our main contribution concerns the algebraic concepts used in this area (tensor ranks and rigidity). Our main results are following.

(i) An $o(n)$-bit protocol for a communication game for computing shifts, which also gives an upper bound of $o(n^2)$ on the contact rank of the tensor of multiplication of polynomials; this disproves some earlier conjectures. A related probabilistic construction gives an $o(n)$ upper bound for computing all permutations and an $O(n \log\log n)$ upper bound on the communication complexity of pointer jumping with permutations.

(ii) A lower bound on certain restricted circuits of depth 2 which are related to the problem of proving a superlinear lower bound on the size of logarithmic-depth circuits; this bound has interpretations both as a lower bound on the rigidity of the tensor of multiplication of polynomials and as a lower bound on the communication needed to compute the shift function in a restricted model.

(iii) An upper bound on Boolean circuits of depth 2 for computing shifts and, more generally, all permutations; this shows that such circuits are more efficient than the model based on sending bits along vertex-disjoint paths.

1. Introduction.

The problem of proving superlinear lower bounds on the size of circuits for an explicitly defined sequence of Boolean functions is perhaps the most persistent problem in complexity theory. Attempts to solve it have led to several weaker problems which are often of independent interest. The problem is still open even if we look for functions of n input bits with n outputs and impose an additional restriction that the depth of the circuit is $O(\log n)$.

The main motivation for this paper is a related problem in which the computation is restricted to *linear circuits* over a field $\mathbf{F}$, i.e., circuits which have linear functions as gates. The question is to find an explicit linear function which cannot be computed by a linear circuit of size $O(n)$ and depth $O(\log n)$. Clearly, such a function must have a nonconstant number of output bits since every one-output linear function can be computed by a balanced tree with linear gates. If the field is GF_2, this is a variant of the problem for general Boolean circuits. However, strictly speaking, the problem

about linear circuits over GF_2 is not a weaker problem since the class of computable functions is smaller.

Many natural functions are not linear in all of the inputs, but only in some subset of them. For example, matrix multiplication is a bilinear function, which means that whenever one of the matrices is fixed, it is a linear function of the entries of the other matrix. A natural extension of linear circuits which includes circuits for such functions are *semilinear circuits*. Suppose that a function $F(p, \vec{x})$ is linear for every fixed parameter p. We say that a circuit C (with $\vec{x}$ as an input) is a *semilinear circuit* for $F(p, \vec{x})$ if for any fixed parameter p, we can assign linear functions to the gates of C so that we get a linear circuit for $F(p, \vec{x})$. We want to prove a lower bound on the size of a semilinear circuit computing an explicit $F(p, \vec{x})$.

Thus far, superlinear lower bounds have been proved only for infinite fields. Shoup and Smolensky proved a lower bound of $\Omega(n \log n / \log \log n)$ for linear circuits of poly-logarithmic depth [30]; however, their proof works only for functions with very large values. For finite fields, no explicit functions not computable by linear or semilinear circuits of size $O(n)$ and depth $O(\log n)$ are known.

Some superlinear lower bounds have been proved for a much more restricted model of constant-depth circuits with linear gates of unbounded fan-in. (This is again nontrivial only for multioutput functions.) Some of these bounds use results on the complexity of communication networks [13, 24, 26]. The bounds can be extended to bounded-depth Boolean circuits with arbitrary Boolean functions as gates, which proves, for instance, that addition and multiplication cannot be computed by a constant-depth circuit of size $O(n)$.

We are interested in various algebraic and combinatorial concepts related to circuit complexity. First, we review several such concepts that have been devised for proving circuit lower bounds.

The algebraic approach dates back to Strassen, who introduced the concept of the *rank of a tensor* [31]. This rank characterizes up to a constant factor the number of multiplications needed to compute an explicit bilinear function, which is called multiplicative complexity. It is a major open problem in algebraic complexity to prove a superlinear lower bound on the rank of an explicit tensor. Valiant defined the *rigidity of a matrix* [32]. Sufficiently large lower bounds on the rigidity of the matrix defining a linear function would imply superlinear lower bounds on the size of linear circuits of depth $O(\log n)$. However, thus far, the best bounds for explicit matrices are too small [14]. Later, Razborov considered a modification of the tensor rank, called the *contact rank* [27]. This rank characterizes the complexity of certain restricted algebraic circuits (where only multiplications by a variable or a scalar are allowed). He proved a lower bound of $\Omega(n^{3/2})$ on the contact rank of the tensor of multiplication of polynomials and on the contact rank of the tensor of matrix multiplication. He also used the contact rank to prove a lower bound on the rigidity of certain matrices. The combinatorial approach (which can be also characterized as information-theoretic) leads to the *multiparty communication complexity* introduced by Chandra, Furst, and Lipton [16], which was used to prove lower bounds on circuit complexity in various situations [7, 15, 20], and to the concept of computation with *common bits* introduced by Valiant [32, 33].

In this paper, we generalize the concept of the rigidity of a matrix to the *rigidity of a tensor*, where a tensor is essentially a set of matrices. This gives a tool for proving lower bounds on semilinear circuits in the same way as the original concept does for linear circuits. We also define another variant of tensor rank, which we call the

rigidity rank because of its relation to the rigidity of tensors. Furthermore, we define certain refinements of the multiparty communication complexity and computation with common bits and show that they are closely related to the rigidity rank. Thus some bounds can be transferred from communication complexity to the algebraic framework and vice versa.

We consider the complexity of computing all n cyclic shifts of input bits. We prove an $o(n)$ *upper bound* on the corresponding three-party communication game, thus giving a negative answer to a communication complexity question of Nisan and Wigderson motivated by the problem of circuits of depth $O(\log n)$ and size $O(n)$ [20]. A similar problem about computation with common bits was also posed by Valiant [33]. Since each shift is a linear function, computing all shifts can be presented as a problem about semilinear circuits or, equivalently, as a problem about the rigidity of the diagonal tensor, which is the corresponding tensor. We get an upper bound of $o(n^2)$ on the rigidity rank of this tensor. This disproves a conjecture of Razborov [27] that the contact rank of this tensor is $\Omega(n^2)$, since the rigidity rank is at least as large as the contact rank.

This piece of information is quite important since it shows that certain direct approaches to the problem of superlinear lower bounds for Boolean circuits do not work. We have to use more refined notions, like the rigidity of a tensor instead of its contact and rigidity ranks, or special kinds of protocols in the case of communication complexity.

We generalize this upper bound in two ways. First, we consider all permutations instead of just shifts. Using probabilistic methods, we prove that the upper bounds of $o(n)$ on the communication complexity and $o(n^2)$ on the rigidity rank of the corresponding tensor hold even for this much harder problem. Second, for the communication complexity, we consider any constant number of players instead of just three, computing the composition of several shifts. In such a case, we prove that the communication complexity decreases exponentially with the number of players. These results do not exclude the possibility of applying the communication complexity and related combinatorial tools to the problem of proving a superlinear lower bound for Boolean circuits. However, they show that the usual intuition—that for simple functions the natural protocols are essentially the best possible—can be wrong.

Furthermore, we prove a *lower bound* on the size of circuits computing all shifts with common bits. In the algebraic language, this gives a lower bound on the rigidity of the diagonal tensor. As a consequence, we improve the current best lower bound on Boolean circuits of depth 2 with arbitrary gates computing multiplication of two integers (written in binary). We also give a slightly larger lower bound on the rigidity rank of the tensor of multiplication of polynomials than is known for contact rank. However, this bound is not strong enough to prove a lower bound for circuits of logarithmic depth.

Another restricted model of computation used for computing permutations of input bits are networks in which the inputs are routed through the network to the corresponding outputs along vertex disjoint paths [21, 23]. This can be viewed as a special case of semilinear circuits if we allow only projections as the gates instead of general linear functions. We consider the gap between the complexity of *conservative computation* by such networks and *nonconservative computation* by general semilinear circuits. We prove that it is possible to compute all permutations by a semilinear circuit which can be divided into two parts, one with a sublinear number of vertices and the other with $o(n^{3/2})$ edges. Using only routing along vertex-disjoint paths, such

networks cannot compute even all shifts. It is not surprising that circuits are more efficient, but as far as we know, this is the first proof of such a fact for the computation of a set of permutations.

One of our technical tools is Theorem 4.4 concerning *coloring random graphs*, which extends a famous estimate of the chromatic number of the random graph due to Bollobás [10] and may be of independent interest. We also use other powerful probabilistic techniques such as *martingales* and *Janson's inequality*.

Even though our tools are combinatorial and we obtain some lower bounds on the complexity of certain restricted computations, we think that the main contributions of this paper are the refinement of the algebraic concepts used in this area (tensor ranks and rigidity) and results obtained about them, together with the upper bounds on the multiparty communication complexity and on the size of depth-2 circuits.

This paper expands the results of the extended abstract [25] and the note [28] and contains some new results.

Independently of us, Babai, Kimmel, and Lokam [6] proved an $o(n)$ upper bound on the communication complexity of a game corresponding to computing certain set of n permutations (instead of n shifts). Very recently (during the refereeing process of this paper), Ambainis [4] improved some of our results on communication complexity (Theorems 4.2 and 4.9). In another recent paper, Damm, Jukna, and Sgall [11] prove bounds on the k-party communication complexity of the pointer-jumping function in a restricted model not directly corresponding to the models considered here.

Here is an *overview of the paper*. In section 2, we give the basic definitions and facts. Section 3 summarizes the relations between ranks of tensors, size of circuits, and communication games. In section 4, we prove the upper bounds on the communication complexity of computing all permutations and the iterated shift function, as well as the corresponding bound on tensor rigidity. The lower bounds on computation of shifts with common bits and the corresponding bounds on the rigidity and rigidity rank of the diagonal tensor are proved in section 5. In section 6, we prove the gap between conservative and nonconservative computation of shifts. The proof of the estimate on the chromatic number of a random graph is given in section 7.

2. Basic definitions and facts. We index all vectors and tensors starting from 0 since this is convenient for the modular arithmetic. An exception are some tensors that are indexed by a general parameter, which is not necessarily a number, in one coordinate.

2.1. Boolean functions. For circuit bounds, we consider *multioutput functions*, whose values are vectors of n bits. The *shift function*, $Shift^n : \{0,\dots,n-1\}\times\{0,1\}^n \to \{0,1\}^n$, is defined by

$$Shift^n(s,\vec{x}) = \vec{y}, \quad \text{where } y_i = x_{(i+s) \bmod n}.$$

This is a very important function since it can be reduced to many naturally occurring functions, e.g., multiplication of binary numbers, convolution, etc. We believe that linear-size circuits of logarithmic depth cannot compute the shift function, and hence cannot compute any of the functions to which it can be reduced.

If we use general permutations in place of shifts, we obtain the *permutation function*,

$$Perm^n(\pi,\vec{x}) = \vec{y}, \quad \text{where } y_i = x_{\pi(i)}$$

and π is a permutation of the set $\{0,\dots,n-1\}$. Note that the input size for $Perm^n$ is of the order of $n\log n$, while it is only $n+\lceil\log n\rceil$ for $Shift^n$.

Any multioutput function can be transformed into a *one-output function* with one extra argument that indexes the output bits. For any function $F(p, \vec{x}) : Y \times X \to \{0,1\}^n$, we define its one-output variant, $bit_F : \{0, \ldots, n-1\} \times Y \times X \to \{0,1\}$, by

$$bit_F(i, p, \vec{x}) = (F(p, \vec{x}))_i.$$

We use lower-case letters for one-output functions and capitalize the names of corresponding multioutput functions. It is easily seen that we can get a circuit for bit_F by adding only $O(n)$ new gates to the circuit for F so that the depth increases only by $O(\log n)$. As we will see later, the communication complexity of a one-output function is related to the circuit complexity of the corresponding multioutput function.

We define

$$shift^n = bit_{Shift^n}, \quad \text{i.e.,} \quad shift^n(i, j, \vec{x}) = x_{(i+j) \bmod n};$$

$$perm^n = bit_{Perm^n}, \quad \text{i.e.,} \quad perm^n(i, \pi, \vec{x}) = x_{\pi(i)}.$$

These two functions can be generalized to several shifts or permutations. We define

$$shift_k^n(s_1, \ldots, s_{k+1}, \vec{x}) = x_{(s_1 + \cdots + s_{k+1}) \bmod n};$$

$$perm_k^n(i, \pi_1, \ldots, \pi_k, \vec{x}) = x_{\pi_k \ldots \pi_1(i)}.$$

Note that $shift^n(i, j, \vec{x}) = shift_1^n(i, j, \vec{x})$ and $perm^n(i, \pi, \vec{x}) = perm_1^n(i, \pi, \vec{x})$.

All of the functions introduced above are linear in $\vec{x}$. We call such functions semilinear. More precisely, a function $F(p, \vec{x})$ is *semilinear* in $\vec{x}$ if for every fixed parameter p_0, the function $F(p_0, \vec{x})$ is a linear function of $\vec{x}$.

2.2. Circuits. The main motivation for our work is to study methods for proving superlinear lower bounds on the size of circuits with depth $O(\log n)$, where n is the number of inputs and all gates have fan-in 2. No such bounds are known even for functions with n outputs. In a Boolean circuit, the gates are arbitrary binary functions. We also consider algebraic circuits, in which case the gates are arbitrary polynomials over the given field.

Algebraic circuits over the field GF_2 and Boolean circuits are closely related, but there is a difference. In an algebraic circuit, we actually compute in $GF_2(x_1, \ldots, x_n)$, i.e., in GF_2 extended by indeterminates $x_1, \ldots, x_n$, while in a Boolean circuit we use only the elements of GF_2. A Boolean function $f : \{0,1\}^n \to \{0,1\}$ can be identified with a multilinear polynomial p of $GF_2[x_1, \ldots, x_n]$. Then an algebraic circuit for p is a Boolean circuit for f. The converse, however, is not true. A polynomial p' obtained from a Boolean circuit C for f is equal to p only after factorizing by the ideal defined by the equations $x_1^2 = x_1, \ldots, x_n^2 = x_n$.

We are interested mainly in linear and semilinear functions. For that purpose it is natural to consider circuits in which the gates are linear functions. In the case of Boolean circuits, this means that the only gates allowed are parity, projections, and their negations. For linear circuits, the distinction between Boolean and algebraic circuits disappears.

In a circuit for a semilinear function $F(p, \vec{x})$, we consider p to be a parameter of each gate; therefore, it is natural to use the following definition. A *semilinear circuit* for a function $\vec{y} = F(p, \vec{x})$ is a directed acyclic graph with sources labeled by the

variables $\vec{x}$ and sinks labeled by the variables $\vec{y}$ such that for every fixed p, we can assign linear gates to the nodes so that the resulting circuit computes $F(p,\vec{x})$. We measure the dependence of the circuit size on $n = |x|$.

Every one-output semilinear function has a semilinear circuit of size n and depth $\log n$. However, for most multioutput linear functions $F : \{0,1\}^n \to \{0,1\}^n$, the size of a circuit computing F is $\Omega(n^2/\log n)$, and the same is true for semilinear functions and semilinear circuits. It is an open problem to prove that some explicitly defined Boolean semilinear function has no semilinear circuit of size $O(n)$ and depth $O(\log n)$.

An important example of semilinear circuits are algebraic circuits for bilinear functions, which include matrix multiplication, multiplication of polynomials, and convolution. Let $F(\vec{y},\vec{x}) = \sum a_{ij}y_ix_j$ be a bilinear function, let C be an algebraic circuit for $F(\vec{y},\vec{x})$. If we substitute arbitrary constants for $\vec{y}$, the circuit C computes a linear function. It is well known and easy to prove that it is possible to convert a general algebraic circuit for a linear function into a linear circuit computing the same function in such a way that the underlying graph is unchanged. (Let us stress that this does not hold for Boolean circuits; see [24].) Thus C, or, more precisely, the underlying graph, is a semilinear circuit for $F(\vec{y},\vec{x})$.

An important tool for studying the circuits of size $O(n)$ and depth $O(\log n)$ is a reduction discovered by Valiant [32]. We use the terminology that he introduced in [33].

Let F be a multioutput Boolean function with input variables $\vec{x} = (x_0,\dots,x_{n-1})$ and outputs $\vec{y} = (y_0,\dots,y_{n-1})$. Let G be a bipartite graph with nodes $x_0,\dots,x_{n-1}$ and $y_0,\dots,y_{n-1}$. We say that F *can be computed by the graph G with r common bits* if there exist Boolean functions $h_1,\dots,h_r$ and $g_0,\dots,g_{n-1}$ such that

$$y_i = (F(\vec{x}))_i = g_i(h_1(\vec{x}),\dots,h_r(\vec{x}),\vec{x}^{(i)}),$$

where $\vec{x}^{(i)}$ is the substring of input variables adjacent to y_i in G. In other words, F can be computed by a circuit of depth 2 where there are some direct connections from inputs to outputs given by the graph G and some connections through an intermediate level of r gates of unbounded fan-in. By the *degree* of the graph G, we mean the maximal degree of the nodes y_i in the graph G. By the *common bits*, we mean the functions $h_1,\dots,h_r$. We are interested in bounding the degree of G and the number of common bits.

In the analogy with semilinear circuits, we are especially interested in the case where the common bits and the functions g_i are semilinear; we then say that the computation by the graph *uses only semilinear functions*. In this restricted case, we can also use the same notion for algebraic circuits over a general field $\mathbf{F}$; the functions $h_1,\dots,h_r$ and $g_0,\dots,g_{n-1}$ are then required to be semilinear functions with values in $\mathbf{F}$, instead of Boolean functions.

The reduction is based on the following graph-theoretic fact proved in [32, Theorem 5.3].

THEOREM 2.1 (Valiant [32]). *For every $\varepsilon > 0$, c, and d, there exists K such that for any directed acyclic graph C with cn nodes and depth $d\log n$, there exists a set S of $Kn/\log\log n$ edges such that every directed path of length $\varepsilon\log n$ in C contains an edge from S.*

The consequence that is important for us is the following.

THEOREM 2.2 (Valiant [32, 33]). *For every $\varepsilon > 0$, c, and d, there exists K such that if a function F can be computed by a circuit of size cn and depth $d\log n$, then it can be computed by a graph G of degree at most n^ε with $Kn/\log\log n$ common bits.*

Moreover, if the original circuit is semilinear, then the computation by the graph G uses only semilinear functions.

Proof. Let K and S be as in Theorem 2.1. Define the common bits to be the functions computed at the edges from S by the circuit C. From Theorem 2.1, it follows that each output can be expressed as a circuit of depth at most $\varepsilon \log n$ with inputs from S and from the original inputs. Construct the graph G by connecting each output to these inputs. Because the gates have fan-in 2, this circuit depends on at most n^ε original inputs, and hence the degree of G is at most n^ε. The semilinearity is preserved since any function computed in a semilinear circuit is semilinear. □

Let us state explicitly what this reduction means for the shift function Shift^n. No superlinear lower bounds are known for computing explicitly given functions by semilinear circuits. In particular, it is an open problem whether it is possible to compute shifts by a graph G of degree n^ε, $\varepsilon < 1$, with $o(n)$ common bits using only semilinear functions. We show that it is possible to compute by a graph of degree $o(n)$ with $o(n)$ common bits not only all n shifts but in fact all $n!$ permutations. Since the degree of our graph is $\Theta(n \log\log n / \log n)$, which is much larger than n^ε, this does not solve the above open problem. However, it shows that it is possible to compute all permutations by a significantly smaller graph than was expected.

Valiant's reduction suggests that we consider Boolean circuits with gates of unbounded fan-in and constant depth, where the gates are arbitrary Boolean functions or arbitrary linear functions. The size of such a circuit is defined to be the number of edges. (This is a trivial notion for one-output functions.) For this case, some superlinear lower bounds for explicitly given Boolean functions are known; see [13, 21, 22]. These bounds are based on some graph properties of circuits computing particular Boolean functions. For instance, a function can easily be defined so that every circuit for the function is a superconcentrator. Similar graph-theoretic arguments can also be used for the circuits of unbounded fan-in and small depth computing the function Shift^n [26]. For example, for depth 2, this gives the bound of $\Omega(n \log n)$. However, these bounds are very small, and we do not get anything at all for depth $O(\log n)$.

An even more restricted model for computing Shift^n that has been considered requires that the bits are routed along vertex-disjoint paths. A graph with n sources $\{x_0, \ldots, x_{n-1}\}$ and n sinks $\{y_0, \ldots, y_{n-1}\}$ is an *n-shifter* if for every s there exist n vertex disjoint paths $x_{0+s} \to y_0$, $x_{1+s} \to y_1$, $\ldots$, $x_{n-1+s} \to y_{n-1}$, where all indices are computed modulo n; see [23]. Obviously, any shifter is a semilinear circuit for Shift^n, but this condition seems to be much stronger. The lower bounds known for the shifters are much larger than for general semilinear circuits, e.g., shifters of depth 2 have size $\Omega(n^{3/2})$, and general shifters have size $\Omega(n \log n)$ (actually, these bounds are tight). These bounds can be applied to monotone circuits since any circuit with only monotone gates that computes the shift function is a shifter; see [22]. However, for the monotone basis, there are well-known even exponential lower bounds for other explicit functions. The reader interested in further applications of these methods to circuit complexity should consult [21, 24].

It is well known that a general circuit for the shift function is not necessarily a shifter [22]. It is an open problem whether the shift function can be computed more efficiently using general circuits than using circuits that contain shifter graphs. We give a partial result in this direction below by proving that certain circuits of depth 2 are more efficient than corresponding shifters; see Theorems 6.1 and 6.2.

2.3. Multiparty communication complexity. In the most common model of multiparty communication, a function $f(\vec{x}_1, \ldots, \vec{x}_k)$ is computed in the following way.

There are k players; we denote them by Player 1, ..., Player k. Player i knows $\vec{x}_1, \ldots, \vec{x}_{i-1}, \vec{x}_{i+1}, \ldots, \vec{x}_k$. They send messages consisting of binary strings, and the game ends when one of the players knows the answer $y = f(\vec{x}_1, \ldots, \vec{x}_k)$. The communication complexity is the minimal number of bits of communication needed in any protocol which computes $f(\vec{x}_1, \ldots, \vec{x}_k)$ correctly. For more background see, e.g., [19]. We omit the general definition of a protocol because in this paper we consider only some restricted models explained below. In particular, we require that each player sends only one message and that all players send their messages simultaneously. This means that the message can depend only on the input available to the player, not on the previous communication. A lower bound for such a restricted model should be easier to prove, while it would still imply the circuit lower bound.

Now we define our models more precisely. In the *simultaneous* model for computing $f(\vec{x}_1, \ldots, \vec{x}_k)$, there are $k+1$ players, Player 0, Player 1, ..., Player k. The additional Player 0 does not have access to any input, while the others have the same access as in the general model. There is only one round of communication, when each of the Players $1, \ldots, k$ sends a piece of information to Player 0. Then Player 0 produces the answer. A slight modification is an *almost simultaneous protocol*: there are k Players, and the communication has one round, in which Players $1, \ldots, k-1$ independently send a message to Player k, who produces the answer. The *communication complexity* is the total number of bits that has to be communicated for the inputs of given length. By $\mathrm{SCC}(f)$ and $\mathrm{ASCC}(f)$, we denote the simultaneous and almost simultaneous communication complexity of f, respectively. Let us observe that $\mathrm{ASCC}(f)$ differs from $\mathrm{SCC}(f)$ by at most the sum of the sizes of inputs $\vec{x}_1, \ldots, \vec{x}_{k-1}$ since Player k can just send all the inputs he has access to Player 0, which changes an almost simultaneous protocol into a simultaneous protocol. Therefore, if the size of the first inputs is small, the difference can be disregarded. This is true, for example, for shift_k^n, where the size of the first two inputs is only $\log n$.

A *semilinear protocol* is an almost simultaneous protocol such that for every fixed $\vec{x}_1, \ldots, \vec{x}_{k-1}$, the message sent by each Player i consists of a vector of fixed linear functions of $\vec{x}_k$. A *restricted protocol* is an almost simultaneous protocol for three players such that for any fixed $\vec{x}_1$, the message sent by Player 2 consists of a fixed substring of $\vec{x}_3$. A *restricted semilinear protocol* satisfies both conditions, i.e., Player 1 sends a vector determined by linear functions of $\vec{x}_3$ and Player 2 sends a substring of $\vec{x}_3$.

We study the communication complexity of the functions shift_k^n and perm_k^n.

Let us first examine our intuition about restricted protocols for $\mathit{shift}^n(i, j, \vec{x})$. If Player 2 does not send anything, the only knowledge of Player 3 about $\vec{x}$ comes from Player 1. Therefore, Player 1 has to send n bits about $\vec{x}$ because without knowledge of j he cannot determine which of the bits is relevant. (More precisely, for any two $\vec{x} \neq \vec{x}'$, the message sent by Player 1 has to be different.) Player 2 has to select a subset of bits without the knowledge of i; therefore, if he sends only a small number of bits, in most cases he does not send the bit x_{i+j}. It would appear then that his message can hardly be of any significant help in determining the output, and therefore Player 1 has to send a long message even in this case. A natural conjecture is that the total number of communicated bits for shift^n must be $\Omega(n)$. As we shall see, this would yield a proof that there is no circuit of size $O(n)$ and depth $O(\log n)$ computing Shift^n. However, we disprove this conjecture by showing that even for the more general function perm^n, there exists a restricted semilinear protocol with a total communication of only $O(n \log\log n / \log n)$ bits; see Corollary 4.8.

Clearly, the multiparty communication complexity of these functions can only decrease with increasing k in any of the above models. It is a major open problem to study the growth rate of the communication complexity when k increases. It seems beyond the present means to prove any good bounds for increasing k. For the function $shift_k^n$, we have a partial result in that direction. We construct a restricted semilinear protocol with a total communication of only $O(n(\log\log n/\log n)^k)$ bits for any constant k.

The best known lower bound for $shift_k^n$ is given in the following proposition. It is a straightforward generalization of the bound for $k = 1$ by Nisan and Wigderson [20].

PROPOSITION 2.3. *For every constant k,* $\mathrm{SCC}(shift_k^n) \geq \Omega(n^{\frac{1}{k+1}})$.

Proof. Assume that the numbers $s_1, \ldots, s_{k+1}$ are written as $(k+1)$-digit numbers in the basis of $b = \lceil n^{\frac{1}{k+1}} \rceil$. We restrict the domain of $shift_k^n(s_1, \ldots, s_{k+1}, \vec{x})$ so that in s_1 only the first digit may be nonzero, in s_2 only the second digit may be nonzero, etc. (Thus for $k = 1$, s_1 ranges over $0, \sqrt{n}, 2\sqrt{n}, \ldots, n$ and s_2 ranges over $0, 1, \ldots, \sqrt{n}$.) Each s_i can have only b different values, but $s_1 + \cdots + s_{k+1}$ can be any number between 0 and $b^{k+1} \geq n$.

Now consider any simultaneous protocol for $shift_k^n$, and for a fixed x, write down the information communicated by each player on all inputs $s_1, \ldots, s_{k+1}$ from our restricted range. The total amount of communication is at most $O(n \cdot \mathrm{SCC}(shift_k^n))$ bits. Because the protocol is simultaneous, the information communicated by each player depends only on the inputs available to him. For every input of a given player, there are b different values of the input that he does not see, and therefore the same output appears at b predetermined positions. Thus the information contained in all communication is only $O(n\mathrm{SCC}(shift_k^n)/b)$ bits. Given this information, it is possible to reconstruct the whole vector $\vec{x}$ because we can reconstruct any bit x_i by choosing inputs such that $s_1 + \cdots + s_k = i$ and following the protocol. Thus for any two different vectors $\vec{x}$, this information must be different, and hence it has at least n bits for some $\vec{x}$. This gives us $\mathrm{SCC}(shift_k^n) \geq \Omega(b) \geq \Omega(n^{\frac{1}{k+1}})$. □

The best known lower bound on multiparty communication complexity is $\Omega(n/c^k)$ for the generalized inner product [7]. This means that we have no lower bounds at all for $k = \Omega(\log n)$. If we could extend the lower bounds on the almost simultaneous communication complexity to $k = \mathrm{polylog}(n)$, it would yield a lower bound on ACC circuits, which is a major open problem; see [8, 15, 34].

One function often considered in this context is pointer jumping in a directed acyclic graph with one source and k additional levels with n vertices on each level. (The out-degree of each vertex is 1, except for the last level.) The inputs are divided between the players so that every player sees everything except for one level. Intuitively, the most difficult instances should be those in which all vertices in the graph are reachable, which means that on each level, the mapping given by the pointers is one to one. This restriction of pointer jumping is essentially a variation of our function $perm_k^n$. We define

$$jump_k^n(i, \pi_1, \ldots, \pi_k) = \pi_k \ldots \pi_1(i).$$

We can use our bound for the function $perm_k^n$, Corollary 4.8, to improve the obvious upper bound of $O(n \log n)$ on the communication complexity of $perm_k^n$ by a factor of $\log n/\log\log n$.

PROPOSITION 2.4. *For all $k \geq 2$,* $\mathrm{ASCC}(jump_k^n) \leq O(n \log\log n)$.

Proof. We can compute the $\lceil \log n \rceil$ bits of $jump_k^n(i, \pi_1, \ldots, \pi_k)$ by computing the value of $perm_{k-1}^n(i, \pi_1, \ldots, \pi_{k-1}, Perm^n(\pi_k, \vec{x}))$ for $\log n$ vectors $\vec{x}$ as follows. Define

vectors $\vec{x}^{(j)}$, $1 \le j \le \lfloor \log n \rfloor$, so that $\vec{x}_i^{(j)}$, $0 \le i < n$, is the jth digit in the binary representation of i. By the definitions of $Perm^n$, $perm_{k-1}^n$, and $jump_k^n$, the jth bit of $jump_k^n(i, \pi_1, \ldots, \pi_k)$ is $perm_{k-1}^n(i, \pi_1, \ldots, \pi_{k-1}, Perm^n(\pi_k, \vec{x}^{(j)}))$. We can run the $\lceil \log n \rceil$ protocols for $perm_{k-1}^n$ in parallel since they are completely independent; note that all players have the necessary information since the input is divided in the same way for $jump_k^n$ as for all the instances of $perm_{k-1}^n$. The total communication is $\lceil \log n \rceil \mathrm{ASCC}(perm_{k-1}^n) = O(n \log \log n)$ by Corollary 4.8. □

Our results do not exclude the function $jump_k^n$ as a candidate for lower bounds, but we think that they give some insight into the difficulties that are encountered in the attempted proofs.

2.4. Tensors. By a *tensor* over a field $\mathbf{F}$, we simply mean a three-dimensional matrix or, equivalently, a finite sequence of matrices of the same size with entries from $\mathbf{F}$. We use the following notation to denote the *slices* of tensors in different directions. For a tensor T, the symbol $T_{i,*,*}$ denotes the matrix consisting of all entries of T with the first coordinate i; the matrix is indexed in the same way as the remaining two coordinates of the tensor. Similarly, $T_{i,j,*}$ denotes the vector of all entries with the first coordinates i and j, i.e., the jth row of the matrix $T_{i,*,*}$. We define $T_{*,j,*}$, $T_{*,j,k}$, etc. similarly.

Tensors can be naturally associated with semilinear functions. Given a tensor T, for each parameter p, the matrix $T_{*,p,*}$ determines a linear function. Thus the function defined by $F(p, \vec{x}) = T_{*,p,*}\vec{x}$ is a semilinear function naturally corresponding to the tensor T. Conversely, let $F(p, \vec{x})$ be a function linear in $\vec{x}$. Then there exists a tensor T^F and a vector $\vec{c}^F$ such that for all p,

$$F(p, \vec{x}) = T^F_{*,p,*}\vec{x} + \vec{c}^F_p.$$

The constants $\vec{c}^F_p$ have almost no influence on the complexity of computing F. The main information is contained in the tensor T^F, which we call a *tensor corresponding to* F.

We study the tensors corresponding to the functions introduced in section 2.1. The tensor corresponding to $Shift^n$ is defined by $D^n = T^{Shift^n}$, i.e.,

$$\begin{aligned} D^n_{i,j,k} &= 1 \quad \text{if} \quad i + j \equiv k \pmod{n}, \\ &= 0 \quad \text{otherwise.} \end{aligned}$$

D^n is called a *diagonal tensor*, or the *tensor of multiplying polynomials* modulo $x^n - 1$ since it is connected with algebraic circuits computing this bilinear operation [12].

The tensor corresponding to $Perm^n$ is defined by $P^n = T^{Perm^n}$, i.e.,

$$\begin{aligned} P^n_{i,\pi,k} &= 1 \quad \text{if} \quad k = \pi(i), \\ &= 0 \quad \text{otherwise.} \end{aligned}$$

It turns out that the size of a circuit computing a semilinear function is related to some variants of the algebraic concept of rank.

Let $\mathbf{F}$ be some fixed field. For a positive integer k, let $e^k_0, \ldots, e^k_{k-1}$ denote the standard basis of the vector space $\mathbf{F}^k$, i.e., $e^k_i(j) = 0$ for $i \ne j$ and $e^k_i(i) = 1$. For $u \in \mathbf{F}^l$, $v \in \mathbf{F}^m$, and $w \in \mathbf{F}^n$, the *tensor product* of u, v, and w denoted by $u \otimes v \otimes w$ is the $l \times m \times n$ tensor T defined by $T_{i,j,k} = u_i v_j w_k$ for $0 \le i < l$, $0 \le j < m$, and $0 \le k < n$.

We define three different ranks of a tensor. In all three cases, the rank of T is defined to be the minimal number of rank-1 tensors T^i such that $T = \sum_i T^i$; it is 0 if

all entries of T are zeros. Note that the matrix rank can be defined in a similar way since matrices of rank 1 are the matrices of the form $u \otimes v$, where u and v are nonzero vectors.

The usual *tensor rank*, $\mathrm{rank}(T)$, was introduced by Strassen [31] and is determined by

$$\mathrm{rank}(T) = 1 \quad \text{iff } T = u \otimes v \otimes w, \text{ for some nonzero vectors } u, v, w.$$

The *contact rank*, $\mathrm{rank}^{2,2}(T)$, was introduced by Razborov [27] and is determined by

$$\mathrm{rank}^{2,2}(T) = 1 \quad \text{iff } T = e_i^l \otimes v \otimes w \quad \text{or} \quad T = u \otimes e_j^m \otimes q, \text{ for some nonzero vectors } u, v, w, q \text{ and some } i, j.$$

In other words, $\mathrm{rank}^{2,2}(T) = 1$ if all nonzero entries of T are either in the slice $T_{i,*,*}$ or in the slice $T_{*,j,*}$, for some i or j, and the matrix rank of that slice is 1.

We introduce the *rigidity rank* and denote it by $\mathrm{rank}^{2,1}(T)$; it is determined by

$$\mathrm{rank}^{2,1}(T) = 1 \quad \text{iff } T = u \otimes e_j^m \otimes w \quad \text{or} \quad T = e_i^l \otimes v \otimes e_k^n, \text{ for some nonzero vectors } u, v, w \text{ and some } i, j, k.$$

Thus $\mathrm{rank}^{2,1}(T) = 1$ if either

(i) all nonzero entries of T are in the slice $T_{*,j,*}$, for some j, and the matrix rank of $T_{*,j,*}$ is 1 or

(ii) all nonzero entries of T are in the column $T_{i,*,k}$, for some i and k, and at least one entry is not zero.

From these definitions, it is easy to see that for every tensor T,

$$\mathrm{rank}(T) \le \mathrm{rank}^{2,2}(T) \le \mathrm{rank}^{2,1}(T).$$

To give yet another equivalent definition of $\mathrm{rank}^{2,1}$, we define $\mathrm{diff}(T, U)$ to be the *set of different columns* for T and U, i.e.,

$$\mathrm{diff}(T, U) = \{(i, k); \exists j \; T_{i,j,k} \neq U_{i,j,k}\}.$$

Using the fact that the rank of a matrix M is the minimal number of matrices of rank 1 that add to M, it is easy to see that

$$\mathrm{rank}^{2,1}(T) = \min_U \left(\sum_j \mathrm{rank}(U_{*,j,*}) + |\mathrm{diff}(T, U)| \right), \tag{1}$$

where the minimum is taken over all tensors U of the appropriate dimensions.

Now we extend the concept of rigidity from matrices to tensors. The *rigidity of a matrix* M is the function $R_M(r)$ equal to the minimal number of changes needed to reduce the rank of M to r or less [32]. If we want to work with a set of matrices, we can represent them as slices $T_{*,j,*}$ of a tensor T. The *rigidity of a tensor* T is the function $R_T(r)$ which for each r gives the minimal number of columns in which we have to change the tensor in order to reduce the rank of each slice to r or less. More precisely,

$$R_T(r) = \min\{|\mathrm{diff}(T, U)|; U \text{ is a tensor such that } \forall j \; \mathrm{rank}(U_{*,j,*}) \le r\}. \tag{2}$$

Note that in the special case of a single matrix, we just get Valiant's rigidity.

It is known that the rank of the diagonal tensor D^n is $\Theta(n)$ for any field; for small fields, it was proved only in 1987 by Chudnovsky and Chudnovsky [17] using methods from algebraic geometry; see also [29] for a more detailed presentation. The growth rate of $\operatorname{rank}^{2,2}(D^n)$ and $\operatorname{rank}^{2,1}(D^n)$ is not known.

Razborov proved that $\operatorname{rank}^{2,2}(D^n) = \Omega(n^{3/2})$, which shows that the gap between rank and $\operatorname{rank}^{2,2}$ can be big [27]. He conjectured that $\operatorname{rank}^{2,2}(D^n) = \Omega(n^2)$.

We disprove this conjecture by proving an upper bound on $\operatorname{rank}^{2,1}(D^n)$. In fact, we prove a stronger result, an upper bound on the rigidity of P^n, the tensor of computing all permutations,

$$R_{P^n}(r) = n^{2-\Omega(r/n)}.$$

This implies an upper bound on the rigidity rank of the same tensor,

$$\operatorname{rank}^{2,1}(P^n) = O\left(n^2 \frac{\log\log n}{\log n}\right).$$

The diagonal tensor D^n is a subtensor of P^n; hence the same upper bounds hold for D^n. The rigidity rank is always greater than or equal to the contact rank, so we get the upper bound

$$\operatorname{rank}^{2,2}(D^n) = O\left(n^2 \frac{\log\log n}{\log n}\right).$$

Rigidity and rigidity rank are closely related. From equations (1) and (2), it follows easily that

$$\operatorname{rank}^{2,1}(T) \le R_T(r) + nr. \tag{3}$$

Using this fact, it is theoretically possible to get a lower bound on the rigidity of a tensor from a lower bound on the rigidity rank of it. However, the lower bounds needed for this approach to work are far beyond what we are able to prove nowadays.

In this paper, we prove a lower bound on the rigidity of D^n directly. We get

$$R_{D^n}(r) = \Omega\left(\frac{n^2}{r}\log\frac{n}{r}\right).$$

The same bound was proved even for a single matrix by Friedman [14]. However, because we prove our bound for a special set of matrices, it enables us to prove the following lower bound on the rigidity rank:

$$\operatorname{rank}^{2,1}(D^n) = \Omega\left(n^{3/2}(\log n)^{1/2}\right).$$

This bound in turn implies some improvement of the lower bounds on the size of certain circuits of depth 2.

3. Mutual relations. The concepts of computing a function by a graph with common bits, rigidity of the corresponding tensor, and communication complexity of the corresponding one-output function are closely related and can all be potentially useful for proving lower bounds on the size of circuits. We survey these relations in this section. Some parts of this material has been known and has appeared either explicitly or implicitly in the literature; see [19, 20, 32, 33]. We quantify the connections as

precisely as possible because our upper bounds show that this might be necessary for proving lower bounds.

We first demonstrate the connections on an example. We show a restricted semilinear protocol for the function $shift^n(i, j, \vec{x})$ in which Player 2 sends only 1 bit and Player 1 sends $\lfloor n/2 \rfloor$ bits. This protocol also demonstrates some of the ideas used in our more complicated upper bounds. According to the intuition discussed before Proposition 2.3, Player 2 almost never sends the bit that is to be computed. Before reading on, the reader can try to imagine how this single bit could possibly be used so that it saves half of the communication of the other player.

All indices in the protocol are computed modulo n. The protocol works as follows.

- Player 1 sends the bits $x_0 \oplus x_j$, $x_1 \oplus x_{j-1}$, ..., i.e., parities of all pairs $x_k \oplus x_{j-k}$.
- Player 2 sends the bit x_{n-i}.
- Player 3 computes x_{i+j} as the parity of x_{n-i} (from Player 2) and $x_{n-i} \oplus x_{i+j}$ (from Player 1).

The corresponding bound on computation by a graph with common bits is for the function $Shift^n(j, \vec{x})$. We construct a graph of degree 1 with $\lfloor n/2 \rfloor$ common bits that computes $Shift^n(j, \vec{x})$. Every y_i is adjacent to x_{n-i}, which corresponds to the bit sent by Player 2. For every j, the common bits are the same as the bits sent by Player 1 in the protocol. The output level computes x_{i+j} in the same way as Player 3 in the protocol.

The corresponding bound on the rigidity says that $R_{D^n}(\lfloor n/2 \rfloor) \leq n$ for the diagonal tensor D^n. To prove this, we flip all the entries $D_{i,j,n-i}$. It is easy to verify that the rank of each matrix $D_{*,j,*}$ is at most $\lfloor n/2 \rfloor$ because the matrix is essentially a matrix with ones only along the main diagonal and along the diagonal running from the lower left corner to the upper right corner (and zero in the intersection of the diagonals).

Now we state these relationships formally.

PROPOSITION 3.1. *A function $F(p, \vec{x})$ can be computed by a graph of maximal degree d with r common bits if and only if there exists a restricted protocol for computing $bit_F(i, p, \vec{x})$ in which Player 1 sends r bits and Player 2 sends d bits.*

The computation by the graph uses only semilinear functions if and only if the protocol is a restricted semilinear protocol.

Proof. Suppose that we have a graph that computes the function F. The protocol for f is as follows. Player 1 sends the value of the common bits for the given input $(p, \vec{x})$. If the first input is i, Player 2 sends the value of all inputs x_k that are adjacent to the output y_i in the graph. Player 3 can compute the output because he knows all of the inputs of the output gate. Clearly, this protocol is a restricted protocol with the required number of bits sent by each player.

Given a protocol, we construct a graph that computes F as follows. The output y_i is adjacent to all inputs x_k such that Player 2 sends the value of input x_k if the first input is i. This graph computes F if the common bits compute the values communicated by Player 1 on the given input. Clearly, the degree of the graph and the number of the common bits are as required.

For both directions, semilinearity is preserved since the functions computed in the protocol and used in the computation by the graph are identical. □

Computing F by a graph with a bounded number of edges and a bounded number of common bits using only semilinear functions is equivalent to a bound on the rigidity of the tensor T.

PROPOSITION 3.2. *Let $F(p,\vec{x})$ be a semilinear function. Then the rigidity of the corresponding tensor T^F satisfies $R_{T^F}(r) \le R$ if and only if there exists a graph G with at most R edges such that for every p, $F(p,\vec{x})$ can be computed by G with r common bits using only semilinear functions.*

Proof. First, assume that the condition on the rigidity is satisfied, which means that we have a tensor U such that $|\mathrm{diff}(T^F,U)| \le R$ and $\forall p\ \mathrm{rank}(U_{*,p,*}) \le r$. We choose the graph G so that the input x_k and the output y_i are adjacent if $(i,k) \in \mathrm{diff}(T^F,U)$. Obviously, there are at most R edges.

Now we show how this graph can compute F for fixed p with only r common bits. Let us denote the ith row of the matrix $U_{*,p,*}$ by $\vec{u}^{(i)}$. The ith output function is then given by

$$(F(p,\vec{x}))_i = T^F_{i,p,*} \cdot \vec{x} + c_i = \vec{u}^{(i)} \cdot \vec{x} + \sum_{(i,k)\in \mathrm{diff}(T^F,U)} a_{i,k}x_k + c_i,$$

where $a_{i,k}$ and c_i are some scalar constants from the given field. It follows that it suffices to set the common bits so that $\vec{u}^{(i)} \cdot \vec{x}$ can be computed from them for all i since the rest of the expression can be computed based on the inputs adjacent to the given output in G.

From the condition on the rank, it follows that there exist r vectors $\vec{v}^{(1)},\dots,\vec{v}^{(r)}$ such that any $\vec{u}^{(i)}$ is their linear combination. We set the common bits to $\vec{v}^{(1)} \cdot \vec{x},\dots,\vec{v}^{(r)} \cdot \vec{x}$; hence any $\vec{u}^{(i)} \cdot \vec{x}$ can be computed as their linear combination.

For the other direction, we assume that F can be computed by a graph G. We want to find a tensor U which proves that the rigidity of T^F is small. For a fixed p, we know that

$$(F(p,\vec{x}))_i = g_i(h_1(\vec{x}),\dots,h_r(\vec{x}),\vec{x}^{(i)}),$$

where $\vec{x}^{(i)}$ is the substring of input variables adjacent to y_i in G and both g_i and the common bits $h_1,\dots,h_r$ are linear functions. Therefore, the function g_i can be written as a linear combination of the common bits, the extra inputs, and a constant. Similarly to the other direction, we set $U_{i,p,*}$ to be a vector which corresponds to the linear combination of the common bits used for the given output. The rank of the tensor is bounded by the number of common bits, and it differs from T^F only in columns corresponding to the edges of G. □

The relation between the rigidity of tensors and the communication complexity of the corresponding semilinear function now follows easily. We just have to examine the proof of Proposition 3.1 and verify that if we replace the maximal degree of the graph by the number of edges, the bound on the number of bits communicated by Player 2 is replaced by the average number of bits.

PROPOSITION 3.3. *Let $F(p,\vec{x})$ be a semilinear function. Then the rigidity of the corresponding tensor T^F satisfies $R_{T^F}(r) \le dn$ if and only if there exists a restricted semilinear protocol for the associated one-output function $bit_F(i,p,\vec{x})$ in which Player 1 always sends r bits and Player 2 sends d bits on the average, where the average is taken over all values of i.*

Using Valiant's reduction, Theorem 2.2, we get the following two theorems.

THEOREM 3.4. *If $F(p,\vec{x})$ can be computed by a circuit of size $O(n)$ and depth $O(\log n)$, then for any $\varepsilon > 0$, there exists a constant K such that*

(i) *F can be computed by a graph G of degree at most n^ε and with $Kn/\log\log n$ common bits*;

(ii) *there exists a restricted protocol for* $bit_F(i,p,\vec{x})$ *such that Player* 1 *sends* $O(n/\log\log n)$ *bits and Player* 2 *sends* n^ε *bits.*

THEOREM 3.5. *If a semilinear function* $F(p,\vec{x})$ *can be computed by a semilinear circuit of size* $O(n)$ *and depth* $O(\log n)$*, then for any* $\varepsilon > 0$*, there exists a constant* K *such that*

(i) F *can be computed by a graph* G *of degree at most* n^ε *and with* $Kn/\log\log n$ *common bits using only semilinear functions*;

(ii) *there exists a restricted semilinear protocol for* $bit_F(i,p,\vec{x})$ *in which Player* 1 *sends* $O(n/\log\log n)$ *bits and Player* 2 *sends* n^ε *bits*;

(iii) *the rigidity of the corresponding tensor* T^F *satisfies* $R_{T^F}(Kn/\log\log n) \le n^{1+\varepsilon}$.

Originally, several researchers believed that a superlinear lower bound for circuits of depth $O(\log n)$ can be proved by showing that

(i) $Shift^n$ cannot be computed by a graph of degree $o(n)$ with $o(n)$ common bits,

(ii) $\mathrm{SCC}(shift^n) = \Omega(n)$, or

(iii) $\mathrm{rank}^{2,1}(D^n) = \Omega(n^2)$ (which would give bounds for semilinear circuits).

We prove that all these statements are false by exhibiting an almost simultaneous protocol for $shift^n$ in which both players send $O(n\log\log n/\log n)$ bits. This does not mean that these approaches cannot be used at all—to demonstrate that, we would need a protocol in which Player 2 sends only n^ε, which is less than our bound. However, it shows that it is not sufficient to consider the total communication—to prove a lower bound that way, it would be necessary to prove that more than $\omega(n/\log\log n)$ bits are needed, and our bound shows that this is not the case. Hence it is necessary to consider more precise information, namely to estimate the number of bits sent by each of the two players instead of the total amount of communication, to use rigidity instead of the rigidity rank, or to estimate the degree of the graph in a different way than the number of common bits.

4. Upper bounds. In section 4.1, we present the constructive proof of the upper bound on the communication complexity of the shift function $shift^n$. Then we generalize it in two different ways. In section 4.2, we extend the upper bound to the permutation function $perm^n$ using the probabilistic method. These bounds also apply to the rigidity of the corresponding functions. In section 4.3, we extend the upper bound to the function $shift_k^n$.

4.1. The shift function. The constructive proof of the upper bound for the function $shift^n$ is based on a suggestion of Wigderson to use arithmetic progressions.

The idea of the protocol is to divide the input $\vec{x}$ into groups. Player 1 sends the parity of each group and Player 2 sends some substring of $\vec{x}$ such that all but one elements of the group of x_{i+j} are sent, similarly as in the simple protocol at the beginning of section 3. For the function $shift^n$, we can do this constructively based on the next lemma, which says that there exists a sparse subset B of $[0,n-1]$ such that every $a \in [0,n-1]$ can be surrounded by an arithmetic progression with all elements in B except possibly a itself.

LEMMA 4.1. *For every* n *and every* $l < \log n/(2\log\log n)$*, there exists a set* $B \subseteq [0,n-1]$ *of size* $O(ln^{1-1/(2l-1)})$ *such that for every* $a \in [0,n-1]$*, there exist* $a_1,\dots,a_{2l-2} \in B$ *such that* $a_1,\dots,a_{l-1}$, a, $a_l,\dots,a_{2l-2}$ *is an arithmetic progression (computing modulo* n*) with modulus* $m = m(a)$ *bounded by* $m \le O(n^{1-1/(2l-1)})$.

Proof. From the well-known bounds on the distribution of primes, it is easy to prove that there exist $2l-2$ primes $p_1,\dots,p_{2l-2}$ larger than $\Omega(n^{1/(2l-1)})$ whose

product is at most $n^{1-1/(2l-1)} < n/l$. Define B to be the set of all integer multiples of these primes between $-n$ and $2n$, taken modulo n, i.e.,

$$B = \{b \bmod n; b \in [-n, 2n] \wedge (p_1|b \vee p_2|b \vee \cdots \vee p_{2l-2}|b)\}.$$

For a given $a \in [0, n-1]$, consider the following system of linear congruences:

$$\begin{aligned}
a - (l-1)m &\equiv 0 \pmod{p_1}\\
a - (l-2)m &\equiv 0 \pmod{p_2}\\
&\vdots\\
a - m &\equiv 0 \pmod{p_{l-1}}\\
a + m &\equiv 0 \pmod{p_l}\\
a + 2m &\equiv 0 \pmod{p_{l+1}}\\
&\vdots\\
a + (l-1)m &\equiv 0 \pmod{p_{2l-2}}.
\end{aligned}$$

Since $0 \le l < p_1, \ldots, p_{2l-2}$, we can divide the congruences by $l-1$, $l-2, \ldots, 1$, 1, 2, $\ldots$, $l-1$ and apply the Chinese remainder theorem to solve for m. We obtain a solution $0 < m \le p_1 p_2 \cdots p_{2l-2}$, which is a modulus satisfying the requirements, because all the numbers $a_1 = a - (l-1)m$, $a_2 = a - (l-2)m, \ldots, a_{l-1} = a - m$, $a_l = a + m$, $\ldots$, $a_{2l-2} = a + (l-1)m$ taken modulo n are in B. □

THEOREM 4.2. *There exists a restricted semilinear protocol for the shift function $shift^n$ which requires only $O(n \log\log n/\log n)$ bits of communication.*

Proof. Let B be a set with the properties as in Lemma 4.1 for an l which we choose later. For a set $C \subseteq [0, n-1]$, let $x[C]$ denote the subsequence of the bits of x indexed by C. All indices of x are taken modulo n. The protocol is as follows.

- Player 1 partitions the interval $[0, n-1]$ into $n' = O(n/l)$ arithmetic progressions $C_0, \ldots, C_{n'-1}$ of length at most l with modulus $m(j)$. Player 1 communicates $\bigoplus x[C_\alpha]$ for all $\alpha = 0, \ldots, l$, i.e., parity of bits of x indexed by each of the progressions, a total of $O(n/l)$ bits.
- Player 2 sends $x[B + i]$, i.e., bits x_{b+i} for all $b \in B$.
- Player 3 computes x_{i+j} as described below.

Let C be the C_α containing $i + j$, and let $c \in C$, $c \ne i + j$. By the definition of C, $c - i - j$ is a small nonzero multiple of $m(j)$. By the definition of B and $m(j)$, it follows that $j + (c - i - j) = c - i \in B$, and hence $c \in B + i$. This means that Player 2 communicated all bits of $x[C]$ except possibly x_{i+j}. Hence Player 3 can compute x_{i+j} by subtracting these bits sent by Player 2 from $\bigoplus x[C]$ sent by Player 1, using the fact that he knows i and j and therefore knows the meaning of the bits sent by Players 1 and 2.

For $l = \log n/(4 \log\log n)$, the size of B is $O(n/\log n) = O(n \log\log n/\log n)$, and each player communicates $O(n \log\log n/\log n)$ bits. □

COROLLARY 4.3. $\operatorname{rank}^{2,1}(D^n) = O(n^2 \log\log n/\log n)$.

Proof. By Proposition 3.3, we get $R_{D^n}(n \log\log n/\log n) = O(n^2 \log\log n/\log n)$; the result follows using the relation of the rigidity and the rigidity rank (3). □

4.2. The permutation function. We prove an upper bound on the rigidity of the tensor $Perm^n$ using the following bound on the chromatic number χ of a random graph $\mathbf{G}(n, q)$, which is an undirected random graph on n vertices with each edge chosen independently at random with probability q.

THEOREM 4.4. *For every $\varepsilon > 0$, there exists $\delta > 0$ and n_0 such that*

$$\Pr\left[\chi(\mathbf{G}(n,q)) \le \left(\frac{1}{2}+\varepsilon\right)\frac{-n\log(1-q)}{\log n}\right] > 1-\exp\left(-n^{1+\delta}\right),$$

as long as $7/8 < q < 1 - 1/n^{\frac{1}{2}-\varepsilon}$ and $n \ge n_0$.

This is essentially the theorem which was proved by Bollobás for every *constant* q [9]. However, for our application, we are interested in cases when q approaches 1 as n increases, which have not been considered in the literature. Therefore, we give the proof of Theorem 4.4 in section 7.

Let $\mathbf{S}(n,p)$ be the sum of independent Bernoulli random variables with mean p.

LEMMA 4.5. *Let $n, r, d, 0 < p < 1$ be numbers such that*

$$n! \cdot \Pr\left[\chi(\mathbf{G}(n,1-p^2)) > r\right] + n \cdot \Pr\left[\mathbf{S}(n,p) > d\right] < 1. \tag{4}$$

Then $perm^n$ can be computed by a restricted semilinear protocol where Player 1 sends r bits and Player 2 sends d bits.

Proof. Let $\{x_0,\dots,x_{n-1}\}$ and $\{y_0,\dots,y_{n-1}\}$ be disjoint sets of distinct vertices. Take a random bipartite graph $\mathbf{H}$ with each edge (x_k, y_i) chosen independently with probability p. Let π be a permutation on $\{0,\dots,n-1\}$. Let $\mathbf{G}_\pi$ be an undirected graph on $\{0,\dots,n-1\}$ such that for $i \ne j$, (i,j) is and edge of $\mathbf{G}_\pi$ if both edges $(x_i, y_{\pi^{-1}(j)})$ and $(x_j, y_{\pi^{-1}(i)})$ are in $\mathbf{H}$. Then $\mathbf{G}_\pi$ is a random graph with the same distribution as $\mathbf{G}(n,p^2)$, and its complement $\overline{\mathbf{G}}_\pi$ is a random graph from $\mathbf{G}(n,1-p^2)$. By assumption (4), there exists a graph H such that the degree of H is at most d and for each π, $\chi(\overline{\mathbf{G}}_\pi) \le r$. This means that for each π, the graph $\mathbf{G}_\pi$ can be covered by at most r cliques.

Using such a graph H, we construct a protocol for $perm^n(i,\pi,\vec{x})$. (In fact, this protocol demonstrates that $Perm(\pi,\vec{x})$ can be computed by H with r common bits.) For a fixed π, let $C_1,\dots,C_r$ be the cliques covering $\mathbf{G}_\pi$.

- Player 1 sends the vector $(\bigoplus x[C_1],\dots,\bigoplus x[C_r])$ (for notation, see Theorem 4.2).
- Player 2 sends all inputs x_k adjacent to y_i in H.
- Player 3 takes the clique C_s containing $\pi(i)$. Since for every $k \in C_s - \{\pi(i)\}$ the edge $(k,\pi(i))$ is in $\mathbf{G}_\pi$, it follows that x_k is adjacent to $y_{\pi^{-1}\pi(i)} = y_i$ in H. Thus the message of Player 2 contains the bit x_k for every $t \in C_s - \{\pi(i)\}$. Hence Player 3 can compute $x_{\pi(i)}$ by subtracting these bits from $\bigoplus x[C_s]$ sent by Player 1. ∎

THEOREM 4.6. *For every $\varepsilon > 0$ and $1/n^{\frac{1}{4}-\varepsilon} < p < 1/5$, there exists n_0 such that for every $n \ge n_0$, $perm^n$ can be computed by a restricted semilinear protocol where Player 1 sends $(1+\varepsilon)(-n\log p)/\log n$ bits and Player 2 sends $(1+\varepsilon)pn$ bits.*

Proof. Let ε and p satisfying the condition above be given, and let n be sufficiently large. In order to apply Lemma 4.5, we only need to estimate the probabilities for the chromatic number and independent Bernoulli variables. The first one is proved by Theorem 4.4,

$$n! \cdot \Pr\left[\chi(\mathbf{G}(n,1-p^2)) > (1+\varepsilon)\frac{-n\log p}{\log n}\right] < \exp(n\log n - n^{1+\delta}) = o(1).$$

The second one is a direct consequence of Chernoff–Hoeffding bounds,

$$n \cdot \Pr\left[\mathbf{S}(n,p) > (1+\varepsilon)pn\right] \le n \cdot 2\exp(-\Omega(pn)) = o(1). \qquad ∎$$

COROLLARY 4.7. *There exist constants $c, \delta > 0$ such that for $cn/\log n < r < \delta n$,*

$$R_{P^n}(r) \leq n^{2-(1-o(1))\frac{r}{n}}.$$

Proof. The result follows from Theorem 4.6 and Proposition 3.3 by a computation. □

COROLLARY 4.8.

(i) *There exists a restricted semilinear protocol for $perm^n$ which uses at most $O(n \log\log n/\log n)$ bits of communication. Thus for every k, $\mathrm{ASCC}(perm_k^n) = O(n \log\log n/\log n)$.*

(ii) $\mathrm{rank}^{2,1}(R^n) = O(n^2 \log\log n/\log n)$.

Proof. (i) Apply Theorem 4.6 with $p = \log\log n/\log n$. For larger k, the communication complexity can only be smaller.

(ii) This follows from (i) using Proposition 3.3. □

4.3. The iterated shift function. In this section, we generalize the upper bound from section 4.1 to the iterated shift function. This generalization is possible because the protocol for the function *shift* is given explicitly. We are not able to generalize the nonconstructive protocol of the previous section; thus we are not able to prove a bound on $\mathrm{ASCC}(perm_k^n)$ which decreases with increasing k.

THEOREM 4.9. *There exists a semilinear protocol for the k-times iterated shift function $shift_k^n(s_1, \ldots, s_{k+1}, \vec{x})$ such that if k is an arbitrary constant, each player sends at most $O(n(\log\log n/\log n)^k)$ bits, and if $k \geq c \log n$, for some constant c, each player sends at most $O(n^{6/7})$ bits.*

Proof. Remember that in the construction for $k = 1$, Player 1 divides the input x into several groups and communicates the parity of all of them. However, only one of these bits is really used by the last player. In our generalized construction, we compute this one bit recursively, using the first k players. It turns out that if we are careful, this is very similar to computing the function $shift_{k-1}^n$.

The length l of the arithmetic sequences we use will be chosen later to balance the number of bits communicated by individual players. Let $B \subseteq [0, n-1]$ be the set constructed in Lemma 4.1.

Player $k+1$ acts as Player 2 in the construction for $k = 1$, he sends $x[B + s_1 + \cdots + s_k]$, i.e., bits $x_{b+s_1+\cdots+s_k}$ for all $b \in B$. (All indices of x are taken modulo n.)

Players 1 to k all know the input s_{k+1}; hence they can compute the modulus $m = m(s_{k+1})$ as in Lemma 4.1. First they pad the input x by zeros so that its length is the smallest $n' \geq n$ divisible by ml. Then they divide the interval $[0, n'-1]$ into sequences $C_0, \ldots, C_{n''-1}$ of length l and modulus m as follows. Sequence C_0 starts with 0, C_1 starts with 1, ..., C_{m-1} starts with $m-1$ (this covers the subinterval $[0, ml-1]$), C_m starts with x_{ml}, and so on.

Let $y_j = \bigoplus x[C_j]$ be the parity of the bits of x indexed by the jth sequence. Let $f(j)$ be a number such that $j \in C_{f(j)}$. The goal of Players 1 to k is to compute $y_{f((s_1+\cdots+s_k) \bmod n')}$. If it were true that $f((s_1 + \cdots + s_{k+1}) \bmod n') = (f(s_1) + \cdots + f(s_k) + t) \bmod n''$ for some constant t, we would just use the protocol for $shift_{k-1}^n(f(s_1), \ldots, f(s_k), y')$, where y' is y shifted by t. This is not exactly the case, but we show that from the point of view of any player, there are only constantly many possible values of t.

Every player can compute t under the assumption that the input he does not see is 0. This value differs from the correct value by $f(r+s) - f(s) - f(r)$, where s is the input he does not see and r is the sum of all other inputs s_i (taken modulo n'). We now show that the only possible values of this difference are $-m$, 0, or m. Let the

numbers $a, a', a'' < m$, and $b, b', b'' < l$, and c, c', c'' be such that $s = cml + bm + a$, $r = cml + bm + a$, and $r + s = cml + bm + a$. Then $f(s) = cm + a$, $f(r) = c'm + a'$, and $f(r + s) = c''m + a''$. The claim is proved by observing that the value of a'' is either $a + a'$ or $a + a' - m$ and the value of c'' is either $c + c'$ or $c + c' + 1$. This works even for $r + s \geq n'$ since we have chosen n' divisible by ml.[1]

If each player communicates information according to the protocol for all three possible values of t, he certainly communicates the information for the correct t. Player $k + 2$ knows all $s_1, \ldots, s_{k+1}$; hence he can determine which t is correct and recover the result. Here we use the fact that the protocol is almost simultaneous; hence a player can follow a protocol even if other players do not, as he is not dependent on them.

It is obvious that the iterated protocol is semilinear. It remains to compute the amount of communication. Let $F(n, k)$ denote the maximal number of bits sent by an individual player in our protocol for $shift_k^n$. As a base case, we know by Theorem 4.2 that $F(n, 1) = O(n \log \log n / \log n)$. From the previous analysis, we know that Players 1 to k send at most $3F(n'', k-1)$ bits. As long as Player $k+1$ does not send more bits, we have $F(n, k) \leq 3F(n'', k - 1)$.

If k is constant, we choose $l = \log n/((k + 2) \log \log n)$ for each level of recursion. Since $n'' \leq 2n/l$, the recurrence gives $F(n, k) = O(n(\log \log n / \log n)^k)$. By Lemma 4.1, the size of B is $O(n(\log n)^{-k})$; hence the number of bits communicated by the last player is small, and our use of the recurrence is correct.

If k is not constant, we choose $l = 4$. In this case, the bound on the modulus is $o(n)$ and hence $n'' = (1 + o(1))n/l = n(3/4 + o(1))$. By induction, we get $F(n, k) \leq n(3/4 + o(1))^k$. By Lemma 4.1, the size of B is $O(n^{6/7})$. Therefore, we can iterate only as long as $cn^{6/7} \leq n(3/4 + o(1))^k$, i.e., up to some $k = \Theta(\log n)$. At that point, $F(n, k) = O(n^{6/7})$. □

5. Lower bounds. In this section, we prove a trade-off between the size of graphs and common bits which are needed to compute the shift function. This implies lower bounds on the rigidity function and the rigidity rank of the tensor D^n. As corollaries, we obtain the best known lower bounds for depth-2 circuits computing the shift function and multiplication. The same technique also shows that the protocols based on disjoint parities used in our upper bound cannot be extended so that Player 2 sends less than $n^{1/3}$ bits.

Let H^n be defined as $H^n = \{(x_i, y_j); 0 \leq j < i < n\}$. We first show that this graph cannot compute identity very well.

LEMMA 5.1. *Suppose that the graph H^n computes the identity function with r common bits, either in the Boolean case or using only linear functions over an arbitrary field. Then $r \geq n$.*

Proof. In the linear case, the computed function is represented by a matrix which is a sum of a matrix of rank r (the part with the common bits) and an upper triangular matrix with zeros on the diagonal (the edges). Such a matrix can be a diagonal matrix only if $r \geq n$.

In the Boolean case, we proceed by induction. The basis $n = 1$ is trivial. For the step from n to $n+1$, let $z_1, \ldots, z_r$ be the common bits for H^{n+1}. Since y_n is isolated in H^{n+1}, $y_n = x_n = g(z_1, \ldots, z_r)$ for some function g. Let $a \in \{0, 1\}$ be such that there

[1] It might be clearer to look at special examples. If $s = ml$, then $f(s) = m$ and it is easy to check that $f(r+s) = f(r)+m = f(r)+f(s)$ for all r. If $s = m$, then $f(s) = 0$ and either $f(r+s) = f(r)$ or $f(r+s) = f(r)+m$ (if $r+s$ is a multiple of ml). If $s = 1$, then $f(s) = 1$ and either $f(r+s) = f(r)+1$ or $f(r + s) = f(r) + 1 - m$ (if $r + s$ is a multiple of m but not a multiple of ml).

are at most 2^{r-1} elements $\vec{z} \in \{0,1\}^r$ with $g(\vec{z}) = a$. The set $\{\vec{z} \in \{0,1\}^r;\ g(\vec{z}) = a\}$ can be represented as a subset of $\{0,1\}^{r-1}$, and thus we can compute Id^n with these $r-1$ common bits with the graph H^n. By the inductive assumption, $r-1 \geq n$; hence $r \geq n+1$. □

THEOREM 5.2. *For every $\alpha > 0$, there exists $\delta > 0$ such that for every n and $r \geq n^\alpha$, if $Shift^n(s, \vec{x})$ can be computed by a graph G with r common bits for any $n/2$ values of $s \in \{0, \ldots, n-1\}$, either in the Boolean case or using only semilinear functions over an arbitrary field, then the size of G satisfies*

$$|G| \geq \delta \frac{n^2}{r} \log \frac{n}{r}. \tag{5}$$

Proof. Suppose that a graph $G \subseteq \{x_0, \ldots, x_{n-1}\} \times \{y_0, \ldots, y_{n-1}\}$ computes $n/2$ shifts with r common bits. Let $d = 4|G|/n$, and let $A = \{i; \text{degree}(x_i) \leq d\}$ and $B = \{i; \text{degree}(y_i) \leq d\}$ be the sets of vertices with small degrees in G. Clearly $|A|, |B| \geq 3n/4$ since d is four times the average degree of G.

Now consider a particular shift s computed by G. Let $A' = A \cap (B + s)$, where $B + s = \{(i + s) \bmod n; i \in B\}$. Clearly $|A'| \geq n/2$. Let G_s be a graph with vertices A' such that (a, b) is an edge if $(x_{a+s}, y_b) \in G$ and $a \leq b$. Let S be the set of all shifts s such that G_s has at most $n/4$ loops (edges of type (a, a)). If $|S| < n/4$, there are at least $n^2/16$ loops in all graphs G_s, and (5) is satisfied since each edge of G corresponds to at most one loop. Hence we assume that $|S| \geq n/4$ and restrict ourselves to shifts $s \in S$.

Suppose that for some $s \in S$ the graph G_s has less than $n/24$ triangles. Then there is a set $A'' \subseteq A'$, $|A''| \geq n/8$, which induces a triangle-free graph with no loops. Ajtai, Komlós, and Szemerédi [1] proved that a triangle-free graph of degree at most d contains an independent set of size at least

$$t \geq \frac{|A''| \log d}{100d} = \frac{n \log d}{800d}.$$

If there is an independent set K in G_s, it follows that $a > b$ whenever $(x_{a+s}, y_b) \in G$ for $a, b \in K$. Hence the graph G restricted to the nodes $\{x_{a+s}; a \in K\}$ and $\{y_b; b \in K\}$ is essentially a subgraph of $H^{|K|}$, and it computes the identity function, assuming G computes the shift s correctly. By Lemma 5.1, the number of common bits r is at least $|K| \geq t$. It follows that

$$d = \Omega\left(\frac{n}{r} \log \frac{n}{r}\right)$$

and (5) is satisfied.

The remaining case is that each of the $n/4$ graphs G_s, $s \in S$, contains at least $n/24$ triangles. Let $c < a < b$ be vertices of a triangle in G_s. From the definition of G_s, it follows that $(x_{a+s}, y_b, x_{c+s}, y_a)$ is a path in G. Such a path determines s (as the difference of the indices of the first and the last nodes); hence there are at least $|S|n/24 \geq n^2/96$ such paths. However, since the degree of nodes in G indexed by A and B is bounded by d, the number of paths is at most nd^3. This gives $nd^3 \geq n^2/96$; hence $d = \Omega(n^{1/3})$, $|G| = \Omega(n^{4/3})$, and (5) is satisfied if $r \geq n^{2/3} \log n$.

Now suppose $n^\alpha < r < n^{2/3} \log n$. We reduce this case to the previous part of the proof. Take an ε such that

$$n^{\frac{2}{3}\varepsilon} \log n^\varepsilon < r < n^{\frac{5}{6}\varepsilon}.$$

Thus $6x/5 < \varepsilon < 1$. Divide each of the sets $\{x_0, \ldots, x_{n-1}\}$ and $\{y_0, \ldots, y_{n-1}\}$ into $n^{1-\varepsilon}$ disjoint intervals of size n^ε. Let $U \subseteq \{x_0, \ldots, x_{n-1}\}$ and $V \subseteq \{y_0, \ldots, y_{n-1}\}$ be two such intervals. Then $G \cap (U \times V)$ realizes $n^\varepsilon/2$ noncyclic shifts with r common bits. A simple modification of this graph ("wrapping around") gives a graph with the same number of edges which computes $n^\varepsilon/2$ cyclic shifts with r common bits. Thus for each of the $n^{2-2\varepsilon}$ disjoint sections of G, we have a lower bound $\Omega((n^{2\varepsilon}/r)\log(n^\varepsilon/r))$ and thus

$$|G| = n^{2-2\varepsilon}\,\Omega\left(\frac{n^{2\varepsilon}}{r}\log\frac{n^\varepsilon}{r}\right) = \Omega\left(\varepsilon\frac{n^2}{r}\log\frac{n^\varepsilon}{r}\right) = \Omega\left(\frac{n^2}{r}\log\frac{n}{r}\right)$$

because ε is bounded by the constant α. □

COROLLARY 5.3.

(i) *Let $\alpha > 0$ be fixed. Then $R_{D^n}(r) = \Omega((n^2/r)\log(n/r))$, for $r \geq n^\alpha$.*

(ii) *Let $\alpha > 0$ be fixed. In any restricted protocol that computes $shift^n$ in which Player 1 sends at most r bits, $r \geq n^\alpha$, Player 2 sends at least $\Omega((n/r)\log(n/r))$ bits. Thus the total communication is at least $\Omega(\sqrt{n\log n})$ bits.*

(iii) $\operatorname{rank}^{2,1}(D^n) = \Omega\left(n^{3/2}(\log n)^{1/2}\right)$.

Proof. (i) and (ii) follow from Theorem 5.2 using Propositions 3.2 and 3.1.

(iii) Let $r = n^{1/2}(\log n)^{1/2}$. Let a decomposition of D^n into tensors of the form $u \otimes e_j^n \otimes w$ and $e_i^n \otimes v \otimes e_k^n$ be given. Let S be the sum of the tensors of the first type. If $\operatorname{rank}(S_{*,j,*}) \geq r$ for at least $n/2$ of the slices, we are done, so suppose the converse. Using Theorem 5.2 for the set of shifts j such that $\operatorname{rank}(S_{*,j,*}) < r$ and the transformation from Proposition 3.2, it follows that the number of tensors of type $e_i^n \otimes v \otimes e_k^n$ is at least

$$\Omega\left(\frac{n^2}{r}\log\frac{n}{r}\right) = \Omega\left(n^{3/2}(\log n)^{1/2}\right). \qquad \square$$

COROLLARY 5.4.

(i) *For any field $\mathbf{F}$, any depth-2 semilinear circuit for $Shift^n$ has size at least $\Omega\left(n(\log n)^{3/2}\right)$.*

(ii) *Any depth-2 circuit with arbitrary Boolean functions as gates which computes $Shift^n$ has size at least $\Omega\left(n(\log n)^{3/2}\right)$.*

Proof. In both cases, let a circuit for $Shift^n$ be given. Fix $\alpha > 0$. Let $d_1 \geq d_2 \geq \cdots$ be the degrees of the vertices on the middle level. For an arbitrary $r \geq n^\alpha$, we construct a graph with r common bits that computes $Shift^n$ as follows. We take the common bits to be the functions computed at r vertices with maximal degree. The graph is constructed by connecting an input to an output if they are connected by a path going through one of remaining vertices. This graph has at most $\sum_{j>r} d_j^2$ edges. By Theorem 5.2, it follows that

$$\sum_{j>r} d_j^2 \geq \Omega\left(\frac{n^2}{r}\log\frac{n}{r}\right).$$

This bound (for $n^\alpha \leq r \leq n$) implies

$$\sum_{j\geq 1} d_j = \Omega\left(n(\log n)^{3/2}\right).$$

See [24, Lemma 4] for a proof of this implication. □

COROLLARY 5.5.

(i) *Every depth-2 algebraic circuit for multiplying two polynomials has size* $\Omega\left(n(\log n)^{3/2}\right)$.

(ii) *Every depth-2 Boolean circuit for multiplying two n-bit numbers has size* $\Omega\left(n(\log n)^{3/2}\right)$.

Proof. Reduce the function $Shift^n$ to these functions. □

These are the best lower bounds for these functions for depth 2. Also, the bound $\Omega\left(n(\log n)^{3/2}\right)$ is the asymptotically largest lower bound for any explicitly given Boolean function. Previously, such a bound for general depth-2 circuits was known only for functions which contain a superconcentrator [2]. For linear circuits, such a bound can also be proved using the bound on rigidity of the parity-check matrix of a good code; see [14, 24].

The technique of counting triangles from Theorem 5.2 can be used to prove a stronger result for a more restricted model of computation by graphs.

THEOREM 5.6. *Suppose that* $Shift^n(s,\vec{x})$ *can be computed by a graph G with* $n/3$ *common bits using only semilinear functions, with an additional condition that for every s, the common bits compute parities of* pairwise-disjoint *subsets of bits of* $\vec{x}$. *Then the degree of G is at least* $\Omega(n^{1/3})$.

Proof. Suppose that the degree of G is $d = o(n^{1/3})$. Similarly as in Theorem 5.2, we consider the graph G_s for each shift. By counting the edges, for most values of s, the graph G_s has at most $o(n^{1/3})$ loops. This means that for such a value of s, the only way how to compute the value of other outputs is to use one of the common bits and the other input bits used by that common bit. Since each input is used only by a single common bit, the corresponding vertices in G_s have to induce a complete graph (more precisely, a tournament). Because there are only $n/3$ common bits which have to use all of $n - o(n^{1/3})$ input bits not in loops, these complete graphs contain $\Omega(n)$ triangles for each s, a total of $\Omega(n^2)$ triangles. By the same argument as in Theorem 5.2, the total number of triangles is at most $nd^3 = o(n^2)$, which is a contradiction. □

Similarly as in Theorem 5.2, we can extend this result to all graphs computing some constant fraction of shifts and prove that the number of edges has to be at least $n^{4/3}$, which is slightly stronger.

If we could prove a similar result without the additional restriction on the computation, it would follow that there are no linear circuits of logarithmic depth for the function $Shift^n$. Or, conversely, this result says that the protocols from section 4, which are all based on disjoint parities, are not powerful enough to break the bound of Theorem 3.5.

6. Conservative and nonconservative computation. Now we show that a conservative model of computations of shifts, which is based on sending information along vertex disjoint paths, is less efficient than a Boolean circuit (with parity gates) or a linear circuit over any field. We show this for circuits of depth 2 when the complexity is measured as the number of edges, with a modification that we do not count edges incident to a small set of vertices (of size $o(n)$). In fact, we show a stronger result, namely that in this way we can compute even all permutations more efficiently than one can compute only shifts using shifters. Ideally, we would like to prove the result when counting all edges; however, we are not able to do so at present time.

THEOREM 6.1. *There exists a semilinear circuit of depth* 2 *for* $Perm^n$ *and a set X of vertices on the middle level such that* $|X| = o(n)$ *and there are only* $o(n^{3/2})$ *edges disjoint with X.*

Before we prove Theorem 6.1, we prove the complementary lower bound for shifters, which is quite simple.

THEOREM 6.2. *If G is an n-shifter of depth 2, then G has $\Omega(n^{3/2})$ edges, even if we remove any $o(n)$ vertices and the edges incident with them.*

Proof. Suppose G is an n-shifter of depth 2. Let A be an arbitrary set of vertices of size $o(n)$. Suppose that there are only $o(n^{3/2})$ edges of G which are not incident with A. Let B be the set of vertices incident with $n^{1/2}$ such edges. By the assumption, $|B| = o(n)$. Since G is an n-shifter, there are $n - |A \cup B|$ paths from inputs to outputs disjoint with $A \cup B$ for each shift, a total of $n^2(1 - o(1))$ paths disjoint with $A \cup B$. However, each edge which is not incident with $A \cup B$ can belong only to $n^{1/2}$ paths; hence there are $n^{3/2}(1 - o(1))$ edges not incident with $A \cup B$, a contradiction. □

Bounds on the size of bounded-depth shifters have been proved in [23], including a lower bound $\Omega(n^{3/2})$ for depth 2. Let us also mention a related unpublished result of Maass which gives a bound $\Omega(n^{3/2})$ on the size of the circuits of depth 2 that compute $Shift^n$, with the restriction that there is a constant-size set of Boolean functions assigned to each vertex and for every shift we can only use as a gate assigned to this vertex either one of these functions or an arbitrary projection.

The proof of Theorem 6.1 is again probabilistic. A constructive proof for $Shift^n$ also seems possible. The basic idea is the same as in the upper bounds of section 4. Instead of sending the bits directly, we partition the inputs into $o(n)$ blocks, send the parities of the blocks through the extra $o(n)$ vertices, and then compute the individual bits from the parities of the blocks using direct connections realized by vertex-disjoint paths. The difficult part is to realize these direct connections with only $o(n^{3/2})$ edges. We prove that a random graph with suitable parameters satisfies this condition. We show that for each permutation, it is possible to choose one block of inputs with the necessary vertex-disjoint paths with a very large probability. This enables us to choose the blocks one by one until only $o(n)$ inputs remain. The values of these remaining inputs are also sent using the extra $o(n)$ vertices.

We need to make some preliminary considerations before we begin the proof. For the rest of this section, a graph means a graph of a circuit of depth 2, formally a quadruple (V_1, V_2, V_3, E) such that V_1, V_2, and V_3 are disjoint sets of vertices and the edges are $E \subseteq (V_1 \times V_2) \cup (V_2 \times V_3)$. An *embedding* of (V_1, V_2, V_3, E) into (V_1', V_2', V_3', E') is a one-to-one mapping g that maps vertices to vertices in the corresponding set and edges to edges. For technical reasons, we assume that the sets V_1 and V_1' are ordered and that any embedding has to preserve this ordering as well, i.e., if $V_1 = \{x_1, \ldots, x_n\}$, $V_1' = \{x_1', \ldots, x_{n'}'\}$, and $g(x_1) = x_{i_1}', \ldots, g(x_n) = x_{i_n}'$, then $i_1 < i_2 < \cdots < i_n$.

Let $G_k = (U_1, U_2, U_3, E)$ be the graph with k inputs and k outputs which realizes by vertex-disjoint paths all connections between all pairs of inputs and outputs, except for the corresponding pairs, i.e.,

$$\begin{aligned} U_1 &= \{u_1, \ldots, u_k\}, \\ U_2 &= \{w_{i,j};\ 1 \le i, j \le k, i \ne j\}, \\ U_3 &= \{v_1, \ldots, v_k\} \\ E &= \{(u_i, w_{i,j}), (w_{i,j}, v_j);\ \text{for } w_{i,j} \in U_2\}. \end{aligned}$$

The proof of the theorem is based on the following lemma, which we prove later.

LEMMA 6.3. *Let $k > 2$ be an arbitrary constant. Then for sufficiently large n, there exists a graph $G = (V_1, V_2, V_3, E)$, $|V_1| = |V_3| = n$, $|V_2| = nk^2$, with $n^{3/2}/k$ edges such that for every m, $n/k \le m \le n$, every $W_1 \subseteq V_1$, $W_2 \subseteq V_2$, $W_3 \subseteq V_3$, $|W_1| = |W_3| = m$, $|W_2| = mk^2$, and every bijection $f : W_3 \to W_1$, there exists an*

embedding g of G_k into subgraph of G induced by $W_1 \cup W_2 \cup W_3$ such that if $g(v_j) = x$, then $g(u_j) = f(x)$.

Proof of Theorem 6.1. For given n, pick the largest k such that the condition of Lemma 6.3 holds. Because k was an arbitrary constant, we have $k = \omega(1)$. Take the graph G from Lemma 6.3. Add a set X of $2n/k = o(n)$ extra vertices connected to all inputs $V_1 = \{x_1, \dots, x_n\}$ and all outputs $V_3 = \{y_1, \dots, y_n\}$. By Lemma 6.3, the graph has at most $n^{3/2}/k = o(n^{3/2})$ edges. Hence it remains only to prove that this circuit computes $Perm^n(\pi, \vec{x})$.

Fix a permutation π. By repeated applications of Lemma 6.3, we can choose disjoint embeddings of G_k into the graph G such that at most n/k inputs of G are left uncovered, and whenever an embedding maps an output to y_i, the corresponding input is mapped to $x_{\pi(i)}$.

For each of the chosen embeddings of G_k, take one of the extra vertices in X and connect inputs of G_k with outputs of G_k through it. Thus for an input x_j of G_k and an output y_i of G_k, we have just one path $x \to y$ through X if $j = \pi(i)$ and one path through X and one path in G_k if $j \neq \pi(i)$. Connect the inputs and the outputs not covered by the embeddings of G_k paths through the remaining vertices in X. This is possible since we need at most n/k vertices in X for G_k's and at most n/k vertices in X for inputs and outputs not covered by G_k's.

Assign values to the edges as follows. All edges of the selected paths through X have value 1. For each embedding of G_k, the edges going from V_1 to V_2 have value 1 and the edges going from V_2 to V_3 have value -1. The remaining edges have value 0. We set the linear function at each vertex to be the sum of the values on its predecessors, each multiplied by the value of the connecting edge. Thus for $j = \pi(i)$, there is only one path from x_j to y_i with nonzero value and its value is 1. For $j \neq \pi(j)$, there are either no nonzero paths or one with value 1 and one with value -1. Hence the circuit computes $Perm^n(\pi, \vec{x})$. □

For the rest of this section, we set

$$p = n^{\frac{5/4-k^2}{2(k^2-k)}} = n^{-\frac{1}{2}-\frac{4k-5}{8(k^2-k)}}.$$

Let $\mathbf{R}_{p,m}$ denote the random graph with vertices

$$\begin{aligned} V_1 &= \{x_1, \dots, x_m\}, \\ V_2 &= \{z_1, \dots, z_{mk^2}\}, \\ V_3 &= \{y_1, \dots, y_m\} \end{aligned}$$

and each edge from $V_1 \times V_2$ and $V_2 \times V_3$ chosen independently at random with probability p.

Proof of Lemma 6.3. We prove that for sufficiently large n, the graph $\mathbf{R}_{p,n}$ satisfies the conditions of Lemma 6.3 with high probability. The expected number of edges of $\mathbf{R}_{p,n}$ is

$$2n^2k^2p = 2k^2n^{\frac{3}{2}-\frac{4k-5}{8(k^2-k)}} = o(n^{3/2}/k);$$

hence the condition on the number of edges is satisfied with high probability.

The number of possible quadruples W_1, W_2, W_3, f is bounded by $e^{O(n \log n)}$. For a fixed quadruple W_1, W_2, W_3, f, the probability that an appropriate embedding of G_k exists is the same as the probability that there exists an embedding g of G_k into $\mathbf{R}_{p,m}$ satisfying

$$g(u_i) = x_j \quad \text{iff} \quad g(v_i) = y_j, \tag{6}$$

where $m = |W_1|$. Hence the proof is completed by the following lemma. □

LEMMA 6.4. *Let $k > 2$ be an arbitrary constant. Then for n sufficiently large and any m, $n/k \le m \le n$,*

$$\Pr[\textit{there exists no embedding of } G_k \textit{ into } \mathbf{R}_{p,m} \textit{ satisfying (6)}] \le e^{-n^{5/4+o(1)}}.$$

Proof. Let $X(H, G)$ denote the number of embeddings of H into G satisfying (6). We want to prove an upper bound on $Pr[X(G_k, \mathbf{R}_{p,m}) = 0]$. We use Janson's inequality, see [3, Theorem 1.1, Chapter 8, p. 96].

Let $G_k(1), \ldots, G_k(i), \ldots$ denote all possible occurrences of G_k in $\mathbf{R}_{p,m}$ satisfying the condition (6). Let

$$\begin{aligned}
\varepsilon &= \Pr[G_k(i) \subseteq \mathbf{R}_{p,m}],\\
\mu &= E\big(X(G_k, \mathbf{R}_{p,m})\big),\\
\Delta &= \sum_{i \sim j} \Pr[G_k(i) \subseteq \mathbf{R}_{p,m} \wedge G_k(j) \subseteq \mathbf{R}_{p,m}],
\end{aligned}$$

where we sum over the pairs of distinct occurrences of G_k which have at least one common edge. By Janson's inequality, we have

$$\Pr[X(G_k, \mathbf{R}_{p,m}) = 0] \le e^{-\mu + \frac{1}{1-\varepsilon}\frac{\Delta}{2}}.$$

Clearly, $\varepsilon = p^{2(k^2-k)} = o(1)$. We prove that $\mu = \Theta(n^{5/4})$ and $\Delta = o(\mu)$, which gives the desired bound.

First, we compute μ as the number of all possible occurrences times the probability of one fixed occurrence. (Remember that k is a constant.)

$$\mu = \binom{m}{k}\binom{mk^2}{k^2-k} p^{2(k^2-k)} = \Theta(n^k n^{k^2-k} n^{\frac{5/4-k^2}{2(k^2-k)} \cdot 2(k^2-k)}) = \Theta(n^{5/4}).$$

We can bound Δ as in [18] by

$$\Delta \le \sum_{\emptyset \ne H \subset G_k} \frac{\mu^2}{E(X(H, \mathbf{R}_{p,m}))} X(H, G_k)^2,$$

where the sum is over all graphs H with at least one edge which may occur as intersections $G_k(i) \cap G_k(j)$ for $i \ne j$. Since k is a constant, the number of such graphs is bounded and the values of $X(H, G_k)$ are bounded as well, and therefore

$$\Delta \le O\left(\frac{\mu^2}{\min E(X(H, \mathbf{R}_{p,m}))}\right).$$

For a given graph H, let r, $1 \le r \le k$, be the number of its vertices from V_1. The vertices on the middle level of H have degree at most 2. Let s_0, s_1, and s_2 denote the number of vertices of H on the middle level whose degree in H is 0, 1, and 2, respectively. Now we estimate the growth rate of $E(X(H, \mathbf{R}_{p,m}))$ and prove that it is at least $\omega(n^{5/4}) = \omega(\mu)$ for every H.

$$\begin{aligned}
E(X(H, \mathbf{R}_{p,m})) &= \binom{m}{r}\binom{mk^2}{s_2}\binom{mk^2-s_2}{s_1}\binom{mk^2-s_2-s_1}{s_0} p^{2s_2+s_1}\\
&\approx n^{r+s_2+s_1+s_0} p^{2s_2+s_1} \ge n^r (np^2)^{s_2} (np)^{s_1}\\
&= n^{r - s_2\left(\frac{4k-5}{4(k^2-k)}\right) + s_1\left(\frac{1}{2} - \frac{4k-5}{8(k^2-k)}\right)}.
\end{aligned}$$

We estimate the exponent separately for the following three cases.

(i) Let $r = 1$. Then $s_2 = 0$ since in G_k there is no path from u_i to v_i for any i. Since H is has at least one edge, $s_1 \geq 1$ and the exponent is at least $1 + 1/2 - (4k - 5)/(8(k^2 - k)) > 5/4$.

(ii) Suppose $2 \leq r \leq k - 1$. Since there are at most $r^2 - r$ vertices of degree 2 on the middle level of H, the exponent is minimized for $s_1 = 0$ and $s_2 = r^2 - r$, and then it is

$$\alpha = r - (r^2 - r)\frac{4k - 5}{4(k^2 - k)}.$$

This is a concave-down function in r; thus it is minimized at one of the endpoints of the interval, i.e., for $r = 2$ or $r = k-1$. For $r = 2$, $\alpha = 2+(4k-5)/(2(k^2-k)) > 5/4$. For $r = k - 1$, a short calculation gives $\alpha = 9/4 - 5/(2k) > 5/4$.

(iii) Finally, let $r = k$. Then $s_2 < k^2 - k$ since H is required to be a proper subgraph of G_k. Thus the exponent is minimized at $s_2 = k^2 - k - 1$ and $s_1 = 0$, when the value is $5/4 + (4k - 5)/(4(k^2 - k)) > 5/4$.

Hence $\Delta \leq \mu^2/\omega(\mu) = o(\mu)$ and we can apply Janson's inequality. □

7. The chromatic number of a random graph. In this section, we prove the estimate on the chromatic number of a random graph for a large probability of an edge, Theorem 4.4. In our presentation of the proof, we follow the lines of [3, Chapter 7]. The proof is based on the following lemma, where clique(G) denotes the size of a maximal clique in a graph G.

LEMMA 7.1. *For every $\varepsilon > 0$, there exist $\delta > 0$ and n_0 such that*

$$\Pr\left[\text{clique}(\mathbf{G}(n,p)) > (2-\varepsilon)\frac{\log n}{-\log p}\right] > 1 - \exp(-n^{1+\delta})$$

as long as $1/n^{\frac{1}{2}-\varepsilon} < p < 1/8$ and $n \geq n_0$.

First, we deduce Theorem 4.4 from Lemma 7.1. Set $m = n/(\log n)^2$, $\varepsilon' = \varepsilon/2$ and $p = 1 - q$. Let A be the event that every induced subgraph H of $\mathbf{G}(n, q)$ with m vertices has an independent set of size $\alpha(H) > (2-\varepsilon)(\log m)/(-\log(1-q))$. Note that $(2-\varepsilon')(\log m)/(-\log(1-q)) \geq (2-\varepsilon)(\log n)/(-\log(1-q))$ for n sufficiently large. Then by Lemma 7.1 applied with $\varepsilon' = \varepsilon/2$,

$$\Pr(A) > 1 - \binom{n}{m}\exp(-n^{1+\delta}) > 1 - \exp\left(-n^{\delta}\right).$$

This means that with probability at least $1 - \exp\left(-n^{\delta}\right)$, the random graph $\mathbf{G}(n, q)$ can be colored by

$$\frac{n-m}{(2-\varepsilon)\frac{\log m}{-\log(1-q)}} + m \leq \left(\frac{1}{2} + \varepsilon\right)\frac{-n\log(1-q)}{\log n}$$

colors. This finishes the proof of Theorem 4.4.

Before we give a proof of Lemma 7.1 we prove another lemma. Let $p = p(n)$ be given, $1/n^{\frac{1}{2}-\varepsilon} < p < 1/8$, $\varepsilon > 0$ constant. Let $k = k(n)$ be the largest integer such that

$$\binom{n}{k} p^{\binom{k}{2}} \geq n^3; \tag{7}$$

note that $(1-\varepsilon)(\log n)/(-\log p) \le k \le 2(\log n)/(-\log p)+1$ for every sufficiently large n. Let $Y = Y(\mathbf{G}(n,p))$ be the maximal size of a family of edge-disjoint k-cliques in $\mathbf{G}(n,p)$.

LEMMA 7.2. $E(Y) \ge n^2 p/(2k^5)$.

Proof. Let K denote the family of all k-cliques so that $E(|K|) = \binom{n}{k} p^{\binom{k}{2}} \ge n^3$. Let W be the set of ordered pairs $\{S,T\}$ of k-cliques of $\mathbf{G}(n,p)$ with $2 \le |S \cap T| < k$. Then

$$E(|W|) = \binom{n}{k} \sum_{i=2}^{k-1} \binom{k}{i} \binom{n-i}{k-i} p^{2\binom{k}{2}-\binom{i}{2}}.$$

Set

$$A_i = \binom{k}{i} \binom{n-i}{k-i} p^{2\binom{k}{2}-\binom{i}{2}}.$$

Since for $p < 1/8$, the sequence

$$B_i = \frac{A_i}{A_{i+1}} = \frac{(n-i)(i+1)}{(k-i)^2} p^i$$

decreases, we infer that for some i_0, $A_i \ge A_{i+1}$ for $i < i_0$ and $A_i \le A_{i+1}$ for $i \ge i_0$. A straightforward calculation using (7) shows that $A_{k-1} \le A_2$. Hence $A_i \le A_2$ for all $i = 2, \dots, k-1$ and thus

$$E(|W|) \le \binom{n}{k} k \binom{k}{2} \binom{n-2}{k-2} p^{2\binom{k}{2}-1}.$$

Let K' be a random subfamily of K, where every $S \in K$ is chosen independently with

$$\Pr[S \in K'] = \gamma = \frac{1}{4p^{\binom{k}{2}-1} k \binom{k}{2} \binom{n-2}{k-2}}.$$

Now construct a family $L \subseteq K'$ by removing each pair $S,T \in K'$ such that $\{S,T\} \in W$. No two cliques in L intersect; hence $|L| \le Y$. Thus

$$\begin{aligned} E(Y) &\ge E(|L|) \ge \gamma |K| - 2\gamma^2 E(|W|) \\ &= \gamma \binom{n}{k} p^{\binom{k}{2}} - 2\gamma^2 \binom{n}{k} k \binom{k}{2} \binom{n-2}{k-2} p^{2\binom{k}{2}-1} = \frac{1}{2} \gamma \binom{n}{k} p^{\binom{k}{2}} \ge \frac{n^2 p}{2k^5}. \end{aligned}$$

□

Furthermore, we need the following definition. A *martingale* is a sequence $Y_0, Y_1, \dots, Y_m$ of random variables such that for $0 \le i < m$,

$$E(Y_{i+1}|Y_i) = Y_i$$

holds. We use the following estimate.

THEOREM 7.3 (Azuma's inequality [3, 5]). *Let $0 = X_0, X_1, \dots, X_m$ be a martingale with $|X_{i+1} - X_i| \le 1$ for all $0 \le i < m$. Let $\lambda > 0$ be arbitrary. Then*

$$\Pr[X_m > \lambda] < e^{-\frac{\lambda^2}{2m}}.$$

Proof of Lemma 7.1. Let $Y_0, Y_1, \ldots, Y_m$, $m = \binom{n}{2}$, be the edge-exposure martingale on $\mathbf{G}(n,p)$ with function Y defined above. (See [3] for the definitions.) Y_i is the conditional expectation of Y when we know the first i edges (for a fixed arbitrary ordering of the edges); thus $y_0 = E(Y)$ and $Y_m = Y$. Since Y is the cardinality of a family of edge-disjoint cliques, $|Y_{i+1} - Y_i| \leq 1$ holds, and hence by Azuma's inequality, taking $X_i = Y_i - E(Y)$,

$$\begin{aligned}\Pr[\text{clique}(\mathbf{G}) < k] = \Pr[Y = 0] &\leq \Pr[Y - E(Y) \leq -E(Y)] \\ &\leq \exp\left(\frac{-E(Y)^2}{2\binom{n}{2}}\right) = \exp\left(-\frac{n^2p^2}{4k^{10}}(1+o(1))\right) \\ &\leq \exp(-n^{1+\delta}). \qquad \square\end{aligned}$$

8. Conclusions and open problems. We have shown relations between circuit complexity, multiparty complexity, and the algebraic characteristics of rigidity and rigidity rank. The particular versions of these concepts that we have considered are related to the problem of proving superlinear lower bounds on circuit complexity and on the size of bounded-depth circuits with arbitrary Boolean gates.

We have proved some upper bounds. Though it is only a small improvement, it disproves some earlier conjectures. The conclusion is that the problems are apparently harder than was expected.

We have also improved some lower bounds. This is an example of how nontrivial results in combinatorics may help in complexity theory. Still, the gaps between upper and lower bounds remain very large.

There many open problems in this area; several of them are implicit in the above text. Here we state only two which we consider to be the most challenging.

Problem 1. Does the function $Shift^n$ have circuits of size $O(n)$ and depth $O(\log n)$? This is open for semilinear circuits as well.

Problem 2. Improve the easy lower bound $\Omega(\sqrt{n})$ for the simultaneous communication complexity of $shift^n$.

We believe that $\mathrm{SCC}(shift^n)$ is large; however, even our slightly larger lower bound $\Omega(\sqrt{n \log n})$ from Corollary 5.3 works only under the restriction that Player 2 always sends a substring of the input string $\vec{x}$.

Acknowledgments. The first author would like to thank to Wolfgang Maass, from whom he learned problems on circuits with arbitrary Boolean functions as gates, and to Avi Wigderson for an idea which eventually led to the constructive upper bound in Theorem 4.2. We also thank Steven Rudich for valuable comments.

UNAMBIGUOUS COMPUTATION: BOOLEAN HIERARCHIES AND SPARSE TURING-COMPLETE SETS*

LANE A. HEMASPAANDRA† AND JÖRG ROTHE‡

Abstract. It is known that for any class $\mathcal{C}$ closed under *union and intersection*, the Boolean closure of $\mathcal{C}$, the Boolean hierarchy over $\mathcal{C}$, and the symmetric difference hierarchy over $\mathcal{C}$ all are equal. We prove that these equalities hold for any complexity class closed under *intersection*; in particular, they thus hold for unambiguous polynomial time (UP). In contrast to the NP case, we prove that the Hausdorff hierarchy and the nested difference hierarchy over UP both fail to capture the Boolean closure of UP in some relativized worlds.

Karp and Lipton proved that if *nondeterministic* polynomial time has sparse Turing-complete sets, then the polynomial hierarchy collapses. We establish the first consequences from the assumption that *unambiguous* polynomial time has sparse Turing-complete sets: (a) UP $\subseteq \mathrm{Low}_2$, where Low_2 is the second level of the low hierarchy, and (b) each level of the unambiguous polynomial hierarchy is contained one level lower in the promise unambiguous polynomial hierarchy than is otherwise known to be the case.

Key words. unambiguous computation, Boolean hierarchy, sparse Turing-complete sets

1. Introduction.

NP and NP-based hierarchies—such as the polynomial hierarchy [47, 57] and the Boolean hierarchy over NP [9, 10, 41]—have played such a central role in complexity theory, and have been so thoroughly investigated, that it would be natural to take them as predictors of the behavior of other classes or hierarchies. However, over and over during the past decade it has been shown that NP is a singularly poor predictor of the behavior of other classes (and, to a lesser extent, that hierarchies built on NP are poor predictors of the behavior of other hierarchies).

As examples regarding hierarchies, we have the following: though the polynomial hierarchy possesses downward separation (that is, if its low levels collapse, then all its levels collapse) [47, 57], downward separation does not hold "robustly" (i.e., in every relativized world) for the exponential time hierarchy [24, 36] or for limited-nondeterminism hierarchies [32] (see also [4]). As examples regarding UP, we have the following: NP has $\leq_m^p$-complete sets, but UP does not robustly possess $\leq_m^p$-complete sets [22] or even $\leq_T^p$-complete sets [31]; NP positively relativizes, in the sense that it collapses to P if and only if it does so with respect to every tally oracle [45] (see also [1]), but UP does not robustly positively relativize [29]; NP has "constructive programming systems," but UP does not robustly have such systems [52]; NP (actually, nondeterministic computation) admits time hierarchy theorems [25], but it is an open question whether unambiguous computation has nontrivial time hierarchy theorems; NP displays upward separation (that is, NP − P contains sparse sets if and

only if NE $\neq$ E) [24], but it is not known whether UP does (see [32], which shows that R and BPP do not robustly display upward separation, and [51], which shows that FewP does possess upward separation).

In light of the above list of the many ways in which NP parts company with UP, it is clear that we should not merely assume that results for NP hold for UP, but, rather, we must carefully check to see to what extent, if any, results for NP suggest results for UP. In this paper, we study, for UP, two topics that have been intensely studied for the NP case: the structure of Boolean hierarchies, and the effects of the existence of sparse Turing-complete/Turing-hard sets.

For the Boolean hierarchy over NP, which has generated quite a bit of interest and the collapse of which is known to imply the collapse of the polynomial hierarchy [37, 16, 3], a large number of definitions are known to be equivalent. For example, for NP, all the following coincide [9]: the Boolean closure of NP, the Boolean (alternating sums) hierarchy, the nested difference hierarchy, and the Hausdorff hierarchy. The symmetric difference hierarchy also characterizes the Boolean closure of NP [41]. In fact, these equalities are known to hold for all classes that contain Σ^* and $\emptyset$ and are closed under union and intersection [26, 9, 41, 5, 20, 15, 14]. In section 3, we prove that both the symmetric difference hierarchy (SDH) and the Boolean hierarchy (CH) remain equal to the Boolean closure (BC) *even in the absence of the assumption of closure under union.* That is, for any class $\mathcal{K}$ containing Σ^* and $\emptyset$ and closed under intersection (e.g., UP, US, and DP, first defined, respectively, in [59], [6], and [50] and each of which is not currently known to be closed under union): $\mathrm{SDH}(\mathcal{K}) = \mathrm{CH}(\mathcal{K}) = \mathrm{BC}(\mathcal{K})$. However, for the remaining two hierarchies, we show that not all classes containing Σ^* and $\emptyset$ and closed under intersection robustly display equality. In particular, the Hausdorff hierarchy over UP and the nested difference hierarchy over UP both fail to robustly capture the Boolean closure of UP. In fact, the failure is relatively severe; we show that even low levels of other Boolean hierarchies over UP—the third level of the symmetric difference hierarchy and the fourth level of the Boolean (alternating sums) hierarchy—fail to be robustly captured by either the Hausdorff hierarchy or the nested difference hierarchy.

It is well known, thanks to the work of Karp and Lipton [39] (see also the related references given in section 4), that if NP has sparse Turing-hard sets, then the polynomial hierarchy collapses. Unfortunately, the promise-like definition of UP—its unambiguity, the very core of its nature—seems to block any similarly strong claim for UP and the unambiguous polynomial hierarchy (which was introduced recently by Niedermeier and Rossmanith [48]). Section 4 studies this issue and shows that if UP has sparse Turing-complete sets, then the levels of the unambiguous polynomial hierarchy "slip down" slightly in terms of their location within the promise unambiguous polynomial hierarchy (a version of the unambiguous polynomial hierarchy that requires only that computations *actually executed* be unambiguous), i.e., the kth level of the unambiguous polynomial hierarchy is contained in the $(k-1)$st level of the promise unambiguous polynomial hierarchy. Various related results are also established. For example, if UP has Turing-hard sparse sets, then (a) UP $\subseteq \mathrm{Low}_2$, where Low_2 is the second level of the low hierarchy [53], and (b) the kth level of the unambiguous polynomial hierarchy can be accepted via a deterministic polynomial-time Turing transducer given access to both a Σ_2^p set and the $(k-1)$st level of the promise unambiguous polynomial hierarchy.

2. Notation. In general, we adopt the standard notations of Hopcroft and Ullman [35]. Fix the alphabet $\Sigma = \{0, 1\}$. Σ^* is the set of all strings over Σ. For each

string $u \in \Sigma^*$, $|u|$ denotes the length of u. The empty string is denoted by ϵ. For each set $L \subseteq \Sigma^*$, $\|L\|$ denotes the cardinality of L and $\overline{L} = \Sigma^* - L$ denotes the complement of L. $L^{=n}$ ($L^{\leq n}$) is the set of all strings in L having length n (less than or equal to n). Let Σ^n and $\Sigma^{\leq n}$ be shorthands for $(\Sigma^*)^{=n}$ and $(\Sigma^*)^{\leq n}$, respectively. A set S is said to be *sparse* if there is a polynomial q such that for every $m \geq 0$, $\|S^{\leq m}\| \leq q(m)$. To encode a pair of strings, we use a polynomial-time computable pairing function, $\langle \cdot, \cdot \rangle : \Sigma^* \times \Sigma^* \to \Sigma^*$, that has polynomial-time computable inverses; this notion is extended to encode every k-tuple of strings, in the standard way. Let $\leq_{\text{lex}}$ denote the standard quasi-lexicographical ordering on Σ^*, that is, for strings x and y, $x \leq_{\text{lex}} y$ if either $x = y$, or $|x| < |y|$, or ($|x| = |y|$ and there exists some $z \in \Sigma^*$ such that $x = z0u$ and $y = z1v$). $x <_{\text{lex}} y$ indicates that $x \leq_{\text{lex}} y$ but $x \neq y$.

For sets A and B, their join, $A \oplus B$, is $\{0x \,|\, x \in A\} \cup \{1x \,|\, x \in B\}$, and their symmetric difference, $A \,\Delta\, B$, is $(A - B) \cup (B - A)$. For any class $\mathcal{C}$, define $\text{co}\mathcal{C} \stackrel{\text{df}}{=} \{L \,|\, \overline{L} \in \mathcal{C}\}$, and let $\text{BC}(\mathcal{C})$ denote the Boolean algebra generated by $\mathcal{C}$, i.e., the smallest class containing $\mathcal{C}$ and closed under all Boolean operations. For any classes $\mathcal{A}$ and $\mathcal{B}$, let $\mathcal{A} \oplus \mathcal{B}$ denote the class $\{A \oplus B \,|\, A \in \mathcal{A} \wedge B \in \mathcal{B}\}$. Similarly, for classes $\mathcal{C}$ and $\mathcal{D}$ of sets, define

$$\mathcal{C} \wedge \mathcal{D} \stackrel{\text{df}}{=} \{A \cap B \,|\, A \in \mathcal{C} \wedge B \in \mathcal{D}\}, \qquad \mathcal{C} \;\boldsymbol{\Delta}\; \mathcal{D} \stackrel{\text{df}}{=} \{A \,\Delta\, B \,|\, A \in \mathcal{C} \wedge B \in \mathcal{D}\},$$
$$\mathcal{C} \vee \mathcal{D} \stackrel{\text{df}}{=} \{A \cup B \,|\, A \in \mathcal{C} \wedge B \in \mathcal{D}\}, \qquad \mathcal{C} - \mathcal{D} \stackrel{\text{df}}{=} \{A - B \,|\, A \in \mathcal{C} \wedge B \in \mathcal{D}\}.$$

We will abbreviate "polynomial-time deterministic (nondeterministic) Turing machine" by DPM (NPM). An *unambiguous* (sometimes called categorical) polynomial-time Turing machine (UPM) is an NPM that on no input has more than one accepting computation path [59]. UP is the class of all languages that are accepted by some UPM [59]. For the respective oracle machines, we use the shorthands DPOM, NPOM, and UPOM.

Note, crucially, that whether a machine is categorical or not depends on its oracle. In fact, it is well known that machines that are categorical with respect to all oracles accept only easy languages [23] and thus create a polynomial hierarchy analogue that is completely contained in a low level of the polynomial hierarchy (Allender and Hemachandra as cited in [29]). So, when we speak of a UPOM, we will simply mean an NPOM that, with the oracle the machine has in the context being discussed, happens to be categorical.

For any Turing machine M, $L(M)$ denotes the set of strings accepted by M, and the notation $M(x)$ means "M on input x." For any oracle Turing machine M and any oracle set A, $L(M^A)$ denotes the set of strings accepted by M relative to A, and the notation $M^A(x)$ means "M^A on input x." Without loss of generality, we assume each NPM and NPOM (in our standard enumeration of such machines) M has the property that for every n, there is an integer ℓ_n such that, for every x of length n, every path of $M(x)$ is of length ℓ_n, and furthermore, in the case of oracle machines, that ℓ_n is independent of the oracle. Let A and B be sets. We say A is *Turing reducible* to B (denoted by $A \leq_T^p B$ or $A \in \text{P}^B$) if there is a DPOM M such that $A = L(M^B)$. A set B is *Turing-hard* for a complexity class $\mathcal{C}$ if for all $A \in \mathcal{C}$, $A \leq_T^p B$. A set B is *Turing-complete* for $\mathcal{C}$ if B is Turing-hard for $\mathcal{C}$ and $B \in \mathcal{C}$.

3. Boolean hierarchies over classes closed under intersection. The Boolean hierarchy is a natural extension of the classes NP [17, 44] and DP $\stackrel{\text{df}}{=}$ NP $\wedge$ coNP [50]. Both NP and DP contain natural problems, as do the levels of the Boolean hierarchy. For example, graph minimal uncolorability is known to be complete for DP [13]. Note

that DP clearly is closed under intersection but is not closed under union unless the polynomial hierarchy collapses (due to [37]; see also [15, 14]).

DEFINITION 3.1. [9, 41, 26] *Let $\mathcal{K}$ be any class of sets.*

1. *The* Boolean ("alternating sums") hierarchy over $\mathcal{K}$*:*

$$\mathrm{C}_1(\mathcal{K}) \stackrel{\mathrm{df}}{=} \mathcal{K}, \quad \mathrm{C}_k(\mathcal{K}) \stackrel{\mathrm{df}}{=} \begin{cases} \mathrm{C}_{k-1}(\mathcal{K}) \vee \mathcal{K} & \text{if } k \text{ is odd,} \\ \mathrm{C}_{k-1}(\mathcal{K}) \wedge \mathrm{co}\mathcal{K} & \text{if } k \text{ is even,} \end{cases} \quad k \geq 2, \quad \mathrm{CH}(\mathcal{K}) \stackrel{\mathrm{df}}{=} \bigcup_{k \geq 1} \mathrm{C}_k(\mathcal{K}).$$

2. *The* nested difference hierarchy over $\mathcal{K}$*:*

$$\mathrm{D}_1(\mathcal{K}) \stackrel{\mathrm{df}}{=} \mathcal{K}, \qquad \mathrm{D}_k(\mathcal{K}) \stackrel{\mathrm{df}}{=} \mathcal{K} - \mathrm{D}_{k-1}(\mathcal{K}), \quad k \geq 2, \qquad \mathrm{DH}(\mathcal{K}) \stackrel{\mathrm{df}}{=} \bigcup_{k \geq 1} \mathrm{D}_k(\mathcal{K}).$$

3. *The* Hausdorff ("union of differences") hierarchy over $\mathcal{K}$:[1]

$$\mathrm{E}_1(\mathcal{K}) \stackrel{\mathrm{df}}{=} \mathcal{K}, \ \mathrm{E}_2(\mathcal{K}) \stackrel{\mathrm{df}}{=} \mathcal{K} - \mathcal{K}, \ \mathrm{E}_k(\mathcal{K}) \stackrel{\mathrm{df}}{=} \mathrm{E}_2(\mathcal{K}) \vee \mathrm{E}_{k-2}(\mathcal{K}), \ k > 2, \ \mathrm{EH}(\mathcal{K}) \stackrel{\mathrm{df}}{=} \bigcup_{k \geq 1} \mathrm{E}_k(\mathcal{K}).$$

4. *The* symmetric difference hierarchy over $\mathcal{K}$*:*

$$\mathrm{SD}_1(\mathcal{K}) \stackrel{\mathrm{df}}{=} \mathcal{K}, \qquad \mathrm{SD}_k(\mathcal{K}) \stackrel{\mathrm{df}}{=} \mathrm{SD}_{k-1}(\mathcal{K}) \ \boldsymbol{\Delta} \ \mathcal{K}, \quad k \geq 2, \qquad \mathrm{SDH}(\mathcal{K}) \stackrel{\mathrm{df}}{=} \bigcup_{k \geq 1} \mathrm{SD}_k(\mathcal{K}).$$

It is easily seen that for any X chosen from {C, D, E, SD}, if $\mathcal{K}$ contains $\emptyset$ and Σ^*, then for any $k \geq 1$,

$$\mathrm{X}_k(\mathcal{K}) \cup \mathrm{coX}_k(\mathcal{K}) \subseteq \mathrm{X}_{k+1}(\mathcal{K}) \cap \mathrm{coX}_{k+1}(\mathcal{K}).$$

The following fact is shown by an easy induction on n.

FACT 3.2. *For every class $\mathcal{K}$ of sets and every $n \geq 1$,*

1. $\mathrm{D}_{2n-1}(\mathcal{K}) = \mathrm{coC}_{2n-1}(\mathrm{co}\mathcal{K})$ *and*
2. $\mathrm{D}_{2n}(\mathcal{K}) = \mathrm{C}_{2n}(\mathrm{co}\mathcal{K})$.

Proof. The base case holds by definition. Suppose both statements of the fact to be true for $n \geq 1$. Then

$$\begin{aligned} \mathrm{D}_{2n+1}(\mathcal{K}) &= \mathcal{K} \wedge (\mathrm{co}\mathcal{K} \vee \mathrm{D}_{2n-1}(\mathcal{K})) \stackrel{\text{hyp.}}{=} \mathcal{K} \wedge (\mathrm{co}\mathcal{K} \vee \mathrm{coC}_{2n-1}(\mathrm{co}\mathcal{K})) \\ &= \mathcal{K} \wedge \mathrm{co}(\mathcal{K} \wedge \mathrm{C}_{2n-1}(\mathrm{co}\mathcal{K})) = \mathcal{K} \wedge \mathrm{coC}_{2n}(\mathrm{co}\mathcal{K}) \\ &= \mathrm{co}(\mathrm{co}\mathcal{K} \vee \mathrm{C}_{2n}(\mathrm{co}\mathcal{K})) = \mathrm{coC}_{2n+1}(\mathrm{co}\mathcal{K}) \end{aligned}$$

shows part 1 for $n+1$, and

$$\mathrm{D}_{2n+2}(\mathcal{K}) = \mathcal{K} - (\mathcal{K} - \mathrm{D}_{2n}(\mathcal{K})) \stackrel{\text{hyp.}}{=} \mathcal{K} \wedge (\mathrm{co}\mathcal{K} \vee \mathrm{C}_{2n}(\mathrm{co}\mathcal{K})) = \mathrm{C}_{2n+2}(\mathrm{co}\mathcal{K})$$

shows part 2 for $n+1$. □

COROLLARY 3.3. $\mathrm{CH(UP)} = \mathrm{coCH(UP)} = \mathrm{DH(coUP)}$ *and* $\mathrm{CH(coUP)} = \mathrm{coCH(coUP)} = \mathrm{DH(UP)}$.

[1] Hausdorff hierarchies [26] (see [9, 5, 20], respectively, for applications to NP, R, and ~~G~~P are interesting both in the case where, as in the definition here, the sets are arbitrary sets from $\mathcal{K}$, and, as is sometimes used in definitions, the sets from $\mathcal{K}$ are required to satisfy additional containment conditions. For classes closed under union and intersection, such as NP, the two definitions are identical, level by level [26] (see also [9]). In this paper, since UP, for example, is not known to be closed under union, the distinction is nontrivial.

We are interested in the Boolean hierarchies over classes closed under intersection (but perhaps not under union or complementation), such as UP, US, and DP. We state our theorems in terms of the class of primary interest to us in this paper, UP. However, many apply to any nontrivial class (i.e., any class containing Σ^* and $\emptyset$) closed under intersection (see Theorem 3.10). Although it has been proven in [9] and [41] that all the standard normal forms of Definition 3.1 coincide for NP,[2] the situation for UP seems to be different since UP is probably not closed under union. (The closure of UP under intersection is straightforward.) Thus all the relations among those normal forms have to be reconsidered for UP.

We first prove that the symmetric difference hierarchy over UP (or any class closed under intersection) equals the Boolean closure. Though Köbler, Schöning, and Wagner [41] proved this for NP, their proof gateways through a class whose proof of equivalence to the Boolean closure uses closure under union, and thus the following result is not implicit in their paper.

THEOREM 3.4. SDH(UP) = BC(UP).

Proof. The inclusion from left to right is clear. For the converse inclusion, it is sufficient to show that SDH(UP) is closed under all Boolean operations since BC(UP), by definition, is the smallest class of sets that contains UP and is closed under all Boolean operations. Let L and L' be arbitrary sets in SDH(UP). Then for some $k, \ell \geq 1$, there are sets $A_1, \ldots, A_k, B_1, \ldots, B_\ell$ in UP representing L and L':

$$L = A_1 \,\Delta\, \cdots \,\Delta\, A_k \quad \text{and} \quad L' = B_1 \,\Delta\, \cdots \,\Delta\, B_\ell.$$

So

$$L \cap L' = \left(\Delta_{i=1}^{k} A_i\right) \cap \left(\Delta_{j=1}^{\ell} B_j\right) = \Delta_{i \in \{1,\ldots,k\},\, j \in \{1,\ldots,\ell\}} (A_i \cap B_j),$$

and since UP is closed under intersection and SDH(UP) is (trivially) closed under symmetric difference, we clearly have that $L \cap L' \in$ SDH(UP). Furthermore, since $\overline{L} = \Sigma^* \,\Delta\, L$ implies that $\overline{L} \in$ SDH(UP), SDH(UP) is closed under complementation. Since all Boolean operations can be represented in terms of complementation and intersection, our proof is complete. □

Next, we show that for any class closed under intersection, instantiated below to the case of UP, the Boolean (alternating sums) hierarchy over the class equals the Boolean closure of the class. Our proof is inspired by the techniques used to prove equality in the case where closure under union may be assumed.

THEOREM 3.5. CH(UP) = BC(UP).

Proof. We will prove that SDH(UP) $\subseteq$ CH(UP). By Theorem 3.4, this will suffice.

Let L be any set in SDH(UP). Then there is a $k > 1$ (the case $k = 1$ is trivial) such that $L \in \mathrm{SD}_k(\mathrm{UP})$. Let $U_1, \ldots, U_k$ be the witnessing UP sets; that is, $L = U_1 \,\Delta\, U_2 \,\Delta\, \cdots \,\Delta\, U_k$. By the inclusion–exclusion rule, L satisfies the equalities below. For odd k,

$$L = \left(\cdots \left(\left((U_1 \cup U_2 \cup \cdots \cup U_k) \cap \left(\overline{\bigcup_{j_1 < j_2} (U_{j_1} \cap U_{j_2})} \right) \right) \right.\right.$$

[2] Due essentially to its closure under union and intersection, and this reflects a more general behavior of classes closed under union and intersection, as studied by Bertoni et al. [5] (see also [26, 9, 41, 15, 14]).

$$\cup \left(\bigcup_{j_1<j_2<j_3} (U_{j_1} \cap U_{j_2} \cap U_{j_3}) \right) \Bigg) \cap \cdots \cup \left(\bigcup_{j_1<\cdots<j_k} (U_{j_1} \cap \cdots \cap U_{j_k}) \right) \Bigg),$$

where each subscripted j term must belong to $\{1, \ldots, k\}$. For even k, we similarly have

$$L = \Bigg(\cdots \Bigg(\Bigg((U_1 \cup U_2 \cup \cdots \cup U_k) \cap \left(\overline{\bigcup_{j_1<j_2} (U_{j_1} \cap U_{j_2})} \right) \Bigg)$$
$$\cup \left(\bigcup_{j_1<j_2<j_3} (U_{j_1} \cap U_{j_2} \cap U_{j_3}) \right) \Bigg) \cap \cdots \cap \left(\overline{\bigcup_{j_1<\cdots<j_k} (U_{j_1} \cap \cdots \cap U_{j_k})} \right) \Bigg).$$

For notational convenience, let us use $A_1, \ldots, A_k$ to represent the respective terms in the above expressions (ignoring the complementations). By the closure of UP under intersection, each A_i, $1 \le i \le k$, is the union of $\binom{k}{i}$ UP sets $B_{i,1}, \ldots, B_{i,\binom{k}{i}}$. Using the fact that $\emptyset$ is clearly in UP, we can easily turn the union of n arbitrary UP sets (or the intersection of n arbitrary coUP sets) into an alternating sum of $2n-1$ UP sets. So for instance, $A_1 = U_1 \cup U_2 \cup \cdots \cup U_k$ can be written

$$\Big(\cdots \Big(\Big(\Big(U_1 \cap \overline{\emptyset} \Big) \cup U_2 \Big) \cap \overline{\emptyset} \Big) \cup \cdots \cup U_k \Big);$$

call this C_1. Clearly, $C_1 \in \mathrm{C}_{2k-1}(\mathrm{UP})$. To transform the above representation of L into an alternating sum of UP sets, we need two (trivial) transformations holding for any $m \ge 1$ and for arbitrary sets S and $T_1, \ldots, T_m$:

$$S \cap \left(\overline{T_1 \cup T_2 \cup \cdots \cup T_m} \right) = \left(\cdots \left(\left(S \cap \overline{T_1} \right) \cap \overline{T_2} \right) \cap \cdots \right) \cap \overline{T_m} \tag{3.1}$$

$$S \cup (T_1 \cup T_2 \cup \cdots \cup T_m) = (\cdots ((S \cup T_1) \cup T_2) \cup \cdots) \cup T_m. \tag{3.2}$$

Using (3.1) with $S = C_1$ and $T_1 = B_{2,1}, \ldots, T_m = B_{2,\binom{k}{2}}$ and the fact that $\emptyset$ is in UP, $A_1 \cap \overline{A_2}$ can be transformed into an alternating sum of UP sets; call this C_2. Now apply (3.2) with $S = C_2$ and $T_1 = B_{3,1}, \ldots, T_m = B_{3,\binom{k}{3}}$ to obtain, again using that $\emptyset$ is in UP, an alternating sum $C_3 = (A_1 \cap \overline{A_2}) \cup A_3$ of UP sets, and so on. Eventually, this procedure of alternately applying (3.1) and (3.2) will yield an alternating sum C_k of sets in UP that equals L. Thus $L \in \mathrm{CH}(\mathrm{UP})$. □

COROLLARY 3.6. SDH(UP) *and* CH(UP) *are both closed under all Boolean operations.*

Note that the proofs of Theorems 3.5 and 3.4 implicitly give a recurrence yielding an upper bound on the level-wise containments. We find the issue of equality to BC(UP), or lack thereof, to be the central issue, and thus we focus on that. Nonetheless, we point out in the corollary below that losing the assumption of closure under union seems to have exacted a price: though the hierarchies SDH(UP) and CH(UP) are indeed equal, the above proof embeds $\mathrm{SD}_k(\mathrm{UP})$ in an exponentially higher level of the C hierarchy over UP. Similarly, the proof of Theorem 3.4 embeds $\mathrm{C}_k(\mathrm{UP})$ in an exponentially higher level of SDH(UP).

COROLLARY 3.7.

1. *For each* $k \ge 1$, $\mathrm{SD}_k(\mathrm{UP}) \subseteq \mathrm{C}_{2^{k+1}-k-2}(\mathrm{UP})$.
2. *For each* $k \ge 1$, $\mathrm{C}_k(\mathrm{UP}) \subseteq \mathrm{SD}_{T(k)}(\mathrm{UP})$, *where* $T(k) = 2^k - 1$ *if* k *is odd, and* $T(k) = 2^k - 2$ *if* k *is even.*

Proof. For an $\mathrm{SD}_k(\mathrm{UP})$ set L to be placed into the $R(k)$th level of $\mathrm{CH}(\mathrm{UP})$, L is represented (in the proof of Theorem 3.5) as an alternating sum of k terms $A_1, \ldots, A_k$, each A_i consisting of $\binom{k}{i}$ UP sets $B_{i,j}$. In the subsequent transformation of L according to equations (3.1) and (3.2), each A_i requires as many as $\binom{k}{i} - 1$ additional terms $\emptyset$ or $\overline{\emptyset}$, respectively, to be inserted, and each such insertion brings us one level higher in the C hierarchy. Thus

$$R(k) = \sum_{i=1}^{k} \binom{k}{i} + \left(\binom{k}{i} - 1 \right) = -k + 2 \sum_{i=1}^{k} \binom{k}{i} = 2^{k+1} - k - 2.$$

A close inspection of the proof of $\mathrm{C}_k(\mathrm{UP}) \subseteq \mathrm{SD}_{T(k)}(\mathrm{UP})$ according to Theorem 3.4 leads to the recurrence

$$T(1) = 1 \quad \text{and} \quad T(k) = \begin{cases} 2T(k-1) + 3 & \text{if } k > 1 \text{ is odd,} \\ 2T(k-1) & \text{if } k > 1 \text{ is even} \end{cases}$$

since any set $L \in \mathrm{C}_k(\mathrm{UP})$ can be represented by sets $A \in \mathrm{C}_{k-1}(\mathrm{UP})$ and $B \in \mathrm{UP}$ as follows:

$$\begin{array}{ll} L = A \cup B = \overline{\overline{A} \cap \overline{B}} = \Sigma^* \,\Delta\, ((\Sigma^* \,\Delta\, A) \cap (\Sigma^* \,\Delta\, B)) & \text{if } k \text{ is odd,} \\ L = A \cap \overline{B} = A \cap (\Sigma^* \,\Delta\, B) & \text{if } k \text{ is even.} \end{array}$$

The above recurrence is in (almost) closed form:

$$T(k) = \begin{cases} 2^k - 1 & \text{if } k \geq 1 \text{ is odd,} \\ 2^k - 2 & \text{if } k \geq 1 \text{ is even,} \end{cases}$$

as can be proven by induction on k (we omit the trivial induction base): For odd k (i.e., $k = 2n - 1$ for $n \geq 1$), assume $T(2n-1) = 2^{2n-1} - 1$ to be true. Then

$$T(2n+1) = 2T(2n) + 3 = 4T(2n-1) + 3 \stackrel{\text{hyp.}}{=} 4\left(2^{2n-1} - 1\right) + 3 = 2^{2n+1} - 1.$$

For even k (i.e., $k = 2n$ for $n \geq 1$), assume $T(2n) = 2^{2n} - 2$ to be true. Then

$$T(2n+2) = 2T(2n+1) = 2(2T(2n) + 3) \stackrel{\text{hyp.}}{=} 4\left(2^{2n} - 2\right) + 6 = 2^{2n+2} - 2. \qquad \square$$

Remark 3.8. The upper bound in the second part of the above proof can be slightly improved using the fact that $\Sigma^* \,\Delta\, \Sigma^* \,\Delta\, A = \emptyset \,\Delta\, A = A$ for any set A. This gives the recurrence

$$T(1) = 1 \quad \text{and} \quad T(k) = \begin{cases} 2T(k-1) + 1 & \text{if } k > 1 \text{ is odd,} \\ 2T(k-1) & \text{if } k > 1 \text{ is even,} \end{cases}$$

or, equivalently, $T(1) = 1$, $T(2) = 2$, and $T(k) = 2^{k-1} + T(k-2)$ for $k \geq 3$. Though this shows that the upper bound given in the above proof is not optimal, the new bound is not a strong improvement, since it still embeds $\mathrm{C}_k(\mathrm{UP})$ in an exponentially higher level of $\mathrm{SDH}(\mathrm{UP})$. We propose as an interesting task the establishment of *tight* level-wise containments, at least up to the limits of relativizing techniques, between the hierarchies $\mathrm{SDH}(\mathrm{UP})$ and $\mathrm{CH}(\mathrm{UP})$, both of which capture the Boolean closure of UP.

We conjecture that there is some relativized world in which an exponential increase (though less dramatic than the particular exponential increase of Corollary 3.7) indeed is necessary.

Theorem 3.9 below shows that each level of the nested difference hierarchy is contained in the same level of both the C and the E hierarchy. Surprisingly, it turns out (see Theorem 3.13 below) that, relative to a recursive oracle, even the fourth level of CH(UP) and the third level of SDH(UP) are not subsumed by any level of the EH(UP) hierarchy. Consequently, neither the D nor the E normal forms of Definition 3.1 capture the Boolean closure of UP.

THEOREM 3.9. *For every* $k \geq 1$, $\mathrm{D}_k(\mathrm{UP}) \subseteq \mathrm{C}_k(\mathrm{UP}) \cap \mathrm{E}_k(\mathrm{UP})$.

Proof. For the first inclusion, by [11, Proposition 2.1.2], each set L in $\mathrm{D}_k(\mathrm{UP})$ can be represented as

$$L = A_1 - (A_2 - (\cdots (A_{k-1} - A_k) \cdots)),$$

where $A_i = \bigcap_{1 \leq j \leq i} L_j$, $1 \leq i \leq k$, and the L_j's are the original UP sets representing L. Note that since the proof of [11, Proposition 2.1.2] only uses intersection, the sets A_i are in UP. A special case of [11, Proposition 2.1.3] says that sets in $\mathrm{D}_k(\mathrm{UP})$ via decreasing chains such as the A_i are in $\mathrm{C}_k(\mathrm{UP})$, and so $L \in \mathrm{C}_k(\mathrm{UP})$.

The proof of the second inclusion is done by induction on the odd and even levels separately. The induction base follows by definition in either case. For odd levels, assume $\mathrm{D}_{2n-1}(\mathrm{UP}) \subseteq \mathrm{E}_{2n-1}(\mathrm{UP})$ to be valid, and let L be any set in $\mathrm{D}_{2n+1}(\mathrm{UP}) = \mathrm{UP} - (\mathrm{UP} - \mathrm{D}_{2n-1}(\mathrm{UP}))$. By our inductive hypothesis, L can be represented as

$$L = A - \left(B - \left(\bigcup_{i=1}^{n-1} \left(C_i \cap \overline{D_i} \right) \cup E \right) \right),$$

where A, B, C_i, D_i, and E are sets in UP. Thus

$$\begin{aligned} L &= A \cap \left(\overline{B \cap \left(\overline{\bigcup_{i=1}^{n-1} \left(C_i \cap \overline{D_i} \right) \cup E} \right)} \right) \\ &= A \cap \left(\overline{B} \cup \left(\bigcup_{i=1}^{n-1} \left(C_i \cap \overline{D_i} \right) \cup E \right) \right) \\ &= (A \cap \overline{B}) \cup \left(\bigcup_{i=1}^{n-1} A \cap C_i \cap \overline{D_i} \right) \cup (A \cap E) \\ &= \left(\bigcup_{i=1}^{n} F_i \cap \overline{D_i} \right) \cup G, \end{aligned}$$

where $F_i = A \cap C_i$, for $1 \leq i \leq n-1$, $F_n = A$, $D_n = B$, and $G = A \cap E$. Since UP is closed under intersection, each of these sets is in UP. Thus $L \in \mathrm{E}_{2n+1}(\mathrm{UP})$. The proof for the even levels is analogous except that the set E is dropped. □

Note that most of the above proofs used only the facts that the class is closed under intersection and contains Σ^* and $\emptyset$.

THEOREM 3.10. *Theorems* 3.4, 3.5, *and* 3.9 *and Corollaries* 3.6 *and* 3.7 *apply to all classes that contain* Σ^* *and* $\emptyset$ *and are closed under intersection.*

Remark 3.11. Although DP is closed under intersection but seems to lack closure under union (unless the polynomial hierarchy collapses to DP [37, 15, 14]) and thus

Theorem 3.10 in particular applies to DP, we note that the known results about Boolean hierarchies over NP [9, 41] in fact even for the DP case imply stronger results than those given by our Theorem 3.10, due to the very special structure of DP. Indeed, since, e.g., $\mathrm{E}_k(\mathrm{DP}) = \mathrm{E}_{2k}(\mathrm{NP})$ for any $k \geq 1$ (and the same holds for the other hierarchies), it follows immediately that all the level-wise equivalences among the Boolean hierarchies (and also their ability to capture the Boolean closure) that are known to hold for NP also hold for DP even in the absence of the assumption of closure under union. This appears to contrast with the UP case (see Remark 3.8).

The following combinatorial lemma will be useful in proving Theorem 3.13.

LEMMA 3.12. [12] *Let $G = (S, T, E)$ be any directed bipartite graph with out-degree bounded by d for all vertices. Let $S' \subseteq S$ and $T' \subseteq T$ be subsets such that $S' \supseteq \{s \in S \mid (\exists t \in T)\,[\langle s, t\rangle \in E]\}$, and $T' \supseteq \{t \in T \mid (\exists s \in S)\,[\langle t, s\rangle \in E]\}$. Then either*

1. $\|S'\| \leq 2d$, *or*
2. $\|T'\| \leq 2d$, *or*
3. $(\exists s \in S')\,(\exists t \in T')\,[\langle s, t\rangle \notin E \wedge \langle t, s\rangle \notin E]$.

For papers concerned with oracles separating internal levels of Boolean hierarchies over classes other than those of this paper, we refer the reader to [9, 8, 20, 7, 18] (see also [21]). Theorem 3.13 is optimal since clearly $\mathrm{C}_3(\mathrm{UP}) \subseteq \mathrm{EH}(\mathrm{UP})$ and $\mathrm{SD}_2(\mathrm{UP}) \subseteq \mathrm{EH}(\mathrm{UP})$, and both these containments relativize.

THEOREM 3.13. *There are recursive oracles A and D (though we may take $A = D$) such that*

1. $\mathrm{C}_4(\mathrm{UP}^A) \not\subseteq \mathrm{EH}(\mathrm{UP}^A)$ *and*
2. $\mathrm{SD}_3(\mathrm{UP}^D) \not\subseteq \mathrm{EH}(\mathrm{UP}^D)$.

COROLLARY 3.14. *There is a recursive oracle A such that*

1. $\mathrm{EH}(\mathrm{UP}^A) \neq \mathrm{BC}(\mathrm{UP}^A)$ *and* $\mathrm{DH}(\mathrm{UP}^A) \neq \mathrm{BC}(\mathrm{UP}^A)$, [3] *and*
2. $\mathrm{EH}(\mathrm{UP}^A)$ *and* $\mathrm{DH}(\mathrm{UP}^A)$ *are not closed under all Boolean operations.*

Proof of Theorem 3.13. Although the theorem claims that there is an oracle keeping $\mathrm{C}_4(\mathrm{UP})$ from being contained in any level of $\mathrm{EH}(\mathrm{UP})$, we will only prove that for any fixed k we can ensure that $\mathrm{C}_4(\mathrm{UP})$ is not contained in $\mathrm{E}_k(\mathrm{UP})$, relative to some oracle $A^{(k)}$. In the standard way, by interleaving diagonalizations, the sequence of oracles, $A^{(k)}$, can be combined into a single oracle, A, that fulfills the claim of the theorem. An analogous comment holds for the second claim of the theorem, with a sequence of oracles $D^{(k)}$ yielding a single oracle D. Similarly, both statements of the theorem can be satisfied simultaneously via just one oracle, via interleaving with each other the constructions of A and D. Though below we construct just $A^{(k)}$ and $D^{(k)}$, as a notational shorthand we will use A and D below to represent $A^{(k)}$ and $D^{(k)}$.

Before the actual construction of the oracles, we state some preliminaries that apply to the proofs of both statements in the theorem.

For any $n \geq 0$ and any string $v \in \Sigma^{\leq n}$, define $S^n_v \stackrel{\mathrm{df}}{=} \{vw \mid vw \in \Sigma^n\}$. The sets S^n_v are used to distinguish between different segments of Σ^n in the definition of the test languages, L_A and L_D.

Fix any standard enumeration of all NPOMs. Fix any $k > 0$. We need only consider even levels of $\mathrm{EH}(\mathrm{UP})$ since each odd level is contained in some even level. Call any collection of $2k$ NPOMs, $H = \langle N_{1,1}, \ldots, N_{k,1}, N_{1,2}, \ldots, N_{k,2}\rangle$, a potential

[3] Since both Corollary 3.3 (establishing $\mathrm{DH}(\mathrm{UP}) = \mathrm{CH}(\mathrm{coUP})$) and Theorem 3.5 ($\mathrm{BC}(\mathrm{UP}) = \mathrm{CH}(\mathrm{UP})$) relativize, this oracle A also separates the Boolean (alternating sums) hierarchy over coUP from the fourth level of the same hierarchy over UP and thus from BC(UP).

(relativized) $\mathrm{E}_{2k}(\mathrm{UP})$ machine, and for any oracle X, define its language to be:

$$L(H^X) \stackrel{\mathrm{df}}{=} \bigcup_{i=1}^{k} \left(L(N_{i,1}^X) - L(N_{i,2}^X)\right).$$

If for some fixed oracle Y, a potential (relativized) $\mathrm{E}_{2k}(\mathrm{UP})$ machine H^Y has the property that each of its underlying NPOMs with oracle Y is unambiguous, then $L(H^Y)$ indeed is in $\mathrm{E}_{2k}(\mathrm{UP}^Y)$. Clearly, our enumeration of all NPOMs induces an enumeration of all potential $\mathrm{E}_{2k}(\mathrm{UP})$ oracle machines. For $j \geq 1$, let H_j be the jth machine in this enumeration. Let p_j be a polynomial bounding the length of the computation paths of each of H_j's underlying machines (and thus bounding the number of and length of the strings they each query). As a notational convenience, we henceforth will use H and p as shorthands for H_j and p_j, and we will denote the underlying NPOMs by $N_{1,1}, \ldots, N_{k,1}, N_{1,2}, \ldots, N_{k,2}$.

The oracle X, where X stands for A or D, is constructed in stages, $X = \bigcup_{j \geq 1} X_j$. In stage j, we diagonalize against H by satisfying the following requirement R_j for every $j \geq 1$:

R_j: Either there is an $n > 2$ and an i, $1 \leq i \leq k$, such that one of $N_{i,1}^{X_j}$ or $N_{i,2}^{X_j}$ on input 0^n is ambiguous (thus H is in fact not an $\mathrm{E}_{2k}(\mathrm{UP})$ machine relative to X), or $L(H^X) \neq L_X$, where L_X is as defined below.

Let X_j be the set of strings contained in X by the end of stage j, and let X_j' be the set of strings forbidden membership in X during stage j. The restraint function $r(j)$ will satisfy the condition that at no later stage will strings of length smaller than $r(j)$ be added to X. Also, our construction will ensure that $r(j)$ is so large that X_{j-1} contains no strings of length greater than $r(j)$. Initially, both X_0 and X_0' are empty, and $r(1)$ is set to be 2.

We now start the proof of Part 1 of the theorem. Define the test language

$$L_A \stackrel{\mathrm{df}}{=} \{0^n \mid (\exists x)\,[x \in S_0^n \cap A] \wedge (\forall y)\,[y \notin S_{10}^n \cap A] \wedge (\forall z)\,[z \notin S_{11}^n \cap A]\}.$$

Clearly, L_A is in $\mathrm{NP}^A \wedge \mathrm{coNP}^A \wedge \mathrm{coNP}^A$. However, if we ensure in the construction that the invariant $\|S_v^n \cap A\| \leq 1$ is maintained for $v \in \{0, 10, 11\}$ and every $n \geq 2$, then L_A is even in $\mathrm{UP}^A \wedge \mathrm{coUP}^A \wedge \mathrm{coUP}^A$ and thus in $\mathrm{C}_4(\mathrm{UP}^A)$. We now describe stage $j > 0$ of the oracle construction.

Stage j: Choose $n > r(j)$ so large that $2^{n-2} > 3p(n)$.

Case 1: $0^n \in L(H^{A_{j-1}})$. Since $0^n \notin L_A$, we have $L(H^A) \neq L_A$.

Case 2: $0^n \notin L(H^{A_{j-1}})$. Choose some $x \in S_0^n$ and set $B_j := A_{j-1} \cup \{x\}$.

Case 2.1: $0^n \notin L(H^{B_j})$. Letting $A_j := B_j$ implies $0^n \in L_A$, so $L(H^A) \neq L_A$.

Case 2.2: $0^n \in L(H^{B_j})$. Then there is an i, $1 \leq i \leq k$, such that $0^n \in L(N_{i,1}^{B_j})$ and $0^n \notin L(N_{i,2}^{B_j})$. "Freeze" an accepting path of $N_{i,1}^{B_j}(0^n)$ into A_j'; that is, add those strings queried negatively on that path to A_j', thus forbidding them from A for all later stages. Clearly, at most $p(n)$ strings are "frozen."

Case 2.2.1: $(\exists z \in (S_{10}^n \cup S_{11}^n) - A_j')\,[0^n \notin L(N_{i,2}^{B_j \cup \{z\}})]$.
Choose any such z. Set $A_j := B_j \cup \{z\}$. We have $0^n \in L(H^A)$ but $0^n \notin L_A$.

Case 2.2.2: $(\forall z \in (S_{10}^n \cup S_{11}^n) - A_j')\,[0^n \in L(N_{i,2}^{B_j \cup \{z\}})]$.
To apply Lemma 3.12, define a directed bipartite graph $G =$

(S, T, E) by $S \stackrel{\text{df}}{=} S_{10}^n - A_j'$, $T \stackrel{\text{df}}{=} S_{11}^n - A_j'$, and for each $s \in S$ and $t \in T$, $\langle s, t\rangle \in E$ if and only if $N_{i,2}^{B_j \cup \{s\}}$ queries t along its lexicographically first accepting path, and $\langle t, s\rangle \in E$ is defined analogously. The out-degree of all vertices of G is bounded by $p(n)$. By our choice of n, $\min\{\|S\|, \|T\|\} \geq 2^{n-2} - p(n) > 2p(n)$, and thus alternative 3 of Lemma 3.12 applies. Hence there exist strings $s \in S$ and $t \in T$ such that $N_{i,2}^{B_j \cup \{s\}}(0^n)$ accepts on some path p_s on which t is not queried, and $N_{i,2}^{B_j \cup \{t\}}(0^n)$ accepts on some path p_t on which s is not queried. Since p_s (p_t) changes from reject to accept exactly by adding string s (t) to the oracle, s (t) must have been queried on p_s (p_t). We conclude that $p_s \neq p_t$, and thus $N_{i,2}^{B_j \cup \{s,t\}}(0^n)$ has at least two accepting paths. Set $A_j := B_j \cup \{s, t\}$.

In each case, requirement R_j is fulfilled. Let $r(j+1)$ be $\max\{n, w_j\}$, where w_j is the length of the largest string queried through stage j.

End of stage j.

We now turn to the proof of part 2 of the theorem. The test language here, L_D, is defined by:

$$L_D \stackrel{\text{df}}{=} \left\{ 0^n \left| \begin{array}{l} ((\exists x)\,[x \in S_0^n \cap D] \wedge (\exists y)\,[y \in S_{10}^n \cap D] \wedge (\exists z)\,[z \in S_{11}^n \cap D]) \vee \\ ((\forall x)\,[x \notin S_0^n \cap D] \wedge (\forall y)\,[y \notin S_{10}^n \cap D] \wedge (\exists z)\,[z \in S_{11}^n \cap D]) \vee \\ ((\exists x)\,[x \in S_0^n \cap D] \wedge (\forall y)\,[y \notin S_{10}^n \cap D] \wedge (\forall z)\,[z \notin S_{11}^n \cap D]) \vee \\ ((\forall x)\,[x \notin S_0^n \cap D] \wedge (\exists y)\,[y \in S_{10}^n \cap D] \wedge (\forall z)\,[z \notin S_{11}^n \cap D]) \end{array} \right. \right\}.$$

Again, provided that the invariant $\|S_v^n \cap D\| \leq 1$ is maintained for $v \in \{0, 10, 11\}$ and every $n \geq 2$ throughout the construction, L_D is clearly in $\mathrm{SD}_3(\mathrm{UP}^D)$, as for all sets A, B, and C,

$$A \,\Delta\, B \,\Delta\, C = (A \cap B \cap C) \cup (\overline{A} \cap \overline{B} \cap C) \cup (A \cap \overline{B} \cap \overline{C}) \cup (\overline{A} \cap B \cap \overline{C}).$$

Stage $j > 0$ of the construction of D is as follows.

Stage j: Choose $n > r(j)$ so large that $2^{n-2} > 3p(n)$.

Case 1: $0^n \in L(H^{D_{j-1}})$. Since $0^n \notin L_D$, we have $L(H^D) \neq L_D$.

Case 2: $0^n \notin L(H^{D_{j-1}})$. Choose some $x \in S_0^n$ and set $E_j := D_{j-1} \cup \{x\}$.

Case 2.1: $0^n \notin L(H^{E_j})$. Letting $D_j := E_j$ implies $0^n \in L_D$, so $L(H^D) \neq L_D$.

Case 2.2: $0^n \in L(H^{E_j})$. Then there is an i, $1 \leq i \leq k$, such that $0^n \in L(N_{i,1}^{E_j})$ and $0^n \notin L(N_{i,2}^{E_j})$. "Freeze" an accepting path of $N_{i,1}^{E_j}(0^n)$ into D_j'. Again, at most $p(n)$ strings are "frozen."

Case 2.2.1: $(\exists w \in (S_{10}^n \cup S_{11}^n) - D_j')\,[0^n \notin L(N_{i,2}^{E_j \cup \{w\}})]$.

Choose any such w and set $D_j := E_j \cup \{w\}$. We have $0^n \in L(H^D)$ but $0^n \notin L_D$.

Case 2.2.2: $(\forall w \in (S_{10}^n \cup S_{11}^n) - D_j')\,[0^n \in L(N_{i,2}^{E_j \cup \{w\}})]$.

As before, Lemma 3.12 yields two strings $s \in S_{10}^n - D_j'$ and $t \in S_{11}^n - D_j'$ such that $N_{i,2}^{E_j \cup \{s,t\}}(0^n)$ is ambiguous. Set $D_j := E_j \cup \{s, t\}$.

Again, R_j is always fulfilled. Define $r(j+1)$ as before.

End of stage j. □

Finally, we note that a slight modification of the above proof establishes the analogous result (of Theorem 3.13) for the case of US [6] (which is denoted 1NP in [21, 18]).

4. Sparse Turing-complete and Turing-hard sets for UP. In this section, we show some consequences of the existence of sparse Turing-complete and Turing-hard sets for UP. This question has been carefully investigated for the class NP [39, 34, 40, 1, 45, 54, 38].[4] Kadin showed that if there is a sparse $\leq_T^p$-complete set in NP, then the polynomial hierarchy collapses to $\mathrm{P}^{\mathrm{NP[log]}}$ [38]. Due to the promise nature of UP (in particular, UP probably lacks complete sets [22]), Kadin's proof does not seem to apply here. But does the existence of a sparse Turing-complete set in UP cause at least some collapse of the unambiguous polynomial hierarchy (which was introduced recently in [48])?[5]

Cai, Hemachandra, and Vyskoč [12] observe that ordinary Turing access to UP, as formalized by P^{UP}, may be too restrictive a notion to capture adequately one's intuition of Turing access to unambiguous computation since in that model the oracle machine has to be unambiguous on *every* input—even those the base DPOM never asks (on any of *its* inputs). To relax that unnaturally strong uniformity requirement, they introduce the class denoted $\mathrm{P}^{\mathcal{UP}}$, in which NP oracles are accessed in a *guardedly* unambiguous manner, a natural notion of access to unambiguous computation—suggested in the rather analogous case of NP $\cap$ coNP by Grollmann and Selman [19]—in which *only computations actually executed need be unambiguous.* Lange, Niedermeier, and Rossmanith [43], [48, p. 482] generalize this approach to build up an entire hierarchy of unambiguous computations in which the oracle levels are guardedly accessed (Definition 4.1, part 3)—the *promise unambiguous polynomial hierarchy.*

Definition 4.1.

1. *The* polynomial hierarchy [47, 57] *is defined as follows:*
$\Sigma_0^p \stackrel{\mathrm{df}}{=} \mathrm{P}$, $\Delta_0^p \stackrel{\mathrm{df}}{=} \mathrm{P}$, $\Sigma_k^p \stackrel{\mathrm{df}}{=} \mathrm{NP}^{\Sigma_{k-1}^p}$, $\Pi_k^p \stackrel{\mathrm{df}}{=} \mathrm{co}\Sigma_k^p$, $\Delta_k^p \stackrel{\mathrm{df}}{=} \mathrm{P}^{\Sigma_{k-1}^p}$, $k \geq 1$, *and* $\mathrm{PH} \stackrel{\mathrm{df}}{=} \bigcup_{k\geq 0} \Sigma_k^p$.

2. *The* unambiguous polynomial hierarchy [48] *is defined as follows:*
$\mathrm{U}\Sigma_0^p \stackrel{\mathrm{df}}{=} \mathrm{P}$, $\mathrm{U}\Delta_0^p \stackrel{\mathrm{df}}{=} \mathrm{P}$, $\mathrm{U}\Sigma_k^p \stackrel{\mathrm{df}}{=} \mathrm{UP}^{\mathrm{U}\Sigma_{k-1}^p}$, $\mathrm{U}\Pi_k^p \stackrel{\mathrm{df}}{=} \mathrm{coU}\Sigma_k^p$, $\mathrm{U}\Delta_k^p \stackrel{\mathrm{df}}{=} \mathrm{P}^{\mathrm{U}\Sigma_{k-1}^p}$, $k \geq 1$, *and* $\mathrm{UPH} \stackrel{\mathrm{df}}{=} \bigcup_{k\geq 0} \mathrm{U}\Sigma_k^p$.

3. *The* promise unambiguous polynomial hierarchy [43], [48, p. 482] *is defined as follows:* $\mathcal{U}\Sigma_0^p \stackrel{\mathrm{df}}{=} \mathrm{P}$, $\mathcal{U}\Sigma_1^p \stackrel{\mathrm{df}}{=} \mathrm{UP}$, *and for* $k \geq 2$, $L \in \mathcal{U}\Sigma_k^p$ *if and only if* $L \in \Sigma_k^p$ *via NPOMs* $N_1, \ldots, N_k$ *satisfying for all inputs* x *and every* i, $1 \leq i \leq k-1$, *that if* N_i *asks some query* q *during the computation of* $N_1(x)$, *then* $N_{i+1}(q)$ *with oracle* $L(N_{i+2}^{L(N_{i+3}^{\cdot^{\cdot^{\cdot^{L(N_k)}}}})})$ *has at most one accepting path.* $\mathcal{UPH} \stackrel{\mathrm{df}}{=} \bigcup_{k\geq 0} \mathcal{U}\Sigma_k^p$. *The classes* $\mathcal{U}\Delta_k^p$ *and* $\mathcal{U}\Pi_k^p$, $k \geq 0$, *are defined analogously. As a notational shorthand, we often use* $\mathrm{P}^{\mathcal{UP}}$ *to represent* $\mathcal{U}\Delta_2^p$; *we stress that both notations are used here to represent the class of sets accepted via* guardedly unambiguous *access to an NP oracle* (*that is, the class of sets accepted by some P machine with an NP machine's language as its*

[4] For reductions less flexible than Turing reductions (e.g., $\leq_m^p$, $\leq_{btt}^p$, etc.), this issue has been studied even more intensely (see, e.g., the surveys [61, 28]).

[5] Note that it is not known whether such a collapse implies a collapse of PH. Note also that Toda's [58] result on whether P-selective sets can be truth-table hard for UP does not imply such a collapse since truth-table reductions are less flexible than Turing reductions.

oracle such that on no input does the P machine ask its oracle machine any question on which the oracle machine has more than one accepting path).

4. *For each of the above hierarchies, we use* $\Sigma_k^{p,A}$ (*respectively,* $\mathrm{U}\Sigma_k^{p,A}$ *and* $\mathcal{U}\Sigma_k^{p,A}$) *to denote that the* Σ_k^p (*respectively,* $\mathrm{U}\Sigma_k^p$ *and* $\mathcal{U}\Sigma_k^p$) *computation is performed relative to oracle* A; *similar notation is used for the* Π *and* Δ *classes of the hierarchies.*

The following facts follow from the definition (see also [48]) or can easily be shown.

FACT 4.2. *For every* $k \geq 1$, *the following hold:*

1. $\mathrm{U}\Sigma_k^p \subseteq \mathcal{U}\Sigma_k^p \subseteq \Sigma_k^p$ *and* $\mathrm{U}\Delta_k^p \subseteq \mathcal{U}\Delta_k^p \subseteq \Delta_k^p$.
2. *If* $\mathrm{U}\Sigma_k^p = \mathrm{U}\Pi_k^p$, *then* $\mathrm{UPH} = \mathrm{U}\Sigma_k^p$.
3. *If* $\mathrm{U}\Sigma_k^p = \mathrm{U}\Sigma_{k-1}^p$, *then* $\mathrm{UPH} = \mathrm{U}\Sigma_{k-1}^p$.
4. $\mathrm{U}\Sigma_k^{p,\mathrm{UP}\cap\mathrm{coUP}} = \mathrm{U}\Sigma_k^p$ *and* $\mathrm{P}^{\mathrm{U}\Sigma_k^p\cap\mathrm{U}\Pi_k^p} = \mathrm{U}\Sigma_k^p \cap \mathrm{U}\Pi_k^p$.

The classes "$\mathrm{UP}_{\leq k}$," the analogues of UP in which up to k accepting paths are allowed, have been studied in various contexts [60, 27, 2, 12, 30, 33]. One motivation for $\mathrm{U}\Sigma_k^p$ is that, for each k, $\mathrm{UP}_{\leq k} \subseteq \mathrm{U}\Sigma_k^p$ [48].

Although we are not able to settle affirmatively the question posed at the end of the first paragraph of this section, we do prove in the theorem below that if there is a sparse Turing-complete set for UP, then the levels of the unambiguous polynomial hierarchy are simpler than one would otherwise expect: they "slip down" slightly in terms of their location within the promise unambiguous polynomial hierarchy, i.e., for each $k \geq 3$, the kth level of UPH is contained in the $(k-1)$st level of $\mathcal{UPH}$.

THEOREM 4.3. *If there exists a sparse Turing-complete set for* UP, *then*

1. $\mathrm{UP}^{\mathrm{UP}} \subseteq \mathrm{P}^{\mathcal{UP}}$ *and*
2. $\mathrm{U}\Sigma_k^p \subseteq \mathcal{U}\Sigma_{k-1}^p$ *for every* $k \geq 3$.

Proof. For the first statement, let L be any set in $\mathrm{UP}^{\mathrm{UP}}$. By assumption, L is in $\mathrm{UP}^{\mathrm{P}^S} = \mathrm{UP}^S$ for some sparse set $S \in \mathrm{UP}$. Let q be a polynomial bounding the density of S, that is, $\|S^{\leq m}\| \leq q(m)$ for every $m \geq 0$, and let N_S be a UPM for S. Let N_L be a UPOM witnessing that $L \in \mathrm{UP}^S$, that is, $L = L(N_L^S)$. Let $p(n)$ be a polynomial bounding the length of all query strings that can be asked during the computation of N_L on inputs of length n. Define the polynomial $r(n) \stackrel{\mathrm{df}}{=} q(p(n))$ that bounds the number of strings in S that can be queried in the run of N_L on inputs of length n.

To show that $L \in \mathrm{P}^{\mathcal{UP}}$, we shall construct a DPOM M that may access its $\mathcal{UP}$ oracle D in a guarded manner (more formally, "may access its NP oracle D in a guardedly unambiguous manner," but we will henceforth use $\mathcal{UP}$ and other $\mathcal{U}\cdots$ notations in this informal manner). Before formally describing machine M (Figure 4.1), we give some informal explanations. M will proceed in three basic steps: First, M determines the exact census of that part of S that is relevant for the given input length, $\|S^{\leq p(n)}\|$. Knowing the exact census, M can construct (by prefix search) a table T of all strings in $S^{\leq p(n)}$ without asking queries that make its oracle's machine ambiguous, so the $\mathrm{P}^{\mathcal{UP}}$-like behavior is guaranteed. Finally, M asks its oracle D to simulate the computation of N_L on input x (answering N_L's oracle queries by table-lookup using table T), and accepts accordingly.

In the formal description of machine M (given in Figure 4.1), three oracle sets A, B, and C are used. Since M has only one $\mathcal{UP}$ oracle, the actual set to be used is $D = A \oplus B \oplus C$ (with suitably modified queries to D). A, B, and C are defined as follows (we assume the set T below is coded in some standard reasonable way):

$$A \stackrel{\mathrm{df}}{=} \left\{ \langle 1^n, k\rangle \;\middle|\; \begin{array}{l} n \geq 0 \wedge 0 \leq k \leq r(n) \wedge (\exists c_1 <_{\mathrm{lex}} c_2 <_{\mathrm{lex}} \cdots <_{\mathrm{lex}} c_k) \\ (\forall \ell : 1 \leq \ell \leq k)\,[|c_\ell| \leq p(n) \wedge N_S(c_\ell) \text{ accepts}\,] \end{array} \right\},$$

Description of DPOM M.
input x;
begin
$n := |x|$;
$k := r(n)$;
loop
if $\langle 1^n, k\rangle \in A$ **then exit loop**
else $k := k - 1$
end loop (* k is now the exact census of $S^{\leq p(n)}$ *)
$T := \emptyset$; (* T collects the strings of $S^{\leq p(n)}$ *)
for $j = 1$ **to** k **do**
$c_j := \epsilon$;
$i := 1$;
repeat
if $\langle 1^n, i, j, k, 0\rangle \in B$ **then** $c_j := c_j 0$; $i := i + 1$
else
if $\langle 1^n, i, j, k, 1\rangle \in B$ **then** $c_j := c_j 1$; $i := i + 1$
else $i := 0$ (* the lex. jth string of $S^{\leq p(n)}$ has no ith bit *)
until $i = 0$;
$T := T \cup \{c_j\}$
end for
if $\langle x, T\rangle \in C$ **then accept**
else reject
end
End of description of DPOM M.

FIG. 4.1. *DPOM M guardedly unambiguously accessing an* NP *oracle to accept a set in* $\mathrm{UP}^{\mathrm{UP}}$.

$$B \stackrel{\mathrm{df}}{=} \left\{ \langle 1^n, i, j, k, b\rangle \;\middle|\; \begin{array}{l} n \geq 0 \wedge 1 \leq j \leq k \wedge 0 \leq k \leq r(n) \wedge \\ (\exists c_1 <_{\mathrm{lex}} c_2 <_{\mathrm{lex}} \cdots <_{\mathrm{lex}} c_k)\,(\forall \ell : 1 \leq \ell \leq k) \\ [|c_\ell| \leq p(n) \wedge N_S(c_\ell) \text{ accepts} \wedge \text{the } i\text{th bit of } c_j \text{ is } b] \end{array} \right\},$$

$$C \stackrel{\mathrm{df}}{=} \{\langle x, T\rangle \mid \|T\| \leq r(|x|) \wedge N_L^T(x) \text{ accepts}\}.$$

It is easy to see that M runs deterministically in polynomial time. This proves that $L \in \mathrm{P}^{\mathcal{UP}}$.

In order to prove the second statement, let L be a set in $\mathrm{U}\Sigma_k^p$ for any fixed $k \geq 3$. By assumption, there exists a sparse set S in UP such that L is in $\mathrm{U}\Sigma_{k-1}^{p,\mathrm{P}^S} = \mathrm{U}\Sigma_{k-1}^{p,S}$; let $N_1, N_2, \ldots, N_{k-1}$ be the UPOMs that witness this fact, that is, $L = L(N_1^{L(N_2^{\cdot^{\cdot^{\cdot^{L(N_{k-1}^S)}}}})})$.

Now we describe the computation of a $\mathcal{U}\Sigma_{k-1}^p$ machine N recognizing L. As before, N on input x computes in $\mathrm{P}^{\mathcal{UP}}$ its table of advice strings, $T = S^{\leq p(|x|)}$, and then simulates the $\mathrm{U}\Sigma_{k-1}^{p,S}$ computation of $N_1^{L(N_2^{\cdot^{\cdot^{\cdot^{L(N_{k-1}^S)}}}})}(x)$ except with N_1, $N_2, \ldots, N_{k-1}$ modified as follows. If in the simulation some machine N_i, $1 \leq i \leq k-2$, consults its original oracle $L(N_{i+1}^{(\cdot)})$ about some string, say z, then the modified machine N_i' queries the modified machine at the next level, N_{i+1}', about the string $\langle z, T\rangle$ instead. Finally, the advice table T, which has been "passed up" in this manner,

is used to correctly answer all queries of N_{k-1}.

Note that N's oracle in this simulation, $L(N_2'^{L(N_3'^{\cdot^{\cdot^{\cdot^{L(N_{k-1}')}}}})})$, is not in general a $\mathrm{U}\Sigma_{k-2}^p$ set (and L is thus not in $\mathrm{U}\Sigma_{k-1}^p$ in general) since the above-described computation depends on the advice table T, and so, for some bad advice T, the unambiguity of the modified machines $N_1', N_2', \ldots, N_{k-1}'$ is no longer guaranteed. But since our base machine N is able to provide *correct* advice T, we have indeed shown that $L \in \mathcal{U}\Sigma_{k-1}^p$. □

In the above proof, the assumption that the sparse set S is in UP is needed to determine the exact census of S using the UPM for S. Let us now consider the weaker assumption that UP has only a Turing-*hard* sparse set. Karp and Lipton have shown that if there is a sparse Turing-hard set for NP, then the polynomial hierarchy collapses to its second level [39].[6] Hopcroft [34] dramatically simplified their proof, and Balcázar, Book, and Schöning [1, 54] generalized, as Theorem 4.6, the Karp–Lipton result; the general approach of Hopcroft and Balcázar, Book, and Schöning will be central to our upcoming proof of Theorem 4.7. Schöning's low hierarchy [53] gives a way of classifying the complexity of NP sets that seem to be neither in P nor NP-complete. Of particular interest to us is the class $\mathrm{Low}_2 \stackrel{\mathrm{df}}{=} \{A \mid A \in \mathrm{NP} \text{ and } \mathrm{NP}^{\mathrm{NP}^A} \subseteq \mathrm{NP}^{\mathrm{NP}}\}$. Note that for the special case $k = 0$, Theorem 4.6 below says that $\mathrm{Low}_2 \supseteq \mathrm{NP} \cap \mathrm{P/poly} \cap \{L \mid L \text{ is self-reducible}\}$.

DEFINITION 4.4. [46]

1. *A partial order* $<_{\mathrm{pwl}}$ *on* Σ^* *is* polynomially well-founded and length-related *if and only if* (a) *every strictly decreasing chain is finite and there is a polynomial* p *such that every finite* $<_{\mathrm{pwl}}$*-decreasing chain is shorter than* p *of the length of its maximum element, and* (b) $(\exists q : q \text{ polynomial})(\forall x, y \in \Sigma^*)\,[x <_{\mathrm{pwl}} y \implies |x| \leq q(|y|)]$.

2. *A set* A *is* self-reducible *if and only if there exist a polynomially well-founded and length-related order* $<_{\mathrm{pwl}}$ *on* Σ^* *and a DPOM* M *such that* $A = L(M^A)$ *and on any input* $x \in \Sigma^*$, M *queries only strings* y *with* $y <_{\mathrm{pwl}} x$.

LEMMA 4.5. [1] *Let* A *be a self-reducible set and let* M *witness* A*'s self-reducibility. For any set* B *and any* n, *if* $(L(M^B))^{\leq n} = B^{\leq n}$, *then* $A^{\leq n} = B^{\leq n}$.[7]

THEOREM 4.6. [1] *If* A *is a self-reducible set and there is a* $k \geq 0$ *and a sparse set* S *such that* $A \in \Sigma_k^{p,S}$, *then* $\Sigma_2^{p,A} \subseteq \Sigma_{k+2}^p$.

We now state and prove our results regarding sparse Turing-hard sets for UP.

THEOREM 4.7. *If there exists a sparse Turing-hard set for* UP, *then*

1. $\mathrm{UP} \subseteq \mathrm{Low}_2$ *and*
2. $\mathrm{U}\Sigma_k^p \subseteq \mathrm{U}\Sigma_j^{p,\Sigma_2^{p,\,\mathcal{U}\Sigma_{k-j-3}^p}} \cap \mathrm{P}^{\mathcal{U}\Sigma_{k-1}^p \oplus \Sigma_2^p}$ *for every* $k \geq 3$ *and* j, $0 \leq j \leq k-3$.

Proof. 1. Let $L \in \Sigma_2^{p,A}$, where $A \in \mathrm{UP}$ via UPM N_A and polynomial-time bound t. (We assume that each step is nondeterministic—one can require this, without loss of generality, while maintaining categoricity.) Our proof uses the well-known fact that the "left set" [55, 49] of any UP set is self-reducible and is in UP. More precisely, to apply Theorem 4.6 we would need A to be self-reducible. Although that cannot be assumed in general of an arbitrary UP set, the left set of A, i.e., the set of prefixes of

[6] Very recently, Köbler and Watanabe [42] have improved this collapse to $\mathrm{ZPP}^{\mathrm{NP}}$, and they have also obtained new consequences from the assumption that $\mathrm{UP} \subseteq (\mathrm{NP} \cap \mathrm{coNP})/\mathrm{poly}$, whereas we obtain different consequences from the assumption that $\mathrm{UP} \subseteq \mathrm{P/poly}$ (see [42] for the notations not defined in this footnote).

[7] A can be viewed as a "fixed point" of M.

Description of self-reducer M_{self} for B.
  input $\langle x, y\rangle$;
  begin
    if $|y| > t(|x|)$ **then reject**;
    if $N_A(x)$ accepts on path y **then accept**
    else
      if $\langle x, y0\rangle \in B$ or $\langle x, y1\rangle \in B$ **then accept**
      else reject
  end
End of description of self-reducer M_{self} for B.

FIG. 4.3. *A Turing reduction from a* UP *set A to its left set B via prefix search.*

witnesses for elements in A defined by

$$B \stackrel{\text{df}}{=} \{\langle x, y\rangle \mid (\exists z)\,[|yz| = t(|x|) \wedge N_A(x) \text{ accepts on path } yz]\},$$

does have this property and is also in UP. A self-reducing machine M_{self} for B is given in Figure 4.2. Note that the queries asked in the self-reduction are strictly less than the input with respect to a polynomially well-founded and length-related partial order $<_{\text{pwl}}$ defined by the following: For fixed x and all strings $y_1, y_2 \in \Sigma^{\leq p(|x|)}$, $\langle x, y_1\rangle <_{\text{pwl}} \langle x, y_2\rangle$ if and only if y_2 is a prefix of y_1.

By assumption, since B is a UP set, $B \in \mathrm{P}^S$ for some sparse set S, so Theorem 4.6 with $k = 0$ applies to B. Furthermore, A is in P^B, via prefix search by DPOM M_A (Figure 4.3). Thus $L \in \Sigma_2^{p,\mathrm{P}^B} \subseteq \Sigma_2^{p,B} \subseteq \Sigma_2^p$, which shows that $A \in \text{Low}_2$.

2. For $k = 3$ (thus $j = 0$), both inclusions have already been shown in part 1, as $\Sigma_2^p \subseteq \Delta_3^p$. Now fix any $k > 3$, and let $L \in \mathrm{U}\Sigma_k^p = \mathrm{U}\Sigma_{k-1}^{p,A}$ be witnessed by UPOMs $N_1, N_2, \ldots, N_{k-1}$ and $A \in \mathrm{UP}$. Define B to be the left set of A as in part 1, so $A \in \mathrm{P}^B$ via DPOM M_A (see Figure 4.3), B is self-reducible via M_{self} (see Figure 4.2), and B is in UP. By hypothesis, $B \in \mathrm{P}^S$ for some sparse set S; let M_B be the reducing machine, that is $B = L(M_B^S)$, and let m be a polynomial bound on the runtime of M_B. Let q

be a polynomial such that $\|S^{\leq m}\| \leq q(m)$ for every $m \geq 0$. Let $p(n)$ be a polynomial bounding the length of all query strings whose membership in the oracle set B can be asked in the run of N_1 (with oracle machines N_2, $N_3, \ldots, N_{k-1}$, M_A^B) on inputs of length n. Define the polynomials $r(n) \stackrel{\text{df}}{=} m(p(n))$ and $s(n) \stackrel{\text{df}}{=} q(r(n))$.

To show that $L \in \mathrm{P}^{\mathcal{U}\Sigma_{k-1}^p \oplus \Sigma_2^p}$, we will describe a DPOM M that on input x, $|x| = n$, using the Σ_2^p part D (defined below) of its oracle, performs a prefix search to extract the lexicographically smallest of all "good" advice sets (this informal term will be formally defined in the next paragraph), say T, and then calls the $\mathcal{U}\Sigma_{k-1}^p$ part of its oracle to simulate the $\mathrm{U}\Sigma_{k-1}^{p,A}$ computation of $N_1^{L(N_2^{\cdot^{L(N_{k-1}^A)}})}(x)$ except with N_1, N_2, $\ldots, N_{k-1}$ modified in the same way as was described in the proof of Theorem 4.3. In more detail, if in the simulation some machine N_i, $1 \leq i \leq k-2$, consults its original oracle $L(N_{i+1}^{(\cdot)})$ about some string, say z, then the modified machine N_i' queries the modified machine at the next level, N_{i+1}', about the string $\langle z, T\rangle$ instead. Finally, if N_{k-1} consults its original oracle A about some query y, then the modified machine N_{k-1}' runs the P computation $M_A^{L(M_B^T)}$ on input $\langle y, T\rangle$ instead to correctly answer this query without consulting an oracle.

An advice set T is said to be *good* if the set $L(M_B^T)$ is a fixed point of B's self-reducer M_{self} up to length $p(n)$, that is, $(L(M_{\text{self}}^{L(M_B^T)}))^{\leq p(n)} = (L(M_B^T))^{\leq p(n)}$, and thus $B^{\leq p(n)} = (L(M_B^T))^{\leq p(n)}$ by Lemma 4.5. This property is checked for each guessed T in the Σ_2^p part of the oracle. Formally,

$$D \stackrel{\text{df}}{=} \left\{ \langle 1^n, i, j, b\rangle \;\middle|\; \begin{array}{l} n \geq 0 \wedge (\exists T \subseteq \Sigma^{\leq r(n)})\,(\forall w : |w| \leq p(n)\,)\,[T = \{c_1, \ldots, c_k\} \\ \wedge\ 0 \leq k \leq s(n) \wedge c_1 <_{\text{lex}} \cdots <_{\text{lex}} c_k \wedge \text{the } i\text{th bit of } c_j \text{ is } b \\ \wedge\ (w \in L(M_B^T) \iff w \in L(M_{\text{self}}^{L(M_B^T)}))] \end{array} \right\}.$$

The prefix search of M is similar to the one performed in the proof of Theorem 4.3 (see Figure 4.1); M queries D to construct each string of T bit by bit.

To prove the other inclusion, fix any j, $0 \leq j \leq k-3$. We describe a UPOM N witnessing that $L \in \mathrm{U}\Sigma_j^{p,\Sigma_2^{p,\,\mathcal{U}\Sigma_{k-j-3}^p}}$. On input x, N simulates the $\mathrm{U}\Sigma_j^p$ computation of the first j UPOMs $N_1, \ldots, N_j$. In the subsequent Σ_2^p computation, two tasks have to be solved in parallel: the computation of N_{j+1} and N_{j+2} is to be simulated, and good advice sets T have to be determined. For the latter task, the base machine of the Σ_2^p computation guesses all possible advice sets and the top machine checks if the guessed advice is good (that is, if $L(M_B^T)$ is a fixed point of M_{self}). Again, each good advice set T is "passed up" to the machines at higher levels $N_{j+3}, \ldots, N_{k-1}$ (in the same fashion as was employed earlier in this proof and also in the proof of Theorem 4.3) and is used to correctly answer all queries of N_{k-1} without consulting an oracle. This proves the theorem. □

Since Theorem 4.7 relativizes and there are relativized worlds in which UP^A is not Low_2^A [56], we have the following corollary.

COROLLARY 4.8. *There is a relativized world in which* (*relativized*) UP *has no sparse Turing-hard sets.*

Acknowledgments. We are very grateful to Gerd Wechsung for his help in bringing about this collaboration, and for his kind and insightful advice over many years. RAY SHOOTING AMIDST SPHERES IN THREE DIMENSIONS AND RELATED PROBLEMS*

SHAI MOHABAN† AND MICHA SHARIR‡

Abstract. We consider the problem of ray shooting amidst spheres in 3-space: given n arbitrary (possibly intersecting) spheres in 3-space and any $\varepsilon > 0$, we show how to preprocess the spheres in time $O(n^{3+\varepsilon})$ into a data structure of size $O(n^{3+\varepsilon})$ so that any ray-shooting query can be answered in time $O(n^{\varepsilon})$. Our result improves previous techniques (see [P. K. Agarwal, L. Guibas, M. Pellegrini, and M. Sharir, "Ray shooting amidst spheres," unpublished note] and [P. K. Agarwal and J. Matoušek, *Discrete Comput. Geom.*, 11 (1994), pp. 393–418]), where roughly $O(n^4)$ storage was required to support fast queries. Our result shows that ray shooting amidst spheres has complexity comparable with that of ray shooting amidst planes in 3-space. Our technique applies to more general (convex) objects in 3-space, and we also discuss these extensions.

1. Introduction.

The *ray shooting* problem can be defined as follows:

Given a collection $\mathcal{S}$ of n objects in $\mathbb{R}^d$ preprocess $\mathcal{S}$ into a data structure so that one can quickly determine the first object of $\mathcal{S}$ intersected by a query ray.

The ray-shooting problem has received considerable attention in the past few years because of its applications in computer graphics and other geometric problems [1, 4, 5, 6, 10, 11, 13, 16, 21]. Most of the work to date has studied the planar case, where $\mathcal{S}$ is a collection of line segments in $\mathbb{R}^2$. Chazelle and Guibas proposed an optimal algorithm for the special case where $\mathcal{S}$ is the boundary of a simple polygon [16]. Their algorithm answers a ray-shooting query in $O(\log n)$ time using $O(n)$ space; simpler algorithms with the same asymptotic performance bounds were recently developed in [13, 24]. If $\mathcal{S}$ is a collection of arbitrary segments in the plane, the best known algorithm answers a ray-shooting query in time $O((n/\sqrt{s})\log^{O(1)} n)$ using $O(s^{1+\varepsilon})$ space and preprocessing[1] [1, 6, 10], where s is a parameter that can vary between n and n^2. Although no lower bound is known for this case, it is conjectured that this bound is close to optimal.

In spite of some recent developments, the three-dimensional ray-shooting problem seems much harder, and it is still far from being fully solved. The general three-dimensional ray-shooting problem is to preprocess a collection $\mathcal{S}$ of n convex objects so that the first object hit by a query ray can be computed efficiently. Most studies of

[1] Throughout this paper, bounds of this kind mean that, given any arbitrarily small positive constant ε, the algorithm can be fine-tuned so that its performance satisfies the bound; the multiplicative constants in such bounds usually depend on ε and tend to ∞ as $\varepsilon \downarrow 0$.

this problem consider the case where $\mathcal{S}$ is a collection of triangles. If these triangles are the faces of a convex polyhedron, then an optimal algorithm with $O(\log n)$ query time and linear space can be obtained using the hierarchical-decomposition scheme of Dobkin and Kirkpatrick [19]. If the triangles form a *polyhedral terrain* (a piecewise-linear surface intersecting every vertical line in exactly one point), then the technique of Chazelle et al. [15] yields an algorithm that requires $O(n^{2+\varepsilon})$ space and answers ray-shooting queries in $O(\log n)$ time. Nontrivial solutions to the general problem (involving triangles) were obtained only recently; see [4, 6, 11] for some of these results. The best known algorithm for ray-shooting among triangles in three dimensions is due to Agarwal and Matoušek [5]; it answers a ray shooting query in time $O(n^{1+\varepsilon}/s^{1/4})$ with $O(s^{1+\varepsilon})$ space and preprocessing. The parameter s can range between n and n^4. If s assumes its maximum value, queries can be answered in $O(\log^2 n)$ time; see [5, 6] for more details. A variant of this technique was given recently in [7] for the case of ray shooting amidst a collection of convex polyhedra. We remark that no nontrivial lower bounds are known for the three-dimensional problem (for triangles) as well, although such bounds are known for the related *simplex range-searching* problem [12], which is used as a subprocedure in the solutions just mentioned. These bounds are close to $\Omega(n/s^{1/4})$ and thus might suggest that the known ray-shooting algorithms for triangles in $\mathbb{R}^3$ are close to optimal.

On the other hand, there are certain special cases of the three-dimensional ray-shooting problem which can be solved more efficiently. For example, if the objects of $\mathcal{S}$ are planes or half-planes, ray shooting amidst them can be performed in time $O(n^{1+\varepsilon}/s^{1/3})$ with $O(s^{1+\varepsilon})$ space and preprocessing; see [4] for details. It is therefore of interest to identify additional classes of objects for which ray shooting can also be performed more efficiently.

In this paper, we consider the case of spheres. This problem has recently been studied in [5] and in a yet unpublished work [3]. The algorithm presented in [5] has query time $O(n^{1+\varepsilon}/s^{1/4})$ with $O(s^{1+\varepsilon})$ space and preprocessing, that is, the same performance as in the case of triangles. The algorithm of [3] achieves similar performance for $s = n^4$.

We present an improved solution for the case where large storage is allowed. Specifically, we achieve query time $O(n^{\varepsilon})$ with only $O(n^{3+\varepsilon})$ space and preprocessing. Thus we show that in some sense, the case of spheres is essentially no harder than the case of planes, which might sound somewhat surprising given that spheres are more complex objects (and require four real parameters to specify, as opposed to only three for planes). Our solution is fairly general—the spheres may have arbitrary radii and may also intersect one another.

Our technique adapts some ideas from [3]. Roughly speaking, in both approaches, we reduce the ray-shooting problem to the following problem (although certain parts of our reduction are simpler than those of [3]). We are given a collection $\mathcal{S}$ of n arbitrary spheres in 3-space, $S_1, \ldots, S_n$, and we want to preprocess them so that we can answer the following queries efficiently: we are given a line ℓ such that for each sphere S_i, either ℓ intersects S_i or else S_i contains no point that lies vertically above some point on ℓ, and we want to determine whether ℓ intersects any of these spheres. The reduction of the ray-shooting problem to this problem is fairly routine using mostly standard machinery.

We solve this main subproblem in a more careful manner than in [3]. This subproblem can be mapped onto the four-dimensional parametric space that represents lines in 3-space, and it reduces to the problem of point location in the region of this 4-

space lying above the upper envelope of certain low-degree algebraic surface patches, each representing an "upper tangency" between a line and one of the spheres. Almost a year after the original submission of this paper, it was shown by Aronov et al. [2] that point location above such an envelope can be performed fast (in polylogarithmic time) using only $O(n^{3+\varepsilon})$ storage and $O(n^{3+\varepsilon})$ randomized expected time. This gives an alternative solution with roughly the same asymptotic performance as our solution. However, (a) the algorithm of [2] is randomized, whereas our solution is deterministic, and (b) our solution analyzes and exploits the geometric structure of the problem much more explicitly, and we hope that its analysis will find additional applications. Although our approach is more geometric in nature, it does not exploit any special properties of spheres and is thus much more general. As a matter of fact, our technique can be viewed as an explicit solution of the problem of point location above an envelope in 4-space for the special type of surfaces arising in the context of ray shooting. In section 3, we indeed present a generalization of our technique to ray shooting among more general convex objects in 3-space and exemplify it for the case of axis-parallel ellipsoids.

2. The algorithm.

2.1. Overview. We use the general approach to ray shooting due to Agarwal and Matoušek [4]. This approach, which is based on the parametric searching technique of Megiddo [27], reduces the ray-shooting problem to the *segment-emptiness* problem. Namely, we need to preprocess the spheres so that given any segment e in 3-space, we can quickly determine whether e intersects any of the spheres. As shown in [4], the time for the actual ray-shooting query is only within a logarithmic factor of the query time for the segment-emptiness problem.

We first describe the preprocessing scheme. We construct a multilevel data structure, where each level of the structure filters out spheres that satisfy a different geometric relationship with respect to the query segment, so a sphere satisfying the conjunction of all these relationships must intersect the query segment; see [26] for a more detailed discussion of multilevel data structures of this kind. Each level of the data structure consists of a tree-like structure $\mathcal{T}$, where each node of $\mathcal{T}$ corresponds to some "canonical" subset of spheres. The root of the top-level structure represents the entire collection $\mathcal{S}$ of spheres.

First, here is a brief overview of our approach. It is fairly easy to show that a segment e intersects a sphere S if and only if one of the following two conditions hold:

(i) One endpoint of e lies inside S and the other lies outside S.

(ii) Both endpoints of e lie outside S, the center of S lies inside the slab Σ_e bounded by the two planes passing through the endpoints of e and perpendicular to e, and the line containing e intersects S. See Figure 1 for an illustration.

Consequently, we construct two data structures, one for testing whether condition (i) holds for any sphere, and the other for testing condition (ii).

2.2. First data structure. We start by describing the first (and simpler) data structure. Its first level $\mathcal{T}_1$ is used to find all spheres of $\mathcal{S}$ containing a query point. The root of $\mathcal{T}_1$ is associated with the entire set $\mathcal{S}$. We fix some sufficiently large constant parameter r and construct a $(1/r)$-net $\mathcal{E}$ of $O(r \log r)$ spheres from $\mathcal{S}$ for certain ranges (subsets of $\mathcal{S}$) that will be defined in a moment. ($\mathcal{E}$ is a $(1/r)$-net if each range that contains more than $|\mathcal{S}|/r$ elements must contain an element of $\mathcal{E}$; see [23] for more details.) $\mathcal{E}$ is constructed by the deterministic technique of Matoušek [25] (or by simply choosing a random sample of $O(r \log r)$ spheres). We next construct

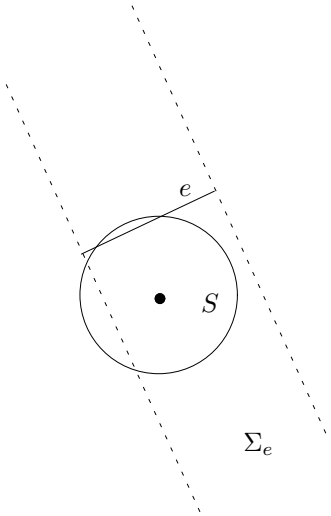

FIG. 1. *Illustration of condition* (ii) *for segment-intersection detection.*

the arrangement $\mathcal{A}(\mathcal{E})$ of these spheres and apply the *vertical decomposition* technique of [18] (see also [14]) to that arrangement. It decomposes 3-space into $O(r^{3+\varepsilon})$ cells of "constant description complexity" so that the interior of each cell is not crossed by any of the spheres of $\mathcal{E}$; see [18] for more details. The ranges with respect to which $\mathcal{E}$ has to be a $(1/r)$-net are sets of spheres of $\mathcal{S}$, each consisting of those spheres intersecting a region having the shape of a cell of the vertical decomposition in an arrangement of spheres, as above. As is easy to see, the resulting range space has so-called finite VC-dimension, which thus implies the existence of a $(1/r)$-net $\mathcal{E}$ with only $O(r \log r)$ spheres. (We again refer the reader to [23] for more details.) For each cell C of the decomposed arrangement, we create a child of the root of $\mathcal{T}_1$ and associate with it the set $\mathcal{S}_C$ of spheres intersecting C. Since $\mathcal{E}$ is a $(1/r)$-net, none of the sets $\mathcal{S}_C$ contains more than n/r spheres. We also store with each cell C the set $\mathcal{S}_C^0$ of all spheres that completely contain C in their interior. We then continue the preprocessing recursively at each child of the root with its associated set $\mathcal{S}_C$.

The second-level structure is built for each of the nodes of the first level. The set of spheres associated with the root of the second-level structure at a node corresponding to some cell C in the first-level decomposition is the set $\mathcal{S}_C^0$ defined above. The purpose of the second-level structure is to test whether any of the given spheres does not contain a query point. This is achieved using almost the same preprocessing as for the first level, except that here we define the set $\mathcal{S}_C^0$ to be the set of all spheres whose enclosed ball is disjoint from the cell C.

Given a query segment $e = pq$, we first search with p through the first-level structure, obtaining the set of spheres containing p as a disjoint union of sets $\mathcal{S}_C^0$. For each of these sets, we search with q through the corresponding second-level structure; if we find a node there whose set $\mathcal{S}_C^0$ is nonempty, we stop and conclude that e intersects a sphere of $\mathcal{S}$. Otherwise, we repeat this procedure, searching with q in the first-level structure and with p in the second-level structures. Again, we either detect an intersection between e and some sphere or else conclude that no intersection of type (i) occurs, and then we move on to search in the second data structure.

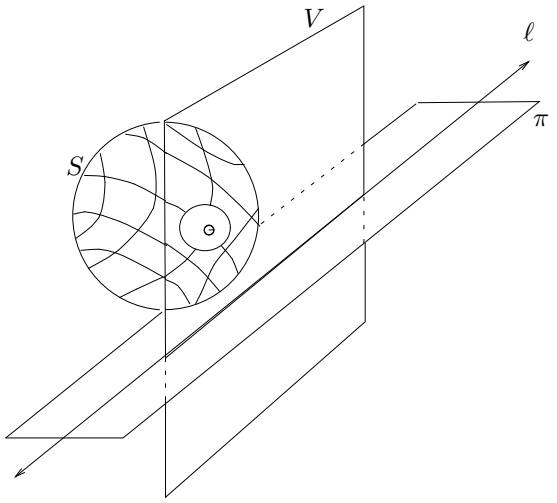

FIG. 2. *The planes V and π and their relationships to a sphere.*

2.3. Second data structure. The first two levels of the second data structure are very similar to those of the first data structure. Their purpose is to filter out all spheres that do not contain any of the endpoints of the query segment e. These levels are constructed in much the same way as above, except that the sets $\mathcal{S}_C^0$ in both levels are the sets of spheres whose enclosed balls are disjoint from the corresponding cell C. We search with e in these two levels as described above, and the search results in a collection of canonical sets $\mathcal{S}_C^0$ of spheres whose (disjoint) union is the subset of all spheres whose enclosed balls do not contain any endpoint of e.

The next two levels of the structure aim at finding all spheres whose centers lie in the slab Σ_e as defined in condition (ii) above. In both levels, we take the set of the centers of the relevant spheres and preprocess them for half-space range searching in three dimensions (using, e.g., the method of [17]). Since Σ_e is the intersection of two half-spaces H_1 and H_2, we search with H_1 in the third-level structures and with H_2 in the fourth-level structures, and we wind up with a collection of canonical sets of spheres whose (disjoint) union is the set of all spheres that satisfy the first two parts of condition (ii). Hence for each of the resulting sets of spheres, we only need to determine whether the line ℓ containing the query segment e intersects any sphere in that set.

The fifth level of our structure is also a half-space range-searching structure on the centers of the relevant spheres. We search in that level with the two half-spaces bounded by the plane π passing through ℓ and orthogonal to the vertical plane V passing through ℓ. Let π^+ denote the half-space lying above π, and let π^- denote the half-space lying below π. Let S be a sphere whose center lies in π^+ and which intersects V in a disc D. Then the center of D lies above ℓ, so either ℓ intersects S or else it *passes below* S, in the sense that ℓ and S are disjoint and there is a point on ℓ that lies vertically below a point in S. See Figure 2 for an illustration. A symmetric property holds if the center of S lies in π^-; we will continue the description of our data structure so that it handles only the latter situation since the handling of the former case is fully symmetric.

To recap, we have reduced our problem to the following subproblem. We are

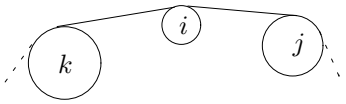

FIG. 3. *Two bridges connecting a disc D_i to two larger discs.*

given a collection of arbitrary spheres in 3-space, which is a canonical set of spheres in the output of the fifth level of our structure, and we want to preprocess it so that we can answer the following queries efficiently: we are given a line ℓ such that for each sphere S in our collection, either ℓ intersects S or else there is no point of S that lies vertically above ℓ. We want to determine whether ℓ intersects any of the given spheres. For brevity of notation, we call the given collection $\mathcal{S}$ and assume its size to be n.

2.4. Detecting intersection between a line and the upper hull of a vertical planar cross-section of $\mathcal{S}$. We begin by describing a few constructs that will be used in our technique. For each point (ξ_1, ξ_2), let $V = V_{\xi_1,\xi_2}$ denote the vertical plane passing through the line $y = \xi_1 x + \xi_2$. We denote by (ρ, z) the coordinates within V, where ρ is the horizontal coordinate (along the line $y = \xi_1 x + \xi_2$) and z is the vertical coordinate. Let $\mathcal{E} = \{S_1, \ldots, \mathcal{S}_t\}$ be a subset of t spheres of $\mathcal{S}$. Let $D_1, \ldots, D_t$ denote the (possibly empty) two-dimensional discs formed by intersecting the corresponding spheres $S_1, \ldots, S_t$ with V. We consider the upper convex hull of these discs. This hull consists of *bridges*, namely common tangents between pairs of discs which form edges of the hull, and of circular arcs which are portions of the boundaries of the discs and which lie between two adjacent bridges; see Figure 3. Suppose the disc D_i is part of the upper convex hull of these t discs (within V), and consider the set of bridges that connect D_i with other discs whose radius is greater than or equal to that of D_i. It is easily checked that there can be at most two such bridges, at most one connecting D_i to a disc D_j following it in the positive ρ-direction and at most one connecting D_i to a disc D_k preceding it; see Figure 3 again. (This claim is trivial if the discs are pairwise disjoint, but it also holds if they are allowed to intersect.) For each bridge b, we denote by b^+ the half-plane lying above the line containing it. For each circular arc γ of the hull, we denote by γ^+ the region above it (that is, we erect a vertical ray upwards from each point on γ and take the union of all these rays); see Figure 4.

Here is a quick overview of our approach: we fix some sufficiently large constant parameter r and construct a set $\mathcal{E} \subseteq \mathcal{S}$ of size $t = O(r \log r)$, which will serve as a $(1/r)$-net with properties that will be explained in a moment. Consider a query line ℓ and the vertical plane V passing through it. We will build a data structure on $\mathcal{E}$, from which we will be able to quickly determine the set of bridges of the upper convex hull of the t intersection discs of the spheres of $\mathcal{E}$ with V. We will then check if ℓ intersects this hull. If it does, we are done—ℓ intersects a sphere of $\mathcal{S}$. Otherwise, we find two bridges b and b' whose slopes are nearest to the slope of ℓ so that ℓ lies completely in the union of the regions b^+, b'^+, and γ^+, where γ is the circular arc between b and b'; see Figure 4. We then continue the query recursively in the set of spheres intersecting each of these three regions. For this approach to be efficient, we need each of the regions b^+ and γ^+ to be intersected by a small number of spheres (at most n/r spheres). We will actually define two range spaces here, where each of the ranges of each of these spaces is defined in terms of a constant number of spheres and both range spaces have finite VC-dimension. The first range space deals with ranges

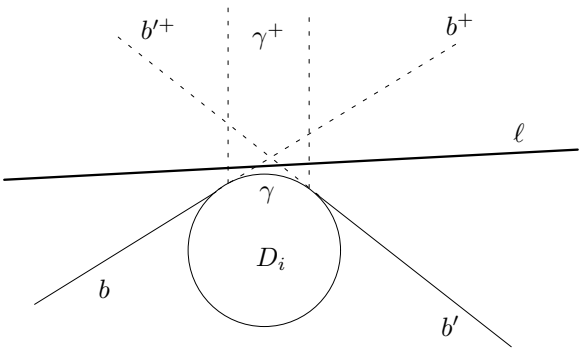

FIG. 4. *A line ℓ passing above the upper convex hull, and the three regions whose union contains ℓ.*

related to the regions b^+, and the second range space deals with ranges related to the regions γ^+. We will build a $(1/r)$-net $\mathcal{E}_1$ of size $O(r \log r)$ for the first range space and another $(1/r)$-net $\mathcal{E}_2$ of size $O(r \log r)$ for the second range space, so the union $\mathcal{E} = \mathcal{E}_1 \cup \mathcal{E}_2$ is a $(1/r)$-net for both range spaces of size $t = O(r \log r)$.

2.5. The planar maps $M^{\pm}(S_i)$. We now describe our technique in detail. We build a data structure so that given any vertical plane $V = V_{\xi_1,\xi_2}$ represented by the point (ξ_1, ξ_2) as above, the bridges and circular arcs of the upper convex hull of the discs D_i within V can be found quickly. For each sphere $S \in \mathcal{E}$, we construct two planar maps $M^+(S)$ and $M^-(S)$ in the $\xi_1\xi_2$-coordinate system, where ξ_1 is the slope and ξ_2 is the intercept of the xy-projection of a line in 3-space. If D_i contributes to the upper convex hull and the unique larger disc following it along the hull in the positive ρ-direction is D_j, we label in $M^+(S_i)$ the point (ξ_1, ξ_2) by the index j; similarly, if D_i contributes to the upper convex hull and the unique larger disc following it along the hull in the negative ρ-direction is D_k, we label in $M^-(S_i)$ the point (ξ_1, ξ_2) by the index k; otherwise, we label (ξ_1, ξ_2) by 0 in the respective map. (This alternative labeling also applies in the cases where D_i is empty or does not appear at all along the upper hull.) The faces of $M^+(S_i)$ and of $M^-(S_i)$ are maximal connected regions, all of whose points have the same label; edges and vertices of these maps are defined accordingly. The edge between two adjacent cells of the map $M^+(S_i)$ $(M^-(S_i))$, which are labeled by j and k, respectively, consists of points (ξ_1, ξ_2) where the disc following (preceding) D_i along the hull is about to change from D_j to D_k, or the radius of D_j becomes equal to the radius of D_i, or D_i is getting out of the hull boundary by another disc. Thus each edge e of any of these maps consists of points (ξ_1, ξ_2) at which the upper hull of the discs in the plane V_{ξ_1,ξ_2} has a bridge tangent to three discs, or has two adjacent discs of equal radius, or has a disc degenerating to a single point. See below for a more detailed analysis of these maps; we will show that the overall complexity of all these maps is only roughly cubic in r. We next construct a vertical decomposition of each of the planar maps $M^+(S_i)$ and $M^-(S_i)$ by erecting a vertical segment from each vertex and from the points with ξ_2-vertical tangency on each edge, and we extend it upwards and downwards until it hits another edge of the map. Note that the set of labels of a point (ξ_1, ξ_2) in all of these maps provides complete information about the structure of the upper convex hull of the intersection discs D_i in the vertical plane V_{ξ_1,ξ_2}.

Let C be a cell in, say, the vertical decomposition of the map $M^+(S_i)$, and suppose

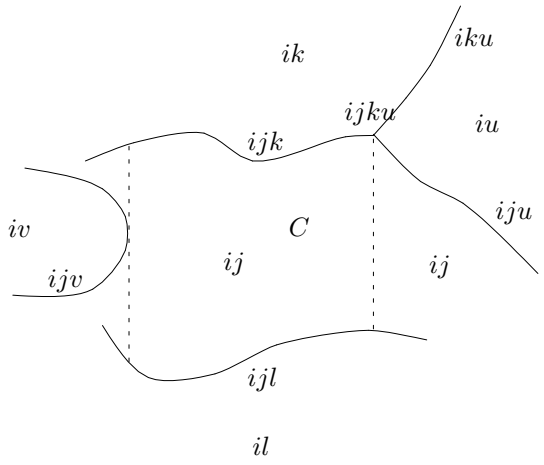

FIG. 5. *A cell C labeled by $j > 0$ in the map $M^+(S_i)$.*

that its label is $j > 0$ (cells with label 0 can be ignored in this process). For each point (ξ_1, ξ_2) in C, we consider the plane $V = V_{\xi_1,\xi_2}$ as defined above. We know that S_i contributes to the upper convex hull of the discs of intersection of the spheres of $\mathcal{E}$ with this plane, and we know that the unique next larger disc along the hull in the positive ρ-direction is D_j. Let b denote the bridge connecting the two discs in the upper convex hull; we denote by $b^+(\xi_1, \xi_2)$ the half-plane of V above the line containing b (that is, the half-plane supporting the discs D_i and D_j from above). Consider the three-dimensional region $R_C = \bigcup_{(\xi_1,\xi_2)\in C} b^+(\xi_1, \xi_2)$, and let $\mathcal{S}_C$ be the subset of all the original spheres intersecting R_C. We define similar regions R_C for all the cells C in all the other maps $M^{\pm}(S_k)$ for $k = 1, \ldots, t$.

Note that each of the regions R_C is the union of half-planes $b^+(\xi_1, \xi_2)$, where b is a bridge determined by a fixed pair of spheres of $\mathcal{E}$ and where (ξ_1, ξ_2) ranges over a cell C of one of the maps $M^{\pm}(S_i)$, which is a region of constant complexity. Actually, suppose C has label $j > 0$. Then C is defined in terms of at most six spheres: at most three spheres, S_i, S_j, and another sphere S_k, define the top edge of C, at most three spheres, S_i, S_j, and another S_l, define its bottom edge, at most one more sphere is needed to define the left vertical edge of C, and at most one more sphere is needed to define its right edge. See Figure 5 for an illustration. It follows that C is defined by at most six spheres of $\mathcal{E}$. Moreover, the two spheres forming the bridge b belong to this collection of six spheres, so R_C is also defined in terms of at most six spheres and is thus a region of constant complexity. The ranges with respect to which $\mathcal{E}_1$ (and hence $\mathcal{E}$) should be a $(1/r)$-net are subsets of the form $\mathcal{S}_C$, defined for regions R_C which are defined in terms of at most six spheres, as just outlined. Again, it is easy to verify that the resulting range space has finite VC-dimension. Since by construction none of the spheres of $\mathcal{E}$ intersects any of the regions R_C, it follows by definition that the maximum cardinality of the sets $\mathcal{S}_C$ over all cells C of all the $2t$ maps $M^{\pm}(S_i)$ is at most n/r.

We construct the sets $\mathcal{S}_C$ using any brute-force method, which takes $O(n)$ time since we assume r to be constant. For each cell C in each map, we then create a child of the root node of $\mathcal{T}$, associate the set $\mathcal{S}_C$ of spheres with that child, and continue the construction of the data structure recursively at each child with the corresponding set

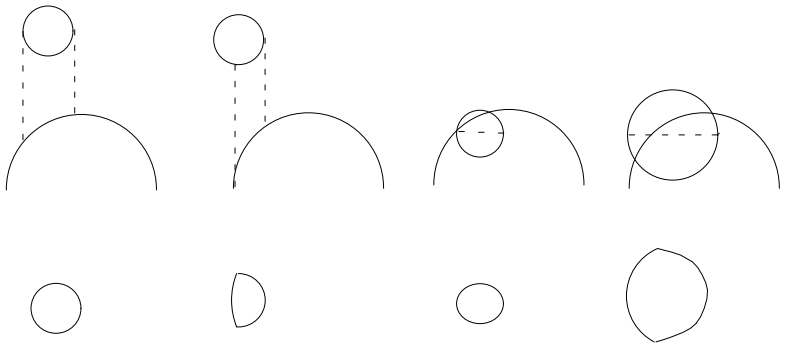

FIG. 6. *The possible xy-projections of the portions S_j^+. (The projections have smooth boundaries, but some are drawn with nonsmooth boundary to illustrate the fact that they are composed of two different arcs.)*

of spheres. There is, however, a second set of children of the root, obtained through a second decomposition scheme, which we now proceed to describe.

2.6. The spatial maps $N(S_i)$. We now define our second range space, with respect to which $\mathcal{E}_2$ (and hence $\mathcal{E}$) should be a $(1/r)$-net. Let N denote the three-dimensional parametric space with coordinates (ξ_1, ξ_2, ρ), where, as above, (ξ_1, ξ_2) give the dual representation of a line $\lambda(\xi_1, \xi_2) : \ y = \xi_1 x + \xi_2$ in the xy-plane and where ρ measures the distance along $\lambda(\xi_1, \xi_2)$. Note that each point $(\xi_1, \xi_2, \rho) \in N$ actually represents (in a many-to-one manner) a point in the xy-plane, namely the point $\sigma(\xi_1, \xi_2, \rho)$ with coordinate ρ along the line $\lambda(\xi_1, \xi_2)$. The reason for this three-dimensional representation of the xy-plane will become clearer later on.

For each of the t spheres $S_i \in \mathcal{E}$, we form in N a spatial subdivision $N(S_i)$ consisting of roughly $O(t^2)$ cells of constant complexity, as follows. For any other sphere $S_j \in \mathcal{E}$, let S_j^+ denote the portion of S_j that lies above S_i and let S_j^* denote the xy-projection of S_j^+. We obtain a collection of at most t planar regions, each of which is the intersection of Q_i, the xy-projection of S_i, with either a disc, an ellipse, or a convex region with a smooth boundary which is the union of a circular arc and an elliptic arc; see Figures 6 and 7.

Let K_i denote the complement (within Q_i) of the union $\bigcup_{j \neq i} S_j^*$. We map K_i into the following set in our parametric space N:

$$\tilde{K_i} = \{(\xi_1, \xi_2, \rho) \ : \ \rho \in K_i(\xi_1, \xi_2)\},$$

where $K_i(\xi_1, \xi_2) = K_i \cap \lambda(\xi_1, \xi_2)$. In other words, $\tilde{K_i}$ is the preimage of K_i under the mapping σ from N onto the xy-plane, as defined above. Note that a point (ξ_1, ξ_2, ρ) is in $\tilde{K_i}$ if and only if the vertical line (in actual 3-space) passing through the point on $\lambda(\xi_1, \xi_2)$ with coordinate ρ does not meet any sphere of $\mathcal{E}$ above its highest intersection with S_i.

We next decompose $\tilde{K_i}$ into constant-complexity cells by applying a standard vertical decomposition (with ρ being the "vertical" coordinate) as in [14, 18]. This yields the spatial map $N(S_i)$. As observed in the papers just cited (and as is easily seen), the complexity (number of resulting cells) of $N(S_i)$ is proportional to the number of *vertically visible* pairs (e, e') of edges of $\tilde{K_i}$ (where we also include among these edges the loci of points with vertical tangency along the boundary of $\tilde{K_i}$). Such

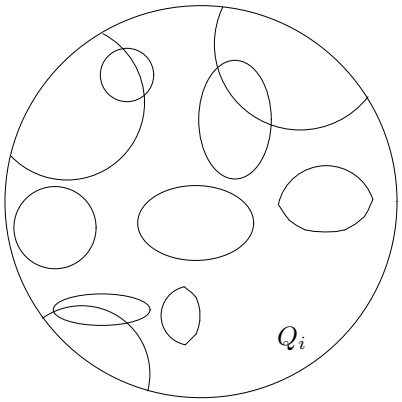

FIG. 7. *The arrangement of the xy-projections of the portions* S_j^+.

a pair of edges (e, e') is vertically visible if there exists a point (ξ_1, ξ_2) such that the vertical line in N passing through that point intersects both e and e' and the segment between these points of intersection lies fully in $\tilde{K}_i$. An edge e of $\tilde{K}_i$ consists of points (ξ_1, ξ_2, ρ) such that the line $\lambda(\xi_1, \xi_2)$ passes through a vertex of K_i or is tangent to the boundary of K_i and ρ is the coordinate of that vertex or point of tangency along $\lambda(\xi_1, \xi_2)$. Thus each vertically visible pair (e, e') of edges of $\tilde{K}_i$ corresponds to a line $\lambda(\xi_1, \xi_2)$ which passes through two points, each being either a vertex of K_i or a point of tangency between $\lambda(\xi_1, \xi_2)$ and the boundary of K_i, so that the interval between these two points is fully contained in K_i.

In other words, the number of vertically visible pairs (e, e') as above is proportional to $\sum_f c_f^2$, where the sum extends over all faces f of K_i and where c_f is the complexity of f. All of these faces are faces of a planar arrangement of $O(t)$ circular and elliptic arcs, and each pair of these arcs intersect in at most four points. Hence, as shown in [20], we have $\sum_f c_f^2 = O(\lambda_6^2(t))$, where $\lambda_6(t) = t \cdot 2^{O(\alpha^2(t))}$ is the (nearly linear) maximum length of a $(t, 6)$ *Davenport–Schinzel sequence* [8]. We have thus shown that the number of cells (each having constant complexity) in all the subdivisions $N(S_i)$ is $O(t\lambda_6^2(t))$, and it is thus nearly cubic in r (recall that $t = O(r \log r)$).

We next associate a set $\mathcal{S}_C$ of spheres with each cell C of $N(S_i)$. For each point $(\xi_1, \xi_2, \rho) \in C$, let $\ell(\xi_1, \xi_2, \rho)$ denote the vertical line (in actual 3-space) passing through the point of coordinate ρ on the line $\lambda(\xi_1, \xi_2)$, and let $\ell^+(\xi_1, \xi_2, \rho)$ denote the portion of $\ell(\xi_1, \xi_2, \rho)$ above its highest intersection point with S_i. Let R_C denote the union of all the rays $\ell^+(\xi_1, \xi_2, \rho)$ for $(\xi_1, \xi_2, \rho) \in C$. The set $\mathcal{S}_C$ consists of all spheres of $\mathcal{S}$ that intersect R_C. We note that R_C is a region of constant complexity defined in terms of only a constant number of spheres of $\mathcal{E}$. The ranges with respect to which $\mathcal{E}_2$ (and hence $\mathcal{E}$) should be a $(1/r)$-net are subsets $\mathcal{S}_C$, each consisting of those spheres that intersect a region of the form R_C defined for cells C in N that have the same structure as the cells of the vertical decompositions constructed above. Again, it is easily seen that the resulting range space has finite VC-dimension. (Intuitively, this is due to the fact that each of the regions R_C has constant description complexity; see, e.g., [29] for more details.)

We next observe that none of the spheres of $\mathcal{E}$ intersect R_C. Indeed, if one of these spheres, S_j, did intersect R_C, then there would exist a point $(\xi_1, \xi_2, \rho) \in \tilde{K}_i$ such that the vertical line $\ell(\xi_1, \xi_2, \rho)$ meets S_j at a point that lies above S_i. Then,

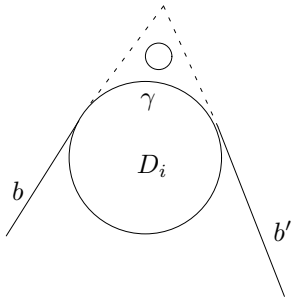

FIG. 8. *An original sphere intersecting V in a disc meeting the small region between D_i and the extension of its two bridges.*

however, by definition, the line $\ell(\xi_1, \xi_2, \rho)$ meets the xy-plane at a point belonging to S_j^*, so by definition of K_i, ρ does not belong to $K_i(\xi_1, \xi_2)$ and thus (ξ_1, ξ_2, ρ) does not belong to $\tilde{K}_i$, a contradiction. We thus conclude that the maximum cardinality of the sets $\mathcal{S}_C$ over all cells C of $N(S_i)$ and over all spheres S_i of $\mathcal{E}$ is at most n/r. We construct the sets $\mathcal{S}_C$ by any brute-force method in linear time (r is assumed to be a constant), create a new set of additional children of the root of the tree $\mathcal{T}$, one child for each cell C in each of the subdivisions $N(S_i)$, associate with that node the corresponding set $\mathcal{S}_C$ of spheres, and continue the construction of the data structure recursively at each child with the corresponding set of spheres. This concludes the description of the sixth (and last) level of our data structure.

2.7. Answering a query. We next describe how a query is processed. Let $e = pq$ be a query segment in 3-space. We have already described how to search with e in the first data structure and how to search with e in the first five levels of the second data structure. Let $\mathcal{S}$ be a canonical set of spheres in the output of the search in the first five levels of the second structure, and let ℓ be the line containing e. We assume with no loss of generality that for each sphere $S \in \mathcal{S}$, either ℓ meets S or else S has no point that lies vertically above ℓ. Our goal is to determine whether ℓ intersects any sphere in $\mathcal{S}$.

Suppose ℓ is represented by the two equations $y = \xi_1 x + \xi_2$ and $z = \xi_3 x + \xi_4$. We start at the root of the sixth-level tree of $\mathcal{S}$ and locate the point (ξ_1, ξ_2) in each of the $2t$ maps $M^+(S_i)$ and $M^-(S_i)$ of the root. Let $C_1, \ldots, C_k$, for some $k \leq 2t$, denote the cells of these maps which contain (ξ_1, ξ_2) and whose label is not 0. As noted, the labels of these cells provide a complete description of the upper convex hull of the t intersection discs D_i of our net spheres with the plane V_{ξ_1,ξ_2}. We compute the slopes $\mu_1, \ldots, \mu_k$ of the k bridges of that hull and compare each of them with the slope of the query line within V, which is, as is easily verified, $\kappa = \xi_3/\sqrt{1+\xi_1^2}$. If one of the bridges, say b, has slope $\mu_b = \kappa$, we simply check whether our query line passes below b, in which case ℓ intersects a sphere of $\mathcal{S}$, so we can return a positive answer to the query. Otherwise, ℓ passes above (the line containing) b, and we recurse in the subtree corresponding to the cell C that defines b. (Only spheres in $\mathcal{S}_C$ can meet ℓ.) In general, though, we will obtain two adjacent bridges, b and b', both tangent to the same sphere of $\mathcal{E}$, say S_i, such that $\mu_b \leq \kappa \leq \mu_{b'}$. In this case, if an original sphere S intersects ℓ, then either S meets one of the two half-planes $b^+(\xi_1, \xi_2)$ and $b'^+(\xi_1, \xi_2)$ or $S \cap V_{\xi_1,\xi_2}$ meets the small region R enclosed between S_i and the two lines containing b and b'; see Figure 8 for an illustration. Let γ denote the (upper) arc of D_i between

its two points of tangency with b and b'. It is clear that no sphere of $\mathcal{E}$ intersects the region γ^+ consisting of all points of V_{ξ_1,ξ_2} that lie above γ, which implies that the xy-projection γ^* of γ is fully contained in (a single connected component of) the region $K_i(\xi_1,\xi_2)$, as defined above. It thus follows that the set $\tilde{\gamma}$ consisting of all points (ξ_1,ξ_2,ρ), where ρ is the coordinate along $\lambda(\xi_1,\xi_2)$ of a point of γ^*, is fully contained in $\tilde{K}_i$ and, in fact, is fully contained within a single cell of the subdivision $N(S_i)$ of $\tilde{K}_i$. ($\tilde{\gamma}$ is a vertical segment contained in $\tilde{K}_i$, and such a segment must be fully contained in a single cell of its vertical decomposition.)

We thus continue the search recursively at the two nodes of $\mathcal{T}$ associated with the cells corresponding to the bridges b and b' and with the node corresponding to the cell C of $N(S_i)$ containing the arc $\tilde{\gamma}$. This concludes the description of the query processing.

2.8. Complexity analysis. We next analyze the complexity of our algorithm in terms of space, preprocessing time, and query time. The first five levels of our second structure (as well as the two levels of the first structure) involve half-space range searching and structures for point location among spheres in $\mathbb{R}^3$. At each of these levels, the size of the structure for a set of m spheres, excluding substructures at deeper levels, is $O(m^{3+\varepsilon})$ for any $\varepsilon > 0$. Indeed, for half-space range searching, this follows from [17]. For point location among spheres, this follows by noting that the maximum storage $S(m)$ and preprocessing cost $P(m)$ for this structure on m spheres satisfy the following recurrences:

$$P(m) \le c_1 r^{3+\varepsilon} P(m/r) + c_2 m r^{3+\varepsilon}$$

and

$$S(m) \le c_1 r^{3+\varepsilon} S(m/r) + c_2' r^{3+\varepsilon}$$

for appropriate constants c_1, c_2, and c_2' (some of which depend on ε). The solution of these recurrences is easily seen to be $O(m^{3+\varepsilon'})$ for another, still arbitrarily small $\varepsilon' > \varepsilon > 0$, where the constant of proportionality depends on ε.

As observed in [26] (and as is easy to verify), the overall size and preprocessing cost of a multilevel data structure of the type considered here can be deduced from the maximum size and preprocessing at any fixed level. In particular, if we show that the sixth level of our structure also requires $O(m^{3+\varepsilon})$ storage and preprocessing for a set of m spheres, it will follow that the overall storage and preprocessing cost of the full multilevel structure will also be $O(n^{3+\varepsilon})$ (with a larger constant of proportionality); see [26] for more details.

We thus turn to consider the cost of the sixth level of our structure, which involves the upper convex hull structure of the intersection discs. We first claim that the total complexity of all the $2t$ planar maps $M^+(S_i)$ and $M^-(S_i)$ is only roughly $O(r^3)$. To see this, ignore for now the added complexity caused by the vertical segments forming the vertical decompositions of the maps. (This increases the complexity by only a small constant factor.) Fix a sphere $S_i \in \mathcal{E}$ and let C be a cell of, say, $M^+(S_i)$ with a nonzero label j. Each edge e on the boundary of C consists of points (ξ_1,ξ_2) at which either the sphere S_j following S_i in the upper hull is about to change, or S_i itself is about to disappear from the upper hull, or the sizes of the two intersection discs D_i and D_j become equal. In the first two cases, either D_i shrinks to a point and then disappears from V or the (line containing the) bridge connecting D_i and D_j in the plane V_{ξ_1,ξ_2} becomes tangent to a third disc D_k (it is also possible that D_i

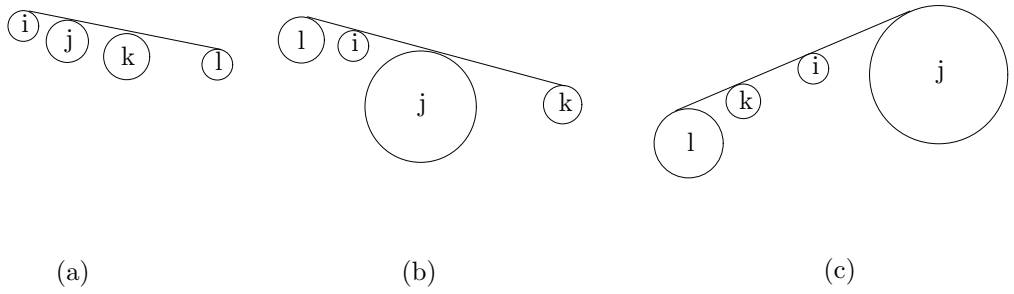

FIG. 9. *The three possible configurations that can occur at a vertex of the map* $M^+(S_i)$.

and D_j become tangent to each other); in the first case, D_k is between D_i and D_j or after D_j, and in the second case, D_k precedes D_i. Each vertex v of C is formed by the intersection of two such boundary edges e and e'. Suppose first that both e and e' represent events of triple tangency. Then v must be of one of the following three types:

- Each of the edges e and e' represents a change in the sphere following S_i. Denote the two corresponding new spheres that are about to replace S_j as the next sphere by S_k and S_l. Since v lies on e, the discs D_i, D_j, and D_k have a common tangent that appears as a bridge in the upper convex hull. Similarly, since v also lies on e', the same is true for D_i, D_j, and D_l. Hence at v the four discs D_i, D_j, D_k, and D_l have a common tangent bridge. See Figure 9(a) for an illustration.
- One of the edges, say e, represents a change in the sphere following S_i, say from S_j to some S_k, and the other edge e' represents a situation where S_i is displaced from the upper convex hull by another sphere S_l preceding S_i along the hull. As is easily verified, in this case as well, the four corresponding discs D_i, D_j, D_k, and D_l must have a common tangent bridge at v. See Figure 9(b) for an illustration.
- Each of the edges e and e' represents a situation where S_i is displaced from the upper convex hull, by two respective other spheres S_k and S_l preceding S_i along the hull. In this case as well, the four corresponding discs D_i, D_j, D_k, and D_l must have a common tangent bridge at v. See Figure 9(c) for an illustration.

We have thus shown that each vertex of $M^+(S_i)$ of these types is a point (ξ_1, ξ_2) for which the plane V_{ξ_1,ξ_2} contains a line tangent to four intersection discs and passing above all other spheres. Similar arguments imply that this also holds for all the other maps $M^{\pm}(S_k)$. Note that, assuming general position of the spheres, each such vertex can be present in at most eight of the $2t$ maps, twice for each of the at most four spheres that define it. (It has no effect on the labeling of cells in other maps.) Similarly, each edge in one of these maps is defined in terms of at most three spheres and can thus appear only in the maps of those three spheres.

Note that if two edges e and e', both representing situations where the size of D_i becomes equal to that of the following disc on the upper hull, meet at a point v, then v also lies on an edge of a triple tangency, as is easily seen.

The next case to consider is thus that of vertices formed by the intersection of two edges e and e', where e consists of points (ξ_1, ξ_2) at which the upper hull of the intersection discs in the plane V_{ξ_1,ξ_2} contains a bridge tangent to D_i and to two other discs, D_j and D_k, and e' consists of points (ξ_1, ξ_2) at which the size of D_i becomes equal to the size of one of these discs, say D_j. It is easily seen that the number of

such vertices is only $O(t^3)$ over the entire collection of maps $M^{\pm}(S_i)$ because each such vertex is defined by three spheres of $\mathcal{E}$, and each triple of spheres gives rise to only a constant number of such vertices.

Finally, consider cases where a disc D_i shrinks to a point or becomes tangent to an adjacent disc along the upper hull. Again, it is easily verified that a vertex v of $M^{\pm}(S_i)$ at which this occurs is defined in terms of at most three spheres (S_i plus two other spheres defining an edge of triple tangency on which v lies, or S_i, S_j, and another sphere becoming tangent to the common tangent line to D_i and D_j). Thus the total number of such vertices over all maps is $O(t^3)$.

We thus need to bound the number of points (ξ_1, ξ_2) at which the upper convex hull of the intersection discs between the spheres and the vertical plane V_{ξ_1,ξ_2} has a bridge tangent to four discs. To do so, we apply the following transformation to the problem. For each sphere $S \in \mathcal{E}$, we define a partial trivariate function $F_S(\xi_1, \xi_2, \xi_3)$ as follows. Suppose that the intersection disc $D = S \cap V_{\xi_1,\xi_2}$ is not empty (otherwise, $F_S(\xi_1, \xi_2, \xi_3)$ is undefined). We define $F_S(\xi_1, \xi_2, \xi_3)$ to be the value of ξ_4 for which the line $y = \xi_1 x + \xi_2$, $z = \xi_3 x + \xi_4$ is tangent to D from above. Note that F_S is (partially) well defined and that its graph is an algebraic surface patch of low constant degree.

It follows by definition that the upper envelope of the functions F_S represents the locus of all lines that are tangent to the upper convex hull of any vertical planar cross-section of the spheres of $\mathcal{E}$. Moreover, each vertex of the upper envelope represents a line tangent to such an upper convex hull and touching four of the corresponding intersection discs, and each such "critical" line is indeed a vertex of the envelope.

By the recent results of [22, 28], the complexity of the upper envelope of n algebraic surface patches of constant maximum degree in d-space is $O(n^{d-1+\varepsilon})$ for any $\varepsilon > 0$. Hence it follows that the complexity of the upper envelope of the $t = O(r \log r)$ functions F_S is $O(r^{3+\varepsilon})$ for any $\varepsilon > 0$. This implies that the number of vertices of the types considered above in our $2t$ maps $M^{\pm}(S_i)$ is $O(r^{3+\varepsilon})$, which is thus also a bound on the overall complexity of the vertical decompositions of these maps. As already argued, this bound also dominates the overall complexity of the spatial subdivisions $N(S_i)$ and implies that the number of children of any node in any sixth-level tree structure is $O(r^{3+\varepsilon})$.

We can finally complete the analysis of the performance of our algorithm. Assuming r to be a (sufficiently large) constant, the construction of the $(1/r)$-net $\mathcal{E}$ can be done in $O(n)$ time, as in [25]. The construction of the $2t$ maps $M^{\pm}(S_i)$ can be done in constant time. More precisely, we first need to construct the upper envelope of the functions F_{S_i}. As shown in [2], this can be done in time $O(r^{3+\varepsilon})$ for any $\varepsilon > 0$. The features of these envelopes are then distributed among the maps $M^{\pm}(S_i)$, the additional edges and vertices of these maps are constructed in a straightforward manner, and the maps are then vertically decomposed, within the same asymptotic running time.

The construction of the t spatial subdivisions $N(S_i)$ can also be performed in constant time. For each fixed sphere $S_i \in \mathcal{E}$, we first compute the "top portions" S_j^+ of the other spheres of $\mathcal{E}$, project them onto the xy-plane, and compute the complement K_i of their union. We then construct all vertices of $N(S_i)$ by examining every pair of vertices and/or edges of each face of K_i in the manner described above, from which the complete subdivision $N(S_i)$ is easy to construct.

For any cell C in each of these maps, we compute the set $\mathcal{S}_C$ of all spheres intersecting its associated region R_C. This can be done in $O(n)$ time since each such region is of constant complexity and the number of regions is also constant. More

precisely, all the canonical sets $\mathcal{S}_C$ can be computed in $O(nr^{3+\varepsilon})$ time. As already noted, the maximum size of any set $\mathcal{S}_C$ is $\leq n/r$.

Let $S_6(n)$, $T_6(n)$, and $Q_6(n)$ denote, respectively, the expected space complexity, preprocessing time, and query time for the sixth level of the data structure on a canonical set of n spheres. Then we have the following recurrence relations:

$$P_6(n) \leq c_1 r^{3+\varepsilon} P_6(n/r) + c_2 n r^{3+\varepsilon}$$

and

$$S_6(n) \leq c_1 r^{3+\varepsilon} S_6(n/r) + c_2' r^{3+\varepsilon}$$

for appropriate constants c_1, c_2, and c_2' (some of which depend on ε). As above, the solution of these recurrences is easily seen to be $O(n^{3+\varepsilon'})$ for another, still arbitrarily small $\varepsilon' > \varepsilon > 0$, where the constant of proportionality depends on ε.

As for the query time $Q_6(n)$, we have the following recurrence:

$$Q_6(n) \leq 3Q_6(n/r) + O(r^{3+\varepsilon}).$$

(The factor 3 appears since we search recursively in at most three children of any node that is visited during the query processing.) The solution of this recurrence is easily seen to be $Q_6(n) = O(n^{\varepsilon})$, again with a constant of proportionality that depends on ε.

If we now combine the sixth level of the structure with the preceding five levels, apply the observations of [26] concerning multilevel structures, as mentioned above, and also take into account the overhead of the parametric searching, we easily conclude the following main result.

THEOREM 2.1. *Given a collection $\mathcal{S}$ of n arbitrary spheres in 3-space and any $\varepsilon > 0$, one can preprocess $\mathcal{S}$ in time $O(n^{3+\varepsilon})$ into a data structure of size $O(n^{3+\varepsilon})$ which supports ray shooting queries among the spheres of $\mathcal{S}$ in time $O(n^{\varepsilon})$ per query.*

3. Extensions. In this section, we extend our algorithm so that it applies to more general classes of objects. As a matter of fact, we present a general approach to ray shooting in three dimensions amidst a collection $\mathcal{S}$ of n (possibly intersecting) convex objects, each of constant description complexity. The approach is modular and consists of several stages, where each stage filters out objects that satisfy a certain geometric constraint with respect to the query ray so that the query ray intersects all objects that satisfy the conjunction of all of these constraints; using this property, the actual ray shooting is then easy to perform. Thus to obtain a ray shooting algorithm for a specific class of objects, we need to provide appropriate and efficient filtering mechanisms for this class at each level separately. These mechanisms and their efficiency depend on the class in question; we will exemplify them for two classes of objects: triangles and ellipsoids.

As above, we only consider the case where we want to obtain fast queries ($O(n^{\varepsilon})$ time per query) and are willing to use large storage. We follow the general approach of [4], reducing the ray-shooting problem to the segment-emptiness problem. We then proceed through the following stages:

(1) We begin by reducing the segment-emptiness problem to the line-emptiness problem, and we accomplish this in the first two stages. Let $e = pq$ be the query segment and let ℓ be the line containing e. In the first stage, we want to partition our objects into three categories:

(i) *Objects that contain exactly one endpoint of e in their interior.* If there is any such object, we can stop the query immediately with a positive answer. We can compute this subset of objects (and also the two other subsets in (ii) and (iii) below) using the same technique that we have used for spheres since we did not exploit any special properties of spheres there. The main tool that we used there was the existence of a vertical decomposition of an arrangement of objects in 3-space into a slightly supercubic number of cells of constant complexity each. This can be done, e.g., for any collection of objects whose boundary is defined in terms of a constant number of algebraic equalities and inequalities of constant maximum degree [14]. Thus, in general, this stage can be performed using $O(n^{3+\varepsilon})$ storage and preprocessing and $O(\log n)$ query time.

(ii) *Objects that contain both endpoints of e in their interior.* Since the objects are assumed to be convex, we can ignore such objects because e cannot intersect any of them.

(iii) *Objects that do not contain any endpoint of e.* These objects require further treatment and are passed to the subsequent stages.

(2) Let S be an object of the third type with respect to our query segment e, and suppose that e intersects S. Since p lies outside S, there exists a plane through p that avoids S, and it is clear that q and S lie on the same side of this plane. (As a matter of fact, this holds for any plane that passes through p and avoids S.) A symmetric property holds at q. Conversely, if there exist a pair of such planes, then, as is easily seen, e intersects S if and only if ℓ intersects S. Thus at this stage, we want to sift out all objects for which there exist a pair of planes with these properties.

Here is a way (perhaps not always the most efficient way) of doing this. Suppose that each object $S \in \mathcal{S}$ is defined by a polynomial inequality $Q(x, y, z) \leq 1$. Since p lies outside S, there is $\lambda > 1$ such that $Q = \lambda$ at p. The plane π_p through p tangent to the surface $Q = \lambda$ is a plane that contains S fully on one side. The equation of the half-space bounded by π_p and containing S is

$$Q_x(p)(x - x_p) + Q_y(p)(y - y_p) + Q_z(p)(z - z_p) \leq 0,$$

where (x_p, y_p, z_p) are the coordinates of p. Since q also has to lie in this half-space, we obtain the constraint

$$Q_x(p)(x_q - x_p) + Q_y(p)(y_q - y_p) + Q_z(p)(z_q - z_p) \leq 0,$$

where (x_q, y_q, z_q) are the coordinates of q. A symmetric condition has to hold at q, namely

$$Q_x(q)(x_q - x_p) + Q_y(q)(y_q - y_p) + Q_z(q)(z_q - z_p) \geq 0.$$

Both inequalities are linear in the coefficients of Q. Thus if we represent each $S \in \mathcal{S}$ as a point in $\mathbb{R}^k$, where k is the number of distinct monomials appearing in the partial derivatives of the corresponding polynomials Q, the testing for the present condition amounts to two half-space range-searching queries in $\mathbb{R}^k$.

Of course, this method is not ideal if k is large, but it is nevertheless a fairly general technique. It works well for spheres: indeed, if the equation of a sphere $S_i \in \mathcal{S}$ is $(x - a_i)^2 + (y - b_i)^2 + (z - c_i)^2 = r_i^2$, then the above two constraints become

$$(x_p - a_i)(x_q - x_p) + (y_p - b_i)(y_q - y_p) + (z_p - c_i)(z_q - z_p) \leq 0$$

and

$$(x_q - a_i)(x_q - x_p) + (y_q - b_i)(y_q - y_p) + (z_q - c_i)(z_q - z_p) \geq 0,$$

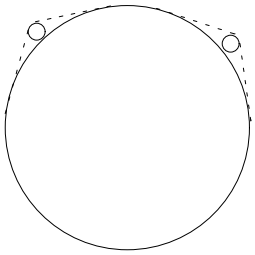

FIG. 10. *A disc appearing more than once along the upper convex hull.*

which, interestingly enough, are identical to the testing of the condition that the center of S_i lies inside the slab Σ_e, as used in our previous algorithm.

(3) At this stage, we have reduced our problem to that of detecting an intersection between a query line ℓ and the objects of $\mathcal{S}$ (or, more precisely, of some canonical subset of $\mathcal{S}$). We next need to further reduce it to the problem of detecting an intersection between ℓ and the planar upper convex hull of the cross-sections of the objects of $\mathcal{S}$ in the vertical plane V passing through ℓ, as we did for spheres. To do this we wish to partition $\mathcal{S}$ into two subsets; none of the objects in the first subset should intersect V in a cross-section that lies fully above ℓ, and none of the objects in the second subset should intersect V in a cross-section that lies fully below ℓ. We have shown that this step can be performed for spheres using an appropriate half-space range searching on the set of centers of the spheres.

(4) In the last stage, we need to decide whether our query line ℓ passes above the upper convex hull of the cross-sections of the objects of (a canonical subset of) $\mathcal{S}$ in the vertical plane V passing through ℓ. However, our solution for this stage is fairly general and can be adapted to apply to objects other than spheres. Indeed, a close inspection of our technique shows that the only place where we have used specific geometric properties of spheres is in the definition of the maps $M^{\pm}(S_i)$, where each map records the spheres that are adjacent to a sphere S_i along the upper hull, provided that the intersection of such a sphere with V is larger than the intersection of S_i with V. This was done in order to overcome the technical difficulty that the sphere following (or preceding) S_i along the hull need not be unique since one intersection disc may appear more than once along the hull; see Figure 10. Here is a way to overcome this difficulty if we assume that the objects of $\mathcal{S}$ are pairwise disjoint. In this case, their cross-sections in any vertical plane are pairwise-disjoint convex regions. We say that one such region D_i is *wider* than another region D_j if the length of the projection of D_i on the x-axis is larger than that of D_j. We now define the maps $M^{\pm}(S_i)$ in complete analogy to their definition in the case of spheres, with the proviso that a bridge connecting a cross-section D_i with a cross-section D_j is recorded in the appropriate map of the narrower of the two regions. It is easily verified that there can be at most one bridge connecting D_i with a wider D_j which follows D_i in the upper hull and at most one bridge connecting D_i with a wider region preceding D_j along the hull. Hence the maps are all well defined, and we can proceed in exactly the same manner as for spheres. If the objects in $\mathcal{S}$ can intersect, we need to devise an alternative method for recording all bridges on the upper hull in a well-defined manner. Assuming that this is indeed possible, the remainder of our algorithm applies to more general classes of objects, with only some obvious and simple modifications. We only need to require that each object in $\mathcal{S}$ has constant description complexity; this will

suffice to show that the overall complexity of the maps $M^{\pm}(S_i)$ and (the vertically decomposed) $N(S_i)$ is only $O(r^{3+\varepsilon})$. This implies that this stage of the algorithm can be performed on a set of n objects with $O(n^{3+\varepsilon})$ preprocessing and storage and with $O(n^{\varepsilon})$ query time. It is interesting that the most complex stage of our algorithm in the case of spheres is the most general stage, which applies with comparable efficiency to general classes of objects.

We now combine all these stages into a multilevel data structure, as we did for spheres. The preprocessing time and storage of the overall structure are roughly dominated by those of the most "expensive" stage, as already mentioned above and as will be illustrated below.

We next illustrate how the various stages of the algorithm can be performed for two specific classes of objects: triangles and ellipsoids.

3.1. The case of triangles. Most of the stages of the algorithm are easy to perform in the case of triangles. The first stage is void, assuming nondegenerate position of the query segment. In the second stage, it suffices to find the set of all triangles such that the two endpoints of the query segment are separated by the plane containing the triangle. This is easy to do using half-space range searching in three dimensions. The fourth stage applies in full generality, as we have noted, and the technical difficulty concerning relative sizes of the intersection objects (line segments in this case) is easy to handle; we leave details of this to the reader.

The most expensive stage, in the case of triangles, is the third one. Here we want to find all triangles passing below (resp. above) a query line or intersecting it. For each triangle Δ, we can find an edge s so that it suffices to determine whether the query line ℓ passes above (resp. below) the line containing s. This in turn can be done by mapping the problem into a half-space range-searching problem in Plücker 5-space, which can be done using $O(n^{4+\varepsilon})$ preprocessing and storage; see [15] for details. Thus the third stage is the bottleneck in obtaining an efficient ray-shooting method for triangles, and in this case, our approach does not seem to yield a better solution than those already known [5].

3.2. The case of ellipsoids. We next consider the case where our objects are ellipsoids whose axes are parallel to the coordinate axes. Each ellipsoid $S_i \in \mathcal{S}$ can be represented by the equation $A_i(x-a_i)^2 + B_i(y-b_i)^2 + C_i(z-c_i)^2 = 1$ for appropriate parameters A_i, B_i, C_i, a_i, b_i, and c_i, where A_i, B_i, and C_i are positive.

As noted above, the first stage can be applied in a general setting, which includes the case of ellipsoids. The second stage calls for the testing of the inequalities

$$A_i(x_p - a_i)(x_q - x_p) + B_i(y_p - b_i)(y_q - y_p) + C_i(z_p - c_i)(z_q - z_p) \le 0$$

and

$$A_i(x_q - a_i)(x_q - x_p) + B_i(y_q - b_i)(y_q - y_p) + C_i(z_q - c_i)(z_q - z_p) \ge 0.$$

These are homogeneous linear inequalities in the six parameters $(A_i, A_i a_i, B_i, B_i b_i, C_i, C_i c_i)$, and so this stage can be performed in projective 5-space using $O(n^{5+\varepsilon})$ storage and preprocessing and logarithmic query time.

Remark. Since this stage is the bottleneck in the case of ellipsoids, it is useful to observe that we can make this stage more efficient if our ellipsoids satisfy additional properties. For example, if they are all ellipsoids of revolution (about their vertical axis), then $A_i = B_i$ and the above inequalities become homogeneous linear inequalities

in projective 4-space, so they can be tested in $O(\log n)$ time using only $O(n^{4+\varepsilon})$ storage and preprocessing.

The third stage can be carried out as follows. Suppose that the query line ℓ is represented by the equations $y = \xi_1 x + \xi_2$ and $z = \xi_3 x + \xi_4$. Take an ellipsoid S_i and project it onto the xy-plane, obtaining the ellipse $S_i^* : A_i(x - a_i)^2 + B_i(y - b_i)^2 = 1$. The intersection of S_i^* with the projection $\ell^* : y = \xi_1 x + \xi_2$ of ℓ leads to the equation

$$A_i(x^2 - 2a_i x + a_i^2) + B_i(\xi_1^2 x^2 - 2(b_i - \xi_2)\xi_1 x + (b_i - \xi_2)^2) = 1,$$

or

$$(A_i + B_i\xi_1^2)x^2 - 2(A_i a_i + B_i b_i \xi_1 - B_i \xi_1 \xi_2)x + (A_i a_i^2 + B_i(b_i - \xi_2)^2 - 1) = 0.$$

The midpoint between the two intersection points (if they exist) thus satisfies

$$x_m = \frac{A_i a_i + B_i b_i \xi_1 - B_i \xi_1 \xi_2}{A_i + B_i \xi_1^2}.$$

It suffices to compare $z_m = \xi_3 x_m + \xi_4$ with c_i; if $z_m > c_i$, then the cross-section $S_i \cap V$ cannot lie fully above ℓ, and if $z_m < c_i$, then this cross-section cannot lie fully below ℓ. This yields the classification of the ellipsoids that we seek.

The required comparison is equivalent to the testing of the sign of the expression

$$A_i a_i \xi_3 + A_i \xi_4 + B_i b_i \xi_1 \xi_3 + B_i(\xi_1^2 \xi_4 - \xi_1 \xi_2 \xi_3) - A_i c_i - B_i c_i \xi_1^2,$$

which is a linear homogeneous expression in the six coefficients $(A_i a_i, A_i, B_i b_i, B_i, A_i c_i, B_i c_i)$. Thus the testing in this stage reduces to half-space range searching in projective 5-space. Moreover, since we are looking for a solution that uses large storage and small query time, the problem becomes, in a dual setting, that of point location among an arrangement of hyperplanes in 5-space. Since the query points lie on a four-dimensional low-degree algebraic surface (they are parametrized by the four parameters $(\xi_1, \ldots, \xi_4)$), we can exploit the zone theorem of Aronov et al. [9] to solve this problem using $O(n^{4+\varepsilon})$ storage and preprocessing with logarithmic query time (see [5] for more details).

The fourth stage is applicable in the general setting, and the technical difficulty concerning multiple bridges from the same cross-section can be overcome for pairwise-disjoint ellipsoids, as described above. Hence, putting it all together, we obtain the following result.

THEOREM 3.1. *Ray shooting amidst n axis-parallel pairwise-disjoint ellipsoids in 3-space can be performed in $O(n^{\varepsilon})$ time using $O(n^{5+\varepsilon})$ preprocessing time and storage. This can be reduced to $O(n^{4+\varepsilon})$ for ellipsoids of revolution.*

4. Conclusion. In this paper, we have developed a new and improved technique for ray shooting amidst spheres in three dimensions. Our method requires $O(n^{3+\varepsilon})$ preprocessing time and storage and performs a ray-shooting query in time $O(n^{\varepsilon})$ for any $\varepsilon > 0$, improving previous solutions by roughly an order of magnitude (in terms of preprocessing and storage costs). We have also shown that our technique can be extended to obtain a general algorithm for ray shooting amidst convex objects (of constant description complexity) in 3-space, and we have demonstrated this extension for the case of triangles (where the resulting algorithm is no worse than known solutions) and for the case of axis-parallel ellipsoids, where we obtain an algorithm that appears to be new and yields fast queries using $O(n^{5+\varepsilon})$ preprocessing and storage.

The weakness of our algorithm is that it does not seem to yield a good trade-off between storage and query time (in contrast with the less efficient solution of [4], which does have such a trade-off). Of course, we can combine our solution with that of [4] to obtain some trade-off. Readers familiar with this technique can easily check that the resulting algorithm yields a query time of $O(n^{9/8+\varepsilon}/s^{3/8})$ for $n \leq s \leq n^3$ using $O(s^{1+\varepsilon})$ storage and preprocessing. It would be interesting (and we pose it as an open problem) to design an algorithm for ray shooting amidst spheres, which takes close to linear storage and can answer ray-shooting queries in time close to $O(n^{2/3})$.

Another set of open problems is to apply our general technique for various specific classes of objects, attempting to find solutions to each stage that are as efficient as possible. In particular, can the algorithm be improved for the case of ellipsoids to require only $O(n^{4+\varepsilon})$ storage?

Finally, no lower bounds are known for the ray-shooting problem. Is our solution for the case of spheres close to optimal in the worst case?

ON THE COMPLEXITY OF FINDING A MINIMUM CYCLE COVER OF A GRAPH*

CARSTEN THOMASSEN†

Abstract. We prove that the problem of finding a cycle cover of smallest total length is NP-hard. This confirms a conjecture of Itai, Lipton, Papadimitriou, and Rodeh from 1981.

Key words. complexity, minimum cycle cover

AMS subject classifications. 05C38, 68Q25

PII. S0097539794267255

1. Introduction. A *path* $x_1x_2\dots x_n$ is a graph with distinct vertices $x_1, x_2, \dots, x_n$ and edges $x_1x_2, x_2x_3, \dots, x_{n-1}x_n$. If we add the edge x_nx_1, we obtain a *cycle*. The *length* of a path or a cycle is the number of edges in it. A *cycle cover* of a graph G is a collection of cycles in G such that every edge is in at least one cycle. The *length* of a cycle cover is the sum of lengths of the cycles. The smallest length of a cycle cover of G is denoted $\mathrm{cc}(G)$.

There are several good upper bounds on $\mathrm{cc}(G)$ that are computable by polynomial-time algorithms; for references, see [4, 5]. However, we show that the question "Is $\mathrm{cc}(G) \le k$?" is *NP*-complete as conjectured by Itai et al. [3]. The problem is also mentioned in [4, 5] and discussed in the survey of Bondy [1].

2. Covers by paths and cycles. The subgraph induced by the vertices p_1, $p_2, \dots, p_9$ in Figure 1 together with a new vertex p_{10} joined to p_1, p_2, p_3 is the Petersen graph P.

LEMMA 2.1. $\mathrm{cc}(P) > 20$.

Proof. Consider a cycle cover of length $\mathrm{cc}(P)$. Since all vertices of P have odd degree, each vertex of P must be incident with at least one edge which is covered an even number of times. Hence $\mathrm{cc}(P) \ge 20$. Suppose equality holds. Then each vertex of P is incident with precisely one edge which is covered twice. Thus P minus the edges that are covered twice is a graph—say H—in which each vertex has degree 2. Hence H is the union of disjoint cycles. Since P has no cycle of length 10 and no cycle of length smaller than 5, H is the union of two disjoint cycles C_1 and C_2, each of length 5. If C: $z_1z_2z_3\dots$ is a cycle in the cycle cover and z_1z_2 is in C_1, say, then z_2z_3 goes from C_1 to C_2, z_3z_4 is in C_2, etc. Hence C has the same number of edges in C_1 as in C_2. Moreover, the edges of $C \cap C_1$ must be nonadjacent and hence C has at most two edges in C_1. It follows that C has length 8. Then, however, 8 divides $\mathrm{cc}(P)$, a contradiction. □

It is easy to show that $\mathrm{cc}(P) = 21$, but we shall not use this fact.

We denote by $H(k,q)(k \ge 1, q \ge 1)$ the graph obtained from the graph of Figure 1 by replacing each edge y_iz_i by a path of length k $(i = 1, 2, 3)$ and each edge of the form $p_ip_j(1 \le i < j \le 9)$ by a path of length q. By a *path-cycle cover* of $H(k,q)$, we mean a collection of cycles and paths covering the edges of $H(k,q)$ such that each path in the collection connects two vertices in $\{x_1, x_2, x_3\}$. If s_i is the number of

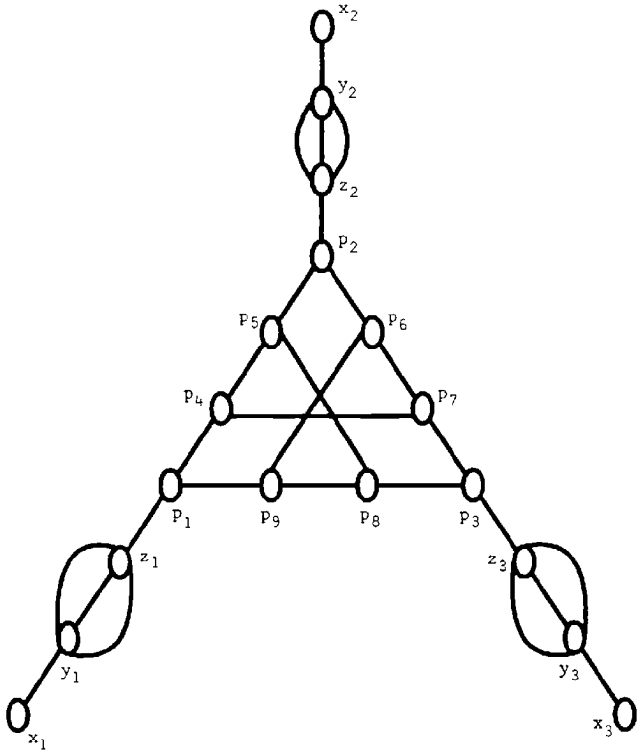

FIG. 2.1.

paths with an end vertex in x_i $(i = 1, 2, 3)$, we speak of an (s_1, s_2, s_3)-*cover*. Because of symmetry, we can assume that $1 \leq s_1 \leq s_2 \leq s_3$.

LEMMA 2.2. *If $k \geq 16(q+1) > 80$, then the sum of lengths of the paths and cycles in an (s_1, s_2, s_3)-cover of $H(k, q)$ is at least $16q + 10k + 12$. Equality can be achieved only for $(s_1, s_2, s_3) = (1, 2, 3)$.*

Proof. The paths $x_1y_1z_1p_1p_9p_6p_7p_4p_5p_8p_3z_3y_3x_3$, $x_2y_2z_2p_2p_5p_4p_1p_9p_8p_3z_3y_3x_3$, $x_2y_2z_2p_2p_6p_7p_3z_3y_3x_3$ and two cycles $y_1z_1y_1$ and $y_2z_2y_2$ form a $(1, 2, 3)$-cover of $H(k, q)$ with total length $16q + 10k + 12$.

Now suppose there exists an (s_1, s_2, s_3)-cover of total length $\leq 16q + 10k + 12$ such that $(s_1, s_2, s_3) \neq (1, 2, 3)$. Since $s_1 + s_2 + s_3$ is the total number of ends of the paths, $s_1 + s_2 + s_3$ is even and hence some s_i $(1 \leq i \leq 3)$ is even. Therefore one of the three paths between y_i and z_i is covered twice. If there exists a $j \in \{1, 2, 3\} \backslash \{i\}$ such that s_j is also even, then one of the paths between y_j and z_j is also covered twice and hence the total length of the path-cycle cover is at least $11k$, which is greater than $16q + 10k + 12$, a contradiction. Thus precisely one s_i is even.

A similar argument shows that the total length of the path-cycle cover is at least $11k$ if $s_3 \geq 5$. Hence $1 \leq s_1 \leq s_2 \leq s_3 \leq 4$.

Suppose now that $s_3 = 4$. Then either both of p_3p_8 and p_3p_7 are covered twice or one is covered three times. Since s_1 and s_2 are odd and every vertex in $\{p_1, p_2, \ldots, p_9\}$ is incident with an edge covered an even number of times, it follows that the total length of the path-cycle cover is at least $17q + 10k + 12$, a contradiction. Thus $1 \leq s_1 \leq s_2 \leq s_3 \leq 3$. This leaves the possibilities $(s_1, s_2, s_3) = (2, 3, 3)$ or $(1, 1, 2)$.

In the former case, the total length of the path-cycle cover is at least $16q + 10k + 16$, a contradiction.

Assume finally that $(s_1, s_2, s_3) = (1, 1, 2)$. It follows from Lemma 1 that the path-cycle cover restricted to the graph induced by $\{p_1, p_2, \ldots, p_9\}$ has total length at least $17q$. Hence the path-cycle cover has total length at least $17q + 10k + 8$, a contradiction. □

3. Cycle covers and the 3-edge-coloring problem. The 3-*edge-coloring* problem is the following: Given a cubic graph G (i.e., every vertex of G has degree 3), is it possible to assign a color in $\{1, 2, 3\}$ to each edge such that no two edges of the same color are incident with the same vertex? Holyer [2] proved that the 3-edge-color problem is *NP*-complete.

THEOREM 3.1. *The* 3*-edge-color problem can be reduced by a polynomial-time transformation to the question "Is* $\mathrm{cc}(G) \leq k$*?". Since the former is NP-complete, so is the latter.*

Proof. Let G be a cubic graph (which we would like to 3-edge-color). Let n be the number of vertices of G. We insert a vertex of degree 2 on every edge of G. Call the resulting graph G_1. If v is a vertex of degree 3 in G_1, then we delete v and replace it by a copy of $H(100,5)$ in such a way that x_1, x_2, and x_3 get degree 2 in the resulting graph, which we call M. We claim that G is 3-edge-colorable if and only if

$$\mathrm{cc}(M) \leq 1092n.$$

Every path-cycle cover of $H(100,5)$ has total length at least 1092 by Lemma 2. Hence $\mathrm{cc}(M) \geq 1092n$. Moreover, if equality holds, then each $H(100,5)$ is covered by a $(1, 2, 3)$-cover, and this results in a 3-edge-coloring of G. (An edge e in G is colored by i, where $i \in \{1, 2, 3\}$, and the new vertex of degree 2 on e is contained in precisely i cycles in the cycle cover of M.) Conversely, if G has a 3-edge-coloring, then we let $C_1, C_2, \ldots, C_r$ denote the cycles of color 1, 3 and $C'_1, C'_2, \ldots, C'_s$ denote the cycles of color 2, 3. Now the system $C_1, C_2, \ldots, C_r, C'_1, C'_1, C'_2, C'_2, \ldots, C'_s, C'_s$ covers each edge of color i precisely i times $(i = 1, 2, 3)$. By modifying this collection of cycles using the paths in the beginning of the proof of Lemma 2, we obtain a cycle cover of M of length $1092n$. □

AN OPTIMAL ALGORITHM FOR SCANNING ALL SPANNING TREES OF UNDIRECTED GRAPHS*

AKIYOSHI SHIOURA†, AKIHISA TAMURA‡, AND TAKEAKI UNO§

Abstract. Let G be an undirected graph with V vertices and E edges. Many algorithms have been developed for enumerating all spanning trees in G. Most of the early algorithms use a technique called "backtracking." Recently, several algorithms using a different technique have been proposed by Kapoor and Ramesh (1992), Matsui (1993), and Shioura and Tamura (1993). They find a new spanning tree by exchanging one edge of a current one. This technique has the merit of enabling us to compress the whole output of all spanning trees by outputting only relative changes of edges. Kapoor and Ramesh first proposed an $O(N+V+E)$-time algorithm by adopting such a "compact" output, where N is the number of spanning trees. Another algorithm with the same time complexity was constructed by Shioura and Tamura. These are optimal in the sense of time complexity but not in terms of space complexity because they take $O(VE)$ space. We refine Shioura and Tamura's algorithm and decrease the space complexity from $O(VE)$ to $O(V+E)$ while preserving the time complexity. Therefore, our algorithm is optimal in the sense of both time and space complexities.

1. Introduction.

Let G be an undirected graph with V vertices and E edges. A spanning tree of G is defined as a connected subgraph of G which contains all vertices but no cycle. In this paper, we consider the enumeration of all spanning trees in an undirected graph. Many algorithms for solving this problem have been developed, e.g., [7, 8, 4, 5, 6, 9], and these may be divided into several types.

The first type [7, 8, 4], to which many of the early algorithms belong, uses a technique called "backtracking." This is a useful technique for listing the kinds of subgraphs, e.g., cycles, paths, and so on. Gabow and Myers [4] refined the algorithms of Minty [7] and Read and Tarjan [8]. Their algorithm uses $O(NV+V+E)$ time and $O(V+E)$ space, where N is the number of all spanning trees. If we enumerate all spanning trees by outputting all edges of each spanning tree, their algorithm is optimal in terms of time and space complexities.

Recently, several algorithms [5, 6, 9] that use another technique have been developed. These algorithms find a new spanning tree by exchanging one pair of edges instead of backtracking. Furthermore, if we enumerate all spanning trees by outputting only relative changes of edges between spanning trees, we can compress the size of output to $\Theta(N+V)$, and hence the total time complexity may be reduced. In fact, Kapoor and Ramesh [5] proposed an $O(N+V+E)$ time and $O(VE)$-space algorithm by adopting such a "compact" output, which is optimal in the sense of time complexity. On the other hand, Matsui [6] developed an $O(NV+V+E)$-time and $O(V+E)$-space algorithm for enumerating all spanning trees explicitly, by applying the reverse-search scheme [3]. Reverse search is a scheme for general enumeration

problems (see [1, 2]). Shioura and Tamura [9] also developed an algorithm generating a compact output with the same time and space complexities as the Kapoor–Ramesh algorithm by using the reverse-search technique. The Kapoor–Ramesh algorithm and the Shioura–Tamura algorithm, however, are not efficient in terms of space complexity because they take $O(VE)$ space.

The main aim of this paper is to obtain an algorithm that generates a compact output and is optimal in the sense of both time and space complexities by refining the Shioura–Tamura algorithm. When the process goes to a lower-level node of the computation tree of the original algorithm, some edge set can be efficiently divided without requiring extra information. However, in order to efficiently restore such an edge set when the process goes back to the higher-level node, the algorithm requires extra $O(E)$ information. Since the depth of the computation tree is $V-1$, it takes $O(VE)$ space. We propose a useful property for efficiently restoring the edge set and a technique for restoring it which uses extra $O(V)$ space in all, while the time complexity remains $O(N+V+E)$.

In section 2, we explain the technique for enumeration of spanning trees and compact outputs. In section 3, we define a nice child–parent relationship between spanning trees and propose a naïve algorithm. In section 4, we show some properties which are useful for efficient manipulation of data structures in our implementation. Our implementation is presented in section 5, and the time and space complexities are analyzed.

2. Compact output. Let G be an undirected graph (not necessary simple) with V vertices $\{v_1, \ldots, v_V\}$ and E edges $\{e_1, \ldots, e_E\}$. We define two types of edge sets which are necessary for our algorithm, so-called fundamental cuts and fundamental cycles. Let T be a spanning tree of G. Throughout this paper, we represent a spanning tree by its edge set of size $V-1$. For any edge $f \in T$, the deletion of f from T yields two connected components. The *fundamental cut* associated with T and f is defined as the set of edges connecting these components and is denoted by $Cut(T \backslash f)$. Likewise, we define the *fundamental cycle* associated with T and $g \notin T$ as the set of edges contained in the unique cycle of $T \cup g$. We will denote it as $Cyc(T \cup g)$. By definition, $T \backslash f \cup g$ is a spanning tree for any $f \in T$ and any $g \in Cut(T \backslash f)$. Similarly, for any $g \notin T$ and any $f \in Cyc(T \cup g)$, $T \cup g \backslash f$ is also a spanning tree. These properties are useful for enumerating spanning trees because by using fundamental cuts or cycles, we can construct a different spanning tree from a given one by exchanging exactly one edge.

Given a graph G, let $\mathcal{S}(G) = (\mathcal{T}, \mathcal{A})$ be the graph whose vertex set $\mathcal{T}$ is the set of all spanning trees of G and whose edge set $\mathcal{A}$ consists of all pairs of spanning trees which are obtained from each other by exchanging exactly one edge using some fundamental cut or cycle. For example, the graph $\mathcal{S}(G_1)$ of the left one, G_1, is shown in Figure 2.1.

Our algorithm finds all spanning trees of G by implicitly traversing some spanning tree $\mathcal{D}$ of $\mathcal{S}(G)$. In order to output all $(V-1)$ edges of each spanning tree, $\Theta(|\mathcal{T}| \cdot V) = \Theta(N \cdot V)$ time is required. However, if we output all edges of the first spanning tree and then only the sequence of exchanged edge pairs of G obtained by traversing $\mathcal{D}$, we need only $\Theta(|\mathcal{T}| + V) = \Theta(N+V)$ time because $|\mathcal{D}| = |\mathcal{T}|-1$ and exactly two edges of G are exchanged for each edge of $\mathcal{D}$. Furthermore, by scanning such a "compact" output, one can construct all spanning trees. Since we adopt such a compact output, it becomes desirable to find the next spanning tree from a current one efficiently in constant time.

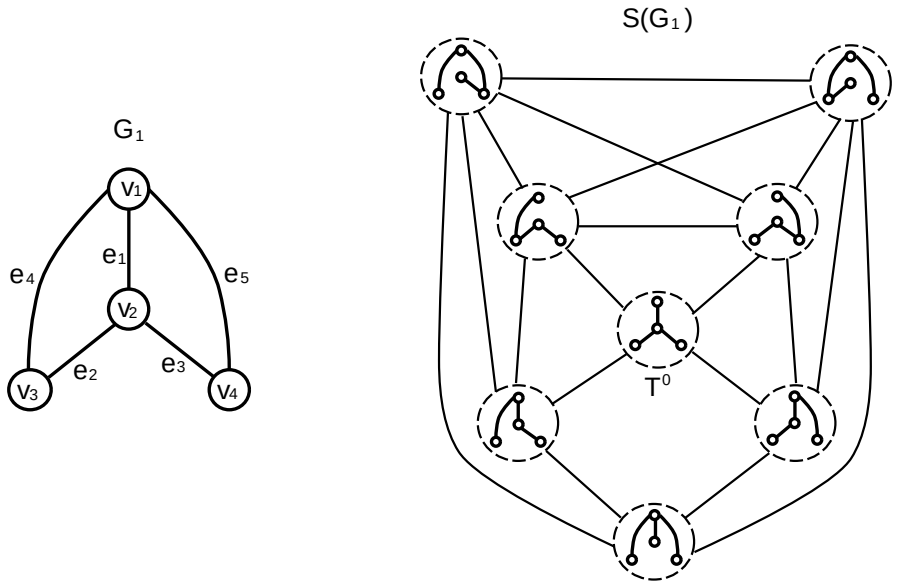

FIG. 2.1. *Graph G_1 and graph $\mathcal{S}(G_1)$.*

3. Basic ideas and the naïve algorithm. In this section, we explain the basic ideas and the naïve algorithm.

We define the total orders over the vertex set $\{v_1, \ldots, v_V\}$ and the edge set $\{e_1, \ldots, e_E\}$ of G by their indices as $v_1 < v_2 < \cdots < v_V$ and $e_1 < e_2 < \cdots < e_E$. Particularly, we call the smallest vertex v_1 the *root*. For each edge e, we call the smaller incident vertex the *tail*, denoted by $\partial^+ e$, and call the larger one the *head*, denoted by $\partial^- e$. Relative to a spanning tree T of G, if the unique path in T from the vertex v to the root v_1 contains a vertex u, then u is called an *ancestor* of v and v is a *descendant* of u. Similarly, for two edges e and f in T, we call e an *ancestor* of f and f a *descendant* of e if the unique path in T from f to the root v_1 contains e. A "depth-first spanning" tree of G is a spanning tree which is found by some depth-first search of G. It is known that a *depth-first spanning tree* is defined as a spanning tree such that for each edge of G, its one incidence vertex is an ancestor of the other.

In our algorithm, we make several assumptions regarding the vertex set and the edge set of G.

ASSUMPTION 1. *T^0 is a depth-first spanning tree of G.*

ASSUMPTION 2. $T^0 = \{e_1, \ldots, e_{V-1}\}$.

ASSUMPTION 3. *Any edge in T^0 is smaller than its proper descendants.*

ASSUMPTION 4. *Each vertex v is smaller than its proper descendants relative to T^0.*

ASSUMPTION 5. *For any two edges $e, f \notin T^0$, if $e < f$, then $\partial^+ e \leq \partial^+ f$.*

Vertices and edges of graph G_2 in Figure 3.1 satisfy these assumptions. In fact, one can find T^0 and sort vertices and edges of G in $O(V+E)$ time so that G satisfies the above assumptions by applying Tarjan's depth-first search [10]. We note that Assumptions 1, 2, and 3 are sufficient for the correctness of our algorithm. However, we further need Assumptions 4 and 5 for an efficient implementation.

For any nonempty subset S of $\{e_1, \ldots, e_E\}$, $\mathrm{Min}(S)$ denotes the smallest edge in

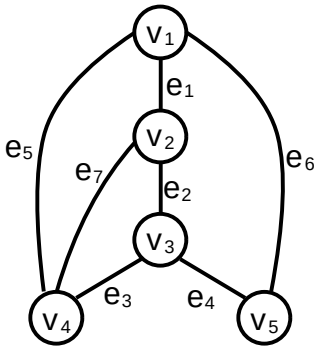

FIG. 3.1. *Graph* G_2.

S. For convenience, we assume that $\mathrm{Min}(\emptyset) = e_V$.

LEMMA 3.1 (see [9]). *Under Assumptions* 1 *and* 3*, for any spanning tree* $T^c \neq T^0$*, if* $f = \mathrm{Min}(T^0 \setminus T^c)$*, then* $Cyc(T^c \cup f) \cap Cut(T^0 \backslash f) \setminus f$ *contains exactly one edge.*

Proof. The set $T^0 \setminus f$ has exactly two components, one containing $\partial^- f$ and the other containing $\partial^+ f$. Therefore, the unique path $Cyc(T^c \cup f) \setminus f$ from $\partial^- f$ to $\partial^+ f$ in T^c contains at least one edge in $Cut(T^0 \backslash f)$. Hence $Cyc(T^c \cup f) \cap Cut(T^0 \backslash f) \setminus f \neq \emptyset$.

Since T^0 is a depth-first spanning tree, we may assume without loss of generality that the head of any edge is a descendant of its tail relative to T^0. Let e be the first edge from $\partial^- f$ on the path such that $e \in Cut(T^0 \backslash f)$. Then the head $\partial^- e$ is a descendant of $\partial^- f$ relative to T^0, and the tail $\partial^+ e$ is an ancestor of $\partial^+ f$. From Assumption 3 and the minimality of f, $\partial^+ e$ and $\partial^+ f$ are connected in $T^c \cap T^0$. Thus there is no edge contained in $Cut(T^0 \backslash f)$ between $\partial^+ e$ and $\partial^+ f$ in the path $Cyc(T^c \cup f) \setminus f$. Hence e is the only edge in $Cyc(T^c \cup f) \setminus f$ and $Cut(T^0 \backslash f)$. □

Consider the graph G_2 of Figure 3.1. Here let $T^0 = \{e_1, e_2, e_3, e_4\}$ and $T^c = \{e_4, e_5, e_6, e_7\}$. In graph G_2,

$$\begin{aligned} f &= \mathrm{Min}\{e_1, e_2, e_3\} = e_1, \\ Cyc(T^c \cup f) &= \{e_1, e_5, e_7\}, \\ Cut(T^0 \backslash f) &= \{e_1, e_5, e_6\}. \end{aligned}$$

Therefore, $Cyc(T^c \cup f) \cap Cut(T^0 \backslash f) \setminus f = \{e_5\}$.

Given a spanning tree $T^c \neq T^0$ and the edge $f = \mathrm{Min}(T^0 \setminus T^c)$, let g be the unique edge in $Cyc(T^c \cup f) \cap Cut(T^0 \backslash f) \setminus f$. Clearly, $T^p = T^c \cup f \backslash g$ is a spanning tree. We call T^p the *parent* of T^c and T^c a *child* of T^p. Lemma 3.1 guarantees that each spanning tree other than T^0 has a unique parent. Since $|T^p \cap T^0| = |T^c \cap T^0| + 1$ holds, T^0 is the ancestor of all spanning trees. For the graph G_1 in Figure 2.1, all child–parent pairs are shown by the arrows in Figure 3.2. Each arrow goes from a child to its parent. We can see that all arrows construct a spanning tree of $\mathcal{S}(G_1)$ rooted at T^0.

Let $\mathcal{D}$ be the spanning tree of $\mathcal{S}(G)$ consisting of all child–parent pairs of spanning trees. Our algorithm implicitly traverses $\mathcal{D}$ from T^0 by recursively scanning all children of a current spanning tree. Thus we must find all children of a given spanning tree, if they exist. The next lemma gives a useful idea for this.

LEMMA 3.2 (see [9]). *Let* T^p *be an arbitrary spanning tree of* G*, and let* f *and* g *be two distinct edges. Under Assumptions* 1*,* 2*, and* 3*,* $T^c = T^p \backslash f \cup g$ *is a child of* T^p

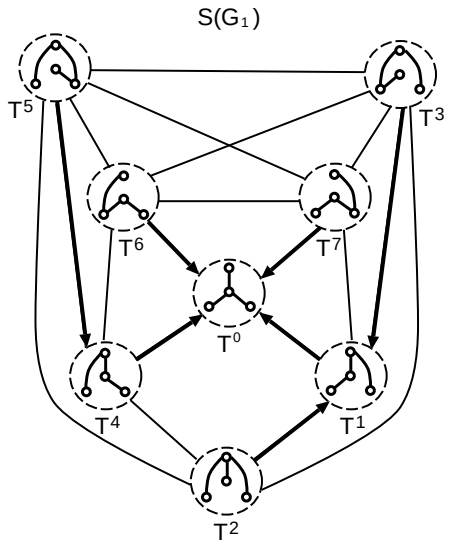

FIG. 3.2. *Child–parent relations in* $\mathcal{S}(G_1)$.

if and only if f *and* g *satisfy the following conditions:*

$$f < \mathrm{Min}(T^0 \setminus T^p) \quad \textit{and} \quad g \in Cut(T^p \backslash f) \cap Cut(T^0 \backslash f) \setminus f. \tag{3.1}$$

Proof. Under Assumptions 1 and 3, T^c is a child of T^p if and only if the following conditions hold:

$$T^c \text{ is a spanning tree different from } T^0; \tag{3.2}$$

$$f' = \mathrm{Min}(T^0 \setminus T^c) \quad \text{and} \quad g' \in Cyc(T^c \cup f') \cap Cut(T^0 \backslash f') \setminus f', \tag{3.3}$$

$$T^p = T^c \cup f' \backslash g'. \tag{3.4}$$

We first show that $f = f'$ and $g = g'$. From (3.2), (3.3), and (3.4), T^c and T^p are different spanning trees. Assume to the contrary that $f \notin T^p$; then $T^p \setminus f = T^p$. Since T^c is a spanning tree and $f \neq g$, we have $g \in T^p$ and $T^c = T^p \backslash f \cup g = T^p$, which is a contradiction. Thus $f \in T^p$ and $g \notin T^p$. From (3.4), $T^p = \{T^p \backslash f \cup g\} \cup f' \backslash g'$, and hence $f = f'$ and $g = g'$ must hold.

Conditions (3.2), (3.3), and (3.4) imply

$$f \in T^p \cap T^0 \quad \text{and} \quad g \notin T^p \cup T^0. \tag{3.5}$$

On the other hand, under Assumption 2, (3.1) implies (3.5). Moreover, (3.1) and (3.5) imply (3.2) and (3.4). All we have to do is to show that (3.1) and (3.3) are equivalent under conditions (3.2), (3.4), and (3.5).

From the definition of T^c and (3.5), $T^0 \setminus T^c = T^0 \setminus (T^p \backslash f \cup g) = (T^0 \setminus T^p) \cup \{f\}$. Hence $\mathrm{Min}(T^0 \setminus T^c) = \mathrm{Min}(\mathrm{Min}(T^0 \setminus T^p) \cup \{f\})$. This implies that $f = \mathrm{Min}(T^0 \setminus T^c)$ if and only if $f < \mathrm{Min}(T^0 \setminus T^p)$. Since T^p and $T^c = T^p \backslash f \cup g$ are distinct, $g \in Cyc(T^c \cup f)$ is equivalent to $g \in Cut(T^p \backslash f)$. Therefore, the second condition of (3.1) is equivalent to the second condition of (3.3). ∎

Let e_k be the largest edge less than $\mathrm{Min}(T^0 \setminus T^p)$. From Lemma 3.2, we can find all children of T^p if we know the edge sets $Cut(T^p \backslash e_j) \cap Cut(T^0 \backslash e_j) \setminus e_j$ for $j = 1, 2, \ldots, k$. Consider the graph $G = G_1$ defined in Figure 2.1 and $T^p = T^1$ (see Figure 3.2). In this case, e_1 and e_2 are the only edges smaller than $\mathrm{Min}(T^0 \setminus T^1) = e_3$ and

$$Cut(T^1 \backslash e_2) \cap Cut(T^0 \backslash e_2) \setminus e_2 = \{e_2, e_4\} \cap \{e_2, e_4\} \setminus e_2 = \{e_4\},$$
$$Cut(T^1 \backslash e_1) \cap Cut(T^0 \backslash e_1) \setminus e_1 = \{e_1, e_3, e_4\} \cap \{e_1, e_4, e_5\} \setminus e_1 = \{e_4\}.$$

Therefore, T^1 has only the two children, $T^1 \backslash e_2 \cup e_4$ and $T^1 \backslash e_1 \cup e_4$.

In the rest of paper, we abbreviate $Cut(T^p \backslash e_j) \cap Cut(T^0 \backslash e_j) \setminus e_j$ as $Entr(T^p, e_j)$ on the grounds that any edge in $Cut(T^p \backslash e_j) \cap Cut(T^0 \backslash e_j) \setminus e_j$ can be "entered" into T^p in place of e_j. From the above consideration, we can construct the following algorithm.

ALGORITHM all-spanning-trees(G);
input: a graph G with a vertex set $\{v_1, \ldots, v_V\}$ and an edge set $\{e_1, \ldots, e_E\}$;
begin
by using a depth-first search,
• find a depth-first spanning tree T^0 of G,
• sort vertices and edges to satisfy Assumptions 2, 3, 4, and 5;
output("$e_1, e_2, \cdots, e_{V-1}, tree,$") ;{output T^0}
find-children(T^0,$V-1$);
end.

PROCEDURE find-children(T^p,k);
input: a spanning tree T^p and an integer k with $e_k < \mathrm{Min}(T^0 \setminus T^p)$;
begin
if $k \leq 0$ **then** return;
for each $g \in Entr(T^p, e_k)$ **do begin**
{output all children of T^p not containing e_k}
$T^c := T^p \backslash e_k \cup g$;
output("$-e_k, +g, tree,$");
find-children(T^c,$k-1$); {find the children of T^c}
output("$-g, +e_k,$");
end;
find-children(T^p,$k-1$); {find the children of T^p not containing e_{k-1}}
end.

In this algorithm, procedure find-children( ) finds all children of each spanning tree. When it is called with two arguments T^p and k, it finds all children of T^p not containing an edge e_k. Whenever it finds such a child T^c, it recursively calls itself again to find all children of T^c. In this stage, arguments are set to T^c and $k-1$ because if $k > 1$, then e_{k-1} becomes the largest edge less than $\mathrm{Min}(T^0 \setminus T^c)$. If all children of T^p not containing e_k have been found, it recursively calls itself again to find all children of T^p not containing e_{k-1}. In this case, arguments are T^p and $k-1$. Initially, algorithm all-spanning-trees(G) calls find-children( ) with arguments T^0 and $V-1$, and all spanning trees of G are found. Figure 3.3 shows the enumeration tree of spanning trees in graph G_1.

THEOREM 3.3 (see [9]). *Algorithm* all-spanning-trees( ) *outputs each spanning tree exactly once.*

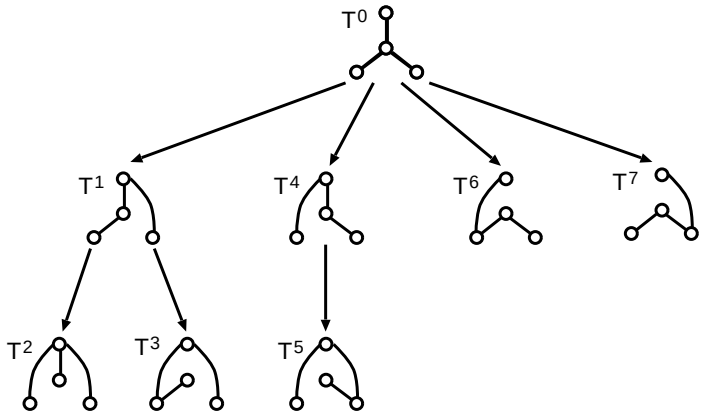

FIG. 3.3. *Enumeration tree of spanning trees in* G_1.

Proof. From Lemma 3.2, every spanning tree different from T^0 is output once for each time its parent is output. From Lemma 3.1, for any spanning tree T^c other than T^0, its parent always exists and is uniquely determined. Since T^0 is the ancestor of all spanning trees, the algorithm outputs each spanning tree exactly once. □

4. Manipulating data structures. In our algorithm, we define each state when we find all children of T^p not containing e_k by a pair (T^p, k). When we call procedure find-children(T^p, k), the current state becomes (T^p, k), and if we find a child T^c of T^p not containing e_k, the state moves to $(T^c, k-1)$. After all children of T^p not containing e_k have been found, the state moves to $(T^p, k-1)$. At the state (T^p, k), the entering edge set $Entr(T^p, e_k)$ is required to output all children of T^p not containing e_k. After the state moves to $(T^c, k-1)$ (or $(T^p, k-1)$), the entering edge set $Entr(T^c, e_{k-1})$ (or $Entr(T^p, e_{k-1})$) is required for the first time. The key point is finding an entering edge set $Entr(T^c, e_{k-1})$ (or $Entr(T^p, e_{k-1})$) efficiently. To construct an entering edge set efficiently, our implementation maintains the edge sets $Can(e_j; T^p, k)$ for $j = 1, \ldots, k$ defined below. Let T^p be a spanning tree and k be a positive integer with $e_k < \mathrm{Min}(T^0 \setminus T^p)$. For each edge e_j $(j = 1, \ldots, k)$, we define $Can(e_j; T^p, k)$ by

$$Can(e_j; T^p, k) = Entr(T^p, e_j) \setminus \bigcup_{h=j+1}^{k} Entr(T^p, e_h). \tag{4.1}$$

Here we use this notation in the sense that $Can(e_j; T^p, k)$ is a set of "candidates" of the entering edges $Entr(T^p, e_j)$ for a leaving edge e_j at the state (T^p, k). We can find $Entr(T^p, e_k)$ very easily by maintaining $Can(e_j; T^p, k)$ for $j = 1, \ldots, k$ because $Can(e_k; T^p, k) = Entr(T^p, e_k)$ from the definition in (4.1). When we find a child T^c of T^p, we update $Can(e_j; T^p, k)$ for $j = 1, \ldots, k$ to $Can(e_j; T^c, k-1)$ for $j = 1, \ldots, k-1$. On the other hand, after we have found all children of T^p not containing e_{k-1}, we construct $Can(e_j; T^p, k-1)$ for $j = 1, \cdots, k-1$ from $Can(e_j; T^p, k)$ for $j = 1, \ldots, k$. The efficiency of our implementation depends on how to maintain $Can(*; *, *)$ efficiently.

Figure 4.1 shows the states and edge sets $Can(*; *, *)$ during the enumeration of all spanning trees of G_1 in Figure 2.1. For example, at the initial state $(T^0, 3)$,

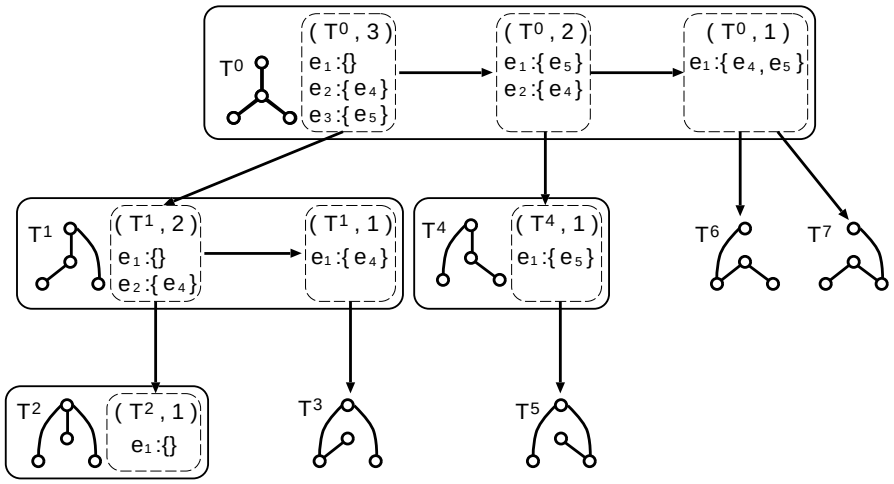

FIG. 4.1. *Movement of the state and* $Can(*;*,*)$.

$$Can(e_1;T^0,3)=\emptyset,$$
$$Can(e_2;T^0,3)=\{e_4\},$$
$$Can(e_3;T^0,3)=\{e_5\}.$$

At the succeeding states $(T^1,2)$ and $(T^0,2)$,

$$Can(e_1;T^1,2)=\emptyset,$$
$$Can(e_2;T^1,2)=\{e_4\},$$

and

$$Can(e_1;T^0,2)=\{e_5\},$$
$$Can(e_2;T^0,2)=\{e_4\}.$$

Here we consider how to maintain such edge sets. First, we show that the initial edge sets $Can(e_j;T^0,V-1)$ for $j=1,\ldots,V-1$ can be found easily.

LEMMA 4.1 (see [9]). *Under Assumptions* 1, 2, 3, *and* 4,

$$Can(e_j;T^0,V-1)=\{e \mid e\notin T^0,\ \partial^+e\le\partial^+e_j \text{ and } \partial^-e=\partial^-e_j\} \quad (j=1,\ldots,V-1) \tag{4.2}$$

Proof. Since $Entr(T^0,e_j)=Cut(T^0\backslash e_j)\setminus e_j$, $Can(e_j;T^0,V-1)$ can be written as

$$Can(e_j;T^0,V-1)=\left[Cut(T^0\backslash e_j)\setminus e_j\right]\setminus\bigcup_{h=j+1}^{V-1}\left[Cut(T^0\backslash e_h)\setminus e_h\right].$$

Under Assumptions 1 and 4, an edge $e\notin T^0$ belongs to $Cut(T^0\backslash e_j)$ if and only if ∂^-e is a descendant of ∂^-e_j and ∂^+e is an ancestor of ∂^+e_j relative to T^0. In addition, under Assumption 3, for $e\notin T^0$, e_j is the largest edge with $e\in Cut(T^0\backslash e_j)$ if and only if $\partial^-e=\partial^-e_j$ and $\partial^+e\le\partial^+e_j$. ∎

From Lemma 4.1, we can find $Can(e_j; T^0, V-1)$ for $j = 1, \ldots, V-1$ in $O(V+E)$ time by applying a depth-first search.

LEMMA 4.2. *For any spanning tree T^p and any positive integer k with $e_k < \mathrm{Min}(T^0 \setminus T^p)$, let g be an arbitrary edge in $Entr(T^p, e_k) \cup \{e_k\}$. Under Assumptions 1, 2, 3, and 4, the following relation holds for a spanning tree $T = T^p \backslash e_k \cup g$ and an edge e_j with $j < k$:*

$$Entr(T, e_j) = \begin{cases} Entr(T^p, e_j) & \text{if } e_j \in A, \\ Entr(T^p, e_j) \setminus Entr(T^p, e_k) & \text{otherwise,} \end{cases} \tag{4.3}$$

where A is the set of ancestors of the edge e_t in T^0 with $\partial^- e_t = \partial^+ g$ if it exists; otherwise, $A = \emptyset$.

Proof. We note that if $g \in Entr(T^p, e_k)$, then T is a child of T^p and if $g = e_k$, then $T = T^p$. Each descendant of $\partial^- e_k$ relative to T^p is a descendant of $\partial^- g$ relative to T, and vice versa. Therefore, for any $e_j \in A$, $Entr(T, e_j) = Entr(T^p, e_j)$. If $e_j \notin A$ is an ancestor of e_k, then $Entr(T, e_j) \subseteq Entr(T^p, e_j)$. More precisely, for any edge $e \in Entr(T^p, e_j)$ such that $\partial^- e$ is a descendant of $\partial^- e_k$ relative to T^p, e does not belong to $Entr(T, e_j)$, and the other edges obviously belong to $Entr(T, e_j)$. That is, $Entr(T, e_j) = Entr(T^p, e_j) \setminus Entr(T^p, e_k)$. If e_j is not an ancestor of e_k, $Entr(T, e_j) = Entr(T^p, e_j) = Entr(T^p, e_j) \setminus Entr(T^p, e_k)$ holds because $Entr(T^p, e_j) \cap Entr(T^p, e_k) = \emptyset$. □

LEMMA 4.3 (see [9]). *Let T^p be a spanning tree and let k be a positive integer with $e_k < \mathrm{Min}(T^0 \setminus T^p)$. Under Assumptions 1, 2, 3, and 4, for any edge $g \in Can(e_k; T^p, k) \cup \{e_k\}$ and for a spanning tree $T = T^p \backslash e_k \cup g$, the following relation holds*:

$$Can(e_j; T, k-1) = \begin{cases} Can(e_j; T^p, k) \cup [Can(e_k; T^p, k) \cap \{e \mid \partial^+ e < \partial^+ g\}] \\ \qquad \text{if } \partial^- e_j = \partial^+ g, \\ Can(e_j; T^p, k) \quad \text{if } \partial^- e_j \neq \partial^+ g. \end{cases} \tag{4.4}$$

Proof. From the assumptions, for two edges e and f with $e, f < \mathrm{Min}(T^0 \setminus T^p)$, e is an ancestor of f relative to T^0 if and only if e is an ancestor of f relative to T^p, so we will omit the phrase "relative to T^0 (or T^p)" for such edges. Let e_t be the edge with $\partial^- e_t = \partial^+ g$ if it exists, and let A be the set of edges in T^0 which are ancestors of e_t if e_t exists; otherwise, $A = \emptyset$. We prove (4.4) by using relation (4.3).

Case 1. If $e_j \notin A$, then

$$\begin{aligned} &Can(e_j; T, k-1) \\ &\quad = [Entr(T^p, e_j) \setminus Entr(T^p, e_k)] \\ &\qquad \setminus \left[\bigcup_{h=j+1,\, e_h \notin A}^{k-1} (Entr(T^p, e_h) \setminus Entr(T^p, e_k)) \cup \bigcup_{h=j+1,\, e_h \in A}^{k-1} Entr(T^p, e_h) \right] \\ &\quad = Entr(T^p, e_j) \setminus \bigcup_{h=j+1}^{k} Entr(T^p, e_h) = Can(e_j; T^p, k). \end{aligned}$$

Case 2. If $e_j \in A$, then

$$\begin{aligned} &Can(e_j; T, k-1) \\ &\quad = Entr(T^p, e_j) \setminus \left[\bigcup_{h=j+1,\, e_h \notin A}^{k-1} (Entr(T^p, e_h) \setminus Entr(T^p, e_k)) \cup \bigcup_{h=j+1,\, e_h \in A}^{k-1} Entr(T^p, e_h) \right] \end{aligned}$$

$$= Can(e_j; T^p, k) \bigcup \left[Entr(T^p, e_j) \cap \left(Entr(T^p, e_k) \setminus \bigcup_{h=j+1,\, e_h \in A}^{k-1} Entr(T^p, e_h) \right) \right].$$

If $e_j = e_t$, then there is no edge e_h with $j < h < k$ and $e_h \in A$. Therefore,

$$\begin{aligned} Can(e_j; T, k-1) &= Can(e_j; T^p, k) \bigcup [Entr(T^p, e_j) \cap Entr(T^p, e_k)] \\ &= Can(e_j; T^p, k) \bigcup \left[Can(e_k; T^p, k) \cap \{e \mid \partial^+ e < \partial^- e_t\} \right]. \end{aligned}$$

If e_j is a proper ancestor of e_t, then $Entr(T^p, e_j) \cap Entr(T^p, e_k) \subseteq Entr(T^p, e_t)$, and e_t satisfies $j < t < k$ and $e_t \in A$. Hence $Can(e_j; T, k-1) = Can(e_j; T^p, k)$. □

Lemma 4.3 guarantees that at most one of the sets $Can(*; T^p, k)$ is updated when we want to find all children of T^c or all children of T^p containing e_k. In Figure 4.1, when the state moves from $(T^0, 3)$ to $(T^0, 2)$, e_1 is the edge such that $\partial^- e_1 = \partial^+ e_3$ and the following equations hold:

$$\begin{aligned} Can(e_2; T^0, 2) &= Can(e_2; T^0, 3) \;=\; \{e_4\} \\ Can(e_1; T^0, 2) &= Can(e_1; T^0, 3) \cup \left[Can(e_3; T^0, 3) \cap \{e \mid \partial^+ e < \partial^+ e_3\} \right] \\ &= \emptyset \cup \left[\{e_5\} \cap \{e \mid \partial^+ e < v_2\} \right] \;=\; \{e_5\}. \end{aligned}$$

On the other hand, when the state moves from $(T^0, 3)$ to $(T^1, 2)$, no candidate edge set is updated because there is no edge with $\partial^- e_t = \partial^+ e_5$:

$$\begin{aligned} Can(e_2; T^1, 2) &= Can(e_2; T^0, 3) = \{e_4\}, \\ Can(e_1; T^1, 2) &= Can(e_1; T^0, 3) = \emptyset. \end{aligned}$$

In our implementation, we use the global variables `candi`$(*)$ and `leave`. At the state (T^p, k), variable `candi`(e_j) $(j{=}1, \ldots, k)$ represents the edge set $Can(e_j; T^p, k)$ and variable `leave` represents the edge set $\{e_j \mid j \le k \text{ and } Can(e_j; T^p, k) \neq \emptyset\}$. We can check in constant time whether or not the current spanning tree has children by checking to see if `leave` $\neq \emptyset$. Suppose that each edge set is represented as an ascending ordered list realized by a doubly linked list. We also use (i) a data structure for a given graph G so that two incidence vertices of any edge are found in constant time and (ii) a data structure for the initial spanning tree T^0 so that for any vertex v other than the root, the unique edge e with $\partial^- e = v$ is found in constant time. Recall that graph G satisfies the following assumption.

ASSUMPTION 5. *For any two edges $e, f \notin T^0$, if $e < f$, then $\partial^+ e \le \partial^+ f$.*

From this assumption, one can find the edge set $Can(e_k; T^p, k) \cap \{e | \partial^+ e < \partial^+ g\}$ by searching the ordered list `candi`(e_k) from the beginning. Thus we can complete this in time proportional to the size of this edge set. Merging two edge sets can be executed in time proportional to the sum of the size of two edge sets. Therefore, it takes $O(|Can(e_t; T^p, k)| + |Can(e_k; T^p, k) \cap \{e | \partial^+ e < \partial^+ g\}|)$ time to update edge sets `candi`$(*)$ when the current state (T^p, k) goes to a succeeding state $(T, k{-}1)$. If `candi`(e_t) changes from empty to nonempty, then we must insert an edge e_t into `leave`. Since `leave` is an ascending ordered list, we can complete it in $O(|\{e \in$ `leave` $| e < e_t\}|) = O(|\{e_j | j < t \text{ and } Can(e_j; T^p, k) \neq \emptyset\}|)$ time.

On the other hand, when the state goes back from $(T, k{-}1)$ to (T^p, k), we must reconstruct $Can(*; T^p, k)$ from $Can(*; T, k{-}1)$. To do this, we must restore the edges $Can(e_k; T^p, k) \cap \{e | \partial^+ e < \partial^+ g\}$ from `candi`(e_t) to `candi`(e_k). In the Shioura–Tamura algorithm [9], such a restoration is efficiently executed by recording $Can(e_k; T^p, k) \cap$

$\{e|\partial^+e<\partial^+g\}$ before state (T^p,k) goes to $(T,k-1)$. However, this idea requires $O(VE)$ extra space since the depth of recursive calls of the algorithm is $O(V)$. In the rest of this section, we discuss our idea for reducing extra space.

Let $Head(e_j;T^p,k)$ denote the head set of edges contained in $Can(e_j;T^p,k)$. Then we have the following result.

LEMMA 4.4. *Under Assumptions* 1, 2, 3, *and* 4, *all head sets* $Head(e_j;T^p,k)$ *for* $j=1,\ldots,k$ *are mutually disjoint at any state* (T^p,k).

Proof. From Lemma 4.1, $Head(e_j;T^0,V-1)=\{\partial^-e_j\}$ at the initial state $(T^0,V-1)$ if $Can(e_j;T^0,V-1)$ is nonempty. Thus the assertion is true at the initial state.

We assume that the lemma holds at state (T^p,k) and prove that this holds at the next state $(T^p\backslash e_k\cup g,k-1)$, where $g\in Can(e_k;T^p,k)\cup\{e_k\}$. From Lemma 4.3, the following relation holds:

$$Head(e_j;T,k-1)=\begin{cases}Head(e_j;T^p,k)\cup HS & \text{if } \partial^-e_j=\partial^+g,\\ Head(e_j;T^p,k) & \text{if } \partial^-e_j\neq\partial^+g,\end{cases} \tag{4.5}$$

where HS is the head set of all edges in $Can(e_k;T^p,k)\cap\{e|\partial^+e<\partial^+g\}$. Because $HS\subseteq Head(e_k;T^p,k)$ and each $Head(e_j;T^p,k)$ for $j=1,\ldots,k-1$ does not intersect HS, all head sets $Head(e_j;T^p,k-1)$ for $j=1,\ldots,k-1$ are mutually disjoint. ∎

By Lemma 4.4, the head set HS of edges in $Can(g;T^p,k)\cap\{e|\partial^+e<\partial^+g\}$ has no intersection with any head set $Head(e_j;T^p,k)$ $(j=1,\ldots,k-1)$. Hence if we can find HS before restoring $\texttt{candi}(*)$, it is easy to pick up the edges $Can(e_k;T^p,k)\cap\{e|\partial^+e<\partial^+g\}=\{e\in Can(e_t;T,k-1)|\partial^-e\in HS\}$ from $Can(e_t;T,k-1)$.

In Figure 4.1, when the state goes back from $(T^0,1)$ to $(T^0,2)$, all edges in $Can(e_2;T^0,2)\cap\{e|\partial^+e<\partial^+e_2\}=\{e_4\}$ must be restored from $\texttt{candi}(e_1)=Can(e_1;T^0,1)=\{e_4,e_5\}$ to $\texttt{candi}(e_2)$. The head set of $Can(e_2;T^0,2)\cap\{e|\partial^+e<\partial^+e_2\}$ is equal to $\{v_3\}$. In this case, $e_4\in\texttt{candi}(e_1)$ is put back into $\texttt{candi}(e_2)$ to reconstruct $Can(e_2;T^0,2)$.

Our implementation uses the global variables $\texttt{head}(*)$ to represent each $Head(e_j;T^p,k)$ for $j=1,\ldots,k$ at state (T^p,k). Suppose that each head set is represented by a (not necessarily ascending) doubly linked list. From Lemma 4.4, we require $O(V)$ space for manipulating these head sets.

Now we describe two procedures for manipulating the data structures $\texttt{candi}(*)$, `leave`, and $\texttt{head}(*)$ when the current state (T^p,k) goes to a succeeding state $(T,k-1)$ or $(T,k-1)$ goes back to (T^p,k), respectively. The procedure for the first case is shown below.

PROCEDURE update-data-structure(e_k,g);
{the current state (T^p,k) goes to a succeeding state $(T,k-1)=(T^p\backslash e_k\cup g,k-1)$}
begin
  e_t := the edge in T^0 with $\partial^-e_t=\partial^+g$ if it exists, otherwise return;
  move $\{e\in\texttt{candi}(e_k)|\partial^+e<\partial^+g\}$ from $\texttt{candi}(e_k)$ to $\texttt{candi}(e_t)$;
  if $\texttt{candi}(e_t)$ changes from empty to nonempty **then** insert e_t into `leave`;
  HS := the head set of the edges in $\{e\in\texttt{candi}(e_k)|\partial^+e<\partial^+g\}$;
  for each maximal sublist of consecutive elements of HS in $\texttt{head}(e_k)$ **do begin**
    record the first element of the sublist and its position in $\texttt{head}(e_k)$ on a stack;
    delete the sublist from $\texttt{head}(e_k)$;
    add this to the end of $\texttt{head}(e_t)$;
  end;
  record the position of the first element of HS in $\texttt{head}(e_t)$ on a stack;
end.

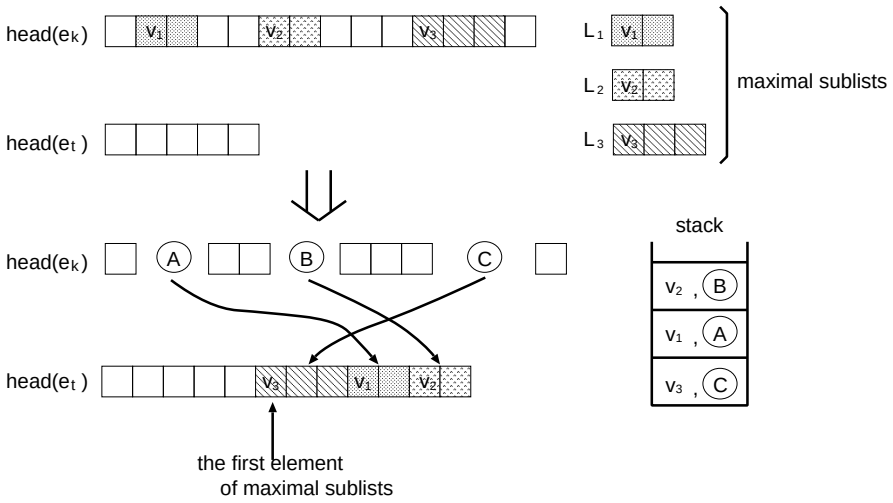

FIG. 4.2. *Update of* `head`$(*)$.

When the state changes from (T^p, k) to $(T, k-1)$, we must move the head set HS of all edges in $Can(e_k; T^p, k) \cap \{e | \partial^+ e < \partial^+ g\}$ from `head`(e_k) to `head`(e_t). At this time, we do not move each element of HS one by one but move each maximal sublist of consecutive elements of HS in `head`(e_k) to `head`(e_t) as Figure 4.2. Then the extra space for recording positions of such maximal sublists is $O(V)$ in all because the number of maximal sublists is at most $|\texttt{head}(e_k) \setminus HS| + 1$, and `head`$(e_k) \setminus HS$ is unchanged until the state comes back to (T^p, k). It is easy to manipulate `head`$(*)$ in the same time as `candi`$(*)$ because $|HS| \leq |Can(e_k; T^p, k) \cap \{e | \partial^+ e < \partial^+ g\}|$. Here we omit details. Thus the time complexity of the procedure is $O(|Can(e_t; T^p, k)| + |Can(e_k; T^p, k) \cap \{e | \partial^+ e < \partial^+ g\}| + |\{e_j | j < t \text{ and } Can(e_j; T^p, k) \neq \emptyset\}|)$.

The second procedure restores data structures in the following way.

PROCEDURE restore-data-structure(e_k,g);
{the state $(T^p \backslash e_k \cup g, k-1)$ goes back to (T^p, k)}
begin
  e_t := the edge in T^0 with $\partial^- e_t = \partial^+ g$ if it exists, otherwise return;
  find HS by the record of the position of its first element in `head`(e_t);
  delete HS from `head`(e_t);
  move $\{e \in$ `candi`$(e_t) | \partial^- e \in HS\}$ from `candi`(e_t) to the beginning of `candi`(e_k);
  if `candi`(e_t) changes from nonempty to empty **then** delete e_t from `leave`;
  move each sublist in HS to the correct place in `head`(e_k)
    by using records on a stack;
end.

Since we recorded the first element of head vertices which were added to `head`(e_t), we can find HS in constant time. For each edge in `candi`(e_t), we can check in constant time whether it is in HS by marking all elements of HS in advance. Hence we can restore `candi`$(*)$ in $O(|Can(e_t; T, k-1)|) = O(|Can(e_t; T^p, k)| + |\{e \in Can(e_k; T^p, k) | \partial^+ e < \partial^+ g\}|)$ time. The deletion of an edge from `leave` is completed in constant time. The

head set HS is returned from $\texttt{head}(e_t)$ to $\texttt{head}(e_k)$ in time proportional to the number of maximal sublists by the information of the places in $\texttt{head}(e_k)$. Therefore, procedure restore-data-structure( ) takes $O(|Can(e_t; T^p, k)| + |\{e \in Can(e_k; T^p, k) | \partial^+ e < \partial^+ g\}|)$ time.

5. An optimal implementation and its analysis. Finally, we describe our efficient implementation and analyze its time and space complexities. Our implementation is shown below.

ALGORITHM all-spanning-trees(G);
input: a graph G with a vertex set $\{v_1, \ldots, v_V\}$ and an edge set $\{e_1, \ldots, e_E\}$;
begin
by using a depth-first search, (simultaneously) execute
- find a depth-first spanning tree T^0 of G,
- sort vertices and edges to satisfy assumptions 2, 3, 4, and 5,
- for each $e_j \in T^0$, $\texttt{candi}(e_j) := \{e | e \notin T^0, \partial^+ e \leq \partial^+ e_j \text{ and } \partial^- e = \partial^- e_j\}$,
- for each $e_j \in T^0$, $\texttt{head}(e_j) := \{\partial^- e_j\}$,
- $\texttt{leave} := \{e_j \in T^0 | \texttt{candi}(e_j) \neq \emptyset\}$;

output("$e_1, e_2, \ldots, e_{V-1}, tree$,"); {output T^0}
find-children( ); {of T^0}
end.

PROCEDURE find-children( ); {T^p:current spanning tree}
begin
if $\texttt{leave} = \emptyset$ **then** return;
$Q := \emptyset$;
$e_k :=$ the last entry of leave;
delete e_k from leave;
while $\texttt{candi}(e_k) \neq \emptyset$ **do begin**
$g :=$ the last entry of $\texttt{candi}(e_k)$;
delete g from $\texttt{candi}(e_k)$, and add g to the beginning of Q;
output("$-e_k, +g, tree$,"); {output $T^c := T^p \backslash e_k \cup g$}
update-data-structure(e_k,g);
find-children( ); {find children of T^c}
restore-data-structure(e_k,g);
output("$-g, +e_k$,"); {reconstruct $T^p := T^c \cup e_k \backslash g$}
end;
move all entries of Q to $\texttt{candi}(e_k)$;
update-data-structure(e_k,e_k);
find-children( ); {find children of T^p containing e_k}
restore-data-structure(e_k,e_k);
add e_k to the end of leave;
end.

Now we discuss the time complexity of our implementation. The next lemma is useful for analyzing the time complexity.

LEMMA 5.1 (see [9]). *Suppose that T is a spanning tree and that k is a positive integer with $e_k < \text{Min}(T^0 \setminus T)$. Under Assumptions* 1, 2, 3, *and* 4, *for any edge $g_j \in \{e_j\} \cup Can(e_j; T, k)$ $(j \leq k)$, $T' = T \setminus \{e_1, \ldots, e_k\} \cup \{g_1, \ldots, g_k\}$ is a spanning tree.*

Proof. Let $T^j = T \setminus \{e_j, \ldots, e_k\} \cup \{g_j, \ldots, g_k\}$ for $j = 1, \ldots, k$. Obviously, T^k is a spanning tree. We suppose that T^j is a spanning tree. If $j \geq 2$, from Lemma 4.3, $Can(e_{j-1}; T, j-1) \subseteq Can(e_{j-1}; T^j, j-1)$. Thus $T^{j-1} = T^j \backslash e_{j-1} \cup g_{j-1}$ is a spanning tree. □

In algorithm all-spanning-tree( ), the time required other than for calling find-children( ) is $O(V+E)$. At state (T^p, k), $O(\#$ of children of T^p not containing $e_k)$ time is taken to execute procedure find-children( ) other than for the maintenance of data structures. Now we consider the time complexities of the maintenance of data structures. From the discussion in section 4, it takes $O(|Can(e_t; T^p, k)| + |Can(e_k; T^p, k) \cap \{e|\partial^+ e < \partial^+ g\}| + |\{e_j | j < t \text{ and } Can(e_j; T^p, k) \neq \emptyset\}|)$ time to maintain data structures when the state changes between (T^p, k) and $(T^p \backslash e_k \cup g, k-1)$, where e_t is an edge with $\partial^- e_t = \partial^+ g$. We consider the following two cases.

Case A. Maintenance for finding children of T^c (i.e., $g \in Can(e_k; T^p, k)$).

Case B. Maintenance for finding children of T^p containing e_k (i.e., $g = e_k$).

Note that Case A occurs exactly one time for each spanning tree T^c other than T^0 and that Case B occurs at most one time for each spanning tree T^p and for each edge $e_k \in \{e | e_1 \leq e < \mathrm{Min}(T^0 \setminus T^p)\}$. In Case A, $|Can(e_t; T^p, k)| + |Can(e_k; T^p, k) \cap \{e|\partial^+ e < \partial^+ g\}|$ is bounded by the number of children of T^c not containing e_t. Moreover, for each edge e_j with $j < t$ and $Can(e_j; T^p, k) \neq \emptyset$, there is a child of T^c not containing e_j. Therefore, the time complexity in Case A is $O(\#$ of children of $T^c)$. In Case B, $|Can(e_k; T^p, k) \cap \{e|\partial^+ e < \partial^+ e_k\}|$ is bounded by the number of children of T^p not containing e_k. From Lemma 5.1, T^p has at least $|\{e \in Can(e_k; T^p, k) | \partial^+ e < \partial^+ e_k\}| \times |Can(e_t; T^p, k)|$ grandchildren which contain neither e_k nor e_t. Similarly, $|\{e_j | j < t \text{ and } Can(e_j; T^p, k) \neq \emptyset\}|$ is bounded by the number of grandchildren of T^p not containing e_k. Thus the time complexity in Case B is

$$O(\#\text{ of children of } T^p \text{ not containing } e_k) + O(\#\text{ of grandchildren of } T^p \text{ not containing } e_k).$$

We recall that procedure find-children( ) checks in constant time whether T^p has children. From the above discussion, the total required time of find-children( ) at state (T^p, k) is

$$O(\#\text{ of children and grandchildren of } T^p \text{ not containing } e_k).$$

Thus the total time complexity of our implementation is $O(N+V+E)$.

Finally, we consider the space complexity. At any state, the edge sets `candi`(e_j) $(j = 1, \ldots, V-1)$ have no intersection with each other, and neither do the head sets `head`(e_j) $(j = 1, \ldots, V-1)$. Thus we need $O(V+E)$ space for `candi` and $O(V)$ space for `head`. Obviously, the cardinality of `leave` is at most $V-1$. As we described in section 4, the size of the stack recording positions maximal sublists of HS is $O(V)$ in all. The total size of local variables Q in find-children( ) is $O(E)$ because each edge is stored in one of the global variables `candi`$(*)$ or local variables Q. Hence the space complexity of our implementation is $O(V+E)$.

THEOREM 5.2. *The time and space complexities of our implementation are $O(N+V+E)$ and $O(V+E)$, respectively.*

In this paper, we proposed an efficient algorithm for enumerating all spanning trees. This is optimal in sense of time and space complexities.

Acknowledgment. We are greatly indebted to Professor Yoshiko T. Ikebe of Science University of Tokyo for her kind and valuable comments on this manuscript.

SIZE–DEPTH TRADEOFFS FOR THRESHOLD CIRCUITS*

RUSSELL IMPAGLIAZZO†, RAMAMOHAN PATURI†, AND MICHAEL E. SAKS‡

Abstract. The following size–depth tradeoff for threshold circuits is obtained: any threshold circuit of depth d that computes the parity function on n variables must have at least $n^{1+c\theta^{-d}}$ edges, where $c > 0$ and $\theta \leq 3$ are constants independent of n and d. Previously known constructions show that up to the choice of c and θ this bound is best possible. In particular, the lower bound implies an affirmative answer to the conjecture of Paturi and Saks that a bounded-depth threshold circuit that computes parity requires a superlinear number of edges. This is the first superlinear lower bound for an explicit function that holds for any fixed depth and the first that applies to threshold circuits with unrestricted weights.

The tradeoff is obtained as a consequence of a general restriction theorem for threshold circuits with a small number of edges: For any threshold circuit with n inputs, depth d, and at most kn edges, there exists a partial assignment to the inputs that fixes the output of the circuit to a constant while leaving $\lfloor n/(c_1k)^{c_2\theta^d} \rfloor$ variables unfixed, where $c_1, c_2 > 0$ and $\theta \leq 3$ are constants independent of n, k, and d.

A tradeoff between the number of gates and depth is also proved: any threshold circuit of depth d that computes the parity of n variables has at least $(n/2)^{1/2(d-1)}$ gates. This tradeoff, which is essentially the best possible, was proved previously (with a better constant in the exponent) for the case of threshold circuits with polynomially bounded weights in [K. Siu, V. Roychowdury, and T. Kailath, *IEEE Trans. Inform. Theory*, 40 (1994), pp. 455–466]; the result in the present paper holds for unrestricted weights.

Key words. threshold circuits, circuit complexity, lower bounds

1. Introduction.

A fundamental problem in complexity theory is to prove lower bounds on the size and the depth of general Boolean circuits for specific problems of interest such as arithmetic operations, graph reachability, linear programming, and satisfiability [11, 8, 5]. Unfortunately, current research has not begun to provide lower bounds for such computationally significant problems in general models. For example, the best known lower bound on the size of Boolean circuits over the standard basis {AND, OR, NOT} for any problem in **NP** is a $4n - 4$ bound on the parity function [20]; over the basis of all two-input functions, the best known lower bound is $3n - 3$ [4].

Since proving bounds for general circuits seems very difficult, it is interesting to look at restricted families of circuits, for example, small-depth circuits over various bases. Some of these classes of circuits are interesting on their own. For example, the size and the depth required for unbounded-fan-in circuits over the basis {AND, OR, NOT} to compute a function f are the same as the number of processors (up to a polynomial factor) and the parallel time (up to a constant factor) required to compute f on a CREW PRAM model.

Another basis of interest is the family of linear threshold gates. Circuits over this basis, threshold circuits, have attracted interest as a model for neural networks [14, 12] and because of the potential that hardware implementations of threshold circuits might become a reality [15]. Bounded-depth threshold circuits are also appealing theoretically since they provide a surprisingly strong bounded-depth computational model. Indeed, it has been shown that basic operations like addition, multiplication, division, and sorting can be performed by bounded-depth polynomial-size threshold circuits [7, 17, 22, 5, 2, 6, 24, 27, 13]. On the other hand, unbounded-fan-in bounded-depth polynomial-size circuits over the standard basis (even when supplemented with mod p gates for prime p) cannot compute majority [5, 21, 25]. Therefore, separating the class of functions computable by bounded-depth polynomial-size threshold circuits, TC^0, from those computable by polynomial-time Turing machines would be an extremely interesting result in complexity theory.

In this paper, we give the first superlinear separation between bounded-depth threshold circuits and **P**. More precisely, our main result (Theorem 1 and its refinement, Theorem 3) says that for any threshold circuit with n inputs, depth d, and kn edges, there exists a partial assignment to the inputs that fixes the output of the circuit to a constant while leaving at least $\lfloor n/(c_1k)^{c_2\theta^d} \rfloor$ variables unfixed, where $c_1, c_2 > 0$ and $\theta \leq 3$ are constants. In particular, this implies (Corollary 2 and its refinement, Corollary 4) that any depth-d circuit that computes the parity function on n variables must have at least $n^{1+c\theta^{-d}}$ edges for the same θ and some constant $c > 0$, proving the conjecture of Paturi and Saks [18]. (The value of θ obtained in this paper is $1 + \sqrt{2} = 2.414\ldots$, as compared to the value $(1 + \sqrt{5})/2 = 1.618\ldots$ in the upper bound given in [18].) In particular, any linear-size threshold circuit for parity requires depth $\Omega(\log \log n)$, matching the upper bound given in [18].

The only lower bounds known previously for the number of edges needed to compute the parity function were for depth-2 and depth-3 circuits with polynomial-size weights. In [18], it is proved that $\Omega(n^2/\log^2 n)$ edges are required for depth-2 threshold circuits and $\Omega(n^{1.2}/\log^{5/3} n)$ edges are required for depth-3 circuits. These results are obtained by showing that small-size depth-2 and depth-3 threshold circuits can be approximated by low-degree rational functions. The results in this paper are more general in that they hold for threshold circuits with arbitrary weights and all depths. However, for the special cases mentioned above, our techniques yield weaker bounds.

Our proof uses a random restriction method as in [1, 9, 26, 10, 16]. However, unlike previous proofs, our proof uses a distribution on the partial assignments that depends on the structure of the circuit. The main restriction lemma (Lemma 3.1) shows that for any family of linear threshold gates on a common set of n variables with a total of δn edges, there is a partial assignment that leaves $n/(4\delta^2 + 2)$ variables free and makes every gate in the family dependent on at most one variable. Given a threshold circuit, this lemma can be applied to the set of gates at the first level in order to reduce the depth of the circuit by 1. A straightforward induction argument then yields the main result with $\theta = 3$. A more careful induction argument improves this to $\theta = 1 + \sqrt{2}$.

In fact, the restriction lemma applies to a more general class of functions than threshold functions, called *generalized monotone* functions. A Boolean function $f(\vec{x})$ is *generalized monotone* if $f(\vec{x}) = g(\vec{x} \oplus \vec{b})$ for some monotone Boolean function g and Boolean vector $\vec{b}$, where $\oplus$ represents the componentwise addition mod 2. (These functions are sometimes referred to in the literature as "unate.")

We also prove analogous results for the number of gates in a small-depth threshold

circuit. We prove a lemma (Lemma 3.2) that is analogous to Lemma 3.1 and says that for any family of N generalized monotone function gates on a common set of n variables there is a partial assignment that leaves $n/(N^2+1)$ variables free and fixes all of the functions. This result, together with a simple induction argument, proves Theorem 2—that for any threshold circuit with n inputs, depth d, and N gates, there exists a partial assignment to the inputs that fixes the output of the circuit to a constant while leaving at least $\lfloor n/2N^{2(d-1)} \rfloor$ variables unfixed. This theorem easily implies a $(n/2)^{1/2(d-1)}$ bound on the number of threshold gates required to compute parity by a depth-d threshold circuit (Corollary 3). A similar bound ($\Omega(dn^{1/d}/\log^2 n)$) was obtained previously in [23] in the special case of circuits with polynomial-size weights. Beigel [3] obtains similar bounds for a more general circuit model that allows any subexponential number of AND, OR, and NOT gates.

Section 2 contains definitions and some preliminary observations. In section 3, we state the main restriction theorem with $\theta = 3$ and show how it follows from Lemma 3.1. We also formalize the statement of Theorem 2 and show how it follows from Lemma 3.2. These two lemmas are proved in the succeeding two sections. In section 6, a more careful argument is used to improve the value of θ in the main restriction theorem to $1+\sqrt{2}$. In the last section, we present some related combinatorial results and discuss some possible strengthenings.

2. Preliminaries. A *threshold gate* with fan-in n is an $(n+1)$-tuple $g = (\vec{w}; b)$, where $\vec{w} \in \mathbf{R}^n$ and $b \in \mathbf{R}$. w_i is called the *weight* of variable i and b is called the *threshold value* for the gate. The Boolean function $f_g : \{0,1\}^n \to \{0,1\}$ computed by g is defined on input $(x_1, \ldots, x_n) = \vec{x} \in \{0,1\}^n$ by $f_g(\vec{x}) = \operatorname{sgn}(g(\vec{x}))$, where the weighted sum $g(\vec{x})$ is given by $g(\vec{x}) = \langle \vec{w}, \vec{x} \rangle - b = \sum_{i+1}^{n} w_i x_i - b$ and $\operatorname{sgn} : \mathbf{R} \to \{0,1\}$ is defined as

$$\operatorname{sgn}(\alpha) = \begin{cases} 1 & \text{if } \alpha > 0, \\ 0 & \text{otherwise.} \end{cases}$$

A Boolean function f which is representable as f_g for some threshold gate is called a *threshold function*.

A threshold circuit T on n inputs is a directed acyclic graph with a designated node (output) and exactly n *source* nodes, one for each input. Each nonsource node is labeled by a threshold gate with its fan-in equal to the in-degree of the node. The function $f_v(x_1, \ldots, x_n)$ computed by the node v is obtained by functional composition in the obvious way. The function $f_T : \{0,1\}^n \to \{0,1\}$ computed by T is the function computed by the designated output node.

The *gate complexity* of T is defined as the number of nonsource nodes of T. The *edge complexity* of T is defined as the number of edges in T.

The *level* of a node in a circuit T is defined inductively. The level of each source node is 0. The level of any other node i is one more than the maximum level of its immediate predecessors. The *depth* of T is the level of the output node. The circuit T is *layered* if the inputs to each gate are from gates of level one less.

It will be convenient to fix a variable set X of cardinality n and define an *assignment* of X to be a function $\alpha : X \to \{0,1\}$. Letting $\mathcal{A}(X)$ denote the set of assignments, we then view an n-variable Boolean function f as a function from $\mathcal{A}(X)$ to $\{0,1\}$. We say that f *depends on* variable $x \in X$ if there are two assignments α and β that differ only in their values at x such that $f(\alpha) \neq f(\beta)$. The set of variables that f depends on is denoted by $S(f)$, and $s(f) = |S(f)|$.

As usual, we write $\alpha \leq \beta$ if $\alpha(x) \leq \beta(x)$ for all $x \in X$, and we denote the complement of α by $\overline{\alpha}$. A monotone Boolean function h is one that satisfies $h(\alpha) \leq h(\beta)$ whenever $\alpha \leq \beta$. The sum $\alpha \oplus \beta$ of two assignments is defined by $(\alpha \oplus \beta)(x) = (\alpha(x) + \alpha(y)) \bmod 2$. A Boolean function f is a *generalized monotone* function if there exists an assignment β and a monotone function h such that $f(\alpha) = h(\alpha \oplus \beta)$. The assignment β is called an *orientation* of f. It is easy to see that any threshold function is a generalized monotone function g and β is an orientation of g if and only for each in variable x in $S(f)$, $\beta(x) = \operatorname{sgn}(w_x)$, where w_x is the weight of the variable x.

A *partial assignment* α of X is a function from a subset Y of X to $\{0,1\}$. The domain Y of α is denoted $\Delta(\alpha)$, and elements $x \in Y$ are said to be *assigned* or *fixed* by α. The variables in the set $\Phi(\alpha) = X - \Delta(\alpha)$ are said to be *unassigned* or *free*. We denote by $\mathcal{P}(X)$ the set of all partial assignments of X. This set contains $\mathcal{A}(X)$; if we wish to emphasize that an assignment α is in $\mathcal{A}(X)$, we say that it is a *total assignment*. If Y is a subset of variables and α is a total assignment, then α_Y denotes the partial assignment with domain Y and $\alpha_Y(x) = \alpha(x)$ for $x \in Y$.

If α and β are partial assignments such that $\Delta(\beta) \subseteq \Delta(\alpha)$ and $\beta(x) = \alpha(x)$ for $x \in \Delta(\beta)$, then we say that α *extends* or is an *extension* of β. If α and β are partial assignments that fix disjoint sets of variables, then the partial assignment $\alpha\beta$ is the unique minimal extension of both α and β. For a Boolean function f and a partial assignment α, the *restriction of f induced by α*, written as $f(\alpha)$, is the Boolean function with variable set $\Phi(\alpha)$ obtained by assigning the variables in $\Delta(\alpha)$ according to α.

An *ordering* of a set Y is a bijection $\Gamma : [|Y|] \to Y$, where $[k]$ denotes the set $\{1, 2, \ldots, k\}$. Given Γ, we refer to $\Gamma(i)$ as the ith element of Y. Also, $\Gamma(\leq i)$ denotes the set $\{\Gamma(j) : j \leq i \text{ and } j \in [|Y|]\}$ and $\Gamma(\geq i)$ denotes the set $\{\Gamma(j) : j \geq i \text{ and } j \in [|Y|]\}$.

The following simple lemma states the main property of the generalized monotone functions that is used in this paper.

LEMMA 2.1. *Let f be a nonconstant generalized monotone function on X with an orientation β, and let Γ be an ordering of X. Then there exists a $j \in \{0, 1, \ldots, n\}$ such that $f(\beta_{\Gamma(\leq j)})$ is identically 0 and $f(\bar{\beta}_{\Gamma(\geq j)})$ is identically 1.*

Proof. Label the elements of X as $x_1, \ldots, x_n$ according to the ordering Γ. Any assignment α is identified with the vector $(\alpha(x_1), \ldots, \alpha(x_n))$. Consider first the case that f is monotone, i.e., $\beta = 0^n$. Since f is not a constant function, we have $f(0^n) = 0$ and $f(1^n) = 1$. Let j be the least index such that $f(0^j 1^{n-j}) = 0$. This implies that $f(\beta_{\Gamma(\leq j)})$ is identically 0. $j \geq 1$ since f is not a constant function. Then $f(0^{j-1}1^{n-j+1}) = 1$, which implies that $f(\bar{\beta}_{\Gamma(\geq j)})$ is identically 1 by monotonicity since every total assignment that extends $\bar{\beta}_{\Gamma(\geq j)}$ is greater than or equal to $0^{j-1}1^{n-j+1}$.

In the case that f is not monotone, the desired result follows immediately by applying the previous argument to the monotone function $h(\alpha) = f(\alpha \oplus \beta)$. □

One useful consequence of this lemma is the following.

COROLLARY 1. *Any generalized monotone function f on n variables has a partial assignment α that leaves at least $\lfloor n/2 \rfloor$ variables free, such that $f(\alpha)$ is constant.*

3. Results. Our main result concerns the computational power of depth-d threshold circuits with a small number of edges.

THEOREM 1. *Let C be an n-input threshold circuit with depth d and nk edges, where $k \geq 1$. Let f denote the function computed by C. Then there exists a partial assignment α that leaves at least $\lfloor n/(2(3k)^{3^{d-1}-1}) \rfloor$ variables free such that $f(\alpha)$ is a*

constant function.

If f is the parity function, then $f(\alpha)$ is constant only if α is a total assignment. Thus it follows from Theorem 1 that if C is a depth-d circuit with nk edges that computes the parity function on n variables, then $n < 2(3k)^{3^{d-1}-1}$. This yields the following result.

COROLLARY 2. *Any threshold circuit of depth d that computes parity of n variables has at least $n^{1+1/(3^{d-1}-1)}/(3\sqrt{2})$ edges.*

The key to proving Theorem 1 is the following.

LEMMA 3.1 (main lemma). *Let F be a collection of generalized monotone functions on n variables and let $\delta = (1/n)\sum_{f\in F} s(f)$ (so the total support of the functions is $n\delta$). Then there exists a partial assignment α that leaves at least $n/(4\delta^2+2)$ variables free such that for every $f \in F$, $f(\alpha)$ depends on at most one variable.*

Proof of Theorem 1 *from main lemma.* We proceed by induction on the depth d of the circuit. If $d = 1$, the circuit consists of a single threshold gate and the conclusion follows from Corollary 1. For $d > 1$, let F be the family of functions corresponding to the gates at depth 1. By hypothesis, the sum of the fan-ins of these gates is at most nk. Lemma 3.1 implies that there is a partial assignment that leaves at least $n' = n/(4k^2+2) \geq n/(6k^2)$ variables free such that the induced restriction of each function in F depends on at most one variable. We may then collapse the first level of the circuit, i.e., if g is a gate at depth 2, then each input to g is either an input to the circuit or the output of a gate at level 1, which after the restriction is equal to a variable or its complement. Thus each gate g at depth 2 can now be reexpressed as a threshold gate that depends only on the original inputs. (Note that g may have several edges entering which depend on the same variable, but these can be combined into one edge by adjusting the weights of g.) Hence we obtain a depth-$(d-1)$ circuit C' on at least n' variables with at most $n'k'$ edges, where $k' = 6k^3$ and $nk = n'k'$. By the induction hypothesis, there exists a partial assignment to the variables of C' such that the number of free variables is at least

$$\left\lfloor \frac{n'}{2(3k')^{3^{d-2}-1}} \right\rfloor \geq \left\lfloor \frac{n/(6k^2)}{2(3(6k^3))^{3^{d-2}-1}} \right\rfloor \geq \left\lfloor \frac{n}{2(3k)^{3^{d-1}-1}} \right\rfloor,$$

as required to prove the theorem. □

Remark. Since the main lemma applies to generalized monotone functions, it might appear that Theorem 1 could be generalized to apply to circuits whose gates compute arbitrary generalized monotone functions. However, the proof fails to generalize because when the circuit is collapsed in the induction step, a level-2 gate may have more than one input corresponding to the same variable. In that case, it is not true that the gate computes a generalized monotone function of the original variables; indeed, it is easy to see that *every* n-variable Boolean function can be represented as a single generalized monotone function on $2n$ variables by identifying variables in pairs.

To bound the number of gates in a small-depth circuit instead of the number of edges, we use the following (simpler) relative of Lemma 3.1.

LEMMA 3.2. *Let F be a collection of generalized monotone functions on n variables. Then there exists a partial assignment α that leaves at least $\lfloor n/(|F|^2+1)\rfloor$ variables free such that for each $f \in F$, $f(\alpha)$ is a constant function.*

This leads to the following result for threshold circuits with a small number of gates. In this case, the result holds for generalized monotone functions.

THEOREM 2. *Let C be a circuit consisting of generalized monotone function gates of depth d on n inputs with at most N gates. Then there exists a partial assignment α leaving $\lfloor n/2N^{2(d-1)} \rfloor$ variables free such that $f_C(\alpha)$ is constant.*

Proof of Theorem 2 *from Lemma* 3.2. We proceed by induction on the depth d of the circuit, as in the proof of Theorem 1. If $d = 1$, the circuit consists of a single threshold gate and the conclusion follows from Corollary 1. For $d > 1$, consider the family F of threshold functions corresponding to the depth-1 gates. Note that $|F| \leq N - 1$. We apply Lemma 3.2 to F to obtain a partial assignment that leaves at least $n' = \lfloor n/(|F|^2 + 1) \rfloor \geq \lfloor n/N^2 \rfloor$ variables free such that the induced restriction of each function in F is constant. After the restriction, the only nonconstant inputs to the second-level gates are the inputs to the circuit. Thus the resulting circuit C' has depth at most $d-1$, at most N gates, and at least n' variables. By the induction hypothesis, there exists a partial assignment of the variables of C' which leaves at least $\lfloor n'/2(N)^{2(d-2)} \rfloor \geq \lfloor n/2(N)^{2(d-1)} \rfloor$ variables free (where the inequality follows from the fact that for positive integers n, A, and B, $\lfloor \lfloor n/A \rfloor / B \rfloor = \lfloor n/AB \rfloor$). □

Again using the fact that the only partial assignments that make the parity function constant are the total assignments, we deduce that the number N of gates of a depth-d parity circuit satisfies $2N^{2(d-1)} \geq n$, and thus we have the following.

COROLLARY 3. *Any circuit of depth d consisting of generalized monotone function gates that computes the parity of n inputs has at least $(n/2)^{1/2(d-1)}$ gates.*

Slightly stronger bounds (removing the half from the exponent of the lower bound) than those obtained in Theorem 2 and Corollary 3 were previously proved in [17, 23] for the case of threshold circuits with polynomially bounded weights.

It remains to prove Lemmas 3.1 and 3.2, and these proofs constitute the main part of the paper. The proofs of these lemmas are similar; both use a probabilistic method to demonstrate the existence of the required partial assignment.

The proof of Lemma 3.2 is somewhat simpler, so we present the proof in the next section. The proof of Lemma 3.1 will be presented in section 5.

4. Proof of Lemma 3.2. In the probabilistic arguments in this section and the next, we adopt the following notational convention. Random variables are denoted by placing a ˜ over the identifier. When we refer to a specific value that a random variable may assume, we denote that value by an identifier without a ˜.

We have a family F of Boolean generalized monotone functions on n variables and seek a partial assignment that makes all of the functions constant. It will be convenient to fix an indexing $f^1, f^2, \ldots, f^m$ of the functions in F. Let β^i be an orientation for f^i.

Fix an ordered partition $Y_1, Y_2, \ldots, Y_q$ of the variable set X into $q = m^2+1$ blocks of nearly equal size (each having $\lfloor n/q \rfloor$ or $\lfloor n/q \rfloor + 1$ variables). The desired partial assignment will be obtained by fixing the variables in all but one of the blocks. We describe a randomized procedure P which produces such a partial assignment $\tilde{\alpha}$ and show that with positive probability $f^i(\tilde{\alpha})$ is constant for all $i \in [m]$.

The procedure P is as follows. Let $\mathcal{U}$ be a symbol (meaning "unallocated"). Choose uniformly at random a 1–1 function $\tilde{M}$ from $[m] \times [m] \cup \{\mathcal{U}\}$ to $[q]$. Intuitively, we think of $\tilde{M}$ as "allocating" sets $Y_{\tilde{M}(i,1)}, \ldots, Y_{\tilde{M}(i,m)}$ to function f^i, while leaving set $Y_{\tilde{M}(\mathcal{U})}$ unallocated. In addition, choose a vector $(\tilde{t}_1, \tilde{t}_2, \ldots, \tilde{t}_m)$ uniformly from the set $\{0, 1, 2, \ldots, m\}^m$. For each $1 \leq i, j \leq m$, if $j \leq \tilde{t}_i$, then fix the variables in $Y_{\tilde{M}(i,j)}$ according to β^i, and if $j > \tilde{t}_i$, then fix the variables in $Y_{\tilde{M}(i,j)}$ according to $\bar{\beta}^i$. Thus all of the variables except those in the unique block $Y_{\tilde{M}(\mathcal{U})}$ are fixed. Call the resulting partial assignment $\tilde{\alpha}$.

The key property of this distribution is given by the following lemma.

LEMMA 4.1. *For each $h \in [m]$, the probability that $f^h(\tilde{\alpha})$ is not constant is at most $1/(m+1)$.*

It follows from this lemma that the probability that there exists $i \in [m]$ with $f^i(\tilde{\alpha})$ not constant is at most $m/(m+1)$. Thus there exists a particular α such that $f^i(\alpha)$ is constant for all $i \in [m]$, and this α satisfies the conclusion of Lemma 3.2.

Proof of Lemma 4.1. Fix $h \in [m]$. We define a modification P^h of the procedure P. It will be easy to see that this modified construction produces the same distribution; we then use the modified construction to verify the conclusion of the lemma.

The modified construction is as follows. Choose $\tilde{t'}_i \in \{0, \ldots, m\}$ uniformly at random for $i \neq h$, and pick $\tilde{t'}_h \in \{1, \ldots, m+1\}$ uniformly at random. Pick $\tilde{M'}$, a random 1–1 function from $[m] \times [m] \cup \{(h, m+1)\}$ to $[q]$. For $i \neq h$, assign variables in $Y_{\tilde{M'}(i,j)}$ as before, according to β^i if $j \leq \tilde{t'}_i$ and according to $\bar{\beta^i}$ otherwise. For $j < \tilde{t'}_h$, assign the variables in $Y_{\tilde{M'}(h,j)}$ according to β^h, and for $j > \tilde{t'}_h$, assign them according to $\bar{\beta^h}$. We leave the variables in $Y_{\tilde{M'}(h,\tilde{t'}_h)}$ unassigned.

As in the original procedure, each gate is allocated m random sets of variables, with one random set of variables being unallocated. For each gate, the number of these sets fixed according to the orientation of the gate is randomly chosen between 0 and m, and the rest are set according to the negation of the orientation. Thus the two distributions are identical. More formally, we could define $\tilde{M}(i,j) = \tilde{M'}(i,j)$ for $i \neq h$, $\tilde{M}(h,j) = \tilde{M'}(h,j)$ for $j < \tilde{t_h}'$, $\tilde{M}(h,j) = \tilde{M'}(h,j+1)$ for $\tilde{t'}_h < j \leq m$, and $\tilde{M}(\mathcal{U}) = \tilde{M'}(h, \tilde{t_h}')$ and define $\tilde{t}_i = \tilde{t'}_i$ for $i \neq h$, $\tilde{t}_h = \tilde{t'}_h - 1$. Then the distributions on $\tilde{M}$ and $\tilde{t}$ are identical to those in the original process, and all values M and $t_1, \ldots, t_m$ of these random variables, if chosen by the original process, would determine the same value of α as M' and the t'_i's do in the modified process.

Thus it will suffice to upper bound the probability that $f^h(\tilde{\alpha})$ is not constant when $\tilde{\alpha}$ is constructed according to P^h. For this, fix any value M' for $\tilde{M'}$, and fix values t'_i for $\tilde{t'}_i$, $i \neq h$. This determines the setting of $\tilde{\alpha}$ for all the variables in $Y_{M'(i,j)}$ for $i \neq h$. We will show that, given the above information, the probability that f^h is nonconstant when restricted by $\tilde{\alpha}$ is at most $1/m + 1$. Let g be f^h restricted to the variables in the blocks $Y_{h,j}$, $1 \leq j \leq m+1$, with the other variables set according to $\tilde{\alpha}$. (As we noted before, the value of $\tilde{\alpha}$ at all other variables has been fixed by the information that we are conditioning on.) g is a generalized monotone function with the same orientation β^h as f^h.

For each block $Y_{M'(h,j)}$, fix an arbitrary order on variables of the block; extend these orders to an ordering Γ on all the variables for g by ordering the blocks according to j. Then we can apply Lemma 2.1 to obtain an index l such that the functions $g(\beta^h_{\Gamma(\leq l)})$ and $g(\bar{\beta}^h_{\Gamma(\geq l)})$ are both constant. Let $0 \leq r \leq m+1$ be such that $\Gamma(l) \in Y_{M'(h,r)}$, i.e., the lth variable is in the rth block allocated to f^h. We claim that $g(\tilde{\alpha})$—and hence $f^h(\tilde{\alpha})$—is constant unless $\tilde{t'}_h = r$, an event which happens with probability $1/(m+1)$ (since $\tilde{t'}_h \in [m+1]$ is chosen independently from $\tilde{M'}$ and the $\tilde{t'}_i$'s for $i \neq h$.). If $\tilde{t'}_h > r$, all variables in blocks labeled r or less are fixed by $\tilde{\alpha}$ to β^h, so $\tilde{\alpha}$ extends $\beta^h_{\Gamma(\leq l)}$, so $g(\tilde{\alpha})$ is constant. Similarly, if $\tilde{t'}_h < r$, $\tilde{\alpha}$ extends $\bar{\beta^h}_{\Gamma(\geq l)}$ and $g(\tilde{\alpha})$ is constant. Thus with probability $1 - 1/(m+1)$, $f^h(\tilde{\alpha}) = g(\tilde{\alpha})$ is constant, as required to complete the proof of Lemma 4.1 and hence of Lemma 3.2. □

5. Proof of the main lemma. Again, index the functions in F as $f^1, \ldots, f^m$ and let β^i denote an orientation for f^i. For each variable x, let D_x be the subfamily of F that consists of those functions that depend on variable x and let $\delta_x = |D_x|$.

Thus the quantity $\delta = (1/n)\sum_{f\in F} s(f)$ in the lemma is also the average of the δ_x's. We seek a partial assignment α that leaves at least $n/(4\delta^2+2)$ variables free and such that for every $f \in F$, $f(\alpha)$ depends on at most one variable.

We will describe a randomized algorithm $A(L)$, where L is a positive real parameter, for constructing a partial assignment $\tilde{\alpha}$ and show that, for an appropriate choice of L, $\tilde{\alpha}$ has the desired properties with positive probability. The random procedure in the previous proof can be viewed as associating a fraction $m/(m^2+1)$ of the variables to each function and then fixing the variables associated with a function in a way that is determined by the orientation of the function. We will do something similar here; however, here we will require that the set of variables assigned to f^i is a subset of $S(f^i)$, the set of variables on which f^i depends.

PROCEDURE $A(L)$.

1. *Partition the variables.* (Intuitively, this step assigns each function a set of variables in proportion to its support size, leaving a few variables unassigned.) Construct a random partition of the variable set X into $m+1$ parts $\tilde{R}, \tilde{C}_1, \tilde{C}_2, \ldots, \tilde{C}_m$. For each variable x, the block of the partition containing x is determined independently according to the following rule. With probability $1/(1+L\delta_x)$, $x \in \tilde{R}$. Otherwise, x is assigned to block $\tilde{C}_{\tilde{i}(x)}$, where $\tilde{i}(x)$ is the index of a uniformly chosen element of D_x. In other words, for each $f^i \in D_x$, the probability that $x \in \tilde{C}_i$ is $L/(1+L\delta_x)$. Let $\tilde{r} = |\tilde{R}|$ and for each $i \in [m]$, let $\tilde{c}_i = |\tilde{C}_i|$.

2. *For each $i \in [m]$, fix all of the variables in $\tilde{C}_i$.* (Intuitively, this step fixes the variables assigned to each f^i so that any particular function f^i becomes constant with a good probability.) For each $i \in [m]$, choose $\tilde{b}_i$ uniformly at random from $\{0, 1, \ldots, \tilde{c}_i\}$. Choose a subset $\tilde{B}_i$ of $\tilde{C}_i$ uniformly from all $\tilde{b}_i$-element subsets of $\tilde{C}_i$. Let $\tilde{\gamma}^i$ denote the partial assignment which fixes the variables of $\tilde{B}_i$ according to β^i and fixes the variables of $\tilde{C}_i - \tilde{B}_i$ according to $\bar{\beta}^i$. Let $\tilde{\gamma}$ be the union of the partial assignments $\tilde{\gamma}^i, i \in [m]$.

3. *Fix some of the variables in $\tilde{R}$.* (Intuitively, this step cleans up the few remaining functions that are still nonconstant so that they depend on at most one variable.) For each $i \in [m]$, let $\tilde{T}_i$ denote the set of variables on which $f^i(\tilde{\gamma})$ depends, and if $\tilde{T}_i \neq \emptyset$, let $\tilde{T'}_i$ be an arbitrary subset containing all but one element of $\tilde{T}_i$; otherwise, $\tilde{T'}_i = \emptyset$. Let $\tilde{\alpha}$ be the restriction obtained from $\tilde{\gamma}$ by setting all the elements of each $\tilde{T'}_i$ to 1.

The third step above ensures that the partial assignment $\tilde{\alpha}$ has the required property that $f^i(\tilde{\alpha})$ depends on at most one variable for each i. Thus it remains to show that with positive probability the number $\tilde{\phi}$ of variables left free is sufficiently large.

The set of free variables of $\tilde{\alpha}$ consists of those variables in $\tilde{R}$ that are not fixed during step 3. Thus $\tilde{\phi} \geq \tilde{r} - \sum_{i=1}^{m} \max\{0, |\tilde{T}_i| - 1\}$. Our goal is to obtain a lower bound on the expectation of $\tilde{\phi}$. Note that $\mathbf{E}[\tilde{r}] = \sum_{x\in X} 1/(L\delta_x + 1)$.

The harder part is to upper bound the expectation of $a(|\tilde{T}_i|)$, where $a(m) = \max\{0, m-1\}$. The key lemma of this section is the following.

LEMMA 5.1. *For each $h \in [m]$,*

$$\mathbf{E}[a(|\tilde{T}_h|)] \leq \frac{1}{L} \sum_{x\in S(f^h)} \frac{1}{L\delta_x + 1}.$$

Assuming this lemma for the moment, we have

$$\begin{aligned}
\mathbf{E}[\tilde{\phi}] &\geq \mathbf{E}[\tilde{r}] - \sum_{i=1}^{m} \mathbf{E}[a(|\tilde{T}_i|)] \\
&\geq \sum_{x \in X} \frac{1}{(Ld_x + 1)} - \sum_{i=1}^{m} \frac{1}{L} \sum_{x \in S(f^i)} \frac{1}{L\delta_x + 1} \\
&\geq \sum_{x \in X} \frac{1}{(Ld_x + 1)} - \frac{1}{L} \sum_{x \in X} \sum_{f_i \in D_x} \frac{1}{L\delta_x + 1} \\
&\geq \sum_{x \in X} \frac{1}{(Ld_x + 1)} - \sum_{x \in X} \frac{\delta_x / L}{L\delta_x + 1} \\
&= \sum_{x \in X} \frac{1 - \delta_x / L}{L\delta_x + 1} \\
&\geq n \left(\frac{1 - \delta / L}{L\delta + 1} \right),
\end{aligned}$$

where the last inequality follows from the convexity of the function $\lambda(z) = (1 - z/L)/(Lz + 1)$ for positive z and the fact (Jensen's inequality) that the arithmetic mean of a convex function on a set is at least the function evaluated at the mean value of the set. Choosing the parameter $L = 2\delta$ to (approximately) maximize this quantity, we will have that the expectation of $\tilde{\phi}$ is at least $n/(4\delta^2 + 2)$. Thus among the partial assignments that could be produced by the procedure $A(2\delta)$, there must exist a partial assignment that leaves at least $n/(4\delta^2 + 2)$ variables free, as required to prove the main lemma.

It remains to prove Lemma 5.1. Fix $h \in [m]$. Let $\tilde{\chi}_h$ denote the random variable which is 1 if the hth function is not fixed after step 2, i.e., if $f^h(\tilde{\gamma})$ is not constant, and is 0 if $f^h(\tilde{\gamma})$ is constant. Clearly, $\tilde{T}_h$ is empty if $\tilde{\chi}_h = 0$, and otherwise $\tilde{T}_h$ is a subset of the set $\tilde{U}_h = \tilde{R} \cap S(f^h)$. Letting $\tilde{u}_h$ denote the cardinality of $|\tilde{U}_h|$, we have $a(|\tilde{T}_h|) \leq \tilde{\chi}_h a(\tilde{u}_h)$. Lemma 5.1 is an immediate consequence of the following Lemma.

LEMMA 5.2. *Let $h \in [m]$ and let q be an arbitrary nonnegative-valued function defined on the natural numbers. Then*

$$\mathbf{E}[\tilde{\chi}_h q(\tilde{u}_h)] \leq \frac{1}{L} \mathbf{E}[q(\tilde{u}_h + 1)].$$

Applying this lemma with $q = a$, the right-hand side of the inequality is just $\mathbf{E}[\tilde{u}_h]/L$, which by linearity of expectation is

$$\frac{1}{L} \sum_{x \in S(f^h)} \mathbf{P}[x \in \tilde{R}] = \frac{1}{L} \sum_{x \in S(f^h)} \frac{1}{L\delta_x + 1},$$

as required to prove Lemma 5.1.

Proof of Lemma 5.2. Let $\tilde{K} = \tilde{C}_h \cup \tilde{U}_h$, i.e., the set of variables on which f^h depends that are assigned to either $\tilde{C}_h$ or $\tilde{R}$. Let $\tilde{k} = |\tilde{K}|$.

Fix a particular instantiation C_i and B_i for all $i \neq h$ and let Ξ denote the event that $\tilde{C}_i = C_i$ and $\tilde{B}_i = B_i$ for all $i \neq h$. Note that Ξ determines the value K of $\tilde{K}$ and also determines $\tilde{\gamma}$ on all variables in $S(f^h) - \tilde{K}$. Thus let g be the function of the variables in K determined by restricting f^h according to $\tilde{\gamma}_i$ for each $i \neq h$.

We will show that for any such event Ξ,

$$\mathbf{E}[\tilde{\chi}_h q(\tilde{u}_h) \mid \Xi] \leq \frac{1}{L}\mathbf{E}[q(\tilde{u}_h + 1) \mid \Xi].$$

The lemma then follows by deconditioning the expectation.

Given Ξ, the variables in K are partitioned into the two sets $\tilde{C}_h$ and $\tilde{U}_h$ as follows: for $x \in K$, the conditional probability given Ξ that x is in $\tilde{R}$ (and hence in $\tilde{U}_h$) is $p = 1/(L+1)$, and otherwise (with probability $L/(L+1)$) x is in $\tilde{C}_h$. Furthermore, these events are independently determined for each $x \in K$. Thus the conditional distribution given Ξ of $\tilde{u}_h$ is a binomial distribution $B(k,p)$, i.e., $\mathbf{P}[\tilde{u}_h = i \mid \Xi] = \binom{k}{i}p^i(1-p)^{k-i}$. We have

$$\begin{aligned}\mathbf{E}[\tilde{\chi}_h q(\tilde{u}_h) \mid \Xi] &\leq \sum_{i=0}^{k} q(i)\mathbf{P}[\tilde{u}_h = i \mid \Xi]\mathbf{P}[g(\tilde{\gamma}) \text{ is not constant} \mid \Xi \wedge (\tilde{u}_h = i)] \\ &= \sum_{i=1}^{k} q(i)\binom{k}{i}p^i(1-p)^{k-i}\mathbf{P}[g(\tilde{\gamma}) \text{ is not constant} \mid \Xi \wedge (\tilde{u}_h = i)].\end{aligned}$$

We next determine an upper bound for $\mathbf{P}[g(\tilde{\gamma})\text{is not constant} \mid \Xi \wedge (\tilde{u}_h = i)]$.

The conditional distribution of $\tilde{C}_h, \tilde{B}_h$ given $\Xi \wedge (\tilde{u}_h = i)$ can be described as follows. $\tilde{C}_h$ is a uniformly chosen $(k-i)$-element subset of K, $\tilde{b}_h$ is chosen uniformly at random from $\{0, 1, \ldots, k-i\}$, and $\tilde{B}_h$ is a uniformly chosen $\tilde{b}_h$-element subset of $\tilde{C}_h$.

An alternative way to generate this same distribution on $\tilde{B}_h, \tilde{C}_h$ is as follows: Choose an order $\tilde{\Gamma}$ of the elements of K uniformly at random. Choose $\tilde{b}_h$ uniformly from $\{0, 1, \ldots, k-i\}$. Let $\tilde{B}_h$ be the first $\tilde{b}_h$ elements of K and let $\tilde{C}_h$ consist of $\tilde{B}_h$ together with the last $k - i - \tilde{b}_h$ elements of K. It is clear that this distribution is equivalent to the one described in the previous paragraph.

We want to determine the conditional probability that g is not constant given Ξ and $\tilde{u}_h = i$. Lemma 2.1 applied to the function g and the ordering $\tilde{\Gamma}$ of K implies that there is an index $\tilde{j} = \tilde{j}(\tilde{\Gamma})$ in $\{0, 1, \ldots, k\}$ such that $f(\beta^h_{\tilde{\Gamma}(\leq \tilde{j})})$ is identically 0 and $f(\bar{\beta}^h_{\tilde{\Gamma}(\geq \tilde{j})})$ is identically 1. Now observe that if $\tilde{b}_h$ is chosen to be greater than or equal to $\tilde{j}$, then the partial assignment $\tilde{\gamma}^h$ is an extension of $\beta^h_{\tilde{\Gamma}(\leq \tilde{j})}$ and $f(\tilde{\gamma}^h)$ is thus identically 0. Similarly, if $\tilde{b}_h$ is chosen to be less than $\tilde{j} - i$, then the partial assignment $\tilde{\gamma}^h$ is an extension of $\bar{\beta}^h_{\tilde{\Gamma}(\geq \tilde{j})}$ and $f(\tilde{\gamma}^h)$ is thus identically 1. Thus the only way that $\tilde{\Xi}_h$ can be nonzero is if $\tilde{b}_h$ satisfies $\tilde{j} - i \leq \tilde{b}_h \leq \tilde{j} - 1$, and since $\tilde{b}_h$ is chosen uniformly in the range $\{0, 1, \ldots, k-i\}$, this happens with probability at most $i/(k-i+1)$. We conclude that the conditional probability given $\Xi \wedge (\tilde{u}_h = i)$ that g is not constant is at most $i/(k-i+1)$. Using this probability, we can rewrite the expression for the conditional expectation of $\tilde{\chi}_h q(\tilde{u}_h)$ as

$$\begin{aligned}\mathbf{E}[\tilde{\chi}_h q(\tilde{u}_h) \mid \Xi] &\leq \sum_{i=1}^{k} q(i)\binom{k}{i}p^i(1-p)^{k-i}\frac{i}{k-i+1} \\ &= \frac{p}{1-p}\sum_{i=1}^{k} q(i)\binom{k}{i-1}p^{i-1}(1-p)^{k-(i-1)} \\ &= \frac{p}{1-p}\sum_{i'=0}^{k-1} q(i'+1)\binom{k}{i'}p^{i'}(1-p)^{k-i'}\end{aligned}$$

$$
\begin{aligned}
&= \frac{p}{1-p} \sum_{i'=0}^{k-1} q(i'+1)\mathbf{P}[\tilde{u}_h = i' \mid \Xi] \\
&\leq \frac{p}{1-p}\mathbf{E}[q(\tilde{u}_h + 1) \mid \Xi] \\
&= \frac{1}{L}\mathbf{E}[q(\tilde{u}_h + 1) \mid \Xi],
\end{aligned}
$$

as required to complete the proof of Lemma 5.2, which in turn completes the proofs of Lemma 5.1 and the main lemma. □

6. An improved lower bound. In this section, we present refined versions of Theorem 1 and Corollary 2 for which the parameter θ is reduced from 3 to $1 + \sqrt{2}$. In the following, our results are stated for layered threshold circuits. This is sufficient for our purposes since an arbitrary threshold circuit can be converted to a layered one that computes the same function by increasing the number of edges by a factor of at most d.

To state the improvement of Theorem 1, define ν_i for $i \geq 1$ to be the solution to the recurrence equation $\nu_{i+2} = 2\nu_{i+1} + \nu_i$ with the initial conditions $\nu_1 = 1$ and $\nu_2 = 3$. Note that the explicit expression for ν_i is of the form $A(1+\sqrt{2})^i + B(1-\sqrt{2})^i$, where $A \neq 0$ and B are easily determined constants, and so $\nu_i \in \Theta((1+\sqrt{2})^i)$.

THEOREM 3. *Let C be a layered depth-d threshold circuit with n inputs d and nk edges, where $k \geq 1$. Let f denote the function computed by C. Then there exists a partial assignment α that leaves at least $\lfloor n/4(11k)^{\nu_d - 1} \rfloor$ variables free such that $f(\alpha)$ is a constant function.*

As before, this theorem immediately implies a size–depth tradeoff for the parity function.

COROLLARY 4. *Any threshold circuit of depth $d \geq 2$ that computes parity of n variables has at least $(n/11)^{1+\frac{1}{\nu_d - 1}}$ edges.*

To motivate the proof of Theorem 3, we first summarize the main inductive argument of the previous proof. In each inductive step, the depth of the circuit is decreased by 1 by fixing some variables in order to eliminate the first level. The fraction of variables left unfixed after each step is inversely proportional to the square of the parameter δ, the ratio of the number of edges at the first level to the number of unfixed variables before the step. In analyzing the resulting recurrence, we upper bounded the number of edges at the first level by the total number of edges in the circuit.

The idea for improving this analysis is to substantially improve this upper bound on the number of edges at the first level, thereby increasing the fraction of variables that are known to survive each reduction step. It might seem that since the circuit is arbitrary, we cannot do better than to bound the number of edges at the first level by the total number of edges in the circuit. This is indeed true the first time the reduction is applied. However, it turns out that for all subsequent reduction steps, there is a better bound available. This is because the partial assignment produced by $A(L)$ in the proof of Lemma 3.1 has a very useful side effect: for each first-level gate whose output is fixed to a constant by the partial assignment, the edges leaving that gate can be eliminated from the circuit. We will show that with high probability the number of edges in the second level of the circuit (which becomes the first level) is decreased by a large amount. This allows us to keep a larger fraction of variables

unassigned when we recursively perform the reduction on the first level of the resulting circuit.

To make this idea precise, we need a modified version of Lemma 3.1.

LEMMA 6.1. *Let F be a collection of generalized monotone functions on n variables, and suppose that each function $f \in F$ has a nonnegative weight $w(f)$. Let $\delta = (1/n)\sum_{f\in F} s(f) \geq 1$ and $W = \sum_{f\in F} w(f)$. Then assuming that $n/(9\delta)^2 \geq 4$, there exists a partial assignment α that leaves at least $n/(9\delta)^2$ variables free such that*

1. *for every $f \in F$, $f(\alpha)$ depends on at most one variable*;
2. *$\sum_{f:f(\alpha)\ is\ not\ constant} w(f) \leq W/8\delta$.*

Note that when we apply this lemma in the inductive argument, the weights of the functions will correspond to the out-degree of the corresponding gates. The point is that the total number of edges remaining on the new first level can then be bounded above by $1/8\delta$ times the number of edges in the circuit.

Proof of Lemma 6.1. The proof is a modification of that of Lemma 3.1, and we retain the notation of that lemma. We use procedure $A(L)$ to generate the random restriction $\tilde{\alpha}$. We show the following:

1. With probability at least $1/2$, the sum of the weights of the nonconstant gates is at most $2W/L$.

2. Assuming that $n \geq 16(1 + L\delta)$, then with probability exceeding $1/2$, the number $\tilde{\phi}$ of free variables is at least $n(1 - 8\delta/L)/2(L\delta + 1)$.

If we choose $L = 16\delta$, then it follows immediately that with positive probability $\tilde{\alpha}$ satisfies the conclusion of the lemma, and thus such a partial assignment exists.

Thus it suffices to prove the two claims. For the first claim, using the notation of Lemma 5.2, the sum of the weights of the nonconstant gates can be bounded above by

$$\sum_{h=1}^{m} \tilde{\chi}_h w(f^h).$$

The expectation of a generic term of the sum can be bounded above by $w(f^h)/L$ using Lemma 5.2 with q being the constant function $w(f^h)$. Thus the expectation of the sum is at most W/L. By Markov's inequality, with probability greater than $1/2$, the sum does not exceed $2W/L$.

We now verify the second claim. As in the proof of the main lemma, we write $\tilde{\phi} \geq \tilde{r} - \tilde{s}$, where $\tilde{s}$ denotes $\sum_{i=1}^{m} \max\{0, |\tilde{T}_i| - 1\}$.

Recall that $\tilde{r}$ is the cardinality of $\tilde{R}$. For each $x \in X$, let $\tilde{r}_x$ denote the random variable that is 1 if $x \in \tilde{R}$ and is 0 otherwise; then $\tilde{r} = \sum_{x\in X} \tilde{r}_x$. Thus as observed previously, $\mathbf{E}[\tilde{r}] = \sum_{x\in X} 1/(1 + L\delta_x)$, which is at least $n/(1 + L\delta)$ by the convexity of the function $\lambda(y) = 1/(1 + Ly)$ for nonnegative y. Furthermore, since the variables $\tilde{r}_x$ are mutually independent, we may use Chernoff-type bounds (see, e.g., Theorem 2 of [19]) to bound the probability that $\tilde{r}$ is less than half its mean: $\mathbf{P}[\tilde{r} < \mathbf{E}[\tilde{r}]/2] < e^{-\mathbf{E}[\tilde{r}]/8} = e^{-n/8(1+L\delta)}$. In particular, for $n \geq 16(1 + L\delta)$, this is less than $1/4$.

On the other hand, by Markov's inequality, $\mathbf{P}[\tilde{s} > 4\mathbf{E}[\tilde{s}]] \leq 1/4$. Combining this with the previous inequality, we get $\mathbf{P}[(\tilde{r} \geq \mathbf{E}[\tilde{r}]/2) \wedge (\tilde{s} \leq 4\mathbf{E}[\tilde{s}])] > 1/2$, which implies that $\mathbf{P}[\tilde{r} - \tilde{s} \geq \mathbf{E}[\tilde{r}]/2 - 4\mathbf{E}[\tilde{s}]] > 1/2$. As noted above, $\mathbf{E}[\tilde{r}] \geq n/(1 + L\delta)$, and from Lemma 5.1, $\mathbf{E}[\tilde{s}] \leq \sum_{x\in X} (\delta_x/L)/(L\delta_x + 1)$ which is at most $(\delta/L)/(L\delta + 1)$ (by the concavity of the function $\lambda(y) = (y/L)/(Ly + 1)$ for positive y). Substituting these bounds, we get $\mathbf{P}[\tilde{\phi} \geq n(1 - 8\delta/L)/2(L\delta + 1)] > 1/2$. □

COROLLARY 5. *Let C be a depth-d layered threshold circuit with n inputs and nk edges, where $k \geq 1$. Let f denote the function computed by C. For $i \geq 0$, let*

$\rho_i = (11k)^{\nu_{i+1}-1}$. Then for each $i \in \{0, 1, \ldots, d-1\}$ such that $n \geq 4\rho_i$, there exists a partial assignment α^i that leaves at least n/ρ_i variables free such that $f(\alpha^i)$ can be computed by a layered circuit C_i of depth $d - i$.

Proof. For $i = 0$, we take α^i to be the trivial restriction and $C_0 = C$. For $i \in [d-1]$, we will use Lemma 6.1 repeatedly to define partial assignments α^i and circuits C_i that have depth $d - i$. For C_i, we let n_i denote the number of inputs, m_i denote the number of edges entering the level-1 gates, and F_i denote the family of functions computed by the level-1 gates.

For $0 \leq i \leq d-2$, we construct C_{i+1} from C_i as follows: Apply Lemma 6.1 to the set F_i with $w(f)$ equal to the fan-out (in C_i) of the gate into level 2. Note that the quantity δ in this application of the lemma is equal to m_i/n_i. Thus the hypothesis of the lemma holds as long as $n_i \geq 4(9(m_i/n_i))^2$. Assuming this holds, then after the application of the lemma, we can eliminate the level-1 gates to produce C_{i+1}.

It remains to verify that for $0 \leq i \leq d-2$, $n_i \geq 4(9(m_i/n_i))^2$ (so that Lemma 6.1 can be applied in constructing C_{i+1}) and $n_{i+1} \geq n/\rho_{i+1}$ (which is the conclusion of the corollary). From the conclusion of Lemma 6.1, $n_{i+1} \geq n_i/(9(m_i/n_i))^2$. Thus if we define $p_0 = n$ and $p_i = n_{i-1}^3/(9m_{i-1})^2$ for $i \geq 1$, then the condition for applying the lemma to construct C_{i+1} for $0 \leq i \leq d-2$ is $p_{i+1} \geq 4$ and the conclusion of the lemma gives $n_{i+1} \geq p_{i+1}$. Furthermore, Lemma 6.1 implies that the number of edges into the level-1 gates of C_{i+1} is at most $1/8\delta$ times the number of edges into the level-2 gates of C_i, and hence $m_{i+1} \leq nkn_i/8m_i$. Squaring this and multiplying both sides by $81p_{i+2}n_i$, we obtain $n_i n_{i+1}^3 \leq (81nk/8)^2 p_{i+2}p_{i+1}$. Substituting the bounds $n_{i+1} \geq p_{i+1}$ and $n_i \geq p_i$ yields the following recurrence entirely in terms of p_i: for $i \geq 0$,

$$p_{i+2} \geq \left(\frac{8}{81nk}\right)^2 p_{i+1}^2 p_i \geq \left(\frac{1}{11nk}\right)^2 p_{i+1}^2 p_i$$

with the initial conditions $p_0 = n$ and $p_1 \geq n^3/(9nk)^2 \geq n/(11k)^2$.

If we set $l_i = \log p_i$, we get a linear recurrence which is easily shown to imply $p_i \geq n/\rho_i$. (Alternatively, this inequality can be verified directly by induction on i.)

Thus for each $i \in \{0, 1, \ldots, d-2\}$, if $n \geq 4\rho_{i+1}$, then $p_{i+1} \geq 4$ and $n_{i+1} \geq p_{i+1} \geq n/\rho_{i+1}$, as required. □

We can now finish the proof of Theorem 3. If $n < 4\rho_{d-1}$ then we can choose any total assignment for α and the conclusion holds trivially. Otherwise, we may apply Corollary 5 with $i = d-1$ to find a partial assignment α^{d-1} with at least n/ρ_{d-1} unfixed variables such that the resulting restricted function can be computed by a single threshold gate. Applying Corollary 1, we need to fix at most half the remaining variables to make the function constant. □

7. Final remarks and open problems. This paper gives the first nontrivial lower bounds, for threshold circuits with arbitrary weights and any fixed depth, on the number of edges and gates needed to compute an explicit function. The results show that there are functions $\epsilon(d)$ and $\gamma(d)$ such that any depth-d threshold circuit that computes parity on n variables must have at least $n^{1+\epsilon(d)}$ edges and $n^{\gamma(d)}$ gates. In our case, the functions $\epsilon(d)$ and $\gamma(d)$ tend to 0 as d tends to ∞. An apparently difficult challenge would be to prove an n^ϵ lower bound, with $\epsilon > 1$ a constant independent of depth, on the number of gates needed to compute some explicit function.

For each fixed depth, there is a gap between the bounds provided by our results and the best constructions for parity circuits. For instance, for depth-2 circuits, the

result in this paper gives an $\Omega(n^{3/2})$ bound on the number of edges and an $n^{1/2}$ bound on the number of gates, while the best construction requires $O(n^2)$ edges and $O(n)$ gates. One way to reduce this gap is to improve Lemma 3.1 by increasing the number of variables left free in the restrictions.

PROBLEM 1. *What is the smallest exponent r such that the conclusions of Lemmas* 3.1 *and* 6.1 *hold with $n/(4\delta^2+2)$ replaced by $\Omega(n/\delta^r)$?*

The best possible r is at least 1, as shown by the family $F = \{T_i : 0 \le i \le n\}$ of n-variable functions, where T_i is the function which is 1 on inputs with at least i 1's. If the conclusion holds for $r = 1$, then this would lead to an $\Omega(n^2)$-edge lower bound for depth-2 circuits that compute parity and, more generally, to an improvement in the value of θ in the main theorem to $\theta = (1+\sqrt{5})/2$. This would exactly match the value of θ in the known upper bounds. Note that for purposes of applications to circuits, it would suffice to consider the above problem for families of threshold functions rather than for generalized monotone functions.

It is interesting also to look for a similar improvement to Lemma 3.2.

PROBLEM 2. *What is the smallest exponent r such that the conclusion of Lemma* 3.2 *holds with $n/(4\delta^2+2)$ replaced by $\Omega(n/|F|^r)$?*

Again, the best lower bound on r we have is 1. Any value of $r < 2$ would give a corresponding improvement in Theorem 2: the number of variables left free would be $\Omega(n/N^{r(d-1)})$.

For the special case of monotone functions, it is easy to show that Lemma 3.2 has such a strengthening.

PROPOSITION 1. *Let F be a collection of monotone functions on n variables. Then there exists a partial assignment α that leaves at least $\lfloor n/(|F|+1)\rfloor$ variables free such that for each $f \in F$, $f(\alpha)$ is a constant function.*

Proof. Fix an ordering Γ for the variables X and for each $f \in F$, let $j(f)$ be the index promised by Lemma 2.1. Order the functions as $f_1, f_2, \ldots, f_m$ so that $j_1 \le j_2 \le \cdots \le j_m$, where $j_i = j(f_i)$, and let $j_0 = 0$ and $j_{m+1} = n+1$. Let i be an index such that $j_{i+1} - j_i$ is maximum (and hence at least $(n+1)/(m+1)$) and let α be the assignment which sets all variables in $\Gamma(\le j_i)$ to 0 and $\Gamma(\ge j_{i+1})$ to 1. Then $f_h(\alpha)$ is identically 0 for all $h \le i$ and $f_h(\alpha)$ is identically 1 for all $h \ge i+1$. The number of free variables of α is $j_{i+1} - j_i - 1 \ge \lfloor n/(m+1)\rfloor$. □

BOUNDS FOR THE COMPUTATIONAL POWER AND LEARNING COMPLEXITY OF ANALOG NEURAL NETS*

WOLFGANG MAASS†

Abstract. It is shown that high-order feedforward neural nets of constant depth with piecewise-polynomial activation functions and arbitrary real weights can be simulated for Boolean inputs and outputs by neural nets of a somewhat larger size and depth with Heaviside gates and weights from $\{-1, 0, 1\}$. This provides the first known upper bound for the computational power of the former type of neural nets. It is also shown that in the case of first-order nets with piecewise-linear activation functions one can replace arbitrary real weights by rational numbers with polynomially many bits without changing the Boolean function that is computed by the neural net. In order to prove these results, we introduce two new methods for reducing nonlinear problems about weights in multilayer neural nets to linear problems for a transformed set of parameters. These transformed parameters can be interpreted as weights in a somewhat larger neural net.

As another application of our new proof technique we show that neural nets with piecewise-polynomial activation functions and a constant number of analog inputs are probably approximately correct (PAC) learnable (in Valiant's model for PAC learning [*Comm. Assoc. Comput. Mach.*, 27 (1984), pp. 1134–1142]).

1. Introduction.

We examine in this paper the computational power and learning complexity of high-order analog feedforward neural nets $\mathcal{N}$, i.e., of circuits with analog computational elements in which certain parameters are treated as programmable parameters. We focus on neural nets $\mathcal{N}$ of bounded depth in which each gate g computes a function from $\mathbf{R}^m$ into $\mathbf{R}$ of the form $\langle y_1, \ldots, y_m \rangle \mapsto \gamma^g(Q^g(y_1, \ldots, y_m))$. We assume that, for each gate g, γ^g is some fixed piecewise-polynomial activation function (also called response function). This function is applied to some polynomial $Q^g(y_1, \ldots, y_m)$ of bounded degree with arbitrary real coefficients, where $y_1, \ldots, y_m$ are the real-valued inputs to gate g. One usually refers to the degree of the polynomial Q^g as the *order* of the gate g. It should be noted that (following the conventions in the neural net literature) the order of a gate g does not refer to the degree of its activation function γ^g. We will specify bounds for that degree separately.

The coefficients ("weights") of Q^g are the *programmable variables* of $\mathcal{N}$ whose values may arise from some learning process.

We are primarily interested in the case where the neural net $\mathcal{N}$ computes (respectively, learns) a Boolean-valued function. For that purpose we assume that the real-valued output of the output gate g_{out} of $\mathcal{N}$ is "rounded off." More precisely, we assume that there is an *outer threshold* T_{out} (which belongs to the programmable parameters of $\mathcal{N}$) such that the output of $\mathcal{N}$ is 1 whenever the real-valued output z of g_{out} satisfies $z \geq T_{\text{out}}$ and 0 if $z < T_{\text{out}}$. In some results of this paper we also assume that the input $\langle x_1, \ldots, x_n \rangle$ of $\mathcal{N}$ is Boolean valued. It should be noted that this does

not affect the capacity of $\mathcal{N}$ to carry out, on its intermediate levels (i.e., in its "hidden units"), computation over reals, whose real-valued results are then transmitted to the next layer of gates.

Circuits of this type have rarely been considered in computational complexity theory, and they give rise to the principal question whether these intermediate *analog* computational elements will allow the circuit to compute more complex Boolean functions than a circuit with a similar layout but *digital* computational elements. Note that circuits with analog computational elements have an extra source of potentially unlimited parallelism at their disposal, since they can execute operations on numbers of arbitrary bit-length in one step, and they can transmit numbers of arbitrary bit-length from one gate to the next.

One already knows quite a bit about the special case of such neural nets $\mathcal{N}$, where each gate g is a linear threshold gate. In this case each polynomial $Q^g(y_1, \ldots, y_m)$ is of degree ≤ 1 (i.e., a weighted sum), and each activation function γ^g in $\mathcal{N}$ is the Heaviside function (also called hard limiter) $\mathcal{H}$ defined by

$$\mathcal{H}(y) = \begin{cases} 1 & \text{if } y \geq 0, \\ 0 & \text{if } y < 0 \end{cases}$$

(e.g., see [R], [Ni], [Mu], [MP], [PS], [HMPST], [GHR], [SR], [SBKH], [BH], [A], [B], [L]). The analog versus digital issue does not arise in this case, since the output of each gate is a single bit. Still, it requires some work to bound the potential power of arbitrary weights (in the weighted sums) for the computation of Boolean functions on such circuit. Since there are only finitely many Boolean circuit inputs, it is obvious that only rational weights have to be considered. The key result for the analysis of these circuits was the discovery of Muroga [Mu] that it is sufficient to consider for a linear threshold gate with m Boolean inputs only weights $\alpha_1, \ldots, \alpha_m$ and a bias α_0 that are integers of size $2^{O(m \log m)}$. (This upper bound is optimal according to a recent result of Håstad [Has].) With the help of this a priori bound on the relevant bit-length of weights, it is easy to show that the same arrays $(F_n)_{n \in \mathbf{N}}$ of Boolean functions $F_n : \{0,1\}^n \to \{0,1\}$ are computable by arrays $(\mathcal{N}_n)_{n \in \mathbf{N}}$ of neural nets of depth $O(1)$ and size $O(n^{O(1)})$ with linear threshold gates, no matter whether one uses as weights arbitrary reals, rationals, integers, or elements of $\{-1, 0, 1\}$; see [Mu], [CSV], [HMPST], [GHR], [MT]. The resulting class of arrays $(F_n)_{n \in \mathbf{N}}$ of Boolean functions is called (nonuniform) TC^0 (see [HMPST], [J]).

In comparison, very little is known about upper bounds for the computational power and the learning complexity of feedforward neural nets whose gates g employ more general types of activation functions γ^g. This holds in spite of the fact that "real neurons and real physical devices have continuous input-output relations" [Ho]. In the analysis of information processing in natural neural systems, one usually views the firing rate of a neuron as its current output. Such firing rates are known to change between a few and several hundred spikes per second (see Chap. 20 in [MR]). Hence the activation function γ^g of a gate g that models such a neuron should have a graded response. It should also be noted that the customary learning algorithms for artificial neural nets (such as backward propagation [RM]) are based on gradient descent methods which require that all gates g employ *smooth* activation functions γ^g.

In addition, it has frequently been pointed out that it is both biologically plausible and computationally relevant to consider gates g that pass to γ^g instead of a weighted sum $\sum_{i=1}^m \alpha_i y_i + \alpha_0$ some polynomial $Q^g(y_1, \ldots, y_m)$ of bounded degree, where $y_1, \ldots, y_m$ are circuit inputs or outputs of the immediate predecessors

of g. Such gates are called sigma-pi units or high-order gates in the literature (see p. 73 and Chap. 10 in [RM]; see also [DR], [H], [PG], [MD]). From the point of view of approximation theory there has been particular interest in the case in which $Q^g(y_1, \ldots, y_m) = \sum_{i=1}^m \alpha_i (y_i - c_i)^2$ measures a "distance" of its input $\langle y_1, \ldots, y_m \rangle$ from some "center" $\langle c_1, \ldots, c_m \rangle$ (the latter may be determined through a learning process). Apparently Theorems 3.1 and 4.3 of this paper provide the first upper bounds for the computational power and learning complexity of high-order feedforward neural nets with non-Boolean activation functions.

The power of feedforward neural nets with other activation functions besides $\mathcal{H}$ has previously been investigated in [RM, Chap. 10], [S1], [S2], [H], [MSS], [DS], [SS]. It was shown in [MSS] for a very general class of activation functions γ^g that neural nets $(\mathcal{N}_n)_{n \in \mathbf{N}}$ of constant depth and size $O(n^{O(1)})$ with real weights of size $O(n^{O(1)})$ and output separation $\Omega(1/n^{O(1)})$ (between the unrounded circuit outputs for rejected and accepted inputs) can compute only Boolean functions in TC^0. It follows from a result of Sontag [S2] that the assumptions on the weight size and separation are essential for this upper bound: he constructed an arbitrarily smooth monotone function Θ (which can be made to satisfy the conditions on γ^g in the quoted result of [MSS]) and neural nets $\mathcal{N}_n$ of size 2 (!) with activation function Θ such that $\mathcal{N}_n$ can compute with sufficiently large weights *any* Boolean function $F_n : \{0,1\}^n \to \{0,1\}$ (hence $\mathcal{N}_n$ has VC dimension 2^n).

These results leave open the question about the computational power and learning complexity of feedforward neural nets with arbitrary weights that employ "natural" analog activation functions γ^g. For example there has previously been no upper bound for the set of Boolean functions computable by analog neural nets with the very simple piecewise-linear activation function π defined by

$$\pi(y) = \begin{cases} 0 & \text{if } y \leq 0, \\ y & \text{if } 0 \leq y \leq 1, \\ 1 & \text{if } y \geq 1. \end{cases}$$

([L] refers to a gate g with $\gamma^g = \pi$ as a threshold logic element.) On the other hand, there exist results which suggest that such upper bound would be nontrivial. It has already been shown in [MSS] that constant size neural nets of depth 2 with activation function π and small integer weights can compute *more* Boolean functions than constant size neural nets of depth 2 with linear threshold gates (and arbitrary weights). [DS] exhibits an even stronger increase in computational power for the case of quadratic activation functions.

Hence even *simple* non-Boolean activation functions provide more computational power to a neural net than the Heaviside function. However it has been an open problem by *how much* they can increase the computational power (in the presence of arbitrary weights). From the technical point of view, this difficulty in proving an upper bound for the computational power was caused by the lack of an upper bound on the amount of information that can be encoded in such a neural net by the assignment of weights. For the case of neural nets with Heaviside gates, this upper bound on the information capacity of weights is provided by the quoted result of Muroga [Mu]. However, this problem is substantially more difficult for neural nets with piecewise-linear activation functions. For this model it is no longer sufficient to analyze a single gate with Boolean inputs and outputs. Even if the inputs and outputs of the neural net are Boolean valued, the signals that are transmitted between the hidden units are real valued. Furthermore, one can give no a priori bound on the

precision required for such analog signals between hidden units, since one has no control over the maximal size of weights in the neural net. Obviously a large weight will magnify any imprecision. Note also that a computation on a multilayer neural net of the type considered here involves *products* of weights from subsequent levels. Hence, if some of the weights are arbitrarily large, one needs arbitrarily high precision for the other weights.

The main technical contribution of this paper is two new methods for reducing nonlinear problems about weights in multilayer neural nets to linear problems for a transformed set of parameters. These two methods are presented in sections 2 and 3 of this paper. We introduce in section 2 of this paper a method that allows us to prove an upper bound for the information capacity of weights for neural nets with piecewise-linear activation functions (hence in particular for π). It is shown that for the computation of Boolean functions on neural nets $\mathcal{N}_n$ of constant depth and polynomially in n many gates (where n is the number of input variables) it is sufficient to use as weights rational numbers with polynomially in n many bits. As a consequence, one can simulate any such analog neural net by a digital neural net of constant depth and polynomial size with the Heaviside activation function (i.e., linear threshold gates) and binary weights (i.e., weights from $\{0, 1\}$). This result also implies that the VC dimension of $\mathcal{N}_n$ can be bounded above by a polynomial in n.

In section 3 we introduce another proof technique that allows us to derive the same two consequences for neural nets with piecewise-*polynomial* activation functions and nonlinear gate inputs $Q^g(y_1, \ldots, y_m)$ of bounded degree. These results show that in spite of the previously quoted evidence for the superiority of non-Boolean activation functions in neural nets, there is some limit to their computational power as long as the activation functions are piecewise-polynomial. On the other hand the polynomial upper bound on the VC dimension of such neural nets may be interpreted as *good news*: it shows that neural nets of this type can in principle be trained with a sequence of examples that is not too long.

We conclude in section 4 with a positive result for learning on neural nets in Valiant's model [V] for probably approximately correct learning (PAC learning). We consider the problem of learning on neural nets with a fixed number of analog (i.e., real-valued) input variables. We exploit here the implicit linearization of the requirements for the desired weight assignment that is achieved in the new proof techniques from sections 2 and 3. In this way one can show that such neural nets are properly PAC learnable in the case of piecewise-linear activation functions and PAC learnable with a hypothesis class that is given by a somewhat larger neural net in the case of piecewise-polynomial activation functions. Another application of our parameter transformation method from section 2 to PAC learning has subsequently been given by Koiran [K94].

The results of this paper were first announced in [M92], and an extended abstract of these results appeared in [M93a]. Another result of [M93a], the construction of neural nets whose VC dimension is superlinear in the number of weights, has subsequently been improved to apply for depth 3 also. A full version of that proof appears in [M93b].

DEFINITION 1.1. *A* network architecture *(or neural net) $\mathcal{N}$ of order k is a labeled acyclic directed graph $\langle V, E\rangle$. Its nodes of fan-in* 0 *are labeled by the input variables $x_1, \ldots, x_n$. Each node g of fan-in $m > 0$ is called a computation node (or gate) and is labeled by some activation function $\gamma^g : \boldsymbol{R} \to \boldsymbol{R}$ and some polynomial $Q^g(y_1, \ldots, y_m)$ of degree $\leq k$. Furthermore, $\mathcal{N}$ has a unique node of fan-out 0 which is called the*

output node of $\mathcal{N}$ and which carries as an additional label a certain real number T_{out} (called the outer threshold of $\mathcal{N}$).

The coefficients of all polynomials $Q^g(y_1, \ldots, y_m)$ for gates g in $\mathcal{N}$ and the outer threshold T_{out} are called the programmable parameters *of $\mathcal{N}$. Assume that $\mathcal{N}$ has w programmable parameters and that some numbering of these has been fixed. Then each assignment $\underline{\alpha} \in \boldsymbol{R}^w$ of reals to the programmable parameters in $\mathcal{N}$ defines an analog circuit $\mathcal{N}^{\underline{\alpha}}$, which computes a function $\underline{x} \mapsto \mathcal{N}^{\underline{\alpha}}(\underline{x})$ from $\boldsymbol{R}^n$ into $\{0,1\}$ in the following way: assume that some input $\underline{x} \in \boldsymbol{R}^n$ has been assigned to the input nodes of $\mathcal{N}$. If a gate g in $\mathcal{N}$ has m immediate predecessors in $\langle V, E\rangle$ which output $y_1, \ldots, y_m \in \boldsymbol{R}$, then g outputs $\gamma^g(Q^g(y_1, \ldots, y_m))$. Finally, if g_{out} is the output gate of $\mathcal{N}$ and g_{out} gives the real-valued output z (according to the preceding inductive definition), we define*

$$\mathcal{N}^{\underline{\alpha}}(\underline{x}) := \begin{cases} 1 & \text{if } z \geq T_{\text{out}}, \\ 0 & \text{if } z < T_{\text{out}}, \end{cases}$$

where T_{out} is the outer threshold that has been assigned by $\underline{\alpha}$ to g_{out}.

Any parameters that occur in the definitions of the activation functions γ^g of $\mathcal{N}$ are referred to as architectural parameters *of $\mathcal{N}$.*

DEFINITION 1.2. *A function $\gamma : \boldsymbol{R} \to \boldsymbol{R}$ is called* piecewise-polynomial *if there are thresholds $t_1, \ldots, t_k \in \boldsymbol{R}$ and polynomials $P_0, \ldots, P_k$ such that $t_1 < \cdots < t_k$ and for each $i \in \{0, \ldots, k\}$: $t_i \leq x < t_{i+1} \Rightarrow \gamma(x) = P_i(x)$ (we set $t_0 := -\infty$ and $t_{k+1} := \infty$).*

If k is chosen minimal for γ, we refer to k as the number of polynomial pieces of γ; to $P_0, \ldots, P_k$ as the polynomial pieces of γ; and to $t_1, \ldots, t_k$ as the thresholds of γ. Furthermore we refer to $t_1, \ldots, t_k$ together with all coefficients in the polynomials $P_0, \ldots, P_k$ as the parameters *of γ. The maximal degree of $P_0, \ldots, P_k$ is called the degree of γ. If the degree of γ is ≤ 1 then we call γ* piecewise-linear*, and we refer to $P_0, \ldots, P_k$ as the linear pieces of γ.*

If γ occurs as activation function γ^g of some network architecture $\mathcal{N}$, then one refers to the parameters of γ as architectural parameters *of $\mathcal{N}$.*

Note that *we do not require that γ is continuous* (*or monotone*). It should also be pointed out that according to Definition 1.1 the order k of a neural net does *not* bound the degrees of the polynomial pieces of its activation functions. Finally, we would like to mention that in contrast to [MSS], we do not require here any minimal distance between the real-valued network outputs z and the outer threshold T_{out}.

DEFINITION 1.3. *Assume that $\mathcal{N}$ is an arbitrary network architecture with n inputs and w programmable parameters and that $S \subseteq \boldsymbol{R}^n$ is an arbitrary set. Then one defines the* VC dimension *of $\mathcal{N}$ over S in the following way:*

$$\begin{aligned} \textit{VC dimension}(\mathcal{N}, S) := \max\{|S'| \,|\, & S' \subseteq S \textit{ has the property that for every function} \\ & F : S' \to \{0,1\} \textit{ there exists a parameter assignment} \\ & \underline{\alpha} \in \boldsymbol{R}^w \textit{ such that } \forall\, \underline{x} \in S' (\mathcal{N}^{\underline{\alpha}}(\underline{x}) = F(\underline{x}))\}. \end{aligned}$$

Remark 1.4. VC dimension is an abbreviation for Vapnik–Chervonenkis dimension. It has been shown in [BEHW] (see also [BH], [A]) that the VC dimension of a neural net $\mathcal{N}$ essentially determines the number of examples that are needed to train $\mathcal{N}$ (in Valiant's model for PAC learning [V]). Sontag [S2] has shown that the VC dimension of a neural net can be drastically increased by using activation functions with non-Boolean output instead of the Heaviside function $\mathcal{H}$. The methods described in

this paper were used in [M93a] to give the first proof of a polynomial upper bound for the VC dimension of the here-considered neural nets. Subsequently [GJ] have shown that such bounds for the VC dimension can also be derived more directly via Milnor's theorem. However their method does not yield upper bounds for the *computational* power of these neural nets.

2. A bound for the information—capacity of weights in neural nets with piecewise-linear activation functions. We consider for arbitrary $a \in \mathbf{N}$ the following set of rationals with up to a bits before and after the comma:

$$\mathbf{Q}_a := \left\{ r \in \mathbf{Q} \;\middle|\; r = s \cdot \sum_{i=-a}^{a-1} b_i \cdot 2^i \quad \text{for } b_i \in \{0,1\},\ i = -a, \ldots, a-1, \text{ and } s \in \{-1, 1\} \right\}.$$

Note that for any $r \in \mathbf{Q}_a : |r| \leq 2^a \leq 2^{2a} \cdot \min\{|r'| \mid r' \in \mathbf{Q}_a \text{ and } r' \neq 0\}$.

THEOREM 2.1. *Consider an arbitrary network architecture $\mathcal{N}$ of order 1 over a graph $\langle V, E \rangle$ with n input nodes in which every computation node has fan-out ≤ 1. Assume that each activation function γ^g in $\mathcal{N}$ is piecewise-linear with parameters from $\boldsymbol{Q}_a$. Let $w := |V| + |E| + 1$ be the number of programmable parameters in $\mathcal{N}$.*

Then for every $\underline{\alpha} \in \boldsymbol{R}^w$ there exists a vector $\underline{\alpha}' = \langle \frac{s_1}{t}, \ldots, \frac{s_w}{t} \rangle \in \boldsymbol{Q}^w$ with integers $s_1, \ldots, s_w, t$ of absolute value $\leq (2w+1)!\ 2^{2a(2w+1)}$ such that $\forall \underline{x} \in \boldsymbol{Q}_a^n (\mathcal{N}^{\underline{\alpha}}(\underline{x}) = \mathcal{N}^{\underline{\alpha}'}(\underline{x}))$. In particular $\mathcal{N}^{\underline{\alpha}'}$ computes the same Boolean function as $\mathcal{N}^{\underline{\alpha}}$.

Remark 2.2. The condition of Theorem 2.1 that all computation nodes in $\mathcal{N}$ have fan-out ≤ 1 is automatically satisfied for $d \leq 2$. For larger d one can simulate any network architecture $\mathcal{N}$ of depth d with s nodes by a network architecture $\mathcal{N}'$ with $\leq \frac{s}{s-1} \cdot s^{d-1} \leq \frac{3}{2} s^{d-1}$ nodes and depth d that satisfies this condition (replace each computation node with fan-out k by k identical nodes with fan-out 1, starting from the output layer). Hence this condition is not too restrictive for network architectures of a constant depth d.

It should also be pointed out that there is in the assumption of Theorem 2.1 no explicit bound on the number of linear pieces of γ^g (apart from the requirement that its thresholds are from $\mathbf{Q}_a$). For example, these activation functions may consist of 2^a linear pieces (with discontinuous jumps in between). Furthermore γ^g is not required to be monotone.

Finally, it should be mentioned that a corresponding version of Theorem 2.1 also holds for rational numbers that do not have a finite binary representation, i.e., for all rationals from $\mathbf{Q}'_a := \{r \in \mathbf{Q} : r$ is the quotient of integers of bit-length $\leq a\}$ instead of $\mathbf{Q}_a$.

Remark 2.3. Previously, one had *no* upper bound for the computational power (or for the VC dimension) of multilayer neural nets $\mathcal{N}$ with arbitrary weights and analog computational elements (i.e., activation functions with non-Boolean output). Theorem 2.1 implies that any $\mathcal{N}$ of the considered type can compute with the help of arbitrary parameter assignments $\underline{\alpha} \in \mathbf{R}^w$ at most $2^{O(aw^2 \log w)}$ different functions from $\mathbf{Q}_a^n$ into $\{0,1\}$, hence VC dimension $(\mathcal{N}, \mathbf{Q}_a^n) = O(w^2(a + \log w))$ (see Remark 3.9 for a slightly better bound and for a related bound for the case of inputs from $\mathbf{R}^n$).

Furthermore Theorem 2.1 implies that one can *replace* all *analog computations inside* $\mathcal{N}$ by *digital arithmetical operations on not too large integers* (the proof gives an upper bound of $O(wa + w \log w)$ for their bit-length). It is well known that each of

these digital arithmetical operations (multiple addition, multiplication, division) can be carried out on a circuit of small constant depth with $O(a^{O(1)} \cdot w^{O(1)})$ MAJORITY-gates, hence also on a network architecture of depth $O(1)$ and size $O(a^{O(1)} \cdot w^{O(1)})$ with Heaviside gates and weights from $\{-1, 0, 1\}$ (see [CSV], [PS], [HMPST], [GHR], [SR], [SBKH]). Thus one can simulate for inputs from $\{0,1\}^n$ any depth d network architecture $\mathcal{N}$ as in Theorem 2.1 with arbitrary parameter assignments $\underline{\alpha} \in \mathbf{R}^w$ by a network architecture of depth $O(d)$ and size $O(a^{O(1)} \cdot w^{O(1)})$ with Heaviside gates and weights from $\{-1, 0, 1\}$. The same holds for inputs from $\mathbf{Q}_a^n$ if they are given to $\mathcal{N}$ in digital form.

The size of this simulating digital neural net with Heaviside gates is polynomial in the number of real-valued parameters of the simulated analog neural net $\mathcal{N}$ but exponential in the depth of $\mathcal{N}$. Subsequent to [M93a], Koiran [K93] has proven a complementary simulation result, where the size of the simulating digital neural net is exponential in the number of real-valued parameters in $\mathcal{N}$ but subexponential in the depth of $\mathcal{N}$.

Proof of Theorem 2.1. In the special case where $\gamma^g = \mathcal{H}$ for all gates in $\mathcal{N}$ this result is well known [Mu]. It follows by applying separately to each gate in $\mathcal{N}$ the following result.

LEMMA 2.4 (folklore; see [MT] for a proof). *Consider a system $A\underline{x} \leq \underline{b}$ of some arbitrary finite number of linear inequalities in l variables. Assume that all entries in A and $\underline{b}$ are integers of absolute value $\leq K$.*

If this system has any solution in $\boldsymbol{R}^l$, then it has a solution of the form $\langle \frac{s_1}{t}, \ldots, \frac{s_l}{t} \rangle$, where $s_1, \ldots, s_l, t$ are integers of absolute value $\leq (2l+1)!\, K^{2l+1}$.

Sketch of the proof for Lemma 2.4. Let k be the number of inequalities in $A\underline{x} \leq \underline{b}$. One writes each variable in $\underline{x}$ as a difference of two nonnegative variables and adds to each inequality a "slack variable." In this way one gets an equivalent system

$$A'\underline{x}' = \underline{b}, \quad \underline{x}' \geq \underline{0}, \tag{1}$$

over $l' := 2l + k$ variables for some $k \times l'$ matrix A'. The k columns of A' for the k slack variables in $\underline{x}'$ form an identity matrix. Hence A' has rank k.

The assumption of the lemma implies that (1) has a solution over $\mathbf{R}$. Hence by Carathéodory's theorem (Corollary 7.1i in [Sch]) one can conclude that there is also a solution over $\mathbf{R}$ of a system

$$A''\underline{x}'' = \underline{b}, \quad \underline{x}'' \geq \underline{0}. \tag{2}$$

Subsequent to the first publication of the techniques of this article in [M93a], Koiran [K93] has proven a complementary result without assumption that the depth is bounded but where one has to assume that the number of real-valued parameters in the given neural net $\mathcal{N}$ is bounded by a constant where A'' consists of k linearly independent columns of A'. Since A'' has full rank, (2) has in fact a unique solution that is given by Cramer's rule: $x_j'' = \det(A_j'')/\det A''$ for $j = 1, \ldots, k$, where A_j'' results form A'' by replacing its jth column by $\underline{b}$. Since all except up to $2l$ columns of A'' contain exactly one 1 and else only 0's, we can bring each of the matrices A'', A_j'' by permutations of rows and columns into a form

$$B = \begin{pmatrix} C & 0 \\ D & I \end{pmatrix},$$

where C is a square matrix with $2l+1$ rows. Hence the determinant of B is an integer of absolute value $\leq (2l+1)!\, K^{2l+1}$. □

The difficulty of the proof of Theorem 2.1 lies in the fact that with *analog* computational elements one can no longer treat each gate separately, since intermediate values are no longer integers. Furthermore, the total computation of $\mathcal{N}$ can in general *not* be described by a system of *linear* inequalities, where the w variable parameters of $\mathcal{N}$ are the variables in the inequalities (and the fixed parameters of $\mathcal{N}$ are the constants). This becomes obvious if one just considers the composition of two very simple analog gates g_1 and g_2 on levels 1 and 2 of $\mathcal{N}$, whose activation functions γ_1, γ_2 satisfy $\gamma_1(y) = \gamma_2(y) = y$. Assume $x = \sum_{i=1}^{n} \alpha_i x_i + \alpha_0$ is the input to gate g_1, and g_2 receives as input $\sum_{j=1}^{m} \alpha'_j y_j + \alpha'_0$, where $y_1 = \gamma_1(x) = x$ is the output of gate g_1. Then g_2 outputs $\alpha'_1 \cdot (\sum_{i=1}^{n} \alpha_i x_i + \alpha_0) + \sum_{j=2}^{m} \alpha'_j y_j + \alpha'_0$. Obviously this term is not linear in the weights $\alpha'_1, \alpha_1, \ldots, \alpha_n$. Hence if the output of gate g_2 is compared with a fixed threshold at the next gate, the resulting inequality is not linear in the weights of the gates in $\mathcal{N}$.

If the activation functions of all gates in $\mathcal{N}$ were linear (as in the example for g_1 and g_2), then there would be no problem because a composition of linear functions is linear. However for *piecewise*-linear activation functions it is not sufficient to consider their composition, since intermediate results have to be compared with boundaries between linear pieces of the next gate.

We introduce in this paper a new method in order to handle this difficulty. We simulate $\mathcal{N}^{\underline{\alpha}}$ by another neural net $\hat{\mathcal{N}}[\underline{c}]^{\underline{\beta}}$ (which one may view as a "normal form" for $\mathcal{N}^{\underline{\alpha}}$) that uses the same graph $\langle V, E\rangle$ as $\mathcal{N}$ but different activation functions and different values $\underline{\beta}$ for its variable parameters. The activation functions of $\hat{\mathcal{N}}[\underline{c}]$ depend on $|V|$ new parameters $\underline{c} \in \mathbf{R}^{|V|}$, which we call *scaling parameters* in the following. Although this new neural net has the disadvantage that it requires $|V|$ additional parameters $\underline{c}$, it has the advantage that we can choose in $\hat{\mathcal{N}}[\underline{c}]$ all weights on edges between computation nodes to be from $\{-1, 0, 1\}$. Since these weights from $\{-1, 0, 1\}$ are already of the desired bit-length, we can treat them as constants in the system of inequalities that describes computations of $\hat{\mathcal{N}}[\underline{c}]$. Therefore, all variables that appear in the inequalities that describe computations of $\hat{\mathcal{N}}[\underline{c}]$ (the variables for weights of gates on level 1, the variables for the biases of gates on all levels, the variable for the outer threshold, *and the new variables for the scaling parameters* $\underline{c}$) appear only *linearly* in those inequalities. Hence we can apply Lemma 2.4 to the system of inequalities that describes the computations of $\hat{\mathcal{N}}$ for inputs from $\mathbf{Q}_a^n$ and thereby get a rational solution $\underline{\beta}'$, $\underline{c}'$ for all variable parameters in $\hat{\mathcal{N}}$. Finally we observe that we can transform $\hat{\mathcal{N}}[\underline{c}']^{\underline{\beta}'}$ back into the original neural net $\mathcal{N}$ with an assignment of rational numbers $\underline{\alpha}'$ to all variable parameters in $\mathcal{N}$.

We will now fill in some of the missing details. Consider the gate function γ of an arbitrary gate g in $\mathcal{N}$. Since γ is piecewise-linear, there are fixed parameters $t_1 < \cdots < t_k, a_0, \ldots, a_k, b_0, \ldots, b_k$ in $\mathbf{Q}_a$ (which may be different for different gates g) such that with $t_0 := -\infty$ and $t_{k+1} := +\infty$ one has $\gamma(x) = a_i x + b_i$ for $x \in \mathbf{R}$ with $t_i \leq x < t_{i+1}$; $i = 0, \ldots, k$. For an arbitrary scaling parameter $c \in \mathbf{R}^+$ we associate with γ the following piecewise-linear activation function γ^c: the thresholds of γ^c are $c \cdot t_1, \ldots, c \cdot t_k$, and its output is $\gamma^c(x) = a_i x + c \cdot b_i$ for $x \in \mathbf{R}$ with $c \cdot t_i \leq x < c \cdot t_{i+1}$; $i = 0, \ldots, k$ (set $c \cdot t_0 := -\infty$, $c \cdot t_{k+1} := +\infty$). Thus for all reals $c > 0$ the function γ^c is related to γ through the equality: $\forall\, x \in \mathbf{R}(\gamma^c(c \cdot x) = c \cdot \gamma(x))$.

Assume that $\underline{\alpha} \in \mathbf{R}^w$ is some arbitrarily given assignment to the variable parameters in $\mathcal{N}$. We transform $\mathcal{N}^{\underline{\alpha}}$ into a normal form $\hat{\mathcal{N}}[\underline{c}]^{\underline{\beta}}$, in which all weights on edges between computation nodes are from $\{-1, 0, 1\}$ such that $\forall\, \underline{x} \in \mathbf{R}^n(\mathcal{N}^{\underline{\alpha}}(\underline{x}) = \hat{\mathcal{N}}[\underline{c}]^{\underline{\beta}}(\underline{x}))$. We proceed inductively from the output level towards the input level.

Assume that the output gate g_{out} of $\mathcal{N}^{\underline{\alpha}}$ receives as input $\sum_{i=1}^{m} \alpha_i y_i + \alpha_0$, where $\alpha_1, \ldots, \alpha_m, \alpha_0$ are the weights and the bias of g_{out} (under the assignment $\underline{\alpha}$) and $y_1, \ldots, y_m$ are the (real-valued) outputs of the immediate predecessors $g_1, \ldots, g_m$ of g. For each $i \in \{1, \ldots, m\}$ with $\alpha_i \neq 0$ such that g_i is not an input node we replace the activation function γ_i of g_i by $\gamma_i^{|\alpha_i|}$, and we multiply the weights and the bias of gate g_i with $|\alpha_i|$. Finally we replace the weight α_i of gate g_{out} by

$$sgn(\alpha_i) := \begin{cases} 1 & \text{if } \alpha_i > 0, \\ -1 & \text{if } \alpha_i < 0. \end{cases}$$

This operation has the effect that the multiplication with $|\alpha_i|$ is carried out *before* the gate g_i (rather than after g_i, as done in $\mathcal{N}^{\underline{\alpha}}$) but that the considered output gate g_{out} still receives the same input as before. The analogous operation is then inductively carried out for the predecessors g_i of g_{out} (note, however, that the weights of g_i are no longer the original ones from $\mathcal{N}^{\underline{\alpha}}$, since they have been changed in the preceding step). We exploit here the assumption that each gate has fan-out ≤ 1.

Let $\underline{\beta}$ consist of the new weights on edges adjacent to input nodes, the resulting biases of all gates in $\hat{\mathcal{N}}$, and the (unchanged) outer threshold T_{out}. Let $\underline{c}$ consist of the resulting scaling factors at the gates of $\mathcal{N}$. Then we have $\forall\, \underline{x} \in \mathbf{R}^n (\mathcal{N}^{\underline{\alpha}}(\underline{x}) = \hat{\mathcal{N}}[\underline{c}]^{\underline{\beta}}(\underline{x}))$.

Finally we have to replace all *strict* inequalities of the form "$s_1 < s_2$" that are needed to describe the computation of $\hat{\mathcal{N}}[\underline{c}]^{\underline{\beta}}$ for some input $\underline{x} \in \mathbf{Q}_a^n$ by inequalities of the form "$s_1 + 1 \leq s_2$". This concerns inequalities of the form $s < c \cdot t_i$, where $c \cdot t_i$ is the threshold of some gate g in $\hat{\mathcal{N}}[\underline{c}]$ and s is its gate input, inequalities of the form $s < T_{\text{out}}$ where s is the output of g_{out}, and inequalities of the form $0 < c$ for each scaling parameter c. In order to achieve this stronger separation it is sufficient to multiply all parameters $\underline{\beta}$, $\underline{c}$ in $\hat{\mathcal{N}}$ by a sufficiently large constant K. For simplicity we write again $\underline{\beta}$, $\underline{c}$ for the resulting parameters. We now specify a system $\mathcal{A}\underline{z} \leq \underline{b}$ of linear inequalities in w variables $\underline{z}$ that play the role of the w parameters $\underline{\beta}$, $\underline{c}$ in the computations of $\hat{\mathcal{N}}[\underline{c}]^{\underline{\beta}}$ for all inputs $\underline{x}$ from $\mathbf{Q}_a^n$. The constants of these inequalities are the coordinates of all inputs $\underline{x} \in \mathbf{Q}_a^n$, the parameters of the activation functions γ in $\mathcal{N}$, the constants $-1, 1$ that occur in $\hat{\mathcal{N}}$ as weights of edges between computation nodes, and the constants 1 that arise from the replacement of strict inequalities "$s_1 < s_2$" by "$s_1 + 1 \leq s_2$."

For each fixed input $\underline{x} \in \mathbf{Q}_a^n$ one places into the system $\mathcal{A}\underline{z} \leq \underline{b}$ up to two linear inequalities for each gate g in $\mathcal{N}$. These inequalities are defined by induction on the depth of g. If g has depth 1, $t_1 < \cdots < t_k$ are the thresholds of its activation functions γ in $\mathcal{N}$, and its input $\sum_{i=1}^{n} \alpha_i x_i + \alpha_0$ in $\hat{\mathcal{N}}[\underline{c}]^{\underline{\beta}}$ satisfies $c \cdot t_j \leq \sum_{i=1}^{n} \alpha_i x_i + \alpha_0$ and $\sum_{i=1}^{n} \alpha_i x_i + \alpha_0 + 1 \leq c \cdot t_{j+1}$, then one adds these two inequalities to the system (more precisely, if $j = 0$ or $j = k$ then only one inequality is needed since the other one is automatically true).

If g' is a successor gate of g, it receives from g for some specific $j \in \{0, \ldots, k\}$ an output of the form $a_j \cdot (\sum_{i=1}^{n} \alpha_i x_i + \alpha_0) + c \cdot b_j$ (where c is the scaling factor of gate g). Note that this term is linear, since a_j, b_j are fixed parameters of gate g'. In this way one can express for circuit input $\underline{x}$ the input $I(\underline{x})$ of gate g' as a linear term in the weights, biases, and scaling factors of its preceding gates. (We exploit here that in $\hat{\mathcal{N}}$ the weight on the edge between g' and each predecessor gate is a fixed parameter from $\{-1, 0, 1\}$, not a variable.) If this input $I(\underline{x})$ satisfies in $\hat{\mathcal{N}}[\underline{c}]^{\underline{\beta}}$ the inequalities $c' \cdot t'_{j'} \leq I(\underline{x})$ and $I(\underline{x}) + 1 \leq c' \cdot t'_{j'+1}$ (where $t'_1 < \cdots < t'_{k'}$ are the thresholds of g' in $\mathcal{N}$, and c' is the scaling factor of g' in $\hat{\mathcal{N}}$), then one adds these two

inequalities to the system $\mathcal{A}\underline{z} \leq \underline{b}$ (respectively, only one if $j' = 0$ or $j' = k'$). Note that all resulting inequalities are linear, in spite of the fact that the system contains variables for the biases of *all* gates. It should also be pointed out that the definition of this system of inequalities is more involved than it may first appear, since the sum of terms $I(\underline{x})$ depends on the chosen inequalities for all predecessor gates (e.g., on j in the example above). Hence a precise definition has to be similar to that of the proof of Theorem 3.1.

It is clear that the resulting system $\mathcal{A}\underline{z} \leq \underline{b}$ has a solution in $\mathbf{R}^w$, since $\underline{z} := \langle \underline{\beta}, \underline{c} \rangle$ is a solution. Hence we can apply Lemma 2.4, which provides a solution $\underline{z}'$ of the form $\langle \frac{s_i}{t} \rangle_{i=1,\ldots,w}$ with integers $s_1, \ldots, s_w, t$ of absolute value $\leq (2w+1)!\ 2^{2a(2w+1)}$. Let $\hat{\mathcal{N}}[\underline{c}']^{\underline{\beta}'}$ be the neural net $\hat{\mathcal{N}}$ with this new assignment $\langle \underline{\beta}', \underline{c}' \rangle := \underline{z}'$ of "small" parameters. By definition we have $\forall\, \underline{x} \in \mathbf{Q}_a^n (\mathcal{N}^{\underline{\alpha}}(\underline{x}) = \hat{\mathcal{N}}[\underline{c}']^{\underline{\beta}'})$. We show that one can transform this neural net $\hat{\mathcal{N}}[\underline{c}']^{\underline{\beta}'}$ into a net $\mathcal{N}^{\underline{\beta}'}$ with the *same activation functions* as $\mathcal{N}^{\underline{\alpha}}$ but a new assignment $\underline{\alpha}'$ of rational parameters (that can easily be computed from $\underline{\beta}'$, $\underline{c}'$). This transformation proceeds inductively from the input level towards the output level. Consider some gate g on level 1 in $\hat{\mathcal{N}}$ that uses (for the new parameter assignment $\underline{c}'$) the scaling factor $c > 0$ for its activation function γ^c. Then we replace the weights $\alpha_1, \ldots, \alpha_n$ and bias α_0 of gate g in $\hat{\mathcal{N}}[\underline{c}']^{\underline{\beta}'}$ by $\frac{\alpha_i}{c}, \ldots, \frac{\alpha_n}{c}, \frac{\alpha_0}{c}$ and γ^c by γ. Furthermore if $r \in \{-1, 0, 1\}$ was in $\hat{\mathcal{N}}$, the weight on the edge between g and its successor gate g, we assign to this edge the weight $c \cdot r$. Note that g' receives in this way from g the same input as in $\hat{\mathcal{N}}[\underline{c}']^{\underline{\beta}'}$ (for every circuit input). Assume now that $\alpha'_1, \ldots, \alpha'_m$ are the weights that the incoming edges of g' get assigned in this way, that α'_0 is the bias of g' in the assignment $\underline{z}' = \langle \underline{\beta}', \underline{c}' \rangle$, and that $c' > 0$ is the scaling factor of g' in $\hat{\mathcal{N}}[\underline{c}']^{\underline{\beta}'}$. Then we assign the new weights $\frac{\alpha'_1}{c'}, \ldots, \frac{\alpha'_m}{c'}$ and the new bias $\frac{\alpha'_0}{c'}$ to g', and we multiply the weight on the outgoing edge from g' by c'.

By construction we have that $\forall\, \underline{x} \in \mathbf{R}^n (\mathcal{N}^{\underline{\alpha}'}(\underline{x}) = \hat{\mathcal{N}}[\underline{c}']^{\underline{\beta}'}(\underline{x}))$; hence $\forall\, \underline{x} \in \mathbf{Q}_a^n (\mathcal{N}^{\underline{\alpha}'}(\underline{x}) = \mathcal{N}^{\underline{\alpha}}(\underline{x}))$. □

3. Upper bounds for neural nets with piecewise-polynomial activation functions.

THEOREM 3.1. *Consider an arbitrary array $(\mathcal{N}_n)_{n \in \boldsymbol{N}}$ of high-order network architectures $\mathcal{N}_n$ of depth $O(1)$ with n inputs and $O(n^{O(1)})$ gates in which the gate function γ^g of each gate g is piecewise-polynomial of degree $O(1)$ with $O(n^{O(1)})$ polynomial pieces, with arbitrary reals as architectural parameters.*

Then there exists an array $(\hat{\mathcal{N}}_n)_{n \in \boldsymbol{N}}$ of first-order network architectures $\hat{\mathcal{N}}_n$ of depth $O(1)$ with n inputs and $O(n^{O(1)})$ gates such that each gate g in $\hat{\mathcal{N}}_n$ uses as its activation function the Heaviside function $\mathcal{H}$ (i.e., g is a linear threshold gate) and such that for each assignment $\underline{\alpha}_n$ of arbitrary reals to the programmable parameters in $\mathcal{N}_n$ there is an assignment $\tilde{\underline{\alpha}}_n$ of $O(n^{O(1)})$ numbers from $\{-1, 0, 1\}$ to the programmable parameters in $\hat{\mathcal{N}}_n$ such that $\forall\, \underline{x} \in \{0,1\}^n (\mathcal{N}_n^{\underline{\alpha}_n}(\underline{x}) = \tilde{\mathcal{N}}_n^{\tilde{\underline{\alpha}}_n}(\underline{x}))$.

Hence for any assignment $(\underline{\alpha}_n)_{n \in \boldsymbol{N}}$ of real-valued parameters the Boolean functions that are computed by $(\mathcal{N}_n^{\underline{\alpha}_n})_{n \in \boldsymbol{N}}$ are in TC^0. In particular, VC dimension $(\mathcal{N}_n, \{0,1\}^n) = O(n^{O(1)})$.

Remark 3.2.

(a) The proof of Theorem 3.1 shows that one can replace in its claim the Boolean domain $\{0,1\}^n$ by $\{-K, \ldots, K\}^n$ for any $K \in \mathbf{N}$.

(b) Theorem 3.1 yields no bound for the computational power of neural nets with the activation function $\sigma(y) = 1/(1 + e^{-y})$. However it provides bounds for

the case where the activation functions are spline approximations to σ of arbitrarily high degree d, provided that $d \in \mathbf{N}$ is fixed.

Proof of Theorem 3.1. This proof is quite long and involved, even for the simplest nonlinear case where the activation functions consist of two polynomial pieces of degree 2. Note that in contrast to the model in [SS] the magnitude of the given weights in $\mathcal{N}_n$ may grow arbitrarily fast as a function of n.

We first note that one can eliminate all nonlinear polynomials $\mathbf{Q}^g$ as arguments of activation functions by introducing intermediate gates with linear gate inputs and quadratic activation functions. One exploits here the obvious fact that $y \cdot z = \frac{1}{2}((y + z)^2 - y^2 - z^2)$. In this way one can transform the given network architectures into *first-order* network architectures which still satisfy the assumptions of Theorem 3.1. One should note, however, that this transformation does *not* affect the degrees of polynomial pieces in the activation functions.

Subsequently we transform each given network architecture $\mathcal{N}_n$ into a normal form $\hat{\mathcal{N}}_n$ of constant depth and size $O(n^{O(1)})$ in which all gates g have fan-out ≤ 1 and in which all gates g use as activation functions γ^g piecewise-polynomial functions of the following special type: γ^g consists of up to three pieces, of which at most one is not identically 0 and in which the nontrivial piece outputs the constant 1 or computes a power $y \mapsto y^k$ (where $k \in \mathbf{N}$ satisfies $k = O(1)$). The preceding "normalization" of activation functions is easy to achieve, since every activation function of a gate in $\mathcal{N}_n$ can be written as linear combination of activation functions of this normalized type. The transformation from $\mathcal{N}_n$ to $\hat{\mathcal{N}}_n$ can be carried out in such a way that for every assignment $\underline{\alpha}_n$ of real values to the programmable parameters of $\mathcal{N}_n$ there exists an assignment $\underline{\beta}_n$ of real numbers to the programmable parameters of $\hat{\mathcal{N}}_n$ such that

$$\forall \underline{x} \in \{0,1\}^n (\mathcal{N}_n^{\underline{\alpha}_n}(\underline{x}) = \hat{\mathcal{N}}_n^{\underline{\beta}_n}(\underline{x})),$$

and such that any strict inequality "$s_1 < s_2$" that arises in the computation of $\hat{\mathcal{N}}_n^{\underline{\beta}_n}$ for some input $\underline{x} \in \{0,1\}^n$ (when one compares some subresult of that computation with a threshold of the activation function of some gate or with the outer threshold of $\hat{\mathcal{N}}_n^{\underline{\beta}_n}$) can be replaced by the stronger inequality "$s_1 + 1 \leq s_2$."

It would also be possible to push all nontrivial weights to the gates on level 1 in correspondence to the construction in the proof of Theorem 2.1. However, in the present context this additional operation does not eliminate nonlinear conditions on the weights. Assume for example that g is a gate on level 1 with input $\alpha_1 x_1 + \alpha_2 x_2$ and activation function $\gamma^g(y) = y^2$. Then this gate g outputs $\alpha_1^2 x_1^2 + 2\alpha_1\alpha_2 x_1 x_2 + \alpha_2^2 x_2^2$. Hence the variables α_1, α_2 will not occur linearly in an inequality which describes the comparison of the output of g with some threshold of a gate at the next level.

Although it does not eliminate nonlinear conditions on the weights if one pushes all weights toward level 1, the resulting network provides some notational advantage because all weights between computation nodes can be treated as constants (with three possible values). This approach has therefore been chosen in [M92] and [M93a]. However, this approach is disadvantageous if one wants to apply the method of this proof in the context of agnostic PAC learning on analog neural nets [M93c]. In this application one has to be able to control the bit-length of the (rational) weights. Therefore, one cannot afford to push all weights toward level 1, since this may increase the bit-length of weights in an unbounded manner. For example, if one pushes the weight 2 through a gate g with activation function $\gamma^g(y) = y^2$, then this weight is changed to $\sqrt{2}$ (since $2\gamma^g(y) = \gamma^g(\sqrt{2} \cdot y)$).

Since the nonlinearity of the conditions on the weights cannot be eliminated in the same way as for Theorem 2.1, we have to introduce an alternative method. We fix an arbitrary assignment $\underline{\beta}_n$ of real numbers to the programmable parameters of $\hat{\mathcal{N}}_n$. We introduce for the system of inequalities $L(\hat{\mathcal{N}}_n^{\underline{\beta}_n}, \{0,1\}^n)$ (that describes the computations of $\hat{\mathcal{N}}_n^{\underline{\beta}_n}$ for all inputs $\underline{x} \in \{0,1\}^n$) new variables v for all nontrivial parameters in $\hat{\mathcal{N}}_n^{\underline{\beta}_n}$ (i.e., for the weights and bias of each gate g, for the outer threshold T_{out}, and for the *thresholds* t_1^g, t_2^g *of each gate* g). In addition we introduce new variables for all *products* of such parameters that arise in the computation of $\hat{\mathcal{N}}_n^{\underline{\beta}_n}$. We have to keep the inequalities linear in order to apply Lemma 2.4. Hence we cannot demand in these inequalities that the value of the variable $v_{v_1^g, v_2^g}$ (that represents the product of α_1^g and α_2^g) is the product of the values of the variables v_1^g and v_2^g (that represent the weights α_1^g, respectively, α_2^g). We solve this problem by describing in detail in the linear inequalities $L(\hat{\mathcal{N}}_n^{\underline{\beta}_n}, \{0,1\}^n)$ which *role* the product of α_1^g and α_2^g plays in the computations of $\hat{\mathcal{N}}_n^{\underline{\beta}_n}$ for inputs from $\{0,1\}^n$. It turns out that this can be done in such a way that it does not matter whether a solution $\mathcal{A}$ of $L(\hat{\mathcal{N}}_n^{\underline{\beta}_n}, \{0,1\}^n)$ assigns to the variable $v_{v_1^g, v_2^g}$ a value $\mathcal{A}(v_{v_1^g, v_2^g})$ that is equal to the product of the values $\mathcal{A}(v_1^g)$ and $\mathcal{A}(v_2^g)$ (that are assigned by $\mathcal{A}$ to the variables v_1^g and v_2^g). In any case $\mathcal{A}(v_{v_1^g, v_2^g})$ is forced to behave like the product of $\mathcal{A}(v_1^g)$ and $\mathcal{A}(v_2^g)$ in the computations of $\hat{\mathcal{N}}_n^{\underline{\beta}_n}$.

We would like to emphasize that the parameters $\underline{\beta}_n$ do not occur as constants in the system $L(\hat{\mathcal{N}}_n^{\underline{\beta}_n}, \{0,1\}^n)$ of inequalities. They are also replaced by variables. The reason the real-valued parameters $\underline{\beta}_n$ occur nevertheless in our notation $L(\hat{\mathcal{N}}_n^{\underline{\beta}_n}, \{0,1\}^n)$ of inequalities is the following. These inequalities consist of conditions which demand that for any input $\underline{x} \in \{0,1\}^n$ the computation on the neural net proceeds exactly as for the parameter assignment $\underline{\beta}_n$ (i.e., the same inequalities with thresholds of the piecewise-polynomial activation functions are satisfied and the same pieces of the activation functions are used at each gate as in the computation with parameter assignment $\underline{\beta}_n$).

Before we present the formal definitions and proofs, we give a high-level description of the proof idea and the purpose of the formal definitions. These preceding informal remarks should be real *interactively* with the subsequent formal part.

In more abstract terms, one may view any solution $\mathcal{A}$ of $L(\hat{\mathcal{N}}_n^{\underline{\beta}_n}, \{0,1\}^n)$ as a model of a certain linear fragment $L(\hat{\mathcal{N}}_n^{\underline{\beta}_n}, \{0,1\}^n)$ of the theory of the role of the parameters $\underline{\beta}_n$ in the computations of $\hat{\mathcal{N}}_n^{\underline{\beta}_n}$ on inputs from $\{0,1\}^n$. Such a model $\mathcal{A}$ (which will be given by Lemma 2.4) may be viewed as some type of nonstandard model of the theory of computations of $\hat{\mathcal{N}}_n^{\underline{\beta}_n}$, since it replaces products of weights by values that one might call nonstandard products. Such a nonstandard model $\mathcal{A}$ does not provide a new assignment of (small) weights to the network architecture $\hat{\mathcal{N}}_n$, only to a nonstandard version $\mathcal{M}_n^{\mathcal{A}}$ of the neural net $\hat{\mathcal{N}}_n^{\underline{\beta}_n}$. However the linear fragment $L(\hat{\mathcal{N}}_n^{\underline{\beta}_n}, \{0,1\}^n)$ can be chosen in such a way that $\mathcal{M}_n^{\mathcal{A}}$ computes the same Boolean function as $\hat{\mathcal{N}}_n^{\underline{\beta}_n}$. Furthermore, if $\mathcal{A}$ consists of a solution with rational numbers as given by Lemma 2.4, then $\mathcal{M}_n^{\mathcal{A}}$ can be simulated by a constant-depth polynomial-size Boolean circuit whose gates g are all MAJORITY-gates (i.e., $g(y_1, \ldots, y_m) = 1$ if $\sum_{i=1}^m y_i \geq m/2$; otherwise $g(y_1, \ldots, y_m) = 0$). This implies that the Boolean functions

that are computed by $(\mathcal{M}_n^{\mathcal{A}})_{n\in\mathbf{N}}$ are in TC^0. However, by construction these are the same Boolean functions that are computed by $(\mathcal{N}_n^{\underline{\alpha}_n})_{n\in\mathbf{N}}$.

We will now describe the details of the previously sketched proof of Theorem 3.1. We will simply write $\mathcal{N}$ instead of $\hat{\mathcal{N}}_n^{\underline{\beta}_n}$ (where $\underline{\beta}_n$ is some assignment of real numbers to the programmable parameters of the network architecture $\hat{\mathcal{N}}_n$). We will define for each gate g in $\mathcal{N}$ by induction on the depth of g,

(1) in Definition 3.3 a set V^g of variables and a set M^g of formal terms that are needed to describe the operation of gate g.

[The intuition is here that one writes for any network input $\underline{x}$ the output of g as a sum of products (of programmable parameters, of architectural parameters, and of components of $\underline{x}$). *Which* of these terms will occur for a specific circuit input $\underline{x}$ will depend on the course of the computation in $\mathcal{N}$ up to gate g: for different inputs the involved gates may use different pieces of their activation function. The set M^g contains a separate formal term for each product that *may* possibly occur in this sum. Each term in M^g consists of a variable $w \in V^g$ (that represents a programmable or architectural parameter of $\mathcal{N}$ or some product of these) and of a product $P \equiv \pm \boldsymbol{x}_1^{j_1} \cdot \ldots \cdot \boldsymbol{x}_n^{j_n}$ of input *variables* $\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n$.]

(2) in Definition 3.4 for any fixed network input $\underline{x} \in \mathbf{R}^n$ a set $L^g(\underline{x})$ of linear inequalities associated with gate g (with variables from $V^{\mathcal{N}} := \cup\{V^{g'} | g'$ is a gate of $\mathcal{N}\}$) that hold for the computation of $\mathcal{N}$ on input $\underline{x}$ if all formal terms $t \in M^g$ are replaced by their actual value $W(t, \underline{x})$ for the given parameter assignment in $\mathcal{N}$. We also define in Definition 3.4 a set $S^g(\underline{x})$ of formal terms whose sum represents the input of g and a set $T^g(\underline{x}) \subseteq M^g$ of formal terms whose sum represents the output of g for circuit input $\underline{x}$.

[$L^g(\underline{x})$ specifies in particular which piece of γ^g is used by gate g for network input $\underline{x}$.]

(3) in Definition 3.6 for any input set $S \subseteq \mathbf{R}^n$, any solution $\mathcal{A}$ of the resulting system $L(\mathcal{N}, S) := \cup\{L^g(\underline{x}) \mid \underline{x} \in S$ and g is a gate in $\mathcal{N}\}$ of linear inequalities, and any term $t \in M^g$ a network architecture $\mathcal{M}_{g,t}^{\mathcal{A}}$ that decides for any network input $\underline{x} \in S$ whether t occurs as a summand in the output of g in $\mathcal{N}$.

[For any input $\underline{x} \in S$ the network architectures $(\mathcal{M}_{g,t}^{\mathcal{A}})_{t\in M^g}$ together compute the characteristic function of the set $T^g(\underline{x}) \subseteq M^g$ which represents the output of gate g in $\mathcal{N}$. In this way one can replace in a recursive manner the analog computations in $\mathcal{N}$ by digital manipulations of formal terms, with "nonstandard products" of weights in place of real products.]

One verifies in Lemma 3.5 that $L(\mathcal{N}, S)$ describes correctly the role of the parameters $\underline{\beta}_n$ in the computations of $\mathcal{N} := \hat{\mathcal{N}}_n^{\underline{\beta}_n}$ for inputs $\underline{x} \in S$. Unfortunately, $L(\mathcal{N}, S)$ does not provide a complete description of the properties of the parameters $\underline{\beta}_n$ in these computations, since it represents only a linear fragment of their theory. Nevertheless, one can prove with the help of Lemmas 3.7 and 3.8 that for *any* solution $\mathcal{A}$ of $L(\mathcal{N}, S)$ the network architectures $\mathcal{M}_{g,t}^{\mathcal{A}}$ carry out a truthful simulation of the corresponding initial segments of $\mathcal{N}$.

We would like to point out a difference to the proof of Theorem 2.1 regarding the treatment of architectural parameters. In the proof of Theorem 3.1 the programmable parameters $\underline{\alpha}_n$ of $\mathcal{N}_n^{\underline{\alpha}_n}$ and the architectural parameters of the given network architecture $\mathcal{N}_n$ (the thresholds of activation functions γ^g and the coefficients of the polynomial pieces of γ^g) are all changed simultaneously in the transformation to $\hat{\mathcal{N}}_n^{\underline{\beta}_n}$. Consequently, $\underline{\beta}_n$ denotes the values of *all* nontrivial parameters in $\hat{\mathcal{N}}_n^{\underline{\beta}_n}$ (i.e., of all

programmable and architectural parameters). As a consequence of this treatment of parameters one can allow in the given network architectures $\mathcal{N}_n$ of Theorem 3.1 *arbitrary reals* as architectural parameters (i.e., for the thresholds and coefficients of the polynomial pieces of the given activation functions γ^g).

We refer to an analog network architecture $\mathcal{N}$ with the properties of $\hat{\mathcal{N}}_n^{\underline{\beta}_n}$ as a network architecture in *normal form.* This means that $\mathcal{N}$ is a first-order network architecture whose gates have fan-out ≤ 1; all gates g in $\mathcal{N}$ use as activation function γ^g a piecewise-polynomial function that consists of three pieces, of which at most one piece is not identically 0 and in which the nontrivial piece (if it exists) outputs the constant 1 or computes a power $y \mapsto y^k$ for some $k \in \mathbf{N}$.

In order to simplify our notation, we assume that for a network architecture $\mathcal{N}$ in normal form the nontrivial piece of the activation function γ^g of each gate g is defined over a half-open interval $[t_1^g, t_2^g)$ with certain reals $t_1^g < t_2^g$. It is easy to see that the subsequent proof can also be carried out without this simplifying assumption. We also assume without loss of generality (w.l.o.g.) that $\mathcal{N}$ is leveled, i.e., each gate g in $\mathcal{N}$ has the property that all paths in $\mathcal{N}$ from an input node to g have the same length.

DEFINITION 3.3. *Assume that $\mathcal{N}$ is a network architecture in normal form with n input variables $x_1, \ldots, x_n$, where arbitrary reals have been assigned to all parameters of $\mathcal{N}$. We define by induction on the depth of g for each gate g in $\mathcal{N}$ a set V^g of variables, a value $W(v)$ for each variable $v \in V^g$ (that arises from the assignment $\underline{\beta}_n$ in $\hat{\mathcal{N}}_n^{\underline{\beta}_n} := \mathcal{N}$), and a set M^g of (formal) terms. Each element of M^g is of the form $v \cdot P$, where $v \in V^g$ is a variable and P is some formal polynomial term of the form $\pm \boldsymbol{x}_1^{j_1} \cdot \ldots \cdot \boldsymbol{x}_n^{j_n}$, with $j_1, \ldots, j_n \in \boldsymbol{N}$. The here-occurring* formal variables $\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n$ *for the input components should be distinguished from the* concrete values $x_1, \ldots, x_n \in \boldsymbol{R}$ *for these variables that are considered later (starting in Definition* 3.4).

We consider first the case where g has depth 1. *If γ^g gives on its nontrivial piece $[t_1^g, t_2^g)$ the constant* 1 *as output, we set*

$$V^g := \{v_0^g, \ldots, v_n^g\} \cup \{v_{\text{const}}^g\} \cup \{v_{\text{I}}^g, v_{\text{II}}^g\} \text{ and } M^g := \{v_{\text{const}}^g\}.$$

We define $W(v_i^g) := \alpha_i^g$ for $i = 0, \ldots, n$, $W(v_{\text{const}}^g) := \alpha^g$, $W(v_{\text{I}}^g) := t_1^g$, and $W(v_{\text{II}}^g) := t_2^g$ ($\alpha_1^g, \ldots, \alpha_n^g$ are the weights and α_0^g is the bias of gate g in $\mathcal{N}$, α^g is the weight on the edge that leaves g, and t_1^g, t_2^g are the thresholds of the activation function γ^g). In the other case γ^g computes a power $y \mapsto y^k$ on its nontrivial piece. Then we introduce for each ktuple $\langle w_1 \cdot P_1, \ldots, w_k \cdot P_k \rangle \in (\{v_0^g\} \cup \{v_1^g \cdot \boldsymbol{x}_1, \ldots, v_n^g \cdot \boldsymbol{x}_n\})^k$ a new variable $v_{w_1,\ldots,w_k}^g$ in V^g and a term $v_{w_1,\ldots,w_k}^g \cdot \prod_{i=1}^k P_i$ in M^g. We assume here that a formal multiplication $P \cdot P'$ for formal terms P, P' of the form $\pm \boldsymbol{x}_1^{j_1} \cdot \ldots \cdot \boldsymbol{x}_n^{j_n}$ is defined in the obvious way. We define

$$V^g := \{v_0^g, \ldots, v_n^g\} \cup \{v_{\text{I}}^g, v_{\text{II}}^g\} \cup \{v_{w_1,\ldots,w_k}^g \mid \langle w_1, \ldots, w_k \rangle \in \{v_0^g, \ldots, v_n^g\}^k\}.$$

We set $W(v_{w_1,\ldots,w_k}^g) := \alpha^g \cdot \prod_{i=1}^k W(w_i)$, and we define $W(v)$ for the other variables as before. We define

$$M^g := \left\{ v_{w_1,\ldots,w_k}^g \cdot \prod_{i=1}^k P_i \mid \langle w_1 \cdot P_1, \ldots, w_k \cdot P_k \rangle \in (\{v_0^g\} \cup \{v_1^g \cdot \boldsymbol{x}_1, \ldots, v_n^g \cdot \boldsymbol{x}_n\})^k \right\}.$$

[The terms in M^g denote the summands that one gets from the output $(\alpha_0^g + \sum_{i=1}^m \alpha_i^g \cdot x_i)^k$ of γ^g by multiplying this output with the weight α^g on the next edge and then rewriting it as a sum of products.]

We now consider the case where g is a gate on level $l+1$, with edges from the gates $g_1, \ldots, g_m$ on level l leading into g. Assume that $\alpha_1^g, \ldots, \alpha_m^g$ are in $\mathcal{N}$, the weights on these edges, that α^g is the weight on the edge out of g, and that α_0^g is the bias of g. If g is an output gate (i.e., g has fan-out 0) then we set $\alpha^g := 1$. If γ^g outputs the constant 1 on its nontrivial piece, we set

$$V^g := \{v_0^g, v_{\text{const}}^g\} \cup \{v_{\text{I}}^g, v_{\text{II}}^g\} \text{ and } M^g := \{v_{\text{const}}^g\}.$$

We set $W(v_0^g) := \alpha_0^g$, $W(v_{\text{const}}^g) := \alpha^g, W(v_{\text{I}}^g) := t_1^g$, and $W(v_{\text{II}}^g) := t_2^g$. If γ^g computes the power $y \mapsto y^k$ on its nontrivial piece, we introduce for each $k$tuple

$$\langle w_1 \cdot P_1, \ldots, w_k \cdot P_k \rangle \in \left(\{v_0^g\} \cup \bigcup_{j=1}^m M^{g_j} \right)^k$$

a new variable $v_{w_1,\ldots,w_k}^g$ in V^g and a term $v_{w_1,\ldots,w_k}^g \cdot \prod_{i=1}^k P_i$ in M^g. Thus we set

$$V^g := \{v_0^g\} \cup \{v_{\text{I}}^g, v_{\text{II}}^g\} \cup \{v_{w_1,\ldots,w_k}^g \mid \langle w_1 \cdot P_1, \ldots, w_k \cdot P_k \rangle \in \left(\{v_0^g\} \cup \bigcup_{j=1}^m M^{g_j} \right)^k,$$

for arbitrary polynomial terms $P_1, \ldots, P_k$ and variables $w_i \in (\{v_0^g\} \cup \bigcup_{j=1}^m V^{g_j})\}$.

We define $W(v_{w_1,\ldots,w_k}^g) := \alpha^g \cdot \prod_{i=1}^k W(w_i)$, $W(v_0^g) := \alpha_0^g$, $W(v_{\text{I}}^g) := t_1^g$, $W(v_{\text{II}}^g) := t_2^g$.
We set

$$M^g := \left\{ v_{w_1,\ldots,w_k}^g \cdot \prod_{i=1}^k P_i \mid \langle w_1 \cdot P_1, \ldots, w_k \cdot P_k \rangle \in \left(\{v_0^g\} \cup \bigcup_{j=1}^m M^{g_j} \right)^k \right\}.$$

[The argument of γ^g is a sum of α_0^g and of summands that are denoted by terms in $\cup_{j=1}^m M^{g_j}$. Hence the terms in M^g correspond to the summands that one gets by multiplying the output of γ^g with the weight on the next edge and then rewriting this product as a sum of products by multiplying out.]

Finally, for the output gate g_{out} of $\mathcal{N}$, we place into V^g in addition the variable $v^{g_{\text{out}}}$. We define $W(v^{g_{\text{out}}})$ as the value of the outer threshold of $\mathcal{N}$.

DEFINITION 3.4. *Assume that $\mathcal{N}$ is a network architecture in normal form with n input variables and some fixed assignment of reals to its parameters. Let $\underline{x} \in \boldsymbol{R}^n$ be a fixed input for $\mathcal{N}$. We define for each gate g in $\mathcal{N}$ by simultaneous induction on the depth of g*

(1) *a set $L^g(\underline{x})$ of inequalities (that are linear in the variables from V^G),*

(2) *a set $S^g(\underline{x})$ of formal terms (whose sum represents the argument of γ^g for network input $\underline{x}$),*

(3) *a set $T^g(\underline{x}) \subseteq M^g$ (whose sum represents the output of g for network input $\underline{x}$ after multiplication with the weight on the next edge).*

Since $\underline{x}$ is now a fixed element of $\boldsymbol{R}^n$, one can assign a specific value $W(P, \underline{x}) \in \boldsymbol{R}$ to each term P of the form $\pm \boldsymbol{x}_1^{j_1} \cdot \ldots \cdot \boldsymbol{x}_n^{j_n}$ that occurs in a formal term of the preceding

definition. Hence one can assign to any formal term $t = v \cdot P$ *(that belongs to some* M^g*) a specific value* $W(t, \underline{x}) := W(v) \cdot W(P, \underline{x})$*. For a set* S *of formal terms we define* $W(S, \underline{x}) := \sum_{t \in S} W(t, \underline{x})$*. For the case* $S = \phi$ *we set* $W(\phi, \underline{x}) := 0$*.*

The value $W(t, \underline{x})$ *of a formal term* t *reflects the value of this term for network input* $\underline{x}$ *under the fixed parameter assignment in* $\mathcal{N}$*. These values* $W(t, \underline{x})$ *are needed for the definition of the systems* $L^g(\underline{x})$ *and* $L(\mathcal{N}, \underline{x})$ *of linear inequalities that describe the computation of* $\mathcal{N}$*.*

If g *has depth* 1*, then we define*

$$S^g(\underline{x}) := \{v_0^g\} \cup \{v_i^g \cdot \boldsymbol{x}_i \mid i = 1, \ldots, n\}.$$

Assume that g *is a gate on level* $l + 1$ *with edges from gates* $g_1, \ldots, g_m$ *on level* l *leading into* g*. Then we set*

$$S^g(\underline{x}) := \{v_0^g\} \cup \bigcup_{j=1}^{m} T^{g_j}(\underline{x}).$$

We define $L^g(\underline{x})$ *and* $T^g(\underline{x})$ *as follows for any gate* g *in* $\mathcal{N}$*. If* $W(S^g(\underline{x}), \underline{x}) < t_1^g$*, then* $L^g(\underline{x})$ *contains the inequality* $[\sum S^g(\underline{x}) + 1]_{\underline{\boldsymbol{x}}}[\underline{x}] \leq v_{\mathrm{I}}^g$*. If* $W(S^g(\underline{x}), \underline{x}) \geq t_2^g$*, then* $L^g(\underline{x})$ *contains the inequality* $[\sum S^g(\underline{x})]_{\underline{\boldsymbol{x}}}[\underline{x}] \geq v_{\mathrm{II}}^g$*. In either case we set* $T^g(\underline{x}) := \phi$*.*

[We use here and in the following the notation $[H]_{\underline{\boldsymbol{x}}}[\underline{x}]$ for any sum H of formal terms to indicate that each variable $\boldsymbol{x}_i$ in H is replaced by the value of the ith coordinate x_i of the concrete input $\underline{x} \in \mathbf{R}^n$. Note that the only variables that are left in $[H]_{\underline{\boldsymbol{x}}}[\underline{x}]$ are the variables of the form v_{const}^g, v_i^g, or $v_{w_1,\ldots,w_k}^g$. This substitution is necessary to make sure that the only variables that occur in the resulting system $L(\mathcal{N}, S)$ of linear inequalities are of this type or are variables of the form $v_{\mathrm{I}}^g, v_{\mathrm{II}}^g$.]

If $t_1^g \leq W(S^g(\underline{x}), \underline{x}) < t_2^g$*, then* $L^g(\underline{x})$ *contains the inequalities* $v_{\mathrm{I}}^g \leq [\sum S^g(\underline{x})]_{\underline{\boldsymbol{x}}}[x]$ *and* $[\sum S^g(\underline{x}) + 1]_{\underline{\boldsymbol{x}}}[\underline{x}] \leq v_{\mathrm{II}}^g$*. If* γ^g *gives on its nontrivial piece a constant* a^g *as output, we set in this case* $T^g(\underline{x}) := \{v_{\mathrm{const}}^g\}$*. If* γ^g *computes on its nontrivial piece a power* $y \mapsto y^k$*, we set*

$$T^g(\underline{x}) := \left\{ v_{w_1,\ldots,w_k}^g \cdot \prod_{i=1}^{k} P_i \mid \langle w_1 \cdot P_1, \ldots, w_k \cdot P_k \rangle \in (\{v_0^g\} \cup \{v_1^g \cdot \boldsymbol{x}_1, \ldots, v_n^g \cdot \boldsymbol{x}_n\})^k \right\}$$

if g *has depth* 1*, and in the general case*

$$T^g(\underline{x}) := \left\{ v_{w_1,\ldots,w_k}^g \cdot \prod_{i=1}^{k} P_i \mid \langle w_1 \cdot P_1, \ldots, w_k \cdot P_k \rangle \in \left(\{v_0^g\} \cup \bigcup_{j=1}^{m} T^{g_j}(\underline{x}) \right)^k \right\}.$$

Finally, if g *is the output gate* g_{out} *of* $\mathcal{N}$ *and* $W(T^{g_{\mathrm{out}}}(\underline{x}), \underline{x}) < W(v^{g_{\mathrm{out}}})$*, we add to* $L^{g_{\mathrm{out}}}(\underline{x})$ *also the inequality* $[\sum T^{g_{\mathrm{out}}}(\underline{x}) + 1]_{\underline{\boldsymbol{x}}}[\underline{x}] \leq v^{g_{\mathrm{out}}}$*. If* $W(T^{g_{\mathrm{out}}}(\underline{x}), \underline{x}) \geq W(v^{g_{\mathrm{out}}})$*, we add to* $L^{g_{\mathrm{out}}}(\underline{x})$ *also the inequality* $[\sum T^{g_{\mathrm{out}}}(\underline{x})]_{\underline{\boldsymbol{x}}}[\underline{x}] \geq v^{g_{\mathrm{out}}}$*.*

We define

$$L(\mathcal{N}, \underline{x}) := \bigcup \{L^g(\underline{x}) \mid g \text{ is a gate of } \mathcal{N}\},$$

and for $S \subseteq \boldsymbol{R}^n$

$$L(\mathcal{N}, S) := \bigcup \{L(\mathcal{N}, \underline{x}) \mid \underline{x} \in S\}.$$

The following lemma verifies that for any $\underline{x} \in \boldsymbol{R}^n$ the system $L(\mathcal{N}, \underline{x})$ of inequalities provides a truthful description of the computation of $\mathcal{N}$ for input $\underline{x}$.

LEMMA 3.5. *Assume that $\mathcal{N}$ is a network architecture in normal form with n input variables and some arbitrary assignment to its parameters and that $\underline{x} \in \boldsymbol{R}^n$ is an arbitrary concrete input.*

Then we have for any gate g in $\mathcal{N}$ that $W(S^g(\underline{x}), \underline{x})$ is the input and $W(T^g(\underline{x}), \underline{x})$ is the output of gate g (multiplied with the weight on the next edge) in the computation of $\mathcal{N}$ for input $\underline{x}$. Furthermore,

$$W(S^g(\underline{x}), \underline{x}) < t_1^g \Leftrightarrow \text{“}[S^g(\underline{x}) + 1]_{\underline{\boldsymbol{x}}}[\underline{x}] \leq v_{\mathrm{I}}^g\text{”} \in L(\mathcal{N}, \underline{x})$$
$$W(S^g(\underline{x}), \underline{x}) < t_2^g \Leftrightarrow \text{“}[S^g(\underline{x}) + 1]_{\underline{\boldsymbol{x}}}[\underline{x}] \leq v_{\mathrm{II}}^g\text{”} \in L(\mathcal{N}, \underline{x})$$
$$W(S^g(\underline{x}), \underline{x}) \geq t_1^g \Leftrightarrow \text{“}[S^g(\underline{x})]_{\underline{\boldsymbol{x}}}[\underline{x}] \quad\; \geq v_{\mathrm{I}}^g\text{”} \in L(\mathcal{N}, \underline{x})$$
$$W(S^g(\underline{x}), \underline{x}) \geq t_2^g \Leftrightarrow \text{“}[S^g(\underline{x})]_{\underline{\boldsymbol{x}}}[\underline{x}] \quad\; \geq v_{\mathrm{II}}^g\text{”} \in L(\mathcal{N}, \underline{x}).$$

Proof. The claim about $L(\mathcal{N}, \underline{x})$ follows immediately from the definition of $L(\mathcal{N}, \underline{x})$ in Definition 3.4.

One shows by induction on g that for any network input $\underline{x}$ the input of g in $\mathcal{N}$ is equal to $W(S^g(\underline{x}), \underline{x})$, and the output of g in $\mathcal{N}$ (after multiplication with the weight on the next edge) is equal to $W(T^g(\underline{x}), \underline{x})$.

If g is of depth 1 then we have by the definition of $S^g(\underline{x})$ in Definition 3.4 and by the definition of the values $W(t, \underline{x})$ for terms t in Definition 3.3 that $W(S^g(\underline{x}), \underline{x}) = \alpha_0^g + \sum_{i=1}^n \alpha_i^g \cdot x_i$, where $\alpha_1, \ldots, \alpha_n^g$ are the weights and α_0^g is the bias of gate g in $\mathcal{N}$ under the given parameter assignment in $\mathcal{N}$. Hence $W(S^g(\underline{x}), \underline{x})$ is equal to the input of g in $\mathcal{N}$ for network input $\underline{x}$. Furthermore if $\alpha_0^g + \sum_{i=1}^n \alpha_i^g \cdot x_i < t_1^g$ or $\alpha_0^g + \sum_{i=1}^n \alpha_i^g \cdot x_i \geq t_2^g$ then $T^g(\underline{x}) = \phi$; hence $W(T^g(\underline{x}), \underline{x}) = 0$. If $t_1^g \leq \alpha_0^g + \sum_{i=1}^n \alpha_i^g \cdot x_i < t_2^g$ then $W(T^g(\underline{x}), \underline{x}) = \alpha^g$ if γ^g outputs the constant 1 on its nontrivial piece (where α^g is the weight on the edge out of g). If γ^g computes $y \mapsto y^k$ on its nontrivial piece, then $W(T^g(\underline{x}), \underline{x}) = \alpha^g \cdot \sum(\{\alpha_0^g\} \cup \{\alpha_i^g \cdot x_i \mid i = 1, \ldots, n\})^k$. In either case $W(T^g(\underline{x}), \underline{x})$ is equal to the output of g in $\mathcal{N}$ (multiplied with α^g) for network input $\underline{x}$.

If g is of depth $l+1$ with immediate predecessors $g_1, \ldots, g_m$ then $W(S^g(\underline{x}), \underline{x}) = \alpha_0^g + \sum_{j=1}^m W(T^{g_j}(\underline{x}), \underline{x})$. By induction hypothesis this value is equal to the input of gate g in $\mathcal{N}$ for network input $\underline{x}$. In the most interesting case, where gate g applies the polynomial piece $y \mapsto y^k$ to this input, its output (multiplied with α^g) is equal to

$$\alpha^g \cdot \left(\alpha_0^g + \sum_{j=1}^m W(T^{g_j}(\underline{x}), \underline{x}) \right)^k$$

$$= \alpha^g \cdot \sum \left\{ \sum_{i=1}^k W(w_i \cdot P_i, \underline{x}) | \langle w_1 \cdot P_1, \ldots, w_k \cdot P_k \rangle \in \left(\{v_0^g\} \cup \bigcup_{j=1}^m T^{g_j}(\underline{x}) \right)^k \right\}$$

$$= \sum \left\{ W(v^g_{w_1, \ldots, w_k}) \cdot \prod_{i=1}^k W(P_i, \underline{x}) | \langle w_1 \cdot P_1, \ldots, w_k \cdot P_k \rangle \in \left(\{v_0^g\} \cup \bigcup_{j=1}^m T^{g_j}(\underline{x}) \right)^k \right\}$$

$$= W(T^g(\underline{x}), \underline{x}). \qquad \square$$

DEFINITION 3.6. *Assume that $\mathcal{N}$ is a neural act in normal form with n inputs. Furthermore, assume that $S \subseteq \boldsymbol{R}^n$ and $\mathcal{A} : V^{\mathcal{N}} \to \boldsymbol{R}$ is an arbitrary solution of the system $L(\mathcal{N}, S)$ of inequalities with the variable set $V^{\mathcal{N}} := \bigcup\{V^g \mid g \text{ is a gate in } \mathcal{N}\}$.*

We define by induction on the depth of gate g in $\mathcal{N}$ for each term $t \in M^g$ a first-order network architecture $\mathcal{M}^{\mathcal{A}}_{g,t}$. Together the network architectures $(\mathcal{M}^{\mathcal{A}}_{g,t})_{t\in M^g}$ mimic the initial segment of $\mathcal{N}$ between the input and gate g. The first-order network architecture $\mathcal{M}^{\mathcal{A}}_{g,t}$ consists of gates with activation functions from the class $\{$Heaviside, $y \mapsto y$, $y \mapsto y^2\}$. For any circuit input $\underline{x} \in S$ the output of the first-order network architecture $\mathcal{M}^{\mathcal{A}}_{g,t}$ will be 1 if $t \in T^g(\underline{x})$; otherwise it will be 0.

One associates with each network architecture $\mathcal{M}^{\mathcal{A}}_{g,t}$ for $t \in M^g$ of the form $t \equiv v \cdot P$ another network architecture $\tilde{\mathcal{M}}^{\mathcal{A}}_{g,t}$ that outputs for any network input $\underline{x} \in S$ the real number

$$\mathcal{A}(t, \underline{x}) := \begin{cases} \mathcal{A}(v) \cdot W(P, \underline{x}) & \text{if } \mathcal{M}^{\mathcal{A}}_{g,t}(\underline{x}) = 1, \\ 0 & \text{if } \mathcal{M}^{\mathcal{A}}_{g,t}(\underline{x}) = 0. \end{cases}$$

The extension from $\mathcal{M}^{\mathcal{A}}_{g,t}$ to $\tilde{\mathcal{M}}^{\mathcal{A}}_{g,t}$ is done in a canonical manner with the help of subcircuits that simulate product gates via the equality $y \cdot z = \frac{1}{2}((y+z)^2 - y^2 - z^2)$. Obviously, $\tilde{\mathcal{M}}^{\mathcal{A}}_{g,t}$ just has to compute the product of $\mathcal{A}(v)$, $W(P, \underline{x})$ and of the output of $\mathcal{M}^{\mathcal{A}}_{g,t}$ for network input $\underline{x}$.

The definition of a value $\mathcal{A}(t, \underline{x})$ for each term t and each $\underline{x} \in S$ is extended in a canonical way to arbitrary sets M of terms

$$\mathcal{A}(M, \underline{x}) := \sum_{t\in M} \mathcal{A}(t, \underline{x}), \qquad \mathcal{A}(\phi, \underline{x}) := 0.$$

We consider first the case where g has depth 1. Let H^g_1 be a linear threshold gate that checks whether $\mathcal{A}(v^g_{\mathrm{I}}) \le \mathcal{A}(S^g(\underline{x}), \underline{x})$, and let H^g_2 be a linear threshold gate that checks whether $\mathcal{A}(S^g(\underline{x}), \underline{x}) + 1 \le \mathcal{A}(v^g_{\mathrm{II}})$. For each term $t \in M^g$ we define $\mathcal{M}^{\mathcal{A}}_{g,t}$ to be the AND of H^g_1 and H^g_2.

Assume then that g is a gate on level $l+1$ with edges from the gates $g_1, \ldots, g_m$ on level l leading into g. According to Definition 3.4 we have in this case $S^g(\underline{x}) = \{v^g_0\} \cup \bigcup_{j=1}^m T^{g_j}(\underline{x})$ for every $\underline{x} \in S$. By induction hypothesis we have already defined network architectures $\mathcal{M}^{\mathcal{A}}_{g_j,t}$, and hence also network architectures $\tilde{\mathcal{M}}^{\mathcal{A}}_{g_j,t}$ for all $t \in M^{g_j}$, $j = 1, \ldots, m$. For each term $t \in M^g$ the network architecture $\mathcal{M}^{\mathcal{A}}_{g,t}$ employs two linear threshold gates H^g_1 and H^g_2, which receive their inputs from the network architectures $\tilde{\mathcal{M}}^{\mathcal{A}}_{g_j,t}$ for $t \in M^{g_j}$, $j = 1, \ldots, m$. The linear threshold gate H^g_1 has the task to check for any $\underline{x} \in S$ whether $\mathcal{A}(v^g_{\mathrm{I}}) \le \mathcal{A}(S^g(\underline{x}), \underline{x})$. Obviously it can easily accomplish this task provided that for input $\underline{x}$ the network architectures $\tilde{\mathcal{M}}^{\mathcal{A}}_{g_j,t}$ for $t \in M^{g_j} (j = 1, \ldots, m)$ give as output the value $\mathcal{A}(t, \underline{x})$. Analogously the linear threshold gate H^g_2 has the task to check whether $\mathcal{A}(S^g(\underline{x}), \underline{x}) + 1 \le \mathcal{A}(v^g_{\mathrm{II}})$.

If γ^g outputs the constant 1 on its nontrivial piece, $\mathcal{M}^{\mathcal{A}}_{g,v^g_{\mathrm{const}}}$ is defined as the AND of H^g_1 and H^g_2.

If γ^g computes $y \mapsto y^k$ on its nontrivial piece, then each $t \in M^g$ is of the form $v^g_{w_1,\ldots,w_k} \cdot \prod_{i=1}^k P_i$ for some ktuple $\langle w_1 \cdot P_1, \ldots, w_k \cdot P_k\rangle \in (\{v^g_0\} \cup \bigcup_{j=1}^m M^{g_j})^k$. In this case $\mathcal{M}^{\mathcal{A}}_{g,t}$ is defined as the AND of H^g_1, H^g_2 and of the outputs of the network architectures $\mathcal{M}^{\mathcal{A}}_{g_j,w_i\cdot P_i}$ for all $i \in \{1, \ldots, k\}$ and $j \in \{1, \ldots, m\}$ with $w_i \cdot P_i \in M^{g_j}$.

[A word of caution: Although the variable $v^g_{w_1,\ldots,w_k}$ is supposed to play the role of the product of $w_1,\ldots,w_k$ and α^g (where α^g is the weight on the edge out of g), the assignment $\mathcal{A}$ will in general *not* satisfy $\mathcal{A}(v^g_{w_1,\ldots,w_k}) = \mathcal{A}(\alpha^g)\cdot\prod_{i=1}^k \mathcal{A}(w_i)$.]

Finally we define the network architecture $\mathcal{M}^{\mathcal{A}}$ by using as components the network architectures $\mathcal{M}^{\mathcal{A}}_{g_{\text{out}},t}$ for all $t \in M^{g_{\text{out}}}$. The output of $\mathcal{M}^{\mathcal{A}}$ is given by a linear threshold gate H that checks whether $\sum_{t:\mathcal{M}^{\mathcal{A}}_{g_{\text{out}},t}(\underline{x})=1} \mathcal{A}(t,\underline{x}) \geq \mathcal{A}(v^{g_{\text{out}}})$.

LEMMA 3.7. *Assume that $S \subseteq \boldsymbol{R}^n$ and $\mathcal{A}$ is an arbitrary solution of $L(\mathcal{N},S)$. Then the following holds for any gate g in $\mathcal{N}$, for any term $t \in M^g$, and any input $\underline{x} \in S$:*

(a) *For network input $\underline{x}$ the gate H^g_1 in $\mathcal{M}^{\mathcal{A}}_{g,t}$ outputs 1 if and only if $t^g_1 \leq W(S^g(\underline{x}),\underline{x})$. Similarly the output of the gate H^g_2 in $\mathcal{M}^{\mathcal{A}}_{g,t}$ is 1 if and only if $W(S^g(\underline{x}),\underline{x}) + 1 \leq t^g_2$.*

(b) *$t \in T^g(\underline{x}) \Leftrightarrow$ ($\mathcal{M}^{\mathcal{A}}_{g,t}$ outputs 1 for network input $\underline{x}$).*

(c) *$\tilde{\mathcal{M}}^{\mathcal{A}}_{g,t}$ outputs $\mathcal{A}(t,\underline{x})$ for network input $\underline{x}$.*

Proof. The proof proceeds by induction on the depth of gate g. The claim is obvious from the definition if g is of depth 1. If g is of depth $l+1>1$ we exploit the induction hypothesis for the network architectures $\mathcal{M}^{\mathcal{A}}_{g_j,t}$ and $\tilde{\mathcal{M}}^{\mathcal{A}}_{g_j,t}$ with $t \in M^{g_j}$ (for the immediate predecessors g_j of gate g). Hence we may assume that gate H^g_1 in $\mathcal{M}^{\mathcal{A}}_{g,t}$ outputs 1 if and only if $\mathcal{A}(v^g_{\text{I}}) \leq \mathcal{A}(S^g(\underline{x}),\underline{x})$. Since $\mathcal{A}$ is a solution of $L(\mathcal{N},S)$, the latter inequality holds if and only if $L(\mathcal{N},S)$ contains the inequality $v^g_{\text{I}} \leq [S^g(\underline{x})]_{\underline{x}}[\underline{x}]$. By Lemma 3.5 this holds if and only if $t^g_1 \leq W(S^g(\underline{x}),\underline{x})$. The claim for H^g_2 is verified analogously.

The least trivial case for part (b) of the claim is the case where γ^g computes $y \mapsto y^k$ on its nontrivial piece. Then each $t \in M^g$ is of the form $v_{w_1,\ldots,w_k}\cdot\prod_{i=1}^k P_i$ for some $k$tuple $\langle w_1\cdot P_1,\ldots,w_k\cdot P_k\rangle \in (\{v^g_0\}\cup\bigcup_{j=1}^m M^{g_j})^k$. By definition of $T^g(\underline{x})$ we have $t \in T^g(\underline{x})$ if and only if $t^g_1 \leq W(S^g(\underline{x}),\underline{x}) < t^g_2$ and $w_i\cdot P_i \in T^{g_j}(t)$ for all $i \in \{1,\ldots,k\}$ and $j \in \{1,\ldots,m\}$ with $w_i\cdot P_i \in M^{g_j}$. By construction of $\mathcal{M}^{\mathcal{A}}_{g,t}$ and by the induction hypothesis we have that $\mathcal{M}^{\mathcal{A}}_{g,t}$ outputs 1 for network input $\underline{x}$ if and only if all of the preceding conditions are satisfied.

Part (c) of the claim for gate g follows immediately from part (b) and the definition of $\tilde{\mathcal{M}}^{\mathcal{A}}_{g,t}$. □

LEMMA 3.8. *Assume that $\mathcal{N}$ is a network architecture in normal form with n input variables, $S \subseteq \boldsymbol{R}^n$ is an arbitrary set of inputs, and $\mathcal{A}$ is an arbitrary solution of $L(\mathcal{N},S)$. Then $\mathcal{N}$ and $\mathcal{M}^{\mathcal{A}}$ compute the same function from S into $\{0,1\}$.*

Proof. This is an immediate consequence of Lemmas 3.5 and 3.7. By the definition of $\mathcal{M}^{\mathcal{A}}$ the output of $\mathcal{M}^{\mathcal{A}}$ for any network input $\underline{x} \in S$ is 1 if and only if $\sum_{t:\mathcal{M}^{\mathcal{A}}_{g_{\text{out}},t}(\underline{x})=1} \mathcal{A}(t,\underline{x}) \geq \mathcal{A}(v^{g_{\text{out}}})$. By Lemma 3.7 we have that $\mathcal{M}^{\mathcal{A}}_{g_{\text{out}},t}(\underline{x}) = 1 \Leftrightarrow t \in T^{g_{\text{out}}}(\underline{x})$. Hence, since $\mathcal{A}$ is a solution of $L(\mathcal{N},S)$, the preceding inequality holds if and only if $L(\mathcal{N},S)$ contains the inequality $[\sum T^{g_{\text{out}}}(\underline{x})]_{\underline{\boldsymbol{x}}}[\underline{x}] \geq v^{g_{\text{out}}}$. By definition of $L(\mathcal{N},S)$ the latter holds if and only if $W(T^{g_{\text{out}}}(\underline{x}),\underline{x}) \geq W(v^{g_{\text{out}}})$. By Lemma 3.5 the value $W(T^{g_{\text{out}}}(\underline{x}),\underline{x})$ is the output of g_{out} in $\mathcal{N}$ for network input $\underline{x}$. Hence $W(T^{g_{\text{out}}}(\underline{x}),\underline{x}) \geq W(v^{g_{\text{out}}})$ holds if and only if $\mathcal{N}$ outputs 1 for network input $\underline{x}$. □

We are now in a position where we can complete the proof of Theorem 3.1. Assume that a given array $(\mathcal{N}_n)_{n\in\mathbf{N}}$ of neural nets satisfies the assumption of Theorem 3.1 and that $(\underline{\alpha}_n)_{n\in\mathbf{N}}$ is an arbitrary array of real-valued assignments $\underline{\alpha}_n$ to the variable parameters in $\mathcal{N}_n$. One can transform the given neural nets $(\mathcal{N}_n^{\underline{\alpha}_n})_{n\in\mathbf{N}}$ into an array $(\hat{\mathcal{N}}_n^{\underline{\beta}_n})_{n\in\mathbf{N}}$ of neural nets in normal form (with properties as specified above) such that

$\hat{\mathcal{N}}_n^{\underline{\beta}_n}$ computes the same Boolean function as $\mathcal{N}_n^{\underline{\alpha}_n}$. We then apply the machinery from the definition and Lemmas 3.5 to 3.8 to each neural net $\mathcal{N} := \hat{\mathcal{N}}_n^{\underline{\beta}_n}$ with $S := \{0,1\}^n$. By construction of $\hat{\mathcal{N}}_n^{\underline{\beta}_n}$ the resulting system $L(\mathcal{N}, \{0,1\}^n)$ of inequalities has some solution over $\mathbf{R}$. We exploit here in particular that $\underline{\beta}_n$ was chosen so that all relevant strict inequalities "$s_1 < s_2$" in computations of $\hat{\mathcal{N}}_n^{\underline{\beta}_n}$ on inputs $\underline{x} \in \{0,1\}^n$ were strengthened to "$s_1 + 1 \leq s_2$." Since $|\bigcup\{M^g \mid g \text{ gate in } \hat{\mathcal{N}}_n^{\underline{\beta}_n}\}| = O(n^{O(1)})$, it follows that the number of gates in $\mathcal{M}^{\mathcal{A}}$ is bounded by $O(n^{O(1)})$.

The number of variables in $L(\mathcal{N}, \{0,1\}^n)$ is polynomial in n, and it only contains small constants. Hence by Lemma 2.4 there is a solution $\mathcal{A}$ of $L(\mathcal{N}, \{0,1\}^n)$ that consists of rationals of the form $\frac{s}{t}$ (with a common integer t) such that s and t are integers of size $2^{O(n^{O(1)})}$. By Lemma 3.8 the constructed network architecture $\mathcal{M}^{\mathcal{A}}$ computes the same Boolean function as $\mathcal{N}$. Furthermore all constants and parameters in $\mathcal{M}^{\mathcal{A}}$ are quotients of integers with polynomially in n many bits. Thus (see [SBKH], [SR]) one can carry out all arithmetical operations in $\mathcal{M}^{\mathcal{A}}$ for inputs from $\{0,1\}^n$ by polynomial-sized digital subcircuits of constant depth with linear threshold gates (or, equivalently, with MAJORITY-gates, see [CSV]). In the resulting circuit all parameters from $\mathcal{A}$ are replaced by corresponding sequences of bits. Hence one gets in this way neural nets $\tilde{\mathcal{N}}_n$ which satisfy the claim of Theorem 3.1. □

Remark 3.9. Sontag [S3] suggested using the quasilinearization that is achieved in the proof of Theorem 3.1 in order to also get upper bounds for the VC dimension over $\mathbf{R}^n$ by counting the number of components into which the weight space is partitioned by the hyperplanes that are defined by some arbitrary finite set $S \subseteq \mathbf{R}^n$ of inputs.

By letting $\underline{\alpha}_n$ vary and keeping the neural net $\mathcal{N}_n$ and the input $\underline{x} \in S$ fixed one gets up to $2^{O(n^{O(1)})}$ different systems $L(\hat{\mathcal{N}}_n^{\underline{\beta}_n}, \underline{x})$ in the proof of Theorem 3.1. Hence the total number l_n of linear inequalities that arise in this way for different $\underline{x} \in S$ and different parameters $\underline{\alpha}_n$ is bounded by $|S| \cdot 2^{O(n^{O(1)})}$. Furthermore, the total number w_n of variables that occur in these l_n inequalities is bounded by $O(n^{O(1)})$. Therefore the hyperplanes that are associated with these l_n inequalities partition the range $\mathbf{R}^{w_n}$ of the variables into at most $\sum_{k=0}^{w_n} \sum_{i=0}^{k} \binom{w_n - i}{k-i} \binom{l_n}{w_n - i} = |S|^{O(n^{O(1)})}$ connected components (Theorem 1.3 in [E]). Each $\mathcal{A} \in \mathbf{R}^{w_n}$ gives rise to at most $2^{O(n^{O(1)})}$ different network architectures $\mathcal{M}^{\mathcal{A}}$ when $\mathcal{N}_n$ and S are kept fixed, but the parameters $\underline{\alpha}_n$ vary. Thus each $\mathcal{A} \in \mathbf{R}^{w_n}$ can be used to compute at most $2^{O(n^{O(1)})}$ different functions $S \to \{0,1\}$ on the resulting circuits. Furthermore, if $\mathcal{A}$ and $\tilde{\mathcal{A}}$ belong to the *same* connected component of the partition of $\mathbf{R}^{w_n}$ then for all $\underline{\alpha}_n$ the network architectures $\mathcal{M}^{\mathcal{A}}$ and $\mathcal{M}^{\tilde{\mathcal{A}}}$ compute the same function $S \to \{0,1\}$. Hence if S is shattered by $\mathcal{N}_n$ (i.e., *any* function $S \to \{0,1\}$ can be computed by $\mathcal{N}_n^{\underline{\alpha}_n}$ for suitable parameters $\underline{\alpha}_n$) then $2^{|S|} \leq |S|^{O(n^{O(1)})} \cdot 2^{O(n^{O(1)})}$; hence $|S| = O(n^{O(1)})$. This implies that VC dimension $(\mathcal{N}_n, \mathbf{R}^n) = O(n^{O(1)})$.

One can apply in a similar fashion the linearization that is achieved in the proof of Theorem 2.1. Consider a neural net $\mathcal{N}$ over a graph $\langle V, E\rangle$ as in Theorem 2.1, but allow that each activation function γ^g consists of $\leq p$ linear pieces with arbitrary fixed *real* parameters. Then one can show that VC dimension $(\mathcal{N}, \mathbf{R}^n) = O(w^2 \log p)$, where $w := |V| + |E| + 1$ is the number of variable parameters in $\mathcal{N}$. It is sufficient to observe that for different $\underline{x} \in S$ and different initial assignments $\underline{\alpha}$ altogether at most $|S| \cdot 2^{O(w \log p)}$ linear inequalities arise in the description of the computations of the associated nets $\hat{\mathcal{N}}[\underline{c}]^{\underline{\beta}}$ for input $\underline{x}$. The associated hyperplanes partition the "weight space" $\mathbf{R}^w$ for the variable parameters $\underline{\beta}$, $\underline{c}$ into $\leq |S|^{O(w)} \cdot 2^{O(w^2 \log p)}$ connected

components. The vectors from each connected component can be used to compute at most $2^{O(w)}$ different functions $S \to \{0,1\}$ (note that in general more than one function $S \to \{0,1\}$ can be computed because of different weights from $\{-1,0,1\}$ between computation nodes). Hence $2^{|S|} \leq |S|^{O(w)} \cdot 2^{O(w^2 \log p)} \cdot 2^{O(w)}$ if S is shattered by $\mathcal{N}$; thus $|S| = O(w^2 \log p)$.

Subsequent to this observation from [M92] and [M93a], our polynomial upper bound for the VC dimension of analog neural nets of constant depth has been extended to neural nets of unbounded depth via an application of a well-known theorem of Milnor [GJ]. In [M93c] this result has been further generalized to yield a polynomial upper bound for the *pseudodimension* (see [H]) of analog neural nets of arbitrary depth which takes over the role of the VC dimension in the case of learning on analog neural nets with real-valued outputs.

4. PAC learning on analog neural nets. We now turn to the analysis of learning on analog neural nets in Valiant's model [V] for probably approximately correct learning (PAC learning). More precisely, we consider the common extension of this model to real-valued domains due to [BEHW]. Unfortunately, most results about PAC learning on neural nets are negative (see [BR], [KV]). This could mean either that learning on neural nets is impossible or that the common theoretical analysis of learning on neural nets is not quite adequate.

We want to point to one somewhat problematic aspect of the traditional asymptotic analysis of PAC learning on neural nets. In analogy to the standard asymptotic analysis of the run time of algorithms in terms of the number n of input bits one usually formalizes PAC learning on neural nets in exactly the same fashion. However in contrast to the common situation for computer algorithms (which typically receive their input in digital form as a long sequence of n bits) for many important applications of neural nets the input is given in analog form as a vector of a *small* number n of analog real-valued parameters. These relatively few input parameters may consist for example of sensory data, or they may be the relevant components of a longer feature vector (which were extracted by some other mechanism). If one analyzes PAC learning on neural nets in this fashion, the relevant asymptotic problem becomes a different one: can a given analog neural net with a fixed number n of analog inputs approximate the target concept arbitrarily close after it has been shown sufficiently many training examples?

We show that for those types of neural nets which were considered in the preceding sections the previously discussed PAC learning problem has in fact a positive solution.

THEOREM 4.1. *Let $\mathcal{N}$ be an arbitrary network architecture of order 1 as in Theorem 2.1, where the fixed parameters of the piecewise-linear activation functions may now be arbitrary reals. Let $\mathcal{C}_{\mathcal{N}} := \{C \subseteq \boldsymbol{R}^n | \exists \underline{\alpha} \in \boldsymbol{R}^w \, \forall \underline{x} \in \boldsymbol{R}^n (\chi_C(\underline{x}) = \mathcal{N}^{\underline{\alpha}}(\underline{x}))\}$ be the associated concept class, where χ_C is the characteristic function of a concept C. Then $\mathcal{C}_{\mathcal{N}}$ is properly PAC learnable.*

This means that one can design for the given network architecture $\mathcal{N}$ a learning algorithm $LA^{\mathcal{N}}$ such that for any distribution Q over $\boldsymbol{R}^n$, any target concept $C_T \in \mathcal{C}_{\mathcal{N}}$, and any given ε, $\delta \in \boldsymbol{R}^+$ the learning algorithm $LA^{\mathcal{N}}$ with inputs ε and δ carries out in $O((\frac{1}{\varepsilon})^{O(1)}, (\frac{1}{\delta})^{O(1)})$ computations steps (with respect to the uniform cost criterion on a RAM) the following task: it computes a suitable number m and draws some sequence S of m examples for C_T according to distribution Q. Then it computes from S an assignment $\underline{\alpha}_S \in \boldsymbol{R}^w$ for the programmable parameters of $\mathcal{N}$ such that $Q[\{\underline{x} \in \boldsymbol{R}^n | \chi_{C_T}(\underline{x}) \neq \mathcal{N}^{\underline{\alpha}_S}(\underline{x})\}] \leq \varepsilon$ with probability $\geq 1 - \delta$.

Proof. We have VC dimension $(\mathcal{C}_{\mathcal{N}}) < \infty$ by Remark 3.9. Hence according

to [BEHW], it suffices to show that for any given set S of m examples for C_T one can compute from S within a number of computation steps that is polynomial in $m, \frac{1}{\varepsilon}, \frac{1}{\delta}$ an assignment $\underline{\alpha}_S \in \mathbf{R}^w$ to the programmable parameters of $\mathcal{N}$ such that $\forall \underline{x} \in S(\chi_{C_T}(\underline{x}) = \mathcal{N}^{\underline{\alpha}_S}(\underline{x}))$. The construction in the proof of Theorem 2.1 implies that it is sufficient if one computes instead with polynomially in m, $\frac{1}{\varepsilon}$, $\frac{1}{\delta}$ computation steps an assignment $\underline{\beta}_S$, $\underline{c}_S$ of parameters for the associated neural net $\hat{\mathcal{N}}$ such that $\forall \underline{x} \in S(\chi_{C_T}(\underline{x}) = \hat{\mathcal{N}}[\underline{c}_S]^{\underline{\beta}_S}(\underline{x}))$. The latter task is easier because the role of the parameters $\underline{\beta}$, $\underline{c}$ in a computation of $\hat{\mathcal{N}}$ for a specific input $\underline{x}$ can be described by *linear* inequalities (provided one knows which linear piece is used at each gate).

Nevertheless, the following technical problem remains. Although we know which *output* $\hat{\mathcal{N}}[\underline{c}_S]^{\underline{\beta}_S}$ should give for an input $\underline{x} \in S$, we do not know *in which way* this output should be produced by $\hat{\mathcal{N}}[\underline{c}_S]^{\underline{\beta}_S}$. More specifically, we don't know which particular piece of each piecewise-linear activation function γ^g of $\hat{\mathcal{N}}$ will be used for this computation. However, this detailed information would be needed for each $\underline{x} \in S$ and for all gates g of $\hat{\mathcal{N}}$ in order to describe the resulting constraints on the parameters $\underline{\beta}$, $\underline{c}$ by a system of linear inequalities.

However, one can generate a set of polynomially in m many systems of linear inequalities such that at least one of these systems provides for all $\underline{x} \in S$ satisfiable and sufficient constraints for $\underline{\beta}, \underline{c}$. By definition $\mathcal{C}_{\mathcal{N}}$ we know that there are parameters $\underline{\beta}_T$, $\underline{c}_T$ such that $\hat{\mathcal{N}}[\underline{c}_T]^{\underline{\beta}_T}$ computes χ_{C_T}. Consider any inequality $I(\underline{\beta}, \underline{c}, \underline{x}) \leq 0$ (with $I(\underline{\beta}, \underline{c}, \underline{x})$ linear in $\underline{\beta}, \underline{c}$ for fixed $\underline{x}$, *and* linear in $\underline{x}$ for fixed $\underline{\beta}, \underline{c}$) as they were introduced in the proof of Theorem 2.1 in order to describe the comparison with a threshold at some gate g of $\hat{\mathcal{N}}$. The hyperplane $\{\underline{x} \in \mathbf{R}^n \mid I(\underline{\beta}_T, \underline{c}_T, \underline{x}) = 0\}$ defines a partition of S into $\{\underline{x} \in S \mid I(\underline{\beta}_T, \underline{c}, \underline{x}) \leq 0\}$ and $\{\underline{x} \in S \mid I(\underline{\beta}_T, \underline{c}, \underline{x}) > 0\}$. Hence it suffices to produce (e.g., with the algorithm of [EOS]) in polynomially in m many computation steps all partitions of S that can be generated by as many hyperplanes as there are linear inequalities $I(\underline{\beta}, \underline{c}, \underline{x}) \leq 0$ in the proof of Theorem 2.1. One of these partitions will agree with the partition of S that is defined by the hyperplanes $\{\underline{x} \in \mathbf{R}^n \mid I(\underline{\beta}_T, \underline{c}_T, \underline{x}) = 0\}$ for the "correct values" $\underline{\beta}_T, \underline{c}_T$ of the parameters. Each of these partitions corresponds to a guess which linear pieces of the activation functions γ^g of $\hat{\mathcal{N}}$ are used for the different inputs $\underline{x} \in S$, and hence it defines a unique system of linear inequalities in $\underline{\beta}, \underline{c}$ (with the inputs $\underline{x} \in S$ as fixed coefficients). Furthermore, it is guaranteed that one of these guesses is correct for $\underline{\beta}_T, \underline{c}_T$.

For each of the resulting polynomially in m many systems of inequalities we apply the method of the proof of Lemma 2.4 (i.e., we reduce the solution of each system of inequalities to the solution of polynomially in m many systems of linear equalities), or we apply Megiddo's polynomial time algorithm for linear programming in a fixed dimension [Me] in order to find values $\underline{\beta}_s, \underline{c}_s$ for which $\hat{\mathcal{N}}[\underline{c}_s]^{\underline{\beta}_s}$ gives the desired outputs for all $\underline{x} \in S$. By construction, this algorithm will succeed for at least one of the selected system of inequalities. □

Remark 4.2. Assume $\mathcal{N}$ is some arbitrary network architecture of order 1 according to Definition 1.1 with arbitrary piecewise-linear activation functions, and $\mathcal{N}$ does not satisfy the condition that all computation nodes of $\mathcal{N}$ have fan-out ≤ 1. Then Theorem 4.1 does not show that $C_{\mathcal{N}}$ is *properly* PAC learnable. However, it implies that $C_{\mathcal{N}}$ is PAC learnable, with $\mathcal{C}_{\mathcal{N}'}$ for a somewhat larger network architecture $\mathcal{N}'$ of the same depth used as hypothesis class (see Remark 2.2 for the definition of $\mathcal{N}'$).

Note that this result may lead toward a theoretical explanation of an effect that has been observed in many experiments: one often achieves better learning results on artificial neural nets if one uses a neural net with somewhat more units than necessary

(i.e., necessary in order to compute the target concept on the neural net).

THEOREM 4.3. *Let $\mathcal{N}$ be an arbitrary network architecture with arbitrary piecewise-polynomial activation functions and arbitrary polynomial gate inputs $Q^g(y_1, \ldots, y_m)$. Then the associated concept class $\mathcal{C}_{\mathcal{N}}$ is PAC learnable with a hypothesis class of the form $\mathcal{C}_{\tilde{\mathcal{N}}}$ for a somewhat larger network architecture $\tilde{\mathcal{N}}$.*

Proof. One can reduce this problem to the case of network architectures with linear gate inputs as indicated at the beginning of the proof of Theorem 3.1. One uses as hypotheses, sets which are defined by a network architecture $\tilde{\mathcal{N}}$ of the same structure as the network architecture $\mathcal{M}^{\mathcal{A}}$ in the proof of Theorem 3.1. For this network architecture $\tilde{\mathcal{N}}$ one can express the constraints on the assignment $\mathcal{A}$ by *linear* inequalities. Remark 3.9 implies that VC dimension $(\tilde{\mathcal{N}}, \mathbf{R}^n) < \infty$.

One applies the method from the proof of Lemma 2.4 in a manner analogous to the proof of Theorem 4.1 or linear programming in a fixed dimension [Me] to polynomially in m many systems of linear inequalities. There is one small obstacle in generating the associated partitions of S since the corresponding inequalities are not linear in the circuit inputs $\underline{x}$. One overcomes this difficulty by going to an input space of higher dimension (where the variables represent monomials of bounded degree in the original variables). □

Remark 4.4. It is shown in [M93c] that the positive learning results of this section can be extended to analog neural nets with real-valued outputs. Furthermore it is shown in that paper that these learning results can be extended to Haussler's refinement [H] of Valiant's model [V], where no a priori assumptions about the target function are required and where arbitrary noise in the training examples is permitted.

Acknowledgments. We would like to thank Eduardo D. Sontag for drawing our attention to the problem of finding upper bounds for neural nets with π-gates and for his insightful comments. We thank Peter Auer, Franz Aurenhammer, Philip M. Long, and Gerhard Wöginger for various helpful discussions on this research.

ON THE AMOUNT OF NONDETERMINISM AND THE POWER OF VERIFYING*

LIMING CAI† AND JIANER CHEN‡

Abstract. The relationship between nondeterminism and other computational resources is investigated based on the "guess-then-check" model *GC*. Systematic techniques are developed to construct natural complete languages for the classes defined by this model. This improves a number of previous results in the study of limited nondeterminism. Connections of the model *GC* to computational optimization problems are exhibited.

Key words. computational complexity, nondeterminism, complete languages, computational optimization

1. Introduction.

The study of the power of nondeterminism is central to complexity theory. The relationship between nondeterminism and other computational resources still remains unclear. Two fundamental questions are those of how much computational resource we should pay in order to eliminate nondeterminism and how much computational resource we can save if we are granted nondeterminism. A computation with nondeterminism can basically be decomposed into the phase of guessing (nondeterministically) and the phase of verifying (using other computational resources). In general, the phase of guessing and the phase of verifying work interactively.

The notion of classifying problems according to the amount of nondeterminism and the power of verifying in a computation has appeared in recent research. Díaz and Torán [14] studied the classes β_k, for $k \geq 1$, by allowing a deterministic polynomial-time computation to make an $O(\log^k n)$ amount of nondeterminism.[1] The class β_f for a more general function $f(n)$ was studied by Farr [16]. Buss and Goldsmith [5] considered the classes $N^k P_h$, for $k, h \geq 1$, in which languages can be recognized by an $O(n^h \log^{O(1)} n)$-time multitape Turing machine making at most $k \log n$ binary nondeterministic choices. Wolf [25] studied models that are *NC* circuits with nondeterministic gates. Papadimitriou and Yannakakis [21] considered a set of optimization problems that can be solved by computations with an $O(\log^2 n)$ amount of nondeterminism.

We generalize the above ideas by introducing the computation model *GC* (guess-then-check). Let $s(n)$ be a function and let $\mathcal{C}$ be a complexity class; then $GC(s(n), \mathcal{C})$ is the class of languages that can be recognized by first nondeterministically guessing

[1] These classes were originally introduced in Kintala and Fisher [19].

$O(s(n))$ binary bits then using the power of $\mathcal{C}$ to verify. The reader should realize that the GC model is a restricted version of the interactive-proof systems that have received considerable attention recently (for a survey, see [18]).

We develop systematic and powerful techniques to show that for a large class of functions $s(n)$ and for many complexity classes $\mathcal{C}$, the class $GC(s(n), \mathcal{C})$ has natural complete languages. The techniques involve characterizing the computation of a verifier by a circuit and encoding a nondeterministic string of length $s(n)$ as an input of length $(n \cdot s(n))/\log n$ to the circuit. Our techniques improve a number of previous results in the study of completeness for complexity classes with limited nondeterminism. In particular, we show that the weight-k circuit-satisfiability problem is complete under quasi-linear-time reduction for the class N^kP_1 proposed by Buss and Goldsmith [5]. This gives a complete language for the class N^kP_1 which is more natural than the previously known complete languages for the class [5] in the sense that no explicit mention of "$k \log n$" appears in its statement. Moreover, we prove that one can obtain complete languages for the class β_k by restricting the amount of nondeterminism in NP-complete languages. This result is opposite to a conjecture made by Díaz and Torán [14] that by restricting the amount of nondeterminism in NP-complete languages, one would not get complete languages for the class β_k. We also derive complete languages for the classes $NNC^k(\log^i n)$ studied by Wolf [25], for which it was unknown whether there exist complete languages.

Of special interest is the class $GC(s(n), \Pi_k^B)$, where $s(n)$ is a function larger than $\Theta(\log n)$ and Π_k^B is the class of languages accepted by log-time alternating Turing machines of k alternations. The model $GC(s(n), \Pi_k^B)$ has guessing ability presumably stronger than and verifying ability provably weaker than deterministic polynomial-time Turing machines [27]. More careful analysis is given to show that for many functions $s(n)$ and for all integers $k > 1$, the class $GC(s(n), \Pi_k^B)$ has natural complete languages.

The importance of the class $GC(s(n), \Pi_k^B)$ is its close connection to computational optimization problems. We show that the optimization classes $LOGSNP$ and $LOGNP$ introduced by Papadimitriou and Yannakakis [21] can be precisely characterized by $GC(\log^2 n, \Pi_2^B)$ and $GC(\log^2 n, \Pi_3^B)$, respectively. An inequality $GC(\log^2 n, \Pi_2^B) \neq GC(\log^2 n, \Pi_3^B)$ is established to show the difference between $LOGSNP$ and $LOGNP$. We explain based on our characterization of the class $LOGSNP$ why the problems LOG^{2}SAT, LOG CLIQUE, and LOG CHORDLESS PATH do not seem to be complete for the class $LOGSNP$. This partially answers a question posed by Papadimitriou and Yannakakis [21]. Our characterizations also give a restricted version of the satisfiability problem that is polynomial-time equivalent to the problem TOURNAMENT DOMINATING SET, improving a result of Meggido and Vishkin [20]. The GC model also has nice applications in the study of the fixed-parameter tractability of optimization problems [15].

The paper is organized as follows. Section 2 introduces the necessary preliminaries. The model GC is defined in section 3, in which complete languages are constructed for several GC classes. Section 4 studies the GC models with very weak verifiers. Connections of the GC models to computational optimization problems are given in section 5.

2. Preliminaries. We assume reader's familiarity with the basic definitions in circuit complexity theory and alternating Turing machines. For more detailed descriptions of these topics, the reader is referred to [3, 23].

Let $b > 0$ be an integer. A string x of length n can be partitioned into $\lceil n/b \rceil$

segments of b consecutive characters (the last segment may contain less than b characters). The segments will be called *b-blocks* of x.

To simplify expressions, we will denote $2^{\lceil \log \log n \rceil}$ by $\ell(n)$. Note that $\ell(n) = \Theta(\log n)$. Moreover, a deterministic Turing machine can multiply or divide a number of $O(\log n)$ bits by $\ell(n)$ in $O(\log n)$ time. The $(\ell(n))$-blocks of a string x of length n will be simply called *ℓ-blocks* of x.

An *$O(\log n)$-time alternating Turing machine* (log-*time ATM*) is equipped with a *random-access input tape* and a read-write *input address tape* such that the Turing machine has access to the bit of the input tape denoted by the contents of the input address tape. Several input read-modes have been proposed. The one that we adopt here is the standard read-mode introduced in [11] with the restriction that in the last phase of each computation path, a log-time ATM only reads inputs from a constant number of ℓ-blocks of the input. This input read-mode is a Turing machine implementation of the *Block Transfer* mode of RAMs proposed in [1] (see [7] for discussions).

A *Π_k^B-ATM* is a log-time ATM that makes at most k alternations and must begin with $\wedge$ states. Define Π_k^B to be the class of languages accepted by Π_k^B-ATMs.

An (unbounded fan-in) *Boolean circuit* α_n with n inputs $x_1, \ldots, x_n$ is a directed acyclic graph. The nodes of fan-in 0 are called *input nodes* and are labeled from the set $\{0, 1, x_1, \overline{x}_1, \ldots, x_n, \overline{x}_n\}$. The nodes of fan-in greater than 0 are called *gates* and are labeled either AND or OR. A set of the nodes is designated the *output* nodes. The *size* is the number of gates, and the *depth* is the maximum distance from an input to an output. Each node in a circuit of size s has a unique node number of length $O(\log s)$. We assume that circuits are of a special form where all AND and OR gates are organized into alternating levels with edges only between adjacent levels. Any circuit may be converted to one of this form without increasing the depth and by at most squaring the size [12]. In this special form, the gates connected to input nodes are called *level-1 gates*. We also assume that circuits are topologically ordered in the sense that the node number of a gate is always larger than the node numbers of its inputs.

A *family* of circuits is a sequence $F = \{\alpha_n \mid n \geq 1\}$ of circuits, where circuit α_n has n inputs and one output. A family of circuits may be used to accept a language in $\{0,1\}^*$. The circuit family F is log-*space uniform* if there is an $O(\log n)$-space deterministic Turing machine that on input 1^n prints the encoding of the circuit α_n.

Let $x = x_1 x_2 \ldots x_n$ be a string of n Boolean variables and let $b > 0$ be an integer. A *specimen* of a b-block $x_{ib+1} \ldots x_{(i+1)b}$ of x is a string $s(x_{ib+1}) \ldots s(x_{(i+1)b})$, where $s(x_j)$ is either x_j or $\overline{x}_j$, for $ib + 1 \leq j \leq (i+1)b$.

DEFINITION 2.1. *A family $F = \{\alpha_n \mid n \geq 1\}$ of circuits is called a Π_k^{poly, B_c}-*family *if there is a polynomial p such that each α_n is a circuit with an* AND *output gate and of size at most $p(n)$ and depth at most $k+1$ in which the input of each level-1 gate consists of exactly c specimens of ℓ-blocks of $x_1 x_2 \ldots x_n$.*

Cai and Chen [7] have shown the equivalence of Π_k^B-ATMs and Π_k^{poly, B_c}-families of circuits under a proper uniformity. For the present paper, the following theorem will be sufficient (see Lemma 5.2 and Remark 5.1 in [7]).

THEOREM 2.2 (see [7]). *If a language $L \in \{0,1\}^*$ is accepted by a Π_k^B-ATM M, then L is accepted by a* log-*space uniform Π_k^{poly, B_c}-family $F = \{\alpha_n \mid n \geq 1\}$ of circuits, where $c \geq 1$ is an integer. Moreover, if the input of a level-1 gate of α_n consists of specimens of ℓ-blocks $B_1, \ldots, B_c$ of the input, then there is a computation path of M that reads only from these ℓ-blocks.*

In order to let a Π_k^B-ATM simulate the computation of a circuit efficiently, we introduce a regular way to encode a circuit. An input node labeled "x_i" (resp. "$\overline{x}_i$") is called a *positive input* (resp. *negative input*).

DEFINITION 2.3. *The* normal encoding *of a circuit α with inputs $x_1 \dots x_n$ is a sequence $s = \langle n, g_1, \dots, g_m \rangle$, where the g_i's are nodes of α, $|g_i| = 2^{c\ell(n)}$ for a fixed constant c. For a gate g_i with inputs $h_1, \dots, h_j$, g_i is encoded as $\langle id, op, a(h_1), \dots, a(h_j) \rangle$, where id is the gate number, op is the gate type, and $a(h_p)$ is the address of the node h_p in the sequence s. Moreover, if g_i is a level-1 gate, then the negative inputs of g_i should be listed first.*

3. The *GC* model and complete languages. Informally, $GC(s(n), \mathcal{C})$ is a restricted interactive-proof system in which a prover passes a proof of length $O(s(n))$ to a verifier that has the power of $\mathcal{C}$. A more formal definition is given as follows.

DEFINITION 3.1. *Let $s(n)$ be a function and let $\mathcal{C}$ be a complexity class. A language L is in the class $GC(s(n), \mathcal{C})$ if there is a language $A \in \mathcal{C}$ together with an integer $c > 0$ such that for all $x \in \{0,1\}^*$, $x \in L$ if and only if $\exists y \in \{0,1\}^*$, $|y| \le c \cdot s(|x|)$, and $\langle x, y \rangle \in A$.*

We point out that in the above definition, the condition $|y| \le c \cdot s(|x|)$ can be replaced by the equality $|y| = c's(|x|)$, where $c' = 2c$, if we encode 0 by 00, 1 by 01, and "useless symbol" by 10 or 11 and use the useless symbols to make up the guessed string y to be of length exactly $2c \cdot s(|x|)$.

If we require that the length $|y|$ of the guessed string y be strictly bounded by $s(|x|)$ (i.e., the constant c be strictly 1), we call the model a "strict *GC*, " written as $sGC(s(n), \mathcal{C})$.

Many complexity classes can be characterized by the *GC* model. For example, the class *NP* can be characterized by $GC(n^{O(1)}, P)$. We will develop a systematic technique to show that many *GC* classes have natural complete languages. The technique is illustrated in detail by deriving complete languages for the classes $N^k P_1$ introduced in [5].

Let P_1 be the class of languages accepted by deterministic Turing machines of running time $O(n \log^{O(1)} n)$. A circuit family $F = \{\alpha_n \mid n \ge 1\}$ is P_1-*uniform* if there is a deterministic Turing machine M that, on input 1^n, generates the circuit α_n in time $O(n \log^{O(1)} n)$.

LEMMA 3.2. *A language L is in P_1 if and only if L is accepted by a P_1-uniform family of circuits.*

Proof. That $L \in P_1$ implies L accepted by a P_1-uniform family of circuits follows directly from the classical work of Fischer and Pippenger [17]. Conversely, if L is accepted by a P_1-uniform circuit family $F = \{\alpha_n \mid n \ge 1\}$, then L can be accepted by an $O(n \log^{O(1)} n)$-time deterministic Turing machine M as follows: on input x of length n, M first generates the circuit α_n in time $O(n \log^{O(1)} n)$, then simulates the circuit α_n on input x in time $O(|\alpha_n| \log^2 |\alpha_n|) = O(n \log^{O(1)} n)$ using an algorithm by Pippenger [22]. □

Let $N^k P_1$ denote the class of languages that is accepted by a deterministic $O(n \log^{O(1)} n)$-time Turing machine that can make at most $k \log n$ binary guesses [5]. It is easy to see that $N^k P_1$ is identical to the class $sGC(k \log n, P_1)$.

A language L is *complete* for the class $N^k P_1$ under *quasi-linear-time reduction* if (i) L is in $N^k P_1$, (ii) for every language L' in $N^k P_1$, there is a function f such that $x \in L'$ if and only if $f(x) \in L$, and (iii) the function $f(x)$ is computable in deterministic $O(n \log^{O(1)} n)$ time.

Define the *weight* of a binary string to be the number of 1's in the string. Consider the following language, where f is a function.

BWCS[f] (bounded-weight circuit satisfiability)
Instance: A circuit α of m inputs.
Question: Does α accept an input of weight $\leq f(m)$?

In particular, for any fixed constant k, we denote by BWCS[k] the language BWCS[c_k], where c_k is the constant function $c_k(n) \equiv k$.

Let d be an integer. A binary string y of length $d \log m$ is a *weight representation* of a binary string v_y of length m if the ith bit of v_y is 1 if and only if a $(\log m)$-block of y is a binary representation of the integer $i-1$.

LEMMA 3.3. *For each integer $k \geq 1$, the language* BWCS[k] *is in the class* $sGC(k \log n, P_1)$.

Proof. For each fixed integer $k \geq 1$, we construct a deterministic Turing machine M_k as follows: on an input of the form $\langle \alpha, y \rangle$, where α is a circuit with m inputs and y is a binary string of length $d \log m$, $d \leq k$, M_k writes down on a worktape a string v_y of length m whose weight representation is y. Then M_k simulates the circuit α on input v_y and accepts if and only if the circuit α accepts the input v_y.

The simulation of the circuit α on input v_y can be implemented by the algorithm of Pippenger [22], which runs in time $O(|\alpha| \log^2 |\alpha|)$. All other steps of the Turing machine M_k can easily be implemented in time $O(|\alpha| \log^{O(1)} |\alpha|)$. Thus, the language A_k accepted by M_k is in the class P_1. It is easy to see that a circuit α of m inputs is in BWCS[k] if and only if $\langle \alpha, y \rangle \in A_k$ for a binary string y of length $\leq k \log |\alpha|$. That is, the language BWCS[k] is in the class $sGC(k \log n, P_1)$. □

We introduce a special function ψ from binary numbers to binary numbers as follows.

$$\psi(x) = \begin{cases} i & \text{if } x = 0^{i-1}10^{n-i} \text{ and } i < 2^{\lfloor \log |x| \rfloor}, \\ 0^{\lfloor \log |x| \rfloor} & \text{if } x = 0^{i-1}10^{n-i} \text{ and } i \geq 2^{\lfloor \log |x| \rfloor}, \\ \text{arbitrary} & \text{otherwise} \end{cases}$$

Note that for any binary number i of length $\lfloor \log n \rfloor$, there is a length-n binary number x of the form $0^{i-1}10^{n-i}$ such that $\psi(x) = i$. It is also easy to see that the function ψ can be computed by a P_1-uniform family of circuits.

Now we are ready to prove our first main theorem. For a circuit α, we denote by $I(\alpha)$ the input of α.

THEOREM 3.4. *The language* BWCS[k] *is complete for the class* $sGC(k \log n, P_1)$ $(= N^k P_1)$ *under quasi-linear-time reduction, for all $k \geq 1$.*

Proof. By Lemma 3.3, it suffices to show that BWCS[k] is hard for the class $sGC(k \log n, P_1)$ under quasi-linear-time reduction. Let L be a language in the class $sGC(k \log n, P_1)$. Then there is a language $A \in P_1$ such that for any x, $x \in L$ if and only if there is a $y \in \{0,1\}^*$, $|y| \leq k \log |x|$, such that $\langle x, y \rangle \in A$. We show how to reduce the language L to the language BWCS[k] in deterministic $O(n \log^{O(1)} n)$ time.

Since $A \in P_1$, by Lemma 3.2, there is a P_1-uniform family $F_A = \{\gamma_n \mid n \geq 1\}$ of circuits accepting A. Given an instance x to the language L, $|x| = n$, we consider the circuits γ_n, $\gamma_{n+1}, \ldots, \gamma_{n+k \log n}$ in F_A. Let $\tau_i(x)$ be the circuit with i inputs that is obtained from the circuit γ_{n+i} with the first n input bits being assigned by the value x, $0 \leq i \leq k \log n$. Thus $x \in L$ if and only if at least one of the circuits $\tau_i(x)$ is satisfiable.

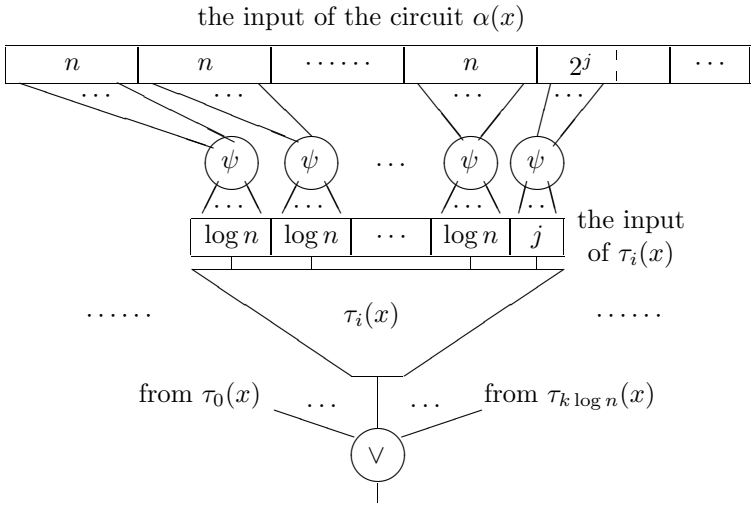

FIG. 1. *The structure of the circuit* $\alpha(x)$.

We construct a circuit $\alpha(x)$ based on these circuits $\tau_0(x), \ldots, \tau_{k\log n}(x)$. The circuit $\alpha(x)$ has kn input nodes and one output gate, plus the $k\log n + 1$ circuits $\tau_i(x)$, $0 \le i \le k\log n$. For each i, $0 \le i \le k\log n$, suppose $i = d\log n + j$, where $0 \le d \le k$ and $0 \le j < \log n$. For each q, $1 \le q \le d$, we construct a subcircuit $\sigma_{i,q}$ with n inputs and $\log n$ outputs that computes the function ψ on domain $\{0,1\}^n$ such that the n inputs of $\sigma_{i,q}$ are the qth n-block of the input $I(\alpha(x))$ of the circuit $\alpha(x)$ and the $\log n$ outputs of $\sigma_{i,q}$ replace the qth $(\log n)$-block of the input $I(\tau_i(x))$ of the circuit $\tau_i(x)$ in $\alpha(x)$. Similarly, we construct a subcircuit $\sigma_{i,d+1}$ with 2^j inputs and j outputs that computes the function ψ on domain $\{0,1\}^{2^j}$ such that the 2^j inputs of $\sigma_{i,d+1}$ are the first 2^j positions of the $(d+1)$st n-block of $I(\alpha(x))$ and the j outputs of $\sigma_{i,d+1}$ replace the $(d+1)$st $(\log n)$-block of $I(\tau_i(x))$. Finally, the output gate of the circuit $\alpha(x)$ is an OR gate that receives inputs from output gates of all the circuits $\tau_i(x)$ in $\alpha(x)$, $i = 0, 1, \ldots, k\log n$. See Figure 1.

By the definition of the function ψ, every assignment to the qth $(\log n)$-block of $I(\tau_i(x))$ can be realized in $\alpha(x)$ by a weight-1 assignment to the qth n-block of $I(\alpha(x))$. Furthermore, through the circuit $\sigma_{i,q}$, every assignment to the qth n-block of $I(\alpha(x))$ (not necessarily weight 1) realizes an assignment to the qth $(\log n)$-block of $I(\tau_i(x))$ of the circuit $\tau_i(x)$ in $\alpha(x)$. Therefore, for each $\tau_i(x)$ in $\alpha(x)$, $0 \le i \le k\log n$, every assignment to $I(\tau_i(x))$ can be realized by an assignment to $I(\alpha(x))$, in which each n-block has weight 1. Moreover, each assignment to $I(\alpha(x))$ (not necessarily with weight-1 n-blocks) realizes an assignment to $I(\tau_i(x))$ for each $\tau_i(x)$.

If the circuit $\alpha(x)$ accepts an input of weight at most k, then at least one of the circuits $\tau_i(x)$ in $\alpha(x)$ is satisfiable, which implies that $x \in L$. Conversely, suppose that $x \in L$. Then one of the circuits, say $\tau_i(x)$, is satisfiable by an assignment y to $I(\tau_i(x))$. We can construct an assignment z to $I(\alpha(x))$ in which every n-block has weight 1 such that z realizes the assignment y to $I(\tau_i(x))$. The weight of z is k. With this assignment z to $I(\alpha(x))$, the circuit $\alpha(x)$ has value 1.

By the above discussion, we conclude that $x \in L$ if and only if the circuit $\alpha(x)$ accepts an input of weight at most k, i.e., if and only if $\alpha(x)$ is in the language BWCS[k]. Moreover, since the circuit family $F_A = \{\gamma_n \mid n \ge 1\}$ is P_1-uniform,

there is a deterministic Turing machine M that constructs the circuit γ_{n+i} in time $O((n+i)\log^{O(1)}(n+i)) = O(n\log^{O(1)} n)$, for all $0 \le i \le k\log n$. Therefore, the circuit $\alpha(x)$ has size $O(n\log^{O(1)} n)$ and can be constructed in time $O(n\log^{O(1)} n)$.

Thus the language BWCS[k] is complete for the class $N^kP_1 = sGC(k\log n, P_1)$ under quasi-linear-time reduction for all $k \ge 1$. □

Theorem 3.4 presents a new complete language for the class N^kP_1 under quasi-linear-time reduction. The language BWCS[k] is more natural than the previously known complete languages for N^kP_1 (see [5]) in the sense that there is no explicit mention of "$k\log n$" or "$n\log^{O(1)} n$" in the statement of BWCS[k]. We point out that the above proofs can easily be extended to derive natural complete languages under proper reductions for the classes N^kP_h studied by Buss and Goldsmith [5], for $h > 1$.

Theorem 3.4 and its proof illustrate a systematic technique for constructing complete languages for the class $GC(s(n), \mathcal{C})$. Roughly speaking, what we need is a circuit characterization of the complexity class $\mathcal{C}$ together with an encoding of a nondeterministic string of length $s(n)$ by a length $(n \cdot s(n))/\log n$ string of weight $s(n)/\log n$. Below we list a few more examples and briefly describe the proofs.

Let f be a function. Define β_f to be the class of languages that are accepted by deterministic polynomial-time Turing machines that can make an $O(f(n))$ amount of nondeterminism. The class β_f was introduced by Kintala and Fisher [19] and studied in detail by Díaz and Torán [14]. By our GC model, the class β_f is identical to the class $GC(f(n), P)$.

THEOREM 3.5. *Let $f(n)$ be a function constructible in deterministic $O(\log n)$ space. Then the language* BWCS[f] *is complete for the class $GC(f(n)\log n, P) = \beta_{f\log n}$ under* log*-space reduction.*

Proof. The proof that BWCS[f] is in the class $GC(f(n)\log n, P)$ is similar to the proof of Lemma 3.3.

To show that BWCS[f] is hard for the class $GC(f(n)\log n, P)$ under log-space reduction, let L be a language in $GC(f(n)\log n, P)$. Then there is a language A in P with a constant c such that for all x, $x \in L$ if and only if there is a y, $|y| = cf(|x|)\log|x|$, and $\langle x, y\rangle \in A$. By the results of Borodin [4], there is a log-space uniform circuit family $F_A = \{\gamma_n \mid n \ge 1\}$ that accepts A. Given an x, $|x| = n$, let $\tau_{cf(n)\log n}(x)$ be the circuit with $cf(n)\log n$ inputs that is obtained from $\gamma_{n+cf(n)\log n}$ with the first n input bits assigned by the value x. Thus $x \in L$ if and only if the circuit $\tau_{cf(n)\log n}(x)$ is satisfiable.

Now the proof goes similarly to that of Theorem 3.4. We construct a circuit $\alpha(x)$ based on the circuit $\tau_{cf(n)\log n}(x)$. The circuit $\alpha(x)$ has $m = f(n)n^c$ inputs, and for each (n^c)-block of $I(\alpha(x))$, there is a subcircuit with n^c inputs that computes the function ψ whose n^c inputs are from the (n^c)-block of $I(\alpha(x))$ and whose $c\log n$ outputs are connected to the corresponding $(c\log n)$-block of the input of $\tau_{cf(n)\log n}(x)$. Now if the circuit $\alpha(x)$ accepts an input of weight at most $f(m)$, then this input of $\alpha(x)$ should produce a satisfiable input to the circuit $\tau_{cf(n)\log n}(x)$ via the ψ function, which implies that $x \in L$. Conversely, if $x \in L$, then a weight-$f(n)$ input of $\alpha(x)$, $f(n) \le f(m)$, can be constructed to produce via the ψ function a satisfiable input to the circuit $\tau_{cf(n)\log n}(x)$. Thus this weight-$f(n)$ input should satisfy the circuit $\alpha(x)$, and $\alpha(x)$ is in BWCS[f]. □

In particular, the language BWCS[$\log^{i-1} n$] is complete for the class $GC(\log^i n, P) = \beta_{\log^i n} \stackrel{\text{def}}{=} \beta_i$, for all integers $i \ge 2$. Note that the language BWCS[$\log^{i-1} n$] is a restricted version of the circuit-satisfiability problem that is complete for the class *NP*. This answers a question posed by Díaz and Torán [14], who were able to

construct complete languages for β_i from certain complete languages for the class P by adding nondeterminism, and who conjectured that one might not be able to construct complete languages for β_i from complete languages for the class NP by restricting nondeterminism. We point out that a different approach has been adopted by Szelepcsényi [24] and Farr [16] to study complete languages for the class β_f.

Let f be a function. Now we consider the class $GC(f(n), NC^d)$ for all $d \geq 1$. In particular, the classes $GC(\log^i n, NC^d)$ have been investigated by Wolf [25]—in his notation, $NNC^d(\log^i n)$.

Consider the following language.

BWCS$_d[f]$
Instance: A circuit α with m inputs and depth $\log^d m$.
Question: Does α accept an input of weight $\leq f(m)$?

THEOREM 3.6. *Let f be a function constructible in deterministic $O(\log n)$ space and let $d \geq 1$ be an integer. Then the language* BWCS$_d[f]$ *is complete for the class $GC(f(n)\log n, NC^d)$ under* log*-space reduction.*

Proof. Using the *universal-depth NC^d* circuit family developed by Cook and Hoover [13], we can show that the language BWCS$_d[f]$ is in $GC(f(n)\log n, NC^d)$.

The proof that the language BWCS$_d[f]$ is hard for the class $GC(f(n)\log n, NC^d)$ under log-space reduction is completely similar to that of Theorem 3.5. □

In particular, the language BWCS$_d[\log^{i-1} n]$ is complete for the class $NNC^d(\log^i n)$ under log-space reduction, for all $i \geq 2$. This is the first language that is known to be complete for the class $NNC^d(\log^i n)$.

4. The *GC* classes with very weak verifiers. In this section, we derive complete languages for GC classes with verifiers strictly weaker than deterministic polynomial-time Turing machines.

The basic idea here is the same as that in section 3: we characterize the verifier by a circuit family and encode the nondeterministic string of length $s(n)$ by an input of length $(n \cdot s(n))/\log n$ to the circuit. However, implementation of these methods on models such as Π_k^B-ATMs becomes more subtle. For example, it would not be proper to encode the string of length $s(n)$ using the function ψ defined in section 3 because that would increase the depth of the circuit. Similar difficulty also occurs when we test the bounded-weight satisfiability of circuits of depth k using a Π_k^B-ATM. We will present a number of new techniques to overcome these difficulties.

Recall that in the last phase of each computation path, a Π_k^B-ATM M can read input bits from at most a constant number of ℓ-blocks of the input. We further require that if the input to a Π_k^B-ATM M is of the form $\langle x, y\rangle$, then the last phase of each computation path of M can read input bits from at most *one* ℓ-block from the second string y. It is easy to see that this additional requirement has no influence on the class accepted by Π_k^B-ATMs. Furthermore, we also assume that the pairing function $\langle x, y\rangle$ is simple and can be decoded into x and y in deterministic $O(\log n)$ time [2].

We first consider the GC classes whose verifier is Π_{2k}^B, for $k \geq 1$. A circuit is a Π-*circuit* if it has a single output gate, which is of type AND. A circuit α is *semimonotone* if at most two inputs of each level-1 gate of α are negative input nodes.

DEFINITION 4.1. BWCS$(s(n), k)$ *is the set of pairs $x = \langle \alpha, w\rangle$, where α is a semimonotone* Π*-circuit of depth k in the normal encoding such that α accepts an input of weight w, $w \leq s(|x|)$.*

LEMMA 4.2. *For any function $s(n)$ and any $k \geq 1$, the language* BWCS $(s(n), 2k)$ *is in the class $GC(s(n)\ell(n), \Pi_{2k}^B)$.*

Algorithm BWCS-Simulator

Input: $\langle x, y\rangle$, where $x = \langle \alpha, w\rangle$ and α is a circuit with m inputs.

1. Reject if $w > m$, or if y does not consist of exactly w different input-node numbers of α, each of length $\ell(|x|)$, or if α is not in the normal encoding, or if α is not a semimonotone Π-circuit of depth $2k$;
2. Let g be the output gate of α;
3. Repeat the following loop $(2k-1)$ times:
   Suppose $g = \langle id, op, a(h_1), \ldots, a(h_j)\rangle$:
   If $op =$ AND, then universally choose an $a(h_i)$. Let $g = h_i$;
   If $op =$ OR, then existentially guess an $a(h_i)$. Let $g = h_i$;
4. {At this point, $g = \langle id, op, a(h_1), \ldots, a(h_j)\rangle$ is a level-1 gate.}
   (a) Deterministically find the negative input nodes in h_1, ..., h_j. For each such negative input node h_i, universally check whether h_i is contained in y.
   (b) If any of these negative input nodes is not contained in y, then accept; otherwise, existentially guess a positive input node $a(h_i)$ of g and accept if and only if the node number of h_i is contained in y.

FIG. 2. *The algorithm* BWCS-*Simulator.*

Proof. Consider the algorithm BWCS-Simulator in Figure 2. We will prove that this algorithm can be implemented by a Π^B_{2k}-ATM such that for all $x = \langle \alpha, w\rangle$, $x \in \mathrm{BWCS}(s(n), 2k)$ if and only if there is a string $y \in \{0,1\}^*$, $|y| \le s(|x|)\ell(|x|)$ such that the algorithm accepts $\langle x, y\rangle$.

Let $z = \langle x, y\rangle$ be an input to the algorithm BWCS-Simulator, where $x = \langle \alpha, w\rangle$. In deterministic $O(\log |z|)$ time, we can compute the lengths $|x|$ and $|y|$ (see [2]) and check the relation $w > m$. Note that $w \le m$ implies $|w| \le \log |z|$, so multiplying and dividing w by $\ell(|x|)$ can be done in deterministic $O(\log |z|)$ time.

The Boolean string y of length $w\ell(|x|)$ is used as the weight representation of an input v_y of weight w to the circuit α. To verify that y contains exactly w different input-node numbers of α, each of length $\ell(|x|)$, we universally check that (i) $|y| = w\ell(|x|)$, (ii) each $\ell(|x|)$-block of y is a binary number $\le m$, and (iii) no two $\ell(|x|)$-blocks of y are identical. To check whether α is in the normal encoding and whether α is a semimonotone Π-circuit of depth $2k$, we universally check the gates of α level by level, starting from the output gate of α.

Since the output gate of α is an AND gate, the first execution of the loop in step 3 is a universal branch. Therefore, steps 1 and 2 combined with the first execution of the loop in step 3 form the first phase, which is a universal phase of the algorithm.

The loop execution of step 3 simply simulates the computation of the circuit α. After $2k-1$ executions of the loop in step 3, the algorithm is in its $(2k-1)$st phase, which is a universal phase, and the current gate g is a level-1 gate of the circuit α, which is an OR gate. Therefore, the universal checking in step 4(a) can be combined into the $(2k-1)$st phase. Since α is semimonotone, only h_1 and h_2 can be negative input nodes to the gate g, which can be checked in deterministic $O(\log |z|)$ time.

If any of the negative input nodes of g is not in y, then all universal branches in step 4(a) accept according to the "then" part of step 4(b). This is correct because this forces the gate g to have value 1 on input v_y. On the other hand, if all negative input nodes of g are in y, then we must check the positive input nodes of g. Thus the algorithm starts its $(2k)$th phase in the "else" part of step 4(b). Each path in this phase checks whether a positive input node h_i of g is contained in y. For this, the algorithm existentially checks an $\ell(|x|)$-block in y. Note that in this phase, the algorithm reads one $\ell(|x|)$-block from the first string x (the address $a(h_i)$ of the gate h_i) and one $\ell(|x|)$-block from the second string y in the input $\langle x, y\rangle$.

This concludes that the algorithm BWCS-Simulator is a Π^B_{2k}-ATM which accepts $\langle x, y\rangle$, where $x = \langle \alpha, w\rangle$, if and only if y contains exactly w different input-node numbers of α and the circuit α accepts the weight-w input v_y whose weight representation is y.

Now it is easy to see that $x = \langle \alpha, w\rangle \in \mathrm{BWCS}(s(n), 2k)$ if and only if the Π^B_{2k}-ATM BWCS-Simulator accepts $\langle x, y\rangle$ for a binary string of length bounded by $s(|x|)\ell(|x|)$. Thus the language $\mathrm{BWCS}\,(s(n), 2k)$ is in the class $GC(s(n)\ell(n), \Pi^B_{2k})$. □

Now we show the completeness of $\mathrm{BWCS}(s(n), 2k)$ in the class $GC(s(n)\ell(n), \Pi^B_{2k})$. A proof for the following lemma can be found in [6].

LEMMA 4.3. *Let $b > 0$ and $c > 0$ be two integers, and let τ be a Π-circuit of depth k in which the input of each level-1 gate is a specimen of a b-block of $x_1 \dots x_n$. Then there is a Π-circuit γ of depth k and size $\le 2^{cb}\mathit{size}(\tau)$ computing the same function in which the input of each level-1 gate is a specimen of a (cb)-block of $x_1 \dots x_n$.*

THEOREM 4.4. *Let $s(n) \le n$ be a nondecreasing function computable in deterministic $O(\log n)$ space. Then the language $\mathrm{BWCS}(s(n), 2k)$ is complete for the class $GC(s(n)\ell(n), \Pi^B_{2k})$ under $O(\log n)$-space reduction, for $k \ge 1$.*

Proof. By Lemma 4.2, we only need to prove hardness.

Let L be a language in $GC(s(n)\ell(n), \Pi^B_{2k})$. By definition, there is a Π^B_{2k}-ATM M with an integer $c > 0$ such that $x \in L$ if and only if there is a $y \in \{0,1\}^*$, $|y| = c\,s(|x|)\ell(|x|)$, and M accepts $\langle x, y\rangle$. Without loss of generality, assume that c is an even number. Moreover, we can assume that no phase except the last phase of each computation path of M has access to the input [7]. By Theorem 2.2, there is a log-space uniform Π_{2k}^{poly, B_h}-family $\{\tau_m \mid m \ge 1\}$ of circuits that accepts $L(M)$, where h is a constant.

Given an instance x of the language L, we show how to reduce x to an instance $z = \langle \alpha(x), w(x)\rangle$ for the language $\mathrm{BWCS}\,(s(n), 2k)$ such that $x \in L$ if and only if z is in $\mathrm{BWCS}\,(s(n), 2k)$. Let $|x| = n$, and $|\langle x, y\rangle| = m$, where y is a binary string of length $c\,s(n)\ell(n)$. Let $\tau_m(x)$ be the circuit τ_m with the first part of the input assigned by the value of x. $\tau_m(x)$ is a circuit with $c\,s(n)\ell(n)$ inputs, and $x \in L$ if and only if the circuit $\tau_m(x)$ is satisfiable.

Since $|y| = c\,s(n)\ell(n) = O(n \log n)$, $|x| = n \le m = |\langle x, y\rangle| \le n^2$. Therefore, we have either $\ell(m) = \ell(n)$ or $\ell(m) = 2\ell(n)$. Thus the number of inputs of the circuit $\tau_m(x)$ can be written as $as(n)\ell(m)$, where a is an integer such that $a = c$ if $\ell(m) = \ell(n)$ or $a = c/2$ if $\ell(m) = 2\ell(n)$.

Recall that the circuit τ_m is a Π-circuit of depth $2k + 1$ in which the input of each level-1 gate consists of exactly h specimens of ℓ-blocks of $\langle x, y\rangle$. Moreover, the last phase of each computation path of M reads inputs from at most one ℓ-block from the string y. By Theorem 2.2, at most one specimen in the input of each level-1 gate of τ_m is from an ℓ-block of the string y. Therefore, the circuit $\tau_m(x)$ is a Π-circuit with $as(n)\ell(m)$ inputs and of depth $2k + 1$ in which the input of each level-1 gate is a specimen of an $\ell(m)$-block of its input. By Lemma 4.3, there is a Π-circuit $\gamma_m(x)$ of depth $2k + 1$ and size bounded by a polynomial of m that computes the same function as $\tau_m(x)$ such that the input of each level-1 gate of $\gamma_m(x)$ is a specimen of an $(a\ell(m))$-block of its input.

Now we are ready to describe the circuit $\alpha(x)$.

The input $I(\alpha(x)) = v_1 \dots v_{s(n)2^{a\ell(m)}}$ of the circuit $\alpha(x)$ is of length $s(n)2^{a\ell(m)}$ and partitioned into $s(n)$ $2^{a\ell(m)}$-blocks. Similarly, the input $I(\gamma_m(x)) = u_1 \dots u_{as(n)\ell(m)}$ of the circuit $\gamma_m(x)$ is partitioned into $s(n)$ $(a\ell(m))$-blocks. The circuit $\alpha(x)$ will be

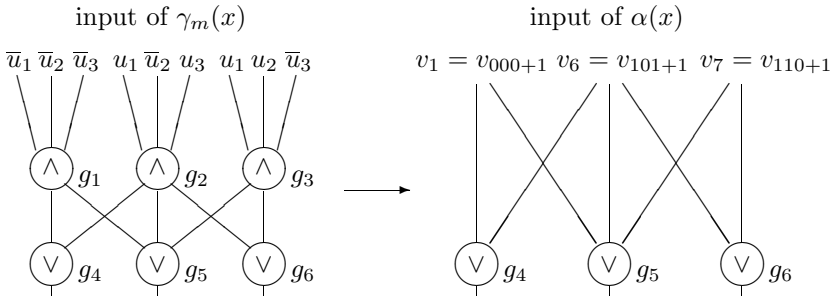

FIG. 3. *From circuit $\gamma_m(x)$ to circuit $\alpha(x)$.*

constructed from the circuit $\gamma_m(x)$ by replacing each level-1 gate in $\gamma_m(x)$ by an input node of $\alpha(x)$. As we have done in section 3, for each q, we will use a position in the qth $2^{a\ell(m)}$-block of $I(\alpha(x))$ to represent an assignment to the qth $(a\ell(m))$-block of $I(\gamma_m(x))$. To simplify discussion, we describe the construction of the first $2^{a\ell(m)}$-block of $I(\alpha(x))$ based on the first $(a\ell(m))$-block of $I(\gamma_m(x))$. The construction of the qth $2^{a\ell(m)}$-block of $I(\alpha(x))$ for general q can be done similarly.

Let g be a level-1 gate of the circuit $\gamma_m(x)$ whose input is a specimen of the first $(a\ell(m))$-block of $I(\gamma_m(x))$. Note that g is an AND gate; thus there is a unique Boolean assignment b_g to the first $(a\ell(m))$-block of $I(\gamma_m(x))$ that makes the gate g have value 1. Regarding b_g as a binary number between 0 and $2^{a\ell(m)} - 1$, we replace the gate g in $\gamma_m(x)$ by the positive input node v_{b_g+1} in $I(\alpha(x))$, which is in the first $2^{a\ell(m)}$-block of $I(\alpha(x))$. In the same way, we perform this replacement on each level-1 gate in the circuit $\gamma_m(x)$. See Figure 3. The resulting circuit $\alpha(x)$ has depth $2k$. Also, note that so far the circuit $\alpha(x)$ contains no negative input nodes.

By construction, each assignment of the qth $(a\ell(m))$-block of $I(\gamma_m(x))$ in $\gamma_m(x)$ can be implemented by a weight-1 assignment of the qth $2^{a\ell(m)}$-block of the input $I(\alpha(x))$ in the circuit $\alpha(x)$. Therefore, each assignment of $I(\gamma_m(x))$ in $\gamma_m(x)$ can be implemented by a weight-$s(n)$ assignment of $I(\alpha(x))$ in $\alpha(x)$, in which the assignment to each $2^{a\ell(m)}$-block has weight 1. We conclude that if the circuit $\gamma_m(x)$ is satisfiable, then the circuit $\alpha(x)$ accepts an input of weight $s(n)$.

The construction has not yet been completed. Note that if in an assignment of $I(\alpha(x))$, a $2^{a\ell(m)}$-block has weight different from 1, then the assignment does not implement any assignment of $I(\gamma_m(x))$. To ensure that each $2^{a\ell(m)}$-block of $I(\alpha(x))$ is assigned exact one 1, we let

$$\phi(v_1, \ldots, v_t) = (v_1 \vee \ldots \vee v_t) \bigwedge \left(\bigwedge_{i,j} (\overline{v}_i \vee \overline{v}_j) \right).$$

It is easy to see that $\phi(v_1, \ldots, v_t) = 1$ if and only if exactly one v_i is 1. The function $\phi(v_1, \ldots, v_t)$ can be implemented by a Π-circuit of depth 2 in which at most two negative input nodes appear in the input of each level-1 gate. Now for each $2^{a\ell(m)}$-block of $I(\alpha(x))$, we add a Π-subcircuit of depth 2 that implements the function ϕ with $2^{a\ell(m)}$ variables, and we connect the output of this subcircuit to the output gate of the circuit $\alpha(x)$ (which is the output gate of the circuit $\gamma_m(x)$). Note that this does not increase the depth of the circuit $\alpha(x)$ since both the output gate of such a subcircuit and the output gate of the circuit $\alpha(x)$ are AND gates, and the depth of the circuit $\alpha(x)$ is at least 2. This completes the construction of the circuit $\alpha(x)$.

Algorithm antiBWCS-Simulator

Input: $\langle x, y\rangle$, where $x = \langle \alpha, w\rangle$ and α is a circuit with m inputs.

1. Reject if $w > m$, or if y does not consist of exactly w different input node numbers, each of length $\ell(|x|)$, or if α is not in the normal encoding, or if α is not a semiantimonotone Π-circuit of depth $2k+1$;
2. Let g be the output gate of α;
3. Repeat the following loop $2k$ times:
   Suppose $g = \langle id, op, a(h_1), \ldots, a(h_j)\rangle$:
   If $op =$ AND, then universally choose an $a(h_i)$. Let $g = h_i$;
   If $op =$ OR, then existentially guess an $a(h_i)$. Let $g = h_i$;
4. {At this point, $g = \langle id, op, a(h_1), \ldots, a(h_j)\rangle$ is a level-1 gate.}
   (a) Deterministically find the positive input nodes in $h_1, \ldots, h_j$. For each such positive input node h_i, existentially check whether h_i is contained in y.
   (b) If any of these positive input nodes is not contained in y, then reject; otherwise, universally guess a negative input node $a(h_i)$ of g and reject if and only if the node number of h_i is contained in y.

FIG. 4. *The algorithm anti*BWCS-*Simulator.*

The circuit $\alpha(x)$ is semimonotone because only the subcircuits that implement the function ϕ contain negative input nodes.

Now if the circuit $\alpha(x)$ accepts an assignment of weight $s(n)$, then each $2^{a\ell(m)}$-block of the assignment must have weight 1. Thus the assignment implements a satisfying assignment to the circuit $\gamma_m(x)$.

Since the circuit $\gamma_m(x)$ is satisfiable if and only if $x \in L$, we conclude that the circuit $\alpha(x)$ accepts a weight-$s(n)$ input if and only if $x \in L$. Consequently, the mapping from x to $\langle \alpha(x), s(n)\rangle$ is a many–one reduction from the language L to the language BWCS$(s(n), 2k)$.

By assumption, the function $s(n)$ can be constructed in deterministic $O(\log n)$ space and the circuit τ_m can be constructed in deterministic $O(\log m) = O(\log n)$ space. It is also easy to see that the circuit constructions from τ_m to $\tau_m(x)$, from $\tau_m(x)$ to $\gamma_m(x)$, and from $\gamma_m(x)$ to $\alpha(x)$ (in the normal form) can all be done in deterministic $O(\log n)$ space. Therefore, the reduction can be implemented in deterministic $O(\log n)$ space. This completes the proof of the theorem. □

Unfortunately, the above methods do not seem to work for $GC(s(n)\ell(n), \Pi_{2k+1})$. In fact, we are even unable to prove that the language BWCS$(s(n), 2k+1)$ is in the class $GC(s(n)\ell(n), \Pi_{2k+1})$. For this, we need to introduce another special type of circuits that are dual to the semimonotone circuits. A circuit α is *semiantimonotone* if at most two inputs of each level-1 gate of α are positive input nodes.

DEFINITION 4.5. *anti* BWCS$(s(n), k)$ *is the set of pairs* $x = \langle \alpha, w\rangle$*, where* α *is a semiantimonotone* Π*-circuit of depth* k *in the normal encoding such that* α *accepts an input of weight* w*,* $w \le s(|x|)$*.*

LEMMA 4.6. *For any function* $s(n)$ *and any* $k \ge 1$*,* antiBWCS$(s(n), 2k+1)$ *is in the class* $GC(s(n)\ell(n), \Pi^B_{2k+1})$*.*

Proof. We first design an algorithm antiBWCS-Simulator as shown in Figure 4. As in the proof of Lemma 4.2, we can prove that the algorithm antiBWCS-Simulator can be implemented by a Π^B_{2k+1}-ATM M. In particular, since the circuit α is in the normal encoding, the positive input nodes should always appear at the end of the input list of a level-1 gate. Thus they can be found in deterministic $O(\log n)$ time since α is semiantimonotone. It can also be proved that M accepts $\langle x, y\rangle$, where $x = \langle \alpha, w\rangle$, if and only if y contains exactly w different input-node numbers of the semiantimonotone circuit α, and the circuit α accepts the input v_y of weight w whose weight

representation is y. Consequently, for any $x = \langle \alpha, w \rangle$, $x \in \text{antiBWCS}(s(n), 2k+1)$ if and only if there is a string $y \in \{0,1\}^*$ of length $s(|x|)\ell(|x|)$ such that the algorithm antiBWCS-Simulator accepts $\langle x, y \rangle$. We leave the detailed proof to the interested reader. □

THEOREM 4.7. *Let $s(n) \leq n$ be a nondecreasing function computable in deterministic $O(\log n)$ space. Then* antiBWCS$(s(n), 2k+1)$ *is complete for the class $GC(s(n)\ell(n), \Pi^B_{2k+1})$ under $O(\log n)$-space reduction, for $k \geq 1$.*

Proof. Let L be a language in $GC(s(n)\ell(n), \Pi^B_{2k+1})$. For an instance x of L, let $n = |x|$, $m = |\langle x, y \rangle|$, where y is a binary string of length $as(n)\ell(m)$ for an integer $a > 0$. As in the proof of Theorem 4.4, we can construct a Π-circuit $\gamma_m(x)$ with $as(n)\ell(m)$ inputs and of depth $2k+2$ in which the input of each level-1 gate is a specimen of an $(a\ell(m))$-block of its input such that $x \in L$ if and only if the circuit $\gamma_m(x)$ is satisfiable.

The construction of the circuit $\alpha(x)$ from the circuit $\gamma_m(x)$ is in some sense dual to the one in the proof of Theorem 4.4.

Let g be a level-1 gate of the circuit $\gamma_m(x)$ whose input is a specimen of the first $(a\ell(m))$-block of $I(\gamma_m(x))$. Note that g is an OR gate; thus there is a unique Boolean assignment b_g to the first $(a\ell(m))$-block of $I(\gamma_m(x))$ that makes the gate g have value 0. Regarding b_g as a binary number between 0 and $2^{a\ell(m)} - 1$, we replace the gate g in $\gamma_m(x)$ by the negative input node $\overline{v}_{b_g+1}$ in $I(\alpha(x))$. We perform this replacement on each level-1 gate in the circuit $\gamma_m(x)$. The resulting circuit $\alpha(x)$ has depth $2k+1$. Also, note that so far the circuit $\alpha(x)$ contains no positive input nodes.

To ensure that each $2^{a\ell(m)}$-block of $I(\alpha(x))$ is assigned exactly one 1, we again use the function ϕ in the proof of Theorem 4.4. However, this time we implement the function ϕ by a Π-circuit C_ϕ of depth 3 so that all level-1 gates of the circuit C_ϕ have fan-in 1. Thus the circuit C_ϕ is semiantimonotone. Now including the subcircuits C_ϕ into the circuit $\alpha(x)$ ensures that the circuit $\alpha(x)$ accepts an input of weight $s(n)$ if and only if the circuit $\gamma_m(x)$ is satisfiable. Moreover, adding the subcircuits C_ϕ to $\alpha(x)$ does not increase the depth of the circuit $\alpha(x)$ because the depth of $\alpha(x)$ is at least 3.

All other parts of the proof are exactly the same as that in the proof of Theorem 4.4. □

In many cases, the function $\ell(n)$ in $GC(s(n)\ell(n), \Pi^B_k)$ can be replaced by $\log n$, as stated in the following theorem. A proof of this theorem can be found in [6].

THEOREM 4.8. *If the function $s(n)$ is computable in deterministic $O(\log n)$ time and $|s(n)| = O(\log n / \log\log n)$ for all n, then for all $k \geq 1$,*

$$GC(s(n)\ell(n), \Pi^B_k) = GC(s(n)\log n, \Pi^B_k).$$

5. *GC* classes and optimization problems. In this section, we present a number of interesting connections of the GC classes to computational optimization problems.

Following Papadimitriou and Yannakakis [21], define $LOGNP_0$ to be the class of all problems described as follows:

$$\{I : \exists S \in [n]^{\log n},\ \forall x \in [n]^p,\ \exists y \in [n]^q,\ \forall j \in [\log n],\ \phi(I, s_j, x, y, j)\}, \tag{1}$$

where $I \subseteq [n]^m$ is the input relation, x and y are tuples of first-order variables ranging over $[n] = \{1, 2, \ldots, n\}$, j is a first-order variable ranging over $[\log n]$, S is an ordered subset $S = (s_1, \ldots, s_{\log n})$ of $[n]$, and ϕ is a quantifier-free first-order

expression involving the relation symbol I and the variables in x and y as well as the variables j and s_j.

A weaker class $LOGSNP_0$ contains all problems definable by one less alternation of quantifiers:

$$\{I : \exists S \in [n]^{\log n},\ \forall x \in [n]^p,\ \exists j \in [\log n],\ \phi(I, s_j, x, j)\}. \tag{2}$$

The class $LOGNP$ is defined to be the class of languages that can be polynomial-time reduced to a problem in $LOGNP_0$, and the class $LOGSNP$ is defined to be the class of languages that can be polynomial-time reduced to a problem in $LOGSNP_0$.

The complexity of a number of interesting optimization problems can be nicely characterized by the classes $LOGNP$ and $LOGSNP$. For instance, it has been shown [21] that the problems LOG DOMINATING SET, TOURNAMENT DOMINATING SET, RICH HYPERGRAPH COVER, and LOG ADJUSTMENT are complete under polynomial-time reduction for the class $LOGSNP$ and that the problem V-C DIMENSION is complete under polynomial-time reduction for the class $LOGNP$.

The following two theorems characterize the classes $LOGNP$ and $LOGSNP$ by the GC models.

THEOREM 5.1. *A language L is in the class $LOGSNP$ if and only if L is polynomial-time reducible to a language in $GC(\log^2 n, \Pi_2^B)$.*

Proof. We first show that the language BWCS$(\log n, 2)$ is in the class $LOGSNP_0$ when circuits are encoded properly. A circuit is in the *edge-relation encoding* if it is represented by a collection of five kinds of tuples: $e(g, g')$ if node g is an input of node g', $p(i, g)$ if the ith input of the level-1 gate g is a positive input node, $n(i, g)$ if the ith input of the level-1 gate g is a negative input node, $pos(k, g)$ if the positive input node x_k is an input of the level-1 gate g, and $neg(k, g, i)$ if the ith input of the level-1 gate g is the negative input node $\overline{x}_k$. Note that for a semimonotone circuit, $neg(k, g, i)$ is false for all $i \geq 3$. It is easy to see that the edge-relation encoding of circuits and the normal encoding of circuits can be converted to each other in polynomial time.

With the edge-relation encoding, it is easy to see the language BWCS$(\log n, 2)$ is defined by the following logic expression:

$$\{\langle \alpha, w\rangle : \exists S \in [n]^{\log n},\ \forall g \in [n],\ \forall a, b \in [\log n],\ \exists j \in [\log n],\ ([A] \wedge [B] \wedge [C] \wedge [D])\},$$

where

$$\begin{aligned}
[A] &= e(g, g_0) \wedge p(1, g) \rightarrow pos(s_j, g),\\
[B] &= e(g, g_0) \wedge n(1, g) \wedge p(2, g) \wedge (a \leq w)\\
&\qquad \rightarrow pos(s_j, x) \vee [(a = j) \wedge \overline{neg(s_j, g, 1)}],\\
[C] &= e(g, g_0) \wedge n(1, g) \wedge n(2, g) \wedge (a, b \leq w)\\
&\qquad \rightarrow pos(s_j, x) \vee [(a = j) \wedge \overline{neg(s_j, g, 1)}] \vee [(b = j) \wedge \overline{neg(s_j, g, 2)}],\\
[D] &= (j \leq w),
\end{aligned}$$

where g_0 is the output gate of the circuit α.

Thus the language BWCS$(\log n, 2)$ is in the class $LOGSNP_0$ when circuits are in the edge-relation encoding. By Theorems 4.4 and 4.8, the language BWCS$(\log n, 2)$ is complete under $O(\log n)$-space reduction for class $GC(\log^2 n, \Pi_2^B)$ when circuits are in the normal encoding. Since the normal encoding of a circuit can easily be converted into the edge-relation encoding of the circuit, we conclude that all languages in the class $GC(\log^2 n, \Pi_2^B)$ are in $LOGSNP$. Consequently, all languages that are polynomial-time reducible to a language in the class $GC(\log^2 n, \Pi_2^B)$ are contained in the class $LOGSNP$.

To prove the inverse, we consider the following problem. A *tournament* is a directed graph in which for any two vertices exactly one of the two directed edges is presented. It is not difficult to see that a tournament of n vertices has a dominating set of size $\log n$ [21]. Thus the following problem has a trivial solution when $k \geq \log n$.

TOURNAMENT DOMINATING SET: "Given a tournament with n vertices and integer k, does it have a dominating set of size k?"

Papadimitriou and Yannakakis [21] have shown that TOURNAMENT DOMINATING SET is complete for *LOGSNP* under polynomial-time reduction. Therefore, to show that all languages in *LOGSNP* are polynomial-time reducible to a language in the class $GC(\log^2 n, \Pi_2^B)$, we only have to show that TOURNAMENT DOMINATING SET is in $GC(\log^2 n, \Pi_2^B)$. It can be easily done as follows: given an input $\langle G, k, y\rangle$, where y is of length $k \log n$ and encodes k vertices of the tournament G, the Π_2^B-ATM M first universally picks a vertex v of G, then existentially guesses a vertex w in y, and finally verifies if $v = w$ or $[w, v]$ is an edge of G.

This completes the proof. □

The proof of Theorem 5.1 also shows that TOURNAMENT DOMINATING SET is complete for the class $GC(\log^2 n, \Pi_2^B)$ under polynomial-time reduction.

THEOREM 5.2. *A language is in the class LOGNP if and only if it is polynomial-time reducible to a language in* $GC(\log^2 n, \Pi_3^B)$.

Proof. Since the proof is similar to that of Theorem 5.1, we only describe the differences here.

The language antiBWCS$(\log n, 3)$ can be given by the following logic expression:

$$\{\langle \alpha, w\rangle : \exists S \in [n]^{\log n},\ \forall g' \in [n],\ \exists g \in [n],\ \exists a, b \in [\log n],\ \forall j \in [\log n],\ ([A] \wedge [B] \wedge [C] \wedge [D])\},$$

where

$$[A] = e(g', g_0) \wedge e(g, g') \wedge n(1, g) \wedge (j \leq w) \rightarrow \overline{neg(s_j, g)},$$
$$[B] = e(g', g_0) \wedge e(g, g') \wedge p(1, g) \wedge n(2, g) \wedge (j \leq w) \rightarrow \overline{neg(s_j, x)} \wedge [(a \neq j) \vee pos(s_j, g, 1)],$$
$$[C] = e(g', g_0) \wedge e(g, g') \wedge p(1, g) \wedge p(2, g) \wedge (j \leq w) \rightarrow \overline{neg(s_j, x)} \wedge [(a \neq j) \vee pos(s_j, g, 1)] \wedge [(b \neq j) \vee pos(s_j, g, 2)],$$
$$[D] = (a \leq w) \wedge (b \leq w).$$

To show that every language in the class *LOGNP* is polynomial-time reducible to a language in $GC(\log^2 n, \Pi_3^B)$, we will show that the problem V-C DIMENSION, which is known to be complete for the class *LOGNP* [21], is contained in the class $GC(\log^2 n, \Pi_3^B)$.

Let $\mathcal{C}$ be a family of subsets of a universe U. The *V-C dimension* of $\mathcal{C}$ is the largest cardinality of a subset S of U such that the following holds: For all subsets T of S there is a set $C[T] \in \mathcal{C}$ such that $S \cap C[T] = T$. Closer inspection reveals that the V-C dimension of a family $\mathcal{C}$ is at most $\log |\mathcal{C}|$.

V-C DIMENSION: "Given a finite family $\mathcal{C}$ of finite sets and an integer k, is the V-C dimension of $\mathcal{C}$ at least k?"

To show that the problem V-C DIMENSION is in the class $GC(\log^2 n, \Pi_3^B)$, we construct a Π_3^B-ATM M as follows. Let $n = |\mathcal{C}|$. On input $\langle \mathcal{C}, k, y\rangle$, where y is a binary string of length $k \log n$ that encodes a subset S of U of k elements, the Π_3^B-ATM M first universally picks a subset T of S (this can be done by picking a binary string of length k to indicate which elements of S are included in T), then existentially guesses a subset $C[T]$ in $\mathcal{C}$, and finally universally checks for each element v in S that v is in T if and only if v is in $C[T]$. It is not hard to see that with a proper encoding of the

family $\mathcal{C}$, the machine M can be implemented by a Π_3^B-ATM. □

The proof of Theorem 5.2 also shows that V-C DIMENSION is complete for the class $GC(\log^2 n, \Pi_3^B)$ under polynomial-time reduction.

One may not expect an easy proof that the classes *LOGSNP* and *LOGNP* are different because that would imply $P \neq NP$. However, based on the *GC* model characterizations of these classes, we can show strong evidence that these two classes are distinct.

THEOREM 5.3. *For all integer $k \geq 1$, the class $GC(\log^2 n, \Pi_k^B)$ is a proper subclass of the class $GC(\log^2 n, \Pi_{k+1}^B)$.*

Proof. By Boppana and Sipser [3, Thm. 3.13], for any integer $k \geq 1$, there is a language L_{k+1} that is accepted by a Π_{k+1}^B-ATM but not by any family of Σ-circuits of size $O(n^{O(\log n)})$ and depth $k+2$ in which the fan-in of the level-1 gates is bounded by $O(\log n)$. Thus the language L_{k+1} is in the class $GC(\log^2 n, \Pi_{k+1}^B)$.

Suppose that the language L_{k+1} is also in the class $GC(\log^2 n, \Pi_k^B)$. Then there is a Π_k^B-ATM M such that for every instance x of L_{k+1}, $x \in L_{k+1}$ if and only if there is a binary string y of length $c\log^2 n$ such that $\langle x, y\rangle$ is accepted by M, where c is a fixed constant. By Theorem 2.2, there is a Π_k^{poly,B_d}-family $F = \{\alpha_m \mid m \geq 1\}$ of circuits that accepts the same language as M. Now we can construct a circuit family $F' = \{\gamma_n \mid n \geq 1\}$ to accept L_{k+1} as follows. Given an instance x of L_{k+1}, $|x| = n$, let $m = n + c\log^2 n$. Note that by definition, $x \in L_{k+1}$ if and only if $\langle x, y\rangle$ is accepted by the circuit α_m, for a binary string y of length $c\log^2 n$. For each binary string y of length $c\log^2 n$, we construct a circuit $\alpha_m(y)$ that is the circuit α_m with the last $c\log^2 n$ input variables assigned by the value of y. Now let γ_n be the OR of all these $2^{c\log^2 n} = n^{c\log n}$ circuits $\alpha_m(y)$, $y \in \{0,1\}^{c\log^2 n}$. Then the Σ-circuit γ_n has size $O(n^{O(\log n)})$ and depth $k+2$ in which the fan-in of the level-1 gates is bounded by $O(\log n)$ (recall that the circuit family $F = \{\alpha_m | m \geq 1\}$ is a Π_k^{poly,B_d}-family of circuits), and γ_n accepts x if and only if $x \in L_{k+1}$. However, this contradicts the definition of the language L_{k+1}.

This completes the proof that the language L_{k+1} is in the class $GC(\log^2 n, \Pi_{k+1}^B)$ but not in the class $GC(\log^2 n, \Pi_k^B)$. □

Papadimitriou and Yannakakis [21] have shown that the following three problems are in *LOGSNP*.

> LOG^{2}SAT: "Given a CNF Boolean formula with n clauses and $\log^2 n$ variables, does it have a satisfying truth assignment?"
>
> LOG CLIQUE: "Given a graph with n vertices, does it have a clique of size $\log n$?"
>
> LOG CHORDLESS PATH: "Given a graph with n vertices, does it have a chordless path of length $\log n$?"

It was asked in [21] whether these three problems are complete for the class *LOGSNP*. Based on our characterization, we show that it is unlikely that these problems are complete for the class *LOGSNP*.

The problem LOG CLIQUE is actually in the class $GC(\log^2 n, \Pi_1^B)$ if on input $\langle x, y\rangle$, we allow each computation path of a Π_1^B-ATM to read two ℓ-blocks from the second parameter y. In fact, let G be a graph and let y encode $\log n$ vertices of G; then on input $\langle G, y\rangle$, a Π_1^B-ATM can universally pick a pair (v, w) of vertices from the string y and check with G if there is an edge connecting them. Similarly, the problem LOG CHORDLESS PATH can be shown to be in the class $GC(\log^2 n, \Pi_1^B)$. Note that in the proof of Theorem 5.3, the fact that the last phase of each computation path of a Π_k^B-ATM reads at most one ℓ-block from y was actually not used. Thus even though

we allow each computation path of a Π_1^B-ATM to read two ℓ-blocks from y, the class $GC(\log^2 n, \Pi_1^B)$ is still a proper subclass of the class $GC(\log^2 n, \Pi_2^B)$. Therefore, the problems LOG CLIQUE and LOG CHORDLESS PATH seem not hard enough to be complete for the class *LOGSNP*. Similarly, the problem LOG^{2}SAT can be shown to belong to the class $GC(\log^2 n, \Pi_2^{B*})$, where Π_2^{B*} is the class of languages accepted by restricted Π_2^B-ATMs in which the last phase of each computation path runs at most $O(\log \log n)$ steps and reads at most constant number of input bits. A proof similar to that of Theorem 5.3 can be derived to show that $GC(\log^2 n, \Pi_2^{B*})$ is a proper subclass of $GC(\log^2 n, \Pi_2^B)$. Therefore, the problem LOG^{2}SAT also seems not hard enough to be complete for the class $GC(\log^2 n, \Pi_2^B)$ (for detailed discussions on the problem LOG^{2}SAT, see [6]).

Meggido and Vishkin [20] studied the problem TOURNAMENT DOMINATING SET and proved that the problem LOG^{2}SAT is polynomial-time reduced to TOURNAMENT DOMINATING SET and that TOURNAMENT DOMINATING SET is polynomial-time reduced to a generalization of the LOG^{2}SAT problem. They asked whether there is a version of the satisfiability problem that precisely characterizes the problem TOURNAMENT DOMINATING SET. Our Theorem 5.1 concludes that the problem TOURNAMENT DOMINATING SET is polynomial-time equivalent to the problem BWCS$(\log n, 2)$, which is the standard satisfiability problem with a weight restriction on the truth assignment and the restriction that in each clause of the CNF formula there are at most two negative literals.

We point out that one can also derive from a result in [21] that the problem SPARSE SAT ("Given a CNF Boolean formula of n variables, does it have a satisfying truth assignment of weight at most $\log n$?") is also polynomial-time equivalent to TOURNAMENT DOMINATING SET [26]. However, the language BWCS$(\log n, 2)$ characterizes the problem TOURNAMENT DOMINATING SET more precisely in the sense that both BWCS$(\log n, 2)$ and TOURNAMENT DOMINATING SET belong to the class LOGSNP$_0 \cap GC(\log^2 n, \Pi_2^B)$ under standard encodings, while SPARSE SAT does not seem to belong to either LOGSNP$_0$ or $GC(\log^2 n, \Pi_2^B)$ under standard encodings.

Finally, we point out that the *GC* model also has nice applications in the study of fixed-parameter tractability of optimization problems [15]. We refer interested readers to our related work [9, 10].

Acknowledgments. The authors thank Rod Downey, Mike Fellows, Don Friesen, Judy Goldsmith, Christos Papadimitriou, Robert Szelepcsényi, Marty Wolf, Mihalis Yannakakis, and Chee Yap for their comments and constructive discussions. The authors also thank the referees for their careful reading and many useful comments, which have greatly improved the presentation.

BOUNDS ON THE NUMBER OF EXAMPLES NEEDED FOR LEARNING FUNCTIONS*

HANS ULRICH SIMON†

Abstract. We prove general lower bounds on the number of examples needed for learning function classes within different natural learning models which are related to pac-learning (and coincide with the pac-learning model of Valiant in the case of $\{0,1\}$-valued functions). The lower bounds are obtained by showing that all nontrivial function classes contain a "hard binary-valued subproblem." Although (at first glance) it seems to be likely that real-valued function classes are much harder to learn than their hardest binary-valued subproblem, we show that these general lower bounds cannot be improved by more than a logarithmic factor. This is done by discussing some natural function classes like nondecreasing functions or piecewise-smooth functions (the function classes that were discussed in [M. J. Kearns and R. E. Schapire, *Proc. 31st Annual Symposium on the Foundations of Computer Science*, IEEE Computer Society Press, Los Alamitos, CA, 1990, pp. 382–392, full version, J. Comput. System Sci., 48 (1994), pp. 464–497], [D. Kimber and P. M. Long, *Proc. 5th Annual Workshop on Computational Learning Theory*, ACM, New York, 1992, pp. 153–160]) with certain restrictions concerning their slope.

Key words. function learning, sample complexity

1. Introduction.

The question of how many examples are necessary and sufficient for learning has found a very satisfactory answer within the distribution-free learning model for deterministic concept classes C (the pac-learning model of Valiant [12]). There is a lower bound of $\Omega((d(C)+\ln(1/\delta))/\epsilon)$ (see [3] and [4]) and an upper bound of $O((d(C)\ln(1/\epsilon)+\ln(1/\delta))/\epsilon)$ (see [3]), where $d(C)$ denotes the Vapnik–Chervonenkis dimension of C. Since these bounds are within a logarithmic factor of each other, it is fairly well known how the sample complexity scales with the parameters ϵ and δ (which specify the demanded accuracy and confidence of learning).

The distribution-free learning model has been transferred to probabilistic concept classes (also called p-concept classes) by Kearns and Schapire (see [6]) and to function classes by Haussler (see [5]). In this paper, we restrict ourselves to functions with real values in the range $[0,1]$ (hereafter simply called functions).[1] The main difference between p-concept learning and function learning lies in the kind of feedback. A labeled example for a function f has the form $(x,f(x))$, i.e., the learning algorithm obtains the correct value of f at point x. For p-concept learning, the feedback is weaker. Here $f(x)$ is interpreted as a probability (that x fits into the concept). A labeled example has the form $(x,l(x))$, where $l(x)\in\{0,1\}$ is the outcome of a coin which produces 1 with probability $f(x)$ and 0 with probability $1-f(x)$. Note that learning f as a function is easier than learning f as a p-concept since the feedback is much stronger.

[1] It will become evident, however, that all results are easily extended to functions with bounded range.

This paper will demonstrate that the sample complexity of function learning can be characterized very well in terms of a quantity $d_F(\gamma)$, which is related to the Natarajan dimension of F (see [9]), but depends on a given width γ of shattering.[2] We first derive some general lower bounds. They are obtained by showing that all nontrivial function classes contain a "hard binary-valued subproblem." Although (at first glance) it seems to be likely that real-valued function classes are much harder to learn than their hardest binary-valued subproblem, we show that these general lower bounds cannot be improved by more than a logarithmic factor. This is done by discussing some natural function classes like nondecreasing functions or piecewise-smooth functions (the function classes that were discussed in [6] and [7]) with certain restrictions concerning their slope.[3]

Although our general lower bounds cannot be substantially improved (because there are "almost matching" upper bounds for some specific function classes), we are not aware of general upper bounds which match the lower ones modulo a logarithmic factor. Recently, Anthony and Shawe-Taylor derived general upper bounds for function learning in terms of several other notions of dimension associated with F and γ (see [2]). Their results are incomparable to ours because the variation within the different notions of dimension is too large. In particular, their general upper bounds cannot be directly applied to the specific function classes considered in this paper (the corresponding dimensions are not finite). Thus closing the gap between the general upper and lower bounds is a major object of future research.

This paper is structured as follows. Section 2 presents the definition of the learning models. Section 3 presents the general lower bounds. Section 4 presents "almost matching" upper bounds for some natural function classes. Section 5 presents generalizations to higher-dimensional domains. Section 6 discusses some open problems.

2. The learning models. Let F be a class of functions from a domain X into $[0,1]$. The environment for learning consists of a hidden target function $f \in F$ and an unknown distribution D on X.[4] A *random sample I of size m* w.r.t. D, f consists of m sample points $x_1, \ldots, x_m$ drawn randomly according to D^m and the corresponding values $f(x_1), \ldots, f(x_m)$ of the target function. A function $h : X \to [0,1]$ is called an *(ϵ, γ)-good model for f* if

$$D(\{x|\ |f(x) - h(x)| \geq \gamma\}) < \epsilon.$$

The *expected absolute difference* and the *expected quadratic difference* of h (w.r.t. D, f) are given by

$$e_1(h) = E_D[|f(x) - h(x)|] \quad \text{and} \quad e_2(h) = E_D[(f(x) - h(x))^2],$$

respectively.

A *learning algorithm* A for F with sample size $m = m(\epsilon, \gamma, \delta)$ gets as input the parameters ϵ, γ, and δ and a random sample of size m w.r.t. D and f. It outputs a hypothesis $h_I : X \to [0,1]$. Note that the output h_I depends on the randomly chosen

[2] In a similar way, Kearns and Schapire defined a variant of the combinatorial dimension which depends on a width γ of shattering (see [6]).

[3] The reader interested in related work for p-concept learning is referred to [11].

[4] Formally, D is a probability measure for $(X, \mathcal{A})$, where $\mathcal{A}$ denotes a σ-algebra of X. We assume that all functions from F and all hypotheses h used are measurable functions from $(X, \mathcal{A})$ into $([0,1], \mathcal{B})$, where $\mathcal{B}$ denotes the standard algebra of Borel sets in $[0,1]$. This assumption will guarantee that throughout the paper all probabilities or expectations are well defined.

sample I. It is therefore meaningful to speak about the probability (w.r.t. D^m) that h_I has a particular property. For some of the learning models (to be defined below), parameter γ is missing.

We say that *A learns F with an (ϵ,γ)-good model* if for all $f \in F$, all domain distributions D, all $0 < \epsilon, \gamma, \delta < 1$, and $m = m(\epsilon,\gamma,\delta)$, there is a probability of at least $1-\delta$ (w.r.t. D^m) that h_I is an (ϵ,γ)-good model for f.

Similarly, we say that *A learns F with ϵ-bounded absolute (or ϵ-bounded quadratic) difference* if for all $f \in F$, all domain distributions D, all $0 < \epsilon, \delta < 1$, and $m = m(\epsilon,\delta)$, there is a probability of at least $1-\delta$ (w.r.t. D^m) that h_I satisfies $e_1(h) < \epsilon$ (or $e_2(h) < \epsilon$, respectively).

3. General lower bounds. We begin this section with the definition of the function $d_F(\gamma)$ associated with a function class F and a given width γ of shattering. A sequence

$$S = ((x_1, r_1, s_1), \ldots, (x_d, r_d, s_d)) \in (X \times [0,1] \times [0,1])^d$$

is called γ-shattered by F if the following hold:

1. $(\forall b \in \{0,1\}^d) \quad (\exists f = f_b \in F) \quad (\forall i = 1, \ldots, d) \quad f(x_i) = \begin{cases} r_i & \text{if } b_i = 0, \\ s_i & \text{if } b_i = 1. \end{cases}$
2. $(\forall i = 1, \ldots, d)\ s_i \geq 2\gamma + r_i$.

In other words, for each point x_i there exists a low function value r_i and a high function value s_i. Function class F is sufficiently rich to allow all combinations of low and high values, and the high value exceeds the low one by at least 2γ. We define $d_F(\gamma)$ as the maximal number d (possibly ∞) such that there exists a sequence of length d which is γ-shattered by F.

We would like to make some informal comments on the motivation behind this definition. Without demanding that $s_i \geq 2\gamma + r_i$, we would obtain the definition of the so-called Natarajan dimension $d_N(F)$ (defined in [9], where it is called the generalized dimension). However, the existence of low and high function values (and free combinations there of) is not really "dangerous" for learning algorithms A. If r_i and s_i are very close to each other, A may make a trivial guess (such as $(r_i + s_i)/2$, for instance) and still approximate the true function value quite accurately. For this reason, in [6], Kearns and Schapire proposed to incorporate the width γ of shattering into the definition. Their results show that $d_F(\gamma)$ is a lower bound for p-concept learning.[5] In this section, we strengthen this result in two directions. First, we derive a higher lower bound. Second, we show that the lower bound is even valid w.r.t. function learning. (Recall that the feedback for p-concept learning is weaker; lower bounds for function learning are therefore always lower bounds for p-concept learning, but not vice versa.)[6]

Consider, for example, the class *ND* of nondecreasing functions from the real domain $\Re$ into $[0,1]$ (discussed as a p-concept class in [6]). It is not hard to show that

$$((0,0,2\gamma), (2\gamma, 2\gamma, 4\gamma), (4\gamma, 4\gamma, 6\gamma), \ldots)$$

is a γ-shattered sequence of maximal length. Thus

$$d_{ND}(\gamma) = \lfloor 1/(2\gamma) \rfloor.$$

[5] They used a slightly different definition of $d_F(\gamma)$. Both definitions coincide for the function classes considered in this paper.

[6] The reader interested in almost optimal lower bounds for p-concept learning is referred to [11].

As a second example, consider the class $\mathcal{F}_1$ of continuous functions from $[0,1]$ into $[0,1]$ which are piecewise continuously differentiable and satisfy

$$\int_0^1 |f'(x)|dx \leq 1$$

(i.e., the average slope of f is bounded by 1). A more restricted class is $\mathcal{F}_\infty$, which consists of all continuous functions from $[0,1]$ into $[0,1]$ which are piecewise continuously differentiable and whose slope is bounded by 1 at each $x \in [0,1]$. (For points at which two pieces are stuck together, there are "two slopes" depending on whether we differentiate from the left or from the right; for functions $f \in \mathcal{F}_\infty$, "both slopes" must then be bounded by 1.) It is obvious that the sequence

$$((0,0,2\gamma),(2\gamma,0,2\gamma),(4\gamma,0,2\gamma),\ldots)$$

is γ-shattered by $\mathcal{F}_1$ and $\mathcal{F}_\infty$. Thus

$$d_{\mathcal{F}_1}(\gamma) \geq d_{\mathcal{F}_\infty}(\gamma) \geq 1 + \lfloor 1/(2\gamma) \rfloor.$$

In section 4, we show that these inequalities can be turned into equalities. In [7], Kimber and Long discuss a hierarchy of function classes which starts in $\mathcal{F}_\infty$ and ends in $\mathcal{F}_1$. They were interested in (different variants of) on-line learning of function classes. Their results are incomparable to ours. (For instance, $\mathcal{F}_1$ is not learnable in the on-line model, but it is learnable in our model, as we will show in section 4.) However, it is worth mentioning that we will obtain (see section 4) an upper bound on the sample complexity of $\mathcal{F}_1$ (the most general class of the hierarchy) which is tight to within a logarithmic factor to a lower bound on the sample complexity of $\mathcal{F}_\infty$ (the least general class of the hierarchy). Our bounds are therefore "almost tight" for the whole hierarchy considered by Kimber and Long.

We are now ready to derive our general lower bounds. We say that two functions f_1 and f_2 on domain X are *disjoint* if $f_1(x) \neq f_2(x)$ for all $x \in X$. A function class F is called *trivial* if its functions are pairwise disjoint. Note that a single example is sufficient for learning a trivial function class. (Each labeled example reveals the identity of the function.) Our attention will therefore be focused on nontrivial classes. The quantity $\Delta(F)$ is defined as follows:

$$\Delta(F) = \sup\{|g(x) - f(x)|, \text{ where } x \in X \text{ and } f \text{ and } g \text{ are nondisjoint functions from } F\}.$$

It measures how much two nondisjoint functions may differ on some point of domain X. For instance, $\Delta(F) = 1$ for $F = ND, \mathcal{F}_\infty, \mathcal{F}_1$. This is witnessed by the identity and the constant-zero function on $[0,1]$ in the obvious way.

THEOREM 3.1. *Let A be an algorithm which learns function class F with an (ϵ,γ)-good model.*

1. *If F is nontrivial, $\epsilon < 1/2$, and $\gamma < \Delta(F)/2$, then A needs $\Omega(\ln(1/\delta)/\epsilon)$ examples.* 2. *If $0 < \epsilon \leq 1/8$, $0 < \delta \leq 1/100$, then A needs $\Omega((d_F(\gamma) - 1)/\epsilon)$ examples.*

Proof. 1. Since F is nontrivial, there exist two nondisjoint functions $f, g \in F$ and two points $a, b \in X$ such that

$$f(a) = g(a) \quad \text{and} \quad f(b) + 2\gamma \leq g(b).$$

W.l.o.g., $X = \{a, b\}$ and $F = \{f, g\}$. Let $\bar{f}$ and $\bar{g}$ be given by

$$\bar{f}(a) = \bar{g}(a) = 0, \qquad \bar{f}(b) = 0, \quad \text{and} \quad \bar{g}(b) = 1,$$

and $\bar{F} = \{\bar{f}, \bar{g}\}$. $\bar{F}$ is a nontrivial deterministic concept class. It is well known that $\Omega(\ln(1/\delta)/\epsilon)$ examples are needed for pac-learning $\bar{F}$ under domain distribution $D(a) = 1 - \epsilon,\ D(b) = \epsilon$ (see [3]). The assertion of our theorem is now easily obtained because algorithm A can be converted into a pac-learning algorithm $\bar{A}$ for $\bar{F}$ as follows.

Let $\bar{t} \in \bar{F}$ denote the target concept. A sample for $\bar{t}$ can be converted into a sample for t by substituting $(a, f(a))$ for $(a, 0)$, $(b, f(b))$ for $(b, 0)$, and $(b, g(b))$ for $(b, 1)$. Algorithm A then runs on the converted sample and produces (with high confidence) a hypothesis h which is an (ϵ, γ)-good model for $t \in \{f, g\}$. W.l.o.g., $h(a) = f(a)$ because both possible target functions attain the same value at a. Since f and g differ by at least 2γ at point b, $h(b)$ differs from $f(b)$ or $g(b)$ by at least γ. It follows w.l.o.g. that $h(b) \in \{f(b), g(b)\}$. Thus $h \in F$. Finally, observe that $\bar{h}$ is an ϵ-good hypothesis for $\bar{t}$ w.r.t. pac-learning if h is an (ϵ, γ)-good model for t.

2. Let $d = d_F(\gamma)$ and $S = ((x_1, r_1, s_1), \ldots, (x_d, r_d, s_d))$, the γ-shattered sequence. W.l.o.g., $X = \{x_1, \ldots, x_d\}$ and F consists of the 2^d shattering concepts f_b for S ($b \in \{0, 1\}^d$). We associate with each f_b the deterministic concept $\bar{f}_b$ given by $\bar{f}_b(x_i) = b_i$. $\bar{F}$ denotes the corresponding deterministic concept class. Note that S is shattered by $\bar{F}$ (in the traditional sense) and d coincides with the Vapnik–Chervonenkis dimension of $\bar{F}$. It is well known that $\Omega((d-1)/\epsilon)$ examples are needed for pac-learning $\bar{F}$ under domain distribution $D(x_1) = 1 - 8\epsilon$, and $D(x_i) = 8\epsilon/(d-1)$ for $i = 2, \ldots, d$ (see [4]). The assertion of the theorem is now easily obtained because A can be converted into a pac-learning algorithm $\bar{A}'$ for $\bar{F}$. The design for $\bar{A}'$ is similar to the aforementioned design of $\bar{A}$. Now the labels r_i and s_i correspond to the labels 0 and 1, respectively. We omit the details. □

COROLLARY 3.2. *Any algorithm which learns one of the function classes ND, $\mathcal{F}_\infty$, $\mathcal{F}_1$ with an (ϵ, γ)-good model needs at least $\Omega(1/(\epsilon\gamma))$ examples.*

We shall see in section 4 that this bound is tight to within a logarithmic factor. To keep the assertion of the following corollary simple, we assume that $d_F(\gamma)$ is polynomially bounded in $1/\gamma$ and that ϵ and δ are sufficiently small.

COROLLARY 3.3. 1. *Let F be a nontrivial function class. Any algorithm which learns F with ϵ-bounded absolute (or quadratic) difference needs at least $\Omega(\ln(1/\delta)\Delta(F)/\epsilon)$ (or $\Omega(\ln(1/\delta)\Delta^2(F)/\epsilon)$) examples.*

2. *Any algorithm which learns F with ϵ-bounded absolute (or quadratic) difference needs at least $\Omega(d_F(\epsilon))$ (or $\Omega(d_F(\sqrt{\epsilon}))$) examples.*

Proof. The assertions follow immediately from Theorem 3.1 and the following facts from [6]:

Let $0 < c \leq 1$. If $e_1(h) < \epsilon$, then h is an $(\epsilon/c, c)$-good model. If $e_2(h) < \epsilon$, then h is an $(\epsilon/c^2, c)$-good model.

Assertion 1 is obtained by setting $c < \Delta(F)/2$ (for instance, $c = \Delta(F)/3$). Assertion 2 is obtained by setting $c = 8\epsilon$ or $\sqrt{8\epsilon}$, respectively. □

COROLLARY 3.4. *Any algorithm which learns one of the function classes ND, $\mathcal{F}_\infty$, $\mathcal{F}_1$ with an ϵ-bounded absolute (or quadratic) difference needs at least $\Omega(\ln(1/\delta)/\epsilon)$ examples.*

We shall see in section 4 that this bound is tight to within a logarithmic factor.

4. Upper bounds. In this section, we define the class BV of functions with bounded variation, which contains ND and $\mathcal{F}_1$ as subclasses. We describe learning algorithms for BV whose consumption of examples meets the lower bounds of section 3

within a logarithmic factor. (Note that the upper bounds hold for the most general class BV and the "almost matching" lower bounds hold already for subclasses.)

We say that a function f on domain $X \subseteq \Re$ has *bounded variation* if

$$\sum_{i=1}^{r-1} |f(x_{i+1}) - f(x_i)| \leq 1$$

for all $r \geq 1$ and all sequences $x_1 < \cdots < x_r$ of numbers from X. BV denotes the class of functions with bounded variation.[7]

LEMMA 4.1. *$ND, \mathcal{F}_1 \subseteq BV$.*

Proof. Nondecreasing functions from $\Re$ to $[0,1]$ satisfy

$$\sum_{i=1}^{r-1} |f(x_{i+1}) - f(x_i)| = \sum_{i=1}^{r-1} f(x_{i+1}) - f(x_i) = f(x_r) - f(x_1) \leq 1 - 0 = 1.$$

Thus $ND \subseteq BV$. Now let $f \in \mathcal{F}_1$ and define

$$t_i = \int_{x_i}^{x_{i+1}} |f'(x)| dx.$$

It follows that $\sum_{i=1}^{r-1} t_i \leq 1$. If f is monotonic in $[x_i, x_{i+1}]$, then

$$t_i = \int_{x_i}^{x_{i+1}} |f'(x)| dx = \left| \int_{x_i}^{x_{i+1}} f'(x) dx \right| = |f(x_{i+1)} - f(x_i)|.$$

A simple shortcut construction (illustrated in Figure 1) shows that a function f which is not monotonic in some interval $[a,b]$ can be transformed into a function which is monotonic, takes the same values at points a and b, and has an average slope which is not higher than the original one. This shows that, in general, $t_i \geq |f(x_{i+1}) - f(x_i)|$. Thus f has bounded variation. Therefore, $\mathcal{F}_1 \subseteq BV$. □

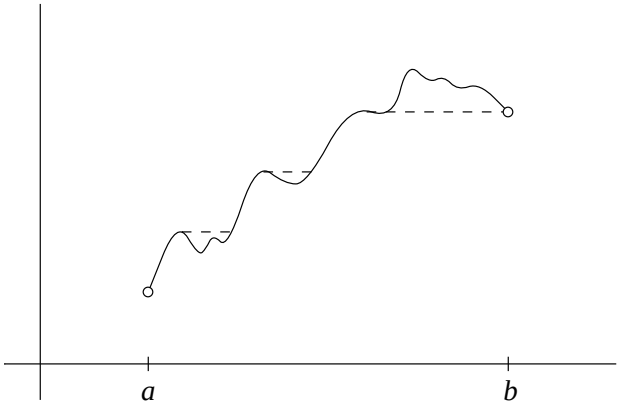

FIG. 1. *Making nonmonotonic functions monotonic by shortcuts (drawn dotted).*

The following lemma is useful for the analysis of functions with bounded variation.

[7] All the following results are easily extended to the class $BV[B]$, where we allow an arbitrary bound B on the variation. This class contains functions whose average slope is bounded by B, or which consist of B monotonic segments.

LEMMA 4.2. *Let $d \geq 2$. Let $0 \leq r_i < s_i \leq 1$ and $\lambda_i = s_i - r_i$ for $i = 1, \ldots, d$. Then it is possible to choose $t_i \in \{r_i, s_i\}$ such that*

$$\sum_{i=1}^{d-1} |t_{i+1} - t_i| \geq \frac{\lambda_1 + \lambda_d}{2} + \sum_{i=2}^{d-1} \lambda_i.$$

Proof. Choose the sequences $T = (t_i)$ and $T' = (t'_i)$ as

$$T = r_1, s_2, r_3, s_4, \ldots \quad \text{and} \quad T' = s_1, r_2, s_3, r_4, \ldots.$$

As illustrated in Figure 2, the following condition holds:

$$\sum_{i=1}^{d-1} (|t_{i+1} - t_i| + |t'_{i+1} - t'_i|) \geq \sum_{i=1}^{d-1} (\lambda_i + \lambda_{i+1}).$$

Thus T or T' satisfies the assertion of the lemma. □

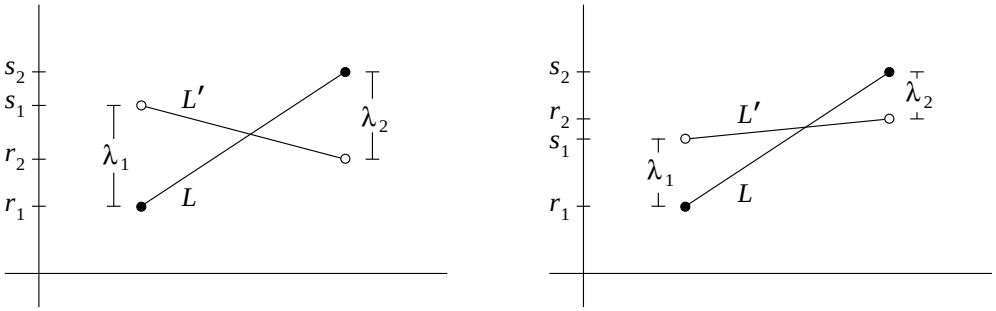

FIG. 2. *Two dual line segments L and L'. Their combined height difference $|s_2 - r_1| + |s_1 - r_2|$ is at least $\lambda_1 + \lambda_2$.*

COROLLARY 4.3. $d_{BV}(\gamma) = d_{\mathcal{F}_1}(\gamma) = d_{\mathcal{F}_\infty}(\gamma) = 1 + \lfloor 1/(2\gamma) \rfloor$.

Proof. Since $\mathcal{F}_\infty \subseteq \mathcal{F}_1 \subseteq BV$ and $d_{\mathcal{F}_\infty}(\gamma) \geq 1 + \lfloor 1/(2\gamma) \rfloor$, it suffices to show that $d = d_{BV}(\gamma) \leq 1 + \lfloor 1/(2\gamma) \rfloor$. Assume that $S = (x_i, r_i, s_i)_{1 \leq i \leq d}$ is γ-shattered by BV. Remember that $s_i \geq r_i + 2\gamma$. Choose the sequence $t_i \in \{r_i, s_i\}$ according to Lemma 4.2. Choose $b \in \{0,1\}^d$ such that the shattering function $f = f_b$ attains value t_i at point x_i. It follows from Lemma 4.2 and the definition of BV that the following holds:

$$(d-1)2\gamma \leq \sum_{i=1}^{d-1} |f(x_{i+1}) - f(x_i)| \leq 1.$$

Thus $d \leq 1 + 1/(2\gamma)$. Since d is an integer, the assertion of the corollary follows. □

The following two theorems are the main results of this section.

THEOREM 4.4. $O((1/\epsilon) \cdot ((1/\gamma)\ln(1/\epsilon) + \ln(1/\delta)))$ *examples are sufficient for learning BV with an (ϵ, γ)-good model.*

Proof. We first describe a learning function which transforms a labeled sample I of target function f into a hypothesis h. Let (after sorting of the sample points)

$$I = (x_1, \alpha_1), \ldots, (x_m, \alpha_m), \quad x_1 \leq x_2 \leq \cdots \leq x_m.$$

It will be technically convenient to define $x_0 = \inf X, x_{m+1} = \sup X$. For all $x \in X$, let $i(x) = j$ if and only if x_j is the sample point closest to x (breaking ties in favor of smaller indices). We come up with the hypothesis $h(x) = \alpha_{i(x)}$. Note that h is consistent with the sample. The critical question is how well h models f within the open intervals (x_j, x_{j+1}).

We now turn to the statistical analysis of this learning function. Let D denote the unknown domain distribution. The *variation* in interval $I_j = [x_j, x_{j+1}] \cap X$ is defined as

$$v_j = \sup_{a,b \in I_j} |f(b) - f(a)|.$$

Since $f \in BV$, the sum of all variations is bounded by 1. The open interval $I'_j = (x_j, x_{j+1})$ is said to be *wild* if $v_j \geq \gamma$. Otherwise, it is said to be *tame*. Within tame intervals, our hypothesis is certainly γ-close to f. Thus all that remains to do is to bound (with high confidence) the total probability of hitting a wild interval by ϵ. Since the variations sum up to at most one, there are at most $1/\gamma$ wild intervals. The "dangerous" region U of the real line is therefore always a union of at most $1/\gamma$ open intervals. The class $\mathcal{U}$ of all regions of this form has Vapnik–Chervonenkis dimension $2\lfloor 1/\gamma \rfloor$. Note that region U does not contain any point from random sample I. Applying a uniform convergence theorem from [3] (with improved constants from [1] or [10]), it follows that the following holds with a confidence of at least $1 - \delta$ for all sample sizes

$$m \geq \frac{4\lfloor 1/\gamma \rfloor \ln(6/\epsilon) + \ln(2/\delta)}{\epsilon(1 - \sqrt{\epsilon})}$$

and all $U \in \mathcal{U}$: if U does not contain any point from I, then $D(U) < \epsilon$. From this the theorem follows. □

THEOREM 4.5. *$O\left(\ln(1/(\epsilon\delta))/\epsilon\right)$ examples are sufficient for learning ND with an ϵ-bounded absolute or quadratic difference.*

Proof. Since $e_2(h) \leq e_1(h)$, it suffices to show the assertion w.r.t. ϵ-bounded absolute difference. The hypothesis h is constructed from the sample I in the same way as in the proof of Theorem 4.4. Also, the notations from this proof are reused. It follows easily that the expected absolute difference of h satisfies

$$e_1(h) \leq \sum_{j=0}^{m} v_j \cdot D(I'_j) \leq \max_{0 \leq j \leq m} D(I'_j)$$

because the variations sum up to at most 1. It suffices therefore to bound (with high confidence) the maximal probability of hitting an open interval I'_j by ϵ. Using the same uniform convergence theorem as in the proof of Theorem 4.4 (now applied to the system of open intervals, which has Vapnik–Chervonenkis dimension 2), we conclude that the following holds with a confidence of at least $1 - \delta$ for all sample sizes

$$m \geq \frac{4\ln(6/\epsilon) + \ln(2/\delta)}{\epsilon(1 - \sqrt{\epsilon})}$$

and all open intervals U: if U does not contain any point from I, then $D(U) < \epsilon$. From this the theorem follows. □

5. Higher-dimensional domains. In this section, we investigate the learnability of classes of functions with bounded variation which depend on several variables. We first discuss the two-dimensional case. Later, we briefly mention the generalization to more dimensions.

We call the sequence

$$(x_1, y_1), \ldots, (x_r, y_r) \in \Re \times \Re$$

an *ascending* (or *descending*) *chain* if $x_1 \leq \cdots \leq x_r$ and $y_1 \leq \cdots \leq y_r$ (or $y_1 \geq \cdots \geq y_r$, respectively). We say that a function f on a domain $X = X_1 \times X_2 \subseteq \Re^2$ has *bounded variation* if condition

$$\sum_{i=1}^{r-1} |f(x_{i+1}, y_{i+1}) - f(x_i, y_i)| \leq 1$$

is satisfied for all (ascending or descending) chains. We say that f has *semibounded variation* if this condition must hold only for ascending chains. The corresponding function classes are denoted by $BV(2)$ and $SBV(2)$, respectively. Note that both classes collapse to BV for functions which only depend on one of the two variables.

A *product distribution* on $\Re \times \Re$ is given by two independent distributions on $\Re$. Thus the x- and y-coordinates of a randomly drawn point $(x, y) \in \Re \times \Re$ are independent. We want to show that $SBV(2)$ (which contains $BV(2)$) is efficiently learnable under product distributions. The learning algorithm A will use a suitable partition of domain X into $r \times r$ orthogonal cells, given by $r-1$ horizontal and $r-1$ vertical lines, respectively. We associate with each cell C its indices $i(C), j(C) \in \{1, \ldots, r\}$ in the partitioning, where indexing goes from left to right and from bottom to top. We say that a sequence $C_1, \ldots, C_r$ of cells is an *ascending chain* if

$$i(C_1) < \cdots < i(C_r) \text{ and } j(C_1) < \cdots < j(C_r).$$

The basic idea in the design of A is to draw sufficiently many random examples such that with high confidence, each cell is hit at least once. If the first sample point which hits C has label $\alpha(C)$, then A's hypothesis is set to $\alpha(C)$ for all points in C. This definition is ambiguous at the boundary of the cells. We will, however, use partitionings which avoid this ambiguity. Thus if all cells are hit at least once, A comes up with a well-defined hypothesis h. An important notion is the *variation* of target function $f \in SBV$ within a cell, defined by

$$v(C) = \sup_{z', z'' \in C} |f(z'') - f(z')|.$$

Our analysis is based on the following lemma.

LEMMA 5.1. *If $C_1, \ldots, C_r$ is an ascending chain, then $\sum_{i=1}^{r} v(C_i) \leq 2$.*

Proof. Since the variation of f on ascending chains is bounded by 1, it suffices to show that there exists an ascending chain $z_1, \ldots, z_s$ which satisfies

$$\sum_{i=1}^{s-1} |f(z_{i+1}) - f(z_i)| \geq \frac{1}{2} \cdot \sum_{i=1}^{r} (v(C_i) - \Delta)$$

for arbitrarily small $\Delta > 0$. Because $C_1, \ldots, C_r$ is an ascending chain of cells, it suffices to find an ascending pair $z, \bar{z}$ within each cell $C \in \{C_1, \ldots, C_r\}$ which satisfies

$|f(z) - f(\bar{z})| \approx v(C)/2$. The sequence of these pairs then forms an appropriate ascending chain of length $2r$. Cell C contains two points z' and z'' which satisfy $|f(z'') - f(z')| \approx v(C)$. W.l.o.g., z' is left of z''. If z' is below z'', then z', z'' is an appropriate ascending pair. If z' is to the left of and above z'', then let z be the point which shares the x-coordinate with z' and the y-coordinate with z'' (see Figure 3). Then z, z' and z, z'' are both ascending pairs of points. At least one of these pairs witnesses a variation of approximately $v(C)/2$. This completes the proof of the lemma. □

FIG. 3. *A "descending pair" z', z'' and two "ascending pairs" z, z' and z, z''.*

COROLLARY 5.2. *The variations of all r^2 cells sum up to at most $4r - 2$.*

Proof. The r^2 cells partition into $2r - 1$ diagonal ascending chains. According to Lemma 5.1, each diagonal contributes at most 2 to the total sum of variations. □

Assume that there is a constant k such that the hitting probability $D(C)$ of each cell C satisfies

$$\frac{1}{kr^2} \leq D(C) \leq \frac{k}{r^2} \quad \text{(condition of } k\text{-uniformity)}.$$

For instance, if $X = [0,1] \times [0,1]$ and D is the uniform distribution on X, a regular partitioning into r^2 cells has this property with $k = 1$. The expected absolute difference of h can then be bounded as follows:

$$e_1(h) \leq \frac{k}{r^2} \cdot \sum_C v(C) < \frac{4k}{r}.$$

Thus $e_1(h) < \epsilon$ if $r \geq 4k/\epsilon$. Standard arguments show that $m = kr^2(2\ln(r) + \ln(1/\delta))$ random examples are sufficient to hit each cell at least once with a confidence of $1 - \delta$. This shows that $O(\ln(1/(\epsilon\delta))/\epsilon^2)$ examples are sufficient given the assumption of k-uniformity. We are now ready to prove the main result of this section.

THEOREM 5.3. *$O(\ln(1/(\epsilon\delta))/\epsilon^2)$ examples are sufficient to learn $SBV(2)$ with ϵ-bounded absolute (or quadratic) difference if the domain distribution is a product distribution.*

Proof. We may assume w.l.o.g. that two different sample points never share a coordinate.[8] It is then possible to cut X into r horizontal and r vertical slices such that each (open) slice contains m/r sample points. (W.l.o.g., assume that m is a multiple of r.) The system of slices has a Vapnik–Chervonenkis dimension of 2. We may therefore apply a uniform convergence theorem from [3] (Theorem A3.1) which (when applied separately to horizontal and vertical slices with confidence parameter $\delta/4$, respectively) states the following: there exists a constant c such that for all $m \geq$

[8] For product distributions given by continuous density functions, this is almost certainly the case. For general product distributions, one can use the trick of Kearns and Schapire in [6] which guarantees the technical assumption by formally changing the domain X into a new one, where different occurrences of the same coordinate are regarded as different. Geometrically, this means that, loosely speaking, horizontal or vertical lines get (artificially) a nonzero width. We omit the details of this construction.

$cr\ln(r/\delta)$, all slices S satisfy $1/(2r) \le D(S) \le 2/r$ with a confidence of $1-\delta/2$. Since D is a product distribution, each of the resulting r^2 cells C satisfies $1/(4r^2) \le D(C) \le 4/r^2$. In other words, we can achieve k-uniformity with $k=4$. Now $O(\ln(1/(\epsilon\delta))/\epsilon^2)$ additional examples are sufficient to guarantee with a confidence of $1-\delta/2$ that each cell is hit at least once. □

Using the simple fact (see [6]) that $e_1(h) < \epsilon\gamma$ implies that h is an (ϵ,γ)-good model, we obtain the following result.

COROLLARY 5.4. *$O(\ln(1/(\epsilon\gamma\delta))/\epsilon^2\gamma^2)$ examples are sufficient to learn $SBV(2)$ with an (ϵ,γ)-good model of probability if the domain distribution is a product distribution.*

There is no chance to generalize the results about $SBV(2)$ to arbitrary domain distributions because $d_{SBV(2)}(\gamma) = \infty$ for all $0 < \gamma \le 1/2$. Consider, for instance, the functions

$$f_b(x,y) = \begin{cases} b(x,y) & \text{if } x+y=0, \\ 1/2 & \text{otherwise,} \end{cases}$$

where b is an arbitrary function from $\Re^2$ to $\{0,1\}$. Each function f_b has semibounded variation. On the other hand, these functions γ-shatter the sequence

$$((x,-x),0,1)_{x\in\Re}$$

for all $\gamma \le 1/2$. According to the lower bounds derived in section 3, $SBV(2)$ is not learnable in the distribution-free model. We leave it as an open question whether $BV(2)$ is learnable under arbitrary domain distributions. All that we know is a lower bound on the number of examples required for learning. It is obtained from the general lower bounds in section 3 and the following result.

LEMMA 5.5.

$$\left\lfloor \frac{1}{2\gamma} \right\rfloor^2 \le d_{BV(2)}(\gamma) \le \left(1+\frac{1}{2\gamma}\right)^2.$$

Proof. The lower bound for $d_{BV(2)}(\gamma)$ follows from a close inspection of Figure 4 which shows a grid consisting of $r^2 \times r^2$ points ($r=4$ in the figure). r^2 of them are drawn black; the remaining ones are drawn white. Let the function class F consist of functions which attain value γ on white points and value 0 or 2γ on black points. Obviously, the r^2 black points are γ-shattered by F. We claim that all functions from F belong to $BV(2)$ if $r = \lfloor 1/(2\gamma) \rfloor$. This can be seen as follows. Each ascending or descending chain of grid points contains at most r black points. The induced variation is therefore bounded by $2\gamma r \le 1$.

We have still to verify the upper bound. Assume that there is a sequence S of length d which is γ-shattered by $BV(2)$. According to a classical result of Erdös (reported in [8]), S contains an ascending or a descending chain of length at least $\sqrt{d}$. At least one of the shattering functions must have a total variation of $2\gamma\cdot(\sqrt{d}-1)$ on this chain. (The proof for this is similar to the proof of Corollary 4.3.) Thus $2\gamma\cdot(\sqrt{d}-1) \le 1$, and the assertion of the lemma follows. □

We denote the obvious generalization of $BV(2)$ and $SBV(2)$ to n dimensions by $BV(n)$ and $SBV(n)$, respectively. Although the generalization of the above results to n dimensions is tedious, it uses basically the same ideas. We state without proof that the following holds.

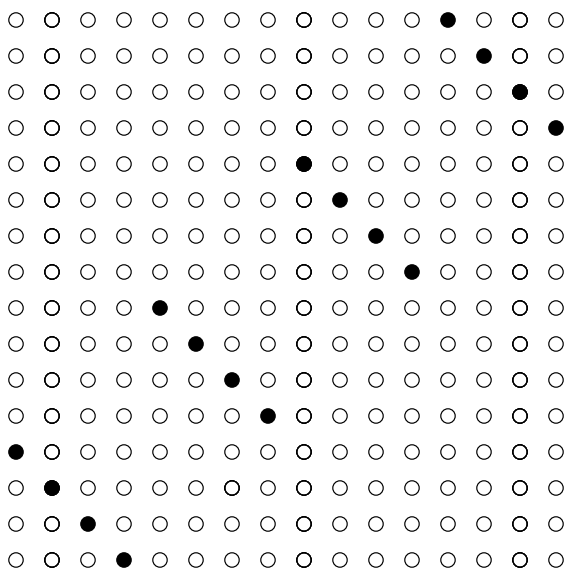

FIG. 4. *A* (16×16)*-grid with* 16 *black points.*

COROLLARY 5.6. $O\left((2en/\epsilon)^n \cdot (n\ln(n/\epsilon) + \ln(1/\delta))\right)$ *examples are sufficient to learn* $SBV(n)$ *with* ϵ*-bounded absolute difference if the domain distribution is a product distribution.*

As in the two-dimensional case, we obtain the corresponding bound for learning with an (ϵ, γ)-good model by substituting $\epsilon\gamma$ for ϵ in the bound of Corollary 5.6. Of course, $SBV(n)$ is not learnable in the distribution-free model for all $n \geq 2$. We do not know whether $BV(n)$ is learnable in this model. However, we know the following bounds:

$$\left\lfloor \frac{1}{2n\gamma} \right\rfloor^n \leq d_{BV(n)}(\gamma) \leq \left(1 + \frac{1}{2\gamma}\right)^{2^{n-1}}.$$

We made no serious attempt to close the large gap between the lower and the upper bound on $d_{BV(n)}(\gamma)$.

6. Conclusions and open problems. Some statisticians prefer learning models where expectation is also taken over all random samples. The confidence parameter δ then becomes superfluous. Each of the models considered in this paper has its "partner model" in this setting. We state without proof that all of our (lower and upper) bounds can be transferred to the partner models without changing the respective order of magnitude by more than a logarithmic factor.

It is an open problem whether there are general upper bounds which match our general lower bounds modulo a logarithmic factor. We do not know how the general lower and upper bounds change when we restrict the resources of time or space for the learning algorithms. It would be interesting to show a relation between nonlearnability of functions by polynomial-time learning algorithms and complexity theory (similar to the relation which is known for deterministic concept learning). It would also be interesting to know supplementary lower bounds (perhaps completely unrelated to the combinatorial or Natarajan dimension) which succeed in cases where our bound fails. We do not know whether $BV(n)$ is learnable in the distribution-free model and, if so,

whether our lower bound on the required number of examples in terms of $d_{BV(n)}(\gamma)$ is (almost) tight. We do not know whether the upper bound on the number of examples for learning $SBV(n)$ under product distributions is (almost) tight. It would be interesting to derive distribution-dependent lower bounds for function learning.

Acknowledgments. We thank Svetlana Anoulova and Martin Dietzfelbinger for valuable conversations.

A PUMPING CONDITION FOR REGULAR SETS*

STEFANO VARRICCHIO†

Abstract. We prove that a language of a finitely generated free monoid is regular if and only if it satisfies the positive block pumping property. This gives a positive answer to a problem posed by Ehrenfeucht, Parikh, and Rozenberg [*SIAM J. Comput.*, 10 (1981), pp. 536–541].

Key words. automata theory, regular languages, pumping conditions

AMS subject classifications. 68Q45, 20M35

PII. S0097539790179944

1. Introduction. Pumping properties have always had great importance in formal languages theory and have frequently been used in order to prove that some sets of words do not belong to a certain family of languages. Several pumping conditions have been found for various families of languages. In particular, we recall the well-known "pumping lemma" for regular languages (cf. [9, pp. 55–56]) that gives a necessary condition for a language to be regular.

This condition alone does not enforce the regularity of a language, so one may be induced to consider stronger pumping properties in order to obtain conditions equivalent to regularity, and in fact many papers have been devoted to this problem [1], [3], [7], [8].

The block pumping properties introduced in [3] are quite interesting. In that paper it is proved that the regularity of a language is equivalent to a block pumping property with a nonnegative pump. Moreover, it is questioned whether a positive block pumping property is a regularity condition.

In this paper we will give a positive answer to that question, proving that a language of a finitely generated free monoid is regular if and only if it satisfies a block pumping property with positive pump. de Luca and Varricchio [1], [2] have given a partial answer to the problem when the pumping condition is assumed to be uniform. In this case the pumping property may be expressed as an iteration property of the syntactic monoid, and, for a language L, the problem is led back to the finiteness of $M(L)$.

In the following, A will denote a finite set, or *alphabet*, and A^* will denote the *free monoid* over A. The elements of A are called *letters* and those of A^* are called *words*. The identity element of A^* is denoted by Λ. For any word w, $|w|$ denotes its *length*. Let $u, v \in A^*$. We then say that u is a *factor* (resp., *prefix*) of v if there exist $\lambda, \mu \in A^*$ such that $v = \lambda u \mu$ (resp., $v = u\mu$). We set $u < v$ when u is a prefix of v. A^k (resp., $A^{[k]}$) denotes the set of the words having length k (resp., length $\leq k$). A *(right) infinite word* is a map b: $\mathbb{N} \to A$. The set of infinite words is denoted by A^ω. Moreover we set $A^\infty = A^* \cup A^\omega$. For any $b \in A^\infty$, $F(b)$ will denote the set of all finite words which are factors of b. The subsets of A^* are called *languages*. If L is a language, $F(L)$ is the set of the factors of words of L. Let L be a language of A^* and $\sigma \in A^*$, we set $L_\sigma = \{x \in A^* \mid \sigma x \in L\}$. Let $u, v \in A^*$ and $L \subseteq A^*$. We set $u \equiv_L v$ (resp., $u \ N_L \ v$) if the following condition holds: $\forall\, x, y \in A^*\ xuy \in L \Leftrightarrow xvy \in L$

(resp., $\forall x \in A^*\ ux \in L \Leftrightarrow vx \in L$). N_L and $\equiv_L$ are called, respectively, the *right Nerode congruence* and *the syntactic congruence* of L. The *syntactic monoid* of L is the quotient monoid $M(L) = A^*/\equiv_L$. A monoid M is called *periodic* if for any $m \in M$, there exist two positive integers n, k, such that $m^n = m^{n+k}$.

The reader is referred to the books of Eilemberg [4] and Hopcroft and Ullman [9] for the basic notions concerning the theory of formal languages. Here we recall the fundamental theorem of Myhill–Nerode [10], [11] which says that a language L is regular if and only if the right congruence N_L has finite index.

2. Preliminaries. In this section we will recall some recent results of combinatorics on words that are fundamental tools in the study of finiteness condition for semigroups and in several combinatorial problems.

DEFINITION 2.1. *Let $b \in A^\omega$ be an infinite word. We say that b is* uniformly recurrent *if there exists a function c: $A^* \to \mathbb{N}$ such that if w, $v \in F(b)$ and $|v| \geq c(w)$, then w is a factor of v.*

We observe that, given a uniformly recurrent word b, it is possible to consider the function C: $\mathbb{N} \to \mathbb{N}$, defined by

$$C(n) = \max\{c(w) \mid w \in F(b) \cap A^n\}.$$

This function satisfies the following property. For any $n > 0$ and $v \in F(b)$ with $|v| > C(n)$, one has that

$$F(b) \cap A^{[n]} \subseteq F(v).$$

The importance of uniformly recurrent infinite words is due to the following.

THEOREM 2.1. *Let L be an infinite language of A^*. Then there exists an infinite word $b \in A^\omega$ such that*

(i) *b is uniformly recurrent,*

(ii) *$F(b) \subseteq F(L)$.*

The previous theorem is proved in [5] using techniques of symbolic dynamics; a combinatorial proof is given in [2]. Let us consider now some combinatorial properties of uniformly recurrent infinite words.

LEMMA 2.2. *Let $b \in A^\omega$ be a uniformly recurrent infinite word. For any $n > 0$ there exists a positive integer $K(n)$ such that for any $w \in A^*$, $a \in A$, with $wa \in F(b)$ and $|w| \geq K(n)$ one has that*

$$w = \lambda w_1 w_2 \cdots w_n,$$

with $\lambda \in A^*$, $w_i \in aA^*$ for $i \in \{1, \ldots, n\}$, and $w_i \in w_{i+1} \cdots w_n a A^*$ for $i \in \{1, \ldots, n-1\}$.

Proof. The proof is by induction on n. For $n = 1$ let $K(1) = C(1)$, where C is the function associated to the word b. Let $w \in A^*$, $|w| \geq K(1)$, and $wa \in F(b)$. Then w must contain the letter a, so $w = xay$ with x, $y \in A^*$. The statement follows if we set $w_1 = ay$.

Now let $n > 1$. By the induction hypothesis we may suppose that there exists an integer $K(n-1)$ that satisfies the statement for $n-1$. Then we set

$$K(n) = C(K(n-1) + 1) + K(n-1).$$

Let $w \in A^*$, $a \in A$ such that $|w| \geq K(n)$ and $wa \in F(b)$. We can write $w = xv$, with $|x| \geq C(K(n-1)+1)$ and $|v| = K(n-1)$. Since $va \in F(b)$, by the induction hypothesis one has

$$v = \lambda' w_2 \cdots w_n,$$

with $\lambda \in A^*$, $w_i \in aA^*$ for $i \in \{2, \ldots, n\}$ and $w_i \in w_{i+1} \cdots w_n a A^*$ for $i \in \{2, \ldots, n-1\}$. By the properties of the function C, one has that x contains va as a factor and hence also $w_2 \cdots w_n a$. Then one can write $x = \lambda w_2 \cdots w_n a \mu$, with λ, $\mu \in A^*$, so that

$$w = \lambda w_2 \cdots w_n a \mu \lambda' w_2 \cdots w_n.$$

Therefore, if we let $w_1 = w_2 \cdots w_n a \mu \lambda'$, one has $w_1 \in aA^*$, $w_1 \in w_2 \cdots w_n a A^*$, and the statement is true. □

3. Pumping conditions. In this section we recall the definitions of the pumping properties. Later on, after some technical lemmas, we will show that the positive block pumping property is a regularity condition. The proof is inspired by the techniques used in [3] to prove a similar result for the block cancellation property.

DEFINITION 3.1. *Let L be a language of A^*, $x \in A^*$, and $x = uvw$. We say that v is a* pump *for x relative to L if and only if for every $i \geq 0$*

$$u(v)^i w \in L \Leftrightarrow x \in L.$$

We say that v is a positive pump *if the latter condition is satisfied for every $i > 0$.*

DEFINITION 3.2. *Let L be a language of A^*. We say that L satisfies the property BP_m (resp., PP_m) if for any x, $w_1, w_2, \ldots, w_m$, $y \in A^*$, there exist $i, j, 1 \leq i < j \leq m+1$ such that $w_i \cdots w_{j-1}$ is a pump (resp., positive pump) for $x w_1 w_2 \cdots w_m y$ relative to L. We say that L satisfies the* block pumping property *(resp.,* positive block pumping property*) if there exists an integer $m > 0$ such that L satisfies BP_m (resp., PP_m).*

DEFINITION 3.3. *Let L be a language of A^*. We say that S satisfies BC_m if for any $x, w_1, w_2, \ldots, w_m, y \in A^*$, there exist $i, j, 1 \leq i < j \leq m+1$ such that*

$$x w_1 w_2 \cdots w_m y \in L \Leftrightarrow x w_1 w_2 \cdots w_{i-1} w_j \cdots w_m y \in L.$$

We say that L satisfies the block cancellation property *if there exists an integer $m > 0$ such that L satisfies BC_m.*

Remark. In the former definitions the integers i, j depend on the context (x, y) in which the block $w_1 w_2 \cdots w_m$ is considered. If they do not depend on the context, then the corresponding properties will be called, respectively, *uniform block pumping property* and *uniform block cancellation property.* For instance, S satisfies the uniform block cancellation property if there exists an integer $m > 0$ such that for any $w_1, w_2, \ldots, w_m \in A^*$ there exist i, j (depending only on $w_1, w_2, \ldots, w_m$), $1 \leq i < j \leq m+1$ such that for all x, $y \in A^*$

$$x w_1 w_2 \cdots w_m y \in L \Leftrightarrow x w_1 w_2 \cdots w_{i-1} w_j \cdots w_m y \in L.$$

We observe that BP_m implies BC_m and PP_m. Moreover, as shown in [3], BC_m implies BP_m. The contribution of this paper is to show that all are the same and equivalent to regularity. We recall that in [3] it has been proved that if a language L satisfies the block cancellation property, then L is regular. In [1] a similar result is proved for the uniform positive block pumping property. In what follows we will prove that any language satisfying the positive block pumping property is regular (Theorem 3.7). First we prove that the languages satisfying PP_m are closed under the map

$L \to L_\sigma$ (Lemma 3.4) and are finitely many in number (Lemma 3.6). The regularity of the languages satisfying PP_m will hence follow from a Nerode-type argument (Lemma 3.3).

Now we recall a version of the Ramsey theorem (cf. [6]). Let X be a set and r a positive integer; we denote by $P(X)$ the family of all the subsets of X, and we set $P_r(X) = \{Y \in P(X) \mid \mathrm{card}(Y) = r\}$.

THEOREM 3.1 (Ramsey). *Let r, k be positive integers with $1 \leq r \leq k$. Then there exists an integer $R(r,k)$ such that for any set X, with $\mathrm{card}(X) = R(r,k)$, and for any bipartition Y_1, Y_2 of $P_r(X)$ there exists $Y \in P_k(X)$ such that either $P_r(Y) \subseteq (Y_1)$ or $P_r(Y) \subseteq (Y_2)$.*

LEMMA 3.2. *Let m be a positive integer and $F = \{L \subseteq A^* \mid L \text{ satisfies } PP_m\}$. Then for any $k > 0$ there exists an integer M (depending on k) such that for any $(x_1, y_1, L_1), (x_2, y_2, L_2), \ldots, (x_k, y_k, L_k) \in A^* \times A^* \times F$ and for any $w_1, w_2, \ldots, w_M \in A^*$ there exist i, j, $1 \leq i < j \leq M+1$ such that $w_i \cdots w_{j-1}$ is a simultaneous positive pump for $x_s w_1 w_2 \cdots w_M y_s$ relative to L_s for $s \in \{1, 2, \ldots, k\}$.*

Proof. The proof is by induction on k. If $k = 1$, then the statement is true for $M = m$, since L_1 satisfies PP_m. Let $k > 1$. By the induction hypothesis there exists an integer M' that satisfies the statement for $k-1$.

Then let us set $M = R(2, M'+1)$, where R is the function of the Ramsey theorem. Let $w_1, w_2, \ldots, w_M \in A^*$ and $X = \{1, 2, \ldots, M\}$. Let us consider the following bipartition of $P_2(X)$:

$$Y_1 = \{\{i,j\} \mid w_i \cdots w_{j-1} \text{ is a positive pump for } x_k w_1 \cdots w_M y_k \text{ relative to } L_k\},$$

$$Y_2 = P_2(X) - Y_1.$$

For the Ramsey theorem there exists $Y \in P_{M'+1}(X)$ such that either $P_2(Y) \subseteq Y_1$ or $P_2(Y) \subseteq Y_2$. Let $Y = \{j_1, j_2, \ldots, j_{M'+1}\}$, $v_1 = w_{j_1} \cdots w_{j_2-1}, \ldots, v_{M'} = w_{j_{M'}} \cdots w_{j_{M'+1}-1}$. Since $M' \geq m$, there exist s, t with $1 \leq s < t \leq M'+1$ such that $v_s \cdots v_{t-1}$ is a positive pump for $x_k w_1 \cdots w_M y_k$ relative to L_k. Since $v_s \cdots v_{t-1} = w_{j_s} \cdots w_{j_t-1}$, one has that

$$\{j_s, j_t\} \in Y_1 \cap P_2(Y) \neq \emptyset;$$

hence $P_2(Y) \subseteq Y_1$. This means that for any i, j, with $1 \leq i < j \leq M'+1$, $v_i \cdots v_{j-1}$ is a positive pump for $x_k w_1 \cdots w_M y_k$ relative to L_k. By the induction hypothesis, we can choose i, j, with $1 \leq i < j \leq M'+1$ such that, for any $s \in \{1, \ldots, k-1\}$, $v_i \cdots v_{j-1}$ is a positive pump for $x_s w_1 \cdots w_M y_s$ relative to L_s. □

The following lemma has already been proved in [3]; however, we will report the proof for the sake of completeness.

LEMMA 3.3. *Let P be a property defined in $P(A^*)$. If the following two conditions are satisfied, then any language satisfying P is regular:*

(a) *L satisfies $P \Rightarrow L_\sigma$ satisfies P for any $\sigma \in A^*$,*

(b) *the languages of A^* satisfying P are finitely many.*

Proof. Let L be a language satisfying P and let N_L be the Nerode congruence of L. One has that for any x, $y \in A^*$

$$x N_L y \Leftrightarrow L_x = L_y.$$

Since the languages L_σ with $\sigma \in A^*$ are finitely many, then N_L has finite index and, by the Myhill–Nerode theorem, L is regular. □

LEMMA 3.4. *Let $L \subseteq A^*$ be a language satisfying PP_m; then for any $\sigma \in A^*$, L_σ satisfies PP_m.*

Proof. Since L satisfies PP_m, there exist i, j with $1 \leq i < j \leq m+1$ such that for any $s > 0$

$$\sigma x w_1 \cdots w_m y \in L \Leftrightarrow \sigma x w_1 \cdots w_{i-1} (w_i \cdots w_{j-1})^s w_j \cdots w_m y \in L.$$

Therefore, for any $s > 0$ one has

$$x w_1 \cdots w_m y \in L_\sigma \Leftrightarrow x w_1 \cdots w_{i-1} (w_i \cdots w_{j-1})^s w_j \cdots w_m y \in L_\sigma,$$

and L_σ satisfies PP_m. □

LEMMA 3.5. *Let $L \subseteq A^*$ be a language satisfying PP_m. Then the syntactic monoid $M(L)$ is periodic.*

Proof. Let $w \in L$. We prove that for any x, $y \in A^*$

$$x w^m y \in L \Leftrightarrow x w^{m+m!} y \in L.$$

The condition PP_m, applied to $w_1 = w_2 = \cdots = w_m = w$, shows that there exists an integer $k < m$ such that for any $s > 0$

$$x w^m y \in L \Leftrightarrow x w^{m+sk} y \in L.$$

Since k divides $m!$, there exists an integer $s > 0$ such that $sk = m!$ and the statement is true. □

Remark. Let L, $L' \subseteq A^*$ be two languages such that $M(L)$ and $M(L')$ are periodic. Then for any $w \in A^*$ there exist positive integers n, k, n', k' such that $w^n \equiv_L w^{n+k}$ and $w^{n'} \equiv_{L'} w^{n'+k'}$. We can obviously suppose that $n = n'$ and $k = k'$, otherwise n and n' could be replaced by $\max(n, n')$ and k, k' by $\operatorname{lcm}(k, k')$ and the former relations still would hold.

LEMMA 3.6. *The languages of A^* satisfying PP_m are finitely many.*

Proof. Suppose that there exists an integer $k > 0$ such that for any L_1, $L_2 \subseteq A^*$ satisfying PP_m one has

$$L_1 \cap A^{[k]} = L_2 \cap A^{[k]} \Rightarrow L_1 = L_2.$$

Then the statement is trivially true.

Let us suppose by contradiction that there exist infinitely many languages of A^* satisfying PP_m. Then such an integer k could not exist. Hence for any $k > 0$ there exists a word $w_k \in A^*$ and two languages $L_{1,k}$, $L_{2,k}$ satisfying PP_m such that

$$L_{1,k} \cap A^{[k]} = L_{2,k} \cap A^{[k]}$$

and

$$w_k \in L_{1,k}, \qquad w_k \notin L_{2,k}.$$

Moreover we may suppose that w_k has minimal length; that is, for any $l < |w_k|$ one has

$$L_{1,k} \cap A^{[l]} = L_{2,k} \cap A^{[l]};$$

moreover, $|w_k| > k$.

Let us consider now the language $L = \{w_1, w_2, \ldots, w_k, \ldots\}$. Since L is infinite, by Theorem 2.1 there exists a uniformly recurrent infinite word $b \in A^\omega$ such that $F(b) \subseteq F(L)$. Let C, K: $\mathbb{N} \to \mathbb{N}$ be the functions associated with the infinite word b as in Definition 2.1 and Lemma 2.2. Let M be a positive integer satisfying Lemma 3.2 for $k = 4$.

Let $N = (M+1) \cdot C(K(M))$. Let u be a factor of b such that $|u| = N$. Since $F(b) \subseteq L$, there exist $w \in L$, x, $y \in A^*$ such that $w = xuy$. Moreover, there exist two languages L_1, $L_2 \subseteq A^*$ satisfying PP_m such that for any $l < |w|$

$$L_1 \cap A^{[l]} = L_2 \cap A^{[l]}$$

and

$$w \in L_1, \qquad w \notin L_2.$$

Since $|u| = N$, we can write $u = u_1 u_2 \cdots u_{M+1}$, with $|u_i| \geq C(K(M))$ and all u_i are in $F(b)$. Therefore, there exists a word $v \in F(b)$ with $|v| = K(M)$ such that

$$u_i = \lambda_i v \mu_i,$$

$\lambda_i, \mu_i \in A^*, 1 \leq i \leq M+1$. Hence, since $w = xuy$, one can write

$$w = \lambda v_1 v_2 \cdots v_{M+1} \mu,$$

where $\lambda = x\lambda_1, \mu = \mu_{n+1} y, v_i \in vA^*, |v| = K(M)$, and $v_1 v_2 \cdots v_{M+1} \in F(b)$.

By Lemma 3.2 there exist i, j with $1 \leq i < j \leq M+1$ such that $z = v_i, \cdots v_{j-1}$ is a positive pump for $w = \lambda v_1 v_2 \cdots v_{M+1} \mu$ relative to L_1 and L_2. Therefore, letting $x' = \lambda v_1 v_2 \cdots v_{i-1}, y' = v_j \cdots v_{M+1} \mu$, one has $w = x'zy', y' \in vA^*$, $zv \in F(b)$, and for any $s > 0$

$$w = x'zy' \in L_t \Leftrightarrow x'z^s y' \in L_t \tag{3.1}$$

for $t = 1, 2$.

By Lemma 3.5, $M(L_1)$ and $M(L_2)$ are periodic. Then there exist n, $k > 0$ such that

$$z^n \equiv_{L_t} z^{n+k} \tag{3.2}$$

for $t = 1, 2$.

From (3.1) for $s = k$ we have

$$x'zy' \in L_t \Leftrightarrow x'z^k y' \in L_t \tag{3.3}$$

for $t = 1, 2$.

Now let z' be the maximal common prefix of z^n and y'. Since $v < z^n$ and $v < y'$ we have that $|z'| \geq |v| \geq K(M)$. Let $y'' \in A^*$ such that $y' = z'y''$.

We now prove the following claim.

Claim A. There exists $\lambda \in A^*$ such that

$$x'z'y'' \in L_t \Leftrightarrow x'z^n \lambda y'' \in L_t \tag{3.4}$$

and

$$x'z^k z'y'' \in L_t \Leftrightarrow x'z^k z^n \lambda y'' \in L_t \tag{3.5}$$

for $t = 1, 2$.

The proof is by induction on $q = |z^n| - |z'|$. If $q = 0$ then $z' = z^n$ and (3.4), (3.5) hold for $\lambda = \Lambda$. Let $q > 0$ and z' be a proper prefix of z^n. Let z'' be the suffix of z' such that $|z''| = K(M)$ and let $a \in A$ such that $z'a < z^n$. Since $|v| = K(M) = |z''|$ and $z \in vA^*$, as $z''a \in F(z^n)$, one can easily see that $z''a \in F(zv) \subseteq F(b)$. Then by Lemma 2.2 we can write

$$z'' = \zeta w_1 w_2 \cdots w_M,$$

with $\zeta \in A^*$, $w_i \in aA^*$ for $i \in \{1, \ldots, M\}$ and $w_i \in w_{i+1} \cdots w_M a A^*$ for $i \in \{1, \ldots, M-1\}$. Since z'' is a suffix of z', one has

$$z' = \zeta' w_1 w_2 \cdots w_M$$

for a suitable $\zeta' \in A^*$.

Now we may apply Lemma 3.2 to the four terms $(x'\zeta', y'', L_1)$, $(x'\zeta', y'', L_2)$, $(x'z^k\zeta', y'', L_1)$, and $(x'z^k\zeta', y'', L_2)$. Therefore, there exist i, j with $1 \le i < j \le M+1$ such that

(3.6)
$$x'z'y'' = x'\zeta' w_1 \cdots w_M y'' \in L_t \Leftrightarrow x'\zeta' w_1 \cdots w_{i-1}(w_i \cdots w_{j-1})^2 w_j \cdots w_M y'' \in L_t$$

and

(3.7)
$$x'z^k z'y'' = x'z^k\zeta' w_1 \cdots w_M y'' \in L_t \Leftrightarrow x'z^k\zeta' w_1 \cdots w_{i-1}(w_i \cdots w_{j-1})^2 w_j \cdots w_M y'' \in L_t$$

for $t = 1, 2$.

Now, considering that $w_i \in w_j \cdots w_M a A^*$ for $i < j$, then for a suitable $\xi \in A^*$ $w_i \cdots w_M = w_j \cdots w_M a \xi$, and substituting on the right side of (3.6) and (3.7) we have

$$x'z'y'' \in L_t \Leftrightarrow x'z'a\xi y'' \in L_t \tag{3.8}$$

and

$$x'z^k z'y'' \in L_t \Leftrightarrow x'z^k z'a\xi y'' \in L_t \tag{3.9}$$

for $t = 1, 2$.

Therefore, since $z'a < z^n$ and $|z^n| - |z'a| = q - 1$, by the induction hypothesis there exists $\xi' \in A^*$ such that

$$x'z'a\xi y'' \in L_t \Leftrightarrow x'z^n\xi'\xi y'' \in L_t \tag{3.10}$$

and

$$x'z^k z'a\xi y'' \in L_t \Leftrightarrow x'z^k z^n \xi'\xi y'' \in L_t \tag{3.11}$$

for $t = 1, 2$.

So if we set $\lambda = \xi'\xi$, comparing (3.8) with (3.10) and (3.9) with (3.11), we obtain (3.4) and (3.5), respectively, and Claim A is proved.

From (3.3), (3.5), and (3.2), considering that $z'y'' = y'$, one derives

$$x'zy' \in L_t \Leftrightarrow x'z^k y' = x'z^k z'y'' \in L_t \Leftrightarrow x'z^{k+n}\lambda y'' \in L_t \Leftrightarrow x'z^n \lambda y'' \in L_t$$

for $t = 1, 2$.

Therefore, from (3.4) it follows that

$$x'zy' \in L_t \Leftrightarrow x'y' \in L_t \tag{3.12}$$

for $t = 1, 2$.

We recall that $L_1 \cap A^{[l]} = L_2 \cap A^{[l]}$ for $l < |w|$ and therefore

$$x'y' \in L_1 \Leftrightarrow x'y' \in L_2.$$

Hence by (3.12),

$$x'zy' \in L_1 \Leftrightarrow x'zy' \in L_2.$$

From here, since $x'zy' = w$, we have

$$w \in L_1 \Leftrightarrow w \in L_2,$$

which is a contradiction, because $w \in L_1$ and $w \notin L_2$. □

THEOREM 3.7. *Let $L \subseteq A^*$. Then L is regular if and only if L satisfies the positive block pumping property.*

Proof. If L satisfies the positive block pumping property then there exists an integer m such that L satisfies PP_m. From Lemmas 3.6, 3.4, and 3.3 it follows that L is regular. Conversely, if L is regular, then it is easy to prove [3] that L satisfies PP_m for a suitable $m > 0$. □

LEADER ELECTION IN COMPLETE NETWORKS*

GURDIP SINGH†

Abstract. Leader election is a fundamental problem in distributed computing and has a number of applications. This paper studies the problem of leader election in complete asynchronous networks. We present a message-optimal protocol that requires $O(N \log N)$ messages and $O(N/\log N)$ time, where N is the number of nodes in the system. The time complexity of this protocol is a significant improvement over currently known protocols for this problem. We also give a family of protocols with message and time complexities $O(Nk)$ and $O(N/k)$, respectively, where $\log N \leq k \leq N$. Many problems such as spanning-tree construction and computing a global function are equivalent to leader election in terms of their message and time complexities, and therefore our result improves the time complexity of these problems as well.

Key words. distributed algorithms, leader election, time complexity, complete networks

1. Introduction.

In the leader-election problem, there are N nodes in the network, each having a unique identity. Initially all nodes are *passive*. An arbitrary subset of nodes, called the *candidates*, wake up spontaneously and start the protocol. On the termination of the protocol, exactly one node announces itself the leader. Leader election is a fundamental problem in distributed computing and has several applications. It is an important tool for breaking symmetry in a distributed system. By distinguishing a single node as a leader, it is possible to execute centralized protocols in a decentralized environment.

The problem of leader election has been studied in various computation models and topologies. For an asynchronous network with an arbitrary topology, a lower bound of $\Omega(E + N \log N)$ messages holds, where E is the number of edges in the network, and a protocol with this complexity was given in [5]. The time complexity of this protocol is $O(N \log N)$. In [3], an improved protocol with time complexity $O(N)$ was proposed. Several protocols for ring topologies have also been proposed [6, 4]. In this paper, we consider the problem of electing a leader in asynchronous complete networks. In a complete network, each pair of nodes is connected by a bidirectional link. Complete networks have been studied extensively since they provide bounds for other types of networks (with less connectivity). In the rest of the paper, by a network, we will mean a complete network.

In [2], a lower bound of $\Omega(N \log N)$ was proved on the message complexity of leader election for synchronous networks and showed that any protocol sending at most $O(N \log N)$ messages must require at least $\Omega(\log N)$ time. For asynchronous networks, it was shown in [7] that $\Omega(N \log N)$ messages are required for leader election and proposed a protocol which requires $O(N \log N)$ messages and $O(N \log N)$ time. In [1], the complexity was further improved by giving a series of protocols for asynchronous networks, each with $O(N \log N)$ message complexity and $O(N)$ time complexity.

In [2], it was conjectured that $\Omega(N)$ is a lower bound on the time complexity of any message-optimal election protocol for asynchronous networks. We disprove this conjecture by proposing a protocol which requires $O(N \log N)$ messages and $O(N/\log N)$ time. There are many problems such as spanning-tree construction, computing a global function, and counting which are equivalent to leader election in terms of message and time complexities [3]. Therefore, our protocol leads to improvements in the time complexity of these problems as well. To arrive at this protocol, we first develop two protocols, Γ and $\mathcal{A}$. Γ has message and time complexities $O(N^2)$ and $O(1)$, respectively. $\mathcal{A}$ is a variation of the protocol **A** of [1] and has message and time complexities $O(N \log N)$ and $O(N)$, respectively. We combine features of these protocols to obtain our final protocol with the desired complexity. We find that the problem of awakening N nodes using $O(N \log N)$ messages dominates the time complexity of our protocol. We also present a modified message optimal protocol which requires $O(\min(r, N/\log N) + \log N)$ time. In this protocol, the $\min(r, N/\log N)$ factor corresponds to the time required to awaken all nodes to participate in the protocol. In [8], it was also shown that any protocol sending $O(N \log N)$ messages requires at least $\Omega(N/\log N)$ time, which implies that our protocol is message and time optimal.

The interaction between time and message complexities for any problem is an important issue and it is desirable to have a spectrum of protocols which trade off message complexity for execution time. For asynchronous complete networks, we give a family of protocols, $D(k)$, where $\log N \leq k \leq N$. The message and time complexities of $D(k)$ are (Nk) and $O(N/k)$, respectively.

This paper in organized as follows. In the next section, we give a brief description of our model of distributed computation. In section 3, we describe the component protocols Γ and $\mathcal{A}$. Section 4 presents our protocol and its complexity analysis and correctness. In section 5, we extend this protocol to obtain a family of protocols. Section 6 deals with extensions of our protocol. Finally, we conclude in section 7.

2. Model. We model the communication network as a complete graph (N, E), where N and E represent the processors and communication links, respectively. We assume that each node has a unique identity. By a node i, we will mean a node with identity i. We assume that the network is asynchronous, i.e., message-transmission and processing times are unpredictable but finite. Messages sent over a link arrive at their destination in the order sent and are not lost.

The message complexity of a protocol is the maximum number of messages sent during any possible execution of the protocol. The time complexity of a protocol is the worst-case execution time assuming that each message takes at most one time unit to reach its destination and computation time is negligible. Furthermore, intermessage delay on a link is assumed to be at most one time unit. This assumption is made only for calculating the time complexity and the correctness of the protocol does not depend on this assumption.

In the leader-election problem, an arbitrary subset of nodes, called the *candidates*, wake up spontaneously to start the protocol. All other nodes are *passive*. A passive node wakes up on receiving a message of the protocol. Initially, a node knows only its own identity. At the termination of the protocol, exactly one node among the candidates is elected and all nodes know the identity of this node. All additions in the paper are assumed modulo N.

3. Component leader-election protocols. In this section, we develop two protocols, Γ and $\mathcal{A}$, for leader election. Protocol Γ has $O(N^2)$ message complexity

and $O(1)$ time complexity while $\mathcal{A}$ has $O(N \log N)$ message complexity and $O(N)$ time complexity. We will then combine these protocols to obtain the final protocol.

3.1. Protocol Γ. In this protocol, a *candidate* attempts to capture all other nodes. The node that is able to capture all other nodes declares itself the leader. On waking up, a candidate sends its identity in an *elect* message on all incident edges. When a node j receives an *elect*(i) message over edge e, it behaves as follows:

If j is a candidate and $j > i$, then no response is sent over e.

Otherwise, j sends an *accept* message over e.

A node that receives an *accept* message on all incident edges declares itself the leader and notifies all nodes of this fact. In this protocol, the candidate node with the largest identity is elected the leader. The time complexity of this protocol is $O(1)$. However, its message complexity is $O(N^2)$ since the number of candidate nodes may be $O(N)$, each of which sends $O(N)$ messages.

3.2. Protocol $\mathcal{A}$. Protocol $\mathcal{A}$ is a modification of the protocol **A** of [1]. We cannot use **A** directly to obtain the protocol with $O(N/\log N)$ time complexity since it suffers from link congestion, which is one of the sources of $O(N)$ time complexity. We will first describe the protocol **A** of [1], which has $O(N \log N)$ message complexity. Section 3.3 describes the modifications required to obtain $\mathcal{A}$.

The protocol described here is a slight variation of **A** (for simplicity, we use additional message types). The outline of the protocol is as follows:

A candidate node tries to capture other nodes in a sequential manner by sending *capture* messages on its incident edges one at a time. A node that is successful in capturing all other nodes is elected the leader. A candidate node i sends its identity and a variable, $level_i$, in the *capture* messages to contest with other nodes ($level_i$ is the number of nodes which i has captured so far). If a capture message from i reaches a node j which has not yet been captured and $(level_i, i)$ is greater than $(level_j, j)$ (lexicographically), then i captures j; otherwise, i is killed. If j is a captured node, then i has to kill j's owner before claiming j. If i is successful in capturing j, then it increments $level_i$ and proceeds with its conquest by sending a capture message to another node.

We will now describe the protocol in detail. Each node maintains the following variables:

- Each node has a variable $state_i$ which is either *passive*, *candidate*, *captured*, or *killed*. Initially, $state_i$ is *passive* for all nodes i.
- Every candidate node i maintains a list of edges, called $untraversed_i$, over which it has not yet sent a message to capture the node at the other end. Initially, $untraversed_i$ is the set of edges incident on i.
- The $owner_i$ of a node i is the identity of the node which captured it, and $owner\text{-}link_i$ is the edge leading to $owner_i$.
- Each node i has a variable $level_i$ which is initially 0. For a candidate node i which has not yet been captured, $level_i$ is the number of nodes it has captured so far. For any other node i, $level_i$ is the maximum level number received in any message by i.
- $maxid_i$ is the identity of the node from which the message containing the maximum level number was received. ($maxid_i$ is initially 0, and for an uncaptured candidate node, $maxid_i = i$.) Hence at any time, as far as i can tell, $(level_i, maxid_i)$ is the largest such pair in the system.

In the following, by setting (l, d) to (l', d'), we will mean the execution of the statements $l := l'$ and $d := d'$. Also, $(l, d) > (l', d')$ if $(l > l')$ or $(l = l'$ and $d > d')$.

On waking up spontaneously, a candidate node i sends a $capture(level_i, i)$ message on an edge in $untraversed_i$. When node j receives a $capture(l, i)$ message over edge e, it behaves as follows:

• *Case* 1: $state_j \neq$ captured.

⋆ If $(level_j, maxid_j) > (l, i)$, then j does not send any response over e. (If no response is sent to i, then i is blocked and will therefore never become the leader.) In this case, j knows that there is a node with a higher $(level, id)$ than (l, i).

⋆ Otherwise, j sets $(level_j, maxid_j)$ to (l, i). i becomes j's owner and e is marked as $owner\text{-}link_j$. Further, j sends an *accept* message over e and changes $state_j$ to captured.

• *Case* 2: $state_j =$ captured.

⋆ If $(level_j, maxid_j) > (l, i)$, then no response is sent to i.

⋆ Otherwise, j sets $(level_j, maxid_j)$ to (l, i). In this case, i must kill j's owner before claiming j. This is done to ensure that, at any time, the sets of nodes captured by candidate nodes are disjoint. For this purpose, j sends a $kill\text{-}owner(l, i)$ message over $owner\text{-}link_j$.

When $owner_j$ receives a $kill\text{-}owner(l, i)$ message over edge e', it behaves as follows:

If $(level_{owner_j}, maxid_{owner_j}) > (l, i)$, then $owner_j$ does not respond.

Otherwise, $owner_j$ sets $(level_{owner_j}, maxid_{owner_j})$ to (l, i) and sends an $owner\text{-}accept(i)$ message over e'. If $owner_j$ is not a captured node, then it changes *state* to *killed*. A *killed* node does not attempt to capture any more nodes. In this case, i cannot include $owner_j$ in its set of captured nodes. To capture $owner_j$, it must send a *capture* message directly to it.

If j receives an $owner\text{-}accept(i)$ message and $maxid_j$ is i (i.e., no other *capture* message with a higher $(level, id)$ has been received), then i becomes j's owner and the edge over which the *capture* message from i was received is marked as $owner\text{-}link_j$. Further, an *accept* message is sent over this edge.

If node i receives an *accept* message and is not *killed* or *captured* then it increases $level_i$ by 1 and proceeds by sending a *capture* message over the next edge in $untraversed_i$. A node that captures all other nodes declares itself the leader.

A candidate node stops capturing nodes if it is *killed* or *captured* or its *capture* message reaches a node with a higher $(level, id)$. We say that a candidate node becomes *dormant* when it stops capturing nodes. Notice that node i may not know that it has become *dormant* if this is due to its *capture* message reaching a node with a higher $(level, id)$.

The message and time complexities of protocol **A** are $O(N \log N)$ and $O(N)$, respectively [1]. The following lemma is given in [1]. (The proof of this lemma relies on the property that at any time, the sets of nodes captured by different candidates are disjoint.)

LEMMA 3.1. *For any given k, where $1 \leq k < N$, the number of nodes that own N/k nodes or more is at most k.*

3.3. Modifications to protocol A. One of the sources of $O(N)$ time complexity of **A** is possible congestion on the links. For example, consider the situation where j is a captured node, *capture* messages from nodes $i_1, i_2, i_3, \ldots, i_m$ arrive at node j in the order given, and in each case j sends a *kill-owner* message to $owner_j$. Further, assume that only the *kill-owner* message of i_m is successful in killing $owner_j$. *kill-owner* messages for all nodes i_l, $1 \leq l \leq m$, are sent over the same edge and each may take one time unit to arrive at $owner_j$. Since the intermessage delay on a particular

edge may be one time unit, the *kill-owner* message for i_m may arrive at $owner_j$ only after m time units. Since m could be $O(N)$, it may take $O(N)$ time for i_m to capture j. Thus capturing a node may take up to $O(N)$ time.

In the following, we modify **A** to obtain $\mathcal{A}$, in which if a node is able to capture another node, then it does so in a constant amount of time. The algorithm for a node j when $state_j$ = candidate is given in Figure 3.1, and the algorithm for a node j when $state_j \neq$ candidate is given in Figure 3.2. We have omitted the subscript j from variables in the figures for clarity.

```
state := candidate; level := 0;
untraversed := list of incident edges; maxid := j
while state = candidate
do
    if level = N − 1
        then send elected(j) to all incident edges; state := elected
        else select an edge e from untraversed;
             delete e from untraversed;
             send capture(level, j) over e;
             Received := false
    while state = candidate and ¬Received
    do
        receive M on edge e
            Case M of
            capture(l, i):   if (level, maxid) < (l, i) then
                                 (level, maxid) := (l, i); owner := i;
                                 owner-link := e; send accept over e;
                                 state := captured
            accept:          level := level + 1; Received := true
            kill-owner(l, i): if (level, maxid) < (l, i) then
                                 (level, maxid) := (l, i); state := killed;
                                 send owner-accept(i) over e;
                              else send killed(i) over e
            elected(i):      state := captured
    od
od
```

FIG. 3.1. *Protocol for a candidate node j.*

The only modification to **A** is in the response to the *capture* message by a captured node. (The rest of the protocol is the same.) Each node j maintains a variable $waiting_j$ which is true if j has sent a *kill-owner* message but has received no response from $owner_j$. Let a *captured* node j receive a $capture(l, i)$ message over edge e.

• If $(level_j, maxid_j) > (l, i)$, then no response is sent over e. Otherwise, j sets $(level_j, maxid_j)$ to (l, i). Further,

⋆ if $\neg waiting_j$, then the $kill\text{-}owner(l, i)$ message is sent over $owner\text{-}link_j$ and $waiting_j$ is set to true;

⋆ if $waiting_j$, then the response to node i is delayed.

• When $owner_j$ receives a $kill\text{-}owner(l, i)$ message over e', it behaves as follows: If $(level_{owner_j}, maxid_{owner_j}) > (l, i)$, then $owner_j$ sends a $killed(i)$ message over e' (indicating the fact that node i did not survive). Otherwise, it sets $(level_{owner_j}, maxid_{owner_j})$

```
finished := false; waiting := false
while ¬finished
do
    receive M over edge e
    if M is the first message received then
                        state := captured; maxid := 0; level := 0
    case M of
    capture(l, i):      if (level, maxid) < (l, i) then
                            if state = killed then
                                send accept over e; (level, maxid) := (l, i);
                                state := captured; owner-link := e
                            else
                                (level, maxid) := (l, i); potential-owner := e
                                if ¬waiting then
                                    send kill-owner(l, i) over owner-link;
                                    waiting := true;
    kill-owner(l, i):   if (level, maxid) < (l, i) then
                            (level, maxid) := (l, i);
                            send owner-accept(i) over e;
                        else send killed(i) over e
    owner-accept(i):        owner := maxid; owner-link := potential-owner;
                            send accept over owner-link
    killed(i):          if maxid ≠ i then
                            send kill-owner(level, maxid) over owner-link
                        else waiting := false;
    elected(i):         finished := true
od
```

FIG. 3.2. *Protocol for a noncandidate node j.*

to (l, i) and sends an *owner-accept*(i) message over e'. If $owner_j$ is not a captured node, then it changes *state* to *killed*.

• If j receives a *killed*(i) message from its owner and $maxid_j$ is not i, then j sends a *kill-owner*$(level_j, maxid_j)$ message over $owner\text{-}link_j$. If j receives an *owner-accept*(i) message, then $maxid_j$ becomes j's owner. The edge over which the capture message from $maxid_j$ was received is marked as $owner\text{-}link_j$ and an *accept* message is sent over this edge.

LEMMA 3.2. *If node i is successful in capturing node j, then it does so in a constant amount of time.*

Proof. Consider a node i which is successful in capturing node j. After the *capture*(l, i) message from i reaches j, then depending on the state of j, we have the following cases:

(1) If j is not a captured node, then j will send an *accept* message. This message will reach i within two time units (because there may already be a message in transit from j to i). Hence capturing j in this case will take at most three time units.

(2) Let j be a captured node. If j is not *waiting*, then a *kill-owner* message will be sent to $owner_j$ and $owner_j$ will respond with an *owner-accept* message. This message will be received by j within three time units of it sending the *kill-owner*

message (because there may be an *accept* message in transit from j to $owner_j$ when the *kill-owner* message is sent). Node j will then send an *accept* message to i. This capturing will take a total of at most five time units.

If j is *waiting*, then a response from j's owner will be received within three time units. If an *owner-accept* message is received by j, then it will send an *accept* message to i (since i captures node j). If a *killed* message is received, then a *kill-owner*(l, i) message will be sent to $owner_j$. A response to this will be received within two time units. Thus, if j is *waiting*, it will take at most seven time units to capture j.

Hence if node i successfully captures node j, then it does so in a constant amount of time (at most seven time units).

4. A composite protocol. We will now combine Γ and $\mathcal{A}$ to obtain a protocol $\mathcal{B}$. Protocol $\mathcal{B}$ has $O(N \log N)$ message complexity and requires $O(N/\log N)$ time after the node which is elected the leader wakes up. However, due to a specific wakeup pattern, the time complexity of $\mathcal{B}$ is still $O(N)$. We first present $\mathcal{B}$ and then discuss the modification to eliminate this second source of $O(N)$ time complexity.

Protocol Γ requires $O(N^2)$ messages because the number of candidates for election (which are the *candidates*) can be $O(N)$. However, if the number of candidates is reduced to $O(\log N)$ before this protocol is executed, then it will require $O(N \log N)$ messages. In protocol $\mathcal{A}$, there can be at most $\log N$ nodes at level $N/\log N$ (from Lemma 3.1). In protocol $\mathcal{B}$, we use protocol $\mathcal{A}$ to reduce the number of candidates for protocol Γ by requiring a node to execute $\mathcal{A}$ until its level number reaches $N/\log N$ and Γ thereafter. Protocol $\mathcal{B}$ is as follows:

On waking up spontaneously, a node starts executing protocol $\mathcal{A}$. When a node reaches level $N/\log N$, it sends an *elect* message with its identity on all incident edges. Let node j receive an *elect*(i) message over e. If $(level_j, maxid_j)$ is less than $(N/\log N, i)$, then j changes *state* to *killed* and sends an *accept* message over e. A node which receives an *accept* message on all incident edges declares itself the leader.

Since the message complexity of $\mathcal{A}$ is $O(N \log N)$ and at most $\log N$ nodes broadcast an *elect* message, the message complexity of $\mathcal{B}$ is $O(N \log N)$. Since it takes a constant amount of time to capture a node (from Lemma 3.2), it will take $O(N/\log N)$ time for a node to reach level $N/\log N$ after it wakes up (if it reaches this level). After a node reaches this level, it broadcasts an *elect* message. If it is elected the leader, it will receive all replies in a constant amount of time and will declare itself the leader. Therefore, the node which is elected the leader takes $O(N/\log N)$ time after waking up spontaneously to declare itself the leader. (Note that if we had used **A** instead of $\mathcal{A}$, then $\mathcal{B}$ would still require $O(N)$ time after the leader wakes up.)

However, a node may wake up spontaneously $O(N)$ time units after the first node wakes up and be elected the leader as shown in the following example. Assume that nodes have identities in the range $1, \ldots, N$ (as shown in Figure 4.1) and node 1 is the first node to wake up spontaneously. After waking up spontaneously, node i sends a *capture* message to node $i+1$. Assume that the message from i reaches $i+1$ just after $i+1$ wakes up and $i+1$ sends the message to capture $i+2$ before receiving the message from i. In this case, no response will be sent to i since it has the same level number as $i+1$ but a smaller identity. If this happens for all sites i, $1 \leq i \leq N$, then only node N will survive and capture all other nodes. If the capture message for each node takes exactly one time unit to arrive (as shown in Figure 4.1), node N will wake up at time $N-1$ and therefore the protocol will require $O(N)$ time units.

Protocol $\mathcal{B}$, however, satisfies the following two lemmas. In the following, when we say that a node wakes up, we will mean either spontaneously or on receiving a

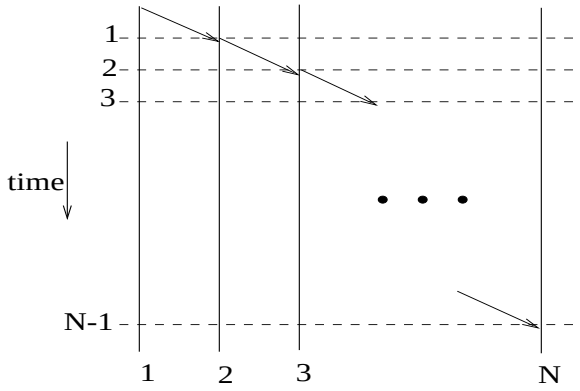

FIG. 4.1. *Example illustrating $O(N)$ time complexity.*

message of the protocol.

LEMMA 4.1. *If all nodes wake up within $O(N/\log N)$ time of each other, then $\mathcal{B}$ will terminate in $O(N/\log N)$ time.*

LEMMA 4.2. *After the level number of a node reaches $\log N$, $\mathcal{B}$ terminates within $O(N/\log N)$ time.*

Proof. There can be at most $N/\log N$ nodes at level $\log N$ (from Lemma 3.1). Let i be the first node to reach level $\log N$. Then in the next seven time units, i will either become *dormant* or increase its level number (because it takes at most seven time units to capture a node). Only a node at level $\log N$ can cause i to become dormant. If j causes i to become *dormant*, then by the same reasoning, in the next seven time units, j will either become *dormant* or increase its level number. Therefore, in every interval of seven time units after the first node reaches level $\log N$, the node with the highest $(level, id)$ at the beginning of the interval will either become *dormant* or increase its level number. Consider a sequence of $(2N/\log N) - \log N - 1$ slots in an execution after the first node reaches level $\log N$, where each slot is seven time units. At most $N/\log N - 1$ slots can be associated with nodes at level at least $\log N$ becoming *dormant*. Each of the remaining $N/\log N - \log N$ slots must correspond to a level increase. Therefore, $7((2N/\log N) - \log N - 1)$ time units after the first node reaches level $\log N$, the level number of a node will reach at least $N/\log N$. After a node reaches level $N/\log N$, Γ is executed, which takes $O(1)$ time. Hence $\mathcal{B}$ will terminate in $O(N/\log N)$ time units.

Given Lemma 4.2, we are led to the following protocol:

On waking up spontaneously, node i executes an initial phase in which it sends $\log N$ *capture*$(0, i)$ messages simultaneously on different edges. (The rules for capturing are as in $\mathcal{A}$.) If it receives an *accept* response to all *capture* messages and it has not been *killed* or *captured*, then it increases its level from 0 to $\log N$ (thus $level_i$ never has a value in between 0 and $\log N$) and proceeds with protocol $\mathcal{B}$.

Since each node can send $\log N$ *capture* messages on waking up spontaneously, the message complexity of this protocol is $O(N \log N)$. However, for this protocol, we can also construct an example similar to the one in Figure 4.1 in which a node reaches level $\log N$ after $N - \log N$ time units of the first node waking up. In this protocol, when node i tries to capture $\log N$ nodes in parallel, it is allowed to capture nodes that may have awakened at any time in the past. In the following, we develop a protocol $\mathcal{C}$ in which the nodes that i can capture when it is executing its initial phase

are restricted to those which wake up within a constant time of i waking up.

If $\log N$ nodes wake up every c time units, where c is a constant, then all nodes will wake up in $cN/\log N$ time units. Then from Lemma 4.1, the protocol will terminate in $O(N/\log N)$ time. Thus if we can ensure that

in every interval of c time units, either at least $\log N$ nodes wake up or some node reaches level at least $\log N$ by the end of this interval,

then from Lemmas 4.1 and 4.2, the protocol will require $O(N/\log N)$ time. For this purpose, we require a candidate node to execute two initial phases on waking up spontaneously. If it successfully executes these phases, then it qualifies as a candidate for election and proceeds by executing $\mathcal{B}$. In the first phase, a node requests permission to enter the second phase from $\log N$ different nodes. A node which has finished executing its first phase denies the request while others grant it. As we will show later, nodes which grant i permission to enter the second phase are those which wake up within c time units of i waking up. In the second phase, node i tries to capture the $\log N$ nodes from which it obtained permission in the first phase. The second phase ensures that if fewer than $\log N + 1$ nodes wake up in an interval of c time units (as a result, any new node that wakes up in this interval will not get permission to enter the second phase), then some candidate node reaches level $\log N$ by the end of this interval. For the initial two phases, the algorithm for a node j with $state_j =$ candidate is given in Figure 4.2, and the algorithm for a node j with $state_j \neq candidate$ is given in Figure 4.3. In Figure 4.3, for a response to the *capture* message, only those actions which correspond to the initial two phases are given. (In addition to these actions, any action required by protocol $\mathcal{B}$ must also be performed.)

First phase.

• On waking up spontaneously, node i enters the first phase. It selects $\log N$ incident edges and sends a $first\text{-}phase(i)$ message on each of these edges.

• When node j receives a $first\text{-}phase(i)$ message over e, it behaves as follows:

(1) If j is not captured, then

⋆ if j has finished executing the first phase, then j sends a $finish$ message over e;

⋆ if j is *passive*, then i becomes j's owner and j marks e as *owner-link*$_j$; it sends an *accept* message over e and changes its state to *captured*;

⋆ if j is in the first phase, then j sends a *proceed* message over e.

(2) If j is *captured*, then it has to check whether its owner has finished the first phase. For this purpose, it sends a *check* message over *owner-link*$_j$. If j has already sent a *check* message to which no response has been received, then the response to i is delayed.

If *owner*$_j$ has finished its first phase when the *check* message reaches it, then it responds with a $finish$ message. Otherwise, it responds with an *in-first-phase* message.

If j receives a $finish$ message over *owner-link*$_j$, then it sends a $finish$ message over e and also on any other edge over which it may have received a *first-phase* message in the meantime (or will receive one in the future). If j receives an *in-first-phase* message from its owner, then it sends a *proceed* message over e and also on any other edge over which it may have received a *first-phase* message in the meantime.

(3) If j has already received a *capture* message or receives a *capture* message after receiving the *first-phase* message from i (a *capture* message can be sent by a node which is in the second phase or has finished the second phase) and no response has been sent to i, then it sends a $finish$ message to i over e.

```
state := candidate; phase := 1;
select a set S of log N edges from untraversed;
delete S from untraversed;
send first-phase(j) over edges in S; Response := 0
while state = candidate and Response < log N
do
    receive M on edge e
    Case M of
    first-phase(i):     send proceed over e
    proceed:            Response := Response + 1
    accept:             Response := Response + 1; S = S − {e}
    finish:             state := killed
    check:              send in-first-phase over e
    capture(l, i):      state := captured; owner := i; owner_link := e;
                        maxid := i; phase := 2
                        send accept over e
od
if Response = log N then phase := 2;
if state = candidate then
    send capture(0, j) over edges in S; Response = 0
    while state = candidate and Response < |S|
    do
      receive M on edge e
      Case M of:
      capture(l, i):      if (l, i) > (0, j) then
                              state := captured; maxid := i; owner-link := e;
                              send accept over e
      kill-owner(l, i):   if (l, i) > (0, j) then
                              state := killed; send owner-accept over e
                          else send killed(i) over e
      accept:             Response := Response + 1
      first-phase(i):     send finish over e
      check:              send finish over e
    od
if state = candidate then level := log N
```

FIG. 4.2. *Initial phases for a candidate node j.*

• After node i has received responses to all $\log N$ *first-phase* messages, it behaves as follows: It exits the first phase. If it has received a *finish* message, then it does not enter the second phase and it changes *state* to *killed*. Otherwise, it proceeds to the second phase.

Second phase.

• In the second phase, node i tries to reach level $\log N$ by capturing $\log N$ nodes. For this purpose, it sends a *capture*$(0, i)$ message on each edge on which it received a *proceed* message in the first phase. (It has already captured nodes from which it received an *accept* message.) The rules for capturing are the same as in protocol $\mathcal{B}$

```

FIG. 4.3. *Initial phases for a noncandidate node j.*

with the following changes:

A node which has not started the second phase is regarded as *passive*. Therefore, if a $capture(0, i)$ message reaches j and j is in the first phase or has finished the first phase but was not successful in entering the second phase, then i becomes j's owner. In case j is a captured node, then j sends a *kill-owner* message as in $\mathcal{B}$. If $owner_j$ has not started its second phase, then it is *killed*. Further, a node increases its level number from 0 to $\log N$ only after receiving an *accept* response to all *capture* messages.

Since the level number sent in the *capture* messages is 0, capturing in the second phase is only on the basis of node identities. If node i receives all *accept* responses and it is not *killed* or *captured*, then it sets $level_i$ to $\log N$ and proceeds with protocol $\mathcal{B}$. It deletes the $\log N$ edges from $untraversed_i$ over which it had sent the *first-phase* messages.

Hence in protocol $\mathcal{C}$, a node executes the first and second phases before executing $\mathcal{B}$. In order to show that $\mathcal{C}$ terminates with an elected leader, we have to show that some node will finish its second phase and participate in $\mathcal{B}$. Since nodes in $\mathcal{B}$ cannot be killed by nodes in the initial two phases (nodes in $\mathcal{B}$ have a higher level number)

and $\mathcal{B}$ does elect a leader, $\mathcal{C}$ also terminates with an elected leader. This is shown in the following two lemmas.

LEMMA 4.3. *In any execution of $\mathcal{C}$, there will be a node which enters the second phase.*

Proof. Assume that no node enters its second phase in an execution. Then every candidate node must have received a $finish$ message in response to at least one of its $first\text{-}phase$ messages. Let $i_1, i_2, \ldots$ be a sequence of candidate nodes such that i_l receives a $finish$ message from i_{l+1} or from one of the nodes captured by i_{l+1}. Node i_{l+1} (or a node captured by i_{l+1}) can send a $finish$ message only after i_{l+1} has finished its first phase. (The $finish$ message cannot be sent by i_{l+1} due to the fact that it received a *capture* message from some other node because a *capture* message can only be received from a node in the second phase or which has finished the second phase, which contradicts the assumption.) Therefore, the first phase of i_{l+1} terminates before the first phase of i_l. This is true for all l's, and therefore $i_k \neq i_m$, where $k < m$. This is a contradiction since the number of nodes is finite. Hence there will be a node in the sequence which does not receive a $finish$ message and which will therefore enter the second phase.

LEMMA 4.4. *In any execution of $\mathcal{C}$, there will be a node which finishes the second phase.*

Proof. By Lemma 4.3, there is a node which enters the second phase. Only a node in its second phase (or which has finished the second phase) can cause another node in its second phase to become *dormant*. Further, any two nodes in the second phase cannot both cause each other to become *dormant* (because only a node with a higher identity can cause a node to become dormant). Therefore, there will be a node which will finish its second phase and participate in $\mathcal{B}$.

LEMMA 4.5. *The time complexity of $\mathcal{C}$ is $O(N/\log N)$.*

Proof. A candidate node finishes its first phase within five time units of waking up. (The proof is similar to the proof of Lemma 3.2.) If node i wakes up spontaneously at time t, then for i to participate in the second phase, each of its $first\text{-}phase$ messages must go to a node which is in its first phase (this node must have awakened spontaneously after time $t-5$; otherwise it would have finished its first phase by time t) or is captured (in this case, its owner must have awakened after time $t-5$; otherwise it would have finished its first phase by time t) or is *passive* (this node will wake up by time $t+1$ as a result of i's message). Therefore, i is able to proceed to the second phase only if at least $\log N$ nodes other than i wake up in the interval $[t-5, t+1]$.

Consider an interval of five time units, say $[m, m+5]$, where $m \geq 0$, during the execution of the protocol. We have the following cases:

(1) At least $\log N + 1$ nodes wake up in the interval $[m-5, m+6]$.

(2) Fewer than $\log N + 1$ nodes wake up in the interval $[m-5, m+6]$. In this case, we will show that some node will reach level at least $\log N$ (i.e., some node will successfully finish the second phase). We will first show that there must exist a node which has entered the second phase by time $m+5$. On the contrary, assume that no such node exists. All nodes that wake up before time m finish the first phase by time $m+5$ (since it takes five time units to execute the first phase), and by assumption, none of these nodes enter the second phase. Furthermore, any node which wakes up in the interval $[m, m+5]$ will be denied permission to enter the second phase (since fewer than $\log N$ nodes wake up in the internal $[m-5, m+6]$). If in this execution no node wakes up spontaneously after time $m+5$, then there will not exist a node which enters the second phase, which is a contradiction (Lemma 4.4). Hence there

must exist a node which enters the second phase by time $m + 5$.

Among the nodes which enter the second phase, if no node has finished the second phase by time $m + 5$, then there must exist at least one node in the second phase at time $m + 5$. Let i be the node with the highest identity among the nodes which are in the second phase at time $m + 5$. Let a *capture* message from i reach a node j. If j is not a captured node, we have the following cases:

(a) If j has not started the second phase, then it will respond with an *accept* message.

(b) If j has started the second phase, then it must be the case that j entered the second phase at or before time $m + 5$. Assume not. Since nodes that wake up before time m enter the second phase before time $m + 5$ and nodes that wake up in the interval $[m, m + 5]$ do not participate in the second phase, j must have awakened after time $m + 5$. Because i sent a capture message to j in the second phase, it must have also sent a *first-phase* message to j. In this case, the *first-phase* message from i must have reached j before time $m + 5$. Since j is passive before time $m + 5$, j will be captured by i's message, and hence j cannot enter the second phase. Thus j must have entered the second phase at or before time $m + 5$. In this case, $j < i$ (by assumption), and therefore j will respond with an *accept* message.

If j is a captured node, then it will forward the message to its owner. If the $owner_j$ has not started the second phase, then it will send an *accept* message. Otherwise, $owner_j$ must have entered the second phase at or before time $m + 5$. Assume not. Since nodes that wake up before time m enter the second phase before time $m + 5$ and nodes that wake in the interval $[m, m + 5]$ do not participate in the second phase, $owner_j$ must have awakened after time $m + 5$. Because i sent a capture message to j in the second phase, it must have also sent a *first-phase* message to j. In this case, the *first-phase* message from i must have reached j before time $m + 5$. In this case, it is not possible for $owner_j$ to capture j. ($owner_j$ could not have captured j in its first phase because only a passive node can be captured in the first phase; if $owner_j$ captured j in its second phase, then it would have received a *proceed* message for $\log N$ nodes which awakened in the interval $[m - 5, m + 6]$, which is a contradiction.) Thus $owner_j$ must have entered the second phase at or before time $m + 5$. In this case, $owner_j$ will be killed and an *accept* message will be sent to i since $owner_j < i$ by assumption. Thus i will receive all *accept* responses, and therefore i will finish its second phase.

Hence in each interval of 11 time units ($[m-5,\ m + 6]$), either at least $\log N$ nodes wake up or some node will reach level $\log N$. Therefore, by time $11N/\log N$, either all nodes will be awake or some node will have reached level $\log N$. Then from Lemma 4.1 and Lemma 4.2, the protocol will terminate in $O(N/\log N)$ time units.

5. A family of protocols. In this section, we generalize protocol $\mathcal{C}$ to obtain a family of protocols, $D(k)$, where $\log N \leq k \leq N$. Informally, $D(k)$ is the same as $\mathcal{C}$ except that k is used instead of $\log N$. $D(\log N)$ is the same as $\mathcal{C}$. The changes required in $\mathcal{C}$ to obtain $D(k)$ are as follows:

In the first phase, node i sends k *first-phase* messages (instead of $\log N$). If it does not receive a *finish* message in response to any of the *first-phase* messages, then i enters the second phase. In the second phase, node i sends a *capture* message on all edges on which it received a *proceed* response in the first phase. If it receives an *accept* response to all *capture* messages, then it increases its level to k and proceeds with protocol $\mathcal{A}$. When the level number of i reaches N/k, it executes protocol Γ, i.e., it sends its identity in an *elect* message over all edges. If all responses are *accept*,

then it declares itself the leader.

The time complexity of $D(k)$ is $O(N/k)$. The execution of the first and second phases requires $O(Nk)$ messages. Since there can be at most k nodes at level N/k, the execution of protocol Γ after the level number of a node reaches N/k requires $O(Nk)$ messages. Hence the message complexity of the protocol is $O(Nk)$.

6. Extensions to the protocol. The execution time of $\mathcal{C}$ depends on its ability to wake up all nodes within $O(N/\log N)$ time units of each other. Let r be the number of candidate nodes. In the following, we present a modification of the protocol to achieve a time complexity of $O(\min(r, N/\log N) + \log N)$. In protocol $\mathcal{A}$, nodes are captured in a sequential manner. In [2], a protocol for synchronous networks was presented in which a node is allowed to capture many nodes in parallel. In particular, a node i in phase l tries to capture 2^l nodes in parallel by sending $capture(l, i)$ message over 2^l untraversed edges. Node i increases its level number from l to $l + 1$ only on receiving an *accept* response to all 2^l capture messages. The time complexity of this protocol of [2] is $\log N$ since a node has to go through $\log N$ phases. By employing this style of capturing, we can extend our protocol to obtain a protocol with $O(\min(r, N/\log N)+\log N)$ time. In this protocol, the $\min(r, N/\log N)$ factor is the time required to awaken all nodes (and is the complexity of the first two phases). Since at most r nodes wake up, the chain of messages shown in Figure 4.1 can be at most r units (and hence the node which is elected leader must wake up within r time units of the first node waking up). Thus if $r < N/\log N$, then it will take r time units in the first two phases; if $r \geq N/\log N$, then the first two phases ensure that some node will reach level $\log N$ within $O(N/\log N)$ time units. After the second phase, a node which is elected leader has to go through $\log N$ phases, where each phase requires a constant amount of time.

7. Conclusion. In this paper, we have presented a distributed algorithm for leader election in an asynchronous complete network. The protocol has $O(N \log N)$ message complexity and $O(N/\log N)$ time complexity. This is an improvement over existing protocols for the this problem. We further extended the result to obtain a family of protocols, $D(k)$, where $\log N \leq k \leq N$. The message and time complexities of $D(k)$ are $O(Nk)$ and $O(N/k)$, respectively.

THE COST OF DERANDOMIZATION: COMPUTABILITY OR COMPETITIVENESS*

XIAOTIE DENG† AND SANJEEV MAHAJAN‡

Abstract. Recently, much work has been done in game theory towards understanding the bounded rationality of players in infinite games. This requires the strategies of realistic players to be restricted to have bounded resources of reasoning. (See [H. Simon, *Decision and Organization*, North–Holland, Amsterdam, 1972, pp. 161–176] for an extensive discussion; also see [X. Deng and C. H. Papadimitriou, *Math. Oper. Res.*, 19 (1994), pp. 257–266], [C. Futia, *J. Math. Econom.*, 4 (1977), pp. 289–299], [V. Knoblauch, *Games Econom. Behav.*, 7 (1994), pp. 381–389], [E. Kalai and W. Stanford, *Econometria*, 56 (1988), pp. 397–410], [A. Neyman, *Econom. Lett.*, 19 (1985), pp. 227–229], and [C. H. Papadimitriou, *Game Theory Econom. Behav.*, 4 (1992), pp. 122–131].) In this paper, we discuss infinite two-person games, focusing on the case where our player follows a computable strategy and the adversary may use any strategy, which formulates the notion of computer against extremely formidable nature. In this context, we say that an infinite game is semicomputably determinate if either the adversary has a winning strategy or our player has a computable winning strategy.

We show that, whereas all open games are semicomputably determinate, there is a semicomputably indeterminate closed game. Since we want to prove an indeterminacy result for closed games and since the adversary's strategy set is uncountable and our player's strategy set is countable, our proof for the indeterminacy result requires a new diagonalization technique, which might be useful in other similar cases. Our study of semicomputable games was inspired by online computing problems. In this direction, we discuss several possible applications to derandomization in online computing, with the restriction that the strategies of our player should be computable.

We also study the power of randomization for the classical case where our player is allowed to play according to unrestricted strategies. An indeterminate game is obtained for which both players have a simple randomized winning strategy against all of the deterministic strategies of the opponent.

1. Introduction.

In an online problem, requests come one at a time and need to be served as soon as they come. A cost function is associated with serving each request, which depends on the history of requests and the serving strategy. The object is to minimize the total cost incurred while serving the request sequence. If the request sequence is known in advance, it can be served optimally. However, since the future requests are not known in advance, we cannot in general design a strategy which will optimally serve the requests. To measure the performance of a strategy σ, the concept of the competitive ratio was introduced [ST, KMRS, MMS], i.e., the worst-case ratio (over all finite request sequences) of the cost of serving a request sequence by σ (one may allow an extra addition constant) to the minimum cost of serving the

same request sequence. A strategy of serving requests is called *α-competitive* if its competitive ratio is no more than α.

A request–answer game formulation is introduced to explore the power of randomization in online problems for finite games in [BBKTW] and for infinite games in [RiS]. The idea is that, since we defined the competitive ratio as a worst-case ratio, we can think of the requests as coming from an adversary. The adversary and our player alternate between giving requests and serving them. Since the adversary is assumed to be omnipotent and omniscient, we also assume that the adversary serves her own requests with the minimum cost. An infinite game can be described as an infinite tree on which two players make their moves in turn, starting at the root.

In this formulation, we have two distinguished players: Player I, *the adversary*; and Player II, *our player*. The adversary makes choices at even levels, starting at level 0, the root, and our player makes choices at odd levels. The set of all the infinite paths is partitioned into two subsets: the winning set for our player and the winning set of the adversary. A strategy for the adversary (our player) corresponds to a pruned tree from the original game tree on which each branching at even (odd) levels is pruned to allow at most one possible child. The resulting play for a given pair of strategies corresponds to a path in the game tree. A strategy for our player is a winning strategy if all of the paths in the corresponding pruned tree belong to the winning set of our player. The winning strategies for the adversary are defined similarly. A game is called *determinate* if one of the players has a winning strategy.

Denote by OC the cost of our player and by AC the adversary's cost. Then by the above discussion, a strategy of our game is *α-competitive* if there is a constant c such that the request–answer sequence generated by playing with any adversary has the property that $OC \leq \alpha \cdot AC + c$. Under this formulation, the winning paths of our player form a closed set under the Hausdorff topology, and hence the corresponding game is called a *closed* game. (A formal definition is introduced in the next section). We call this *type* I *competitiveness*. In [RaS], a more relaxed definition is introduced by requiring

$$\cup_i \cup_j \cap_{k \geq j} \{(x_0, x_1, \ldots) : OC(x_0, \ldots, x_k) - \alpha \cdot AC(x_0, \ldots, x_k) \leq i\},$$

which leads to a countable union of closed sets, called by an F_σ game. This case considers how our cost increases as the adversary cost grows unboundedly in each branch of the game tree. We call it *type* II *competitiveness*.

Since both closed games and F_σ games are determinate [GS], it follows that, when playing against an offline adaptive adversary, randomization does not yield more competitive algorithms [BBKTW, RaS]. In essence, it is shown in [RaS] that for any determinate game, *a randomized winning strategy guarantees a deterministic winning strategy.* In this sense, we can say that the *derandomization hypothesis* holds for online problems. Raghavan and Snir point out that although the randomized strategy may be computable, the deterministic strategy guaranteed by this theorem may not be computable [RaS].

To address this question, we formulate the *computable derandomization hypothesis: a computable randomized winning strategy guarantees a computable deterministic winning strategy.* Following the approach in [BBKTW, RaS], we want to know if closed games or F_σ games are all semicomputably determinate. If this is true for closed (F_σ) games, then type I (type II) competitive randomized algorithms would guarantee computable type I (type II) competitive deterministic algorithms. On the contrary, we show that, whereas all open games are semicomputably determinate,

there is a semicomputably indeterminate closed game. This opens the door for the possibility that there exists an online problem for which there is a computable randomized competitive strategy but there is no computable deterministic competitive strategy. Indeed, we are able to construct an F_σ game for which there is a simple randomized strategy which wins almost surely but there is no computable deterministic winning strategy. Thus the computable derandomization hypothesis does not hold, even for F_σ games. This confirms the belief in [RaS]. With a certain cost function assigned for the game, this shows that there is a simple randomized strategy which is type II competitive almost surely, but there is no computable type II competitive deterministic strategy. We can also extend the result, in a slightly weaker form, to closed games for the notion of type I competitiveness. Therefore, the computable derandomization hypothesis does not hold for online problems, neither under the notion of type I competitiveness nor under the notion of type II competitiveness.

In our discussion, on one hand, we take an extremely pessimistic view of nature: it is formulated as an offline adaptive adversary [BBKTW] with complete power. On the other hand, we restrict our player to computable strategies. Such situations occur when strategies are designed to make dynamic decisions with an unpredictable future. One case is in the task of designing online algorithms to serve an unknown sequence of future requests, such as paging [ST], server problems [MMS, KP], and metrical task systems [BLS]. Robot navigation in an unknown world [PY, BRS] and robot learning [RiS, DP2] are similar situations. In all of these cases, while we may assume that the adversary may have unlimited power, our player is restricted by the computing machinery that is available. In a not unrelated problem, Papadimitriou has discussed asymmetric players in two-person games in terms of computational complexity by formulating nature as an amiable indifferent adversary: a randomized adversary with equal probabilities on choices of its moves [Pa2]. Many authors have considered players with restricted computational power [DP1, Fu, KS, Ne, Si].

The study of situations dealing with unknown future events leads to the concept of *competitiveness*. An online algorithm is α-competitive if its cost on any finite sequence of requests is within a factor of α of the optimal cost (up to an additive constant) by an algorithm that knows all of the future requests [KMRS]. For one problem of this type, the k-server problem, a matched upper bound and lower bound of k are conjectured [MMS]. The conjecture remains unsolved in spite of many efforts, even though it is shown to be true on several particular metric spaces [CL, CKPV, MMS]. A recent result [KP] comes very close to resolving this problem (see also [FRR, Gro]). The above-mentioned result in [BBKTW, RaS] provides another approach to solving the conjecture. Thus if one can design a k-competitive randomized online algorithm for the k-server problem, the above conjecture is proven even though one may not be able to design a computable deterministic algorithm. This approach depends very much on the possibility of a k-competitive algorithm against the offline adaptive adversary. However, all known k-competitive randomized algorithms for the server problem are against an online adaptive adversary [RaS, CDRS]. The failure in resolving the conjecture for general metric space, however, may not be attributed to the conjecture being false. *The optimal strategy may simply be noncomputable.* Though one may doubt whether this is the case for this natural game of the k-server problem since there is a computable strategy conjectured to be optimal, it is always helpful to look into other possibilities. Indeed, there are known cases of naturally defined games for which the optimal response strategy of our player to an adversary strategy cannot be computable. A very interesting example is the well-

known prisoner's dilemma game [Kn]. This motivation provides another perspective to the formalism discussed in this paper. However, this does not exclude the possibility that for some games, computable optimal strategies are possible to construct. In fact, Ben-David et al. show several such cases for the request–answer game, which can be applied to the k-server problem.

In section 2, we will formally introduce necessary notations and related definitions. We will discuss semicomputable determinacy of infinite games in section 3. In section 4, we look into possible implications of our main result to the semicomputable derandomization hypothesis for games and for online computation problems. Section 5 contains a discussion on the derandomization hypothesis for indeterminate games, a classic case without the computability restriction on our player. Section 6 concludes the paper with remarks and some open problems.

2. Definitions and notation. An infinite game can be described as an infinite tree on which two players make their moves in turn, starting at the root. We distinguish the players by naming Player I as *the adversary* and Player II as *our player*. The adversary makes choices at even levels, starting at level 0, the root, and our player makes choices at odd levels. We also call a pair of two moves a *stage*; thus level $2n$ and $2n+1$ are classified as stage n, $n = 0, 1, \ldots$. For convenience, we restrict the choice space of each player's moves to be finite, though some results may also extend to infinite choice spaces. The set of all of the infinite paths is partitioned into two subsets A and B, where A is the winning set for our player and B is the winning set of the adversary. A strategy τ (σ) for the adversary (our player) corresponds to a pruned tree T_τ (T_σ) from the original game tree on which each branching at even (odd) levels is pruned to allow at most one possible child. The resulting play (σ, τ) for a given τ and a given σ corresponds to a path in the game tree. We call σ a *winning strategy* for our player if for every τ, the path (σ, τ) belongs to A. The winning strategies for the adversary are defined similarly. Finally the game is *determinate* if either player has a winning strategy.

We now define a topology on the set of all plays. A subset S of all the paths is defined as being *open* iff for every path $(a_0, a_1, \ldots) \in S$, there exists a number n such that for all $b_{n+1}, b_{n+2}, \ldots$,

$$(a_0, a_1, \ldots, a_n, b_{n+1}, b_{n+2}, \ldots) \in S.$$

Let $O(a_0, a_1, \ldots, a_n) = \{(a_0, a_1, \ldots, a_n, b_{n+1}, b_{n+2}, \ldots) : \text{ all } b_{n+1}, b_{n+2}, \ldots\}$ and call it an elementary open set. A set of paths is *closed* if it is the complement of an open set. An important feature of this topology is that an elementary open set is also closed [Mos].

A game is *open* (*closed*) if the winning set of our player is open (closed). In their classical paper on infinite games [GS], Gale and Stewart show that all open and closed games are determinate and that there exists a game that is indeterminate. Martin [Mar] further proves that all Borel games are determinate. (A game is *Borel* if the winning set of Player I (or II) is Borel under the topology defined above.) Observe that in classical infinite-game theory, there is no restriction on the strategies in terms of computability.

In [BBKTW], online problems are formulated as finite games, and in [RaS], an infinite-game formulation is given. Depending on the criteria of competitiveness, one may get different winning sets for an online problem. Let us denote by OC the cost of our player and by AC the adversary's cost. A simple α-competitiveness requirement is defined by $OC \leq \alpha \cdot AC$. We will call it the type I *competitive* condition. When the cost

function is accumulative, e.g., in the case of the server problem, type I competitiveness will define a closed game: the adversary wins iff the play reaches a node where the condition is violated. A slightly different definition is to allow an additive constant $c > 0$ and use $OC \leq \alpha \cdot AC + c$ instead. This is not much different. Raghavan and Snir [RaS] use a formulation which allows an arbitrary additive constant, which gives rise to a game with a winning set in F_σ (the countable union of closed sets):

$$\cup_i \cup_j \cap_{k \geq j} \{(x_0, x_1, \ldots) : OC(x_0, \ldots, x_k) - \alpha \cdot AC(x_0, \ldots, x_k) \leq i\}.$$

Thus infinite paths of constant costs are always in the winning set of our player. In section 1, this was defined as the *type* II *competitive* condition.

A randomized strategy for our player is a function that makes an assignment of probability to all the possible choices of our player depending on the position of the node on the game tree. We say a randomized strategy is *computable* if, firstly, the probability density function on the choice space is a computable function and, secondly, the rules for the assignment of probabilities for different nodes on the game tree are computable. As noted in [RaS, HT], a statement about a randomized algorithm is true if it is true against all adversary strategies. Thus, given a randomized strategy, we consider each adversary deterministic strategy τ and the induced probability distribution for the pruned tree T_τ. We specify a topology and a probability measure on the smallest σ-algebra generated by the topology by specifying them on all the basic open sets. A basic open set U is specified by a node x on T_τ such that it contains all of the paths passing through x and its probability measure is the probability that the randomized strategy reaches x. The measure is extended to all of the Borel sets in the topology by the standard method [CT]. When we specify an adversary strategy τ, a similar method is applied to define the conditional distribution on the pruned tree T_τ. Again, a randomized strategy is α-competitive almost surely iff for all of the pruned trees T_τ, it is α-competitive almost surely with respect to this probability distribution.

With the terminologies defined above, it is not difficult to construct a semicomputably indeterminate game if we drop the requirement that it is closed (for the purpose of applications to online problems.) We simply take the list of all of the computable strategies that each player can have: $\tau_1, \tau_2, \ldots, \tau_n, \ldots$ for the adversary and $\sigma_1, \sigma_2, \ldots, \sigma_n, \ldots$ for our player. Using a standard diagonalization technique, we construct the winning paths of our player and the adversary as follows. Initially, choose $\langle \sigma_1, \tau_1 \rangle$ to be B_1, denote $\tau_1 = \tau_{\sigma_1}$, and let $A_0 = \emptyset$. In general, suppose for $k \geq 1$ that B_k and A_{k-1} are constructed, with $B_k = \{\langle \sigma_i, \tau_{\sigma_i} \rangle : i = 1, 2, \ldots, k\}$, $A_{k-1} = \{\langle \sigma_{\tau_i}, \tau_i \rangle : i = 1, 2, \ldots, k-1\}$, and $B_k \cap A_{k-1} = \emptyset$. Let m to be the minimum index such that $\langle \sigma_m, \tau_k \rangle \notin B_k$. This is well defined since $\{\langle \sigma_n, \tau_k \rangle : n = 1, 2, \ldots\}$ is an infinite set but B_k is finite. Denote $\sigma_m = \sigma_{\tau_k}$ and set $A_k = A_{k-1} \cup \{\langle \sigma_m, \tau_k \rangle\}$. Similarly, let p to be the minimum index such that $\langle \sigma_{k+1}, \tau_p \rangle \notin A_k$. This is well defined since $\{\langle \sigma_{k+1}, \tau_n \rangle : n = 1, 2, \ldots\}$ is an infinite set but A_k is finite. Denote $\tau_p = \tau_{\sigma_{k+1}}$ and set $B_{k+1} = B_k \cup \{\langle \sigma_{k+1}, \tau_p \rangle\}$. Take $A = \cup_{n=1}^{\infty} A_n$ and $B = \cup_{n=1}^{\infty} B_n$. We have two subsets A and B of infinite paths of plays such that for each computable strategy σ of the adversary, there is a computable strategy τ_σ of our player with the path $\langle \sigma, \tau_\sigma \rangle \in A$; for each computable strategy τ of our player, there is a computable strategy σ_τ of the adversary with the path $\langle \sigma_\tau, \tau \rangle \in B$.

The above sets of A and B may not partition the set of all plays. We can put all of the other paths in the winning set of our player. This proves the following:

0. There exists an indeterminate game when both players are restricted to using only computable strategies.

Moreover, this is in fact a semicomputably indeterminate game.

$0'$. There exists a semicomputably indeterminate game.

With possible applications to online problems in mind, however, we want to study the semicomputable determinacy of F_σ games and closed games. Our main results are the following:

1. There is a semicomputably indeterminate closed game.

Since a closed game is also in F_σ (that is, games in which the winning set is a countable union of closed sets), this also means there is a semicomputably indeterminate F_σ game. In contrast, for open games, the following is true.

2. All open games are semicomputably determinate.

To study randomized strategies for infinite games, we also need to specify the proper probability distribution. Raghavan and Snir formally defined it through a probability distribution over the strategy space of our player [RaS]. When the adversary's strategy is specified, it induces a probability distribution over the pruned tree corresponding to the adversary strategy. Halpern and Tuttle [HT] had a similar idea for distributed systems. Thus a statement about a randomized algorithm is true iff it is true for all the pruned trees. We prove that the computable derandomization hypothesis is not always true, even for F_σ games.

3. There exists an F_σ game
   - which is semicomputably indeterminate and
   - in which our player has a simple randomized computable strategy that wins all most surely.

We can also assign a cost function on paths of this game to transform it into an online problem to obtain the following result.

$3'$. There exists an F_σ game on which we can define an online problem such that our player has a randomized computable strategy which is type II competitive almost surely but has no deterministic computable type II competitive strategy.

Similarly, we can construct a closed game and get a slightly weaker result for type I competitiveness.

$3''$. For any $\epsilon > 0$, there is a closed game on which we can define an online problem such that our player has a randomized computable strategy which is type I competitive with probability $1 - \epsilon$ but has no deterministic computable type I competitive strategy.

The above result for type II competitiveness also holds when we use the expected value instead of high probability. A weaker result holds for the type I competitiveness. When none of the players is restricted in computational power, we show that the derandomization hypothesis is not true in general for indeterminate games.

4. There exists an indeterminate game for which both players have a randomized strategy which wins against all of the deterministic strategies of the other player.

3. Semicomputable determinacy of infinite games. While all Borel games are determinate [Mar], we would like to know under what topological conditions a game is semicomputably determinate. First, we have the following.

THEOREM 1. *There is a semicomputably indeterminate closed game.*

We give both players two choices of actions: $r0$ and $r1$ for the adversary and $a0$ and $a1$ for our player. We first give some intuition on the proof of the theorem. We need to partition the set of all of the paths into two sets A (the winning set for our player, which is closed) and B (the winning set for the adversary) such that for each computable strategy σ of our player, there exists an adversary strategy τ such that (σ, τ) is in B (call it condition C1), and for each adversary strategy τ of the adversary, there exists a computable strategy of our player σ such that (σ, τ) is

in A (call it condition C2). C1 and C2 force certain plays to be put in A and B, respectively, and we should make sure that (A, B) is a partition. Moreover, we want a construction that makes A a closed set.

Observe that the indeterminacy proof given in [GS] cannot be translated into this case. Our result is obtained via a new method which may be useful in other similar situations.

We construct A and B in stages. Let the computable strategies of our player be ordered as $\sigma_i, i = 0, 1, 2, \ldots$. Say that a strategy σ is *killed* in stage j if we put $(\sigma, \tau') \in B$ for some τ' of the adversary in B in stage j (and similarly for an adversary strategy). At each stage, we kill at least one σ and perhaps an uncountable number of τ's so that A and B remain disjoint, and we make sure that each σ and each τ is killed in some finite stage without destroying the disjointness criterion. An indeterminate game is thus constructed. The construction will guarantee that A constructed thusly is closed. We now give the technical details of the result.

Proof of Theorem 1. For simplicity, we assume that the adversary's choice space is $r0$, $r1$ and our player's choice space is $a0$, $a1$. We list all (computable) strategies of our player in the set

$$\Sigma = \{\sigma_0, \sigma_1, \ldots, \sigma_n, \ldots\}$$

such that σ_0 is the strategy that chooses move $a0$ all the time. Informally, we need to construct a game with winning sets A for our player and B for the adversary such that the following conditions hold.

C1. For each $\sigma \in \Sigma$, there is $\tau \in \mathcal{T}$ and $(\sigma, \tau) \in B$.

C2. For each $\tau \in \mathcal{T}$, there is $\sigma \in \Sigma$ and $(\sigma, \tau) \in A$.

Construction of A, B. Initially, set A_0 contain all of the paths along which the adversary never requests $r1$. $B_0 = \emptyset$. Let $A = A_0$ and $B = B_0$. Denote the root of the game tree as being level 0. Incrementally assign level numbers to the tree. We will prune the tree in levels. First, level 0 is processed, and then we show inductively how to process level n for each $n = 1, 2, 3, \ldots$.

Level 0. Denote by $\mathcal{T}_1$ all of the adversary strategies that make $r1$ as their first request. Choose some $\tau_0 \in \mathcal{T}_1$ and assign the path $\langle \sigma_0, \tau_0 \rangle$ in B_1. Moreover, we make B_1 an elementary open set containing the path $\langle \sigma_0, \tau_0 \rangle$. To be specific, from the root on the path $\langle \sigma_0, \tau_0 \rangle$, we take the $(2K + 1)$-st node N_1, for some $K > 1$, and make B_1 contain all of the infinite paths that pass N_1. Assign all of the other paths that start with $r1$ to A_1. Update $A \leftarrow A \cup A_1$ and $B \leftarrow B \cup B_1$. Thus condition C1 holds for σ_0 and condition C2 holds for all $\tau \in \mathcal{T}_1$. Remove σ_0 from the strategy set of our player. Now we consider all of the paths that start with $r0$. At level 1, according to the choice of our player, the strategy set for our player is partitioned into two subsets Σ_0 and Σ_1, where the lists for Σ_0 and Σ_1 keep the same order as the list in Σ.

Level $2i - 1$, $i \geq 1$. We keep the following inductive assumption for the pruning process at the end of level $2i - 2$. Each remaining node at level $2i - 1$ is a descendent of the adversary that played $r0$ at all of the past i requests. Thus each node can be denoted by an i-bit binary number that corresponds to plays made by our player from the root to the node. At node j, Σ_j represents all of our player strategies that are consistent with j up to this node. Σ_j's, $j = 0^i, 0^{i-1}1, 0^{i-2}10, \ldots, 1^i$, form a partition of the remaining members in Σ which do not yet satisfy condition C1. All of the adversary strategies that remain at node j are those which make i consecutive requests of $r0$'s when played against our player which answers j correspondingly. We will denote them by $\mathcal{T}_j$. From the above discussion for levels 0 and 1, this holds for $i = 1$.

Level $2i$. Consider each node independently. Without loss of generality, let us look at node 0^i. Let

$$\Sigma_{0^i} = \{\sigma_{0^i{}_0}, \sigma_{0^i{}_1}, \ldots, \sigma_{0^i{}_n}, \ldots\}.$$

Denote by $\mathcal{T}_{0^i1}$ all of the strategies in $\mathcal{T}_{0^i}$ that make the $(i+1)$st request as $r1$. We assign the path $\langle \sigma_{0^i{}_0}, \tau_{0^i{}_0}\rangle$ to the set B_{0^i1} for some $\tau_{0^i{}_0} \in \mathcal{T}_{0^i1}$. Moreover, we make B_{0^i1} an elementary open set containing the path $\langle \sigma_{0^i{}_0}, \tau_{0^i{}_0}\rangle$. To be specific, from the node j on the path $\langle \sigma_{0^i{}_0}, \tau_{0^i{}_0}\rangle$, we take the $(2K+1)$st node N_{0^i1}, for the same $K > 1$ as in level 0, from the first $r1$ request and make B_{0^i1} contain all of the paths that pass N_{0^i1}. All of the other paths that start from 0^i and continue with $r1$ are assigned to A_{0^i1}. At level $2i+1$, according to the choice of our player, the strategy set for our player is partitioned into two subsets Σ_{0^i0} and Σ_{0^i1}, where the lists for Σ_{0^i0} and Σ_{0^i1} keep the same order as the list in Σ. Thus condition C1 holds for $\sigma_{0^i{}_0}$ and condition C2 holds for all $\tau \in \mathcal{T}_{0^i1}$. We also perform similar operations on all of the nodes j of i bits. For all j nodes of i bits, condition C1 holds for σ_{j_0} and condition C2 holds for all $\tau \in \mathcal{T}_{j1}$. Update the set A and B by assigning $A \leftarrow A \cup \bigcup_{j=0^i}^{1^i} A_{j1}$ and $B \leftarrow B \cup \bigcup_{j=0^i}^{1^i} B_{j1}$. It follows from these definitions that the inductive hypothesis holds for level $(2i+1)$.

Correctness proof. We now prove that conditions C1 and C2 are true for all adversary strategies and our player strategies. Notice that our player's strategies are first enumerated in the set Σ, and the ordering is kept when they are partitioned at each level. For the first strategy σ in Σ_j, there is an adversary strategy τ such that $(\sigma, \tau) \in B$ according to our pruning process. Therefore, for each $i = 1, 2, \ldots$, σ_i satisfies condition C1 no later than at level $2i-1$ in our construction. To prove that condition C2 holds for all adversary strategies, we consider two cases: one is the case where the adversary plays $r0$ all the time; the other is the case where the adversary plays $r1$ at least once for some strategy. The first case is done by the initial assignment of set A. For the second case, we notice that for any other strategy τ of the adversary, it will play $r1$ at least once for a strategy of our player at a finite level. If the strategy of our player is not a computable strategy, we can simply truncate the infinite strategy at that finite level and append it by always playing $a0$. This will be a computable strategy $\sigma(\tau)$. Suppose j is the node for the first step where the adversary plays an $r1$; then the adversary strategy τ will lose to $\sigma(\tau)$ at one path in $\mathcal{T}_{j1}$.

To show that A is a closed set, we notice that B_1 is an open set and so are all the B_{j1}'s. Thus B is open since it is the union of a countably many open sets. A and B partition the whole space; therefore, A is closed. □

In contrast, all open games with a finite choice space for the adversary have enough mathematical structure to make them semicomputably determinate. To prove this, we need the following lemma (see, e.g., [Ku].)

LEMMA 2 (Koenig). *Every finitely branching infinite tree has an infinite path.* □

THEOREM 3. *All open games are semicomputably determinate if the choice space for the adversary is finite.*

Proof. Suppose no adversary strategy wins over all strategies of our player. Since open games are determinate [GS, Mar], there is a strategy σ of our player which wins against all of the adversary strategies (though σ may not be computable). Consider the pruned tree T_σ. Every infinite path in T_σ is in the winning set A of our player. Since A is open, for each infinite path in T_σ, there is a node x on the path such that all the paths passing through x are in A. We can thus remove the branch from x

down and make x a terminal node on which our player wins. This will not change the win/lose situation of the tree since all of the paths that pass x are in A. The game tree thus pruned has no infinite path. By Lemma 2, since this pruned tree is finitely branching and has no infinite paths, it is finite. Therefore, if there is no adversary winning strategy, our player can win by simply coding the structure of the pruned *finite* tree and choosing its moves accordingly. □

By exchanging the role of our player and the adversary, we can further obtain the following corollary.

COROLLARY 4. *For closed games, there is either a finite-state adversary strategy that wins against all strategies of our player or a strategy of our player that wins against all adversary strategies if the choice spaces for both the adversary and our player are finite.*

For the notion of type I competitiveness, the winning set of our player is closed. If there is no deterministic winning strategy of our player, then the winning strategy of the adversary will enable us to prune the tree to a finite tree according to Corollary 4. We thus easily conclude that there is no competitive randomized strategy for our player. The result of [BBKTW, RaS] for infinite games follows immediately. Corollary 4 also implies that if we allow our player to use unlimited power, we only need to look for a lower bound forced by adversaries with a simple computational power: finite-state machines. Thus it is easier to establish a general lower bound than a lower bound tailored to computable strategies of our player.

4. Applications to online algorithms. While online problems are formulated as closed and F_σ games, we would also like to formulate closed and F_σ games as online problems such that there is a winning strategy for our player in a given game iff there is an α-competitive online algorithm for the corresponding online problem. This may not be true in general. However, for semicomputable indeterminate games constructed in this paper, we want to make sure that the above condition is satisfied. First, we construct a game similar to the one given in section 3 for this goal.

THEOREM 5. *There exists a semicomputably indeterminate F_σ game such that there is a computable randomized winning strategy (almost surely). Moreover, on this game, we can define an online problem of accumulative cost such that there is a computable randomized type* II *competitive strategy (almost surely) but there is no computable deterministic type* II *competitive strategy.*

An F_σ semicomputably indeterminate game. We construct a game similar to the one for proving Theorem 1. The changes are as follows. We choose A_0 in the same way as we did in Theorem 1. Notice that A_0 is closed because it can be obtained by removing countably many disjoint elementary open sets as follows:

for $n = 0$ **to** ∞ **do** remove the $r1$ branch for level $2n$.

Actually, A_0 is a Cantor-type set (see, e.g., [Bi]).

In level 0, we will put (σ_0, τ_0) in B_1, instead of an elementary open set containing the path, and all the other paths starting with $r1$ are put into A_1. Similarly, at node j, we also put one path $\langle \sigma_{j_0}, \tau_{j_0} \rangle$ in B_{j1}, and all of the other paths that start at node j and continue with $r1$ are put in A_{j1}. The rest of the construction follows the same pattern as before. Notice that A_{j1} consists of countably many elementary open sets. However, as noticed while defining the topology in section 2, an elementary open set is also closed. Thus each A_{j1} is an F_σ set. Therefore, A is also an F_σ set.

Although A is no longer closed, the proof that the game is semicomputably indeterminate follows from the same reason as in Theorem 1. The only differences are

assignments of paths that are irrelevant to the proof of semicomputably indeterminacy.

A simple randomized winning strategy. Consider the randomized algorithm that always chooses $a0$ and $a1$ with probability 0.5:0.5. We claim that this simple (computable) randomized algorithm wins almost surely.

To discuss the proof carefully, for any adversary strategy τ, consider its corresponding pruned tree T_τ. For the root level, if the adversary chooses $r1$, there is exactly one winning path of the adversary in its strategy tree T_τ. We can remove all of the nodes below this node to reduce this tree to one root node, leading to one leaf node through an edge labeled $r1$. On the collection of paths from this leaf node, our player wins with probability 1.

In general, our player wins with probability 1 in each branch on a node reached from the root by a consecutive sequence of $r0$ requests followed by the first $r1$ request. With this observation, we further prune the tree T_τ as follows. Move from the root down the tree T_τ until the first request $r1$ is encountered. Then delete the branch after that node. Thus infinite paths of the further pruned tree will all contain request $r0$ only. They are all in the winning set of our player. On all of the leaves created by the above pruning procedure, our player wins with probability 1. It follows immediately that this simple randomized strategy wins with probability 1 against any adversary strategy.

A cost function. We want to have an accumulative cost function such that it increases smoothly as plays proceed. All nodes at even levels are assigned a cost of 0. Thus in the following, all of the nodes assigned costs are nodes at odd levels. On the winning paths of the adversary in the game tree, we assign the cost of each node to be 1 until the first $r1$ is encountered. After the first $r1$ request, the cost of each node on the winning paths of the adversary in the game tree is its level minus the level of the node the first $r1$ request is made. At all other nodes, a cost of 1 is assigned. The accumulative cost (informally, the online cost) of our player along a path will be the sum of the costs of nodes it has passed on the game tree. The cost of the adversary (informally, the offline cost) will be the minimum cost over all the paths with the same request sequence. That is, we consider an offline adaptive adversary [BBKTW]. Therefore, for a fixed request sequence, the offline cost grows linearly with the length of the request sequence. Along a winning path of the adversary with at least one $r1$ request, the growth rate of the online cost is asymptotically quadratic in the length of the request sequence. Along all other paths, the growth rate of the online cost is asymptotically linear with the length of the request sequence.

Competitiveness. Denote an infinite path by $\langle \tau, \sigma \rangle$. We will denote by $\langle \tau, \sigma \rangle_k$ the subpath consisting of the first k edges in the infinite path $\langle \tau, \sigma \rangle$. From the above game construction and the cost function, we have the following:

(a) For any $\langle \tau, \sigma \rangle$,

$$AC(\langle \tau, \sigma \rangle_k) = \lceil k/2 \rceil.$$

This holds since we can always obtain a subpath with any given sequence of $\lceil k/2 \rceil$ requests which does not shares any edge with an adversary winning path except probably the first one. In either case, the cost on each odd-level node is 1. The total cost is thus $\lceil k/2 \rceil$.

(b) For any $\langle \tau, \sigma \rangle \in A$, there is a constant c such that

$$\lim_{k \to \infty} [OC(\langle \tau, \sigma \rangle_k) - \lceil k/2 \rceil] \leq c.$$

Suppose $\langle \tau, \sigma \rangle$ is not in the adversary winning set. Let f be the number of edges that it shares with an adversary winning path after the first $r1$ request. Then the cumulative cost along path P at a node of level $k = 2j$ is bounded by $j + (1 + 3 + \cdots + f) = j + (f+1)^2/4$. The offline cost is at least j. Therefore, $OC(\langle \tau, \sigma \rangle) - \lceil k/2 \rceil \leq (f+1)^2/4$, for all $k \geq 0$. The claim follows by choosing $c = (f+1)^2/4$.

(c) For any $\langle \tau, \sigma \rangle \in B$ and for any constant c,

$$\lim_{k \to \infty} [AC(\langle \tau, \sigma \rangle_k) - c\lceil k/2 \rceil] = \infty.$$

Let the first $r1$ request on $\langle \tau, \sigma \rangle$ is at level $2j$. Then the cost at level $2i+1$ is 1, if $0 \leq i < j$ and is $2(i-j)+1$ if $i \geq j$. Therefore, the cumulative cost at level $k = 2i+1$, or $2i+2$, for $i \geq j$, is $j + \sum_{t=j}^{i}(2(t-j)+1)$, which is $\Omega(k^2)$ as k goes to infinity. Then it cannot be bounded by any linear function. The claim follows.

From the construction of the game, for any deterministic strategy σ_s, there exists a τ_s such that $\langle \tau_s, \sigma_s \rangle \in B$. Therefore, σ_s cannot have any constant competitive ratio by (c). On the other hand, for any adversary strategy τ, at most one path of T_τ is in B, which is taken by our randomized strategy with probability 0. By (b), the randomized strategy has a constant competitive ratio on all the paths in B, which holds with probability 1. Theorem 5 follows. Notice that the value f and thus c in (b) depends on the particular strategy T_τ. It follows that the competitive ratio on any infinite path in the winning set of our player is one according to the definition of type II. □

With regard to the issue of derandomization for type I competitiveness, one may insist that we compare randomized competitive algorithms with type I deterministic competitive ones. This would lead to a closed game. In this case, we can use the closed game constructed for Theorem 1 and use the same cost function as defined above.

COROLLARY 6. *For any integer $K > 0$, there exists a closed game for which one can define an online problem such that there is no computable deterministic type* I *competitive strategy but there is a computable randomized strategy that is type* I *K-competitive with probability $1 - 2^{-K}$.*

Proof. For simplicity, we first consider adversary strategies that make $r1$ the first request. The cost as defined above of each node for the tree T_τ will be as follows:

1. All nodes at even levels have cost 0.

2. There is only one node at level $l = 2j+1$ with cost $2j+1$ for $j \leq K$, which is the node on the winning path of the adversary; all other nodes on level $l = 2j+1$ have cost 1 for $j \leq K$.

3. There are only 2^{j-K} nodes at level $l = 2j+1$, with cost $2j+1$ ($j \geq K$); all other nodes on level $l = 2j+1$ have cost 1.

Since nodes at even levels will have the same cumulative cost as their parents, we focus our discussion on nodes at odd levels. Therefore, the cumulative cost of nodes of the pruned tree T_τ at level $k = 2j+1$ ($j \geq K$) will be as follows:

1. 2^{j-K} nodes of cumulative cost $1+3+\cdots+(2j-3)+(2j-1)+(2j+1) = (j+1)^2$;

2. 2^{j-K} nodes of cumulative cost $1 + 2 \cdots + (2K-1) + \sum_{t=K}^{j} 1 = K^2 + (j-K)$;

3. 2^{j-K+1} nodes of cumulative cost $1 + 2 + \cdots + (2K-3) + \sum_{t=K-1}^{j} = (K-1)^2 + (j-K+1)$;

...

($i+2$). 2^{j-K+i} nodes of accumulative cost $(K-i)^2 + j - K + i$, for $i : 1 \leq i < K$,

...

$(K+1)$. 2^{j-1} nodes of accumulative cost $j+1$.

Therefore, for any deterministic strategy σ_s of our player, there exists an adversary strategy τ_s such that $(\langle \tau_s, \sigma_s \rangle)$ is in the winning set of the adversary. From the above, we have $OC(\langle \tau_s, \sigma_s \rangle_k) = (\lceil k/2 \rceil)^2$. Similarly to the proof of Theorem 5, $AC(\langle \tau, \sigma \rangle_k) = \lceil k/2 \rceil$. σ_s cannot be type I competitive.

The fraction of nodes with cumulative cost $(j+1)^2$ at level $2j+1$ is 2^{-K}. The cumulative cost for any other node at level $2j+1$ is no more than K^2+j-K, which grows linearly with j as j goes to infinity. On these paths, we have $OC(\langle \tau, \sigma \rangle_k) - 2 \cdot AC(\langle \tau, \sigma \rangle_k) \leq K^2 - K - j$. Since $K^2 - K - j \leq 0$ as $j \to \infty$, choosing $c = 0$, we have that $\lim_{k\to\infty}[OC(\langle \tau, \sigma \rangle_k) - 2 \cdot AC(\langle \tau, \sigma \rangle_k)] \leq c$ holds with probability $1 - 2^{-K}$.

If the adversary does not make $r1$ its first request, the analysis is similar and the same claim holds for j greater than K plus the number of requests before the first $r1$. □

The above results are for randomized algorithms that are competitive with high probability. For randomized algorithms that are competitive in expected values, we have a similar result for type II competitiveness and a slightly weaker result for type I competitiveness.

COROLLARY 7. *There exists a game on which one can define an online problem such that there is no computable deterministic type* II *competitive strategy* (*no computable deterministic type I* $(2^K - 1)$*-competitive strategy*) *but there is a computable randomized strategy which is type* II *competitive strategy in the expected value* (*a computable randomized type* I $(K+2)$*-competitive strategy*).

Proof. For the type II competitiveness, we use the same game and the same cost function as defined in the proof of Theorem 5. In fact, one may conclude that the claim holds in the expected value by verifying conditions for the *monotone convergence theorem* or *Fatou's lemma* [CT] in this case. For completeness, we present a direct proof. Suppose our player faces an adversary τ which makes its first move $r1$. The cost as defined before of each node for the tree T_τ will be as follows:

1. All nodes at even levels have cost zero.

2. There is only one node at level $l = 2j+1$ with cost $2j+1$ $(j \geq 1)$, which is the node on the winning path of the adversary; all other nodes on level $l = 2j+1$ have cost 1.

Therefore, the cumulative cost on nodes of the pruned tree T_τ at level $l = 2j+1$ $(j \geq 1)$ will be as follows:

1. one node of cumulative cost $1+3+\cdots+(2j-3)+(2j-1)+(2j+1) = (j+1)^2$;
2. one node of cumulative cost $1+3\cdots+(2j-3)+(2j-1)+1 = j^2+1$;
3. two nodes of cumulative cost $1+3+\cdots+(2j-3)+1+1 = (j-1)^2+2$;

...

$(i+1)$. 2^{i-1} nodes of cumulative cost $(j-i+1)^2+i$, for $i < j$;

...

$(j+1)$. 2^{j-1} nodes of cumulative cost $j+1$.

Therefore, there are $2^{j-\sqrt{j}+1}$ nodes in level $l = 2j+1$ with cumulative cost at least $(j-j+\sqrt{j})^2 + j - \sqrt{j} + 1$. In other words, at level $l = 2j+1$, with probability at most $2^{-\sqrt{j}}$, the randomized strategy has cumulative cost at least $2j - \sqrt{j} + 1$ (but less than or equal to $(j+1)^2$). Therefore, the expected value is bounded by $(j+1)^2 2^{-\sqrt{j}} + (2j - \sqrt{j} + 1)$, which is dominated by the first term $2j$ as $j \to \infty$. Since the optimal cost is j, the claim holds in this case.

However, in general, the adversary may start with the first request $r0$. We prune T_τ further as follows. Start from the root until a request $r1$ is encountered, delete the

branch after that node, and mark this node. Thus the only infinite paths of the newly pruned tree will contain only request $r0$. We may, however, have an infinite number of marked nodes. Now consider all of the nodes at level $l = 2j + 1$. For each marked node v at level $2j_1$, let $j_2 = j - j_1$. From the above discussion, the cumulative cost at a leaf node (of level $2j + 1$) in the subtree rooted at v is at most $j_1 + (j_2 + 1)^2$ according to our cost function. Thus if $j_2 \leq \sqrt{j}$, this is bounded by $2j + 1$; we again have a competitive ratio bounded by 2. However, if $j_2 \geq \sqrt{j}$, the cumulative cost at a leaf node (of level $2j + 1$) in the subtree rooted at v is at most $j_1 + 2j_2 + 1 \leq 2j$ with probability at least $1 - 2^{-\sqrt{j_2}-1}$; the cumulative cost for remaining leaf nodes (of level $2j+1$) in the subtree rooted at v is at most is $(j+1)^2$ (with probability at most $2^{-\sqrt{j_2}-1}$). The competitive ratio of 2 again holds. For nodes at level $2j + 1$ with no ancestors marked, their competitive ratio is 1. The claim for type II competitiveness follows.

For type I competitiveness, we use the game constructed in Theorem 1. We need a special cost function. Again, we make all of the nodes at even levels cost 0 and discuss nodes at odd levels only.

1. For the adversary strategies that start with request $r1$, the construction chooses τ_0 according to σ_0 and takes the $(2K + 1)$st node N_1, $K > 1$, on the path $\langle \sigma_0, \tau_0 \rangle$, making all of the infinite paths that pass N_1 winning paths of the adversary. Along the path from the root to N_1, we assign the first node after the first $r1$ request a cost of $2^0 = 1$, the third node a cost of 2, ..., and the $(2i + 1)$th node at odd levels a cost of 2^i, $0 \leq i \leq K$. Thus the node N_1 is assigned a cost of 2^K. For any other node w in the branch that started with the $r1$ request at the root, its cost is assigned to be the maximum cost of nodes that we meet when moving down from the root to w. Thus at level $l = 2j + 1$ for $j \leq K$, there are one node of cost 2^j, one node of cost 2^{j-1}, two nodes of cost $2^{j-2}, \ldots, 2^{i-1}$ nodes of cost $2^{j-i}, \ldots, 2^{j-1}$ nodes of costs 1. Let S_j be the sum of the cost at level $2j + 1$. $S_j = 2^j + j2^{j-1} = (j + 2)2^{j-1}$ for $j \leq K$. Let E_j be the expected cumulative cost at level $2j + 1$. Thus E_j $(j \leq K)$ of the simple randomized algorithm is $1/2^j$ times $\sum_{i=0}^{j} 2^{j-i} \cdot S_i$ since each node at level $2i + 1$ is used in 2^{j-i} paths leading to level $(2j + 1)$. Thus the expected cost is $(j + 4)(j + 1)/4$ for level $2j + 1$ $(j \leq K)$. This is $(K + 4)(K + 1)/4$ at level $2K + 1$ while its optimal cost is $K + 1$. The competitive ratio is $K + 4/4$. Then $S_{j+1} = 2S_j$ and $E_j 2^j + S_{j+1} = E_{j+1} 2^{j+1}$. Thus $E_{j+1} = E_j/2 + S_{j+1}/2^{j+1}$ for $j \geq K$. As j goes to infinity, E_j goes to $2 \cdot S_K/2^K = 2 \cdot (K + 2)2^{K-1}/2^K = K + 2$. Therefore, the competitive ratio is $K + 2$.

2. For adversary strategies that start with $r0$, we assign a cost of 1 to a node from the root down until the first $r1$ request is reached. Then we will use the same cost function from the $r1$ request on. The same competitive ratio $(K + 2)$ holds for the simple randomized algorithm.

On the other hand, any computable strategy will results in a path with all nodes after a certain node costing 2^K, while an optimal path with the same request sequence will have all nodes costing 1. Thus the competitive ratio cannot be better than $2^K - 1$. □

5. Indeterminacy and randomization. In this section, we digress from our requirement that our player be restricted to a computable strategy and discuss the power of randomization in classical indeterminate games.

The result of [BBKTW, RaS] says basically that for a determinate game, whenever there is a randomized strategy for Player I which wins with probability 1, there is a deterministic winning strategy for Player I. If this result can be extended to inde-

terminate games, it means that for every indeterminate game, there is no randomized winning strategy for any of the players. The following theorem gives a negative answer to this question. Moreover, the game constructed for our theorem has another counterintuitive implication. Even though Player I has a randomized strategy that wins almost surely against all of the deterministic strategies of Player II, that randomized strategy does not necessarily win almost surely against all of the randomized strategies of Player II.

THEOREM 8. *Assuming the axiom of choice and the continuum hypothesis, there is an indeterminate game for which Player* I *has a randomized winning strategy which wins almost surely against any deterministic strategy of Player* II *and vice versa.*

The theorem shows that the result of [BBKTW, RaS] is the best possible in the sense that if we drop the condition that the game be determinate, the derandomization hypothesis does not always hold. This result assumes the axiom of choice and the continuum hypothesis. The axiom of choice seems necessary here because it is not even known if indeterminate games exist in its absence.

Proof of Theorem 8. We assume that each player has two choices at any point in the game. By the axiom of choice, we can well order Player I's deterministic strategies as σ_α for $\alpha < 2^{\aleph_0}$ and Player II's deterministic strategies as τ_β for $\beta < 2^{\aleph_0}$.

Our randomized strategy for either Player I or II (δ and γ, respectively) assigns a probability of 0.5 to each of the two possible moves. We now construct the winning set for Player I and the winning set for Player II so that both of these strategies are winning strategies if the other player uses only deterministic strategies.

We need to satisfy the following conditions:

1. For each deterministic strategy σ of Player I, only countably many paths in the pruned tree corresponding to σ belong to the winning set of Player I, and the rest belong to the winning set of Player II.

2. For each deterministic strategy τ of Player II, only countably many paths in the pruned tree corresponding to τ can belong to the winning set of Player II.

It is clear that if we can satisfy these conditions, then δ wins with probability 1 against any deterministic strategy of Player II, and γ wins with probability 1 against any deterministic strategy of Player I. (Each path has probability measure 0, and by the countable additivity of probability measure, countably many such paths will have measure 0.)

We say a deterministic strategy σ is *killed* if we can satisfy condition 1 for this σ (define killing of τ symmetrically). We kill σ's and τ's in stages. At stage $\alpha < 2^{\aleph_0}$, we kill σ_α and then τ_α, making sure that the winning sets of the two players are disjoint. We denote the winning set of Player I by A and the winning set of Player II by B. Initially, they are empty. They are updated in each stage by transfinite induction on the stages.

At stage α, we put in B all paths of the pruned tree T_{σ_α} corresponding to σ_α that have not already been put in A. Then we put in A all paths of the pruned tree T_{τ_α} corresponding to τ_α that have not already been put in B.

This completes the construction. It is easy to see that the disjointness condition of A and B was automatically satisfied when these sets were constructed. We prove conditions 1 and 2 by transfinite induction on stages. To verify condition 1, consider stage α. In the pruned tree T_{σ_α} for Player I's strategy σ_α, the paths already put in A are $T_{\sigma_\alpha} \cap A$. Since $A \subseteq \cup_{\beta<\alpha} T_{\tau_\beta}$, $T_{\sigma_\alpha} \cap A \subseteq \cup_{\beta<\alpha}(T_{\sigma_\alpha} \cap T_{\tau_\beta})$. By the continuum hypothesis, each $\alpha < 2^{\aleph_0}$ is either finite or countable. $T_{\sigma_\alpha} \cap T_{\tau_\beta}$ is a single path. Therefore, $T_{\sigma_\alpha} \cap A \subseteq \cup_{\beta<\alpha}(T_{\sigma_\alpha} \cap T_{\tau_\beta})$ contains only a countable number of paths.

This proves condition 1. Condition 2 can be proven similarly. □

We notice that the above proof still works with minor modifications even if the continuum hypothesis is replaced by a strictly weaker axiom, Martin's axiom. One of the consequences of Martin's axiom is that for any cardinal κ strictly between $\aleph_0$ and $2^{\aleph_0}$, the union of κ sets (as subsets of R) of Lebesgue measure 0 has Lebesgue measure 0. The topology that we use for the game tree is similar to the real line, and the probability measure on the paths induced by γ or δ is similar to the Lebesgue measure. This consequence thus applies to our case. In fact, we could even replace Martin's axiom by the following strictly weaker axiom: the union of κ many sets of measure 0 has measure 0 for any $\kappa < 2^{\alpha}$.

Although the randomized strategy δ for Player I (γ for Player II) wins against all deterministic strategies of Player II (Player I), it does not win against all randomized strategies of Player II (Player I). In particular, δ does not win against γ (and vice versa). Perhaps the power of randomization in this case results from its easy access to all deterministic strategies at once.

We have addressed the situation when one player uses a randomized strategy and the other uses a deterministic strategy. What happens when both use randomized strategies? Is it possible to obtain an equilibrium solution? That is, is there a pair of randomized strategies of the players such that none can gain by deviating from this randomized strategy? The problem has long been open when the choice space is continuous [Mc]. We conjecture that this is true for games with universally measurable winning sets. A set is universally measurable if it is measurable under any probability measure. Even if the conjecture is confirmed, we still need to know if there is an indeterminate game which is also universally measurable. For a complete understanding of the exact power that randomization provides to infinite games, we need to resolve these problems.

6. Remarks and open problems. While the result of [BBKTW, RaS] is a first step in understanding the relationship between randomized strategies and deterministic strategies in online problems, our study attempts to obtain a more refined understanding of this relationship in terms of computability. For the derandomization hypothesis to hold, we may have to drop in general the computability requirement for our strategies. The answer to our main question is not very satisfactory since it comes from an artificially constructed problem. It would be much more interesting if it could come from natural problems. In [Kn], there is a discussion of computable strategies in the prisoner's dilemma, a natural two-person game that has perplexed game-theorists for years.

Although online problems can be easily formulated as infinite games [BBKTW, RaS], there is no immediate transformation from the latter to the former. Even though we tried to construct a game to emulate the behavior of online problems, one may notice that the construction of the specific game for our main result needs the power of enumerating all computable strategies, which makes the game noncomputable. Thus there is still a gap to be filled between our result and the result of [BBKTW, RaS]. More legitimate candidates for infinite games as online problems are closed computable games. A closed game is computable if there is a Turing machine that can test for membership of basic open sets of the winning set of the adversary. We thus have an immediate question.

1. Does computable derandomization hypothesis hold for all computable closed games?

For a large class of problems, it has been shown in [BBKTW] that derandomiza-

tion may cost an extra multiplicative factor of $(1+\epsilon)$ on the competitive ratio. A related question is whether or not the result of [BBKTW, RaS] can be strengthened to apply to all semicomputably determinate games.

2. If there is an α-competitive randomized strategy against an offline adaptive adversary for a semicomputably determinate game, is there always an α-competitive *computable* deterministic strategy?

We know that the k-server game whose winning set is defined by the set of all those paths which achieve a ratio of less than c for any $c < k$ is semicomputably determinate from the lower-bound results of [MMS]. We also know from the results of Koutsoupias and Papadimitriou [KP] that when $c \geq 2k$, the k-server game is semicomputably determinate for every metric space. (Observe that the two-server game is semicomputably determinate for any c and any metric space since there is a computable algorithm [MMS] whose competitive ratio is 2).

3. Can we show that the k-server game is semicomputably determinate when c is in neither of these ranges?

Acknowledgments. We owe many thanks to the anonymous referees. Their critical readings of the manuscript were very important and allowed the authors to correct several errors in early drafts. We wish to thank Tiko Kameda for many discussions, his encouragement, and the support from his grant during the course of this research. Thanks are also due to Christos Papadimitriou, Prabhakar Raghavan, and Mike Saks for their many helpful suggestions and comments on the early versions of this paper and to Randall Dougherty and Gerald A. Edgar for suggesting some of the references.

TIGHTER UPPER BOUNDS ON THE EXACT COMPLEXITY OF STRING MATCHING*

RICHARD COLE† AND RAMESH HARIHARAN‡

Abstract. This paper considers how many character comparisons are needed to find all occurrences of a pattern of length m in a text of length n. The main contribution is to show an upper bound of the form of $n + O(n/m)$ character comparisons, following preprocessing. Specifically, we show an upper bound of $n + \frac{8}{3(m+1)}(n-m)$ character comparisons. This bound is achieved by an online algorithm which performs $O(n)$ work in total and requires $O(m)$ space and $O(m^2)$ time for preprocessing. The current best lower bound for online algorithms is $n + \frac{16}{7m+27}(n-m)$ character comparisons for $m = 16k + 19$, for any integer $k \geq 1$, and for general algorithms is $n + \frac{2}{m+3}(n-m)$ character comparisons, for $m = 2k + 1$, for any integer $k \geq 1$.

1. Introduction.

String matching is the problem of finding all occurrences of a pattern $p[1 \ldots m]$ in a text $t[1 \ldots n]$. We assume that the characters in the text are drawn from a general (possibly infinite) alphabet unknown to the algorithm. We investigate the time complexity of string matching measuring both the exact number of comparisons and the time complexity counting all operations. As is standard, the time complexity refers to operations performed following preprocessing of the pattern; prepossessing of the text is not allowed. Our goal is to minimize the number of comparisons while still maintaining a total linear-time complexity and a polynomial-in-m preprocessing cost.

Note that if the algorithm is permitted to know the alphabet, then there is a finite automaton which performs string matching by reading each text character exactly once (which can be obtained from the failure function of [KMP77]). However, in this case the running time depends on the alphabet size.

Perhaps the most widely known linear-time algorithms for string matching are the Knuth–Morris–Pratt [KMP77] and Boyer–Moore [BM77] algorithms. We refer to these as the KMP and BM algorithms, respectively. The KMP algorithm makes at most $2n - m + 1$ comparisons and this bound is tight. The exact complexity of the BM algorithm was an open question until recently. It was shown in [KMP77] that the BM algorithm makes at most $6n$ comparisons if the pattern does not occur in the text. Guibas and Odlyzko [GO80] reduced this to $4n$ under the same assumption. Cole [Co91] finally proved an essentially tight bound of $3n - \Omega(n/m)$ comparisons for the BM algorithm, whether or not the pattern occurs in the text. Colussi [Col91] gave a simple variant of the KMP algorithm which makes at most $\frac{3}{2}n$ comparisons. Apostolico and Giancarlo [AG86] gave a variant of the BM algorithm which makes at

most $2n - m + 1$ comparisons. Crochemore et al. [CCG92] showed that remembering just the most recently matched portion reduces the upper bound of BM from $3n$ to $2n$ comparisons.

Recently, Galil and Giancarlo [GG92] gave a string-matching algorithm which makes at most $\frac{4}{3}n$ comparisons. This was the strongest upper bound for string matching known prior to our work. In fact, [GG92] gave this bound in a sharper form as a function of the period z of the pattern; the bound becomes $n + \min\{\frac{1}{3}, \frac{\min\{z, m-z\}+2}{2m}\}$ $(n - m)$.

Galil and Giancarlo [GG91] gave a lower bound of $n(1 + \frac{1}{2m})$ comparisons. For online algorithms, [GG91] showed an additional lower bound of $n(1+\frac{2}{m+3})$. An online algorithm is an algorithm which examines text characters only in a window of size m sliding monotonically to the right; further, the window can slide to the right only when all matching pattern instances to the left of the window or aligned with the window have been discovered. Recently, Zwick and Paterson gave additional lower bounds, including a bound of $\frac{4n}{3}$ for patterns of length 3 in the general case [ZP92].

Our contribution is a linear-time online algorithm for string matching which makes at most $n(1 + \frac{8}{3(m+1)})$ character comparisons. Our algorithm requires $O(m)$ space and $O(m^2)$ preprocessing time and runs in $O(m + n)$ time overall (exclusive of preprocessing). Independently, Breslauer and Galil discovered a similar algorithm which performs at most $n + O(\frac{n \log m}{m})$ comparisons [BG92]; this algorithm requires $O(m)$ preprocessing space and time and runs in linear time. Recently, Hancart [Ha93] and Breslauer et al. [BCT93] have independently shown an upper and lower bound of $(2 - \frac{1}{m})n$ on the number of comparisons required for string matching when comparisons must involve only text characters in a window of size one sliding monotonically to the right.

Nearly matching lower bounds are given in a companion paper [CHPZ92]. They show the following bounds: for online algorithms, a bound of $n + \frac{16}{7m+27}(n - m)$ character comparisons for $m = 16k + 19$, for any integer $k \geq 1$; and for general algorithms, a bound of $n + \frac{2}{m+3}(n - m)$ character comparisons, for $m = 2k + 1$, for any integer $k \geq 1$.

Even if exponential (in m) preprocessing and exponential space are available, it is not clear that the above upper bound can be achieved (assuming that a result independent of the alphabet size is sought). The difficulty is that text characters which are mismatched may need to be compared repeatedly. In order to minimize the total number of comparisons, this has to be offset by other text characters which do not need to be compared. The hardest patterns to handle are those which have proper suffixes which are also prefixes of the pattern. We refer to such substrings as *presufs*.[1] Our algorithm has two parts: a basic algorithm and a presuf handler. The basic algorithm handles primary patterns, i.e., patterns with no presufs; this is also the core of the algorithm for the general case. The presuf handler copes with presufs; its design constituted the main challenge in this work. Understanding the structure of the presufs was a key ingredient in its design. Understanding this structure also led to the new lower bound constructions given in [CHPZ92].

The flavor of the algorithm is as follows. Initially, the pattern is aligned with the left end of the text. Repeatedly, an attempt to match the pattern against the text is made. When a mismatch is found or the pattern is fully matched the pattern is shifted to the right. The goal is to maximize this shift without missing any possible

[1] Presufs are also called *borders* in the literature. Strings without presufs are called *primary* strings.

matches. The basic algorithm has the property that the length of each shift is at least equal to the number of comparisons since the previous shift (or the start of the algorithm). This results in an algorithm that performs at most n comparisons if the pattern has no presuf (the algorithms of [GG92] and [CP89] also have this property).

The presuf handler cannot quite match the performance of the basic algorithm (which is not surprising given that the lower bounds for this problem are larger than n comparisons). Here the approach is to follow the basic algorithm until a suffix which is also a prefix is matched. The only possible matches in which a new instance of the pattern overlaps the current partially (or fully) matched instance arise with an overlap by a presuf. Ignoring, for the moment, problems introduced by periodic patterns, it is the case that at most one of these overlapping pattern instances can result in a match. An elimination is performed to determine which one, if any, of the overlapping pattern instances might result in a match. Following this elimination, a further nontrivial sequence of comparisons is made; this can lead to one of two situations: another match of a suffix which is also a prefix, or a mismatch which causes a return to the basic algorithm. The presuf handler is invoked at most once for every $\frac{m}{2}$ text characters and performs a number of comparisons at most two greater than the number of characters shifted over. (Actually, there are two possible scenarios: an invocation after $\frac{3}{4}m$ text characters and at most two excess comparisons, or an invocation after $\frac{m}{2}$ text characters and at most one excess comparison.) Periodic patterns have the added difficulty that the presuf handler could be invoked more frequently. In this case, we show the additional fact that if the presuf handler is invoked after fewer than $\frac{m}{2}$ text characters, then the number of comparisons is at most the number of characters shifted over.

This structure of the algorithm of Breslauer and Galil is similar; their analogue of the presuf handler works in a completely different way, however.

Section 2 provides several definitions. The basic algorithm is described in section 3. In section 4, the presuf handler for nonperiodic strings is presented. Section 5 gives a technical construction deferred from section 4. Finally, in section 6, the result is extended to periodic patterns.

We remark here that the properties of strings which we develop in section 4 and later are mostly new and appropriate references are given otherwise.

2. Definitions and preliminaries. A string v is a *presuf* of p if it is both a proper suffix and a proper prefix of p. Let x be the length of the largest presuf of p. The *period* of a pattern p with length m is defined to be $m - x$. x is called the *s-period* (or shift period) of p. A string p is *cyclic* in string v if it is of the form v^k, $k > 1$. A *primitive* string is a string which is not cyclic in any string.

A string p is *periodic* if $p = wv^k$, where w is a (possibly null) proper suffix of v and $k > 1$. The smallest such v is called the *core* of p and the corresponding w is called the *head* of p. Note that the core is primitive. A *cyclic shift* of p is any string vu where $p = uv$. $|v$ and $v|$ refer, respectively, to the leftmost and rightmost characters in string v; on occasion, we will call these characters, respectively, the left end and right end of v. Two characters are said to be *distance* d apart if they are separated by $d - 1$ other characters.

For the rest of the paper, let p be a pattern with length m. Let the text t have length n. $p[i]$ denotes the ith character of p, reading from the left end; i is called the *index* of $p[i]$ in p. The same notation and terminology is used for string t.

The algorithm will be comparing the pattern with substrings of the text with which the pattern is aligned; as the algorithm proceeds, the pattern is shifted to the

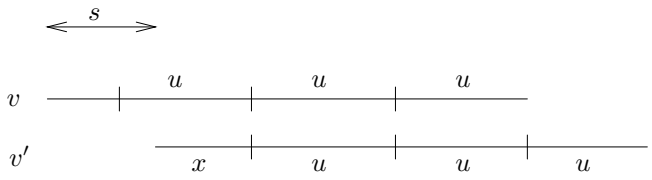

FIG. 1. *Periodicity.*

right across the text. Each possible alignment of the pattern with the text is called an *instance* of the pattern. Note that an instance is not necessarily an occurrence.

For each pair of overlapping instances of the pattern a location at which the two differ, if any, will be precomputed. This location is called the *difference point* of the two instances. Note, however, that for a given pair, a difference point may not exist, but this can happen only if the pattern has a nonempty presuf. Let p_1 and p_2 denote two pattern instances, where $p_1[i]$ is aligned with $p_2[1]$; then dif_i is the difference point if any; i.e., $p_1[dif_i] \neq p_2[dif_i - i + 1]$.

Let q be a pattern instance. Those pattern instances to the right of q, overlapping q, but which do not have a difference point with q are called the *presuf overlaps* of q.

We quote a few standard results concerning strings.

LEMMA 2.1. *Let w be a presuf of string v. If $|w| > \frac{|v|}{2}$, then v is periodic.*

Proof. See Fig. 1. Let $s = |v| - |w|$. Let v' denote string v shifted distance s to the right. Then the portion of v' overlapping v is presuf w which matches the corresponding portion of v. Let u denote the suffix of v' of length s. An easy induction shows that $v = xu^k$ for some $k \geq 2$, where x is a proper suffix of u. □

The following appear in different forms in [Lo82] (see Propositions 1.3.2, 1.3.4, and 1.3.5 there).

LEMMA 2.2 (see [LS62, FW65]). *If x and y are two distinct periods of a string v such that $x + y \leq m + \gcd\{x, y\}$, then $\gcd\{x, y\}$ is also a period of v.*

LEMMA 2.3. *Suppose that $v = xy$, where both x and y are presufs of v. Then v is cyclic in some string w of length $\gcd\{|x|, |y|\}$.*

LEMMA 2.4. *If v is periodic and can be expressed both as $x_1u_1^{k_1}$ and $x_2u_2^{k_2}$, where x_i is a suffix of u_i, $u_1 > u_2$, and $k_1, k_2 \geq 2$, then either u_1 is cyclic in u_2 or both u_1 and u_2 are cyclic in some smaller string.*

3. The basic algorithm. The algorithm in this section also appears in [Col91] and is also exposed in [GG92]. We describe it again for the sake of completeness.

If all the characters in p are identical, then it is easily seen that the KMP algorithm makes at most n character comparisons. Further, if $m = 2$ and p consists of two distinct characters, then the BM algorithm makes at most n character comparisons. Henceforth, we assume that $m > 2$ and that p has at least two distinct characters.

The algorithm proceeds by eliminating pattern instances as possible matches. It repeatedly performs the following two steps: first, it attempts to match the leftmost surviving pattern instance with the aligned text substring; then, it shifts to the next leftmost surviving pattern instance.

After a shift occurs, the strategy followed depends on the nature of the shift. The order in which pattern characters are compared ensures that all the shifts satisfy one of the following two properties.

1. A shift has size greater than or equal to the number of comparisons made since the previous shift. This is called a *basic shift.*
2. When property 1 is not true, a proper prefix x of p is completely matched with the text after the shift. Moreover, x is also a suffix of p. This is called a *presuf shift.*

Following a basic shift, the basic algorithm is continued; a presuf shift results in a transfer to the presuf handler.

The following observation is the key to the basic algorithm. Consider two overlapping instances of the pattern p. Then comparing either of the two pattern characters at their difference point with the aligned text character is sure to eliminate one of the two pattern instances from being a potential match. As long as the overlap is not a presuf of p, there will be a difference point. This is exactly the notion of *duelling* introduced by Vishkin [Vi85].

More formally, let p_a and p_b be the two leftmost surviving pattern instances, where p_b is not a presuf overlap of p_a. Let d be the difference point of p_a and p_b. $p_a[d]$ is compared with the aligned text character. A match eliminates p_b; a mismatch eliminates p_a.

Next, we give the exact sequence of comparisons made by the above strategy. We precompute the following sequence S. S is the sequence of indices $dif_2, dif_3, \ldots, dif_m$ omitting repetitions and undefined indices. Henceforth, where no ambiguity will result, we will use the sequence S to refer both to the indices it contains and to the corresponding characters in p_a.

The characters in p_a are compared with their corresponding text characters in two passes, stopping if a mismatch is found. In pass 1, those characters in p_a contained in S are compared in sequence. If all of these match, then the remaining pattern characters are compared from right to left in pass 2.

LEMMA 3.1. *If a mismatch occurs at the character given by the kth index in S, then the resulting shift has size at least k.*

Proof. Let the kth index in S be dif_l. Note that $k < l$. Recall that $l \leq dif_l \leq m$ and $p[dif_l] \neq p[dif_l - l + 1])$. Suppose for a contradiction that the shift was of length $j < k$. Let p_a and p_b be the pattern instances as specified in the algorithm above, before this shift. Note that p_b becomes p_a after the shift; i.e., p_b is p_a shifted j units. But then p_a and p_b have a difference point and hence dif_{j+1} is defined. dif_{j+1} is the ith index in S, for some $i \leq j$; hence since $j < k$, dif_{j+1} occurs prior to dif_l in S. Therefore, $p_a[dif_{j+1}]$ would have been matched against the text and one of p_a or p_b eliminated before $p_a[dif_l]$ was compared. The contradiction proves the lemma. □

Consequently, all shifts resulting from mismatches in pass 1 are basic shifts. When a basic shift is made, the basic algorithm is restarted. It is easy to see that if all shifts are basic shifts, then the total number of comparisons made is upper bounded by n.

Next, suppose that all comparisons in pass 1 result in matches.

LEMMA 3.2. *Suppose pass 2 results in a mismatch at $p_a[l]$. The resulting shift has length at least l.*

Proof. Suppose for a contradiction that the resulting shift has length i, $i < l$. Let p_b be p_a shifted distance i. Then l is a difference point for p_a and p_b; hence one of p_a and p_b would have been eliminated in pass 1, a contradiction. □

Consequently, for each shift resulting from pass 2 with length less than the number of comparisons made since the previous shift, a proper prefix of p (which is also a suffix of p) is matched with the text; i.e., it is a presuf shift. The main challenge in minimizing the exact number of comparisons is to handle presuf shifts.

Preprocessing. The sequence S, as defined above, is not unique. We show that a particular instance of S can be precomputed in a manner akin to the computation of the KMP shift function or the BM shift function. The KMP shift function comprises, for each j, $1 < j \leq m$, a number s_j. s_j is the largest i, $i < j$, such that $p[1 \ldots i-1] = p[j-i+1 \ldots j-1]$ and $p[i] \neq p[j]$; note that $i = dif_{j-i+1}$. If no such i exists, then s_j is defined to be zero. Consider the set of all those values of j for which $s_j > 0$. Furthermore, let this set be ordered by the increasing value of $j - s_j + 1$. This provides the sequence S. For every k, $2 \leq k \leq m$, if dif_k is defined, then for some $l \in S$, $k \leq l \leq m$, $p[1 \ldots l-k] = p[k \ldots l-1]$ and $p[l-k+1] \neq p[l]$; hence the value dif_k occurs in S (though not necessarily indexed by k). Finally, it is straightforward to compute S in $O(m)$ time.

4. The presuf handler. In this section, the presuf handler for nonperiodic patterns p is described. This presuf handler also deals with some presuf shifts for periodic p, as specified in the next few paragraphs.

With each presuf shift, we associate a presuf x'_1 of p, defined as follows. If p is not periodic, then x'_1 is the longest presuf of p. Otherwise, suppose $p = u_p v_p^{i_p}$ is periodic with core v_p and head u_p. Then if the presuf of p matching the text is at least $|v_p|$ long, $x'_1 = u_p v_p^{i_p - 1}$. Otherwise, if the above presuf is shorter than $|v_p|$, then x'_1 is defined to be the longest presuf of p of length less than $|v_p|$.

In this section, we give an algorithm for handling presuf shifts for the case $|x'_1| < \frac{m}{2}$. The case $|x'_1| \geq \frac{m}{2}$ is considered in section 6. Note that $|x'_1| < \frac{m}{2}$ always holds for nonperiodic p and may hold for periodic p.

Consider the situation immediately following a presuf shift. Some prefix of p, which is also a presuf, matches the text substring that it is aligned with. It is convenient for the presuf handler to assume that the pattern was shifted by $m - |x'_1|$ characters and that x'_1 matches the text. Note that this will not be the case if pass 2 in the basic algorithm mismatches before x'_1 is completely matched. A simple check will prevent the declaration of any incorrect complete match that might result from the above assumption. To facilitate this check, a variable t_{last} is used. Suppose pass 2 in the basic algorithm ends in a mismatch. Then t_{last} is set to the index of the text character where the mismatch occurred. Otherwise, if no mismatch occurs, $t_{\text{last}} \leftarrow \phi$.

Since $|x'_1| < \frac{m}{2}$, $p = x'_1 u x'_1$, for some string u. Let t_A be the substring of the text aligned with the prefix x'_1 of p immediately following the presuf shift; note that x'_1 matches t_A. Order all the presufs of x'_1 by decreasing length and let this order be $x_1, x_2, x_3, \ldots, x_k, x_{k+1}$, where x_k is the smallest nonnull presuf of x'_1 and x_{k+1} is the null string and hence a trivial presuf of x'_1. Note that $x_1 = x'_1$. Let the future instances of p (i.e., potential match instances) before its left end slides beyond $t_A|$, in left to right order, be $p_1, p_2, \ldots, p_k$. Let p_{k+1} be the pattern instance whose left end is to the immediate right of $t_A|$. Then p_i, $1 \leq i \leq k+1$, is the pattern instance with the prefix x_i of p aligned with the suffix x_i of t_A. x_i is said to be the presuf associated with p_i. $p_1, p_2, \ldots, p_k, p_{k+1}$ are called the *presuf pattern instances.*

LEMMA 4.1. *If $|x'_1| < \frac{m}{2}$, then at most one of $p_1, \ldots, p_k, p_{k+1}$ can lead to a complete match.*

Proof. This is a proof by contradiction. Suppose some two of them, say p_i and p_j, $i < j$, each result in a complete match. It follows that there is a prefix of p of size $m - |x_i| + |x_j|$ that matches a suffix of p. Since $|x_i| - |x_j| < \frac{m}{2}$, $m - |x_i| + |x_j| > \frac{m}{2}$; also, $|x_i| - |x_j| \leq |x'_1|$. This implies that p is periodic with core of length at most $|x'_1|$, contrary to our assumption. □

The presuf handler begins by eliminating all but at most one of $p_1, p_2, \ldots, p_k, p_{k+1}$.

This is carried out by a procedure that performs $j \leq k$ comparisons; at most two of these comparisons are unsuccessful. We seek to minimize the number of unsuccessful comparisons because while successful comparisons can be remembered, unsuccessful comparisons may lead to repeated comparison of some text characters.

The elimination procedure is described in section 4.1. The remainder of the presuf handler procedure for all but two special cases is given in section 4.2, and its analysis is presented in section 4.3. The special cases are handled in section 4.4. Finally, data structure details are described in section 4.5.

4.1. Elimination strategy. Before describing the exact sequence of comparisons made by the elimination strategy, we need to understand some structural properties of these overlapping instances of p.

LEMMA 4.2. *Suppose $x_i = uv^l$ is the ith presuf, where u is a proper suffix of v, v is primitive, and $l \geq 2$. Then $x_{i+1} = uv^{l-1}$.*

Proof. Certainly, uv^{l-1} is a presuf, so the only question is whether there is a presuf x between uv^l and uv^{l-1}. Suppose there is such an x. Since $|uv^{l-1}| < |x| < |uv^l|$ and since x is a prefix of uv^l, the suffix of x of length $|v|$ is a cyclic shift of v. But x is a suffix of uv^l, which implies that a proper cyclic shift of v matches v. By Lemma 2.3, v is cyclic, contrary to our assumption. □

LEMMA 4.3. *The presuf pattern instances can be partitioned into $g = O(\log m)$ groups*[2] *$A_1, A_2, \ldots, A_g$. The groups preserve the left-to-right ordering of the pattern instances; i.e., the pattern instances in group A_i are all to the left of those in group A_{i+1}, for $i = 1, \ldots, g-1$. Let B_i be the set of presufs associated with the pattern instances in A_i. Then either $B_i = \{u_i v_i^{k_i}, \ldots, u_i v_i^3, u_i v_i^2\}$ or $B_i = \{u_i v_i^{k_i}, \ldots, u_i v_i\}$ or $B_i = \{u_i v_i^{k_i}, \ldots, u_i v_i, u_i\}$, where $k_i \geq 1$ is maximal, u_i is a proper suffix of v_i, and v_i is primitive.*

Proof. The proof is by construction. The groups are constructed in left-to-right order. Inductively suppose A_i is being built presently and all presuf pattern instances with associated presufs longer than $u_i v_i^{k_i}$ have been placed in groups to the left of A_i.

$\{u_i v_i^{k_i}, \ldots, u_i v_i^2\}$ are all added to B_i. $u_i v_i$ is also added if and only if it is not periodic; otherwise, $u_i v_i$ starts set B_{i+1}. By Lemma 4.2, all presuf pattern instances with associated presufs longer than $u_i v_i$ are in group A_i or by induction in a group to its left. In addition, if u_i is empty and v_i has no presufs, then u_i is also added.

The maximality of k_i can be seen as follows. Suppose k_i is not maximal; i.e., there exists a presuf w of the form $u_i v_i^{k_i+1}$, $k_i+1 \geq 2$. By the inductive hypothesis describing the construction, this presuf would already be in one of the groups $B_1, \ldots, B_{i-1}$. By Lemma 4.2, it follows that w is the smallest presuf in B_{i-1}. w is clearly periodic. By construction, $w = u_{i-1} v_{i-1}^2 = u_i v_i^{k_i+1}$, $k_i + 1 \geq 2$. Then by Lemma 2.4, v_{i-1} must be cyclic, which contradicts the assumption that v_{i-1} is primitive. Thus k_i must be maximal.

This shows that the presuf pattern instances are partitioned into groups. It remains to show that there are only $O(\log m)$ groups. Let x_{j_i} be the leftmost presuf in B_i. If $x_{j_{i+1}} = u_i v_i$, then $|x_{j_{i+1}}| \leq \frac{2}{3}|x_{j_i}|$, and otherwise $|x_{j_{i+1}}| \leq \frac{1}{2}|x_{j_i}|$. (The latter claim follows because $x_{j_{i+1}}$ is both a prefix and a suffix of x_{j_i} and this prefix and suffix are nonoverlapping.) The $O(\log m)$ bound follows immediately. □

LEMMA 4.4. *The groups satisfy the following properties.*

Property 1. *Consider the presufs x_i corresponding to the pattern instances p_i in some group A_j. For $j \neq g$, all of these presufs x_i, except possibly the rightmost one,*

[2] Actually, a sharper bound of $\log_\phi m$ groups is known [KMP77, B94], where ϕ is the golden ratio.

are periodic with the same core and head. For $j = g$, all but the rightmost two presufs are periodic with the same core and head.

Property 2. *Let p_i be the rightmost instance in its group. If x_i is periodic then so is x_{i+1}.*

Property 3. *Suppose p_i is the rightmost instance in its group A_j and x_i is periodic with head u and core v; then $|x_{i+2}| < |v|$. Further, suppose $x_{i+1} = u'(v')^l$, where v' is primitive and u' is a proper suffix of v'. Then $|v'| > |u|$.*

Property 4. *Suppose p_i is the rightmost instance in its group A_j, where $|A_j| > 1$; further, suppose that x_{i-1} is periodic with core v and x_i is not periodic. Then $|x_{i+1}| < |v|$.*

Property 5. *Both p_k and p_{k+1} are in the group A_g.*

Proof. Let p_i be in group A_j.

Property 1 is true by definition. To see Property 2, note that since x_i is periodic, $x_i = uv^l$, where u is a proper suffix of primitive v and $l \geq 2$. But if $l > 2$, then the pattern instance corresponding to either presuf uv^2 or presuf uv would be the rightmost item in A_j. Thus $l = 2$; however, by definition, the pattern instance corresponding to uv is not in A_j only if uv is periodic. Finally, by Lemma 4.2, $x_{i+1} = uv$.

Property 3 can be seen as follows. As in the previous paragraph, $x_i = uv^2$ and $x_{i+1} = uv$. Again uv is periodic; that is, $uv = u'(v')^l$ for some $l \geq 2$, where u' is a proper suffix of v' and v' is primitive. By Lemma 4.2, $x_{i+2} = u'(v')^{l-1}$. Suppose $|v'| \leq |u|$. Since v is primitive, there must be a substring v' of $u'(v')^l = uv$ which straddles the boundary between u and v. Thus the substring of $u'(v')^l$ aligned with the rightmost $|v'|$-sized substring of u is a proper cyclic shift of v'. But since u is a suffix of v this substring is also identical to v'. By Lemma 2.3, v' is cyclic, a contradiction. Thus $|v'| > |u|$ and hence $|x_{i+2}| < |v|$.

Property 4 can be seen as follows. As with the previous properties, it follows that $x_i = uv$, where u is a proper suffix of v and v is primitive. If $|x_{i+1}| \geq |v|$, then $|x_{i+1}| > |x_i|/2$. But x_{i+1} is a presuf of x_i; by Lemma 2.1, x_i would be periodic, a contradiction.

Property 5 can be seen as follows. Since x_k is the smallest nonnull presuf of p, no nonnull prefix of x_k matches a suffix of x_k. Therefore, all strings in B_g have the form $u_g v_g^l$, $0 \leq l \leq k_g$, where u_g is the null string and $v_g = x_k$. Since both x_k and x_{k+1} have this form, Property 5 is true. □

Remark. The elimination strategy described below and the algorithm in section 4.2, which uses this elimination strategy to handle presuf shifts, work for most patterns p. However, there are some patterns for which presuf shifts must be handled differently. The reason for this is made clear in section 5, which gives a technical portion of the analysis of the algorithm in section 4.2. These exception patterns are precisely those in which x_k, the smallest nonnull presuf, is a single character and g, the number of groups, is one. Presuf shifts for these exception patterns are handled separately in section 4.4.

DEFINITION. *A clone set is a set $Q = \{s_1, s_2, \ldots\}$ of strings, with $s_i = uv^{k_i}$, where u is a proper suffix of primitive v and $k_i \geq 0$. A set U of pattern instances is* half-done *if $|U| \leq 2$ or the set of associated presufs forms a clone set.*

The following lemma is the key to our elimination strategy.

LEMMA 4.5. *Consider three presuf pattern instances p_a, p_b, p_c, $a < b < c$. (The order of the indices corresponds to the left-to-right order of the pattern instances.) Suppose the set $\{x_a, x_b, x_c\}$ is not a clone set. Then there exists an index d in p_1*

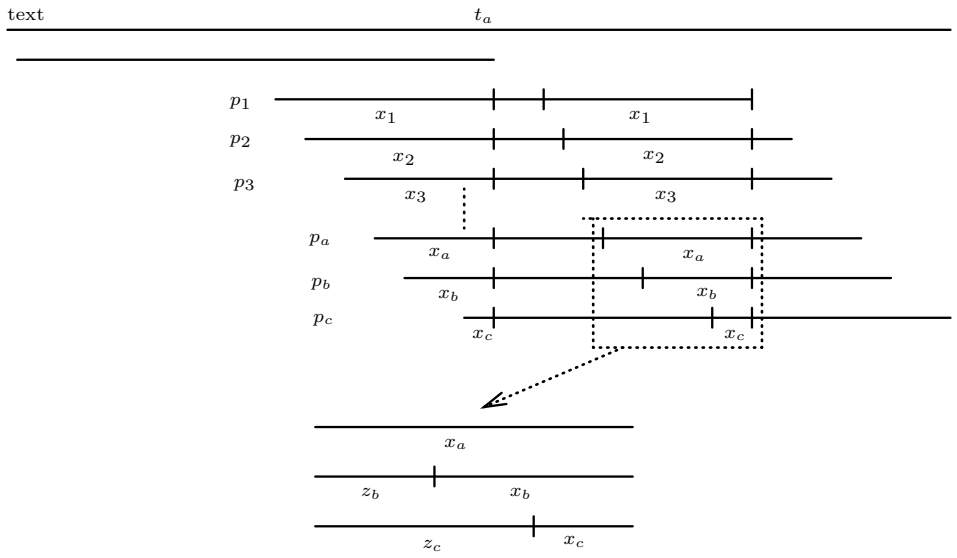

FIG. 2. *Overlapping pattern instances.*

with the following properties. The characters in $p_1, p_2, \ldots, p_a$ *aligned with* $p_1[d]$ *are all equal*; *however, the character aligned with* $p_1[d]$ *in at least one of* p_b *and* p_c *differs from* $p_1[d]$. *Moreover,* $m - |x_a| + 1 \leq d \leq m$; *i.e.,* $p_1[d]$ *lies in the suffix* x_a *of* p_1.

Proof. The substrings of $p_1, \ldots, p_a$ aligned with the suffix x_a of p_1 are all identical to the string x_a. Let the substring of p_b (respectively, p_c) aligned with the suffix x_a of p_1 be y_b (respectively, y_c). See Fig. 2. It suffices to show that at least one of y_b or y_c is not identical to x_a. Suppose for a contradiction that $y_b = y_c = x_a$.

Let $y_b = z_b x_b$ and $y_c = z_c x_c$. Note that z_b is a suffix of z_c. Since $y_b = y_c$, a simple induction shows that $y_b = uv^l$, where u is a proper prefix of v and $l \geq 1$, $|v|$ is either $|x_b| - |x_c|$ or some proper divisor of $|x_b| - |x_c|$, and v is primitive. Since $x_a = y_b$, if $l \geq 2$, x_a is periodic with core v.

First, suppose x_a is periodic with head u and core v. By Lemma 4.2, if $|x_b| > |uv|$, $x_b = uv^h$ for some h, $1 \leq h < l$. If $|x_b| < |uv|$, since $|x_b| - |x_c|$ is a multiple of $|v|$, $|x_b| = |v| + |x_c|$, so $x_b = wv$ for some string w, $|w| < |u|$. But then wv is a prefix of uv, which implies that v is cyclic; this is a contradiction. Thus $x_b = uv^h$. Since $|x_b| - |x_c|$ is a multiple of $|v|$, $x_c = uv^j$ for some j, $0 \leq j < h$, contradicting the fact that $\{x_a, x_b, x_c\}$ is not a clone set.

Consequently, $x_a = uv$. If x_a is not periodic, then $|x_b| < \frac{|x_a|}{2}$ and $|v| \leq |x_b| - |x_c| < \frac{|x_a|}{2}$. But then $|x_a| < 2|v| < |x_a|$, a contradiction. If x_a is periodic, $x_a = u'(v')^k$ for some $k \geq 2$. Also, $|v'| > |u|$ by Property 3 of Lemma 4.4. Hence $|x_b| < |v|$. But $|x_c| \leq |x_b| - |v| < 0$, a contradiction. □

Lemma 4.5 implies that a comparison of $p_1[d]$ with the aligned text character has the following effect: if it is a mismatch, all of $p_1, \ldots, p_a$ are eliminated, while if it is a match, at least one of p_b and p_c is eliminated.

Lemma 4.5 enables the elimination of essentially all but one group of pattern instances with at most one mismatch. At each step, for the rightmost d yielded by Lemma 4.5, $p_1[d]$ is compared with the aligned text character. If there is a mismatch, the surviving set of pattern instances is half-done, as we show in the following lemma. If there is no such d, the surviving set of pattern instances is half-done by Lemma

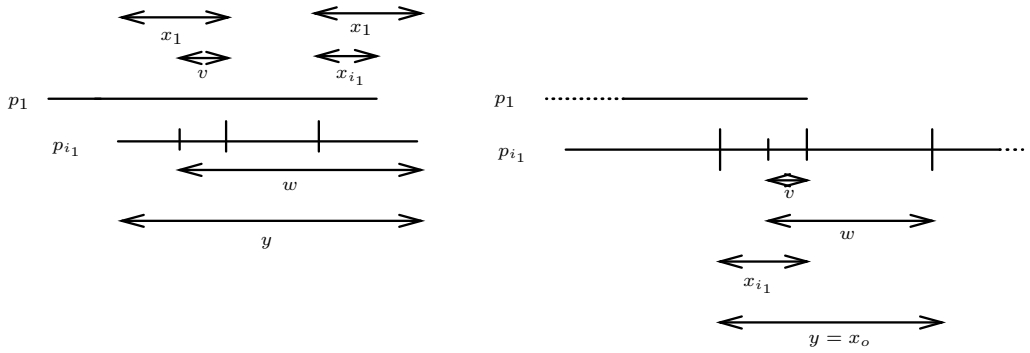

FIG. 3. (a) $p_{i_1} \in A_1$. (b) $p_{i_1} \notin A_1$.

4.5. This procedure comprises Phase 1 of the elimination procedure.

LEMMA 4.6. *If there is a mismatch in Phase* 1 *of the elimination procedure, the set* X *of surviving pattern instances is half-done.*

Proof. Suppose it was not; i.e., for some subset $\{p_a, p_b, p_c\}$ of X, $\{x_a, x_b, x_c\}$ is not a clone set. The characters in the x_i suffix of p_1, for $i = a, b, c$, match the aligned substring of p_i. Hence the mismatch at $p_1[d]$, which created set X, lies to the left of the suffix x_i of p_1, for $i = a, b, c$. However, by Lemma 4.5, at least one of p_a, p_b, and p_c could have been eliminated by a comparison made within the suffix of p_1 of size $\max\{|x_a|, |x_b|, |x_c|\}$. This contradicts the choice of d as the rightmost index at which a comparison eliminates some pattern instance. □

The elimination among the remaining half-done set of pattern instances also requires at most one mismatch.

LEMMA 4.7. *Let* $O = \{p_{i_1}, p_{i_2}, \ldots, p_{i_l}\}$, $l \geq 2$, *be an uneliminated half-done set and let* $p_{i_1} \in A_r$. *Then* $x_{i_j} = uv^{h-j}$, *where* u *is a proper suffix of primitive* v *and* $h \geq l$. *Further, there exists an index* d *such that the characters in* $\{p_{i_1}, p_{i_2}, \ldots, p_{i_{l-1}}\}$ *aligned with* $p_{i_l}[d]$ *are all equal, but differ from the character* $p_{i_l}[d]$. $p_{i_l}[d]$ *is aligned with or to the left of* $p_{i_1}[m]$. *In addition, if* $p_{i_1} \notin A_1$ *then* $p_{i_l}[d]$ *is to the right of* $p_1[m]$ *and within distance* $|x_o| - |x_{i_1}|$ *of* $p_1[m]$, *where* p_o *is the rightmost pattern instance in* A_{r-1}. *If* $p_{i_1} \in A_1$, *then* $p_{i_l}[d]$ *is to the right of* t_A *and aligned with or to the left of* $p_1[m]$.

Proof. Each x_{i_j}, $1 \leq j \leq l$, is of the form uv^{h_j}, for some $h_j \geq 0$, where u is a proper suffix of primitive string v.

See Fig. 3. Let y denote the string p_{i_1} if $p_{i_1} \in A_1$ and the string x_o otherwise. Clearly, y cannot be periodic with core v. If $p_{i_1} \in A_1$, then let w denote the suffix of p_{i_1} of length $m - |x_1| + |v|$. If $p_{i_1} \notin A_1$, then let w denote the substring of p_{i_1} which has length $|x_o| - |x_{i_1}| + |v|$ and which overlaps p_1 in exactly $|v|$ characters. Note that $w \neq uv^{h'}$, where $h' > 0$; otherwise, by Lemma 2.3 and the fact that v is primitive, the suffix of y of length $|w| - |v|$ is cyclic in v and therefore y is periodic with core v, contrary to our assumption.

Let w' be the smallest suffix of w which is not of the form $u'v^{h'}$, with u' a suffix of v and $h' > 0$. Define d to be the index in p_{i_1} corresponding to $|w'|$. Clearly, $|w'| > |x_{i_1}| \geq (l-1)|v|$. Therefore, $p_{i_1}[d + (l-1)|v|]$ is a character in w. In addition, if $p_{i_1} \in A_1$, then $|w'| > |x_1|$ and therefore $p_{i_1}[d + (l-1)|v|]$ is aligned with or to the left of $p_1[m]$. The lemma follows if $p_{i_l}[d]$ is aligned with $p_{i_1}[d + (l-1)|v|]$ and the characters in $p_{i_1}, \ldots, p_{i_{l-1}}$ which are aligned with $p_{i_l}[d]$ are all identical and different

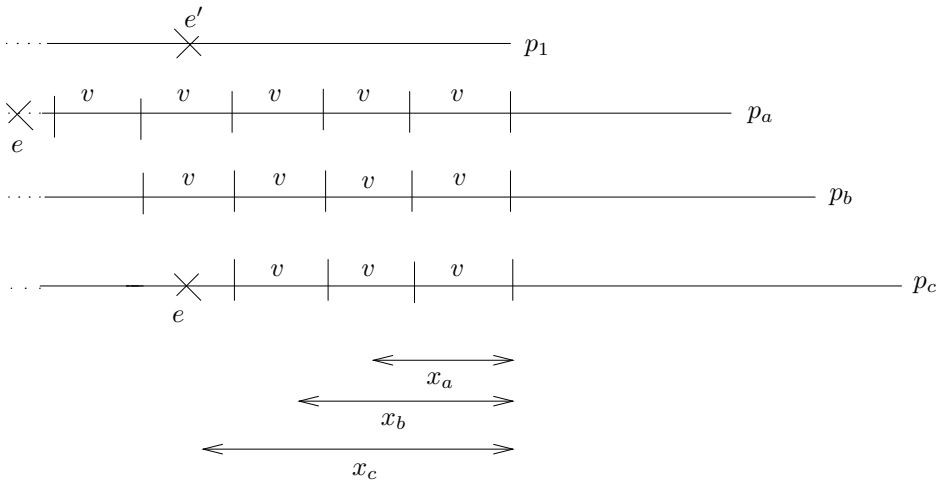

FIG. 4. *The half-done set is complete.*

from $p_{i_l}[d]$. We show that these two claims are indeed true.

First, we show that $|x_{i_j}| - |x_{i_{j+1}}| = |v|$, for $1 \le j < l$. Suppose for a contradiction that there is a pattern instance $p_b \notin O$ with $x_b = uv^{h''}$, $h'' > 0$, and there are pattern instances $p_a, p_c \in O$, p_a to the left of p_b and p_c to the right of p_b. See Fig. 4. Let $p_a[e]$ be the rightmost character in p_a such that the substring of p_a which starts at $p_a[e]$ and overlaps p_1 is longer than $|x_a|$ and not periodic with core v. Consider the character $p_1[e']$ aligned with $p_c[e]$. The portions of p_a, p_b, and p_c which overlap the suffix of p_1 to the right of e' are all identical. If Phase 1 had stayed to the right of e', then p_a, p_b, and p_c would all have been eliminated by the mismatch at the end of Phase 1. Thus $p_1[e']$ must have been compared in Phase 1. A mismatch at e' eliminates p_a and p_b while a match eliminates p_c. Either way, a contradiction results.

Finally, note that the character in p_{i_j}, $1 \le j \le l-1$, which is aligned with $p_{i_l}[d]$ is precisely the character $p_{i_l}[d + (l-j)|v|]$. But $p_{i_l}[d] \ne p_{i_l}[d + |v|] = p_{i_l}[d + 2|v|] = \cdots = p_{i_l}[d + (l-1)|v|]$. □

COROLLARY 4.8. *To eliminate all but one of the pattern instances in any half-done set (in particular, the Phase* 1 *survivors set)* $\{p_{i_1}, p_{i_2}, \ldots, p_{i_j}\}$*, it suffices to compare a sequence of characters with the property that any two consecutive characters in the sequence are distance* $|v|$ *apart, where* v *is the core of* x_{i_1}*. Further, the pattern instances in this set are eliminated in right-to-left order by this comparison sequence (i.e., in decreasing value of* j*).*

Let p_{i_l} be as in Lemma 4.7; the character in p_{i_1} aligned with $p_{i_l}[d]$ is compared with the aligned text character. A match eliminates p_{i_l}; a mismatch leaves only p_{i_l} surviving. Iteration of this step ends with one pattern instance surviving after at most one mismatch. This comprises Phase 2 of the elimination procedure.

The sequence of comparisons made in Phase 2 is clearly a right-to-left sequence. If p_1 is eliminated in Phase 1, then all comparisons in Phase 2 are made to the right of the characters compared in Phase 1. Otherwise, if p_1 is not eliminated in Phase 1, all comparisons in Phase 2 are made to the left of the characters compared in Phase 1.

We recapitulate the elimination strategy now. In Phase 1, characters in p_1 at in-

dices given by a precomputed sequence S_1 are compared in sequence until a mismatch occurs or until the sequence is exhausted. Associated with a mismatch at the ith comparison given by S_1 is an auxiliary sequence S_{2_i} of indices. If a mismatch occurs at the ith comparison in S_1, Phase 2 begins and comparisons are now made according to the auxiliary sequence S_{2_i}. A mismatch at any index in the relevant auxiliary sequence completes the elimination process as does the exhaustion of that auxiliary sequence. In either case, only one pattern instance from the set $\{p_1, \ldots, p_k, p_{k+1}\}$ survives.

Let $|S_1| = j$. The sequences S_1 and $S_{2_1}, S_{2_2}, \ldots, S_{2_j}$ collectively form a tree ET (the *elimination tree*). ET is a binary tree. Each internal node x of ET stores an index indicating the comparison to be made. Each internal node has two children. The computation continues at the left child if the comparison at x is successful and at the right child otherwise. The computation starts at the root of ET. Each external node stores the one pattern instance to survive the two phases of comparisons leading to that external node. The external nodes are also called terminal nodes. Note that no pattern instance p_i can be the survivor at two distinct terminal nodes of ET. This is because one of the two outcomes of the comparison at the least common ancestor of these two nodes in ET is bound to eliminate p_i. It follows that the size of ET is $O(k)$.

The total number of mismatches occurring in the elimination process is at most two because each phase terminates when a mismatch occurs.

LEMMA 4.9. *All but at most one of $p_1, \ldots, p_k, p_{k+1}$ can be eliminated by making up to k comparisons using the $O(k)$-sized binary comparison tree ET. At most two of these comparisons result in mismatches. The sequence of comparisons made by the elimination strategy consists of two left-to-right sequences. The second sequence is either entirely to the right or entirely to the left of the first one.*

4.2. Strategy for handling presuf shifts. Subsequent to the elimination due to tree ET, the presuf handler proceeds in a manner reminiscent of the basic algorithm. That is, there is a current pattern instance, p_a, which is being matched and which is the leftmost surviving pattern instance. The next leftmost surviving pattern instance, p_b, which has a difference point with p_a is a candidate for elimination. Indeed, a comparison of p_a with the text is made at the difference point.

The analysis of the presuf handler has the following flavor. With a few exceptions, comparisons are charged to distinct text characters. To be precise, for each suffix shift, at most two comparisons are charged to the shift rather than to text characters. Even more precisely, if two comparisons are charged to the shift, the next presuf shift is at distance at least $\frac{3(m+1)}{4}$ to the right, and otherwise it is at distance at least $\frac{m+1}{2}$ to the right. The complexity bound of the algorithm now follows readily.

THEOREM 4.10. *The algorithm performs at most $n + \frac{8}{3(m+1)}(n-m)$ character comparisons.*

There are three ways in which text characters are charged:

(i) The character compared is charged.

(ii) The text character aligned with the left end of the pattern instance eliminated by the comparison is charged.

(iii) The text character to the immediate right of $t_A|$ (i.e., aligned with $|p_{k+1}$) is charged.

The three charging methods do not interact readily. To ensure that no text character is charged twice, the switching from one charging method to the other will occur only at carefully selected points in the algorithm. In addition, mismatches

are not charged according to rule (i) since the text characters in question may be compared again.

Basically, charging method (i) is used if a pattern instance is successfully matched (at least up to a suffix which is a presuf). Charging method (iii) is used only for the comparison that eliminates the presuf pattern instance which survives the elimination procedure ET. Charging method (ii) is used otherwise. A partial exception arises for the characters compared by procedure ET; this is discussed further below.

Following the use of procedure ET, the aim is to perform comparisons essentially as in the basic algorithm, that is, to compare the character at the difference point of the two leftmost surviving pattern instances which are not prefix overlaps of each other. The analysis ceases to be as straightforward because of the additional $j \leq k$ comparisons performed by procedure ET; indeed, to cope with this, a modified form of the basic algorithm is needed.

There are two objectives:

1. to avoid repeating comparisons at the text characters successfully compared by procedure ET;

2. to perform essentially j fewer comparisons than in the basic algorithm.

Objective 1 is achieved by keeping a record of the successful comparisons in a bit vector of length roughly m.

The major difficulty, however, is caused by the method used for charging the j comparisons made by procedure ET. It is natural to charge these comparisons to the text characters compared. Unfortunately, this may conflict with charging using method (ii). To avoid this difficulty, a single additional comparison, with text character t_b, is performed before using procedure ET. The following lemma can then be shown.

LEMMA 4.11. *For each text character t_c compared by procedure ET, with at most $\alpha \leq 2$ exceptions, there is a distinct previously uncharged text character $t_{c'}$, with $t_{c'}$ aligned with or to the left of t_c and to the right of $|p_{k+1}$, such that the pattern instance q_c whose left end is aligned with $t_{c'}$ mismatches either the text character t_b or some text character matched in procedure ET.*

Let β be the number of mismatches performed by procedure ET. Then, in addition, $\alpha + \beta \leq 2$.

The lemma is proven by specifying a transfer function f, which associates c with c'. The form of f depends on the sequence of comparisons performed by procedure ET. The proof of the lemma is quite nontrivial; it is deferred until section 5.

Lemma 4.11 is used as follows. Let q_e be the next pattern instance to match the text (or at least to have a suffix, which is also a presuf, matching the text). All pattern instances to the left of q_e, eliminated by comparisons made after the use of procedure ET, are charged used charging method (ii). Using the transfer function, those comparisons to the left of $|q_e$ made by procedure ET are charged to text characters which are not otherwise charged. By contrast, text characters aligned with q_e are charged using charging method (i). There will be no more than two comparisons performed by the presuf handler that are not thereby charged to a text character; these comparisons are charged to the presuf handler itself.

The algorithm requires a total of five subphases, whose details depend on exactly how q_e arises.

It is helpful to distinguish three scenarios that may ensue. To this end, let p_e denote the presuf pattern instance to survive the elimination using tree ET. In addition, let t_a denote the text character $t_A|$.

The three scenarios follow:

1. All pattern instances overlapping p_e are eliminated apart from its presuf overlaps, and p_e or at least a suffix of p_e is matched.

2. p_e is eliminated. In addition, there is some pattern instance q_c overlapping p_e such that all pattern instances overlapping q_c are eliminated apart from its presuf overlaps; further, q_c or at least a suffix of q_c is matched.

3. p_e is eliminated, as are all pattern instances overlapping p_e. Let q_d denote the leftmost surviving pattern instance in this case.

The first scenario causes no problems from the perspective of the analysis. It suffices to ensure that none of the successful comparisons made by ET are repeated. The third scenario is handled by using charging scheme (iii) for the comparison which eliminates p_e and charging scheme (ii) for the remaining comparisons in the post-ET phase. Lemma 4.11 ensures that for each comparison made by ET (with at most two exceptions) with a text character strictly between t_a and $|q_d$, there is a distinct pattern instance whose left end lies strictly between $|p_{k+1}$ and $|q_d$ and which is eliminated by the comparisons made by ET plus the one other comparison at text character t_b. Again, this leads to the desired complexity bound without difficulty.

The second scenario provides the greatest difficulty. In order to avoid unnecessary comparisons, the locations of successful comparisons are recorded. Then if a difference point occurs at one of these matched text characters, the present pattern instance p_b (see the first paragraph of the subsection) can be removed without further comparisons. However, following a mismatch, it is not clear how to maintain this property: with only linear storage, it is not clear how to ensure that the current pattern instance following the mismatch agrees with the text on a previously matched character, at least if the total work bound is to be linear. (There is no problem if exponential-in-m space is available for precomputed structures.) To avoid this difficulty, only the successful comparisons since the last mismatch are recorded.

In fact, this is not quite good enough. It appears necessary to keep track of the characters compared by procedure ET regardless of how many characters are compared. This avoids subsequent comparison of these characters. Indeed, any pattern instances mismatching on one or more of these characters are eliminated immediately after the computation with procedure ET. This is done with the help of precomputed information.

With this motivation, we proceed with a precise description of the presuf handler procedure. It proceeds in five steps.

Step 1 (before the use of tree ET). The characters in $p_1, \ldots, p_k$ aligned with $p_1[m]$, the rightmost character in p_1, are identical. If the character in p_{k+1} aligned with $p_1[m]$ is also identical to it, then $p_1[m]$ is compared with the aligned text character. A mismatch eliminates all of $p_1, \ldots, p_k, p_{k+1}$ and the basic algorithm is restarted with $|p_a$ placed immediately to the right of $|p_{k+1}$. A match is not immediately beneficial since it does not eliminate any of $p_1, \ldots, p_k, p_{k+1}$. However, it ensures the elimination of sufficiently many appropriate pattern instances for scenarios 2 and 3 described above.

Step 2. The elimination strategy using tree ET is applied to the pattern instances $p_1, \ldots, p_k, p_{k+1}$.

Following Step 2, at most one presuf pattern instance survives. Call it p_e. Let Q denote the set of pattern instances which overlap p_e and have their left end to the right of $|p_{k+1}$. In the elimination process, some elements of Q may have also been eliminated from being potential matches. They need not be reconsidered. Indeed,

since the characters successfully matched in Step 2 must not be compared anew, it appears that these pattern instances must not be considered anew. To this end, a subset Q_x of Q is associated with each terminal node x in ET.

Let T_x denote the indices of the text characters successfully compared in Steps 1 and 2. Q_x contains those pattern instances in Q which match at all the text indices in T_x, except possibly the last. This seemingly odd exception is necessary in order to store Q_x efficiently. Actually, Q_x satisfies further constraints, but they are not needed for this section. The complete definition of Q_x and the method for computing it are described in section 4.5. Here it suffices to work with the following property: all but at most two of the comparisons in Steps 1 and 2 are successful and are remembered by pattern instances in Q_x.

Suppose that the elimination process terminates at terminal node x. Let $Q' = \{p_e\} \cup Q_x$. The elimination procedure of Step 3 is applied to the pattern instances in Q'.

Step 3. This step eliminates among the elements of Q'. q_c will denote the leftmost pattern instance to survive Step 3. If $q_c = p_e$, then every surviving pattern instance overlapping q_c will be a presuf overlap of q_c.

The strategy used here is similar to the one for the basic algorithm. One of two overlapping pattern instances is eliminated by comparing at the difference point of the two instances.

To prevent repeated comparisons of text characters to the right of t_a, two additional data structures are used. The first is a bit vector $BV[1 \ldots 2m]$. $BV[i] = 1$ if the ith text character to the right of t_a has been successfully compared in Steps 1 and 2 or in Step 3 since the last mismatch. The second is a list LBV; it stores the indices of the bits in BV set to one in Step 3 since the last mismatch. Initially, LBV is empty.

The elimination procedure for Step 3 follows. Let q_a and q_b denote the two leftmost uneliminated pattern instances in Q'. Suppose that q_b lies i units to the right of q_a. The reader is advised to refer to section 2 to review the definition of dif_{i+1}. If dif_{i+1} is undefined, then q_b is removed from Q'.

If dif_{i+1} is defined, then the bit in BV corresponding to the text character aligned with $q_a[dif_{i+1}]$ is read. If this bit is 1, then q_b is removed from Q'. (q_b can be eliminated since it does not match an already compared text character.) Otherwise, $q_a[dif_{i+1}]$ is compared with the aligned text character. If the two characters are equal, the corresponding bit in BV is set, the bit's index is added to LBV, and q_b is eliminated. If they are not equal, then the bits in BV at all indices currently in LBV are reset to 0, LBV is reset to empty, and q_a is eliminated.

The elimination procedure is iterated until only one pattern instance remains in Q'. Let q_c denote this remaining pattern instance.

Step 4. In this step, either all pattern instances overlapping q_c, apart from presuf overlaps, are eliminated or q_c is eliminated.

Let Q'' be the set of pattern instances whose left end lies to the right of $p_e|$ but not to the right of $q_c|$. The following step is repeated until either q_c is eliminated or $Q'' = \phi$. Let q_d be the leftmost pattern instance in Q''. Suppose q_d lies i units to the right of q_c. If dif_{i+1} does not exist, then q_d is removed from Q''. Otherwise, the following bit in BV is read: the bit corresponding to the text character aligned with $q_c[dif_{i+1}]$. If this bit is 1, q_d is eliminated. If it is 0, $q_c[i]$ and the aligned text character are compared. If they match, then the corresponding bit in BV is set, its index is added to LBV, and q_d is eliminated. Otherwise, q_c is eliminated and Step 4

comes to an end.

If q_c is eliminated, then LBV is reset to be empty, BV is reset to 0, and the basic algorithm is restarted with $p_a = q_d$. Otherwise, Step 5 is performed.

Step 5. This step seeks to complete the match of q_c. If at least a presuf of q_c is matched, the complete match or the partial match results in a new presuf shift. Otherwise, the basic algorithm is resumed with $|p_a$ immediately to the right of $q_c|$.

Step 5 compares the characters in q_c to the right of t_a, apart from those matched in Steps 1 and 2, and those matched in Steps 3 and 4 following the most recent mismatch. (Incidentally, there was no mismatch in Step 4 since q_c survived Step 4 if Step 5 is performed.) These characters are identified with the help of bit vector BV. They are matched in right-to-left order until either a mismatch occurs or they are all matched.

If they all match q_c is declared a complete match if either $t_{\text{last}} = \phi$ or t_{last} lies to the left of $|q_c$. Recall that t_{last} is the index of the text character mismatched, if any, immediately prior to the most recent presuf shift (if there was no mismatch, $t_{\text{last}} = \phi$).

Next, BV is reset to zero, LBV is reset to be empty, and t_{last} is updated as follows. If the above right-to-left pass results in a mismatch, then t_{last} is set to the index of the text character at which the mismatch occurs. Otherwise, t_{last} retains its value unless $|q_c$ is to its right. In the latter case, $t_{\text{last}} := \phi$.

The present situation is identical to that preceding a presuf shift in the basic algorithm. This resulting shift is treated in the same way; it too is called a presuf shift.

4.3. The analysis. The comparison complexity of the algorithm of section 4.2 is given by the following lemma.

LEMMA 4.12. *If p is not a special case pattern and $|x'_1| < \frac{m}{2}$ for each presuf shift, then the comparison complexity of the algorithm is bounded by $n(1 + \frac{8}{3(m+1)})$.*

Proof. We give a charging scheme to account for the comparisons made by the algorithm. This scheme charges almost every comparison to a distinct text character. The only exceptions are a few of the comparisons made by the presuf shift handler. For each presuf shift, depending on the distance between this presuf shift and the next one, the charging scheme fails to charge for up to two of the comparisons made by the presuf shift handler. We refer to the number of comparisons which the charging scheme fails to charge to distinct text characters as the *overhead* of the presuf shift. If a presuf shift has an overhead of two, we show that the next presuf shift must occur at least distance $\frac{3(m+1)}{4}$ to the right of the current presuf shift. The comparison complexity of our algorithm now follows from the fact that any two consecutive presuf shifts must occur at least distance $\frac{m+1}{2}$ apart.

Charging scheme. The charging scheme charges in phases. The phases begin and end at shifts and at reversions to the basic algorithm. There are four types of phases; for each phase type, a different charging scheme is used:

1. a phase beginning and ending with a basic shift;
2. a phase beginning in the basic algorithm and ending with a presuf shift;
3. a phase beginning with a presuf shift and ending with a reversion to the basic algorithm;
4. a phase beginning and ending with a presuf shift.

Consider any phase and let q_1 and q_2 refer to the leftmost surviving pattern instances at the beginning and end of the phase, respectively. Note that for Type 3 and Type 4 phases, q_1 is a presuf overlap of the pattern instance q', the leftmost uneliminated pattern instance prior to the presuf shift which initiated this phase.

Specifically, the prefix x'_1 of q_1 is aligned with the suffix x'_1 of q'. (Recall from the start of section 4 that on a presuf shift, we assume that the suffix x'_1 of q_1 matches the text.)

The charging scheme obeys the following properties.

1. At the start of a Type 1 or Type 2 phase, only text characters to the left of q_1 have been charged.

2. At the start of a Type 3 or Type 4 phase, only text characters aligned with or to the left of the prefix x'_1 of q_1 have been charged.

Type 1 *phase.* Suppose i comparisons were made in this phase. These i comparisons are charged to text characters which are aligned with q_1 but to the left of $|q_2$. By Lemma 3.1, $|q_2$ lies at least i characters to the right of $|q_1$. Thus each text character aligned with q_1 and to the left of $|q_2$ is charged at most once in this process. Clearly, property 1 holds at the start of the next phase.

Type 2 *phase.* In each comparison, a distinct character in q_1 is compared with the aligned text character. Each of these comparisons is charged to the text character compared. Thus each text character aligned with q_1 is charged at most once in this process. Clearly, property 2 holds at the start of the next phase.

The charging scheme for Type 3 and Type 4 phases is more involved. Before describing the scheme, we mention the ranges of the text characters charged in each case.

Type 3 *phase.* The text characters charged lie to the right of the right end of the prefix x'_1 of q_1 and to the left of $|q_2$. Each text character in this range is charged at most once. Clearly, property 1 holds at the start of the next phase.

Type 4 *phase.* The text characters charged lie to the right of the right end of the prefix x'_1 of q_1 and are aligned with or to the left of the rightmost character in the prefix x'_1 of q_2. Each text character in this range is charged at most once. Clearly, property 2 holds at the start of the next phase.

Clearly, the ranges of the text characters charged for different phases are disjoint. Next, we specify the charging scheme for Type 3 and Type 4 phases and justify the claims regarding the overhead.

Consider a presuf shift which initiates a new Type 3 or Type 4 phase. Let q' be the leftmost uneliminated pattern instance immediately before the presuf shift. Recall that t_a is the text character aligned with $q'|$. Consider the comparisons made by the current use of the presuf shift handler. If a mismatch occurs in Step 1, the current phase ends immediately and the basic algorithm is resumed. The presuf shift in this case has overhead 1 and the next presuf shift occurs at least distance $m+1$ to the right. Next, suppose that the comparison in Step 1 is successful. Let p_e be the presuf pattern instance that survives the elimination using tree ET in Step 2. After the presuf shift handler finishes, one of the three scenarios mentioned in section 4.2 ensues. We consider each in turn.

1. All pattern instances overlapping p_e are eliminated, apart from its presuf overlaps, and p_e or at least a suffix of p_e is matched. This is a Type 4 phase.

All comparisons made by the presuf shift handler, except the unsuccessful comparisons in Step 2, are charged to the text characters compared. The bit vector BV ensures that each of these comparisons involves a different text character. Thus each text character which lies to the right of t_a and is aligned with or to the left of $p_e|$ is charged at most once. At most two comparisons in Step 2 are unsuccessful, so this shift has overhead at most 2.

Consider the situation when there are exactly two mismatches in Step 2. p_1 is clearly eliminated in this case. In addition, we show in the next paragraph that if x_1 is periodic, with core v and head u, say, then all pattern instances whose associated presufs have the form uv^o, $o \geq 1$, are also eliminated. Let x_e be the presuf associated with p_e. It follows that $x_1 = x_e w x_e$ for some nonempty string w. Since $p = x_1 z x_1$, for some nonempty string z, $|x_e| \leq \frac{m-3}{4}$. This guarantees that the next presuf shift occurs at least distance $\frac{3(m+1)}{4}$ to the right. If there is just one mismatch in Step 2, then since $|x_1'| < \frac{m}{2}$, the next presuf shift occurs at least distance $\frac{m+1}{2}$ to the right.

To see that two mismatches in Step 2 eliminate all presuf pattern instances with associated presufs of the form uv^o, $o \geq 1$, it suffices to show that at most one such pattern instance survives the first mismatch; the second mismatch will surely eliminate this pattern instance. Suppose two pattern instances p_{i_1} and p_{i_2}, $i_1 < i_2$, $i_1, i_2 \neq 1$, $x_{i_1} = uv^{o_1}$, $x_{i_2} = uv^{o_2}$, $o_1, o_2 \geq 1$, survive the first mismatch, which occurs at text character t_x, say. The portions of p_1 and p_{i_1} to the right of t_x match each other while the characters in p_1 and p_{i_1} aligned with t_x are different. This implies that p_1 and p_{i_2} have a difference point strictly between t_x and t_b; more precisely, the character in p_1 which is distance $(o_2 - o_1)|v|$ to the right of t_x is a difference point. Therefore, either p_1 or p_{i_2} would have been eliminated before the first mismatch, which is a contradiction.

2. p_e is eliminated. In addition, there is some pattern instance q_c overlapping p_e such that all pattern instances overlapping q_c are eliminated apart from its presuf overlaps; further, q_c or at least a suffix of q_c is matched. This is also a Type 4 phase.

Each comparison in Steps 1 and 2 with a text character to the left of $|q_c$ for which function f is defined is charged to the text character specified by the function f, called its f value; f values are distinct by definition. Comparisons in Step 3 fall into one of three categories (see Lemma 4.11 and the following paragraph):

1. comparisons which eliminate pattern instances whose left ends lie to the right of $|p_{k+1}$ and to the left of $|q_c$;
2. comparisons which eliminate pattern instances whose left ends are aligned with or to the right of $|q_c$;
3. the comparison which eliminates p_e.

Each comparison in the first category is charged to the text character aligned with the left end of the pattern instance eliminated. By the definition of the function f, these text characters do not occur in the range of f values. Comparisons in the second category, along with the comparisons made in Steps 4 and 5 and those successful comparisons in Steps 1 and 2 that involve text characters overlapping q_c, are charged to the text characters compared. BV ensures that each of these comparisons involves a distinct text character. Thus each text character which lies to the right of $|p_{k+1}$ and is aligned with or to the left of $q_c|$ is charged at most once. The comparison that eliminates p_e is charged to the text character aligned with $|p_{k+1}$. Since all f values lie to the right of $|p_{k+1}$ and all pattern instances eliminated by comparisons in the first category are with left ends to the right of $|p_{k+1}$, this text character is charged exactly once. The two comparisons in Step 2 lacking f values constitute the overhead of this presuf shift. Since p_e is eliminated, the next presuf shift occurs at least distance $m+1$ to the right of the current presuf shift.

3. p_e is eliminated, as are all pattern instances overlapping p_e. This is a Type 3 phase.

Let q_d denote the leftmost surviving pattern instance. All comparisons in Steps 1 and 2 for which function f is defined are charged to their f values. f values are

distinct by definition. Excluding the comparison which eliminates p_e, each comparison in Steps 3 and 4 eliminates some pattern instance whose left end lies to the right of $|p_{k+1}$ and to the left of $|q_d$. Each such comparison is charged to the text character aligned with the left end of the pattern instance eliminated. These text characters cannot occur in the range of the function f and hence are charged only once. Thus each text character which lies to the right of $|p_{k+1}$ and to the left of $|q_d$ is charged at most once. The comparison that eliminates p_e is charged to the text character aligned with $|p_{k+1}$. The two comparisons in Step 2 lacking f values constitute the overhead of this presuf shift. Since p_e is eliminated, the next presuf shift occurs at least distance $m+1$ to the right of the current presuf shift. □

The following lemma is shown in section 4.5.

LEMMA 4.13. *The total space used by the algorithm for the case when $|x'_1| < \frac{m}{2}$ for all presuf shifts is $O(m)$. Further, for any terminal node x of ET, Q_x can be obtained in $O(m)$ time. The preprocessing required by the algorithm can be accomplished in $O(m^2)$ time.*

LEMMA 4.14. *Suppose that p is not a special-case pattern and $|x'_1| < \frac{m}{2}$ for all presuf shifts. Then the total time taken by the algorithm is $O(n+m)$, following preprocessing of the pattern, which takes $O(m^2)$ time.*

Proof. By Lemma 4.12, the number of character comparisons made is $O(n)$. It remains to count the time spent in all other operations. The basic algorithm makes only character comparisons. Next, consider the presuf handler of section 4.2. Steps 1 and 2 make only character comparisons. Following Step 2, computing Q_x takes $O(m)$ time by Lemma 4.13. Steps 3 and 4 take $O(m)$ time because $|Q'|, |Q''| = O(m)$ and each of the operations in these steps, except the operations used for resetting BV, leads to the removal of a pattern instance from one of Q'' or Q'. Further, the total time spent by Steps 3 and 4 in resetting BV is bounded by the time taken by these steps to set bits in BV, which is $O(m)$. Clearly, Step 5 takes $O(m)$ time. Thus the total time taken by the presuf handler of section 4.2 is $O(m)$. Since any two presuf shifts occur at least $m-|x'_1| > \frac{m}{2}$ distance apart, the total time taken by the algorithm is $O(n+m)$. □

4.4. Handling presuf shifts for special-case patterns. As mentioned in section 4.1, a different algorithm is needed to handle presuf shifts for patterns for which $|x_k| = 1$ and $g = 1$. We give an algorithm which handles presuf shifts for such patterns when $|x'_1| < \frac{m}{2}$. (Recall that x'_1 for a presuf shift was defined towards the start of section 4.) The case where $|x'_1| \geq \frac{m}{2}$ is handled in section 6.

The goal of this algorithm is to reach one of the following two situations:

1. the identification of a pattern instance q_c satisfying the following property: no pattern instance q_d which precedes q_c survives and a pattern instance overlapping q_c survives only if it is a presuf overlap of q_c;

2. a return to the basic algorithm.

Further, this is achieved with at most two mismatches.

Let $x_k = b$. Any character other than b is called a non-b character. Since we assume that the pattern contains at least two different characters, it contains a non-b character. Let $p[j]$ be the leftmost non-b character in p and let t_c denote the text character aligned with $|p_{k+1}$. Let t_d be the leftmost non-b text character, if any, to the right of, and including, t_c.

By the definition of special-case patterns, all presufs consist solely of b's. Therefore, $p_1[j]$ lies to the right of t_a. Note that no complete match can occur with one of $p[1 \ldots j-1]$ aligned with t_d. Thus if t_d lies to the left of $p_1[j]$, then the next potential

match instance of p would have its left end to the right of t_d. Otherwise, the next potential match instance of p has $p[j]$ aligned with t_d. Also notice that if t_d does not exist, then there are no more complete matches. These observations lead to the following three-step procedure.

Step 1. This step locates t_d and then eliminates all but at most one pattern instance q_c overlapping t_d. Starting at t_c, a left-to-right scan of the text is performed to locate t_d (i.e., each text character is compared to b; t_d is the character at which the first mismatch occurs). If t_d does not exist, the algorithm halts. If t_d exists and lies to the left of $p_1[j]$, then the basic algorithm is restarted with $|p$ placed to the immediate right of t_d. Otherwise, q_c is chosen to be the pattern instance such that $q_c[j]$ is aligned with t_d. q_c is the next potential match instance to be considered.

Step 2. In this step, either q_c is eliminated or all pattern instances overlapping q_c, except for presuf overlaps of q_c, are eliminated. This is done using the basic algorithm, slightly modified to account for the matched prefix. Suppose the leftmost difference points are used in the sequence S in the basic algorithm, as against any arbitrary difference points. Then $dif_2, \ldots, dif_j$ are all equal to j and $dif_{j+1}, \ldots, dif_m$ are all greater than j, whenever defined. In Step 2, the characters in q_c to the right of $q_c[j]$ which are at the indices given by S are compared with the aligned text characters in the order in which they appear in S. This continues until either a mismatch occurs or the sequence is exhausted. A mismatch leads to the basic algorithm with $|p$ shifted to the right of q_c by distance at least $j-1$ plus the number of comparisons made in this step. If no mismatch occurs, then Step 3 follows.

Step 3. Characters in q_c which are not yet matched are compared from right to left with their aligned text characters until a mismatch occurs or q_c is fully matched. The present situation is now identical to the situation at the beginning of a presuf shift and is handled in the same way.

The comparison complexity of the above algorithm is determined by the following lemma.

LEMMA 4.15. *If p is a special-case pattern and $|x'_1| < \frac{m}{2}$ for each presuf shift, then the comparison complexity of the algorithm is $n(1 + \frac{2}{m+1})$.*

Proof. We give a charging scheme to account for the comparisons made by the algorithm for handling special-case patterns. The definition of a phase, the charging scheme for Type 1 and Type 2 phases, and the ranges of text characters charged in each phase type remain the same as in Lemma 4.12. Only the charging scheme for Type 3 and Type 4 phases needs to be modified in accordance with the presuf shift handler for special-case patterns.

Consider a presuf shift which initiates a new Type 3 or Type 4 phase. We show that it has an overhead of at most one. The comparison complexity of the algorithm now follows from the fact that $|x'_1| < \frac{m}{2}$ and therefore any two consecutive presuf shifts must occur at least $\frac{m+1}{2}$ characters apart.

Charging scheme for the presuf shift handler. Let q' and q_1 be the leftmost uneliminated pattern instances immediately before and after the presuf shift, respectively. Recall that t_a is the text character aligned with $q'|$.

We show that presuf shifts have overhead at most one for these patterns. Let q_c be the leftmost pattern instance which survives Step 1. All successful comparisons in Step 1 are charged to the text characters compared. These text characters lie to the left of $q_c[j]$, where j is the least index such that $p[j]$ differs from $p[m]$. The lone unsuccessful comparison in Step 1 constitutes the overhead of this shift. Now consider two cases.

1. Suppose q_c survives Step 2. All comparisons made in Steps 2 and 3 are charged to the text characters compared. Thus each text character which lies to the right of t_a and is aligned with or to the left of $q_c|$ is charged at most once. All future comparisons will be charged to text characters to the right of $q_c|$.

2. Suppose q_c does not survive Step 2. Each successful comparison in Step 2 eliminates some pattern instance lying entirely to the right of $q_c[j]$ and is charged to the text character aligned with the left end of that pattern instance. The unsuccessful comparison which eliminates q_c in Step 2 is charged to the text character aligned with $q_c[j]$. Thus each text character lying strictly between t_a and $|q_d$ is charged at most once, where q_d is the leftmost surviving pattern instance at the end of Step 2. All future comparisons will be charged to text characters aligned with or to the right of $|q_d$. □

LEMMA 4.16. *Suppose that p is a special-case pattern and $|x'_1| < \frac{m}{2}$ for all presuf shifts. Then the total time taken by the algorithm is $O(n+m)$, following preprocessing of the pattern, which takes $O(m^2)$ time. The total space used by the algorithm is $O(m)$.*

Proof. The lemma, except for the preprocessing time, is obvious from the above description. Since no extra preprocessing is required for special-case patterns, the lemma follows from Lemma 4.14. □

THEOREM 4.17. *Suppose for all presuf shifts that $|x'_1| < \frac{m}{2}$. Then the total space used by the algorithm is $O(m)$ and the total time taken by the algorithm, after preprocessing, is $O(n+m)$. The preprocessing required by the algorithm takes $O(m^2)$ time.*

Proof. The proof follows from Lemmas 4.14 and 4.16. □

4.5. Data structure details. We prove Lemma 4.13 in this section. The following data structures are used by the algorithm:

1. the array S used in the basic algorithm;
2. an array, indexed by i, storing dif_i, $2 \le i \le m$, used by the presuf shift handler;
3. BV and LBV, the bit vector and its associated list;
4. ET, the elimination tree;
5. Q_x, for each terminal node x of ET, as defined after Step 2 in section 4.2.

Of these, the first three have size $O(m)$ by definition. By Theorem 4.9, ET also has size $O(m)$.

It remains to show how to represent Q_x, for each terminal node x of ET, using $O(m)$ space overall. The following definitions are helpful. Let t_b be the text character aligned with $p_1|$. Let Q refer to the set of pattern instances which overlap p_{k+1}, have left ends to the right of $|p_{k+1}$ and either match or do not overlap t_b.

Before showing how to maintain Q_x, it is helpful to recapitulate some structural properties of ET. ET is a binary tree with each internal node having two children. At each internal node y, a character c_y in p is potentially compared with the text character tc_y. A successful comparison leads to the left child of y while a mismatch leads to the right child. Comparisons are made starting at the root of ET and continuing until a terminal node (a leaf) is reached. A node in ET lies in the right subtree of at most two of its ancestors.

Node x is said to be a *failing descendant* of node y if x is a proper descendant of y and lies in the right subtree of y. A terminal node x can be a failing descendant of at most two nodes in ET. Let $p(x)$ denote the parent of x. For each terminal node x, let $Anc(x)$ be defined as follows. If both children of $p(x)$ are terminal nodes and

$p(x)$ is the right child of $p(p(x))$, then $Anc(x)$ is the set of proper ancestors of $p(x)$. Otherwise, $Anc(x)$ is the set of proper ancestors of x.

$q \in Q$ is said to *occur* at terminal node x of ET if $q \in Q_x$. In section 4.2, we tentatively defined Q_x to be the set of pattern instances in Q which match at all text characters compared successfully at nodes in $Anc(x)$ (actually, the definition was not this precise). Now we refine this definition by letting Q_x satisfy some additional constraints. Informally, q should occur at x if it is consistent with all comparisons made at nodes in $Anc(x)$. This motivates the following characterization of Q_x. Let $Y \subset Anc(x)$ consist of those nodes with respect to which x is a failing descendant. Then Q_x is the maximal subset of Q such that each $q \in Q_x$ satisfies the following properties:

1. $\forall y \in Anc(x) - Y$, the character in q aligned with tc_y, if any, matches the character c_y;
2. $\forall y \in Y$, the character in q aligned with tc_y, if any, is different from c_y.

ET may have $\theta(m)$ terminal nodes. Even though $|Q_x| < m$ for each terminal node x, storing Q_x explicitly for each terminal node x could require $\Omega(m^2)$ space overall. We show how to store the sets Q_x so that $O(m)$ space is used in total and any particular Q_x can be retrieved in $O(m)$ time.

Let $l_1, l_2, \ldots, l_h$, in that order, be the nodes along the leftmost path in ET starting at the root and ending at the terminal node l_h. Define the right subtree of l_i to be the subtree rooted at the right child of l_i. Note that $tc_{l_1}, \ldots, tc_{l_{h-1}}$ form a right-to-left sequence. We show how to maintain Q_x, for all terminal nodes x in the right subtrees of $l_1, \ldots, l_{h-1}$, in $O(m)$ space altogether. Only the terminal node l_h remains and Q_{l_h} can be stored explicitly in $O(m)$ space.

We mark some of the nodes $l_1, \ldots, l_{h-1}$. Node l_i is marked if its right child is neither a terminal node nor the parent of two terminal nodes. Thus node l_i is marked if Phase 2 could make at least two comparisons following a mismatch at tc_{l_i}. Let $l'_1, \ldots, l'_s$, in that order, be the nodes marked.

The following lemmas are helpful.

LEMMA 4.18. *Consider terminal nodes x_1 and x_2 of ET and let their least common ancestor be y. Suppose at most one of the following is true: first, y is the parent of both x_1 and x_2, and second, y is the right child of $p(y)$. If q occurs at x_1 and at x_2, then q does not overlap tc_y.*

Proof. Clearly, $y \in Anc(x_1)$ and $y \in Anc(x_2)$. Suppose q overlaps tc_y. Let c be the character in q aligned with tc_y. Without loss of generality, assume that x_1 is a failing descendant of y. Then x_2 is not a failing descendant of y. By the definition of Q_{x_1}, $c \neq c_y$. By the definition of Q_{x_2}, $c = c_y$, a contradiction. □

COROLLARY 4.19. *Let $i \geq 1$ be the smallest number such that $q \in Q$ does not overlap tc_{l_i}. q can occur at terminal nodes in the right subtrees of at most one of $l_1, \ldots, l_{i-1}$. Further, if q occurs at some terminal node in the subtree rooted at l_i, it cannot occur at terminal nodes in the right subtrees of any of $l_1, \ldots, l_{i-1}$.*

LEMMA 4.20. *Let $i \geq 1$ be the smallest number such that $q \in Q$ does not overlap tc_{l_i}. Suppose q occurs at a terminal node in the subtree rooted at l_i. Then q occurs at all terminal nodes in the right subtrees of each of those nodes among $l_i, \ldots, l_{h-1}$ which are unmarked. Further, q occurs at l_h.*

Proof. Clearly, the characters in q which overlap $tc_{l_1}, \ldots, tc_{l_{i-1}}$ match the characters $c_{l_1}, \ldots, c_{l_{i-1}}$, respectively. Further, q does not overlap $tc_{l_i}, \ldots, tc_{l_{h-1}}$. Therefore, q occurs at l_h. In addition, if a terminal node x is in the right subtree of an unmarked node l_j, $j \geq i$, then either $l_j = p(x)$ or $l_j = p(p(x))$ and $p(x) \notin Anc(x)$. From the

definition of Q_x, q must occur at x. □

LEMMA 4.21. *Consider marked node l'_i, $1 \le i \le s$, and let j be the smallest number such that $tc_{l'_i}$ is to the left of the suffix x_j of p_1. p_{j-1} must be the rightmost pattern instance in its group. In addition, p_j is the leftmost presuf pattern instance to survive a mismatch at $tc_{l'_i}$.*

Proof. Since l'_i is marked, at least three presuf pattern instances must survive a mismatch at $tc_{l'_i}$. Let the leftmost three such pattern instances be p_a, p_b, and p_c (listed in left-to-right order). Let A_w be the group containing p_j. Write x_j as uv^e, where $e \ge 1$, u is a proper suffix of primitive v, and all presufs associated with A_w have the form $uv^{e'}$, $e' \ge 1$.

By Lemma 4.5, successful comparisons within the suffix x_j of p_1 suffice to eliminate all but at most two of the pattern instances in the groups $A_{w+1}, \ldots, A_g$. (At most two pattern instances in $A_{w+1}, \ldots, A_g$ can form a half-done set with p_j.) Therefore, $p_a \in A_w$ and $x_a = uv^{e_a}$, $e_a \ge 1$. Since p_a, p_b, and p_c all survive the mismatch at $tc_{l'_i}$, $\{p_a, p_b, p_c\}$ is a half-done set and therefore $e_a \ge 2$. It follows that $x_b = uv^{e_b}$, $e_b \ge 0$, and $x_c = uv^{e_c}$, $e_c \ge 0$.

Next, suppose p_{j-1} is not the rightmost pattern instance in its group. Then $p_{j-1} \in A_w$ and x_{j-1} has the form uv^{e+1}, $e+1 \ge 2$. We show that p_b would have been eliminated by a comparison to the right of $tc_{l'_i}$, which is a contradiction. Note that p_{j-1} and p_a have a difference point, which is aligned with or to the right of $tc_{l'_i}$ and aligned with p_1. Let $p_{j-1}[d]$ be the rightmost such difference point. Clearly, $p_{j-1}[d]$ is to the left of the suffix x_a of p_1. $p_{j-1}[d + (e_a - e_b)|v|]$ is a difference point of p_{j-1} and p_b which is aligned with p_1. A match at this difference point would have eliminated p_b.

Finally, suppose $p_a \ne p_j$. Then p_j and p_a have a difference point, which is aligned with or to the right of $tc_{l'_i}$ and aligned with p_1. Let $p_j[d]$ be the rightmost such difference point. An argument similar to the one in the previous paragraph shows that p_j and p_b have a difference point to the right of $p_j[d]$ and aligned with p_1; a match at this difference point would have eliminated p_b, which is a contradiction. □

COROLLARY 4.22. *Consider marked nodes l'_{i_1} and l'_{i_2}, $1 \le i_1 < i_2 \le s$. Let x_{i-1} and x_{j-1} be the smallest suffixes (which are also presufs) of p_1 which overlap $tc_{l'_{i_1}}$ and $tc_{l'_{i_2}}$, respectively. Then $i \ne j$.*

Proof. If $i = j$, then by Lemma 4.21, p_j is the leftmost presuf pattern instance to survive the mismatches at both $tc_{l'_{i_1}}$ and $tc_{l'_{i_2}}$. But since a p_j survives a mismatch at $tc_{l'_{i_1}}$, it cannot survive a match at $tc_{l'_{i_1}}$ and therefore it cannot survive a mismatch at $tc_{l'_{i_2}}$. □

LEMMA 4.23. *The size of the presuf corresponding to the rightmost pattern instance in A_j, $1 \le j \le g$, is at most $\frac{m}{(3/2)^j}$.*

Proof. For $j = 1$, the claim is clearly true. Assume that the claim is true for A_{j-1}; i.e.; the size of the presuf corresponding to rightmost pattern instance p_e in A_{j-1} is less than $\frac{m}{(3/2)^{j-1}}$. x_e has either the form uvv or the form uv, where u is a proper suffix of v. In the former case, $x_{e+1} = uv$, and in the latter case, $x_e = x_{e+1} z x_{e+1}$ for some nonempty string z (since uv is not periodic). Thus $|x_{e+1}| < \frac{2|x_e|}{3}$. The claim follows. □

LEMMA 4.24. *The number of pattern instances in Q which overlap t_b and are entirely to the right of $tc_{l'_i}$ is less than $\frac{m}{(3/2)^{s-i+1}}$, for all i, $1 \le i \le s$.*

Proof. From Lemma 4.21 and Corollary 4.22, the rightmost presuf pattern instance p_j such that the suffix x_j of p_1 overlaps $tc_{l'_i}$ must be the rightmost pattern instance in some group $A_{j'}$, $j' \geq s - i + 1$. The lemma follows from Lemma 4.23. □

Consider the right subtrees of $l'_1, \ldots, l'_s$. Note that the comparisons made in each of these subtrees are aimed at eliminating half-done sets whose leftmost pattern instances are in distinct groups. Each of these comparisons is made to the right of $p_1[m]$, as described in Lemma 4.7 and Corollary 4.8.

LEMMA 4.25. *The number of pattern instances in Q which are entirely to the right of t_b and overlap some text character compared in the right subtree of l'_i is at most $\frac{m}{(3/2)^{s-i+1}}$, for all i, $1 \leq i \leq s$.*

Proof. Recall from Lemma 4.7 that a half-done set whose leftmost pattern instance is in group A_j, $j > 1$, is eliminated in Phase 2 of the elimination strategy by making comparisons at text characters which are at most distance $|x_{j'-1}| - |x_{j'}|$ to the right of t_b, where $p_{j'}$ is the leftmost presuf pattern instance in A_j. From Lemma 4.23, $|x_{j'-1}| < \frac{m}{(3/2)^{j-1}}$, and the lemma follows. □

LEMMA 4.26. *Consider a marked node l'_i and the set of terminal nodes in its right subtree. If a pattern instance q occurs at two of these terminal nodes, say w and y, then q occurs at all terminal nodes in the subtree rooted at the least common ancestor z of w and y.*

Proof. By Lemma 4.18, q does not overlap the character tc_z. Since comparisons made in the right subtree of l'_i constitute a right-to-left sequence, q does not overlap $tc_{z'}$, where z' is any descendant of z. The lemma now follows immediately from the definition of the sets Q_x. □

We are now ready to describe the data structure for storing the Q_x's. The following subsets of Q are required: $Z_1, \ldots, Z_{h-1}$, $Y_1, \ldots, Y_{h-1}$ and $W_1, \ldots, W_s$. The Z and the Y sets are used for terminal nodes which lie in the right subtrees of the unmarked nodes among $l_1, \ldots, l_{h-1}$. The W sets are used for terminal nodes which lie in the right subtrees of marked nodes.

The Z sets are defined first. For each i, $1 \leq i \leq h-1$, where l_i is unmarked, define Z_i to be the set of pattern instances in Q which overlap $tc(l_i)$ and occur only at terminal nodes in the right subtree of l_i. Clearly, $\sum_{i=1}^{h-1} Z_i = O(m)$.

The Y sets are defined next. For each i, $1 \leq i \leq h-1$, define Y_i to be the set of pattern instances $q \in Q$ with the following properties.

1. q does not overlap tc_{l_i}.
2. If $i > 1$, q overlaps $tc_{l_{i-1}}$.
3. q occurs at a terminal node in the subtree rooted at l_i.

Clearly, $\sum_{i=1}^{h-1} Y_i = O(m)$. Further, each pair of Y sets is disjoint and Z_i is disjoint from $Y_1, \ldots, Y_i$. The following lemma explains the significance of the Y and Z sets.

LEMMA 4.27. *If terminal node x is in the right subtree of unmarked node l_i, $Q_x = Y_1 \cup Y_2 \cup \cdots \cup Y_i \cup Z_i$.*

Proof. Suppose $q \in Q_x$. If q overlaps tc_{l_i} then by Corollary 4.19, $q \in Z_i$. If q does not overlap tc_{l_i}, then clearly q must be in some Y_j, $j \leq i$.

Next, suppose $q \in Y_j$, $j \leq i$. By Lemma 4.20, $q \in Q_x$. Finally, if $q \in Z_i$, then $q \in Q_x$ since the only internal node (if any) in the right subtree of l_i is not in $Anc(x)$. □

Finally, the W sets are defined. For each i, $1 \leq i \leq s$, W_i consists of those pattern instances which occur at some terminal node in the right subtree of marked node l'_i. Let W'_i denote the set obtained from W_i by removing those pattern instances which

do not overlap any of the text characters compared in the right subtree of l'_i.

LEMMA 4.28. $\sum_{i=1}^{s} |W'_i| = O(m)$.

Proof. Split W'_i into two disjoint subsets, W_i^1 and W_i^2. W_i^1 consists of those pattern instances which overlap $tc_{l'_i}$ and W_i^2 consists of pattern instances which do not overlap $tc_{l'_i}$.

By Lemma 4.18, pattern instances in W_i^1 occur only at terminal nodes in the right subtree of l'_i. Therefore, it suffices to show that $\sum_{i=1}^{s} |W_i^2| = O(m)$. From Lemmas 4.24 and 4.25, it follows that $\sum_{i=1}^{s} |W_i^2| = \sum_{i=1}^{s} (2\frac{m}{(3/2)^{s-i+1}}) = O(m)$. □

Consider some i, $1 \leq i \leq s$. The manner in which W_i is maintained so as to facilitate the recovery of Q_x for each terminal node x in the right subtree of marked node l'_i remains to be shown. Clearly, pattern instances in $W_i - W'_i$ occur at all such nodes x and can be stored implicitly in constant space by just storing the rightmost text position compared in the right subtree of l'_i. For the terminal nodes x in l_i's right subtree, we show how to store the pattern instances in $Q_x \cap W'_i$ using a total of $O(|W'_i|)$ space (summing over all x). The linear-space bound then follows from Lemma 4.28.

At each internal node y in the right subtree T of l'_i, a set Com_y is stored. At each terminal node x in T, a set $Spec_x$ is stored. For each $q \in W'_i$, if q occurs only at terminal node x, then it is added to $Spec_x$. Otherwise, if q occurs at more than one terminal node in T, then q is added to the set Com_y, where y is the least common ancestor of those terminal nodes at which q occurs. Clearly, all Com and $Spec$ sets are disjoint and therefore the total space taken by them is $O(|W'_i|)$. The following lemma shows how Q_x can be retrieved from the Com and $Spec$ sets, for each terminal node x in T.

LEMMA 4.29. *For each terminal node $x \in T$, $Q_x = (W_i - W'_i) \cup Com_{y_1} \cup Com_{y_2} \cup \cdots \cup Com_{y_j} \cup Spec_x$, where $y_1, \ldots, y_j$ are the proper ancestors of x in T.*

Proof. The proof follows immediately from Lemma 4.26. □

To compute Q_x as an ordered list, it suffices to maintain each of the Y, Z, Com, and $Spec$ sets as ordered lists which are then appended together in $O(m)$ time according to either Lemma 4.27 or Lemma 4.29, as the case may be.

This concludes the data structure description. We remark that all of the data structures mentioned at the beginning of this section can be computed using naïve algorithms in $O(m^2)$ time.

5. The transfer function f. Before giving the definition of the function f, we prove a number of preliminary lemmas.

5.1. Preliminary lemmas. These lemmas describe some properties of periodic strings and the distribution of text characters compared in Step 2 (the elimination-tree phase) of the presuf handler described in section 4.2.

Let $V = \{p_1, p_2, \ldots, p_k, p_{k+1}\}$. Consider the set of pattern instances in V which are rightmost in their respective groups. Let p_i be a pattern instance in this set. We introduce a function $h(x_i)$ which is central to the analysis.

DEFINITION. *If $i < k$, then $h(x_i)$ is defined by one of the following three cases:*

1. *x_i is periodic. Then x_{i+1} is also periodic. Let u and v be the head and core, respectively, of x_i. Let w be the core of x_{i+1}. $h(x_i)$ is defined to be the suffix of p_1 of length $|v| + |w|$.*

2. *$x_i = uvu$ is not periodic, where $|u|$ is its s-period. Further, x_{i+1} is periodic with core w. $h(x_i)$ is defined to be the suffix of p_1 of length $|v| + |u| + |w|$.*

3. *$x_i = uvu$ is not periodic, where $|u|$ is its s-period. Further, x_{i+1} is not periodic. $h(x_i)$ is defined to be the suffix of p_1 of length $|u|$.*

If $i = k + 1$, then $h(x_i)$ is defined to be the empty string. Note that $i \neq k$ as p_k and p_{k+1} are both in the same group.

The first two lemmas consider the case when $i < k$ and x_{i+1} is periodic with core w. They show that $h(x_i)$ cannot be periodic with core w.

LEMMA 5.1. *Suppose $x_i = uv^2$, where v is the core of x_i. Further, suppose $x_{i+1} = uv = w'w^{k1}$ is periodic with core w, $|w| < |v|$. Then $h(x_i)$ is not periodic with core w.*

Proof. w is a suffix of v. Since v is primitive, $|v|$ is not a multiple of $|w|$. If $h(x_i)$ were periodic with core w, then the prefix of $h(x_i)$ of size $|w|$ would have the form xy, with x a proper suffix of w and y a proper prefix of w. But this prefix of $h(x_i)$ is a suffix of v and hence is the string w. This implies that w is cyclic and cannot be the core of x_{i+1}, a contradiction. □

LEMMA 5.2. *Suppose $x_i = uvu$ is not periodic, where $|u|$ is the s-period of x_i. Suppose the string $x_{i+1} = u = w'w^{k1}$ is periodic with core w, $|w| < |u|$. Then $h(x_i)$ is not periodic with core w.*

Proof. w is a suffix of u. vu is primitive; otherwise, x_i would be periodic. Suppose $h(x_i)$ is periodic with core w. Then $|vu|$ is not a multiple of $|w|$. Therefore, the prefix of $h(x_i)$ of size $|w|$ is of the form xy, with x a proper suffix and y a proper prefix of w. But this prefix of $h(x_i)$ is a suffix of u and hence is the string w. This implies that w is cyclic and cannot be the core of x_{i+1}, a contradiction. □

The next lemma describes the order in which pattern instances in a half-done set are eliminated in Step 2 of the presuf shift handler.

LEMMA 5.3. *Let $p_{i_1}, \ldots, p_{i_r}$, $r \geq 3$, be pattern instances in V comprising a half-done set. For any l, $3 \leq l \leq r$, if p_{i_1} and p_{i_l} both survive at any instant in Step 2, then $p_{i_1}, \ldots, p_{i_{l-1}}$ also survive at that instant.*

Proof. We show that the lemma is true for any instant in Phase 1 and at the end of Phase 1. For Phase 2, the lemma follows from Corollary 4.8.

Consider the rightmost position e such that $p_{i_1}[e]$ is to the left of t_b (recall that t_b is the text character aligned with $p_1[m]$) and different from the character in p_{i_l} aligned with it. The portions of $p_{i_1}, \ldots, p_{i_l}$ whose left and right ends are aligned with $p_{i_1}[e+1]$ and t_b, respectively, are identical and periodic with core v, where v is the core of x_{i_1}. The portions of $p_{i_1}, \ldots, p_{i_{l-1}}$ whose left and right ends are aligned with $p_{i_1}[e]$ and t_b, respectively, are identical. Therefore, a comparison to the right of $p_{i_1}[e]$ eliminates none or all of $p_{i_1}, \ldots, p_{i_l}$ depending upon whether it succeeds or fails. A comparison at $p_{i_1}[e]$ eliminates either p_{i_l} or all of $p_{i_1}, \ldots, p_{i_{l-1}}$. Thus if p_{i_1} and p_{i_l} survive at any instant in Phase 1 or at the end of Phase 1, then all comparisons made until that instant are to the right of $p_{i_1}[e]$. Each of these comparisons eliminates none or all of $p_{i_1}, \ldots, p_{i_l}$. □

The next lemma establishes that if all comparisons in the suffix x_i of p_1 are successful, then at most two pattern instances to the right of p_i survive.

LEMMA 5.4. *Suppose all comparisons made by S_1 within the suffix x_i of p_1 result in matches. Then at most two instances in V among those lying to the right of p_i survive. Further, if two instances p_y and p_z survive, then $\{x_i, x_y, x_z\}$ is a clone set.*

Proof. First, suppose x_i is periodic. Then by the manner in which groups were defined, x_i has the form uv^2. Let $p_a, p_b \in V$, $a, b > i$. If $\{x_i, x_a, x_b\}$ is not a clone set then by Lemma 4.5, successful comparisons in the suffix x_i of p_1 suffice to eliminate one of p_a, p_b. Thus two or more pattern instances in V to the right of p_i can survive

only if their presufs form a clone set with x_i. But the only candidates are the pattern instances p_y and p_z whose presufs are uv and u, respectively.

Second, suppose x_i is not periodic. Then it is of the form uvu, where u is its s-period. For no two pattern instances p_y and p_z, $y, z > i$, can $\{x_i, x_y, x_z\}$ be a clone set. By Lemma 4.5, one of p_y, p_z, for every such y and z, can be eliminated by a successful comparison made within the suffix x_i of p_1. Thus in this case, at most one pattern instance in V to the right of p_i survives. □

The next two lemmas establish that if all comparisons within $h(x_i)$ are successful, then at most two pattern instances in V to the right of p_i survive.

LEMMA 5.5. *Suppose x_{i+1} is periodic with core w and all comparisons made by S_1 within $h(x_i)$ result in matches. Then at most two instances in V among those to the right of x_i survive.*

Proof. Since the case $i = k + 1$ is vacuous, we assume that $i < k$.

The proof is based on Lemmas 5.1, 5.2, 5.3, and 5.4. Let A_s be the group containing p_i. Let $p_{i+1}, \ldots, p_y$ be the pattern instances in group A_{s+1}. Consider the set V' of pattern instances in V which are to the right of p_i and which survive successful comparisons in the suffix x_y of p_1. By Lemma 5.4, with at most one exception (call it p_o), the pattern instances in V' form a half-done set. By Lemma 5.3, the presufs corresponding to the pattern instances in this half-done set comprise the set $\{w'w^{k2}, \ldots, w'w^{k3+1}, w'w^{k3}\}$, where $k3$ equals 0, 1, or 2. Let $V' = \{p_{i_1}, p_{i_2}, \ldots, p_{i_j}, p_o\}$. We show that successful comparisons in $h(x_i)$ eliminate all but at most one of $\{p_{i_1}, p_{i_2}, \ldots, p_{i_j}\}$.

Note that $\{p_{i_1}, p_{i_2}, \ldots, p_{i_j}\}$ is a half-done set. By Lemmas 5.1 and 5.2, the suffix $h(x_i)$ of p_1 (and of x_i) is not periodic with core w. Let the rightmost suffix of p_1 which is longer than $|x_{i+1}|$ and not periodic with core w begin at $p_1[e]$; $p_1[e]$ lies in $h(x_i)$. Consider the largest h, $1 \le h \le j$, such that p_{i_h} survives all comparisons made to the right of $p_1[e]$. Then by Lemma 5.3, $p_{i_1}, \ldots, p_{i_{h-1}}$ also survive these comparisons while $p_{i_{h+1}}, \ldots, p_{i_j}$ are eliminated. If $h \le 1$, then we are done. Otherwise, as shown in the next paragraph, the characters in $p_{i_1}, \ldots, p_{i_{h-1}}$ aligned with $p_1[e]$ are identical to each other yet different from $p_1[e]$. Hence there will be a comparison involving $p_1[e]$, which by assumption is a match; this leaves only p_{i_h} and p_o uneliminated.

Since the rightmost eligible character is always chosen by the elimination strategy for comparison, the portions of $p_{i_1}, \ldots, p_{i_h}$ aligned with the suffix of p_1 which lies to the right of $p_1[e]$ match that suffix. Suppose for some r, $1 \le r < h$, $a = p_{i_r}[c] \ne p_{i_r}[c + |w|] = b$, where $p_{i_r}[c]$ is aligned with $p_1[e]$. Since $p_{i_{r+1}}$ is $|w|$ units to the right of p_{i_r}, the character in $p_{i_{r+1}}$ aligned with $p_{i_r}[c + |w|] = b$ is an a, a contradiction. Therefore, the characters in $p_{i_1}, \ldots, p_{i_{h-1}}$ aligned with $p_1[e]$ are all equal to the character $p_1[e + |w|]$. However, from the definition of e, $p_1[e + |w|] \ne p_1[e]$. This proves the lemma. □

LEMMA 5.6. *Suppose x_{i+1} is not periodic and all comparisons made by S_1 within the suffix $h(x_i)$ of p_1 result in matches. Then at most two instances in V among those to the right of p_i survive.*

Proof. Since the case $i = k + 1$ is vacuous, we assume that $i < k$.

By the manner in which groups were defined, x_i is not periodic. Since x_{i+1} is not periodic, p_{i+1} is the rightmost instance in its group. Thus x_{i+1} cannot form a clone set with any two of its presufs. By Lemma 5.4, at most one pattern instance to the right of p_{i+1} survives successful comparisons in the suffix $x_{i+1} = h(x_i)$ of p_1. □

The following lemma relates the length of the presufs x_i and x_{i+2} with the suffix $h(x_i)$ of p_1 for $i \le k - 1$.

LEMMA 5.7. $|x_{i+2}| + |h(x_i)| \le |x_i|$.

Proof. First, suppose $x_i = uvu$ is not periodic, where u is its s-period. Then $|x_{i+2}| < |u|$. If x_{i+1} is not periodic, then $h(x_i) = u$ and $|x_{i+2}| + |h(x_i)| < 2|u| < |x_i|$. If x_{i+1} is periodic with core w, then $|h(x_i)| = |u| + |v| + |w|$ and $x_{i+2} = |u| - |w|$. This implies that $|x_{i+2}| + |h(x_i)| = |x_i|$.

Next, suppose x_i is periodic with core v and head u. Then x_{i+1} is also periodic, say with core w. Thus $|h(x_i)| = |v|+|w|$ and $|x_{i+2}| = |v|+|u|-|w|$. Then $|x_{i+2}|+|h(x_i)| = 2|v| + |u| = |x_i|$. □

DEFINITIONS. *Let the term* misfit *refer to any character that differs from the rightmost character of p. If $|x_k| > 1$, let r_i be the number of pattern instances in V which lie to the right of p_i. Otherwise, if $|x_k| = 1$, let r_i be one more than the number of pattern instances in V which lie to the right of p_i and do not belong to the rightmost group. For convenience, we define r_i to be 0 if $|x_k| = 1$ and p_i belongs to the rightmost group.*

We provide some lower bounds on the number of occurrences of misfit characters in the presufs of p and in the cores of periodic presufs.

LEMMA 5.8. *Let $|x_k| > 1$. Let p_j, $j \le k$, be any pattern instance in V. Then x_j contains at least r_j instances of the string x_k and hence r_j misfit characters.*

Proof. Since x_k is the smallest nonnull suffix of p that matches a prefix of p, no nonnull suffix of x_k matches a prefix of x_k. Hence all instances of x_k in any string are disjoint. Since x_k itself contains x_k and $r_k = 1$, the lemma is true for $j = k$. Next, suppose $j < k$ and assume inductively that x_{j+1} contains at least r_{j+1} instances of x_k. Then since x_{j+1} is a proper prefix and a proper suffix of x_j, x_j must contain at least $r_{j+1} + 1 = r_j$ instances of x_k. Since the first character of x_k differs from its last character, x_j has at least r_j misfit characters. □

LEMMA 5.9. *Suppose $|x_k| = 1$. Let p_j be any pattern instance in V. Then x_j has at least r_j misfit characters.*

Proof. If p_j belongs to the rightmost group, then $r_j = 0$ and the lemma holds trivially. Therefore, suppose p_j is not in the rightmost group. Let p_y be the rightmost pattern instance not in the rightmost group. x_y contains at least one misfit character; otherwise, it would be in the rightmost group. Since $r_y = 1$, the lemma is true for $j = y$. Next, assume that $j < y$ and assume inductively that x_{j+1} contains at least r_{j+1} misfit characters. Then since x_{j+1} is a proper prefix and a proper suffix of x_j, x_j must have at least $r_{j+1} + 1 = r_j$ misfit characters. □

LEMMA 5.10. *Let p_j be any instance in V and suppose x_j is periodic with head u and core v, $|v| > 1$. Then v contains a misfit character.*

Proof. If v does not contain a misfit character, then x_j does not contain a misfit character either. This implies that all the characters in x_j are identical. This contradicts the assumption that $|v| > 1$. □

We conclude this section of lemmas with two key lemmas, the *h-suffix mapping lemma* and the *half-done set mapping lemma.* In the h-suffix mapping lemma, a set $R_1(i)$ of text characters is defined for each i, $1 \le i \le k-1$, such that p_i is the rightmost instance in its group. In the half-done set mapping lemma, a set $R_2(O)$ of text characters is defined for a half-done set O consisting of pattern instances from V. These two sets are used as ranges for the f function.

Recall that $V = \{p_1, \ldots, p_k\}$ and t_b is the text character aligned with the rightmost character of p_1.

Let $i \le k-1$ and p_i be the rightmost instance in its group. Let h'_i be the suffix of length $|x_{i+2}|$ of the prefix x_i of p. Let $R_1(i)$ be the set of text characters with which $|p$ is aligned when some misfit character in h'_i is aligned with t_b.

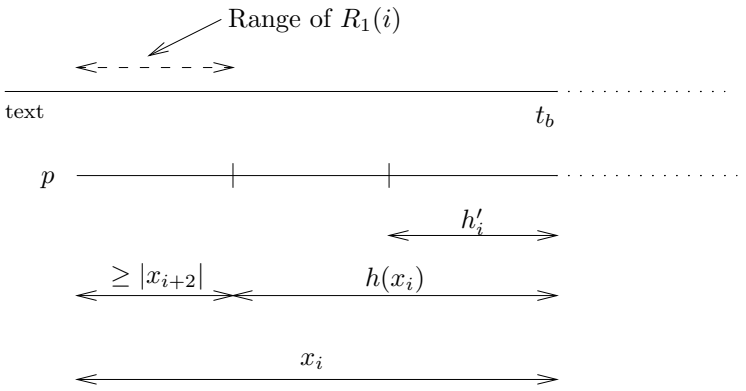

FIG. 5. *The h-suffix mapping lemma.*

LEMMA 5.11 (the h-suffix mapping lemma). $|R_1(i)| \geq r_i - 2$. *All text characters in* $R_1(i)$ *lie strictly to the left of* $|h(x_i)$ *but within the suffix* x_i *of* p_1.

Proof. (See Fig. 5.) By Lemmas 5.8 and 5.9, x_{i+2} and hence h'_i contain at least $r_{i-2} = \max\{0, r_i - 2\}$ misfit characters. Therefore, $|R_1(i)| \geq r_i - 2$. By Lemma 5.7, the left end of any pattern instance in which h'_i overlaps t_b is strictly to the left of $|h(x_i)$ and within the suffix x_i of p_1. □

DEFINITION. *Let* $O \subset V$ *be a half-done set consisting of the pattern instances* $\{p_{h_1}, \ldots, p_{h_j}\}$, $j \geq 3$, $p_{h_1} = p_1$. *Let the head and core of* x_{h_1} *be denoted* u *and* v, *respectively. Let* $v = u'u$. *Suppose* $|v| > 1$. *Further, suppose* p_{h_i} *is* $p_{h_{i-1}}$ *shifted distance* $|v|$ *to the right, for* $1 < i \leq j$. *Let* i_c, $2 \leq c \leq j$, *be the largest index such that* $p_{h_1}[i_c]$ *is different from the character in* p_{h_c} *aligned with it* (*such an index exists by Lemma* 4.7). *Note that* $i_c - i_{c-1} = |v|$, *for all* c, $3 \leq c \leq j$, *and that* $p_{h_1}[i_2] = p_{h_1}[i_3] = \cdots = p_{h_1}[i_j]$. *The text character* t_{i_c} *aligned with* $p_{h_1}[i_c]$ *is called the* characteristic character *of* p_{h_c}.

Let d be the leftmost character in the prefix uu' of p which differs from $p_{h_1}[i_2]$. Define $R_2(t_{i_c})$, $3 \leq c \leq j$, to be the text character with which $|p$ is aligned when d is aligned with t_{i_c}. In addition, define $R_2(O_e)$ to be the set of text characters $R_2(t_{i_c})$, $3 \leq c \leq e \leq j$. For convenience, let $R_2(O)$ denote $R_2(O_j)$.

LEMMA 5.12 (the half-done set mapping lemma). *All text characters in* $R_2(O_j)$ *are distinct.* $R_2(t_{i_c})$ *is aligned with or to the left of* t_{i_c} *and strictly to the right of* $t_{i_{c-1}}$, *for* $3 \leq c \leq j$. *All characters in* $R_2(O_c)$ *are aligned with or to the left of the characteristic character of* p_{h_c}; *in addition, they are strictly to the right of* $|p_{k+1}$, *for* $3 \leq c \leq j$.

Proof. By construction, $R_2(t_{i_c})$ is aligned with or to the left of t_{i_c}, $3 \leq c \leq j$. In addition, $R_2(t_{i_c})$ is at most distance $|v| - 1$ to the left of t_{i_c}. Since $i_c - i_{c-1} = |v|$, $R_2(t_{i_c})$ is strictly to the right of $t_{i_{c-1}}$.

The only part of the lemma still unproven is the claim that all characters in $R_2(O_j)$ are strictly to the right of $|p_{k+1}$. Note that t_{i_3} is distance $|v|$ to the right of t_{i_2}, $R_2(t_{i_3})$ is at most distance $|v| - 1$ to the left of t_{i_3}, and all characters in $R_2(O_j)$ are aligned with or to the right of $R_2(t_{i_3})$. Since t_{i_2} is aligned with or to the right of $|p_{k+1}$, the lemma follows. □

Note that p_{h_c} is eliminated by the time a comparison is made strictly to the left of its characteristic character, for $3 \leq c \leq j$. Further, if a successful comparison

eliminates p_{h_c}, then this comparison must involve its characteristic character.

5.2. The transfer function f. Let C be the set of text characters involved in comparisons in Steps 1 and 2 of the presuf shift handler of section 4.2. For each character $t_c \in C$, with at most two exceptions, we define $f(t_c)$ to be a text character t_d satisfying the following properties.

1. t_d is to the right of $|p_{k+1}$.
2. t_d either coincides with t_c or lies to the left of t_c.
3. The pattern instance whose left end is aligned with t_d is eliminated as a result of comparisons in Steps 1 and 2 of the presuf shift handler.
4. For every distinct $t_{c_1}, t_{c_2} \in C$, $f(t_{c_1}) \neq f(t_{c_2})$.

Furthermore, the mismatches, if any, are always included among the exceptions. We refer to the above properties as Properties 1, 2, 3 and 4, respectively.

Since patterns with $g = 1$ and $|x_k| = 1$ are special-case patterns, we assume that $g > 1$ if $|x_k| = 1$. Further, if $p_1[m]$ does not match the text, then Steps 1 and 2 of the presuf shift handler together make at most one comparison. Therefore, we also assume that $p_1[m]$ matches the text. Let p_l be the rightmost pattern instance in A_1. Let p_r be the rightmost pattern instance in V outside A_g, if any.

We split the sequence C' of comparisons made in Steps 1 and 2 of the presuf shift handler into three disjoint classes as follows.

1. Class 1 consists of the comparison in Step 1. In addition, if $|x_k| = 1$, then Class 1 contains the comparisons which comprise the smallest prefix of C' having the following property: either the last comparison in this prefix is unsuccessful or following that comparison, exactly one pattern instance in A_g survives.

2. Class 2 consists of the comparisons in C' which follow all Class 1 comparisons and are made in the suffix $h(x_l)$ of p_1.

3. Class 3 consists of comparisons in C' which follow all Class 2 comparisons.

Note that if Class 1 contains an unsuccessful comparison, then Class 2 is empty because no further comparisons are made in the suffix $h(x_l)$ of p_1. Thus Classes 1 and 2 together have at most one unsuccessful comparison. The only other possibly unsuccessful comparison is the last comparison in Class 3. We do not define an f value for the last comparison in Class 3. In addition, one other comparison may not receive an f value. If Classes 1 and 2 contain an unsuccessful comparison, then this comparison does not receive an f value. If all comparisons in Classes 1 and 2 are successful, then one successful comparison in one of the three classes may not receive an f value. All other comparisons receive f values. Thus f values are never defined for mismatches and at most two comparisons in C' do not receive f values.

We define f values for each class in turn. f values for Class 2 comparisons are always defined using the set $R_1(l)$. These f values are aligned with the suffix x_l of p_1 and to the left of $h(x_l)$. f values for Class 3 comparisons are defined in one of three ways. If all comparisons in Classes 1 and 2 are successful, then these f values are to the left of the suffix x_l of p_1. If Class 2 contains a mismatch, then these f values are defined using the set $R_1(l)$. If Class 2 is empty and Class 1 contains a mismatch, then these f values are aligned with or to the right of the suffix x_{r+1} of p_1. f values for Classes 2 and 3 are easily seen to be distinct. f values for Class 1 comparisons are aligned either with the suffix x_r of p_1 or with the suffix x_{r-1} of p_1; in Lemma 5.17, we show that these f values do not clash with the f values for Classes 2 and 3.

Classes 2 *and* 3. We consider three cases.

Case 1. Class 2 contains an unsuccessful comparison.

Classes 2 and 3 together contain at most $r_l - 1$ comparisons in addition to this unsuccessful comparison. To see this, note that $r_l - 1$ comparisons in addition to the comparisons in Class 1 suffice to eliminate all but one of the pattern instances in V to the right of p_l. Further, excluding the unsuccessful Class 2 comparison and the last comparison in Class 3, all other comparisons in Classes 2 and 3 are successful. f is defined to map the text characters involved in these $r_l - 2$ successful comparisons to the text characters in $R_1(l)$ in some arbitrary order. By the h-suffix mapping lemma and the fact that all Class 3 comparisons are to the right of $p_1[m]$ in this case, all the text characters in $R_1(l)$ lie to the left of all the text characters involved in Class 2 and Class 3 comparisons. Clearly, Properties 2, 3, and 4 are true for these f values. Property 1 follows from the fact that $|x_l| \leq |x_1| < \frac{m}{2}$, and hence $|p_{k+1}$ is to the left of the suffix x_l of p_1.

Case 2. All comparisons in Classes 1 and 2 are successful.

There are at most r_l comparisons in Class 2, all of which are successful. f is defined to map the text characters involved in $r_l - 2$ of these r_l comparisons to the text characters in $R_1(l)$ in some arbitrary order. As in Case 1, Properties 1, 2, 3, and 4 are satisfied by these f values. This leaves at most s Class 2 comparisons for some $s \leq 2$.

Next, we define f values for Class 3 comparisons and s Class 2 comparisons. These f values will be defined for all comparisons in Class 3 plus the s comparisons in Class 2, with at most two exceptions. These f values will be to the left of the suffix x_l of p_1 and thus clearly distinct from f values for Class 2 comparisons.

Following Class 2 comparisons, at most $\min\{r_l, 2\} - s$ of the pattern instances to the right of p_l survive along with pattern instances in A_1. Let O' denote the following set of $\min\{r_l, 2\}$ pattern instances: those pattern instances to the right of p_l which survive Class 1 and Class 2 comparisons and those pattern instances which are eliminated by one of the s Class 2 comparisons under consideration. Let O refer to the largest half-done set consisting of pattern instances in A_1 and O'. Redefine O' by removing pattern instances in it which are also in O. Considering comparisons which eliminate pattern instances in O and O' is equivalent to considering Class 3 comparisons plus the s Class 2 comparisons.

Let $O = \{p_{h_1}, \ldots, p_{h_e}\}$. If $l = 1$, then the number of comparisons in Class 3 plus s is at most $2 - s + s = 2$. In this case, we do not define f values for the comparisons in Class 3 and the s comparisons in Class 2. Therefore, suppose that $l > 1$. Each successful comparison which eliminates a pattern instance in O involves the characteristic character of the pattern instance eliminated. Let v and u be the core and head, respectively, of x_{h_1} and let $v = u'u$. $|v| > 1$ because either $|x_k| > 1$ or $|x_k| = 1$ and $g > 1$. By Lemma 5.10, v contains a misfit character.

First, consider successful comparisons which eliminate pattern instances in O. If $|O| \leq 2$, there is at most one such comparison in Class 3 and we do not define an f value for it. Therefore, suppose $|O| > 2$. There are two subcases depending on the location of the characteristic character t_{i_e} of p_{h_e}.

Subcase 2a. Either O' is not empty and t_{i_e} is strictly to the left of the left end of the suffix $x_{h_{e-1}}$ of p_1 or O' is empty and t_{i_e} is strictly to the left of the left end of the suffix $x_{h_{e-2}}$ of p_1.

For $3 \leq c \leq e$, if a successful comparison is made at t_{i_c}, $f(t_{i_c})$ is defined to be $R_2(t_{i_c})$. By the half-done set mapping lemma, these f values are strictly to the left of the suffix $x_{h_{e-1}}$ of p_1 if O' is not empty and strictly to the left of the suffix $x_{h_{e-2}}$ of p_1 if O' is empty. A simple case analysis (O' equals 0, 1, 2) shows that these f values

are strictly to the left of the left end of the suffix x_l of p_1, as claimed. Properties 1, 2, and 4 for these f values follow easily from the half-done set mapping lemma while Property 3 follows from the definition of the set $R_2(O)$. At most one successful comparison eliminating pattern instances in O does not have an f value: the one eliminating p_{h_2}.

Subcase 2b. Either O' is not empty and t_{i_e} is aligned with some character in the suffix $x_{h_{e-1}}$ of p_1 or O' is empty and the characteristic character of p_{h_e} is aligned with some character in the suffix $x_{h_{e-2}}$ of p_1.

In the first case, t_{i_c}, the characteristic character of p_{h_c}, is aligned with some character in the suffix $x_{h_{c-1}}$ of p_1, for $2 \leq c \leq e$. Consider the set R'_2 of $e-2$ text characters with which $|p$ is aligned when the rightmost misfit character in the prefix x_{h_c} of p, $1 \leq c \leq e-2$, is aligned with t_b. Since v contains a misfit character, the cth leftmost text character in R'_2 is aligned with some character in the suffix x_{h_c} of p_1 and is strictly to the left of the left end of the suffix $x_{h_{c+1}}$ of p_1. A successful comparison at t_{i_c}, $3 \leq c \leq e$, is mapped by f to the $(c-2)$nd leftmost character in R'_2. Clearly, all characters in R'_2 are distinct and $f(t_{i_c})$ is strictly to the left of t_{i_c}. All characters in R'_2 are aligned with some character in the suffix x_1 of p_1. Thus Properties 1, 2, 3, and 4 are satisfied by these f values. These f values are strictly to the left of the left end of the suffix $x_{h_{e-1}}$ of p_1. Since O' is not empty, $h_{e-1} \leq l$. Therefore, these f values are strictly to the left of the left end of the suffix x_l of p_1. Again, the only successful comparison without an f value, if any, is the one eliminating p_{h_2}.

In the second case, t_{i_c}, $4 \leq c \leq e$, is aligned with some character in the suffix $x_{h_{c-2}}$ of p_1. f values are not defined for the two leftmost comparisons under consideration. The remaining comparisons involve text characters aligned with some character in the suffix x_{h_2} of p_1. A successful comparison at t_{i_c}, $4 \leq c \leq e$, is mapped by f to the $(c-3)$rd leftmost character in R'_2. Clearly, $f(t_{i_c})$ is strictly to the left of t_{i_c}. As in the first case, Properties 1, 2, 3, and 4 are satisfied by these f values. All of these f values are to the left of the left end of the suffix $x_{h_{e-2}}$ of p_1. Since $h_{e-2} \leq l$ for this case, these f values are strictly to the left of the left end of the suffix x_l of p_1. The only successful comparisons without f values, if any, are those eliminating p_{h_3} and p_{h_2}. This ends Subcase 2b.

Before we define f values for comparisons which eliminate pattern instances in O', we need a lemma which will be used later when Class 3 comparisons are defined. This lemma can be verified easily from the above description.

LEMMA 5.13. *If $O \subset A_1$ and $|O'| \leq 1$, then the f values defined in Subcases* 2a *and* 2b *are to the left of the suffix x_{l-1} of p_1.*

Next, consider successful comparisons which eliminate pattern instances in O'. If $|O'| < 2$ or no successful comparison eliminates a pattern instance in O', then no further f values are defined. Therefore, suppose $|O'| = 2$ and a successful comparison is made to eliminate one of the pattern instances in O'. By Lemma 4.5, this comparison involves a text character t_c which is aligned with some character in the suffix x_{h_e} of p_1. $f(t_c)$ is defined to be the text character with which $|p$ is aligned when the rightmost misfit character in the prefix $x_{h_{e-1}}$ of p_1 is aligned with t_b. Since v contains a misfit character, $f(t_c)$ is aligned with some character in the suffix $x_{h_{e-1}}$ of p_1 and is strictly to the left of the suffix x_{h_e} of p_1. $f(t_c)$ is thus to the right of and distinct from all f values defined previously for comparisons which eliminate pattern instances in O. Further, $f(t_c)$ is to the left of t_c because t_c is aligned with the suffix x_{h_e} of p_1. Since $|O'| = 2$, $l = h_e$, and therefore $f(t_c)$ is strictly to the left of the suffix x_l of p_1, as claimed. Now Properties 1, 2, 3, and 4 are easily seen to be true for all Class 2

and 3 comparisons.

LEMMA 5.14. *For Case* 2, f *values have been defined for all but two of the comparisons in Classes* 2 *and* 3. *Further, the omitted comparisons include mismatches, if any.*

Proof. We just need to show that at most two of the comparisons among those which eliminate pattern instances in O and O' do not receive f values, for the mismatches never receive f values.

If $|O| < 2$, then there are at most two comparisons which eliminate pattern instances in O and O'. If O' is empty, then f values are defined for all but the last two comparisons which eliminate pattern instances in O. Therefore, suppose O' is not empty and $|O| \geq 2$. The only possible successful comparisons for which an f value might not be defined are those which eliminate p_{h_2} or one of the pattern instances in O'. There are two cases.

First, suppose $|O'| = 1$. Let $O' = \{p_z\}$. The only possible successful comparisons for which an f value is not defined are those which eliminate p_{h_2} or p_z. We show that if one of these successful comparisons actually occurs, then there can be at most one mismatch, and if both these successful comparisons occur, then there are no mismatches. (Recall that all comparisons in Classes 1 and 2 are successful.) Suppose p_{h_2} is eliminated by a successful comparison. p_{h_1} must be alive immediately before this comparison and $p_{h_3} \ldots p_{h_e}$ must have been eliminated prior to this comparison. This implies that no mismatch could have occurred before this comparison and only the pattern instances p_{h_1} and p_z survive this comparison. Therefore, if p_{h_2} is eliminated by a successful comparison, then there is at most one unsuccessful comparison, and if both p_{h_2} and p_z are eliminated by successful comparisons, then there are no unsuccessful comparisons. Next, suppose p_z is eliminated by a successful comparison but no successful comparison eliminates p_{h_2}. Each of the other comparisons in Class 3 eliminates some pattern instance in O and the first such unsuccessful comparison eliminates all but one of the instances in O. Therefore, there is at most one unsuccessful comparison in this case.

Second, suppose $|O| \geq 2$ and $|O'| = 2$. If one of the pattern instances in O' is eliminated by a successful Class 2 or 3 comparison, then an f value is defined for this comparison. From this point onwards, $|O| \geq 2$ and $|O'| = 1$. Therefore, the argument in the previous paragraph applies. On the other hand, if no successful Class 2 or 3 comparison eliminates a pattern instance in O', then the first comparison in Class 3 must be unsuccessful. This comparison leaves at most two pattern instances uneliminated and thus there are at most two comparisons which eliminate pattern instances in O and O'. □

Case 3. Class 1 contains an unsuccessful comparison.

In this case, $|x_k| = 1$ and Class 2 is empty as mentioned before. We define f values for all but the last of the comparisons in Class 3. These f values are aligned with or to the right of the suffix x_{r+1} of p_1. All Class 3 comparisons are made to the right of $p_1[m]$ in this case. Each such successful comparison matches an instance of the character x_k in p_{r+1} against a text character t_c; t_c is aligned with a non-x_k character in some pattern instance p_s, $s > r$. f is defined to map a text character t_c matched successfully by a Class 3 comparison to the text character with which $|p$ is aligned when the leftmost non-x_k character in p is aligned with t_c. Clearly, these f values are aligned with or to the right of the suffix x_{r+1} of p_1 and Properties 1, 2, 3, and 4 are satisfied by these f values.

This finishes the description of the f function for Classes 2 and 3. The following lemma is obvious from the above description.

LEMMA 5.15. *f values for Class 2 and 3 comparisons belong to one of the following sets of text characters:*

(i) *the set $R_1(l)$;*
(ii) *the set of text characters to the left of the suffix x_l of p_1 and to the right of $|p_{k+1}$;*
(iii) *the set of text characters aligned with or to the right of the suffix x_{r+1} of p_1.*

Further, an f value can be in set (i) *only if $r_l - 2 > 0$ and in set* (iii) *only if Class* 1 *contains an unsuccessful comparison.*

Class 1. We consider two cases, $|x_k| > 1$ and $|x_k| = 1$.

Case 1. $|x_k| > 1$.

The only comparison in Class 1 matches t_b with $p_1[m]$. $f(t_b)$ is defined to be t_b. This mapping satisfies Property 3 because the leftmost character in p is a misfit character in this case. If $g = 1$, then all other comparisons in C' are made to the left of t_b, and therefore all other f values are to the left of t_b. If $g > 1$, then all other f values are either to the left of the suffix x_l of p_1 or to the left of the suffix $h(x_l)$ of p_1. Since $|h(x_l)| \geq 1$ if $g > 1$, these f values are to the left of t_b. Therefore, Property 4 is satisfied by all f values. Properties 1 and 2 are obvious for $f(t_b)$.

Case 2. $|x_k| = 1$.

$g > 1$ by assumption. f values are defined for all comparisons in Class 1 unless either Class 1 contains an unsuccessful comparison or $r = l = 1$. If Class 1 contains an unsuccessful comparison or if $r = l = 1$, then one comparison in Class 1 does not receive an f value. However, in these cases, there is at most one comparison in Classes 2 and 3 for which an f value was not defined earlier. To see this, note that if the last Class 1 comparison is successful and $r = l = 1$, then Classes 2 and 3 together can have at most one comparison, and if the last Class 1 comparison is unsuccessful, then Class 2 is empty and Case 3 must hold for Class 3 comparisons.

All f values defined for Class 1 comparisons will be to the left of the suffix x_{r+1} of p_1 and aligned with either the suffix x_{r-1} of p_1 or the suffix x_r of p_1. Clearly, if $p_l \neq p_r, p_{r-1}$, then these f values are distinct from all f values defined earlier for Class 2 and 3 comparisons. If $p_l = p_{r-1}$, then $r_l - 2 = 0$ and all f values for Class 2 and 3 comparisons are either to the left of the suffix x_{r-1} of p_1 or aligned with or to the right of the suffix x_{r+1} of p_1. Therefore, f values for comparisons in Class 1 are distinct from f values for comparisons in Classes 2 and 3 in this case. If $p_l = p_r$, then $r_l - 2 < 0$ and, by Lemma 5.15, all f values for Class 2 and 3 comparisons are either to the left of the suffix x_r of p_1 or aligned with or to the right of the suffix x_{r+1} of p_1. In this case, we show that if an f value for some Class 1 comparison is aligned with the suffix x_{r-1} of p_1 and to the left of the suffix x_r of p_1, then all f values for Class 2 and Class 3 comparisons are to the left of the suffix x_{r-1} of p_1. Thus all f values are distinct.

The following lemma describes the distribution of Class 1 comparisons.

LEMMA 5.16. *Let d be the rightmost misfit character in p_1. Each Class* 1 *comparison involves a text character which is aligned with or to the right of d.*

Proof. Suppose two pattern instances $p_{j_1}, p_{j_2} \in A_g$, $j_1 < j_2$, are left uneliminated by comparisons made at or to the right of d. Let c_{j_1} and c_{j_2} be the portions of p_{j_1} and p_{j_2}, respectively, which overlap the suffix z of p_1 starting at d. Then $c_{j_1} = c_{j_2} = z$. Consider the characters in p_{j_1} and p_{j_2} aligned with the $(j_2 - j_1)$th character to the right of d in p_1. Clearly, the first of these matches x_k while the second is a misfit

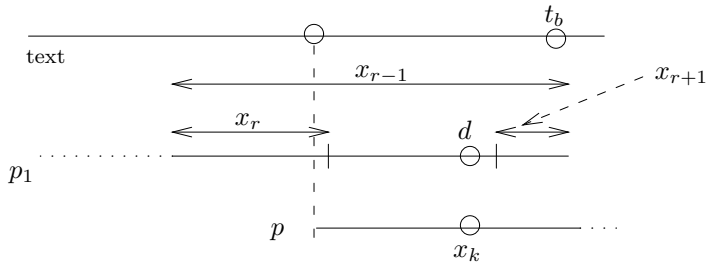

FIG. 6. *The set* R_3, $r > 1$.

character. This is a contradiction. □

Note that x_r contains a misfit character. Further, its suffix and prefix x_{r+1} are disjoint. Each contains at least $k - r$ instances of x_k. We define a set R_3 of text characters which serves as the range of f values for Class 1 comparisons. The definition has the following property. All characters in R_3 are to the left of the suffix x_{r+1} of p_1. If all successful Class 1 comparisons are made to the right of d or if $r = 1$, then all characters in R_3 are aligned with the suffix x_r of p_1. If a successful Class 1 comparison is made at d and $r > 1$, then characters in R_3 are aligned with the suffix x_{r-1} of p_1.

First, suppose all successful Class 1 comparisons are made to the right of d. Each successful comparison matches an occurrence of x_k to the right of d against the text. R_3 is defined to be the set of text characters with which $|p$ is aligned when d', the leftmost misfit character in p, is aligned with one of the text characters matched by a Class 1 comparison. Clearly, all characters in R_3 are aligned with the suffix x_r of p_1. f is defined to map the text characters compared by Class 1 comparisons to the text characters in R_3 in some arbitrary order. Properties 2, 3, and 4 readily follow for these f values. Property 1 follows from the fact that $|x_r| \leq |x_1| < \frac{m}{2}$.

Next, suppose a successful Class 1 comparison is made at d. In this case, all comparisons in Class 1 are successful and there are at most $k + 1 - r$ comparisons in Class 1. R_3 is defined differently depending upon whether $r = 1$ or $r > 1$.

First, suppose $r = 1$. R_3 is defined to contain the $k - r$ text characters with which $|p$ is aligned when one of $k - r$ instances of x_k to the left of d' (recall that d' is the leftmost misfit character in p) is aligned with d. The text characters in R_3 are clearly aligned with the suffix x_r of p_1. f is defined to map up to $k - r$ of the text characters compared by Class 1 comparisons to the $k - r$ text characters in R_3 in some arbitrary order. All of these f values are distinct and are aligned with or to the left of d. Properties 2, 3, and 4 immediately follow for these f values. Property 1 follows from the fact that $|x_r| \leq |x_1| < \frac{m}{2}$.

Next, suppose $r > 1$. See Fig. 6. When p is placed with $|p$ aligned with the left end of the suffix x_{r-1} of p_1, there exist at least $2(k - r) \geq k - r + 1$ instances of x_k to the left of d in p. R_3 is defined to be the set of $2(k - r)$ text characters with which $|p$ is aligned when one of these $2(k - r)$ instances of x_k is aligned with d. Clearly, characters in R_3 are aligned with the suffix x_{r-1} of p_1. f is defined to map the text characters compared by Class 1 comparisons to some $k - r + 1$ of the $2(k - r)$ text characters in R_3 in some arbitrary order. Properties 2 and 3 readily follow for these f values. Property 1 follows from the fact that $|x_{r-1}| \leq |x_1| < \frac{m}{2}$. The distinctness of these f values from the f values for Classes 2 and 3 follows from the following lemma.

LEMMA 5.17. *If $r > 1$, $p_l = p_r$, and a successful Class 1 comparison is made at d, then f values for Class 2 and 3 comparisons are to the left of the suffix x_{r-1} of p_1.*

Proof. At most one pattern instance $p_{r'} \in A_g$ survives a successful comparison at d. Further, Class 1 does not contain an unsuccessful comparison. Since $r_l = 1$, Class 2 contains at most one comparison. If this comparison is unsuccessful, then only $p_{r'}$ survives; no f values are defined for Class 2 or 3 comparisons in this case. If the sole Class 2 comparison is a successful one, then Case 2 must hold for all Class 2 and 3 comparisons. Since $r_l = 1$, $r_l - 2 < 0$ and, by Lemma 5.15, no f values are defined using the set $R_1(l)$. Therefore, all f values for Class 2 and 3 comparisons in this case are defined as in Subcases 2a and 2b. Refer to these subcases. Note that, in this case, O consists of the pattern instances in A_1 and $O' = \{p_{r'}\}$. From Lemma 5.13, all f values for Class 2 and 3 comparisons are to the left of the suffix x_{r-1} of p_1 in this case. □

This concludes the definition of the f function.

6. Presuf shifts with $|x'_1| \geq \frac{m}{2}$. This case can occur only for periodic patterns. Therefore, assume that p is periodic and has the form $u_p v_p^{i_p}$, where v_p and u_p are the core and head of p, respectively, and $i_p \geq 2$.

Recall that the lower bound of $\frac{m+1}{2}$ on the distance between consecutive presuf shifts was crucial in deriving the comparison complexity for the case where $|x'_1| < \frac{m}{2}$. This lower bound does not hold if $|x'_1| \geq \frac{m}{2}$. Consecutive presuf shifts can occur distance $|v_p| \ll \frac{m+1}{2}$ apart. Even a single mismatch per presuf shift leads to a large comparison complexity. Since the problem in this case lies only in the frequency of occurrence of presuf shifts, we use the same basic algorithm, changing only the presuf shift handler. The new presuf shift handler ensures that either two consecutive presuf shifts are at least distance $\frac{m+1}{2}$ apart or no mismatch occurs between consecutive presuf shifts. In fact, we show the following stronger claim about the performance of the presuf shift handler. A presuf shift has overhead 0 if the next presuf shift occurs a distance less than $\frac{m+1}{2}$ ahead, overhead 1 if the next presuf shift occurs a distance less than $\frac{3(m+1)}{4}$ ahead, and overhead at most 2 otherwise. A comparison complexity of $n(1 + \frac{8}{3(m+1)})$ comparisons follows.

6.1. The presuf shift handler for $|x'_1| \geq \frac{m}{2}$. Before describing the presuf shift handler, we recall some definitions and assumptions made in section 4. Let t_A refer to the portion of the text with which the prefix x'_1 of p is aligned following the shift. We assume that prefix x'_1 of p matches t_A following a presuf shift and that the variable t_{last} has been appropriately set to prevent this assumption from leading to an incorrect inference. Let t_a refer to the rightmost character in t_A.

As for the case where $|x'_1| < \frac{m}{2}$, the presuf shift handler considers all presuf pattern instances, i.e., those pattern instances in which a prefix (possibly null) of p matches some suffix of t_A. In a presuf pattern instance, the prefix matching a suffix of t_A is a presuf of p and is called the presuf corresponding to this presuf pattern instance. Presuf pattern instances are of two types. The first type consists of those presuf pattern instances whose corresponding presufs have the form $u_p v_p^l$, $1 \leq l \leq i_p - 1$. The second type consists of those presuf pattern instances whose corresponding presufs are less than $|v_p|$ in length. We identify a presuf pattern instance p'_α of the second type as follows. If $|u_p| > 0$, then p'_α is the presuf pattern instance corresponding to the presuf u_p. If $|u_p| = 0$, then p'_α is the presuf pattern instance corresponding to the null presuf; i.e., $|p'_\alpha$ is to the immediate right of t_a. The following observation

enables us to work with only presuf pattern instances of the second type while making comparisons within a text window γ of length $|v_p|$ to the right of t_a.

LEMMA 6.1. *A presuf pattern instance of the first type matches all text characters in the window γ if and only if p'_α matches all characters in that window.*

Proof. The portion of p'_α which overlaps γ is identical to v_p, as is the corresponding portion of any presuf pattern instance of the first type. □

If p'_α is eliminated by comparisons in γ, then so are all presuf pattern instances of the first type. This forces the next presuf shift to occur at least distance $m - |v_p| \geq \frac{m}{2} + 1$ to the right. If p'_α is not eliminated by comparisons in γ, then presuf pattern instances of the first type also survive, and therefore the next presuf shift can occur as little as distance $|v_p|$ to the right. In this case, it is important to ensure that no mismatches are made in γ.

The presuf shift handler has five steps and works broadly as follows. As in the presuf shift handler of section 4.2, the first two steps identify a presuf pattern instance p'_e with the following property: all presuf pattern instances that survive the first two steps are presuf overlaps of p'_e. This is accomplished by making comparisons in a manner similar to the presuf shift handler of section 4.2, but with a single difference. This difference is aimed at ensuring that the first mismatch eliminates p'_α. Steps 3, 4, and 5 are, however, identical to the corresponding steps of the earlier presuf shift handler.

Steps 1 and 2 proceed as follows to determine p'_e. They consider only presuf pattern instances of the second type and eliminate all but one of these. The survivor determines p'_e; i.e., if the survivor is p'_α, then p'_e is the leftmost presuf pattern instance, and otherwise p'_e is the survivor itself. We show that in order to eliminate among presuf pattern instances of the second kind, it suffices to consider suitable prefixes of these presuf pattern instances. We need the following definitions in order to describe Steps 1 and 2 in detail. Consider the leftmost presuf pattern instance of the second type and let β be the length of the corresponding presuf. Suppose there are $k'' + 1$ presuf pattern instances of the second type. We define $p''_1, \ldots, p''_{k''}, p''_{k''+1}$ such that p''_j, $1 \leq j \leq k'' + 1$, is the prefix of length $m'' = \beta + |v_p|$ of the jth leftmost presuf pattern instance of the second type. Let x''_j, $1 \leq j \leq k'' + 1$, be the presuf corresponding to the jth leftmost presuf pattern instance of the second type. We call x''_j the presuf corresponding to p''_j. Let p''_α refer to the length m'' prefix of p'_α and p'' refer to the length m'' prefix of p. The following lemma shows that in order to eliminate all but one of the presuf pattern instances of the second kind, it suffices to consider only $p''_1, \ldots, p''_{k''}, p''_{k''+1}$.

LEMMA 6.2. *At most one of $p''_1, \ldots, p''_{k''}, p''_{k''+1}$ matches γ.*

Proof. Let x and y be the portions overlapping γ in some two of $p''_1, \ldots, p''_{k''+1}$. Then x and y are different cyclic shifts of v_p. If $x = y$, then v_p is cyclic, a contradiction. □

Let $V'' = \{p''_1, \ldots, p''_{k''+1}\}$. Note that Lemmas 4.3–4.7 continue to hold if p_j, x_j, V, p, and m are replaced by p''_j, x''_j, V'', p'', and m'', respectively, for $1 \leq j \leq k'' + 1$. Henceforth, these substitutions are implicit in all references to these lemmas. The elements in V'' are divided into groups $A''_1, \ldots, A''_{g''}$ in accordance with Lemma 4.3.

Remark. The presuf shift handler being described does not work for patterns for which $|x''_{k''}| = 1$ and $g'' = 1$. Presuf shifts for these exception patterns are handled separately in section 6.5.

With this background, we describe the five steps of the presuf shift handler.

Step 1. The characters in $p''_1, \ldots, p''_{k''}$ aligned with $p''_1[m'']$, the rightmost character

in p''_1, are identical. If the character in $p''_{k''+1}$ aligned with $p''_1[m]$ is also identical to it, then $p''_1[m]$ is compared with the aligned text character. A mismatch eliminates all of $p''_1, \ldots, p''_{k''}, p''_{k''+1}$ and the basic algorithm is restarted with $|p$ placed immediately to the right of $|p_{k''+1}$. A match leads to Step 2.

Step 2. All but one of $p''_1, \ldots, p''_{k''+1}$ are eliminated in this step by making up to k'' comparisons, at most two of which are unsuccessful. Further, p''_α is eliminated by the first unsuccessful comparison. As in Step 2 of section 4.2, there are two phases.

Phase 1 is identical to Phase 1 of section 4.2; i.e., at every step the rightmost character c in p''_1 having the following property is compared with the aligned text character: the character aligned with c in at least one of the surviving elements in V'' is different from c. By Lemma 4.6, the outcome of Phase 1 is a half-done set O.

LEMMA 6.3. *$p''_\alpha \in O$ if and only if all of the comparisons in Phase* 1 *are successful.*

Proof. All comparisons in Phase 1 are made in the suffix x''_1 of p_1 because, by Lemma 4.5, successful comparisons in that suffix leave a half-done set uneliminated. x''_1 is a presuf of p''_1 and therefore a suffix of v_p. By the manner in which p'_α is defined, the portion of p''_α that overlaps γ is identical to the string v_p. Therefore, a mismatch in Phase 1 eliminates both p''_1 and p''_α while a match in Phase 1 eliminates neither. The lemma follows. □

If Phase 1 ends with a mismatch or if $p''_\alpha = p''_1$, then Phase 2 is identical to Phase 2 of section 4.2; i.e., all but one of the elements in O are eliminated by making comparisons according to a right-to-left sequence. Note that in both cases, the first mismatch eliminates p''_α. Otherwise, if $p''_\alpha \neq p''_1$ and all comparisons in Phase 1 are successful, then we modify Phase 2 as follows so as to ensure that the first mismatch eliminates p''_α.

Phase 2 proceeds exactly as Phase 2 of Step 2 in section 4.2 until p''_α becomes the rightmost element in O. Any mismatch in this process terminates Phase 2 and eliminates p''_α and all elements in O to the left of p''_α. If no mismatch occurs in this process, then let the surviving elements in O be $\{p''_{h_1}, \ldots, p''_{h_e}\}$, where $p''_{h_1} = p''_1$ and $p''_{h_e} = p''_\alpha$. These elements are eliminated using a left-to-right sequence of comparisons instead of the right-to-left sequence used in Step 2 of section 4.2. This left-to-right sequence ensures that a mismatch eliminates p''_α. Let d_e be the leftmost character in p''_{h_e} such that p''_{h_e} differs from the aligned character in $p''_{h_{e-1}}$. By Lemma 6.2, d_e is aligned with or to the left of $p''_1[m'']$ and to the right of t_a. If $e = 2$, then a comparison at d_e terminates Phase 2 with a mismatch eliminating p''_{h_e} and a match eliminating p''_{h_1}. Suppose $e > 2$. Then x''_{h_1} is periodic with core, say, v. Let d_j, $2 \leq j \leq e-1$, be the character in p''_{h_e} which is distance $(e-j)|v|$ to the left of d_e. The characters $d_2, \ldots, d_e$ are compared with the aligned text characters in sequence until either a mismatch occurs or the sequence is exhausted. The following lemma shows that at most one element of O survives these comparisons.

LEMMA 6.4. *A mismatch at d_j leaves only $p_{i_{j-1}}$ uneliminated. A match at d_j eliminates $p_{i_{j-1}}$.*

Proof. If $e = 2$, then the lemma is clearly true. Suppose $e > 2$. From the definition of d_e, it follows that the prefix of p''_{h_e} ending at d_e is periodic with core of size $|v|$ while the prefix of $p''_{h_{e-1}}$ is not; therefore, $d_2 = d_3 = \cdots = d_e \neq d_{e+1}$, where d_{e+1} is the character which is distance $|v|$ to the right of d_e. It follows that the characters in $p''_{h_j}, \ldots, p''_{h_e}$ aligned with d_j are identical to each other but different from the character in $p''_{h_{j-1}}$ aligned with d_j. Therefore, a match at d_j eliminates $p''_{h_{j-1}}$. A mismatch at d_j eliminates $p''_{h_j}, \ldots, p''_{h_e}$ and the preceding successful comparisons at

$d_2, \ldots, d_{j-1}$ eliminate $p''_{h_1}, \ldots, p''_{h_{j-2}}$. The lemma follows. □

This completes Step 2. At most k'' comparisons are made in this step, at most two of which result in mismatches. Further, p''_α survives only if there are no mismatches. The sequence of comparisons made in Step 2 can be represented by a tree ET'', akin to the tree ET of section 4.2. The only difference between ET'' and ET is that the sequence corresponding to a portion of Phase 2 may now be a left-to-right sequence if Phase 1 does not end in a mismatch and $p''_\alpha \neq p''_1$. We conclude Step 2 with the following lemma.

LEMMA 6.5. *All but at most one of $p''_1, \ldots, p''_{k''}, p''_{k''+1}$ can be eliminated by making up to k'' comparisons using the $O(k'')$-sized binary comparison tree ET''. At most two of these comparisons result in mismatches. If p''_α survives, then no comparisons result in mismatches. Moreover, the sequence of comparisons made by the elimination strategy consists of two sequences: a right-to-left sequence followed by either another right-to-left sequence or a left-to-right sequence.*

We describe Steps 3, 4, and 5 next. Let p''_e be the only element of V'' to survive Steps 1 and 2. If $p''_e = p''_\alpha$, then define p'_e to be the leftmost presuf pattern instance. If $p''_e \neq p''_\alpha$, then let p'_e be the presuf pattern instance of which p''_e is a prefix; i.e., p'_e and p''_e have their left ends aligned. Clearly, p'_e is the leftmost presuf pattern instance to survive Steps 1 and 2. Let Q denote the set of pattern instances which overlap p'_e and have their left end to the right of $|p''_{k''+1}$. In the elimination process, some elements of Q may also have been eliminated from being potential matches. They need not be reconsidered. To this end, a subset Q_x of Q consisting of pattern instances consistent with comparisons in Steps 1 and 2 is associated with each terminal node x in ET''. The maintenance of Q_x is similar to the description in section 4.5 and is described in section 6.4. Suppose that the elimination process terminates at terminal node x. Let $Q' = \{p'_e\} \cup Q_x$. Steps 3, 4, and 5 are now identical to the corresponding steps in section 4.2.

6.2. Comparison complexity. In order to determine the comparison complexity, we need to define a transfer function f'' akin to the transfer function f defined in section 5. We state the following lemma describing the properties of f''. The proof of this lemma is deferred to section 6.3.

LEMMA 6.6. *Let C be the set of text characters involved in comparisons in Steps 1 and 2 of the presuf shift handler of section 6.1. For each character $t_c \in C$, with at most two exceptions, there exists a text character $f''(t_c) = t_d$ satisfying the following properties:*

1. *t_d is to the right of $|p''_{k''+1}$.*
2. *t_d either coincides with t_c or lies to the left of t_c.*
3. *The pattern instance whose left end is aligned with t_d is eliminated as a result of comparisons in Steps 1 and 2 of the presuf shift handler.*
4. *For every distinct $t_{c_1}, t_{c_2} \in C$, $f(t_{c_1}) \neq f(t_{c_2})$.*

Furthermore, mismatches, if any, are always included among the exceptions.

The following lemma determines the comparison complexity of the algorithm.

LEMMA 6.7. *If p is not a special-case pattern, then the comparison complexity of the algorithm is bounded by $n(1 + \frac{8}{3(m+1)})$.*

Proof. A presuf shift occurs either with $|x'_1| < \frac{m}{2}$ or with $|x'_1| \geq \frac{m}{2}$. In the former case, it was shown in Lemma 4.12 that a presuf shift can have overhead at most two and that an overhead of two implies that the next presuf shift occurs at least distance $\frac{3(m+1)}{4}$ to the right. Further, $\frac{m+1}{2}$ is a lower bound on the distance between two consecutive presuf shifts in this case. We show similar properties for presuf shifts

with $|x'_1| \geq \frac{m}{2}$. Specifically, we show that a presuf shift can have overhead at most two. Further, we show that an overhead of one forces the next presuf shift to occur at least distance $\frac{m+1}{2}$ to the right and an overhead of two forces the next presuf shift to occur at least distance $\frac{3(m+1)}{4}$ to the right. We show the above by giving a charging scheme for the presuf shift handler of section 6.1. The comparison complexity of the algorithm now follows.

Charging scheme. As in Lemma 4.12, the run of the algorithm is divided into phases; a phase can be of one of four types. The ranges of the text characters charged in each phase type remain exactly the same as in Lemma 4.12. The charging scheme for Type 1 and Type 2 phases also remains exactly the same. Only the charging scheme for Type 3 and Type 4 phases is modified in accordance with the presuf shift handler of section 6.1.

We consider a single phase, which could be a Type 3 or a Type 4 phase. We assume that this phase begins with a presuf shift with $|x'_1| \geq \frac{m}{2}$. Let q_1 and q_2 refer to the leftmost surviving pattern instances at the beginning and end of that phase, respectively. Note that q_1 is a presuf overlap of the pattern instance q', the leftmost uneliminated pattern instance prior to the presuf shift which initiated this phase. Specifically, the prefix x'_1 of q_1 is aligned with the suffix x'_1 of q' (recall that on a presuf shift, we assume that the prefix x'_1 of q_1 matches the text). Recall that t_a is the text character aligned with $q'|$.

Consider the comparisons made by the current use of the presuf shift handler of section 6.1. If a mismatch occurs in Step 1, the current phase ends immediately and the basic algorithm is resumed. The presuf shift in this case has overhead one and the next presuf shift occurs at least distance $m + 1$ to the right. Next, suppose that the comparison in Step 1 is successful. Let p'_e be the presuf pattern instance to survive the elimination using tree ET'' in Step 2. After the presuf shift handler finishes, one of three scenarios ensues. We consider each in turn.

1. All pattern instances overlapping p'_e are eliminated apart from its presuf overlaps, and p'_e or at least a suffix of p'_e is matched. This is a Type 4 phase. We consider two cases, depending upon whether p'_e is a presuf pattern instance of the first or the second type.

First, suppose p'_e is of the first type; i.e., it is the leftmost presuf pattern instance. Then no mismatches are made in Steps 1, 2, 3, 4, or 5. All comparisons made by the presuf shift handler are charged to the text characters compared. The bit vector BV ensures that each of these comparisons involves a different text character. Thus each text character which lies to the right of t_a and is aligned with or to the left of $p'_e|$ is charged at most once. In this case, the overhead of this presuf shift is zero.

Next, suppose p'_e is of the second type. Then p''_α is eliminated in Step 2. All comparisons in Steps 1, 3, 4, and 5 and all but at most two comparisons in Step 2 are successful. Each successful comparison is charged to the text character compared. The bit vector BV ensures that each of these comparisons involves a different text character. Thus each text character which lies to the right of t_a and is aligned with or to the left of $p'_e|$ is charged at most once. At most two comparisons in Step 2 are unsuccessful, so this shift has overhead at most two. If there are two mismatches in Step 2, then we claim that p''_1 is eliminated; in addition, if x''_1 is periodic, with core v and head u, say, then all elements in V'' whose associated presufs have the form uv^o, $o \geq 1$, are also eliminated. (This can be shown in a manner similar to the corresponding proof in Lemma 4.12.) Let p''_e be the m''-length prefix of p'_e and let x''_e be the presuf associated with p''_e. From the above, it follows that $x''_1 = x''_e z x''_e$, for

some nonempty string z. Since $|x''_1| < |v_p|$, $p''_e = x''_1 w x''_1$ for some nonempty string w. Therefore, $|x''_e| \leq \frac{m''-3}{4} \leq \frac{m-3}{4}$. This guarantees that the next presuf shift occurs at least distance $\frac{3(m+1)}{4}$ to the right. If there is just one mismatch in Step 2, then since $|x''_1| < |v_p| \leq \frac{m}{2}$, the next presuf shift occurs at least distance $\frac{m+1}{2}$ to the right.

2. p'_e is eliminated. In addition, there is some pattern instance q_c overlapping p'_e, such that all pattern instances overlapping q_c are eliminated apart from its presuf overlaps; further, q_c or at least a suffix of q_c is matched. This is also a Type 4 phase.

Each comparison in Steps 1 and 2 with a text character to the left of $|q_c$ for which function f'' is defined is charged to the text character specified by the function f'', called its f'' value; f'' values are distinct by definition. Comparisons in Step 3 fall into one of three categories:

1. comparisons which eliminate pattern instances whose left ends lie to the right of $|p''_{k''+1}$ and to the left of $|q_c$;
2. comparisons which eliminate pattern instances whose left ends lie to the right of $|q_c$;
3. the comparison which eliminates p'_e.

Each comparison in the first category is charged to the text character aligned with the left end of the pattern instance eliminated. By the definition of the function f'', these text characters do not occur in the range of f'' values. Comparisons in the second category, along with the comparisons made in Steps 4 and 5 and those successful comparisons in Steps 1 and 2 that involve text characters overlapping q_c, are charged to the text characters compared. BV ensures that each of these comparisons involves a distinct text character. Thus each text character which lies to the right of $|p''_{k''+1}$ and is aligned with or to the left of $q_c|$ is charged at most once. The comparison that eliminates p'_e is charged to the text character aligned with $|p''_{k''+1}$. Since all f'' values lie to the right of $|p''_{k''+1}$ and all pattern instances eliminated by comparisons in the first category have left ends to the right of $|p''_{k''+1}$, this text character is charged exactly once. The two comparisons in Step 2 lacking f'' values constitute the overhead of this presuf shift. Since p'_e is eliminated, the next presuf shift occurs at least distance $m+1$ to the right of the current presuf shift.

3. p'_e is eliminated as are all pattern instances overlapping p'_e. This is a Type 3 phase.

Let q_d denote the leftmost surviving pattern instance. All comparisons in Steps 1 and 2 for which function f'' is defined are charged to their f'' values. f'' values are distinct by definition. Excluding the comparison which eliminates p'_e, each comparison in Steps 3 and 4 eliminates some pattern instance whose left end lies to the right of $|p''_{k''+1}$ and to the left of $|q_d$. Each such comparison is charged to the text character aligned with the left end of the pattern instance eliminated. These text characters cannot occur in the range of the function f'' and hence are charged only once. Thus each text character which lies to the right of $|p''_{k''+1}$ and to the left of $|q_d$ is charged at most once. The comparison that eliminates p'_e is charged to the text character aligned with $|p''_{k''+1}$. The two comparisons in Step 2 lacking f'' values constitute the overhead of this presuf shift. Since p'_e is eliminated, the next presuf shift occurs at least distance $m+1$ to the right of the current presuf shift. □

6.3. The transfer function f''. In this section, we prove Lemma 6.6. The definition of the function f'' is similar to that of the function f in section 5. This is hardly surprising since the elimination procedure ET'' is similar to the elimination process ET, the only difference between the two being that the former switches to a left-to-right comparison sequence in some cases.

First, note that each of the definitions and lemmas in section 5.1 continue to hold if p''_j, x''_j, V'', p'', A'', g'', k'', and m'' replace p_j, x_j, V, p, A, g, k, and m, respectively, for $1 \leq j \leq k'' + 1$.

Since patterns with $g'' = 1$ and $|x''_k| = 1$ are special-case patterns, we assume that $g'' > 1$ if $|x''_k| = 1$. If $p''_1[m'']$ does not match the text, then Steps 1 and 2 of the presuf shift handler make at most one comparison. Therefore, we also assume that $p''_1[m]$ matches the text. Let p''_l be the rightmost element in A''_1. Let p''_r be the rightmost element in V'' outside $A''_{g''}$, if such a pattern instance exists.

As in section 5.2, we split the sequence C' of comparisons made in Steps 1 and 2 of the presuf shift handler into three classes as follows.

1. Class 1 consists of the comparison in Step 1. In addition, if $|x''_k| = 1$, then Class 1 contains the comparisons which comprise the smallest prefix of C' having the following property: either the last comparison in that prefix is unsuccessful or following that comparison, exactly one pattern instance in $A''_{g''}$ survives.

2. Class 2 consists of the comparisons in C' which follow all Class 1 comparisons and are made in the suffix $h(x''_l)$ of p''_1.

3. Class 3 consists of comparisons in C' which follow all Class 2 comparisons.

f'' values are defined by considering 3 cases.

Case 1. Suppose Phase 1 of Step 2 terminates with a mismatch or $p''_\alpha = p''_1$. Then ET'' eliminates among elements in V'' exactly as ET eliminates among the elements of V. Therefore, f'' values for comparisons are defined exactly as in section 5.2 with p''_j, x''_j, V'', p'', A'', g'', k', and m'' replacing p_j, x_j, V, p, A, g, k, and m, respectively, for $1 \leq j \leq k'' + 1$.

Case 2. Suppose $p''_\alpha = p''_2$ or the half-done set left uneliminated by Phase 1 has at most two elements. The only difference between the way ET'' eliminates among the elements in V'' and ET eliminates among elements in V is in the last comparison of Step 2. Note that in section 5.2, the last comparison in Step 2 is not given an f value. Therefore, f'' values for comparisons in this case are again defined exactly as in section 5.2 with p''_j, x''_j, V'', p'', A'', g'', k'', and m'' replacing p_j, x_j, V, p, A, g, k, and m, respectively, for $1 \leq j \leq k'' + 1$.

Case 3. Suppose all comparisons in Phase 1 are successful, $p''_\alpha \neq p''_1, p''_2$, and the half-done set which survives Phase 1 has at least three elements. The only difference between the way ET'' eliminates among the elements in V'' and ET eliminates among the elements in V is in the portion of Phase 2 that makes comparisons according to a left-to-right sequence. As we will show in Lemma 6.11, this left-to-right sequence involves only text characters to the left of the suffix x''_1 of p''_1. Consequently, Class 1 and Class 2 comparisons are not affected by this sequence.

f'' values for comparisons in Class 1 are defined exactly as in section 5.2 with p''_j, x''_j, V'', p'', A'', g'', k'', and m'' replacing p_j, x_j, V, p, A, g, k, and m, respectively, for $1 \leq j \leq k'' + 1$. Consider Class 2 comparisons next. At most one element of V'' will survive a mismatch in Class 2, if any, because Phase 1 has no mismatches. Therefore, if a mismatch occurs in Class 2, then Class 3 is empty and f'' values for Class 2 comparisons are defined exactly as in section 5.2 with the appropriate substitutions mentioned above. Otherwise, if all comparisons in Class 2 are successful, then f'' values for all but some s, $s \leq 2$, of the comparisons in Class 2 are defined in the same manner. It remains to define f'' values for Class 3 comparisons and s Class 2 comparisons when all comparisons in Class 2 are successful. This involves modifying only Case 2 of the definition of f values for Class 2 and Class 3 comparisons in section 5.2. We define f'' values for all but two of these comparisons. The range of these f''

values is the same as the range of the f values defined for this subcase, i.e., to the left of the suffix x''_l of p''_1 and to the right of $|p''_{k+1}$.

Following Class 1 and 2 comparisons, at most $\min\{r_l, 2\} - s$ of the elements of V'' to the right of p''_l survive along with the elements in A''_1. Let O' refer to the set of $\min\{r_l, 2\}$ elements in V'' which includes elements which survive comparisons in $h(x''_l)$ and elements which are eliminated by one of the s Class 2 comparisons under consideration. Let O refer to the largest half-done set consisting of elements in A''_1 and O'. Redefine O' by removing pattern instances in it which are also in O. Considering comparisons which eliminate pattern instances in O and O' is equivalent to considering Class 3 comparisons plus s of the Class 2 comparisons. Let $O = \{p''_{h_1}, \ldots, p''_{h_e}\}$. Let v and u be the core and head, respectively, of x''_{h_1} and let $v = u'u$. $|v| > 1$ because either $|x''_k| > 1$ or $|x''_k| = 1$ and $g' > 1$. By Lemma 5.10, v contains a misfit character. If $l = 1$, then the number of comparisons in Class 3 plus s is at most $2 - s + s = 2$. In this case, we do not define an f'' value for the comparisons in Class 3 and the s comparisons in Class 2. Therefore, suppose that $l > 1$.

The comparisons given by tree ET'' in this case form two sequences; the first sequence which includes Phase 1 and part of Phase 2 is a right-to-left sequence and the second sequence is a left-to-right sequence. The following lemmas show some properties which are necessary for defining f''.

LEMMA 6.8. *The portion of p''_α which overlaps the suffix x''_i, $1 \le i \le \alpha$, of p''_1 matches x''_i.*

Proof. x''_i is a suffix of v_p. The length $|v_p|$ substring of p''_α which is to the immediate right of t_a is identical to v_p. □

LEMMA 6.9. *$p''_\alpha \in O$ and $|O| \ge 3$.*

Proof. Since all comparisons in Phase 1 are successful, p''_1 survives Phase 1. By Lemma 6.3, p''_α also survives. If $p''_\alpha \notin O$, then p''_1 and p''_α do not form a half-done set with any other element in V''. Therefore, the cardinality of the half-done set which survives Phase 1 would be at most 2, which is a contradiction. Thus $p''_\alpha \in O$. p''_2 must form a half-done set along with p''_1 and p''_α; otherwise, no other element in V'' forms a half-done set with p''_1 and p''_α and, consequently, at most two elements in V'' would survive the successful Phase 1 comparisons. By Lemma 6.8, p''_1 and p''_α survive successful comparisons in $h(x''_l)$, and then by Lemma 5.3, p''_2 also survives these comparisons. Therefore, $p''_2 \in O$ also. Since $p''_\alpha \ne p''_1, p''_2$, the lemma follows. □

COROLLARY 6.10. *The half-done set which survives Phase* 1 *must be a subset of O.*

Proof. Both p''_1 and p''_α survive successful comparisons in Phase 1 and both are elements of O. The only elements in V'' which can form a half-done set with p''_1 and p''_α are those in O. □

LEMMA 6.11. *The leftmost character compared by ET'' in the first (right-to-left) sequence is at least distance $|v|$ to the right of the rightmost character compared in the second (left-to-right) sequence. The rightmost character compared in the latter sequence is to the left of the suffix x''_1 of p''_1.*

Proof. Let d'' be the rightmost position in p''_α such that $p''_\alpha[d'']$ is aligned with some character in p''_1 and $p''_\alpha[d''] \ne p''_\alpha[d'' + |v|]$. Such an index exists by Lemma 4.7. All comparisons in the second sequence are aligned with or to the left of $p''_\alpha[d'']$. All characters in the first sequence compared in Phase 2 are aligned with or to the right of $p''_\alpha[d'' + |v|]$. All characters compared in Phase 1 involve characters in the suffix x''_1 of p''_1. By Lemma 6.8, $p''_\alpha[d'']$ is to the left of the suffix x''_1 of p''_1. The lemma

follows. □

COROLLARY 6.12. *Successful comparisons which eliminate elements of O are made at least distance $|v|$ apart.*

LEMMA 6.13. *The portion of p''_{h_e} that overlaps the suffix $x''_{h_{e-2}}$ of p''_1 matches that suffix.*

Proof. Since $p''_\alpha \in O$ and $p''_\alpha \neq p''_1, p''_2$, it follows from Lemma 6.8 that $(uu')^2$ is a suffix of $p''[1 \ldots m'' - |x''_1|]$. Therefore, the portion of p''_{h_e} that overlaps the suffix $x''_{h_{e-2}}$ of p''_1 matches that suffix. □

COROLLARY 6.14. *All successful comparisons which eliminate an element of O are made to the left of the suffix $x''_{h_{e-2}}$ of p''_1.*

We now define the f'' function for this case.

First, consider comparisons which eliminate elements of O'. From Corollary 6.10, it follows that all elements of O' must be eliminated by Phase 1 comparisons. These comparisons have to be successful because all comparisons in Phase 1 are successful. If $|O'| = 2$, then, by Lemma 4.5, the first such comparison is made in the suffix x''_{h_e} of p''_1. If $|O'| = 2$ or $|O'| = 1$, then, by Lemma 6.13, the portion of p''_{h_e} which overlaps the suffix $x''_{h_{e-1}}$ of p''_1 matches that suffix and therefore, by Lemma 4.5, the last comparison which eliminates an element of O' is made in the suffix $x''_{h_{e-1}}$ of p''_1. Consider the text characters t_c and t'_c with which $|p''$ is aligned when the rightmost misfit characters in the prefixes $x''_{h_{e-1}}$ and $x''_{h_{e-2}}$, respectively, of p'' are aligned with t_b. Since v is a suffix of $x''_{h_{e-1}}$ and $x''_{h_{e-2}}$ and since v contains a misfit character, t_c is aligned with the suffix $x''_{h_{e-1}}$ of p''_1 and to the left of the suffix x''_{h_e} of p''_1 while t'_c is aligned with the suffix $x''_{h_{e-2}}$ of p''_1 and to the left of the suffix $x''_{h_{e-1}}$ of p''_1. If $|O'| = 2$, then f'' is defined to map the text characters involved in comparisons which eliminate elements of O' to the text characters t_c and t'_c. If $|O'| = 1$, then f'' is defined to map the text character involved in the comparison which eliminates the only element of O' to the text character t'_c. A simple case analysis ($p''_l = p''_{h_e}, p''_{h_{e-1}}, p''_{h_{e-2}}$) shows that these f'' values are to the left of p''_l, as claimed. The two f'' values are clearly distinct and to the left of their respective text characters. Further, they are aligned with the suffix x''_1 of p''_1. Since $|x''_1| < \frac{m''}{2}$, these f'' values are to the right of $|p''_{k''+1}$.

Next, consider comparisons which eliminate elements of O, excluding the leftmost and the last such comparison. The remaining comparisons must be successful. f is defined to map the text character t_c involved in such a comparison to the text character with which $|p''$ is aligned when the leftmost character in p'' which differs from t_c is aligned with t_c. Clearly, $f''(t_c)$ is aligned with or to the left of t_c. Since uu' contains at least two characters, $f''(t_c)$ is at most distance $|v| - 1$ to the left of t_c. It follows from Corollary 6.12 that $f''(t_c)$ is distinct from the f'' values for all other text characters involved in successful comparisons which eliminate elements of O. By Corollary 6.14, these f'' values are to the left of f'' values for successful comparisons which eliminate elements of O' and therefore to the left of p''_l. Only the leftmost text character involved in a comparison which eliminates an element of O is within distance $|v|$ of t_a; the rest are at least distance $|v| + 1$ to the right of t_a. Therefore, these f'' values are to the right of $|p''_{k''+1}$.

This concludes the definition of the transfer function f''.

6.4. Data-structure details. It remains to describe the maintenance of the sets Q_x for each terminal node x of tree ET''. These sets can be maintained exactly as described in section 4.5 but with the following difference: the sequence of comparisons corresponding to Phase 2 in Step 2 of the elimination strategy using ET'' is a left-to-

right sequence if all comparisons in Phase 1 are successful.

As in section 4.5, let $l_1, \ldots, l_h$ be the nodes, in order of appearance, on the leftmost path from the root of ET''. Consider the largest i such that $tc_{l_i}, \ldots, tc_{l_{h-1}}$ (recall from section 4.5 that tc_x is the text character compared at node x of ET'') is a left-to-right sequence. For all terminal nodes in ET'' which are not in the subtree rooted at l_i, the data structure is maintained exactly as in section 4.5. Q_{l_h} can be stored explicitly. It remains to describe the data structure for terminal nodes in the right subtrees of $l_i, \ldots, l_{h-1}$.

Note that if a mismatch occurs at tc_{l_j}, $i \leq j \leq h-1$, at most two elements in V'' survive. Therefore, for each terminal node x in the right subtree of l_j, either $p(x)$ or $p(p(x))$ equals l_j, where $p(x)$ is the parent of x. From the definition of the sets Q_x in section 4.5, it follows that for terminal nodes x and y in the right subtree of l_j, $Q_x = Q_y$. The following lemma is crucial.

LEMMA 6.15. *Let terminal node x_1 be in the right subtree of l_{j_1} and terminal node x_2 be in the right subtree of l_{j_2}, $i \leq j_1, j_2 \leq h-1$, $j_2 > j_1$. If $q \in Q_{x_1}$ and $q \in Q_{x_2}$, then q occurs at all terminal nodes in the right subtrees of $l_i, \ldots, l_{j_1}$.*

Proof. Clearly, q cannot overlap $tc_{l_{j_1}}$. Since $tc_{l_i}, \ldots, tc_{l_{h-1}}$ form a left-to-right sequence, q cannot overlap $tc_i, \ldots, tc_{j_1}$. Further, since q occurs at some terminal node in the subtree rooted at l_i, characters in q which overlap $tc_{l_1}, \ldots, tc_{l_{i-1}}$ match the characters $c_1, \ldots, c_{h-1}$, respectively. The lemma follows from the definition of the sets Q_x. □

COROLLARY 6.16. *Suppose q occurs at some terminal node in the subtree T rooted at l_i. Further, suppose j is the largest number, if any, such that $i \leq j \leq h-1$ and q does not overlap tc_{l_j}. Then q occurs at all terminal nodes in the right subtrees of $l_i, \ldots, l_j$.*

Corollary 6.16 immediately gives a linear-space scheme for storing the sets Q_x for terminal nodes x in the subtree T rooted at l_i. Two sets Com_j and $Spec_j$ are maintained at each node l_j, $i \leq j \leq h-1$. A pattern instance q is added to Com_j if it occurs at some terminal node in T and overlaps $tc_{l_{j+1}}$ but not tc_{l_j}. A pattern instance q is added to $Spec_j$ if it overlaps tc_{l_j} and occurs at a terminal node in the right subtree of l_j. Each q can be added to at most one Com set and one $Spec$ set; thus, the total space used is linear. Q_x is readily seen to equal $Com_j \cup Com_{j+1} \cup \cdots \cup Com_{h-1} \cup Spec_j$. Note that each pair of Com sets is disjoint and Com_k is disjoint from $Spec_j$, for each $j \leq k \leq h-1$. In order to obtain Q_x as a sorted list, it suffices to maintain each of the Com and $Spec$ sets as ordered lists which are then appended together. Thus obtaining any particular Q_x takes $O(m)$ time. Q_{l_h} is stored explicitly and hence can be obtained as a list in constant time.

6.5. Presuf shift handler for special-case patterns. We describe the presuf shift handler for patterns for which $|x''_k| = 1$ and $g'' = 1$. This presuf shift handler leads to an overhead of at most two per presuf shift. We show that if a presuf shift has overhead two, then the next presuf shift must occur distance at least $\frac{3(m+1)}{4}$ to the right, and if a presuf shift has overhead one, then the next presuf shift must occur distance at least $\frac{m+1}{2}$ to the right. A comparison complexity of $n(1+\frac{8}{3(m+1)})$ follows.

Let $b = x''_k$. p contains at least two different characters. Therefore, v_p and p'' both contain at least two different characters. Let $p''[j]$ and $p''[j']$ be, respectively, the leftmost and rightmost characters in p'' which differ from b. Let t_c be the text character to the immediate right of t_a.

We consider two cases, namely $|x''_1| < \frac{|v_p|}{2}$ and $|x''_1| \geq \frac{|v_p|}{2}$. The former case has the advantage that if all presuf pattern instances of the first type (recall that presuf

pattern instances were classified into two types in section 6) are eliminated, then the next presuf shift occurs distance at least $\frac{3(m+1)}{4}$ to the right. The absence of this property in the latter case makes it more complicated.

Case 1. $|x''_1| < \frac{|v_p|}{2}$.

Step 1. Step 1 locates the leftmost non-b text character t_d to the right of t_a. Following Step 1, either the basic algorithm is resumed or p'_e, the leftmost surviving pattern instance, is determined and Step 2 follows. This is done as follows. Text characters to the right of t_a and to the left of $p''_\alpha[j]$ are compared from left to right with the character b. A mismatch in this process terminates Step 1. If no mismatch occurs, then $p''_\alpha[j]$ is compared with the aligned text character. A match terminates Step 1. In case of a mismatch, text characters aligned with or to the right of $p''_\alpha[j]$ are compared from left to right with the character b. Step 1 then terminates when a mismatch occurs or when the right end of the text is reached.

One of the following situations now holds:

1. t_d is to the left of $p''_1[j]$. $p''_1, \ldots, p''_{k+1}$ are eliminated and the basic algorithm is resumed with $|p$ placed to the right of the text character that mismatched.

2. t_d is aligned with $p''_i[j]$, $i \neq \alpha$. p'_e is the pattern instance whose left end is aligned with $|p''_i$.

3. t_d is aligned with $p''_\alpha[j]$ and $t_d = p''_\alpha[j]$. p'_e is defined to be the leftmost presuf pattern instance.

4. t_d is aligned with $p''_\alpha[j]$ but $t_d \neq p''_\alpha[j]$. The basic algorithm is resumed with $|p$ immediately to the right of t_e.

5. t_d exists but does not satisfy any of the above cases. p'_e is the pattern instance such that $p'_e[j]$ is aligned with t_d.

6. t_d does not exist. There are no further occurrences of the pattern in the text and the algorithm terminates.

Steps 2 *and* 3. Let q_c denote p'_e. Then Steps 2 and 3 are identical to the corresponding steps in the presuf shift handler for special-case patterns described in section 4.4.

Note that at most two mismatches are made in Step 1 and the first mismatch eliminates p''_α.

LEMMA 6.17. *If p is a special-case pattern and $|x''_1| < \frac{|v_p|}{2}$, then the comparison complexity of the algorithm is $n(1 + \frac{8}{3(m+1)})$.*

Proof. We give charging strategies to show that a presuf shift can have overhead at most two. Further, we show that an overhead of one forces the next presuf shift to occur at least distance $\frac{m+1}{2}$ to the right and an overhead of two forces the next presuf shift to occur at least distance $\frac{3(m+1)}{4}$ to the right. The lemma follows.

As in Lemma 4.12, the run of the algorithm is divided into phases; a phase can be of one of four types. The range of text characters charged in each type of phase remains exactly the same as in Lemma 4.12. The charging scheme for Type 1 and Type 2 phases also remains exactly the same. Only the charging scheme for Type 3 and Type 4 phases is modified in accordance with the presuf shift handlers described above.

We consider a single phase, which could be a Type 3 or a Type 4 phase. We assume that this phase begins with a presuf shift with $|x'_1| \geq \frac{m}{2}$.

The charging scheme. Let q_c be the leftmost pattern instance which survives Step 1. Note that q_c is the leftmost presuf pattern instance if and only if no mismatches occur in Step 1. All successful comparisons in Step 1 are charged to the text characters compared. These text characters lie to the left of $q_c[j]$ if q_c is not the leftmost presuf

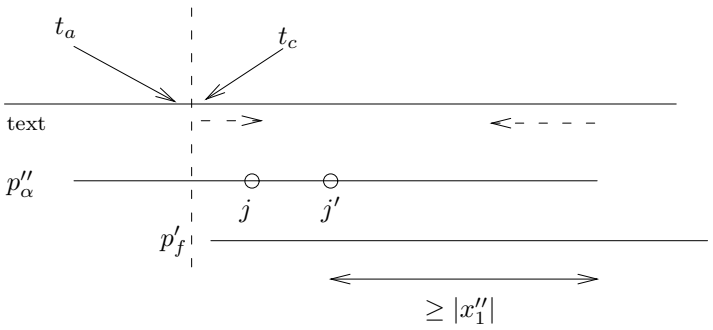

FIG. 7. *Step* 1 *of Case* 2.

pattern instance and are aligned with or to the left of $q_c[j]$ otherwise. If unsuccessful comparisons occur in Step 1, then these comparisons constitute the overhead of this shift. Otherwise, if all comparisons in Step 1 are successful, the only possible comparison which constitutes the overhead of this shift is the comparison in Step 2 which eliminates q_c. Thus the overhead is at most two. Since the first mismatch in Steps 1 and 2 eliminates all presuf pattern instances of the first type and since $|x''_1| < \frac{|v_p|}{2}$, either the overhead is zero or the next presuf shift occurs distance at least $\frac{3(m+1)}{4}$ to the right.

Now consider two cases.

1. Suppose q_c survives Step 2. All comparisons made in Steps 2 and 3 are charged to the text characters compared. Thus each text character which lies to the right of t_a and is aligned with or to the left of $q_c|$ is charged at most once over Steps 1, 2, and 3. All future comparisons will be charged to text characters to the right of $q_c|$.

2. Suppose q_c does not survive Step 2. Each successful comparison in Step 2 eliminates some pattern instance lying entirely to the right of $q_c[j]$ and is charged to the text character aligned with the left end of that pattern instance. The unsuccessful comparison which eliminates q_c in Step 2 is charged to the text character aligned with $q_c[j]$ if q_c is not the leftmost presuf pattern instance. Thus each text character lying between t_a and $|q_d$ is charged at most once, where q_d is the leftmost surviving pattern instance at the end of Step 2. All future comparisons will be charged to text characters aligned with or to the right of $|q_d$. □

Case 2. $|x''_1| \geq \frac{|v_p|}{2}$.

There are five steps in the presuf shift handler for this case. At most five mismatches are made in these steps. We show that three of these mismatches can be charged to unmatched text characters; consequently, the overhead of the current presuf shift is at most two. Further, the first mismatch in Step 1 eliminates p''_α and the second mismatch eliminates all of the presuf pattern instances.

Step 1. Step 1 eliminates all but at most one of $p''_1, \ldots, p''_{k+1}$ as follows. See Fig. 7. The following sequence of text characters is compared with the aligned characters in p''_α: t_b, followed by the text characters strictly between t_b and $p''_\alpha[j']$ considered right to left, followed by the text characters strictly between t_a and $p''_\alpha[j]$ considered left to right. Step 1 terminates when the first mismatch occurs or when this sequence is exhausted.

Let p'_e be the leftmost surviving presuf pattern instance following Step 1. Consider the pattern instance p'_f, $|p'_f$ aligned with the text character to the immediate right of

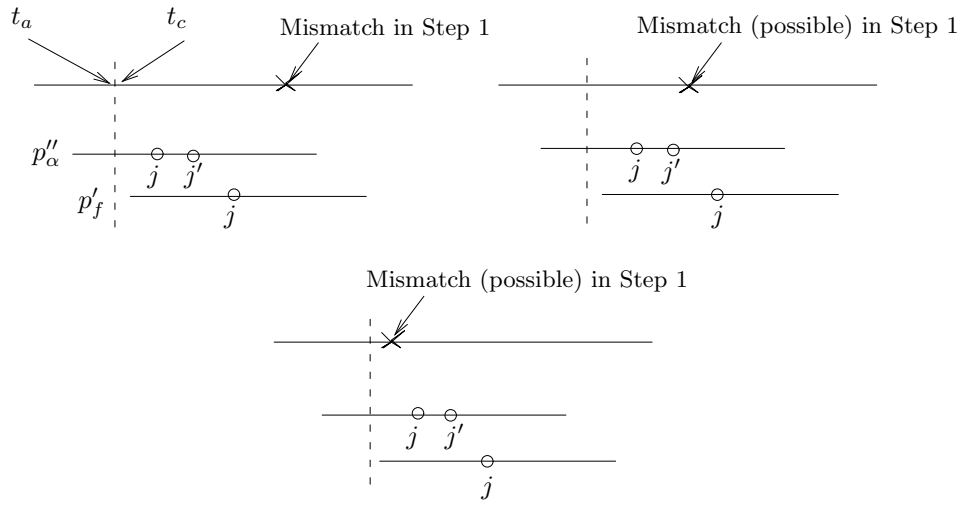

FIG. 8. *Possible outcomes of Step* 1.

t_c. Let t_e be the text character at which the mismatch occurred, if any. Note that since $j \geq |x''_1| + 1$ and $|x''_1| \geq \frac{|v_p|}{2}$, by Lemma 6.8, $p'_f[j]$ must be to the right of $p''_\alpha[j']$. The outcome of Step 1 depends upon which of the following two cases occurs (see Fig. 8).

Case 1.1. $p'_f[j]$ is aligned with or to the left of t_e (first diagram in Fig. 8). Clearly, $p''_\alpha[j']$ is to the left of t_e. We show that a transfer function similar to the function f'' of section 6.1 (see Lemma 6.6) can be used to account for the comparisons made in Step 1. In this case, the rest of the steps are identical to Steps 3, 4, and 5 of the presuf shift handler of section 6.1.

Case 1.2. Either there is no mismatch in Step 1 or $p'_f[j]$ is to the right of t_e (second and third diagrams in Fig. 8). The leftmost surviving pattern instance with left end to the right of t_c has its jth character to the right of t_b; we show this claim in the next paragraph. Step 2 follows in this case.

Recall that $p'_f[j]$ is to the right of $p''_\alpha[j']$. The mismatch, if any, in Step 1 occurs to the left of $p'_f[j]$. Therefore, all text characters aligned with or to the right of $p'_f[j]$ and to the left of (and including) t_b are identical to b. The claim follows.

Step 2. If p'_e does not extend to the right of t_b, then no comparisons are made in this step (this happens if and only if p'_e is the leftmost presuf pattern instance). Otherwise, Step 2 attempts to extend the match of p'_e. Characters in p'_e to the right of t_b (if any) are compared from left to right until a mismatch occurs or a non-b character is matched against the text. To see that p'_e will have a non-b character to the right of t_b if it extends to the right of t_b, note that the distance between t_b and t_c equals $|v_p| - 1$ and that p'_e has at least two non-b characters distance $|v_p|$ apart, neither of which can be to the left of t_c.

The successful comparisons in this step will be charged to the text characters compared. Clearly, all of these text characters are to the right of the text characters compared in Step 1.

Step 3. A pattern instance p'_g with the following properties is determined in this step.

1. p'_g is the leftmost surviving pattern instance.

2. All surviving pattern instances which overlap $p'_g[i]$ are presuf overlaps of p'_g, where i is defined as follows. If $p'_g \neq p'_e$, $i = j$. If $p'_g = p'_e$ and p'_e is the leftmost presuf pattern instance, then $p'_g[i]$ is the character aligned with t_b. Otherwise, if $p'_g = p'_e$ and p'_e is not the leftmost presuf pattern instance, then $p'_g[i]$ is the leftmost non-b character in p'_g which is to the right of t_b.

All text characters compared successfully in this step will be distinct from all text characters compared successfully in Steps 1 and 2. There are two cases depending upon the outcome of Step 2.

Case 2.1. p'_e is eliminated in Step 2. At most two mismatches could have occurred in Steps 1 and 2. Note that p'_e cannot be the leftmost presuf pattern instance in this case. The leftmost surviving pattern instance must have its left end to the right of t_c. As shown in Step 1, its jth character must be to the right of t_b. There are two subcases.

Case 2.1a. Step 2 terminates in a mismatch at a non-b character t_h in p'_e. Then, starting at t_h, a left-to-right pass is made in which each text character is compared with b. This pass ends when a mismatch occurs or when the right end of the text is reached. In the latter case, there are no further occurrences of the pattern and the algorithm terminates. In the former case, p'_g is defined to be the pattern instance in which $p'_g[j]$ is aligned with the text character t_x at which the mismatch occurs. Since all text characters strictly between t_b and t_x are identical to b, p'_g is the leftmost surviving pattern instance and all pattern instances to the right of p'_g which overlap $p'_g[j]$ are eliminated. Note that the number of mismatches made in Steps 1–3 is at most three in this case.

Case 2.1b. Step 2 terminates in a mismatch at a character t_h in p'_e which is a b. p'_g is defined to be the pattern instance in which $p'_g[j]$ is aligned with the text character at which the mismatch occurs. As in the previous case, p'_g is the leftmost surviving pattern instance and all pattern instances to the right of p'_g which overlap $p'_g[j]$ are eliminated. The number of mismatches made in Steps 1–3 is at most two in this case.

Case 2.2. p'_e survives Step 2. At most one mismatch could have occurred so far. There are two subcases.

Case 2.2a. p'_e is not the leftmost presuf pattern instance; i.e., it extends to the right of t_b. Let t_x be the rightmost text character matched in Step 2. t_x must be a non-b character. Consider the pattern instance p'_h, where $p'_h[j]$ is aligned with t_x.

Clearly, all pattern instances to the right of p'_h which overlap t_x are eliminated since each has a b aligned with t_x. We claim that all pattern instances strictly between p'_e and p'_h have also been eliminated. This is shown as follows. All pattern instances to the right of p'_e which overlap t_c have been eliminated in Step 1. Recall from Step 1 that the leftmost surviving pattern instance after Step 1 with left end to the right of t_c has its jth character to the right of t_b. Since all text characters to the right of t_b and up to but not including t_x are identical to b, the claim follows.

If p'_e and p'_h lack a difference point or if $p'_h[j]$ does not match t_x, then $p'_g = p'_e$. Otherwise, if p'_e and p'_h have a difference point, the character in p'_e at that difference point is compared with the aligned text character and one of p'_e and p'_h is eliminated; the difference point itself is to the right of $p'_h[j]$. Let p'_g denote the survivor. Clearly, p'_g is the leftmost surviving pattern instance in both cases. Further, all pattern instances to the right of p'_g which overlap t_x (note that t_x is aligned with $p_g[i]$) have either been eliminated or are presuf overlaps of p'_g.

At most two mismatches are made in Steps 1–3 in Case 2.2a.

Case 2.2b. Second, suppose p'_e is the leftmost presuf pattern instance. Recall that $p'_e[m]$ is aligned with t_b. In this case, no comparisons are made in Step 2. Consider the pattern instance p'_h, where $p'_h[j]$ is to the immediate right of t_b. Recall from Step 1 that p'_h is the leftmost surviving pattern instance with left end to the right of t_c. The only surviving pattern instances to the right of p'_e which overlap t_c are presuf overlaps of p'_e. Therefore, p'_h is the leftmost surviving pattern instance, barring p'_e and its presuf overlaps. In addition, note that any pattern instance which overlaps p'_e but not $p''_\alpha[j']$ and has its jth character to the right of t_b is a presuf overlap of p'_e.

If $|p'_h$ is to the right of $p''_\alpha[j']$, then p'_h is a presuf overlap of p'_e as are all pattern instances to the right of p'_h which overlap p'_e. Step 5 follows with $p'_g = p'_e$ in this case.

Otherwise, if p'_h overlaps $p''_\alpha[j']$ then p'_h is not a presuf overlap of p'_e. The character $p''_\alpha[j']$ is then compared with the text. A match eliminates all pattern instances which overlap $p''_\alpha[j']$ but are not presuf overlaps of p'_e. (This can be seen from the following two facts: (a) all pattern instances with left end to the right of t_c which survive Step 1 have their jth character to the right of $p''_\alpha[j']$, and (b) all surviving pattern instances which overlap t_c are presuf overlaps of p'_e.) Clearly, all surviving pattern instances which overlap t_b are presuf overlaps of p'_e. In this case, Step 5 follows with $p'_g = p'_e$. Otherwise, if a mismatch occurs at $p''_\alpha[j']$, p'_e is eliminated as are all its presuf overlaps which overlap t_c. Text characters to the right of t_b are now compared from left to right with the character b until either a mismatch occurs or the right end of the text is reached. In the former case, Step 4 follows with p'_g denoting the pattern instance such that $p'_g[j]$ is aligned with the text character at which the mismatch occurs. Clearly, p'_g is the leftmost surviving pattern instance and all pattern instances which overlap $p'_g[j]$ have been eliminated. In the latter case (i.e., the right end of the text is reached), the algorithm terminates as there are no further occurrences of the pattern.

At most two mismatches are made in Steps 1–3 in Case 2.2b.

Step 4. In this step, either all surviving pattern instances which overlap p'_g are eliminated (except for presuf overlaps) or p'_g is eliminated. In the latter case, the basic algorithm is resumed with the leftmost surviving pattern instance. In the former case, Step 5 follows. All comparisons in this step are to the right of all text characters matched in the previous steps. In addition, the left end of each pattern instance eliminated in this step is also to the right of any text character matched in one of the previous steps.

In Step 4, difference-point comparisons are used. This step has a number of iterations. In each iteration, a different pattern instance overlapping p'_g but strictly to the right of $p'_g[i]$ is considered. If it is a presuf overlap of p'_g, then nothing is done. Otherwise, if it is not a presuf overlap of p'_g, the character in p'_g at the difference point of the two pattern instances is considered. If the text character aligned with this character has not been successfully compared earlier (this is ascertained using a bit vector), the two characters are compared. Step 4 ends when a mismatch occurs or when all pattern instances overlapping p'_g (excluding presuf overlaps) are eliminated.

If no mismatch occurs in Step 4, then all comparisons in this step will be charged to the text characters compared; otherwise, they will be charged to left ends of the pattern instances eliminated. In both cases, the text characters charged are to the right of all text characters matched in previous steps.

Step 5. This step attempts to complete the match of p'_g. Characters in p'_g which have not yet been matched are compared with the aligned text characters from right to left until a mismatch occurs or all of its characters are matched. In either case, another presuf shift follows. All comparisons in this step will be charged to the text

characters compared.

LEMMA 6.18. *If p is a special-case pattern with $|x_1''| \geq \frac{|v_p|}{2}$, then the comparison complexity of the algorithm is $n(1 + \frac{8}{3(m+1)})$.*

Proof. We give charging strategies to show that a presuf shift can have overhead at most two. Further, we show that an overhead of one forces the next presuf shift to occur at least distance $\frac{m+1}{2}$ to the right and an overhead of two forces the next presuf shift to occur at least distance $\frac{3(m+1)}{4}$ to the right. The lemma follows.

As in Lemma 4.12, the run of the algorithm is divided into phases; a phase can be of one of four types. The range of text characters charged in each type of phase remains exactly the same as in Lemma 4.12. The charging scheme for Type 1 and Type 2 phases also remains exactly the same. Only the charging scheme for Type 3 and Type 4 phases is modified in accordance with the presuf shift handler described above.

We consider a single phase, which could be a Type 3 or a Type 4 phase. We assume that this phase begins with a presuf shift with $|x_1'| \geq \frac{m}{2}$.

The charging scheme. We consider two cases.

Case A. Suppose a mismatch occurs in Step 1 at a text character t_e to the right of $p_\alpha''[j']$ and $p_f'[j]$ is aligned with or to the left of t_e (i.e., Case 1.1 in Step 1 holds).

Each successful comparison in Step 1 matches the character b against the text. The charging scheme for this case is identical to the charging scheme in Lemma 6.7 with the function f'' defined as follows. f'' is defined to map each text character compared successfully in Step 1 to the text character which is distance $j-1$ to its left. This definition of f'' is easily verified to satisfy all four required properties of f'' stated in Lemma 6.6. Further, only the last Step 1 comparison can possibly be unsuccessful and might not receive an f'' value. From the above charging scheme, it follows that the overhead of the current presuf shift is at most one.

Case B. Suppose all comparisons in Step 1 are successful or $p_f'[j]$ is to the right of t_e, the character at which the mismatch in Step 1 occurs (i.e., Case 1.2 in Step 1 holds).

Recall from Step 1 that the leftmost surviving pattern instance completely to the right of t_c must have its jth character to the right of t_b. There are three subcases to consider.

Subcase B1. Suppose p_e' (the leftmost of the presuf pattern instances to survive Step 1) survives Steps 2, 3, and 4.

All successful comparisons in Steps 1, 2, 3, and 4 and all comparisons in Step 5 are charged to the text characters compared. All of these comparisons involve distinct text characters, and thus each text character which is to the right of t_a and aligned with p_e' is charged at most once. Further, at most one mismatch is made in Step 1 and no mismatches are made in Steps 2, 3, and 4 (otherwise, p_e' would be eliminated). In addition, a mismatch in Step 1 eliminates p_α'', thus forcing the next presuf shift to occur at least distance $\frac{m+1}{2}$ to the right. Thus the current presuf shift has overhead at most one and an overhead of one forces the next presuf shift to occur distance at least $\frac{m+1}{2}$ to the right.

Subcase B2. Suppose p_e' is eliminated in one of Steps 2, 3, and 4; further, suppose p_e' is the leftmost presuf pattern instance.

In this case, the next presuf shift occurs distance at least $m+1$ to the right. We show an overhead of at most two for this case.

All comparisons in Step 1 are successful and are charged to the text characters compared. No comparisons are made in Step 2. p_e' must be eliminated in Step 3 since

Step 5 follows directly from Step 3 otherwise (see Case 2.2b in Step 3). All successful comparisons in Step 3 are charged to the text characters compared. At most two mismatches are made in Step 3 and these constitute the overhead of this shift. All text characters matched in Steps 1–3 are to the left of $p'_g[j]$. If p'_g survives Step 4, then all comparisons in Step 4 are charged to the text characters compared. If p'_g does not survive Step 4, then the comparison which eliminates p'_g is charged to the text character aligned with $p'_g[j]$ and all other comparisons in Step 4 are charged to the left ends of the respective pattern instances eliminated. (From the definition of p'_g in Step 3, note that the left ends of these pattern instances are to the right of $p'_g[j]$.) Thus all text characters charged in Step 4 are distinct and are aligned with or to the right of $p'_g[j]$. All comparisons in Step 5 are charged to the text characters compared. These text characters are distinct from all text characters matched in the previous steps. Therefore, if p'_g survives Step 4, then each text character to the right of t_a and aligned with or to the left of $p'_g|$ is charged at most once. Otherwise, if p'_g is eliminated in Step 4 and p'_l is the leftmost surviving pattern instance following Step 4, each text character strictly between t_a and $|p'_l$ is charged at most once.

Subcase B3. Suppose p'_e is eliminated in one of Steps 2, 3, and 4 and p'_e is not the leftmost presuf pattern instance.

In this case, the next presuf shift occurs distance at least $m+1$ to the right. We show an overhead of at most two for this case.

All successful comparisons in Steps 1 and 2 and all comparisons in Step 5 are charged to the text characters compared. If p'_e does not survive Step 2 (Case 2.1 of Step 3), then all successful comparisons in Step 3 are charged to the text characters compared. Otherwise, if p'_e survives Step 2 (Case 2.2a of Step 3), there is at most one comparison in Step 3 and it is accounted for later. If p'_g survives Step 4, then all successful comparisons in Step 4 are charged to the text characters compared. In this case, each text character to the right of t_a and aligned with or to the left of $p'_g|$ is charged at most once. Otherwise, if p'_g is eliminated in Step 4, each successful comparison in Step 4 (except the one which eliminates p'_g) is charged to the text character aligned with the left end of the pattern instance eliminated by this comparison; this text character is to the right of $p'_g[j]$. In this case, each text character strictly between t_a and $|p'_l$ is charged at most once, where p'_l is the leftmost surviving pattern instance after p'_g is eliminated.

At most four comparisons have not yet been accounted for. These include the mismatch in Step 1, the mismatch in Step 4 (which eliminates p'_g), and either the mismatches in Steps 2 and 3 or the only comparison in Step 3, depending on whether or not p'_e survives Step 2. Note that if mismatches occur in all of Steps 2, 3, and 4, then the text character aligned with $p'_g[j]$ is not charged for any comparison. In addition, we show that the text character aligned with $p''_\alpha[j]$ is also not charged for any comparison. An overhead of two for the current presuf shift follows immediately.

Clearly, $p''_\alpha[j]$ is not compared in Step 1. All comparisons in Steps 2, 3, and 4 are made to the right of t_b and hence to the right of $p''_\alpha[j]$. Further, $p'_g[i]$ (i as defined in Step 3) is aligned with or to the right of t_b. Therefore, the text character aligned with $p''_\alpha[j]$ is not charged for any of the comparisons made in Steps 1–4. Consider Step 5 next. If p'_e survives Steps 2 and 3 and is eliminated in Step 4, then the presuf shift handler terminates after Step 4 and the basic algorithm is resumed. Therefore, suppose that p'_e is eliminated in Step 2 or Step 3. From the definition of p'_g in Step 3, $p'_g \neq p'_e$ and therefore $i = j$. To show that all comparisons in Step 5 are made to the right of $p''_\alpha[j]$, it suffices to show that $|p'_g$ is to the right of $p''_\alpha[j]$.

We show this by considering two cases. First, suppose $p''_\alpha \neq p''_1$. Then, by Lemma 6.8, it follows that the character in p'' which is to the immediate left of its suffix x''_1 is a b. Since x''_1 is the longest presuf of p'', it follows that $j = |x''_1| + 1$. By Lemma 6.8, $p''_\alpha[j']$ and hence $p''_\alpha[j]$ are to the left of the suffix x''_1 of p''_1. Since $|p'_g[j]$ is to the right of t_b, $|p'_g$ is aligned with or to the right of the suffix x''_1 of p''_1. The claim follows for this case.

Next, suppose $p''_\alpha = p''_1$. A mismatch occurs in Step 1 since p'_e is not the leftmost presuf pattern instance. Further, this mismatch occurs at some text character t_e to the right of $p''_\alpha[j]$ since no comparisons are made to the left of $p''_\alpha[j]$ in Step 1 in this case. Each comparison in Step 1 compares a text character with b. Since $p'_g[j]$ must be to the right of t_b, either $|p'_g$ is to the right of t_e or a b in p'_g overlaps t_e. However, p'_g will not survive in the latter case. The claim follows.

The lemma follows. □

Finally, we state the following theorem; the proof is similar to the proof of Theorem 4.17.

THEOREM 6.19. *There is a string-matching algorithm with a comparison complexity of* $n(1+\frac{8}{3(m+1)})$ *comparisons which uses* $O(m)$ *space and takes* $O(n+m)$ *time following preprocessing of the pattern*; *the preprocessing time is* $O(m^2)$.

Acknowledgment. We thank Dany Breslauer for a number of comments and suggestions and in particular for the observation that p_{k+1} could be viewed as a presuf pattern instance. This contributed to an improvement of our upper bound from $n + \frac{3(n-m)}{m+1}$ to $n + \frac{8(n-m)}{3(m+1)}$.

THE k-STEINER RATIO IN GRAPHS*

AL BORCHERS† AND DING-ZHU DU†

Abstract. A Steiner minimum tree (SMT) is the shortest-length tree in a metric space interconnecting a set of points, called the regular points, possibly using additional vertices. A k-size Steiner minimum tree (kSMT) is one that can be split into components where all regular points are leaves and all components have at most k leaves. The k-Steiner ratio, ρ_k, is the infimum of the ratios SMT/kSMT over all finite sets of regular points in all possible metric spaces, where the distances are given by a complete graph. Previously, only ρ_2 and ρ_3 were known exactly in graphs, and some bounds were known for other values of k. In this paper, we determine ρ_k exactly for all k. From this we prove a better approximation ratio for the Steiner tree problem in graphs.

1. Introduction.

Given a set of points in a metric space, the *Steiner minimum tree* on the point set is the shortest network interconnecting all points in the set. Those points in the set are called *regular points*, and vertices other than regular points are called *Steiner points*. Computing the Steiner minimum tree in various metric spaces is NP-hard [12, 7, 8, 10, 6].

A tree interconnecting a regular point set is called a *Steiner tree* if every leaf is a regular point. However, a regular point in a Steiner tree may not be a leaf. A Steiner tree is *full* if every regular point is a leaf. When a regular point is not a leaf, the tree can be decomposed into several smaller trees at this point. In this way, every Steiner tree can be decomposed into smaller trees in each of which every regular point is a leaf. These smaller trees are called *full components* of the tree. The *size* of a full component is the number of regular points in the full component. For brevity, we will refer to a full component simply as a component.

A k-size Steiner tree is a Steiner tree with all components of size at most k. The k-size Steiner minimum tree is the shortest one among all k-size Steiner trees. The 2-size Steiner minimum tree is also called the minimum spanning tree. The k-Steiner ratio in a metric space E is defined by

$$\rho_k(E) = \inf_{P \subset E} \frac{L_S(P)}{L_{kS}(P)},$$

where $L_S(P)$ is the length of the Steiner minimum tree for the finite set of points P and $L_{kS}(P)$ is the length of the k-size Steiner minimum tree for P. The 2-Steiner ratio is simply called the Steiner ratio. It is known that in the rectilinear plane L_1, $\rho_2(L_1) = 2/3$ [11], and in the Euclidean plane L_2, $\rho_2(L_2) = \sqrt{3}/2$ [9, 3].

Every weighted graph can be seen as a metric space with the distance between two vertices equal to the minimum total length of a path connecting them. Then

$$\rho_k = \inf_G \rho_k(G) = \inf_E \rho_k(E).$$

That is, the k-Steiner ratio in graphs is the same as the k-Steiner ratio over all metric spaces. It is a well-known fact that $\rho_2 = 1/2$ [9, 14].

The k-Steiner ratio is important because of Steiner-tree-approximation algorithms. It was a long-standing open problem [2] whether there exists a polynomial-time approximation for the Steiner minimum tree in each metric space with a performance ratio smaller than the inverse of the Steiner ratio. (The performance ratio of an approximation algorithm is the largest lower bound for the ratio of lengths between the approximate solution and the Steiner minimum tree for the same set of points.) Zelikovsky [15] made the first breakthrough. He found a polynomial-time 11/6 approximation for the Steiner minimum tree in graphs, which beat the inverse of the Steiner ratio in graphs, $\rho_2^{-1} = 2$. By extending Zelikovsky's idea, Berman and Ramaiyer [1] gave a polynomial-time 92/72 approximation for the Steiner minimum tree in the rectilinear plane, and Du, Zhang, and Feng [4] gave a general solution to the open problem. They showed that in any metric space, there exists a polynomial-time approximation with performance ratio better than the inverse of the Steiner ratio provided that for any set of a fixed number of points, the Steiner minimum tree is polynomial-time computable. A main part of these works was to establish the lower bound for the k-Steiner ratio. A better lower bound will give a better performance ratio for their approximations. Zelikovsky [15] showed that $\rho_3 \geq 3/5$. Du [5] showed that $\rho_3 \leq 3/5$. Therefore, $\rho_3 = 3/5$. Berman and Ramaiyer [1] proved that $\rho_3(L_1) = 4/5$ and for $k \geq 4$, $\rho_k(L_1) \geq (2k-2)/(2k-1)$. Du, Zhang, and Feng [4] showed that $\rho_k \geq \lfloor \log_2 k \rfloor / (1 + \lfloor \log_2 k \rfloor)$.

In this paper, we determine the k-Steiner ratio in graphs exactly. For $k = 2^r + s$, where $0 \leq s < 2^r$, the k-Steiner ratio is

$$\rho_k = \frac{r2^r + s}{(r+1)2^r + s}.$$

This value agrees with the lower bound determined by Du, Zhang, and Feng [4] when k is a power of 2; however, they gave no upper bound for ρ_k. In section 2, we prove that this value is an upper bound on ρ_k, and in section 3, we prove that it is also a lower bound.

Using these values for ρ_k and Berman and Ramaiyer's algorithm, we get a $1.734\ldots$ approximation to the Steiner tree problem in graphs, improving on their $1.746\ldots$ approximation.

When we talk about a Steiner tree in a graph, the edges of the Steiner tree are actually shortest paths between vertices of the graph. We could think of the graph vertices along such a path as degree-2 Steiner points, though normally we do not. The Steiner points are vertices of the graph, but a vertex can be used more than once as a Steiner point in different components of the same Steiner tree.

We call a binary tree where every internal vertex has exactly two children a *regular binary tree*. A *complete binary tree* is a regular binary tree where all leaves have the same depth. A binary tree that is *complete except perhaps at the bottom level* is a regular binary tree where all leaves have depth t or $t+1$ for some t.

2. Upper bound for ρ_k. To prove the upper bound for the k-Steiner ratio, we consider the following particular metric space M_n based on a weighted tree B_n. Let B_n be a complete binary tree with n levels of edges and a final bottom level where each internal vertex has only one child. The edges at level $1 \leq i \leq n$ have length 2^{n-i} and the edges at the bottom level, level $n+1$, have length 1. See Figure 1.

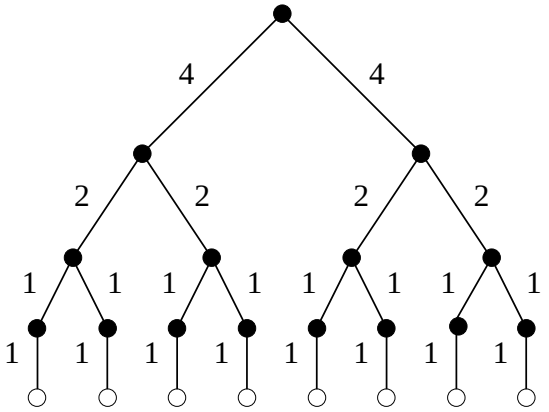

FIG. 1. *The weighted tree B_3 for the metric space M_3.*

The points of M_n are the vertices of B_n; the distance between two points is the length of the shortest path between them in B_n. It is easy to see this forms a metric space. We can think of edges between two points of M_n as paths between those points in B_n.

Let the leaves of B_n be the set P_n of regular points. We will calculate the limit of the ratio $L_S(P_n)/L_{kS}(P_n)$ as $n \to \infty$. This will give us an upper bound for ρ_k.

LEMMA 2.1. *The length of the Steiner minimum tree for P_n is the total length of B_n; that is, $L_S(P_n) = (n+1)2^n$.*

Proof. The tree B_n interconnects P_n, and it is clear that every edge of B_n must be used to interconnect all of P_n. Therefore, this is the shortest tree interconnecting P_n.

In B_n the sum of the lengths of the edges at any fixed level is 2^n—this is true at the bottom two levels, and each level above has half as many edges each with twice the length. Since there are $n+1$ levels, we get $L_S(P_n) = (n+1)2^n$. □

LEMMA 2.2. *There is a k-size Steiner minimum tree for P_n where each Steiner point has degree exactly 3.*

Proof. The regular points of a component in any k-size Steiner minimum tree can be interconnected by a binary tree embedded in B_n, and as in Lemma 2.1, this must be a shortest tree interconnecting these points. Steiner points of degree 2 can be removed and the two adjacent edges replaced by a single edge (which is a path in B_n) between the two adjacent vertices. Therefore, we can assume all Steiner points in this component tree have degree 3. These components make up the desired k-size minimum tree. □

We think of a component in a k-size Steiner minimum tree for P_n as a regular binary tree with at most k leaves embedded in B_n, where the edges are paths in B_n. The root of this component tree is the highest-level degree-2 Steiner point; we will refer to it as the *component root*.

LEMMA 2.3. *There is a k-size Steiner minimum tree for P_n where each Steiner point has degree 3 and where no point of B_n is used more than once as a Steiner point or component root of any component.*

Proof. Consider a k-size Steiner minimum tree T as described in Lemma 2.2. Let v be a vertex at the highest level of B_n that is used as a root or Steiner point of two components, A and B, in T. Let u and w be the children of v. The edges $\overline{vu}$ and $\overline{vw}$

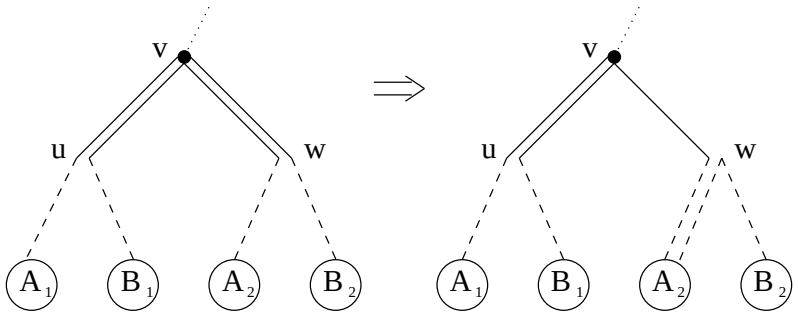

FIG. 2. *Components A and B share a root or Steiner point.*

are used in both components A and B. Let A_1 and B_1 be the parts of components A and B, respectively, that lie below u, and let A_2 and B_2 be the parts that lie below w. See Figure 2.

Components A and B must be connected by some path in T, but because this is a tree, the path cannot go through both B_1 and B_2. Say it does not go through B_2.

Remove the edge $\overline{vw}$ from component B, make B_2 a separate component, and connect B_2 to component A by a path from w to a regular point in A_2 (a leaf in B_n). See Figure 2.

Note that in B_n the length of edge $\overline{vw}$ is the same as the length of the path from w to a leaf—this follows because the length of the edges doubles at each level up the tree. Therefore, this change does not increase the length of the Steiner tree; it does not increase the size of any component; and it does not add any Steiner points, so all Steiner points are still of degree 3. Vertex w has become the root of a new component, so we may have added points that are used as roots or Steiner points of more than one component; however, we have only added them below v.

If we repeat this process, by induction, we can successively remove the Steiner points or component roots that overlap at vertices of B_n from level to level going down the tree until there are no such points remaining. □

LEMMA 2.4. *There is a k-size Steiner minimum tree for P_n where each Steiner point has degree 3 and where every internal vertex of B_n, except at the lowest level, is used exactly once as a Steiner point or component root of some component.*

Proof. We know from Lemma 2.3 that there is a k-size Steiner minimum tree T where every internal vertex of B_n is used at most once. The lowest-level internal vertices cannot be component roots or Steiner points because they have only one child. We will show that $2^n - 1$ Steiner points and roots are needed to interconnect all 2^n points in P_n, and since there are only $2^n - 1$ internal vertices of B_n not at the lowest level, every point must be used exactly once.

Remove the component roots and Steiner points one by one from T. When a component root is removed, split the tree into two pieces at the root. When a Steiner point is removed, split the tree into two pieces by disconnecting one of the two children of the Steiner point. After all points are removed, the 2^n regular points must be completely disconnected. Since removing one point adds only one new piece, we must have removed $2^n - 1$ points to create the 2^n disconnected pieces. □

THEOREM 2.5 (upper bound for ρ_k). *For any k, with $k = 2^r + s$, where $0 \le s <$*

2^r, *we have*

$$\rho_k \le \frac{r2^r + s}{(r+1)2^r + s}. \tag{1}$$

Proof. Let $T_{k,n}$ be a k-size Steiner minimum tree on P_n that satisfies Lemma 2.4.

We can think of a component C in $T_{k,n}$ as a regular binary tree; the internal vertices of this tree are the component root and the Steiner points. Below each of these internal vertices are two edges of B_n; all Steiner points have two edges below them by Lemma 2.2, and the component root must have two edges below it in a minimum tree. Call these edges of B_n the *peak edges* of C, and denote them by $\mathcal{P}_C$. Call the rest of the edges used by C the *connecting edges* of C, and denote them by $\mathcal{C}_C$. Denote all of the peak edges of $T_{k,n}$ by $\mathcal{P}_{k,n}$ and all the connecting edges by $\mathcal{C}_{k,n}$. When we refer to a *peak*, we mean two peak edges and their common vertex.

We want to show that

$$\sum_{e\in\mathcal{C}_C} \text{length}(e) \ge \left(\frac{2^r}{r2^r + s}\right) \sum_{e\in\mathcal{P}_C} \text{length}(e). \tag{2}$$

If this is true, then summing over all components of $T_{k,n}$ gives

$$\sum_{e\in\mathcal{C}_{k,n}} \text{length}(e) \ge \left(\frac{2^r}{r2^r + s}\right) \sum_{e\in\mathcal{P}_{k,n}} \text{length}(e). \tag{3}$$

Assume that we have inequality (3). By Lemma 2.4 the Steiner points and component roots of $T_{k,n}$ cover all of the internal vertices of B_n exactly once, except at the lowest level. Thus the peak edges of $T_{k,n}$ cover all of the edges of B_n exactly once, except for the edges at the lowest level. The sum of the lengths of the edges at the lowest level is 2^n, and the sum of the lengths of all edges of B_n is $L_S(P_n)$ by Lemma 2.1. Thus

$$L_S(P_n) = 2^n + \sum_{e\in\mathcal{P}_{k,n}} \text{length}(e).$$

Then by inequality (3),

$$\begin{aligned} L_{kS}(P_n) &= \sum_{e\in\mathcal{P}_{k,n}} \text{length}(e) + \sum_{e\in\mathcal{C}_{k,n}} \text{length}(e) \\ &\ge \left(1 + \frac{2^r}{r2^r + s}\right) \sum_{e\in\mathcal{P}_{k,n}} \text{length}(e) \\ &= \frac{(r+1)2^r + s}{r2^r + s}(L_S(P_n) - 2^n). \end{aligned}$$

Then

$$\begin{aligned} \rho_k &\le \frac{L_S(P_n)}{L_{kS}(P_n)} \\ &\le \frac{r2^r + s}{(r+1)2^r + s} + \frac{2^n}{L_{kS}(P_n)} \\ &\le \frac{r2^r + s}{(r+1)2^r + s} + \frac{1}{(n+1)} \end{aligned}$$

since ρ_k is the infimum of $L_S(P)/L_{kS}(P)$ and since $L_{kS}(P_n) \geq L_S(P_n) = (n+1)2^n$. Letting $n \to \infty$ gives the upper bound for ρ_k, inequality (1).

To complete the proof of Theorem 2.5, we must establish inequality (2). This inequality depends on $k = 2^r + s$, but the component C can be k-size or smaller. We will prove it for a full k-size component in a k-size tree for all k. It is easy to see that for $k' \leq k$ and $k' = 2^{r'} + s'$, where $0 \leq s' < 2^{r'}$, we have

$$\frac{2^{r'}}{r'2^{r'} + s'} \geq \frac{2^r}{r2^r + s}.$$

From this it follows that inequality (2) is true for any component of size less than k in a k-size Steiner tree.

Note that we always assume that Steiner points have degree 3, as we can by Lemma 2.2, so we can always think of a component as a regular binary tree.

We will prove inequality (2) for k-size components by induction on the sum of the depths of the peaks from the root of the component. We compute the depths of the peaks by counting edges in B_n, not edges in M_n; and we count each edge the same, ignoring the lengths of the edges. The sum of the peak depths is minimum when the peaks form a complete binary tree, except perhaps at the lowest level, so we will treat this case first.

In a k-size component C whose peaks form a complete binary tree, except perhaps at the lowest level, we have 2^r peak edges at the second to lowest level and $2s$ peak edges at the lowest level. Say a peak edge at the lowest level has length w. Then the peak edges at the lowest level have total length $2sw$ and at the r higher levels each level has total length $2^{r+1}w$. Thus we get

$$\sum_{e \in \mathcal{P}_C} \text{length}(e) = 2w(r2^r + s).$$

The connecting edges of C form paths from the lowest-level peak edges down to regular points at the leaves of B_n. By the construction of B_n, these paths have the same length as the lowest-level peak edge where they originate. There are $2s$ such paths of length w at the lowest level and $2^r - s$ such paths of length $2w$ one level higher. Thus

$$\sum_{e \in \mathcal{C}_C} \text{length}(e) = 2w \cdot 2^r.$$

In this case, inequality (2) is satisfied; in fact, it is an equality.

Next, we will show that the ratio of the length of the connecting edges to the length of the peak edges decreases as the sum of the depths of the peaks decreases. In fact, as we change the shape of the component by moving a peak up, the length of the connecting edges remains constant, while the length of the peak edges increases. When the peaks cannot move up any further, the sum of the peak depths is minimum, and as we just showed, inequality (2) holds. Hence it will hold for any shape component. Here are the details.

There are two cases in which the sum of the peak depths might not be minimum: either a peak has a nonpeak edge above it or else there are two bottom-level peak edges whose depths differ by more than 1. We assume that inequality (2) has been established for all possible components where the sum of the peak depths is at most N and that the sum of the peak depths of component C is $N + 1$, so it is not minimum.

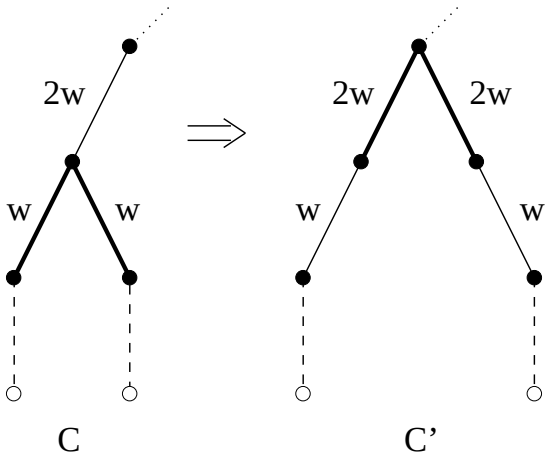

FIG. 3. *C has a peak with a nonpeak edge above it.*

Case 1. C has a peak with a nonpeak edge above it.

Suppose the peak edges with the nonpeak edge above have length w. Consider the component C' obtained by moving the peak with the nonpeak edge above it up one level; see Figure 3. This decreases the sum of the peak depths by 1, so our induction hypothesis applies to C'.

The sum of the lengths of the connecting edges of C and C' are the same—the connecting edge of length $2w$ above the peak in C has been replaced by two connecting edges of length w in C'. The sum of the lengths of the peak edges of C is less than that in C'—the two peak edges of length w in C have been moved up so they each have length $2w$ in C'. Combining this with the induction hypothesis on C', we get

$$\begin{aligned}\sum_{e\in\mathcal{C}_C}\text{length}(e) &= \sum_{e\in\mathcal{C}_{C'}}\text{length}(e)\\ &\geq \left(\frac{2^r}{r2^r+s}\right)\sum_{e\in\mathcal{P}_{C'}}\text{length}(e)\\ &> \left(\frac{2^r}{r2^r+s}\right)\sum_{e\in\mathcal{P}_C}\text{length}(e). \qquad (4)\end{aligned}$$

Case 2. C has two bottom-level peak edges whose depths differ by more than 1.

Consider the lowest and highest bottom-level peak edges in C. The lowest peak must have two paths to two leaves below it; the highest such peak must have at least one path to a leaf below it. Say the highest peak edge is of length $2a$ and the lowest peak edge is of length b; the paths below these peak edges are also of lengths $2a$ and b, respectively, by the construction of B_n.

Consider the component C' constructed from C by moving the lowest peak just below the highest bottom-level peak edge. See Figure 4. This decreases the sum of the peak depths by at least 1, so our induction hypothesis applies to C'.

The sum of the lengths of the connecting edges of C and C' are again the same—the connecting path of length $2a$ below the high peak in C has been replaced by two connecting paths of length a in C', and the two connecting paths of length b below the lowest peak in C have been replaced by one connecting path of length $2b$ in C'.

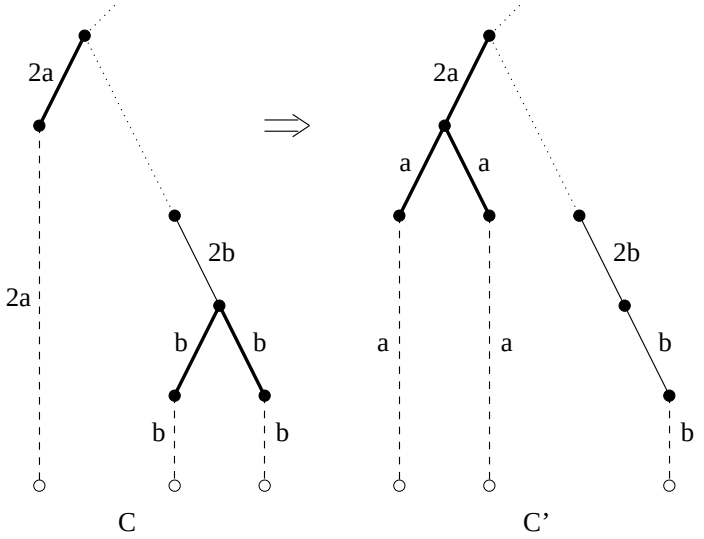

FIG. 4. *C has two bottom-level peak edges whose depths differ by more than* 1.

The sum of the lengths of the peak edges of C is less than that in C'—the two lowest peak edges of length b in C have been moved up, so they have length a in C'. Since the lowest and highest bottom-level peaks differ in depth by at least 2, we know that indeed $b < a$.

Combining this with the induction hypothesis on C', we again get inequality (4).

These two cases complete the induction step, and so we have proved inequality (2) and completed the proof of Theorem 2.5. □

3. Lower bound for ρ_k. The proof of the lower bound will follow the same general outline as the lower bound proof in [4]. We first convert a Steiner tree into a weighted regular binary tree. Then by labeling the vertices of this binary tree, we construct $r2^r + s$ different k-size Steiner trees and show that one of these trees has small enough length to give us the lower bound.

We will use the following lemma from that paper.

LEMMA 3.1. *For any regular binary tree, there exists a one-to-one mapping f from internal vertices to leaves, such that*

(a) *for any internal vertex u, $f(u)$ is a descendant of u;*

(b) *all tree paths $p(u)$ from u to $f(u)$ are edge disjoint.*

Proof. First, we add the following additional requirement:

(c) There is a leaf v so that the path from the root to v is edge disjoint from all other paths $p(u)$.

We prove by induction on the height of the tree that all three conditions can be met. When the tree has height 0, this is trivially true.

Let T be a tree of height $d \geq 1$. T has two subtrees, T_1 and T_2, each of height at most $d-1$ and rooted at the two children of the root of T. By induction, there are functions f_1 and f_2 on the internal vertices of T_1 and T_2 satisfying (a) and (b). There are also vertices v_1 and v_2 in T_1 and T_2, respectively, satisfying (c). Define f as the union of f_1 and f_2 and define $f(\text{root of } T) = v_1$. Clearly, f satisfies (a) and (b) and v_2 satisfies (c) for T. This completes the induction. □

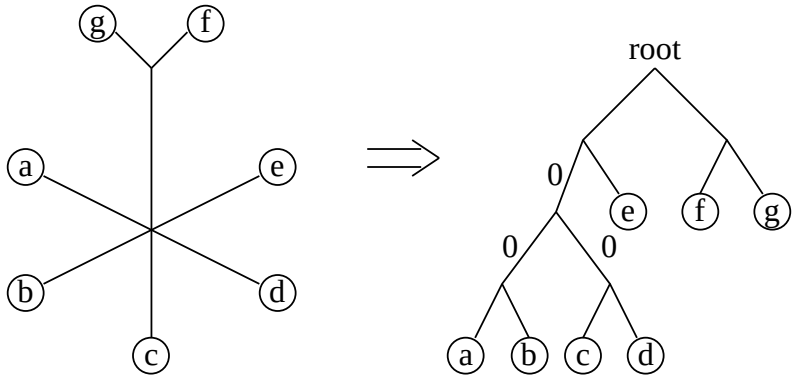

FIG. 5. *Constructing a regular binary tree from a Steiner tree.*

THEOREM 3.2 (lower bound for ρ_k). *For any k, with $k = 2^r+s$, where $0 \le s < 2^r$, we have*

$$\rho_k \ge \frac{r2^r + s}{(r+1)2^r + s}. \tag{5}$$

Proof. We want to prove that for any metric space and any set of points P in that space,

$$\frac{L_S(P)}{L_{kS}(P)} \ge \frac{r2^r + s}{(r+1)2^r + s}. \tag{6}$$

Equation (5) follows immediately because ρ_k is the infimum of these ratios.

We do this by induction on n, the number of points in P. If $n \le k$, then the inequality is true since $L_S(P)/L_{kS}(P) = 1$. For $n > k$, consider the Steiner minimum tree T on P. If T is not a full Steiner tree, then we can split it at a regular point into two smaller Steiner trees, each with fewer than n regular points. Say the regular points of these trees are given by the sets P_1 and P_2. Then we have $L_S(P) = L_S(P_1)+L_S(P_2)$ and $L_{kS}(P) \le L_{kS}(P_1) + L_S(P_2)$, and so

$$\frac{L_S(P)}{L_{kS}(P)} \ge \frac{L_S(P_1) + L_S(P_2)}{L_{kS}(P_1) + L_{kS}(P_2)} \ge \min\left\{\frac{L_S(P_1)}{L_{kS}(P_1)}, \frac{L_S(P_2)}{L_{kS}(P_2)}\right\} \ge \frac{r2^r + s}{(r+1)2^r + s}$$

by our induction hypothesis. Therefore, we only have to consider the case where T is a full Steiner tree, that is, where all regular points are leaves.

By adding zero-length edges and Steiner points, we first modify T to be a tree where every Steiner point has degree exactly 3. Then we choose a root in the middle of an edge to convert T into a weighted regular binary tree; call it T'. The weight of each edge is the length of the edge in the metric space. See Figure 5.

We label all internal vertices of T' with sets of size exactly 2^r chosen from the numbers $\{1, 2, \ldots, r2^r + s\}$. The labeling of a vertex is determined inductively by the labeling of the r vertices above it on a path to the root, its r immediate ancestors.

To begin this labeling, we label the vertex on the first level (the root) with the set $\{1, 2, \ldots, 2^r\}$; we label the two vertices on the second level with the set $\{2^r + 1, 2^r + 2, \ldots, 2 \cdot 2^r\}$; and in general, we label all vertices on the ith level, for $1 \le i \le r$, with the set $\{(i-1)2^r + 1, (i-1)2^r + 2, \ldots, i2^r\}$.

The inductive labeling will maintain the following property, which the labeling of the first r levels clearly satisfies.

Disjointness property. The label sets of up to r consecutive vertices on a path up the tree are disjoint.

Assume that the first i levels have been labeled, $i \geq r$, and that the disjointness property holds up to level i. We label the vertices at level $i+1$ by the following two rules.

Rule 1. Let v be a vertex at level $i+1-r$ with label set $S_v = \{\ell_1, \ell_2, \ldots, \ell_{2^r}\}$. Label the jth descendant of v on level $i+1$ with the set $S_j = \{\ell_j, \ell_{j+1}, \ldots, \ell_{j+2^r-s-1}\}$, where we reduce the subscripts (mod 2^r) so that they are in the range 1 to 2^r.

Vertex v has at most 2^r descendents on level $i+1$, so we need at most the sets $S_1, S_2, \ldots, S_{2^r}$. The sets S_j each have $2^r - s$ elements, and each label ℓ_k from S_v appears in at most $2^r - s$ of the sets, namely $\ell_k \in S_k, S_{k-1}, \ldots, S_{k-2^r+s+1}$, where again we reduce the subscripts (mod 2^r).

To complete the labeling at the $(i+1)$st level, we must add s numbers to each labeling set.

Rule 2. For a vertex at level $i+1$, add to its label set those s labels that are not in the label sets of any of its immediate r ancestors.

By our disjointness property, the r immediate ancestors of a vertex at level $i+1$ are labeled by r disjoint sets of size 2^r, so there must be exactly s numbers from $\{1, 2, \ldots, r2^r + s\}$ unused. Also, the labels added by Rule 2 will be different from the labels added by Rule 1, so all vertices at level $i+1$ are given exactly 2^r labels by the two rules.

The disjointness property now holds up to level $i+1$, since a vertex u at level $i+1$ has labels taken from its rth ancestor's label set, which by the disjointness property at level i are unused by u's $r-1$ immediate ancestors, and s other labels, which are also unused by its $r-1$ immediate ancestors.

By induction, we can label the entire tree. See Figure 6 for an example of this labeling process when $k = 5$.

Now we use this labeling to give us $r2^r + s$ k-size Steiner trees. Each label $\ell = 1, 2, \ldots, r2^r + s$ determines the k-size Steiner tree T_ℓ. Each node labeled ℓ becomes the component root of a component in T_ℓ. In addition, we always have a component in T_ℓ whose component root is the root of T', even if the root of T' is not labeled by ℓ. A component that begins at vertex v, the component root, then connects by paths in T' to the first vertices below v that are also labeled by ℓ; call these vertices the *intermediate leaves* of the component. From the intermediate leaf u, the component then follows the path $p(u)$ to the tree leaf $f(u)$, as given by Lemma 3.1. If there are no vertices labeled ℓ on a path below v, then the component extends along that path all the way down to a tree leaf. See Figure 7.

First, we verify that T_ℓ is in fact a tree that spans P. (Remember that the points of P are the leaves of T'.) This follows by induction on the height of the tree T'. It is trivially true when the height is 0. Look at the component at the top of T_ℓ, the component whose component root is the root of T'; then look at a subtree below an intermediate leaf of this top component. By induction, T_ℓ restricted to this subtree is a tree spanning those points in P that are leaves of the subtree. The top component, which is itself a tree, then joins one tree leaf from each of the subtrees below its intermediate leaves (and any tree leaves of T' that are not below any intermediate leaves) into one large tree.

Now look at a component in tree T_ℓ that has component root v. We verify that

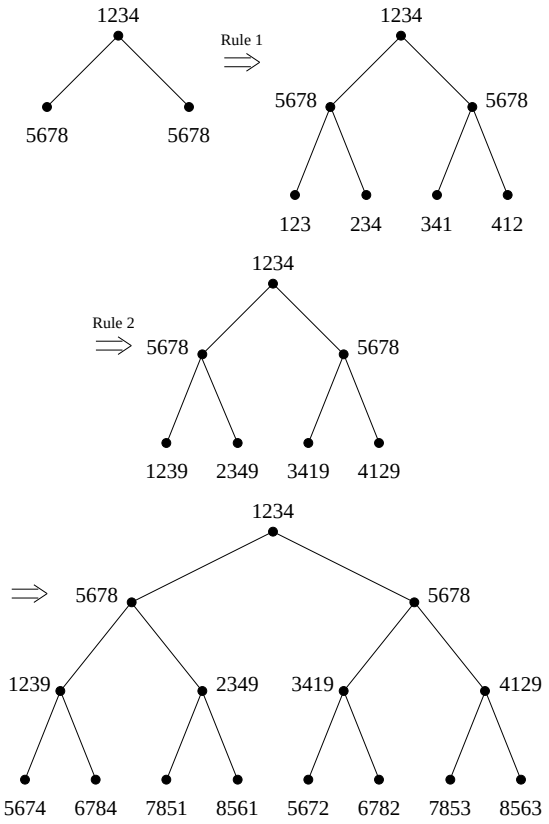

FIG. 6. *Labeling a binary tree when* $k = 5$.

these components are always of size at most k. If a component stops at a tree leaf before reaching an intermediate leaf, its size will be smaller, so we only look at the maximum-sized components that have all possible intermediate leaves.

Suppose v is not labeled by ℓ, so v must be the root of the tree T' and $\ell \geq 2^r + 1$. By the initial labeling, $2^r + 1, 2^r + 2, \ldots, r2^r$ appear on all vertices of one of the $r - 1$ levels below the root, and by Rule 2, the remaining s labels appear on all vertices of the rth level below the root. Thus the intermediate leaves are all at the rth level or above, and so it is of size at most $2^r \leq k$.

Therefore, we can assume that v is itself labeled by ℓ. By Rule 1 of the labeling process, we know that s of the descendants of v r levels below are not labeled by ℓ, and the remaining $2^r - s$ descendants are labeled by ℓ.

Now look at a vertex w that is r levels below the component root v and that is not labeled by ℓ. Since ℓ does label v, by the disjointness property, it cannot label any of the $r - 1$ vertices on the path from v to w. Since ℓ does not label w, by Rule 2 of the labeling process, the children of w must be labeled by ℓ and they will be intermediate leaves.

Thus the component rooted at v has $2s$ intermediate leaves $r + 1$ levels below v and $2^r - s$ intermediate leaves r levels below. Therefore, there are $2^r + s = k$ intermediate leaves, and thus the component is of size k. Hence all components are of size at most k, and T_ℓ is a k-size Steiner tree on the set P of regular points.

In T_ℓ, let L_ℓ be the sum of the lengths of the paths $p(u)$ from intermediate leaves

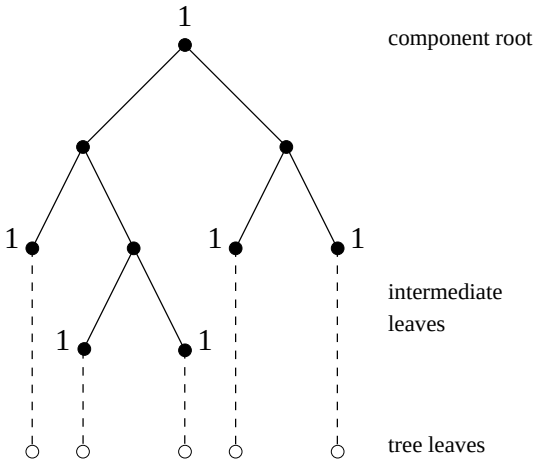

FIG. 7. *A component in T_1 from the labeling of Figure* 6.

u in T_ℓ to tree leaves. Consider the sum $L_1 + L_2 + \cdots + L_{r2^r+s}$. Since each internal vertex u in T' is an intermediate leaf in exactly 2^r of the k-size Steiner trees, namely T_ℓ for each ℓ in the label set of u, the length of the path $p(u)$ will be counted exactly 2^r times in the sum. Since these paths are disjoint for different intermediate leaves, the sum of all of the paths in all of the terms of the sum will be at most 2^r times the length of the entire tree T', which is the length of the Steiner minimum tree. Thus

$$L_1 + L_2 + \cdots + L_{r2^r+s} \leq 2^r L_S(P).$$

Then there must be a d so that

$$L_d \leq \frac{2^r}{r2^r + s} L_S(P).$$

Now the entire length of T_d is the length of the components from the component roots to the intermediate leaves plus the length from the intermediate leaves to the tree leaves. The components from the component roots to the intermediate leaves cover T' exactly once, so this part has length $L_S(P)$. The other part has length L_d. Therefore,

$$\text{length}(T_d) = L_S(P) + L_d \leq \left(1 + \frac{2^r}{r2^r + s}\right) L_S(P).$$

Since $L_{kS}(P) \leq \text{length}(T_d)$, we get

$$\frac{L_S(P)}{L_{kS}(P)} \geq \frac{L_S(P)}{\text{length}(T_d)} \geq \frac{1}{(1 + \frac{2^r}{r2^r+s})} = \frac{r2^r + s}{(r+1)2^r + s}.$$

This is equation (6), and so Theorem 3.2 is proved. □

4. Discussion. Berman and Ramaiyer [1] showed that their polynomial-time approximation algorithm has performance ratio

$$\rho_2^{-1} - \frac{\rho_2^{-1} - \rho_3^{-1}}{2} - \frac{\rho_3^{-1} - \rho_4^{-1}}{3} - \cdots - \frac{\rho_{k-1}^{-1} - \rho_k^{-1}}{k-1}.$$

Our result determined all ρ_k. It follows that there exists a polynomial-time approximation for the Steiner minimum tree in graphs with performance ratio r for any r larger than

$$2 - \frac{2 - \frac{5}{3}}{2} - \frac{\frac{5}{3} - \frac{3}{2}}{3} - \frac{\frac{3}{2} - \frac{13}{9}}{4} - \cdots = 1.734\ldots.$$

Recently, Zelikovsky [16] gave a polynomial-time approximation for the Steiner minimum tree in graphs with performance ratio $\rho_k^{-1}(1 - \log \rho_2 + \log \rho_k)$ which approaches $(1 - \log \rho_2) = 1.693\ldots$ as $k \to \infty$. This approximation is better than Berman and Ramaiyer's for k sufficiently large; however, for smaller k, Berman and Ramaiyer's algorithm still has a better performance ratio. Karpinski and Zelikovsky [13] have improved the algorithm further to give a $1.644\ldots$ approximation.

The interesting open question is whether there exists a polynomial-time approximation for the Steiner minimum tree in graphs with a performance ratio which beats this value.

A NOTE ON "AN ON-LINE SCHEDULING HEURISTIC WITH BETTER WORST CASE RATIO THAN GRAHAM'S LIST SCHEDULING"*

R. CHANDRASEKARAN†, BO CHEN‡, GÁBOR GALAMBOS§, P. R. NARAYANAN†, ANDRÉ VAN VLIET¶, AND GERHARD J. WOEGINGER‖

Key words. combinatorial problems, scheduling, worst-case bounds, on-line algorithms

AMS subject classifications. 90B35, 90C27

PII. S0097539793258775

1. Introduction. This is an erratum for the paper by Galambos and Woeginger [2]. The proofs of two basic results in [2], Lemmas 4.3 and 4.5, are incorrect. The flaw in the proof of Lemma 4.3 can be easily fixed, but a rather different approach is needed in order to prove Lemma 4.5.

2. Corrections.

2.1. Correction to Lemma 4.3. The assertion "$L_1 > \alpha L_m \geq \alpha C^*$" on line 15 of page 352 is incorrect and should be replaced by "$L_1 > \alpha \min\{C^*, L_m\}$." Inequality (8) should be strengthened to

$$L_1 + x \leq \beta \min\{C^*, L_m\}.$$

Then (9) can be replaced by

$$\begin{aligned} L_2 + x &\leq (mC^* - L_1 - x)/(m-1) + x \\ &= mC^*/(m-1) - L_1 + (L_1 + x)(m-2)/(m-1) \\ &< mC^*/(m-1) + (\beta(m-2)/(m-1) - \alpha) \min\{C^*, L_m\} \\ &\leq C^*(m + (m-2)\beta - (m-1)\alpha)/(m-1). \end{aligned}$$

2.2. Correction to Lemma 4.5. In the proof, the claim "Moreover by the definition of M_j, no other machine received a job between the primed and the unprimed moment" is incorrect. However, Lemma 4.5 follows directly as a corollary of the following result.

LEMMA 4.5′. *Assume the algorithm enters Step* 4. *Denote by a_i the job assigned last to machine M_i. Then there exists a $k \geq 2$ such that*

$$\text{(a)} \quad L_j - a_j \leq L_1 \quad \forall j \geq 2,\ j \neq k,$$
$$\text{(b)} \quad L_k - a_k \leq \beta L_1.$$

Proof. Choose $k \geq 2$ such that M_k is the machine that received its last job a_k earlier than all other machines M_j received their last job a_j ($j \geq 2$). Since $\sim (L_1 + x, L_2, \ldots, L_m)$ and $L_1 \leq \alpha L_m$, we have $L_1 \leq \alpha\beta L_k$ and $L_1 \leq \alpha\beta L_j$.

Proof of (a). Since a_j is the last job on M_j, it cannot have been placed in Step 4.1. We consider the cases where a_j was placed in Step 2, 3, or 4.2. Let us denote by L'_i the workload of machine M_i, $1 \leq i \leq m$, just before machine M_j receives its last job a_j.

Suppose that M_j received its last job in Step 4.2. Before M_j received a_j, the current schedule at that time satisfied $\sim (L'_1, L'_2, \ldots, L'_m)$. Thus

$$L_1 \geq L'_1 \geq \frac{1}{\beta} L'_k = \frac{1}{\beta} L_k \geq \frac{1}{\alpha\beta^2} L_1.$$

This contradicts our initial assumption that $\alpha \leq \frac{1}{3}$ and $\beta \leq \frac{5}{4}$. Therefore, we conclude that a_j was not placed in Step 4.2.

Suppose that M_j received its last job in Step 3. This means that L'_j was the second smallest workload at that time. Denote the minimum workload at that moment by $L'_{\min}$. If we had assigned job a_j to the machine of minimum workload, then the schedule would have become similar. This implies that $L'_k \sim L'_{\min} + a_j$ and $L'_k \sim L'_j$. Since $L_j \sim L_k$, we can write $L_j = xL_k$, where $\frac{1}{\beta} \leq x \leq \beta$. Then

$$L_j = xL_k = xL'_k \leq x\beta L'_j = x\beta(L_j - a_j).$$

On the other hand, we have

$$\frac{1}{\beta} L_j - xa_j = x\left(\frac{1}{\beta} L'_k - a_j\right) \leq xL'_{\min} \leq xL_1 \leq x\alpha\beta L_k = \alpha\beta L_j.$$

Combining the above two relations gives us

$$\left(\frac{1}{\beta} - \alpha\beta\right) L_j \leq xa_j \leq \left(x - \frac{1}{\beta}\right) L_j \quad \Rightarrow \quad \frac{1}{\beta} - \alpha\beta \leq x - \frac{1}{\beta} \leq \beta - \frac{1}{\beta},$$

which contradicts the initial assumptions that $\beta + 1 > \beta^3(\alpha + 1)$ and $\beta \geq 1$. We then conclude that a_j was not placed in Step 3.

The only possibility that remains is that M_j received a_j in Step 2. This means that L'_j was the smallest workload at that moment. Hence $L_j - a_j = L'_j \leq L'_1 \leq L_1$.

Proof of (b). We again need to consider the three cases where a_k was placed in Step 2, 3, or 4.2. If a_k was placed in Step 2, then machine M_k had the smallest workload at that time. Thus $L_k - a_k \leq L_1$. If a_k was placed in Step 3, then from conclusion (a), we know that all other machines had workloads less than or equal to L_1 at that time. Since M_k had the second smallest workload, we conclude that $L_k - a_k \leq L_1$. The last possibility that remains is that a_k was placed in Step 4.2. Since the schedule was similar just before a_k was placed, we conclude that $L_k - a_k \leq \beta L_1$. □

3. Remarks. As we have seen, Lemma 4.5 has been strengthened to Lemma 4.5′. A claim stronger than Lemma 4.3 that allows us to give the exact worst-case bound of RLS has also been established. Further investigations of RLS yield an improved algorithm, RLS2. Interested readers are referred to [1] for details.

AN OPTIMAL PROBABILISTIC PROTOCOL FOR SYNCHRONOUS BYZANTINE AGREEMENT*

PESECH FELDMAN† AND SILVIO MICALI‡

Abstract. Broadcasting guarantees the recipient of a message that everyone else has received the same message. This guarantee no longer exists in a setting in which all communication is person-to-person and some of the people involved are untrustworthy: though he may claim to send the same message to everyone, an untrustworthy sender may send different messages to different people. In such a setting, *Byzantine agreement* offers the "best alternative" to broadcasting. Thus far, however, reaching Byzantine agreement has required either many rounds of communication (i.e., messages had to be sent back and forth a number of times that grew with the size of the network) or the help of some external trusted party.

In this paper, for the standard communication model of synchronous networks in which each pair of processors is connected by a private communication line, we exhibit a protocol that, in probabilistic polynomial time and without relying on any external trusted party, reaches Byzantine agreement in an expected constant number of rounds and in the worst natural fault model. In fact, our protocol successfully tolerates that up to 1/3 of the processors in the network may deviate from their prescribed instructions in an arbitrary way, cooperate with each other, and perform arbitrarily long computations.

Our protocol effectively demonstrates the power of randomization and zero-knowledge computation against errors. Indeed, it proves that "privacy" (a fundamental ingredient of one of our primitives), even when is not a desired goal in itself (as for the Byzantine agreement problem), can be a crucial tool for achieving correctness.

Our protocol also introduces three new primitives—graded broadcast, graded verifiable secret sharing, and oblivious common coin—that are of independent interest, and may be effectively used in more practical protocols than ours.

Key words. broadcasting, Byzantine agreement, fault-tolerant computation, randomization

1. The problem.

A motivating scenario. We are in Byzantium, the night before a great battle. The Byzantine army, led by a commander in chief, consists of n legions, each one separately encamped with its own general. The empire is declining: up to 1/3 of the generals—including the commander in chief—may be traitors. No radios (sic!) are available: all communication is via messengers on horseback. To make things worse, the loyal generals do not know who the traitors are. During the night each general receives a messenger with the order of the commander for the next day: either "attack" or "retreat." If all the good generals attack, they will be victorious; if they all retreat, they will be safe; but if some of them attack and some retreat they will be defeated. Since a treasonous commander in chief may give different orders to different generals, it is not a good idea for the loyal ones to directly execute his orders. Asking the opinion of other generals may be quite misleading too: traitors may represent their orders differently to different generals, they may not send any information to someone,

and they may claim to have received nothing from someone else. On the other hand, should the honest generals always—say—attack (independently of the received orders and of any discussion), they would not follow any meaningful strategy. What they need is a way to exchange messages so as to always reach a common decision while respecting the chief's order, should he happen to be honest. They need *Byzantine agreement*.

Byzantine agreement. As insightfully defined by Pease, Shostak, and Lamport [32], Byzantine agreement essentially consists of providing "the best alternative" to broadcasting when all communication is person-to-person (as in an ordinary telephone network) and some of the people involved are untrustworthy. In order to briefly describe what this alternative is, we must first sketch its classic underlying communication model, the most convenient and simplest one in which the need for Byzantine agreement arises.

Modernizing the motivating scenario a bit, generals are processors of a computer network. Every two processors in the network are joined by a separate communication line, but no way exists to broadcast messages. (Thus, though a processor can directly send a given message to all other processors, each recipient has no way to know whether everyone else has received the same message.) The network otherwise has some positive features. Each processor in it has a distinct identity and knows the identities of the processors on the other end of its lines. The network is *synchronous*, that is, messages are reliably delivered in a sufficiently timely fashion: there is a common clock, messages are sent at each clock tick (say, on the hour) and are guaranteed to be delivered by the next tick (though not necessarily simultaneously). Each communication line is *private*, that is, no one can alter, inject, or read messages traveling along it. Indeed, the only way for an adversary to disturb the communication of two good processors is by corrupting one of them. We will refer to such a network as a *standard network* since it is the one generally adopted for discussing the problem of Byzantine agreement.[1]

Now assume that each of the processors of a standard network has an initial value. Then, speaking informally, a Byzantine agreement protocol should guarantee that for *any* set of initial values, the following two properties hold:

1. *Consensus*: All honest (i.e., following the protocol) processors adopt a common value.
2. *Validity*: If all honest processors start with the same value, then they adopt that value.[2]

Byzantine faults. Having briefly discussed our communication model, we must now mention our fault model. Processors become faulty when they deviate from their prescribed programs. "Crashing" (i.e., ceasing all activities) is a *benign* way for a processor in a network to become faulty. The faulty behavior considered in this paper is instead much more adversarial: faulty processors may deviate from their prescribed programs in an arbitrary fashion, perform an arbitrary amount of computation, and

[1] Standard networks are advantageous to consider in that they allow one to focus on the novel characteristics of Byzantine agreement without being distracted by legitimate but "orthogonal" concerns. We wish to stress, however, that, while the absence of broadcasting is crucial for the problem of Byzantine agreement to be meaningful, we shall see in section 9.1 that most of the fine details of the adopted communication model can be significantly relaxed without affecting our result.

[2] Notice that we have stated Byzantine agreement a bit more generally than in the motivating scenario; namely, the processors are not given their initial values by a distinguished member of their group but have their own individual sources for these values. Consider, for instance, the case of party bosses who, before an election, call each other on the phone to select a common candidate to back: even though their initial choices do not arise from the suggestion of a distinguished boss, they still need Byzantine agreement.

even coordinate their disrupting actions. Modeling software and hardware faults as malicious behavior may not be unreasonable when dealing with the interaction of very complex programs, but it is actually *very* meaningful, and even mandatory, if there are people behind their computers. Indeed, whenever we wish to emphasize the possibility of human control—and thus that of malicious behavior—we do employ the term "player" instead of processor.

The goal of the faulty players is to disrupt either the consensus or the validity requirement or simply to delay reaching Byzantine agreement for as long as possible (as when, say, they prefer the status quo to any of the two alternatives being voted on). Here is an example of what malicious players may do against a simple-minded protocol.

Assume that the honest generals of the motivating scenario try to reach agreement as follows: they send their initial orders to each other and then execute the most "popular" order. Then the dishonest generals can easily cause disagreement. To make our example more dramatic, let us suppose that 2/3 of the generals are loyal, that half of the loyal ones start with the value "attack," and that the other loyal half start with "retreat."[3] In this situation, the traitors simply tell every loyal general in the first half that their initial value is "attack" and every loyal one in the second half that their value is "retreat." Consensus is then disrupted in a most dramatic way: half of the loyal generals will attack and the other half will retreat. Indeed, reaching Byzantine agreement is a tricky business.[4]

The significance of Byzantine agreement. Byzantine agreement is widely considered the standard bearer in the field of fault-tolerant distributed computation. While it is indisputable that this problem has attracted an enormous amount of attention, we are skeptical about its relevance in the context of errors *naturally* occurring in a distributed computation. In our opinion, Byzantine agreement is relevant to the field of *secure computation protocols*, which includes problems such as electronic elections, electronic negotiations, or electronic bids.

Secure protocols (see [30] for a satisfactory and general definition) is a new and exciting branch of mathematics that has experienced impressive growth in recent years. A problem in this field consists of enabling a group of mutually distrustful parties to achieve, in a interaction in which some of the players do not follow the rules of the game, the same results that are obtainable by exchanging messages in a prescribed manner when there is total and honest collaboration. Indeed, it is thanks to insights from the field of secure protocols that we have succeeded in finding our optimal probabilistic solution to the synchronous Byzantine agreement problem.

Byzantine agreement plays an important role in secure protocol theory; essentially, it dispenses with the need to hold a meeting when, because of the presence of adversaries among us, it is useful to establish in a public manner who said what or what was decided upon. In the simplest secure protocol or in the most complex one,

[3] These initial values are not at all unlikely if they represent (as in our motivating scenario) the individual version of an alleged unique message sent by a dishonest party. In any case, consensus and validity are very strong requirements: they should hold for any initial values!

[4] As we shall mention in the next section, at least t rounds of communications are needed to reach Byzantine agreement whenever (1) t parties are dishonest and (2) the honest ones follow a deterministic protocol. This fact immediately yields an alternative way to dismiss the simple-minded strategy discussed above: it is deterministic and can be implemented in *two* rounds, no matter how many players there are and no matter how many of them can be faulty. The same fact allows one to dismiss a good deal of other simple-minded strategies as well. As we shall see, it is only through a careful use of randomization that a strong majority of honest players may reach Byzantine agreement very fast.

the honest players cannot possibly make any progress without keeping a meaningful and consistent view of the world. This is what Byzantine agreement gives us.

The quality of a Byzantine agreement protocol. Several aspects are relevant in determining the quality of a Byzantine agreement protocol. As for most protocols, the amount of local computation and the total number of message bits exchanged continue to be important. But in this archetypal problem in distributed adversarial computation, two are the most relevant (and most investigated) aspects: the *round complexity* and the *fault model*.

The round complexity measures the amount of interaction that a protocol requires.[5] Since, at each clock tick, a player may send messages to more than one processor (and their recipients will receive them by the next tick), the round complexity of a protocol naturally consists of the total number of *rounds* (i.e., clock pulses and thus "waves" of messages) necessary for completing the protocol.

The fault model specifies what can go wrong (while still being tolerable somehow) in executing a protocol, namely the following: How many processors can become faulty? How much can they deviate from their prescribed programs? How long can faulty processors compute to pursue their disruptive goals?

In this light, the goal of a Byzantine agreement protocol naturally consists of simultaneously "decreasing" the round complexity while "increasing" the fault model.

Our solution. We present a probabilistic-polynomial-time protocol that reaches Byzantine agreement in an expected constant number of rounds (thus minimizing the round complexity) while tolerating the maximum possible number of faulty players and letting them exhibit a most malicious behavior.

2. Previous solutions and ours.

2.1. The worst natural fault model. Though several weaker models for Byzantine agreement can be considered (see the excellent surveys of Fischer [19] and Chor and Dwork [11] for a more comprehensive history of this subject), in this paper, we concentrate on a most adversarial setting. Speaking informally for now, the *worst (natural) fault model* is characterized by the following three conditions:

1. the good players are bound to polynomial-time computation;
2. a constant fraction of the total number of players may become faulty; and
3. the faulty players can deviate from their prescribed instructions in any arbitrary way, perform arbitrarily long computations, and perfectly coordinate their actions.

The worst fault model is not only the most difficult one to handle but also, in our opinion, the most meaningful one to consider. Condition 1 essentially expresses that for a Byzantine agreement protocol to be useful, the computational effort required by the honest processors should be reasonable. Condition 2 properly captures our intuition about the nature of faults, independently of whether we consider players as machines or people controlling machines. Indeed, while we do expect that the number of faulty players grows with the size of the network, it would be quite counterintuitive to expect that it grows sublinearly in this size. (For instance, assume that in a network of n players the number of bad ones is $n/\log n$. Then this would mean that, while we expect 1% of a group of 1000 players to be faulty, we expect a *smaller* percentage of faulty players in a much larger group.) Condition 3 essentially captures that there may be people behind their computers: dishonest people follow whatever strategy is

[5] In a distributed setting, this is the most expensive resource. Typically, the time invested by the processors for performing their local computation is negligible with respect to the time necessary to send electronic mail back and forth several times.

best for them, try much harder than honest ones, and effectively cooperate with one another. In any case, by successfully taming *malicious* faults, we would a fortiori succeed in taming all other more benign—though not necessarily more reasonable—ones.

Let us thus review the main protocols in this difficult model.

2.2. Previous solutions. Dolev et al. [12] exhibited the first solution in the worst fault model. Letting n denote the total number of players in the network and t denote an upperbound on the number of faulty players, they showed that as long as $t < n/3$, Byzantine agreement can be reached deterministically in $\Theta(t)$ rounds. Recently, by a different protocol, Moses and Waarts [31] tightened their number of rounds to be $t+1$ for $t < n/8$. This is optimal for their choice of t, since Fischer and Lynch [20] proved that t rounds are required by any deterministic protocol if t faults may occur in its execution.

In light of the lower bound mentioned, all hope for faster agreement is entrusted to probabilism. Indeed, since the pioneering work of Ben-Or [5], randomization has been extensively used for reaching agreement. In particular, Rabin's notion of a *common coin* [34] has emerged as the right version of probabilism for this setting. A network with a common coin can be described as a network in which a random bit becomes available to all processors at each round but is unpredictable before then. The interest of this notion is due to a reduction of Rabin showing that as long as $t < n/4$, Byzantine agreement can be reached in expected constant number of rounds with the help of a common coin. Of course, common coins are not a standard feature of a point-to-point network; thus this reduction raises a natural and important question: *Are there efficient Byzantine agreement protocols implementable "within the network" and in the worst fault model*?

Prior to our work, no efficient within-the-network Byzantine agreement protocol was known for the worst fault model. Rabin [34] devised a cryptographic Byzantine agreement protocol running in an expected constant number of rounds but relying on a incorruptible party external to the network.[6] Bracha [6] exhibited Byzantine agreement protocols that do not require trusted parties, but his protocols are slowers (they run in expected $O(\log n)$ rounds) and are not explicitly constructed (their existence is proved by counting arguments). Chor and Coan [8] exhibit an explicit and within-the-network Byzantine agreement protocol, but their solution, though attractively simple, is much slower (their protocol tolerates any $t < n/3$ faults but runs in $O(t/\log n)$ rounds; thus it requires expected $O(n/\log n)$ rounds in the worst fault model). Feldman and Micali [18] explicitly exhibited a cryptographic within-the-network protocol that, after a preprocessing step consisting of a single Byzantine agreement (on some specially generated keys), allows any subsequent agreement to be reached in an expected constant number of rounds.[7] While their protocol is actually very practical after the first agreement has been reached, the first agreement may

[6] Rabin's algorithm uses digital signatures—which implies that dishonest processors are bound to polynomial-time computation—and a *trusted party*—i.e., an incorruptible processor outside the network. In his solution, if the trusted party distributes k pieces of reliable information to the processors in the networks in preparation, then these processors can, subsequently and without any external help, compute k common coins. Thus the number of reachable agreements is bounded by the amount of information distributed by the trusted party in the preprocessing stage. A cryptographic Byzantine agreement protocol with a trusted party but without the latter limitation was later found by the authors in [18], in addition to other results mentioned later on.

[7] Thus their protocol does not require any preprocessing if a trusted party distributes the right keys beforehand. The present result can thus be viewed as removing cryptography and preprocessing from their protocol.

very well be the most important one (i.e., whether or not to hold a meeting).

To complete the picture, let us mention that Dwork, Shmoys, and Stockmeyer [16] found a beautiful Byzantine agreement protocol running in expected constant round but not in the worst fault model. (Their algorithm tolerates only $O(n/\log n)$ faults.)

2.3. Our solution. The main theorem in this paper can be informally stated as follows:

There exists an explicit protocol $\mathcal{P}$ reaching Byzantine agreement in the worst fault model and running in in an expected constant number of rounds. Protocol $\mathcal{P}$ actually tolerates any number of faults less than one third of the total number of processors.

Our protocol is probabilistic in the "best possible way": it is *always correct* and *probably fast*; that is, an unlucky sequence of coin tosses may cause our protocol to run longer, but when it halts both consensus and validity are guaranteed to hold. Our algorithm not only exhibits optimal (within a constant) round complexity, but it also achieves optimal fault tolerance. In fact, Karlin and Yao [28] have extended the earlier deterministic lower bound of [32] by showing that even probabilistically Byzantine agreement is unreachable if $t = n/3$ faults may occur.[8]

3. Model of computation. As of today, unfortunately, no reasonable treatment of the notion of probabilistic computation in a malicious fault model can be conveniently pulled off the shelf. (A comprehensive effort in this direction—in the more general context of *secure computation*—was made in [30], but this paper has not yet appeared in print.[9]) Thus we have found it *necessary* to devote a few pages to discuss—though only at a semiformal level— of definitions in what we intended to be a purely algorithmic paper.

The definitions below, presented only at a semiformal level, focus solely on what we immediately need to discuss our Byzantine agreement protocol, purposely ignoring many other subtle issues (addressed in the quoted paper [30]). We only wish to clarify what it means that, in the execution of an n-party protocol, t of the processors may make errors (i.e., deviate from their prescribed instructions) in a most malicious way and that the protocol tolerates these faults.

Basic notation. Below we assume that a proper encoding scheme is adopted. Thus we can treat a string or a set of strings over an arbitrary alphabet as a binary string, we may consider algorithms that output (the encoding of) another algorithm, etc.

We assume that each finite set mentioned in our paper is ordered. If $S_1, \ldots, S_k$ are finite sets, we let the instruction $\forall x_1 \in S_1 \ldots \forall x_k \in S_k\ Alg(x_1, \ldots, x_k)$ stand for the program consisting of running algorithm Alg first on input the first element of $S = S_1 \times \cdots \times S_k$, then ("from scratch," i.e., in a memoryless fashion) on input the second element of S, and so on.

[8] This remains true, as proved by Dolev and Dwork [14], even if one abandons the worst fault model so as to include cryptographic protocols (against faulty processors with polynomially bounded resources). Thus the optimality of our algorithm is retained in this setting as well.

[9] Byzantine agreement aims only at guaranteeing *correctness* in the presence of an adversary (about what was decided upon) but not at keeping secret the original single-bit inputs of the players. A secure protocol must instead simultaneously ensure that a given computation (on inputs some of which are secret) is both correct and *private*, that is, roughly, not revealing the initially secret individual inputs more than is implicitly done by the desired output of the computation. This is much more difficult both to handle and to formalize.

The symbol ":=" denotes the *assignment* instruction. The symbol "$\circ$" denotes the concatenation operator. If σ is a string and τ is a prefix of σ, we denote by the expression "σ/τ" the string ρ such that $\sigma = \tau \circ \rho$.

If *Alg* is a probabilistic algorithm, I is a string, and R is a infinite sequence of bits, by running *running Alg on input I and coins R* we mean the process of executing *Alg* on input I so that, whenever *Alg* flips a coin and $R = b \circ R'$, the bit b is returned as the result of the coin toss and $R := R'$.

Protocols. To avoid any issue of nonconstructiveness, we insist that protocols be uniform.

DEFINITION 1. *Let n be an integer greater than* 1. *An* n-party protocol *is an n-tuple of probabilistic algorithms, $P_1, \ldots, P_n$, where each P_i (which is intended to be run by player i) satisfies the following property. On any input (usually representing player i's previous history in an execution), P_i halts with probability* 1 *computing either an n-tuple of binary strings (possibly empty, representing i's messages to the other players for the next round) or a triple consisting of an n-tuple of strings (with the same interpretation as before), the special character* TERMINATE, *and value v (as its output).*

Notice that each time that P_i is run, one also obtains as "side products" the sequence of coin tosses actually made by P_i and the sequence of its "future" coin tosses.

A protocol *is a probabilistic algorithm that, for all integers $n > 1$, on input the unary representation of n, outputs (the encoding of) an n-party protocol.*

In this paper, the expression *round* denotes a natural number; in the context of an n-party protocol, the expression *player* denotes an integer in the closed interval $[1, n]$.

Executing protocols without adversaries. Let us first describe the notion of executing a protocol when all players are honest. Intuitively, each party runs his own component of the protocol. The only coordination with other parties is via messages exchanged in an organized fashion. Namely, there is a common clock accessible by all players, messages are sent at each clock tick along private communication channels, and they are received by the next tick. The interval of time between two consecutive ticks is called a *round*. At the beginning of a round, a player reads the messages sent to him in the previous round, and then runs (his component of) the protocol to compute the messages he sends in response. These outgoing messages are computed by a player by running the protocol on the just-received incoming messages and its own past "history," (i.e., an encoding of all that has happened to the player during the execution of the protocol up to the last round). We now describe this intuitive scenario a bit more precisely, though not totally formally. In so doing, parties, hardware, private communication channels, and clocks will disappear. However, they will remain in our terminology for convenience of discourse.

DEFINITION 2. *Let n be an integer > 1, $P = (P_1, \ldots, P_n)$ be an n-party protocol, $p_1, \ldots, p_n$ be finite strings, and $R_1, \ldots, R_n$ be infinite binary sequences. Then by* executing P on private inputs $p_1, \ldots, p_n$ and coins $R_1, \ldots, R_n$, *we mean the process of generating, for each player i and round r, the quantities*

- H_i^r, *a string called the* history of player i at round r (*a triple consisting of* (1) *i's history prior to round r,* (2) *the messages received by i in round r, and* (3) *the coin tosses of i in round r*),
- $M_{i\rightarrow}^r$, *the* messages sent by player i in round r (*an n-tuple of strings whose jth entry, $M_{i\rightarrow}^r[j]$, is called* the message sent by i to j in round r),
- $M_{\rightarrow i}^r$, the messages received by player i at round r (*an n-tuple of strings, whose*

jth entry, $M^r_{\to i}[j]$, is called the message received by i from j in round r),

- C^r_i, the coin tosses of i in round r (*a substring of* R_i), *and*
- R^r_i, the coin tosses of i after round r (*a substring of* R_i)

by executing the following instructions:

(Start) *Set* $C^0_i = \epsilon$, $R^0_i = R_i$, $M^0_{i\to} = M^0_{\to i} = (\epsilon, \ldots, \epsilon)$, *and* $H^0_i = (p_i, M^0_{\to i}, C^0_i)$.

"Only the individual input is available at the start of an execution: no message has yet been sent or received, and no coin has been flipped."

(Halt) *Say that* player i halts at round r (*and his* output is σ) *if* r *is the minimum round* s *for which* P_i, *on input* H^{s-1}_i *and coins* R_i, *computes a triple whose second entry is the special character* TERMINATE (*and whose third entry is* σ.) *If* i *halts in round* r, *then* $\forall s > r$, $M^s_{i\to} := (\epsilon, \ldots, \epsilon)$, $M^s_{\to i} := (M^s_{1\to}[i], \ldots, M^s_{n\to}[i])$, $C^s_i := \epsilon$, $R^s_i := R^r_i$, *and* $H^s_i := (H^{s-1}_i, M^s_{\to i}, \epsilon)$.

(Continue) *If* i *has not halted in a round* $< r$, *run* P_i *on input* H^{r-1}_i *and coins* R^{r-1}_i *so as to compute either* (a) *an* n*-tuple of string* M *or* (b) *a triple* $(M, \text{TERMINATE}, v)$, *where* M *is an* n*-tuple of strings,* TERMINATE *is a special character, and* v *is a string. If* C *is actually the entire sequence of coin tosses that* P_i *has made in this computation—and thus* C *is a prefix of* R^{r-1}_i*—then* $C^r_i := C$, $R^r_i := R^{r-1}_i / C$, $M^r_{i\to} := M$, $M^r_{\to i} := (M^r_{1\to}[i], \ldots, M^r_{n\to}[i])$, *and* $H^r_i := (H^{r-1}_i, M^r_{\to i}, C^r_i)$.

For simplicity's sake (since each P_i, on any input, halts with probability 1), above we have neglected dealing with protocol "divergence." Also for simplicity, we let a player, at each round, run his own version of the protocol, P_i, on the just-received messages and on the entire history of his execution of the protocol. This is certainly wasteful. In most practical examples, in fact, it suffices to remember very little of the past history. Also notice that the current round number is not an available input to P_i, but it can be easily derived from the current history. In our protocols, however, we make players very much aware of the round number. In fact, we actually spell out what each P_i should do separately for each round. Notice also that the strings R_i need not to be given "in full." It suffices that a mechanism is provided that "retrieves and deletes" R_i's first bit.

Adversaries. We now allow malicious errors to occur in the execution of a protocol. A processor that has made an error is called *faulty* or *bad*. To formalize the idea that faulty processors may coordinate their strategies in an optimal way, we envisage a single external entity, *the adversary*, that chooses which processors to corrupt and sends messages on behalf of the corrupted processors. Since we wish our adversary to be as strong as possible, we allow it to be a nonuniform probabilistic algorithm. (In fact, in our protocol, we might as well assume that an adversary is an arbitrary probabilistic noncomputable function.)

DEFINITION 3. *Let* n *be an integer greater than* 1. *An* n-party adversary *is a probabilistic algorithm that, on any input* (*usually representing* A*'s previous activity in an execution*) *halts with probability* 1 *and outputs either an integer in the range* $[1, n]$ (*the identity of a newly corrupted player*) *or a sequence of pairs* (j, M), *where* j *is an integer between* 1 *and* n (*the identity of a corrupted player*) *and* M *is an* n*-tuple of strings* (*the messages sent by* j *in the current round*). *An* adversary, A, *is a sequence of* n*-party adversaries:* $A = \{A(n) : n = 2, 3, \ldots\}$.

Executing protocols with an adversary. We now define what it means for an n-party protocol P to be executed with an n-party adversary A. A enters the execution with an *initial adversarial history*, a string denoted symbolically by H^0_A, and an *initially bad set*, $\text{BAD}^0 \subset [1, n]$. String H^0_A may contain some a priori knowledge about the inputs of the players, the result of previous protocols, and so on. Set BAD^0 represents the players corrupted at round 0, that is, before the protocol starts. (In

other words, if P were the first protocol "ever to be executed," BAD^0 would be empty. If, as we shall see, P were called as a subprotocol, BAD^0 would comprise all the players that have been corrupted prior to calling P.) Adversary A may, at any round, *corrupt* an additional processor, j. When this happens, all of j's history becomes available to A;[10] as for all corrupted processors, all future messages sent to j will be read by A; and A will also compute all of the messages that j will be sending. Essentially, j becomes an extension of A. Thus if $k \in \text{BAD}^0$, k's private input is what becomes available to A at the start of P, and A will totally control player k for the entire execution of P.

Since we want to prepare for the worst, we let the adversary be even more powerful by allowing *rushing*; that is, we let the message delivery (which is not simultaneous) be as adversarial as possible. At the beginning of each round, all currently good players read the messages sent to them in the previous round and compute the ones that they wish to send in the present round. We pessimistically assume that the messages addressed to the currently corrupted processors are always delivered immediately, and if based on this information the adversary decides to corrupt an additional processor j, we pessimistically assume that it succeeds in doing so before j has sent any messages to the currently good players, thus giving A a chance to change these messages. Further, we consistently "iterate this pessimism" within the same round. That is, once j is corrupted in round r, we assume that the messages addressed to j by the currently good processors are immediately delivered, while j has not yet sent any messages to the remaining good players. This way A may decide whom to corrupt next in the same round, and so on, until A does not wish to corrupt anyone else in round r. At this point, A computes all messages sent by the corrupted processors in round r. These "bad" messages will be read by the good processors (of course, each processor receives the messages addressed to him), together with all "good" messages, at the beginning of round $r+1$.

The privacy of the communication channels of a concrete network is captured in the formulation below by the fact that messages exchanged between uncorrupted processors are never an available input to the adversary algorithm.

The history of a bad player is essentially frozen at the moment in which he is corrupted because A has essentially subsumed him from that point on.

DEFINITION 4. *Let n be an integer > 1, H_A^0, $p_1, \ldots, p_n$ be finite strings, $R_A, R_1, \ldots, R_n$ infinite binary sequences, BAD^0 be a subset of $[1,n]$ and GOOD^0 be its complement, $P = (P_1, \ldots, P_n)$ be an n–party protocol, and A be an n-party adversary. Then by* executing P with A on initial adversarial history H_A^0, inputs $p_1, \ldots, p_n$, initially bad set BAD^0, and coins R_A and $R_1, \ldots, R_n$, *we mean the process of* (i) *generating, for all players i and rounds r, the quantities*

- H_i^r, $M_{i\rightarrow}^r$, $M_{\rightarrow i}^r$, C_i^r, *and* R_i^r (*whose interpretation, as well as their setting for $r = 0$, is the same as in Definition* 2)

and the new quantities

- H_A^r (*a string called the* history of the adversary at round r),
- C_A^r (*a binary string called* the coin tosses of the adversary at round r),
- R_A^r (*an infinite subsequence of R_A called* the coin tosses of A after round r),

and

- BAD^r *and* GOOD^r (*two sets of players called, respectively, the* bad players at round r *and the* good players at round r, *such that* $\forall r$, $\text{GOOD}^r = [1,n] - \text{BAD}^r$)

[10] This is a clean but pessimistic approach (which makes our result stronger). In practice, though j may wish to fully collaborate with A by sharing all information he has, he may still have trouble in remembering—say—all previously received messages or all previously made coin tosses.

by setting $C_A^0 = \epsilon$ *and* $R_A^0 = R_A$ *and* (ii) *executing the following instructions for* $r = 1, 2, \ldots$:

0. $\text{TEMPH}_A^r := H_A^{r-1}$; $\text{TEMPR}_A^r := R_A^{r-1}$; $\text{TEMPGOOD}^r := \text{GOOD}^{r-1}$; $\text{TEMPBAD}^r := \text{BAD}^{r-1}$.
   "Because A's history, future coin tosses, and sets of good and bad players dynamically change within a round, we shall keep track of these changes in temporary variables. However, their final values within round r, respectively, H_A^r, R_A^r, GOOD^r, *and* BAD^r, *are unambiguously defined."*
1. *"Just as when all processors are honest,"* $\forall g \in \text{GOOD}^{r-1}$, *generate* $M_{g\rightarrow}^r$, *"the messages that g wishes to send in this round (which may be reset if g is corrupted in this round)," and* C_g^r, R_g^r *by running* P_g *on input* H_g^{r-1} *and coins* R_g^{r-1}.
2. $\forall g \in \text{GOOD}^{r-1}$ and $\forall b \in \text{BAD}^{r-1}$, $\text{TEMPH}_A^r := (\text{TEMPH}_A^r, g, b, M_{g\rightarrow}^r[b])$.
3. *Run A on input* TEMPH_A^r *and coins* TEMPR_A^r.
   If in this execution of step 3 *A has output* $j \in \text{TEMPGOOD}^r$ *and made the sequence of coin tosses C, then*
   - $\text{TEMPBAD}^r := \text{TEMPBAD}^r \cup \{j\}$, $\text{TEMPGOOD}^r := \text{TEMPGOOD}^r - \{j\}$,
   - $\text{TEMPH}_A^r := (\text{TEMPH}_A^r, H_j^{r-1}, C_j^r, C)$ *"so that from* H_j^{r-1} *and* C_j^r *A can reconstruct all of the messages that j wished to send in round r, and from* TEMPH_A^r *and C she can reconstruct why she has corrupted j,"*
   - $\text{TEMPR}_A^r := \text{TEMPR}_A^r/C$ *"adjust A's future coin tosses,"*
   - $\forall g \in \text{TEMPGOOD}^r$, $\text{TEMPH}_A^r := (\text{TEMPH}_A^r, g, j, M_{g\rightarrow}^r[j])$, *"i.e., according to rushing, A is also given the messages that the currently good players wish to send to j in this round," and*
   - *go to step* 3 *"to corrupt next processor."*

   Otherwise, if in this execution of step 3, *A has output,* $\forall b \in \text{TEMPBAD}^r$, *a vector* $M_b \in (\{0,1\}^*)^n$ *"as b's round-r messages"*[11] *and made the sequence of coin tosses C, then*
   - $\forall b \in \text{BAD}^r$, $M_{b\rightarrow}^r := M_b$,
   - $\text{TEMPH}_A^r := (\text{TEMPH}_A^r, C)$ *"so that she can reconstruct the bad players' messages of round r," and*
   - $\text{TEMPR}_A^r := \text{TEMPR}_A^r/C$, *and "adjust the final round-r quantities as follows."*
4. *Letting* $\mathcal{C}$ *be the sequence of coin tosses A has made since the last execution of step* 2,
   - $H_A^r := \text{TEMPH}_A^r$; $C_A^r := \mathcal{C}$; *and* $R_A^r := \text{TEMPR}_A^r$;
   - $\text{GOOD}^r := \text{TEMPGOOD}^r$ *and* $\text{BAD}^r := \text{TEMPBAD}^r$;
   - $\forall i, j \in [1, n]$, $M_{\rightarrow i}^r[j] := M_{j\rightarrow}^r[i]$;
   - $\forall g \in \text{GOOD}^r$, $H_g^r := (H_g^{r-1}, M_{\rightarrow g}^r, C_g^r)$;
   - $\forall b \in \text{BAD}^{r-1}$, $H_b^r := (H_b^{r-1}, bad)$, *and* $\forall b \in \text{BAD}^r - \text{BAD}^{r-1}$, $H_b^r := (H_b^{r-1}, C_b^r, bad)$.

Let E be the sequence (of tuples of quantities resulting from the above computation) so defined:

$$E = E_0, E_1, \ldots,$$

where

$$E_r = (H_1^r,\ M_{1\rightarrow}^r,\ M_{\rightarrow 1}^r,\ C_1^r,\ R_i^r,\ \ldots,\ H_n^r,\ M_{n\rightarrow}^r,\ M_{\rightarrow n}^r,\ C_n^r,\ R_n^r,\ H_A^r,\ C_A^r,\ R_A^r,\ \text{BAD}^r, \text{GOOD}^r).$$

[11] By convention, if A's output is not of this format, then it is assumed that $M_b = (\epsilon, \ldots, \epsilon)$ $\forall b \in \text{TEMPBAD}^r$.

We call E the execution of P with A on initial quantities H_A^0, BAD^0, and $p_1, \ldots, p_n$, and coins R_A and $R_1, \ldots, R_n$. *The value E_r is called* round r of E. *If R is a positive integer, by the expression E* up to round R, *in symbols $E_{[0,R]}$, we mean the finite subsequence $E_0, \ldots, E_R$.*

(Note: *The quantities H_i^r, $M_{i\rightarrow}^r$, $M_{\rightarrow i}^r$, C_i^r, R_i^r, H_A^r, C_A^r, R_A^r, BAD^r, and GOOD^r may carry an additional superscript or prefix to emphasize the protocol during the execution of which they have been generated.*)

Remark. The ability of an adversary to corrupt players at arbitrary points in time of a protocol is crucial in a randomized protocol. For a deterministic protocol, the adversary's optimal strategy may be calculated beforehand, but it may profitably change during the execution of a randomized protocol. For example, consider a probabilistic protocol for randomly selecting a "leader," that is, a processor to be put in charge of a given task. Depending on the specifics of the protocol, it may be impossible for the adversary to corrupt a few players beforehand and coordinate their actions so that one of them is guaranteed to be elected leader. It is, however, very easy for her to wait and see which processor is selected as leader and then corrupt it! (This feature models a "real-life" phenomenon: nobody is born a thief, but some may become thieves if the right circumstances arise .... To capture this realistic feature, we must allow—and successfully deal with—adversaries that can corrupt players, during run time, in a dynamic fashion.)

Fractional adversaries. Above we have presented the mechanics of executing a protocol with an adversary exhibiting what is essentially an arbitrarily malicious behavior. To keep things meaningful, however, we wish to put a cap on the *number* of players that an adversary may corrupt without otherwise limiting its actions in any way. In fact, we assume that no n-party adversary may corrupt n players in an execution with an n-party protocol (otherwise, no meaningful property about such an execution could possibly be guaranteed).

We will actually be focusing on adversaries that may corrupt at most a constant fraction of the players. Let c be a constant between 0 and 1; we say that an adversary A is a *c-adversary* if for all $n > 1$ and all n-party protocols P, in any execution with P on an initially bad set with $< cn$ elements, the cardinality of the bad set always remains $< cn$. Whenever we consider an execution of an n-party protocol with a c-adversary, we implicitly assume that the initially bad set contains less than cn players.

We also assume that no more than one adversary is active in an execution of a protocol. Actually, because the adversary that never corrupts any processor is a special type of adversary (indeed, a c-adversary for all possible $c \in (0, 1)$), we shall assume that in every execution of a protocol there is *exactly one adversary* active. Thus the expression "an execution of protocol P" really means "an execution of protocol P with adversary A, for some adversary A."

Initial quantities. As we have seen, to run an n-party protocol with an n-party adversary A, we need to specify, other than the coin tosses of A and the n players, the following initial quantities: (1) the initial adversarial history H_A^0, (2) the initially bad set BAD^0, and (3) the inputs $(p_1, \ldots, p_n)$. For the purpose of defining the mechanics of executing an n-party protocol with an n-adversary, we define $\mathcal{IQ}_n$, the set of *the initial quantities (of size n)* in a most "liberal" manner; that is, $\mathcal{IQ}_n = \{0,1\}^* \times 2^{\{1,\ldots,n\}} \times (\{0,1\}^*)^n$. In an accordingly liberal manner, we let $\mathcal{IQ} = \{\mathcal{IQ}_n : n > 1\}$ be the set of *all (possible) initial quantities.*

In general, however, it is meaningful to prove properties of protocols if the initial quantities of their executions satisfy a given constraint (e.g., reaching Byzantine

agreement on "the message" sent by a given member of a network is meaningful only if the identity of this sender is a common input to all processors in the network). We actually prefer to dismiss nonmeaningful initial quantities from consideration altogether. That is, we *define* each n-party protocol $P(n)$ together with the set of its own *proper* initial quantities, denoted by $\mathcal{IQ}_n^P$, on which—and solely on which—$P(n)$ can be run. Thus whenever we say that some specific values IQ are initial quantities for $P(n)$, it is assumed that $IQ \in \mathcal{IQ}_n^P$. Also, whenever we refer to an execution of a protocol P with some specific initial quantities IQ, if $IQ \in \mathcal{IQ}_n$, we actually refer to an execution of $P(n)$ on initial quantities IQ—quantities which actually belong to $\mathcal{IQ}_n^P$. (Indeed, it should be noticed that n can easily be computed from any member of $\mathcal{IQ}_n$.) In summary, all initial quantities of a protocol are deemed to be proper—and we shall use the expression "proper" only for emphasis.

Notice that by specifying the proper initial quantities of a given protocol, one could easily "cheat" by disallowing certain initial adversarial histories or initially bad sets so as to make protocol design artificially easy. In this paper, however, the proper initial quantities of a protocol will never in any way constrain the initial adversarial history or the initially bad set, except for its cardinality. Moreover, in this paper, proper initial quantities will never impose any restrictions on the inputs of the initially corrupted players. When defining a new protocol, though, we find it convenient to describe the generic element of its (proper) initial quantities by specifying (in particular) the inputs of all players, with the understanding that all constraints on the initially bad players must be dropped; that is, by saying that $(H_A^0, \text{BAD}^0, (p_1, \ldots, p_n)) \in \mathcal{IQ}_n^P$, we simply mean that the private input of player i is p_i if i does not belong to BAD^0. (In other words, if we wish a more extensive notation, an element of $\mathcal{IQ}_n^P$ is of the form $(H_A^0, \text{BAD}^0, \{(i, p_i) : i \notin \text{BAD}^0\})$.)

Random executions and probabilities.

DEFINITION 5. *Let n be an integer > 1, P be an n-party protocol, A be an n-party adversary, and $IQ \in \mathcal{IQ}_n^P$. By* randomly executing P with A on initial quantities IQ, *we mean the process consisting of generating the infinitely long bit sequences R_A, $R_1, \ldots, R_n$ by randomly and independently selecting each of their bits in $\{0,1\}$ and then executing P with A on initial quantities IQ and coins R_A, $R_1, \ldots, R_n$. We call the execution resulting from this process a* random execution *of P with A on initial quantities IQ.*

Thus the probability that an event e occurs in a random execution of P with A on initial quantities IQ is solely computed over the coin tosses of P and A. (Only if we have assumed a probability distribution on the private inputs as well—and if we explicitly say so—we may compute the probability of an event also over the random choices in selecting the private inputs.) The probabilities of events that are most important to us are those that are *intrinsic* properties of our protocols *alone*; that is, we shall prove bounds for these probabilities that are valid for any adversaries, any initial adversarial history, any initially corrupted players, and any players' inputs.

Fault tolerance. The fault tolerance of a protocol is essentially the highest fraction of faults it can tolerate.

DEFINITION 6. *Let Ψ be a property (i.e., a predicate) and c be a constant between 0 and 1. We say that a protocol P is a* c-fault tolerant *protocol (or a protocol* with fault tolerance c) with respect to Ψ *if $\Psi(E) = true$ for any execution E of P with a c-adversary.*

If the property Ψ is clear from context, we may simply say that P is a protocol *with fault tolerance* c rather than with fault tolerance c with respect to Ψ.

Legal shortcuts. For simplicity of discourse, we wish to "legalize" some handy

notation.

• *Highlighting something.* When we want to focus only on some of the quantities determining an execution, we just omit mentioning the others. For instance, the sentence "Let E be an execution of n-party protocol P with n-party adversary A on inputs $p_1, \ldots, p_n$ and initial corrupted set BAD^0" stands for "Let E be an execution of n-party protocol P with n-party adversary A on inputs $p_1, \ldots, p_n$, initially bad set BAD^0, initial adversarial history H_A^0, and coin tosses $R_1, \ldots, R_n$ and R_A, for some string H_A^0 and bit sequences $R_1, \ldots, R_n$ and R_A."

• *Matching types.* If P is an n-party protocol and we say that P is executed with an adversary A, we implicitly assume that A is an n-party adversary. Any adversary mentioned in the context of a protocol with fault tolerance c is meant to be a c-adversary. If P is a protocol and A is an adversary, by saying that n parties execute P with A, we mean that they execute $P(n)$ with adversary $A(n)$. By saying that a value IQ represents some initial quantities, we implicitly assume that $IQ \in \{0,1\}^* \times 2^{[1,n]} \times (\{0,1\}^*)^n$ for some positive integer n. By saying that a protocol P is executed with adversary A on initial quantities $IQ = (H_A^0, \text{BAD}^0, (p_1, \ldots, p_n))$, we mean executing $P(n)$ with $A(n)$ on initial adversarial history H_A^0, initially bad set BAD^0, and inputs $p_1, \ldots, p_n$. By an execution of protocol P with adversary A, we mean an execution of $P(n)$ with $A(n)$ for some number of players n (on some proper initial quantities).

Good, bad, and end. In an execution of a protocol, we say that processor i is *good at round* r if the adversary has not corrupted i at a round $\leq r$, and say that it is *bad at round* r otherwise. When, in an execution, the round under consideration is not specified, we say that a player i is *currently good* (respectively, *currently bad*) to mean that it is good at round r (respectively, bad at round r) if the round under consideration is r. We say that i is *eventually bad* in an execution if it is corrupted at some round of it, and say that it is *always good* otherwise. When no confusion can arise, we may use the simpler expression *good* (respectively, *bad*) instead of currently or always good (respectively, currently or eventually bad).

We say that an execution of a protocol *halts at round* r if r is the smallest integer s for which every good processor has halted in a round $\leq s$. (*Note:* If an execution of an n-party protocol Q has not halted at round r, it continues to be considered an execution of an n-party protocol after that round, whether or not some of the good processors have halted by round r and no longer execute the protocol.) Let R be a constant and P be a protocol; we say that P is an *R-round protocol* if in all executions of P every good processor halts at round R. (*Note:* In every execution of an R-round protocol, all good processors halt "simultaneously," but if an execution of a protocol which is not R-round halts at round R, the good processors may not halt in the same round of that execution.) We say that P is a *fixed-round* protocol if it is an R-round protocol for some value R. All of our protocols, except for the last one, are fixed-round. We say that a protocol *does not halt before round* r if in all its executions no good processor halts at a round $\leq r$.

Subprotocols. To facilitate the description of our Byzantine agreement protocol and to make it possible to use parts of it in other contexts, we have constructed it in a modular way. We thus need the notion of a *subprotocol*, that is, a protocol that is called as a subroutine by another protocol. Fortunately, in this paper, all subprotocols are fixed-round, they are called at rounds specified a priori by protocols (no execution of which halts by those rounds), and n-party protocols call only n-party subprotocols. (This simplifies our formalization somewhat; for instance, it makes it very clear when the call starts and when it ends.)

Let Q be a $> r$-round protocol calling an R-round protocol P at a prescribed round r. Then an execution of Q will be suspended once it reaches round r. At that point, the input value of each player i, p_i, is specified by either P itself (i.e., as when p_i is a constant) or player i's prior history, H_i^{r-1}. (If this is the case, we formally assume that there is a function $\mathcal{I}_i^P$ specified a priori, that, evaluated on H_i^{r-1}, determines p_i.) The execution of P on these inputs then starts. The good players execute P as if it were (rather than a subprotocol) "the first protocol they ever execute in their life," that is, their execution is independent of their prior histories. The adversary, on the other hand, is allowed to take advantage of what it has "learned" in the execution of Q to fine tune its strategy in the execution of P.[12] Moreover, should the adversary corrupt an additional player k during the execution of P, she will get, in addition to k's current history in the execution of P, its "suspended" history in Q. When P ends, each player appends its final "P-history" to its "suspended Q-history," and Q's computation is resumed. Processors corrupted in the execution of P are also considered corrupted in the resumed execution of Q.

DEFINITION 7. *Let n be an integer > 1, A be an adversary, P be an n-party R-round protocol, Q be an n-party protocol calling P at round r, and R_A^1, R_A^P, R_A^2, $R_1^{Q1}, \ldots, R_n^{Q1}$, $R_1^P, \ldots, R_n^P$, $R_1^{Q2}, \ldots, R_n^{Q2}$ be infinite binary sequences. By executing Q with A on initial quantities IQ and coins*

$$R_A^1, R_A^P, R_A^2, R_1^{Q1}, \ldots, R_n^{Q1}, R_1^P, \ldots, R_n^P, R_1^{Q2}, \ldots, R_n^{Q2},$$

we mean the following:

1. *To execute Q "a first time" with adversary A on initial quantities IQ and coins $R_A^1, R_1^{Q1}, \ldots, R_n^{Q1}$ "up to round r" so as to generate an execution up to round R, E^1, and thus quantities $H_A^{r,Q}$, $\text{BAD}^{r,Q}$, and $H_i^{r,Q}$ for each player i.*

2. (*For each player i, we let p_i be the input specified by $H_i^{r,Q}$.*) *To generate an execution up to round R, E^2, by running P with A on initial inputs $p_1, \ldots, p_n$, initial adversarial history $H_A^{r,Q}$, initially bad set $\text{BAD}^{r,Q}$, and coins $R_A^P, R_1^P, \ldots, R_n^P$ as usual except for the following. If A corrupts a new player j at a round x, it receives as an input not only the history of player j in the present execution, $H_j^{x,P}$, but also $H_j^{r,Q}$ ("j's suspended history in Q").*

3. *To generate an execution E^3 by running Q with A on initial adversarial history $H_A^{R,P}$, initially corrupted set $\text{BAD}^{R,P}$, and inputs $(H_1^{r,Q}, H_1^{R,P}), \ldots, (H_n^{r,Q}, H_n^{R,P})$.*

We let the corresponding execution (*of calling protocol Q with A on the above initial quantities and coins*) *consist of the sequence E whose first r elements are the elements of E^1, next R elements are those of E^2, and remaining elements are those of E^3.* (*In other words, the execution of a protocol Q that calls an R-round subprotocol P at round r is obtained by identifying, for each $\rho \in [1, R]$, round ρ of P with round $r + \rho$ of Q.*)

The notion of randomly executing a protocol and that of a random execution of a protocols are extended in the natural way to a protocol that calls a subprotocol at a prescribed round.

The notion of a subprotocol is immediately generalized to allow *nesting* of subprotocols, that is, to allow Q itself to be a subprotocol. Assume that for $1 \leq x < k$, protocol Q_x has called fixed-round protocol Q_{x+1} at round r_x. Then if protocol

[12] For instance, assume that a player j has been corrupted by A during the execution of Q before P was called. Then it is conceivable that from the Q-history of player j at the time of the call, the adversary may infer the Q-history at the time of the call of a good player i well enough to predict i's input to P. (That is, Q may induce some correlation among the inputs of subprotocol P that need not to be there if P were executed "from scratch.")

$Q = Q_k$ calls P at round r, all of the mechanics for calling P, executing P, and including the result of P's execution in the Q-histories remain the same, except that if a new processor i is corrupted during the execution of P, the "suspended history" of player i learned by the adversary, rather than simply being $H_i^{r,Q}$, is actually $(H_i^{r,Q_1}, \ldots, H_i^{r_k Q_k})$.

Concurrent protocols. Since it is the goal of this paper to squeeze as much computation as possible into a few rounds, we need to introduce the notion of concurrently executing more protocols, each protocol on its own inputs.

DEFINITION. *Let R be a positive integer, n be an integer > 1, and $\mathcal{L}$ be a finite set (of labels). Then an* (n-party R-round) concurrent protocol *is a mapping from $\mathcal{L}$ into the set of n-party R-round protocols.*

For each $x \in \mathcal{L}$, we denote by P^x the image of x under P and by P_i^x the program of player i within P^x, that is, $P^x = (P_1^x, \ldots, P_n^x)$.

In an execution of a concurrent protocol P, the good players execute each of the P^x's *independently* of the others. This restriction does not apply to the adversary, who can make use of the information learned in the execution of one of the protocols to choose her actions in the execution of another. Moreover, if the adversary corrupts player i at round ρ of the execution of a protocol P^x, then i becomes corrupted in the execution of every other protocol in P, but the total number of bad player increases only by one. Let us now be more precise.

DEFINITION 8. *Let R be a positive integer, n be an integer > 1, $\mathcal{L}$ be a finite set, $P : x \in \mathcal{L} \to P^x$ be an n-party R-round concurrent protocol, A be an n-party adversary, H_A^0 be a string, R_A be an infinite binary sequence,* BAD^0 *be a subset of* $[1, n]$, *$p_1^x, \ldots, p_n^x$ strings, and $R_1^x, \ldots, R_n^x$ be infinite binary sequences. By* executing P (*or, equivalently, by* concurrently executing $\forall x \in \mathcal{L}\ P^x$) with adversary A on initial adversarial history H_A^0, initially bad set BAD^0, inputs $p_1^x, \ldots, p_n^x$, and coins R_A and $R_1^x, \ldots, R_n^x$, *we mean performing the following instructions for each* player $i \in [1, n]$ *and each round* $r = 0, 1, \ldots$:

(a) *$\forall i \in \text{GOOD}^{r-1}$ and $\forall x \in \mathcal{L}$, compute $M_{\to i}^{r,P^x}$, $M_{i\to}^{r,P^x}$, C_i^{r,P^x}, and H_i^{r,P^x} from $M_{\to i}^{r-1,P^x}$, $M_{i\to}^{r-1,P^x}$, and H_i^{r-1,P^x} by running P_i^x so that the kth coin toss of P_i^x is the kth bit of R_i^x.*

(b) *Execute $H_A^r := H_A^{r-1}$, $\text{GOOD}^r := \text{GOOD}^{r-1}$, $\text{BAD}^r := \text{BAD}^{r-1}$, and $\forall g \in \text{GOOD}^r$, $\forall b \in \text{BAD}^r$, $\forall x \in \mathcal{L}$, $H_A^r := (H_A^r, M_{g\to}^{r,P^x}[b])$.*

(c) *Run A on input H_A^r so that A's kth coin toss is the k-bit of R_A. If C is the sequence of coin tosses made by A in this execution of step* 3, *then $H_A^r := (H_A^r, C)$. If A outputs $j \in \text{GOOD}^r$ in this execution of step* 3, *then $\text{BAD}^r := \text{BAD}^r \cup \{j\}$, $\text{GOOD}^r := \text{GOOD}^r - \{j\}$, and $\forall g \in \text{GOOD}^r$, $\forall x \in \mathcal{L}$, $H_A^r := (H_A^r, M_{g\to}^{r,P^x}[j])$, and go to step* (c). *Else "A has output for each bad player b and label x an n-message vector M_b^x."*

(d) *Letting C be the sequence of coin tosses made by A since the last execution of step* (b), *set $C_A^r = C$ and $\forall b \in \text{BAD}^r$, $\forall x \in \mathcal{L}$, $M_{b\to}^r = M_b^x$.*

The execution corresponding to the above process is $E = E_1, \ldots, E_R$, where

$$E_r = (H_1^r,\ M_{1\to}^r,\ M_{\to 1}^r,\ C_1^r, \ldots,\ H_n^r,\ M_{n\to}^r,\ M_{\to n}^r,\ C_n^r,\ H_A^r,\ C_A^r,\ \text{BAD}^r, \text{GOOD}^r),$$

where $H_i^r = \{(x, H_i^{r,x}) : x \in \mathcal{L}\}$, $M_{i\to}^r = \{(x, M_{i\to}^{r,x}) : x \in \mathcal{L}\}$, $M_{\to i}^r = \{(x, M_{\to i}^{r,x}) : x \in \mathcal{L}\}$, and $C_i^r = \{(x, C_i^{r,x}) : x \in \mathcal{L}\}$. That is, each quantity relative to protocol P^x is labeled with x.

The notions of randomly executing a concurrent protocol and that of a random execution of a concurrent protocol are obtained in the natural way.

A concurrent protocol $P : x \in \mathcal{L} \to P^x$ can be called at a prescribed round r by another protocol Q very much like an ordinary subprotocol. (In this case, the players

Q-histories at round r must specify, for each $x \in \mathcal{L}$, the inputs $p_1^x, \ldots, p_n^x$ on which to run protocol P^x; that is, $\forall x \in \mathcal{L}$, each Q_i^r specifies p_i^x.)

Sequenced protocols. We will also need the notion of a *sequenced protocol*. This consists of a pair of protocols (P, Q), where Q is run after P and on the histories of P. In this paper we actually need to consider only the case of sequenced protocols (P, Q), where P is R-round. Thus after an execution E of P, for all player i, i's input to Q consists of i's round-R history in E.

Like any other protocol, a sequenced protocol may be called as a subprotocol. Note that if (P, Q) is a sequenced protocol, then P and Q can never be executed concurrently. However, if $(P_1, Q_1), \ldots, (P_k, Q_k)$ are sequenced protocols, then it might be possible to concurrently execute $P_1, \ldots, P_k$ and then concurrently execute subprotocols $Q_1, \ldots, Q_n$, running each Q_i on the history of the execution of P_i.

Message bounds. As we have seen, at each round in the execution of a protocol $P = (P_1, \ldots, P_n)$, the adversary sends a message to each currently good player g, which then feeds it to P_g (among other inputs). Thus by sending g arbitrarily long messages, the adversary could arbitrarily increase the amount of g's local computation. To meaningfully discuss complexity issues, we thus need to modify the mechanics of protocol execution by introducing *message bounds*.

The message bound is a variable internal to each processor that at each round evaluates to a positive integer or to $+\infty$ a special value greater than all positive integers. If at round r the message bound of a currently good player g is set to a positive integer k, then g is allowed to compute the k-bit prefix of any incoming message at round r in k computational steps; only after this truncation will a message become part of the input to P_g.

A simple and flexible way to specify the message bounds of a player at every round is to give him a special input, the *message-bound input*: in any execution in which the value of this input is v, a player sets to v the message bound of every round. (With an eye to complexity, these special inputs will be presented in *unary*; in fact, because we charge v steps for extracting the v-bit prefix of a string, we do not wish this operation to be exponential in the message-bound input.) Alternatively, a protocol can specify the message bound of round r within the code of round r itself—and thus may set it to a lower value when shorter messages are expected (from the good players). In either way, if it wishes to keep its own running time under control, a protocol must set the message bounds of each round to finite values. (If it fails to do so in even a single round, it will be in that round that the adversary will send extremely long messages.)

Let us now see what happens to message bounds if a protocol P calls a subprotocol Q. If Q has message-bound inputs, then P calls Q, specifying the values of these inputs, as for all other inputs of Q. If Q sets its own message bounds as part of its code at each round, then it is enough for P to call Q. In either case, throughout the execution of Q, Q's message bounds are to be enforced; only after the call is over and the execution of P is resumed will P's message bounds become effective again.

Complexity measures. We now wish to discuss the two notions of round complexity and local complexity. In so doing, we focus directly on the two cases that are really relevant to this paper; that is, *constant* round complexity and *polynomially bounded* local computation. We leave to the reader—if she so desires—the task of generalizing these notions in meaningful ways.

DEFINITION 9. *Let P be a protocol with fault tolerance ϕ. We say that P* runs in an expected constant number of rounds *if there exists a positive constant d such that for all numbers of players n, for all ϕ-adversaries A, and for all proper initial*

quantities IQ, the expected number of rounds for a random execution of $P(n)$ with $A(n)$ on IQ to halt is d.

In measuring the amount of local computation in an execution of a protocol P with an adversary A, we count only the steps taken by the currently good players. (The adversary attacking the protocol can, of course, compute as much as it wants, but its steps do not contribute to the local computation of the protocol.) Recall that we have defined protocols to be uniform programs. Thus before running a protocol P in an n-size network, the players must first run P on input n so as to compute the exact n-tuple of programs, $P(n)$, that they should execute. (Player i will, in fact, execute the ith component of $P(n)$.) We thus also count as P's local computation the steps necessary for the players of an n-size network to compute $P(n)$.

Following the current tradition, we identify efficiency with polynomial-time computation, and we insist that our polynomial-time bounds hold for any possible adversary attacking the protocol.

DEFINITION 10. *Let P be a protocol with fault tolerance ϕ. We say that P* runs in (expected) polynomial time *if there exists a polynomial Q such that the following hold:*

1. *For all sufficiently large n, the (expected) number of steps for protocol P to output $P(n) = (P_1, \ldots, P_n)$ on input n is less than $Q(n)$.*

2. *For all integers n, for all ϕ-adversaries A, and for all initial quantities IQ, if L is the sum of the lengths of the inputs of the players outside the initially bad set, the (expected) number of protocol steps for a random execution of $P(n)$ with A on IQ to halt is less than $Q(n + L)$.*

(*Here by "protocol step" we mean any step executed by P_g for any currently good player g.*) [13]

Notice that to establish the local complexity of a given protocol P, we regard as an input the size n of the network in which P is run. This is indeed necessary because we consider the steps used to compute $P(n)$ as local computation, but it is also reasonable with respect to the rest of P's local computation. Indeed, even for protocols that have no inputs (and thus $L = 0$, as in the case of our protocol OC of section 7), we expect that when they are "really" executed among n players, at least n messages will be sent, which entails that the local computation is at least $O(n)$.[14]

Notice also that although we have not demanded that a protocol set its message bounds to finite values for the purpose of defining its local complexity, the amount of local computation of a protocol P can be small—or just bounded, for that matter—only if P sets proper message bounds.

4. Presentation and organization. We have chosen to build our Byzantine agreement algorithm in a modular way. We first introduce graded broadcast, a simple primitive weakly simulating the capability of broadcasting. We then use this primitive to build another one: graded verifiable secret sharing. Both primitives are of independent interest. Next, we present a technical construction from graded verifiable secret

[13] Note that the notion of polynomial time is convenient in that we should not worry too much about fine tuning the balance between the effort of computing $P(n)$ and that necessary to run the protocol, nor should we worry about whether the polynomial Q should be evaluated on $n + L$ or—say—the maximum between n and L, or n times the maximum length of the inputs of the initially good players. These specific choices would instead be crucial for defining that a protocol runs in a—say—quadratic amount of time. Similarly, a round complexity that is constant (and thus independent of all possible quantities affecting the computation) is "more or less uncontroversially defined;" however, the same cannot be said if the round complexity of a protocol were—say—quadratic.

[14] In any case, in a Byzantine agreement protocol each player has a single-bit input, and thus $L = O(n)$ in a network of size n.

sharing to a special protocol for collectively generating a special coin flip, that is, a bit that is both sufficiently random and sufficiently often visible by all good players. Finally, we show that Byzantine agreement is reducible to this special coin-flipping protocol.

Let us now discuss the additional choices we have made in presenting our protocols.

Proofs. Everything important becomes easy with time, and we believe that this will be the fate of adversarial computation. However, at this stage of its development, it is so easy to make mistakes that we have chosen to expand our proofs more than is legitimate and bearable in a more familiar setting. (Proofs are, after all, social processes and ought only to be convincing to a given set of researchers at a given point in time.) We have, however, consistently broken our proofs up into shorter claims so as to enable the reader to skip what she personally considers obvious.

Steps. As usual, we conceptually organize the computation of our protocols into *steps*. The primary reason for grouping certain instructions in a step is clarity of exposition. As a result, one step may require many rounds to be implemented, while another may require only one round.

In this paper, we adopt the convention of treating each step as a *subprotocol* in itself; that is, executing a step composed of certain instructions means calling a protocol consisting of those instructions. In view of our mechanism for subprotocol calling, a consequence of our convention is that each step starts being executed at a "new" round; that is, a step requires at least one round to be implemented.

The advantage of this convention is that we gain a more immediate correspondence between steps and rounds. For instance, the number of rounds of a protocol simply becomes the sum of the number of rounds of its steps; for another example, in our proofs, it will be quite easy upon encountering the expression "round r" to realize which is its corresponding step.

A (superficial) disadvantage of our convention is that our protocols "seem longer" since one round may be artificially added for each step. In fact, whenever the last round of a given step consists solely of internal computations of the processors, it can be merged in any practical implementation with the first round of the following step. This is no great loss, however, since we are not interested in claiming $O(1)$ improvements in the running times of our protocols.

Random selections. As we have seen, by saying that a player i flips a coin, we mean that he reads the next unread bit of a string R_i. The use of the expression "flips a coin" is justified by the fact that we will be focusing on random executions of our protocols, in which case, since each bit of R_i is independently and uniformly selected, all coin tosses of i are "genuine" and independent. In describing our protocols, however, we make use of additional suggestive language. By saying that i "randomly selects element e in a set S of cardinality k," we mean that the elements of the set are put in one-to-one correspondence with the integer interval $[0, k-1]$ and that the player i keeps on reading $\lceil \log k \rceil$ consecutive unread bits from string R_i until the "name" of an element in S is found.[15] Thus when executing an instruction of the type "$\forall y \in T$ randomly select $e_y \in S$"—where both T and S are finite sets—all of the resulting selections will be *random* (since no portion of R_i is skipped) and *independent* (since

[15] Thus the possibility that an execution *diverges* exists here, though we do not "protect" ourselves against such an event for two reasons. First, handling divergence properly would have translated into much heavier definitions and notations without adding much to the specific content of this paper. Second, we focus on random executions, and the probability of divergence in a random execution is 0.

no overlapping portions of R_i are ever used). This notation holds for adversaries as well.

Hiding message bounds. Only one of our protocols, *Gradecast*, makes use of message-bound inputs; all others specify their message bounds at each round in their codes. To lighten these codes, however, we omit making the message bounds explicit at any round in which they can be simply computed. For instance, if round $r-1$ consists, for all players, of the instruction

> "if predicate $\mathcal{P}$ is true, then send your name to all players; else send them the empty word ε,"

then for any good player, the message bound for round r is $\lceil \log n \rceil$, the maximum length of a player's name (assuming that the name of a player i is encoded by the binary representation of integer i).[16]

Sending and receiving. When processor j is instructed to send a value v to the processor i, we let v^* denote the value actually received by i since it can be different from v in case j is bad. It may happen that such a value v^* must itself be sent to other processors. In this case, we may write v^{**} for $(v^*)^*$.

It is implicitly understood that whenever a message easily recognizable as not being of the proper form is sent to a good processor, this interprets it as ε, the empty string. Any predicate of ε is defined to evaluate to false.

For any string σ, we let *distribute* σ denote the instruction of sending σ to every processor.

For every *nonempty* string σ, the expression *tally*(σ), which occurs in round $r+1$ of the code for player i of a given protocol, denotes the number of players that sent σ to i in round r. If $\mathcal{P}$ is a predicate, the notation $\mathcal{P}$(*tally*(x)) is shorthand for "there exists a nonempty string x such that $\mathcal{P}$(*tally*(x))."

Self and others. Variables internal to processor i will sometimes carry the subscript i to facilitate the comparison of internal variables of different processors.

Whenever processor i should perform an instruction for all j, this includes $j = i$. For example, when i sends a message to all players, he also sends a message to himself. A distinguished processor follows the code for all players in addition to his special code.

Math. We are concerned only with integral intervals. Thus if x and y are integers, the expression $[x, y]$ stands for the set of integers $\{i \,:\, x \le i \le y\}$.

If S is a set, we let S^2 stand for the Cartesian product of S and itself and 2^S stand for the set of subsets of S.

All logarithms in this paper are in base 2 (but we still use the natural base e for other purposes).

Genders. We will refer to a player as a "he" and an adversary as a "she."[17]

Protocols. To describe a protocol P, we just describe $P(n)$, leaving it to the reader to check that this code can be uniformly generated on input n.

Comments. We interleave the code of our protocols with clearly labeled comments. Often, we label short comments by writing them within quotation marks. In fact, in our protocols, all words within quotation marks are comments, not instructions.

Numberings. Definitions and claims that appear within the proof of a lemma or theorem are not expected to have interest—or even "meaning"—outside of their local

[16] Of course, our "English" protocols can be implemented in polynomial time only if a proper encoding is used. For instance, if for sending the name of a player i we chose to send a string consisting of 2^i 1's, some of our English protocols would not have a polynomial-time implementation. However, any "reasonable" encoding would do.

[17] This gender assignment has been made at random. (Moreover, any additional motive is no longer valid.)

context. To emphasize this, while allowing cross-referencing within the same proof of, say, Theorem X or Lemma Y, claims are given "local" labels, that is, TX-1, TX-2, ..., LY-1, LY-2, ... General definitions, lemmas, and theorems, however, have "global" labels that consist of progressive numbers.

QEDs. We end each claim's proof with the symbol "■" so that, if you find a claim obvious, you can easily locate the next ■ and continue reading after it. For lemmas and theorems, a proof's end (whether or not the proof is easy) is marked by the symbol "□" (per standard SIAM journal style).

5. Graded broadcasting.

5.1. The notion of graded broadcast. Broadcasting is a very useful feature in a network since a processor receiving a message is guaranteed that all other processors are receiving the *same* message.[18] Byzantine agreement provides the best "simulation" of broadcasting when all communication is person-to-person: each time a processor should broadcast a message, it simply sends it to all other processors, which then reach Byzantine agreement on its value. On our way towards fast Byzantine agreement, though, we first need to introduce a new primitive, *graded broadcasting*; this is a weaker simulation of broadcasting, but despite its simplicity, it is quite useful.

DEFINITION 11. *Let P be a protocol in which every player's input comprises the identity of a common distinguished processor, the* sender*, and a common unary string, the* message bound*, while the sender has an additional input string, the* sender's message*, whose length does not exceed the message bound.*[19]

We say that P is a graded broadcast protocol (with fault tolerance c) *if, for all c-adversaries A and for all initial quantities IQ, in every execution of P with A on IQ, each good player i outputs a pair $(value_i, grade_i)$—where $value_i$ is a string at most k-bit long and $grade_i$ equals 0, 1, or 2—so that the following three properties are satisfied:*

1. *If i and j are good players and $grade_i \neq 0 \neq grade_j$, then $value_i = value_j$.*
2. *If i and j are good players, then $|grade_i - grade_j| \leq 1$.*
3. *If the sender is good, then for every good player i, $grade_i = 2$ and $value_i =$ the sender's message.*

Remark. A simpler but weaker simulation of broadcasting was provided by crusader agreement, as introduced in [13] and refined by Turpin and Coan [37]. Basically, sending a message using crusader agreement is like sending a message on a broadcast channel in which some messages may not get delivered: recipients of the message are guaranteed that all other recipients receive the same messages. However, recipients have no guarantee that any other player receives the message. The advantage of graded broadcast over crusader agreement is that when a good player sends a message using graded broadcast, each good player can verify that all other good players receive the same message.

[18] The power of broadcasting is well exemplified by the fact that it allows one to reach Byzantine agreement in a trivial way: each processor (1) broadcasts his input value (the default value being assumed for those processors who do not broadcast anything) then (2) outputs the majority value broadcast (with, say, default 0 in case of a tie).

[19] That is, specifying the initial quantities in extensive notation, an element of $\mathcal{IQ}_n^P$ is a triplet of the form

$$(H_A^0,\ \text{BAD}^0, \{(h,k):\ i \in \text{BAD}^0 \cup \{h\}\}\ \cup\ \{(h,k,\sigma) : h \notin \text{BAD}^0\}),$$

where $H_A^0 \in \{0,1\}^*$, $\text{BAD}^0 \in 2^{[1,n]}$, $h \in [1,n]$, $k \in 1^*$, and σ is a string whose length is less than k.

5.2. A graded broadcast protocol.

PROTOCOL *Gradecast*(n)
Input for every player i: h, the identity of the sender, and k, the message bound.
Additional input for sender h: σ, the sender's message.
1. (for sender h): Distribute σ.
2. (for every player i): Distribute σ^*.
3. (for every player i): If $tally(z) \geq 2n/3$, distribute z; otherwise, send no messages.
4. (for every player i):
4.1. If $tally(x) \geq 2n/3$, output $(x, 2)$ and halt. Else:
4.2. If $tally(x) \geq n/3$, output $(x, 1)$ and halt. Else:
4.3. Output $(\varepsilon, 0)$ and halt.

THEOREM 1. *Gradecast is a four-round, polynomial-time, graded broadcast protocol with fault tolerance* 1/3.

Proof. That protocol *Gradecast* is four-round and polynomial-time is obvious. Before proving the remaining properties, let us establish the following simple claim.

CLAIM T1-1. *In any execution of Gradecast with message bound k, no good player sends a message longer than k.*

Proof. A good player may send messages only at steps 1, 2, and 3. If he sends a message at step 1, then he is the dealer, and the only message he sends in this step is his input string σ, which is guaranteed to be no longer than k. As for steps 2 and 3, what a good player distributes is a message that he has received at the start of the same step; thus, due to the message-bound mechanism, such a message is at most k-bit long. ∎

Let us now show that *Gradecast* is a graded broadcast protocol with fault tolerance 1/3. First, consider property 1. Let i be a player that is good throughout the entire execution of the protocol, and assume that $grade_i > 0$. Then because of message bounding, there must exist a nonempty string X, whose length is at most k, such that i computes $tally(X) \geq n/3$ in step 4. Thus i must receive X from at least a good player g at the start of round 4. Because X is at most k bits long and because of Claim T1-1, this implies that g had actually distributed X in round 3. In turn, this implies that g had received X as the round-2 message from at least $2n/3$ players. Letting w ($w < n/3$) of these players be bad, because of Claim T1-1, at least $2n/3 - w$ good players had thus distributed X in round 2. Therefore, at most $n/3$ good players could have distributed any value other than X in round 2. Thus for any k-bit string Y, $Y \neq X$, at most $n/3$ good players and hence $< 2n/3$ players overall could have sent Y to a good player in round 2. Thus no good player may have distributed Y in round 3, nor—because of Claim T1-1—may a good player have distributed a string Y' longer than k whose k-bit prefix coincides with Y. Hence for all good players, $tally(Y) < n/3$ at round 4 (which, in particular, implies that $value_i$ is uniquely determined). Now let j be another player, good until the end of the protocol, whose output has a positive grade component. Since this implies that there exists a string Z, whose length is at most k, such that j has received Z from at least $n/3$ players in step 4, and since we have just proved that Z cannot be different from X, it must be that in step 4 $tally(X) \geq n/3$ also for player j; that is, also $value_j = X$, which proves property 1.

Property 2 follows from the fact that if a good player i sets $grade_i = 2$, then he has received a k-bit string X from at least $2n/3$ players in round 4. Therefore, by Claim T1-1, at least $n/3$ good players distributed X in step 3; thus all good players must have received X at the start of round 4 from at least $n/3$ players, and thus all good players must decide according to 4.1 or 4.2.

Property 3 is easily verified since if h is good, all good players receive and distribute σ in rounds 2 and 3. □

Remarks.

• Protocol *Gradecast* is still a graded broadcast protocol with fault tolerance 1/3 when it is run on a network whose communication lines are not private (i.e., if the adversary can monitor the messages exchanged by the good players).

• If all message bounds were dropped from *Gradecast*, the resulting protocol would still satisfy properties 1, 2, and 3 of graded broadcast but would no longer be polynomial-time.

Theorem 1 guarantees that certain relationships hold among internal variables of good processors whenever protocol *Gradecast* is executed with a 1/3-adversary. These variables, being internal, are not observable by the adversary. The following simple lemma, however, guarantees that the adversary can infer them from her history—actually, from just a portion of her history, something that will be useful much later in this paper.

LEMMA 1. *For any given adversary A, any execution of* Gradecast *with A is computable from A's initial history and coin tosses after round* 0 *if the sender is bad at the start of the protocol, and from A's initial history and coin tosses after round* 0 *and the sender's message otherwise.*

Proof. As for any determinist protocol, an execution of *Gradecast* with an adversary is solely determined by (1) the inputs of the initially good players and (2) the adversary's history and coin tosses after round 0. Now, for protocol *Gradecast*, quantity (1) coincides with the sender's message if the sender is initially good, and is empty otherwise. □

The use of protocol *Gradecast* in our paper is so extensive that it is worth establishing a convenient notation.

Notation. After an execution of *Gradecast* in which player i is the sender, we use the following terminology:

• If a player j outputs a pair $(v, 2)$, we say that j *accepts* i's gradecast of v, or accepts v from i. If we do not wish to emphasize the value v, we may simply say that j accepts i's gradecast.

• If j outputs (v, x), for $x \geq 1$, we say that j *hears* i's gradecast of v, or hears v from i. If we do not want to emphasize the value v, we simply say that j hears i's gradecast.

• If j outputs $(v, 0)$ for some value v, we say that j *rejects* i's gradecast.

In what follows, we shall make extensive use of *Gradecast* as a subprotocol. It will thus be convenient to specify a call to *Gradecast* at step z of an n-party protocol in a compact way. In particular, since message bounds are necessary only for guaranteeing the polynomiality of *Gradecast*, it will be convenient to keep them in the background as much as possible. For instance, if we are guaranteed that, when executing *Gradecast* at step z of a given protocol, the sender's message is a single bit, we avoid explicitly specifying that *Gradecast* is called with message bound $k = 1$. More generally:

• If, given the possible choices for string σ, k is the least upper bound to the length of σ, then

$$z\text{: (for player } i\text{): gradecast } \sigma$$

means that step z consists of executing *Gradecast*(n) with sender i, sender's message σ, and message bound k.

• If, given the possible choices for the strings σ_i, k is the least upper bound to

their length, then

$$z\text{: (for every player } i\text{): gradecast } \sigma_i$$

means that step z consists of executing *Gradecast* concurrently n times, one for each label $i \in [1, n]$, so that in execution i the sender is i, his message is σ_i, and the message bound is k.

• If, given the possible choices for the strings σ_x, k is the least upper bound to their length, then

$$z\text{: (for player } i\text{): } \forall x \in S\text{, gradecast } \sigma_x$$

means that step z consists of executing *Gradecast* concurrently, once for each label $x \in S$, so that in execution x, the sender is i, his message is σ_x, and the message bound is k.

• If, given the possible choices for the strings σ_{xi}, k is the least upper bound to their length, then

$$z\text{: (for every player } i\text{): } \forall x \in S\text{, gradecast } \sigma_{xi}$$

means that step z consists of executing *Gradecast* concurrently, once for each label xi, where $x \in S$ and $i \in [1, n]$, so that in execution xi, the sender is i, his message is σ_{xi}, and the message bound is k.

Any of the above calls can be made dependent on whether a given property $\mathcal{P}$ holds, with the understanding that *if $\mathcal{P}$ is not true, then the gradecast still takes place, but the sender's message is the empty string.* For instance, if, given the possible choices for the strings σ_x, k is the least upper bound to their length, then

$$z\text{: (for player } i\text{): if } \mathcal{P}\text{, } \forall x \in S\text{, gradecast } \sigma_x$$

means that step z consists of executing *Gradecast* concurrently, once for each label $x \in S$, so that in execution x, the sender is i, the message bound is k, and the sender's message is σ_x if $\mathcal{P}$ evaluates to TRUE (in general, on x and i's current history) and ε otherwise.

Therefore, step z always consists of four rounds. Indeed, though a bit wasteful, the above convention is convenient to keep our protocols and subprotocols fixed-round.[20]

6. Graded verifiable secret sharing. We now need to adapt the earlier and powerful notion of verifiable secret sharing, developed for a different communication model, to the present scenario.

6.1. Verifiable secret sharing and collective coin flipping. The somewhat paradoxical concept of *verifiable secret sharing* (VSS for short) was introduced by Chor et al. [9], who also provided its first cryptographic implementation (tolerating $O(\log n)$ faults). Informally, a VSS protocol consists of two stages. In the first stage, a *dealer* "secretly commits" to a value of its choice. In the second stage, this value is recovered. The value is *secret* at the end of stage 1 in the sense that no subset of players of suitably small size can guess it better than at random, even if they exchange all of the information in their possession thus far (which good players never do in the first stage). The value is *committed* in stage 1 in the sense that a good player can verify that there exists a unique (and unknown) value x such that whenever stage 2

[20] By adopting more complex mechanics for subprotocol calling, we may interpret the above (conditioned) steps differently, and occasionally save rounds and messages.

is performed, with or without the help of the dealer and *no matter what the current or future bad players might do,* all of the good players will recover x. Moreover, this unique but unknown x is the value originally chosen by the dealer.

Verifiable secret sharing has by now found very sophisticated applications, [21] but we will be interested in the simpler, original application of [9]: enabling a group of players, a minority of which may be faulty, to generate a common and random bit. Informally, VSS allows such players to "collectively flip a coin" as follows. Each player privately selects his own random bit and secretly commits to it in stage 1 of a VSS protocol. When all have done so, all of these committed bits are recovered in stage 2 of the corresponding VSS protocol and the common, random bit is set to be the sum modulo 2 of all the decommitted bits.

Since we have already mentioned that the problem of Byzantine agreement is reducible to that of generating a common random bit, the possibility exists of using VSS for reaching Byzantine agreement. Indeed, as we shall see, we will use a special version of VSS (graded VSS) and a much more special version of the above coin-flipping algorithm (oblivious common coin) so as to produce a bit that is "common enough" and "random enough" to reach Byzantine agreement in constant expected time. Why don't we use ordinary VSS to collectively flip a coin in the straightforward way? The reason is simple: we want to use collective coin flipping for reaching fast Byzantine agreement in our point-to-point communication networks, but all implementations of VSS prior to our work either made use of *broadcasting* (an unavailable primitive in our networks!) or Byzantine agreement (which for us is a goal and not a tool!).

6.2. The notion of graded verifiable secret sharing. We now introduce a weaker version of VSS that is more easily obtainable on our networks without broadcasting. We call it *graded verifiable secret sharing* (graded VSS for short). Informally, this is a sequenced protocol with two components: *Graded Share-Verify*, which roughly corresponds to stage 1 of a VSS protocol, and *Graded Recover*, which roughly corresponds to stage 2. To properly define graded VSS, we need the notion of a an event becoming "fixed" at some point of the execution of a protocol.

DEFINITION 12. *Let $\mathcal{X}$ be an event that may occur only after round r in an execution of a protocol P, and let E be an execution of P. We say that $\mathcal{X}$ is* fixed at round r in E *if $\mathcal{X}$ occurs in every execution E' coinciding with E up to round r.*

DEFINITION 13. *Let P be a sequenced protocol, P = (Graded Share-Verify, Graded Recover), in which*

- *all players have a common input consisting of the identity of a distinguished processor, the* dealer*, and (the encoding of) a set of integers, called the* candidate-secret set;
- *the dealer has an additional input, called the* secret*, consisting of an element of the candidate-secret set*; *and*
- *each processor x is instructed to output a value verification$_x \in \{0, 1, 2\}$ at the end of Graded Share-Verify and an element of the candidate-secret set at the end of Graded Recover (if this latter component is ever executed on the history of the first one).*

We say that P is a graded verifiable secret sharing protocol with fault tolerance *c if the following four properties hold:*

1. Semiunanimity. *For all initial quantities (IQ), for all c-adversaries A, and for all executions of Graded Share-Verify with A on IQ, if a good player i outputs*

[21] For instance, since [26], it has become the crucial subroutine of all subsequent completeness theorems for protocols with honest majority, most notably those in [2], [3], [10], [21], and [35].

verification$_i = 2$, *then verification*$_j > 0$ *for all good players* j.

2. Acceptance of good secrets. *For all IQ c-adversaries A and for all executions of Graded Share-Verify with A on IQ, if the dealer is always good, then verification*$_i = 2$ *for all good players* i.

3. Verifiability. *For all on IQ c-adversaries A and for all executions E of Graded Share-Verify with A on IQ, if verification*$_i > 0$ *for a good player* i, *then there exists a value* σ *in the candidate-secret set such that the event that all good players output* σ *when executing Graded Recover* (*on their histories in E*) *is fixed at the end of E. Moreover, if the dealer is always good in E,* σ = *the secret.*

4. Unpredictability. *For all c-adversaries A, for all players h, for all integer m, and for all cardinality-m set S, if*

- *s is randomly chosen in S,*
- *Graded Share-Verify is randomly executed with A, dealer h, candidate-secret set S, and secret s, and*
- *dealer h is good throughout this execution, and the adversary outputs a value* $a \in S$ *(as her "guess" for the secret) at its end,*

then $\text{Prob}(a = s) = 1/m$.

Here the probability is taken not only over the coin tosses of P and A but also over the choice of s. [22]

Remarks.

- Notice that simply saying—in the verifiability condition—"all good players output σ in *Graded Recover*" is not sufficient for our purposes. In fact, although the adversary cannot prevent the good players from outputting the same value, this formulation still allows her to decide what the value of σ should be while executing *Graded Recover*. (An example of this has been constructed by the second author.) Thus *Graded Share-Verify* would not model a secret commitment as discussed above. For this we need the value of σ to be *fixed* at the end of *Graded Share-Verify* (when σ coincides with the dealer's secret and is totally unpredictable to the adversary if the dealer is currently good).
- A definition of VSS can be obtained from the above definition of graded VSS by replacing throughout "*verification*$_i = 2$" by "*verification*$_i > 0$." (The definition of VSS obtained in this way is actually, in our opinion, the most general and satisfactory one in the literature to date.) Similarly, jumping ahead, from our protocol *Graded-VSS*, one can easily derive a verifiable secret sharing protocol with broadcasting by essentially replacing all gradecast instructions with broadcast instructions. (It is the transformation of a verifiable secret sharing protocol with broadcasting to a graded

[22] An equivalent formulation of Unpredictability that does not require that the secret be chosen at random in the candidate secret set can be informally described as follows.

Let $PS(A, h, H_A^0, H_{-\{h\}}^0, S, s)$ denote the probability space over the final histories of A obtained by first randomly executing *Graded Share-Verify* with adversary A, dealer h, initial adversarial history H_A^0, initial histories (in a suitable encoding, of all initially good players other than dealer h) $H_{-\{h\}}^0$, candidate-secret set S, and secret s and then outputting the final adversarial history if dealer h has not been corrupted. Then unpredictability can be reformulated as follows:

4′. For all c-adversaries A, $\forall h$, $\forall H_A^0$, $\forall H_{-\{h\}}$, $\forall S$, and $\forall s_1, s_2 \in S$,

$$PS(A, h, H_A^0, H_{-\{h\}}^0, S, s_1) = PS(A, h, H_A^0, H_{-\{h\}}^0, S, s_2).$$

(The reason for including the histories of all players except the dealer is that we want to maintain unpredictability even when *Graded Share-Verify* is called as a subprotocol. In which case, though the prior histories of the players do not affect the execution of *Graded Share-Verify*, they will appear—for the corrupted players—in the final history of A.)

Personally, we find the above formulation (after properly "cleaning it up") generally preferable, but the one in the main text is in a more convenient form for the purposes of this paper.

VSS protocol without broadcasting that proves to be trickier.)

• Let P be a graded verifiable secret sharing protocol with fault tolerance c, $P = (GSV, GR)$. Then if there are too few players (i.e., if $\lfloor n \cdot c \rfloor = 0$), even a single player (over than the dealer) may at the end of an execution of GSV possess sufficient information to predict with probability 1 the dealer's secret. However, this does not contradict Unpredictability. Indeed, this property demands that no *adversary* can predict a good dealer's secret better than at random, and whenever $\lfloor n \cdot c \rfloor = 0$, she cannot corrupt any player. (The reader who perceives this phenomenon as awkward may prefer to define graded verifiable secret sharing protocols only when there are sufficiently many players. Personally, we prefer to define protocols so that any number of players greater than 1 is admissible, and we find it awkward to make exceptions for c-fault-tolerant protocols.)

6.3. A graded verifiable secret sharing protocol. This subsection is devoted to constructing the first graded VSS protocol. The basis of our construction was provided by an ingenious VSS protocol developed by Ben-Or, Goldwasser, and Wigderson [3]. Their protocol runs in $O(n)$ rounds—when there may be $O(n)$ faults—in a special type of communication network: the *standard-plus-broadcast* network. This is a network in which not only each pair of users communicate via their own private line, but all processors also share a broadcast channel.[23] We have adapted their protocol to our needs in two phases:

1. First, we have improved their result by providing a VSS protocol for standard-plus-broadcast networks, *FastVSS*, that (1) runs in a constant number of rounds and (2) is conceptually simpler.[24] (Ben-Or, Goldwasser, and Wigderson have told us that they have independently found a constant-round version of their result, but it is more complicated than ours.)

2. Second, we have transformed *FastVSS* (a protocol for standard-plus-broadcast networks) into *GradedVSS*, a constant-round graded VSS rotocol for *standard* networks (i.e., without any broadcasting facilities).

For the sake of conciseness, since the focus of this paper is on standard networks, we forgo providing an explicit description of *FastVSS*. (Below we present just the basic intuition behind it since this can effectively be used for *GradedVSS* as well.) Indeed, in our protocol *GradedVSS*, we have merged the above two steps into a single one. (The reader can, however, easily reconstruct the code of *FastVSS* from that of *GradedVSS*.) We will, however, provide separate intuition for each of the above two phases.

Phase 1: *FastVSS.* In *FastVSS*, the dealer encodes his own secret in a special and redundant way. Namely, if the adversary can corrupt at most t players, the dealer selects a bivariate polynomial $f(x, y)$ of degree t in each variable such that $f(0, 0)$ equals his secret. He then privately gives to player i the polynomials $P_i(y) = f(i, y)$ and $Q_i(x) = f(x, i)$ as his shares of the secret, an x-share and a y-share. As we shall see, the shares of any $\leq t$ players do not betray the secret at all. On the other hand, as expressed by the following lemma, any $t + 1$ genuine x-shares determine the secret (and the same is true for the y-shares).

[23] Actually, they share a bit more powerful means of communication: each recipient of a message m traveling along this special shared channel is guaranteed not only that all processors receive the same string m that he does but also that all processors know who the sender of m is.

[24] The protocol of [3] made use of Reed–Solomon codes, while our *FastVSS* does not rely on any error-correcting codes—or at least it succeeds in hiding them away while remaining self-contained in a very simple manner.

Our choice of encoding for the dealer's secret does not guarantee verifiability per se. In fact, a good player cannot check whether his received x-share is genuine or—say—a random polynomial of degree t. It is here that the y-shares come into play. In fact, *FastVSS* performs several checks centered around the following simple property: if two players i and j both hold genuine shares, then it should be that $P_i(j) = Q_j(i)$.

Unpredictability is guaranteed since *FastVSS* is constructed so that, in every check, the information about the secret of a good dealer obtainable by the adversary can be computed from the shares in her possession—which we have already claimed to be insufficient to predict the dealer's secret.

Phase 2: *From VSS to graded VSS.* Our transformation of *FastVSS* into *GradedVSS* possesses a somewhat general flavor: it appears to provide a compiler-type algorithm that, on input any *known* VSS protocol for standard-plus-broadcast networks, outputs a graded VSS protocol running in a standard network, with the same fault tolerance of the input protocol and with essentially the same time and number of rounds.[25] This simple transformation is thus potentially useful: one may be able to turn more efficient VSS protocols developed in the future into more efficient graded VSS protocols.

Quite intuitively, the essence of our transformation consists of replacing the broadcast instructions of the input VSS protocol by gradecast instructions and then of properly branching on the grade produced by each gradecast. As the expression "properly" indicates, however, some care is needed in deciding how to branch. Though some degree of freedom is available, it is crucial to exploit the fact that grades are 3-*valued*. It should be noticed that after a gradecast instruction of *GradedVSS*, we sometimes branch based on whether the gradecast is accepted or not (i.e., on whether the resulting grade is 2 or less than 2) and other times based on whether the gradecast is heard or not (i.e., on whether the resulting grade is ≥ 1 or equal to 0). Now, although some of these "accepted-or-not" branchings could be replaced by "heard-or-not" branchings (and vice versa), it can be shown that adopting only a single type of branching does not work. Carrying VSS from standard-plus-broadcast networks to standard ones without losing too much meaning is indeed the very reason that we have introduced our 3-valued graded broadcasting primitive.

(If going from VSS protocols to graded VSS protocols requires a minimum of attention, the "reverse" transformation is instead quite straightforward. Protocol *FastVSS* is in fact immediately obtainable from protocol *GradedVSS*.)

Before presenting protocol *GradedVSS*, let us state and prove a variant of the classic Lagrange interpolation theorem.

LEMMA 2. *Let p be a prime, t be a nonnegative integer, $x_1, \ldots, x_{t+1}$ be distinct elements in Z_p, and $Q_1(y), \ldots, Q_{t+1}(y)$ be polynomials* mod p *of degree t. Then there exists a unique bivariate polynomial $F(x, y)$ of degree t (in each of the variables x and y) such that*

$$(*) \qquad F(x_i, y) = Q_i(y) \quad \textit{for } i = 1, \ldots, t+1.$$

Proof. Define (Lagrange interpolation)

$$F(x, y) = \sum_{i=1}^{t+1} Q_i(y) \frac{\prod_{j \neq i} (x - x_j)}{\prod_{j \neq i} (x_i - x_j)}.$$

[25] While our transformation works for all known VSS protocols, it is still conceivable that it cannot be applied to some future "bizarre" one.

Then $F(x, y)$ has degree t and satisfies $(*)$. We now argue that this polynomial is unique. Now assume that there exist two different t-degree bivariate polynomials $F_1(x, y)$ and $F_2(x, y)$ that satisfy $(*)$. We will prove that the polynomial

$$R(x, y) = F_1(x, y) - F_2(x, y) = \sum_{i,j} r_{ij} x^i y^j$$

is identically 0. For each $k = 1, \ldots, t + 1$, we have

$$\sum_{i,j=0}^{t} r_{ij} x_k^i y^i = R(x_k, y) \stackrel{\text{def.}}{=} F_1(x_k, y) - F_2(x_k, y) \stackrel{(*)}{=} Q_k(y) - Q_k(y) = 0.$$

That is, for each $k = 1, \ldots, t+1$, the polynomial in $y \sum_{j=0}^{t} (\sum_{i=0}^{t} r_{ij} x_k^i) y^j$ is identically 0. Thus for each fixed $\bar{j}$, $\sum_{i=0}^{t} r_{i\bar{j}} x_k^i = 0$ for $k = 1, \ldots, t + 1$, that is, the polynomial $\sum_{i=0}^{t} r_{i\bar{j}} x^i$ evaluates to 0 at the $t + 1$ points $x_1, \ldots, x_{t+1}$. This implies that $r_{i\bar{j}} = 0$ for all $i = 1, \ldots, t + 1$. Thus $R(x, y)$ is identically 0, which proves the uniqueness of $F(x, y)$. □

Notation for protocol GradedSV. In most of the scientific literature, the upper bound on the number of corruptable processors, denoted by t, is integral and explicitly given as an input to a fault-tolerant protocol. Having t as an input to each protocol would, however, be a bit cumbersome in our case: we have quite a few subprotocol calls and thus we would need to continuously specify the value of t for each call. Also, we are primarily interested in the highest possible value of t (i.e., $t = \lfloor (n - 1)/3 \rfloor$) and our protocols—with the singular exception of *GradedVSS*—do not become more efficient for smaller values of t. However, to allow the reader to appreciate how the efficiency of *GradedVSS* decreases with t, we set $t = \lfloor (n - 1)/3 \rfloor$ at its start (rather than making t an input to the protocol).

THEOREM 2. *GradedVSS is a graded verifiable secret sharing protocol with fault tolerance* 1/3 *that runs in expected polynomial time*; *GradedSV is a* 25*-round protocol, and GradedR is a two-round protocol.*

Proof. The claims about the number of rounds of *GradedSV* and *GradedR* are trivially verified. Equally simple to verify is the claim about the running time. (Recall that our choice of notation allows us to hide our message bounds.) The only difficulty that perhaps arises is about the computation of the prime p in step 1 of *GradedSV*(n). Actually, this prime can be found in deterministic polynomial time. In fact, for all sufficiently large k, there is a prime in the interval $[k, 2k]$. Thus, letting k be the maximum between n and m, we can in poly(k) time (and thus in time polynomial in n plus the total length of our inputs since $h < n$ and m is presented in unary) consider all integers in $[k, 2k]$ in increasing order until one is found that is proved prime by exaustive search of its divisors.

Let us now address the other claims.

Semiunanimity. If any good player G outputs $\mathit{verification}_G = 2$, he has received *recoverable* from at least $2t + 1$ players, of which at least $t + 1$ are good. Thus every other good player g has received *recoverable* from at least $t + 1$ players, so he outputs $\mathit{verification}_g \geq 1$.

Acceptance of good secrets. Let us first show that if the dealer is good (throughout *GradedSV*), then no good player gradecasts *badshare* in step 6. Since in this step a good player G can gradecast *badshare* only in three cases, let us show that none of them can occur.

Case 1. Assume that G has accepted the gradecast of *disagree*(j) from a player k in step 4. Then because of property 2 of any gradecast protocol, the dealer has heard

PROTOCOL *GradedSV*(n)

Input for every player i: h, the identity of the dealer, and m, a unary string encoding the candidate-secret interval $[0, m-1]$.

1. (for every player i): Compute p, the smallest prime greater than n and m, and set $t = \lfloor (n-1)/3 \rfloor$.
   Comment. All computations are done modulo p.
2. (for dealer h): Randomly select a t-degree bivariate polynomial $f(x, y)$ such that $f(0,0) = s$. "In other words, set $a_{00} = s$, for all $(i, j) \in [1, t]^2 - \{(0,0)\}$, randomly select a_{ij} in $[0, p-1]$, and set $f(x, y) = \sum_{i,j} a_{ij} x^i y^j$." For all i, privately send (P_i, Q_i) to player i, where $P_i = P_i(y) = f(i, y)$ and $Q_i = Q_i(x) = f(x, i)$.
   Comment. $f(0,0) = s$, your secret. $P_i(j) = Q_j(i)$ for all i and j.
3. (for every player i): For all j, if the dealer has not sent you a pair of t-degree polynomials mod p, send ε to player j; else, privately send j the value $Q_i^*(j)$.
4. (for every player i): For all j, if $P_i^*(j) \neq (Q_j^*(i))^*$, gradecast *disagree* (j).
   Comment. Either j or the dealer is bad or both are bad.
5. (for dealer h): For all $(i, j) \in [1, n]^2$, if you heard *disagree* (j) from player i in step 4, gradecast $(i, j, Q_j(i))$.
   Comment. i or j is bad or both are bad: what you reveal is already known to the adversary.
6. (for every player i): For all $(k, j) \in [1, n]^2$, if you accepted *disagree* (j) from player k in step 4 and
   - in the previous step you did not accept from the dealer exactly one value of the form (k, j, V), where $V \in [0, p-1]$; or
   - you accepted such a value and $k = i$, "i.e., you are player k," but $V \neq P_i^*(j)$; or
   - you accepted such a value and $j = i$, "i.e., you are player j," but $V \neq Q_i^*(k)$,

   gradecast *badshare*. "The dealer is bad."
7. (for dealer h): For all i, if you heard *badshare* from player i in step 6, gradecast $(i, P_i(y), Q_i(x))$.
   Comment. i is bad: what you reveal is already known to the adversary.
8. (for every player i): If
   (a) you gradecasted *badshare* in step 6; or
   (b) you accepted *badshare* from more than t players in step 6; or
   (c) for each player j whose gradecast of *badshare* in step 6 you have accepted, a step ago you did not accept from the dealer the gradecast of a value (j, U, V), where U and V are t-degree polynomials, or you accepted such a value but $Q_i^*(j) \neq U(i)$ or $P_i^*(j) \neq V(i)$,

   distribute *badshare*. "The dealer is bad."
9. (for each player i): If $tally(badshare) \leq t$, distribute *recoverable*.
10. (for each player i):
    If $tally(recoverable) > 2t$, output $verification_i = 2$.
    Comment. The secret is recoverable and all good players know it.
    Else: If $tally(recoverable) > t$, output $verification_i = 1$.
    Comment. You know that the secret is recoverable, but other good players may not know it.
    Else: Output $verification_i = 0$.
    Comment. The secret may or may not be recoverable.

PROTOCOL *GradedR*(n)

1. (for every player i): Distribute P_i^* and Q_i^*.
2. (for every player i):
   For each player j, set $P_j^i(y) = P_j^{**}$ and $Q_j^i(y) = Q_j^{**}$. If you have accepted *badshare* from j in step 6 of *GradedSV* and you have heard $(j, U(y), V(x))$ from the dealer in step 7, reset $P_j^i(y) = U(y)$ and $Q_j^i(x) = V(x)$.
   Comment. $P_j^i(y)$ and $Q_j^i(x)$ are your own view of player j's *final* shares.
   Let $count_i(j)$ consist of the number of players k for which $P_j^i(k) = Q_k^i(j)$.
   Comment. If a good player has output *verification* > 0 in *GradedSV*, all good players are given *count* $> 2t + 1$. However, a bad player may be given *count* $> 2t + 1$ by some good player and a low count by another good player.
   If possible, select a set of $t + 1$ players k such that $count_i(k) \geq 2t + 1$. Let $k_1, \ldots, k_{t+1}$ be the members of this set.
   Comment. If a good player has output *verification* > 0 in *GradedSV*, there will be such a set. In this case, although different good players may select different sets and some of these sets may contain bad players, each set determines the same bivariate polynomial
   Compute the unique bivariate polynomial $\mathcal{P}(x, y)$ such that $\mathcal{P}(k_j, y) = P_{k_j}^i(y)$ $j \in [1, t + 1]$ and output $\mathcal{P}(0, 0)$ mod m as the dealer's secret.

k's gradecast and has thus responded in step 5 by gradecasting $(k, j, Q_j(k))$. Since the dealer's gradecast is proper, it is necessarily accepted by G.

Case 2. If G gradecasts *disagree*(j) in step 4, the dealer accepts this proper gradecast and thus properly responds by gradecasting $(G, j, Q_j(G))$, and $Q_j(G)$ coincides with G's x-share, $P_G^*(y)$, evaluated at point j since for a good dealer $P_G^*(j) = P_G(j) = f(G, j) = Q_j(G)$.

Case 3. If G has accepted *disagree*(G) from k in step 4, the dealer has at least heard this value and has thus responded by properly gradecasting $(k, G, Q_G(k))$. This value is thus accepted by G; moreover, since the dealer is good, $Q_G^*(x) = Q_G(x)$ and thus $Q_G^*(k) = Q_G(k)$. Thus if the dealer is good, in no case does a good player G gradecast *badshare* in step 6. This implies that no good player can distribute *badshare* in step 8 according to conditions 8(a) or 8(b). Moreover, as long as the dealer continues to be good in step 7, a good player G cannot distribute *badshare* because of 8(c) as well. In fact, if G has accepted *badshare* from j in step 6, the dealer has at least heard this value and responded by properly gradecasting the polynomials $P_j(y)$ and $Q_j(x)$; since G accepts all proper gradecasts, and because when the dealer is good $P_j^*(i) = P_j(i) = Q_i(j) = Q_i^*(j)$ for all i and j, all of G's checks in steps 8 will be passed. We conclude that if the dealer is good in *GradedSV*, only the bad players may distribute *badshare* in step 8. Thus, since they are at most t in number, all good players G will distribute *recoverable* in Step 9 and output $verification_G = 2$ in step 10.

Verifiability. Let $\mathcal{S}$ be an execution of *GradedSV* in which at most $t < n/3$ players are corrupted and a good player outputs *verification* > 0, and let $\mathcal{R}$ be an execution of *GradedR* on the histories of $\mathcal{S}$. We need to show that (1) there exists a value $\sigma_{\mathcal{S}}$ such that the event that all good players output $\sigma_{\mathcal{S}}$ in $\mathcal{R}$ is fixed at the end of $\mathcal{S}$ and (2) $\sigma_{\mathcal{S}}$ coincides with the dealer's secret if he is always good in $\mathcal{S}$.

To this end, let us establish a convenient notation and a sequence of simple claims relative to $\mathcal{S}$ and $\mathcal{R}$. Recall that, since (*GradedVSS, GradedR*) is a sequenced protocol,

any player good in $\mathcal{R}$ (actually, in $\mathcal{R}$'s first round) is always good in $\mathcal{S}$.

LOCAL DEFINITION. *In an execution of GradedVSS, a player is said to be* satisfied *if he is good throughout the execution and does not distribute badshare in step* 8.

CLAIM T2-0. *In $\mathcal{S}$, there is a set of $t+1$ satisfied players.*

Proof. The proof is by contradiction. Were our claim false, then since there are at least $2t+1$ good players in $\mathcal{S}$, at least $t+1$ of them would have distributed *badshare* in step 8. Thus no good player would have distributed *recoverable* in step 9, and no good player would have output *verification*> 0 in step 10. ■

Due to condition 8(a), we also know that a satisfied player does not gradecast *badshare* in step 6 either; thus for all satisfied players i and j, $P_i^*(j) = Q_j^*(i)$. In view of Claim T2-0 and Lemma 2, we can thus present the following (local) definition.

LOCAL DEFINITION. *In execution $\mathcal{S}$, we let $\mathcal{G}_\mathcal{S}$ denote the lexicographically first set of $t+1$ satisfied players,*[26] *and we let $\mathcal{F}_\mathcal{S}$ denote the unique, bivariate, t-degree polynomial associated with $\mathcal{G}_\mathcal{S}$ by Lemma* 2; *that is, $\mathcal{F}(i,y) = P_i^*(y)\ \forall i \in \mathcal{G}_\mathcal{S}$.*

CLAIM T2-1. *$\forall i \in \mathcal{G}_\mathcal{S}$, $P_i^*(y) = \mathcal{F}_\mathcal{S}(i,y)$ and $Q_i^*(x) = \mathcal{F}_\mathcal{S}(x,i)$.*

Proof. Clearly, $P_i^*(y) = \mathcal{F}_\mathcal{S}(i,y)\ \forall i \in \mathcal{G}_\mathcal{S}$ by construction. We now prove the second set of equalities. Let $i \in \mathcal{G}_\mathcal{S}$; since we are dealing with polynomials of degree t, it is enough to prove that $\mathcal{F}_\mathcal{S}(x,i)$ equals $Q_i^*(x)$ at $t+1$ points. Indeed, for all $j \in \mathcal{G}_\mathcal{S}$, we have

$$\mathcal{F}_\mathcal{S}(j,i) \overset{\text{by construction}}{=} P_j^*(i) = Q_i^*(j),$$

where the last equality has been checked to hold by satisfied player j in step 4 since good player i sent him $Q_i^*(j)$ in step 3. ■

CLAIM T2-2. *Let G and i be good in $\mathcal{R}$, and let i also be satisfied in $\mathcal{S}$. Then $P_i^* = P_i^G$ and $Q_i^* = Q_i^G$.*

Proof. Informally, we must show that G's own view of i's final shares coincides with that of i himself. Being good in $\mathcal{R}$, i sends P_i^* and Q_i^* to G in step 1 of $\mathcal{R}$. Thus G sets $P_i^G = P_i^*$ and $Q_i^G = Q_i^*$ at the beginning of step 2 of $\mathcal{R}$. Finally, G does not reset these variables in the remainder of step 2. Indeed, he may reset these variables only under certain conditions, which include having accepted *badshare* from i in step 6 of *GradedSV*; however, no satisfied player gradecasts *badshare* in step 6. ■

CLAIM T2-3. *Let G and g be good in $\mathcal{R}$. Then $P_g^G(y) = \mathcal{F}_\mathcal{S}(g,y)$ and $Q_g^G(x) = \mathcal{F}_\mathcal{S}(x,g)$.*

Proof. We prove only the first equality since the second one is proved similarly. To this end, it is enough to show that $\mathcal{F}_\mathcal{S}(g,y)$ and $P_g^G(y)$ agree on every $i \in \mathcal{G}_\mathcal{S}$. Indeed, by Claim T2-3, we have

$$\forall i \in \mathcal{G}_\mathcal{S}, \quad \mathcal{F}_\mathcal{S}(g,i) = Q_i^*(g).$$

We now prove that

$$\forall i \in \mathcal{G}_\mathcal{S}, \quad Q_i^*(g) = P_g^G(i).$$

We break the proof of the above statement into two cases:

(a) G does not reset $P_g^G(y)$ (i.e., $P_g^G(y)$ coincides with the polynomial in y that g sent to G in step 1 of $\mathcal{R}$);

(b) G resets $P_g^G(y)$ (i.e., $P_g^G(y)$ is the polynomial in y gradecasted by the dealer in step 7 of $\mathcal{S}$).

[26] Any uniquely specified set of $t+1$ satisfied players in $\mathcal{S}$ would do.

Case (a). In this case, $P_g^G(y) = P_g^*(y)$. We must now argue that if $i \in \mathcal{G}_\mathcal{S}$, then $Q_i^*(g) = P_g^*(i)$. To begin with, notice that since i privately sent value $Q_i^*(g)$ to g in step 3 of $\mathcal{S}$, player g could compare these two values. We now show that $P_g^*(i) \neq Q_i^*(g)$ leads to a contradiction. In fact, if the latter inequality holds, g gradecasts *disagree*(i) in step 4 of $\mathcal{S}$. Since i accepts this gradecast, to remain satisfied he must accept $(g, i, Q_i^*(g))$ from the dealer in step 5 of $\mathcal{S}$. This causes player g to gradecast *badshare* in step 6 of $\mathcal{S}$—either because he does not accept the dealer's answer or because he accepts exactly the same answer that i does by property 1 of gradecast and thus we still have $Q_i^*(g) \neq P_g^*(i)$. Since i must accept g's gradecast of *badshare*, to keep him satisfied, the dealer must reply by gradecasting g's x-share and y-share in step 7 of $\mathcal{S}$ in order to have these values accepted by i. Thus these shares are at least heard by G, who thus resets P_g^G and Q_g^G. This contradicts the assumption that we are in Case (a).

Case (b). In this case, G must have first accepted the gradecast of *badshare* from g in step 6. Since g is good, this gradecast must have been accepted by good player i as well. Since i is satisfied, he must also have accepted the value replied by the dealer, $(g, U(y), V(x))$. By property 1 of gradecast, U and V are the same values heard by G and are thus G's own view of g's final shares; that is, $U(y) = P_g^G(y)$ and $V(x) = Q_g^G(x)$. The reason that now $Q_i^*(g) = P_g^G(i)$ is that i satisfactorily checked in step 8 that $Q_i^*(g) = U(i)$. ∎

Claim T2-4. *For all G good in $\mathcal{R}$ and for all k, $count_G(k) \geq 2t+1 \Rightarrow P_k^G(y) = \mathcal{F}_\mathcal{S}(k, y)$.*

Proof. Since $P_k^G(y)$ and $\mathcal{F}_\mathcal{S}(k, y)$ are t-degree univariate polynomials, it is sufficient to show that they agree on $t+1$ points. Indeed, if $count_G(k) \geq 2t+1$ and the bad players are at most t, there must exist $t+1$ good players g such that

$$P_k^G(g) \overset{\text{def. of } count_G}{=} Q_g^G(k) \overset{\text{Claim T2-3}}{=} \mathcal{F}_\mathcal{S}(k, g). \qquad \blacksquare$$

We are now ready to prove that in step 2 of $\mathcal{R}$, every good player G computes the bivariate polynomial $\mathcal{F}_\mathcal{S}$ and thus outputs $\mathcal{F}_\mathcal{S}(0,0) \bmod m$. To this end, first notice that there will be at least $t+1$ players k such that $count_G(k) \geq 2t+1$. In fact, for all good players g_1 and g_2, we have

$$P_{g_1}^G(g_2) \overset{\text{Claim T2-3}}{=} \mathcal{F}_\mathcal{S}(g_1, g_2) \overset{\text{Claim T2-3}}{=} Q_{g_2}^G(g_1).$$

Thus $count_G(g_1)$ will be at least $2t+1$, that is, at least the number of good players g_2; since there are at least $2t+1$ such players g_1, it will be possible for G to select $t+1$ players for which $count_G \geq 2t+1$. Let $k_1, \ldots, k_{t+1}$ be the ones he actually selects—some of them possibly bad. Then G outputs the polynomial $\mathcal{P}(x, y)$ such that

$$\forall l \in [1, \ldots, t+1], \quad \mathcal{P}(k_l, y) = P_{k_l}^G(y) \overset{\text{Claim T2-4}}{=} \mathcal{F}_\mathcal{S}(k_l, y).$$

Thus by Lemma 2, $\mathcal{P}$ and $\mathcal{F}_\mathcal{S}$ must be equal, and all good players output $\mathcal{F}_\mathcal{S}(0,0) \bmod m$ at the end of $\mathcal{R}$. Because $\mathcal{R}$ was just any execution of *GradedR* on the histories of $\mathcal{S}$, because $\mathcal{F}_\mathcal{S}$ is determined by execution $\mathcal{S}$, and because $\mathcal{F}_\mathcal{S}(0,0) \bmod m$ is guaranteed to belong to the candidate-secret interval $[0, m-1]$, this shows that the event that all good players in an execution of *GradedR* on the histories of $\mathcal{S}$ output $\sigma_\mathcal{S} = \mathcal{F}_\mathcal{S}(0,0) \bmod m$ is fixed at the end of $\mathcal{S}$.

Let us now show that if the dealer is good throughout $\mathcal{S}$, $\mathcal{F}_\mathcal{S}$ actually coincides with the polynomial $f(x, y)$ originally selected by the dealer in step 2 of $\mathcal{S}$. By

Lemma 2, it is enough to prove that there are $t+1$ distinct values v such that $\mathcal{F}_{\mathcal{S}}(v,y) = f(v,y)$. This is our case. In fact, letting G be a fixed good player, for any good player g, we have

$$\mathcal{F}_{\mathcal{S}}(g,y) \overset{\text{Claim T2-3}}{=} P_g^G(y) \overset{\text{Claim T2-2}}{=} P_g^*(y) \overset{\text{good dealer}}{=} P_g(y) \overset{\text{by def.}}{=} f(g,y).$$

Because a good dealer chooses $f(x,y)$ so that $f(0,0)$ coincides with his secret, which belongs to the candidate-secret interval $[0, m-1]$, whenever the dealer is good, the value output by the good players in $\mathcal{R}$, $\sigma_{\mathcal{S}} = \mathcal{F}_{\mathcal{S}}(0,0) \bmod m$, fixed at the end of $\mathcal{S}$, coincides with the dealer's secret.

Because $\mathcal{S}$ was just any execution of *GradedSV* in which $\mathit{verification}_i > 0$ for some good player i, this completes the proof that Verifiability holds for *GradedVSS*.

Unpredictability. An appealing, rigorous, and general proof of Unpredictability is obtainable utilizing the notion of "secure (or zero-knowledge) computation" [30]. As we have remarked, however, such a notion has not yet been published, and it is too difficult to be quickly summarized here. Therefore, we shall use an ad hoc and "quick-and-dirty" argument.

Our proof consists of showing that, in an execution of *GradedSV* in which the dealer is never corrupted, there exists a special piece of information (a string), independent of the secret, from which the adversary's history can be deterministically computed. Because the adversary cannot but predict the secret on the basis of her history (and of her coin tosses, which are clearly independent of the secret), this proves that the adversary cannot predict the secret better than at random.

The existence of such a special piece of information follows in part from the general mechanics of (any) protocol execution, and in part from the specific characteristics of our *GradedSV* protocol. We find it useful to present separately the following two parts of our argument: we present the first part in claims T2-5 and T2-6 and the second part in claim T2-8. Let us first establish some convenient notation.

Local definitions. Let P be a protocol, A be an adversary, E be an execution of P with A, and r be a round in E. Then:

- we say that a player is *eventually bad* in E if he is corrupted at some point of it and *always good* otherwise.
- we denote by $M_r^{AG \to EB}$ the set of messages (labeled with their senders and receivers) sent by the always good players to the eventually bad ones in round r.
- We refer to the quantities
  1. BAD^r
  2. the round-r history of A,
  3. the round-r histories of the eventually bad players,
  4. the coin tosses of A after round r, and
  5. the coin tosses of the eventually bad players after round r

  as the *final quantities of round r*. (Thus, the final quantities of round 0 include A's initial history.) If x is a step of P and r is x's last round, we refer to round r's final quantities as *the final quantities of step x*.

Claim T2-5. Given a protocol P and an adversary A in an execution of P with A, the final quantities of a round r ($r > 0$) are computable from the final quantities of round $r-1$ and $M_r^{AG \to EB}$.

Proof. The proof consists of recalling Definition 4 (i.e., how a protocol is executed with an adversary) and verifying that one can execute instructions 0–4 of Definition 4 to the extent necessary to compute the desired final quantities.

(In essence, A's history and coin tosses after each point of the execution of round r are computable given A's history and coin tosses after round $r-1$ (available by hypothesis), the history of each newly corrupted processor at the end of round $r-1$ (also available by hypothesis), and the message that each currently good processor g wishes to send to each currently bad processor b in round r. Now, if g is always good, such a message is among the available inputs, and if g is eventually bad, it can be computed by running P_g on g's history and g's future coin tosses at the end of round $r-1$, both of which belong to the available inputs. The history and coin tosses of each eventually bad player i after round r can be computed from the corresponding and available quantities after round $r-1$ by running P_i.) ■

Repeated application of Claim T2-5 immediately yields the following claim.

CLAIM T2-6. Given a protocol P and an adversary A, in an execution of P with A, A's final history is computable from the final quantities of round 0 and $\{M_r^{AG\to EB} : r = 1, 2, \ldots\}$.

Properties stronger than those of Claim T2-6 hold for our *Gradecast* and *GradedSV* protocols. Indeed, Lemma 1 implies that the final quantities of round 0 and only $M_0^{AG\to EB}$ suffice for reconstructing an entire execution of *Gradecast*. (Notice that in fact, in an execution of *Gradecast*, $M_0^{AG\to EB}$ coincides with the sender's message whenever the sender is always good.) As we show below for protocol *GradedSV*, the final quantities of round 0 and $M_1^{AG\to EB}$ suffice for reconstructing the final history of the adversary. (Notice that in an execution of *GradedSV*, $M_1^{AG\to EB}$ coincides with the x- and y-shares of the eventually bad players whenever the dealer is always good.)

CLAIM T2-7. *Given an adversary A, in an execution of* GradedSV *with A in which the dealer is good, A's final history is computable from the final quantities of round 0 and the x- and y-shares of the eventually bad players.*

Proof. Let us show how we compute (one by one) the final quantities of each step of *GradedSV* from the quantities available by hypothesis. For the reader's convenience, we recall (emphasizing it and omitting our comments) each step of *GradedSV*.

1. *(For every player i): Compute p, the smallest prime greater than n and m, and set $t = \lfloor (n-1)/3 \rfloor$.*

This step consists of a single round in which no good player sends any message (i.e., denoting by r the single round of this step, $M_r^{AG\to EB}$ is empty). Thus, as per Claim T2-5, we compute the final quantities of step 1 from the final quantities of round 0 alone.

2. *(For dealer h): Randomly select a degree-t bivariate polynomial $f(x, y)$ such that $f(0, 0) = s$. For all i, privately send (P_i, Q_i) to player i, where $P_i = P_i(y) = f(i, y)$ and $Q_i = Q_i(x) = f(x, i)$.*

This step consists of a single round. Denoting it by r, $M_r^{AG\to EB}$ coincides with the x- and y-shares of the eventually bad players (which are available by hypothesis). Thus, as per Claim T2-5, we can compute the final quantities of step 2 from the final quantities of step 1 and $M_r^{AG\to EB}$.

3. *(For every player i): For all j, if the dealer has not sent you a pair of t-degree polynomials mod p, send ε to player j; else, privately send j the value $Q_i^*(j)$.*

This step also consists of a single round. Denote it by r, and let i be an always good player and j be an eventually bad one. Because the dealer is good, the message sent by i to j is not ε but $Q_i^*(j) = Q_i(j)$. Although we do not know Q_i, we compute $Q_i^*(j)$ by evaluating polynomial P_j (which is available as the x-share of player j) at point i. Doing so for each always good player and each eventually bad one, we compute the entire $M_r^{AG\to EB}$. We compute the final quantities of step 3 from $M_r^{AG\to EB}$ and the final quantities of step 2, as per Claim T2-5.

4. *(For every player i): For all j, if $P_i^*(j) \neq (Q_j^*(i))^*$, gradecast* disagree(j).

Step 4 consists of four rounds in which n^2 simultaneous executions of *Gradecast*, properly labeled, take place.[27] Let us now show that for each execution of *Gradecast* in which the sender is (currently) good, we readily compute the sender's message. Let ij be the label of such an execution (and thus i its good sender). There are two mutually exclusive cases to consider: (a) j is a currently bad player and (b) j is currently good. In case (a) the message $(Q_j^*(i))^*$ sent by j to i in step 3 is contained in A's history of the previous round, and thus in the computed final quantities of step 3. In addition, because both the dealer and i are good, we know that $P_i^*(j) = P_i(j) = Q_j(i)$. Thus we compute $Q_j(i)$ by evaluating polynomial Q_j (which is available as the y-share of eventually bad player j) on input i. Consequently, we compute whether i's message in this execution of *Gradecast* is *disagree (j)*. In case (b) we know a priori that j has sent the proper quantity to i, and thus i will not gradecast *disagree (j)*. In either case, therefore, whenever the sender is good we compute the sender's message. Consequently, as per Lemma 1, we compute all executions of *gradecast* of step 4.

5. *(For dealer h): For all $(i, j) \in [1, n]^2$, if you heard* disagree (j) *from player i in step* 4*, gradecast* $(i, j, Q_j(i))$.

Because we have computed all executions of *Gradecast* of step 4, in particular we have computed, for each label (i, j), whether the dealer has heard *disagree (j)* from player i in execution (i, j). That is, we have computed whether execution (i, j) of *Gradecast* occurs. Moreover, whenever this is the case we can also compute the sender's message of execution (i, j). (The proof of this fact is similar to the corresponding fact of step 4; namely, if both i and j are good, then we know that no execution of *Gradecast* labeled ij occurs. Else, if i is good and j is bad, we compute the sender's message, $(i, j, Q_j(i))$, by evaluating polynomial Q_j—available as the y-share of bad player j—on input i.) Thus, as per Lemma 1, from these sender's messages and from the final quantities of step 4, we compute the final quantities of step 5 as well as the grades and values output by the good players in step 5.

6. *(For every player i): For all $(k, j) \in [1, n]^2$, if you accepted disagree* (j) *from player k in Step* 4 *and*
   - *in the previous step you did not accept from the dealer exactly one value of the form (k, j, V), where $V \in [0, p-1]$; or*
   - *you accepted such a value and $k = i$ but $V \neq P_i^*(j)$; or*
   - *you accepted such a value and $j = i$ but $V \neq Q_i^*(k)$,*

   gradecast badshare.

Because we have reconstructed the grades and values output by the good players in steps 4 and 5, we easily determine whether a good player gradecasts *badshare* in step 6. Thus, as per Lemma 1 and per the computed final quantities of step 5, we readily compute the final quantities of step 6 as well as all grades and values output in it by the currently good players.

7. *(For dealer h): For all i, if you heard* badshare *from player i in step* 6*, gradecast* $(i, P_i(y), Q_i(x))$.

Given the final quantities of step 6 and the grades and values output by the good players in step 6, we compute per Lemma 1 the final quantities of step 7 as well as the grades and values output by the good players of step 7.

8. *(For every player i): If*
   (a) *you gradecasted* badshare *in step* 6; *or*
   (b) *you accepted* badshare *from more than t players in step* 6; *or*

[27] Recall the notation established at the end of section 6.

(c) *for each player j whose gradecast of* badshare *in step* 6 *you have accepted, if a step ago you did not accept from the dealer the gradecast of a value (j, U, V)—where U and V are t-degree polynomials—or, if you accepted such a value but $Q_i^*(j) \neq U(i)$ or $P_i^*(j) \neq V(i)$,*

distribute badshare.

This step consists of a single round which we now denote by r. We then compute $M_r^{AG \to EB}$ by computing which good players distribute *badshare*. This determination is easily made from the computed senders' messages, grades, and outputs of step 6 and from the following three facts: (a) If both i and j are good, then i does not distribute *badshare*; (b) because the dealer is good, $Q_i^*(j) = Q_i(j)$ and $P_i^*(j) = P_i(j)$; and (c) if i is good and j is bad, then both $Q_i(j)$ and $P_i(j)$ are computable from the available x- and y-shares of bad player j. Thus, as per Claim T2-5 and per the final quantities of step 7, we compute the final quantities of step 8.

9. *(For each player i): If tally(badshare) $\leq t$ distribute* recoverable.

Note that we have just computed in step 8 which good players distribute *badshare*. Moreover, whether or not in that step a bad player sends *badshare* to a good player appears in A's history of step 8 (computed as part of the final quantities of step 8). Therefore, we compute *tally(badshare)* for each currently good player and thus determine which currently good players wish to distribute *recoverable* in step 9. Thus, as per Claim T2-5 and the final quantities of step 8, we compute the final quantities of step 9.

10. *(For each player i):*
If tally(recoverable) $> 2t$, output verification$_i = 2$.
Else, if tally(recoverable) $> t$, output verification$_i = 1$.
Else, Output verification$_i = 0$.

Since in this last step no good player sends any message, given just the final quantities of step 9, we compute, as per Claim T2-5, the final quantities of step 10.

Because the final history of the adversary is part of the final quantities of step 10, we have established our claim. ■

We can now easily finish the proof of Unpredictability. In Claim T2-6 we saw that A's final history in *GradedSV* depends solely on (1) the final quantities of round 0 and (2) the x- and y-shares of the eventually bad players. Now, in a random execution of *GradedSV* in which the dealer is always good and the secret s is randomly selected in $[0, m-1]$, the value of the secret is clearly independent of quantities (1). Thus, to prove that no strategy exists for the adversary to guess this secret with probability greater than $1/m$, it is sufficient to show that the dealer's secret is also independent of the x- and y-shares of the $t' \leq t < n/3$ players corrupted by A. Since we can modify any adversary so that she corrupts an additional $t - t'$ players just prior to finishing her last round of *GradedSV*, we can actually limit ourselves to prove our claim for the case $t' = t$. (In fact, if the adversary is such that the x- and y-shares of the first t' corrupted players are not independent of the dealer's secret, then by adding the shares of $t - t'$ other players we cannot obtain shares that are independent of the secret.) Thus, we now want to prove that for any choice of t eventually bad players, $b_1, \ldots, b_t$, any choice of $2t$ t-degree polynomials $P_{b_1}(y), Q_{b_1}(x), \ldots, P_{b_t}(y), Q_{b_t}(x)$, and any choice of secret s in $[0, m-1]$, there exists a unique bivariate polynomial $F(x, y)$ such that

(A) $F(b_i, y) = P_{b_i}(y) \ \ \forall i \in [1, t]$,
(B) $F(x, b_i) = Q_{b_i}(x) \ \ \forall i \in [1, t]$, and
(C) $F(0, 0) = s$.

We first show F's existence. Set $b_0 = 0$ and let $P_{b_0}(y)$ be the univariate, t-degree polynomial passing through the $t+1$ points $(0, s)$ and $(b_i, Q_{b_i}(0))$, $i \in [1, t]$. Then, by Lemma 2, there exists a unique bivariate polynomial F satisfying $F(b_i, y) = P_{b_i}(y)$ $\forall i \in [0, t]$. We now show that F enjoys three of the above required properties:

(A) By construction.

(B) Fix $a \in [1, t]$. We prove that $F(x, b_a) = Q_{b_a}(x)$ by showing that these two t-degree polynomials are equal at $t+1$ points. In fact, by construction we have $\forall j \in [1, \ldots, t]$ $F(b_j, b_a) = P_{b_j}(b_a) = Q_{b_a}(b_j)$, and $F(0, b_a) = P_0(b_a) = Q_{b_a}(0)$.

(C) By construction, $F(0, 0) = P_0(0) = s$.

The uniqueness of F is thus a consequence of the uniqueness of $P_0(y)$. This proves that "unpredictability" holds for *GradedSV* and thus completes the proof of Theorem 2. ∎

Remark. We have chosen the VSS protocol of [3] as the basis of our *GradedSV* protocol because it relied solely on private and broadcast channels but not on cryptography. (Several beautiful cryptographic VSS protocols are available, but our transformation would have yielded a cryptographic graded VSS protocol, and thus a Byzantine agreement algorithm tolerating only computationally bounded adversaries.) Another ingenious VSS protocol for standard networks that, *in addition*, possess broadcast channels, was found by Chaum, Crépeau, and Damgård [10]. We could have also adapted their protocol in our setting, but at the expenses of some additional complications since their protocol allows a—controllable but positive—probability of error.

Theorem 2 guarantees that whenever protocol *GradedSV* is executed with a 1/3-adversary, certain properties hold for the verification values of the good players. These values, however, are internal to the good players and not directly "observable" by the adversary at that point. The following simple lemma, however, shows that these values can be inferred from (a portion of) the adversarial history. We will make use of this result in the next section.

LEMMA 3. *At the end of any execution of* GradedSV*, the verification value output by each good player is computable from the final history of the adversary.*

Proof. If, in an execution of *GradedSV*, all players are good, then the dealer must have been good throughout the protocol. Thus, due to property 2 of verifiable secret sharing (acceptance of good secrets), we do know that every good player must output 2 as his own verification value. Now assume that one or more players are bad—including, possibly, the dealer. Then the verification value output by a good player i at the end of *GradedSV* is determined by the number of players that sent him *recoverable* in step 9. Now, the number of bad players that sent *recoverable* to i is immediately evident from the messages sent from bad players to good players (messages that are part of the final history of the adversary). Moreover, the number of good players that have sent *recoverable* to i is immediately computable from the messages sent from the good players to the bad players (messages that are also part of the final history of the adversary); in fact, a good player g sends *recoverable* to i if and only if he distributes it to all players, including the bad ones. □

7. Oblivious common coins. In this section, we want to show that processors of a network with private channels can exchange messages so that, in the presence of any 1/3-adversary, the outcome of a reasonably unpredictable coin toss becomes available to all good players. We start by defining what this means.

7.1. The notion of an oblivious common coin.

DEFINITION 14. *Let P be a fixed-round protocol in which each processor x has no input and is instructed to output a bit r_x. We say that P is an* oblivious common coin protocol (with fairness p and fault tolerance c) *iff for all bits b, for all c-adversaries A, and for all initial quantities IQ, in a random execution of P with A on IQ,*

$$\text{Prob}(\forall \text{ good players } i,\ r_i = b) \geq p.$$

We will refer to an execution of P as a coin; *by saying that this coin is* unanimously *b, we mean that $r_i = b$ for every good processor i.*

Remarks.

• Our notion of an oblivious coin is a strengthening of Dwork, Shmoys, and Stockmeyer's *persuasive coin* [16], which they implemented for at most $O(n/\log n)$ faults.

• We chose the term *oblivious* to emphasize that, at the end of the protocol, the good processors are "unaware" of whether the outcome of the reasonably unpredictable coin toss is "common." That is, by following the protocol, each good processor computes a bit, but it does not know whether the other good processors compute the same bit. We shall see how to successfully cope with this ambiguity in section 8, but let us first exhibit an oblivious common coin protocol with fault tolerance 1/3.

7.2. An oblivious common coin protocol.

LEMMA 4. *At the end of every execution of steps* 1—3 *of OC with a* 1/3 *adversary, for every good player i and every player j, whether $SUM_{ij} = bad$ can be computed from the final history of the adversary.*

Proof. The adversary's history at the end of step 3 of OC includes the adversary's history at the end of step 1. Thus, as per lemma 3, from the latter history we compute the value $verification_i^{hj}$ for all good players i and players j.

Consequently, as per Lemma 1, we compute each entire execution of *Gradecast* of step 2 of OC. From this information we readily compute, for each good player i and player j, whether conditions (3.a), (3.b), and (3.c) apply, and thus whether $player_{ij}$ (and consequently SUM_{ij}) equals *bad*. □

LEMMA 5. *In every execution of OC with a* 1/3*-adversary, for all good players g and G, $SUM_{gG} \neq bad$.*

Proof. This is so because of the following:

(a) By property 3 of graded broadcast, g accepts G's gradecast of G's confidence list.

(b) By the semiunanimity property of *GradedSV*, $|verification_g^{hj} - verification_G^{hj}| \leq 1$ for all labels hj.

(c) By the acceptance-of-good-secrets property of *GradedSV*, $verification_G^{hG} = 2$ for each of the $n - t$ good players h. □

LEMMA 6. *For all $n > 1$, for all executions of $OC(n)$ with a* 1/3*-adversary, and for all players j, there exists an integer $sum_j \in [0, n-1]$ such that for all good g, either $SUM_{gj} = sum_j$ or $SUM_{gj} = bad$.*

Proof. We distinguish three mutually exclusive cases.

Case 1: *Player j looks bad to all good players.* In this case, setting $sum_j = 1$ trivially satisfies our claim.

Case 2: *j looks okay to a single good player g and bad to all other good players.* In this case, choosing $sum_j = SUM_{gj}$ satisfies our claim for the following reasons. First, notice that SUM_{gj} is a well-defined integer value belonging to the interval

PROTOCOL $OC(n)$
Input for every player i: None.

1. (for every player i): For $j = 1 \ldots n$, randomly and independently choose a value $s_{ij} \in [0, n-1]$. "We will refer to s_{ij} as the ith secret assigned to j, or the secret assigned to j by i."
   Concurrently run *GradedSV* n^2 times, one for each label hj, $1 \le h, j \le n$. In execution hj, the candidate-secret set is $[0, n-1]$ "and thus the number of possible secrets equals the number of players," the dealer is h, and the secret is s_{hj}, "i.e., the dealer chooses s_{hj} to be his secret whenever he is good."
   Let $verification_i^{hj}$ be your output of execution hj, "that is, your own opinion about the existence/recoverability of s_{hj}."
2. (for every player i): Gradecast the value $(verification_i^{1i}, \ldots, verification_i^{ni})$. "This is your confidence list, that is, your own opinion about the existence/recoverability of each secret assigned to you."
3. (for every player i): for all j, if
   (a) in the last step, you have accepted j's gradecast of a vector $\vec{e}_j \in \{0,1,2\}^n$, "i.e., j's own confidence list—thus if j's is good, $\vec{e}_j = (verification_j^{1j}, \ldots, verification_j^{nj})$";
   (b) for all h, $|verification_i^{hj} - \vec{e}_j[h]| \le 1$, "that is, your opinion about the recoverability of every secret assigned to j differs by at most 1 from the opinion that j has gradecasted to you"; and
   (c) $\vec{e}_j[h] = 2$ for at least $n - t$ values of h,
   set $player_{ij} = ok$, "meaning that j looks okay to you;" otherwise, set $player_{ij} = bad$, "in which case j looks bad to you and he is bad."
4. (for every player i): "Recover all possible secrets:"
   Concurrently run *GradedR* on the n^2 histories of *GradedSV* that you generated in step 1, and denote by $value_i^{hj}$ your output for execution hj.
   If $player_{ij} = bad$, set $SUM_{ij} = bad$. Else: Set

$$SUM_{ij} = \left(\sum_{\substack{h \text{ such that} \\ \vec{e}_j[h]=2}} value_i^{hj} \right) \bmod n.$$

   "That is, if player j looks okay to i, SUM_{ij} equals the sum modulo n of all those secrets assigned to j that j *himself* thinks are optimally verified."
   If for some player j, $SUM_{ij} = 0$, output $r_i = 0$; otherwise, output $r_i = 1$.

$[0, n-1]$. This is so because each of the addenda contributing to SUM_{gj} is a well-defined integer (and thus taking the sum of these addenda mod n necessarily yields a value in $[0, n-1]$). Indeed, if $value_g^{hj}$ is an addendum of SUM_{gj}, then in the confidence list of j accepted by g, $\vec{e}_j[h] = 2$. Moreover, since j looks okay to g, step 3(b) ensures that $verification_g^{hj} > 0$. In turn, by the verifiability property of *GradedSV*, this guarantees that the corresponding secret is "well shared," that is, that the value output by g running *GradedR*, $value_g^{hj}$, belongs to the candidate-secret set $[0, n-1]$, as we wished to prove.

Case 3: *Player j looks okay to more than one good player.* Let g and G be any two such good players—thus $SUM_{gj} \neq bad \neq SUM_{Gj}$. To begin with, notice that the

value $\vec{e}_j$ is the same for both g and G due to property 1 of graded broadcast. We now show that $SUM_{gj} = SUM_{Gj}$. Indeed, we have

$$SUM_{Gj} = \left(\sum_{\substack{h \text{ such that} \\ \vec{e}_j[h]=2}} value_G^{hj} \right) \bmod n$$

and

$$SUM_{gj} = \left(\sum_{\substack{h \text{ such that} \\ \vec{e}_j[h]=2}} value_g^{hj} \right) \bmod n.$$

First, notice that the set of values h for which $\vec{e}_j[h] = 2$ are the same for both G and g—in fact, both g and G accepted j's gradecast of his own confidence list in step 2 and by virtue of property 1 of any graded broadcast protocol, their accepted lists are equal. Moreover, corresponding addenda in the two summations are equal. In fact, since j looks okay to G, $\vec{e}_j[h] = 2$ implies that $verification_G^{hj} > 0$, which in turn, due to the verifiability property of *GradedVSS*, implies that all good players will recover the same value as the secret of execution hj of *GradedSV*. □

LEMMA 7.[28] *Let $n > 1$ and let S and $\mathcal{G}$ be subsets of $[1, n]$. Let the set*

$$\mathcal{O} = \{\mathcal{O}_{gj} \in \{ok, bad\} : g \in \mathcal{G},\ j \in [1, n]\}$$

be such that for all $j \in S$, there exists $g \in \mathcal{G}$ such that $\mathcal{O}_{gj} = ok$. Then for all 1/3-adversaries A, in a random execution of $OC(n)$ with $A(n)$ in which $\mathcal{G}$ is the set of always good players and $\forall g \in \mathcal{G}\ \forall j \in [1, n]$ $player_{gi} = \mathcal{O}_{gj}$, the values $\{sum_j : j \in S\}$ are uniformly and independently distributed in $[0, n-1]$.

Before proving Lemma 7, let us consider a simpler but naïve argument. We have three good reasons for doing so: to use this naive argument as an introduction to our subsequent proof; to reassure the reader that our subsequent proof, though admittedly somewhat tedious, at least does not possess any obvious shortcuts; and to bring to light a subtle point that, unless it becomes known, may become a common as well as "fatal" logical trap in similar cryptographic contexts. For simplicity, let us state our naïve argument in a particularly simple case, that is, when S's cardinality equals 1, $S = \{1\}$. In this case, all we have to prove is that the unique sum_j is uniformly distributed in $[0, n-1]$.

Naïve argument: If $SUM_{gj} \neq bad$, then $sum_j = SUM_{gj} = \alpha + \beta \bmod n$, where

$$\alpha = \left(\sum_{\substack{h \text{ such that } h \text{ is good,} \\ verification_j^{hj}=2}} value_g^{hj} \right) \bmod n$$

[28] We condition the uniform and independent distribution of the sum_j's on a rather rich set of events. This is so because Lemma 7 will be invoked in rather diverse contexts, each with its own "conditioning," and we wish to make it very easy to see that it applies properly.

and

$$\beta = \left(\sum_{\substack{h \text{ such that } h \text{ is bad,} \\ verification_j^{hj}=2}} value_g^{hj} \right) \bmod n.$$

(These two values are well defined at the end of *GradedSV*, though no good player knows them because he does not know who else is good.) Value α is uniformly distributed in $[0, n-1]$ and is, in addition, unpredictable to the adversary at the end of step 1. Value β is controllable by the adversary (since each secret that contributes to it might have been chosen by the adversary via a processor h corrupted sufficiently early in step 1). Nonetheless, since at the end of *GradedSV* each of the secrets contributing to SUM_{gj} is fixed, so is β; that is, β is fixed at a point in which α is unpredictable. "Thus" no matter how much the adversary can control β, $\alpha+\beta$ is uniformly distributed in $[0, n-1]$.

Why is this naïve? The flaw in the above argument is that, in principle, the unpredictability of α may be consistent with the fact that, say, $\alpha + \beta$ always equals 0. Indeed, in principle, the adversary may be capable of guarateeing that $\beta = -\alpha \bmod n$ without knowing α nor (necessarily!) β.[29] This "magic correlation," though possible in principle, is actually impossible to achieve in our protocol due to many of its *specificities*, which have been ignored by the above reasoning. For instance, our protocol is such that the value β is actually "*known*" to the adversary at the end of step 1. This and other specificities are indeed an integral part of the following simulation-based argument, which properly corrects and formalizes the above naïve argument. The reader who, at this point, finds it obvious can proceed to Theorem 3.

Proof of Lemma 7. The proof is by induction on k, the cardinality of the set S. For $k = 0$, our statement is vacuously true. We now prove the inductive step by contradiction. Assume that our statement holds for $k-1$ but not for k. Then a simple averaging argument implies the following proposition.

PROPOSITION P1. *There exist an integer $n > 1$, a subset $\mathcal{G} \subset [1, n]$, a set of values $\mathcal{O} = \{\mathcal{O}_{gi} \in \{ok, bad\} : g \in \mathcal{G}\ i \in [1, n]\}$, a subset $S' \subset [1, n]$, whose cardinality is $k-1$, an additional player $j \notin S'$ such that $\forall i \in S' \cup \{j\} \exists g \in \mathcal{G}\ \mathcal{O}_{gi} = ok$, a set of $k-1$ values $\{v_i \in [0, n-1]\ :\ i \in S'\}$, an additional value $v \in [0, n-1]$, a distinguished*

[29] Mutatis mutandis, consider the following simpler scenario (simpler because it envisages computationally bounded players and thus the possibility of successfully using uniquely decodable encryptions) in which this is indeed the case. Two players desire to compute a common and random bit in the following manner. First, player 1 chooses a random bit b_1 and announces its encryption $E_1(b_1)$. Then player 2 chooses a random bit b_2 and announces its encryption $E_2(b_2)$. Then player 1 releases his own decryption key, d_1, and, finally, player 2 releases his own decryption key, d_2. This will enable both players to compute bits b_1 and b_2 and thus b, their sum modulo 2. Is such a b a random bit if, say, player 2 is bad? The answer is no. Player 2 may force bit b to be 0. Although he cannot predict b_1, he may exploit the fact that player 1 announces his encrypted bit first. (Recall that in our scenario, simultaneity is not guaranteed! Messages arrive by the next clock tick, but the adversary is allowed "rushing.") The strategy of player 2 is as follows. First, he announces the same ciphertext that player 1 does. Then he announces the same decryption key that player 1 does. This is a quite serious problem and does not have easy solutions. Simply requiring that the second player announce a different value than the one announced by the first is not a solution. However, discussion of this point is beyond the scope of this paper. (Let us just say that Micali devised a cryptographic protocol that enables two mutually distrusting people to announce independent values—but the protocol and its proof are not at all straightforward. Dolev, Dwork, and Naor [15] have provided a new type of public-key cryptosystem that would make easy to solve this and similar problems. Neither method, however, can be applied to the context of this paper, where the adversary is not restricted in the amount of computation she can perform and thus could break any public-key cryptosystem.)

player $G \in \mathcal{G}$ such that $\mathcal{O}_{Gj} = ok$, a constant $\varepsilon > 0$, a 1/3-adversary A, a string H, and a subset $B \subset [1,n]$, whose intersection with $\mathcal{G}$ is empty, such that, in a random execution of OC(n) *with $A(n)$ on initial adversarial history H and initially bad set B, letting "$\mathcal{G} = AG$" denote the event that the set of always good players coincides with $\mathcal{G}$ and defining*

$$\mathcal{X} = (\mathcal{G} = AG) \ \wedge \ (\forall i \in [1,n] \ \forall g \in \mathcal{G}, \ player_{gi} = \mathcal{O}_{gi}),$$

then

(a) $\text{Prob}(\mathcal{X}) > \varepsilon$;

(b) $\text{Prob}(\forall i \in S', \ sum_i = v_i \mid \mathcal{X}) = (1/n)^{k-1}$; *and*

(c) $\text{Prob}(\forall i \in S', \ sum_i = v_i \ \wedge \ sum_j = v \mid \mathcal{X}) > (1/n)^k$.[30]

CLAIM L7-0. *Let n, S', $\mathcal{G}$, $\mathcal{O}$, j, v, G, ϵ, A, H, B, and $\mathcal{X}$ be as in Proposition* P1*, and let $\mathcal{Y}$ be the event defined as follows:*

$$\mathcal{Y} = \mathcal{X} \ \wedge \ (\forall i \in S', \ sum_i = v_i).$$

Then in a random execution of steps 1–3 *of OC(n) with A on initial adversarial history H and initially bad set B in which G is not corrupted, the following holds:*

1. *$\mathcal{Y}$ occurs with positive probability.*

2. *Whether $\mathcal{Y}$ occurs is computable on the following inputs:* (2.1) *the set of the always good players,* (2.2) *the vectors $\vec{e}_x \in \{0,1,2\}^n$ accepted by at least one good player in step* 2*, and* (2.3) *for all good players g and for all players $x \neq j$, g's history of execution gx of GradedSV.*

3. *If $\mathcal{Y}$ occurs (and thus $G \in \mathcal{G}$ is good), the secret s_{Gj} (i.e., the secret—randomly selected in $[0, n-1]$—of execution Gj of GradedSV, where good G is the dealer) is predictable with probability $> 1/n$ on inputs* (2.1)*,* (2.2)*, and* (2.3) *above.*

Proof of Claim L7-0.1. First, notice that, because $G \in \mathcal{G}$, G is not corrupted whenever $\mathcal{X}$ occurs. Thus $\text{Prob}(\mathcal{Y} \mid G \text{ good}) = \text{Prob}(\mathcal{Y}) = \text{Prob}(\mathcal{Y} \mid \mathcal{X}) \cdot \text{Prob}(\mathcal{X})$. Now $\text{Prob}(\mathcal{X}) > \varepsilon$ by Proposition P1(a), and $\text{Prob}(\mathcal{Y} \mid \mathcal{X}) = (1/n)^{k-1}$ by Proposition P1(b).

Proof of Claim L7-0.2. Inputs (2.1) and (2.2) are by definition sufficient to determine whether $\mathcal{X}$ holds, and if this is the case, $\forall i \in S'$, $sum_i \neq bad$, and thus $sum_i = sum_{gi}$ for some good player g who has accepted i's gradecast of a vector $\vec{e}_i$ in step 3. Also, inputs (2.3) and (2.4) are more than sufficient to compute which actual value in $[0, n-1]$ sum_{gi} takes because this value depends only on $\vec{e}_i$ and g's history of execution hi of *GradedSV*, $h = 1, \ldots, n$, none of which coincides with execution Gj since $i \in S' and S' \not\ni j$.

Proof of Claim L7-0.3. If $\mathcal{Y}$ occurs, $SUM_{Gj} \neq bad$ and, on inputs (2.1), (2.2), and (2.3), one can compute all addenda that contribute to SUM_{Gj}, with the singular exception of $value_G^{Gj}$. Indeed, for each $h \neq G$ such that $\vec{e}_j[h] = 2$, the occurrence of $\mathcal{Y}$ implies that G is good, that $player_{Gj} = ok$, that $|verification_G^{hj} - \vec{e}_j[h]| \leq 1$, and thus that $verification_G^{hj} > 0$. In turn, $verification_G^{hj} > 0$ implies that the secret of each such execution hj is recoverable no matter what the currently bad players (and those which may become bad while running *GradedR*) may do. In particular, the secret of each such execution hj is recoverable if no more players are corrupted during *GradedR* and the bad players do not send any messages during *GradedR*. Thus when one has the histories of the currently good players (i.e., those in $\mathcal{G}$) at the end of each such

[30] Statement (c) is equivalent to the following statement:

($\tilde{c}$) $\text{Prob}(\forall i \in S, \ sum_i = v_i \ \wedge \ sum_j = v \mid \mathcal{X}) \neq (1/n)^k$.

In fact, (c) clearly implies ($\tilde{c}$) and the converse can again be established by averaging.

execution hj of *GradedSV*, one can run *GradedR* so as to reconstruct $value_G^{hj}$ for each of the above labels hj. Having done this, one can trivially compute the sum modulo n of these values; that is, one can compute

$$\omega = \left(\sum_{\substack{h \text{ such that } h \neq G \\ \vec{e}j[h]=2}} value_G^{hj} \right) \bmod n$$

and output $v - \omega$ as a prediction for $value_G^{Gj} = s_{Gj}$. We now show that $\text{Prob}(v - \omega = value_G^{Gj}) > 1/n$. Indeed, given the above notation, in Proposition P1 we can rewrite inequality (c) as follows:

(c) $\text{Prob}(sum_j = v \mid \mathcal{Y}) \cdot \text{Prob}(\mathcal{Y} \mid \mathcal{X}) > (1/n)^k$.

Thus, since $\text{Prob}(\mathcal{Y} \mid \mathcal{X}) = (1/n)^{k-1}$, Proposition P1(b) implies that

$$\text{Prob}(sum_j = v \mid \mathcal{Y}) > 1/n.$$

Now, whenever $\mathcal{Y}$ occurs, we have, in particular, $SUM_{Gj} \neq bad$, and thus $sum_j = value_G^{Gj} + \omega \bmod n$. Therefore, as we wanted,

$$\text{Prob}(value_G^{Gj} = v - \omega \mid \mathcal{Y}) > 1/n. \qquad \blacksquare$$

Notice that Claim L7-0 is not (yet!) a violation of the unpredictability of *GradedSV*.[31] To reach such a contradiction, we now show that (letting n, S', $\mathcal{G}$, $\mathcal{O}$, G, j, v, ϵ, A, H, B, and $\mathcal{X}$ be as in Claim L7-0 and Proposition P1) Claim L7-0 implies the existence of a 1/3-adversary for *GradedSV*, A' $(= A'_{n,S',\mathcal{G},\mathcal{O},j,v,G,\epsilon,A,H,B})$, that in a random execution with *GradedSV*(n) succeeds in achieving the following two goals. First, her random execution with *GradedSV*(n) coincides with execution Gj of *GradedSV* in a random execution of the first three steps of *OC*(n) with $A(n)$. Second, she possesses all inputs (2.1), (2.2), and (2.3) relative to said execution of *OC*(n) with $A(n)$.

Informal description of A' $(= A'_{n,S',\mathcal{G},\mathcal{O},G,j,\epsilon,A,H,B})$. Although adversaries A' and A are different and attack different protocols, they both act on networks with n players. Thus for any given player $i \in [1, n]$, we must specify at all points whether he is a player executing *GradedSV*(n) with A' or a player executing *OC*(n) with A. We find it convenient to do so by writing i' in the first case and i in the second.

Let us now describe the behavior of A' in a random execution, E', with *GradedSV* when the dealer is G' and both the adversarial history and the initially bad set are empty. During E', A' orchestrates and monitors portions of a "*virtual*" execution, E, of *OC*(n) with adversary A. (We thus think of adversary A' as acting in the actual network N'—where *GradedSV*(n) is executed—and of A as acting in the virtual network N where *OC*(u) is executed.)

Since we shall only consider n-party executions of protocols *GradedSV* and *OC* (where n is as in Proposition P1) in the proof of our lemma, we may more simply write *GradedSV* and *OC* instead of, respectively, *GradedSV*(n) and *OC*(n).

Adversary A' causes E to start by letting the adversarial history of A be H, the initially bad set be B (where H and B are as in Proposition P1), and the initial

[31] Indeed, for this to be the case, it is necessary that a 1/3-adversary succeed in predicting better than at random the random secret of a good dealer in a random execution between this adversary and *GradedSV*, that is, without assuming that such a random execution is embedded into an execution of *OC* for which certain key quantities are an available inputs.

histories of players $1, \ldots, n$ be those of a random execution of *OC*. As usual, the first 25 rounds of E consist of the concurrent execution n^2 times of the 25-round protocol *GradedSV*: one execution for each label hj (where h and j are player names and h is the dealer of execution hj).

For the first 25 rounds, adversary A' keeps E' in *lockstep* with E, *identifying* execution Gj (where G and j are as in Proposition P1) with E'. By "lockstep," we mean that, for each round $\rho > 0$, the round-ρ quantities of E' and E depend on and are generated after the round-$(\rho - 1)$ quantities of both E' and E. By "identifying" E', with execution Gj of *GradedSV* in E, we mean that A' corrupts processors in N' while interfering with the delivery of messages in N in the following way. Adversary A' corrupts player j' in network N' at round ρ if and only if A corrupts j in network N at round ρ. (Since the computation of A starts with initially bad set B, adversary A' corrupts j' in network N' at round 0 for all $j \in B$.) Let us now discuss how A' interferes with the delivery of messages in network N. At every round $\rho = 1, \ldots, 25$, after A has ended her corruption process and computed the messages from each bad player to each good one for all executions xy of *GradedSV*, A' acts as follows:

- For each execution $xy \neq Gj$, she delivers the proper messages to the proper recipients in network N.
- For execution Gj, if A outputs m as the message from bad player b to good player g, then A' has b' send m to g' in network N'; vice versa, if good player g' sends a message m' to bad player b' in execution E', then A' delivers m' as the message from g to b in round ρ of execution Gj.

As we shall prove, after making this description a bit more precise, the virtual execution E thusly generated is actually a "genuine" random execution of the first three steps of $OC(n)$ with A. Moreover, A' will be capable of computing inputs (2.1), (2.2), and (2.3) specified in Claim L7-0. This will enable her to contradict the unpredictability property of *GradedSV*.

More formal description of A' $(= A'_{n,S',\mathcal{G},\mathcal{O},G,j,\epsilon,A,H,B})$. Let us now describe a bit more precisely the way A' acts in a random execution of *GradedSV*(n) in network N', where the dealer is G', the candidate-secret set is $[0, n-1]$, the dealer's secret is randomly chosen in said candidate-secret set, the initial adversarial history equals the empty string, and the initially bad set is empty. We have already specified each player's version of *GradedSV* and the mechanics of an execution of an n-party protocol with an adversary. Thus, choosing the players' and adversary's coin tosses at random, our description of A' specifies the values taken by all possible players' quantities $H^r_{i'}$, $M^r_{i'\rightarrow}$, $M^r_{\rightarrow i'}$, $C^r_{i'}$, and $R^r_{i'}$ as well as the values taken by the adversarial quantities $H^r_{A'}$, $C^r_{A'}$, and $R^r_{A'}$ and by the sets BAD'^r and GOOD'^r.

In order to determine her actions in network N', adversary A' will construct only in part the quantities $H^{r,xy}_i$, $M^{r,xy}_{i\rightarrow}$, $M^{r,xy}_{\rightarrow i}$, $C^{r,xy}_i$, and $R^{r,xy}_i$, where $i \in [1, n]$ and $xy \in [1, n]^2$, but she will construct all of the possible quantities H^r_A, C^r_A, and R^r_A and the sets BAD^r and GOOD^r.

She generates these quantities with the same mechanics of a random execution of the first three steps of protocol $OC(n)$ with adversary A, initially bad set B, and initial adversarial history H. The quantities generated thusly by A', however, fall short of constituting such a random execution because they are *incomplete*. Indeed, they miss some Gj-labeled quantities—e.g., $H^{r,Gj}_i$ whenever $i \in \text{GOOD}^r$.[32]

[32] Since the quantities reconstructed by A' relative to network N do not quite constitute an execution of $OC(n)$ with A, and since it can be recognized that these quantities can be integrated so as to yield a virtual execution only after the entire behavior of A' has been described, it would be improper during our description to use suggestive expressions—such as "good at round r"—that,

It will be clear from our description, however, that if there is no r for which BAD^r contains G, then if one were to integrate these missing quantities with the corresponding quantities of E' (i.e., the execution of *GradedSV*(n) with A' in network N'), one would obtain a random execution of *OC*(n) with A, on initially bad set B and adversarial history H, in which G is not corrupted.

Notice that A' is active in network N' for 25 rounds because *GradedSV*(n) is a 25-round protocol. Notice also that the number of rounds in step 1 of *OC*(n) is also 25 if one imagines (as we do) that in each execution xy of *GradedSV*(n), the dealer randomly chooses the secret in round 0. Thus for $r = 1, \ldots, 25$ and each label $xy \in [1, n]^2$, the ith round of step 1 is the ith round of an execution of *GradedSV*. Indeed, for $r = 0, \ldots, 25$, adversary A' decides her action at round r in network N' "simultaneously" with her generation of round-r quantities in virtual network N (i.e., after having generated round-$(r-1)$ quantities in network N and before generating round-(r_1) quantities in network N).

To facilitate seeing that the round-r quantities generated by A' for virtual network N follow the mechanics of an execution of *OC*(n) with A on initially bad set B and adversarial history H, we break the instructions for this generation into instructions 1∗–4∗, thus matching the instructions 1–4 that we used in section 3 to describe how a protocol is executed with an adversary.

LOCAL DEFINITION. *Let $b_1, \ldots, b_k$ be the elements of subset B; denote by $\mathcal{L}$ the set of all execution labels of GradedSV in step* 1 *(i.e., $\mathcal{L} = \{hj : 1 \le h, j \le n\}$) and by $\mathcal{L}^-$ the set $\mathcal{L} - \{Gj\}$.*

Instructions for round $r = 0$.

(In virtual network N):

Set $H_A^0 = H$, $\text{BAD}^0 = B$, $\text{GOOD}^0 = [1, n] - \text{BAD}^0$, and $C_A^0 = \epsilon$. Then construct a binary string R_A by selecting randomly and independently each of its coins, and set $R_A^0 = R_A$.[33]

For all $xy \in \mathcal{L}^-$, randomly and independently select S_{xy} in $[0, n-1]$, and let C_{xy} denote the sequence of random bits used for this selection.

For all $xy \in \mathcal{L}^-$ and for all $i \in [1, n]$, construct an infinite bit string R_i^{xy} by choosing each of its bits randomly and independently. [34] Then reset $R_x^{xy} := C_{xy} \circ R_x^{xy}$.

Finally, for all $xy \in \mathcal{L}^-$ and for all $i \in [1, n]$, set $C_i^{0,xy} = \epsilon$, $R_i^{0,xy} = R_i^{xy}$, and $M_{i\rightarrow}^{0,xy} = M_{\rightarrow i}^{0,xy} = (\epsilon, \ldots, \epsilon)$, and, if $i \neq x$, $H_i^{0,xy} = ((x, n), M_{\rightarrow i}^{0,xy}, C_i^{0,xy})$—otherwise (i.e., $i = x$), set $H_i^{0,xy} = ((x, n, S_{xy}), M_{\rightarrow i}^{0,xy}, C_i^{0,xy})$.

"In an execution of *GradedSV*(n) with dealer x, the input for any player other than x is (x, m), that is, the name of the dealer and an encoding of the candidate-secret set, $[0, m-1]$. The private input for x is instead (x, m, s), that is, x is given his secret as an *additional* input, unrelated to his sequence of future coin tosses. (Therefore, should the dealer be corrupted by the adversary at round 1, she would discover his input secret but not the random choices made to come up with that secret, even if it were randomly selected.) In any execution xy of *GradedSV*(n) as a subprotocol of *OC*(n), there are two peculiarities. First, $m = n$ (which is easily reflected in the initial histories of the players in execution xy). Second, the dealer x of execution xy is not given his secret S_{xy} as an outside input; rather, he randomly chooses it in $[0, n-1]$

though very useful in building up intuition, presuppose that we are already dealing with a genuine execution. Notice, in fact, that all quantities relative to the virtual network N are constructed using only a syntactic description. Only in our comments do we use suggestive language.

[33] This is expressed thusly for convenience. In reality, each R_A will be constructed on an "as-needed basis."

[34] Again, in reality, each R_i^{xy} will be constructed on an "as-needed basis."

prior to calling *GradedSV*(n). Therefore, should the adversary corrupt player x at round 1 of her execution with $OC(n)$, then, she should be able to discover not only x's random secret relative to each execution xy but also the coin tosses that led x to choose S_{xy}. This is exactly what is accomplished by the above steps (which also accomplish giving these secrets suitable names—i.e., S_{xy}—and making it evident that all of them (for $xy \neq Gj$) are known to A')."

(In network N'):

Corrupt processors $b'_1, \ldots, b'_k$,

Instructions for $r = 1, \ldots, 25$.

0∗ (in virtual network N):

$\text{TEMPH}_A^r := H_A^{r-1}$; $\text{TEMPR}_A^r := R_A^{r-1}$; $\text{TEMPGOOD}^r := \text{GOOD}^{r-1}$; $\text{TEMPBAD}^r := \text{BAD}^{r-1}$.

1∗ (in virtual network N):

For all $g \in \text{GOOD}^{r-1}$ and for all $xy \in \mathcal{L}^-$, generate $M_{g\rightarrow}^{r,xy}$, "the messages g wishes to send in this round (which may be reset if g is corrupted in this round)," $C_g^{r,xy}$, and $R_g^{r,xy}$ by running $GradedSV(n)_g$ on input $H_g^{r-1,xy}$ and coins $R_g^{r-1,xy}$.

2∗ (in virtual network N):

For all $xy \in \mathcal{L}^-$, for all $g \in \text{GOOD}^{r-1}$, for all $b \in \text{BAD}^{r-1}$, $\text{TEMPH}_A^r := (\text{TEMPH}_A^r, g, b, xy, M_{g\rightarrow}^r[b])$.

"In other words, for each message m from a good player g to a bad player b computed by running *GradedSV* relative to label $xy \in \mathcal{L}^-$, deliver m to A as usual (i.e., specifying the name of the sender, the recipient, and the execution label). Then":

For each message m' received by a bad player b' from a good player g' in network N' at round r, $\text{TEMPH}_A^r := (\text{TEMPH}_A^r, g, b, Gj, m')$.

3∗ (in virtual network N):

Run A on input TEMPH_A^r and coins TEMPR_A^r.

(In network N' and in virtual network N):

If in this execution of step 3 A has output j "as the next player to corrupt," then HALT—"both the virtual execution in network N and the real execution in network N' are terminated"—and output a random value in $[0, n-1]$ as your guess for the secret of dealer G'. "You will be correct with probability $1/n$. Else":

(In virtual network N):

If A has output $q \in \text{TEMPGOOD}^r$ and made the sequence of coin tosses C, then

$\text{TEMPBAD}^r := \text{TEMPBAD}^r \cup \{q\}$, $\text{TEMPGOOD}^r := \text{TEMPGOOD}^r - \{q\}$,

$\text{TEMPH}_A^r := (\text{TEMPH}_A^r, xy, H_q^{r-1,xy}, C_q^{r,xy}, C)$,

$\text{TEMPR}_A^r := \text{TEMPR}_A^r / C$,

$\forall xy \in \mathcal{L}^-$, $\forall g \in \text{TEMPGOOD}^r$, $\text{TEMPH}_A^r := (\text{TEMPH}_A^r, g, q, xy, M_{g\rightarrow}^{r,xy}[q])$.

(In network N'):

Corrupt q' in network N', thereby learning his history $H_{q'}^{(r-1)}$ and coin tosses $C_{q'}^{(r-1)}$, as well as $M_{\rightarrow q'}^r[g']$ for all currently good players g',

"i.e., as well as each message sent by a currently good player g' to q'. Note that a player g' (respectively, b') is currently good (respectively, bad) in network N' if $g \in \text{TEMPGOOD}^r$ (respectively, $b \in \text{TEMPBAD}^r$) in the virtual network N."

(In virtual network N):

$\text{TEMPH}_A^r := (\text{TEMPH}_A^r, xy, H_{q'}^{r-1}, C_{q'}^{r-1}, C)$,

$\forall g \in \text{TEMPGOOD}^r$, $\forall b \in \text{TEMPBAD}^r$, $M_{g\rightarrow}^{r,Gj}[b] := M_{g'\rightarrow}^r[b']$.

Go to step 3∗ "to corrupt next processor."

If "A no longer wishes in this round to corrupt additional players," if in this execution of step 3 A has output, for all $xy \in \mathcal{L}$ and for all $b \in \text{TEMPBAD}^r$, a vector

$M_b^{xy} \in (\{0,1\}^*)^n$ "as b's round-r messages" and made the sequence of coin tosses C, then:

(In virtual network N):

$\forall xy \in \mathcal{L}^-$, $\forall b \in \text{BAD}^r$, $M_{b\rightarrow}^{r,xy} := M_b^{xy}$,

$\text{TEMPH}_A^r := (\text{TEMPH}_A^r, C)$ "so that she can reconstruct the bad players' messages of round r,"

$\text{TEMPR}_A^r := \text{TEMPR}_A^r / C$;

(In network N'):

$\forall b \in \text{BAD}^r$, $M_{b'\rightarrow}^r := M_b^{r,Gj}$.

"In other words, for each message m from a bad player b to a currently good player g in network N relative to execution Gj, have b' send m to g' as his round-r message in network N'."

4∗ (In virtual network N):

"Adjust the final round-r quantities as follows." Letting $\mathcal{C}$ be the sequence of coin tosses that A has made since the last execution of step 2,

$H_A^r := \text{TEMPH}_A^r$; $C_A^r := \mathcal{C}$; and $R_A^r := \text{TEMPR}_A^r$;

$\text{GOOD}^r := \text{TEMPGOOD}^r$ and $\text{BAD}^r := \text{TEMPBAD}^r$;

$\forall xy \in \mathcal{L}^-$, $\forall k, i \in [1,n]$, $M_{\rightarrow i}^{r,xy}[k] := M_{k\rightarrow}^{r,xy}[i]$; and

$\forall k \in [1,n]$, $\forall i \in \text{BAD}^r$, $M_{\rightarrow i}^{r,Gj}[k] := M_{k\rightarrow}^{r,Gj}[i]$;

"Adversary A' does not know the messages exchanged among good processors in network N' and thus does not construct the corresponding messages in execution Gj."

$\forall xy \in \mathcal{L}^-$, $\forall g \in \text{GOOD}^r$, $H_g^{r,xy} := (H_g^{r-1,xy}, M_{\rightarrow g}^{r,xy}, C_g^{r,xy})$;

"A' does not know the histories of the good players in N' and thus does not construct $H_g^{r,Gj}$."

$\forall xy \in \mathcal{L}$, $\forall b \in \text{BAD}^{r-1}$, $H_b^{r-1,xy} := (H_b^{r-1,xy}, bad)$, and $\forall b \in \text{BAD}^r - \text{BAD}^{r-1}$, $H_b^{r,xy} := (H_b^{r-1,xy}, C_b^{r,xy}, bad)$.

"Thus far, each time that a new round was added to the partial virtual execution of OC with A, the execution of *GradedSV* with A' also progressed one round. At this point, however, the rounds added to the partial virtual execution only allow A' to make additional internal computations and, possibly, additional corruptions, but her execution with *GradedSV* remains at round 25.

At the start of the execution of step 2 of $OC(n)$, the prior history of a good player consists of an n^2-vector, $\{H_g^{25,xy} : xy \in \mathcal{L}\}$. But at this point of the computation in the virtual network N, there is no quantity $H_g^{25,Gj}$. However, there is a quantity $H_g^{25,xy}$ whenever $g \in \text{GOOD}^{25}$ and $xy \in \mathcal{L}^-$. Such a quantity $H_g^{25,xy}$ specifies the quantity $\mathit{verification}_i^{xy}$ (via some proper input function $\mathcal{I}_g^{steps2-3}$). Thus for all $xy \in \mathcal{L}^-$ and for all $g \in \text{GOOD}^{25}$, $\mathit{verification}_i^{xy}$ is computable by A' because she has already computed $H_g^{25,xy}$."

Additional instructions for round 25.

LOCAL DEFINITION. *We denote by steps* 2–3 *the protocol consisting of steps* 2 *and* 3 *of* $OC(n)$.

For all $g \in \text{GOOD}^{25}$, set $\mathit{verification}_g^{Gj}$ to be the verification value output at round 25 by player g' in the execution of *GradedSV*(n) with you in network N'.

"Although these values are internal to good processors of network N' and thus invisible to you, you can compute them—by virtue of Lemma 3—from your knowledge of the sets of good and bad players and the messages exchanged between good and bad players."

For all $g \in \text{GOOD}^{25}$, set $H_g^{25,Gj} = rc_g^{Gj}$, where rc_g^{Gj} is a reserved character that (via the input function $\mathcal{I}_g^{steps2-3}$) specifies $verification_g^{Gj}$.

Execute subprotocol *steps* 2–3 with A (with the initial adversarial history being the computed quantity H_A^{25}, the initially bad set being the computed quantity BAD^{25}, and the prior history of each good player g being the ("thusly completed") vector $\{H_g^{25,xy} : xy \in \mathcal{L}\}$), handling corruptions as follows.

"In this execution of *Gradecast* as a subprotocol, you know the sender, the sender's message, the set of initially bad players, the active adversary, and the initial adversarial history. Thus you do not need to know the players' prior histories exactly in order to exactly reconstruct all messages exchanged up to the next corruption. Indeed, the good players do not rely on their prior histories (more than is needed to figure out which message to gradecast). Once a corruption occurs, however, in order to update the adversarial history in a proper manner, you need the corrupted player's prior history."

Whenever A corrupts an additional player k, corrupt k' in network N' so as to find his current history, H'_k. In the current *steps* 2–3 history of k, replace the reserved character rc_k^{Gj} by the string H'_k and deliver the thusly updated history to A (in the syntactically proper manner).

Instructions for predicting the secret.

"If you have not already predicted the secret of G' at random, do the following":

Detect whether event $\mathcal{Y}$ "of Claim L7-0" occurs.

"You can do that by virtue of Claim L7-0 because you may compute all inputs (2.1), (2.2), and (2.3) envisaged in that claim."

If $\mathcal{Y}$ has not occurred, then predict the secret of G' by outputting a random number in $[0, n-1]$.

Else output the value $v - \omega \bmod n$ as your prediction of the secret of G'. "v is the value of Proposition P1 and Claim L7-0 and

$$\omega = \left(\sum_{\substack{h \text{ such that } h \neq G \\ verification_j^{hj} = 2}} value_G^{hj}, \right) \bmod n."$$

This ends our description of A'. Notice that Steps 2 and 3 of OC take, respectively, four rounds and one round. Thus the subprotocol consisting of Steps 1–3 of OC is a 30-round protocol.

Let us now more precisely claim (without proof) that if one replaces the missing quantities constructed by A' for the virtual network N with the "corresponding" quantities that arise in the execution of adversary A' with $GradedSV(n)$ in network N', one obtains a random execution of Steps 1—3 of $OC(n)$ with A.

CLAIM L7-1. *Let E' be a random execution of protocol $GradedSV(n)$ with adversary A' in which the initially bad set is empty, the initial adversarial history is the empty string, the dealer is G', the candidate-secret set is $[0, n-1]$, and the secret is randomly selected in $[0, n-1]$.*

- *For all $r = 0, \ldots, 25$, for all $xy \in \mathcal{L}^-$, and for all $i \in [1, n]$, let $H_i^{r,xy}$, $M_{i\rightarrow}^{r,xy}[j]$, $M_{\rightarrow i}^{r,xy}[j]$, $C_i^{r,xy}$, GOOD^r, BAD^r, H_A^r, and C_A^r be the network-N quantities generated by A' during E'.*
- *For all $r = 1, \ldots, 25$ and for all $g \in \text{GOOD}^r$, let $H_{g'}^r$, $M_{g'\rightarrow}^r$, $M_{\rightarrow g'}^r$, and $C_{g'}^r$, be, respectively, the round-r history, messages sent, messages received, and coin tosses of player g' in E'.*

• *For all* $r = 0, \ldots, 25$ *and for all* $g \in \text{GOOD}^r$, *set* $H_g^{r,Gj} = H_{g'}^r$, $M_{g\rightarrow}^{r,Gj} = M_{g'\rightarrow}^r$, $M_{\rightarrow g}^{r,Gj} = M_{\rightarrow g'}^r$, *and* $C_g^{r,Gj} = C_{g'}^r$.[35]

• *For all* $r = 1, \ldots, 25$ *and for all* $xy \in \mathcal{L}$, *set* $H_i^r = \{H_i^{r,xy} : xy \in \mathcal{L}\}$, $M_{i\rightarrow}^r = \{M_{i\rightarrow}^{r,xy} : xy \in \mathcal{L}\}$, $M_{\rightarrow i}^r = \{M_{\rightarrow i}^{r,xy} : xy \in \mathcal{L}\}$, *and* $C_i^r = \{C_i^{r,xy} : xy \in \mathcal{L}\}$.

• *For all* $r = 26, \ldots, 30$ *and for all* $i \in [1, n]$ *let* H_i^r, $M_{i\rightarrow}^r$, $M_{\rightarrow i}^r$, C_i^r, GOOD^r, BAD^r, H_A^r, C_A^r, *and* R_A^r *be the network-*N *quantities generated by* A' *when executing protocol steps* 2–3 *with* A *during* E'.

Then the sequence of tuples

$$E = E_0, \ldots, E_{30},$$

where

$$E_r = (H_1^r,\ M_{1\rightarrow}^r,\ M_{\rightarrow 1}^r,\ C_1^r,\ R_i^r, \ldots,$$
$$H_n^r,\ M_{n\rightarrow}^r,\ M_{\rightarrow n}^r,\ C_n^r,\ R_n^r,\ H_A^r,\ C_A^r,\ R_A^r,\ \text{BAD}^r, \text{GOOD}^r),$$

is a random execution (*up to round* 30) *of protocol* $OC(n)$ *with adversary* A, *on initially bad set* B *and initial adversarial history* H, *in which player* G *is not corrupted.*

The above claim follows from our description of A' and by the observation that all n^2 secrets of E have been randomly and independently selected in $[0, n-1]$: secrets s_{xy} for $xy \in \mathcal{L}$ by construction, and secret s_{Gj} (i.e., the secret of G' in execution E' of *GradedSV*(n) with A') by hypothesis.

Notice that A' is a 1/3-adversary (because A is a 1/3-adversary and because A' corrupts a player in E' if and only if A corrupts the corresponding player in E), that A' may compute all inputs (2.1), (2.2), and (2.3) envisaged in Claim L7-0, and that A' never corrupts dealer G in an execution with *GradedSV*(n) when the initially bad set is empty and the initial adversarial history is the empty string.

Let us now show that A' can predict the secret of G' with probability $> 1/n$. Indeed, whenever A wishes to corrupt G, A' halts, outputting a random number in $[0, n-1]$ as her prediction of the secret of G'. Thus she will be correct with probability $1/n$ in these cases. If A does not corrupt G in E, but neither does event $\mathcal{Y}$ (which A' detects), then A' again guesses the secret of G' at random and is right with probability $1/n$. However, whenever $\mathcal{Y}$ occurs, which by virtue of Claims L7-0 and L7-1 is with positive probability, then A' (per Claim L7-0) correctly guesses the secret of G' with probability $> 1/n$. Finally, because the event that A does not corrupt G occurs whenever $\mathcal{Y}$ occurs, we have that A' correctly guesses the secret of G' with probability $> 1/n$. This contradiction of the unpredictability property of *GradedSV* establishes Lemma 7. □

THEOREM 3. *OC is an expected-polynomial-time* 32*-round oblivious common coin protocol with fairness* $> .35$ *and fault tolerance* 1/3.

Proof. The claims regarding round complexity and running time are easy to verify. (Recall that—though in a "hidden" way—we do make use of message bounds.) Let us thus prove the other claims. We start with some convenient notation.

Let A be a 1/3-adversary and $\mathcal{IQ} \in \mathcal{IQ}_n^{OC}$ be proper initial quantities for OC. Then in an execution of $OC(n)$ with a 1/3-adversary on $\mathcal{IQ}$, let C_0 denote the event that the coin is unanimously 0, C_0^{good} denote the event that $sum_g = 0$ for some good player g (i.e., the coin is unanimously 0 "thanks to a good player"), and C_1 denote the event that the coin is unanimously 1. Correspondingly, let P_0, P_0^{good}, and P_1 denote

[35] Notice that some of these quantities might have already been computed by A' for virtual network N, in which case they would be reset to the same value.

the probabilities of C_0, C_0^{good}, and C_1, respectively, in a random execution of $OC(n)$ with $A(n)$ on $\mathcal{IQ}$. (Notice that $C_0 \neq \neg C_1$, where $\neg E$ denotes the complement of an event E.)

We are now ready to lower-bound both P_0 and P_1.

Lower-bounding P_0. Since $P_0 \geq P_0^{good}$, we lower-bound P_0 by lower-bounding P_0^{good}.[36] If S is a subset of $[1,n]$, let "$AG = S$" denote the event that the set of the always good players coincides with S. Notice that if $\text{Prob}(AG = S) > 0$ then $|S| > 2n/3$ and that $\sum_{|S|>2n/3} \text{Prob}(AG = S) = 1$. (In fact, in any execution with a 1/3-adversary, there must be at least $2n/3$ always good players.) Also notice that (because for all good players G and g, $SUM_{Gg} \neq bad$ by Lemma 5) Lemma 7 implies that whenever $AG = S$ occurs, the values $\{sum_g : g \in S\}$ are independently and uniformly distributed in $[0, n-1]$. Thus, because it is sufficient that any such value equals 0 for the coin to be unanimously 0, and because of S's cardinality, we have

$$\text{Prob}(\neg C_0^{good} \mid AG = S) < (1 - 1/n)^{2n/3} < e^{-2/3}.$$

Hence

$$\text{Prob}(C_0^{good} \mid AG = S) > 1 - e^{-2/3}.$$

Thus

$$\begin{aligned}\text{Prob}(C_0^{good}) &= \sum_{|S|>2n/3} \text{Prob}(C_0^{good} \mid AG = S) \cdot \text{Prob}(AG = S) \\ &> \sum_{|S|>2n/3} (1 - e^{-2/3}) \,\text{Prob}(AG = S) \\ &= (1 - e^{-2/3}) \sum_{|S|>2n/3} \text{Prob}(AG = S) = 1 - e^{-2/3}.\end{aligned}$$

Lower-bounding P_1. If $S \subset [1,n]$, let $bad \neq S$ denote the following event: $S = \{j \in [1,n] : \forall \text{ good } g,\ SUM_{gj} \neq bad\}$. Notice that if $\text{Prob}(bad \neq S) > 0$, then S's cardinality is greater than $2n/3$. (Indeed, $SUM_{gG} \neq bad$ for all good players g and G.) Also notice that $\sum_{|S|>2n/3} \text{Prob}(bad \neq S) = 1$. (Indeed, in any of our random executions, there must be more than $2n/3$ good players.)

We now lower-bound P_1 as follows.

$$\begin{aligned}P_1 &= \sum_{|S|>2n/3} \text{Prob}(\forall j \in S\ sum_j \neq 0 | bad \neq S) \cdot \text{Prob}(bad \neq S) \\ &\overset{\text{Lemma 7}}{=} \sum_{|S|>2n/3} (1 - 1/n)^{|S|} \cdot \text{Prob}(bad \neq S) \\ &\geq \sum_{|S|>2n/3} (1 - 1/n)^n \cdot \text{Prob}(bad \neq S) > e^{-1} \cdot \sum_{|S|>2n/3} \text{Prob}(bad \neq S) = e^{-1}.\end{aligned}$$

Since our lower bounds on P_0 and P_1 do not depend on n, A, or IQ, we have proved that the fairness of protocol OC is $\min(P_0, P_1) = \min(1 - e^{-2/3}, e^{-1}) = e^{-1} > .35$. □

[36] The bad players may also contribute to raising the probability of the coin being unanimously 0. For instance, it is enough that, for some bad player j, the adversary acts so that for all good g, $SUM_{Gj} \neq bad$. By Lemma 7, sum_j then has a $1/n$ chance of being equal to 0. Our lower bound, however, must hold for all possible adversaries; thus we have to disregard this probability from our computation since it may be 0 for some adversaries. Instead, we must consider and guard against such possible behavior of the adversary when lower-bounding the probability of the coin being unanimously 1.

8. Byzantine agreement from oblivious common coins.

8.1. The notion of Byzantine agreement. When Byzantine agreement is needed, the values to be agreed upon may have arbitrary length. Without loss of generality, however, we restrict our attention to the case where every initial value is a single bit; in fact, in [13] and [37], it is proved that general Byzantine agreement is reducible to the binary case in a constant number of rounds.

DEFINITION 15. *We say that a protocol P is a* Byzantine agreement protocol (with fault-tolerance c) *if, for all c-adversaries A, any string H_A^0, any number of players n, and any bits $b_1, \ldots, b_n$, in any execution of $P(n)$ with adversary A on initial adversarial history H_A^0 and inputs $b_1, \ldots, b_n$, there exists a bit d such that the following two properties hold:*

1. Consistency: *Every good player that halts outputs d.*
2. Validity: *If there exists a bit b such that, for all initially good player i, $b_i = b$, then $d = b$.*

Notice that the above definition does not require that a Byzantine agreement protocol ever terminate. A Byzantine agreement protocol is most interesting, however, only if it terminates with positive probability, has high fault tolerance, and requires only a "moderate computational effort" from the good players.

8.2. An optimal Byzantine agreement protocol. We are finally ready to construct our Byzantine agreement protocol from our discussed primitives. It consists of three basic subprotocols: $\mathcal{P}_r$, $\mathcal{P}_1$, and $\mathcal{P}_0$. Subprotocol $\mathcal{P}_r$ includes instructions for "randomly flipping" an oblivious common coin. Protocols $\mathcal{P}_0$ and $\mathcal{P}_1$ actually consist of protocol $\mathcal{P}_r$, where the outcome of the coin flip is *forced* to be, respectively, 0 and 1. Thus, although the coin flips of subprotocols $\mathcal{P}_0$ and $\mathcal{P}_1$ are predictable, they have the advantage that all good processors are "aware" of the result, and this result is always the same for all good processors.

The goal of protocol $\mathcal{P}_r$ is to give the network a chance of reaching an "oblivious agreement" (i.e., with positive probability, all players adopt the same bit without knowing that this has happened). The goal of protocols $\mathcal{P}_0$ and $\mathcal{P}_1$ is to provide a *proof*, if all players are in oblivious agreement, that agreement has indeed been reached, so as to allow everyone to terminate. More precisely, if the good players obliviously agree on 0 (respectively, 1), an execution of $\mathcal{P}_0$ (respectively, $\mathcal{P}_1$) makes them aware that they are in agreement on 0 (respectively, 1) and terminate.

Our Byzantine agreement protocol is not a fixed-round protocol. Rather, each good player i keeps on executing, in order, subprotocols $\mathcal{P}_r$, $\mathcal{P}_0$, and $\mathcal{P}_1$ until he *individually* terminates. It thus may happen that different good processors terminate at different rounds. Nonetheless, in a random execution with a 1/3-adversary, our protocol terminates with probability 1, and when that happens, the outputs of all good players, though produced at different times, will always satisfy the consistency and validity requirements.

THEOREM 4. *BA is a Byzantine agreement protocol with fault tolerance* 1/3 *and runs in expected polynomial time and in an expected constant number of rounds.*

(More precisely, there exists a polynomial Q and constant c such that, for any number of players n, any 1/3-adversary A, any initial quantities IQ, and any positive integer k, the probability that, in randomly executing $BA(n)$ with A on IQ, the protocol does not halt within $Q(n)k$ BA-steps and ck rounds is less than 2^{-k}.)

Proof. Let us start by establishing a convenient notation.

LOCAL DEFINITIONS. *In an execution of BA, we call a good player* dead *if he has already terminated and* alive *otherwise.*

PROTOCOL $BA(n)$

Input for player i: b_i, a bit. "We actually consider b_i as a variable of player i whose initial value coincides with i's input bit."

Code for every P layer i.

0: For all players j, set $B_j = 0$. "B_j represents the last one-bit message received from player j."

(Subprotocol $\mathcal{P}_r$.)

1: Distribute b_i.

2: For all j, if $b_j^* \in \{0,1\}$, then reset $B_j := b_j^*$; else, reset $b_j^* := B_j$. Let $count_i = tally(1)$.

"In other words, for the purpose of computing $tally(1)$, if you did not receive a bit from player j, assume that he *virtually* sent you the same bit that he *really* sent you last."

Run $OC(n)$ and let r_i be your output. Then:

(a) If $count_i \in [0, n/3)$, then reset $b_i := 0$. Else:

(b) If $count_i \in [n/3, 2n/3)$, then reset $b_i := r_i$. Else:

(c) If $count_i \in [2n/3, n]$, then reset $b_i := 1$.

(Subprotocol $\mathcal{P}_0$.)

3: Distribute b_i.

4: For all j, if $b_j^* \in \{0,1\}$, then reset $B_j := b_j^*$; else, reset $b_j^* := B_j$. Let $count_i = tally(1)$. Then:

(a) If $count_i \in [0, n/3)$, then output 0, distribute 0 in next round, and TERMINATE

"In a round from now, you will be dead and will keep on *virtually* distributing 0. Every other good player is either dead and his output is 0, or will terminate, outputting 0."

(b) If $count_i \in [n/3, 2n/3)$, then reset $b_i := 0$. Else:

(c) If $count_i \in [2n/3, n]$, then reset $b_i := 1$.

(Subprotocol $\mathcal{P}_1$)

5: Distribute b_i.

6: For all j, if $b_j^* \in \{0,1\}$, then reset $B_j := b_j^*$; else, reset $b_j^* := B_j$. Let $count_i = tally(1)$. Then:

(a) If $count_i \in [0, n/3)$, then reset $b_i := 0$. Else:

(b) If $count_i \in [n/3, 2n/3)$, then reset $b_i := 1$. Else:

(c) If $count_i \in [2n/3, n]$, then output 1, distribute 1 in next round, and TERMINATE.

"In a round from now, you will be dead and will keep on *virtually* distributing 1. Every other good player is either dead and his output is 1, or will terminate outputting 1."

Go to step 1.

Let $\mathcal{P} \in \{\mathcal{P}_r, \mathcal{P}_1, \mathcal{P}_0\}$ and $b \in \{0,1\}$. Within an execution of BA, we say that at the start (at the end) of an execution of subprotocol $\mathcal{P}$, the network is in agreement *on b if, for all good players g, either g is dead and his output is b or he is alive and the current value of variable b_g is b.*

We say that at the start (at the end) of an execution of $\mathcal{P}$, the network is in agreement *if there exists a bit b such that the network is in agreement on b.*

CLAIM T4-1. *For any subprotocol $\mathcal{P} \in \{\mathcal{P}_r, \mathcal{P}_1, \mathcal{P}_0\}$, any execution of $\mathcal{P}$ with a 1/3-adversary, and any alive good players g and G, $|count_g - count_G| < n/3$.*

Proof. Only the bad processors may send different bits to different players in the same step. Thus, at any given step, the difference between the tallies (of 1) of two good players is upper-bounded by the number of currently bad players and thus by $n/3$. ■

CLAIM T4-2. *For all $\mathcal{P} \in \{\mathcal{P}_r, \mathcal{P}_1, \mathcal{P}_0\}$, for all executions of $\mathcal{P}$ with a 1/3-adversary, and for all bits b, if the network is in agreement on b at the start of the execution, it is in agreement on b at its end.*

Proof. Since each execution of subprotocols $\mathcal{P}_1$ and $\mathcal{P}_0$ is in essence a special execution of $\mathcal{P}_r$, it is sufficient to prove our claim with respect to this latter protocol. Assume that at the start of $\mathcal{P}_r$, the network is in agreement on 0; that is, every good dead player outputs 0 and, for all good alive players g, $b_g = 0$. Then all good players ("really" the alive ones and "virtually" the dead ones) distribute 0 in step 1. This implies that only the bad players can distribute 1 in step 1; thus in step 2, for all good alive g, $count_g < n/3$. As a consequence, independently of his own output of subprotocol OC, at the end of step 2, each good alive player g sets $b_g := 0$ in accordance with instruction 2(a); that is, the network is in agreement on 0 at the end of $\mathcal{P}_r$. The case in which the network is in agreement on 1 at the start of $\mathcal{P}_r$ is handled similarly. ■

CLAIM T4-3. *In any execution of BA with a 1/3-adversary, whenever a good player outputs a bit, the network is in agreement on that bit.*

Proof. A good processor generates an output only during the execution of either subprotocol $\mathcal{P}_1$ or subprotocol $\mathcal{P}_0$. Let E be the first execution of either $\mathcal{P}_1$ or $\mathcal{P}_0$ in which a good player produces an output, and let g be one such player. Assume that E is an execution of $\mathcal{P}_0$; then all good players are alive during E, and g must output 0 at E's end. Thus at E's end, $count_g \in [0, n/3)$. Therefore, by Claim T4-1, for all good G, $count_G \in [0, 2n/3)$. This entails that, because of either rule (a) or rule (b), every good player G resets $b_G := 0$; that is (because there are no dead good players), the network is in agreement on 0 at the end of E (though only those good players whose counter belongs to $[0, n/3)$ are aware of this and will thus output 0 and terminate). If there are no more executions of either $\mathcal{P}_1$ or $\mathcal{P}_0$ in which a good player outputs a bit, then we are done. Otherwise, because of Claim T4-2, since the network is in agreement on 0 at E's end, it will remain in agreement on 0 thereafter. Thus, whenever a good player outputs a bit later on, this bit must be 0, in accordance with our claim. The case in which E is an execution of $\mathcal{P}_1$ is argued in the "symmetric" way. ■

CLAIM T4-4. *For any random execution of BA with a 1/3-adversary and any positive integer k, if the network is not in agreement at the start of the kth execution of subprotocol $\mathcal{P}_r$, then the probability that it will be in agreement at its end is greater than .35.*

Proof. Because of Claim T4-3, our hypothesis implies that all good players are alive throughout our execution of $\mathcal{P}_r$. Moreover, since by Claim T4-1 we have $|count_g - count_G| < n/3$ for any good players g and G, one of the following two cases must occur:

(0) $\forall good\ i,\ count_i \in [0, 2n/3)$, or

(1) $\forall good\ i,\ count_i \in (n/3, n]$.

When case (0) occurs, if the oblivious common coin is unanimously 0, then each good player i resets $b_i := 0$ (if $count_i \in [0, n/3]$ because of rule 2(a), if $count_i \in (n/3, 2n/3)$ because of rule 2(b)) and thus the network is in agreement on 0. Similarly, when case (1) occurs, if the oblivious common coin is unanimously 1, then every good processor i resets $b_i := 1$ and thus—since there are no dead good players to worry about—the

network is in agreement on 1. Since either case (0) or case (1) must occur, and since OC is an oblivious coin protocol with fairness .35, the probability that the network is in agreement at the end of a random execution of $\mathcal{P}_r$ (though the good players may not be "aware" of this event) is greater than .35. ■

CLAIM T4-5. *In any execution of BA with a 1/3-adversary, if at the beginning of an execution of subprotocol $\mathcal{P}_1$ (respectively, $\mathcal{P}_0$), the network is in agreement on 1 (respectively, 0), then one round after the end of the subprotocol execution, BA terminates and the output of every good player is 1 (respectively, 0).*

Proof. Assume that the network is in agreement on 1 at the beginning of an execution of $\mathcal{P}_1$ (the "0 case" is similarly handled). Then all dead good processors have output 1 prior to the present execution of $\mathcal{P}_1$, and all alive good processors distribute 1 in the first step of the execution. Thus, since their tallies of 1 belong to the interval $(n/3, n]$, all good (and alive) processors will perform instruction 4(c) throughout this execution. Therefore, each one of them outputs 1 and will terminate in the next round, unless he will get corrupted in the next round, an event that cannot, in any case, change the output of the still uncorrupted players or the termination of the protocol since, as usual, BA ends when all good players have terminated. ■

It is now easy to complete the proof of Theorem 4; we start by proving our claim about BA's round complexity and fault tolerance. $\mathcal{P}_r$ is a 36-round protocol, while $\mathcal{P}_0$ and $\mathcal{P}_1$ are both two-round protocols. Protocol BA iterates the ordered execution of $\mathcal{P}_r, \mathcal{P}_0$, and $\mathcal{P}_1$ until all good players terminate. Claim T4-4 guarantees that, no matter what the initial quantities and the strategy of a 1/3-adversary may be, in a random execution of BA, the probability that an "oblivious" agreement is not reached after the $2k$th execution of $\mathcal{P}_r$ is less than $(.35)^{2k} < 2^{-k}$. Once oblivious agreement is reached at the end of an execution of $\mathcal{P}_r$, Claim T4-5 guarantees that, no matter what the actions of the 1/3-adversary may be, protocol BA halts—with all the good processors "aware" of having reached Byzantine agreement—within the next five rounds (i.e., at most one round after the end of $\mathcal{P}_1$ if the agreement was on 1). Thus the probability that protocol BA does not reach Byzantine agreement within $80k + 5$ rounds is less than 2^{-k}.

Let us now prove our claim about the amount of local computation of protocol BA. Having set (hidden) message bounds, the good processors do not waste running time reading excessively long messages sent by the adversary. Moreover, except for some occasional random selections, each round of protocol BA can be performed in fixed polynomial-in-n time. As for those random selections, they consist of the random choices of elements in integer intervals of the form $[0, z-1]$. Now, whenever z is a power of 2, a random selection in $[0, z-1]$ can be performed by flipping $\log z$ coins—and thus in fixed (as opposed to expected) polynomial time by a probabilistic Turing machine. However, if z is not a power of 2, then the adopted strategy for this task consists of randomly selecting a $\lceil \log z \rceil$-bit string until a member of the desired interval is found. Clearly, the probability that more than T such trials are needed is less than 2^{-T}. Since in each iteration of $\mathcal{P}_r$, $\mathcal{P}_0$, and $\mathcal{P}_1$, at most $Q(n)$ such selections (where Q is a given polynomial) must be made by the good players, since the rest of the computation can be performed in fixed polynomial time, and because of our recently proven claim about the round complexity of BA, our claim about the running time of BA easily follows. □

Remarks.

• Our reduction of Byzantine agreement to (oblivious) common coins was inspired by an earlier work of Rabin [34]. His reduction is much simpler, but it assumes a common coin that not only is *externally provided* but also is not oblivious (i.e., all

players are *guaranteed* to see the same common random bit[37]), and it requires that the number of faults is $< n/4$.

• As we have seen, protocol BA enjoys the property of being *always correct and probably fast*; that is, our use of probabilism introduces some uncertainty of how long it will take to terminate (a modest uncertainty since we prove that the expected number of rounds is constant), but no possibility of error in the correctness of the final agreement. This desirable property implies that one cannot get rid of "expected" in our round complexity. In fact, an algorithm that reaches a guaranteed agreement in a fixed number of rounds, no matter what the sequence of its coin tosses may be, is immediately transformed to a fixed-round, deterministic algorithm. Thus the result of Fischer and Lynch [20] would imply that at least $O(n)$ rounds are needed if the number of possible faults is $O(n)$.

• In general, as we have said, the input of a processor is a *private* value; that is, the adversary has no way of knowing it unless she corrupts its corresponding processor or this processor is instructed by the protocol to divulge it. Privacy of the initial inputs is also a necessary condition for certain protocols to be meaningful. This is indeed the case, for instance, with protocol *GradedVSS*—indeed, unless the input of an honest dealer is secret, there is no hope that an adversary cannot guess it better than at random. In the case of Byzantine agreement, on the other hand, the privacy of the initial inputs plays no role in defining the problem, which in fact remains totally meaningful even if we assume that the players' initial bits are known to the adversary.[38] Indeed, it should be noted that our protocol BA instructs each good player to distribute his input bit at the very first step, and it thus works even in the case in which the adversary knows the input bits of all players in advance.

• As we know, protocol BA relies on subprotocol OC. One may describe this subprotocol as producing a bit that is "sufficiently random and common." Such a description would, however, be quite incomplete. Namely, the output of OC is also sufficiently *unpredictable* at the start of each execution of the protocol. In fact, if the fairness of the coin that OC produces is positive, then we know that in any random execution both 0 and 1 have a positive probability of being output. It should be noticed that this unpredictability is used in our Byzantine agreement protocol: in protocol $\mathcal{P}_r$, "the oblivious coin" is flipped *after* every processor i distributes his current value b_i; thus in step 1, the adversary must choose which values the bad players distribute when the oblivious coin is still unpredictable. Actually, the unpredictability of the oblivious common coin flip is more than merely *used* in our protocol; it is actually *crucial* to it: should the adversary know the result of the coin flips of OC in advance, she could prevent agreement indefinitely. In fact, a bit more precisely, it can be shown that if all processors have as a common input—at the beginning of the protocol—a sequence of *truly random and independent* (but also, necessarily, *predictable*) coin tosses and use these bits instead of the outcomes of OC in subprotocol $\mathcal{P}_r$, a 1/3-adversary can easily and indefinitely prevent agreement from being reached.

The above discussion can be summarized by saying that our protocol BA relies heavily on hiding—at least temporarily—information. We will further elaborate on this crucial point in section 9.2.

• As we have indicated, the good processors need not terminate simultaneously. Indeed, the adversary can force "staggered termination" if she so desires.

• To avoid staggered termination, one may consider iterating subprotocol $\mathcal{P}_r$ a

[37] In his scenario, random coin flips are "predistributed" by a trusted party. Thus once they are "revealed," all good processors will see the same result.

[38] This is a quite plausible scenario since bad guys tend to "know" more than good ones.

prescribed number of times. If this number of times is large enough, upon termination, agreement would be reached with high probability. However, such a protocol would be unsatisfactory. First, from a theoretical point of view, it would introduce a probability of error. (In other words, there would be a chance that upon termination the good processors may not be in agreement—an event that is not allowed by our definition.) Second, from a "practical" point of view, to ensure that agreement is reached with probability $1 - 2^{-k}$, the envisaged protocol would have *always* to run $\mathcal{P}_r$ k times. By comparison, our protocol will run $\mathcal{P}_r$ k times only "very seldomly," that is, with probability 2^{-k}. (Truly, each time that our protocol runs $\mathcal{P}_r$, it also runs $\mathcal{P}_0$ and $\mathcal{P}_1$, but these latter protocols require only two rounds each and are extremely simple. The brunt of the computation is constituted by $\mathcal{P}_r$ alone, which is a quite complex 34-round protocol.)

• It should be noticed that, since some good processors may be alive and some others may be dead, in some executions of $\mathcal{P}_r$, there may not be a 2/3 majority of good processors. In fact, the dead ones do not participate in the protocol but simply "virtually" send a bit at given times. Under these circumstances, the coin tosses of OC need not to be common or fair in any way. This is not a problem, though. As we have shown, when a good processor terminates, the processors are in agreement and agreement cannot be disrupted. Protocol $\mathcal{P}_r$ is thus executed at most once without an honest majority of players; in fact, all alive good processors will terminate one round after the next execution of either $\mathcal{P}_0$ or $\mathcal{P}_1$, whose coin toss the adversary does not control.

9. Adjustments and improvements.

9.1. The model independence of our Byzantine agreement protocol.

Pros and cons of standard networks. In presenting our Byzantine agreement protocol, following a time-honored tradition, we have chosen standard networks (i.e., networks in which every pair of processors is connected by a dedicated and private communication line) as its underlying communication model. This model has notably simplified our argument and has helped us to focus on the *essential* distributed aspects of the quintessentially distributed problem at hand without getting sidetracked by a variety of important but quite different issues. (*Essence*, of course, is in the eyes of the beholder!) Moreover, the standard-network model is quite realistic in some contexts—for instance, in the case of computer networks whose processors are not directly controlled by humans.[39] Unfortunately, this is also the context in which, in our opinion, Byzantine agreement is less meaningful, at least for the extremely malicious fault model addressed in this paper—which, regrettably, belongs to the domain of human interactions. As a matter of fact, people being what they are, private channels may prove to be too much of an abstraction. If a Byzantine agreement protocol were run in the context of an adversarial negotiation conducted in a computer network, it would be remarkable that impostors would chivalrously confine themselves to purely software attacks, refraining from tampering with the network itself. Indeed, if they did, communication channels would not remain "private" for too long, no matter how much metal they could be shielded with or how deep they could be routed. We thus wish to briefly discuss what happens to our algorithm when its communication model is more... "humanized."

[39] Indeed, when such computers malfunction, they may start running algorithms that are different from their intended ones, may act—due to Murphy's law—as if they coordinate their disruptful efforts, and so on, but they cannot gain access to the dedicated line connecting two properly working processors!

Other possible models. If the adversary may prevent messages between good processors from being delivered, Byzantine agreement would be impossible. However, we may still trust our network to be asynchronous; that is, the adversary might delay messages arbitrarily long but cannot prevent them from eventually reaching their intended recipients. (For a discussion of this model, consult, for instance, [19].) Fortunately, our Byzantine agreement protocol has been ingeniously extended by Feldman [17] and Canetti and Rabin [7] to work on asynchronous networks as well.

If the adversary is able to change the messages exchanged between two good processors, Byzantine agreement would also be impossible since a single faulty processor could impersonate as many processors as it likes. Alternatively, the adversary may be capable of reading messages between good processors but not altering them.[40] In either case, one can still run our protocol using cryptography to simulate the privacy of such "public" lines (assuming, of course, that the adversary is computationally bounded). The basic underlying idea is that injecting or altering messages may be made infeasible by secure digital signatures that are secure in the sense of [25], while reading messages can be made infeasible by an encryption scheme that is secure in the sense of [23]. (One caveat, however: for very subtle reasons that exceed the scope of this paper, this basic strategy is surprisingly hard to implement correctly.)

If the adversary can "disconnect" two good processors, Byzantine agreement would again be impossible. However, rather than assuming that our network is complete, we may trust that it has some special, uncorruptable nodes that do not perform any computation but simply reliably route properly labeled messages. (Indeed, this may allow for quite sparse networks.) In this setting, our protocol would work essentially without any changes and with the same efficiency. Alternatively, one may consider networks with fewer communication lines but with sufficiently high connectivity. This way, for every set of faulty processors with small enough cardinality, every two good processors are still connected by a path consisting solely of good processors. Solving the problem in this new setting would require encrypting each message and sending it to its recipient through several node-disjoint paths. This, of course, would increase the running time of our protocol by a "network-topology" factor, but, most likely, the same increase in running time would be suffered by other protocols.

9.2. Improvements of our results. Our results have been found useful in several ways.

• As we have already mentioned in subsection 9.1, our Byzantine agreement protocol has been extended by Feldman [17] to work on asynchronous networks in which each pair of players is connected by a private channel. His asynchronous protocol tolerates up to $t < n/4$ faults. Using cryptography and assuming a computationally bounded adversary, it regains optimal fault tolerance, $t < n/3$, in the asynchronous case as well. Quite recently, Canetti and Rabin [7] have exhibited (for the same networks) an asynchronous Byzantine agreement protocol running in expected constant time and possessing resiliency 1/3 against an adversary with unbounded computational capabilities—though allowing a probability of error. (Let us note in passing that the notion of "constant time" must—and can—be meaningfully formulated in the asynchronous setting.)

• Ben-Or and El-Yaniv [4] have extended our algorithm to to reach Byzantine agreement in standard networks, in an expected constant number of rounds, for an entire collection of players' initial values.

[40] This may be the case in an ordinary telephone network, whose lines can be easily eavesdropped, while the voices of its users may be hard to imitate.

• Using our results and those of [4], Micali and Rabin [29] have obtained a VSS protocol (i.e., a "nongraded one"!) that works in standard networks (rather than standard-plus-broadcast ones), runs in polynomial time and an expected constant number of rounds, and tolerates any $n/3$ faults in the worst model. They have also exhibited a *nonoblivious* common coin protocol, with fairness $1/2$ and fault tolerance $1/3$, that works in standard networks and runs in expected polynomial time and an expected constant number of rounds. (Dolev, Dwork, and Yung have informed them that they have independently found these same protocols.)

• Goldreich and Petrank [27] have shown how to modify our algorithm so as to keep its expected running time and round complexity, while guaranteeing termination in the worst case (i.e., with the most unlucky sequence of coin tosses) in $t + O(\log t)$ rounds whenever the upper bound on the number of faulty players is t. (Thus termination is guaranteed in $O(n)$ rounds in the worst-fault model.)

10. Significance.

10.1. The "right" significance of Byzantine agreement. Until now, we have been advocating that Byzantine agreement is "the best one can do, in an adversarial scenario, when broadcasting is impossible." At this point, having gained more experience with adversarial behavior, we wish to point out that this informal saying is misleading in that it seems to imply that broadcasting is an available resource, and only when you are deprived of it should you turn to Byzantine agreement as a meaningful substitute. The truth is that, in an adversarial setting, closer scrutiny reveals broadcasting to be "almost always impossible."

Consider, for instance, a radio network. The recipient of a message in such a network cannot tell whether a satellite has aimed its signal to his specific geographical area or to the whole country. Moreover, since imitating (or cutting and pasting recorded pieces of) one's voice is quite possible, the recipient of a radio message cannot have any certainty about the identity of the sender of the message. Indeed, in an adversarial setting, *broadcasting is an abstraction.* Thus a natural question arises:

> In what "reasonable" communication models can one "concretely implement" an abstract notion satisfactorily close to that of broadcasting?

It is in light of this question that Byzantine agreement achieves, in our view, its true significance; namely, it demonstrates that standard networks offer a reasonable communication model to approximate, despite the presence of adversaries, the abstract notion of a broadcasting. Better said:

> We regard Byzantine agreement as showing that the abstraction of broadcasting can be meaningfully approximated by "simpler" abstractions: strong honest majority, synchrony, and private channels (and by even simpler ones, as we have discussed in section 9.1).

10.2. The significance of our results. It is now time to ask ourselves, "What is the significance of our own result?"

While our simplest primitives—*Gradecast* and, for small n, *GradedVSS*—are quite practical, we do not expect our Byzantine agreement protocol to have a *direct* practical impact. In fact, though it does not have any monstrous "hidden constants" and is actually quite feasible, our protocol starts outperforming prior ones when run in standard networks (or networks with "simulated standardness," as discussed in section 9.1) with a few hundred players.[41]

[41] Should standard networks of this size become feasible, our result actually opens the possibility of *artificially increasing* the number of players so as to increase the reliability of the network without

However, our results should have an *indirect* practical impact. Solving a long-standing open problem always marks a technical advance in a given field, and it is reasonable to expect that in our case as well this increased level of understanding will eventually translate into more practical protocols than ours.

More importantly, our techniques will be quite effective when dealing with much more complex problems than Byzantine agreement, that is, with those problems for which the existence of any solution is by itself a blessing and no superpractical answer can be legitimately expected.[42] In fact, it should be appreciated that our protocol solves a more difficult problem than Byzantine agreement (a fact that may perhaps excuse some of our complications): it provides a reasonably fair and fault-tolerant coin-flipping protocol in a quite unmanageable communication and fault model.[43]

Finally, *scientists shall not live by technique alone*, and we now wish to argue that our result is more significant from a purely conceptual point of view.

Probabilism versus determinism. Can randomness speed up computation? This is one of the most intriguing and fundamental questions of complexity theory. The celebrated probabilistic algorithms for primality *testing* of Solovay and Strassen [36] and Rabin [33] (and the more recent and equally beautiful ones for primality *proving* of Goldwasser and Kilian [22] and Adleman and Huang [1]) show that efficient probabilistic solutions exist for problems for which no polynomial-time solution is yet known. We cannot, however, prove that no deterministic, polynomial-time primality algorithm exists. Indeed, the fact that generating a sequence of coin tosses, independently from the problem at hand, may help solve our problem much faster is quite puzzling.

From this point of view, our result takes on a more serious significance. Namely, contrasting its performance with the quoted $t + 1$-round lower bound [20] for any deterministic protocol in which t malicious faults may occur, our Byzantine agreement protocol offers a dramatic example that, at least in some scenarios, probabilistic solutions *are provably vastly superior* to all deterministic ones.

Such a speedup was already demonstrated by Rabin [34], but by making the additional assumption of a common source of randomness *external to the network:* a common coin toss magically available to all processors at every clock tick. We instead demonstrate that randomness alone (i.e., individual and independent random choices made by individual processors), without any additional assumptions, suffices to beat any deterministic Byzantine agreement protocol in a dramatic way.

Privacy versus correctness. Our probabilistic solution to the synchronous Byzantine agreement problem sprung from recent advances in the field of *zero-knowledge computation.* Roughly said, this is the science of communication protocols that need to satisfy both a *correctness* and a *privacy* requirement. (For example, following the original application of Goldwasser, Micali, and Rackoff [24], a *zero-knowledge proof* shows that a given statement indeed possesses a correct proof but does not reveal what this proof might be.)

It should be noticed, however, that while Byzantine agreement has subtle correct-

making the time needed to reach agreement helplessly long. (In fact, if we know that—say—10% of the players are expected to become faulty during a decade, to ensure that 2/3 of them will be working properly in such a period, we are better off having a network of hundreds of processors rather than just a dozen of them.)

[42] Indeed, the usefulness of our algorithm for solving the problems mentioned in section 10.1 provides some support for this claim, and it augurs wonderfully for future ventures.

[43] Indeed, flipping a coin with adversaries does not get much easier even in friendlier scenarios than ours.

ness requirements, it has no constraints whatsoever about privacy.[44] Nonetheless, the correctness and speed of our protocol depend in a fundamental way on *GradedVSS*, a protocol where privacy *is* the central issue. We thus wish to advocate a novel role for privacy: namely, a tool for reaching correctness. This is less puzzling than it sounds. Our intuition behind it is simple:

> *Error in computation can be modeled as an adversary, and if your adversary "knows little," she can do little to disrupt your computation.*

Indeed, we believe that privacy will become a fundamental ingredient in the design of fault-tolerant protocols. Are we right? Time will tell. But may our journey be enjoyable in any case.

Acknowledgments. We are particularly grateful to Michael Fischer, Rosario Gennaro, Nancy Lynch, and David Shmoys for their generous, attentive, and constructive criticism.

Special thanks go to Ray Sidney, Tal Rabin, and Philip Rogaway. As we have already mentioned, the second author has collaborated with Philip Rogaway in modeling computation in the presence of faults in more complicated scenarios than the present one. The computational model of this paper has benefitted from the insights gained during that collaboration.

We would also like to acknowledge Michael Ben-Or, Benny Chor, Cynthia Dwork, Peter Elias, Rosario Gennaro, Oded Goldreich, Shafi Goldwasser, and Michael Rabin for many wonderful discussions about the Byzantine agreement problem.

Thanks also to two anonymous referees for their wonderful comments. The present version of our paper corresponds to the point in which one referee lamented that formalization exceeded intuition and another that intuition outmatched formalization.

Finally, our main motivation for working on the Byzantine agreement problem came from the *beauty* and *novelty* of the ideas of those who preceded us. We have immensely enjoyed standing on such tall shoulders!

ERROR-RESILIENT OPTIMAL DATA COMPRESSION*

JAMES A. STORER† AND JOHN H. REIF‡

Abstract. The problem of communication and computation in the presence of errors is difficult, and general solutions can be time consuming and inflexible (particularly when implemented with a prescribed error detection/correction). A reasonable approach is to investigate reliable communication in carefully selected areas of fundamental interest where specific solutions may be more practical than general purpose techniques.

In this paper, we study the problem of error-resilient communication and computation in a particularly challenging area, *adaptive lossless data compression*, where the devastating effect of error propagation is a long-standing open problem that was posed in the papers of Lempel and Ziv in the late 1970s. In fact, the non-error resilience of adaptive data compression has been a practical drawback of its use in many applications. Protocols that require the receiver to request retransmission from the sender when an error is detected can be impractical for many applications where such two-way communication is not possible or is self-defeating (e.g., with data compression, retransmission may be tantamount to losing the data that could have been transmitted in the mean time). In addition, bits of encoded data that are corrupted while data is in storage will in general not be recoverable and may corrupt the entire decompressed file. By *error resilience*, we mean that even though errors may not be detected, there are strong guarantees that their effects will not propagate.

Our main result is a provable error-resilient adaptive lossless data-compression algorithm which nevertheless maintains optimal compression over the usual input distributions (e.g., stationary ergodic sources). We state our result in the context of a more general model that we call *dynamic dictionary communication*, where a sender and receiver work in a "lock-step" cooperation to maintain identical copies of a *dictionary D* that is constantly changing. For lossless data compression, the dictionary stores a set of strings that have been seen in the past and data is compressed by sending only indices of strings over the channel. Other applications of our model include robotics (e.g., remote terrain mapping) and computational learning theory.

Key words. data compression, adaptive algorithm, communication channel, error propagation

1. Introduction.

1.1. Dynamic dictionary communication.

We use the term *dynamic dictionary* communication to refer to the process of transmitting data over a communication channel that is encoded/decoded with respect to dynamically changing dictionary of data. As depicted in Figure 1, a sender generates an *input stream* of characters drawn from a fixed finite-input alphabet, which are encoded, transmitted over a communication channel (or saved on a storage device), decoded, and received as the *output stream*. The encoder and decoder cooperate to maintain identical copies of a *dictionary D* that is constantly changing. The encoder reads characters from the input stream that form an entry of D, transmits the index of this entry, and updates D with some method that depends only on the current contents of D and the current match. Similarly, the decoder repeatedly receives an index, retrieves the corresponding entry of D to write to the output stream, and then performs the same algorithm as the encoder to update D. Note that although both the encoding and decoding algorithms refer to their dictionary as D, errors on the communication channel or storage medium

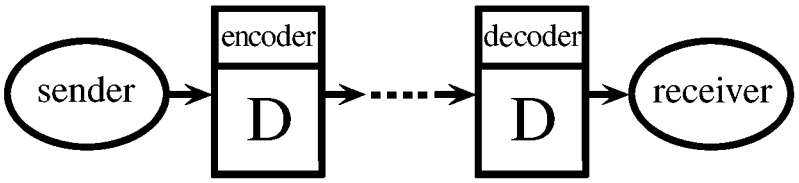

FIG. 1.1. *Dynamic dictionary communication.*

may cause the decoder's dictionary to differ from that of the encoder. Note also that D contains a set of entries (so when we talk about adding a new entry to D, we always mean to add it if it is not already present).

1.2. Applications of dynamic dictionary communication. The major application of dynamic dictionary communication that motivates this work is adaptive lossless data compression by textual substitution (Storer and Szymanski [1978]), where the dictionary stores a set of strings that have been seen in the past and data is compressed by sending only indices of strings over the channel; such compression algorithms are often called "LZ algorithms" after the work of Lempel and Ziv [1976] and Ziv and Lempel [1977, 1978]. (See Storer [1988] for an introduction to the subject and references to the literature.) Other possible applications of dynamic dictionary communication include computational learning theory and robotics (e.g., reporting of data by an autonomous remote robot that is mapping unexplored terrain and transmitting coordinates as displacements from previous locations).

1.3. Error resilience. A potential drawback of dynamic dictionary communication is *error propagation*; that is, a single error on the communication channel (e.g., insertion, deletion, or change of an index sent on the channel) could cause the dictionaries of the encoder and decoder to differ, which in the worst case could corrupt all data to follow. That is, since decoding is guaranteed to be correct only when the dictionary remains the same as the one used to encode the data, there is no way to bound the effects of a single error in the worst case. With *one-way* communication channels, where the decoder cannot send messages to the encoder, the problem becomes even more critical. In addition, with many existing communication systems where the full bandwidth of the channel is consumed, even if a two-way channel is available to let the encoder know that an error has occurred, retransmission of data can often be tantamount to losing new data that could have been transmitted during the time used to retransmit the old data. Retransmission can also introduce further error propagation problems. In addition, a data-storage device where data may be corrupted during storage can be viewed as a one-way communication channel.

In some sense, dynamic dictionary communication can be viewed as "raising the stakes" for the effects of errors on a one-way channel; even if the chance of an error is made very small via a standard error-detection/correction protocol, if an error does occur on a single data item, it can have the catastrophic effect of corrupting an unbounded number of additional data items. We present a technique for "error resilience," where no attempt is made to detect or correct errors but strong guarantees are provided that errors do not propagate. This technique can be combined with standard error-detection/correction protocols to yield one-way dynamic dictionary communication with a low rate of errors that do not propagate.

1.4. Outline. The next section contains basic definitions; it formally defines the dynamic dictionary communication model, which assumes several axioms, reviews

how data compression by textual substitution fits into the model and shows that the axioms hold for key methods that are provably optimal for stationary ergodic sources (the standard assumption in data compression literature), presents a model for errors on the communication channel, and defines error-resilient communication. Section 3 then presents a scheme for protecting against error propagation from k errors for any constant k under any distribution of errors; we make no attempt to analyze how this scheme affects the amount of compression achieved (although it appears to be quite practical). In section 4, we employ randomized techniques to "expand" the k-error technique to give propagation protection with very high probability against a fixed uniformly and independently distributed error rate of probability $1/r$; in particular, for any $k \geq 1$, the probability of error propagation can be made less than $1/r^k$. For example, an error rate of $1/10^{12}$ (a relatively "clean" communication channel with a low-overhead error-correcting mechanism) can be effectively "damped" to $1/10^{48}$ by choosing $k = 4$. In addition, the generalized k-error protocol presented in section 4 has no asymptotic affect on the amount of compression achieved. Section 5 discusses practical considerations.

2. Basic definitions.

2.1. Dynamic dictionary communication. Throughout this paper, when discussing dynamic dictionary communication with respect to a dictionary D, we use the following notation:

- $|D|$ = the current number of entries in D.
- $|D_{\max}|$ = the maximum number of entries that D may contain.
- $|s|$ = the number of characters in the string s.
- $BITS(i)$ = the number of bits needed to write i in binary (i.e., $\text{BITS}(i) = \lfloor \log_2(i) \rfloor + 1$).

Generic encoding and decoding algorithms for dynamic dictionary communication are shown below. Indices of D run from 0 to $|D| - 1$ and are represented using exactly $\text{BITS}(|D| - 1)$ bits, although in practice it is often the case that for simplicity $\text{BITS}(|D_{\max}| - 1)$ bits are used for all indices. We refer to codes sent over the channel that represent indices as *pointers*.

GENERIC ENCODING ALGORITHM.

1. Initialize the local dictionary D with one entry for each character of the input alphabet.
2. **repeat forever**
   - A. {Get the current match pointer p:}
     Use a *match method* to read a string s from the input.
     p = the index of s in D.
     Transmit p using $\text{BITS}(|D| - 1)$ bits.
   - B. {Update D:}
     Add each of the strings specified by an *update method* to D.

GENERIC DECODING ALGORITHM.

1. Initialize the local dictionary D by performing step 1 of the encoding algorithm.
2. **repeat forever**
   - A. {Get the current match string s:}
     Receive $\text{BITS}(|D| - 1)$ bits for the current match pointer p.
     s = the string in D corresponding to p.
     Output s.
   - B. {Update D:}
     Perform step 2B of the encoding algorithm.

The *match heuristic* reads from the input stream a string that is in the dictionary. (It must always be possible to read such a string since all strings of length 1 are always in the dictionary.) After the match has been encoded by the encoder or decoded by the decoder, "learning" consists of modifying the dictionary by adding one or more new strings with an update heuristic. Although it is possible to have the update heuristic employ a deletion heuristic that removes old entries to make room for new ones (see Storer [1988]), we restrict our attention here to update heuristics that do nothing once the dictionary is full so that encoding and decoding continue indefinitely (or until the system is restarted) without any further modification of the dictionary.

The exact choice of the match and update heuristics is not important for the work described here as long as the following axioms are satisfied. (We shall show shortly that these axioms hold for a variety of optimal adaptive lossless data compression methods.)

Succinctness. Except for the dictionary initialization (where entries for each of the characters of the input alphabet are formed), the string (or strings) added by the update heuristic at a given step depend only on the current match and the previous match.

Robustness.

A. There is a constant $1 \leq \rho$ such if the update heuristic adds a new match based on a particular successive pair of matches, it will do so after this successive pair has occurred at most ρ times.

B. There is a constant $1 \leq \alpha$, called the *learning constant*, such that the encoder dictionary reaches size $|D_{\max}|$ after at most $\alpha\rho|D_{\max}|$ entries have been transmitted.

The succinctness axiom addresses how dictionary entries may be formed. The robustness axiom allows the system to be "conservative" and to not form a new entry until it has "proved" itself by appearing a number of times, but not too conservative because this number of times must be bounded by a constant. In addition, the learning constant ensures that progress is made toward filling up the dictionary as data is encoded (and we don't waste too much effort relearning entries that have already been added earlier). Note that condition B of the robustness axiom is somewhat pessimistic because for all of the data-compression methods that we shall consider, if ρ, $\alpha > 1$, then the encoder dictionary reaches size $|D_{\max}|$ after at most $(\alpha + \rho)|D_{\max}|$ entries have been transmitted.

For technical reasons to be discussed shortly, our results will also work for a variation of the succinctness axiom.

Succinctness, version 2. Except for the entries that contain the characters of the input alphabet, the string (or strings) added by the update heuristic at a given step depend only on the current match and the next character.

The second version of the succinctness axiom is similar to the first version except that it is "one step ahead"; it models certain update heuristics that are important for proofs of optimality in applications involving data compression. Both versions have the property that except for the characters of the alphabet, each entry of the dictionary can be constructed from a pair of pointers to two other entries; this is all that will really be needed in our construction (and, as we shall see shortly, suffices for practical data-compression algorithms).

2.2. Applications to data compression. As mentioned earlier, the major application that motivates this work is data compression by textual substitution. In this section, we review a number of textual-substitution algorithms and show that

they can be modified to satisfy the robustness axiom without sacrificing compression. Our definition of "optimal" compression is *optimal in the information-theoretic sense*; that is, for stationary ergodic sources of entropy H, after processing n characters, the method in question sends an average of $H+\varepsilon(n)$ bits per character, where $\varepsilon(n)$ goes to 0 as n goes to ∞. (See Cover and Thomas [1991] or Gallager [1968] for definitions of entropy, etc.) This asymptotic measure of performance for stationary ergodic sources is standard throughout the literature. Furthermore, the methods we discuss here work well in practice for virtually any source. (See Storer [1988] for a detailed presentation of these methods as well as experimental results.)

Typically, the match heuristic used is the *greedy heuristic*; that is, read the longest match possible. Although other heuristics can be used and the greedy match heuristic does not guarantee the best possible compression on finite strings for any of the update heuristics to be discussed below (Storer [1988]), it does perform well in practice and is used in all of the methods that are provably optimal in the information-theoretic sense. Examples of update heuristics that might be used for data compression are as follows.

Uncompressed character (UC). Add the current match concatenated with the next character of the input; the next character of the input is sent along in uncompressed form as part of the current pointer (so that the next match starts after the character following the current match). This heuristic does not fit exactly into the generic encoding and decoding algorithms, but they can easily be modified to accommodate it by not allowing a match to a single character until it has been sent to the decoder. (The cost of dictionary entries "wasted" by characters that have yet to be seen becomes arbitrarily low as the dictionary size increases.) For finite-length strings and dictionaries of bounded size, UC typically does not perform as well in practice as the NC or FC heuristics discussed below, but we include it because it reflects the construction of Ziv and Lempel [1978] that is provably optimal.

Next character (NC). Add the current match concatenated with the next character of the input. This can be viewed as a more practical implementation of UC. It also requires modifications of the generic encoding and decoding algorithms because the next character of the input stream cannot be deduced by the decoder until the following match is received. (For the special "glitch" where the string matched at the current step is the one formed at the previous step, the decoder can deduce that the first and last character of the current match are the same as the first character of the previous match.) This is the heuristic used by Welch [1984] (upon which UNIX "compress" command is based) and Miller and Wegman [1985].

First character (FC). Add the last match concatenated with the first character of the current match. This heuristic performs similarly to NC in practice, but fits cleanly into the generic encoding and decoding algorithms (and does not have the decoding "glitch" mentioned above); it is discussed in Storer [1988].

Current match (CM). Add the last match concatenated with the current match. This heuristic is discussed by Miller and Wegman [1985] and Seery and Ziv [1977, 1978]. A variant of this method is employed by Reif and Storer [1990, 1992] and Royals et al. [1993] in a massively parallel systolic custom VLSI design.

All prefixes (AP). Add the set of strings consisting of the last match concatenated with each of the prefixes of the current match. This heuristic has the fast-growing characteristics of CM but like FC, NC, and UC maintains a dictionary with the prefix property (if a string is in the dictionary, then so are all of its prefixes); it is discussed in Storer [1988].

It is easy to see that the FC, CM, and AP update heuristics satisfy the succinctness axiom and that the UC and NC update heuristics satisfy version 2 of the succinctness axiom.

For part A of the robustness axiom, observe that the learning constant is 1 for the UC and NC heuristics since the greedy match heuristic ensures that the current match together with the next character of the input stream cannot already be in the dictionary. The FC heuristic has a learning constant of ≤ 2 since the greedy match heuristic insures that the only way the last match together with the first character of the current match can already be in the dictionary is when this is the same as the current match, which can only happen once. Similarly, it can be argued that the learning constant for CM and AP is ≤ 2.

Part B of the robustness axiom is satisfied by all of the heuristics listed above for $\rho = 1$. In this paper, we will use $\rho > 1$ in our constructions for error resilience (so that a successive pair of matches may be seen several times before learning takes place). We shall not address how this modification affects the amount of compression achieved by the CM and AP heuristics since they are not provably optimal to start with (Lempel and Ziv [1990]), although they work well in practice, and restrict our attention to the FC, NC, and UC heuristics. The UC heuristic is exactly the algorithm shown optimal in Ziv and Lempel [1978]; a nice proof that it is optimal in the information-theoretic sense appears in Cover and Thomas [1991]. The essence of this proof is to show that any method that parses the input stream into distinct phrases (and sends a number of bits equal to $\varepsilon(n)$ of the current number of phrases to the decoder) must be optimal. Furthermore, as outlined in the appendix, this proof can be modified to show that a *constant-redundant parsing* (one where there is a constant that bounds how many times any phrase may appear in the parsing) is also optimal. Hence a "redundant" version of UC is optimal. In addition, we also show in the appendix that redundant versions of FC and NC are optimal.

2.3. Bounded-size dictionaries. Theoretical proofs of optimality such as presented in Lempel and Ziv [1976] and Ziv and Lempel [1977, 1978] simply assume that the dictionary grows indefinitely as the infinitely long input stream is processed. However, a practical strength of the compression methods outlined earlier is that relatively small bounds on the size of the dictionary (e.g., 2^{12} to 2^{16} entries) provide good performance in practice on virtually all types of data. As mentioned earlier, we take the same approach here and simply assume that once the dictionary fills, it remains fixed for the remainder of the data to be processed (so that the update heuristic is defined to add nothing once the dictionary is full). Although this strategy typically works well on individual files, in practice some method for changing the dictionary over time after it has filled is usually incorporated into the algorithm. (See Storer [1988] for discussion of various strategies.) For example, the UNIX compress command monitors compression and restarts the dictionary-growing process if compression falls off after the dictionary is full. Another simple strategy is a "swapping" arrangement with two dictionaries, where after the dictionary fills for the first time, continue using it to compress data but at the same time start forming new entries in a second dictionary; once the second dictionary is full, it can be used for compression and the first dictionary reset to be empty, and so on. Since restarting or changing of dictionaries occurs infrequently, very secure protocols (e.g., several hundred bits to encode a single bit) can be used to periodically restart the process or to send a swap bit. Such a protocol can also be used to agree that the dictionaries are now "frozen" and will not be modified further. We shall not address these issues further in this

paper.

2.4. A model for error-resilient communication. We use the term *communication channel* to refer to any medium or device over which data is transmitted and received. We assume that pointers sent from the encoder to the decoder over a communication channel are subject to the following errors:

- *add:* An extra pointer, chosen at random, is inserted into the communication stream.
- *delete:* A pointer is deleted from the communication stream.
- *change:* A new pointer, chosen at random from the space of all pointers, replaces a pointer.

We consider the following classes of error distributions:

- *uniform:* Errors occur randomly.
- *arbitrary:* Errors may be arbitrarily correlated.

Note that our results do not apply to the case where an individual bit is inserted or deleted but do allow individual bits to be changed because this is just a special case of a change error. (In fact we are only charging a cost of 1 no matter how many bits of a pointer are changed.)

The goal is to provide guarantees that there is *perfect protection* against error propagation due to a specified number of channel errors; that is, there is no further corruption of the data beyond what is directly due to the channel errors.

3. Protection against k errors. In this section, we present an encoding scheme which, for any fixed integer constant $k \geq 0$, guarantees that k or fewer errors on the channel will not cause *any* error propagation. We will not address how this protocol affects the amount of compression (although it appears reasonable in practice); rather, this protocol will be an important building block for a more general construction, presented in the next section, that does guarantee that compression is not affected asymptotically.

To simplify our presentation, we shall assume that the update heuristic adds at most one new match (e.g., UC, NC, FC, and CM have this property but AP does not); at the end of this section, we describe how this encoding scheme can be generalized to update heuristics that may add more than one new entry. Also, similar modifications as for the generic encoding and decoding algorithms are discussed for the UC and NC heuristics.

The two key ideas are as follows:

- Hashing is used to compute where a new entry is to be placed in the dictionary. For simplicity, throughout this paper, we assume that a truly random hash function is used; in practice, a 2-universal hash function (see Carter and Wegman [1979]) can be used. Hashing has the effect of eliminating the dependence between addresses that is normally present in dynamic dictionary communication so that if a given index is not used right away, it will have no effect on what indices are used in the future.
- Counts are maintained for all pointer pairs seen thus far and a pair is used by the match heuristic only if it "warms up" to be a clear winner over pairs that hash to the same address.

DEFINITION. *Suppose that counts (initially 0) are maintained in the encoder for all pointer pairs sent thus far (i.e., each time a pointer is sent/received, the count of the pair of pointers it represents is incremented) and in the decoder for all pointer pairs received thus far. For a sequence S of pointers sent by the encoder,* $\mathrm{LAG}(S)$ *is the maximum amount that any count in the decoder is incorrectly increased due to errors on the channel plus the maximum amount any count fails to be increased due*

to errors on the channel. For any integer $k \geq 0$, *the* warming value *for* k, $w(k)$, *is the smallest integer such that* $\mathrm{LAG}(S) \leq w(k)$ *over all sequences of pointers with at most* k *errors.*

LAG THEOREM. *For any* $k \geq 1, w(k) \leq 3k$.

Proof. Let

$S = U_0 C_1 U_1 \ldots C_m U_m$ be the sequence of pointers *sent* by the encoder and

$R = U_0 I_1 U_1 \ldots I_m U_m$ be the sequence of pointers *received* by the decoder

where

$U_i, 0 < i < m, |U_i| \geq 1$ are blocks of pointers,

$I_i, 1 \leq i \leq m, |I_i| \geq 0$ are blocks of pointers, and

$|\prod_{i=1}^{m} I_m| \leq k$ (the product denotes string concatenation).

That is, S and R are partitions (which are not necessarily unique) of the input and output streams into blocks of pointers defined as follows. The U's are blocks of pointers that went across the channel *unchanged* and the C's are blocks of pointers that were *correctly* sent to the communication channel but due to errors on the channel were received *incorrectly* by the decoder as the I blocks, where all pointers in a given I block are incorrect.

Now consider a particular block C_i that is received as I_i. Let

$x =$ the number of pointers that are changed,

$y =$ the number of pointers that are deleted, and

$z =$ the number of pointers that are added

and write

$$C_i = q_1 \cdots q_{x+y},$$
$$I_i = r_1 \cdots r_{x+z}.$$

Any way of choosing x, y, and z that corresponds to a way to convert C_i to I_i suffices for our construction. Let p be the last pointer of U_{i-1} and s be the first pointer of U_{i+1}. The only counts that might not be incremented (but should have been) are due to the loss of

$$pq_1, \quad q_1 q_2 \cdots q_{x+y-1} q_{x+y}, \quad q_{x+y} s,$$

which in the worst case can increase the lag by $x + y + 1$. The only counts that might be incorrectly incremented are due to the addition of

$$pr_1, \quad r_1 r_2 \cdots r_{x+z-1} r_{x+z}, \quad r_{x+z} s,$$

which in the worst case can increase the lag by $x + z + 1$. Note that if $i = 1$ and/or $i = m$, then p and/or s may not exist, and this can only lower the number of counts that might not be incremented or might be incorrectly incremented. Thus the total change in lag for the transformation of C_i to I_i is at most $2x + y + z + 2$. In fact, for the case where $y = z = 0$ (there are only change errors), this upper bound can be reduced by observing that if

$$pq_1 = q_1 q_2 = \cdots q_{x+y-1} q_{x+y} = q_{x+y} s,$$

then it follows that $p = q_1 \cdots q_{x+y} = s$, and so it cannot be that $pr_1 = r_1 r_2$ (or that $pr_1 = r_1 s$) or r_1 would not be an incorrect pointer, so the lag can be at most $2x + 1$. Hence we have

$$\mathrm{LAG}(C_i) \leq \left\{ \begin{array}{ll} 2x + 1 & \text{if } (y + z) = 0, \\ 2x + y + z + 2 & \text{if } (y + z) > 0 \end{array} \right\}.$$

Let $e = x + y + z$. For the case where $(y + z) = 0$, assuming that $k > 0$ (otherwise, $\mathrm{LAG}(C_i) = 0$), $2x + 1 \leq 2e + 1 \leq 3e$. For the case where $(y + z) > 0$:

$$\begin{aligned} 2x + y + z + 2 &= 2(e - (y + z)) + (y + z) + 2 \\ &= 2e - (y + z) + 2 \\ &\leq 2e + 1 \\ &\leq 3e. \end{aligned}$$

Hence the warming value for each block of e errors is $\leq 3e$, and the theorem follows.

ENCODING ALGORITHM WITH k-ERROR PROTOCOL.

1. Initialize the *local dictionary* D to have one entry for each character of the input alphabet and to have an empty hash table that is capable of storing pointer pairs; let h denote a hash function that maps pointer pairs to the range $0 \ldots (|D| - 1)$.
2. **repeat forever**
   A. {Get the current match string s and compute the current match pointer p:}
      Read a string s for which there exists pointer pair qr such that
      - s = the string corresponding to the pointer pair qr,
      - $\mathrm{count}(qr) > \mathrm{count}(uv) + w(k)$ for all uv such that $h(uv) = h(qr)$.

      if s does not exist
      then p = the index in D of the next input character
      else begin
      $p = h(qr)$
      $\mathrm{count}(qr) = \mathrm{count}(qr) + 1$
      end
      Transmit p using $\mathrm{BITS}(|D| - 1)$ bits.
   B. {Update D:}
      for each pair xy produced by the update method **do**
      if xy is not already in the dictionary **then** $\mathrm{count}(xy) = 0$

DECODING ALGORITHM WITH k-ERROR PROTOCOL.

1. Initialize the local dictionary D by performing step 1 of the encoding algorithm.
2. **repeat forever**
   A. {Get the current match pointer p and compute the current match string s:}
      Receive $\mathrm{BITS}(|D| - 1)$ bits for the current match pointer p.
      if p represents a single character
      then s = the single character corresponding to p
      else if there is a pointer pair qr such that
      $h(qr) = p$ and $\mathrm{count}(qr)$ is largest among all pairs that hash to p
      then begin
      s = the string corresponding to qr
      $\mathrm{count}(qr) = \mathrm{count}(qr) + 1$
      end
      else s = the empty string
      Output s.
   B. {Update D:}
      Perform step 2B of the encoding algorithm.

Given the lag theorem, the generic encoding and decoding algorithms can be modified, as shown above, to employ the *k-error protocol* to insure perfect protection against any k errors; that is, no bytes are corrupted beyond those corrupted by channel errors.

For correctness of the protocol, observe that for each pointer p in a sequence S of pointers sent by the encoder, the pointer pair qr that p represents is a clear "winner" among all pointer pairs that hash to p; that is, the count of qr is greater by at least $\mathrm{LAG}(S)$ than the count of any other pair uv that hashes to p. Hence when the decoder receives an uncorrupted pointer p, the pointer pair qr with the largest count that hashes to p must be the correct pair for p because k errors cannot cause some other pair uv that hashes to p to have a count equal or greater than that of qr.

As mentioned at the beginning of this section, the encoding and decoding algorithms with the k-error protocol can be adapted to the UC and NC heuristics, and to heuristics such as AP that may add more than one entry. For the UC and NC heuristics, the same modifications as for the generic encoding and decoding algorithms can be used. For the AP heuristic, or any heuristic that may construct more than one match from the last match and the current match, we can hash on triples consisting of the two pointers in question together with an integer that indicates which of the strings corresponding constructed from this pointer pair is being referenced; this integer can be provided by the match heuristic. The lag theorem can still be used to verify the protocol because it is still the case that at most one count is incremented when a pointer is sent by the encoder or received by the decoder.

We leave as an open problem the class of sources for which the k-error protocol produces a constant-redundant parsing for update heuristics that satisfy the succinctness and robustness axioms. All that has been shown here is that k errors will not propagate when using the k-error protocol. Because hash conflicts could in theory cause the counts of two entries that hash to the same location to "race" (so that neither count sufficiently exceeded the other), it is not clear what effect, if any, the protocol has asymptotically on the amount of compression obtained with a given update heuristic (as compared with the same heuristic without the protocol). We conjecture that in practice, performance will not be significantly affected for small values of k and reasonably size dictionaries (e.g., 2^{16} or more entries). In the next section, we make use of the k-error protocol in a way that avoids hash conflicts and insures constant redundancy.

4. High-probability protection against an error rate. In this section, we employ probabilistic analysis to examine more carefully the proof of the lag theorem of the last section. The idea is to show that the k-error protocol actually gives, with high probability, strong protection against a fixed error rate during the period when the dictionary is changing and is vulnerable to error propagation. In addition, by encoding pointers to avoid hash conflicts with high probability, we can guarantee no asymptotic loss of compression.

We employ the Chernoff bound (see Hagerup and Rub [1989]) on the number of heads X in a sequence of independent coin tossings with expected value μ ($e = 2.7182\ldots$ denotes the natural logarithm base defined by $\lim_{n\to\infty}(\frac{n}{n-1})^n$):

$$\text{For } x \geq 0, \quad \mathrm{Prob}(X \geq (1+h)\mu) < \left(\frac{e^h}{(1+h)^{(1+h)}}\right)^{\mu}.$$

To obtain the form of the bound that we shall use here, first we observe that the right-hand side is

$$= \frac{1}{e^{\mu}}\left(\frac{e}{1+h}\right)^{(1+h)u} = \frac{1}{e^{\mu}}\left(\frac{(1+h)\mu}{e\mu}\right)^{-(1+h)\mu}$$

and hence, since $e > 1$, it follows that

$$\text{For } z > e\mu, \quad \text{Prob}(X \geq z) < \frac{1}{e^{\mu}} \left(\frac{z}{e\mu}\right)^{-z} < \left(\frac{z}{e\mu}\right)^{-z}.$$

DAMPING THEOREM. *If a sufficiently large dictionary is employed with a method satisfying the succinctness and robustness axioms together with the k-error protocol of the last section (where $w(k)$ denotes the warming value for k and α denotes the learning constant) on a channel with a uniform independent error probability of $1/r$ (on the average, one error for every r pointers), then the probability that the system looses stability (i.e., the probability that any errors propagate) is*

$$< \frac{1}{\left(\frac{r}{4e\alpha}\right)^{\left(\frac{w(k)}{2}+1\right)}}.$$

In addition, with probability greater than $1 - 1/2^{|D|(1-\varepsilon(|D|))}$, the amount of compression achieved is within a factor of $(1+\varepsilon(|D|))$ of what would be achieved with the same method used on a perfect channel without the protocol, where $\varepsilon(|D|) \to 0$ as $|D| \to \infty$.

Proof. To simplify notation, we assume throughout this proof that all logarithms are base 2.

Although the k-error protocol may work in the presence of hash conflicts, it is difficult to estimate the effect of the hash conflicts on the performance of the protocol for the application in question; for example, for data compression, it is not clear how the compression achieved is affected in the worst case. We avoid this problem by employing a more complicated hashing scheme that has no conflicts with extremely high probability. Although this scheme may increase the number of bits in some pointers, it will have no asymptotic effect on the total number of bits sent.

To store n items in the hash table, we use a table of size $n \log(n)^2$. Since at any time the table contains at most n elements, each time an element is inserted into the table, the probability that it goes to a bucket that already contains an entry is at most $n/(n \log(n)^2) = 1/(\log(n)^2)$, and thus the expected number of hash conflicts after inserting all n elements is bounded above by $n/\log(n)^2$. Hence from the Chernoff bound, with $\mu = n/\log(n)^2$ and $z = n/\log(n)$, it follows that the number of hash conflicts is greater than $n/\log(n)$ with probability

$$\begin{aligned} &< \left(\frac{n/\log(n)}{en/(\log(n)^2)}\right)^{-n/(\log(n)^2)} \\ &= \left(\frac{\log(n)}{e}\right)^{-n/(\log(n)^2)} \\ &< \frac{1}{2^{n/(\log(n)^2)}}. \end{aligned}$$

Thus it follows that

$$\text{Prob}(\text{number of hash conflicts } < n/\log(n)) > 1 - \frac{1}{2^{n/(\log(n)^2)}}.$$

The $n/\log(n)$ conflicting entries can all be hashed again into a table of size $n\log(n)$, the remaining $n/(\log(n)^2)$ conflicting entries can all be hashed again into a table of size n, and so on. In general, each pointer is now being represented by a sequence of indices, each consisting of a number of bits equal to log of the size of the corresponding hash table followed by a bit that is 0 if the index is the last in the pointer or 1 if there is another to follow. By summing the bits sent for a sequence of n pointers, we see that all n pointers use $\log(n\log(n)^2)+1$ bits for the first index, at most $n/\log(n)$ pointers have an additional $\log(n\log(n))+1$ bits for the second index, and so on. The first term is bounded by $(1+\varepsilon(n))n\log(n)$, where $\varepsilon(n)\to 0$ as $n\to\infty$, the second term is $O(n)$, and the remaining terms go down geometrically by a factor of $\log(n)$. Hence the total number of bits sent is asymptotically arbitrarily close to the $n\log(n)$ bits that are sent in any case.

Given that we can assume that there are no hash conflicts for the encoder, the k-error protocol takes care of conflicts at the decoding end. That is, if a pointer is received whose bits are the prefix of the bits of two or more pointers, the one with the largest count wins.

We now bound the average value of the following two quantities:

X_{ij} = the number of times that the count of pair i,j is incorrectly increased by the decoder due to errors on the channel, before the dictionary of the encoder is full;

Y_{ij} = the number of times that the count of a pair i,j fails to be increased when it would otherwise have been increased if there had been no errors on the channel, before the dictionary of the encoder becomes full.

Let

$E(D)$ = the expected number of pointers transmitted by the encoder before its dictionary is full.

From the proof of the lag theorem, we know that each error can cause at most two counts to incorrectly increase, and hence for each of the $E(D)/r$ pointers that are corrupted, at most two counts, which are equally likely to be any of at least $|D_{\max}|$ pairs, can be incorrectly increased. So the expected value of X_{ij}, which we denote by μX_{ij}, is bounded by

$$\mu X_{ij} \le \frac{2E(D)}{r|D_{\max}|}.$$

By the robustness axiom, $E(D)\le \alpha w(k)|D_{\max}|$, and hence

$$\mu X_{ij} \le \frac{2\alpha w(k)}{r}.$$

Since each error can cause at most two counts to incorrectly fail to increase, similar to X_{ij}, we can compute

$$\mu Y_{ij} \le \frac{2\alpha w(k)}{r}.$$

Hence the probability that X_{ij} or Y_{ij} is $\geq (\frac{w(k)}{2}+1)$ is

$$> \left(\frac{\frac{w(k)}{2}+1}{\frac{2e\alpha w(k)}{r}}\right)^{-\left(\frac{w(k)}{2}+1\right)}$$

$$= \frac{1}{\left(\frac{r(w(k)+2)}{4e\alpha w(k)}\right)^{\frac{w(k)}{2}+1}}$$

$$< \frac{1}{\left(\frac{r}{4e\alpha}\right)^{\frac{w(k)}{2}+1}}.$$

From the above bound, the theorem follows since a LAG of more than $w(k)$ cannot occur if no values of X_{ij} or Y_{ij} are more than $w(k)/2$.

Let us now consider the amount of compression achieved. We have already verified that each of the $|D|$ pointers is encoded with only a factor of $1+\varepsilon(|D|)$ more bits, where $\varepsilon(|D|) \to 0$ as $|D| \to \infty$. Hence if the method in question is optimal in the information-theoretic sense, then by the robustness axioms, as $|D| \to \infty$, the same method with the k-error protocol must also be optimal in the information theoretic sense (since it is $w(k)$-redundant).

COROLLARY. *For $\alpha \leq 2$ (which is the case for all data-compression methods that we have considered) and $r \geq 10^{12}$ (a reasonable assumption in practice for a clean channel with a low-overhead error-correction mechanism), choosing $w(k) \geq (2.2509k-2)$ yields a probability that is*

$$< \frac{1}{r^k}.$$

For example, if $k=5$, then by using $w(k)=10$, an error rate of $1/10^{12}$ is effectively "damped" to $1/10^{60}$.

Proof. If we write $w(k) = 2xk-2$, we can solve for the minimum value of x by simplifying the expression above as follows:

$$\leq \frac{1}{r^k\left(\frac{r^{\frac{w(k)}{2}+1-k}}{(8e)^{\frac{w(k)}{2}+1}}\right)}$$

$$= \frac{1}{r^k\left(\frac{r^{x-1}}{(8e)^x}\right)^k}.$$

The expression $\frac{r^{x-1}}{(8e)^x}$, which is monotonically increasing in x, becomes ≥ 1 when $(r/8e)^x \geq r$, which is true when $x \geq \frac{\log(r)}{\log(r)-\log(8e)}$. Assuming $r \geq 10^{12}$, $w(k) \geq 2.2509k-2$ suffices.

5. Practical considerations. The previous section encoded pointers to make the probability of *any* hash conflicts arbitrarily small. Although the protocol may work even in the presence of hash conflicts, this eliminated the need to address the issue of what affect hash conflicts have on performance of the system (e.g., the amount

of compression achieved). We leave it as an open problem whether, in the case of data compression for stationary ergodic sources, performance is affected when hash conflicts are allowed. Here we mention another strategy that can be viewed as a compromise between allowing hash conflicts and rehashing to avoid them. With a small number of extra bits per pointer, we can make the number of hash conflicts small and then simply not use these entries of the dictionary (thus "wasting" a small fraction of the dictionary).

A small constant $c \geq 1$ extra bits are added to each pointer so that the $|D_{\max}|$ dictionary entries are hashed into a space of $|D_{\max}|2^c$ indices. Consider a particular index i that is used for the first time in a sequence of n pairs that are hashed into the dictionary. The probability that all other pairs do *not* hash to index i is

$$
\begin{aligned}
&\geq \left(1 - \frac{1}{n2^c}\right)^{n-1} \\
&> \left(1 - \frac{1}{n2^c}\right)^{n} \\
&= \left(\left(1 - \frac{1}{n2^c}\right)^{n2^c}\right)^{2^{-c}} \\
&\geq \left(\frac{1}{e(n)}\right)^{2^{-c}}, \quad \text{where } e(n) = \left(\frac{n}{n-1}\right)^{n}, \\
&= \frac{\left(\frac{1}{e}\right)^{2^{-c}}}{\left(\frac{e(n)}{e}\right)^{2^{-c}}} \\
&> \frac{1 - (2^{-c})}{\left(\frac{e(n)}{e}\right)^{2^{-c}}}, \quad e^x = \sum_{i=0}^{\infty} \frac{x^i}{i!} \quad \text{and for all } 0 < x < 1, \quad \frac{1}{e^x} > 1 - x.
\end{aligned}
$$

Hence the probability that two pairs hash to index i is

$$
\begin{aligned}
&\leq 1 - \frac{1 - (2^{-c})}{\left(\frac{e(n)}{e}\right)^{(2^{-c})}} \\
&< 2^{-c} + \left(1 - \left(\frac{e}{e(n)}\right)^{(2^{-c})}\right) \quad \text{since for all } n > 1,\ e(n) > e \\
&= 2^{-c} + \varepsilon(n) \quad \text{since } e = \lim_{n \to \infty} e(n),
\end{aligned}
$$

where $\varepsilon(n)$ goes to 0 as n goes to ∞. Thus the expected number of hash conflicts is less than

$$n(2^{-c} + \varepsilon(n)),$$

and by the Chernoff bound it follows that the probability that there are more than εn hash conflicts is

$$< \left(\frac{\varepsilon}{e(2^{-c} + \varepsilon(n))}\right)^{-\varepsilon n}.$$

For any constant $d > 1$, this expression can be made less than $d^{-\varepsilon n}$ if c is made sufficiently large (by choosing n sufficiently large).

Given that the probability of more than εn hash conflicts can be made arbitrarily low, a simple approach is the conservative strategy of "throwing out" all indices that correspond to a hash conflict (even though many or all of these entries may not cause any problems for the decoder). This construction adds c extra bits to each pointer, which can be made to have an insignificant effect on compression by using a very large dictionary (and hence a very large pointer size) but will most likely be significant for dictionary sizes that are used in practice. However, this effect may not be unacceptable. For example, if we take $|D_{\max}| = 2^{16}$ (a common and practical choice for data compression) and $\varepsilon = 0.1$ (again, a reasonable value in practice), then we must choose $c \geq 5$; taking $c \geq 5$ and computing the error term $\varepsilon(n)$, we see that the probability that there are more than $\varepsilon(n)$ hash conflicts is $< 2^{-1,500}$. However, the cost for this security against many hash conflicts is an extra five bits for every 16-bit pointer. If we consider a typical example for lossless compression using a dictionary of size 2^{16}, we might expect the compressed data to be 30 percent of the size of the original data, but now with the extra five bits per pointer, the compressed size will be $\frac{21}{16}30 \approx 39$ percent of the original size. Although this cost might be reasonable in practice, it would be nice to avoid it. We conjecture that this cost can be reduced by a tighter analysis that does not throw out all indices with hash conflicts but rather throws out only those that delay the dictionary-filling process due to "racing" and "thrashing" of counts. We leave such analysis (as well as the effect of hash conflicts on application-dependent performance issues such as compression ratio) as a subject for future research.

Appendix. Constant-redundant parsings are optimal. The UC heuristic is exactly the algorithm shown to be optimal in Ziv and Lempel [1978]; a nice proof appears in Cover and Thomas [1991]. The essence of this proof is to show that *any* method that parses the input stream into distinct phrases (and sends a number of bits equal to $\log_2$ of the current number of phrases to the decoder) must be optimal. This appendix notes how this notion can be generalized and still maintain optimality.

DEFINITION. *A* τ-redundant parsing *of the input stream is one with at most* τ *copies of any given phrase.*

LEMMA. τ*-redundant parsings give optimal data compression for the UC model.*

Proof. We refer to the presentation in section 12.10 of Cover and Thomas [1991] and describe how slight modifications can be made to the formulas. Note that here $c(n)$ denotes the total number of phrases (with repetition), whereas in the original presentation phrases are not repeated. Lemmas 12.10.1 and 12.10.2 do not change if the parsing is τ-redundant. Lemma 12.10.3 (Ziv's inequality) gets a factor of τ inside the log on the right side. (The proof is essentially unchanged except that the 1 in the log on the right side in equation (12.286) becomes τ.) Theorem 12.10.1 (the main theorem) still holds for a τ-redundant parsing; the proof is essentially the same, with the following small changes: A factor of τ goes in the denominator inside the log on the right side of equation (12.288), which is equivalent to adding the term $\tau \log(\rho)$ to the right side of equation (12.288). This term of $c \log(\tau)$ is added to the right side of equation (12.292) and subtracted from the right side of equation (12.293). Finally, the error term $\varepsilon_k(n)$ in equation (12.300) is changed to have $(c/n)\log(\tau)$ added to it; since c is $O(n/\log(n))$ by Lemma 12.10.1, the error term still goes to 0 as n goes to ∞.

COROLLARY. *The lemma holds for the FC and NC heuristics as well.*
Proof. These heuristics can use a phrase at most $\tau|\Sigma|$ times.

CONSTANT-TIME RANDOMIZED PARALLEL STRING MATCHING*

MAXIME CROCHEMORE†, ZVI GALIL‡, LESZEK GĄSIENIEC§, KUNSOO PARK¶, AND WOJCIECH RYTTER‖

Abstract. Given a pattern string of length m for the string-matching problem, we design an algorithm that computes deterministic samples of a sufficiently long substring of the pattern in constant time. This problem used to be the bottleneck in the pattern preprocessing for one- and two-dimensional pattern matching. The best previous time bound was $O(\log^2 m/\log\log m)$. We use this algorithm to obtain the following results (all algorithms below are optimal parallel algorithms on a CRCW PRAM):

1. a deterministic string-matching algorithm which takes $O(\log\log m)$ time for preprocessing and constant time for text search, which are the best possible in both preprocessing and text search;

2. a constant-time deterministic string-matching algorithm in the case where the text length n satisfies $n = \Omega(m^{1+\epsilon})$ for a constant $\epsilon > 0$;

3. a simple string-matching algorithm that has constant time with high probability for random input;

4. the main result: a constant-expected-time Las Vegas algorithm for computing the period of the pattern and all witnesses and thus for string matching itself; in both cases, an $\Omega(\log\log m)$ lower bound is known for deterministic algorithms.

Key words. parallel string matching, randomized algorithms, deterministic samples

1. Introduction.

The string-matching problem is defined as follows: Given pattern $P[0..m-1]$ and text $T[0..n-1]$, find all occurrences of P in T. We study parallel complexity of string matching on a CRCW PRAM. The PRAM (parallel random-access machine) is a shared-memory model of parallel computation which consists of a collection of identical processors and a shared memory. Each processor is a RAM working synchronously and communicating via the shared memory. The CRCW (concurrent-read concurrent-write) PRAM allows both concurrent reads and concurrent writes to a memory location, and it has several variants depending on how concurrent writes are handled. We use the weakest version (called *common* in [7]), in which the only concurrent writes allowed are of the same value, 1. A parallel

algorithm for a problem is *optimal* if its total work is asymptotically the same as the minimum possible work for the problem. All optimal algorithms in this paper have linear work. Most string-matching algorithms consist of two stages. The first preprocesses the pattern and the second uses the data structure constructed in the first to search the text. For the text search, a constant-time optimal parallel algorithm (following optimal $O(\log^2 m/\log\log m)$-time preprocessing) is known [8]. On the other hand, an $\Omega(\log\log m)$ lower bound with a linear number of processors is known for the entire string-matching problem [3].

Let $x[0..r-1]$ be a string of length r. String $x[0..p-1]$, $1 \le p < r$, is a *period* of x if $x[i] = x[i+p]$ for all $0 \le i < r-p$. The shortest period of x is called *the period* of x. We also use the term period for the *length* of the corresponding string. If the period of x is shorter than a half (fourth) of x, x is called *periodic* (4-*periodic*). A *witness* of x against (the periodicity of) i is a position w such that $x[w] \neq x[w-i]$ [12]. Let p be the period of x. When we say that we compute the period of x, we mean computing $\min(p, r/4)$. When we say that we compute the witnesses of x, we mean computing the witnesses against all nonperiods i, $1 \le i < r/4$. The witnesses of x can be computed in optimal $O(\log\log r)$ time by [2]. (It is possible to compute large periods and witnesses using techniques of [1], but we will not need them here.) Given two strings x and y and a position i of y such that x does not occur at position i of y, a *witness to* nonoccurrence at i is a position w such that $y[w] \neq x[w-i]$. A substring of x of length i is called an i-*block* of x. The positions of all strings in this paper start from 0.

Consider a nonperiodic pattern string x of length m. Align $k \le m/2$ copies of x one on top of the other so that the ith copy starts above the ith symbol of the first copy. A deterministic sample (DS) of x for k shifts is an ordered set A of positions and a number f, $1 \le f \le k$, such that $f-1$ consecutive copies of x to the left and $k-f$ consecutive copies to the right have at least one mismatch with copy number f of x in the positions of the set A. The size of a DS is the size of the ordered set A. See Fig. 1. Vishkin [13] introduced the notion of deterministic samples and proved the existence of a DS of size at most $\log m$ for $m/2$ shifts.

The DS is crucial for very fast optimal parallel search of the pattern in a given text. During the text search, we maintain a subset of text positions, referred to as *candidates*, which can be start positions of pattern occurrences. Assume that we can somehow reduce the number of candidates to one in every $\log m$-block of the text. Then for every candidate, we compare the symbols at the positions of the set A of the DS with the corresponding symbols of the text. If a candidate has mismatches, it is no

longer a candidate for an occurrence of the pattern. On the other hand, if a candidate has matches in all the positions of A, then by the definition of the DS, we can eliminate all other candidates in an $m/2$-block of the text. This method was used in a constant-time optimal text search [8]. Very recently, it was also used in a constant-time two-dimensional text search [5]. However, the optimal algorithm suggested by Vishkin and used in [8] for computing the DS was very expensive, taking $O(\log^2 m/\log\log m)$ time. This resulted in two "best" algorithms for string matching: an optimal $O(\log\log m)$-time algorithm for the entire problem [2] (for which an $\Omega(\log\log m)$ lower bound was also proved [3]) and a constant-time text search with expensive preprocessing that was dominated by the computation time of the DS. Thus the DS computation has been the bottleneck.

In section 2, we present a constant-time deterministic algorithm for computing a DS of logarithmic size. We also show how to compute a constant-size DS for $O(\log\log m)$ shifts in constant time. This constant-size DS will be crucial to our main result in section 4. Since we compute deterministic samples for a part of the pattern, we can use more than a linear number of processors.

Section 3 contains three applications of the constant-time algorithm for DS. The first application is that it allows us to have only one best string-matching algorithm with constant-time search and $O(\log\log m)$-time preprocessing. Our new algorithm achieves the best possible time in both preprocessing and text search. The second application is a deterministic $O(k)$-time string-matching algorithm using n processors for the case where $m = O(n^{1-2^{-k}})$, i.e., a constant-time string-matching algorithm using n processors when $n = \Omega(m^{1+\epsilon})$ for a constant $\epsilon > 0$. The third application is a simple string-matching algorithm that has constant time with high probability (and thus constant expected time) for random input.

In section 4, we describe our main result. We present a constant-expected-time Las Vegas algorithm for computing the witnesses. Together with the constant-time text search, we obtain a constant-expected-time Las Vegas algorithm for string matching including preprocessing, solving the main open problem remaining in parallel string matching. Deterministically, an $\Omega(\log\log m)$ lower bound is known for witness computation and string matching [3]. This algorithm is designed based on the lower-bound argument; randomization is used to kill the argument. In the special case where the pattern is periodic and the period of the pattern has only a constant number of prime divisors, randomization is not needed.

Our algorithms will frequently use without mention the constant-time algorithm that finds the maximum (or minimum) position of a nonzero entry in an array [7]. Our algorithms will use the constant-time deterministic polynomial approximate compaction (PAC) of Ragde [11] and its improvement by Hagerup [9]. A d-PAC is an algorithm that compacts an array of size n with at most m nonzero elements into a prefix of size m^d (assuming that $m^d < n$). Ragde gave a $(4+\epsilon)$-PAC and Hagerup gave a $(1+\epsilon)$-PAC for any $\epsilon > 0$.

In many places where we use quantities such as $r/2$, $\log r$, or $\log\log r$ as integers, we mean that any way of rounding them to the nearest integer will do.

2. Constant-time deterministic sampling. Let x be a nonperiodic string of length r. We construct two kinds of DSs in constant time: a $\log k$-size DS for k shifts, $k \le r/2$, and a constant-size DS for $\log\log r$ shifts. We first show how to construct a $\log k$-size DS of x for k shifts, $k \le r/2$, in constant time using r^3 processors and r^2 space. This log-size DS was introduced by Vishkin [13], but its construction takes $O(\log^2 r/\log\log r)$ time using $O(r)$ operations, which is the bottleneck in the

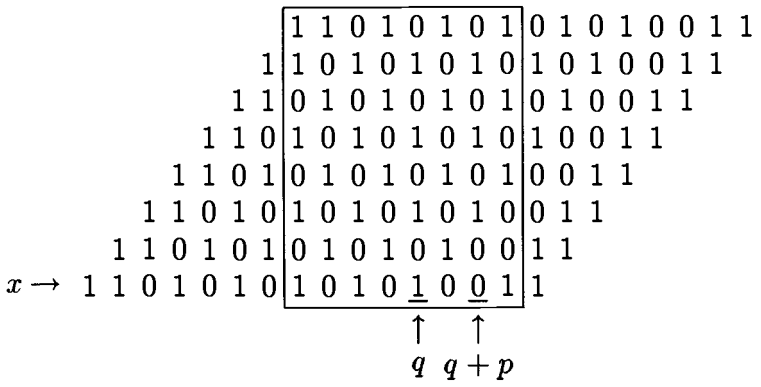

FIG. 2. *A DS with* $A = \{q, q+p\}$ *and* $f = 1$.

preprocessing of string matching [13, 8]. Consider k-blocks starting at positions i for $0 \le i < k$. If two k-blocks are identical, we say that x *has a periodicity*. Note that x has a periodicity if and only if there are i and j for $i < j < k$ (the start positions of the two identical blocks) such that $x[i..j+k-1]$ has a period $p = j - i < k \le r/2$. Using $k^3 < r^3$ processors, the algorithm checks in constant time if x has a periodicity. If it does, the algorithm finds such i, j, and $p = j - i$. p is not necessarily the smallest such period.

Case 1: x has a periodicity in $x[i..j+k-1]$ with period p. Although p is a period of $x[i..j+k-1]$, p cannot be a period of x since x is nonperiodic. That is, the periodicity with period p cannot extend both all the way to the right and all the way to the left of $x[i..j+k-1]$. If it does not extend to the right, let $q > j$ be the smallest position such that $x[q] \ne x[q+p]$ (i.e., end of periodicity). The position q can be found in constant time with r processors. Now the DS is $A = \{q, q+p\}$ and $f = 1$ because in the first copy we have mismatching symbols at positions $q, q+p$ and in the next $k-1$ copies to the right we have matching symbols at the same positions. See Fig. 2, where $k = 8$, $i = 2$, and $j = 4$ ($p = j - i = 2$). If the periodicity extends all the way to the right, let $q < i$ be the largest position such that $x[q] \ne x[p+q]$. The DS is $A = \{q, q+p\}$ and $f = k$.

Case 2: x does not have a periodicity (i.e., all of the k-blocks are distinct). Consider (for discussion only) the compacted prefix tree T of all the blocks (each path from the root of T to a leaf corresponds to a block and every internal node has degree at least 2). Since T has k leaves, there is at least one leaf v of depth $\le \log k$. Let B be the block corresponding to v. The path in T from the root to v hits at most $\log k$ nodes which define at most $\log k$ positions; B is different from each of the other blocks in at least one of these positions. Below we will find such a block B and the (at most $\log k$) positions in B in constant time using r^3 processors and r^2 space. Let b be the start position of B in x. The DS is the derived set of positions in B shifted by b and $f = k - b$. For example, consider Fig. 1. For the block $B = 01000101$, its start position in x is 2 and f is 6.

To find B and the positions in it, we compute a $k \times k$ 0–1 matrix: one row for each block. The matrix is initially set to 0. With r processors per each pair (i, j), $1 \le i, j \le k$, of blocks, find in constant time the smallest index ℓ such that the ith block and the jth block differ at position ℓ (a node in T). Note that we find in this

way exactly all nodes of T (more than once). Set entry ℓ in the two rows i and j to 1. Now we only have to find a row with no more than $s = \log k$ 1's and compress their positions to an array of size s. So we need to solve the following problem for each row of the matrix. Given a 0–1 array of size $k \leq r$ and r^2 processors, find whether it has at most $s = \log k$ 1's and, if it does, compress their positions into an array of size s.

Ragde designed a $(4 + \epsilon)$-PAC [11] and then used it to compress an array of length k with at most s items (= nonzero entries) into an array of size s in time $O(\log s / \log \log k)$. In case the number of items is larger than s, the algorithm fails. Note that when $\log s = O(\log \log k)$, the time is $O(1)$. So to solve the problem above, first the jth processor replaces a 1 in the jth entry with j and then Ragde's compression is applied in constant time. This compression will succeed with at least one of the rows of the matrix and will yield the desired DS.

THEOREM 2.1. *The deterministic algorithm above constructs a* $\log k$*-size DS for* k *shifts,* $k \leq r/2$*, for a nonperiodic string of length* r *in constant time using* r^3 *processors and* r^2 *space.*

Although the DS computation used to be the bottleneck, the algorithm in [8] has another part of the preprocessing (the hitting set) that does not take constant time: the part that enables the algorithm to eliminate all but at most one candidate in every $\log m$-block. The hitting set can be constructed in $O(\log \log m)$ time. Using Theorem 1 and an $O(\log \log m)$-time construction of the hitting set, the algorithm in [8] can be transformed into a string-matching algorithm which takes constant time for text search and $O(\log \log m)$ time for preprocessing. However, in order to derive a randomized constant-time algorithm, we cannot afford to compute a hitting set. Instead of the hitting set, we use the following constant-size DS for $O(\log \log m)$ shifts to design an alternative algorithm called CONST-MATCH in section 3.

We now show how to construct a constant-size DS of x for $\log \log r$ shifts in constant time with $r^2 \log \log r$ processors. This constant-size DS is new and is crucial for constant-time randomized string matching in section 4 as discussed above.

Case 1. If there exists position i in x such that $x[i] \neq x[i + j]$ (or $x[i] \neq x[i - j]$) for every $1 \leq j < \log r$, then we take $A = \{i\}$ and $f = \log r$ (or $A = \{i\}$ and $f = 1$) as the DS for $\log r$ shifts (and therefore for $\log \log r$ shifts as well).

Case 2. Otherwise, every symbol in x occurs very often (with distance shorter than $\log r$ between neighboring ones). So every symbol occurs at least $r/\log r$ times in x, which implies that there are at most $\log r$ different symbols in x. Consider all substrings of length $\log \log r$ in the first half of x. Since there are $(\log r)^{\log \log r}$ different strings of length $\log \log r$ over $\log r$ symbols and since $(\log r)^{\log \log r} < r/(2 \log \log r)$, some substrings of length $\log \log r$ repeat without overlap in the first half of x. Find such a substring y in constant time using $r^2 \log \log r$ processors. Let z be the substring between the two copies of y. The substring yzy has a period $p = |yz| < r/2$. Since x is nonperiodic, period p has a mismatch in x. Let q be the smallest (largest) position such that $x[q] \neq x[q + p]$ to the right (left) of the first copy of y. Then $A = \{q, q + p\}$ and $f = 1$ ($A = \{q, q + p\}$ and $f = \log \log r$) is a constant-size DS for $\log \log r$ shifts.

THEOREM 2.2. *The deterministic algorithm above constructs a constant-size DS for* $\log \log r$ *shifts for a nonperiodic string of length* r *in constant time using* $r^2 \log \log r$ *processors.*

3. Applications of constant-time DS. In this section, we present applications of the constant-time DS computation, and at the same time, we build up procedures which will be used in the constant-time randomized string-matching algorithm in section 4. Thanks to a well-known reduction [2], we can assume without loss of

generality that the pattern in a string matching problem is non-4-periodic.

The text-search algorithm will maintain candidates, which can still be start positions of pattern occurrences. All other positions have gotten witnesses to nonoccurrences. Consider two candidates $i < j$ such that w is a witness against $j - i$ (i.e., $P[w] \neq P[w - j + i]$).

(a) If $T[i + w] \neq P[w]$, $i + w$ is a witness to nonoccurrence at i.
(b) If $T[i + w] \neq P[w - j + i]$, $i + w$ is a witness to nonoccurrence at j.

The two tests above are called a *duel* between i and j [12]. By a duel, we can remove one or both of the candidates. Given $h > 0$, we partition the text T into disjoint h-blocks in the obvious way. If every h-block has at most two candidates, we say that T is *h-good*.

LEMMA 3.1. *If T is h-good and an h-size DS for k shifts is given, then T can be made k-good in optimal constant time.*

Proof. Let A be the ordered set of the h-size DS. For each k-block, there are initially at most $2k/h$ candidates and we have $h/2$ processors per candidate. For each such candidate in the k-block, make h comparisons with the positions of A. If a candidate has a mismatch, it provides a witness against the candidate. Find the leftmost (ls) and rightmost (rs) survivors in the k-block. By the definition of the DS, every survivor i between ls and rs has at least one mismatch in the DS positions of ls or rs. For each such i, make $2h$ comparisons with the DS positions of ls and rs and find a witness against it. □

LEMMA 3.2. *If T is $m^{1/k}$-good for $k > 1$ and the witnesses of the pattern are given, T can be made $m/4$-good in time $O(\log k)$ with $O(n \log k)$ operations.*

Proof. Run $\log k$ rounds of the following until T is $m/4$-good. In a round, we start with at most two candidates per i-block (i-good) and end with at most one per i^2-block (i^2-good) by performing at most $4i^2$ duels in each i^2-block. Duels find witnesses to nonoccurrences. (Note that we actually start each round after the first with at most one candidate per i-block.) □

Given a string x of length r and a number $\ell \leq 2\sqrt{r}$, FIND-SUB finds the first nonperiodic substring z of length ℓ and computes witnesses of z if such z exists, and it otherwise computes the period p of x of length less than $\ell/2$ and witnesses against nonmultiples of p in optimal constant time.

PROCEDURE FIND-SUB:

1. Naïvely check if each of the first $\ell/2$ positions is a period of the prefix of x of length ℓ and compute witnesses against nonperiods.
2. If none is a period, z is the prefix of x of length ℓ. Stop.
3. If there are periods, find the shortest one p. Find the smallest prefix y of x such that p is not the period of y.
4. If p is the period of x (y does not exist), witnesses against nonmultiples of p are easily computed from the witnesses of the first p-block. Stop.
5. Otherwise (y exists, i.e., there is a mismatch with period p), z is the suffix of y of length ℓ. (z is nonperiodic [8].) Naïvely compute the witnesses of z.

The first application of the constant-time DS computation is a simple string-matching algorithm with constant-time search and $O(\log \log m)$-time preprocessing called CONST-MATCH. In order to be used in section 4, CONST-MATCH solves the following problem: Given a (non-4-periodic) pattern P of length m and its witnesses and text T, find all occurrences of P in T and witnesses to nonoccurrences in optimal constant time. Initially, T is 2-good.

PROCEDURE CONST-MATCH:

1. Find the first nonperiodic substring x of P of length $r = m^{1/3}$ and the first nonperiodic substring x' of x of length $2 \log r$ using FIND-SUB, which also computes witnesses of x and x'. Steps 2–4 use Lemma 1.
2. Use the constant-size DS of x for $\log \log r$ shifts to make T $\log \log r$-good.
3. Use the $\log \log r$-size DS of x' for $\log r$ shifts to make T $\log r$-good.
4. Use the $\log r$-size DS of x for $r/2$ shifts to make T $r/2$-good.
5. Perform two rounds of duels to make T $m/4$-good (Lemma 2). Then check the surviving candidates by naïve comparisons.

THEOREM 3.3. *Given the witnesses of the pattern, procedure* CONST-MATCH *performs string matching in optimal constant time.*

COROLLARY 3.4. *Using* CONST-MATCH*, we get a string-matching algorithm with constant-time text search and* $O(\log \log m)$*-time preprocessing.*

The second application is a deterministic $O(k)$-time algorithm for finding a subpattern of length $m^{1-2^{-k}}$ in the text. This application may seem somewhat contrived, but it is useful in the next two applications. We will twice use the case $k = 1$. Let P' be a subpattern of P of length $m^{1-2^{-k}}$. We first compute witnesses of P' in $O(k)$ time by the first k rounds of the preprocessing of [2] and then find all occurrences of P' in the text by CONST-MATCH. (In case P' is 4-periodic, we use the reduction of [2].)

COROLLARY 3.5. *Using* CONST-MATCH*, we get an* $O(k)$*-time algorithm using* n *processors for finding all occurrences of a given subpattern of length* $m^{1-2^{-k}}$ *in the text, or, stated differently, we get a deterministic* $O(k)$*-time algorithm using* n *processors for string matching in case* $m = O(n^{1-2^{-k}})$.

The third application is a simple string-matching algorithm that has constant time with high probability for random input. Let P' be the prefix of the pattern of length $\sqrt{m}$. Compute witnesses of P' in constant time. Find all occurrences of P' in the text by CONST-MATCH. Being able to match P' of length $\sqrt{m}$ in constant time gives us a constant-expected-time parallel algorithm for random text even if we sequentially check the remaining symbols. The probability that the time is larger than some small constant is exponentially small.

COROLLARY 3.6. *Using* CONST-MATCH*, we get a simple string-matching algorithm that has constant time with high probability for random input.*

4. Constant-time randomized string matching. The main application of the constant-time DS computation is a constant-expected-time Las Vegas algorithm for computing the witnesses of the pattern. Together with CONST-MATCH, we obtain a constant-expected-time Las Vegas algorithm for string matching including preprocessing, solving the main open problem remaining in string matching. Thus, randomization is used to "beat" the deterministic $\Omega(\log \log m)$ lower bound for witness computation and string matching [3].

We introduce a notion of *pseudoperiod* (also used in [4]). It has an operational definition: Given a string x of length r, if we compute witnesses against all $i < r/4$ except for multiples of q, we say that q is a pseudoperiod of x. It follows from this definition that if x is 4-periodic, q must divide the period of x. Procedure FIND-PSEUDO computes a large pseudoperiod of x.

PROCEDURE FIND-PSEUDO:

1. Run FIND-SUB with x and $\ell = 2\sqrt{r}$. If the period q of x is $< \sqrt{r}$, stop. Otherwise, FIND-SUB finds the first nonperiodic substring z of x of length $2\sqrt{r}$ and computes witnesses of z.

2. Using CONST-MATCH, find all occurrences of z in x and witnesses to nonoccurrences.
3. Construct the $(r-2\sqrt{r})$-bit binary string x' such that for $0 \le i < r-2\sqrt{r}$, $x'[i] = 1$ if i is an occurrence of z and $x'[i] = 0$ otherwise. Compute the period q of x' in the case where $q < r/4$ and, in addition, all witnesses of x' against nonperiods of x' smaller than $r/4$. Note that if $q < r/4$, all periods of x' smaller than $r/4$ are multiples of q. This computation exploits the special form of x'; it contains at most $\sqrt{r}$ 1's with distance of at least $\sqrt{r}$ between them since z is nonperiodic and of length $2\sqrt{r}$. Thus we can compute witnesses of x' by considering only the 1's.
   3.1. Divide string x' into disjoint $\sqrt{r}$-blocks.
   3.2. There is at most one 1 in every block. Record the position of the 1 in the given block in the first element of that block. (Now every processor can read from the first element of a block the position of 1 in that block.)
   3.3. Let t be the position of the first 1 in x'. For position $i < t$, t is a witness against $t-i$. If $t \ge r/4$ this substep is done. Note that we already have all witnesses against $i < r/4$. Otherwise, consider $i \ge 2t$ (i.e., $i-t \ge t$). If $x'[i] = 0$, then i is a witness against $i-t$. If $x'[i] = 1$, $i-t$ is a potential period of x' since it shifts the first 1 to a 1. Use the $\sqrt{r}$ processors of the block of i to check if $i-t$ is a real period of x' by checking for all k such that $x'[k] = 1$ whether ($x'[k+i-t] = 1$ or $k+i-t \ge r-2\sqrt{r}$) and ($x'[k-i+t] = 1$ or $k-i+t < 0$). If all of these tests succeed, $i-t$ is a period of x'. If the test with k fails, $k+i-t$ or k is a witness against $i-t$. Compute q, the smallest period of x'.
   3.4. From witnesses of x', compute witnesses of x. Let w be the witness of x' against i. Assume that $x'[w] = 0$ and $x'[w-i] = 1$. (The other case is similar.) Since $x'[w] = 0$, w is a nonoccurrence of z in x. Let j be the witness to nonoccurrence of z at w. One can verify that $w+j$ is a witness of x against i.

Procedure FIND-PSEUDO computes q, which satisfies the following:

P1. If $q \le \sqrt{r}$, q is the real period of x.
P2. If $q > \sqrt{r}$, then q is a pseudoperiod of x.

Given q integers, let $\mathrm{LCM}_{k,q}$ be the minimum of $k/4$ and the LCM (least common multiple) of the q numbers. Given a $k \times q$ array B of symbols and for every column c its pseudoperiod $q_c < k/4$ and witnesses against nonmultiples of q_c, procedure FIND-LCM computes $\mathrm{LCM}_{k,q}$ of the pseudoperiods and witnesses against nonmultiples of $\mathrm{LCM}_{k,q}$ smaller than $k/4$ in constant time with kq processors as follows.

Procedure FIND-LCM:

1. Construct a $(k/4-1) \times q$ array B': in the cth column of B', write 1 in the multiples of the pseudoperiod q_c and 0 in other places.
2. For each row that is not all 1's, any 0 entry provides a witness against the row number.
3. If there is a row with all entries 1's, return the smallest such row; otherwise, return $k/4$.

Let p be the period of the pattern P. Recall that the main problem is to compute $\min(p, m/4)$ and the witnesses against all nonperiods i, $1 \le i < m/4$. These nonperiods are exactly all the nonmultiples of p smaller than $m/4$. In the 4-periodic case, witnesses against all i, $1 \le i < p$, are sufficient. The other witnesses against $i < m/4$ can be computed from them in constant time.

We first describe a deterministic $O(\log\log m)$-time algorithm for the main problem. The algorithm consists of rounds and maintains a variable q. The invariant at the end of a round is that q is a pseudoperiod of x. Initially, $q = 1$. We describe one round of the algorithm. A witness against i found during the round is a witness of P against iq.

1. Divide P into blocks of size q and make an array B of $k = m/q$ rows and q columns, where column j contains all $P[i]$ for all $i \equiv j \bmod q$.
2. For each column c of B, find q_c, its pseudoperiod, and witnesses against nonmultiples of q_c using FIND-PSEUDO.
3. If all pseudoperiods are $\leq \sqrt{k}$, all pseudoperiods are real periods. Using FIND-LCM, compute $\mathrm{LCM}_{k,q}$ and witnesses against nonmultiples of $\mathrm{LCM}_{k,q}$ smaller than $k/4$. The period of P that we compute is $q \cdot \mathrm{LCM}_{k,q}$. Stop.
4. Otherwise, choose a column c with $q_c > \sqrt{k}$. Witnesses against nonmultiples of q_c were computed in step 2. $q \leftarrow q \cdot q_c$.
5. If $q < m/4$, then go to the next round; otherwise, stop.

Note that in the first round, we have one column and compute a pseudoperiod of P by FIND-PSEUDO. In subsequent rounds, $q \cdot q_c$ is a pseudoperiod because we compute witnesses for all nonmultiples of $q \cdot q_c$. Since the new value k is at most $\sqrt{k}$, there are at most $O(\log\log m)$ rounds.

This algorithm follows the structure of the lower-bound proof [3]. That proof uses the notion of "possible period length," which is the minimum number that can still be the period of the pattern based on the results of the comparisons so far. The lower-bound argument maintains a possible period length $q \leq m^{1-4^{-i}}$ in round i and forces any algorithm to have at least $\frac{1}{4}\log\log m$ rounds. Here we compute a pseudoperiod q that may not be a period length but must divide it in case the pattern is 4-periodic. $q > m^{1-2^{-i}}$ in round i and the algorithm finds the period in at most $\log\log m$ rounds.

COROLLARY 4.1. *If P is 4-periodic and its period has a constant number of prime divisors, we can compute witnesses and do string matching in optimal deterministic constant time.*

We now describe an $O(1)$-expected-time randomized algorithm for the main problem. Execute the first three rounds of the deterministic algorithm and then execute round 4 below until it stops. At the beginning of round 4, q is a pseudoperiod of x, and B is the $k \times q$ array, $k = m/q$, created by step 1 of the deterministic algorithm. We have $q > m^{7/8}$ and $k = m/q < m^{1/8}$.

Round 4:

1. Randomly choose a multiset of $s = m/k^2$ columns from B, i.e., each of s processors chooses a random column number from the set $\{1, \ldots, q\}$. Find the period of each chosen column naïvely with k^2 processors. Using naïve comparisons, also compute witnesses against nonperiods. Using FIND-LCM, compute $h = \mathrm{LCM}_{k,s}$ and witnesses against nonmultiples of h.
2. If $h = k/4$, the pattern P is not 4-periodic. Stop.
3. Otherwise, check if h is a period of each column of B. If h is a period in all columns, qh is the period of P; stop. Otherwise, let C be the set of columns where h is not a period.
4. Using Hagerup's $(1+\epsilon)$-PAC [9], try to compact C into the set C' of size $m^{3/4}$. If the compaction fails, again try round 4 starting from step 1.
5. If the compaction is successful, compute all periods of columns in C' naïvely (we have enough processors because $m^{3/4}k^2 < m$). Using naïve comparisons, also compute witnesses against nonperiods. Using FIND-LCM, compute $h' =$

$\mathrm{LCM}_{k,m^{3/4}}$ of these periods and witnesses against nonmultiples of h'. The period of P that we compute is $\min(m/4, q \cdot \mathrm{LCM}(h, h'))$.

LEMMA 4.2. *With a very high probability, the size of C in round 4 is smaller than $m^{1/2}$.*

Proof. Let Q be the multiset of the q real periods of the columns of B. We call a period *good* if it appears in Q at least $q^{1/3}$ times; otherwise call it *bad*.

For a good period, the probability that it is not chosen among the s random choices is at most $(1 - q^{1/3}/q)^s < e^{-m^{1/6}}$ since $s = m/k^2 = q^2/m > q^{2/3}m^{1/6}$. Thus the probability that there is some good period that was not chosen is at most $qe^{-m^{1/6}} < me^{-m^{1/6}} \ll 1$.

We showed that with a very high probability only the bad periods will remain in C. Since there are only k different values for periods, the number of occurrences of bad periods in Q is at most $q^{1/3}k = m/q^{2/3} < m/m^{7/12} < m^{1/2}$. □

It follows from Lemma 3 that the PAC will fail (and as a result round 4 will be repeated) with a very small probability and the expected number of rounds is smaller than five.

LEMMA 4.3. *The randomized algorithm is an optimal Las Vegas parallel algorithm for computing the period and the witnesses of the pattern P. It has constant time with high probability.*

THEOREM 4.4. *Together with* CONST-MATCH*, we have a randomized optimal Las Vegas parallel algorithm for string matching, including preprocessing. It has constant time with high probability (and thus constant expected time).*

5. Conclusion. We have shown how to compute deterministic samples for a part of the pattern in constant time, and we obtained a deterministic string-matching algorithm which is probably the best in both preprocessing and text search. We use them to obtain a simple constant-expected-time algorithm for random input and a more sophisticated randomized algorithm for string matching with constant expected time.

The randomized algorithm for string matching leads to constant-expected-time randomized algorithms for several related problems. If we solve $\log m$ (or even more) string-matching problems at the same time, the expected time is still a constant. This converts the algorithms for finding all periods, squares, and palindromes [1] into constant-expected-time randomized algorithms.

We believe that there may be more applications for our superfast deterministic sampling. The DS can be considered as a deterministic fingerprint. No constant-time algorithm is known for the conventional fingerprint computation on a CRCW PRAM. On the EREW PRAM, our algorithm can be translated into an optimal $O(\log m)$-time algorithm [6]; it works for any alphabet since it only performs comparisons on the input symbols. The conventional fingerprint has an optimal randomized $O(\log m)$-time algorithm on the EREW PRAM and it works only when the alphabet is given and is of small size [10]. On the other hand, our DS is only for a subpattern, and while it is computed deterministically, one still needs randomization for computing the witnesses. (The conventional fingerprint, while randomized, is applied deterministically.)

Acknowledgments. We thank Noga Alon and Yossi Matias for helpful suggestions.

LEARNING FROM MULTIPLE SOURCES OF INACCURATE DATA*

GANESH BALIGA†, SANJAY JAIN‡, AND ARUN SHARMA§

Abstract. Most theoretical models of inductive inference make the idealized assumption that the data available to a learner is from a *single* and *accurate* source. The subject of inaccuracies in data emanating from a single source has been addressed by several authors. The present paper argues in favor of a more realistic learning model in which data emanates from *multiple* sources, some or all of which may be *inaccurate*. Three kinds of inaccuracies are considered: spurious data (modeled as *noisy* texts), missing data (modeled as *incomplete* texts), and a mixture of spurious and missing data (modeled as *imperfect* texts).

Motivated by the above argument, the present paper introduces and theoretically analyzes a number of inference criteria in which a learning machine is fed data from multiple sources, some of which may be infected with inaccuracies. The learning situation modeled is the identification in the limit of programs from graphs of computable functions. The main parameters of the investigation are: the kind of inaccuracy, the total number of data sources, the number of faulty data sources which produce data within an acceptable bound, and the bound on the number of errors allowed in the final hypothesis learned by the machine.

Sufficient conditions are determined under which, for the same kind of inaccuracy, for the same bound on the number of errors in the final hypothesis, and for the same bound on the number of inaccuracies, learning from multiple texts, some of which may be inaccurate, is equivalent to learning from a single inaccurate text.

The general problem of determining when learning from multiple inaccurate texts is a restriction over learning from a single inaccurate text turns out to be combinatorially very complex. Significant partial results are provided for this problem. Several results are also provided about conditions under which the detrimental effects of multiple texts can be overcome by either allowing more errors in the final hypothesis or by reducing the number of inaccuracies in the texts.

It is also shown that the usual hierarchies resulting from allowing extra errors in the final program (results in increased learning power) and allowing extra inaccuracies in the texts (results in decreased learning power) hold.

Finally, it is demonstrated that in the context of learning from multiple inaccurate texts, spurious data is better than missing data, which in turn is better than a mixture of spurious and missing data.

Key words. inductive inference, machine learning, inaccurate data, multiple sources

1. Introduction.

A scenario in which an *algorithmic* learner attempts to learn its environment may be described thusly. At any given time, some finite data about the environment is made available to the learner. The learner reacts to this finite information by conjecturing a hypothesis to explain the behavior of its environment. The availability of additional data may cause the learner to revise its old hypotheses. The learner is said to be successful just in case the sequence of hypotheses it conjectures stabilizes to a final hypothesis which correctly represents its environment.

The above model, generally referred to as *identification in the limit*, originated in the pioneering work of Putnam [19], Gold [12], and Solomonoff [25, 26]. More recently, this model has been the subject of numerous studies in computational learning theory

(see, e.g., [13, 20, 10, 27, 1]). A problem with this model is the idealized assumption that the data available to the learner is from a *single* and *accurate* source. The subject of inaccuracies in the data available to a learning machine has been previously studied by Schäfer-Richter [23], Fulk and Jain [11], Osherson, Stob, and Weinstein [17], and Jain [14, 15]. Each of these studies, however, also makes the assumption that the data available to the learner is from a single source. The present paper argues that in realistic learning situations, data available to a learner is from *multiple* sources, some of which may be *inaccurate*. We discuss these issues in the context of a specific learning scenario, namely, scientific inquiry modeled as identification of programs from graphs of computable functions. Although we present our results in the context of this particular learning task, we note that some of our arguments and techniques can be applied to other learning situations as well.

Consider a scientist S investigating a real-world phenomenon F. S performs experiments on F, noting the result of each experiment, while simultaneously conjecturing a succession of candidate explanations for F. A criterion of success is for S to eventually conjecture an explanation which S never gives up and which correctly explains F. Since we never measure a continuum of possibilities, we could treat S as performing discrete experiments x on F and receiving back experimental results $f(x)$. By using a suitable Gödel numbering, we may treat f associated with F as a function from N, the set of natural numbers, into N. Also, assuming a suitable neomechanistic viewpoint about the universe, f is computable. A complete and predictive explanation of F, then, is just a computer program for computing f. Thus algorithmic identification in the limit of programs for computable functions from their graph yields a plausible model for scientific inquiry.

Let us consider some common practices in scientific inquiry. Data is usually collected using different instruments, possibly at different places. (For example, astronomers use data from different telescopes situated at different locations.) In many cases, experimental errors may creep in or the instruments may simply be faulty. In some extreme cases, the same instrument may record conflicting readings at different times. Also, occasionally it may be infeasible to perform experiments (for example, determining the taste of cyanide). Moreover, the experimental findings of one scientist are generally available to others. All of this tends to suggest that a scientist often receives data from multiple sources, many of which are likely to be inaccurate. The present paper incorporates these observations into the standard learning model. We now proceed formally.

Section 2 presents the notation. Section 3 presents the preliminary notions about identification in the limit and inaccurate data. Section 4 introduces the main subject of this paper, viz, learning in the presence of multiple sources of inaccurate data. In this section, we also discuss some of our results informally. Section 5 presents our results with proofs.

2. Notation. The recursion-theoretic concepts not explained below are treated in [22]. N denotes the set of natural numbers, $\{0, 1, 2, 3, \ldots\}$, and N^+ denotes the set of positive integers, $\{1, 2, 3, \ldots\}$. $\in$, $\subseteq$, and $\subset$ denote, respectively, membership, containment, and proper containment for sets.

We let e, i, j, k, l, m, n, r, s, t, u, v, w, x, y, and z, with or without decorations,[1] range over N. We let a, b, and c, with or without decorations, range over $N \cup \{*\}$.

$[m, n]$ denotes the set $\{x \in N \mid m \leq x \leq n\}$. We let S, with or without

[1] Decorations are subscripts, superscripts, primes and the like.

decorations, range over subsets of N and we let A, B, C, and D, with or without decorations, range over finite subsets of N. $\min(S)$ and $\max(S)$, respectively, denote the minimum and maximum element in S ($\max(S)$ is undefined if S contains infinitely many elements). We take $\min(\emptyset)$ to be ∞ and $\max(\emptyset)$ to be 0. $\text{card}(S)$ denotes the cardinality of S. $*$ denotes *unbounded* but *finite*. We let $(\forall n \in N)[n < * < \infty]$. So then "$\text{card}(S) \leq *$" means that $\text{card}(S)$ is finite.

Let $\lambda x, y.\langle x, y\rangle$ denote a fixed pairing function (a recursive, bijective mapping: $N \times N \rightarrow N$) [22]. $\lambda x, y.\langle x, y\rangle$ and its inverses are useful for simulating the effect of having multiple argument functions. π_1 and π_2 are corresponding projection functions, i.e., $(\forall x, y)[\pi_1(\langle x, y\rangle) = x \ \wedge \ \pi_2(\langle x, y\rangle) = y]$.

η and ξ range over partial functions. For $a \in (N \cup \{*\})$, we say that η_1 is an a-variant of η_2 (written $\eta_1 =^a \eta_2$) iff $\text{card}(\{x \mid \eta_1(x) \neq \eta_2(x)\}) \leq a$. Otherwise, we say that η_1 is not an a-variant of η_2 (written $\eta_1 \neq^a \eta_2$). $\text{domain}(\eta)$ and $\text{range}(\eta)$, respectively, denote the domain and range of partial function η. Let $A \subseteq N$ and $c \in N$. We say that $\eta(A) = c$ iff for all $x \in A$, $\eta(x) = c$. If S_1 and S_2 are two sets, then $S_1 \mathbf{\Delta} S_2$ denotes $(S_1 - S_2) \cup (S_2 - S_1)$.

$\mathcal{R}$ denotes the class of all *recursive* functions of one variable, i.e., total computable functions with arguments and values from N. f, g, and h, with or without decorations, range over $\mathcal{R}$. $\mathcal{C}$ and $\mathcal{S}$, with or without decorations, range over subsets of $\mathcal{R}$.

We fix φ to be an *acceptable programming system* [21, 22, 16] for the partial recursive functions: $N \rightarrow N$. φ_i denotes the partial recursive function computed by the φ-program with index i. W_i denotes $\text{domain}(\varphi_i)$. W_i is then the r.e. set/language ($\subseteq N$) accepted (or, equivalently, generated) by the φ-program i. We let Φ be an arbitrary Blum complexity measure [4] associated with an acceptable programming system φ; such measures exist for any acceptable programming system [4]. $W_{i,s}$ denotes the set $\{x \mid x < s \ \wedge \ \Phi_i(x) \leq s\}$.

In some contexts p and q, with or without decorations, range over programs. In other contexts, p and q range over total recursive functions, with the range of p and q being interpreted as (indexes for) programs. In some contexts P, with or without decorations, ranges over programs. In other contexts, P ranges over sets of programs.

For any predicate Q, $\mu n.Q(n)$ denotes the minimum integer n such that $Q(n)$ is true if such an n exists; it is undefined otherwise. For any set A, 2^A denotes the power set of A. A^k denotes the Cartesian product of A with itself k times. The quantifiers "$\overset{\infty}{\forall}$," "$\exists!$," and "$\overset{\infty}{\exists}$" mean "for all but finitely many," "there exists a unique," and "there exist infinitely many," respectively.

3. Preliminaries. The kind of data a scientist handles in the investigation of a phenomenon F is an ordered pair $(x, f(x))$, where f is the function associated with F and $f(x)$ is the result of experiment x on F. At any given time, a scientist conjectures a hypothesis after seeing a finite sequence of such ordered pairs. We let SEQ denote the set of all finite sequences of ordered pairs. Finite sequences are also referred to as initial segments. As already mentioned, a hypothesis is simply a computer program identified by its index in a given fixed acceptable programming system. Based on these observations, we describe a learning machine in Definition 3.1 below. We let σ and τ, with or without decorations, range over SEQ. $\text{content}(\sigma)$ denotes the set of pairs appearing in σ. The length of σ, denoted by $|\sigma|$, is the number of elements in σ. $\sigma \diamond (x, y)$ denotes the *concatenation* of (x, y) at the end of sequence σ.

DEFINITION 3.1. *A* learning machine *is an algorithmic device that computes a mapping from* SEQ *into* N. *We let* $\mathbf{M}$, *with or without decorations, range over learning machines.*

Scientific inquiry is a limiting process. There is no fixed order in which experiments may be performed, and a scientist is never sure if any new evidence would cause a revision of the currently held hypothesis. The notion of a *text* is described in Definition 3.2 to model the infinite sequence of experimental data that a scientist may encounter in the course of investigating a phenomenon.

DEFINITION 3.2.

1. *A* text *is any infinite sequence of ordered pairs. We let T, with or without decorations, range over texts.*
2. *The set of pairs appearing in a text T is denoted by* content(T).
3. *Let a total function $f : N \to N$ and a text T be given. T is for f just in case* content$(T) = \{(x, y) \mid f(x) = y\}$.
4. *The initial finite sequence of T of length n is denoted by $T[n]$.*

Definition 3.3 below describes what it means for a learning machine to converge on a text.

DEFINITION 3.3. *Suppose* $\mathbf{M}$ *is a learning machine and T is a text.* $\mathbf{M}(T)\downarrow$ (*read:* $\mathbf{M}(T)$ converges) $\iff$ $(\exists p)(\overset{\infty}{\forall} n)[\mathbf{M}(T[n]) = p]$. *If* $\mathbf{M}(T)\downarrow$, *then* $\mathbf{M}(T)$ *is defined = the unique p such that* $(\overset{\infty}{\forall} n)[\mathbf{M}(T[n]) = p]$; *otherwise,* $\mathbf{M}(T)$ *is said to diverge* (*written:* $\mathbf{M}(T)\uparrow$).

Definition 3.4 below describes what it means for a learning machine to successfully learn a function.

DEFINITION 3.4. (See [12, 3, 8].)

1. $\mathbf{M}$ $\mathbf{Ex}^a$-identifies *a total function f* (*written:* $f \in \mathbf{Ex}^a(\mathbf{M})$) $\iff$ ($\forall$ *texts T for f*)$(\exists p \mid \varphi_p =^a f)[\mathbf{M}(T)\downarrow = p]$.
2. $\mathbf{Ex}^a = \{\mathcal{S} \mid (\exists \mathbf{M})[\mathcal{S} \subseteq \mathbf{Ex}^a(\mathbf{M})]\}$.

Definition 3.4 above models the situation in which a scientist has access to an *accurate* source of data. Since totally accurate experimental data is seldom available, models of scientific inquiry should accommodate inaccuracies. In the paradigm under discussion, inaccurate data is modeled by inaccurate texts. First, we briefly consider the kinds of inaccuracies that may arise in experimentation. The subject of inaccuracies in the data available to a learning machine has been previously studied by Schäfer-Richter [23], Fulk and Jain [11], Osherson, Stob, and Weinstein [17], and Jain [14, 15].

- *Noisy data*: Experimental error, usually caused by faulty equipment, may result in spurious data that is not representative of the phenomenon under investigation.
- *Incomplete data*: It may not be feasible to perform certain experiments either due to technological limitations or due to ethical considerations. Such situations result in incomplete data.
- *Imperfect data*: In most experimental investigations, the inaccuracies are a mixture of both noisy and incomplete data. Such situations are said to yield imperfect data.

The three kinds of inaccuracies discussed above suggest three natural extensions to the notion of texts defined below.

DEFINITION 3.5. (See [11, 17, 14]; also see [23].) *Let a text T and a function $f \in \mathcal{R}$ be given. Let $a \in N \cup \{*\}$. Then we define the following:*

1. *T is said to be* a-noisy *for f just in case* $\{(x, y) \mid f(x) = y\} \subseteq$ content(T) *and* card(content$(T) - \{(x, y) \mid f(x) = y\}) \leq a$.
2. *T is said to be* a-incomplete *for f just in case* content$(T) \subseteq \{(x, y) \mid f(x) = y\}$ *and* card$(\{(x, y) \mid f(x) = y\} -$ content$(T)) \leq a$.

3. *T is said to be* a-imperfect *for f just in case* $\mathrm{card}(\{(x,y) \mid f(x) = y\} \mathbf{\Delta} \mathrm{content}(T)) \leq a$.

Definition 3.6 below describes what it means for a learning machine to learn a function from inaccurate texts. We give the definition for noisy texts; the corresponding notions for incomplete and imperfect texts (respectively called $\mathbf{In}^a\mathbf{Ex}^b$ and $\mathbf{Im}^a\mathbf{Ex}^b$) can be defined similarly.

DEFINITION 3.6. (See [11, 17, 14]; also see [23].) *Let $a, b \in N \cup \{*\}$.*

1. $\mathbf{M}$ $\mathbf{N}^a\mathbf{Ex}^b$-identifies *a total function f (written: $f \in \mathbf{N}^a\mathbf{Ex}^b(\mathbf{M})$)* $\iff$ $(\forall$ *a-noisy texts T for f*$)(\exists p \mid \varphi_p =^b f)[\mathbf{M}(T)\downarrow = p]$.
2. $\mathbf{N}^a\mathbf{Ex}^b = \{\mathcal{S} \mid (\exists \mathbf{M})[\mathcal{S} \subseteq \mathbf{N}^a\mathbf{Ex}^b(\mathbf{M})]\}$.

4. Multiple inaccurate texts. The previous section described a paradigm that models a scientist receiving data from a *single*, albeit possibly inaccurate, source. In actual scientific practice, a phenomenon is investigated by a number of different scientists, each performing their own experiments. In due course of time, the data of one scientist becomes available to another through scientific journals, word of mouth, personal communications, etc. Thus a scientist conjectures hypotheses based on data coming from a number of different sources. This situation could be modeled in the present paradigm as a machine receiving multiple texts, some or all of which are inaccurate. It should be noted that the presence of inaccuracies in at least some of the texts is essential for this model to be different because learning from multiple texts, each of which are accurate, is equivalent to learning from a single accurate text.

Before we define learning from multiple inaccurate texts, we need to tinker with the definition of a learning machine to account for data coming from more than one source. Definition 4.1 below describes learning machines that receive multiple streams of data.

DEFINITION 4.1. *Let $k \in N^+$. A* learning machine with k streams *is an algorithmic device that computes a mapping from* SEQ^k *into N.*

Again, we let $\mathbf{M}$, with or without decorations, range over learning machines with multiple streams; it will be clear from the context if we mean a learning machine with a single stream. Definition 4.2 below describes what it means for a learning machine to converge on multiple texts.

DEFINITION 4.2. *Let $k \in N^+$. Let $\mathbf{M}$ be a learning machine and $T_1, T_2, \ldots, T_k$ are k texts.* $\mathbf{M}(T_1, T_2, \ldots, T_k)\downarrow$ *(read:* $\mathbf{M}(T_1, T_2, \ldots, T_k)$ *converges)* $\iff$ $(\exists p)(\exists n)(\forall n_1, n_2, \ldots, n_k \mid n_1 \geq n, n_2 \geq n, \ldots, n_k \geq n)[\mathbf{M}(T_1[n_1], T_2[n_2], \ldots, T_k[n_k]) = p]$. *If* $\mathbf{M}(T_1, T_2, \ldots, T_k)\downarrow$, *then* $\mathbf{M}(T_1, T_2, \ldots, T_k)$ *is defined = the unique p such that* $(\exists n)(\forall n_1, n_2, \ldots, n_k \mid n_1 \geq n, n_2 \geq n, \ldots, n_k \geq n)[\mathbf{M}(T_1[n_1], T_2[n_2], \ldots, T_k[n_k]) = p]$; *otherwise,* $\mathbf{M}(T_1, T_2, \ldots, T_k)$ *is said to diverge (written:* $\mathbf{M}(T_1, T_2, \ldots, T_k)\uparrow$*).*

Definition 4.3 below describes what it means for a learning machine to learn a function from multiple inaccurate texts. We give the definition for noisy texts; the corresponding notions for incomplete and imperfect texts may be defined similarly.

DEFINITION 4.3. *Let $j, k \in N^+$. Let $a, b \in N \cup \{*\}$.*

(a) *A learning machine* $\mathbf{M}$ $\mathbf{Mul}^j_k\mathbf{N}^a\mathbf{Ex}^b$-identifies *a total function f (written: $f \in \mathbf{Mul}^j_k\mathbf{N}^a\mathbf{Ex}^b(\mathbf{M})$)* $\iff$ $(\forall$ *k texts $T_1, T_2, \ldots, T_k$ such that at least j out of these k texts are a-noisy for f*$)(\exists p \mid \varphi_p =^b f)[\mathbf{M}(T_1, T_2, \ldots, T_k)\downarrow = p]$.

(b) $\mathbf{Mul}^j_k\mathbf{N}^a\mathbf{Ex}^b = \{\mathcal{S} \mid (\exists \mathbf{M})[\mathcal{S} \subseteq \mathbf{Mul}^j_k\mathbf{N}^a\mathbf{Ex}^b(\mathbf{M})]\}$.

So a machine $\mathbf{Mul}^j_k\mathbf{N}^a\mathbf{Ex}^b$-($\mathbf{Mul}^j_k\mathbf{In}^a\mathbf{Ex}^b$-, $\mathbf{Mul}^j_k\mathbf{Im}^a\mathbf{Ex}^b$-) identifying a function f, upon being fed k texts at least j of which are a-noisy (a-incomplete, a-imperfect) for f, converges to a program for a b-variant for f. Henceforth, when

discussing $\mathbf{Mul}_k^j\mathbf{N}^a\mathbf{Ex}^b$, etc., those texts for which the inaccuracy is within the required bound are referred to as *acceptable* texts. We next note that the only interesting cases are those for which the number of acceptable texts is a majority of the total number of texts.

Consider a collection of recursive functions $\mathcal{C}$. Assume $f_1, f_2 \in \mathcal{C}$ to be such that $f_1 \neq^{2a} f_2$. Then for all k, we have $\mathcal{C} \notin \mathbf{Mul}_k^{\lfloor \frac{k}{2} \rfloor}\mathbf{N}^0\mathbf{Ex}^a$. This is because among k texts there may be $\lfloor \frac{k}{2} \rfloor$ accurate texts for both f_1 and f_2. To avoid such problems, we consider only those cases in which a strict majority of the texts are acceptable.[2]

We now discuss our results before presenting them with proofs in the next section.

One of our central aims is to investigate the relationship between identification from a single inaccurate text and identification from multiple inaccurate texts, where the inaccuracy is of the same kind. For noisy texts, for instance, this question can be phrased as follows: How does $\mathbf{N}^a\mathbf{Ex}^b$ relate to $\mathbf{Mul}_k^j\mathbf{N}^c\mathbf{Ex}^d$ for various values of a, b, c, d and j, k? Similar questions can be posed for incomplete and imperfect texts. This general question turns out to be combinatorially very difficult, and only partial results are presented in this paper.

First, the following immediate proposition states that for the same bound on the number of inaccuracies and the same kind of inaccuracy, identification from multiple inaccurate texts cannot be better than identification from a single inaccurate text, that is, collections of functions that can be identified from multiple inaccurate texts can also identified from a single inaccurate text.

PROPOSITION 4.4. *Let $j, k \in N$ such that $k \geq j$. Let $a, b \in N \cup \{*\}$.*

1. $\mathbf{Mul}_k^j\mathbf{N}^a\mathbf{Ex}^b \subseteq \mathbf{N}^a\mathbf{Ex}^b$.
2. $\mathbf{Mul}_k^j\mathbf{In}^a\mathbf{Ex}^b \subseteq \mathbf{In}^a\mathbf{Ex}^b$.
3. $\mathbf{Mul}_k^j\mathbf{Im}^a\mathbf{Ex}^b \subseteq \mathbf{Im}^a\mathbf{Ex}^b$.

The natural question is "When does the above proposition yield an equality?" That is, we would like to have sufficient conditions for when identification from multiple texts is no worse than identification from a single inaccurate text. The results in section 5.1 give some conditions such that—for each kind of inaccuracy (noise, incompleteness, and imperfection)—if a collection of functions can be learned from a single inaccurate text, then it can also be learned (with the same bound on the number of errors in the final program) from multiple inaccurate texts, provided the bound on the number of inaccuracies in at least a *majority* of the acceptable texts is the same as the bound on the number of inaccuracies in the single inaccurate text.

The next natural question is under what conditions identification from multiple texts, some of which may be inaccurate, constitutes a restriction on identification from a single inaccurate text. More precisely, we would like to answer the following question: For what relationship between a, b, c, d and j, k is $\mathbf{N}^a\mathbf{Ex}^b - \mathbf{Mul}_k^j\mathbf{N}^c\mathbf{Ex}^d \neq \emptyset$? Unfortunately, this question turns out to be very difficult, and we are only able to provide partial results for identification from three texts, at least two of which are acceptable (that is, for the case where $j = 2$ and $k = 3$). Theorem 5.4 in section 5.2 is a very general result that gives sufficient conditions for a, b, c, and d such that $\mathbf{N}^a\mathbf{Ex}^b - \mathbf{Mul}_3^2\mathbf{N}^c\mathbf{Ex}^d \neq \emptyset$. Unfortunately, these conditions turn out to be somewhat intricate, but the reader can get a feel for the special cases of these conditions presented

[2] It should be noted that if for all $f_1, f_2 \in \mathcal{C}$, $f_1 =^{2a} f_2$, then all functions in $\mathcal{C}$ are finite variants of any fixed function in the class. We feel that such cases are not interesting because if at least j out of k input texts are acceptable for a function $f \in \mathcal{C}$, then one can easily find a program p (in the limit) such that at least j out of k input texts are acceptable for φ_p (though this φ_p may not be in $\mathcal{C}$).

in Corollaries 5.5, 5.6, 5.7, and 5.8. These results are presented in section 5.2.

Also in section 5.2, we consider the cases where the restrictive effects of learning from multiple inaccurate texts can be compensated. More precisely, we identify the relationship between a, b, c, and d such that $\mathbf{N}^a\mathbf{Ex}^b \subseteq \mathbf{Mul}_3^2\mathbf{N}^c\mathbf{Ex}^d$. This is achieved by either allowing a greater upper bound on the number of errors tolerated in the final program (that is, by making d greater than b) or making the quality of acceptable texts better than the quality of single inaccurate text (that is, by making c smaller than a). An interesting result along these lines is that for each type of inaccuracy, the collections of functions identified from a single inaccurate text can also be identified from three texts, at least two of which are acceptable with the same bound on the number of inaccuracies as the single text, provided we are prepared to tolerate twice the number of errors in the final program. This follows from Theorems 5.9, 5.19, and 5.22.

In section 5.3, we consider the effects of increasing the bound on the number of errors tolerated in the final program-keeping other parameters the same, and the effects of increasing the bound on the number of inaccuracies in the acceptable texts, keeping other parameters the same. We are able to show the expected result that for each inaccuracy type, larger collections of functions become identifiable if we

- increase the bound on the number of errors allowed in the final program (keeping other parameters the same) or
- decrease the bound on the number of inaccuracies allowed in the input texts (keeping other parameters the same).

The results discussed so far have been about the same kind of inaccuracies. Finally, in Section 5.4, we present results that compare one kind of inaccuracy with another in the context of identification from multiple texts. Our findings show that noisy texts are better for learnability than incomplete texts. This observation may be interpreted as saying that spurious data is preferable to missing data. However, we also show that imperfect texts are worse for learnability than incomplete texts, which can be seen as saying that a mixture of spurious and missing data is less desirable than only missing data.

5. Results. We now present results relating various criteria of inference introduced in section 4. Most results in this paper are about the case in which a learning machine is receiving data from three sources, at least two of which are acceptable. Section 5.1 presents results about those cases in which learning from multiple texts is not a restriction on learning power. Section 5.2 presents results in which learning from multiple texts is a restriction on learning power and also results from cases in which the deleterious effects of learning from multiple inaccurate texts can be compensated by either allowing extra errors in the final program or improving the quality of the acceptable texts. Section 5.3 presents the hierarchy results and section 5.4 presents some results about the interaction between different kinds of inaccuracies.

From a purely technical point of view, the results presented in section 5.2 are the most difficult results of this paper. Also, we are able to establish more results for noisy texts than for incomplete and imperfect texts.

5.1. When identification from multiple texts is not restrictive. We consider cases when learning from multiple inaccurate texts is equivalent to learning from a single inaccurate text. Parts 1, 2, and 3 of the next result show that for each kind of inaccuracy, the collections of functions that can be identified from a single text with a finite number of inaccuracies is exactly the same as the collections of functions that can be identified (with the same bound on the number of errors allowed in the final

program) from multiple texts, at least a majority of which have only a finite number of inaccuracies.

THEOREM 5.1. *Let $j, k \in N$, $k \geq j > \lfloor \frac{k}{2} \rfloor$. Let $a \in N \cup \{*\}$.*

1. $\mathbf{Mul}_k^j\mathbf{N}^*\mathbf{Ex}^a = \mathbf{N}^*\mathbf{Ex}^a$.
2. $\mathbf{Mul}_k^j\mathbf{In}^*\mathbf{Ex}^a = \mathbf{In}^*\mathbf{Ex}^a$.
3. $\mathbf{Mul}_k^j\mathbf{Im}^*\mathbf{Ex}^a = \mathbf{Im}^*\mathbf{Ex}^a$.
4. $\mathbf{Mul}_k^j\mathbf{N}^0\mathbf{Ex}^a = \mathbf{Mul}_k^j\mathbf{In}^0\mathbf{Ex}^a = \mathbf{Mul}_k^j\mathbf{Im}^0\mathbf{Ex}^a = \mathbf{Ex}^a$.

Proof. Given k texts $T_1, T_2, \ldots, T_k$, construct a text T such that $(x, y) \in \text{content}(T) \iff \text{card}(\{i \mid (x, y) \in \text{content}(T_i)\}) \geq \lfloor \frac{k}{2} \rfloor + 1$. It is easy to see that if at least $\lfloor \frac{k}{2} \rfloor + 1$ of the k texts are $*$-noisy ($*$-incomplete, $*$-imperfect, accurate) for f, then so is T. The theorem follows. □

We now introduce a technical notion that is used in later proofs. Let P be a finite set of programs. Define the program $\mathbf{Unify}(P)$ as follows:

begin $\varphi_{\mathbf{Unify}(P)}(x)$
  Search for $i \in P$ such that $\varphi_i(x)\downarrow$.
  If and when such an i is found, output $\varphi_i(x)$ (for the first such i found).
end $\varphi_{\mathbf{Unify}(P)}(x)$

The next result shows that for $a \in N \cup \{*\}$, the collections of functions for which an exact program can be identified from a single text with the number of inaccuracies bounded by a is exactly the same as the collections of functions for which an exact program can be identified from multiple texts, at least a majority of which have at most a inaccuracies.

THEOREM 5.2. *Let $j, k \in N$, $k \geq j > \lfloor \frac{k}{2} \rfloor$. Let $a \in N \cup \{*\}$.*

1. $\mathbf{Mul}_k^j\mathbf{N}^a\mathbf{Ex} = \mathbf{N}^a\mathbf{Ex}$.
2. $\mathbf{Mul}_k^j\mathbf{In}^a\mathbf{Ex} = \mathbf{In}^a\mathbf{Ex}$.
3. $\mathbf{Mul}_k^j\mathbf{Im}^a\mathbf{Ex} = \mathbf{Im}^a\mathbf{Ex}$.

Proof. 1. Proposition 4.4 yields $\mathbf{Mul}_k^j\mathbf{N}^a\mathbf{Ex} \subseteq \mathbf{N}^a\mathbf{Ex}$. We now show that $\mathbf{N}^a\mathbf{Ex} \subseteq \mathbf{Mul}_k^j\mathbf{N}^a\mathbf{Ex}$.

Let $\mathbf{M}$ $\mathbf{N}^a\mathbf{Ex}$-identify $\mathcal{C}$. We show how to $\mathbf{Ex}$-identify $f \in \mathcal{C}$ from k texts, at least j of which are a-noisy for f. Let n, $S = \{i_1, i_2, \ldots, i_j\} \subseteq \{1, 2, \ldots, k\}$, and $P = \{p_{i_1}, p_{i_2}, \ldots, p_{i_j}\}$ be such that

(i) for all $l \in S$ and $m \geq n$, $\mathbf{M}(T_l[m]) = p_l$,
(ii) if $p, q \in P$, then $\text{card}(\{x \mid \varphi_p(x)\downarrow \neq \varphi_q(x)\downarrow\}) = 0$, and
(iii) $\text{card}(S) = j$.

Clearly, such an n, S, and P exist. (Let $S \subseteq \{i \mid T_i \text{ is } a\text{-noisy for } f\}$ be a set of cardinality j; let n be such that for all $l \in S$, $\mathbf{M}$ converges on T_l after seeing at most n inputs; let $P = \{\mathbf{M}(T_l) \mid l \in S\}$. Then n, S, P satisfy (i), (ii), and (iii).) Clearly, a machine $\mathbf{M}'$, given texts $T_1, \ldots, T_k$, can find such an n, S, and P in the limit. Now since $\mathbf{M}$ on $T_l, l \in S$, converges to p_l and $\text{card}(S) > k - j$, there exists an $l \in S$ such that $\varphi_{p_l} = f$. This along with (ii) above implies that $\mathbf{Unify}(P)$ is a program for f. This proves part 1.

Parts 2 and 3 can be proved similarly. □

The next result shows that for $a \in N \cup \{*\}$, the collections of functions for which a $*$-error program can be identified from a single text with the number of inaccuracies bounded by a is exactly the same as the collections of functions for which a $*$-error program can be identified from multiple texts, at least a majority of which have at most a inaccuracies.

THEOREM 5.3. *Let $j, k \in N$, $k \geq j > \lfloor \frac{k}{2} \rfloor$. Let $a \in N \cup \{*\}$.*

1. $\mathbf{Mul}_k^j\mathbf{N}^a\mathbf{Ex}^* = \mathbf{N}^a\mathbf{Ex}^*$.
2. $\mathbf{Mul}_k^j\mathbf{In}^a\mathbf{Ex}^* = \mathbf{In}^a\mathbf{Ex}^*$.
3. $\mathbf{Mul}_k^j\mathbf{Im}^a\mathbf{Ex}^* = \mathbf{Im}^a\mathbf{Ex}^*$.

Proof. 1. Proposition 4.4 yields $\mathbf{Mul}_k^j\mathbf{N}^a\mathbf{Ex}^* \subseteq \mathbf{N}^a\mathbf{Ex}^*$. We now show that $\mathbf{N}^a\mathbf{Ex}^* \subseteq \mathbf{Mul}_k^j\mathbf{N}^a\mathbf{Ex}^*$.

Let $\mathbf{M}$ $\mathbf{N}^a\mathbf{Ex}^*$-identify $\mathcal{C}$. We show how to $\mathbf{Ex}^*$-identify $f \in \mathcal{C}$ from k texts, at least j of which are a-noisy for f. Let n, $S = \{i_1, i_2, \ldots, i_j\} \subseteq \{1, 2, \ldots, k\}$, and $P = \{p_{i_1}, p_{i_2}, \ldots, p_{i_j}\}$ be such that

(i) for all $l \in S$ and $m \geq n$, $\mathbf{M}(T_l[m]) = p_l$,

(ii) if $p, q \in P$, then $\mathrm{card}(\{x \mid \varphi_p(x)\downarrow \neq \varphi_q(x)\downarrow\}) \leq n$, and

(iii) $\mathrm{card}(S) = j$.

Clearly, such an n, S, and P exist. (Let $S \subseteq \{i \mid T_i \text{ is } a\text{-noisy for } f\}$ be a set of cardinality j; let $P = \{\mathbf{M}(T_l) \mid l \in S\}$; let n be so large that for all $l \in S$, $\mathbf{M}$ converges on T_l after seeing at most n inputs and $f =^{n/2} \varphi_p$ for all $p \in P$. Then n, S, and P satisfy (i), (ii), and (iii).) Clearly, a machine $\mathbf{M}'$, given texts $T_1, \ldots, T_k$, can find such an n, S, P in the limit. Now since $\mathbf{M}$ on $T_l, l \in S$, converges to p_l and $\mathrm{card}(S) > k - j$, there exists an $l \in S$ such that $\varphi_{p_l} =^* f$. This along with (ii) above implies that $\mathbf{Unify}(P)$ is a program for a finite variant of f. This proves part 1.

Parts 2 and 3 can be proved similarly. □

5.2. When identification from multiple texts is restrictive. In this section we initially tackle the question of when, for the same kind of inaccuracy, learning from multiple texts, some of which may be inaccurate, is a restriction over learning from a single inaccurate text. That is, we consider the question: For which values of a, b, c, d and j, k is $\mathbf{N}^a\mathbf{Ex}^b - \mathbf{Mul}_k^j\mathbf{N}^c\mathbf{Ex}^d \neq \emptyset$? As already noted, this turns out to be a very difficult question. For the case where $j = 2$ and $k = 3$, we are able to provide significant partial answers. These results follow from a very complex diagonalization argument.

In this section, we then consider the related question of when the restriction of identification from multiple texts can be compensated. That is, for what values of a, b, c, d is $\mathbf{N}^a\mathbf{Ex}^b \subseteq \mathbf{Mul}_3^2\mathbf{N}^c\mathbf{Ex}^d$. These results use simulation arguments.

We first present results for noisy texts (section 5.2.1), followed by results for incomplete texts (section 5.2.2). Only a few results are presented for imperfect texts.

5.2.1. Noisy texts. We present a general theorem (Theorem 5.4) that covers numerous cases in which identification from multiple noisy texts is a restriction over identification from a single noisy text. Unfortunately, the conditions in the theorem turn out to be very complex, and the reader is advised to see the four corollaries presented immediately after the statement of the theorem for cases in which multiple texts pose a restriction. However, we first try to present the intuitive motivation of the theorem. Consider the question of trying to compare identification from a single noisy text and identification from three texts, at least two of which are noisy. Furthermore, let

- a be the bound on the noise level of the single text,
- b be the bound on the number of errors allowed in programs inferred from the single text,
- c be the bound on the noise level of the acceptable texts in the case of identification from multiple texts, and
- d be the bound on the number of errors allowed in programs inferred from multiple texts.

We would like to know when

$$\mathbf{N}^a\mathbf{Ex}^b - \mathbf{Mul}_3^2\mathbf{N}^c\mathbf{Ex}^d \neq \emptyset.$$

Now let us see the effects of altering each of the parameters. Increasing a or decreasing b makes the class $\mathbf{N}^a\mathbf{Ex}^b$ smaller. Similarly, decreasing c and increasing d makes the class $\mathbf{Mul}_3^2\mathbf{N}^c\mathbf{Ex}^d$ larger. The following theorem tells us how much we can "stretch" the parameters a, b, c, and d such that there are still collections of functions that can be identified from single noisy text but not from three texts, at least two of which are acceptable.

THEOREM 5.4. *Let $a, b, c, d \in N$ be given. If there exist $r, \alpha \in N$ such that*

- $r - b \leq \alpha \leq \min(\{b, r\})$,
- $r \leq c$,
- $2r > a$, *and*
- $d < \max(\{b + \alpha - \frac{r}{2}, b + \frac{\alpha}{3}\})$,

then $\mathbf{N}^a\mathbf{Ex}^b - \mathbf{Mul}_3^2\mathbf{N}^c\mathbf{Ex}^d \neq \emptyset$.

Before giving a proof of the above result, we present corollaries. The first corollary says that for given $a, b, c \in N$ such that a is greater, but not too much greater, than c ($c \leq a \leq 2c - 1$) and c is no greater than b, there are collections of functions for which a b-error program can be identified from an a-error text but for which even a $(b + \lceil \frac{c}{2} \rceil - 1)$-error program cannot be identified from three texts, at least two of which are c-noisy for the function being learned.

COROLLARY 5.5. *Let $a, b, c \in N$ be such that $c \leq a \leq 2c - 1$, $c \leq b$. Then* $\mathbf{N}^a\mathbf{Ex}^b - \mathbf{Mul}_3^2\mathbf{N}^c\mathbf{Ex}^{b+\lceil \frac{c}{2} \rceil - 1} \neq \emptyset$.

Proof. Take $r = \alpha = c$ in Theorem 5.4. □

The next three corollaries are more variations on this theme and give insight into how much the parameters a, b, c, and d can be stretched.

COROLLARY 5.6. *Let $a, b, c \in N$ be such that $c \leq a \leq 2c - 1$, $\frac{c}{2} \leq b \leq \frac{3}{4}\lceil \frac{a+1}{2} \rceil$. Then* $\mathbf{N}^a\mathbf{Ex}^b - \mathbf{Mul}_3^2\mathbf{N}^c\mathbf{Ex}^{\lceil \frac{4b}{3} \rceil - 1} \neq \emptyset$.

Proof. Take $r = c$ and $\alpha = b$ in Theorem 5.4. □

COROLLARY 5.7. *Let $a, b, c \in N$ be such that $c \leq a \leq 2c - 1$, $\frac{a}{2} < b \leq c$. Then* $\mathbf{N}^a\mathbf{Ex}^b - \mathbf{Mul}_3^2\mathbf{N}^c\mathbf{Ex}^{\lceil \frac{3b}{2} \rceil - 1} \neq \emptyset$.

Proof. Take $r = \alpha = b$ in Theorem 5.4. □

COROLLARY 5.8. *Let $a, b, c \in N$ be such that $c \leq a \leq 2c-1$, $\max(\{\frac{c}{2}, \frac{3}{4}\lceil \frac{a+1}{2} \rceil\}) \leq b \leq \frac{a}{2}$. Then* $\mathbf{N}^a\mathbf{Ex}^b - \mathbf{Mul}_3^2\mathbf{N}^c\mathbf{Ex}^{\lceil 2b - \frac{a+2}{4} \rceil - 1} \neq \emptyset$.

Proof. Take $r = \lceil \frac{a+1}{2} \rceil$ and $\alpha = b$ in Theorem 5.4. □

We now give a proof of Theorem 5.4. The proof turns out to be somewhat complex because we have to come up with a collection of functions that can be identified from a single noisy text but which cannot be identified from three texts, at least two of which are noisy. To design this collection of functions, we employ a technique from the study of identification from single inaccurate texts [11]. We then employ the operator recursion theorem [5] to construct a diagonalization argument to show that this class cannot be identified from three texts, at least two of which are noisy. The diagonalization technique is an adaptation of the techniques used elsewhere in the study of inductive inference; we direct the reader to a survey of such techniques [6].

Proof of Theorem 5.4. Assume the hypothesis of the theorem and fix r and α satisfying the hypothesis.

Let $A = \{\langle 0, x \rangle \mid 0 \leq x < r\}$.

Consider the following class of functions.

$\mathcal{C} = \{f \in \mathcal{R} \mid$ the following conditions hold:
(1) $f(A) = f(\langle 0,0\rangle) \in \{1,2,3\}$;
(2) $(\forall i \in \{1,2,3\} - \{f(\langle 0,0\rangle)\})[(\max(\{f(\langle i,\langle x,0\rangle\rangle) \mid x \in N\})$ exists) $\wedge$
$(\varphi_{\max(\{f(\langle i,\langle x,0\rangle\rangle)\mid x\in N\})} =^b f)]$;
(3) $(\forall i \in \{1,2,3\})(\forall x,y,z)[f(\langle i,\langle x,y\rangle\rangle) = f(\langle i,\langle x,z\rangle\rangle)]\}$.

Intuitively, A is the set of points where some coding is done. (A is the only place where inaccuracies will matter.) a-noise is not enough to spoil the coding in A for $\mathbf{N}^a\mathbf{Ex}^b$-identification. However, r-noise is enough to spoil the coding for $\mathbf{Mul}_3^2\mathbf{N}^c\mathbf{Ex}^d$-identification.

It is easy to show that $\mathcal{C} \in \mathbf{N}^a\mathbf{Ex}^b$. To see this, suppose that T is an a-noisy text for $f \in \mathcal{C}$. Since $2r > a$, there exist an $i \in \{1,2,3\}$ and $x \in A$ such that $(x,i) \notin \text{content}(T)$. This along with clause (2) in the definition of $\mathcal{C}$ implies that $\varphi_{\max(\{f(\langle i,\langle x,0\rangle\rangle)\mid x\in N\})} =^b f$. Now $\max(\{f(\langle i,\langle x,0\rangle\rangle) \mid x \in N\})$ can be determined in the limit from T due to cylindrification in clause (3). It follows that $\mathcal{C} \in \mathbf{N}^a\mathbf{Ex}^b$.

We now show that $\mathcal{C} \notin \mathbf{Mul}_3^2\mathbf{N}^c\mathbf{Ex}^d$.

The essential idea for diagonalization is that a machine cannot $\mathbf{Ex}^d$-identify $\mathcal{C}$ if the coding in A (due to clause (1) in definition of $\mathcal{C}$) is spoiled. So suppose by way of contradiction that machine $\mathbf{M}$ $\mathbf{Mul}_3^2\mathbf{N}^c\mathbf{Ex}^d$-identifies $\mathcal{C}$.

Then by the operator recursion theorem [5], there exists a recursive, 1–1, and increasing p, with $p(0) > 1$, defined as follows in stages.

We define $\varphi_{p(i)}$ in stages $s \geq 3$. Let x_3^s denote the least x such that for all y, $\varphi_{p(1)}(\langle 3,\langle x,y\rangle\rangle)$ is not defined before stage s.

For $x < \alpha$, let $\varphi_{p(1)}(\langle 0,x\rangle) = 2$. For $\alpha \leq x < r$, let $\varphi_{p(1)}(\langle 0,x\rangle) = 3$. Let $\varphi_{p(1)}(\langle 1,\langle 0,0\rangle\rangle) = p(1)$ and $\varphi_{p(1)}(\langle 2,\langle 0,0\rangle\rangle) = p(2)$.

For $x < \alpha$, let $\varphi_{p(2)}(\langle 0,x\rangle) = 1$. For $\alpha \leq x < r$, let $\varphi_{p(2)}(\langle 0,x\rangle) = 3$. Let $\varphi_{p(2)}(\langle 1,\langle 0,0\rangle\rangle) = p(1)$ and $\varphi_{p(2)}(\langle 2,\langle 0,0\rangle\rangle) = p(2)$.

Let σ_1^3, σ_2^3 and σ_3^3 be such that

$$\text{content}(\sigma_1^3) = \{(x,2) \mid x \in A\} \cup \{(x,3) \mid x \in A\} \cup \{(\langle 1,\langle 0,0\rangle\rangle, p(1)), (\langle 2,\langle 0,0\rangle\rangle, p(2))\},$$
$$\text{content}(\sigma_2^3) = \{(x,1) \mid x \in A\} \cup \{(x,3) \mid x \in A\} \cup \{(\langle 1,\langle 0,0\rangle\rangle, p(1)), (\langle 2,\langle 0,0\rangle\rangle, p(2))\},$$
$$\text{content}(\sigma_3^3) = \{(x,1) \mid x \in A\} \cup \{(x,2) \mid x \in A\} \cup \{(\langle 1,\langle 0,0\rangle\rangle, p(1)), (\langle 2,\langle 0,0\rangle\rangle, p(2))\}.$$

Intuitively, we will form three (nearly identical) texts T_1, T_2, and T_3 with the initial segments σ_1^3, σ_2^3, and σ_3^3 as defined above. Note that these three texts spoil the coding in A (since all possible values of the coding are present in two of these texts). Now the basic idea in the diagonalization below is to either

(1) force infinitely many mind changes by $\mathbf{M}$ (see step 4 in the construction)—in this case T_1 and T_2 form the c-noisy texts for the diagonalizing function—or

(2) based on what the final program $\mathbf{M}(T_1,T_2,T_3)$ does on the inputs from A (see step 2 in the construction), do an appropriate diagonalization of the same form as done in $\mathbf{Ex}$-hierarchy theorem in [8] (see steps 5a, 5c, and 6a in the construction). The diagonalization is done so as to maximize the errors of the final program under the constraint of keeping the diagonalizing function within the class (see the comments at the end of step 2 in the construction). Steps 5b and 6b in the construction are needed since one cannot effectively determine whether program $\mathbf{M}(T_1,T_2,T_3)$ halts on inputs from the set A (we can do it only in the limit).

Let $\varphi_{p(i)}^s$ denote the part of $\varphi_{p(i)}$ defined before stage s. Go to stage 3.

Begin Stage s

1. Let $q = \mathbf{M}(\sigma_1^s, \sigma_2^s, \sigma_3^s)$.

2. Let $D_1 = \{x \mid x \in A \ \wedge \ \Phi_q(x) \leq s \ \wedge \ \varphi_q(x) = 1\}$.
Let $D_2 = \{x \mid x \in A \ \wedge \ \Phi_q(x) \leq s \ \wedge \ \varphi_q(x) = 2\}$.
Let $D_3 = \{x \mid x \in A \ \wedge \ \Phi_q(x) \leq s \ \wedge \ \varphi_q(x) \in N - \{1, 2\}\}$.
Let $err_{1,2} = r - \text{card}(D_3) + b - \alpha$.
Let $err_{2,3} = r - \text{card}(D_1) + b - r + \alpha$.
Let $err_{1,3} = r - \text{card}(D_2) + b - r + \alpha$.
If $err_{1,2} \leq \max(\{err_{1,3}, err_{2,3}\})$, then let $extra\_err = b - r + \alpha$; otherwise, let $extra\_err = b - \alpha$. If $err_{1,3} > err_{2,3}$, then let $l = 1$ and $l' = 2$; otherwise, let $l = 2$ and $l' = 1$.
Let $X^s \subset \{\langle 4, x\rangle \mid x \geq s\}$ denote the (lexicographically least) set of $extra\_err$ elements such that for all $x \in X^s$, $\varphi_{p(1)}(x)$ is not defined before stage s.
(*Note.* Let $T_i = \bigcup_s \sigma_i^s$. D_1 (D_2, D_3) denote the points in A for which φ_q seems to be correct if T_2 and T_3 (T_1 and T_3, T_1 and T_2) are the acceptable texts for the function being learned and $err_{i,j}$ denotes the error that we can force if we chose a function such that T_i and T_j are correct texts for the function. Informally, an attempt is made at every stage to try and make those two texts correct so as to maximize the number of errors made by $\mathbf{M}$'s current output program.)

3. For $x \in A$, let $\varphi_{p(s)}(x) = l'$. Let $\varphi_{p(s)}(\langle 3, \langle x_3^s, 0\rangle\rangle) = \varphi_{p(1)}(\langle 3, \langle x_3^s, 0\rangle\rangle) = \varphi_{p(2)}(\langle 3, \langle x_3^s, 0\rangle\rangle) = p(s)$. For $x \in \text{domain}(\varphi_{p(1)}^s) - A$, let $\varphi_{p(s)}(x) = \varphi_{p(1)}(x)$.

4. For $i \in \{1, 2, 3\}$, let σ_i' be an extension of σ_i^s such that $\text{content}(\sigma_i') = \text{content}(\sigma_i^s) \cup \{(\langle 3, \langle x_3^s, 0\rangle\rangle, p(s))\}$.

5. Dovetail steps 5a, 5b, and 5c until (if ever) one of steps 5a or 5b succeeds and at least one iteration of the loop at step 5c is completed. If step 5a succeeds (before step 5b succeeds (if ever)), then complete the then current iteration of the repeat loop in step 5c and go to step 6a. If step 5b succeeds (before step 5a succeeds (if ever)), then complete the then current iteration of the repeat loop in step 5c and go to step 6b.

5a. Search for $\sigma_i'' \supseteq \sigma_i'$, $i \in \{1, 2, 3\}$, such that $\mathbf{M}(\sigma_1^s, \sigma_2^s, \sigma_3^s) \neq \mathbf{M}(\sigma_1'', \sigma_2'', \sigma_3'')$ and for all $j, j' \in \{1, 2, 3\}$, for all $x, y, z \in N$, the following four conditions hold:

- $\text{content}(\sigma_j'') - \text{content}(\sigma_j') = \text{content}(\sigma_{j'}'') - \text{content}(\sigma_{j'}')$.
- for $x \notin A$, if $(x, y), (x, z) \in \text{content}\ (\sigma_j'')$ then $y = z$.
- If $(\langle j, \langle x, y\rangle\rangle, v) \in \text{content}(\sigma_1'')$ and $(\langle j, \langle x, z\rangle\rangle, w) \in \text{content}(\sigma_1'')$, then $v = w$.
- If $(x, y) \in (\text{content}(\sigma_1'') - \text{content}(\sigma_1'))$, then $[[y = 0 \ \wedge \ x \notin A]$ OR $x \in X^s$ OR [for some $i \in \{1, 2, 3\}$, $u, v \in N$: $x = \langle i, \langle u, v\rangle\rangle$ and $\varphi_{p(1)}(\langle i, \langle u, 0\rangle\rangle)$ has been defined until now and $\varphi_{p(1)}(\langle i, \langle u, 0\rangle\rangle) = y]]$.

(*Remark.* This substep looks for one set of suitable extensions of the currently defined initial segments of the three texts that makes $\mathbf{M}$ change its mind.)

5b. Search for $x \in A - (D_1 \cup D_2 \cup D_3)$ such that $\varphi_q(x)\downarrow$.

5c. Let $Addednew = \emptyset$.
(*Note.* We use *Addednew* in order to identify the set of elements for which we extend $\varphi_{p(1)}$ in step 5c. *Addednew* will be used (in steps 6a and 6b), provided at least one of steps 5a or 5b succeeds).
Repeat
Let x be the least point not in X^s such that $\varphi_{p(1)}(x)$ is not defined until now. If for some $i \in \{1,2,3\}$, x is of the form $\langle i, \langle u, v\rangle\rangle$ and $\varphi_{p(1)}(\langle i, \langle u, 0\rangle\rangle)$ is defined until now, then let $\varphi_{p(1)}(x) = \varphi_{p(2)}(x) = \varphi_{p(s)}(x) = \varphi_{p(1)}(\langle i, \langle u, 0\rangle\rangle)$; otherwise, let $\varphi_{p(1)}(x) = \varphi_{p(2)}(x) = \varphi_{p(s)}(x) = 0$.
Let $Addednew = Addednew \cup \{x\}$.
Forever

6a. For all x and y such that $(x,y) \in \text{content}(\sigma_1'') - \text{content}(\sigma_1^s)$, let $\varphi_{p(1)}(x) = \varphi_{p(2)}(x) = y$. Let σ_i^{s+1} be an extension of σ_i'' such that $\text{content}(\sigma_i^{s+1}) - \text{content}(\sigma_i'') = \{(x, \varphi_{p(1)}(x)) \mid x \in Addednew\}$. Go to stage $s+1$.

6b. Let σ_i^{s+1} be an extension of σ_i' such that $\text{content}(\sigma_i^{s+1}) - \text{content}(\sigma_i') = \{(x, \varphi_{p(1)}(x)) \mid x \in Addednew\}$. Go to stage $s+1$.

End stage s
Now consider the following cases.
Case 1. All stages terminate.
Let

$$f(x) = \begin{cases} 3 & \text{if } x \in A; \\ \varphi_{p(1)}(x) & \text{otherwise.} \end{cases}$$

Clearly, $f \in \mathcal{C}$ (since $\alpha \le b$, $\varphi_{p(1)} =^b f$, and $\varphi_{p(2)} =^b f$). Also, $\mathbf{M}$ on f makes infinitely many mind changes since step 5b can succeed at most finitely many times before step 5a succeeds.

Case 2. Stage s (≥ 3) is the least stage which starts but never terminates.

Let q, $err_{1,2}$, $err_{2,3}$, $err_{1,3}$, D_1 , D_2, and D_3 be as defined in steps 1 and 2 in stage s. Now $\max(\{err_{1,2}, err_{2,3}, err_{1,3}\}) \ge \frac{err_{1,2}+err_{2,3}+err_{1,3}}{3} \ge \frac{3b+\alpha}{3}$. Thus $\max(\{err_{1,2}, err_{2,3}, err_{1,3}\}) \ge b + \frac{\alpha}{3}$. Also, since $err_{1,2} \le r + b - \alpha$, we have $\max(\{err_{1,3}, err_{2,3}\}) \ge \frac{2b-r+2\alpha}{2}$. Thus $\max(\{err_{1,2}, err_{2,3}, err_{1,3}\}) \ge \max(\{b + \alpha - \frac{r}{2}, b + \frac{\alpha}{3}\})$.

Case 2a. In step 2 of stage s it was found that $err_{1,2} \le \max(\{err_{1,3}, err_{2,3}\})$.

Let l and l' be as found in step 2. In this case $\text{domain}(\varphi_{p(s)}) = N - X^s$. Let f be any fixed total extension of $\varphi_{p(s)}$ such that for all $x \in X^s$, we have $f(x) \ne \varphi_q(x)$.

Clearly, $f \in \mathcal{C}$ (since $\varphi_{p(l)} =^b f$, $\varphi_{p(s)} =^b f$, and $f(\langle 0,0\rangle) = l'$). Let T_1, T_2, and T_3 be extensions of σ_1', σ_2', and σ_3' (as defined in step 4 in stage s), respectively, such that $\text{content}(T_1) - \text{content}(\sigma_1^s) = \{(x,y) \mid f(x) = y \ \wedge \ (\forall z)[(x,z) \notin \text{content}(\sigma_1^s)]\}$ and for all j, the $[|\sigma_1'| + j]$th element of T_1, the $[|\sigma_2'| + j]$th element of T_2, and the $[|\sigma_3'| + j]$th element of T_3 are all the same. Clearly, $\mathbf{M}(T_1, T_2, T_3) = q$ (otherwise, step 5a would succeed).

Now for all $x \in A - D_{l'}$, $f(x) \ne \varphi_q(x)$ (since that was the way $D_{l'}$ was chosen in step 2 of stage s). Thus $\varphi_q \ne^{\max(\{err_{1,3}, err_{2,3}\})-1} f$.

Case 2b. In step 2 of stage s it was found that $err_{1,2} > \max(\{err_{1,3}, err_{2,3}\})$.

In this case, $\text{domain}(\varphi_{p(1)}) = N - X^s$. Let f be a fixed total function such that the following three conditions hold:

- $f(A) = 3$,
- $f(x) = \varphi_{p(1)}(x)$ for $x \in \text{domain}(\varphi_{p(1)}) - A$, and
- $(\forall x \in X^s)[f(x) \neq \varphi_q(x)]$.

Clearly, $f \in \mathcal{C}$ (since $\varphi_{p(1)} =^b f$, $\varphi_{p(2)} =^b f$, and $f(\langle 0,0\rangle) = 3$). Let T_1, T_2, and T_3 be extensions of σ_1', σ_2', and σ_3' respectively, such that $\text{content}(T_1) - \text{content}(\sigma_1^s) = \{(x,y) \mid f(x) = y \ \wedge \ (\forall z)[(x,z) \notin \text{content}(\sigma_1^s)]\}$ and for all j, the $[|\sigma_1'| + j]$th element of T_1, the $[|\sigma_2'| + j]$th element of T_2, and the $[|\sigma_3'| + j]$th element of T_3 are all the same. Also, it is clear that $\mathbf{M}(T_1, T_2, T_3) = q$ (otherwise, step 5a would succeed). Now for all $x \in A - D_3$, $f(x) \neq \varphi_q(x)$ (since that was the way D_3 was chosen in step 2 of stage s). Thus $\varphi_q \neq^{err_{1,2}-1} f$.

From the above cases, it follows that $\mathcal{C} \notin \mathbf{Mul}_3^2\mathbf{N}^c\mathbf{Ex}^d$. □

The results established so far identified cases where multiple noisy texts are a restriction over learning from a single noisy text. The natural question that arises is "What are the cases where the restriction of learning from multiple noisy texts can be compensated in some way." That is, for which values of a, b, c, and d is $\mathbf{N}^a\mathbf{Ex}^b \subseteq \mathbf{Mul}_3^2\mathbf{N}^c\mathbf{Ex}^d$? A quick look at the effects of the various parameters yields at least two different ways in which the restrictive impact of multiple texts can be compensated. These are

- by allowing extra errors in the program inferred from multiple texts (that is, by making d larger than b) and
- by having a reduced bound on the number of noise elements in the multiple texts (that is, by making c smaller than a).

Theorems 5.9 and 5.10 use the first technique; Theorems 5.12, 5.13, and 5.14 use the second technique; and Theorem 5.11 can be seen as using a combination of the two techniques to compensate for the deleterious effects of learning from multiple texts. The technique used in these simulation arguments is to first collect all the input points where there is noise in some text. Then construct a program which judiciously chooses the output on these inputs based on the input texts and outputs of the converging programs.

Theorem 5.9 below shows that the collections of functions for which a b-error program can be identified from a single c-noisy text can also be learned from three texts, at least two of which are c-noisy, provided we are prepared to tolerate up to twice the number ($2b$) of errors in the final program.

THEOREM 5.9. *Let $b, c \in N$. Then $\mathbf{N}^c\mathbf{Ex}^b \subseteq \mathbf{Mul}_3^2\mathbf{N}^c\mathbf{Ex}^{2b}$.*

Proof. Suppose machine $\mathbf{M}$ $\mathbf{N}^c\mathbf{Ex}^b$-identifies $\mathcal{C}$. We construct $\mathbf{M}'$ such that $\mathbf{M}'$ $\mathbf{Mul}_3^2\mathbf{N}^c\mathbf{Ex}^{2b}$-identifies $\mathcal{C}$.

Let T_1, T_2, and T_3 be the three given texts out of which at least two are c-noisy for $f \in \mathcal{C}$.

Let i and j be distinct and such that $\mathbf{M}(T_i)\downarrow$ and $\mathbf{M}(T_j)\downarrow$, $P_i = \mathbf{M}(T_i)$ and $P_j = \mathbf{M}(T_j)$, and $\text{card}(\{x \mid \varphi_{P_i}(x)\downarrow \neq \varphi_{P_j}(x)\downarrow\}) \leq 2b$. Let $CLASH = \{x \mid \varphi_{P_i}(x)\downarrow \neq \varphi_{P_j}(x)\downarrow\}$. Let $S \subseteq CLASH$ be a set of cardinality $\lfloor \frac{\text{card}(CLASH)}{2} \rfloor$.

Note that we can easily determine all of the sets defined above and P_i and P_j as above in the limit from the given texts.

$\mathbf{M}'$ in the limit outputs a program p such that

$$\varphi_p(x) = \begin{cases} \varphi_{P_i}(x) & \text{if } x \in S; \\ \varphi_{P_j}(x) & \text{if } x \in CLASH - S; \\ \varphi_{P_i}(x) & x \in N - CLASH \ \wedge \ x \in \text{domain}(\varphi_{P_i}); \\ \varphi_{P_j}(x) & x \in N - CLASH \ \wedge \ x \in \text{domain}(\varphi_{P_j}); \\ \uparrow & \text{otherwise.} \end{cases}$$

Since at least one of P_i and P_j is a b-error program for f, it is clear that p is a $2b$-error program for f. Thus $\mathbf{M}'$ $\mathbf{Mul}_3^2\mathbf{N}^c\mathbf{Ex}^{2b}$-identifies f. □

In order to prove the rest of the results in this section (Theorems 5.10–5.14), it is useful to define certain sets and texts. We will require these sets to satisfy certain assumptions which can be assumed *without loss of generality*. We state these definitions and assumptions next, and we assume them without explicitly stating them in the proofs.

Suppose a machine is trying to $\mathbf{Mul}_3^2\mathbf{N}^c\mathbf{Ex}^d$-identify f (where $c \in N$). Suppose the three texts provided as input to the machine are T_1, T_2, and T_3, such that at least two of these texts are c-noisy for f.

DEFINITIONS. *Let T_1, T_2, and T_3 be texts.*

1. T_{UNION} *is a text such that* $\text{content}(T_{UNION}) = \{(x,y) \mid (x,y) \in \text{content}(T_1) \ \vee \ (x,y) \in \text{content}(T_2) \ \vee \ (x,y) \in \text{content}(T_3)\}$.
2. $NOISE\_POINTS = \{x \mid (\exists y, z)[y \neq z \ \wedge \ (x,y) \in \text{content}(T_{UNION}) \ \wedge \ (x,z) \in \text{content}(T_{UNION})]\}$.
3. $NOISE_{1,2} = \{x \mid \text{card}(\{y \mid (x,y) \in \text{content}(T_1)\}) = \text{card}(\{y \mid (x,y) \in \text{content}(T_2)\}) \geq 2 \ \wedge \ \text{card}(\{y \mid (x,y) \in \text{content}(T_3)\}) = 1\}$.
4. $NOISE_{1,3} = \{x \mid \text{card}(\{y \mid (x,y) \in \text{content}(T_1)\}) = \text{card}(\{y \mid (x,y) \in \text{content}(T_3)\}) \geq 2 \ \wedge \ \text{card}(\{y \mid (x,y) \in \text{content}(T_2)\}) = 1\}$.
5. $NOISE_{2,3} = \{x \mid \text{card}(\{y \mid (x,y) \in \text{content}(T_2)\}) = \text{card}(\{y \mid (x,y) \in \text{content}(T_3)\}) \geq 2 \ \wedge \ \text{card}(\{y \mid (x,y) \in \text{content}(T_1)\}) = 1\}$.
6. $NOISE_{1,2,3} = NOISE\_POINTS - (NOISE_{1,2} \cup NOISE_{1,3} \cup NOISE_{2,3})$.

Assumptions. We make the following assumptions about the notions defined above.

1. For all $i \in \{1,2,3\}$, $\text{card}(\{x \mid (\exists y, z)[y \neq z \ \wedge \ (x,y) \in \text{content}(T_i) \ \wedge \ (x,z) \in \text{content}(T_i)]\}) \leq c$ (since if the cardinality of noise points is greater than c, then we know which two texts are c-noisy texts for f).
2. For all $i, j \in \{1,2,3\}$ and for all $x \in NOISE\_POINTS$, $\text{card}(\{y \mid (x,y) \in \text{content}(T_i) \cap \text{content}(T_j)\}) \geq 1$. (This is so because otherwise at least one of T_i and T_j is not a c-noisy text for f, which implies that the remaining text is a c-noisy text for f.)
3. For all x and y, $\text{card}(\{i \mid (x,y) \in \text{content}(T_i)\}) \neq 1$. (Otherwise, surely $f(x) \neq y$ and we can thus drop (x,y) from consideration.)

Note that if the above assumptions do not hold, then we can convert the texts (in the limit) to T_1', T_2', and T_3' such that at least two of these texts are c-noisy for f and T_1', T_2', and T_3' satisfy the assumptions given above.

The next theorem is a variation on Theorem 5.9 in which we compensate for multiple texts by allowing extra errors in the final program. In this case, instead of allowing twice the number of errors in the final program, the upper bound on the number of errors is expressed in terms of the error bound for single text, b, and the noise level of the single text, c. We would like to note that the simulation carried out in Theorem 5.10 below is optimal in the following sense. If we keep the bound on the

number of inaccuracies in the texts the same for the single text and for the acceptable texts in the multiple case and if $c \leq b$, then for all of the collections of functions for which a b-error program can be identified from a single c-noisy text, a $b + \lceil \frac{c}{2} \rceil$-error program can also be identified from three texts, at least two of which are only c-noisy. The optimality of the result is in the sense that this simulation fails if we reduce the bound on the number of errors allowed in the final program (of the multiple case) by even one. This was the diagonalization result described in Corollary 5.5.

THEOREM 5.10. *Let $b, c \in N$. Then $\mathbf{N}^c\mathbf{Ex}^b \subseteq \mathbf{Mul}_3^2\mathbf{N}^c\mathbf{Ex}^{b+\lceil \frac{c}{2} \rceil}$.*

Proof. Suppose machine $\mathbf{M}$ $\mathbf{N}^c\mathbf{Ex}^b$-identifies $\mathcal{C}$. We construct $\mathbf{M}'$ such that $\mathbf{M}'$ $\mathbf{Mul}_3^2\mathbf{N}^c\mathbf{Ex}^{b+\lceil \frac{c}{2} \rceil}$-identifies $\mathcal{C}$. Let T_1, T_2, and T_3 be three given texts out of which at least two are c-noisy for f.

Let $m = \min(\{\text{card}(NOISE_{1,2}), \text{card}(NOISE_{1,3}), \text{card}(NOISE_{2,3})\})$.

Let S be a set of cardinality $3m$ such that $\text{card}(S \cap NOISE_{1,2}) = \text{card}(S \cap NOISE_{1,3}) = \text{card}(S \cap NOISE_{2,3})$.

Let $X \subseteq NOISE\_POINTS - S$ be a set of cardinality $\lceil \frac{\text{card}(NOISE\_POINTS)-3m}{2} \rceil$.

Let i and j be distinct and such that $\mathbf{M}(T_i)\downarrow$ and $\mathbf{M}(T_j)\downarrow$, $P_i = \mathbf{M}(T_i)$ and $P_j = \mathbf{M}(T_j)$, and $\text{card}(\{x \mid \varphi_{P_i}(x)\downarrow \neq \varphi_{P_j}(x)\downarrow \ \wedge \ x \notin NOISE\_POINTS\}) \leq 2b$. Let $CLASH = \{x \mid \varphi_{P_i}(x)\downarrow \neq \varphi_{P_j}(x)\downarrow \ \wedge \ x \notin NOISE\_POINTS\}$.

Note that we can easily determine all the sets defined above and P_i and P_j as above in the limit from the given texts. $\mathbf{M}'$ in the limit outputs a program p such that

$$\varphi_p(x) = \begin{cases} \varphi_{P_i}(x) & \text{if } x \in X; \\ \varphi_{P_j}(x) & \text{if } x \in NOISE\_POINTS - (X \cup S); \\ y & \text{if } x \in CLASH \ \wedge \ (x, y) \in \text{content}(T_{UNION}); \\ \varphi_{P_i}(x) & \text{if } x \in N - (NOISE\_POINTS \cup CLASH) \text{ and} \\ & x \in \text{domain}(\varphi_{P_i}); \\ \varphi_{P_j}(x) & \text{if } x \in N - (NOISE\_POINTS \cup CLASH) \text{ and} \\ & x \in \text{domain}(\varphi_{P_j}); \\ y & \text{if } x \in S \ \wedge \ (x, y) \in \text{content}(T_1) \cap \text{content}(T_2) \cap \text{content}(T_3); \\ \uparrow & \text{otherwise.} \end{cases}$$

Since at least one of P_i and P_j computes a b-variant of f, the number of errors committed by the φ program $p \leq b + m + \lceil \frac{\text{card}(NOISE\_POINTS-S)}{2} \rceil$, which is at most $b + \lceil \frac{c}{2} \rceil$. ∎

The next theorem uses a combination of increasing the bound on the number of errors in the final program and having a smaller noise level than in the case of single text to compensate for the restrictive effects of multiple texts. The theorem shows that given $b, c, d \in N$ such that b is smaller, but not too much smaller, than c (that is, $\frac{c}{2} \leq b \leq c$), all of the collections of functions for which a b-error program can identified from a single $(2c-1)$-noisy text can also be identified from three texts, at least two of which are c-noisy, provided we are prepared to tolerate a bound of $\geq \max(\{\frac{4b}{3}, 2b - \frac{c}{2}\})$ on the number of errors in the final program. (Compare the following theorem with Corollary 5.6.)

THEOREM 5.11. *Let $b, c, d \in N, \frac{c}{2} \leq b \leq c$, be given. Then $\mathbf{N}^{2c-1}\mathbf{Ex}^b \subseteq \mathbf{Mul}_3^2\mathbf{N}^c\mathbf{Ex}^d$ if $d \geq \max(\{\frac{4b}{3}, 2b - \frac{c}{2}\})$.*

Proof. Suppose that machine $\mathbf{M}$ $\mathbf{N}^{2c-1}\mathbf{Ex}^b$-identifies $\mathcal{C}$. We construct machine $\mathbf{M}'$ such that $\mathbf{M}'$ $\mathbf{Mul}_3^2\mathbf{N}^c\mathbf{Ex}^d$-identifies $\mathcal{C}$. Let T_1, T_2, and T_3 be three texts given for a function $f \in \mathcal{C}$ such that at least two of the three texts are c-noisy for f.

Note that T_{UNION} is a noisy text for f. If T_{UNION} is a $(2c-1)$-noisy text for f, then $\mathbf{M}'$ can just output the programs output by $\mathbf{M}$ on T_{UNION} to identify f with at most d errors. Thus assume that T_{UNION} so formed contains more than $2c-1$ noisy elements. A simple calculation shows that the amount of noise in T_{UNION} is bounded by $\frac{3c+\mathrm{card}(NOISE_{1,2,3})}{2}$. If $\mathrm{card}(NOISE_{1,2,3}) < c$, then T_{UNION} is a $(2c-1)$-noisy text for f. Thus $\mathrm{card}(NOISE_{1,2,3}) = c$. Also, for all $x \in NOISE_{1,2,3}$, we can assume that there exist distinct y_1^x, y_2^x, and y_3^x such that $(x, y_1^x) \in \mathrm{content}(T_2) \cap \mathrm{content}(T_3)$, $(x, y_2^x) \in \mathrm{content}(T_1) \cap \mathrm{content}(T_3)$, and $(x, y_3^x) \in \mathrm{content}(T_1) \cap \mathrm{content}(T_2)$. (Otherwise, T_{UNION} contains at most $2c-1$ noisy elements.)

Let i, j be distinct and such that $\mathbf{M}(T_i)\downarrow$ and $\mathbf{M}(T_j)\downarrow$, $P_i = \mathbf{M}(T_i)$ and $P_j = \mathbf{M}(T_j)$, and $\mathrm{card}(\{x \mid \varphi_{P_i}(x)\downarrow \neq \varphi_{P_j}(x)\downarrow \ \wedge \ x \notin NOISE\_POINTS\}) \leq 2b$. Let $CLASH = \{x \mid [\varphi_{P_i}(x)\downarrow \neq \varphi_{P_j}(x)\downarrow] \wedge [x \notin NOISE\_POINTS]\}$. For $m \in \{i, j\}$, let $\delta_m = \mathrm{card}(\{x \mid x \in NOISE\_POINTS \wedge [(x, \varphi_{P_m}(x)) \in \mathrm{content}(T_i) \cap \mathrm{content}(T_j)]\})$. Let $\delta = \min(\delta_i, \delta_j)$. We can suppose without loss of generality that $c - b \leq \delta \leq b$. (Otherwise, we can determine a text which is guaranteed to be c-noisy for f. For example, suppose that $\delta = \delta_i < c - b$. Then clearly one of T_i and T_j is not a c-noisy text for f. This implies that the remaining text is a c-noisy text for f. Other cases are similar. In any of these cases, $\mathbf{M}'$ can simply input the correct c-noisy text obtained by the above analysis into $\mathbf{M}$ and arrive (in the limit) at a program which is at most b ($\leq d$) variant of f.)

We will pick a $\mu \in N$, $\mu \leq c$, depending on δ. Let $S \subseteq NOISE\_POINTS$ be a set of cardinality μ. Let $X \subseteq NOISE\_POINTS - S$ be a set of cardinality $\lceil \frac{c-\mu}{2} \rceil$.

$\mathbf{M}'$ in the limit outputs a program p_μ such that the following holds:

$$\varphi_{p_\mu}(x) = \begin{cases} y_k^x & \text{if } x \in S \ \wedge \ k \in \{1,2,3\} - \{i,j\}; \\ y_i^x & \text{if } x \in X; \\ y_j^x & \text{if } x \in NOISE\_POINTS - (X \cup S); \\ y & \text{if } x \in CLASH \ \wedge \ (x,y) \in \mathrm{content}(T_{UNION}); \\ \varphi_{P_i}(x) & \text{if } x \in N - (NOISE\_POINTS \cup CLASH) \text{ and} \\ & x \in \mathrm{domain}(\varphi_{P_i}); \\ \varphi_{P_j}(x) & \text{if } x \in N - (NOISE\_POINTS \cup CLASH) \text{ and} \\ & x \in \mathrm{domain}(\varphi_{P_j}); \\ \uparrow & \text{otherwise.} \end{cases}$$

Now the number of errors committed by $\mathbf{M}'$ on f is bounded by $maxerr = \max(\{b-\mu+\delta, b-\delta+\mu+\lceil\frac{c-\mu}{2}\rceil\}) = \lceil\max(\{b-\mu+\delta, b-\delta+\mu+\frac{c-\mu}{2}\})\rceil$. By choosing $\mu = \max(\{0, \lfloor\frac{4\delta-c}{3}\rfloor\})$, we have $maxerr = \lceil\max(\{b+\frac{c-\delta}{3}, b-\delta+\frac{c}{2}\})\rceil$. The value of $maxerr$ is maximized for $\delta = c-b$. Thus $maxerr = \lceil\max(\{\frac{4b}{3}, 2b-\frac{c}{2}\})\rceil$. Thus if $d \geq \lceil\max(\{\frac{4b}{3}, 2b-\frac{c}{2}\})\rceil$, then $\mathbf{N}^{2c-1}\mathbf{Ex}^b \subseteq \mathbf{Mul}_3^2\mathbf{N}^c\mathbf{Ex}^d$. □

We now present three theorems that use the technique of making the bound on the noise level of multiple texts smaller than the bound on the noise level of the single text to compensate for the restrictive effect of multiple texts.

The result below says that for $b, c \in N$ such that b is fairly small compared to c (that is, $b < \lceil\frac{c}{2}\rceil$), if for some collection of functions a b-error program can be identified from a single $(2c-1)$-noisy text, then a b-error program can also be identified from three texts, at least two of which are c-noisy.

THEOREM 5.12. *For* $b < \lceil\frac{c}{2}\rceil$, $\mathbf{N}^{2c-1}\mathbf{Ex}^b \subseteq \mathbf{Mul}_3^2\mathbf{N}^c\mathbf{Ex}^b$.

Proof. Suppose machine $\mathbf{M}$ $\mathbf{N}^{2c-1}\mathbf{Ex}^b$-identifies $\mathcal{C}$. We describe $\mathbf{M}'$ such that $\mathbf{M}'$ $\mathbf{Mul}_3^2\mathbf{N}^c\mathbf{Ex}^b$-identifies $\mathcal{C}$. Let T_1, T_2, and T_3 be the three given texts out of which at least two are c-noisy for $f \in \mathcal{C}$.

As in Theorem 5.11, it can be shown that either T_{UNION} is a $(2c-1)$-noisy for f or else there exists a set X of cardinality c and distinct y_1^x, y_2^x, and y_3^x for each $x \in X$ such that $(\forall x \in X)(\forall i \in \{1,2,3\})(\forall y \in \{y_1^x, y_2^x, y_3^x\} - \{y_i^x\})[(x,y) \in \text{content}(T_i)]$. Now let $i \in \{1,2,3\}$ be such that $\mathbf{M}(T_i)\downarrow$. Let $\mathbf{M}(T_i) = P_i$. For $j \in \{1,2,3\} - \{i\}$, let $D_j = \{x \in X \mid \varphi_{P_i}(x) = y_j^x\}$. Let $j \in \{1,2,3\} - \{i\}$ be such that $\text{card}(D_j) \leq \frac{c}{2}$. Note that such a j exists. Now for all $x \in X$, $f(x) \neq y_j^x$ (since otherwise T_i is a c-noisy text for f and thus φ_{P_i} should be a b-variant of f). Hence T_j is a c-noisy text for f. Thus $\mathbf{M}(T_j)\downarrow$ and $\varphi_{\mathbf{M}(T_j)}$ is a b-variant of f. Clearly, in all the above cases, $\mathbf{M}'$ can in the limit easily output a program which is a b-variant of f. □

Theorem 5.13 is like Theorem 5.12, but it does not require that error bound on the final program, b, be fairly small compared to the bound on the noise level of the multiple texts, c. It says that for $b, c \in N$, if for some collection of functions a b-error program can be identified from a single $(2c)$-noisy text, then a b-error program can also be identified from three texts, at least two of which are c-noisy.

THEOREM 5.13. *Let $b, c \in N$. $\mathbf{N}^{2c}\mathbf{Ex}^b \subseteq \mathbf{Mul}_3^2\mathbf{N}^c\mathbf{Ex}^b$.*

Proof. Suppose machine $\mathbf{M}$ $\mathbf{N}^{2c}\mathbf{Ex}^b$-identifies $\mathcal{C}$. We construct $\mathbf{M}'$ such that $\mathbf{M}'$ $\mathbf{Mul}_3^2\mathbf{N}^c\mathbf{Ex}^b$-identifies $\mathcal{C}$.

Let T_1, T_2, and T_3 be three texts given for a function $f \in \mathcal{C}$ such that at least two of the three texts are c-noisy for f. A simple calculation shows that the amount of noise in T_{UNION} (with respect to the graph of f) is bounded by $\frac{3c+\text{card}(NOISE_{1,2,3})}{2}$. Noting that $\text{card}(NOISE_{1,2,3})$ is bounded by c, it follows that T_{UNION} is a $2c$-noisy text for f. $\mathbf{M}'$ outputs in the limit whatever is output by $\mathbf{M}$ in the limit on the text T_{UNION}. Thus $\mathbf{M}'$ $\mathbf{Mul}_3^2\mathbf{N}^c\mathbf{Ex}^b$-identifies f. This proves the theorem. □

Using a proof technique similar to the above, we can also establish the following variation of the above result. Here the bound on the noise level of the single text is expressed in terms of both the bound in the noise level of the multiple text (c) and the bound on the number of errors in the final program (b). It says that for $b, c \in N$, if for some collection of functions a b-error program can be identified from a single $\frac{3c+2b}{2}$-noisy text, then a b-error program can also be identified from three texts, at least two of which are c noisy. We omit the proof.

THEOREM 5.14. *Let $b, c \in N$. Then $\mathbf{N}^{\frac{3c+2b}{2}}\mathbf{Ex}^b \subseteq \mathbf{Mul}_3^2\mathbf{N}^c\mathbf{Ex}^b$.*

5.2.2. Incomplete texts. In this section, we consider the effects of learning from multiple texts on incomplete data. We first show a result that gives cases in which identification from multiple incomplete texts is a restriction on identification from a single incomplete text. We then give results which show the cases where the restrictive effects of multiple inaccurate texts can be compensated. Unfortunately, our results about incomplete texts are not as extensive as those for noisy texts.

The following theorem shows that given b and c such that $b \geq c > 1$, there are collections of functions for which a b-error program can be identified from a single $(\lfloor \frac{3c}{2} \rfloor - 1)$-incomplete text but for which even a $(b + \lceil \frac{c}{2} \rceil - 1)$-error program cannot be identified from three texts, at least two of which are only c-incomplete for the function being learned.

THEOREM 5.15. *Let $b, c \in N, b \geq c > 1$. Then $\mathbf{In}^{\lfloor \frac{3c}{2} \rfloor - 1}\mathbf{Ex}^b - \mathbf{Mul}_3^2\mathbf{In}^c\mathbf{Ex}^{b+\lceil \frac{c}{2} \rceil - 1} \neq \emptyset$.*

Proof. The proof uses ideas similar to those used in the proof of Theorem 5.4. Suppose b and c are given as in the hypothesis. Let $A = \{\langle 0, x\rangle \mid 0 \leq x < \lfloor \frac{3c}{2} \rfloor\}$, $A_1 = \{\langle 0, x\rangle \mid 0 \leq x < \lfloor \frac{c}{2} \rfloor\}$, $A_2 = \{\langle 0, x\rangle \mid \lfloor \frac{c}{2} \rfloor \leq x < 2\lfloor \frac{c}{2} \rfloor\}$, $A_3 = \{\langle 0, x\rangle \mid 2\lfloor \frac{c}{2} \rfloor \leq x < 3\lfloor \frac{c}{2} \rfloor\}$, and $A_4 = \{\langle 0, x\rangle \mid 3\lfloor \frac{c}{2} \rfloor \leq x < \lfloor \frac{3c}{2} \rfloor\}$.

Note that $\mathrm{card}(A_1) = \mathrm{card}(A_2) = \mathrm{card}(A_3) = \lfloor \frac{c}{2} \rfloor$ and $\mathrm{card}(A_4) = 1$ if c is odd and 0 otherwise.

Consider the following class of functions:

$\mathcal{C} = \{f \in \mathcal{R} \mid$ the following conditions hold:

(1) $(\forall i \in \{1,2,3\})(\forall x \in A_i)[f(x) = f(\langle 0, (i-1)\lfloor \frac{c}{2} \rfloor \rangle) \in \{0,1\}]$;

(2) $(\exists! i \in \{1,2,3\})[f(A_i) = 1]$;

(3) $(\forall i \in \{1,2,3\} \mid f(A_i) = 0)[(\max(\{f(\langle i, \langle x, 0\rangle\rangle) \mid x \in N\})$ exists) $\wedge$ $(\varphi_{\max(\{f(\langle i,\langle x,0\rangle\rangle)\mid x\in N\})} =^b f)]$;

(4) $(\forall i \in \{1,2,3\})(\forall x,y,z)[f(\langle i, \langle x, y\rangle\rangle) = f(\langle i, \langle x, z\rangle\rangle)]$;

(5) $(\forall x \in A_4)[\varphi_{f(x)} =^b f]$ $\}$

Clearly, $\mathcal{C} \in \mathbf{In}^{\lfloor \frac{3c}{2} \rfloor - 1}\mathbf{Ex}^b$. We now show that $\mathcal{C} \notin \mathbf{Mul}_3^2\mathbf{In}^c\mathbf{Ex}^{b+\lceil \frac{c}{2} \rceil - 1}$.

Suppose by way of contradiction that machine $\mathbf{M}$ $\mathbf{Mul}_3^2\mathbf{In}^c\mathbf{Ex}^{b+\lceil \frac{c}{2} \rceil - 1}$-identifies $\mathcal{C}$. Then by the operator recursion theorem [5], there exists a recursive 1–1 increasing p, $p(0) > 1$, defined below in stages.

We define $\varphi_{p(i)}$ in stages $s \geq 3$.

Let x_3^s denote the least x such that for all y, $\varphi_{p(1)}(\langle 3, \langle x, y\rangle\rangle)$ is not defined before stage s.

Let $\varphi_{p(1)}(x) = 0$ for $x \in A_1 \cup A_3$; $\varphi_{p(1)}(x) = 1$ for $x \in A_2$; $\varphi_{p(1)}(\langle 1, \langle 0,0\rangle\rangle) = p(1)$; $\varphi_{p(1)}(\langle 2, \langle 0,0\rangle\rangle) = p(2)$; $\varphi_{p(1)}(x) = p(1)$ for $x \in A_4$.

Let $\varphi_{p(2)}(x) = 0$, for $x \in A_2 \cup A_3$; $\varphi_{p(2)}(x) = 1$ for $x \in A_1$; $\varphi_{p(2)}(\langle 1, \langle 0,0\rangle\rangle) = p(1)$; $\varphi_{p(2)}(\langle 2, \langle 0,0\rangle\rangle) = p(2)$; $\varphi_{p(2)}(x) = p(2)$ for $x \in A_4$.

Let σ_1^3, σ_2^3, and σ_3^3 be initial segments such that

$$\mathrm{content}(\sigma_1^3) = \{(x,0) \mid x \in A_1\} \cup \{(\langle 1, \langle 0,0\rangle\rangle, p(1)), (\langle 2, \langle 0,0\rangle\rangle, p(2))\}.$$
$$\mathrm{content}(\sigma_2^3) = \{(x,0) \mid x \in A_2\} \cup \{(\langle 1, \langle 0,0\rangle\rangle, p(1)), (\langle 2, \langle 0,0\rangle\rangle, p(2))\}.$$
$$\mathrm{content}(\sigma_3^3) = \{(x,0) \mid x \in A_3\} \cup \{(\langle 1, \langle 0,0\rangle\rangle, p(1)), (\langle 2, \langle 0,0\rangle\rangle, p(2))\}.$$

Let $\varphi_{p(i)}^s$ denote the part of $\varphi_{p(i)}$ defined before stage s. Go to stage 3.

Begin stage s

1. Let $q = \mathbf{M}(\sigma_1^s, \sigma_2^s, \sigma_3^s)$.

2. Let $D_1 = \{x \mid \Phi_q(x) \leq s \wedge ((x \in A_1 \wedge \varphi_q(x) = 0) \vee (x \in A_2 \wedge \varphi_q(x) = 1) \vee (x \in A_4 \wedge \varphi_q(x) = p(1)))\}$. Let $D_2 = \{x \mid \Phi_q(x) \leq s \wedge ((x \in A_1 \wedge \varphi_q(x) = 1) \vee (x \in A_2 \wedge \varphi_q(x) = 0) \vee (x \in A_4 \wedge \varphi_q(x) = p(2)))\}$. If $\mathrm{card}(D_1) \geq \mathrm{card}(D_2)$, then let $r = 1$ and $r' = 2$; otherwise, let $r = 2$ and $r' = 1$. Let $X^s \subset \{\langle 4, x\rangle \mid x \geq s\}$ denote the (lexicographically least) set of b elements such that for all $x \in X^s$, $\varphi_{p(1)}(x)$ is not defined before stage s.

3. Let $\varphi_{p(s)}(x) = 0$ for $x \in A_3 \cup A_{r'}$; $\varphi_{p(s)}(x) = 1$ for $x \in A_r$; $\varphi_{p(s)}(x) = p(r')$ for $x \in A_4$; $\varphi_{p(s)}(\langle 3, \langle x_3^s, 0\rangle\rangle) = \varphi_{p(1)}(\langle 3, \langle x_3^s, 0\rangle\rangle) = \varphi_{p(2)}(\langle 3, \langle x_3^s, 0\rangle\rangle) = p(s)$. For $x \in \mathrm{domain}(\varphi_{p(1)}^s) - A$, let $\varphi_{p(s)}(x) = \varphi_{p(1)}(x)$.

4. Let σ_i' be an extension of σ_i^s such that $\mathrm{content}(\sigma_i') = \mathrm{content}(\sigma_i^s) \cup \{(\langle 3, \langle x_3^s, 0\rangle\rangle, p(s))\}$.

5. Dovetail steps 5a, 5b, and 5c until (if ever) one of steps 5a and 5b succeeds and at least one iteration of the loop at step 5c is completed. If step 5a succeeds, (before step 5b succeeds (if ever)), then complete the then current iteration of the repeat loop in step 5c and go to step 6a. If step 5b succeeds

(before step 5a succeeds (if ever)), then complete the then current iteration of the repeat loop in step 5c and go to step 6b.

5a. Search for $\sigma_i'' \supseteq \sigma_i'$, $i \in \{1,2,3\}$, such that $\mathbf{M}(\sigma_1^s, \sigma_2^s, \sigma_3^s) \neq \mathbf{M}(\sigma_1'', \sigma_2'', \sigma_3'')$ and for all $j, j' \in \{1,2,3\}$, for all $x, y, z \in N$, the following hold:

- $\text{content}(\sigma_j'') - \text{content}(\sigma_j') = \text{content}(\sigma_{j'}'') - \text{content}(\sigma_{j'}')$.
- If $(x,y), (x,z) \in \text{content}\ (\sigma_j'')$, then $y = z$.
- If $(\langle j, \langle x, y\rangle\rangle, v) \in \text{content}(\sigma_1'')$ and $(\langle j, \langle x, z\rangle\rangle, w) \in \text{content}(\sigma_1'')$, then $v = w$.
- If $(x,y) \in (\text{content}(\sigma_1'') - \text{content}(\sigma_1'))$, then $[x \notin A] \wedge [y = 0$ OR $x \in X^s$ OR [for some $i \in \{1,2,3\}$, $u, v \in N$: $x = \langle i, \langle u, v\rangle\rangle$ and $\varphi_{p(1)}(\langle i, \langle u, 0\rangle\rangle)$ has been defined until now and $\varphi_{p(1)}(\langle i, \langle u, 0\rangle\rangle) = y]]$.

Intuitively, this substep attempts to look for a mind change.

5b. Search for $x \in (A_1 \cup A_2) - (D_1 \cup D_2)$ such that $\varphi_q(x)\downarrow$.

5c. Let $Addednew = \emptyset$.
(*Note:* We use *Addednew* in order to identify the set of elements for which we extended $\varphi_{p(1)}$ in this step. *Addednew* will be used (in steps 6a and 6b), provided at least one of steps 5a or 5b succeeds).
Repeat
Let x be the least point not in X^s such that $\varphi_{p(1)}(x)$ is not defined until now. If for some $i \in \{1,2,3\}$, x is of the form $\langle i, \langle u, v\rangle\rangle$ and $\varphi_{p(1)}(\langle i, \langle u, 0\rangle\rangle)$ is defined until now, then let $\varphi_{p(1)}(x) = \varphi_{p(2)}(x) = \varphi_{p(s)}(x) = \varphi_{p(1)}(\langle i, \langle u, 0\rangle\rangle)$; otherwise, let $\varphi_{p(1)}(x) = \varphi_{p(2)}(x) = \varphi_{p(s)}(x) = 0$.
Let $Addednew = Addednew \cup \{x\}$.
Forever

6a. For all x and y such that $(x,y) \in \text{content}(\sigma_1'') - \text{content}(\sigma_1^s)$, let $\varphi_{p(1)}(x) = \varphi_{p(2)}(x) = y$. Let σ_i^{s+1} be an extension of σ_i'' such that $\text{content}(\sigma_i^{s+1}) - \text{content}(\sigma_i'') = \{(x, \varphi_{p(1)}(x)) \mid x \in Addednew\}$. Go to stage $s+1$.

6b. Let σ_i^{s+1} be an extension of σ_i' such that $\text{content}(\sigma_i^{s+1}) - \text{content}(\sigma_i') = \{(x, \varphi_{p(1)}(x)) \mid x \in Addednew\}$. Go to stage $s+1$.

End stage s
Now consider the following cases.
Case 1. All stages terminate.
Let

$$f(x) = \begin{cases} 0 & \text{if } x \in A_1 \cup A_2; \\ 1 & \text{if } x \in A_3; \\ \varphi_{p(1)}(x) & \text{otherwise.} \end{cases}$$

Clearly, $f \in \mathcal{C}$ (since $c \leq b$, $\varphi_{p(1)} =^b f$, and $\varphi_{p(2)} =^b f$). Also, $\mathbf{M}$ on f makes infinitely many mind changes since Step 5b can succeed at most finitely many times before Step 5a succeeds.

Case 2. Stage s (≥ 3) is the least stage which never terminates.

In this case, $\text{domain}(\varphi_{p(s)}) = N - X^s$. Let q, D_1, D_2, r, and r' be as defined in steps 1 and 2 of stage s. Consider any total extension f of $\varphi_{p(s)}$ such that $(\forall x \in X^s)[\varphi_q(x) \neq f(x)]$.

Clearly, $f \in \mathcal{C}$ (since $\varphi_{p(r')} =^b f$ and $\varphi_{p(s)} =^b f$). Let T_1, T_2, and T_3 be extensions of σ'_1, σ'_2, and σ'_3 (as defined in step 4 in stage s), respectively, such that $\text{content}(T_1) - \text{content}(\sigma^s_1) = \{(x, y) \mid f(x) = y \ \wedge \ x \notin A \ \wedge \ (\forall z)[(x, z) \notin \text{content}(\sigma^s_1)]\}$ and for all j, the $[|\sigma'_1| + j]$th element of T_1, the $[|\sigma'_2| + j]$th element of T_2, and the $[|\sigma'_3| + j]$th element of T_3 are all same. First, notice that for all such f and corresponding T_1, T_2, and T_3, $\mathbf{M}(T_1, T_2, T_3) = q$. (Otherwise, step 5a would succeed.) Second, notice that for all $x \in (A_1 \cup A_2) - (D_1 \cup D_2)$, $\varphi_q(x)\uparrow$. (Otherwise, step 5b would succeed.) Third, from the choice of r and r', it follows that program q makes at least $\lceil \frac{c}{2} \rceil$ errors on $A_1 \cup A_2 \cup A_4$. Also, from the way f has been chosen, we have $(\forall x \in X^s)[f(x) \neq \varphi_q(x)]$. Thus $\varphi_q \neq^{b+\lceil \frac{c}{2} \rceil - 1} f$.

From the above cases, it follows that $\mathcal{C} \notin \mathbf{Mul}^2_3\mathbf{In}^c\mathbf{Ex}^{b+\lceil \frac{c}{2} \rceil - 1}$. □

Theorem 5.15 demonstrated cases in which identification from multiple inaccurate texts is a restriction over identification from a single inaccurate text. As in the case with noisy texts, we would like to explore situations in which the deleterious effects of learning from multiple texts can be compensated. Again as in the case of noisy texts, this can be achieved in two different ways:

- by increasing the bound on the number of errors in the final program allowed in identification from multiple texts;
- by increasing the bound on missing data in the single incomplete text (this has the same effect as decreasing the bound on missing data in the multiple texts).

Theorem 5.16 below uses the second technique and Theorems 5.19 and 5.20 use the first technique to compensate for the effects of multiple texts. The technique used in these simulation arguments is to first collect the input points on which the converging programs differ, then to construct a program which judiciously chooses the output on these inputs based on the input texts and outputs of the converging programs.

THEOREM 5.16. $\mathbf{In}^{c+\lfloor \frac{c}{2} \rfloor}\mathbf{Ex}^b \subseteq \mathbf{Mul}^2_3\mathbf{In}^c\mathbf{Ex}^b$.

Theorem 5.16 says that given b and c, if for a collection of functions a b-error program can be identified from a single $(c + \lfloor \frac{c}{2} \rfloor)$-incomplete text, then a b-error program can also be identified from three texts, at least two of which are c-incomplete for the function being learned. A proof of this result requires the notion of a stabilizing sequence, which we introduce next. Let L range over sets of ordered pairs.

DEFINITION 5.17. (See [9].) *σ is said to be a stabilizing sequence for $\mathbf{M}$ on L* $\iff$ $[\text{content}(\sigma) \subseteq L$ *and* $(\forall \tau \mid \sigma \subset \tau \ \wedge \ \text{content}(\tau) \subseteq L)[\mathbf{M}(\tau) = \mathbf{M}(\sigma)]]$.

The following lemma is based on a similar lemma by Blum and Blum [3] (see also Osherson and Weinstein [18]).

LEMMA 5.18 (based on a similar lemma in [3, 18]). *Suppose $\mathbf{M}$ $\mathbf{In}^a\mathbf{Ex}^b$-identifies f. Let L be such that $L \subseteq \{(x, y) \mid f(x) = y\} \ \wedge \ \text{card}(\{(x, y) \mid f(x) = y\} - L) \leq a$. Then there exists a stabilizing sequence for $\mathbf{M}$ on L. Moreover, if σ is a stabilizing sequence for $\mathbf{M}$ on L, then $\varphi_{\mathbf{M}(\sigma)} =^b f$.*

We now give a proof of Theorem 5.16.

Proof of Theorem 5.16. Suppose machine $\mathbf{M}$ $\mathbf{In}^{c+\lfloor \frac{c}{2} \rfloor}\mathbf{Ex}^b$-identifies $\mathcal{C}$. We construct $\mathbf{M}'$ such that $\mathbf{M}'$ $\mathbf{Mul}^2_3\mathbf{In}^c\mathbf{Ex}^b$-identifies $\mathcal{C}$.

Let T_1, T_2, and T_3 be three given texts out of which at least two are c-incomplete for $f \in \mathcal{C}$. Let T_{UNION} be a text such that $\text{content}(T_{UNION}) = \text{content}(T_1) \cup$

content$(T_2) \cup$ content(T_3). Without loss of generality, we assume that $(\forall x)[\text{card}(\{y \mid (x,y) \in \text{content}(T_{UNION})\}) \leq 1]$. (If there are x, y, z, i, and j such that $(x,y) \in \text{content}(T_i)$, $(x,z) \in \text{content}(T_j)$, and $y \neq z$, then at least one of T_i and T_j is not a c-incomplete text for f. Thus the third text is a c-incomplete text for f.) We can also assume without loss of generality that $(\forall x)[\text{card}(i \in \{1,2,3\} \mid (\exists y)[(x,y) \in \text{content}(T_i)]) \neq 2]$. (Otherwise, for such x's the value of $f(x)$ is known and thus without loss of generality we can put (x,y) into all three texts.)

In the following, we try to locate a stabilizing sequence for $\mathbf{M}$ on an appropriate subset of $\{(x, f(x)) \mid x \in N\}$. If one of the texts has a "high amount of incompleteness," then this may not be possible (see condition (iii) below); however, in this case, it is possible to determine the text which has a high amount of incompleteness.

Let $n', n'' \in N$, $X \subset \{0, 1, \ldots, n'\}$, and $\sigma \in \text{SEQ}$ be such that (i), (ii), and (iii) below are satisfied.

(i) $(\forall i \in \{1,2,3\})(\forall y \in N)(\forall x \in \{0,1,\ldots,n'\})[(x,y) \in \text{content}(T_i) \Rightarrow (x,y) \in \text{content}(T_i[n''])]$.

(ii) $(\forall x \in X)(\forall y \in N)[\text{card}(\{i \mid (x,y) \in \text{content}(T_i)\}) \leq 1]$.

(iii)

(A) $[(\exists j \in \{1,2,3\})[\text{card}(\{x \mid (x \in X) \ \wedge \ (\forall y \in N)[(x,y) \notin \text{content}(T_j)]\}) > c]]$

OR

(B) $[[[\text{content}(\sigma) \subseteq [\text{content}(T_{UNION}) \cap \{(x,y) \mid (y \in N) \ \wedge \ (x \leq n')\}] - [\{(x,y) \mid (x \in X) \ \wedge \ (y \in N)\}]]$ and σ is a stabilizing sequence for $\mathbf{M}$ on $L = [\text{content}(T_{UNION}) - \{(x,y) \mid (x \in X) \ \wedge \ (y \in N)\}]]$ AND $[(\forall x \leq n')[x \notin X \Rightarrow (\exists y)[\text{card}(\{i \mid (x,y) \in \text{content}(T_i)\}) = 3]]]]$.

It is easy to see that if such n', n'', X, and σ exist, then $\mathbf{M}'$ can find them in the limit. If in (iii) (A) holds, then clearly $\mathbf{M}'$ can know the two texts which are c-incomplete for f and thus output in the limit a b-error program for f. If in (iii) (B) holds, then we claim that $\mathbf{M}(\sigma)$ is a b-error program for f. This would be the case if $\text{card}(\{(x,y) \mid f(x) = y\} - L) \leq c + \lfloor \frac{c}{2} \rfloor$. To prove this, let $\delta_i = \text{card}(\{x \in X \mid (\exists y)[(x,y) \in \text{content}(T_i)]\})$. Let δ be the median of δ_1, δ_2, and δ_3. Now $\text{card}(\{(x,y) \mid f(x) = y\} - L) \leq c - (\text{card}(X) - \delta) + \text{card}(X) \leq c + \delta$ and $\delta \leq \frac{c}{2}$.

To complete the proof, we have to show that such n', n'', X, and σ indeed exist.

Case 1. There exists an $i \in \{1,2,3\}$ such that $\text{card}(\{x \mid (\forall y)[(x,y) \notin \text{content}(T_i)]\}) > c$.

Let n' be such that there exists an i, $\text{card}(\{x \leq n' \mid (\forall y)[(x,y) \notin \text{content}(T_i)]\}) = c + 1$. Let n'' be such that (i) above is satisfied. Let $X = \{x \leq n' \mid \text{card}(\{i \mid (\exists y)[(x,y) \in \text{content}(T_i)]\}) \leq 1\}$. Then it is easy to see that (i), (ii), and (iii) above are satisfied.

Case 2. There does not exist an $i \in \{1,2,3\}$ such that $\text{card}(\{x \mid (\forall y)[(x,y) \notin \text{content}(T_i)]\}) > c$.

Let $X = \{x \mid \text{card}(\{i \mid (\exists y)[(x,y) \in \text{content}(T_i)]\}) \leq 1\}$. Now let $L = \{(x,y) \mid f(x) = y \ \wedge \ x \notin X\}$ and let $\delta_i = \text{card}(\{x \in X \mid (\exists y)[(x,y) \in \text{content}(T_i)]\})$. Let δ be the median of δ_1, δ_2, and δ_3. Now $\text{card}(\{(x,y) \mid f(x) = y\} - L) \leq c - (\text{card}(X) - \delta) + \text{card}(X) \leq c + \delta$ and $\delta \leq \frac{c}{2}$. Thus there exists a stabilizing sequence σ for $\mathbf{M}$ on L. Let $n' = 1 + \max(X \cup \{x \mid (\exists y)[(x,y) \in \text{content}(\sigma)]\})$. Let n'' be chosen so as to satisfy (i) above. Clearly, n', n'', X, and σ satisfy (i), (ii), and (iii).

The above cases prove the existence of σ, X, n', and n'' satisfying (i), (ii), and (iii). □

We now present two results that compensate for the restrictive effects of multiple incomplete texts by allowing a larger bound on the number of errors allowed in the

final program.

THEOREM 5.19. *Let $b, c \in N$. Then* $\mathbf{In}^c\mathbf{Ex}^b \subseteq \mathbf{Mul}_3^2\mathbf{In}^c\mathbf{Ex}^{2b}$.

This result, which is a counterpart of Theorem 5.9, says that the collections of functions for which a b-error program can be identified from a c-incomplete text can also be identified from three texts, at least two of which are c-incomplete, provided we are prepared to tolerate twice ($2b$) the number of errors in the final program. This theorem can be proved using a technique similar to the one used in the proof of Theorem 5.9. We omit the details.

The next result gives a different bound on the number of errors allowed in the final program.

THEOREM 5.20. *Let $b, c \in N, b \geq c$ be given. Then* $\mathbf{In}^c\mathbf{Ex}^b \subseteq \mathbf{Mul}_3^2\mathbf{In}^c\mathbf{Ex}^{b+\lceil \frac{c}{2} \rceil}$.

Proof. Suppose the hypothesis of the theorem holds. Suppose machine $\mathbf{M}$ $\mathbf{In}^c\mathbf{Ex}^b$-identifies $\mathcal{C}$. We construct $\mathbf{M}'$ such that $\mathbf{M}'$ $\mathbf{Mul}_3^2\mathbf{In}^c\mathbf{Ex}^{b+\lceil \frac{c}{2} \rceil}$-identifies $\mathcal{C}$.

Let T_1, T_2, and T_3 be three texts given for a function $f \in \mathcal{C}$ such that at least two of the three texts are c-incomplete for f. Without loss of generality, we can assume that $(\forall x)[\mathrm{card}(\{y \mid (x,y) \in \mathrm{content}(T_1) \cup \mathrm{content}(T_2) \cup \mathrm{content}(T_3)\}) \leq 1]$. (If there is such an x, then let y, z, i, and j be such that $(x,y) \in \mathrm{content}(T_i), (x,z) \in \mathrm{content}(T_j)$, and $y \neq z$. Then at least one of T_i and T_j is not a c-incomplete text for f. Thus the third text is a c-incomplete text for f.)

Let T_{UNION} be a text such that $\mathrm{content}(T_{UNION}) = \{(x,y) \mid (x,y) \in \mathrm{content}(T_1) \vee (x,y) \in \mathrm{content}(T_2) \vee (x,y) \in \mathrm{content}(T_3)\}$. Let i and j be distinct and such that $\mathbf{M}(T_i)\downarrow$ and $\mathbf{M}(T_j)\downarrow$, $P_i = \mathbf{M}(T_i)$ and $P_j = \mathbf{M}(T_j)$, and $\mathrm{card}(CLASH = \{x \mid [\varphi_{P_i}(x)\downarrow \neq \varphi_{P_j}(x)\downarrow] \vee (\exists y)[[(x,y) \in \mathrm{content}(T_{UNION})] \wedge [[\varphi_{P_i}(x)\downarrow \neq y] \vee [\varphi_{P_j}(x)\downarrow \neq y]]]\}) \leq 3b$.

Let $VIS\_IN = CLASH \cap \{x \mid \mathrm{card}(\{i \mid (\exists y)(x,y) \in \mathrm{content}(T_i)\}) \leq 1\}$. For $i \in \{1,2,3\}$, let $IN_i = VIS\_IN \cap \{x \mid (\exists y)[(x,y) \in \mathrm{content}(T_i)]\}$. Let $m = \min(\mathrm{card}(IN_1), \mathrm{card}(IN_2), \mathrm{card}(IN_3))$. Let $S \subseteq VIS\_IN$ be a set of cardinality $3m$ such that $\mathrm{card}(S \cap IN_1) = \mathrm{card}(S \cap IN_2) = \mathrm{card}(S \cap IN_3)$. Let $X \subseteq VIS\_IN - S$ be a set of cardinality $\lceil \frac{\mathrm{card}(VIS\_IN - S)}{2} \rceil$.

Machine $\mathbf{M}'$ outputs (in the limit) program p as follows:

$$\varphi_p(x) = \begin{cases} \varphi_{P_i}(x) & \text{if } x \notin CLASH \ \wedge \ x \in \mathrm{domain}(\varphi_{P_i}); \\ \varphi_{P_j}(x) & \text{if } x \notin CLASH \ \wedge \ x \in \mathrm{domain}(\varphi_{P_j}); \\ y & \text{if } x \in ((CLASH - VIS\_IN) \cup S) \text{ and} \\ & (x,y) \in \mathrm{content}(T_{UNION}) \ ; \\ \varphi_{P_i}(x) & \text{if } x \in X; \\ \varphi_{P_j}(x) & \text{if } x \in VIS\_IN - (S \cup X); \\ \uparrow & \text{otherwise.} \end{cases}$$

Now the number of errors committed by $\mathbf{M}'$ on f is bounded by $m + \lceil \frac{\mathrm{card}(VIS\_IN - S)}{2} \rceil + b$. Observing that $c \geq \mathrm{card}(VIS\_IN) - m$, it follows that $\mathbf{M}'$ $\mathbf{Mul}_3^2\mathbf{In}^c\mathbf{Ex}^{b+\lceil \frac{c}{2} \rceil}$-identifies $\mathcal{C}$. □

We end this section by presenting a somewhat surprising result which says that for $a \in N$ the collection of functions for which a 1-error program can be identified from a single a-incomplete text is exactly the same as the collection of functions for which a 1-error program can be identified from three texts, at least two of which are a-incomplete for the function being learned.

THEOREM 5.21. *Let $a \in N$. Then,* $\mathbf{In}^a\mathbf{Ex}^1 = \mathbf{Mul}_3^2\mathbf{In}^a\mathbf{Ex}^1$.

Proof. The case where $a = 1$ follows from Theorem 5.16. Suppose $a > 1$. Suppose $\mathbf{M}$ $\mathbf{In}^a\mathbf{Ex}^1$-identifies $\mathcal{C}$. We give an $\mathbf{M}'$ such that $\mathbf{M}'$ $\mathbf{Mul}_3^2\mathbf{In}^a\mathbf{Ex}^1$-identifies $\mathcal{C}$. Let

T_1, T_2, and T_3 be the three given texts out of which at least two are a-incomplete for $f \in \mathcal{C}$. Let T_{UNION} denote a text such that content(T_{UNION}) = content$(T_1) \cup$ content$(T_2) \cup$ content(T_3). Without loss of generality, assume that for all x, card$(\{y \mid (x,y) \in \text{content}(T_{UNION})\}) \leq 1$. (Otherwise, let y and z, $y \neq z$, be such that $(x,y) \in$ content(T_i) and $(x,z) \in$ content(T_j) (for $i,j \in \{1,2,3\}$). Clearly, at least one of T_i and T_j is not an a-incomplete text for f. Thus the remaining text is an a-incomplete text for f; in this case, $\mathbf{M}'$ can simply input the a-incomplete text for f to $\mathbf{M}$ to obtain a program (in the limit) which is 1-variant of f.) Also, assume that $(\forall x,y)[\text{card}(\{i \in \{1,2,3\} \mid (x,y) \in \text{content}(T_i)\}) \neq 2]$ (since otherwise $f(x) = y$ and we can assume that (x,y) is in all of the texts). Let i and j be distinct and such that $\mathbf{M}(T_i)\downarrow$ and $\mathbf{M}(T_j)\downarrow$. (Clearly, for $f \in \mathcal{C}$, such i and j exist and $\mathbf{M}'$ can determine i and j in the limit.) Without loss of generality, let $i = 1$ and $j = 2$. (Otherwise, simply rename the texts.) Let $\mathbf{M}(T_1) = P_1$ and $\mathbf{M}(T_2) = P_2$.

Let $CLASH12 = \{x \mid [\varphi_{P_1}(x)\downarrow \neq \varphi_{P_2}(x)\downarrow] \vee [\varphi_{P_1}(x)\downarrow \wedge (\exists y)[(x,y) \in \text{content}(T_2) \wedge y \neq \varphi_{P_1}(x)]] \vee [\varphi_{P_2}(x)\downarrow \wedge (\exists y)[(x,y) \in \text{content}(T_1) \wedge y \neq \varphi_{P_2}(x)]]\}$. Let $CLASH1T3 = \{x \mid [\varphi_{P_1}(x)\downarrow \wedge (\exists y)[(x,y) \in \text{content}(T_3) \wedge y \neq \varphi_{P_1}(x)]]\}$. Let $CLASH2T3 = \{x \mid [\varphi_{P_2}(x)\downarrow \wedge (\exists y)[(x,y) \in \text{content}(T_3) \wedge y \neq \varphi_{P_2}(x)]]\}$.

Now consider the following cases. (Note that $\mathbf{M}'$ can also determine in the limit which of the following cases holds.) In each of the following cases, we either give a correct text for f or a program for a 1-variant of f. For each of the case numbers $i > 1$, we assume without stating that all cases $< i$ do not hold.

Case 1. card$(CLASH12) > 2$.

In this case, T_3 is an a-incomplete text for f.

Case 2. card$(CLASH1T3) > 1$.

In this case, T_2 is an a-incomplete text for f.

Case 3. card$(CLASH2T3) > 1$.

In this case, T_1 is an a-incomplete text for f.

Case 4. card$(CLASH12) = 0$.

In this case, let p be such that $\varphi_p = \varphi_{P_1} \cup \varphi_{P_2}$. Then φ_p is a program for a 1-variant of f.

For Cases 5–7, assume without loss of generality that for all $x \in CLASH12 \cup CLASH1T3 \cup CLASH2T3$, $\varphi_{P_1}(x)\downarrow$ and $\varphi_{P_2}(x)\downarrow$. (Since $CLASH12 \cup CLASH1T3 \cup CLASH2T3$ is finite, we can check in the limit if $\varphi_{P_1}(x), \varphi_{P_2}(x)$ is defined or not. If it is undefined, then we can assume that it converges to an arbitrary value.) Also, for all $x \in CLASH12 \cup CLASH1T3 \cup CLASH2T3$, we can assume that $(\forall y)[[(x,y) \in \text{content}(T_1) \Rightarrow y = \varphi_{P_1}(x)] \wedge [(x,y) \in \text{content}(T_2) \Rightarrow y = \varphi_{P_2}(x)]]$. (Otherwise we can assume that y is the value the program converges to.) Note that this assumption may cause the values of $CLASH12, CLASH1T3$ and $CLASH2T3$, as defined above, to change. It may also cause one of Cases 1, 2, 3, or 4 to hold; however, in this case, the above analysis also holds.

Case 5. card$(CLASH1T3) =$ card$(CLASH2T3) = 1$.

Then for all $x \in N - CLASH12 \cup CLASH1T3 \cup CLASH2T3$ $(\exists i \in \{1,2\})[\varphi_{P_i}(x)\downarrow = f(x)]$. A simple calculation shows that card$(CLASH12 \cup CLASH1T3 \cup CLASH2T3) \leq 3$. If $a \geq$ card$(CLASH12 \cup CLASH1T3 \cup CLASH2T3)$, then text T such that content$(T) = \{(x,y) \mid x \in N - (CLASH12 \cup CLASH1T3 \cup CLASH2T3) \wedge (\exists i \in \{1,2,3\})[\varphi_{P_i}(x) = y]\}$ is an a-incomplete text for f. Otherwise, $a = 2$ and card$(CLASH12 \cup CLASH1T3 \cup CLASH2T3) = 3$. In this case, if there exists $i \in \{1,2,3\}$ such that $(\forall x \in CLASH12 \cup CLASH1T3 \cup CLASH2T3)(\forall y)[(x,y) \notin \text{content}(T_i)]$, then each of the remaining texts are a-

incomplete for f. Otherwise, let p be a program such that

$$\varphi_p(x) = \begin{cases} U(x) & \text{if } x \in N - (CLASH12 \cup CLASH13 \cup CLASH23); \\ y & \text{if } x \in CLASH12 \cup CLASH13 \cup CLASH23 \\ & \quad \wedge (x,y) \in \text{content}(T_{UNION}), \end{cases}$$

where $U(x)$ denotes $(\varphi_{P_1} \cup \varphi_{P_2})(x)$. Then p is program for a 1-variant of f.

Case 6. $\text{card}(CLASH1T3) = 1$ and $\text{card}(CLASH2T3) = 0$. (The case where $\text{card}(CLASH2T3) = 1$ and $\text{card}(CLASH1T3) = 0$ is similar.)

Let p be a program such that:

$$\varphi_p(x) = \begin{cases} U(x) & \text{if } x \in N - CLASH12; \\ \varphi_{P_2}(x) & \text{otherwise,} \end{cases}$$

where $U(x)$ denotes $(\varphi_{P_1} \cup \varphi_{P_2})(x)$. Then p is program for a 1-variant of f. Since if T_2 is an a-incomplete text for f, then this is the case. Otherwise, the number of errors committed by p is $\leq \text{card}(CLASH12 - CLASH1T3) \leq 1$.

Case 7. $\text{card}(CLASH1T3) = \text{card}(CLASH2T3) = 0$.

In this case, for all $(x,y) \in \text{content}(T_3)$, $f(x) = y$. This is the case since if T_3 is the correct text, then it is certainly so; otherwise, for all $x \in N - CLASH12$, $\varphi_{P_1}(x) = f(x) \vee \varphi_{P_2}(x) = f(x)$. Thus if $(x,y) \in \text{content}(T_3)$, then $f(x) = y$. Thus $[\mathbf{M}(T_3)\downarrow]$ or $[\text{card}(\{x \mid (\forall y)(x,y) \notin \text{content}(T_3)\}) > a]$. Note that we can determine in the limit one of the clauses above which holds.

Case 7a. $\text{card}(\{x \mid (\forall y)(x,y) \notin \text{content}(T_3)\}) > a$.

In this case, both T_1 and T_2 are a-incomplete texts for f.

Case 7b. $\mathbf{M}(T_3)\downarrow = P_3$.

Let $CLASH13 = \{x \mid [\varphi_{P_1}(x)\downarrow \neq \varphi_{P_3}(x)\downarrow]\}$. Let $CLASH23 = \{x \mid [\varphi_{P_2}(x)\downarrow \neq \varphi_{P_3}(x)\downarrow]\}$.

Case 7b.1. $\text{card}(CLASH13) > 2$.

In this case, T_2 is an a-incomplete text for f.

Case 7b.2. $\text{card}(CLASH23) > 2$.

In this case, T_1 is an a-incomplete text for f.

For Cases 7b.3–7b.5, assume without loss of generality that for all $x \in CLASH12 \cup CLASH13 \cup CLASH23$, $\varphi_{P1}(x)\downarrow$, $\varphi_{P_2}(x)\downarrow$, and $\varphi_{P_3}(x)\downarrow$. (Since $CLASH12 \cup CLASH13 \cup CLASH23$ is finite, we can check in the limit if $\varphi_{P_1}(x), \varphi_{P_2}(x), \varphi_{P_3}(x)$ is defined or not. If it is not defined, then we can assume that it converges to an arbitrary value.) Also, for all $x \in CLASH12 \cup CLASH13 \cup CLASH23$, we can assume that $(\forall y)[[(x,y) \in \text{content}(T_1) \Rightarrow y = \varphi_{P_1}(x)] \wedge [(x,y) \in \text{content}(T_2) \Rightarrow y = \varphi_{P_2}(x)]]$. (Otherwise, we can assume that y is the value the program converges to.) Note that this assumption may cause the values of $CLASH12$, $CLASH13$, $CLASH23$, $CLASH1T3$, and $CLASH2T3$, as defined above, to change. It may also cause one of Cases 1, 2, 3, 4 , 5, 6, 7b.1, or 7b.2 to hold; however, in this case, the above analysis also holds.

Case 7b.3. $\text{card}(CLASH13) = 0$.

In this case, let p be such that $\varphi_p = \varphi_{P_1} \cup \varphi_{P_3}$. Then φ_p is a program for a 1-variant of f.

Case 7b.4. $\text{card}(CLASH23) = 0$.

In this case, let p be such that $\varphi_p = \varphi_{P_2} \cup \varphi_{P_3}$. Then φ_p is a program for a 1-variant of f.

Case 7b.5. $0 < \text{card}(CLASH13) < 3$ and $0 < \text{card}(CLASH23) < 3$.

Then $(\forall x \in N - CLASH12 \cup CLASH13 \cup CLASH23)$ $(\exists i \in \{1,2,3\})$ $[\varphi_{P_i}(x)\downarrow = f(x)]$. A simple calculation shows that $\text{card}(CLASH12 \cup CLASH13 \cup CLASH23) \leq 3$. If $a \geq \text{card}(CLASH12 \cup CLASH13 \cup CLASH23)$, then text T such that $\text{content}(T) = \{(x,y) \mid x \in N - (CLASH12 \cup CLASH13 \cup CLASH23) \wedge (\exists i \in \{1,2,3\})[\varphi_{P_i}(x) = y]\}$ is an a-incomplete text for f. Otherwise, $a = 2$ and $\text{card}(CLASH12 \cup CLASH13 \cup CLASH23) = 3$. In this case, if there exists $i \in \{1,2,3\}$ such that $(\forall x \in CLASH12 \cup CLASH13 \cup CLASH23)(\forall y)[(x,y) \notin \text{content}(T_i)]$, then each of the remaining texts are a-incomplete texts for f. Otherwise, let p be a program such that

$$\varphi_p(x) = \begin{cases} U(x) & \text{if } x \in N - (CLASH12 \cup CLASH13 \cup CLASH23); \\ y & \text{if } x \in CLASH12 \cup CLASH13 \cup CLASH23 \\ & \wedge\ (x,y) \in \text{content}(T_{UNION}), \end{cases}$$

where $U(x)$ denotes $(\varphi_{P_1} \cup \varphi_{P_2} \cup \varphi_{P_3})(x)$. Then p is a program for a 1-variant of f. □

5.2.3. Imperfect texts. The study of imperfect texts turns out to be very complex. We only present a simulation result which says that for $b, c \in N$, the collection of functions for which a b-error program can be identified from a single c-imperfect text can also be learned from three texts, at least two of which are c-imperfect, provided we are prepared to tolerate up to twice the number of errors in the final program. A proof of this result can be worked out along similar lines to our proof of Theorem 5.9; we omit the details.

THEOREM 5.22. *Let $b, c \in N$.* $\mathbf{Im}^c\mathbf{Ex}^b \subseteq \mathbf{Mul}_3^2\mathbf{Im}^c\mathbf{Ex}^{2b}$.

5.3. Hierarchy results. We now turn our attention to hierarchy results for each of the inaccuracy types. In particular, we show for each inaccuracy type that larger collections of functions become identifiable if we

- increase the bound on the number of errors allowed in the final program (keeping other parameters the same) or
- decrease the bound on the number of inaccuracies allowed in the input texts (keeping other parameters the same).

The following two theorems, which follow from results about identification from single inaccurate texts [11], yield as corollaries the above hierarchies.

THEOREM 5.23. *Let $b, j, k \in N$, $k \geq j > \lfloor \frac{k}{2} \rfloor$.*

(a) $\mathbf{Mul}_k^j\mathbf{Im}^*\mathbf{Ex}^{b+1} - \mathbf{Ex}^b \neq \emptyset$.

(b) $\mathbf{Mul}_k^j\mathbf{Im}^*\mathbf{Ex}^* - \bigcup_{b \in N} \mathbf{Ex}^b \neq \emptyset$.

Proof. The proof follows from Theorem 1 in [11] and Theorem 5.1. □

THEOREM 5.24. $(\forall b, j, k \in N \mid k \geq j > \lfloor \frac{k}{2} \rfloor)$ $[\mathbf{Mul}_k^j\mathbf{Im}^b\mathbf{Ex} - [\mathbf{N}^{b+1}\mathbf{Ex}^* \cup \mathbf{In}^{b+1}\mathbf{Ex}^*] \neq \emptyset]$.

Proof. The proof follows from Theorem 6 in [11] and Theorem 5.2. □

It can be shown that the above two results yield the following two corollaries.

COROLLARY 5.25. *Let $a \in N \cup \{*\}$. Let $j, k \in N$ such that $k \geq j > \lfloor \frac{k}{2} \rfloor$. Then*

1. $\mathbf{Mul}_k^j\mathbf{N}^a\mathbf{Ex}^0 \subset \mathbf{Mul}_k^j\mathbf{N}^a\mathbf{Ex}^1 \subset \cdots \subset \mathbf{Mul}_k^j\mathbf{N}^a\mathbf{Ex}^*$;
2. $\mathbf{Mul}_k^j\mathbf{In}^a\mathbf{Ex}^0 \subset \mathbf{Mul}_k^j\mathbf{In}^a\mathbf{Ex}^1 \subset \cdots \subset \mathbf{Mul}_k^j\mathbf{In}^a\mathbf{Ex}^*$;
3. $\mathbf{Mul}_k^j\mathbf{Im}^a\mathbf{Ex}^0 \subset \mathbf{Mul}_k^j\mathbf{Im}^a\mathbf{Ex}^1 \subset \cdots \subset \mathbf{Mul}_k^j\mathbf{Im}^a\mathbf{Ex}^*$.

COROLLARY 5.26. *Let $a \in N \cup \{*\}$. Let $j, k \in N$ such that $k \geq j > \lfloor \frac{k}{2} \rfloor$. Then*

1. $\mathbf{Mul}_k^j\mathbf{N}^0\mathbf{Ex}^a \supset \mathbf{Mul}_k^j\mathbf{N}^1\mathbf{Ex}^a \supset \cdots \supset \mathbf{Mul}_k^j\mathbf{N}^*\mathbf{Ex}^a$;

2. $\mathbf{Mul}_k^j\mathbf{In}^0\mathbf{Ex}^a \supset \mathbf{Mul}_k^j\mathbf{In}^1\mathbf{Ex}^a \supset \cdots \supset \mathbf{Mul}_k^j\mathbf{In}^*\mathbf{Ex}^a$;
3. $\mathbf{Mul}_k^j\mathbf{Im}^0\mathbf{Ex}^a \supset \mathbf{Mul}_k^j\mathbf{Im}^1\mathbf{Ex}^a \supset \cdots \supset \mathbf{Mul}_k^j\mathbf{Im}^*\mathbf{Ex}^a$.

5.4. Comparison of different types of inaccuracies. Finally, we present results which shed light on how learning from one kind of inaccuracy compares with learning from another kind of inaccuracy.

First, we show a very interesting result which implies that in the context of identification from multiple inaccurate texts, noisy texts are better than incomplete texts. This parallels previous findings about identification from single inaccurate texts. The result below shows that the collections of functions that can be identified from multiple incomplete texts can also be identified from multiple noisy texts, provided the bound on the number of errors allowed in the final program and the bound on the number of inaccuracies are the same in both cases (and also provided the cardinality of multiple texts and of acceptable texts is the same in both cases).

THEOREM 5.27. *Let* $a, b \in N \cup \{*\}$ *and* $j, k \in N$, $k \geq j > \lfloor \frac{k}{2} \rfloor$. *Then* $\mathbf{Mul}_k^j\mathbf{In}^a\mathbf{Ex}^b \subseteq \mathbf{Mul}_k^j\mathbf{N}^a\mathbf{Ex}^b$.

Proof. Let $T_1, T_2, \ldots, T_k$ be the k input texts for f such that at least j of the texts are a-noisy for f. Note that if $f(x) = y$, then at least j of the k texts contain (x, y). Let T_i' be the text formed from T_i such that $\text{content}(T_i') = \{(x, y) \mid \text{card}(\{l \mid (x, y) \in \text{content}(T_l)\}) \geq j \ \wedge \ \text{card}(\{z \mid (x, z) \in \text{content}(T_i)\}) \leq 1 \ \wedge \ (x, y) \in \text{content}(T_i)\}$. Thus we can easily obtain T_i''s from T_i's in the limit. Also, if T_i was an a-noisy text for f, then T_i' is an a-incomplete text for f. The theorem follows. □

As a contrast to the above result, the next result implies that the collections of functions which can be identified from multiple noisy texts cannot always be identified from a single incomplete text (and hence from multiple incomplete texts). The result shows that there are collections of functions for which a 0-error program can be identified from any k texts, at least $j(> \lfloor \frac{k}{2} \rfloor)$ of which are only $*$-noisy, but for which even a $*$-error program cannot be identified from single 1-incomplete text.

THEOREM 5.28. *Let* $j, k \in N$, $k \geq j > \lfloor \frac{k}{2} \rfloor$. *Then* $\mathbf{Mul}_k^j\mathbf{N}^*\mathbf{Ex} - \mathbf{In}^1\mathbf{Ex}^* \neq \emptyset$.

Proof. The proof follows from Theorem 10 in [11] and Theorem 5.1. □

The next two results compare identification from multiple incomplete texts and multiple imperfect texts. As expected, imperfect texts turn out to be worse for identification than incomplete texts.

The next theorem shows that for $i \in N$, there are collections of functions for which a 0-error program (best program) can be identified from any k texts, at least $j(> \lfloor \frac{k}{2} \rfloor)$ of which are $(3i - 1)$-incomplete, but for which even a $*$-error program (worst acceptable program) cannot be identified from any single text which is only $2i$-imperfect (a smaller bound on inaccuracies).

THEOREM 5.29. *Let* $j, k \in N, k \geq j > \lfloor \frac{k}{2} \rfloor$. *Then* $(\forall i \in N)[\mathbf{Mul}_k^j\mathbf{In}^{3i-1}\mathbf{Ex} - \mathbf{Im}^{2i}\mathbf{Ex}^* \neq \emptyset]$.

Proof. The proof follows from Theorem 58 in [14] and Theorem 5.2. □

Our final theorem is along similar lines to the previous theorem and shows the detrimental effects of imperfect text over incomplete texts. The result says that there are collections of functions for which a 0-error program (best possible) can be identified from any k texts, at least $j(> \lfloor \frac{k}{2} \rfloor)$ of which are $*$-incomplete (worst kind of missing data), but for which even a $*$-error program (worst acceptable program) cannot be identified from any single text which is only $*$-imperfect (least harmless imperfection).

THEOREM 5.30. *Let* $j, k \in N$, $k \geq j > \lfloor \frac{k}{2} \rfloor$. *Then* $\mathbf{Mul}_k^j\mathbf{In}^*\mathbf{Ex} - \mathbf{Im}^*\mathbf{Ex}^* \neq \emptyset$.

Proof. The proof follows from Theorem 60 in [14] and Theorem 5.2. □

6. Conclusion. We presented arguments against the idealized assumption in Gold's paradigm that a learning agent receives data from a single and accurate source. Gold's paradigm was suitably extended to account for the possibility that a learning agent may receive data from multiple sources, some of which may be inaccurate. Results were presented for the learning task of scientific inquiry modeled as identification in the limit of computer programs for computable functions from their graphs.

For each kind of inaccuracy, we established sufficient conditions when, for the same bound on the number of inaccuracies in both the multiple inaccurate texts and the single inaccurate text, and for the same bound on the number of errors allowed in the final hypothesis for the multiple and single cases, identification from multiple sources is not a restriction. We provided significant partial results for the difficult problem of determining when identification from multiple inaccurate texts is a restriction over identification from a single inaccurate text. We also demonstrated cases under which the detrimental effects of multiple inaccurate texts can be overcome by either allowing more errors in the final program or by decreasing the bound on the number of inaccuracies. We also established the usual hierarchies for each kind of inaccuracy in which

- keeping all of the other parameters fixed and increasing the bound on the number of errors allowed in the final program improves learnability;
- keeping all of the other parameters fixed and increasing the bound on the number of inaccuracies in the acceptable texts restricts learnability.

Finally, we were able to demonstrate that learning from noisy texts is preferable to learning from incomplete texts, which in turn is preferable to learning from imperfect texts.

It should be noted that several of the results presented in section 5.2 can easily be generalized to the case in which a machine is fed k texts and for at least j of these texts the inaccuracies are acceptable. Also, the results in this are about a simple criterion of success, viz, **Ex**-identification. We can also prove corresponding results for a more general criterion of learning, viz, **Bc**-identification (see [8] for a definition; this is also known as GN^{∞} [2] in the Russian literature). Additionally, we would like to note that similar results can also be shown to hold for another learning task, viz, first-language acquisition modeled as identification in the limit of grammars for recursively enumerable languages from a text of these languages. The criterion of success for language acquisition is known as **TxtEx**-identification (see [7] for a definition).

Finally, we end this paper on a speculatory note pointing to future research directions. Scientific success is often not limited to the success of a single scientist receiving data from multiple, possibly inaccurate, sources. In actual practice, a number of scientists are simultaneously investigating a phenomenon, each receiving data from multiple, possibly inaccurate, sources. Scientific success is achieved if any one of these scientists is successful. This scenario could be modeled as a "team" of learning machines, each member of the team receiving multiple inaccurate texts. The team is successful if at least one member of the team converges to a correct program for the function being learned (see Smith [24] for discussion of team identification from a *single* and *accurate* text). However, given our experience with the combinatorial difficulty of the subject matter of this paper, it is quite likely that a study incorporating teams and multiple inaccurate environments may turn out to be very complex, and it is not clear at this stage what additional insights such an investigation may provide.

Acknowledgments. We would like to thank John Case, Mark Fulk, and Errol Lloyd for encouragement and advice. Helpful discussions were provided by Sudhir Jha, Lata Narayanan, and Rajeev Raman. We would also like to thank Andrea Lobo for careful reading of an earlier draft of the paper.

During the initial stages of this investigation, Ganesh Baliga was in the Department of Computer and Information Sciences at the University of Delaware; Sanjay Jain was in the Department of Computer and Information Sciences at the University of Delaware and at the Institute of Systems Science at the National University of Singapore; and Arun Sharma was in the Department of Brain and Cognitive Sciences at the Massachusetts Institute of Technology.

We would also like to express our gratitude to Prof. S. N. Maheshwari of the Department of Computer Science and Engineering at IIT-Delhi for making the facilities of his department available to us during the preparation of an early draft of this paper.

Finally, we would like to thank the referees for valuable comments.

SINGULAR AND PLURAL NONDETERMINISTIC PARAMETERS*

MICHAL WALICKI† AND SIGURD MELDAL†

Abstract. The article defines algebraic semantics of singular (call-time-choice) and plural (run-time-choice) nondeterministic parameter passing and presents a specification language in which operations with both kinds of parameters can be defined simultaneously. Sound and complete calculi for both semantics are introduced. We study the relations between the two semantics and point out that axioms for operations with plural arguments may be considered as axiom schemata for operations with singular arguments.

Key words. algebraic specification, many-sorted algebra, nondeterminism, sequent calculus

1. Introduction.

The notion of *nondeterminism* arises naturally in describing concurrent systems. Various approaches to the theory and specification of such systems, for instance, CCS [16], CSP [9], process algebras [1], and event structures [26], include the phenomenon of nondeterminism. But nondeterminism is also a natural concept in describing sequential programs, either as a means of indicating a "don't care" attitude as to which among a number of computational paths will actually be utilized in a particular computation (e.g., [3]) or as a means of increasing the level of abstraction [14, 25]. The present work proceeds from the theory of *algebraic specifications* [4, 27] and generalizes the theory so that it can be applied to describing nondeterministic operations.

In deterministic programming the distinction between call-by-value and call-by-name semantics of parameter passing is well known. The former corresponds to the situation where the actual parameters to function calls are evaluated and passed as values. The latter allows parameters which are function expressions, passed by a kind of Algol copy rule [21], and which are evaluated whenever a need for their value arises. Thus call-by-name will terminate in many cases when the value of a function may be determined without looking at (some of) the actual parameters, i.e., even if these parameters are undefined. Call-by-value will, in such cases, always lead to undefined result of the call. Nevertheless, the call-by-value semantics is usually preferred in the actual programming languages since it leads to clearer and more tractable programs.

Following [20], we call the nondeterministic counterparts of these two notions *singular* (call-by-value) and *plural* (call-by-name) parameter passing. Other names applied to this, or closely related distinction, are *call-time-choice* vs. *run-time-choice* [2, 8] or *inside-out* (IO) vs. *outside-in* (OI), which reflect the substitution order corresponding to the respective semantics [5, 6]. In the context where one allows nondeterministic parameters, the difference between the two semantics becomes quite apparent even without looking at their termination properties. Let us suppose that

we have defined operation $g(x)$ as "**if** $x = 0$ **then** a **else** (**if** $x = 0$ **then** b **else** c)" and that we have a nondeterministic choice operation $\sqcup$ returning an arbitrary element from the argument set. The singular interpretation will satisfy the formula $\boldsymbol{\phi}$: $g(x) = (\textbf{if } x = 0 \textbf{ then } a \textbf{ else } c)$, whereas the plural interpretation need not satisfy this formula. For instance, under the singular interpretation $g(\sqcup.\{0,1\})$ will yield either a or c, whereas the set of possible results of $g(\sqcup.\{0,1\})$ under the plural interpretation will be $\{a,b,c\}$. (Notice that in a deterministic environment both semantics would yield the same results.) The fact that the difference between the two semantics occurs already in very trivial examples of terminating nondeterministic operations motivates our investigation.

We discuss the distinction between the singular and the plural passing of nondeterministic parameters in the context of algebraic semantics, focusing on the associated reasoning systems. The singular semantics is given by *multialgebras*, that is, algebras where functions are set valued and where these values correspond to the sets of possible results returned by nondeterministic operations. Thus, if f is a nondeterministic operation, $f(t)$ will denote the set of possible results returned by f when applied to t. We introduce the calculus NEQ which is sound and complete with respect to this semantics.

Although terms may denote sets, the variables in the language range only over individuals. This is motivated by the interest in describing unique results returned by each particular application of an operation (execution of the program). It gives us the possibility of writing instead of a formula $\boldsymbol{\Phi}(f(t))$, which expresses something about the whole set of possible results of $f(t)$, the formula corresponding to $x \in f(t) \Rightarrow \boldsymbol{\Phi}(x)$, which express something about each particular result x returned by $f(t)$. Unfortunately, this poses the main problem of reasoning in the context of nondeterminism—the lack of general substitutivity. From the fact that $h(x)$ is deterministic (for each x has a unique value) we cannot conclude that so is $h(t)$ for an arbitrary term t. If t is nondeterministic, $h(t)$ may have several possible results. The calculus NEQ is designed so that it appropriately restricts the substitution of terms for singular variables.

Although operations in multialgebras are set valued, their carriers are usual sets. Thus operations map individuals to sets. This is not sufficient to model plural arguments. Such arguments can be understood as sets being passed to the operation. The fact that, under plural interpretation, $g(x)$ as defined above need not satisfy $\boldsymbol{\phi}$ results from the two occurrences of x in the body of g. Each of these occurrences corresponds to a repeated application of choice from the argument set x, that is, potentially, to a different value. In order to model such operations we take as the carrier of the algebra a (subset of the) power set—operations map sets to sets. In this way we obtain *power algebra* semantics. The extension of the semantics is reflected at the syntactic level by introduction of *plural variables* ranging over sets rather than over individuals. The sound and complete extension of NEQ is obtained by adding one new rule which allows for usual substitution of arbitrary terms for plural variables.

The structure of the paper is as follows. In sections 2 and 3 we introduce the language for specifying nondeterministic operations and explain the intuition behind its main features. In section 4 we define *multialgebraic* semantics for singular specifications and introduce a sound and complete calculus for such specifications. In section 5 the semantics is generalized to *power algebras* capable of modeling plural parameters, and the sound and complete extension of the calculus is obtained by introducing one additional rule. A comparison of both semantics in section 6 is guided

by the similarity of the respective calculi. We identify the subclasses of multimodels and power models which may serve as equivalent semantics of one specification. We also highlight the increased complexity of the power algebra semantics reflecting the problems with intuitive understanding of plural arguments.

Proofs of the theorems are merely indicated in this presentation. It reports some of the results from [24] where the full proofs and other details can be found.

2. The specification language. A specification is a pair (Σ, Π), where the signature Σ is a pair (**S**,**F**) of sorts **S** and operation symbols **F** (with argument and result sorts in **S**). The set of terms over a signature Σ and variable set X is denoted by $W_{\Sigma,X}$. We always assume that, for every sort S, the set of ground words of sort S, S^{W_Σ}, is not empty.[1]

Π is a set of sequents of atomic formulas written as $a_1, \ldots, a_n \mapsto e_1, \ldots, e_m$. The left-hand side (LHS) of $\mapsto$ is called the *antecedent* and the right-hand side (RHS) the *consequent*, and both are to be understood as sets of atomic formulas (i.e., the ordering and multiplicity of the atomic formulas do not matter). In general, we allow either antecedent or consequent to be empty, though $\emptyset$ is usually dropped in the notation. A sequent with exactly one formula in the consequent ($m = 1$) is called a *Horn formula*, and a Horn formula with empty antecedent ($n = 0$) is a *simple formula* (or a *simple sequent*).

All variables occurring in a sequent are implicitly universally quantified over the whole sequent. A sequent is satisfied if, for every assignment to the variables, one of the antecedents is false or one of the consequents is true (it is valid iff the formula $a_1 \wedge \cdots \wedge a_n \Rightarrow e_1 \vee \cdots \vee e_m$ is valid).

For any term (formula set of formulas) ξ, $\mathcal{V}[\xi]$ will denote the set of variables in ξ. If the variable set is not mentioned explicitly, we may also write $x \in \mathcal{V}$ to indicate that x is a variable.

An atomic formula in the consequent is either an *equation*, $t = s$, or an *inclusion*, $t \prec s$, of terms t, $s \in W_{\Sigma,X}$. An atomic formula in the antecedent, written $t \frown s$, will be interpreted as nonempty intersection of the (result) sets corresponding to t and s. For a given specification $\mathrm{SP} = (\Sigma, \Pi)$, $\mathcal{L}(\mathrm{SP})$ will denote the above language over the signature Σ.

The above conventions will be used throughout the paper. The distinction between the singular and the plural parameters (introduced in the section 5) will be reflected in the notation by the superscript *: a plural variable will be denoted by x^*, the set of plural variables in a term t by $\mathcal{V}^*[t]$, a specification with plural arguments SP^*, the corresponding extension of the language $\mathcal{L}$ by $\mathcal{L}^*$, etc.

3. A note on the intuitive interpretation. Multialgebraic semantics [10, 13] interprets specifications in some form of power structures where the (nondeterministic) operations correspond to *set-valued functions*. This means that a (ground) term is interpreted as a set of *possibilities*; it denotes the set of *possible* results of the corresponding operation. We, on the other hand, want our formulas to express *necessary* facts, i.e., facts which have to hold in *every evaluation* of a program (specification). This is achieved by interpreting terms as *applications* of the respective operations. Every two syntactic occurrences of a term t will refer to *possibly distinct* applications of t. For nondeterministic terms this means that they may denote two distinct values.

[1] This restriction is motivated by the fact (pointed out in [7]) that admitting empty carriers requires additional mechanisms (explicit quantification) in order to obtain sound logic. We conjecture that a similar solution can be applied in our case.

Typically, equality is interpreted in a multialgebra as *set equality* [13, 23, 12]. For instance, the formula $\mapsto t = s$ means that *the sets corresponding to all possible results* of the operations t and s are equal. This gives a model which is mathematically plausible but which does not correspond to our operational intuition. The (set) equality $\mapsto t = s$ does not guarantee that the result returned by some particular application of t will actually be equal to the result returned by an application of s. It merely tells us that *in principle* (in all possible executions) any result produced by t can also be produced by s and vice versa.

Equality in our view should be a *necessary* equality which must hold in every evaluation of a program (specification). *It does not correspond to set equality but to identity of one-element sets.* Thus the simple formula $\mapsto t = s$ will hold in a multistructure M iff both t and s are interpreted in M as one and the same set which, in addition, *has only one element.* Equality is then a *partial equivalence relation*, and terms t for which $\mapsto t = t$ holds are exactly the deterministic terms, denoted by $D_{\boldsymbol{SP},\mathrm{X}}$. This last equality indicates that arbitrary two applications of t have to return the same result.

If it is possible to produce a computation where t and s return different results—and this is possible when they are nondeterministic—then the terms are not equal but, at best, *equivalent.* They are equivalent if they are capable of returning the same results, i.e., if they are interpreted as the same set. This may be expressed using the inclusion relation: $s \prec t$ holds iff the set of possible results of s is included in the set of possible results of t, and $s \asymp t$ if each is included in the other.

Having introduced inclusion one might expect that a nondeterministic operation can be specified by a series of inclusions, each defining one of its possible results. However, such a specification gives only a "lower bound" on the admitted nondeterminism. Consider the following example.

Example 3.1.

S: {Nat},

F:

0:	$\to$ Nat	(zero)
$s\_$:	Nat $\to$ Nat	(successor)
$\_\sqcup\_$:	Nat $\times$ Nat $\to$ Nat	(binary nondeterministic choice)

Π:

(1) $\mapsto 0 = 0$		
(2) $\mapsto s(x) = s(x)$		
(3) $1 \frown 0 \mapsto$		(As usual), we abbreviate $s^n(0)$ as n.)
(4) $\mapsto 0 \prec 0 \sqcup 1$	$\mapsto 1 \prec 0 \sqcup 1$	

The first two axioms make zero and successor deterministic. A limited form of negation is present in $\mathcal{L}$ in the form of sequents with empty consequent. Axiom (3) makes 0 distinct from 1. Axioms (4) make then $\sqcup$ a nondeterministic choice with 0 and 1 among its possible results. This, however, ensures only that in every model both 0 and 1 can be returned by $0 \sqcup 1$. In most models all other kinds of elements may be among its possible results as well, since no extension of the result set of $0 \sqcup 1$ will violate the inclusions of (4). If we are satisfied with this degree of precision, we may stop here and use only the Horn formula. All the results in the rest of the paper apply to this special case. But to specify an "upper bound" of nondeterministic operations we need *disjunction*, the multiple formulas in the consequents. Now, if we write the axiom

$$(5) \quad \mapsto 0 \sqcup 1 = 0, \quad 0 \sqcup 1 = 1,$$

the two occurrences of $0 \sqcup 1$ refer to two arbitrary applications and, consequently, we obtain that either any application of $0 \sqcup 1$ equals 0 or else it equals 1, i.e., that $\sqcup$ is not really nondeterministic but merely underspecified. Since axioms (4) require that both 0 and 1 be among the results of t, the addition of (5) will actually make the specification inconsistent.

What we are trying to say with the disjunction of (5) is that *every application* of $0 \sqcup 1$ returns either 0 or 1; i.e., we need a means of identifying two occurrences of a nondeterministic term as referring to one and the same application. This can be done by *binding* both occurrences to a variable. The appropriate axiom will be

$$(5') \quad x \frown 0 \sqcup 1 \mapsto x = 0,\ x = 1.$$

The axiom says: whenever $0 \sqcup 1$ returns x, then x equals 0 or x equals 1. Notice that such an interpretation presupposes that the variable x refers to a *unique*, *individual* value. Thus bindings have the intended function only if they involve *singular* variables. (Plural variables, on the other hand, will refer to sets and not individuals, and so the axiom

$$(5'') \quad x^* \frown 0 \sqcup 1 \mapsto x^* = 0,\ x^* = 1$$

would have a completely different meaning.) The singular semantics is the most common in the literature on algebraic semantics of nondeterministic specification languages [2, 8, 11], in spite of the fact that it prohibits unrestricted substitution of terms for variables. Any substitution must now be guarded by the check that the substituted term yields a unique value, i.e., is deterministic. We return to this point in the subsection on reasoning, where we introduce a calculus which does not allow one, for instance, to conclude $0 \sqcup 1 = 0 \sqcup 1 \mapsto 0 \sqcup 1 = 0,\ 0 \sqcup 1 = 1$ from the axiom $(5')$ (though it could be obtained from $(5'')$).

4. The singular case: Semantics and calculus. This section defines the multialgebraic semantics of specifications with singular arguments and introduces a sound and complete calculus.

4.1. Multistructures and multimodels.

DEFINITION 4.2 (Multistructures). *Let* Σ *be a signature.* M *is a* Σ-multistructure *if*

(1) *its carrier* $|\mathrm{M}|$ *is an* $\mathbf{S}$*-sorted set,*
(2) *for every* $f\colon \mathrm{S}_1 \times \cdots \times \mathrm{S}_\mathrm{n} \to \mathrm{S}$ *in* $\mathbf{F}$*, there is a corresponding function* $f^M\colon \mathrm{S}_1^\mathrm{M} \times \cdots \times \mathrm{S}_\mathrm{n}^\mathrm{M} \to \mathcal{P}^+(\mathrm{S}^\mathrm{M})$.

A function $\mathbf{\Phi}\colon \mathrm{A} \to \mathrm{B}$ *(i.e., a family of functions* $\mathbf{\Phi}_\mathrm{S}\colon \mathrm{S}^\mathrm{A} \to \mathrm{S}^\mathrm{B}$ *for every* $\mathrm{S} \in \mathbf{S}$*) is a* multihomomorphism *from a* Σ*-multistructure* A *to* B *if*

(H1) *for each constant symbol* $c \in \mathbf{F}$, $\mathbf{\Phi}(c^A) \subseteq c^B$,
(H2) *for every* $f\colon \mathrm{S}_1 \times \cdots \times \mathrm{S}_\mathrm{n} \to \mathrm{S}$ *in* $\mathbf{F}$ *and* $\underline{a}_1 \cdots \underline{a}_n \in \mathrm{S}_1^\mathrm{A} \times \cdots \times \mathrm{S}_\mathrm{n}^\mathrm{A}$: $\mathbf{\Phi}(f^\mathrm{A}(\underline{a}_1 \cdots \underline{a}_n)) \subseteq f^\mathrm{B}(\mathbf{\Phi})(\underline{a}_i) \cdots \mathbf{\Phi}(\underline{a}_n))$.

If all inclusions in H1 *and* H2 *are (set) equalities the homomorphism is* tight*; otherwise it is strictly loose (or just* loose*).*

$\mathcal{P}^+(S)$ denotes the set of nonempty subsets of the set S. Operations applied to sets refer to their unique pointwise extensions. Notice that for a constant $c\colon \to S(2)$ indicates that c^M can be a *set* of several elements of sort S.

Since multihomomorphisms are defined on individuals and not sets they preserve singletons and are $\subseteq$-monotonic. We denote the class of Σ-multistructures by

$\mathrm{MStr}(\Sigma)$. It has the distinguished word structure MW_Σ defined in the obvious way, where each ground term is interpreted as a singleton set. We will treat such singleton sets as terms rather than one-element sets (i.e., we do not take special pains to distinguish MW_Σ and W_Σ). MW_Σ is not an initial Σ-structure since it is deterministic and there can exist several homomorphisms from it to a given multistructure. We do not focus on the aspect of initiality and merely register the useful fact from [11].

LEMMA 4.3. *M is a Σ-multistructure iff for every set of variables X and assignment β: $X \to |\mathrm{M}|$, there exists a unique function $\boldsymbol{\beta}[\_]$: $\mathrm{W}_{\Sigma,\mathrm{X}} \to \mathcal{P}^+(|\mathrm{M}|)$ such that*

(1) $\boldsymbol{\beta}[x] = \{\boldsymbol{\beta}(x)\}$,
(2) $\boldsymbol{\beta}[c] = c^M$,
(3) $\boldsymbol{\beta}[f(t_i)] = \cup\{f^M(y_i) \mid y_i \in \boldsymbol{\beta}[t_i]\}$.

In particular, for $X = \emptyset$ there is a unique interpretation function (not a multihomomorphism) $\mathcal{I}$: $W_\Sigma \to \mathcal{P}^+(|M|)$ satisfying the last two points of this definition.

As a consequence of the definition of multistructures, all operations are $\subseteq$-monotonic, i.e., $\boldsymbol{\beta}[s] \subseteq \boldsymbol{\beta}[t] \Rightarrow \boldsymbol{\beta}[f(s)] \subseteq \boldsymbol{\beta}[f(t)]$. Notice also that assignment in the lemma (and in general whenever it is an assignment of elements from a multistructure) means assignment of individuals, not sets.

Next we define the class of *multimodels* of a specification.

DEFINITION 4.4 (Satisfiability). *A Σ-multistructure* M satisfies *an $\mathcal{L}(\Sigma)$ sequent* π

$$t_i \frown s_i \mapsto p_j = r_j, m_k \prec n_k,$$

written $\mathrm{M} \models \pi$ *iff for every β*: $\mathrm{X} \to \mathrm{M}$ *we have*

$$\bigwedge_i \boldsymbol{\beta}[t_i] \cap \boldsymbol{\beta}[s_i] \neq \emptyset \Rightarrow \bigvee_j \boldsymbol{\beta}[p_j] \equiv \boldsymbol{\beta}[r_j] \vee \bigvee_k \boldsymbol{\beta}[m_k] \subseteq \boldsymbol{\beta}[n_k],$$

where $\mathrm{A} \equiv \mathrm{B}$ *iff* A *and* B *are the same one-element set.*

An SP-multimodel *is a Σ-multistructure which satisfies all the axioms of SP. We denote the class of multimodels of SP by MMod(SP).*

The reason for using nonempty intersection (and not set equality) as the interpretation of $\frown$ in the antecedents is the same as using "elementwise" equality $\equiv$ in the consequents. Since we avoid set equality in the positive sense (in the consequents), the most natural negative form seems to be the one we have chosen. For deterministic terms this is the same as equality, i.e., deterministic antecedents correspond exactly to the usual (deterministic) conditions. For nondeterministic terms this reflects our interest in binding such terms: the sequent "$\ldots s \frown t \ldots \mapsto \ldots$" is equivalent to "$\ldots x \frown s,\ x \frown t \ldots \mapsto \ldots$." A binding "$\ldots x \frown t \ldots \mapsto \ldots$" is also equivalent to the more familiar "$\ldots x \in t \ldots \mapsto \ldots$," so the notation $s \frown t$ may be read as an abbreviation for the more elaborate formula with two $\in$ and a new variable x not occurring in the rest of the sequent.

For a justification of this, as well as other choices we have made here, the reader is referred to [24].

4.2. The calculus for singular semantics. In [24] we introduced the calculus NEQ which is sound and complete with respect to the class MMod(SP). Its rules are as follows:

(R1) $\quad \mapsto x = x, \qquad x \in \mathcal{V},$

(R2) $$\frac{\boldsymbol{\Gamma}^x_{t_2} \mapsto \boldsymbol{\Delta}^x_{t_2} \quad ; \quad \boldsymbol{\Gamma}' \mapsto t_1 = t_2, \boldsymbol{\Delta}'}{\boldsymbol{\Gamma}^x_{t_1}, \boldsymbol{\Gamma}' \mapsto \boldsymbol{\Delta}^x_{t_1}, \boldsymbol{\Delta}'},$$

(R3) $$\frac{\boldsymbol{\Gamma}^x_{t_2} \mapsto \boldsymbol{\Delta}^x_{t_2} \quad ; \quad \boldsymbol{\Gamma}' \mapsto t_1 \prec t_2, \boldsymbol{\Delta}'}{\boldsymbol{\Gamma}^x_{t_1}, \boldsymbol{\Gamma}' \mapsto \boldsymbol{\Delta}^x_{t_1}, \boldsymbol{\Delta}'}, \quad x \text{ not in a RHS of } \prec,$$

(R4) (a) $x \frown y \mapsto x = y$, (b) $x \frown t \mapsto x \prec t$, $x, y \in \mathcal{V}$,

(R5) $$\frac{\boldsymbol{\Gamma} \mapsto \boldsymbol{\Delta}, s \preceq t \quad ; \quad \boldsymbol{\Gamma}', s \frown t \mapsto \boldsymbol{\Delta}'}{\boldsymbol{\Gamma}, \boldsymbol{\Gamma}' \mapsto \boldsymbol{\Delta}, \boldsymbol{\Delta}'}, \quad \text{(CUT)} \quad (\preceq \text{ stands for either } = \text{ or } \prec),$$

(R6) (a) $$\frac{\boldsymbol{\Gamma} \mapsto \boldsymbol{\Delta}}{\boldsymbol{\Gamma} \mapsto \boldsymbol{\Delta}, e}, \qquad \text{(b)} \quad \frac{\boldsymbol{\Gamma} \mapsto \boldsymbol{\Delta}}{\boldsymbol{\Gamma}, e \mapsto \boldsymbol{\Delta}} \qquad \text{(WEAK)},$$

(R7) $$\frac{\boldsymbol{\Gamma}, x \frown t \mapsto \boldsymbol{\Delta}}{\boldsymbol{\Gamma}^x_t \mapsto \boldsymbol{\Delta}^x_t}, \qquad x \in \mathcal{V} - \mathcal{V}[t], \text{ at most one } x \text{ in } \boldsymbol{\Gamma} \mapsto \boldsymbol{\Delta} \qquad \text{(ELIM)}.$$

$\boldsymbol{\Gamma}^{\mathrm{a}}_{\mathrm{b}}$ denotes $\boldsymbol{\Gamma}$ with b substituted for a. Short comments on each of the rules may be in order.

The fact that "=" is a partial equivalence relation is expressed in (R1). It applies only to variables and is sound because all assignments assign individual values to the (singular) variables.

(R2) is a paramodulation rule allowing replacement of terms which may be deterministic (in the case where $t_1 = t_2$ holds in the second assumption). In particular, it allows derivation of the standard substitution rule when the substituted terms are deterministic and prevents substitution of nondeterministic terms for variables.

(R3) allows "specialization" of a sequent by substituting for a term t_2 another term t_1 which is included in t_2. The restriction that the occurrences of t_2 which are substituted for don't occur in the RHS of $\prec$ is needed to prevent, for instance, the unsound conclusion $\mapsto t_3 \prec t_1$ from the premises $\mapsto t_3 \prec t_2$ and $\mapsto t_1 \prec t_2$.

(R4) and (R5) express the relation between $\frown$ in the antecedent and the equality and inclusion in the consequent. The axiom of standard sequent calculus, $e \mapsto e$, (i.e., $s \frown t \mapsto s \preceq t$) does not hold in general here because the antecedent corresponds to nonempty intersection of the result sets while the consequent to the inclusion ($\prec$) or identity of one-element ($=$) result sets. Only for deterministic terms (in particular, variables) s, t do we have that $s \frown t \mapsto s = t$ holds.

(R5) allows us to cut both $\mapsto s = t$ and $\mapsto s \prec t$ with $s \frown t \mapsto \boldsymbol{\Delta}$.

(R7) eliminates redundant bindings, namely those that bind an application of a term occurring at most once in the rest of the sequent.

We will write $\Pi \vdash_{\mathrm{CAL}} \boldsymbol{\pi}$ to indicate that $\boldsymbol{\pi}$ is provable from $\boldsymbol{\Pi}$ with the calculus CAL.

The counterpart of soundness/completeness of the equational calculus is as follows [24].

THEOREM 4.5. *NEQ is sound and complete with respect to MMod(SP):*

$$\textit{MMod(SP)} \models \boldsymbol{\pi} \textit{ iff } \boldsymbol{\Pi} \vdash_{NEQ} \boldsymbol{\pi}.$$

Proof idea. Soundness is proved by induction on the length of the proof $\boldsymbol{\Pi} \vdash_{\mathrm{NEQ}} \boldsymbol{\pi}$. The proof of the completeness part is a standard, albeit rather involved, Henkin-style argument. The axiom set $\boldsymbol{\Pi}$ of SP is extended by adding all $\mathcal{L}$(SP) formulas $\boldsymbol{\pi}$

which are consistent with $\mathbf{\Pi}$ (and the previously added formulas). If the addition of $\boldsymbol{\pi}$ leads to inconsistency, one adds the negation of $\boldsymbol{\pi}$. Since empty consequents provide only a restricted form of negation, the general negation operation is defined as a set of formulas over the original signature extended with new constants. One shows then that the construction yields a consistent specification with a deterministic basis from which a model can be constructed.

We also register an easy lemma that the set-equivalent terms $t \asymp s$ satisfy the same formulas.

LEMMA 4.6. *$t \asymp s$ iff, for any sequent $\boldsymbol{\pi}$, $\mathbf{\Pi} \vdash_{NEQ} \boldsymbol{\pi}^z_t$ iff $\mathbf{\Pi} \vdash_{NEQ} \boldsymbol{\pi}^z_s$.* □

5. The plural case: Semantics and calculus. The singular semantics for passing nondeterminate arguments is the most common notion to be found in the literature. Nevertheless, the plural semantics has also received some attention. In the denotational tradition most approaches considered both possibilities [18, 19, 20, 22]. Engelfriet and Schmidt gave a detailed study of both—in their language, IO and OI—semantics based on tree languages [5] and continuous algebras of relations and power sets [6]. The unified algebras of Mosses [17] and the rewriting logic of Meseguer [15] represent other algebraic approaches distinguishing these aspects.

We will define the semantics for specifications where operations may have both singular and plural arguments. The next subsection gives the necessary extension of the calculus NEQ to handle this generalized situation.

5.1. Power structures and power models. Singular arguments (such as the variables in $\mathcal{L}$) have the usual algebraic property that they refer to a unique value. This reflects the fact that they are evaluated at the moment of substitution and the result is passed to the following computation. Plural arguments, on the other hand, are best understood as textual parameters. They are not passed as a single value, but every occurrence of the formal parameter denotes a distinct application of the operation.

We will allow both singular and plural parameter passing in one specification. The corresponding semantic distinction is between power set functions which are merely $\subseteq$-monotonic and those which also are $\cup$-additive.

In the language, we merely introduce a notational device for distinguishing the singular and plural arguments. We allow annotating the sorts in the profiles of the operation by a superscript, like S^*, to indicate that an argument is plural.

Furthermore, we partition the set of variables into two disjoint subsets of singular X and plural X^* variables. x and x^* are to be understood as distinct symbols. We will say that an operation f is *singular in the ith argument* iff the ith argument (in its signature) is singular. The specification language extended with such annotations of the signatures will be referred to as $\mathcal{L}^*$.

These are the only extensions of the language we need. We may, optionally, use superscripts t^* at any (sub)term to indicate that it is passed as a plural argument. The outermost applications, e.g., f in $f(\ldots)$, are always to be understood plurally, and no superscripting will be used at such places.

DEFINITION 5.1. *Let Σ be a $\mathcal{L}^*$-signature. A is a* Σ-power structure $A \in PStr(\Sigma)$ *iff A is a (deterministic) structure such that*

1. *for every sort* S*, the carrier* S^{A} *is a (subset of the) power set* $\mathcal{P}^+(\mathrm{S}^-)$ *of some basis set* S^-*,*
2. *for every* $f\colon \mathrm{S}_1 \times \cdots \times \mathrm{S}_\mathrm{n} \to \mathrm{S}$ *in* Σ*, f^A is a $\subseteq$-monotonic function* $\mathrm{S}_1^{\mathrm{A}} \times \cdots \times \mathrm{S}_\mathrm{n}^{\mathrm{A}} \to \mathrm{S}^{\mathrm{A}}$ *such that if the ith argument is* S_i *(singular), then f^A is singular in the ith argument.*

The singularity in the ith argument in this definition refers not to the syntactic notion but to its semantic counterpart.

DEFINITION 5.2. *A function* $f^A\colon \mathrm{S}^{\mathrm{A}}_1 \times \cdots \times \mathrm{S}^{\mathrm{A}}_n \to \mathrm{S}^{\mathrm{A}}$ *in a power structure* A *is* singular in the ith argument *iff it is* $\cup$*-additive in the* i*th argument, i.e., iff for all* $x_i \in \mathrm{S}^{\mathrm{A}}_i$ *and all* $x_k \in \mathrm{S}^{\mathrm{A}}_k$ *(for* $k \neq i$*),* $f^A(x_1 \cdots x_i \cdots x_n) = \cup\{f^A(x_1 \cdots \{x\} \cdots x_n) \mid x \in x_i\}$.

Thus, the definition of power structures requires that syntactic singularity be modeled by the semantic one.

Note the unorthodox point in the definition: we do not require the carrier to be the whole power set but allow it to be a *subset* of some power set. Usually one assumes a primitive nondeterministic operation with the predefined semantics as set union. Then all finite subsets are needed for the interpretation of this primitive operator. Also, the join operation (under the set inclusion as partial order) corresponds exactly to set union only if all sets are present (see Example 6.8). None of these assumptions seem necessary. Consequently, we do not assume any predefined (choice) operation but, instead, give the user means of specifying any nondeterministic operation (including choice) directly.

Let Σ be a signature, A a Σ-power structure, X a set of singular variables and X^* a set of plural variables, and $\boldsymbol{\beta}$ an assignment $X \cup X^* \to |A|$ such that for all $x \in X : |\boldsymbol{\beta}(x)| = 1$. (Saying assignment we will from now on mean only assignments satisfying this last condition.) Then, every term $t(x, x^*) \in W_{\Sigma,\mathrm{X},\mathrm{X}^*}$ has a unique set interpretation $\beta[t(x, x^*)]$ in A defined as $t^A(\boldsymbol{\beta}(x), \boldsymbol{\beta}(x^*))$.

DEFINITION 5.3 (Satisfiability). *Let* A *be a* Σ*-power structure and* $\boldsymbol{\pi}$*:* $t_i \frown s_i \mapsto p_j = r_j,\ m_k \prec n_k$ *be a sequent over* $\mathcal{L}^*(\Sigma, X, X^*)$*.* A satisfies $\boldsymbol{\pi}$*,* $A \models \pi$*, iff for every assignment* $\boldsymbol{\beta}$*:* $X \cup X^* \to |A|$*, we have that*

$$\bigwedge_i \boldsymbol{\beta}[t_i] \cap \boldsymbol{\beta}[s_i] \neq \emptyset \Rightarrow \bigvee_j \boldsymbol{\beta}[p_j] \equiv \boldsymbol{\beta}[r_j] \vee \bigvee_k \boldsymbol{\beta}[m_k] \subseteq \boldsymbol{\beta}[n_k].$$

A *is a* power model *of the specification* $\mathrm{SP} = (\Sigma, \boldsymbol{\Pi})$*,* $A \in PMod(SP)$*, iff* $A \in \mathrm{PStr}(\Sigma)$ *and* A *satisfies all axioms from* $\boldsymbol{\Pi}$*.*

Except for the change in the notion of an assignment, this is identical to Definition 4.4, which is the reason for retaining the same notation for the satisfiability relation.

5.2. The calculus for plural parameters. The calculus NEQ is extended with one additional rule:

$$\text{(R8)} \qquad \frac{\boldsymbol{\Gamma} \mapsto \boldsymbol{\Delta}}{\boldsymbol{\Gamma}^{x^*}_{t} \mapsto \boldsymbol{\Delta}^{x^*}_{t}}.$$

Rules (R1)–(R7) remain unchanged, but now all terms t_i belong to $W_{\Sigma,\mathrm{X},\mathrm{X}^*}$. In particular, any t_i may be a plural variable. We let NEQ* denote the calculus NEQ + R8.

The new rule (R8) expresses the semantics of plural variables. It allows us to substitute an arbitrary term t for a plural variable x^*. Taking t to be a singular variable x, we can thus exchange plural variables in a provable sequent $\boldsymbol{\pi}$ with singular ones. The opposite is, in general, not possible because rule (R1) applies only to singular variables. For instance, a plural variable x^* will satisfy $\mapsto x^* \prec x^*$, but this is not sufficient for performing a general substitution for a singular variable. The main result concerning PMod and NEQ* is as follows.

THEOREM 5.4. *For any* $\mathcal{L}^*$*-specification SP and* $\mathcal{L}^*$*(SP) sequent* $\boldsymbol{\pi}$*:*

$$PMod(SP) \models \boldsymbol{\pi} \text{ iff } \boldsymbol{\Pi} \vdash_{NEQ^*} \boldsymbol{\pi}.$$

Proof idea. The proof is a straightforward extension of the proof of Theorem 4.5. □

6. Comparison. Since plural and singular semantics are certainly not one and the same thing, it may seem surprising that essentially the same calculus can be used for reasoning about both. One would perhaps expect that PMod, being a richer class than MMod, will satisfy fewer formulas than the latter and that some additional restrictions of the calculus would be needed to reflect the increased generality of the model class. In this section we describe precisely the relation between the $\mathcal{L}$ and $\mathcal{L}^*$ specifications (section 6.1) and emphasize some points of difference (section 6.2).

6.1. The "equivalence" of both semantics. The following example illustrates a strong sense of equivalence of $\mathcal{L}$ and $\mathcal{L}^*$.

Example 6.1. Consider the following plural definition:

$$\mapsto f(x^*) \prec \text{ if } x^* = x^* \text{ then } 0 \text{ else } 1.$$

It is "equivalent" to the collection of definitions

$$\mapsto f(t) \prec \text{ if } t = t \text{ then } 0 \text{ else } 1$$

for all terms t.

In the rest of this section we will clarify the meaning of this "equivalence."

Since the partial order of functions from a set A to the power set of a set B is isomorphic to the partial order of additive (and strict, if we take $\mathcal{P}$ (all subsets) instead of $\mathcal{P}^+$) functions from the power set of A to the power set of B, $[A \to \mathcal{P}(B)] \simeq [\mathcal{P}(A) \to_\cup \mathcal{P}(B)]$, we may consider every multistructure A to be a power structure A^* by taking $|A^*| = \mathcal{P}^+(A)$ and extending all operations in A pointwise. We then have the obvious lemma.

LEMMA 6.2. *Let SP be a singular specification (i.e., all operations are singular in all arguments), let* $A \in \mathrm{MStr(SP)}$*, and let* $\boldsymbol{\pi}$ *be a sequent in* $\mathcal{L}(\mathrm{SP})$*. Then* $A \models \boldsymbol{\pi}$ *iff* $A^* \models \boldsymbol{\pi}$*, and so* $A \in MMod(SP)$ *iff* $A^* \in PMod(SP)$*.*

Call an $\mathcal{L}^*$ sequent $\boldsymbol{\pi}$ *p-ground* (for plurally ground) if it does not contain any plural variables.

THEOREM 6.3. *Let* $\mathrm{SP}^* = (\Sigma^*, \boldsymbol{\Pi}^*)$ *be an* $\mathcal{L}^*$ *specification. There exists a (usually infinite)* $\mathcal{L}$ *specification* $\mathrm{SP} = (\Sigma, \boldsymbol{\Pi})$ *such that*

(1) $W_{\Sigma,\mathrm{X}} = W_{\Sigma^*,\mathrm{X}}$

(2) *for any* p*-ground* $\boldsymbol{\pi} \in \mathcal{L}^*(\mathrm{SP}^*) : \mathrm{PMod}(\mathrm{SP}^*) \models \boldsymbol{\pi}$ iff $\mathrm{MMod}(\mathrm{SP}) \models \boldsymbol{\pi}$.

Proof. Let Σ be Σ^* with all "*" symbols removed. This makes (1) true. Any p-ground $\boldsymbol{\pi}$ as in (2) is then a $\boldsymbol{\pi}$ over the language $\mathcal{L}(\Sigma, X)$.

The axioms $\boldsymbol{\Pi}$ are obtained from $\boldsymbol{\Pi}^*$ as in Example 6.1. For every $\boldsymbol{\pi}^* \in \boldsymbol{\Pi}^*$ with plural variables $x_1^* \cdots x_n^*$, let $\boldsymbol{\pi} = \{\boldsymbol{\pi}^* \begin{smallmatrix} x_1^* \cdots x_n^* \\ t_1 \cdots t_n \end{smallmatrix} \mid t_1 \cdots t_n \in W_{\Sigma,\mathrm{X}}\}$. Obviously, for any $\boldsymbol{\pi} \in \mathcal{L}(\mathrm{SP})$ if $\boldsymbol{\Pi} \vdash_{\mathrm{NEQ}} \boldsymbol{\pi}$ then $\boldsymbol{\Pi}^* \vdash_{\mathrm{NEQ}^*} \boldsymbol{\pi}$. If $\boldsymbol{\Pi}^* \vdash_{\mathrm{NEQ}^*} \boldsymbol{\pi}$ then the proof can be simulated in NEQ. Let $\boldsymbol{\pi}'(x^*)$ be the last sequent used in the NEQ*-proof which contains plural variables x^* and the sequent $\boldsymbol{\pi}'$ be the next one obtained by (R8). Build the analogous NEQ-proof tree with all plural variables replaced by the terms which occupy their place in $\boldsymbol{\pi}'$. The leaves of this tree will be instances of the $\boldsymbol{\Pi}^*$ axioms with plural variables replaced by the appropriate terms, and all such axioms are in $\boldsymbol{\Pi}$. Then soundness and completness of NEQ and NEQ* imply the conclusion of the theorem. □

We now ask whether, or under which conditions, the classes PMod and MMod are interchangeable as the models of a specification. Let SP*, SP be as in the theorem. The one-way transition is trivial. Axioms of SP are p-ground, so PMod(SP*) will satisfy all these axioms by the theorem. The subclass $\downarrow$ PMod(SP*) $\subseteq$ PMod(SP*), where for every P $\in\downarrow$ PMod(SP*) all operations are singular, will yield a subclass of MMod(SP).

For the other direction, we have to observe that the restriction to p-ground sequents in the theorem is crucial because plural variables range over arbitrary, also undenotable, sets. Let MMod*(SP) denote the class of power structures obtained as in Lemma 6.2. It is not necessarily the case that MMod*(SP) $\models \mathbf{\Pi}^*$, as the following argument illustrates.

Example 6.4. Let $M^* \in$ MMod*(SP) have infinite carrier, $\boldsymbol{\pi}^* \in \mathbf{\Pi}^*$ be $t_i \frown s_i \mapsto p_j = r_j$, $m_k \prec n_k$ with $x^* \in \mathcal{V}[\boldsymbol{\pi}^*]$, and $\boldsymbol{\beta}$: $X \cup X^* \to |M^*|$ be an assignment such that $\boldsymbol{\beta}(x^*) = \{\underline{m}_1 \cdots \underline{m}_l \cdots\}$ is a set which is not denoted by any term in $W_{\Sigma,\mathrm{X}}$. Let $\boldsymbol{\beta}_l$ be an assignment equal to $\boldsymbol{\beta}$ except that $\boldsymbol{\beta}_l(x^*) = \{\underline{m}_l\}$, i.e., $\boldsymbol{\beta} = \cup_l \boldsymbol{\beta}_l$. Then $M^* \models \boldsymbol{\beta}[\boldsymbol{\pi}^*]$ iff

$$M^* \models \boldsymbol{\beta}[t_i] \cap \boldsymbol{\beta}[s_i] \neq \emptyset \Rightarrow \boldsymbol{\beta}[p_j] \equiv \boldsymbol{\beta}[r_j] \vee \,..\, \vee \boldsymbol{\beta}[m_k] \subseteq \boldsymbol{\beta}[n_k] \quad \text{iff}$$

$$\text{(a)}\ \ M^* \models \bigcup_l \boldsymbol{\beta}_l[t_i] \cap \bigcup_l \boldsymbol{\beta}_l[s_l] \neq \emptyset \Rightarrow \bigcup_l \boldsymbol{\beta}_l[p_j] \equiv \bigcup_l \boldsymbol{\beta}_l[r_j] \vee \,..\, \vee \bigcup_l \boldsymbol{\beta}_l[m_k] \subseteq \bigcup_l \boldsymbol{\beta}_l[n_k]$$

since operations in M^* are defined by pointwise extension. $M^* \in$ MMod*(SP) implies that, for all l

$$\text{(b)}\ \ M^* \models \boldsymbol{\beta}_l[t_i] \cap \boldsymbol{\beta}_l[s_l] \neq \emptyset \Rightarrow \boldsymbol{\beta}_l[p_j] \equiv \boldsymbol{\beta}_l[r_j] \vee \,..\, \vee \boldsymbol{\beta}_l[m_k] \subseteq \boldsymbol{\beta}_l[n_k].$$

But (b) does not necessarily imply (a). In particular, even if for all l, all intersections in the antecedent of (b) are empty, those in (a) may be nonempty. So we are not guaranteed that $M^* \in$ PMod(SP*).

Thus, the intuition that the multimodels are contained in the power models is not quite correct. To ensure that no undenotable sets from M^* can be assigned to the plural variables we redefine the lifting operator *: MMod(SP) $\to$ PMod(SP) from Lemma 6.2.

Definition 6.5. *Given a singular specification SP and $M \in MMod(SP)$, we denote by* $\uparrow$M *the following power structure:*

(1) $|\uparrow \mathrm{M}| \subseteq \mathcal{P}^+(|\mathrm{M}|)$ *is such that*

(a) *for every* $\underline{n} \in |M|$: $\{\underline{n}\} \in |\uparrow \mathrm{M}|$,

(b) *for every* $\underline{m} \in |\uparrow \mathrm{M}|$ *there exists a* $t \in W_{\Sigma,\mathrm{X}}$, $\underline{n} \in |\mathrm{M}|$ *such that:* $t^M(\underline{n}) = \underline{m}$.

(2) *The operations in* $\uparrow$M *can be then defined by:* $f(\underline{m})^{\uparrow M} = f(t(\underline{n}))^M$.

Then, for any assignment $\boldsymbol{\beta}$: $X^* \to |\uparrow \mathrm{M}|$ there exists an assignment $\boldsymbol{\theta}$: $X^* \to W_{\Sigma,\mathrm{X}}$ (1b) and an assignment $\boldsymbol{\alpha}$: $X \to |M|$ (1a) such that $\boldsymbol{\beta}(x^*) = \boldsymbol{\alpha}\boldsymbol{\theta}(x^*)]$ (2), i.e., such that the diagram in Figure 1 commutes.

Since $M \in$ MMod(SP), it satisfies all the axioms $\mathbf{\Pi}$ obtained from $\mathbf{\Pi}^*$ and the commutativity of the figure gives us the second part of the following.

Corollary 6.6. *Let SP* and SP be as in Theorem* 6.3. *Then*

$$\downarrow PMod(SP^*) \models \mathbf{\Pi},\ \textit{i.e.,} \downarrow PMod(SP^*) \subseteq MMod(SP),$$
$$\uparrow MMod(SP) \models \mathbf{\Pi}^*,\ \textit{i.e.,} \uparrow MMod(SP) \subseteq PMod(SP^*).$$

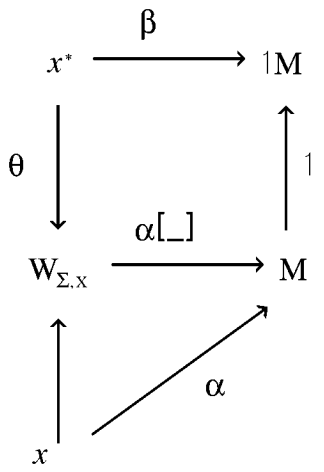

FIG. 1.

The corollary makes precise the claim that the class of power models of a plural specification SP* may be seen as a class of multimodels of some singular specification SP and vice versa. The reasoning about both semantics is essentially the same because the only difference concerns the (arbitrary) undenotable sets which can be referred to by plural variables.

6.2. Plural specification of choice. Plural variables provide access to arbitrary sets. In the following example we attempt to utilize this fact to give a more concise form to the specification of choice.

Example 6.7. The specification

S: { S },
F: { ⊔._ : S* → S },
Π: { ↦ ⊔. $x^* \asymp x^*$ }

defines ⊔. as the choice operator: for any argument t, ⊔. t is capable of returning any element belonging to the set interpreting t.

The specification may seem plausible, but there are several difficulties. Obviously, such a choice operation would be redundant in any specification since the axiom makes ⊔. t observationally equivalent to t, and Lemma 4.6 allows us to remove any occurrences of ⊔. from the (derivable) formulas. Furthermore, observe how such a specification confuses the issue of nondeterministic choice. Choice is supposed to take a *set* as an argument and return *one element* from the set or, perhaps, to convert an argument of type "set" to a result of type "individual." This is the intention behind writing the specification above. But power algebras model all operations as functions on power sets and such a "conversion" simply does not make sense. The only points where conversion of a set to an individual takes place is when a term is passed as a singular argument to another operation. If we have an operation with a singular argument f: S → S, then $f(t)$ will make (implicitly) the choice from t.

This might be particularly confusing because one tends to think of plural arguments as sets and mix up the semantic sets (i.e., the elements of the carrier of a power algebra) and the syntactic ones (as expressed by the profiles of the operations in the

$$\dfrac{\dfrac{\dfrac{x \frown z^*, y \frown z^* \mapsto x \sqcup y \prec z^*}{x \frown p, y \frown p \mapsto x \sqcup y \prec p}\,\text{R8}}{y \frown p \mapsto p \sqcup y \prec p}\,\text{R7}}{\mapsto p \sqcup p \prec p}\,\text{R7} \qquad \dfrac{\mapsto s \prec p \qquad \dfrac{\mapsto t \prec p \quad \mapsto p \sqcup p \prec p \sqcup p}{\mapsto t \sqcup p \prec p \sqcup p}\,\text{R3}}{\mapsto t \sqcup s \prec p \sqcup p}\,\text{R3}$$

$$\dfrac{\mapsto p \sqcup p \prec p \qquad \mapsto t \sqcup s \prec p \sqcup p}{\mapsto t \sqcup s \prec p}\,\text{R3}$$

FIG. 2.

signature). As a matter of fact, the above specification does not at all express the intention of choosing an element from the set. In order to do that it would have to give choice the signature $Set(S) \to S$. Semantically, this would then be a function from $\mathcal{P}^+(Set(S))$ to $\mathcal{P}^+(S)$. Assuming that semantics of $Set(S)$ will somehow correspond to the power set construction, this makes things rather complicated, forcing us to work with a power set of a power set. Furthermore, since $Set(S)$ and S are different sorts, we cannot let the same variable range over both as was done in the example above.

Example 6.7 and remarks illustrate some of the problems with the intuitive understanding of plural parameters. Power algebras, needed for modeling such parameters, significantly complicate the model of nondeterminism as compared with multialgebras.

On the other hand, plural variables allow us to specify the "upper bound" of nondeterministic choice without using disjunction. The choice operation can be specified as the join which under the partial ordering $\prec$ interpreted as set inclusion will correspond to set union (cf. [17]).

Example 6.8. The following specification makes binary choice the join operation wrt. $\prec$:

S: $\{\ \mathrm{S}\ \}$,

F: $\{\ \_\sqcup\_ : \mathrm{S} \times \mathrm{S} \to \mathrm{S}\ \}$,

Π: $\{$ (1) $\mapsto x^* \prec x^* \sqcup y^* \qquad \mapsto y^* \prec x^* \sqcup y^*$

(2) $x \frown z^*, y \frown z^* \mapsto x \sqcup y \prec z^*$ $\}$.

Axiom (2) although using singular variables x, y, does specify the minimality of $\sqcup$ with respect to all terms. (Notice that the axiom $x^* \frown z^*$, $y^* \frown z^* \mapsto x^* \sqcup y^* \prec z^*$ would have a different, and in this context unintended, meaning.) We can show that whenever $\mapsto t \prec p$ and $\mapsto s \prec p$ hold (for arbitrary terms) then so does $\mapsto t \sqcup s \prec p$ (see Figure 2). Violating our formalism a bit, we may say that the above proof shows the validity of the formula stating the expected minimality of join: $t \prec p$, $s \prec p \mapsto t \sqcup s \prec p$.

Thus, in any model of the specification from Example 6.8 $\sqcup$ will be a join. It is then natural to consider $\sqcup$ as the basic (primitive) operation used for defining other nondeterministic operations. Observe also that in order to ensure that join is the same as set union, we have to require the presence of *all* (finite) subsets in the carrier of the model. For instance, the power structure A with the carrier

$$\mathrm{S}^{\mathrm{A}} = \{\ \{1\}, \{2\}, \{3\}, \{1,2,3\}\ \} \text{ and}$$
$$\sqcup^{\mathrm{A}} \text{ defined as } x^{\mathrm{A}} \sqcup^{\mathrm{A}} y^{\mathrm{A}} = \{1,2,3\} \text{ whenever } x^{\mathrm{A}} \neq y^{\mathrm{A}}$$

will be a model of the specification although $\sqcup^{\mathrm{A}}$ is not the same as set union.

7. Conclusion. We have defined the algebraic semantics for singular (call-time-choice) and plural (run-time-choice) passing of nondeterministic parameters. One of the central results reported in the paper is soundness and completeness of two new

reasoning systems NEQ and NEQ*, respectively, for singular and plural semantics. The plural calculus NEQ* is a minimal extension of NEQ which merely allows unrestricted substitution for plural variables. This indicated a close relationship between the two semantics. We have shown that plural specifications have equivalent (modulo undenotable sets) singular formulations if one considers the plural axioms as singular axiom schemata.

Acknowledgments. We are grateful to Manfred Broy for pointing out the inadequacy of our original notation and to Peter D. Mosses for the observation that in the presence of plural variables choice may be specified as join with Horn formulas.

DATA STRUCTURES' MAXIMA*

G. LOUCHARD†, CLAIRE KENYON‡, AND R. SCHOTT§

Abstract. The purpose of this paper is to analyze the maxima properties (value and position) of some data structures. Our theorems concern the *distribution* of these random variables. Previously known results usually dealt with the *mean* and sometimes the variance of the random variables. Many of our results rely on diffusion techniques. This is a very powerful tool that has already been used with some success in algorithm complexity analysis.

Key words. probabilistic analysis of algorithms, data structures, queuing theory, diffusion techniques, Brownian bridges

1. Introduction.

This paper concerns the maximum size reached by a dynamic data structure over a long period of time. The notion of "maximum" is basic to resource preallocation. The expected value of the maximum size has already been studied in numerous probabilistic papers. Our goal here is twofold:

1. Derive more precise asymptotic expressions for the expected maximum (with lower-order terms).

2. When possible, find the whole distribution of the maximum size.

Our proofs involve advanced analytic and probabilistic techniques; in particular, they use Laplace transforms, complex analysis around singularities, diffusion processes, and Brownian motions. They rely on some results that are well known in the world of probabilists. Our hope is to show that diffusion techniques are a powerful tool for the average-case analysis of algorithms.

Given a dynamic data structure whose size evolves through time with each new insertion or deletion, the main requirement for formalizing the maximum-size problem in a mathematical framework is to define the distribution of the sequence of arrivals (insertions) and departures (deletions). The models that we consider come from three main sources.

1. *Probabilistic model* (that is, the world of queuing theory): We study the $M/M/1$, $M/G/1$, $G/M/1$, $M/M/\infty$, and $G/G/\infty$ queuing systems. For example, in the $M/M/\infty$ model, the number of servers is infinite so that a client newly arrived is served right away; there is no waiting time. The interarrivals and service times are all independent and follow an exponential distribution.

2. *Combinatorial models:* In the 1970's, Françon introduced the concept of file histories, which are beautiful combinatorial objects [17]. A file history is a labeled path where each elementary step of the path is of the type $(x, y) \to (x + 1, y \pm 1)$ or $(x + 1, y)$. The x-axis represents time, and the y-axis represents the size of the file. The relative weights of the paths depend on the type of file history considered (stack,

linear list, dictionary, symbol table, or priority file). However, we must remark that not many real-life situations correspond to the distribution of file histories.

3. *Hashing with lazy deletion:* In the non-Markovian data structure introduced by Van Wyk and Vitter [53], the data structure is a separate-chaining hash table, and the arrivals and lifetimes follow a process of type 1 or 2 above, but the items are not removed from the table as soon as they "die." Instead, we wait until there is a new insertion in a chain of the table before removing the "dead" items from that chain. This enables to save on the access cost to the table.

The results are as follows.

In the first part of this paper, we study the maximum size reached by a queue over $[0 \dots t]$ when t goes to infinity for the most classical types of queues.

When there is only one server processing the requests of the arriving customers, we find expressions describing the distribution for an $M/G/1$, $M/M/1$, or $G/M/1$ process. The technique uses Laplace transforms and developments in the neighborhood of a singularity.

When there are an infinite number of servers, there is no waiting time, and a client stays in the system only as long as it takes for him to be served. This was studied in [46], and in [45], there is an equivalent to the expected value of the maximum size in the $M/M/\infty$ case. In this paper, through a different approach, we get more precise expressions on the expectation. We also solve the $G/G/\infty$ case. Our proof involves reducing the problem to an Ornstein–Uhlenbeck diffusion process, whose properties are well known.

In the second part of this paper, we study some specific kinds of dynamic data structures.

First, we look at combinatorial objects defined by [17] and by Knuth for modeling the evolution of dictionaries, stacks, linear lists, priority files, and symbol tables: file histories. The average value of the maximum was evaluated in [45]. Using sophisticated results on Brownian bridges [14], we show how to get a much more precise estimate of the maximum with several lower-order terms. As an example, we analyze priority queues in the standard model.

Second, we study the maximum size of hashing with lazy deletion. In [53], various models of distribution were suggested. By repeated use of Daniels's theorem [14], we get precise estimates of the average maximum in all of the models with lower-order terms (which are not obtainable by the methods of [45]).

Finally, we look at the limiting profiles of a file history, i.e. what fraction of time is spent by the data structure at a given level l. Again we show that we can obtain the asymptotic distributions.

2. Maximum size of a single server queue when $\rho < 1$. In this section, we study several classical queuing theory models, $M/G/1$ and $G/M/1$, to find the evolution of the maximum size reached over a long period of time.

Notation.

- u_a are interarrival times, assumed to be independent, identically distributed (i.i.d.) random variables (r.v.'s).
- $A(t)$ is the distribution function (d.f.) of u_a.
- $1/\lambda$ is the mean of u_a.
- σ^2 is the variance of u_a.
- u_b are the service times, assumed to be i.i.d., r.v.'s.
- $B(t)$ is the d.f. of u_b.
- $1/\mu$ is the mean of u_b.

- $\rho = \lambda/\mu$.
- $\alpha(s) = \int_o^\infty e^{-st} dA(t)$ $(s \geq 0)$.
- $\beta(s) = \int_o^\infty e^{-st} dB(t)$ $(s \geq 0)$.
- $Q(s)$ is the queue length.
- $M(t) = \max_{s\in[0,t]} Q(s)$.
- $\{x\}$ is the fractional part of x.

To solve our problem, three approaches are possible.

First, we can compute the extreme-value distribution of the maximum on a busy period; we then use renewal theory. Since the queue length is a *discrete* random value, classical techniques give upper and lower bounds (see Cohen [10, Chapter VII, Section 4.5] and Aldous [2, Section C.2.6]). However, it is possible to obtain precise limiting distributions with such an approach; see Heyde [26] for $G/M/1$.

Second, we can use the clumping heuristic (see Aldous [2]).

Third, we can deal directly with the hitting-time distribution; this gives more information on the hitting-time behavior and is the approach chosen here. We easily rederive known theorems on $M/M/1$ and $G/M/1$, write an $M/G/1$ solution, and analyze the Fourier expansion of the maximum moments.

We obtain a family of distributions for the maximum $M(t)$ depending on the fractional part of $C_1 \log(t)+C_2$, where C_1 and C_2 are constants to be determined later. This situation is rather similar to other data structures used in computer science; see, for instance, the number of registers in arithmetic expression evaluation (see Flajolet and Prodinger [18] and Louchard [38]), binary tries (see Louchard [38], Flajolet and Steyaert [19], and Jacquet and Szpankowski [32]), digital search trees (see Louchard [39]), suffix trees (see Jacquet, Rais, and Szpankowski [33]), and approximate counting (see Flajolet [20]). The extreme-value distribution $e^{-e^{-x}}$ frequently appears in this context. We first analyze the $M/G/1$ queue and then the $G/M/1$ queue. (We could not obtain a $G/G/1$ limit theorem). The limiting distribution does not exist for all real values because of the discrete character of $M(t)$. See Anderson [4] and our remarks after Theorem 2.3.

2.1. The $M/G/1$ case.

Notation.

- $\tilde{y}$ is the root[1] greater than 1 and nearest to 1 of $\beta[(1-\tilde{y})\lambda] = \tilde{y}$.
- $\eta = j - \log t/\log\tilde{y} - \log A_1/\log\tilde{y}$.
- $B_1 = 1 - \int_0^\infty e^{-(1-\tilde{y})\lambda t}\lambda t dB(t)$.[2]
- $A_1 = -\lambda(1-\rho)^2(\tilde{y}-1)/B_1$.
- $G_1(\eta) = \exp[-\exp[-\eta\log\tilde{y}]]$.
- $\psi_1(t) = \log(A_1 t)/\log\tilde{y}$.
- $f_1(\eta) = G_1(\eta) - G_1(\eta-1)$.

We note that $\eta = j - \lfloor\psi_1(t)\rfloor - \{\psi_1(t)\}$.

We obtain the following theorem.

THEOREM 2.1. *If j is an integer, then*

$$\Pr[M(t) \leq j] \sim G_1(\eta) \quad \text{as } t = \Theta(\tilde{y}^j) \to \infty. \tag{2.1}$$

The asymptotic distribution is a periodic function of $\psi_1(t)$ (with period 1) given by

$$\log\Pr\{M(t) \leq \lfloor\psi_1(t)\rfloor + k\}e^{\{\psi_1(t)\}\log(\tilde{y})} \to e^{-k\log(\tilde{y})}, \quad t \to \infty.$$

[1] By [10, p. 623], this root does exist if $s_0 < 0$, s_0 being the abscissa of convergence of $\beta(s)$, and if $\beta(s) \to_{s\to s_0} \infty$.

[2] By [10, p. 623], $B_1 < 0$.

We also have

$$\Pr[M(t) = j] \sim f_1(\eta).$$

Proof.

(i) The departure times lead to an imbedded Markov chain whose states correspond to the number of customers just *after* a departure.

Notation.

- τ_j is the hitting time into state j.
- $\varphi_j(s) := E[e^{-s\tau_j}]$, $s \geq 0$.
- $[z^j]f(z)$ is the coefficient of z^j in the power expansion of $f(z)$.
- $y(s)$ is the root with smallest absolute value of equation $z = \beta(s + (1-z)\lambda)$.

By [10, Chapter II, Section 4.35], we have

$$\begin{aligned}\varphi_j(s) = [y(s)]^{-j} &\left\{1 - \left(1 + \frac{s}{\lambda} - y(s)\right)\left[z^j\right]\left(\frac{\beta(s+(1-z)\lambda)}{\beta(s+(1-z)\lambda) - z}\right)\right.\\ &\left.\cdot\ \left(\left[z^j\right]\left(\left(1 + \frac{s}{\lambda} - z\right)\frac{\beta(s+(1-z)\lambda)}{\beta(s+(1-z)\lambda) - z}\right)\right)^{-1}\right\}. \qquad (2.2)\end{aligned}$$

By Takáč's lemma, $y(s) < 1$, and by [10, Chapter II, Section 4.40], $y(s) = 1 - s/\mu(1-\rho) + o(s)$. Expanding (2.2) in the neighborhood of $s = 0$, we derive

$$\begin{aligned}\varphi_j(s) \sim &\left(1 + \frac{js}{\mu(1-\rho)}\right)\left[1 + s\frac{C_{1,j}}{C_{2,j}} - s\left(\frac{1}{\lambda(1-\rho)}\right)\left[\frac{C_{3,j} + sC_{4,j}}{C_{2,j}}\right]\right]\\ &\cdot \left[1 + s\frac{C_{1,j}}{C_{2,j}}\right]^{-1}, \quad s \to 0, \quad j \to \infty, \qquad (2.3)\end{aligned}$$

where we use the following notation.

Notation.

- $\beta_1(z) := \beta[\lambda(1-z)]$.
- $\beta_2(z) := -\int_0^\infty te^{-\lambda(1-z)t}dB(t)$.
- $C_{1,j} := \left[z^j\right]\left((1/\lambda)\beta_1(z)/(\beta_1(z) - z) - z(1-z)\beta_2(z)/(\beta_1(z) - z)^2\right)$.
- $C_{2,j} := \left[z^j\right]\left((1-z)\beta_1(z)/(\beta_1(z) - z)\right)$.
- $C_{3,j} := \left[z^j\right]\left(\beta_1(z)/(\beta_1(z) - z)\right)$.
- $C_{4,j} := \left[z^j\right]\left(-z\beta_2(z)/(\beta_1(z) - z)^2\right)$.

Equivalents of $C_{1,j}$, $C_{3,j}$, and $C_{4,j}$, $j \to \infty$, are given by an asymptotic analysis in the neighborhood of $z = 1$:

$$\begin{aligned}C_{1,j} &\sim \frac{1}{\lambda(1-\rho)^2},\\ C_{3,j} &\sim \frac{1}{1-\rho},\\ C_{4,j} &\sim \frac{j+1}{\mu(1-\rho)^2}.\end{aligned}$$

To obtain $C_{2,j}$ and $C_{5,j} := [C_{1,j} - (1/\lambda(1-\rho))C_{3,j}]$ (which appears as coefficient of s in the numerator of (2.3)), we observe that the corresponding z-functions are regular at $z = 1$. However, the equation that defines $\tilde{y}$ allows an asymptotic analysis in the neighborhood of $z = \tilde{y}$. By Darboux's theorem (see, for instance, Flajolet et al. [23]),

the behavior of $[h(z)]_j$, $j \to \infty$, is related to the behavior of $h(z)$ in the neighborhood of the dominant singularities of $h(z)$.

Notation.

- $s_1^* := \lambda(1-\rho)^2(\tilde{y}-1)/[\tilde{y}^j B_1]$.
- $T_\ell \equiv \tau_{\ell-1}$.
- $\epsilon_{1,\ell} := -\tilde{y}s_1^*$.

Omitting the details, we get $C_{2,j} \sim (1-\tilde{y})/[B_1\tilde{y}^j]$ and $C_{5,j} \sim O(\tilde{y}^{-j})$. Finally, from (2.3), we derive

$$\varphi_j(s) \sim \frac{1}{[1-\frac{s}{s_1^*}]}, \quad s \to s_1^*, \quad j \to \infty.$$

Then $\epsilon_{1,\ell}T_\ell$ is asymptotically distributed as an exponential r.v. as $\ell \to \infty$.

(ii) From $\Pr[T_\ell \geq t] \sim e^{-\epsilon_{1,\ell}t}$, we deduce $\Pr[M(t) < \ell] \sim \exp[-\exp[\log t + \log \epsilon_{1,\ell}]]$ as $t \to \infty$. Taking $\ell := j+1$ and $A_1 := -\lambda(1-\rho)^2(\tilde{y}-1)/B_1$, we readily obtain the theorem.

Notation.

- $\tilde{s_1^*} = s_1^*[1+O(\tilde{y}^{-\ell})]$.
- δ is the absolute error on (2.1).

A detailed analysis shows that

$$\varphi_\ell(s) \sim \frac{1+O(s\ell)}{1-\frac{s}{s_1^*}+O(s^2\ell^2)}, \quad s \to \tilde{s_1^*}, \quad \ell \to \infty. \tag{2.4}$$

We also check that $\phi_\ell(s) \sim \tilde{y}^{-\ell}/|s|^\ell, |s| \to \infty$. The absolute error is given by $\delta = e^{s_1^* t}O(s_1^*\ell)$.

(iii) As $t \to \infty$, we see that the error δ is uniformly small. Thus (2.1) can be put in the form

$$\sup_j |\Pr[M(t) \leq j] - G_1(\eta)| \underset{t\to\infty}{\longrightarrow} 0,$$

which is another appropriate form for a limit theorem [2, Equations (A1.a) and (A10.b)]. □

The asymptotic moments of $M(t)$ are also periodic functions of $\psi_1(t)$. They can be written as harmonic sums and analyzed with Mellin transforms; see Flajolet et al. [21].

The asymptotic nonperiodic term in the moments of $M(t)$ is given by the following result.

THEOREM 2.2. *The constant term $\bar{E}$ in the Fourier expansion (in $\psi_1(t)$) of the moments of $M(t)$ is asymptotically given by*

$$\bar{E}[M(t)-\psi_1(t)]^i \sim \int_{-\infty}^{+\infty} \eta^i [G_1(\eta) - G_1(\eta-1)]d\eta.$$

It is known (see Johnson and Kotz [34, p. 272]) that the extreme-value distribution function $e^{-e^{-x}}$ has mean γ and variance $\pi^2/6$. From this, we can derive, for instance,

$$\bar{E}(M(t)) \sim \psi_1(t) + \frac{1}{2} + \frac{\gamma}{\log(\tilde{y})}. \tag{2.5}$$

The other periodic terms have very small amplitude [21].

2.2. The G/M/1 model. By the same hitting-time technique, this case leads to the following result.

Notation.

- $\tilde{z}$ is the (unique) root of $z - \alpha[(1-z)\mu]$ inside the unit circle.
- $B_3 := \int_o^\infty e^{-(1-\tilde{z})t\mu}\mu t dA(t) - 1$.
- $A_3 := -B_3(1-\tilde{z})\lambda$.
- $\eta := j - \log t/\log(\tilde{z}^{-1}) - \log A_3/\log(\tilde{z}^{-1})$.
- $G_3(\eta) := \exp[-\exp[-\eta\log(\tilde{z}^{-1})]]$.
- $\psi_3(t) := \log(A_3 t)/\log(\tilde{z}^{-1})$.

THEOREM 2.3. *If j is an integer, then*

$$\Pr(M(t) \le j) \sim G_3(\eta), \quad t = \Theta(1/\tilde{z}^j) \to \infty.$$

The last part of Theorem 2.1 *is still valid, with $\psi_1(t)$ replaced by $\psi_3(t)$. Theorem* 2.2 *is still applicable, as well as* (2.5)*, with* $\log(\tilde{y})$ *replaced by* $\log(\tilde{z}^{-1})$.

2.3. Related results.

(i) In the $M/M/1$ case, Theorem 2.3 can be applied with $\tilde{z} \equiv \rho$, $B_3 = -(1-\rho)$, and $A_3 = \lambda(1-\rho)^2$. In this case, the theorem corresponds to the lim inf given in Anderson [4, example on p. 112].

(ii) [10, Section III, Theorem 7.5] gives upper and lower bounds for the distribution of $M(n)$ in $G/M/1$, the maximum number of customers in n busy cycles, and the lower bound matches our theorem. Here the notations ψ and c_1 used in [10] correspond to $\psi \equiv (1-\tilde{z})\mu$ and $c_1 \equiv -B_3$. From [10, Section II, Equation 3.49], we know that the busy-cycle mean length is $\bar{\ell} := 1/[\lambda(1-\tilde{z})]$. From renewal theory, we know that $t/n(t) \to \bar{\ell}$, $t \to \infty$ (where $n(t)$ is the number of busy cycles in $[0,t]$). By the second approach described in the beginning of this section, Heyde [26] derived our theorem.

(iii) In Iglehart [30, Theorem 2], for the $G/G/1$ queue, a (positive) quantity γ is defined by $E[e^{\gamma(u_a - u_b)}] = 1$. It is easy to check that here $\alpha(\gamma)/(1-\gamma/\mu) = 1$, which shows that $\gamma \equiv \psi \equiv (1-\tilde{z})\mu$. [30] then implies [10, Theorems 7.2 and 7.5].

(iv) In a recent report, Sadowsky and Szpankowski [48] analyzed the $G/G/s$ case. They proved under some regularity condition that the maximum number of customers on a busy cycle has a geometric tail with parameter $w = \alpha(\gamma)$ (γ as defined above). However, the coefficient K of $\Pr\{\text{tail} \ge n\} \sim Kw^n$ has a very complicated form; see [48, Equation 4.2.6] (with $L_1^{(n)}$ replaced by $1_{\{\bar{Q} \ge n\}}$). The best way to estimate K would be by simulation. Moreover, the busy-cycle mean length ℓ has no explicit form. In Sadowsky et al. [49], an analysis is derived for $Q_n^{\max}$. We could of course also use Heyde's derivation, but K and ℓ have no computable forms.

(v) Limit distributions are available when $\rho \to 1$ in some particular sense [51, 52].

3. The infinite-server queue maximum problem. In the models where there are an infinite number of servers, a customer arriving always finds a server ready to process its requests. For example, this can model a dynamic data structure with items being inserted in the structure (i.e., customers arriving), staying in for a certain length of time (i.e., service time), and finally being deleted and removed (i.e., exiting the system after service). We will assume that the interarrivals (as well as the service times) are independent and that their distribution is known.

To simplify notation, we will assume in this section that $\mu = 1$. A time-scale change will give the general case.

3.1. The $M/M/\infty$ case.

3.1.1. Weak convergence. Consider an $M/M/\infty$ queue $Q_n(t)$ such that $\lambda_n = n$, $\mu = 1$. It is well known [27, Theorem 4.1] that

$$X_n(t) := \frac{Q_n(t) - n}{\sqrt{n}} \underset{n\to\infty}{\Longrightarrow}{}^{3} \mathrm{OU}(t), \quad t \text{ large},$$

where $\mathrm{OU}(t)$ is a Ornstein–Uhlenbeck process, with infinitesimal mean -1, infinitesimal variance 2, and covariance

$$e^{-(t-s)}, \quad t \geq s. \tag{3.1}$$

From Appendix B, we see that the convergence is correct as far as

$$|X_n(t)|^3 = o(\sqrt{n}) \tag{3.2}$$

or, equivalently

$$|X_n(t)| = o(n^{1/6}), \tag{3.3}$$

i.e., the joint distributions have Gaussian tails $(1 - N(x))$ if $x^3 = o(\sqrt{n})$.[4]

3.1.2. Behavior of λ_n with respect to λ_n/μ. In [45], $\max_{t'\in[0,1]} \bar{Q}(t')$ is analyzed when the parameters satisfy the following three subcases: $\log\lambda' = o(\lambda'/\mu')$, $\log\lambda' = O(\lambda'/\mu')$, $\log\lambda' = \Omega(\lambda'/\mu')$. This corresponds here to the behavior of λ_n with respect to λ_n/μ. We change the time-scale. Let t', λ', and μ' be the new parameters (corresponding to [45]). Letting $t' = h(n)t$, $h(n) \downarrow 0$, and $n \to \infty$, we obtain

$$\left.\begin{aligned} \lambda' &= \frac{\lambda_n}{h(n)} = \frac{n}{h(n)} \to \infty, \\ \mu' &= \frac{1}{h(n)} \to \infty, \end{aligned}\right\} \quad \frac{\lambda'}{\mu'} = n.$$

We derive the convergence

$$X_n(t) := \frac{Q_n(t) - n}{\sqrt{n}} \Rightarrow \mathrm{OU}\left[\frac{t'}{h(n)}\right] \quad \text{if } |X_n(t)| = o(n^{1/6}),$$

and for the queue $\bar{Q}$ of [45], we have in this case

$$\left[\max_{t'\in[0,1]} \bar{Q}(t')\right] \sim n + \sqrt{n}\left[\max_{t\in[0,1/h(n)]} \mathrm{OU}(t)\right] \tag{3.4}$$

The three subcases can be described as follows with $n \to \infty$:

(i) $\log\lambda' \sim (\lambda'/\mu')g(n)$ with $g(n) \downarrow 0$. This leads to $\log n - \log[h(n)] \sim ng(n)$, $1/h(n) \sim e^{ng(n)}/n$, and $\log n/n = o(g(n))$.

(ii) $\log\lambda'/n \to \sigma$, $(\log n - \log[h(n)])/n \to \sigma$, $1/h(n) \sim e^{\sigma n}/n$.

(iii) $\log\lambda'/n \sim f(n)$ with $f(n) \uparrow \infty, 1/h(n) \sim e^{nf(n)}/n$.

[3] $\Rightarrow$ denotes the weak convergence of random functions in the space of all right-continuous functions that have left limits and are endowed with the Skorohod metric (see Billingsley [9]).

[4] $N(a)$ is the standard normal distribution function.

3.1.3. The Ornstein–Uhlenbeck process. From (3.4), we analyze

$$\max_{[0,1/h(n)]} \mathrm{OU}(t).$$

Notation.

- $m_t = [\max_{s\in[0,t]} \mathrm{OU}(s)]$.
- $T_a := \inf[s : \mathrm{OU}(s) = a]$.
- $\delta(a) \sim \sqrt{2\pi}\, e^{a^2/2}/a$.
- $C(t) := 2\log t$.

We shall use two different approaches, each starting from a different probabilistic property.

Approach 1. Let $a \gg 1$. From Keilson [35, Equation 2.31], we know that

$$\Pr[T_a \geq t] \sim e^{-t/\delta(a)}. \tag{3.5}$$

The clumping heuristic also confirms this expression [2, D.9].

$$\Pr[m_t \leq a] = \Pr[T_a \geq t] \sim \exp\left[-\exp\left[\log t - \frac{a^2}{2} + \log a - \frac{1}{2}\log 2\pi\right]\right]. \tag{3.6}$$

To obtain a limiting distribution, set the following in (3.6):

$$a(t) := \sqrt{C(t)} + \frac{\log\log t}{2\sqrt{C(t)}} + \frac{v - \frac{1}{2\log\pi}}{\sqrt{C(t)}} + o\left(\frac{1}{\sqrt{C(t)}}\right), \quad a(t) \uparrow \infty. \tag{3.7}$$

After a few computations, we obtain

$$\Pr[m_t \leq a(t)] \sim e^{-e^{-v}} (\text{extreme-value distribution}), \quad t \to \infty. \tag{3.8}$$

This is a classical known result. It is known (see section 1) that this distribution has mean γ.

Approach 2. Another way of deriving (3.8) is to use Berman's approach [6] (see Appendix C). Using his notation, $w(a), v(a)$, $\Gamma'(0)$, α, $u(t)$, and with $a \to \infty$, [6, Equations 4.3 and 7.1] give $w(a) = f(a)/(1 - F(a))$, where $F(a)$ is the stationary distribution of the process. This gives $w(a) \sim a$. Then (3.1) and [6, Section 7] give $u^2[1 - r(1/v] = 1]$, where r is the process-correlation function. Here $a^2(1 - e^{-1/v(a)}) = 1$, and hence $v(a) \sim a^2$ (index $\alpha = 1$ in Berman's notation).

Notation.

- $\Gamma(x) = P[\int_0^\infty I_{[Z(s)>0]} ds > x]$.
- $Z(s)$ is the process $\eta - t + \sqrt{2}B(t)$.
- η is exponentially distributed.
- $B(\cdot)$ is the classical Brownian motion.

[6, Equation 14.9] gives

$$\frac{\Pr[m_t \geq a]}{vt(1 - F(a))} \to -\Gamma'(0).$$

In Berman [7], it is proved that $\Gamma'(0) = -1$. From Berman's proof, it is easily checked that if we change $\sqrt{2}B(t)$ into $\sigma B(t)$, $\Gamma'(0)$ *does not depend on* σ. Here

$$\frac{\Pr[m_t \geq a]}{a^2 t(1 - \mathbf{N}(a))} \sim 1 \quad \text{for fixed } t, \quad a \to \infty. \tag{3.9}$$

As a check, return to (3.5) for fixed t:

$$\Pr[m_t \geq a] \sim 1 - e^{-t/\delta(a)} \sim \frac{t}{\delta(a)} \sim \frac{at}{\sqrt{2\pi}} e^{-a^2/2}, \quad a \to \infty. \tag{3.10}$$

It is well known that

$$1 - \mathbf{N}(a) \sim \frac{e^{-a^2/2}}{\sqrt{2\pi}a}. \tag{3.11}$$

The identification of (3.10) with (3.9) is immediate.

In [6, Equation 16.9], $u(t)$ is computed from the equation $vt[1-F] = 1$, $t \to \infty$; here

$$u^2 \frac{te^{-u^2/2}}{\sqrt{2\pi}\, u} \sim 1,$$

and after some algebra, we obtain

$$u(t) \sim \sqrt{C(t)} + \frac{\log\log t - \log\pi}{2\sqrt{C(t)}} + o\left(\frac{1}{\sqrt{C(t)}}\right), \quad t \to \infty. \tag{3.12}$$

Finally, [6, Equation 19.2] gives

$$\Pr[w(u(t))[m_t - u(t)] \leq x] \sim e^{\Gamma'(0)e^{-x}}, \quad t \to \infty.$$

we immediately recover (3.8).

3.1.4. Maxima. From (3.7) and (3.8), we obtain

$$\Pr\left[m_t \leq \sqrt{C(t)} + \frac{\log\log t}{2\sqrt{C(t)}} + \frac{v - \frac{1}{2\log\pi}}{\sqrt{C(t)}} + o\left(\frac{1}{\sqrt{C(t)}}\right)\right] \sim e^{-e^{-v}}, \quad t \to \infty,$$

and from (3.4),

$$M := \max_{t' \in [0,1]} Q_n(t') \sim n + \sqrt{n}\, m_{1/h(n)}. \tag{3.13}$$

It is now routine to deduce the following theorem.[5]

Notation.

- $\Pr[Z(n) \leq q(n) + x/\sqrt{2ng(n)}] \sim e^{-e^{-x}}$.
- $q(n) := \sqrt{2ng(n)} + \dfrac{\log(ng(n))}{2\sqrt{2ng(n)}} - \dfrac{\log n}{\sqrt{2ng(n)}} + \dfrac{1}{2}\dfrac{(\log n)^2}{(2ng(n))^{3/2}} - \dfrac{\log\pi/2}{\sqrt{2ng(n)}}$.

THEOREM 3.1. *In the $M/M/\infty$ case, if $g(n) = o(n^{-2/3})$, then subcase* (i) *leads to the following result:*

$$M \sim n + \sqrt{n}\, Z(n) + o\left(\frac{1}{\sqrt{g(n)}}\right), \quad n \to \infty.$$

[5]The condition on $g(n)$ with (3.3) assures weak convergence to an Ornstein–Uhlenbeck process.

3.1.5. Subcase (i) with $g(n) = \Omega(n^{-2/3})$. Now assume that

$$g(n) = \xi n^{-\tau}, \quad 0 < \tau \leq \frac{2}{3}. \tag{3.14}$$

Notation.
- $P(t) := Q_n(t) - Q_n(0)$.
- $X(t) := (Q_n(t) - n)/\sqrt{n}$.[6]

As in [6, Equation 3.4], let us first consider

$$w(u)\left[X\left(\frac{t}{v}\right) - u\right] = w(u)[X(0) - u] + w(u)\frac{P(\frac{t}{v})}{\sqrt{n}}$$

conditioned by $X(0) > u$. $P(t/v)$ for large v is made up of two parts: a Poisson process with rate n and a death process based on a population of size Q_0 and a death rate of t/v. Since v is large, this simply leads to a binomial r.v. We will see later (from (3.24)) that (3.14) leads to $u = o(\sqrt{n})$ and $X(0) - u = o(1)$. Thus

$$E\left[P\left(\frac{t}{v}\right)\right] \sim \frac{nt}{v} - [n + \sqrt{n}u]\frac{t}{v} = -\sqrt{n}u\frac{t}{v} \tag{3.15}$$

and

$$E\left[w(u)\frac{P(\frac{t}{v})}{\sqrt{n}}\right] \sim \frac{-uw(u)t}{v} = -t$$

if we set $v = w(u)u$. This gives $m(t)$ from [6, Equation 5.9].

Moreover, for large v, we formally have for ζ_1 and $\zeta_2 : \mathcal{N}(0,1)$[7] that

$$\begin{aligned}\Delta P := P\left(\frac{\Delta t}{v}\right) - E\left[P\left(\frac{\Delta t}{v}\right)\right] &\sim \sqrt{n}\zeta_1\sqrt{\frac{\Delta t}{v}} - \sqrt{(n + \sqrt{n}u)\frac{\Delta t}{v}}\zeta_2 \\ &\sim \frac{\sqrt{n}}{\sqrt{v}}\sqrt{2}B_1(\Delta t)\end{aligned} \tag{3.16}$$

for a classical Brownian motion $B_1(t)$.[8] Therefore,

$$\frac{w(u)\Delta P}{\sqrt{n}} \sim \sqrt{\frac{w^2(u)}{v}}\sqrt{2}B_1(\Delta t) \sim \sqrt{2}B_1(\Delta t)$$

if we set $v = w^2(u)$. We obtain $V(t)$ from [6, Theorem 5.2].

Finally, the exact stationary distribution of $M/M/\infty$ is well known. It is given by a Poisson distribution with rate ρ. Here $\rho = \lambda_n/\mu = n$.

$$\Pr[Q(t) = k] = \frac{e^{-n}n^k}{k!}. \tag{3.17}$$

The variance and third centered moment of this distribution are given by n.

It is easily checked that by [6, Equations 4.1 and 4.3], this leads to

(i) $w(u) = u$ if $u = o(\sqrt{n})$ so that $v = u^2$;

[6] We should write P_n and X_n, but we simplify notation.

[7] (standard Gaussian random variables)

[8] This can be rigorously proved by weak convergence.

(ii) an exponential distribution for $w(u)[X(0)-u], X(0)>u$.

Thus assumption (i) of [6, Theorem 3.1] is satisfied. Let us remark that the same arguments lead to

$$dX(t) = -X(t)dt + \sqrt{2}B_2(dt) \tag{3.18}$$

for $X(t) = o(\sqrt{n})$, which is exactly the stochastic differential equation for OU(t).

It remains to derive u from [6, Equation 16.9]. We could start from the stationary Poisson distribution (3.17) and develop pure analytical asymptotics, but we prefer to use a more probabilistic large-derivation approach in the spirit of [16], which clearly leads to successive corrections.

Let

$$u = \alpha n^{\beta}, \quad 0<\beta<\frac{1}{2}, \tag{3.19}$$

and $Y(t) := Q_n(t) - n$. It is well known that a Poisson input process with rate n is asymptotically equivalent to a uniform repartition of a population of $\tilde{n} := nt_0$ customers on a time interval $[0, t_0]$ (with $t(n) = o(t_0(n))$). Therefore, for large t, the size of the queue at time t is a binomial with parameters $\tilde{n}$ and $\tilde{p} = (1/t_0)\int_o^t e^{-(t-v)}dv \sim 1/t_0$ for large t. [16, Equation 7.3] gives

$$\Psi(s) \sim \log\left\{\left[\frac{1}{t_0}e^s + \left(1-\frac{1}{t_0}\right)\right]e^{-s/t_0}\right\}. \tag{3.20}$$

The variance of the binomial is $\tilde{\sigma^2} = \tilde{p}(1-\tilde{p}) \sim 1/t_0$.

Following the notation of [16], we have here (x in the notation of [16] is given by u in the notation of [6]) that

$$x = \frac{Y}{\tilde{\sigma}\sqrt{\tilde{n}}} \sim \frac{Y}{\sqrt{n}} = u = \alpha n^{\beta}.$$

(3.20) gives

$$\Psi'(s) \sim \frac{e^s-1}{t_0}, \quad \Psi''(s), \Psi'''(s), \Psi''''(s) \sim \frac{e^s}{t_0}. \tag{3.21}$$

[16, Equation 7.8] leads to $(e^s-1)/t_0 = (1/\sqrt{t_0})(\alpha n^{\beta}/\sqrt{\tilde{n}})$ or $e^s - 1 = \alpha n^{\beta-1/2}$, i.e., $s \sim \alpha n^{\beta-\frac{1}{2}}(1-\alpha n^{\beta-1/2}/2)$.

[16, Equation 7.14] gives $\bar{x} - x = s\sqrt{\tilde{n}\frac{e^s}{t_0}} - \alpha n^{\beta} = O(n^{3\beta-1})$ so that $x^2/2 - \bar{x}^2/2 = O(n^{4\beta-1}) = O(u^4/n)$.

Finally, from [16, Equation 7.28], we derive—instead of (3.11)—the following tail for the distribution of $X(t) := Y(t)/\sqrt{n}$:

$$1 - F(u) \sim [1-\mathbf{N}(u)]\exp\left(\frac{\lambda_1 u^3}{\sqrt{n}} + O\left(\frac{u^4}{n}\right)\right), \tag{3.22}$$

where here $\lambda_1 = 1/6$ by (3.21). If $u^4 = o(n)$, [6, Equation 16.9] leads to

$$\frac{u^2 t e^{-\frac{u^2}{2}} e^{\frac{u^3}{6\sqrt{n}}}}{\sqrt{2\pi}u} = 1. \tag{3.23}$$

If we choose $g(n) = \xi_1 n^{-2/3}$, then $C(t) \sim 2\xi_1 n^{1/3}$. The first approximation in (3.12) is $u(t) \sim \sqrt{2\xi_1 n^{1/3}}$, and after a little algebra, (3.23) shows that we must add $\kappa_1 := (2\xi_1^{3/2}/6)$ to $-\log \pi/2$ in $g(n)$ in Theorem 3.1 if the mixing conditions are satisfied (so that we can use [6, Equation 16.9]), i.e., if there is no long-range dependency. However, as mentioned in [8, p. 21], the mixing property is satisfied in the cases of diffusion, random walk, and birth and death processes, which cover the present case. Thus we obtain the following result.

THEOREM 3.2. *If $g(n) = \xi_1 n^{-2/3}$, then Theorem* 3.1 *is valid with $\kappa_1 = (2\xi_1)^{3/2}/6$ added to $-\log \pi/2$ in $g(n)$.*

If $g(n) = \xi_2 n^{-1/2}$, we now use [16, Equation 7.29]; an extra term $C_1 u^4/n$ appears in (3.23) and a similar analysis would lead to another correction in Theorem 3.1 (we omit the details). An increasing number of corrections are needed as τ decreases in (3.14), but we always have:

$$u(t) \sim \sqrt{C(t)} = O(n^{(1-\tau)/2}) = o(\sqrt{n}), \tag{3.24}$$

and (3.19) is satisfied with $\beta = (1-\tau)/2$.

Let us check our result with the clumping heuristic of Aldous. By [2, Equation D.2b], the clump rate is $\lambda_u = f(u)\mu(u)$, where by (3.22), the density $f(u) \sim n(u)\exp(\lambda_1 u^3/\sqrt{n} + O(u^4/n))$, and by (3.18), $\mu(u) = u$. After standard algebra, [2, Equation D.2c] leads to the theorem.

3.1.6. Subcase (ii) with $g(n) = \sigma$. We will see in (3.33) that this subcase corresponds to $u = O(\sqrt{n})$. Let $u = \alpha\sqrt{n}$ (i.e., x in the notation of [16]). [16, Equation 7.8] leads to $e^s - 1 \sim \alpha$ or $s \sim \log(1+\alpha)$. (3.21) and [16, Equation 7.14] give

$$\bar{x} \sim \log(1+\alpha)\sqrt{n}e^{s/2} \sim \sqrt{n}\log(1+\alpha)\sqrt{1+\alpha}.$$

From [16, Equations 7.11 and 7.23], we derive

$$\begin{aligned} 1 - F(u) &\sim \frac{e^{-\frac{\bar{x}^2}{2} + \tilde{n}[\Psi(s) - s\Psi'(s) + \frac{1}{2}s^2\Psi''(s)]}}{\sqrt{2\pi}\bar{x}} \\ &\sim \frac{e^{n[\alpha - (\alpha+1)\log(1+\alpha)]}}{\sqrt{2\pi}\sqrt{n}\log(1+\alpha)\sqrt{1+\alpha}} = \frac{e^{-n\varphi_1(\alpha)}}{\sqrt{n}\varphi_2(\alpha)} \text{ (say)} \end{aligned} \tag{3.25}$$

with $\varphi_1(\alpha) \geq 0$. (This can also be checked directly from (3.17) or by using a large-deviation technique based on the binomial-generating function $[(1 - 1/t_o) + z/t_o]$.)

The corresponding asymptotic density is given by

$$\frac{e^{-n\varphi_1(\alpha)}}{\sqrt{2\pi}\sqrt{1+\alpha}}du. \tag{3.26}$$

(3.25) and [6, Equation 4.3] now lead to

$$w(u) \sim \sqrt{n}\log(1+\alpha). \tag{3.27}$$

With (3.25), it is easily checked that [6, Equation 4.1] gives an exponential distribution for $w(u)[X(0) - u]$.

To obtain $m(t)$ as given in [6, Equation 5.9], we compute, with $P(t) := Q_n(t) - Q_n(0)$,

$$E\left[w(u)\frac{P(t/v)}{\sqrt{n}}\right] \sim \frac{-uw(u)t}{v}. \tag{3.28}$$

This gives $-t$ if we choose

$$v = w(u)u \tag{3.29}$$

or, equivalently, $v = n\alpha\log(1+\alpha)$. Now, however, $P(t/v) = O(1)$, so we instead use $v' = v/c(n)$ with $c(n)$ increasing and $c(n) = o(\sqrt{n})$. (3.28) becomes $-c(n)t$.

Again, the Poisson input and the binomial death process lead to

$$\begin{aligned}\Delta P &\sim \left[\sqrt{n}\zeta_1\sqrt{\frac{\Delta t}{v'}} - \sqrt{n(1+\alpha)}\zeta_2\sqrt{\frac{\Delta t}{v'}}\right]\\ &\sim \sqrt{\frac{(2+\alpha)n}{v'}}B_3(\Delta t).\end{aligned} \tag{3.30}$$

With (3.27) and (3.29), this gives

$$w(u)\frac{\Delta P}{\sqrt{n}} \sim \sqrt{\frac{(2+\alpha)\log(1+\alpha)}{\alpha}}B_3(\Delta t)\sqrt{c(n)},$$

which *depends on* α. This gives $V(t)$ from [6, Theorem 5.2].

Here, in the neighborhood of $\alpha\sqrt{n}$, (3.18) becomes

$$\begin{aligned}dX(t) &= -X(t)dt + \sqrt{2+\alpha}B_6(dt)\\ &= -X(t)dt + \sqrt{2 + \frac{X(t)}{\sqrt{n}B_6(dt)}}.\end{aligned} \tag{3.31}$$

The corresponding diffusion has space-dependent infinitesimal variance. From Berman [5], the limiting distribution for the Maximum exists. With the results of Berman [6], we check that $\Gamma'(0) = -c(n)$; α remains asymptotically constant during the clump ($w(u)[X(0)-u]$ is exponential). Therefore, modulo the mixing conditions, [6, Equation 19.2] leads to

$$\Pr\left[m_t < u(t) + \frac{x'}{w}\right] \sim e^{\Gamma'(0)e^{-x'}}, \quad t\to\infty,$$

where $u(t)$ is given by [6, Equation 16.9], i.e.,

$$\frac{n\alpha\log(1+\alpha)}{c(n)}\frac{e^{n\sigma-\log n-n\varphi_1(\alpha)}}{\sqrt{2\pi}\,\sqrt{n\log(1+\alpha)\sqrt{1+\alpha}}} = 1. \tag{3.32}$$

Set α_0 as the solution of $\sigma - \varphi_1(\alpha_0) = 0$. Then the solution of (3.32) is $\alpha_0 + \Delta\alpha$ with, on the first order,

$$\Delta\alpha \sim \frac{[\log(\frac{\alpha_0}{c(n)\sqrt{2\pi}\sqrt{1+\alpha_0}}) - \frac{1}{2}\log n]}{(n\log(1+\alpha_0))}.$$

Setting $x' = x + \log(c(n))$, this leads to the following result.[9]

THEOREM 3.3. *If* $g(n) = \sigma$ *(i.e.,* $t = e^{n\sigma}/n$*), then* (3.13) *is satisfied, with*

$$\Pr\left[m_{1/h(n)} \le \sqrt{n}[\alpha_0+\Delta\alpha] + \frac{x}{\sqrt{n}\log(1+\alpha_0)}\right] \sim e^{-e^{-x}}, \quad n\to\infty. \tag{3.33}$$

Note that the dominant term $\sqrt{n}\alpha_0$ corresponds to Mathieu and Vitter [45].

Again, [2, Equation D.E.b] confirms our theorem. The density is given by (3.26), the clump rate $= \alpha\sqrt{n}$ is given by (3.31), and routine computation leads to (3.33).

[9] (3.31) entails the mixing property.

3.1.7. Subcase (iii) with $1/h(n) \sim e^{nf(n)}/n$. Let us use the approach of Aldous. (Berman's technique leads to the same result.) We have $t = e^{nf}/n$, which gives $\log t = nf - \log n$.[10] Set $u = \alpha\sqrt{n}g(n)$, where g will be determined later on. Proceeding as in case (ii), we obtain

$$\begin{aligned} 1 - F(u) &\sim \frac{\exp[n(\alpha g - \log(1+\alpha g) - \alpha g \log(1+\alpha g))]}{\sqrt{2\pi}\ \sqrt{n}\log(1+\alpha g)\sqrt{1+\alpha g}} \\ &= \frac{e^{-n\varphi_3(\alpha,g)}}{\sqrt{n}\varphi_4(\alpha,g)} \end{aligned}$$

with φ_3 and φ_4 defined appropriately, and $\varphi_3' = g\log(1+\alpha g)$, $\varphi_3'' \sim g$.

The corresponding density is given by

$$\psi(u) = \frac{e^{-n\varphi_3(\alpha,g)}}{\sqrt{2\pi}\ \sqrt{1+\alpha g}}.$$

By (3.31) we now have, in the neighborhood of $u = \alpha\sqrt{n}g(n)$,

$$dX(t) \sim -X(t)dt + \sqrt{\alpha g}B_6(dt). \tag{3.34}$$

We must give the same order of magnitude to the two parts of (3.34). Thus we make the time-scale change $t = gt'$. This gives

$$dX(t') = -X(t')g dt' + \sqrt{\alpha}g B_6(dt').$$

We now proceed to the space-scale change $z' = z/g$. The new process $Z := X/g$ satisfies

$$\begin{aligned} dZ(t') &= -X(t')dt' + \sqrt{\alpha}B_6(dt') \\ &\sim -\alpha\sqrt{n}g dt' + \sqrt{\alpha}B_6(dt'), \end{aligned}$$

which is again a diffusion stochastic differential equation.

Aldous's clump rate is given by $\lambda_b = g\psi(u)\cdot\alpha\sqrt{n}g$, and with $t' = e^{nf}/(ng)$, [2, Equation D.2.c] leads to

$$\Pr\left[\sup_{[0,t']} Z(s) \le \alpha\sqrt{n}\right] \sim e^{-\lambda_b t'}$$

or

$$\Pr[m_t \le \alpha\sqrt{n}g] \sim e^{-\lambda_b t'}. \tag{3.35}$$

To get a limiting distribution, we choose α and g such that $\log(\lambda_b t') = -x$. We can set $\alpha = 1 + \Delta_\alpha$. The equation for g is given by

$$\begin{aligned} &n[\alpha g - \log(1+\alpha g) - \alpha g\log(1+\alpha g)] + nf - \log n - \log g - \log(\sqrt{2\pi}) \\ &\quad + \frac{3}{2}\log g + \frac{1}{2}\log\alpha + \frac{1}{2}\log n = -x. \end{aligned} \tag{3.36}$$

[10] We drop the n dependency to ease notation.

Set g such that the dominant term (in n) of (3.36) is equal to 0 for $\alpha = 1$. This leads to

$$g - \log(1+g) - g\log(1+g) + f = 0.$$

After some algebra, we obtain

$$g = \frac{f}{\log f}\left[1 + \frac{\log\log f}{\log f} + O\left(\frac{1}{\log f}\right)\right].$$

Note that the full expansion must be used in (3.36). For this value of g, we now compute Δ_α. Then (3.36) gives, on the first order (the other terms can be neglected),

$$\Delta_\alpha \sim \frac{\left[-x + \frac{1}{2}\log n - \frac{1}{2}[\log f - \log\log f] + \log(\sqrt{2\pi})\right]}{(-nf)},$$

and finally, equation (3.35) leads to the following result.

THEOREM 3.4. *If $1/h(n) \sim e^{nf(n)}/n$, then* (3.13) *is satisfied with*

$$\Pr[m_{1/h(n)} \le \sqrt{n} g(1+\Delta_\alpha)] \sim e^{-e^{-x}}, \quad n \to \infty. \tag{3.37}$$

Again, the dominant term $\sqrt{n} f/\log f$ corresponds to Mathieu and Vitter [45].

Remark. A similar analysis can be done for $M/G/\infty$, which is not Markovian but has Poisson arrivals. Note that the analysis of the case $\rho =$ constant is done in Aldous et al. [3].

3.1.8. The maximum mean. We now turn to the mean

$$\bar{M} := E\left[\max_{t' \in [0,1]} Q_n(t')\right] \sim n + \sqrt{n}\, E[m_{1/h(n)}].$$

We deduce the following theorem.

THEOREM 3.5. *In the $M/M/\infty$ case, if $g(n) = o(n^{-2/3})$, the first subcase leads to the following result:*

$$\bar{M} \sim n + \sqrt{n} q(n) + \frac{\gamma}{\sqrt{2ng(n)}} + o\left(\frac{1}{\sqrt{g(n)}}\right), \quad n \to \infty.$$

Proof.

(i) Let $g(n) = \xi_1 n^{-\tau}, 2/3 < \tau < 1$. Theorem 3.1 is valid (i.e., we are in the Gaussian range) if $|x|/\sqrt{ng(n)} = o(n^{1/6})$ (see (3.3)), i.e., if $|x| = o(n^{2/3-\tau/2})$. For instance, we set

$$|x| = O(n^{2/3-\tau/2-\epsilon}), \quad 0 < \epsilon < \frac{1}{6}. \tag{3.38}$$

Let $x_1 = -\xi_2 n^{2/3-\tau/2-\epsilon}$, $0 < \epsilon < 1/6$. Then

$$P_1 := \Pr\left[M \le n + \sqrt{n} q(n) + \frac{x_1}{\sqrt{2\xi_1 n^{-\tau}}}\right] \sim \exp\left[-e^{\xi_2 n^{2/3-\tau/2-\epsilon}}\right].$$

However, nP_1 can be made arbitrary small by choosing n sufficiently large. The contribution to the mean of the lower tail of the distribution of M is asymptotically negligible.

(ii) Let us now turn to the upper tail. Begin the process with the stationary distribution (3.17). Divide the observation interval $e^{ng(n)}/n$ into intervals of size $1/n^{1-\tau}$. This gives $e^{\xi_1 n^{1-\tau}}/n^\tau$ intervals. Then

$$\Pr[M \geq n + \sqrt{n}u] \leq \frac{e^{\xi_1 n^{1-\tau}}}{n^\tau} \Pr\left[\max_{s\in[0,n^{-(1-\tau)}]} Q_n(s) \geq n + \sqrt{n}u\right]. \tag{3.39}$$

Let $x_2 = \xi_2 n^{1-\tau}$, which satisfies (3.38).

We know from Theorem 3.1 that $q(n) \sim \sqrt{2\xi_1 n^{1-\tau}}$. Choose ξ_2 such that $\sqrt{2} + \xi_2/\sqrt{2}\xi_1 = 4$.

We must then analyze the tail $\Pr[M \geq n + \sqrt{n}4u_0]$ with $u_0 = \sqrt{\xi_1 n^{1-\tau}}$.

(ii)a Let us first consider the range $[n + \sqrt{n}4u_0, n(1+\alpha_0)]$, $\alpha_0 > 0$. Note that u_0 is in the Gaussian range. From (3.39), we must consider

$$\begin{aligned}\Pr\left[\max_{[0,n^{-(1-\tau)}]} Q_n(s) \geq n + \sqrt{n}4u_0\right] &\leq \Pr[Q_n(0) \geq n + \sqrt{n}2u_0] \\ &+ \Pr\left[\max_{[0,n^{-(1-\tau)}]} Q_n(s) \geq n + \sqrt{n}4u_0 | Q_n(0) = n + \sqrt{n}2u_0\right].\end{aligned}$$

By (3.11), the first term on the right-hand side is bounded by

$$\frac{e^{-2u_0^2}}{\sqrt{2\pi}2u_0}.$$

For the second term, by (3.15) and (3.16) (setting $v = n^{(1-\tau)}$), we asymptotically obtain

$$\begin{aligned}&\Pr\left[\max_{t\in[0,1]} \left(\frac{-\sqrt{n}2u_0 t}{n^{1-\tau}} + \frac{\sqrt{n}\sqrt{2}B_1(t)}{n^{(1-\tau)/2}}\right) \geq \sqrt{n}4u_0\right] \\ &\quad = \Pr\left[\max_{[0,1]}(-\sqrt{2\xi_1}t + B_1(t)) \geq \sqrt{\frac{\xi_1}{2}}4n^{1-\tau}\right] \\ &\quad \leq \frac{2e^{-4\xi_1 n^{2(1-\tau)}}}{\sqrt{2\pi}\sqrt{\frac{\xi_1}{2}}4n^{1-\tau}}.\end{aligned}$$

By (3.39), we finally obtain

$$\begin{aligned}P_2 &:= \Pr[M \geq n + \sqrt{n}4u_0] \\ &\leq \frac{e^{\xi_1 n^{1-\tau}}}{\sqrt{2\pi}n^\tau}\left[\frac{e^{-2\xi_1 n^{1-\tau}}}{2\sqrt{\xi_1 n^{1-\tau}}} + \frac{2e^{-4\xi_1 n^{2(1-\tau)}}}{\sqrt{\frac{\xi_1}{2}}4n^{1-\tau}}\right].\end{aligned}$$

Obviously, $n(1+\alpha_0)P_2$ can be made arbitrary small by taking n sufficiently large.

(ii)b We now analyze the range $[n(1+\alpha_0), \infty]$. Again, from (3.39), we consider

$$\begin{aligned}\Pr\left[\max_{[0,n^{-(1-\tau)}]} Q_n(s) \geq n + n\alpha\right] &\leq \Pr\left[Q_n(0) \geq n + \frac{n\alpha}{2}\right] \\ &+ \Pr\left[\max_{[0,n^{-(1-\tau)}]} Q_n(s) \geq n + n\alpha | Q_n(0) = n + \frac{n\alpha}{2}\right].\end{aligned}$$

By (3.25), the first term is bounded by

$$\frac{e^{-n\varphi_1(\alpha/2)}}{\sqrt{n}\varphi_2(\frac{\alpha}{2}rgy)}.$$

With (3.30), the second term is asymptotically given by

$$\begin{aligned}
&\Pr\left[\max_{t\in[0,1]}\left(\frac{-n\alpha t}{2n^{(1-\tau)}}+\frac{\sqrt{n(2+\frac{\alpha}{2})}B_3(t)}{n^{(1-\tau)/2}}\right)\geq n\alpha\right]\\
&=\Pr\left[\max_{[0,1]}\left(\frac{-\alpha t n^{\tau/2}}{2\sqrt{2+\frac{\alpha}{2}}}+B_3(t)\right)\geq\frac{\alpha n^{1-\tau/2}}{\sqrt{2+\frac{\alpha}{2}}}\right]\\
&\leq\frac{2e^{-\alpha^2n^{2-\tau}/(2(2+\alpha/2))}\sqrt{2+\frac{\alpha}{2}}}{\sqrt{2\pi}\alpha n^{1-\tau/2}}=\frac{e^{-\varphi_4(\alpha)n^{2-\tau}}\varphi_5(\alpha)}{n^{1-\tau/2}}\ \text{(say)}.
\end{aligned}$$

From (3.39), we finally obtain

$$\begin{aligned}
P_3(\alpha)&=\Pr(M\geq n+n\alpha)\\
&\leq\frac{e^{\xi_1 n^{1-\tau}}}{n^\tau}\left[\frac{e^{-n\varphi_1(\alpha/2)}}{\sqrt{n}\varphi_2(\frac{\alpha}{2})}+\frac{e^{-\varphi_4(\alpha)n^{2-\tau}}\varphi_5(\alpha)}{n^{1-\tau/2}}\right].
\end{aligned}$$

However, $\int_{\alpha_0}^{\infty}P_3(\alpha)nd\alpha$ can be made arbitrary small by choosing some suitable α_0 and n large enough. □

3.2. The $G/M/\infty$ case. Let us again set $\lambda_n=n$, $\mu=1$. Assume that $A(t)$ has a finite variance σ^2. By Iglehart [28, Equation 5.3], we know that

$$\frac{Q_n(t)-n}{\sqrt{n}\sqrt{C_1}}\Rightarrow \mathrm{OU}(t),\quad t\text{ large},$$

where $C_1:=(1+\sigma^2)/2$. We readily obtain the following result.

THEOREM 3.6. *In the $G/M/\infty$ case, if $g(n)=o(n^{-2/3})$, subcase* (i) *leads to*

$$M\sim n+\sqrt{nC_1}\,Z(n)+o\left(\frac{1}{\sqrt{g(n)}}\right),\quad n\to\infty,$$

where $Z(n)$ has the same distribution as in Theorem 3.1.

3.3. The $G/G/\infty$ case. Let $\lambda_n=n,\mu=1$. Assume that $A(t)$ has finite variance σ^2. By Iglehart [29, Example 5.2], we know that if $B(t)$ has a continuous density,[11] then

$$\frac{Q_n(t)-nh(t)}{\sqrt{n}}\Rightarrow X^1(t)+X^2(t),$$

where $h(t):=\int_o^t[1-B(\tau)]d\tau$. Here $X^1(t)$ is a Gaussian process with covariance $(s\leq t)$

$$\int_o^s B(s-\tau)[1-B(t-\tau)]d\tau$$

[11] Actually, less severe constraints are sufficient; see [29] for details.

and

$$X^2(t) := \int_o^t [1 - B(t-\tau)]\sqrt{\sigma^2} B_7(d\tau),$$

where B_7 is a classical Brownian motion. As $s, t \to \infty$, it is easily seen that $h(t) \to 1$ and the covariance of $X^1(t) + X^2(t)$ is given by $(s \le t)$

(3.40)
$$\Sigma(t-s) \sim \sigma^2 \int_o^\infty [1 - B(t-s+\tau)][1 - B(\tau)]d\tau + \int_o^\infty B(\tau)[1 - B(t-s+\tau)]d\tau.$$

This is clearly a non-Markovian stationary Gaussian process.

Note that the particular case $\sigma^2 = 1$ leads to the simple form

$$\Sigma(t-s) \sim \int_o^\infty [1 - B(t-s+\tau)]d\tau.$$

This is true, for instance, for the $M/G/\infty$ case.

Returning to (3.41), we see that for $\epsilon \to 0$, the correlation coefficient of the limiting process is given by

(3.41)
$$r(\epsilon) := \frac{\Sigma(\epsilon)}{\Sigma_2} \sim 1 - \frac{\epsilon}{2}\frac{[\sigma^2 + 1]}{C_2} = 1 - r_1\epsilon \text{ (say)},$$

with $\Sigma_2 := \Sigma(0) = 1 + (\sigma^2 - 1)\int_o^\infty [1 - B(\tau)]^2 d\tau$.

(3.41) and [6, Equation 7.2] give $a^2[1 - r(\frac{1}{v})] = 1$, and hence $v(a) \sim r_1 a^2$.

From Berman [7], we can again deduce $\Gamma'(0) = -1$. Now [6, Equation 16.9] computes $u(t)$ from

$$r_1 u^2 \frac{te^{-u^2/2}}{\sqrt{2\pi}u} \sim 1,$$

which leads to

$$u(t) \sim \sqrt{C(t)} + \frac{\log\log t - \log\pi + 2\log r_1}{2\sqrt{C(t)}} + o\left(\frac{1}{\sqrt{C(t)}}\right), \quad t \to \infty.$$

(3.7) is still valid if we add $\log r_1/\sqrt{C(t)}$. The mixing condition can be deduced from Leadbetter et al. [37, Theorem 12.3.5].

We finally derive the following theorem.

THEOREM 3.7. *In the $G/G/\infty$ case, if $g(n) = o(n^{-2/3})$ and $\Sigma(t)\log t \to 0$, $t \to \infty$ ($\Sigma(t)$ is given by* (3.41)*), subcase* (i) *leads to*

$$M \sim n + \sqrt{nC_2}\left[Z(n) + \frac{\log r_1}{\sqrt{2ng(n)}}\right] + o\left(\frac{1}{\sqrt{g(n)}}\right), \quad n \to \infty,$$

where $Z(n)$ has the same distribution as in Theorem 3.1.

Theorem 3.2 now uses $\kappa_1 = \mu_{3,Y}(2\xi_1)^{3/2}/6$.

4. List structures' maxima. In this section, we leave the world of queuing theory models to enter that of combinatorial models for dynamic data structures. More specifically, we are interested in file histories as invented by Françon and developed by Flajolet, Françon, and Vuillemin. The size of a dynamic data structure increases by 1 with each insertion and decreases by 1 with each deletion. The successive sizes as a function of time form a path on the plane, which starts at level 0 (the data structure is initially empty) and normally returns to 0 after a sequence of n operations (insertions, deletions, or queries). A probability distribution is defined by weighing the paths according to the data structure being studied. File histories have been studied by Françon, Flajolet, Puech, Vuillemin, and Viennot in particular, and they have discovered beautiful links with orthogonal polynomials, continued fractions, and various combinatorial objects. In [40] and [41], Louchard, Schott, and Randrianarimanana developed a complete probabilistic analysis of these structures. In [45], the average value of the height of the path (maximum size) was given for some kinds of file histories. In this section, once again we look at the distribution of the maximum size. Assume that the operations happen at times $1, 2, \ldots, 2n$. Our technique is based on the observation that the process can be decomposed into two simple components. Let $S(t)$ denote the size of the data structure at time t ($1 \le t \le 2n$). Then $S(t) = n(\tilde{y} + Z(t))$, where $\tilde{y}$, the *average* size of the structure at time t, is a fairly simple curve (for instance a concave parabola in our first subsection), and $Z(t)$ is a (small) Gaussian process.

4.1. Daniels's fundamental result. All of the remaining results are based on a general theorem by Daniels [14]. We want information about $\mathrm{Max}_{t\in[0,1]}Y(t)$, where Y is a certain random process. Assume that $Y(t)$ can be written as

$$Y(t) = \tilde{z}(t) + Z(t),$$

where $\tilde{z}(t)$ is a certain deterministic curve and $Z(t)$ is a random Gaussian process, of covariance $C(s,t)$. Note that $\tilde{z}(t)$ is *not* random. Let M be the maximum of $Y(t)$ for $t \in [0,1]$ and t^* be the first time at which the maximum M is reached. Thus we can look for the hitting time of $Z(t)$ to the absorbing boundary $M - \tilde{z}(t)$. Near that crossing point, $Z(t)$ locally behaves like a Brownian motion (or a variant of one, such as a Brownian bridge) [15]. It is also known that the hitting time and place densities for a Brownian bridge can be deduced from the hitting time density for a Brownian motion (see, for instance, Louchard [41] for a constant boundary and Csaki et al. [12] for a general proof).

Suppose that we are looking at the maximum size of a data structure over a time interval $[0 \ldots 1]$ when some parameter n goes to infinity (for instance, n might be the number of operations). We will assume that $\tilde{z}(t)$ satisfies

$$\tilde{z}(t) = \sqrt{n}z(t),$$

where $z(t)$ is independent of n. (This assumption will be true for all of the applications in this paper.) Moreover, assume that $z(t)$ has a unique maximum, reached at time $\overline{t}$, with $z(\overline{t}) = 0$. (Up to doing a translation, we can always assume that.)

Daniels has matched the local behavior of $C(s,t)$ with the Brownian bridge covariance near $\overline{t}$ [14]. From [14] and [13], we can deduce information about the maximum M and the time t^* when it is reached.

Notation. Let A and B be the constants defined by

$$A = [\partial_s C]_{\overline{t}} + |[\partial_t C]_{\overline{t}}| \quad \text{and} \quad B = (-z''(\overline{t}))^{-1/3}.$$

Let

$$G(x) = \frac{2^{-1/3}}{2\pi i} \int_{-i\infty}^{i\infty} e^{sx} \frac{ds}{A_i(-2^{1/3}s)},$$

where A_i is the classical Airy function, and let λ be the universal constant defined by

$$\lambda = \int_{-\infty}^{\infty} [e^{x^3/6} G(x) - \max(x, 0)] dx \sim 0.99615.$$

Let

$$u = n^{1/3} A^{-1/3} B^{-2} (t^* - \overline{t}).$$

THEOREM 4.1. *With the above assumptions and notations, if* $[\partial_t C(s,t)]_{\overline{t}} \le 0$ *and* $[\partial_s C(s,t)]_{\overline{t}} > 0$*, then we have the following:*

1. *M is asymptotically Gaussian with mean and variance*

$$\begin{cases} E(M) = \lambda B n^{-1/6} A^{2/3} + O(n^{-1/3}), \\ \sigma^2(M) = C(\overline{t}, \overline{t}) + O(n^{-1/3}). \end{cases}$$

2. *The conditional maximum $M|t^*$ is asymptotically Gaussian with mean and variance*

$$\begin{cases} (M|t^*) = n^{-1/6} A^{-1/3} B \left[[\partial_s C]_{\overline{t}} \dfrac{G'(-u)}{G(-u)} + |[\partial_t C]_{\overline{t}}| \dfrac{G'(u)}{G(u)} \right] + O(n^{-1/3}), \\ \sigma^2(M|t^*) = C(\overline{t}, \overline{t}) + O(n^{-1/3}). \end{cases}$$

3. *The joined density of M and t^* is given by*

$$\phi(M,t) = \frac{2}{\sqrt{2\pi C(\overline{t},\overline{t})}} e^{-M^2/2C(\overline{t},\overline{t})} \left\{ G(t)G(-t) + n^{-1/6} B A^{-1/3} \frac{M}{C(\overline{t},\overline{t})} \right.$$

$$\left. [[\partial_s C]_{\overline{t}} G(t) G'(-t) + |[\partial_t C]|_{\overline{t}} G(-t) G'(t)] + O(n^{-1/3}) \right\}.$$

4. *u has density $2G(u)G(-u)[1 + O(n^{-1/3})]$.*

Proof. A direct new proof is given in Appendix A using modern tools such as the Radon–Nikodym derivative for some absolutely continuous probability measure (see Salminen [50]). □

4.2. File histories and list structure in the Markov model. A file history represents the evolution of the size of a dynamic data structure by a path of length $2n$ = number of operations performed (insertions, queries, or deletions), going from level 0 to level 0. In [45], the average value of the height of the path (i.e., the maximum size) was given for some kinds of data structures, but only a rough equivalent was found.

Here we study the example of priority file histories [22]. Other structures, such as linear lists or dictionaries, could be analyzed with similar techniques. A priority list is by definition a data structure on which no queries are performed: only insertions and deletions occur, and, moreover, deletions happen only for the minimum. Thus when a new item is inserted in a priority list of size k, there are $(k+1)$ intervals defined

by the elements already present and to which the new item may belong, but when an item is deleted, there is only one possible choice. This is reflected in the weights of the paths; see [22].

Assume that there are $2n$ operations performed during the history, n insertions and n deletions. Let $Y(t)$ be the size of the data structure after the $\lfloor nt \rfloor$th operations ($0 \le t \le 2$). From Louchard [40], we know that

$$\forall t, \quad \frac{Y(t) - \frac{1}{2}nt(2-t)}{\sqrt{n}} \Rightarrow X(t) \quad \text{when } n \to \infty,$$

where $X(t)$ is a Markovian Gaussian process with mean 0 and covariance

$$C(s,t) = \frac{s^2(2-t)^2}{4} \quad \text{when } s \le t.$$

The error term can be deduced for the various expansions in [40, Section 4]. It appears that the relative error in the density is $O(1/\sqrt{n})$ (nonuniform in X). Thus in this case, using the notations of Daniels's theorem, we have $z(t) = t(2-t)/2 - 1/2$, with a maximum at $\overline{t} = 1$ and $z''(\overline{t}) = -1$. Since the covariance here is a simple function, we can easily apply the theorem, and we find the following.

THEOREM 4.2. *If $Y_n(t)$ denotes the size of a random priority file history of length $2n$ at time $\lfloor nt \rfloor$, we have*

$$E(\mathrm{Max}_t Y_n(t)) \sim \frac{n}{2} + \lambda n^{1/3} + O(n^{1/6}),$$

and, more generally,

$$\mathrm{Max}_t Y_n(t) \sim \frac{n}{2} + \sqrt{n}\, M + O(n^{1/6})$$

is reached at time t^*, with M and t^* given by Daniels's theorem. We can prove that the error term in the weak convergence to $X(t)$ is negligible *with the error in* Max$Y$.

This is not the first example of applications of diffusion processes to computer science. Other structures have been analyzed using Brownian excursions [42, 44] or Brownian meandering; see [38] for height in planar trees and stack structures' maxima.

5. Limiting profiles of list structures. In the last section, we analyzed the distribution of the maximum of file histories. We can also get information on the limiting profile, i.e., on how much time is spent at each level k (for k fixed and n going to infinity). Our investigations are based on the assumption that the size $Y(\lfloor nt \rfloor)$ of the list at time nt (with $0 \le t \le 2$) satisfies a weak convergence property:

$$\frac{Y(\lfloor nt \rfloor) - ny(t)}{\sqrt{n}} \Rightarrow X(t), \quad 0 \le t \le 2,$$

where y is a symmetric function around 1 and X is a Gaussian process with mean 0 and known covariance C. In all applications to either classical or Knuth-type file histories, this assumption is true.

Let k, the level under study, be fixed, and let $\overline{t}$ be the time such that $y(\overline{t}) = k/n$, with $\overline{t} < 1$. If we consider the time u where Y first hits level k, the density of u is given by

$$\begin{aligned} g(u)du &= \Pr\{\min\{u', Y([nu']) = k\} \in du\} \\ &= \Pr\left\{\min\left\{u', X(u') = \sqrt{n}\left(\frac{k}{n} - y(u')\right)\right\} \in du\right\}, \end{aligned}$$

and so

$$u - \overline{t} = O\left(\frac{1}{\sqrt{n}}\right).$$

Thus we examine the behavior of Y near $\overline{t}$. Locally, y can be approximated by a straight line so that if $y'(\overline{t})$ denotes the slope of y at $\overline{t}$, we have

$$g(u)du \sim \Pr\{\min\{u', X(u') = \sqrt{n}(\overline{t} - u')y'(\overline{t})\} \in du\}.$$

However, it is known that X behaves locally like a Brownian motion [15]. Using classical results on the crossing time of a Brownian motion and a straight line (see Cox and Miller [11, p. 221]) and an asymptotic analysis, we find that the density of $\tau := \sqrt{n}(u - \overline{t})$ is

$$\frac{y'(\overline{t})}{\sqrt{2\pi C(\overline{t},\overline{t})}} e^{-(\tau y'(\overline{t}))^2/2C(\overline{t},\overline{t})} d\tau,$$

where C is the covariance of X. Thus u is a Gaussian variable centered at $\overline{t}$.

We now study the *total time spent* at level k. Let $p(u)$, $q(u)$, and $r(u)$ be the probabilities that the next move on the list is an insertion, deletion, and q, respectively, if we start at $Y([nu])$ at time u. The random walk describing the evolution of the data structure is transient, so the sojourn time is $O(1)$. We can thus replace $p(u)$ by $p(\overline{t}) + O(1/n)$, etc. All distributions are affected by errors of order $O(1/n)$. In the neighborhood of $\overline{t}$, we may consider $p(u)$, $q(u)$, and $r(u)$ to be locally constant and equal to the probabilities p, q, and r of insertion, deletion, and query at level k.

If the first step leaving level k is a deletion, we are sure of coming back to level k (since $\overline{t} < 1$). If it is an insertion, then the probability of ever returning to level k is q/p. If we look at the whole file history after hitting level k, the history spends l steps at level k, i steps inserting from k to $k+1$, d steps deleting from k to $k-1$, plus various other operations at other levels.

Thus if $F(z, w, v)$ is the joint multidimensional generating function

$$F(z, w, v) = \sum_{i,d,l} \Pr\{l, i, d\} z^l w^i v^d,$$

we have when $n \to \infty$ that

$$F(z, w, v) = qzvF(z, w, v) + pw\left[\frac{q}{p} zF(z, w, v) + \left(1 - \frac{q}{p}\right)\right] + rzF(z, w, v),$$

which leads to

$$F(z, w, v) = \frac{(p - q)w}{1 - qz(v + w) - rz}.$$

All of the distributions that we need can be extracted from this equation. For instance, the time ℓ spent at level k is characterized by (letting $w = v = 1$)

$$F_\ell(z) = \frac{p - q}{1 - (2q + r)z}, \tag{5.1}$$

which shows that ℓ is a geometric r.v., with mean $E(\ell) = (2q + r)/(p - q)$. The *total* time spent at k has mean $\tilde{E}_\ell := 1 + E(\ell) = 1/(p - q)$.

The number i of insertions steps *from* k is characterized by (letting $z = v = 1$)

$$F_i(w) = \frac{(p-q)w}{p-qw} = \frac{(1-\frac{q}{p})w}{1-w\frac{q}{p}}.$$

This gives

$$P(i=\kappa) = \left(1-\frac{q}{p}\right)\left(\frac{q}{p}\right)^{\kappa-1} \quad (\text{for } i \geq 1) \tag{5.2}$$

with mean

$$E(i) = \frac{1}{1-\frac{q}{p}} \tag{5.3}$$

Finally, the number d of deletion steps *from* k is characterized by (letting $z = w = 1$)

$$F_d(v) = \frac{p-q}{p-qv} = \frac{1-\frac{q}{p}}{1-v\frac{q}{p}}, \tag{5.4}$$

which shows that d is a geometric r.v. with mean

$$E(d) = \frac{\frac{q}{p}}{1-\frac{q}{p}}. \tag{5.5}$$

5.1. Example: Classical priority queues. For priority queues, we have for the average size at t

$$y(t) = \frac{1}{2}t(2-t),$$

and the covariance of X is given by $C(s,t) = s^2(2-t)^2/4$. Thus $\overline{t} = 1-\sqrt{1-2k/n}$, and $y'(\overline{t}) = \sqrt{1-2k/n}$. Now adapting the proof of Lemma 13 in [41], we can prove that

$$p = 1-\frac{\overline{t}}{2}+O\left(\frac{1}{n}\right), \qquad q = \frac{\overline{t}}{2}+O\left(\frac{1}{n}\right), \qquad r = 0.$$

Then we find that

$$E(i) = E(d) = \frac{1}{\sqrt{1-2\frac{k}{n}}},$$

$$\tilde{E}_\ell = 1+E(\ell) = \frac{2}{\sqrt{1-2\frac{k}{n}}}.$$

6. Hashing with lazy deletion. Hashing with lazy deletion was introduced in [53] as a data structure suitable for example for line-sweep algorithms on a set of segments of the plane. When a new item arrives (i.e., the line reaches the extremity of a new segment), it is inserted in a random bucket of a separate hash table, along with the x-coordinate of its right extremity. When an item "dies," i.e., the line goes past the right extremity of the segment, it is not removed from the data structure right away but only at the time of a later insertion within the same bucket. This method presents the advantage of minimizing the number of accesses to the hash table, at the cost of some extra space used. In [53], several models of distribution are suggested to analyze the extra space: two nonstationary models (which are quite similar to one another so that we will only study the first one since we know that the same approach works also for the other model) and one stationary model.

6.1. The first nonstationary model. In the first nonstationary model, there are n segments in $[0\ldots1]$ drawn independently from the following distribution: segment $s = [\min(x,y), \mathrm{Max}(x,y)]$, where x and y are uniform independent r.v.'s in $[0\ldots1]$. Thus the arrival-time density is $2n(1-u)du$ and the lifetime z, conditional on u, has density $ndz/(1-u)$. To remove the conditionality, it is convenient to change the time scale. Let the new time t be given by $1-u = e^{-2t}$. It is easy to see that the arrival times now have density $2e^{-2t}dt$, and the service times have unconditional density $e^{-t}dt$.

Two parameters are of interest here: Need(t), the number of items alive at time t (which have to be present in the data structure); and Use(t), the number of items which are actually present in the table at time t. Thus Waste(t) = Use(t) − Need(t) counts the items that are dead but not yet deleted at time t.

6.1.1. Study of Max_tNeed(t). We note that Need(t) depends on n but not on H. Our calculations are asymptotic when n, the total number of items, goes to infinity. From Louchard [43, Theorem 1], we find that as n grows, Need(t) converges to a Gaussian process:

$$\frac{\mathrm{Need}(t) - nz_{\mathrm{Need}}(t)}{\sqrt{n}} \Rightarrow Q(t),$$

where $z_{\mathrm{Need}(t)}$, the probability that a given item is alive at time t, is defined by

$$z_{\mathrm{Need}}(t) = \int_0^t 2e^{-2u}e^{-(t-u)}du = 2e^{-t}(1-e^{-t}).$$

$Q(t)$ is a Gaussian process with mean 0 and covariance

$$C(s,t) = 2e^{-t}(1-e^{-s}) - 4e^{-t}(1-e^{-t})e^{-s}(1-e^{-s})$$

if $s \le t$. It is easy to check that $z_{\mathrm{Need}}(t)$ is maximized at $\bar{t} = \ln 2$, where its value is $1/2$. Thus we can rewrite the convergence as

$$\mathrm{Need}(t) \sim \sqrt{n}\left[\frac{\sqrt{n}}{2} + Q(t) + \sqrt{n}\left(z_{\mathrm{Need}}(t) - \frac{1}{2}\right)\right],$$

and, applying Daniels's theorem, we obtain the following result after some algebra.

THEOREM 6.1.

$$\mathrm{Max}_t\mathrm{Need}(t) \sim \frac{n}{2} + \sqrt{n}M + O(n^{1/6}),$$

where M is characterized by the Theorem 3.1 *in section* 3.1, *with $A = 1$, $B = 1$, $C(\bar{t},\bar{t}) = 1/4$, $[\partial_s C]_{\bar{t}} = 1/2$ and $[\partial_t C]_{\bar{t}} = -1/2$.*

6.1.2. Study of Max_tUse(t). Use(t) depends heavily on the number of buckets. The larger H is compared to n, the more discrepancy there is between Max_tNeed(t) and Max_tUse(t). We assume that the number H of buckets also goes to infinity, and there are two cases: either $H = rn$, with r fixed, or $H = \alpha(n)n$, with $\alpha(n) \to 0$.

We must now study $M = \mathrm{Max}_t\mathrm{Use}(t)$. Let Waste$(k)$ be the time during which customer k was dead but not yet deleted. The distribution of Waste(k) is known:

$$\Pr\{\mathrm{Waste}_k > t - y\} = \left[1 - \frac{e^{-2t} - e^{-2y}}{H}\right]^{n-1}.$$

If $H = rn$, this gives

$$Pr[\text{Waste}_k \geq t - y] \sim e^{-p(t,y)/r}\left[1 + O\left(\frac{1}{n}\right)\right], \tag{6.1}$$

where $p(t, y) = e^{-2t} - e^{-2y}$.

Modifying the proof of Theorem 1 in [43] slightly (the error term from (6.1) leads to $O(1/n^{3/2})$, similar to the other error terms of our proof), we see that

$$\frac{\text{Use}(t) - nz(t)}{\sqrt{n}} \Rightarrow Q(t),$$

where $Q(t)$ is a Gaussian process with mean 0 and $nz(t)$ is the average number of items in use at time t: $z(t)$ is the probability that a fixed item is in use at time t. The item is alive at time t if it arrived at $u < t$ and lived for more than $t - u$; it is dead but not deleted at time t if it arrived at time u, died at time $y < t$, and was in waste for longer than $t - y$. Thus approximating Waste_k, we get

$$z(t) = \int_0^t 2e^{-2u}e^{-(t-u)}du + \int_0^t 2e^{-2u}du \int_u^t e^{-(y-u)}e^{-(e^{-2y}-e^{-2t})/r}dy.$$

The limit process $Q(t)$ has mean 0, and we must calculate its covariance. Let $\eta_i(s)$ be the random variable, which is 1 if customer i is in use at time s and 0 otherwise. Then the number $\text{Use}(s)$ of customers in use at time s satisfies

$$\text{Use}(s) = \sum_{1 \leq i \leq n} \eta_i(s).$$

Thus the covariance is given by

$$\text{Cov}(\text{Use}(s)\text{Use}(t)) = \sum_{1 \leq i \leq n} E(\eta_i(s)\eta_i(t)) + 2\sum_{i<j} E(\eta_i(s)\eta_j(t)) - n^2 z(s)z(t)$$

for $s \leq t$. The first part of the sum can be expressed easily as a sum of integrals. The second term depends on whether or not i and j are in the same bucket (events which have probabilities $1/H$ and $1 - 1/H$). After careful development in $1/n$, we obtain

$$\begin{aligned}
&\text{Cov}(\text{Use}(s)\text{Use}(t)) \\
&= n\left[2e^{-t}(1 - e^{-s}) + \int_0^s 2e^{-2u}du \int_u^t e^{-(y-u)}e^{-\frac{e^{-2y}-e^{-2t}}{r}}dy\right. \\
&+ \eta(s)z(t) + \eta(t)z(s) - \eta(s)\eta(t) \\
&+ \frac{1}{r}\int_0^s 2e^{-2u}du \int_0^t 2e^{-2v}dv \int_u^s e^{-(x-u)}dx \int_v^t e^{-(y-v)}dy e^{-A([xs]\cup[yt])/r} 1_{[u\notin\{y,t\}]\cap[v\notin\{x,s\}]} \\
&- \frac{1}{r}\int_0^s 2e^{-2u}du \int_u^s e^{-(y-u)}e^{-(e^{-2y}-e^{-2s})/r}dy \int_0^t 2e^{-2u}du \int_u^t e^{-(y-u)}e^{-(e^{-2y}-e^{-2t})/r}dy \\
&\left. - z(s)z(t)\right] + O(1),
\end{aligned}$$

where $z(t)$ is given as above, $\eta(s)$ is defined by

$$\eta(s) = \int_0^s 2e^{-2u}du \int_u^s e^{-(x-u)}e^{-(e^{-2x}-e^{-2s})/r}\frac{e^{-2x} - e^{-2s}}{r}dx,$$

and $A([xs] \cup [yt])$ is the measure of the union of intervals $[xs]$ and $[yt]$ in the distribution $A(x) = 1 - e^{-2x}$.

To apply Daniels's theorem, we must find $\overline{t}$ such that $z'(\overline{t}) = 0$. From [53], it is known that $\overline{t}$ exists only if $r < 0.84$.

If $r < 0.84$, we can apply Daniels's theorem. If $r \geq 0.84$, we know from Iglehart [30] that $\mathrm{Max}_{s \leq t}\mathrm{Use}(s)$ is asymptotically distributed as $\mathrm{Use}(t)$. Letting t go to infinity gives an equivalent of the maximum.

Finally, we have the following result.

THEOREM 6.2. *Assume that $H = rn$.*

1. *If $r \geq 0.84$, then*

$$\mathrm{Max}_t\mathrm{Use}(t) \sim Cn + \sqrt{n}\sqrt{C(1-C) + C'}X,$$

where $X = \mathcal{N}(0,1)$ is the classical Gaussian random variable, C is defined to be $2\int_0^\infty e^{-x}(1-e^{-x})e^{-e^{-2x}/r}dx$, and C' (which can be evaluated numerically) is given by

$$\begin{aligned} C' = {} & 2\eta(\infty)z(\infty) - \eta^2(\infty) \\ & + \frac{1}{r}\int_0^\infty 2e^{-2u}du \int_0^\infty 2e^{-2v}dv \int_u^\infty e^{-(x-u)}dx \\ & \qquad \int_v^\infty e^{-(y-v)}dy e^{-A([xs]\cup[yt])/r} I[[u \notin \{y,t\}] \cap [v \notin \{x,s\}]] \\ & - \frac{1}{r}\left[2\int_0^\infty e^{-x}(1-e^{-x})e^{-e^{-2x}/r}dx\right]^2. \end{aligned}$$

2. *If $r < 0.84$, then*

$$\mathrm{Max}_t\mathrm{Use}(t) \sim n[2e^{-\overline{t}}(1-e^{-\overline{t}}) + r] + \sqrt{n}M + O(n^{-1/6}),$$

where $\overline{t}$ is the solution of

$$2\int_0^{\overline{t}} e^{-x}(1-e^{-x})e^{-(e^{-2x}-e^{-2\overline{t}})/r}dx = r$$

and M is given by Daniels's theorem, with $B = [4e^{-3\overline{t}}(1-2e^{-\overline{t}})/r]^{-1/3}$, and $C(\overline{t},\overline{t})$, $[\partial_s C]_{\overline{t}}$ and $[\partial_t C]_{\overline{t}}$ can be written in terms of complicated multiple integrals.

In the case where $H = \alpha(n)n$ with $\alpha(n) \to 0$, the arrival times in a bucket behave in first approximation like a Poisson process by classical sample distribution analysis. Our goal here is again to apply Daniels's theorem. At each step of the calculation, we write the quantities as power series in α so that we can neglect high powers of α, and the expressions remain simple enough. Apart from some technical complications, the approach is the same as for the case where $H = rn$. Our calculations are accurate if $\alpha(n) = o(1/\sqrt{n})$. If $\alpha(n)$ decreased more slowly than that, it would still be possible to get some results, but that would require writing the power series more accurately.

THEOREM 6.3. *Let $H = \alpha(n)n$, with $\alpha(n) = o(1/\sqrt{n})$. Then we have*

$$\mathrm{Max}_t\mathrm{Use}(t) \sim n\left(\frac{1}{2} + \alpha - 2\alpha^2 + O(\alpha^3)\right) + \sqrt{n}M + O(n^{-1/6}),$$

where M, given by Daniels's theorem, is asymptotically Gaussian, with mean

$$E(M) = 0.99615n^{-1/6}2^{2/3} + O(n^{-1/3}).$$

We have $A = 2 + O(\alpha)$, $B = 1 + O(\alpha)$, and

$$C(\bar{t}, \bar{t}) = \frac{1}{4} + 2\alpha + O(\alpha^2),$$

$$[\partial_s C]_{\bar{t}} = 1 + O(\alpha),$$

$$[\partial_t C]_{\bar{t}} = -1 + O(\alpha).$$

Sketch of proof. The local rate of the arrival times Poisson process is given by $2ne^{-2t}/H = 2e^{-2t}/\alpha(n)$. We must compute $\bar{t}$ such that $\tilde{z}'(\bar{t}) = 0$; this gives (we omit the details) $\bar{t} = \log 2 + 2\alpha - 2\alpha^2 + O(\alpha^3)$ and $\tilde{z}(\bar{t}) = 1/2 + \alpha - 2\alpha^2 + O(\alpha^3)$, $\tilde{z}''(\bar{t}) = -1 + 8\alpha + O(\alpha^2)$. From this point, the proof is the same as for the case where $H = rn$.

6.2. The second nonstationary model. Van Wyk and Vitter [53] suggested another nonstationary model, in which arrivals and deaths are not symmetric. Here again n segments in $[0 \dots 1]$ are drawn independently from a given distribution: segment $[x \dots y]$ is constructed by drawing x uniformly in $[0 \dots 1]$ and then drawing y uniformly in $[x \dots 1]$. Up to a change of scale, we can assume that the densities of the arrival and service times are $e^{-t}dt$. Henceforth, the proof mirrors that of the previous subsection. The only difference in the calculations is that the arrival times have density $e^{-t}dt$ instead of $2e^{-2t}dt$ so that there is no critical value like 0.84; there is always a point at which $z(t)$ is maximized.

THEOREM 6.4.

$$\mathrm{Max}_t\mathrm{Need}(t) \sim \frac{n}{e} + \sqrt{n}M + O(n^{1/6}),$$

where M is characterized by Daniels's theorem, with $A = 2/e$, $B = (1/e)^{-1/3}$, $C(\bar{t}, \bar{t}) = (1 - 1/e)/e$, $[\partial_s C]_{\bar{t}} = 1/e$, and $[\partial_t C]_{\bar{t}} = -1/e$.

THEOREM 6.5. *If $H = \alpha(n)n$, with $\alpha(n) = o(1/\sqrt{n})$, then we have*

$$\mathrm{Max}_t\mathrm{Use}(t) \sim n\left(\frac{1}{e} + \alpha + O(\alpha^2)\right) + \sqrt{n}M + O(n^{1/6}),$$

where M is characterized by Daniels's theorem, with $A = 4/e + O(\alpha)$, $B = (1/e)^{-1/3} + O(\alpha)$,

$$C(\bar{t}, \bar{t}) = \frac{1}{e}\left(1 - \frac{1}{e}\right) + 2\alpha + O(\alpha^2),$$

$[\partial_s C]_{\bar{t}} = 2/e + O(\alpha)$, *and* $[\partial_t C]_{\bar{t}} = -2/e + O(\alpha)$.

7. Conclusion. Diffusion techniques allowed us to derive several new results on data structures' maxima. Many problems remain open and are the object of work in progress. Let us mention the symbol table (the probabilistic properties of which are unknown), the $G/G/\infty$ case, with $\ln(\lambda t) = \Omega(\lambda)$. Let us mention that in a recent report [3], Aldous, Hofri, and Szpankowski analyzed hashing with lazy deletion in the stationary case and proved open conjectures introduced in [45] and [53].

Appendix A. A direct computation of Daniels's formula. Daniels's results [13], [14] are based on the following hitting-time density for a Brownian motion $X(t)$.

Let $w(t) = m + \sqrt{n}\, f(t)$, with $f(t_o) = f'(t_o) = 0$. Daniels obtained the density (see Daniels and Skyrme [13])

$$g(t)dt = Pr[\min(t' : X(t') = w(t')) \in dt] = \frac{e^{-\frac{[w(t)]^2}{2t}}}{\sqrt{2\pi t}}\mu(t)\, dt, \tag{A.1}$$

where

$$\mu(t) = n^{-1/3}(2\beta)^{1/3}F\{n^{1/3}[2\beta]^{2/3}(\bar{t} - t)\}(1 + O(n^{-1/3}))$$

with F given by (4.1), $\beta := f''(\bar{t})/2$, and $\bar{t}$ is such that $h'(\bar{t}) = h(\bar{t})/\bar{t}$.

1. We will first extract all dominant terms from (A.1). As in Daniels and Skyrme [13], set

$$x = n^{1/3}(2\beta)^{2/3}(t_0 - t) = O(1).$$

They computed

$$\bar{t} - t_o = n^{-1/2}\frac{m}{t_0 2\beta} + O(n^{-2/3}),$$

so

$$\bar{t} - t = \frac{xn^{-1/3}}{(2\beta)^{2/3}} + \frac{n^{-1/2}m}{2\beta t_0} + O(n^{-2/3}).$$

Expanding $G(x)$ as given in (4.1), we obtain

$$G(x) = \frac{1}{2^{2/3}}\sum_{k=o}^{\infty}\frac{e^{-\lambda_k x/2^{1/3}}}{A_i'(\lambda_k)},$$

where λ_k are the zeroes of $A_i(x)$. A detailed expansion of (A.1) now leads to

$$g(t) = \frac{(2\beta)^{1/3}}{\sqrt{2\pi t_o}\, 2^{2/3}}\exp\left[\frac{-m^2}{2t_0} + \frac{x^3}{6}\right]\sum_{k=o}^{\infty}\frac{\exp[\frac{-\lambda_k}{2^{1/3}}(x + \frac{m}{t_o(2\beta)^{1/3}n^{1/6}})]}{A_i'(\lambda_k)}(1 + O(n^{-1/3})). \tag{A.2}$$

2. Such a simple formula as (A.2) should be explained in terms of direct hitting-time density for a Brownian motion. This will be done with a technique introduced by Salminen [50]. Let us first remark that to derive (A.2), it is enough to limit ourselves to a second-order boundary (the error is within $O(n^{-1/3})$), so we can simply use

$$w(t) = m + \sqrt{n}\beta(t - t_o)^2$$

with $\bar{x} = w(0) = m + \beta\sqrt{n}\, t_o^2$. Our hitting problem can now be transformed into

$$g(t)dt = Pr_{\bar{x}}[\min(t' : X(t') = h(t')) \in dt]$$

with $h(t) = -\sqrt{n}\,\beta(t - t_o)^2 + \sqrt{n}\,\beta t_o^2$ such that $h(0) = 0$. This also gives $h'(t) = -2\sqrt{n}\,\beta(t - t_o); h'' = -2\beta\sqrt{n}$.

By Salminen [50, Equations (2.6) and (3.9)], we now obtain

(A.3)

$$g(t) = 2\left(\frac{\beta\sqrt{n}}{2}\right)^{2/3} \exp\left[h'(0)\bar{x} - \frac{1}{2}\int_o^t [h'(s)]^2 ds\right] \sum_{k=o}^{\infty} e^{\lambda_k (2\beta^2 n)^{1/3} t}\, \frac{A_i[\lambda_k + 2(\frac{\beta\sqrt{n}}{2})^{1/3}\bar{x}]}{A'(\lambda_k)}.$$

However, $h'(0) = 2\sqrt{n}\,\beta t_o$ and

$$-\frac{1}{2}\int_o^t [h'(s)]^2 ds = -\int_o^t 2n\beta^2 (s - t_o)^2 ds$$
$$= -2n\beta^2\left[\frac{(t - t_o)^3}{3} + \frac{t_0^3}{3}\right] = \frac{x^3}{6} - \frac{2n\beta^2 t_0^3}{3}.$$

By Abramowitz and Stegun [1, Equation (10.4.59)] we know that for large z,

$$A_i(z) \sim \frac{1}{2}\pi^{-1/2} z^{-1/4} e^{-\xi}\left(1 + O\left(\frac{1}{\xi}\right)\right)$$

with $\xi := \frac{2}{3} z^{3/2}$.

From (A.3), we must use

$$z = \lambda_k + 2^{2/3} n^{2/3} \beta^{4/3} t_o^2 + 2^{2/3}\beta^{1/3} m n^{1/6}$$

so that

$$\xi = \frac{4}{3} n\beta^2 t_o^3\left[1 + \frac{3}{2}\,\frac{m}{\beta t_o^2\sqrt{n}} + \frac{3}{8}\,\frac{m^2}{\beta^2 t_o^4 n} + \frac{3}{2}\,\frac{\lambda_k}{2^{2/3} n^{2/3} \beta^{4/3} t_o^2}\right.$$
$$\left. + \frac{3}{4}\,\frac{m\lambda_k}{\beta^{7/3} t_o^4 2^{2/3} n^{7/6}}\right]\left(1 + O\left(\frac{1}{n^{1/3}}\right)\right).$$

Also, we deduce

$$\lambda_k (2\beta^2 n)^{1/3} t = \lambda_k (2\beta^2 n)^{1/3} t_o - \frac{\lambda_k x}{2^{1/3}},$$

$$h'(0)\bar{x} = 2\beta\sqrt{n}\, t_o \bar{x} = 2\beta\sqrt{n}\, m t_o + 2n\beta^2 t_o^3.$$

The identification of (A.3) with (A.2) is now routine.

Appendix B. Rate of convergence for $G/G/\infty$. We prove that for $G/G/\infty$ the asymptotic stationary distribution of $Y_n(t) := [Q_n(t) - n]/\sqrt{n}$ has a Gaussian tail $(1 - N(x))$ if $x^3 = o(\sqrt{n})$. We also analyze the correction term.

1. Let the renewal process associated with arrivals be $A_n(t)$ (related parameters are indexed by $A, \lambda_A = 1$); we count the origin as a renewal. Then it is well known that the process

$$T_n^*(t) := \frac{A_n(t) - nt}{\sqrt{n}}$$

is asymptotically equivalent to a Brownian motion (with variance $\sigma_A^2 t$). However, we need some rate of convergence. We will detail only the $1/\sqrt{n}$ correction to the distribution, but all terms could be obtained by the same method. Thus we write $T_n^*(t)$ as

$$\frac{\left[\sum_{\ell=1}^{A_n(t)} (1-u_{A,\ell}) + Z_n(t)\right]}{\sqrt{n}},$$

where we set $Z_n(t) := \sum_{j=1}^{A_n(t)} u_{A,j} - nt$ (i.e., the residual waiting time).

By Feller [16, Chapter XI, Equation 4.10], we know that for large n, $Z_n(t)$ has a stationary distribution with mean $(1+\sigma_A^2)/2$.

We must compute $E[e^{-\theta T_n^*(t)}]$. Now

$$\Pi(x) := \Pr[A_n(t) \le r] = \Pr[T^r \ge nt]$$

when T^r is the total time for r arrivals and $r = nt + x\sqrt{n}$. Actually, the discrete character of the process entails some correction. On first order, it is enough to set $r = nt + x\sqrt{n} - 1/2$. (We omit the details; this is similar to Euler summation formula first correction.) We immediately obtain

$$\int_0^\infty e^{-\theta x} \int_0^\infty e^{-wnt} \Pi(x) dx d(nt) = \int_0^\infty e^{-\theta x} \frac{[1 - e^{r[\varphi_1(-w)-w]}]}{w} dx, \tag{B.1}$$

where $\varphi_1(s) := (1/2)s^2\sigma_A^2 + (s^3/6)\mu_{3,A} + O(s^4)$.

(B.1) leads to

$$\frac{1}{\theta w} - \frac{e^{[nt-1/2][\varphi_1(-w)-w]}}{w[\theta - \sqrt{n}(\varphi_1(-w)+w)]}.$$

Thus the asymptotic Laplace transform $\varphi_2(\theta) = \int_0^\infty e^{-\theta x}\Pi(dx)$ is given by

$$\varphi_2(\theta) = \mathcal{R}\frac{1}{2\pi i}\int_{c-i\infty}^{c+i\infty} \left[\frac{1}{w} + \frac{\theta e^{(nt-1/2)[\varphi_1(-w)-w]}}{w[\sqrt{n}(\varphi_1(-w)+w) - \theta]}\right] \tag{B.2}$$

with c to the right of integrand singularities.

The first term leads to 1. By classical residue analysis, the coefficient of $(-\theta)$ is given by $m_1 \sim (\sigma_A^2+1)/2\sqrt{n}$, we recover $Z_n(t)$ mean (see also Feller [16, Chapter XI, Equation 3.1]). The coefficient of $\theta^2/2$ is $\sim \sigma_A^2 t$. The third centered moment is $\sim \tilde{\mu}_3 t/\sqrt{n}$ with $\tilde{\mu}_3 = m_3 - 3\sigma_A^2 m_1 + 2m_1^3$ and $m_3 t/\sqrt{n}$ is the coefficient of $-\theta^3/6$ in (B.2). After computation, we obtain $\tilde{\mu}_3 \sim [3\sigma_A^4 - \mu_{3,A}]$. Thus we derive

$$\varphi_2(\theta) \sim \exp\left[-\theta m_1 + \frac{\theta^2\sigma_A^2 t}{2} - \frac{\theta^3 \tilde{\mu}_3 t}{(6\sqrt{n})} + O\left(\frac{\theta^4}{n}\right)\right]. \tag{B.3}$$

2. Let us turn to

$$Y_n(t) := \frac{Q_n(t) - \bar{Q}_n(t)}{\sqrt{n}}.$$

We will analyze the stationary distribution, but k-dimensional distributions can be treated similarly by tedious but routine algebra.

Each customer arriving at time s induces at time t a survival probability $1-B(t-s)$. Set $\gamma := 1-B$ ($\gamma(0)=1$). Thus the survival process has mean $\mu_{1,S} := \gamma$, variance $\mu_{2,S} := \gamma(1-\gamma)$, and third (centered) moment $\mu_{3,S} := \gamma(1-\gamma)(1-2\gamma)$ (all functions with argument $t-s$). Then we can write

(B.4)

$$E[e^{iwY_n(t)/\sqrt{n}}] = E\left\{\exp\left[\int_0^t \left[\frac{iw\mu_{1,S}(t-s)}{\sqrt{n}} - \frac{w^2}{2n}\mu_{2,S}(t-s) + \frac{(iw)^3}{6n^{3/2}}\mu_{3,S}(t-s) + O\left(\frac{w^4}{n}\right)\right] dA(s) - iw\sqrt{n}\int_0^t \mu_1(t-s)ds\right]\right\},$$

and we replace $dA(s)$ by $nds + \sqrt{n}dT_n^*(s)$.

Now using (B.5) in (B.3), we finally obtain for large t

$$\begin{aligned} E[e^{iwY_n(t)/\sqrt{n}}] \sim \exp\Bigg\{ & \frac{-w^2}{2}\int_0^\infty \mu_{2,S}(t-s)ds + \frac{(iw)^3}{6\sqrt{n}}\int_0^\infty \mu_{3,S}(t-s)ds \\ & - \frac{\sigma_A^2}{2}\int_0^\infty \left[w\mu_{1,S}(t-s) - \frac{w^2}{2i\sqrt{n}}\mu_{2,S}(t-s)\right]^2 ds \\ & + \frac{i^3\tilde{\mu}_3}{6\sqrt{n}}\int_0^\infty [w\mu_{1,S}(t-s)]^3 ds + O\left(\frac{w^4}{n}\right)\Bigg\} \cdot \\ & \cdot E\left[\exp\left[\frac{i}{\sqrt{n}}\int_0^\infty w\mu_1(t-s)dZ(t-s)\right]\right]. \end{aligned}$$

Of course, we rediscover the classical asymptotic variance of $Y_n(t)$, $t\to\infty$,

$$\sigma_Y^2 = \int_0^\infty \mu_{2,S}(t-s)ds + \int_0^\infty \sigma_A^2\mu_{1,S}^2(t-s)ds.$$

The third centered moment of $Y_n(t)$ is given by $\mu_{3,Y}/\sqrt{n}$, with

$$\mu_{3,Y} := \left[\int_0^\infty [\mu_{3,S}(t-s) + 3\sigma_A^2\mu_{1,S}(t-s)\mu_{2,S}(t-s) + \tilde{\mu}_3\mu_{1,S}^3(t-s)]ds\right].$$

The mean $\sqrt{n}m_Q (m_Q = \int_0^\infty \mu_{1,S}(t-s)ds = 1/\mu_S)$ of $Q_n(t)/\sqrt{n}$ is now affected by an $O(1/\sqrt{n})$ term that we can obtain as follows:

$$E\left[\int_0^\infty \mu_{1,S}(t-s)dZ(t-s)\right] = E\left[Z(t) - \int_0^\infty f(t-s)Z(t-s)\right]. \tag{B.5}$$

Returning to the original scale, we set $s = v/n$; the last term of (B.5) gives

$$E\left[\int_0^\infty f\left(t-\frac{v}{n}\right) Z\left(t-\frac{v}{n}\right)\frac{dv}{n}\right],$$

and by the ergodic theorem, this gives $(1/2)E(u_A) = 1/2$. Also, from [16, Chapter XI, Equation 4.10], $E[Z(t)] \sim (1+\sigma_A^2)/2$. The final $O(1/\sqrt{n})$ correction to $\sqrt{n}m_Q$ is given by

$$\frac{(1+\sigma_A^2/2)}{\sqrt{n}}.$$

3. We are now ready for a large-deviation analysis of the tail of the $Y_n(t)$ distribution. We will only consider the situation where $Y_n(t)$ is large but $o(\sqrt{n})$. Since we have the first moments of $Y_n(t)$, we can write a Thiele expansion of $E[-\xi Q_n(t)/\sqrt{n}](\xi > 0)$ (the r.v. is positive); this gives $e^{-\xi\sqrt{n}m_Y}e^{\varphi_3(-\xi)}$, with

$$\varphi_3(s) := \frac{1}{2}s^2\sigma_Y^2 + \frac{s^3}{6}\,\frac{\mu_{3,Y}}{\sqrt{n}} + O\left(\frac{s^4}{n}\right) = n\Psi\left(\frac{s}{\sqrt{n}}\right) \quad \text{say,}$$

with

$$\Psi(s) := \frac{1}{2}s^2\sigma_Y^2 + \frac{s^3}{6}\mu_{3,Y} + O(s^4).$$

We will use Feller's [16, Chapter XVI] notation, but we cannot proceed as in [16, Equation 7.6] because we do not deal with a sum of n r.v.'s. Nevertheless, a saddle-point method will provide an equivalent. Let $\tilde{F}$ be the d.f. of $Q_n(t)/\sqrt{n}$. We are interested in

$$1 - \tilde{F}(x\sigma_Y + \sqrt{n}m_Q) = \mathcal{R}\left(\frac{1}{2\pi i}\int_{-i\infty}^{+i\infty}[1 - e^{-\sqrt{n}m_Q\xi + \varphi_3(-\xi)}]e^{\xi[\sqrt{n}m_Q + \sigma_Y x]}\,\frac{d\xi}{\xi}\right).$$

Set $\xi = -s\sqrt{n}$. We obtain

$$\mathcal{R}\left[\frac{1}{2\pi i}\int_{+i\infty}^{-i\infty}[e^{-nm_Q s} - e^{n\Psi(s)}]e^{-s\sigma_Y x\sqrt{n}}\,\frac{ds}{s}\right]. \tag{B.6}$$

We will soon see that our saddle point s^* is positive and of order $x/\sqrt{n}$.

We write $\log[-e^{-nm_Q s} + e^{n\Psi(s)}]$ as

$$n\Psi(s) + \log[1 - e^{-n[sm_Q + \Psi(s)]}].$$

The saddle point s^* of (B.6) is solution of

$$n\Psi'(s^*) - \sqrt{n}x\sigma_Y + \frac{n[m_Q + \Psi'(s^*)]e^{-n[s^*m_Q + \Psi(s^*)]}}{1 - e^{-n[s^*m_Q + \Psi(s^*)]}}. \tag{B.7}$$

After a detailed analysis, the solution of (B.7) is checked to be the solution of $n\Psi'(s^*) - \sqrt{n}x\sigma_Y$ up to exponential small terms $O(e^{-\sqrt{n}x})$, which is exactly equation (7.8) of [16, Chapter XVI].

By a standard saddle-point analysis, (B.6) finally leads to

$$\frac{e^{[n\Psi(s^*) - \sqrt{n}s^*\sigma_Y x]}}{\sqrt{2\pi}s^*\sqrt{n\Psi''(s^*)}},$$

which is exactly [16, Equation (7.11)]. (Use the classical Gaussian tail.) Thus [16, Theorem 2] is still applicable. If $x^3 = O(\sqrt{n})$, we can compute a first correction to the Gaussian tail depending on $\mu_{3,Y}$; we obtain

$$1 - \tilde{F}(x\sigma_Y + \sqrt{n}m_Q) \sim [1 - N(x)]\exp\left(\frac{\mu_{3,Y}x^3}{6\sqrt{n}\sigma_Y^3}\right).$$

Appendix C. Sojourns and extremes of stationary processes. The content of this section is from Berman [6].

THEOREM C.1 (Sojourn limit theorem; [6, Theorem 3.1]). *Let $X(t)$, $-\infty < t < +\infty$, be separable, measurable, and stationary. Suppose that the following two conditions hold:*

(i) *There exists a measurable process $Z(t)$, $-\infty < t < +\infty$, with continuous finite-dimensional distributions and functions $v = v(u)$ and $w = w(u)$, $u > 0$, with $\lim_{u\to\infty} v(u) = \infty$ such that the finite-dimensional distributions of the process*

$$w(u)\left(X\left(\frac{t}{u}\right) - u\right), \quad -\infty < t < +\infty, \tag{C.1}$$

conditioned by $X(0) > u$ converge to those of $Z(t)$.

(ii) *The function v satisfies*

$$\lim_{d\to\infty} \limsup_{u\to\infty} v \int_{d/v}^{t} P(X(s) > u \mid X(0) > u)ds = 0$$

for $0 < t \le T$ for some $T > 0$. Define

$$\Gamma(x) = P\left(\int_0^\infty 1_{[Z(s)>0]}ds > x\right), \quad x > 0.$$

Then

$$\lim_{u\to\infty} \int_x^\infty \frac{P(vL_t(u) > y)}{E(vL_t(u))}dy = \Gamma(x)$$

at all continuity points $x > 0$ of Γ for $0 < t \le T$.

If

$$\lim_{u\to\infty} \frac{1 - F(u + \frac{x}{w})}{1 - F(u)} = e^{-x}, \quad -\infty < x < \infty,$$

the function w is then necessarily of the form

$$w(u) = \frac{1 - F(u)}{\int_u^\infty (1 - F(x))dx}.$$

If $f(x) = F'(x)$ exists and is nonincreasing for all sufficiently large x, then w may be taken as

$$w(u) = \frac{f(u)}{1 - F(u)}.$$

THEOREM C.2 ([6, Theorem 5.2]). *Let $X(t)$ be a stationary process with the marginal distribution function F satisfying conditions $\lim(1-F(u+\frac{x}{w}))/(1-F(u)) = e^{-x}$; and $w(u) = f(u)/(1 - F(u))$. Consider the process*

$$w \cdot \left(X\left(\frac{t}{v}\right) - X(0)\right), \quad -\infty < t < +\infty, \tag{C.2}$$

conditioned by

$$X(0) = u + \frac{y}{w},$$

Suppose that there is a measurable function $\mu(t,x)$ of (t,x) such that the following hold:

(i) *There exists a process $V(t)$, $-\infty < t < +\infty$, with continuous finite-dimensional distributions such that the finite-dimensional distributions of the process*

$$w \cdot \left[X\left(\frac{t}{v}\right) - \mu\left(\frac{t}{v}; u + \frac{y}{w}\right)\right], \quad -\infty < t < +\infty,$$

suitably conditioned, converge to those of $V(t)$ for any fixed real y.

(ii) *There is a function $m(t)$ not depending on y such that*

$$\lim_{u\to\infty} w \cdot \left[\mu\left(\frac{t}{v}, u + \frac{y}{w}\right) - \left(u + \frac{y}{w}\right)\right] = m(t) \quad \textit{for } -\infty < t, y < \infty.$$

Then the finite-dimensional distributions of process (C.2)*, conditioned by $X(0) = u + \frac{y}{w}$, converge to those of the process $V(t) + m(t)$, and so $Z(t)$ in the sojourn limit theorem is of the form*

$$Z(t) = V(t) + m(t) + \eta,$$

where η is a random variable with an exponential distribution, and is independent of the process V.

Let $X(t)$, $-\infty < t < \infty$, be a stationary Gaussian process with mean 0, variance 1, and continuous covariance function $r(t)$. Here F is the standard normal distribution function Φ and $\phi(x)$ is the density function. Φ is in the domain of attraction of the extreme-value distribution function Λ, and according to (4.3) and the well-known asymptotic formula for the tail of the normal distribution, we have

$$w(u) = \frac{\phi(u)}{1 - \Phi(u)} \sim u \quad \text{for } u \to \infty.$$

It follows that the sojourn time theorem is valid for stationary Gaussian processes of a very general type on an interval $[0,t]$, where t is sufficiently small.

We will assume that $1 - r(t)$ is regularly varying of index α for some $0 < \alpha \leq 2$ for $t \to 0$. Define $v = v(u)$ as the largest solution of the equation $u^2(1 - r(1/v)) = 1$; then it follows from the regularity property that

$$u^2\left(1 - r\left(\frac{t}{v}\right)\right) \to t^\alpha \quad \text{for } u \to \infty.$$

Under some regularity conditions (which are satisfied by our processes $X(t)$), the maximum limit theorem gives

$$\lim_{u\to\infty} \frac{P(\max_{[0,t]} X(s) > u)}{vt(1 - F(u))} = -\Gamma'(0)$$

For general stationary processes (not necessarily Gaussian), we take $u(t)$ as the solution of

$$v(u)t(1 - F(u)) = 1.$$

THEOREM C.3 ([6, Theorem 19.1]). *For all sufficiently large t, let $u = u(t)$ and $v = v(t)$ be defined as above, and let $w = w(u(t))$ be defined as before and satisfy*

$$\lim_{u\to\infty} uw(u) = \infty$$

and

$$\lim_{u\to\infty, u'\to\infty, u/u'\to 1} \left(\frac{w(u)}{w(u')}\right) = 1.$$

Let v satisfy $v(u')/v(u) \to 1$, $u \to \infty$. Then under some regularity conditions (which are satisfied by our processes $X(t)$)

$$\lim_{t\to\infty} P\left\{w\left(\max_{[0,t]} X(s) - u\right) \le x\right\} = \exp(\Gamma'(0)e^{-x}),$$

for every x.

Acknowledgments. We thank Ph. Flajolet for helpful discussions on this topic and the anonymous referees for pertinent comments. Maple was of great help for computing complicated expressions.

ORACLES THAT COMPUTE VALUES*

STEPHEN FENNER†, STEVEN HOMER‡, MITSUNORI OGIHARA§, AND ALAN SELMAN¶

Abstract. This paper focuses on complexity classes of partial functions that are computed in polynomial time with oracles in NPMV, the class of all multivalued partial functions that are computable nondeterministically in polynomial time. Concerning deterministic polynomial-time reducibilities, it is shown that

1. a multivalued partial function is polynomial-time computable with k adaptive queries to NPMV if and only if it is polynomial-time computable via $2^k - 1$ nonadaptive queries to NPMV;
2. a characteristic function is polynomial-time computable with k adaptive queries to NPMV if and only if it is polynomial-time computable with k adaptive queries to NP;
3. unless the Boolean hierarchy collapses, for every k, k adaptive (nonadaptive) queries to NPMV are different than $k + 1$ adaptive (nonadaptive) queries to NPMV.

Nondeterministic reducibilities, lowness, and the difference hierarchy over NPMV are also studied. The difference hierarchy for partial functions does not collapse unless the Boolean hierarchy collapses, but, surprisingly, the levels of the difference and bounded query hierarchies do not interleave (as is the case for sets) unless the polynomial hierarchy collapses.

Key words. computational complexity, complexity classes, relativized computation, bounded query classes, Boolean hierarchy, multivalued functions, NPMV

1. Introduction.

In this paper, we study classes of partial functions that can be computed in polynomial time with the help of oracles that are themselves partial functions. We want to know whether there is a difference between computing with function oracles and computing with set oracles. Specifically, we investigate classes of partial functions that can be computed in polynomial time with oracles in NPMV and NPSV, that is, the classes $\mathrm{PF}^{\mathrm{NPMV}}$ and $\mathrm{PF}^{\mathrm{NPSV}}$.

NPMV is the set of all partial multivalued functions that are computed nondeterministically in polynomial time, and NPSV is the set of all partial functions in this class that are single-valued. NPMV captures the complexity of computing witnesses to problems in NP. For example, let *sat* denote the partial multivalued function defined by $sat(x)$ maps to a value y if and only if x encodes a formula of propositional logic and y encodes a satisfying assignment of x. Then *sat* belongs to NPMV, and the domain of *sat* (i.e., the set of all words x for which the output of $sat(x)$ is nonempty) is the NP-complete satisfiability problem, SAT. Also, NPMV captures

the complexity of inverting polynomial-time honest functions. To wit, the inverse of every polynomial-time honest function belongs to NPMV, and the inverse of every one–one polynomial-time honest function belongs to NPSV.

The class of partial functions with oracles in NP, namely, $\mathrm{PF}^{\mathrm{NP}}$ has been well studied [13], as have been the corresponding class of partial functions that can be computed nonadaptively with oracles in NP, viz $\mathrm{PF}_{tt}^{\mathrm{NP}}$ [15], and the classes of partial functions that are obtained by limiting the number of queries to some value $k \geq 1$, namely, $\mathrm{PF}^{\mathrm{NP}[k]}$ and $\mathrm{PF}_{tt}^{\mathrm{NP}[k]}$ [2, 1]. A rich body of results is known about these classes.

Here we raise the question "What is the difference between computing with an oracle in NPMV versus an oracle in NP?" The answer is not obvious. If the partial function *sat* is provided as an oracle to some polynomial-time computation M, then on a query x, where x encodes a satisfiable formula of propositional logic, the oracle will return some satisfying assignment y. However, if the oracle to M is the NP-compete set SAT, then to this query x, the oracle will only return a Boolean value "yes." On the other hand, by the well-known self-reducibility of SAT, M could compute y for itself by judicious application of a series of adaptive queries to SAT. Indeed, Theorem 2.4 states that unbounded access to an oracle in NPMV is no more powerful than such an access to an oracle in NP. However, in section 3 we will see that the situation for bounded query classes is much more subtle. In general, *function oracles cannot be replaced by set oracles*—but set oracles are still useful. We will show that every partial multivalued function in $\mathrm{PF}^{\mathrm{NPMV}[k]}$ can be computed by a partial multivalued function of the form $f \circ g$, where f is in NPMV and g is a single-valued function belonging to $\mathrm{PF}^{\mathrm{NP}[k]}$. Moreover, most surprisingly, the relationship between access to an oracle in NPMV and access to an oracle in NP is tight regarding set recognition; that is, $\mathrm{P}^{\mathrm{NPMV}[k]} = \mathrm{P}^{\mathrm{NP}[k]}$. This means that when we are computing characteristic functions, k bounded queries to an oracle in NPMV give no more information than the same number of queries to an oracle in NP.

We will show that the levels of the nonadaptive and adaptive bounded query hierarchies interleave (for example, k adaptive queries to a partial function in NPMV are equivalent to $2^k - 1$ nonadaptive queries to a partial function in NPMV), and we will show that these bounded query hierarchies collapse only if the Boolean hierarchy collapses.

In section 4, we study nondeterministic polynomial-time reductions to partial functions in NPMV. Unlike the case for deterministic functions, we will see that just one query to an NP oracle can substitute for an unbounded number of queries to any partial function in NPMV. The hierarchy that is formed by iteratively applying NP reductions is an analogue of the polynomial hierarchy, and we will show that this hierarchy collapses if and only if the polynomial hierarchy collapses.

In section 5, we will study the difference hierarchy over NPMV. We define $f - g$ to be a partial multivalued function that maps x to y if and only if f maps x to y and g does *not* map x to y, and we define $\mathrm{NPMV}(k) = \{f_1 - (f_2 - (\cdots - f_k)) \mid f_1, \ldots, f_k \in \mathrm{NPMV}\}$. Since the properties of the bounded query hierarchies over NPMV are largely similar to those over NP, one might hope that the same thing happens here—that the difference hierarchy over NPMV and the difference hierarchy over NP are similar. However, the contour of this hierarchy is, to our astonishment, totally different than its analogue for NP. Although $\mathrm{BH} = \bigcup_k \mathrm{NP}(k) \subseteq \mathrm{P}^{\mathrm{NP}}$, with no assumption, we will show that NPMV(2) is included in $\mathrm{PF}^{\mathrm{NPMV}}$ if and only if $\mathrm{PH} = \Delta_2^{\mathrm{P}}$. Also, in this section, we will introduce the notion of NPMV-lowness, and we will give a complete

characterization of NPMV-lowness.

Consideration of reduction classes with oracles in NPSV, to be studied in section 6, is motivated in part by a desire to understand how difficult it is to compute satisfying assignments for satisfiable formulas. We take the point of view that a partial multivalued function is easy to compute if for each input string in the domain of the function, some value of the function is easy to compute. For this reason, we define the following technical notions. Given partial multivalued functions f and g, define g to be a *refinement* of f if $dom(g) = dom(f)$ and for all $x \in dom(g)$ and all y, if y is a value of $g(x)$, then y is a value of $f(x)$. Let $\mathcal{F}$ and $\mathcal{G}$ be classes of partial multivalued functions. Purely as a convention, if f is a partial multivalued function, we define $f \in_c \mathcal{G}$ if $\mathcal{G}$ contains a refinement g of f, and we define $\mathcal{F} \subseteq_c \mathcal{G}$ if for every $f \in \mathcal{F}$, $f \in_c \mathcal{G}$. This notation is consistent with our intuition that $\mathcal{F} \subseteq_c \mathcal{G}$ should entail that the complexity $\mathcal{F}$ is not greater than the complexity of $\mathcal{G}$. Let PF denote the class of partial functions that are computable deterministically in polynomial time. The assertion "NPMV $\subseteq_c$ PF" means that every partial multivalued function in NPMV has a refinement that can be computed efficiently by some deterministic polynomial-time transducer. It is well known that $sat \in_c$ PF if and only if NPMV $\subseteq_c$ PF if and only if P = NP [15]. Thus one does not expect that $sat \in_c$ PF. Is *sat* computable in some larger single-valued class of partial functions? Selman [15] showed that PF $\subseteq$ NPSV $\subseteq \mathrm{PF}_{tt}^{\mathrm{NP}}$. If $sat \in_c$ NPSV, then the polynomial hierarchy collapses [11], and it is an open question whether $sat \in_c$ NPSV or whether $sat \in_c \mathrm{PF}_{tt}^{\mathrm{NP}}$. (Watanabe and Toda [18] have shown that $sat \in_c \mathrm{PF}_{tt}^{\mathrm{NP}}$ relative to a random oracle.) We will consider classes of the form $\mathrm{PF}^{\mathrm{NPSV}[k]}$ and $\mathrm{PF}_{tt}^{\mathrm{NPSV}[k]}$, where $k \geq 1$, and we will show that the adaptive and the nonadaptive classes form proper hierarchies unless the Boolean hierarchy collapses. Thus these classes form a finer classification in which to study the central question of whether *sat* has a refinement in some interesting class of single-valued partial functions.

Finally, we note in passing that the complexity theory of decision problems, i.e., of sets, is extremely well developed. Although the computational problems in which we are most interested are naturally thought of as partial multivalued functions, the structural theory to support classification of these problems has been slight. By introducing several natural hierarchies of complexity classes of partial multivalued functions, with strong evidence supporting these claims, we intend this paper to make significant steps in correcting this situation.

2. Preliminaries. We fix Σ to be the finite alphabet $\{0, 1\}$. $<$ denotes the standard canonical lexicographic order on Σ^*. Let $f : \Sigma^* \mapsto \Sigma^*$ be a partial multivalued function. We write $f(x) \mapsto y$ (or $f(x)$ maps to y), if y is a value of f on input string x. Define $graph(f) = \{\langle x, y\rangle \mid f(x) \mapsto y\}$, $dom(f) = \{x \mid \exists y(f(x) \mapsto y)\}$, and $range(f) = \{y \mid \exists x(f(x) \mapsto y)\}$. We will say that f is undefined at x if $x \notin dom(f)$.

A transducer T is a nondeterministic Turing machine with a read-only input tape and a write-only output tape and accepting states in the usual manner. A transducer T computes a value y on an input string x if there is an accepting computation of T on x for which y is the final content of T's output tape. (In this case, we will write $T(x) \mapsto y$.) Such transducers compute partial, multivalued functions. (Since transducers do not typically accept all input strings, when we write "function," "partial function" is always intended. If a function f is total, it will always be explicitly noted.)

- NPMV is the set of all partial, multivalued functions computed by nondeterministic polynomial-time bounded transducers;
- NPSV is the set of all $f \in$ NPMV that are single-valued;

- PF is the set of all partial functions computed by deterministic polynomial-time-bounded transducers.

A function f belongs to NPMV if and only if it is polynomially length-bounded and $graph(f)$ belongs to NP. The domain of every function in NPMV belongs to NP. These definitions originate in Book, Long, and Selman's study of restricted-access relativizations [5].

Now we describe oracle Turing machines with oracles that compute partial functions. For the moment, we assume that the oracle is a single-valued partial function. Let $\perp$ be a symbol not belonging to the finite alphabet Σ. In order for a machine M to access a partial function oracle, M contains a write-only input oracle tape, a separate read-only output oracle tape, and a special oracle call state q. When M enters state q, if the string currently on the oracle input tape belongs to the domain of the oracle partial function, then the result of applying the oracle appears on the oracle output tape, and if the string currently on the oracle input tape does not belong to the domain of the oracle partial function, then the symbol $\perp$ appears on the oracle output tape. Thus, if the oracle is some partial function g, given an input x to the oracle, the oracle, if called, returns a value $g(x)$ if one exists and returns $\perp$ otherwise. (It is possible that M may read only a portion of the oracle's output if the oracle's output is too long to read with the resources of M.) We shall assume, without loss of generality, that M never makes the same oracle query more than once, i.e., all of M's queries (on any possible computation path) are distinct. $\mathrm{PF}^{\mathrm{NP}}$ is the class of partial functions computed in polynomial time with oracles in NP. $\mathrm{PF}^{\mathrm{NP}}_{tt}$ is the class of partial functions that can be computed nonadaptively with oracles in NP; that is, a partial function f is in $\mathrm{PF}^{\mathrm{NP}}_{tt}$ if there is a deterministic oracle Turing machine transducer T such that $f \in \mathrm{PF}^{\mathrm{NP}}$ via T with an oracle L in NP and a total polynomial-time computable function $g : \{0,1\}^* \mapsto (c\{0,1\}^*)^*$ such that, for each input x to T, T only makes queries to L from the list $g(x)$.

If g is a single-valued partial function and M is a deterministic oracle transducer as just described, then we let $M[g]$ denote the single-valued partial function computed by M with oracle g.

DEFINITION 2.1. *Let f and g be multivalued partial functions. f* is Turing reducible to g in polynomial time, *$f \leq^{\mathrm{P}}_{\mathrm{T}} g$, if for some deterministic oracle transducer M, for every single-valued refinement g' of g, $M[g']$ is a single-valued refinement of f.*[1]

PROPOSITION 2.1. *Polynomial-time Turing reducibility, $\leq^{\mathrm{P}}_{\mathrm{T}}$, is a reflexive and transitive relation over the class of all partial multivalued functions.*

Let $\mathcal{F}$ be a class of partial multivalued functions. $\mathrm{PF}^{\mathcal{F}}$ denotes the class of partial multivalued functions f that are $\leq^{\mathrm{P}}_{\mathrm{T}}$-reducible to some $g \in \mathcal{F}$. $\mathrm{PF}^{\mathcal{F}[k]}$ (respectively, $\mathrm{PF}^{\mathcal{F}[\log]}$) denotes the class of partial multivalued functions f that are $\leq^{\mathrm{P}}_{\mathrm{T}}$-reducible to some $g \in \mathcal{F}$ via a machine that, on input x, makes k adaptive queries (respectively,

[1] A notion of polynomial-time Turing reducibility between partial functions is defined by Selman [15]. It is important to note that the definition given here is *different* than the one given there. Here the oracle "knows" when a query is not in its domain. In the earlier definition, this is not the case. The authors recommend that the reducibility defined in the earlier paper should in the future be denoted as $\leq^{\mathrm{PP}}_{\mathrm{T}}$, which is the common notation for reductions between promise problems. We make this recommendation because conceptually and technically this reducibility between functions is equivalent to a promise problem reduction. Also, we note that the reducibility defined by Selman [15] is not useful for our purposes here. In particular, it is easy to see that iterating reductions between functions in NPMV does not gain anything new unless the oracle is endowed with the ability to know its domain.

$\mathcal{O}(\log |x|)$ adaptive queries) to its oracle.

$\mathrm{PF}_{tt}^{\mathcal{F}}$ denotes the class of partial multivalued functions f that are $\leq_{\mathrm{T}}^{\mathrm{P}}$-reducible to some $g \in \mathcal{F}$ via an oracle Turing-machine transducer that queries its oracle nonadaptively. That is, a partial multivalued function f is in $\mathrm{PF}_{tt}^{\mathcal{F}}$ if there is an oracle Turing-machine transducer T such that $f \in \mathrm{PF}^{\mathcal{F}}$ via T with an oracle g in $\mathcal{F}$ and a polynomial time computable function $h : \{0,1\}^* \mapsto (c\{0,1\}^*)^*$ such that, for each input x to T, T only calls the oracle g on strings in the list $h(x)$.

$\mathrm{PF}_{tt}^{\mathcal{F}[k]}$ denotes the class of partial multivalued functions f that are $\leq_{\mathrm{T}}^{\mathrm{P}}$-reducible to some $g \in \mathcal{F}$ via a machine that makes k nonadaptive queries to its oracle, i.e., just as in the last paragraph, but with $h : \{0,1\}^* \mapsto (c\{0,1\}^*)^k$.

$\mathrm{P}^{\mathcal{F}}$, $\mathrm{P}^{\mathcal{F}[k]}$, $\mathrm{P}^{\mathcal{F}[\log]}$, $\mathrm{P}_{tt}^{\mathcal{F}}$, and $\mathrm{P}_{tt}^{\mathcal{F}[k]}$, respectively, denote the classes of all characteristic functions contained in $\mathrm{PF}^{\mathcal{F}}$, $\mathrm{PF}^{\mathcal{F}[k]}$, $\mathrm{PF}^{\mathcal{F}[\log]}$, $\mathrm{PF}_{tt}^{\mathcal{F}}$, and $\mathrm{PF}_{tt}^{\mathcal{F}[k]}$.

For a class of sets $\mathcal{C}$, we may say that $\mathrm{PF}^{\mathcal{C}}$ denotes the class of partial multivalued functions that are $\leq_{\mathrm{T}}^{\mathrm{P}}$-reducible to the characteristic function of some set in $\mathcal{C}$. $\mathrm{PF}^{\mathcal{C}[k]}$, $\mathrm{PF}^{\mathcal{C}[\log]}$, $\mathrm{PF}_{tt}^{\mathcal{C}}$, $\mathrm{PF}_{tt}^{\mathcal{C}[k]}$, $\mathrm{P}^{\mathcal{C}}$, $\mathrm{P}^{\mathcal{C}[k]}$, $\mathrm{P}^{\mathcal{C}[\log]}$, $\mathrm{P}_{tt}^{\mathcal{C}}$, and $\mathrm{P}_{tt}^{\mathcal{C}[k]}$ are defined similarly. In particular, $\mathrm{PF}^{\mathrm{NP}}$ is the class of partial multivalued functions computed in polynomial time with oracles in NP, and $\mathrm{PF}_{tt}^{\mathrm{NP}}$ is the class of partial functions that can be computed nonadaptively with oracles in NP. In the current literature, these classes contain single-valued functions only. The reason is that, heretofore, polynomial-time Turing reducibility, $\leq_{\mathrm{T}}^{\mathrm{P}}$, has been defined as a binary relation over single-valued objects. To see that $\mathrm{PF}^{\mathrm{NP}}$ contains partial functions that are not single-valued, consider the partial single-valued function *maxsat* that on an input x, where x encodes a formula of propositional logic, maps to the encoding of the lexicographically largest satisfying assignment of x, if $x \in \mathrm{SAT}$. Clearly, $maxsat \in \mathrm{PF}^{\mathrm{NP}}$, and $sat \leq_{\mathrm{T}}^{\mathrm{P}} maxsat$ by Definition 2.1, so the partial multivalued function *sat* belongs to $\mathrm{PF}^{\mathrm{NP}}$. Readers are free to interpret references to $\mathrm{PF}^{\mathrm{NP}}$ and $\mathrm{PF}_{tt}^{\mathrm{NP}}$ with their familiar meaning because the results that we will state for these classes, and for the corresponding bounded query classes, remain correct if the classes are replaced with the result of including only the single-valued partial functions that they contain.

Given a class of partial multivalued functions $\mathcal{F}$, let $\mathcal{F}/_{sv}$ denote the class of single-valued partial functions that $\mathcal{F}$ contains.

All the classes of partial multivalued functions that we have defined, other than NPMV, are closed "backwards" under refinement. That is, with the exception of NPMV, property (1) below holds for each of these classes $\mathcal{F}$:

$$f \in \mathcal{F} \wedge f \text{ is a refinement of } g \rightarrow g \in \mathcal{F}. \tag{1}$$

Let us say that classes that satisfy property (1) are *c-closed*. The c-closure of a class is c-closed. Let us say that a *basis* for a class $\mathcal{F}$ is a subset $\mathcal{F}'$ of $\mathcal{F}$ such that for all $f \in \mathcal{F}$, there is an $f' \in \mathcal{F}'$ such that f' is a refinement of f. Essentially all interesting c-closed classes are uncountable, but this is not problematic because they all arise as the c-closure of classes that are countable and effectively enumerable (that is, they are indexed by machines of some appropriate type). Property (2) holds for every class of partial functions $\mathcal{F}$ that is Turing reducible in polynomial time to a class of single-valued partial functions.

$$f \in \mathcal{F} \rightarrow \exists f'[f' \text{ is a single-valued refinement of } f \wedge f' \in \mathcal{F}]. \tag{2}$$

For example, property (2) holds for $\mathrm{PF}^{\mathrm{NP}}$. Property (2) states that the set of single-valued functions in $\mathcal{F}$ is a basis for $\mathcal{F}$. (To use an analogy from lattice theory, if

one thinks of the single-valued functions as "atoms," then property (2) is the "atomic basis property.") Also, note that "is a refinement of" is reflexive and transitive over the class of all partial multivalued functions.

PROPOSITION 2.2. *If $\mathcal{F}$ satisfies property* (1)*, then $g \in_c \mathcal{F} \leftrightarrow g \in \mathcal{F}$ and $\mathcal{G} \subseteq_c \mathcal{F} \leftrightarrow \mathcal{G} \subseteq \mathcal{F}$.*

Thus $\in_c$ is identical to class containment and $\subseteq_c$ is identical to class inclusion for the classes we have defined.

PROPOSITION 2.3. *If $\mathcal{F}$ satisfies property* (2) *and $\mathcal{G}$ satisfies property* (1)*, then $\mathcal{F}/_{sv} \subseteq \mathcal{G}/_{sv} \leftrightarrow \mathcal{F} \subseteq \mathcal{G}$.*

Beigel [2] observed that for all $k \geq 1$, $\mathrm{PF}^{\mathrm{NP}[k]}/_{sv} \subseteq \mathrm{PF}_{tt}^{\mathrm{NP}[2^k-1]}/_{sv}$. Using Proposition 2.3, it follows that $\mathrm{PF}^{\mathrm{NP}[k]} \subseteq \mathrm{PF}_{tt}^{\mathrm{NP}[2^k-1]}$. This example illustrates that known inclusion results for the classes we are considering remain true under the new interpretation that these classes contain multivalued functions. Thus passing to multivalued functions does not disturb our current understanding of previously studied function classes. We are recasting the definitions in no small part because we will be dealing with many classes that (most likely) do not satisfy property (2), and hence our results are strictly more general.

Obviously, $\mathrm{PF}^{\mathrm{NP}} \subseteq \mathrm{PF}^{\mathrm{NPMV}}$. Conversely, for a function $f \in \mathrm{NPMV}$, define f' to be a function such that $f'(x) = \min\{y \mid f(x) \mapsto y\}$. The function f' is a single-valued refinement of f and in $\mathrm{PF}^{\mathrm{NP}}$, so $\mathrm{NPMV} \subseteq \mathrm{PF}^{\mathrm{NP}}$ by Proposition 2.2. This implies that $\mathrm{PF}^{\mathrm{NPMV}} \subseteq \mathrm{PF}^{\mathrm{PF}^{\mathrm{NP}}} = \mathrm{PF}^{\mathrm{NP}}$ since $\leq_{\mathrm{T}}^{\mathrm{P}}$ is transitive. Therefore, the following theorem holds.

THEOREM 2.4. $\mathrm{PF}^{\mathrm{NPMV}} = \mathrm{PF}^{\mathrm{NP}}$.

Theorem 2.4 states that unbounded access to an oracle in NPMV is no more powerful than such an access to an oracle in NP.

The following examples, the first of which was pointed out by Buhrman [3], illustrate the power of $\mathrm{PF}^{\mathrm{NPMV}}$ and $\mathrm{PF}_{tt}^{\mathrm{NPMV}}$. Consider the partial multivalued function *maxTsat* defined as follows:

> $maxTsat(x) \mapsto y$ if y is a satisfying assignment of x with the maximum number of *true*s.

Obviously, *maxTsat* belongs to $\mathrm{PF}^{\mathrm{NPMV}}$. Let f be a function that maps a pair (x, n) to y if and only if y is a satisfying assignment of x with n *true*s. Since the number of variables in a formula is bounded by its length, it holds that $maxTsat(x) = f(x, n_x)$, where n_x is the largest $n, 1 \leq n \leq |x|$, such that $(x, n) \in dom(f)$. This implies that $maxTsat \in \mathrm{PF}_{tt}^{\mathrm{NPMV}}$.

Similarly, the partial multivalued function *maxclique* that on input a graph G outputs a clique of maximum size belongs to $\mathrm{PF}_{tt}^{\mathrm{NPMV}}$. The function *MaxEdgeWeightClique* that is defined over edge-weighted graphs and that outputs a clique of maximum weight, if G has a clique, belongs to $\mathrm{PF}^{\mathrm{NPMV}}$ but may not belong to $\mathrm{PF}_{tt}^{\mathrm{NPMV}}$ because weights may grow exponentially.

We should note that several of the classes we investigate here seem to capture the complexity of finding witnesses to NP-optimization problems. This observation is explored by Chen and Toda [9] and by Wareham [17].

3. Bounded query classes. In this section, we prove a number of basic results clarifying the structure of the bounded adaptive and nonadaptive query hierarchies over NPMV, both for computing functions and for set recognition. The new hierarchies are mostly analogous to those over NP, but there are some interesting and subtle differences. General techniques developed in this section are reminiscent of the

"mind-change" technique [2, 19]. We will use them first to compare $\mathrm{PF}^{\mathrm{NPMV}[k]}$ and $\mathrm{PF}_{tt}^{\mathrm{NPMV}[k]}$ with $\mathrm{PF}^{\mathrm{NP}[k]}$ and $\mathrm{PF}_{tt}^{\mathrm{NP}[k]}$, respectively.

The following two propositions are central to the rest of the paper and will be used in several places later on: Theorems 3.3, 3.5, 3.7, and 3.8, Lemma 5.10, and Proposition 6.6. Each proposition abstracts the general idea, common to all these results, that we can replace the oracle queries in any $\mathrm{PF}^{\mathrm{NPMV}}$ computation by nondeterminism in a way that preserves information about outputs of the computation. Proposition 3.1 deals with computations making adaptive queries; Proposition 3.2 deals with nonadaptive queries. After we prove them we will discuss briefly how they are used.

PROPOSITION 3.1. *Let $t \in \mathrm{PF}$. Let f be in $\mathrm{PF}^{\mathrm{NPMV}}$ be computed by a deterministic oracle Turing-machine transducer M with $g \in \mathrm{NPMV}$ as the oracle. Suppose that M on x makes $t(x)$ queries to its oracle. Then there is an* NPMV *function $s[M,g] : \Sigma^* \times \Sigma^* \mapsto \Sigma^*$ that satisfies the following conditions.*

1. *$\lambda x.[s[M,g](x, 0^{t(x)})]$ is total, single-valued, and polynomial-time computable.*
2. *For every x, there uniquely exists $a_x \in \Sigma^{t(x)}$ such that*
   (a) *for every $a \in \Sigma^{t(x)}$, $(x,a) \in dom(s[M,g])$ if and only if $a \leq a_x$,*
   (b) *$f(x)$ is undefined if and only if $s[M,g](x,a_x)$ maps to 0, and*
   (c) *for every y, if $s[M,g](x,a_x)$ maps to $1y$, then $f(x)$ maps to y.*

Proof. Let t, f, M, and g be as in the hypothesis. The idea of the proof is as follows: given an input x, say that a string $a \in \Sigma^{t(x)}$ is *okay* if there is a legitimate computation path of $M(x)$ where the ith query is in $dom(g)$ if and only if the ith bit of a is 1. The "magic" string a_x that we seek will be the lexicographically maximum okay string. Computing the function $s[M,g]$ involves, among other things, guessing if there is an okay string no smaller than the given input string $a \in \Sigma^{t(x)}$. This must be done indirectly since one cannot necessarily verify—even nondeterministically—whether a given string is okay.

Let N be a polynomial-time nondeterministic Turing machine witnessing that $g \in \mathrm{NPMV}$. Define U to be the following machine: On input x and $b \in \Sigma^{t(x)}$, U simulates M on input x in the following manner:

- For each $i, 1 \leq i \leq t(x)$, when M makes its ith query q_i, U behaves as follows:
  —If the ith symbol in b is a 0, then U assumes that the answer is $\perp$.
  —If the ith symbol in b is a 1, then U simulates N on q_i. If N on q_i does not accept, then U halts without accepting, and if N on q_i outputs some z_i, then U assumes that the answer is z_i.
- When M enters a halting state, U behaves as follows:
  —If M rejects, then U outputs 0.
  —If M outputs y, then U outputs $1y$.

Let r be the NPMV function defined by U. For every x, U on $(x, 0^{t(x)})$ makes no nondeterministic guesses. So U on $(x, 0^{t(x)})$ always has a unique output and $\lambda x.[r(x, 0^{t(x)})]$ is polynomial-time computable.

For a given x, let b_x be the largest $b \in \Sigma^{t(x)}$ such that U on (x,b) has an output, and let π be an arbitrary computation path of U on (x, b_x) that leads to an output. Suppose that along path π, U generates query strings $q_1, \ldots, q_{t(x)}$ in this order and computes the answers to them as $z_1, \ldots, z_{t(x)}$, respectively. By definition, for every i such that $z_i \neq \perp$, $g(q_i) \mapsto z_i$. Furthermore, we claim that for every i such that $z_i = \perp$, $q_i \notin dom(g)$. This is seen as follows: Assume that there is some i such that $z_i = \perp$ and $q_i \in dom(g)$. Let j be the smallest such i. By the minimality of j, there exist some c and some computation path π' of U on (x,c) such that along path π',

(i) U has an output,
(ii) the first j queries U computes are $q_1, \ldots, q_j$,
(iii) the first $j-1$ answers U computes are $z_1, \ldots, z_{j-1}$,
(iv) the jth answer U computes is not $\perp$, and
(v) π and π' agree until q_j.

Let $b_x = u0w$ with $|u| = j-1$. By (ii), (iii), and (iv), we have $c = u1v$ for some v. Thus $c > b_x$. By (i), U on (x, c) has an output. So by the maximality of b_x, $b_x \geq c$, which contradicts $c > b_x$. Therefore, for every i such that $z_i = \perp$, $q_i \notin dom(g)$.

Thus we see that all the answers $z_1, \ldots, z_{t(x)}$ are correct. Define g' to be a single-valued refinement of g that is defined by path π. U on (x, b_x) along path π correctly simulates $M[g']$ on x. Thus it holds that

$$\begin{aligned} x \in dom(f) &\leftrightarrow M[g'] \text{ has an output} \\ &\leftrightarrow U \text{ on } (x, b_x) \text{ along path } \pi \text{ outputs a string of the form } 1y, \text{ and} \\ x \notin dom(f) &\leftrightarrow M[g'] \text{ does not have an output} \\ &\leftrightarrow U \text{ on } (x, b_x) \text{ along path } \pi \text{ outputs } 0. \end{aligned}$$

Therefore, U on (x, b_x) along path π outputs 0 if and only if $f(x)$ is undefined, and if U on (x, b_x) along path π outputs $1y$, then $f(x)$ maps to y.

Now define V to be the machine that, on input (x, a) with $|a| = t(x)$, behaves as follows:

- if $a = 0^{t(x)}$, then V simulates U on (x, a), and
- if $a \neq 0^{t(x)}$, then V guesses $b \in \Sigma^{t(x)}$ with $b \geq a$ and simulates U on (x, b).

Let s be the NPMV function defined by V. We claim that s is the desired function. Since V and U are the same on input $(x, 0^{t(x)})$, $\lambda x.[s(x, 0^{t(x)})]$ is total, single-valued, and polynomial-time computable. Let a_x be the largest $a \in \Sigma^{t(x)}$ such that $(x, a) \in dom(s)$. It is not hard to see that $a_x = b_x$. Since b_x is the largest b such that $(x, b) \in dom(r)$, and V on (x, a) simulates U on (x, b) for all $b \geq a$ except when $a = 0^{t(x)}$, it holds that

(i) for every $a > a_x$, $(x, a) \notin dom(s)$,
(ii) for every $a \leq a_x$, $(x, a) \in dom(s)$,
(iii) $x \notin dom(f)$ if and only if $s(x, a_x) \mapsto 0$, and
(iv) if $s(x, a_x) \mapsto 1y$, then $f(x) \mapsto y$.

Hence all the required properties are satisfied. This proves the proposition. □

PROPOSITION 3.2. *Let $t \in$ PF. Let f in $\mathrm{PF}_{tt}^{\mathrm{NPMV}}$ be computed by a deterministic oracle Turing-machine transducer M with $g \in$ NPMV as the oracle. Suppose that M on x makes $t(x)$ queries. Then there is an* NPMV *function $s[M, g] : \Sigma^* \times \{0, \ldots, t(x)\} \mapsto \Sigma^*$ that satisfies the following conditions:*

1. *$\lambda x.[s[M, g](x, 0)]$ is total, single-valued and polynomial-time computable,*
2. *for every x and $0 \leq m \leq n \leq t(x)$, if $(x, n) \in dom(s[M, g])$, then $(x, m) \in dom(s[M, g])$,*
3. *for every x, $f(x)$ is undefined if and only if $s[M, g](x, n_x)$ maps to 0, and*
4. *for every x and y, $f(x)$ maps to y if and only if $s[M, g](x, n_x)$ maps to $1y$, where n_x is the largest $n \in \{0, \ldots, t(x)\}$ such that $(x, n) \in dom(s[M, g])$.*

Proof. Let t, f, M, and g be as in the hypothesis and let N be a nondeterministic Turing machine witnessing that $g \in$ NPMV. The idea of this proof is analogous to, but simpler than, that of the last proposition. The "magic" number n_x that we seek will be the number of queries of $M(x)$ that are in $dom(g)$.

Let h be the function defined by the following machine U: On input x and $n \leq t(x)$, U behaves as follows:

(A) U first computes all the query strings $q_1, \ldots, q_{t(x)}$ of M on x.
(B) If $n = 0$, then for every i, U assumes that the answer to q_i is $\perp$. If $n > 0$, then U does the following:
- For each i, U simulates N on q_i. If N does not accept q_i, then U assumes that the answer to q_i is $\perp$, and if N outputs w on q_i, then U assumes that the answer to q_i is w. After doing this, if the number of answers obtained as $\perp$ is larger than $t(x) - n$, then U halts without accepting.

(C) U simulates M on x using the answers computed in (B). If M rejects, then U outputs 0, and if M outputs z, then U outputs $1z$.

We claim that h is the desired function.

For every x, U on $(x, 0)$ runs deterministically and always has an output. So $\lambda x.[h(x, 0)]$ is total, single-valued, and polynomial-time computable. Suppose $0 < m \leq n \leq t(x)$ and $(x, n) \in dom(h)$. Then U must have an accepting path in step (B), where it obtains at most $t(x) - n$ query answers as $\perp$. The same set of query answers will also allow U to accept on input (x, m).

For each x, let n_x be the maximum n such that $(x, n) \in dom(h)$. For every x, n_x coincides with the number of queries of M on x that are in $dom(g)$. Let π be any computation path of U on (x, n_x) leading to an output. Let $z_1, \ldots, z_{t(x)}$ be the answers that U computes along path π for queries $q_1, \ldots, q_{t(x)}$, respectively. Then by the maximality of n_x, for every i, $z_i = \perp$ if and only if $q_i \notin dom(g)$ and if $z_i \neq \perp$, then $g(q_i)$ maps to z_i. So the output along path π is 0 if and only if $f(x)$ is undefined, and if the output is $1y$, then $f(x)$ maps to y. Therefore, h is the desired function. □

We will use Propositions 3.1 and 3.2 in three ways. First, we can simulate the behavior of a $\mathrm{PF}^{\mathrm{NPMV}}$ (respectively, $\mathrm{PF}_{tt}^{\mathrm{NPMV}}$) computation on input x purely nondeterministically, *provided* we know a_x (respectively, n_x). Such a simulation $s[M, g]$ always accepts, tells us whether $M(x)$ outputs a value, and, if so, provides us with an output. Second, $dom(s[M, g])$ is such that we can find a_x (respectively, n_x) by binary search with an NP oracle. Third, the fact that $s[M, g](x, 0^{t(x)})$ (respectively, $s[M, g](x, 0)$) can be computed deterministically saves us an NP query so that we can get an exact connection between bounded adaptive and nonadaptive NPMV queries in Theorem 3.5.

Let f and g be partial multivalued functions. $f \circ g$ denotes the function h such that for every x,
- $h(x)$ maps to y if and only if there exists some z such that $g(x)$ maps to z and $f(z)$ maps to y.

Let $\mathcal{F}$ and $\mathcal{G}$ be classes of partial multivalued functions. $\mathcal{F} \circ \mathcal{G}$ denotes $\{f \circ g \mid f \in \mathcal{F}$ and $g \in \mathcal{G}\}$.

Although composition is a natural operator and an important tool in our investigations, we should caution that the classes we consider tend not to be closed under composition, and the composition of two easy-to-compute functions may be very difficult. To see this, consider the functions r and s defined as follows: $r(x) \mapsto 1$ for all $x \neq 0$, and r is undefined at $x = 0$; $s(x) \mapsto 0$ for all strings x, and $s(x) \mapsto 1$ if $x \in K$, where K is a complete recursively enumerable set. The partial multivalued functions r and s have refinements in PF, but $dom(r \circ s) = K$, so $r \circ s$ does *not* have a refinement in PF.

The following theorem relates computing with an oracle in NPMV$[k]$ to computing with an oracle in NP$[k]$. In particular, we see that every partial multivalued function in $\mathrm{PF}^{\mathrm{NPMV}[k]}$ can be computed by a partial multivalued function of the form $f \circ g$,

where f is in NPMV and g is a single-valued function in $\mathrm{PF}^{\mathrm{NP}[k]}$.

THEOREM 3.3.

(1) *For every* $k \geq 1$, $\mathrm{PF}^{\mathrm{NPMV}[k]} \subseteq_c \mathrm{NPMV} \circ (\mathrm{PF}^{\mathrm{NP}[k]}/_{sv})$.

(2) *For every* $k \geq 1$, $\mathrm{PF}^{\mathrm{NPMV}[k]} \subseteq \mathrm{NPMV} \circ \mathrm{PF}^{\mathrm{NP}[k]}$.

Proof. Let $f \in \mathrm{PF}^{\mathrm{NPMV}[k]}$ via a deterministic oracle Turing-machine transducer M with $g \in \mathrm{NPMV}$ as the oracle. Let $h = s[M, g]$ be the function defined in Proposition 3.1. Let V be a machine witnessing that $h \in \mathrm{NPMV}$. Define b to be a function that maps x to a_x, where a_x is the largest $a \in \Sigma^k$ such that $(x, a) \in dom(h)$. Recall that $b(x)$ is defined for every x. A binary search algorithm over $\Sigma^k - \{0^k\}$ computes b in polynomial time with oracle $dom(h)$. The number of questions is exactly k, so $b \in \mathrm{PF}^{\mathrm{NP}[k]}/_{sv}$. Now define f' to be a function that maps x to $(x, b(x))$. Define V' to be a machine that on input (x, a) simulates V on (x, a) and does not accept if either V does not accept or V outputs 0, and outputs y if V outputs $1y$. Let h' be the partial multivalued function defined by V'. Then $h' \in \mathrm{NPMV}$.

Now define $r(x) = h'(f'(x))$. It is easy to see that $r(x)$ is undefined if and only if $f(x)$ is undefined, and if $r(x)$ maps to y, then $f(x)$ maps to y. Therefore, r is a refinement of f and is in $\mathrm{NPMV} \circ \mathrm{PF}^{\mathrm{NP}[k]}/_{sv}$. This proves (1).

To prove (2) we proceed exactly as above except that instead of f' we use a new function f'' defined so that for all x and y, $f''(x)$ maps to (x, y) if and only if either

1. $y = b(x)$, or
2. $y = 0^k 1z$ for some z such that $f(x)$ maps to z.

Note that f' is a refinement of f'', so $f'' \in \mathrm{PF}^{\mathrm{NP}[k]}$ by Proposition 2.2. Define V'' to be a machine that on input (x, a) first checks if a is of the form $0^k 1z$ for some z. If so, V'' outputs z and halts. Otherwise, V'' behaves exactly as V' above. Let h'' be the function defined by V''. We have $h'' \in \mathrm{NPMV}$ as before. Now defining $r'(x) = h''(f''(x))$, we show that $r' = f$, completing the proof.

Suppose $f(x)$ maps to z. Then $f''(x)$ maps to $(x, 0^k 1z)$ and $h''(x, 0^k 1z)$ maps to z, so $r'(x)$ maps to z. Conversely, suppose $r'(x)$ maps to z. Then it must be the case that either $f''(x)$ maps to $(x, b(x))$ and $h''(x, b(x))$ maps to z, or $f''(x)$ maps to $(x, 0^k 1z)$ and $h''(x, 0^k 1z)$ maps to z. In the latter case, $f(x)$ maps to z by the definition of f''. In the former case, $V(x, b(x))$ must output $1z$, and thus $f(x)$ maps to z. □

Selman [15] showed that $\mathrm{PF}^{\mathrm{NP}[\log]} \neq \mathrm{PF}_{tt}^{\mathrm{NP}}$ unless P = FewP and R = NP.[2] The next two theorems are interesting because they imply that (i) composing on the left with NPMV is enough to absorb the difference between the two reduction classes and (ii) the NPMV analogue of Selman's result is *false*.

THEOREM 3.4. *For each* $k \geq 1$, $\mathrm{NPMV} \circ \mathrm{PF}^{\mathrm{NP}[k]} = \mathrm{NPMV} \circ \mathrm{PF}_{tt}^{\mathrm{NP}[2^k-1]}$.

Proof. $\mathrm{NPMV} \circ \mathrm{PF}^{\mathrm{NP}[k]} \subseteq \mathrm{NPMV} \circ \mathrm{PF}_{tt}^{\mathrm{NP}[2^k-1]}$ follows immediately from $\mathrm{PF}^{\mathrm{NP}[k]} \subseteq \mathrm{PF}_{tt}^{\mathrm{NP}[2^k-1]}$ [2]. (Recall the comment that follows Proposition 2.3.)

Now we show $\mathrm{NPMV} \circ \mathrm{PF}_{tt}^{\mathrm{NP}[2^k-1]} \subseteq \mathrm{NPMV} \circ \mathrm{PF}^{\mathrm{NP}[k]}$. Let $f = g \circ h \in \mathrm{NPMV} \circ \mathrm{PF}_{tt}^{\mathrm{NP}[2^k-1]}$ with $g \in \mathrm{NPMV}$ and $h \in \mathrm{PF}_{tt}^{\mathrm{NP}[2^k-1]}$. Let $g \in \mathrm{NPMV}$ via a nondeterministic Turing machine N and let h' be a single-valued refinement of h that is computed by a deterministic oracle Turing-machine transducer M with oracle $A \in \mathrm{NP}$. Define s to be a function that maps x to the number of queries in A that M

[2] Actually, it was shown there that $\mathrm{PF}^{\mathrm{NP}[\log]}/_{sv} \neq \mathrm{PF}_{tt}^{\mathrm{NP}}/_{sv}$ unless P = FewP and R = NP, but the two forms of the statement are equivalent by Proposition 2.3. This result also follows by directly modifying a proof of Beigel [1, Theorem 9].

makes on input x. s is a total, single-valued function. Define $B = \{\langle x, n\rangle \mid s(x) \geq n\}$. Clearly B belongs to NP. Since s is total and $0 \leq s(x) \leq 2^k - 1$, a binary search algorithm over $\{1, \ldots, 2^k - 1\}$ computes s in polynomial time with oracle B. The number of queries is exactly k, so $s \in \mathrm{PF}^{\mathrm{NP}[k]}$. Define s' to be a multivalued function that maps x to $\langle x, n\rangle$ if and only if either

1. $n = s(x)$, or
2. $n = 2^k + w$ for some w such that $h(x)$ maps to w.

Clearly, s' has a refinement in $\mathrm{PF}^{\mathrm{NP}[k]}$, so $s' \in \mathrm{PF}^{\mathrm{NP}[k]}$ by Proposition 2.2.

Let $A \in \mathrm{NP}$ be witnessed by a machine D and define E to be the machine that on input $\langle x, n\rangle$ behaves as follows:

(1) If $n \geq 2^k$, then E sets $w = n - 2^k$ and goes to step (6).
(2) E computes the set Q of all query strings of M on x.
(3) E nondeterministically guesses $R \subseteq Q$ of size n.
(4) For each $y \in R$, E simulates D on y. If D on y does not accept for some $y \in R$, then E halts without accepting.
(5) E simulates M on x answering a query $q \in Q$ affirmatively if and only if $q \in R$. If M halts without accepting, so does E. Otherwise (M has an output), E computes the output w.
(6) E simulates N on w. If N outputs a string z, then so does E, and if it does not accept, then E halts without accepting.

Let $t \in \mathrm{NPMV}$ denote the partial multivalued function that E computes. We fix x and z in what follows. Suppose $f(x)$ maps to z. Then by definition there is a w such that $h(x) \mapsto w$ and $g(w) \mapsto z$, but in this case we know that $s'(x) \mapsto \langle x, 2^k + w\rangle$ and $t(x, 2^k + w)$ simulates N on w so $t(x, 2^k + w)$ maps to z. Thus $t \circ s'$ maps x to z.

Conversely, suppose $s'(x)$ maps to some $\langle x, n\rangle$ and $t(x, n)$ maps to z. If $n \geq 2^k$, then it must be that both $n = 2^k + w$ such that $h(x) \mapsto w$, and $g(w)$ maps to z ($t(x, n)$ just simulates N on $w = n - 2^k$). Thus $f(x)$ maps to z in this case. If $n \leq 2^k - 1$, then $n = s(x)$. We have $t(x, s(x)) \mapsto z$ if and only if there exist w and a set $R \subseteq A$ consisting of $s(x)$ query strings of M on x such that (i) given affirmative answers to all strings in R and negative answers to all strings in $Q - R$, M on x computes w and (ii) N on w outputs z on some computation path. Since $s(x)$ is exactly the number of query strings in A, $t(x, s(x)) = g(h'(x))$. Since $g \circ h'$ is a refinement of f, if $t(x, s(x))$ maps to z, then $f(x)$ maps to z.

Therefore, $f = t \circ s' \in \mathrm{NPMV} \circ \mathrm{PF}^{\mathrm{NP}[k]}$. □

Remark. If we restrict s' in the above proof so that $s'(x)$ only maps to $\langle x, s(x)\rangle$, then s' is single-valued and $t \circ s'$ is a refinement of f. This shows that $\mathrm{NPMV} \circ \mathrm{PF}_{tt}^{\mathrm{NP}[2^k-1]} \subseteq_c \mathrm{NPMV} \circ (\mathrm{PF}^{\mathrm{NP}[k]}/_{sv})$.

The left-to-right inclusion in the next theorem is completely analogous with the NP case, given by Beigel [2].

THEOREM 3.5. *For every $k \geq 1$, $\mathrm{PF}^{\mathrm{NPMV}[k]} = \mathrm{PF}_{tt}^{\mathrm{NPMV}[2^k-1]}$.*

Proof. Let $f \in \mathrm{PF}^{\mathrm{NPMV}[k]}$ be computed by a deterministic oracle Turing-machine transducer M with $g \in \mathrm{NPMV}$ as the oracle. Let $h = s[M, g]$ in Proposition 3.1. Define D to be the machine with oracle h that on input x behaves as follows:

(1) D deterministically computes $w(0^k) = h(x, 0^k)$.
(2) For each $a \in \Sigma^k - \{0^k\}$, D sets $w(a)$ to the answer to $h(x, a)$. The number of queries to h is $2^k - 1$.
(3) D sets b to the largest a such that $w(a) \neq \perp$.
(4) If $w(b) = 0$, then D rejects x, and if $w(b) = 1y$ for some y, then D outputs y.

By Proposition 3.1, for every x, $D(x)$ rejects if and only if $x \notin dom(f)$, and if $D(x)$ outputs y, then $f(x) \mapsto y$. So D computes a refinement of f. Thus $f \in \mathrm{PF}_{tt}^{\mathrm{NPMV}[2^k-1]}$. This proves that $\mathrm{PF}^{\mathrm{NPMV}[k]} \subseteq \mathrm{PF}_{tt}^{\mathrm{NPMV}[2^k-1]}$.

Now let $f \in \mathrm{PF}_{tt}^{\mathrm{NPMV}[2^k-1]}$ be computed by a deterministic oracle Turing machine transducer M with $g \in \mathrm{NPMV}$ as the oracle. Let $h = s[M, g]$ in Proposition 3.2. Define D to be the machine with oracle h that on input x behaves as follows:

(1) D deterministically computes $w(0) = h(x, 0)$.

(2) By using a binary search over $[1, 2^k - 1]$ with oracle h, D computes $m = \max\{n \in \{0, \ldots, 2^k - 1\} \mid h(x, n) \text{ has an output}\}$. While doing this, D keeps the answers obtained from the oracle and sets $w(m)$ to the answer to $h(x, m)$.

(3) If $w(m) = 0$, then D rejects x, and if $w(m) = 1y$ for some y, then D outputs y.

By Proposition 3.2, for every x, $D(x)$ rejects if and only if $x \notin dom(f)$, and if $D(x)$ outputs y, then $f(x) \mapsto y$. So D computes a refinement of f. Since the number of queries to h is k, we have $f \in \mathrm{PF}^{\mathrm{NPMV}[k]}$. Thus $\mathrm{PF}_{tt}^{\mathrm{NPMV}[2^k-1]} \subseteq \mathrm{PF}^{\mathrm{NPMV}[k]}$, which proves the theorem. □

The above theorems yield the following corollary.

COROLLARY 3.6. *For every $k \geq 1$, $\mathrm{PF}^{\mathrm{NPMV}[k]} = \mathrm{PF}_{tt}^{\mathrm{NPMV}[2^k-1]} \subseteq_c \mathrm{NPMV} \circ (\mathrm{PF}^{\mathrm{NP}[k]}/_{sv}) \subseteq \mathrm{PF}^{\mathrm{NPMV}[k+1]} = \mathrm{PF}_{tt}^{\mathrm{NPMV}[2^{k+1}-1]}$.*

By Proposition 2.2, $\mathrm{PF}^{\mathrm{NPMV}[k]} \subseteq \mathrm{PF}^{\mathrm{NPMV}[k+1]}$. For general bounded query classes, it is not known whether $\mathrm{PF}^{\mathrm{NPMV}[k]} \subseteq \mathrm{PF}^{\mathrm{NP}[k]}$. But for reduction classes of sets, this type of equivalence holds.

THEOREM 3.7. *For every $k \geq 1$, $\mathrm{P}^{\mathrm{NPMV}[k]} = \mathrm{P}^{\mathrm{NP}[k]}$.*

Proof. Let $k \geq 1$. It suffices to show that $\mathrm{P}^{\mathrm{NPMV}[k]} \subseteq \mathrm{P}^{\mathrm{NP}[k]}$. Let $A \in \mathrm{P}^{\mathrm{NPMV}[k]}$. Then $f = \chi_A$ is in $\mathrm{PF}^{\mathrm{NPMV}[k]}$. Let M and $g \in \mathrm{NPMV}$ be a machine and a partial multivalued function witnessing this property, respectively. Informally, we will show that $f \in \mathrm{P}^{\mathrm{NP}[k]}$ by using Proposition 3.1 to compute f. Namely, by letting $h = s[M, g]$ be the NPMV function given in Proposition 3.1 and letting a_x be the largest a in Σ^k such that $h(x, a)$ is defined, we will show that k queries to an NP oracle suffice both to find a_x and to compute $h(x, a_x) = 1f(x)$. Assume without loss of generality that M always outputs exactly one bit for all oracles. For simplicity, we fix x in the following discussion.

Let a_x be the largest $a \in \Sigma^k$ such that $h(x, a)$ is defined. The function $\lambda x.[h(x, a_x)]$ is total and single-valued, $x \in A$ if and only if $h(x, a_x) = 11$, and $x \notin A$ if and only if $h(x, a_x) = 10$. Let $b \in \Sigma$ such that $1b = h(x, 0^k)$ and ρ_x be the largest $r \in \Sigma^{k-1}$ such that either $h(x, r0)$ or $h(x, r1)$ maps to $1b$. It is not hard to see that $h(x, a_x) = 1b$ if and only if

(a) for every $a > \rho_x 1$, $h(x, a)$ maps to neither 10 nor 11, and

(b) $h(x, \rho_x 1)$ does not map to $1b'$, where $b' = 1$ if $b = 0$ and 0 otherwise.

Since $\rho_x \geq 0^{k-1}$ and $graph(h) \in \mathrm{NP}$, it is easy to see that ρ_x is computed by making $k-1$ questions to an NP oracle: we perform a binary search over Σ^{k-1} in order to find the largest $r \in \Sigma^{k-1}$ such that either $h(x, r0) \mapsto 1b$ or $h(x, r1) \mapsto 1b$. After ρ_x is found, conditions (a) and (b) can be tested by a single question to an NP oracle. Therefore, by making k queries to an NP oracle, $h(x, a_x)$ is computed. Since $h(x, a_x) = 11$ if and only if $x \in A$, this implies that $A \in \mathrm{P}^{\mathrm{NP}[k]}$. This proves the theorem. □

Note that Theorem 3.7 holds even if k is replaced by any polynomially bounded function. This means, remarkably, that in *any* polynomial-time computation of a set

relative to NPMV, the queries to NPMV can be replaced one for one with queries to NP.

THEOREM 3.8. *For every* $k \geq 1$, $\mathrm{P}_{tt}^{\mathrm{NPMV}[k]} = \mathrm{P}_{tt}^{\mathrm{NP}[k]}$.

Proof. Let $k \geq 1$. It suffices to show that $\mathrm{P}_{tt}^{\mathrm{NPMV}[k]} \subseteq \mathrm{P}_{tt}^{\mathrm{NP}[k]}$. Let $A \in \mathrm{P}_{tt}^{\mathrm{NPMV}[k]}$. Then $f = \chi_A$ is in $\mathrm{PF}_{tt}^{\mathrm{NPMV}[k]}$. Let M and $g \in \mathrm{NPMV}$ be a machine and a partial multivalued function witnessing this property, respectively. We assume without loss of generality that M outputs 0 or 1 for all oracles and inputs. We will use Proposition 3.2 to compute f. Namely, we let $h = s[M, g]$ be the NPMV function given in Proposition 3.2, and fixing an input x, we let n_x be the largest n in $\{0, \ldots, k\}$ such that $h(x, n)$ is defined. We will show that k nonadaptive queries to an NP oracle suffice to compute $h(x, n_x) = 1f(x)$. The informal idea of the proof is as follows: we first compute b, the output of $M(x)$ where all query answers are $\perp$. Then we use nonadaptive NP queries to inspect sequences of query answers to $M(x)$ which are *plausible*, i.e., where all non-$\perp$ answers are verifiably legitimate outputs of the oracle function but where each $\perp$ answer may or may not be correct. We look for m, the largest number of non-$\perp$ query answers in any plausible sequence of query answers where M outputs b. Actually, computing m exacty uses all our allotted NP queries without telling us the real output of M, so instead we only compute which of the pairs $\{2i, 2i+1\}$ m belongs to. This uses only about $k/2$ nonadaptive queries. Simultaneously, for each pair $\{2i, 2i+1\}$, we ask NP if *either* there is any plausible sequence with more than $2i+1$ non-$\perp$ answers *or* M outputs $1-b$ for some plausible sequence containing exactly $2i+1$ non-$\perp$ answers. The answer to this NP question for the pair containing m immediately tells us whether M outputs b or $1-b$ for any correct sequence of query answers. This uses up the remaining $k/2$ NP queries.

We now present an exact version of the sketch above, showing that $f \in \mathrm{P}_{tt}^{\mathrm{NP}[k]}$. Note that the value of $h(x, 0)$ encodes the output of $M(x)$ with all queries answered with $\perp$, and $h(x, n)$ for $n > 0$ simply encodes the possible outputs of $M(x)$ over all plausible sequences of queries with at least n non-$\perp$ answers. Also, n_x is the exact number of non-$\perp$ entries in any sequence of correct query answers. We are assuming that M outputs exactly one bit for all possible sets of query answers, so h outputs nothing but 10 or 11.

By Proposition 3.2, $\lambda x.[h(x, n_x)]$ is total and single-valued, $x \in A$ if and only if $h(x, n_x) = 11$, and $x \notin A$ if and only if $h(x, n_x) = 10$. Let $b \in \Sigma$ be such that $1b = h(x, 0)$, and $d = \lfloor k/2 \rfloor$. Define two predicates S and T as follows:

$S(x, r)$ if and only if either $h(x, 2r)$ or $h(x, 2r+1)$ maps to $1b$.

$T(x, r)$ if and only if

- $h(x, n)$ is defined for some $n > 2r+1$, or
- $h(x, 2r+1)$ maps to $1b'$, where $b' = 1 - b$.

Note that S and T are NP-predicates, $S(x, 0) = \mathit{true}$, and if k is even, then $T(x, d) = \mathit{false}$. Define ρ_x to be the largest $r \in \{0, \ldots, d\}$ such that $S(x, r) = \mathit{true}$. It is not hard to see that $h(x, n_x) = 1b$ if and only if $T(x, \rho_x) = \mathit{false}$.

Our goal is to compute $h(x, n_x)$ without making more than k queries to some NP oracle. Our method to accomplish this is to partition the domain $\{0, \ldots, k\}$ into successive pairs. For each pair $\{2r, 2r+1\}$, we make two queries of the form "$S(x, r) = \mathit{true}$?" and "$T(x, r) = \mathit{true}$?". As observed above, $S(x, 0) = \mathit{true}$, and if k is even, $T(x, d) = \mathit{false}$. So we need exactly k queries to S or T. Since S and T are NP-predicates, a single set in NP can answer both types of questions. Thus by making k nonadaptive queries to an NP oracle, we determine whether $h(x, n_x) = 1b$ or not. Since $h(x, n_x) = 11$ if and only if $x \in A$, this implies that $A \in \mathrm{P}_{tt}^{\mathrm{NP}[k]}$. This

proves the theorem. □

Our next goal is to show that bounded query hierarchies probably do not collapse.

LEMMA 3.9. *Let $k \geq 1$. If $\mathrm{PF}^{\mathrm{NPMV}[k+1]} = \mathrm{PF}^{\mathrm{NPMV}[k]}$, then for every $\ell \geq k$, $\mathrm{PF}^{\mathrm{NPMV}[\ell]} = \mathrm{PF}^{\mathrm{NPMV}[k]}$.*

Proof. Let k be as in the hypothesis, let $m \geq 0$, and let $f \in \mathrm{PF}^{\mathrm{NPMV}[k+1+m]}$ be computed by a deterministic oracle Turing-machine transducer M with $g \in \mathrm{NPMV}$ as the oracle. We will show that $f \in \mathrm{PF}^{\mathrm{NPMV}[k+m]}$.

Let N be an oracle transducer that on input x with oracle g outputs an ID of M on x just after obtaining the answer to its mth query to g. Clearly, N makes at most m queries to g, and if g is single-valued, then $N[g]$ is total and single-valued. Define D to be the machine such that, given an ID I of M, (1) D attempts to simulate the computation of M starting from ID I by making at most $k+1$ queries to its oracle, and (2) if M halts without an output, then so does D and if M outputs a string y, then so does D.

It is not hard to see that D with oracle g defines a function r such that for every x and single-valued refinement g' of g, $f(x)$ is defined if and only if r maps the ID $N[g'](x)$ to some output y. And if the latter holds, then $f(x)$ also maps to y. Moreover, it is clear that $r \in \mathrm{PF}^{\mathrm{NPMV}[k+1]} = \mathrm{PF}^{\mathrm{NPMV}[k]}$; thus there is an oracle transducer Q such that for every single-valued refinement g' of g, $Q[g']$ computes a refinement of r making only k queries to g'. Now we combine the machines N and Q by taking the output of N as the input to Q. The resulting machine with oracle g' computes a refinement of f and makes at most $k+m$ queries to g'. Thus $f \in \mathrm{PF}^{\mathrm{NPMV}[k+m]}$ by Proposition 2.2.

By applying this argument repeatedly, we have $\mathrm{PF}^{\mathrm{NPMV}[\ell]} = \mathrm{PF}^{\mathrm{NPMV}[k]}$ for every $\ell \geq k$. □

LEMMA 3.10. *Let $k \geq 1$. If $\mathrm{PF}_{tt}^{\mathrm{NPMV}[k+1]} = \mathrm{PF}_{tt}^{\mathrm{NPMV}[k]}$, then for every $\ell \geq k$, $\mathrm{PF}_{tt}^{\mathrm{NPMV}[\ell]} = \mathrm{PF}_{tt}^{\mathrm{NPMV}[k]}$.*

Proof. Let $k \geq 1$ and suppose that $\mathrm{PF}_{tt}^{\mathrm{NPMV}[k+1]} = \mathrm{PF}_{tt}^{\mathrm{NPMV}[k]}$. Let $m \geq 0$ and $f \in \mathrm{PF}_{tt}^{\mathrm{NPMV}[k+1+m]}$. We will show that $f \in \mathrm{PF}_{tt}^{\mathrm{NPMV}[k+m]}$. By applying the argument repeatedly, for every $\ell \geq k$, we have $\mathrm{PF}_{tt}^{\mathrm{NPMV}[\ell]} = \mathrm{PF}_{tt}^{\mathrm{NPMV}[k]}$.

Let $f \in \mathrm{PF}_{tt}^{\mathrm{NPMV}[k+1+m]}$ be computed by a deterministic oracle Turing-machine transducer M with $g \in \mathrm{NPMV}$ as the oracle. For x, let $q_1(x), \ldots, q_{k+1+m}(x)$ denote the queries of M on x. Define c to be the function that maps x to $(y_1, \ldots, y_{k+1})$ so that for every $i, 1 \leq i \leq k+1$, y_i is a value of $g(q_i(x))$ if $q_i(x) \in \mathit{dom}(g)$ and $y_i = \perp$ otherwise. Obviously, $c \in \mathrm{PF}_{tt}^{\mathrm{NPMV}[k+1]}$, so by our supposition, $c \in \mathrm{PF}_{tt}^{\mathrm{NPMV}[k]}$. Let c be computed by a deterministic oracle Turing-machine transducer N with $h \in \mathrm{NPMV}$ as the oracle. Then we can easily construct a machine that computes f by making k queries to h and m queries to g. Therefore, $f \in \mathrm{PF}_{tt}^{\mathrm{NPMV}[k+m]}$. This proves the lemma. □

The Boolean hierarchy over NP is defined by Wagner and Wechsung [19] and has been studied extensively [6, 7, 8, 12]. We denote the kth level of the Boolean hierarchy as $\mathrm{NP}(k)$. By definition,

1. $\mathrm{NP}(1) = \mathrm{NP}$, and
2. for every $k \geq 2$, $\mathrm{NP}(k) = \mathrm{NP} - \mathrm{NP}(k-1)$.

The Boolean hierarchy over NP, denoted by BH, is the union of all $\mathrm{NP}(k)$, $k \geq 1$.

Kadin [12] proved that the Boolean hierarchy collapses only if the polynomial-time hierarchy collapses.

THEOREM 3.11. *Let $k \geq 1$. If $\mathrm{PF}^{\mathrm{NPMV}[k+1]} = \mathrm{PF}^{\mathrm{NPMV}[k]}$, then* BH *collapses to*

its 2^kth level.

Proof. Suppose that $\mathrm{PF}^{\mathrm{NPMV}[k+1]} = \mathrm{PF}^{\mathrm{NPMV}[k]}$. By Lemma 3.9 and Theorem 3.5, for every $m > k$, $\mathrm{PF}^{\mathrm{NPMV}[m]} \subseteq \mathrm{PF}^{\mathrm{NPMV}[k]} = \mathrm{PF}_{tt}^{\mathrm{NPMV}[2^k-1]}$. So by Theorem 3.7 and results by Köbler, Schöning, and Wagner [14], we have, for every $m > k$, $\mathrm{P}^{\mathrm{NP}[m]} = \mathrm{P}_{tt}^{\mathrm{NP}[2^k-1]} \subseteq \mathrm{NP}(2^k)$. Thus $\mathrm{BH} = \mathrm{NP}(2^k)$. □

The following theorem is proved in a similar manner.

THEOREM 3.12. *Let $k \geq 1$. If $\mathrm{PF}_{tt}^{\mathrm{NPMV}[k+1]} = \mathrm{PF}_{tt}^{\mathrm{NPMV}[k]}$, then* BH *collapses to its $(k+1)$st level.*

Proof. Suppose that $\mathrm{PF}_{tt}^{\mathrm{NPMV}[k+1]} = \mathrm{PF}_{tt}^{\mathrm{NPMV}[k]}$. By Lemma 3.10, for every $m > k$, $\mathrm{PF}_{tt}^{\mathrm{NPMV}[m]} \subseteq \mathrm{PF}_{tt}^{\mathrm{NPMV}[k]}$. So by Theorem 3.8 and results by Köbler, Schöning, and Wagner [14], we have, for every $m > k$, $\mathrm{P}_{tt}^{\mathrm{NP}[m]} = \mathrm{P}_{tt}^{\mathrm{NP}[k]} \subseteq \mathrm{NP}(k+1)$. Thus $\mathrm{BH} = \mathrm{NP}(k+1)$. □

Analogous to the theorems stated so far, the following theorems hold for reduction classes that make logarithmic many queries to partial functions in NPMV. We see in these theorems a different behavior when computing partial multivalued functions with bounded queries to NPMV than when computing partial functions with bounded queries to NP. To wit, in contrast to the following results, Selman [15] shows that $\mathrm{PF}^{\mathrm{NP}[\log]} = \mathrm{PF}_{tt}^{\mathrm{NP}}$ only if P = FewP and R = NP. The reason seems to be, as we showed in Theorems 3.3 and 3.5, that the mind-change argument [2, 19] works for $\mathrm{PF}^{\mathrm{NPMV}}$ (as it does for P^{NP}) but apparently does not work for $\mathrm{PF}^{\mathrm{NP}}$.

THEOREM 3.13.

1. $\mathrm{PF}^{\mathrm{NPMV}[\log]} = \mathrm{PF}_{tt}^{\mathrm{NPMV}} \subseteq \mathrm{NPMV} \circ \mathrm{PF}^{\mathrm{NP}[\log]} = \mathrm{NPMV} \circ \mathrm{PF}_{tt}^{\mathrm{NP}}$.
2. $\mathrm{NPMV} \circ (\mathrm{PF}^{\mathrm{NP}[\log]}/_{sv}) \subseteq \mathrm{PF}^{\mathrm{NPMV}[\log]}$.
3. $\mathrm{PF}^{\mathrm{NPMV}[\log]} \subseteq_c \mathrm{NPMV} \circ (\mathrm{PF}^{\mathrm{NP}[\log]}/_{sv})$.
4. $\mathrm{NPMV} \circ (\mathrm{PF}^{\mathrm{NP}[\log]}/_{sv}) \subseteq \mathrm{NPMV} \circ (\mathrm{PF}_{tt}^{\mathrm{NP}}/_{sv})$.
5. $\mathrm{NPMV} \circ (\mathrm{PF}_{tt}^{\mathrm{NP}}/_{sv}) \subseteq_c \mathrm{NPMV} \circ (\mathrm{PF}^{\mathrm{NP}[\log]}/_{sv})$.

Proof. Note that for any function t such that $t(x) \leq c \log |x|$, $2^{t(x)} - 1$ is polynomially bounded and that for any polynomial p, $\log p(|x|) \leq c \log |x|$ for some constant c. Therefore, a proof similar to that of Theorem 3.5 shows that $\mathrm{PF}^{\mathrm{NPMV}[\log]} = \mathrm{PF}_{tt}^{\mathrm{NPMV}}$, and a proof similar to Theorem 3.3(2) shows that $\mathrm{PF}^{\mathrm{NPMV}[\log]} \subseteq \mathrm{NPMV} \circ \mathrm{PF}^{\mathrm{NP}[\log]}$. A proof similar to that of Theorem 3.4 yields $\mathrm{NPMV} \circ \mathrm{PF}^{\mathrm{NP}[\log]} = \mathrm{NPMV} \circ \mathrm{PF}_{tt}^{\mathrm{NP}}$. Thus (1) holds.

Inclusion (2) follows by a straightforward simulation, and (3) follows by adapting the proof of Theorem 3.3(1). Using a technique of Buss and Hay [4], for any set A, logarithmically many adaptive queries to A can be simulated by polynomially many nonadaptive queries to A, so $\mathrm{PF}^{\mathrm{NP}[\log]}/_{sv} \subseteq \mathrm{PF}_{tt}^{\mathrm{NP}}/_{sv}$. Thus $\mathrm{NPMV} \circ (\mathrm{PF}^{\mathrm{NP}[\log]}/_{sv}) \subseteq \mathrm{NPMV} \circ (\mathrm{PF}_{tt}^{\mathrm{NP}}/_{sv})$. Hence (4) holds. Inclusion (5) follows by adapting the remark following the proof of Theorem 3.4. □

THEOREM 3.14. $\mathrm{P}^{\mathrm{NPMV}[\log]} = \mathrm{P}_{tt}^{\mathrm{NPMV}} = \mathrm{P}^{\mathrm{NP}[\log]} = \mathrm{P}_{tt}^{\mathrm{NP}}$.

The proof is similar to those of Theorems 3.7 and 3.8.

4. Nondeterministic polynomial-time reductions. We define nondeterministic reductions between partial functions so that the access mechanism is identical to that for deterministic reductions. Namely, let g be a single-valued partial function and N be a polynomial-time nondeterministic oracle Turing machine. $N[g]$ denotes a multivalued partial function computed by N with oracle g in accordance with the following mechanism:

- when N asks about $y \in dom(g)$, g returns $g(y)$, and

- when N asks about $y \notin dom(g)$, g answers a special symbol $\perp$.

DEFINITION 4.1. *Let f and g be partial multivalued functions. We say that f* is nondeterministic polynomial-time Turing reducible to *g, denoted by $f \leq_{\mathrm{T}}^{\mathrm{NP}} g$, if there is a polynomial-time nondeterministic Turing machine N such that for every single-valued refinement g' of g, $N[g']$ is a refinement of f.*

Thus for every x and for every single-valued refinement g' of g,

- $x \in dom(f)$ if and only if $x \in dom(N[g'])$, and
- if $N[g']$ maps x to y, then f maps x to y.

Let $\mathcal{F}$ be a class of partial multivalued functions. $\mathrm{NPMV}^{\mathcal{F}}$ denotes the class of partial multivalued functions that are $\leq_{\mathrm{T}}^{\mathrm{NP}}$-reducible to some $g \in \mathcal{F}$. $\mathrm{NPMV}^{\mathcal{F}[k]}$ denotes the class of partial multivalued functions that are $\leq_{\mathrm{T}}^{\mathrm{NP}}$-reducible to some $g \in \mathcal{F}$ via a machine that makes k adaptive queries to its oracle.

For a class of sets $\mathcal{C}$, we write $\mathrm{NPMV}^{\mathcal{C}}$ to denote the class of multivalued partial functions that are computed by a nondeterministic Turing machine relative to an oracle in $\mathcal{C}$. $\mathrm{NPMV}^{\mathcal{C}[k]}$ is defined similarly.

It is easy to see that every nondeterministic polynomial-time reduction to partial functions is replaceable by a reduction that makes nonadaptive queries to its oracle and that preserves the number of queries. For this reason, we do not distinguish classes $\mathrm{NPMV}_{tt}^{\mathcal{F}}$ or $\mathrm{NPMV}_{tt}^{\mathcal{F}[k]}$.

For $k \geq 1$, $\Sigma\mathrm{MV}_k$ denotes $\underbrace{\mathrm{NPMV}^{\cdots^{\mathrm{NPMV}}}}_{k}$.

LEMMA 4.1. *For every $k \geq 1$, $\Sigma\mathrm{MV}_k = \mathrm{NPMV}^{\Sigma_{k-1}^{\mathrm{P}}[1]}$ and for every $f \in \Sigma\mathrm{MV}_k$, $dom(f) \in \Sigma_k^{\mathrm{P}}$.*

Proof. The proof is by an induction on k. The statement trivially holds for $k = 1$. Let $k = 2$. We show that $\mathrm{NPMV}^{\mathrm{NPMV}} \subseteq \mathrm{NPMV}^{\mathrm{NP}[1]}$. Let $f \in \mathrm{NPMV}^{\mathrm{NPMV}}$ via a machine M and a function $g \in \mathrm{NPMV}$. Let N be a machine witnessing $g \in \mathrm{NPMV}$. Define A to be the set of all $(y_1, \ldots, y_m)$, $m \geq 1$, such that $y_1, \ldots, y_m \notin dom(g)$. Obviously, $A \in$ co-NP. Consider a nondeterministic Turing machine T that on input x simulates M on x in the following way:

- When M queries about string w, T simulates N on w. If N on w outputs a string z, then T assumes that the answer from the oracle is z and if N on w does not accept, then T assumes that the answer from the oracle is $\perp$.
- When M enters a halting state, T enumerates all the queries w for which the answer from the oracle are assumed to be $\perp$. T sets $y_1, \ldots, y_m$ to the enumeration.
  - —If $(y_1, \ldots, y_m) \notin A$, then T rejects,
  - —if $(y_1, \ldots, y_m) \in A$ and M rejects, then T rejects, and
  - —if $(y_1, \ldots, y_m) \in A$ and M outputs some string z, then T outputs z.

It is not hard to see that for every x and z, $f(x)$ maps to z if and only if there is a computation of M relative to g that outputs z if and only if there is a computation of T relative to A that outputs z. Thus T relative to A computes a refinement of f. Furthermore, T is polynomial-time bounded and T makes only one question to A. So $f \in \mathrm{NPMV}^{\mathrm{NP}[1]}$. Thus $\mathrm{NPMV}^{\mathrm{NPMV}} = \mathrm{NPMV}^{\mathrm{NP}[1]}$. Moreover, by the above discussions, for every function $f \in \mathrm{NPMV}^{\mathrm{NPMV}}$, $dom(f) \in \Sigma_2^{\mathrm{P}}$.

Now let $k \geq 2$ and suppose that the claim holds for every $k' \leq k$. Since the above proof is relativizable, for any class $\mathcal{C}$ of sets, we have $\mathrm{NPMV}^{\mathrm{NPMV}^{\mathcal{C}}} \subseteq \mathrm{NPMV}^{\mathrm{NP}^{\mathcal{C}}[1]}$. So $\mathrm{NPMV}^{\Sigma\mathrm{MV}_k} = \mathrm{NPMV}^{\mathrm{NPMV}^{\Sigma_{k-1}^{\mathrm{P}}[1]}}$ (by induction hypothesis) $\subseteq \mathrm{NPMV}^{\mathrm{NPMV}^{\Sigma_{k-1}^{\mathrm{P}}}} \subseteq$

$\mathrm{NPMV}^{\mathrm{NP}^{\Sigma_{k-1}^{\mathrm{P}}}[1]} = \mathrm{NPMV}^{\Sigma_k^{\mathrm{P}}[1]}$. This proves the lemma. □

This lemma yields the following theorem.

THEOREM 4.2. *Let f be a partial multivalued function. For every $k \geq 1$, the following statements are equivalent:*

(i) *f is in $\Sigma\mathrm{MV}_k$;*

(ii) *f has a polynomially length-bounded refinement g such that $dom(g) \in \Sigma_k^{\mathrm{P}}$, and $graph(g) \in \Sigma_k^{\mathrm{P}}$;*

(iii) *f has a polynomial length-bounded refinement g such that $graph(g) \in \Sigma_k^{\mathrm{P}}$.*

THEOREM 4.3. *For every $k \geq 1$, $\Sigma\mathrm{MV}_{k+1} = \Sigma\mathrm{MV}_k$ if and only if $\Sigma_{k+1}^{\mathrm{P}} = \Sigma_k^{\mathrm{P}}$.*

Proof. First, suppose that $\Sigma_{k+1}^{\mathrm{P}} = \Sigma_k^{\mathrm{P}}$. Let f be any function in $\Sigma\mathrm{MV}_{k+1}$. By Theorem 4.2(ii), there is a polynomially length-bounded refinement g of f such that $dom(g), graph(g) \in \Sigma_{k+1}^{\mathrm{P}}$, so by our supposition, $dom(g), graph(g) \in \Sigma_k^{\mathrm{P}}$. Therefore, f is in $\Sigma\mathrm{MV}_k$. Hence $\Sigma\mathrm{MV}_{k+1} = \Sigma\mathrm{MV}_k$.

Next, suppose that $\Sigma\mathrm{MV}_{k+1} = \Sigma\mathrm{MV}_k$. Let A be $\leq_m^{\mathrm{P}}$-complete for $\Sigma_{k+1}^{\mathrm{P}}$. Define χ_A^0 to be the function that $\chi_A^0(x) = 1$ if $x \in A$ and undefined otherwise. Obviously, χ_A^0 is in $\Sigma\mathrm{MV}_{k+1}$, so by our supposition, $\chi_A^0 \in \Sigma\mathrm{MV}_k$. On the other hand, $dom(\chi_A^0) = A$. Thus we have $A \in \Sigma_k^{\mathrm{P}}$. Since A is complete for $\Sigma_{k+1}^{\mathrm{P}}$, we have $\Sigma_{k+1}^{\mathrm{P}} = \Sigma_k^{\mathrm{P}}$. □

Thus these classes form function analogues of the polynomial hierarchy, and, unless the polynomial hierarchy collapses, they form a proper hierarchy.

5. The difference hierarchy. Let $\mathcal{F}$ be a class of partial multivalued functions. A partial multivalued function f is in co$\mathcal{F}$ if there exist $g \in \mathcal{F}$ and a polynomial p such that for every x and y,

- $f(x)$ maps to y if and only if $|y| \leq p(|x|)$ and $g(x)$ does not map to y.

Let $\mathcal{F}$ and $\mathcal{G}$ be two classes of partial multivalued functions. A partial multivalued function h is in $\mathcal{F} \wedge \mathcal{G}$ if there exist partial multivalued functions $f \in \mathcal{F}$ and $g \in \mathcal{G}$ such that for every x and y,

- $h(x)$ maps to y if and only if $f(x)$ maps to y and $g(x)$ maps to y.

A partial multivalued function h is in $\mathcal{F} \vee \mathcal{G}$ if there exist partial multivalued functions $f \in \mathcal{F}$ and $g \in \mathcal{G}$ such that for every x and y,

- $h(x)$ maps to y if and only if $f(x)$ maps to y or $g(x)$ maps to y.

$\mathcal{F} - \mathcal{G}$ denotes $\mathcal{F} \wedge \mathrm{co}\mathcal{G}$.

NPMV(k) is the class of partial multivalued functions defined in the following way:

1. NPMV(1) = NPMV, and
2. for $k \geq 2$, NPMV(k) = NPMV − NPMV($k-1$).

LEMMA 5.1. *For every $k \geq 1$, $f \in \mathrm{NPMV}(k)$ if and only if f is polynomially length-bounded and $graph(f) \in \mathrm{NP}(k)$.*

Proof. The proof is by an induction on k. For $k = 1$, the claim trivially holds. Let $k \geq 2$ and suppose that the claim holds for all $k' < k$. Let $f \in \mathrm{NPMV}(k)$. There are functions $g \in \mathrm{NPMV}$ and $h \in \mathrm{NPMV}(k-1)$ such that for every x and y, f maps x to y if and only if g maps x to y but h does not map x to y. So $graph(f) = graph(g) - graph(h)$. By our hypothesis, $graph(h)$ belongs to NP($k-1$). Since $graph(g) \in \mathrm{NP}$, we have $graph(f) = \mathrm{NP}(k)$.

On the other hand, let f be a polynomially length-bounded function whose graph is in NP(k). There are sets $A \in \mathrm{NP}$ and $B \in \mathrm{NP}(k-1)$ such that $graph(f) = A - B$. Define g and h to be functions such that $graph(g) = A$ and $graph(h) = B$. By our hypothesis, $g \in \mathrm{NPMV}$ and $h \in \mathrm{NPMV}(k-1)$. Therefore, $f \in \mathrm{NPMV}(k)$. This proves the lemma. □

We use the above lemma to obtain the following theorem.

THEOREM 5.2. *For every* $k \geq 1$, $\mathrm{NPMV}(k+1) = \mathrm{NPMV}(k)$ *if and only if* $\mathrm{NP}(k+1) = \mathrm{NP}(k)$.

Despite the similarity in appearance, the difference hierarchy over NPMV is probably much stronger than both the difference hierarchy over NP and the bounded query hierarchy over NPMV. For example, it is well known that *maxsat* is complete for $\mathrm{PF}^{\mathrm{NP}} = \mathrm{PF}^{\mathrm{NPMV}}$ [13]. Nonetheless, we have the following.

PROPOSITION 5.3. $maxsat \in \mathrm{NPMV}(2)$.

Proof. Let $f \in \mathrm{NPMV}$ be the function that maps x to y if and only if there is a $z > y$ such that z is a satisfying assignment for x. Clearly, for all x, $maxsat(x) = y$ if and only if $sat(x)$ maps to y and $f(x)$ does not map to y. Therefore, $maxsat \in \mathrm{NPMV}(2)$. □

PROPOSITION 5.4. $\mathrm{co}(\text{co-NPMV}) = \mathrm{NPMV}$.

Proof. Let $f \in \mathrm{NPMV}$. Let p be a polynomial such that for every x and y, if $f(x)$ maps to y, then $|y| \leq p(|x|)$. Let g be the complement of f with respect to p such that for every x and y, $g(x)$ maps to y if and only if $f(x)$ does not map to y and $|y| \leq p(|x|)$. Furthermore, let h be the complement of g with respect to p such that for every x and y, $h(x)$ maps to y if and only if $g(x)$ does not map to y and $|y| \leq p(|x|)$. For every x and y, $h(x)$ maps to y if and only if $f(x)$ maps to y. This implies $h = f$. Therefore, $\mathrm{NPMV} \subseteq \mathrm{co}(\text{co-NPMV})$.

Conversely, let $f \in \mathrm{co}(\text{co-NPMV})$. There exist $g \in \text{co-NPMV}$ and a polynomial p such that for every x and y, $f(x)$ maps to y if and only if $g(x)$ does not map to y and $|y| \leq p(|x|)$. Moreover, since $g \in \text{co-NPMV}$, there exist $h \in \mathrm{NPMV}$ and a polynomial q such that for every x and y, $g(x)$ maps to y if and only if $h(x)$ does not map to y and $|y| \leq q(|x|)$. For every x and y, $f(x)$ maps to y if and only if either ($h(x)$ maps to y and $|y| \leq p(|x|)$) or ($q(|x|) < |y| \leq p(|x|)$). Let M be a nondeterministic Turing machine that computes h. Define N to be the machine that on input x (1) nondeterministically guesses $b \in \{0,1\}$, (2) if $b = 0$, then simulates M on input x and outputs y if M outputs y and $|y| \leq p(|x|)$, and (3) if $b = 1$, then nondeterministically guesses $y, q(|x|) < |y| \leq p(|x|)$ and outputs y. Clearly, N computes f. So $\mathrm{co}(\text{co-NPMV}) \subseteq \mathrm{NPMV}$. □

THEOREM 5.5. *The following statements are all equivalent.*

(a) NP = co-NP.
(b) NPMV ⊆ co-NPMV.
(c) co-NPMV ⊆ NPMV.

Proof. By Proposition 5.4, (b) is equivalent to (c). So it suffices to show that (a) is equivalent to (c). First, suppose that co-NPMV ⊆ NPMV. Define f to be the function that maps x to each of the three strings $\lambda, 0$, and 1 if $x \in \mathrm{SAT}$ and undefined otherwise. Obviously, $f \in \mathrm{NPMV}$. Let p be a polynomial such that $p(n) = 1$ for all n. By taking the complement of f with respect to p, we obtain a function $g \in \text{co-NPMV}$ that maps x to $\lambda, 0, 1$ if $x \notin \mathrm{SAT}$ and undefined otherwise. So $dom(g) = \overline{\mathrm{SAT}}$. Now by our supposition, we have $g \in \mathrm{NPMV}$, so $dom(g) \in \mathrm{NP}$. This implies $\overline{\mathrm{SAT}} \in \mathrm{NP}$, and thus NP = co-NP.

Conversely, suppose that NP = co-NP. Let $f \in \text{co-NPMV}$. There exist $g \in \mathrm{NPMV}$ and a polynomial p such that for every x and y, $f(x)$ maps to y if and only if $g(x)$ does not map to y and $|y| \leq p(|x|)$. The set of all (x, y) such that $g(x)$ does not map to y and $|y| \leq p(|x|)$ is in co-NP, so by our supposition, it is in NP. Thus $graph(f) \in \mathrm{NP}$, so $f \in \mathrm{NPMV}$. Hence co-NPMV ⊆ NPMV. □

Define a function f to be NPMV-*low* if $\mathrm{NPMV}^f \subseteq_c \mathrm{NPMV}$.

THEOREM 5.6. *A function f is* NPMV*-low if and only if $f \in_c$ NPMV with $dom(f) \in$ NP $\cap$ co-NP.*

Proof. Let f be NPMV-low. Since $f \in \text{NPMV}^f$ and $\text{NPMV}^f \subseteq_c$ NPMV, $f \in_c$ NPMV. So $dom(f) \in$ NP. Let $A = \overline{dom(f)}$. We wish to show that A belongs to NP. Define M to be a machine that on input x queries $f(x)$ and outputs 1 if $f(x) = \perp$ and 0 otherwise. The function h that M computes is the characteristic function of A. Since f is NPMV-low and h is single-valued, $h \in$ NPMV, so $A \in$ NP.

Conversely, let $f \in_c$ NPMV with $dom(f) \in \text{NP} \bigcap \text{co-NP}$. Define A to be the set of all $(y_1, \ldots, y_m), m \geq 1$, such that $y_1, \ldots, y_m \notin dom(f)$. By our supposition, $A \in \text{NP} \bigcap \text{co-NP}$. Let $g \in \text{NPMV}^f$ via a machine M. By the proof of Lemma 4.1, there is a polynomial-time nondeterministic Turing machine N that computes a refinement of g by making at most one query to A per computation path. Since $A \in \text{NP} \bigcap \text{co-NP}$, the query to A can be simulated nondeterministically. So $g \in_c$ NPMV. Therefore, f is NPMV-low. □

PROPOSITION 5.7. *For every $k \geq 1$ and $f \in \text{NPMV}(k)$, $dom(f) \in \Sigma_2^{\text{P}}$.*

Proof. By Lemma 5.1, f is polynomially length bounded and $graph(f) \in \text{NP}(k) \subseteq \Sigma_2^{\text{P}}$. There is a polynomial p such that for all x,

$$x \in dom(f) \leftrightarrow (\exists y)[|y| \leq p(|x|) \wedge y \in graph(f)].$$

Thus $dom(f) \in \Sigma_2^{\text{P}}$. □

We show next that Proposition 5.7 is tight, even when $k = 2$.

PROPOSITION 5.8. *Let A be in Σ_2^{P} via a polynomial p and a set B in* co-NP *so that for every x,*

$$x \in A \leftrightarrow (\exists y : |y| \leq p(|x|))[(x, y) \in B].$$

Let f be a function such that for every x and y,

$$f(x) \mapsto y \leftrightarrow |y| \leq p(|x|) \wedge (x, y) \in B.$$

Then $f \in \text{NPMV}(2)$. (Note that $dom(f) = A$.)

Proof. Let A, p, B, and f be as in the hypothesis. Define f_1 to be a function that maps x to each string y in $\Sigma^{\leq p(|x|)}$, and define f_2 to be a function that maps x to each string y in $\Sigma^{\leq p(|x|)}$ such that $(x, y) \notin B$. Obviously, $f_1, f_2 \in$ NPMV. For every x and y, $f(x)$ maps to y if and only if $f_1(x)$ maps to y and $f_2(x)$ does not map to y. So $f \in \text{NPMV}(2)$. □

By Theorem 5.2, the difference hierarchy for partial multivalued functions rises or falls in accordance with the difference hierarchy for sets. Since the difference hierarchy for sets sits entirely within Δ_2^{P}, one might anticipate that the NPMV(k) hierarchy lies within the second level of the polynomial-time hierarchy for partial multivalued functions. The following striking theorem shows that this can be true if and only if the polynomial-time hierarchy collapses.

THEOREM 5.9. $\text{NPMV}(2) \subseteq \text{PF}^{\text{NPMV}}$ *if and only if* $\Sigma_2^{\text{P}} = \Delta_2^{\text{P}}$.

Proof. First, suppose that $\text{NPMV}(2) \subseteq_c \text{PF}^{\text{NPMV}}$. Let A be in Σ_2^{P}. By the above proposition, there is a function $f \in \text{NPMV}(2)$ such that $dom(f) = A$. By our supposition, $f \in_c \text{PF}^{\text{NPMV}}$. So there exist a polynomial-time deterministic Turing machine M and a function $g \in$ NPMV such that for every x, $x \in A$ if and only if $M(x)$ relative to g has an output. By modifying M slightly, we have a machine M' such that for every x, $M'(x)$ relative to g outputs 1 if $x \in A$ and 0 otherwise. Thus $A \in \text{P}^{\text{NPMV}}$, and thus $A \in \text{P}^{\text{NP}}$. Hence $\Sigma_2^{\text{P}} = \Delta_2^{\text{P}}$.

Next, suppose that $\Sigma_2^{\mathrm{P}} = \Delta_2^{\mathrm{P}}$. Let $f \in \mathrm{NPMV}(2)$. By Lemma 5.1, there exist $f_1, f_2 \in \mathrm{NPMV}$ such that $graph(f) = graph(f_1) - graph(f_2)$. Define A to be the set of all pairs (x, y) for which there is some $z \geq y$ such that $(x, z) \in graph(f_1) - graph(f_2)$. Define g to be the partial function that maps x to the largest y such that $(x, y) \in A$ if $x \in dom(f)$. It is not hard to see that g is a single-valued refinement of f and g is polynomial-time computable with oracle A by an obvious binary search algorithm. By definition, $A \in \Sigma_2^{\mathrm{P}}$. So $A \in \Delta_2^{\mathrm{P}}$. Therefore, $g \in \mathrm{PF}^{\Delta_2^{\mathrm{P}}} = \mathrm{PF}^{\mathrm{P}^{\mathrm{NP}}} = \mathrm{PF}^{\mathrm{NP}}$. Thus $f \in_c \mathrm{PF}^{\mathrm{NPMV}}$. □

Theorem 5.9 raises a question: "How powerful is the difference hierarchy?" The following results provide some answers to this question.

LEMMA 5.10. $\mathrm{PF}_{tt}^{\mathrm{NPMV}[k]} \subseteq_c \mathrm{NPMV}(2k+1)$.

Proof. Let $f \in \mathrm{PF}_{tt}^{\mathrm{NPMV}[k]}$ via a polynomial-time deterministic Turing machine M that makes nonadaptive queries to a function $g \in \mathrm{NPMV}$. Let p be a polynomial such that for every x, each query string of M on x is of length $\leq p(|x|)$. Let $h = s[M, g]$ defined in Proposition 3.2. For each x, let n_x be the largest $n \in \{0, \ldots, k\}$ such that $h(x, n)$ is defined. Then for every x,

- either $h(x, n_x)$ maps only to 0 or $h(x, n_x)$ maps only to strings of the form $1z$, and
- if $h(x, n_x)$ maps to 0, then $x \notin dom(f)$ and if $h(x, n_x)$ maps to some $1z$, then f maps x to z.

For each $i \in \{0, \ldots, k\}$, define H_i to be the function that maps x to y if and only if $h(x, i)$ maps to $1y$. For each $i \in \{1, \ldots, k\}$, define G_i to be the function that maps x to each string in $\Sigma^{\leq p(|x|)}$ if for some $j > i$, $(x, j) \in dom(h)$ and undefined otherwise. These functions are obviously in NPMV. Note the following:

(1) for every $i > n_x$, $H_i(x)$ is undefined;
(2) for every $i \geq n_x$, $G_i(x)$ is undefined; and
(3) for every $i < n_x$, $G_i(x)$ maps to every $y \in \Sigma^{\leq p(|x|)}$.

Define F by

$$graph(F) = graph(H_k) \cup \left(\bigcup\nolimits_{0 \leq i \leq k-1} (graph(H_i) - graph(G_i)) \right).$$

Then $dom(f) = dom(F)$ and if $F(x)$ maps to y, then $f(x)$ maps to y. Therefore, F is a refinement of f. Since H_i and G_i are in NPMV,

$$graph(F) \in \mathrm{NP} \vee \underbrace{\mathrm{NP}(2) \vee \cdots \vee \mathrm{NP}(2)}_{k}.$$

So $graph(F) \in \mathrm{NP}(2k+1)$. Therefore, $f \in_c \mathrm{NPMV}(2k+1)$. □

Since $\mathrm{PF}_{tt}^{\mathrm{NPMV}[2^k-1]} = \mathrm{PF}^{\mathrm{NPMV}[k]}$, we have the following theorem.

THEOREM 5.11. $\mathrm{PF}^{\mathrm{NPMV}[k]} \subseteq_c \mathrm{NPMV}(2^{k+1} - 1)$.

By Theorem 5.2, the levels of the difference hierarchy of partial functions are distinct if and only if the same levels of the Boolean hierarchy are distinct. Yet, whereas the Boolean hierarchy resides entirely within P^{NP}, by Theorem 5.9, this is unlikely to be true of the difference hierarchy of partial functions.

6. Reduction classes to NPSV. In this section, we set down some results about reduction classes to NPSV. With two notable exceptions, all of our results are corollaries of theorems that we already proved, and our interest is primarily in Corollaries 6.4 and 6.5 below, which demonstrate that bounded query hierarchies with oracles in NPSV do not collapse unless the Boolean hierarchy collapses.

The following proposition is easy to prove.

PROPOSITION 6.1.

1. $\mathrm{PF}^{\mathrm{NP}} = \mathrm{PF}^{\mathrm{NPSV}}$ (*by Theorem* 2.4).
2. $\mathrm{PF}^{\mathrm{NP}[k]} \subseteq \mathrm{PF}^{\mathrm{NPSV}[k]} \subseteq \mathrm{PF}^{\mathrm{NPMV}[k]}$ *and* $\mathrm{PF}^{\mathrm{NP}[\log]} \subseteq \mathrm{PF}^{\mathrm{NPSV}[\log]} \subseteq \mathrm{PF}^{\mathrm{NPMV}[\log]}$.
3. $\mathrm{PF}_{tt}^{\mathrm{NP}[k]} \subseteq \mathrm{PF}_{tt}^{\mathrm{NPSV}[k]} \subseteq \mathrm{PF}_{tt}^{\mathrm{NPMV}[k]}$.
4. $\mathrm{P}_{tt}^{\mathrm{NP}} = \mathrm{P}_{tt}^{\mathrm{NPSV}}$ (*by Theorem* 3.14).
5. $\mathrm{P}^{\mathrm{NP}} = \mathrm{P}^{\mathrm{NPSV}}$ (*by Theorem* 2.4).
6. $\mathrm{P}^{\mathrm{NP}[k]} \subseteq \mathrm{P}^{\mathrm{NPSV}[k]} \subseteq \mathrm{P}^{\mathrm{NPMV}[k]}$ *and* $\mathrm{P}^{\mathrm{NP}[\log]} \subseteq \mathrm{P}^{\mathrm{NPSV}[\log]} \subseteq \mathrm{P}^{\mathrm{NPMV}[\log]}$.
7. $\mathrm{P}_{tt}^{\mathrm{NP}[k]} \subseteq \mathrm{P}_{tt}^{\mathrm{NPSV}[k]} \subseteq \mathrm{P}_{tt}^{\mathrm{NPMV}[k]}$.

COROLLARY 6.2. *For every* $k \geq 1$, $\mathrm{P}^{\mathrm{NPSV}[k]} = \mathrm{P}^{\mathrm{NP}[k]}$.

Proof. By Proposition 6.1(6), $\mathrm{P}^{\mathrm{NP}[k]} \subseteq \mathrm{P}^{\mathrm{NPSV}[k]} \subseteq \mathrm{P}^{\mathrm{NPMV}[k]}$. By Theorem 3.7, $\mathrm{P}^{\mathrm{NPMV}[k]} = \mathrm{P}^{\mathrm{NP}[k]}$. So $\mathrm{P}^{\mathrm{NPSV}[k]} = \mathrm{P}^{\mathrm{NP}[k]}$. □

COROLLARY 6.3. *For every* $k \geq 1$, $\mathrm{P}_{tt}^{\mathrm{NPSV}[k]} = \mathrm{P}_{tt}^{\mathrm{NP}[k]}$.

COROLLARY 6.4. *If* $\mathrm{PF}_{tt}^{\mathrm{NPSV}[k+1]} = \mathrm{PF}_{tt}^{\mathrm{NPSV}[k]}$ *for some* $k \geq 1$, *then* BH *collapses to its* $(k+1)$*st level.*

Proof. Suppose $\mathrm{PF}_{tt}^{\mathrm{NPSV}[k+1]} = \mathrm{PF}_{tt}^{\mathrm{NPSV}[k]}$. Then we have $\mathrm{P}_{tt}^{\mathrm{NPSV}[k+1]} = \mathrm{P}_{tt}^{\mathrm{NPSV}[k]}$. Therefore, by Corollary 6.3, we have $\mathrm{P}_{tt}^{\mathrm{NP}[m]} = \mathrm{P}_{tt}^{\mathrm{NP}[k]}$ for every m. Since $\mathrm{P}^{\mathrm{NP}[k]} \subseteq \mathrm{NP}(k+1)$, BH collapses to its $(k+1)$st level. □

COROLLARY 6.5. *If* $\mathrm{PF}^{\mathrm{NPSV}[k+1]} = \mathrm{PF}^{\mathrm{NPSV}[k]}$ *for some* $k \geq 1$, *then* BH *collapses to its* 2^k*th level.*

Proof. Suppose $\mathrm{PF}^{\mathrm{NPSV}[k+1]} = \mathrm{PF}^{\mathrm{NPSV}[k]}$. Then we have $\mathrm{P}^{\mathrm{NPSV}[k+1]} = \mathrm{P}^{\mathrm{NPSV}[k]}$. Therefore, by Corollary 6.2, we have $\mathrm{P}^{\mathrm{NP}[m]} = \mathrm{P}^{\mathrm{NP}[k]}$ for every m. Since $\mathrm{P}^{\mathrm{NP}[k]} \subseteq \mathrm{NP}(2^k)$, BH collapses to its 2^kth level. □

The following proposition, which is the NPSV version of Theorem 3.5, requires a somewhat different proof from the NPMV case. It is interesting that our techniques seem insufficient to prove the reverse inclusion.

PROPOSITION 6.6. *For every* $k \geq 1$, $\mathrm{PF}^{\mathrm{NPSV}[k]} \subseteq \mathrm{PF}_{tt}^{\mathrm{NPSV}[2^k-1]}$.

Proof. Let $f \in \mathrm{PF}^{\mathrm{NPSV}[k]}$ via an oracle transducer M making k many queries to an oracle partial function $g \in \mathrm{NPSV}$ computed by an NPSV machine N. We may assume that f is single-valued. Let r be the NPMV function defined by the machine U in the proof of Proposition 3.1, where $t(x) = k$. Since g is single-valued, it follows that r is also single-valued, and hence $r \in \mathrm{NPSV}$. Moreover, we have that $\lambda x.[r(x, 0^k)]$ is total and polynomial-time computable, and if b_x is the lexicographically greatest string $b \in \Sigma^k$ on which $r(x, b)$ is defined, then

$$r(x, b_x) = \begin{cases} 0 & \text{if } x \notin \mathit{dom}(f), \\ 1y & \text{if } f(x) = y. \end{cases}$$

We compute $f(x)$ by querying r in parallel on the $2^k - 1$ values $\{(x, a) \mid a \neq 0^k\}$, recovering $f(x)$ from $r(x, a)$ as above, where a is lexicographically largest such that $r(x, a)$ returns a value. □

The equality in the following theorem depends heavily on the fact that NPSV functions are single-valued, and we do not believe it holds for oracles in NPMV. The first inclusion was found independently by E. Hemaspaandra [16].

THEOREM 6.7. $\mathrm{PF}^{\mathrm{NPSV}[\log]} \subseteq \mathrm{PF}_{tt}^{\mathrm{NPSV}} = \mathrm{PF}_{tt}^{\mathrm{NP}}$.

Proof. The first inclusion arises immediately from adapting the proof of Proposition 6.6. We now show that $\mathrm{PF}_{tt}^{\mathrm{NPSV}} \subseteq \mathrm{PF}_{tt}^{\mathrm{NP}}$. The reverse inclusion is obvious.

If h is any single-valued partial function, define $\mathit{code}(h)$ to be the set of all (x, i, b) such that the ith bit (left to right) of $h(x)$ exists and is b. Suppose $f \in \mathrm{PF}_{tt}^{\mathrm{NPSV}}$ is

computed by a deterministic oracle transducer M running in time $p(n)$ and making parallel queries to an oracle $g \in \mathrm{NPSV}$, which itself is computed by a machine N running in time $q(n)$ (p and q are polynomials). We may assume f is single-valued. Let g' be the function that maps x to $1y$ if $g(x)$ maps to y and is undefined otherwise. Clearly, $code(g') \in \mathrm{NP}$, and since g' is single-valued, at most one of the tuples $(x, i, 0)$ and $(x, i, 1)$ is in $code(g')$, for all x and i.

Given an input x, we compute $f(x)$ by making parallel queries to $code(g')$ as follows: let $q_1, \ldots, q_s$ be the oracle queries made by $M(x)$. We query $code(g')$ on all the tuples (q_i, j, b) for $1 \le i \le s$, $0 \le j \le q(p(|x|))$, and $b \in \{0, 1\}$. Since $dom(g') = dom(g)$ and $g'(q)$ never maps to the empty string, $q_i \in dom(g)$ if and only if one of $(q_i, 0, 0)$ and $(q_i, 0, 1)$ is in $code(g')$. For each $q_i \in dom(g)$, we recover $g(q_i)$ in the usual way by reading from $code(g')$ all but the 0th bit of $g'(q_i)$. Query answers in hand, we continue simulating M to obtain $f(x)$. □

The next corollary was proved independently from scratch by L. Hemaspaandra [10].

COROLLARY 6.8. $\mathrm{P}_{tt}^{\mathrm{NPSV}} = \mathrm{P}_{tt}^{\mathrm{NP}} = \mathrm{P}^{\mathrm{NP[log]}} = \mathrm{P}^{\mathrm{NPSV[log]}}$.

Proof. The first equation follows from Theorem 6.7 by considering only characteristic functions. Also by Theorem 6.7, we have $\mathrm{P}^{\mathrm{NPSV[log]}} \subseteq \mathrm{P}_{tt}^{\mathrm{NP}} = \mathrm{P}^{\mathrm{NP[log]}} \subseteq \mathrm{P}^{\mathrm{NPSV[log]}}$, so the last equation holds. □

Recall from the introduction that it is not known whether *sat* belongs to $\mathrm{PF}^{\mathrm{NPSV}[k]}$ for any k. We know that *maxsat* is complete for $\mathrm{PF}^{\mathrm{NPMV}}$ [13]. Thus by Corollary 6.5, if for any $k \ge 1$, $maxsat \in \mathrm{PF}^{\mathrm{NPSV}[k]}$, then the Boolean and polynomial hierarchies collapse.

Although $\mathrm{PF}^{\mathrm{NPMV[log]}} = \mathrm{PF}_{tt}^{\mathrm{NPMV}}$ (Theorem 3.13), we do not know whether $\mathrm{PF}^{\mathrm{NPSV[log]}}$ and $\mathrm{PF}_{tt}^{\mathrm{NPSV}}$ are equal. In particular, whereas, $\mathrm{PF}_{tt}^{\mathrm{NPSV}} = \mathrm{PF}_{tt}^{\mathrm{NP}}$ (Theorem 6.7) is easy to prove, apparently $\mathrm{PF}^{\mathrm{NPSV[log]}}$ and $\mathrm{PF}^{\mathrm{NP[log]}}$ are not equal, for $\mathrm{NPSV} \subseteq \mathrm{PF}^{\mathrm{NPSV}[1]} \subseteq \mathrm{PF}^{\mathrm{NPSV[log]}}$, while $\mathrm{NPSV} \subseteq \mathrm{PF}^{\mathrm{NP[log]}}$ implies P = UP [15]. Thus $\mathrm{PF}^{\mathrm{NPSV[log]}} \subseteq \mathrm{PF}^{\mathrm{NP[log]}}$ implies P = UP. Similarly, $\mathrm{PF}^{\mathrm{NPMV}[1]} \subseteq \mathrm{PF}^{\mathrm{NP[log]}}$ implies P = NP.

FAST DISCRETE POLYNOMIAL TRANSFORMS WITH APPLICATIONS TO DATA ANALYSIS FOR DISTANCE TRANSITIVE GRAPHS*

J. R. DRISCOLL†, D. M. HEALY, JR.‡, AND D. N. ROCKMORE§

Abstract. Let $\mathcal{P} = \{P_0, \ldots, P_{n-1}\}$ denote a set of polynomials with complex coefficients. Let $\mathcal{Z} = \{z_0, \ldots, z_{n-1}\} \subset \mathbb{C}$ denote any set of *sample points*. For any $f = (f_0, \ldots, f_{n-1}) \in \mathbb{C}^n$, the *discrete polynomial transform* of f (with respect to $\mathcal{P}$ and $\mathcal{Z}$) is defined as the collection of sums, $\{\widehat{f}(P_0), \ldots, \widehat{f}(P_{n-1})\}$, where $\widehat{f}(P_j) = \langle f, P_j \rangle = \sum_{i=0}^{n-1} f_i P_j(z_i) w(i)$ for some associated weight function w. These sorts of transforms find important applications in areas such as medical imaging and signal processing.

In this paper, we present fast algorithms for computing discrete orthogonal polynomial transforms. For a system of N orthogonal polynomials of degree at most $N-1$, we give an $O(N \log^2 N)$ algorithm for computing a discrete polynomial transform at an arbitrary set of points instead of the N^2 operations required by direct evaluation. Our algorithm depends only on the fact that orthogonal polynomial sets satisfy a three-term recurrence and thus it may be applied to any such set of discretely sampled functions.

In particular, sampled orthogonal polynomials generate the vector space of functions on a distance transitive graph. As a direct application of our work, we are able to give a fast algorithm for computing subspace decompositions of this vector space which respect the action of the symmetry group of such a graph. This has direct applications to treating computational bottlenecks in the spectral analysis of data on distance transitive graphs, and we discuss this in some detail.

Key words. fast Fourier transform, FFT, discrete polynomial transform, orthogonal polynomials, three-term recurrence, distance transitive graph

1. Introduction.

The efficient decomposition of a function into a linear combination of orthogonal polynomials is a fundamental tool which plays an important role in a wide variety of computational problems. Applied science abounds with computations using such decompositions, along with the related computational techniques for calculation of correlation or projection of data onto a family of polynomials. To cite just a few examples, this sort of approach is used in spectral methods for solving differential equations [Bo, Te], data analysis [D], signal and image processing [OS], and the construction of Gauss quadrature schemes [Ga1]. In most cases, the choice of a particular family of polynomials is determined by some special property or underlying symmetry of the problem under investigation.

Perhaps the most familiar example is the representation of a discrete data sequence as a linear combination of phase polynomials. In this case, the decomposition is known as the discrete Fourier transform (DFT) and is accomplished both efficiently and reliably through the use of the well-known fast Fourier transform algorithms (FFT) (cf. [ER] and the references therein). The DFT is a particularly simple orthogonal polynomial transform which corresponds to the projection of a data sequence $f = (f_0, \ldots, f_{N-1})$ onto the family of monomials $P_l(x) = m_l(x) = x^l$ evaluated at the roots of unity $z_k = e^{2\pi ik/N}$, $k = 0, 1, \ldots, N-1$. Thus the DFT is the collection of sums

$$\widehat{f}(l) = \sum_{k=0}^{N-1} f_k P_l(z^k) = \sum_{k=0}^{N-1} f_k e^{2\pi ikl/N} \tag{1.1}$$

for the discrete frequencies $l = 0, 1, \ldots, N-1$. The monomials form an orthogonal set whose properties account for the well-documented usefulness and algorithmic efficiency of the FFT algorithms. In particular, these algorithms allow the projections in (1.1) to be computed in $O(N \log N)$ operations as opposed to the N^2 operations that a direct evaluation would require [ER]. (We assume a standard model in which a single complex multiplication and addition are defined as a single operation.)

In this paper, we are concerned with the development of efficient algorithms for computing more general discrete polynomial transforms. Specifically, let $\mathcal{P} = \{P_0, \ldots, P_{n-1}\}$ denote a set of polynomials with complex coefficients. Let $\mathcal{Z} = \{z_0, \ldots, z_{n-1}\} \subset \mathbb{C}$ denote any set of *sample points*. If $f = (f_0, \ldots, f_{n-1})$ is any data vector (often thought of as a function with known values at the sample points), then the *discrete polynomial transform* of f (with respect to $\mathcal{P}$ and $\mathcal{Z}$) is defined as the collection of sums, $\{\widehat{f}(P_0), \ldots, \widehat{f}(P_{n-1})\}$, where

$$\widehat{f}(P_j) = \langle f, P_j \rangle = \sum_{i=0}^{n-1} f_i P_j(z_i) w(i). \tag{1.2}$$

The function w is some associated weight function, often identically 1. Familiar examples of discrete polynomial transforms include the DFT (already mentioned) as well as the related discrete cosine transform (DCT). In fact, both may be obtained as particular cases of *discrete monomial transforms*—i.e., discrete polynomial transforms in which $P_j = m_j$ is the monomial of degree j. Beyond such special cases, we know of no prior general algorithm for computing discrete polynomial transforms which has complexity less than $O(n^2)$.

Inspection of equation (1.2) shows that direct computation of the discrete polynomial transform requires n^2 operations. For large n, this cost quickly becomes prohibitive. The main result of this paper is an algorithm which computes general discrete orthogonal polynomial transforms in $O(n \log^2 n)$ operations. This relies primarily on the three-term recurrences satisfied by any orthogonal polynomial system and as such our algorithms also obtain for computing transforms over any set of spanning functions which satisfy such a recurrence. Related techniques have already found a number of applications attacking computational bottlenecks in problems in areas such as medical imaging, geophysics, and matched filter design [DrH, MHR, HMR, HMMRT].

Our original motivation for studying these sorts of computations comes from problems which arise in performing spectral analysis of data on distance transitive graphs. This analysis is effectively the combinatorial analogue of the more familiar case of spectral analysis on continuous spaces like the circle or the 2-sphere. For instance,

functions defined on distance transitive graphs admit a spectral decomposition which mirrors that of integrable functions on the 2-sphere. In particular, recall that the algebra of functions on the 2-sphere is generated by functions constant on circles of fixed distance from the north pole (circles of latitude), the so-called "zonal spherical functions" for the 2-sphere [He]. For each nonnegative integer m, there is a uniquely defined (up to a constant) spherical function of degree m and the translates of this function under the action of $SO(3)$ (the symmetry group of the 2-sphere given by the group of rotations in 3-space) span a subspace of the vector space of functions on the 2-sphere which is invariant under the action of $SO(3)$. Similarly, distance transitive graphs have an associated symmetry group. After the choice of a distinguished vertex, analogous to the choice of a "north pole" on the 2-sphere, the algebra of functions on a distance transitive graph is generated by analogously defined spherical functions. (Here distance on the graph is the usual shortest path distance between vertices.) It turns out that these discrete functions are sampled orthogonal polynomials. Spectral analysis of data on a distance transitive graph, naturally viewed as a function on the graph, requires the expansion of the function in terms of a basis generated by the discrete spherical functions. The expansion may be reduced to the computation of discrete spherical transforms which are, in fact, discrete orthogonal polynomial transforms.

The spectral approach to data analysis, as described by Diaconis [D], is motivated by the observation that it is often appropriate and useful to view data as a function defined on an suitably chosen group or, more generally, some homogeneous space of a group. The choice of a "natural" group in any given situation depends on various symmetries of the problem. The group-theoretic setting of spectral analysis allows for the techniques of Fourier analysis to be applied. In particular, a data vector will have a natural decomposition into symmetry-invariant components which are calculated by computing the projections of the data vector into the various symmetry-invariant subspaces.

A familiar illustration of this approach comes from digital signal processing. Here the standard analysis of stationary signals proceeds by decomposing the signal as a sum of sines and cosines with coefficients determined by usual abelian FFT. The sines and cosines of a given frequency determine subspaces of functions which are invariant under translation of the origin.

For a possibly less familiar example (due to Diaconis [D]), consider the California Lottery game. Each player chooses a six-element subset of $\{1, \ldots, 49\}$. Every such subset corresponds to a coset of $S_{49}/(S_6 \times S_{43})$. (Here $S_6 \times S_{43}$ is identified with the subgroup of S_{49} that independently permutes the subsets $\{1, \ldots, 6\}$ and $\{7, \ldots, 49\}$.) The vector space of functions defined on the cosets $S_{49}/(S_6 \times S_{43})$ is denoted as $M^{(43,6)}$. Each "run" of the game gives rise to a function $f \in M^{(43,6)}$ such that $f(x)$ is the number of people picking 6-set x.

A spectral analysis approach to analyzing such a data vector is to decompose the vector into symmetry-invariant components, where here a natural choice of symmetry group is the symmetric group S_{49}. Standard analysis from the representation theory of the symmetric group shows that $M^{(43,6)}$ has a unique finest decomposition into seven S_{49}-invariant components, $M^{(43,6)} = S^{(49)} \oplus S^{(48,1)} \oplus \cdots \oplus S^{(43,6)}$. This decomposition has a natural data-analytic interpretation. The invariant subspace $S^{(49)}$ measures the constant contribution. The other invariant subspaces $S^{(49-j,j)}$ naturally measure the "pure" contribution of the popularity of the various j-sets (that is, the number of people including a given j-set in their 6-set). Computation of the projections onto

these subspaces can be reduced to computing the relevant spherical transforms, which in this case turn out to be certain discrete Hahn polynomial transforms. The methods of this paper allow these transforms to be computed efficiently.

The California Lottery example is, in fact, an example of data on a distance transitive graph. More generally, the k-sets of an n-set comprise a distance transitive graph by joining any two k-sets which differ by only a single element. This graph possesses certain Hahn polynomials as its spherical functions (cf. [St3, section II.3]). Other examples include the n-gon graph with dihedral group symmetry as well as the n-dimensional hypercube with hyperoctahedral group of symmetries. In the former case, the spherical functions are obtained from the Chebyshev polynomials, $T_n(x) = \cos(n \arccos(x))$ [Bi], and in the latter case, the Krawtchouk polynomials give the spherical functions (cf. [St3, section II.2]).

As we shall see in section 3, in general, the problem of finding an FFT for distance transitive graphs may be reduced to that of the efficient computation of the projection onto the spherical functions for the graph, which are an orthogonal family of special functions on the graph. In many important examples (cf. [St1, St3] and the many references therein), these spherical functions are actually sampled orthogonal polynomials, and the spherical transform amounts to projection onto these polynomials in a weighted ℓ^2 space.

The organization of the paper is as follows. Section 2 discusses fast orthogonal polynomial transforms, beginning with previously known results for monomial transforms and concluding with our main computational result, which is an efficient discrete orthogonal polynomial transform. This material is elementary and relies on nothing more than the recurrence relations satisfied by the polynomials in question. Section 3 treats our main application of interest: fast algorithms for projection onto spherical functions on distance transitive graphs. We include here the necessary group-theoretic background and notation and give explicit examples of the algorithm for spherical functions on several graphs of interest. The fast spherical transform algorithm may be modified in order to provide a fast inverse transform, and from this we also obtain a fast convolution algorithm for functions on distance transitive graphs. Section 4 discusses the connection of these results to the computation of isotypic projections required for spectral analysis. We close in section 5 with some final remarks.

2. Fast polynomial transforms. The goal of this section is to produce algorithms for fast evaluation of polynomial transforms with an eye to their eventual application to the efficient computation of spherical transforms. The general algorithm proceeds in two steps. The initial phase is an efficient projection onto the monomials. From here we are able to use the three-term recurrence to obtain a divide-and-conquer approach for relevant fast polynomial transforms. In general, our approach is to formulate the initial problem as a particular matrix–vector multiplication and then present the fast algorithm as a particular matrix factorization.

We proceed by first recalling the fast monomial transform. This is obtained by writing it as the transpose of multiple-point polynomial evaluation and then formulating a well-known efficient algorithm for the latter process (cf. [BM, Chapter 4]) as a structured matrix factorization. We explain the full algorithm next and then close this section with an example.

2.1. Fast monomial transforms. The simplest polynomial transform problem that we could consider is the projection of a vector $f = (f_0, \ldots, f_{n-1})$ onto the family

of monomials evaluated at the finite point set $\{z_0, \ldots, z_{n-1}\}$,

$$\widehat{f}(k) = \langle f, z^k \rangle = \sum_{\ell=0}^{n-1} f_\ell (z_\ell)^k \quad (k = 0, \ldots, n-1). \tag{2.1}$$

Note that viewed as a matrix–vector multiplication, this is the evaluation of multiplication of the suitably defined Vandermonde matrix times the vector of samples. That is,

$$\langle f, z^k \rangle = (V \cdot f)_k,$$

where

$$V = V(z_0, \ldots, z_{n-1}) = \begin{pmatrix} 1 & 1 & \cdots & 1 \\ z_0 & z_1 & \cdots & z_{n-1} \\ \vdots & & & \vdots \\ {z_0}^{n-1} & {z_1}^{n-1} & \cdots & {z_{n-1}}^{n-1} \end{pmatrix}. \tag{2.2}$$

The familiar example of the abelian DFT is obtained by taking the evaluation points to be the nth roots of unity in $\mathbb{C}$, $z_\ell = \exp(2\pi i \ell/n)$. This projection may be obtained by the familiar FFT divide and conquer strategy in $O(n \log n)$ operations as opposed to the obvious $O(n^2)$. General references include [BM, ER, N, TAL].

Notice that the abelian FFT gives rise to our first efficient spherical transform, corresponding to the n-gon graph. This is a fast discrete Chebyshev transform with samples at the Chebyshev points, $\cos 2\pi\ell/n$. This can be obtained by applying the usual FFT to a real-valued data sequence.

Our fast monomial transform is based on the formulation of the FFT which considers the *transpose* of projection and develops the algorithm as polynomial evaluation at the roots of unity,

$$\widehat{f}(k) = (V^t \cdot f)_k = \sum_{\ell=0}^{n-1} f_\ell (z_k)^\ell$$

for $z_k = \exp(2\pi i k/n)$. This version of the FFT is achieved by efficient recursive application of the division algorithm (cf. [BM]).

An advantage of this perspective is that it allows an easy generalization to the direct evaluation of polynomials at n real points. We now review a well-known $O(n \log^2 n)$ algorithm for polynomial evaluation which we may formulate as a factorization of the matrix V^t into block-diagonal matrices with Toeplitz blocks of geometrically decreasing size. It is this structure which permits the fast computation of the matrix–vector product. Consequently, we obtain a corresponding factorization of the transpose, V and hence, an algorithm for projection which also requires $O(n \log^2 n)$ operations. For ease of exposition, we assume n is a power of 2.

LEMMA 2.1. *Let $n = 2^k$ and let V be the Vandermonde matrix for the set of complex points $z_0, z_1, \ldots, z_{n-1}$, as defined in* (2.2). *The matrix–vector product $V^t \cdot f$, for $f \in \mathbb{C}^n$ (corresponding to the evaluation of the polynomial $f_0 + f_1 z + \cdots + f_{n-1} z^{n-1}$ at the points $z_0, z_1, \ldots, z_{n-1}$) may be accomplished in $O(n \log^2 n)$ operations. Likewise, the product $V \cdot f$ for $f \in \mathbb{C}^n$ (corresponding to projection of a sampled function f onto the monomials sampled at $z_0, z_1, \ldots, z_{n-1}$) may be accomplished in $O(n \log^2 n)$ operations.*

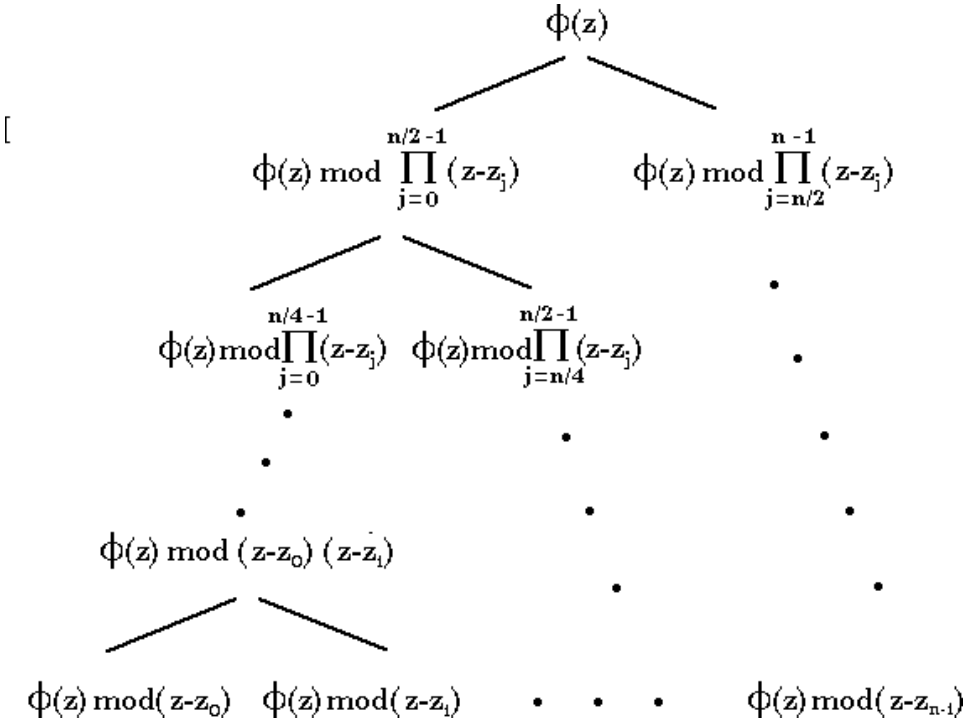

FIG. 2.1. *Tree for evaluating a polynomial $\phi(z)$ at $n = 2^k$ points. Note that it has $k = \log n$ levels.*

Proof. Let $\phi(z) = \sum_{i=0}^{n-1} f_i z^i$, $n = 2^k$, with $k \geq 0$. We may evaluate ϕ at any of the z_j, $j = 0, 1, \ldots, n-1$ by the division algorithm because $\phi(z_j) = \phi(z) \mod (z - z_j)$. The division may be done in $O(n \log n)$ for a given z_j, but to proceed this way for each of the z_j separately is prohibitively expensive.

Instead, we use a familiar divide-and-conquer strategy, simultaneously reducing the original polynomial modulo each linear factor $(z - z_j)$ in $k = \log n$ stages, as shown in Figure 2.1. Notice that fast polynomial arithmetic algorithms allow for the various moduli to be precomputed in $O(n \log^2 n)$ operations (cf. [BM, section 4.3]).

Each downward edge in the tree in Figure 2.1 represents the reduction of a polynomial $p(x)$ modulo another polynomial of form $m_S(z) = \Pi_{z_j \in S}(z - z_j)$, corresponding to a certain subset S of the evaluation points $z_0, \ldots, z_{n-1}$. To move down this edge of the tree, we need an algorithm to efficiently compute the remainder $r_S(x)$, and incidentally $q(x)$, in the division algorithm representation

$$p(x) = q(x) m_S(x) + r_S(x).$$

The input p is a remainder from a previous stage and has degree $d - 1$, where d is a power of 2. The precomputed modulus m_S has degree $d/2$. Therefore, r_S has degree $d/2 - 1$.

The key point is that in this tree, r_S is equivalent mod m_S not only to its immediate ancestor p but also to every ancestor of p, all the way back to the original polynomial ϕ. Indeed, p was itself obtained as a remainder modulo $m_{\tilde{S}}$ from *its* ances-

tor P, and Figure 2.1 shows that always $S \subset \tilde{S}$, so $m_S \,|\, m_{\tilde{S}}$. Therefore, $m_S|(r_S - P)$. So upon reaching the leaves of the tree, we have actually computed $\phi(z)$ modulo the linear factors $(z - z_j)$ as desired.

To see how to compute the basic reduction steps efficiently, we write the division algorithm representation $r = p - qm$ in matrix form. It is natural to split this equation into a high-order and a low-order part, due to the vanishing of the higher-order coefficients of r, corresponding to powers $d/2, \ldots, d-1$. The low-order equation involving the nonzero coefficients of r looks like

$$\begin{pmatrix} r_{\frac{d}{2}-1} \\ \vdots \\ \vdots \\ \vdots \\ r_0 \end{pmatrix} = \begin{pmatrix} p_{\frac{d}{2}-1} \\ \vdots \\ \vdots \\ \vdots \\ p_0 \end{pmatrix} - \begin{pmatrix} m_0 & m_1 & \cdots & \cdots & m_{\frac{d}{2}-1} \\ 0 & \ddots & \ddots & & \vdots \\ \vdots & \ddots & \ddots & \ddots & \vdots \\ \vdots & & \ddots & \ddots & m_1 \\ 0 & \cdots & \cdots & 0 & m_0 \end{pmatrix} \begin{pmatrix} q_{\frac{d}{2}-1} \\ \vdots \\ \vdots \\ \vdots \\ q_0 \end{pmatrix}. \tag{2.3}$$

The upper triangular Toeplitz matrix in (2.3) is comprised of the lower-order coefficients of the polynomial m; for future reference, we call this matrix M.

Now the higher-order terms of r are zero, so the high-order equation reduces to

$$\begin{pmatrix} p_{d-1} \\ \vdots \\ \vdots \\ \vdots \\ p_{\frac{d}{2}} \end{pmatrix} = \begin{pmatrix} m_{\frac{d}{2}} & 0 & \cdots & \cdots & 0 \\ m_{\frac{d}{2}-1} & \ddots & \ddots & & \vdots \\ \vdots & \ddots & \ddots & \ddots & \vdots \\ \vdots & & \ddots & \ddots & 0 \\ m_1 & \cdots & \cdots & m_{\frac{d}{2}-1} & m_{\frac{d}{2}} \end{pmatrix} \begin{pmatrix} q_{\frac{d}{2}-1} \\ \vdots \\ \vdots \\ \vdots \\ q_0 \end{pmatrix}. \tag{2.4}$$

Since $m_{d/2} = 1$, the lower triangular Toeplitz matrix in (2.4) is invertible. Its inverse, G, is also lower triangular and Toeplitz and may be computed in $O(d \log d)$ operations by a Newton iteration and then prestored (cf. [BM, Chapter 4] and Remark 3 following this proof). Insert the result into equation (2.3). This gives

$$\begin{pmatrix} r_{\frac{d}{2}-1} \\ \vdots \\ r_0 \end{pmatrix} = \begin{pmatrix} p_{\frac{d}{2}-1} \\ \vdots \\ p_0 \end{pmatrix} - MG \begin{pmatrix} p_{d-1} \\ \vdots \\ p_{\frac{d}{2}} \end{pmatrix}$$

$$= \left(\begin{array}{c|c} & \\ -MG & I_{d/2} \\ & \end{array}\right) \begin{pmatrix} p_{d-1} \\ \vdots \\ p_{\frac{d}{2}} \\ \hline p_{\frac{d}{2}-1} \\ \vdots \\ p_0 \end{pmatrix}. \tag{2.5}$$

Here $I_{d/2}$ is the $d/2 \times d/2$ identity matrix.

Here we must briefly recall that standard techniques using the FFT allow Toeplitz matrices of dimension b to be multiplied by an arbitrary vector of length b in at most

$O(b \log b)$ operations. This is done by framing the computation as the convolution of two sequences. More specifically, the Toeplitz matrix of order b is extended to a circulant matrix of order $2b$. A zero-padded version of the original data vector is then multiplied by this matrix in order to obtain the appropriate product. The new matrix–vector multiplication is precisely the circular convolution of two sequences of length $2b$ and as such is performed efficiently by computing the FFTs of each of the sequences, performing the pointwise multiplications of the resulting sequences and finally computing an inverse Fourier transform (requiring one more FFT) of this sequence. Thus a total of three FFTs are required as well as one pointwise multiplication of a sequence of length $2b$. If $2b = 2^r$, then an FFT of length $2b$ requires at most $3/2 \cdot 2b \cdot r = 3br$ operations (cf. [BM, p. 84]). Consequently, the multiplication of a Toeplitz matrix of order $b = 2^{r-1}$ by an arbitrary vector requires at most $3 \cdot 3br + 2b$ operations or $O(b \log b)$ operations.

Since M and G are both Toeplitz, the above discussion shows that the product

$$M \cdot G \cdot \begin{pmatrix} p_{d-1} \\ \vdots \\ p_{\frac{d}{2}} \end{pmatrix}$$

can be computed in at most $2(9 \cdot (d/2)r + 2 \cdot d/2) = 9dr + d$ operations, where $d = 2^r$. This is effected by first performing the multiplication

$$G \cdot \begin{pmatrix} p_{d-1} \\ \vdots \\ p_{\frac{d}{2}} \end{pmatrix}$$

and then multiplying this result by M. This means then that the multiplication in (2.5) may be accomplished in $9dr + d + d/2 = 9dr + 3d/2$ operations. The additional term of $d/2$ comes from the multiplication of the identity subblock against the low-order coefficients. Note that this is the cost of a single reduction in a single stage of the algorithm.

Looking back at the tree (see Figure 2.1), we see that the first stage of the algorithm consists of two reductions from order $n = 2^k$ to order $n/2$ by two polynomial divisions. Consequently, if we let $T(n)$ denote the number of operations required to compute the order n problem, then we obtain the following recurrence:

$$T(n) = 2T\left(\frac{n}{2}\right) + 2 \cdot \left(9nk + \frac{3}{2}n\right) = 18n \log n + 3n. \tag{2.6}$$

Iteration of the recurrence (2.6) yields

$$T(n) \leq 18n \log^2 n + 3n \log n, \tag{2.7}$$

which shows that the entire computation can be performed in $O(n \log^2 n)$ operations.

This sequence of reductions can be encoded as a structured matrix factorization of V^t. Let $M_{l,i}$ denote the upper triangular Toeplitz matrix associated (in the sense of (2.3)) with the polynomial which gives the ith modulus at level l of the tree in Figure 2.1. Thus $M_{1,0}$ is associated with $(z - z_0) \cdots (z - z_{n/2-1})$, $M_{1,1}$ is associated with $(z - z_{n/2}) \cdots (z - z_{n-1})$, $M_{2,0}$ is associated with $(z - z_0) \cdots (z - z_{n/4-1})$, and, in general, $M_{l,i}$ is associated with the product $(z - z_{i(n/2^l)}) \cdots (z - z_{(i+1)(n/2^l)-1})$.

Similarly, let $G_{l,i}$ denote *inverse* of the lower triangular Toeplitz matrix associated (in the sense of (2.4)) with the polynomial which gives the ith modulus at level l of the tree in Figure 2.1. As discussed above, $G_{l,i}$ is itself lower triangular and Toeplitz.

Define the matrices $R_{l,i}$ as in (2.5) by

$$R_{l,i} = \begin{pmatrix} & | & \\ -M_{l,i}G_{l,i} & | & I_{2^{k-l}} \\ & | & \end{pmatrix} \begin{matrix} \uparrow \\ 2^{k-l} \\ \downarrow \end{matrix} \tag{2.8}$$
$$\leftarrow 2^{k-l} \rightarrow \quad \leftarrow 2^{k-l} \rightarrow$$

for $1 \le l \le k = \log n$ and $0 \le i < 2^l$. Then the previous discussion shows that V^t has a factorization into $k = \log n$ factors as the matrix product

$$\begin{pmatrix} \begin{pmatrix} R_{k,0} \\ - - - \\ R_{k,1} \end{pmatrix} & & & \bigcirc \\ & \begin{pmatrix} R_{k,2} \\ - - - \\ R_{k,3} \end{pmatrix} & & \\ & & \ddots & \\ \bigcirc & & & \begin{pmatrix} R_{k,n-2} \\ - - - \\ R_{k,n-1} \end{pmatrix} \end{pmatrix}$$
$$\cdots \begin{pmatrix} \begin{pmatrix} & R_{2,0} & \\ - & - & - \\ & R_{2,1} & \end{pmatrix} & & \bigcirc \\ & \ddots & \\ \bigcirc & & \begin{pmatrix} & R_{2,2} & \\ - & - & - \\ & R_{2,3} & \end{pmatrix} \end{pmatrix} \begin{pmatrix} & R_{1,0} & \\ & & \\ - & - & - \\ & & \\ & R_{1,1} & \end{pmatrix}.$$

By transposition, a similarly structured factorization of V is then also obtained. The reversal of order obviously does not change the complexity of the sequence of multiplications; each matrix is still block diagonal, with the blocks themselves comprised of products of triangular Toeplitz subblocks as before. □

Remarks. 1. As mentioned previously, Lemma 2.1 is a restatement of what is now a classical result of the complexity for polynomial evaluation. For variations on this algorithm as well as pointers to the more recent literature, we refer the reader to the survey article of Pan [P] and the extensive bibliography contained therein.

2. Our proof treats only the case of n equal to a power of 2 but may be extended to the general case in a straightforward manner with the same asymptotic result.

3. Notice that the above algorithm requires $O(n \log n)$ storage. To see this, recall that the matrix–vector multiplications involving the matrices $M_{l,i}$ and $G_{l,i}$ are effected by extending these matrices to the appropriate circulant matrices of twice the size and then performing the subsequent matrix–vector multiplications as circular convolutions using the FFTs of the associated sequences. The matrices $M_{l,i}$ and $G_{l,i}$

are of dimension 2^{k-l} (where $n = 2^k$) and thus are extended to circulants of size 2^{k-l+1}. We need only store the DFT of a single row of this circulant, so in total we require $2n \log n$ storage to keep the necessary data from the all of the $M_{l,i}$'s and $G_{l,i}$'s.

To generate this initial data structure, we require $O(n \log^2 n)$ operations. For this, we first note that to generate the necessary DFTs from all of the $M_{l,i}$'s and $G_{l,i}$'s we require at most $O(n \log^2 n)$ operations, assuming that we have constructed the $M_{l,i}$'s and $G_{l,i}$'s. The $M_{l,i}$'s and the $G_{l,i}^{-1}$'s are obtained from the polynomial coefficients of the various supermoduli in the division tree of Figure 2.1. These may be generated recursively from the bottom of the tree up using efficient polynomial multiplication routines which require $O(m \log m)$ operations to multiply two polynomials of degree m (cf. [BM, p. 86]). Thus at most $O(n \log^2 n)$ operations are needed to generate all of the $M_{l,i}$'s and $G_{l,i}^{-1}$'s (cf. [BM, p. 100]). Finally, to invert any particular $G_{l,i}^{-1}$ in order to obtain $G_{l,i}$, an additional $O(l\, 2^l)$ is needed (cf. [BM, p. 96]) so that in total we require $O(n \log^2 n)$ operations to precompute the necessary data structure.

4. Notice that one direct result of an efficient monomial transform is that we can obtain an FFT at nonuniformly spaced frequencies. This amounts to evaluating the polynomial above at n nonuniformly spaced points on the unit circle and can be accomplished in $O(n \log^2 n)$ operations. An application of this to fast scanning for MRI is discussed in [MHR], as are issues of stability of the fast algorithm.

Nonuniform FFTs also immediately provide an $O(n \log^2 n)$ Chebyshev polynomial transform on the uniform grid $\{k/n - 1 | k = 0, \ldots, 2n-1\}$ in $[-1, 1]$ by applying the nonuniform Fourier transform to a real data sequence f at the points $\exp(i\theta_k)$ with $\cos(\theta_k) = k/n$. This turns out to be useful, and we will explore it in more detail later.

Lemma 2.1 has many applications. We record some here for later use.

COROLLARY 2.2. *Each of the following three computations can be obtained in* $O(n \log^2 n)$ *operations:*

(1) *the* ℓ^2 *projections of a discrete function onto the monomials sampled at the points* $x_0, x_1, \ldots, x_{n-1}$ *in* $\mathbb{R}$,

$$\sum_{k=0}^{n-1} f_k {x_k}^l, \quad l = 0, \ldots, n-1,$$

(2) *the* ℓ^2 *projections of a discrete function onto the Chebyshev polynomials* $T_n(x)$ *sampled uniformly at the points*

$$\left\{ u_k = 2\frac{k}{n} - 1 \middle| k = 0, \ldots, n-1 \right\} \subset [-1, 1],$$

$$\sum_{k=0}^{n-1} f_k T_l(u_k), \quad l = 0, \ldots, n-1;$$

(3) *the* ℓ^2 *projections of a discrete function onto the shifted Chebyshev polynomials* $T_n^*(x) = T_n(2x-1)$ *on the regular grid*

$$\left\{ v_k = \frac{k}{n} \middle| k = 0, \ldots, n-1 \right\} \subset [0, 1].$$

Proof. (1) This is an immediate application of the lemma.

(2) Take $\theta_k = \arccos(u_k)$ in $[0, \pi]$, $k = 0, \ldots, n-1$. Define points $z_j, j = 0, \ldots, 2n-1$ in the unit circle by

$$z_j = \begin{cases} e^{i\theta_j} & \text{if } 0 \le j < n-1, \\ e^{i(\theta_{j-n} - \pi)} & \text{if } n \le j < 2n. \end{cases}$$

Then

$$\begin{aligned} \sum_{k=0}^{n-1} f_k T_l(u_k) &= \sum_{k=0}^{n-1} f_k \cos(l\theta_k) \\ &= \sum_{k=0}^{n-1} \frac{1}{2} f_k (z_k^l + \overline{z_k^l}) \\ &= \sum_{j=0}^{2n-1} F(z_j) z_j^l, \end{aligned}$$

where $F(z_0) = f_0$; $F(z_k) = (1/2)f_k$, $k = 1, \ldots, n-1$; $F(z_n) = 0$; and $F(\overline{z}) = F(z)$. The result follows by applying Lemma 2.1 to this last expression.

Alternatively, one may apply Lemma 2.1 separately to the real and imaginary parts of f, evaluating at the points $z_j, j = 0, \ldots, n-1$, and taking the real part.

(3) This follows from (2) by a change of variables. □

For reasons of numerical stability, the projections described in the last two parts of the corollary provide a useful alternative to projection onto monomials on uniform grids. Even though the Chebyshev polynomials are not discretely orthogonal on the uniform grid, they still are much better conditioned than the monomials [Ga2, Hi]. It should also be noted that certain modifications of the resulting algorithm for projection onto the Chebyshev polynomials are required for stable computation. These modifications do not affect the efficiency of the algorithm in any appreciable way (cf. [MHR]).

2.2. Three-term recurrence relations and fast projection. We wish to extend the results of section 2.1 to obtain an algorithm for the fast projection onto functions other than the monomials or the Chebyshev polynomials. In particular, we are interested in doing this for the spherical functions for distance transitive graphs. These functions satisfy three-term recurrence relations, which permits us to make an efficient change of basis from monomials or Chebyshev polynomials. The following theorem demonstrates this in a case of interest for the current paper. It is evident that the argument can be applied in more general situations.

THEOREM 2.3. *Let $n = 2^k$ and let $\Phi_i(x)$, $i = 0, \ldots, n-1$ comprise a family of functions defined at the positive integers $x = 0, 1, \ldots, n-1$ and satisfying a three-term recurrence there:*

$$\Phi_{l+1}(x) = (a_l x + b_l)\Phi_l(x) + c_l \Phi_{l-1}(x),$$

with initial conditions $\Phi_0 = 1$, $\Phi_{-1} = 0$. Then the projections of a data vector $f = (f_0, \ldots, f_{n-1})$ defined by

$$\widehat{f}(l) = \sum_{j=0}^{n-1} f_j \Phi_l(j) w_j = \langle f, \Phi_l \rangle,$$

where w is a weight function, can be computed for all $l < n$ in $O(n \log^2 n)$ operations.

Proof. Without loss of generality, we may assume that $w_i = 1$ for each i. (In the more general case, the weights could be absorbed immediately into f.) By Lemma 2.1, we can effect the projection onto the monomials of degree less than n sampled at the points $x = 0, 1, \ldots, n-1$ in $O(n \log^2 n)$ operations. We now use the three-term recurrence to transform these into the desired projections onto the Φ_l.

Define the sequence Z_l for each $l = 0, 1, \ldots, n-1$ by

$$Z_l(k) = \langle f, x^k \Phi_l \rangle = \sum_{j=0}^{n-1} f_j j^k \Phi_l(j) \tag{2.9}$$

for $k = 0, 1, \ldots, n-1$. Our goal is to obtain the values $Z_l(0) = \langle f, x^0 \Phi_l \rangle$. However, what we may compute efficiently from the initial data are the values $Z_0(k) = \langle f, x^k \rangle$.

In terms of the Z_l, the recurrence

$$\Phi_{l+1}(x) = (a_l x + b_l)\Phi_l(x) + c_l \Phi_{l-1}(x) \tag{2.10}$$

translates into

$$\begin{aligned} Z_{l+1}(k) &= a_l \langle f, x^{k+1} \Phi_l \rangle + b_l \langle f, x^k \Phi_l \rangle + c_l \langle f, x^k \Phi_{l-1} \rangle \\ &= a_l Z_l(k+1) + b_l Z_l(k) + c_l Z_{l-1}(k). \end{aligned} \tag{2.11}$$

Observe that the weights in (2.11) do not depend on the k index. That is, the sequence Z_{l+1} is obtained by adding scalar multiples of the sequences Z_l, Z_{l-1}, and a shifted version of Z_l.

According to Lemma 2.1 and, specifically, equation (2.7), we can compute the sequence Z_0 in $18n \log^2 n + 3n \log n$ operations. Setting $Z_{-1} = 0$, the recurrence (2.11) gives Z_1 in at most $2n$ additional operations. In particular, this gives the value $Z_1(0) = \widehat{f}(1)$. Proceeding in this direct fashion, one could successively build the sequences Z_l and the obtain the values $Z_l(0)$. Of course, this yields no savings, requiring n operations of length $2n$ and thus $O(n^2)$ in total.[1]

Instead, following [DrH], we are able to use a divide-and-conquer approach to solve the problem more efficiently. To explain this, it is instructive to view the computation graphically. For this, consider the coordinate grid in Figure 2.2 with the l-axis in the horizontal direction and the k-axis in the vertical direction. We can consider the function Z defined on the grid with values $Z(l, k) = Z_l(k)$. Using recurrence (2.11), one sees immediately that the computation of $Z_l(k)$ (for $k < n - l$) only requires the prior computation of $Z_i(j)$ for (i, j) in the triangle defined by the vertices $(l, k), (0, k), (0, l + k)$.

Our goal is to compute the values $Z_l(0)$ for $0 \le l \le n-1$. As discussed above, initial computation of the first two columns, $\{Z_j(k) \mid j = 0, 1 \text{ and } 0 \le k \le n-1\}$ can be obtained in $18n \log^2 n + 3n \log n + 2n$ operations. In particular, the values $Z_0(0)$ and $Z_1(0)$ are obtained.

To compute the remaining $Z_l(0)$'s we wish to rewrite the recurrence (2.11) as a matrix equation. For any complex numbers α, β, and γ, define a $2n \times 2n$ matrix

[1] Strictly speaking, the recurrence can be applied to the initial sequence Z_0 to obtain the correct values of $Z_l(k)$ for $k < n - l$. For example, to get $Z_1(n-1)$ with equation (2.11) requires the value of $Z_0(n)$, which we do not have. This "edge effect" propagates as l increases but does not affect the values of the sequences that we actually need for the algorithm.

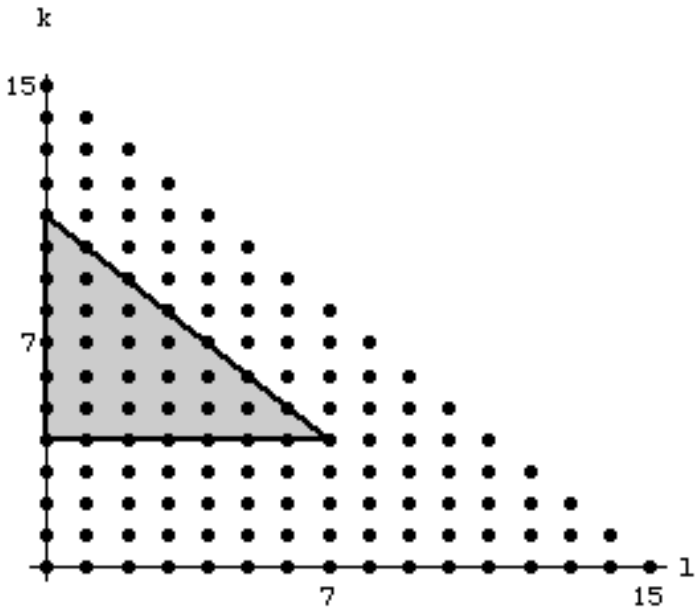

FIG. 2.2. *Computation of $Z_6(4)$ depends only on the computation of $Z_i(j)$ for (i,j) in the shaded triangle.*

$T_n(\alpha,\beta,\gamma)$ by

$$T_n(\alpha,\beta,\gamma) = \begin{pmatrix} 0 & I \\ \gamma I & \beta I + \alpha N \end{pmatrix},$$

where I denotes the $n \times n$ identity matrix and N denotes the $n \times n$ nilpotent matrix with ones on the superdiagonal and zeros elsewhere. Note that $T_n(\alpha,\beta,\gamma)$ is a block matrix composed of four $n \times n$ Toeplitz blocks. With this notation, recurrence (2.11) may be rewritten as

$$\begin{pmatrix} Z_l \\ Z_{l+1} \end{pmatrix} = T_n(a_l, b_l, c_l) \cdot \begin{pmatrix} Z_{l-1} \\ Z_l \end{pmatrix}. \tag{2.12}$$

Iteration of the recurrence is then realized as a product of such matrices, and so for any m,

$$\begin{pmatrix} Z_l \\ Z_{l+1} \end{pmatrix} = R_n(l-m-1, l) \cdot \begin{pmatrix} Z_{l-m-1} \\ Z_{l-m} \end{pmatrix}. \tag{2.13}$$

The product

$$R_n(l-m-1, l) = T_n(\alpha_l, \beta_l, \gamma_l) \cdots T_n(\alpha_{l-m-1}, \beta_{l-m-1}, \gamma_{l-m-1})$$

is still a block matrix made up of four $n \times n$ Toeplitz blocks. Consequently, the values of Z_{l-1} and Z_l can be computed from those of Z_{l-m-1} and Z_{l-m} by a single matrix–vector multiplication using a $2n \times 2n$ matrix with $n \times n$ Toeplitz blocks.

In particular,

$$\begin{pmatrix} Z_{\frac{n}{2}} \\ Z_{\frac{n}{2}+1} \end{pmatrix} = R_n\left(0, \frac{n}{2}\right) \cdot \begin{pmatrix} Z_0 \\ Z_1 \end{pmatrix}. \tag{2.14}$$

Recalling the discussion within the proof of Lemma 2.1, multiplication of an $n \times n$ Toeplitz matrix by a vector may be performed by standard FFT techniques using at most $9n(1 + \log n) + 2n$ operations. Four such matrix–vector multiplications are required to compute (2.14) so that an additional $36n(1 + \log n) + 8n$ operations are required to compute $Z_{\frac{n}{2}}$ and $Z_{\frac{n}{2}+1}$ and, in particular, $Z_{\frac{n}{2}}(0)$ and $Z_{\frac{n}{2}+1}(0)$ from our initial data of Z_0 and Z_1.

The point of this is to decompose the problem into two half-sized subproblems; we shall compute the Z_l for $l > n/2+1$ by applying equation (2.13) to $Z_{\frac{n}{2}}$ and $Z_{\frac{n}{2}+1}$. As we indicated previously in Figure 2.2, the values $Z_l(0)$ for $l > n/2+1$ depend only on the initial half-segments of the sequences $Z_{\frac{n}{2}}$ and $Z_{\frac{n}{2}+1}$. Similarly, the values $Z_l(0)$ for $l < n/2$ may be computed by applying the recurrence to the initial half-segments of the sequences Z_0 and Z_1. This is reexhibited in Figure 2.3, in which the diagonal lines display the dependence of the desired output $Z_l(0)$ on the various "subtriangles" in the grid for a problem of size $n = 16$.

Consequently, we see that to continue to obtain the remaining $Z_l(0)$'s, we need only keep $Z_j(k)$ for $0 \le k < n/2$ and $j = 0, 1, n/2$, and $n/2+1$. Thus step 2 proceeds by throwing away half of each of the sequences Z_0, Z_1, $Z_{\frac{n}{2}}$, and $Z_{\frac{n}{2}+1}$ and then computing $Z_{\frac{n}{4}}(k)$ and $Z_{\frac{n}{4}+1}(k)$ $(0 \le k < n/2)$ from the truncated sequences Z_0 and Z_1 and computing $Z_{\frac{3n}{4}}(k)$ and $Z_{\frac{3n}{4}+1}(k)$ $(0 \le k < n/2)$ similarly from the truncated sequences $Z_{\frac{n}{2}}$ and $Z_{\frac{n}{2}+1}$.

At the end of step 2, we own the first halves of the sequences Z_0, Z_1; $Z_{\frac{n}{4}}, Z_{\frac{n}{4}+1}$; $Z_{\frac{n}{2}}, Z_{\frac{n}{2}+1}$; $Z_{\frac{3n}{4}}, Z_{\frac{3n}{4}+1}$. Again, we throw away the latter halves of each (half-) sequence and continue by performing four multiplications by Toeplitz matrices of size $n/4$, and so on.

All of this is illustrated again by Figure 2.3 for a problem of size $n = 16$ in which we have indicated which values in the grid we have obtained after each step in the algorithm. Thus it shows that step 0 results in the sequences Z_0 and Z_1. After step 1, we have also obtained the sequences Z_8 and Z_9, which we then truncate in half while also cutting the sequences Z_0 and Z_1 in half. From this subset of data, we can then compute one quarter of the sequences Z_4, Z_5, Z_{12}, and Z_{13} and, after truncating each of the previous data sequences in half, a quarter of the sequences Z_0, Z_1, Z_8, and Z_9 as well. Finally, in the last step, we obtain the remaining pieces, one eighth of the sequences Z_2, Z_3, Z_6, Z_7, Z_{10}, Z_{11}, Z_{14}, and Z_{15}.

The complexity of the algorithm follows easily from an argument similar to that of Lemma 2.1. The process of "throwing away" is just a standard projection, so even if we include it in our estimate, it requires at most an additional $4n$ operations at the first step. Having cut the vectors Z_0, Z_1, $Z_{n/2}$, and $Z_{n/2+1}$ in half, we now have two identical subproblems that are half the size of the original problem, in which we computed $Z_{n/2}$ and $Z_{n/2+1}$ from Z_0 and Z_1. Thus if we let $T(n)$ denote the number of operations needed to compute the elements $Z_j(0)$ from the initial data of Z_0 and Z_1, we obtain the recurrence

$$T(n) = 36n(1 + \log n) + 8n + 4n + 2T\left(\frac{n}{2}\right) = 48n + 36n \log n + 2T\left(\frac{n}{2}\right). \tag{2.15}$$

Iterating (2.15) yields

$$T(n) \le 48n \log n + 36n \log^2 n. \tag{2.16}$$

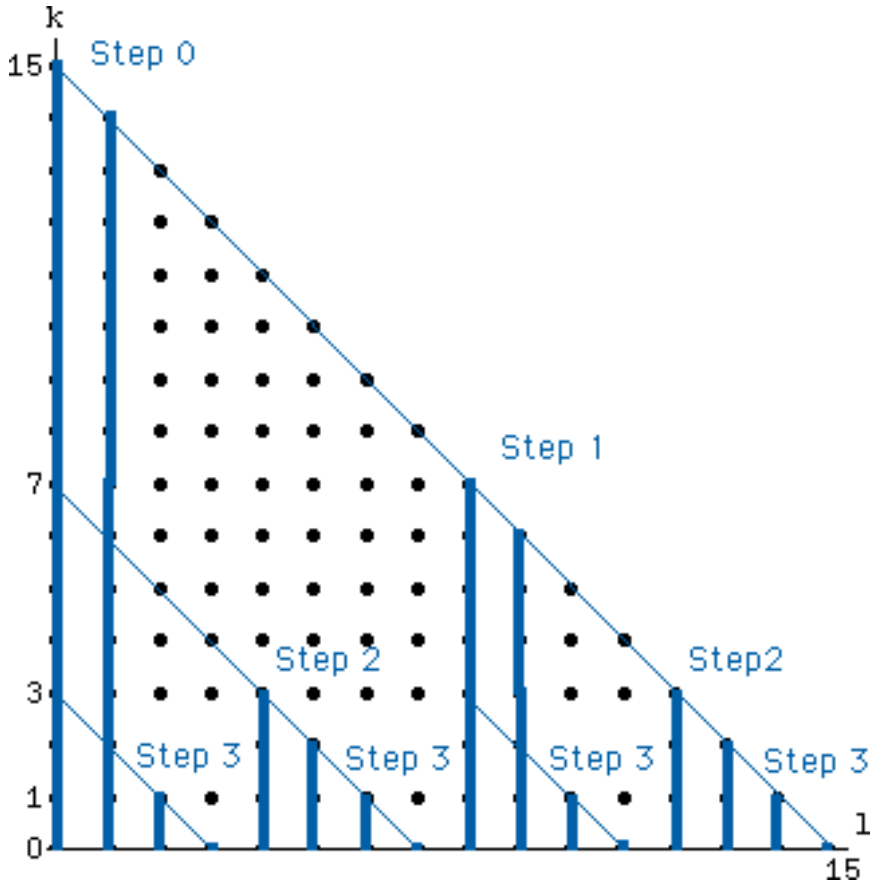

FIG. 2.3. *Computation of the $Z_l(0)$ for $l < n$ by a cascade of convolutions of decreasing size. The relevant ranges of Z are highlighted, and the step in which they are calculated is indicated.*

Finally, throwing in the operations needed to initially compute Z_0 and Z_1, we see that at most $48n \log n + 36n \log^2 n + 9n(1 + \log n) + 2n = O(n \log^2 n)$ operations are needed to compute the projections. □

Remarks. 1. As regards the storage requirements of the precomputed data structure, it is clear that all that is needed are the various Toeplitz matrices in the array:

$$
\begin{array}{ccccc}
 & & R_n\left(0, \frac{n}{2}\right) & & \\
 & R_{\frac{n}{2}}\left(0, \frac{n}{4}\right) & & R_{\frac{n}{2}}\left(\frac{n}{2}, \frac{3n}{4}\right) & \\
R_{\frac{n}{4}}\left(0, \frac{n}{8}\right) & R_{\frac{n}{4}}\left(\frac{n}{4}, \frac{3n}{8}\right) & R_{\frac{n}{4}}\left(\frac{n}{2}, \frac{5n}{8}\right) & R_{\frac{n}{4}}\left(\frac{3n}{4}, \frac{7n}{8}\right) & \\
 & & \vdots & & \\
R_4(0,2) & R_4(4,6) & \dots & \dots & R_4(n-4, n-2)\ .
\end{array}
$$

In fact, each should be suitably augmented to circulant matrices in order to effect an efficient matrix–vector multiplication. Analysis similar to that used in Remark 3

following the proof of Lemma 2.1 shows that this will require $O(n \log n)$ storage.

2. The Toeplitz matrices in the array above may be generated in $O(n \log^2 n)$ operations. The idea here is to build the larger R matrices at the top of this array from the smaller matrices lower down, which will have already been computed.

We start by filling in the bottom level of the array, building all of the matrices of the form $R_4(2j, 2j+2)$. Notice that we actually only need every other one of these for the lowest level of our data structure, but the rest are required for building the next level. These matrices may be combined pairwise, as detailed below, in order to obtain the matrices at the next level. Explicitly, we combine $R_4(4j, 4j+2)$ with $R_4(4j+2, 4j+4)$ to obtain $R_8(4j, 4j+4)$. Again, only half of these results are needed to fill out the second level of the data structure, and the rest are required for building the third level. Continuing in this fashion, we end up with all of the matrices that we need, up to $R_n(0, n/2)$.

The basic step is as follows: given matrices $R_p(j, j+m)$ and $R_p(j+m, j+2m)$, determine $R_{2p}(j, j+2m)$ efficiently. To see this, it is helpful to note that each of the four Toeplitz blocks of one of these matrices, say $R_p(j, j+m)$, may be written as a polynomial expression in the powers of the nilpotent matrix N of degree no more than m. The blocks are completely determined by the coefficients of these polynomials, and multiplication of a pair of R matrices corresponds to 2-by-2 matrix multiplication using polynomial arithmetic on the entries. Thus the entries of $R_{2p}(j, j+2m)$ may be computed from those of $R_p(j, j+m)$ and $R_p(j+m, j+2m)$ using fast polynomial arithmetic for polynomials of degree no more than m. Therefore, this may be done in $O(m \log m)$ operations.

The complexity of obtaining the entire array is now determined as in several similar calculations that we have done earlier; at the lth level (starting at the bottom) of $\log n$ levels, we have $n/2^l$ matrices to compute at $O(l2^l)$ complexity each. This leads to the given complexity of $O(n \log^2 n)$ for the entire array.

2.3. Some practical considerations and an example. The approach of section 2.2, while theoretically interesting, is, in fact, numerically rather suspect. Part of the problem comes from the step of first projecting the data vector onto the monomials. These functions, while linearly independent in exact arithmetic, are so close to being dependent as to be nearly useless in practice. See, for example, [Ga2] for a discussion of the condition number of expansions of polynomial functions in the monomial basis and other bases. Numerical experiments confirm that when the algorithm presented above is implemented in floating-point arithmetic, it can produce very unreliable answers for problems of modest size.

To treat this potential problem, we now prove a slight generalization of the recurrence technique of the last section that permits us to replace the monomials with other polynomial bases that satisfy simple constant coefficient recurrence relations. In particular, we have in mind the shifted Chebyshev polynomials. They satisfy the recurrence

$$T^*_{n+1} = (4x-2)T^*_n(x) - T^*_{n-1}(x). \tag{2.17}$$

Such a recurrence can be run in either the forward direction or the backward direction, in which case we obtain

$$T^*_{n-1}(x) = (4x-2)T^*_n(x) - T^*_{n+1}(x).$$

Consequently, we see that running the recurrence backwards from 0 allows the definition of $T^*_{-k}(x) = T^*_k(x)$ for all values of k. Notice that, in general, $T^*_k(x)$ is a

polynomial of degree $|k|$. Equality for negative and positive indices follows from the fact that the recurrence is the same in either direction.

More generally, any constant coefficient recurrence can be run in either direction, producing polynomials of degree $|k|$ for index k, assuming initial conditions that dictate polynomials of degree 0 and 1 for indices 0 and 1, respectively. For example, if a system satisfies the recurrence

$$p_{k+1}(x) = (\alpha x + \beta)p_k(x) + \gamma p_{k-1}(x),$$

then we obtain the "backward recurrence"

$$p_{k-1}(x) = -\frac{1}{\gamma}(\alpha x + \beta)p_k(x) + \frac{1}{\gamma}p_{k+1}(x).$$

This simple observation allows us to couple our algorithm with polynomials that satisfy such recurrences.

THEOREM 2.4. *Suppose that the polynomial families* $\{p_k(x)| - n \le k < n\}$ *and* $\{\Phi_l(x)|l = 0, \ldots, n-1\}$ *satisfy three-term recurrences*

$$p_{k+1}(x) = (\alpha x + \beta)p_k(x) + \gamma p_{k-1}(x), \tag{2.18}$$

$$\Phi_{l+1}(x) = (a_l x + b_l)\Phi_l(x) + c_l\Phi_{l-1}(x), \tag{2.19}$$

with $\deg(p_k) = |k|$ *and* $\Phi_0 = 1$, *and set* $\Phi_{-1} = 0$. *Suppose that the projections* $\langle f, p_k\rangle$ *are known,* $-n \le k < n$. *From this, the projections* $\langle f, \Phi_l\rangle$, $l = 0, \ldots, n-1$, *can be computed in* $O(n\log^2 n)$ *operations.*

Proof. Again, we may assume without loss of generality that the weight function is identically 1. Define the sequence Z_l for each $l = 0, 1, \ldots, n-1$ by

$$Z_l(k) = \langle f, p_k\Phi_l\rangle \tag{2.20}$$

for $k = -n, \ldots, 0, 1, \ldots, n-1$. Our goal is to obtain the values $Z_l(0) = \langle f, p_0\Phi_l\rangle$. Instead, we have the values $Z_0(k) = \langle f, p_k\Phi_0\rangle$. We hope to proceed by convolution as in Theorem 2.3 and push up from Z_0 to the higher sequences Z_l.

Recurrence (2.19) for the Φ_l shows that for $l > 0$,

$$\begin{aligned} Z_{l+1}(k) &= a_l\langle f, xp_k\Phi_l\rangle + b_l\langle f, p_k\Phi_l\rangle + c_l\langle f, p_k\Phi_{l-1}\rangle \\ &= a_l\langle f, xp_k\Phi_l\rangle + b_l Z_l(k) + c_l Z_{l-1}(k). \end{aligned}$$

Now use recurrence (2.18) for the p_k's to see that

$$\begin{aligned} \langle f, xp_k\Phi_l\rangle &= \frac{1}{\alpha}\langle f, p_{k+1}\Phi_l\rangle - \frac{\beta}{\alpha}\langle f, p_k\Phi_l\rangle - \frac{\gamma}{\alpha}\langle f, p_{k-1}\Phi_l\rangle \\ &= \frac{1}{\alpha}Z_l(k+1) - \frac{\beta}{\alpha}Z_l(k) - \frac{\gamma}{\alpha}Z_l(k-1). \end{aligned}$$

Therefore,

$$Z_{l+1}(k) = \frac{a_l}{\alpha}\left[Z_l(k+1) + \left(\frac{\alpha}{a_l}b_l - \beta\right)Z_l(k) - \gamma Z_l(k-1)\right] + c_l Z_{l-1}(k) \tag{2.21}$$

$$= u_l Z_l(k+1) + v_l Z_l(k) + w_l Z_l(k-1) + c_l Z_{l-1}(k). \tag{2.22}$$

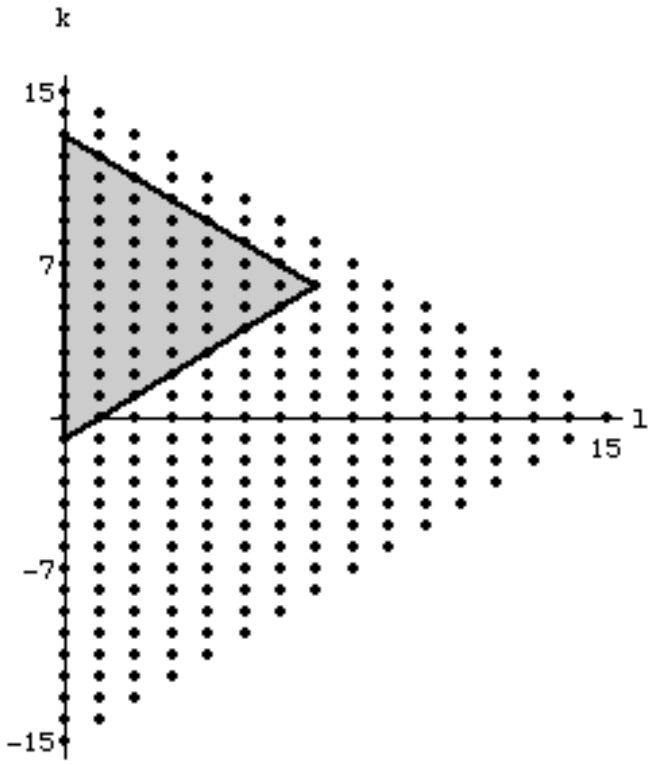

FIG. 2.4. *The computation of $Z_7(6)$ depends only on the computation of $Z_i(j)$ for (i, j) in the shaded triangle.*

Observe that the weights in expression (2.22) are independent of k. As in the case of Theorem 2.3, the sequence Z_{l+1} is obtained from the sequences Z_l and Z_{l-1} by convolving each with a fixed mask and then adding the resulting vectors. However, there is a difference. To describe this, it is again instructive to view the computation graphically. Following Theorem 2.3, we consider a function Z defined on a grid described by the l- and k-axes such that $Z(l, k) = Z_l(k)$. From this point of view, recurrence (2.22) indicates that a given value $Z_{l+1}(k)$ depends on knowing only any two adjacent vertical lines of data contained within the triangle determined by the vertices (l, k), $(0, k + l)$, and $(0, k - l)$. Figure 2.4 is an example.

Because in this case recurrence (2.22) "reaches" both down and up in k, slight modifications to the proof of Theorem 2.3 are required. Since the complexity counts are very similar, we will only point out the major changes and leave the details to the interested reader.

In analogy with Theorem 2.3, our goal is to express the full computation as a

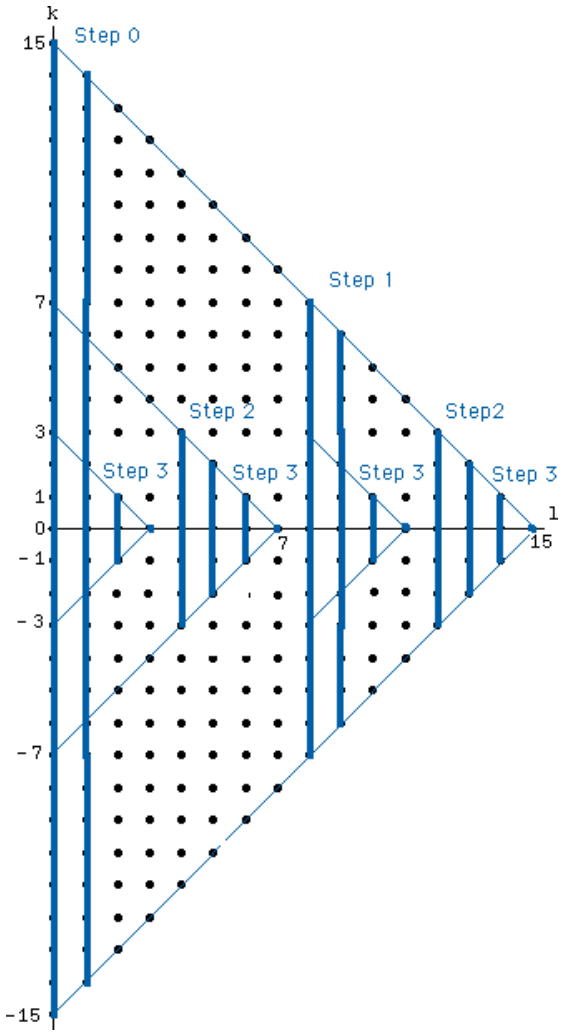

FIG. 2.5. *Computation of the $Z_l(0)$ for $l < 16$ by a cascade of convolutions of decreasing size. The relevant ranges of Z are highlighted, and the step in which they are calculated is indicated.*

divide-and-conquer algorithm. Figure 2.5 indicates how this can be accomplished. Starting with the full data of Z_0 and Z_1, we will construct $Z_{\frac{n}{2}}$ and $Z_{\frac{n}{2}+1}$. The values Z_j for $j < n/2 - 1$ depend on only half of the sequences Z_0 and Z_1, and similarly for $Z_{\frac{n}{2}+j}$, $Z_{\frac{n}{2}}$, and $Z_{\frac{n}{2}+1}$. Thus by keeping only the relevant values of these two pairs of sequences, we will have divided the original computation into two computations of half of the original's size. Continuing in this fashion, we ultimately obtain all values $Z_l(0)$. We need show only that the "divide" portion of the algorithm can be performed efficiently—that is, in $O(j \log j)$ operations for a problem of size j.

Again, we need the initial data of Z_0 and Z_1. We assume that Z_0 is given. By definition,

$$\begin{aligned} Z_1(k) &= \langle f, p_k \Phi_1 \rangle \\ &= \langle f, (a_0 x + b_0) p_k \rangle \\ &= a_0 \langle f, x p_k \rangle + b_0 Z_0(k). \end{aligned}$$

Notice that by using recurrence (2.18) for p_{k+1}, we may build the first summand out of at most three shifted copies of Z_0. Thus as a first step, a total of at most an additional $3n$ operations are needed to compute Z_1 from Z_0.

To compute the remaining Z_l's, we wish to rewrite recurrence (2.22) as a matrix equation. We can do this—up to "edge effects"—as we will now explain. For any complex numbers w, y, and z, let $C_n(w,y,z)$ denote the $2n \times 2n$ circulant matrix determined by setting the second row equal to $w, y, z, 0, \ldots, 0$,

$$C_n(w,y,z) = \begin{pmatrix} y & z & 0 & \cdots & 0 & 0 & w \\ w & y & z & \cdots & 0 & 0 & 0 \\ 0 & w & y & \cdots & 0 & 0 & 0 \\ \vdots & \vdots & \vdots & \cdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & \cdots & w & y & z \\ z & 0 & 0 & \cdots & 0 & w & y \end{pmatrix}. \tag{2.23}$$

Using the convention that

$$Z_l = \begin{pmatrix} Z_l(n-1) \\ \vdots \\ Z_l(0) \\ \vdots \\ Z_l(-n) \end{pmatrix},$$

consider the vectors Z'_l and Z'_{l+1} defined by the expression

$$\begin{pmatrix} Z'_l \\ Z'_{l+1} \end{pmatrix} = \begin{pmatrix} 0 & I_{2n} \\ c_l I_{2n} & C_n(w_l, v_l, u_l) \end{pmatrix} \cdot \begin{pmatrix} Z_{l-1} \\ Z_l \end{pmatrix}. \tag{2.24}$$

Notice that $Z'_l = Z_l$ but that Z'_{l+1} differs from Z_{l+1} by at worst the entries $Z_{l+1}(n-1)$ and $Z_{l+1}(-n)$. This is precisely the aforementioned "edge effect." If we define

$$A_n(l) = \begin{pmatrix} 0 & I_{2n} \\ c_l I_{2n} & C_n(w_l, v_l, u_l) \end{pmatrix}, \tag{2.25}$$

then we can make the following more general statement: a product of matrices of the form of $A_n(l+r)\cdots A_n(l)$ will still be composed of four $2n \times 2n$ circulant blocks, and the edge effects incurred when by multiplying this product by the vector $\left(\begin{smallmatrix} Z_l \\ Z_{l+1} \end{smallmatrix}\right)$ will still affect only (at most) the $r-1$ outermost values of Z_{l+r-1} and Z_{l+r}. More precisely, a simple inductive argument yields the following claim.

CLAIM. *Let $0 \le r < n$. Define Z'_{l+r-1} and Z'_{l+r} by*

$$\begin{pmatrix} Z'_{l+r-1} \\ Z'_{l+r} \end{pmatrix} = A_n(l+r)\cdots A_n(l) \cdot \begin{pmatrix} Z_{l-1} \\ Z_l \end{pmatrix}.$$

Then $Z'_i(j) = Z_i(j)$ for $j = -(n-r-2), \ldots, n-r-2$ and $i = l+r-1, l+r$.

The import of the claim is that if we compute the product $R \cdot \left(\begin{smallmatrix} Z_0 \\ Z_1 \end{smallmatrix}\right)$, where

$$R = A_n(0)\cdots A_n\left(\frac{n}{2}-1\right), \tag{2.26}$$

then we will correctly compute the values $Z_{\frac{n}{2+i}}(j)$ for $i = 0, 1$ and $-(n/2-1) \le j \le n/2-1$. Notice that this is precisely the data we need in order to effect the "divide"

portion of this algorithm (cf. Figures 2.4 and 2.5). The matrix R is composed of four $2n \times 2n$ circulant blocks, and thus the matrix–vector multiplication (2.26) requires at most $64n(1+\log n)+16n$ operations (cf. the discussion in the proof of Theorem 2.3). We continue by throwing away the upper and lower quarters of the vectors Z_0, Z_1, $Z'_{\frac{n}{2}}$, and $Z'_{\frac{n}{2}+1}$, forming two new subproblems of size $n/2$, and repeating the procedure. The analysis now follows that of the proof of Theorem 2.3. □

Remark. Notice that if initially only the projections onto the p_k's for positive k were given, then the projection onto the p_k's for negative k could obtained efficiently by using Theorem 2.3 applied to the backwards recurrence.

In particular, the shifted Chebyshev polynomials satisfy all of our requirements: they have a constant coefficient recurrence relation, fast projection is possible by Corollary 2.2, $T_k = T_{-k}$, and they possess relatively salutary numerical properties, even on a uniform grid. We have applied them in the case of the Hahn polynomial transforms with a great improvement in numerical accuracy over the method of Theorem 2.3.

Example 1: *Fast Hahn polynomial transform.* To illustrate Theorem 2.4 we proceed with an example and discuss its application to the specific case of the *Hahn polynomials*, a well-known discrete orthogonal polynomial family. This is, in fact, the relevant family of orthogonal polynomials for the California Lottery example discussed in section 1, and it provides the spherical functions for the k-sets of n-set graph. We begin by summarizing the relevant properties of the Hahn polynomials. We follow Stanton's notation of [St1], wherein a good bibliography for further sources is also contained. For general facts about orthogonal polynomials, Chihara's book [C] provides a friendly introduction to the subject.

The Hahn polynomials

$$Q_j(x;\alpha,\beta,N) = \sum_{i=0}^{j} \frac{(-j)_i\,(1+\alpha+\beta+j)_i\,(-x)_i}{i!\,(1+\alpha)_i\,(-N)_i}$$

are defined on the finite set $x = 0, 1, \ldots, N$ for $j = 0, 1, \ldots, N$. They are orthogonal with respect to the hypergeometric distribution

$$W(j;\alpha,\beta,N) = \binom{-1-\alpha}{-\beta+\mathrm{N}}\binom{-1-j}{\beta},$$

which is positive in the cases that we consider, $\alpha, \beta < -N$.

For the purpose of our calculations, we scale things so that all of the action takes place on the uniform grid in $[0,1]$, $\{k/(N+1) | k = 0, \ldots, N\}$. For fixed α, β, and N, define

$$Q_n^*(x) = Q_n(\,(N+1)x;\alpha,\beta,N)$$

for x in the grid. Then we have the three-term recurrence

$$Q_{n+1}^*(x) = \left(\frac{b_n + d_n - (N+1)x}{b_n}\right) Q_n^*(x) - \frac{d_n}{b_n} Q_{n-1}^*(x) \tag{2.27}$$

derived from that for Hahn polynomials, with

$$b_n = \frac{(n+\alpha+\beta+1)(n+\alpha+1)(N-n)}{(2n+\alpha+\beta+1)(2n+\alpha+\beta+2)}$$

and

$$d_n = \frac{n(n+\beta)(n+\alpha+\beta+N+1)}{(2n+\alpha+\beta)(2n+\alpha+\beta+1)}.$$

The calculation begins with projections of the data vector f onto the shifted Chebyshev polynomials $T_n^*(x)$. The projections are taken as l^2 inner products on the uniform grid in $[0,1]$, weighted by the hypergeometric distribution W on the grid. For the balance of this example, we will use this weighted l^2 inner product.

As described in Corollary 2.2, all of these projections may be done in $O(N \log^2 N)$ time. We now think of these as projections onto the functions $T_n^* Q_0^*$ and employ the techniques described in Theorem 2.4 for efficiently changing this information into the desired projections onto the Q_n^*'s.

We use the coefficients of recurrence (2.17) to construct the convolution masks described in Theorem 2.4. In practice, we also normalize the recurrences by the l^2 norms of the Hahn polynomials. Define

$$Z_l(k) = \frac{1}{\|Q_l^*\|} \langle f, T_k^* Q_l^* \rangle, \quad -N \le k < N,$$

with $T_k^* = T_{-k}^*$. Then

$$Z_l(k) = A_{l-1} Z_{l-1}(k) + B_{l-1} \{Z_{l-1}(k-1) + Z_{l-1}(k+1)\} + C_{l-1} Z_{l-2}(k),$$

with

$$A_l = \frac{b_l + d_l - \frac{N+1}{2}}{b_l} \frac{\|Q_l^*\|}{\|Q_{l+1}^*\|}.$$

One-step convolution coefficient masks for producing a sequence Z_l from lower index sequences Z_{l_0} and Z_{l_0+1} may be generated by an appropriate recursion. In the derivation that follows, M_j and N_j denote the one-step convolution masks for obtaining Z_{j+1} from Z_j and Z_{j-1}; in the present case, $M_j = \{\ldots, 0, B_j, A_j, B_j, 0, \ldots\}$ and $N_j = \{\ldots, 0, 0, C_j, 0, 0, \ldots\}$. Then

$$\begin{aligned}
Z_{l+1} &= M_l * Z_l + N_l * Z_{l-1} \\
&= M_l * (M_{l-1} * Z_{l-1} + N_{l-1} * Z_{l-2}) + N_l * Z_{l-1} \\
&= (M_l * M_{l-1} + N_l) * Z_{l-1} + (M_l * N_{l-1}) * Z_{l-2} \\
&= M_l(2) * Z_{l-1} + N_l(2) * Z_{l-2}.
\end{aligned}$$

Likewise we can continue all the way down to Z_{l_0} and Z_{l_0+1}:

$$Z_{l+1} = M_l(l - l_0) * Z_{l_0+1} + N_l(l - l_0) * Z_{l_0}$$

with multistep masks $M_l(j)$ and $N_l(j)$ defined recursively by

$$\begin{aligned}
M_l(j+1) &= M_l(j) * M_{l-j} + N_l(j), \\
N_l(j+1) &= M_l(j) * N_{l-j}
\end{aligned}$$

with initial conditions

$$M_l(1) = M_l, \qquad N_l(1) = N_l.$$

Using this, we generate and prestore the various multistep masks as described in Theorem 2.4, and run the tree of convolutions. Figure 2.6 shows the resulting steps of a small calculation, starting with Z_0 and Z_1, and then filling out the various other sequences in the tree.

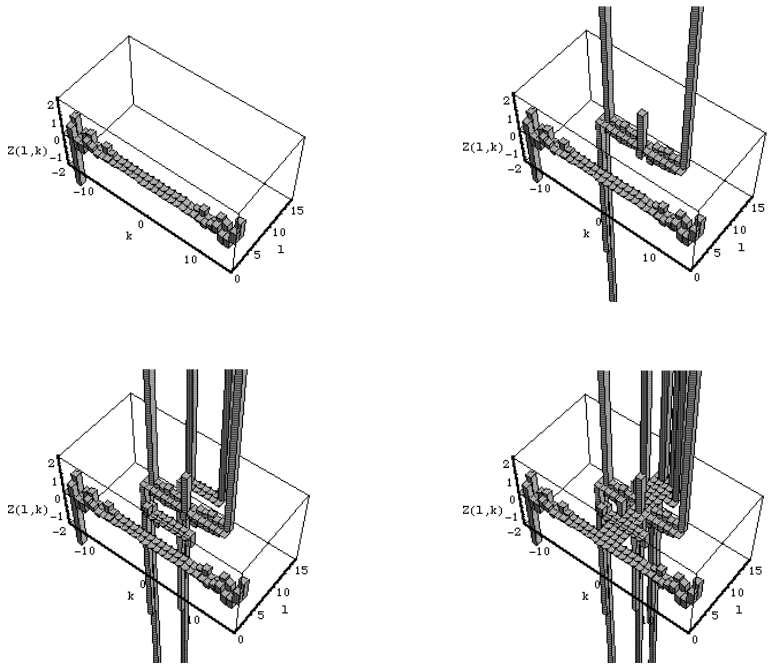

FIG. 2.6. *Stages in the computation of the Z_l for the Hahn polynomials. Z_0 is projection onto the Chebyshev polynomials. The desired transform values are the $Z_l(0)$'s. This example is the transform of Q_8^*.*

3. Fast spherical transforms for distance transitive graphs. We now employ the various results of the last section to obtain results leading up to a fast Fourier transform for distance transitive graphs. As mentioned, these results are of interest in several problems of data analysis, such as the California Lottery example mentioned in section 1.

Briefly, the setting is as follows. Let G be a finite group acting as isometries on a finite graph X with distance function $d(\cdot,\cdot)$ given by the usual measure of shortest path. Recall that X is *distance transitive* (for G) if given any two pairs of points (x,y), $(x',y') \in X$ such that $d(x,y) = d(x',y')$, there exists $s \in G$ such that $(sx,sy) = (x',y')$. Let $L^2(X)$ denote the vector space of complex-valued functions on X. Then $L^2(X)$ affords a linear representation of G by left translation. In this case, $L^2(X)$ may be decomposed into irreducible subspaces

$$L^2(X) = V_0 \oplus \cdots \oplus V_N,$$

where N is the maximum distance between two points in X.

Fix a basepoint $x_0 \in X$ and let H be the stabilizer of x_0 in G. Then X is in a natural 1:1 correspondence with G/H and $L^2(G/H)$ is the vector space of right H-invariant functions on G. If Ω_k denotes the sphere of radius k about x_0, then the algebra of functions constant on each Ω_k is isomorphic to the algebra of H-biinvariant functions on G, denoted $L^2(H\backslash G/H)$.

The fact that $L^2(X)$ is multiplicity free is equivalent to the existence in each V_k of a unique function ϕ_k, constant on each Ω_k and normalized by $\phi_k(x_0) = 1$. Classically,

the function ϕ_k is called the kth *spherical function* on X (cf. [He] and the references therein, as well as the remarks at the close of section 3.1.)

Let $x_j \in \Omega_j$. Then in analogy with the classical case (see, e.g., [He, Chapter 4]), we define for any function f constant on each Ω_k the *spherical transform* of f at ϕ_i to be the sum

$$\widehat{f}(\phi_i) = \sum_{j=0}^{N} f(x_j)\phi_i(x_j)|\Omega_j|.$$

The *discrete spherical transform* (DST) of f is the collection of transforms $\{\widehat{f}(\phi_i)\}_i$.

Direct computation of the DST requires $O(N^2)$ operations. For large N, this cost quickly becomes prohibitive. In this section, we give an algorithm that computes the DST for spherical functions from distance transitive graphs in $O(N \log^2 N)$ operations. By the same techniques, we may also invert the transform in the same number of operations and consequently obtain an $O(N \log^2 N)$ algorithm for convolution of two H-biinvariant functions.

Section 4 will show that the problem of finding an FFT for distance transitive graphs may be reduced to that of finding an efficient projection onto the spherical functions, an orthogonal family of special functions on the graph. This section discusses the fast DST. We begin by giving an expanded review of the group theoretic background (section 3.1), sufficient to present the fast algorithm in section 3.2.

3.1. Background and notation. In the interest of making this paper as self-contained as possible, we sketch the group-theoretic background and notation. We mainly follow Stanton's expositions [St1, St3], which are very accessible and provide a wealth of references. For the necessary graph-theoretic terminology—with special attention paid to distance transitive graphs—see Biggs [Bi]. Serre's book [S] provides a nice introduction to the representation theory of finite groups.

Throughout, X is a *distance transitive graph*. Thus X is a finite metric space with *integer-valued* distance d (taken to be the usual distance of the shortest path on the graph) with G a group of isometries of X (acting on the left) satisfying the property of *two-point homogeneity*:

If $x, y, x', y' \in X$ are such that $d(x, y) = d(x'y')$, then there exists $g \in G$ such that $gx = x'$ and $gy = y$.

In this case, X is also said to be a *two-point homogeneous space* (with respect to G and d).

It is perhaps instructive at this point to recall the analogy here with the usual 2-sphere in $\mathbf{R}^3$. In this case, we know that any pair of points on the sphere which are a fixed distance apart can be moved into any two other such points by a rotation—or isometry of $\mathbf{R}^3$. Thus the rotation group $SO(3)$ acts two-point homogeneously on the 2-sphere. Stanton's papers [St1, St3] do a terrific job of spelling out these analogies.

Thus since $d(x, x) = 0 = d(x', x')$ for every $x, x' \in X$, there is a $g \in G$ such that $gx = x'$, i.e., G acts *transitively* on X. Let $x_0 \in X$ denote a fixed *basepoint* and $H = \{g \in G \mid gx_0 = x_0\}$ denote the stabilizer subgroup of x_0. Since G acts transitively on X, any element $x \in X$ can be written as $x = sx_0$ for some $s \in G$ and if $sx_0 = x = tx_0$, then $s^{-1}tx_0 = x_0$ and hence $s^{-1}t \in H$ and $t \in sH$. Thus there is a natural correspondence between X and the coset space G/H, associating any element $x = sx_0$ with the coset sH. Keeping in mind the analogy with the 2-sphere, consider the subgroup $H = SO(2) < SO(3)$ of rotations that fix the north pole. Cosets are represented by circles of latitude, with coset representatives in 1:1 correspondence

with a choice of points at all possible latitudes. Any two points of the same latitude differ by only a rotation about the north pole.

Under the correspondence between points in X and cosets in G/H, the vector space of complex-valued functions on X, $L^2(X)$, is isomorphic to the vector space of complex-valued functions on G/H, $L^2(G/H)$, by defining

$$f(sH) \equiv f(sx_0).$$

Any function on G/H then naturally extends to $\tilde{f}$, a function defined on the entire group G, by declaring it to be constant on cosets,

$$\tilde{f}(s) \equiv f(sH).$$

It is not hard to check that $\tilde{f}$ is well defined and that

$$\tilde{f}(sh) = \tilde{f}(s). \tag{3.1}$$

Thus $\tilde{f}$ is a (*right*) *H-invariant function on G.* Conversely, it is easy to see that for any subgroup $H < G$, the subspace of $L^2(G)$ satisfying (3.1)) is equivalent to the $L^2(G/H)$. Following along the analogy with the 2-sphere, $L^2(SO(2)\backslash SO(3)/SO(2))$ can be identified with the subspace of functions on the 2-sphere which are constant on latitudes.

The action of G on X gives rise to a *representation* of G in $L^2(X)$ by translation. More precisely, for every $s \in G$ and $f \in L^2(X)$, a new function $\rho(s)f \in L^2(X)$ can be defined by

$$[\rho(s)f](x) \equiv f(s^{-1}x).$$

In this manner, each $\rho(s)$ defines a linear operator on $L^2(X)$ such that $\rho(st) = \rho(s)\rho(t)$ and thus is a *representation* of the group G. This representation is, in general, *reducible* in the sense that there exist proper subspaces of $W_1, \ldots, W_r$ such that each W_i is *G-invariant* (i.e., $\rho(s)W_i \subset W_i$ for all $s \in G$) and $L^2(X) = W_1 \oplus \cdots \oplus W_r$. A subspace W is *G-irreducible* if it contains no proper G-invariant subspaces. For $L^2(X)$, an irreducible decomposition can be understood by considering the action of H.

Let Ω_k denote the sphere of radius k about x_0,

$$\Omega_k = \{x \in X \mid d(x, x_0) = k\}. \tag{3.2}$$

Then the Ω_k's are exactly the H-orbits in X. That is, X is the disjoint union of the Ω_k's and if $x, y \in \Omega_k$, then $hx = y$ for some $h \in H$ and, conversely, if $hx = y$, then $x, y \in \Omega_k$ for some k. In the case of the 2-sphere, the associated "Ω_k's" are the circles of latitude.

A subspace W of $L^2(X)$ is *H-invariant* if for all $f \in W$, $\rho(h)f \in W$ for all $h \in H$. Thus a function constant on each of the Ω_k's is H-invariant and vice versa. Hence if N is the maximum distance occurring in X, then the subspace of H-invariant functions in $L^2(X)$ is of dimension $N+1$. This may be immediately translated into a statement about functions on G: under the association of $L^2(X)$ with right H-invariant functions on G, the H-invariant functions of $L^2(X)$ become functions which are *both* left and right H-invariant, i.e., functions $f \in L^2(G)$ such that

$$f(h_1 s h_2) = f(s)$$

for all $h_1, h_2 \in H$. Such H-biinvariant functions are then naturally associated with the space of functions constant on double cosets $H\backslash G/H$ and thus are denoted as $L^2(H\backslash G/H)$. Hence we see that $L^2(H\backslash G/H)$ is of dimension $N+1$.

Note that the subspaces $L^2(X)$ and $L^2(H\backslash G/H)$ are, in fact, algebras under convolution: if $f, g \in L^2(X)$, then define $f \star g \in L^2(X)$ by

$$f \star g(x) = \sum_{s \in G} \tilde{f}(s) g(s^{-1}x), \tag{3.3}$$

where $\tilde{f}$ is the function on G derived from f by extending it to be constant on cosets of H as in (3.1). It is easy to check that if f and g are H-invariant, then their convolution is as well.

As a complex representation space for a finite group G, $L^2(X)$ may be decomposed into G-irreducible subspaces (cf. [S, section 1.4, Theorem 2]). In the general situation of decomposing the permutation representation arising from a finite group G acting transitively on a set X, this irreducible decomposition need not be unique. However, under the assumption of distance transitivity, an irreducible decomposition is indeed unique.

THEOREM 3.1 ([St1, Theorem 2.6]). *Let all notation be as above. Then as a representation of G, the space $L^2(X)$ has a unique decomposition into irreducible subspaces as*

$$L^2(X) = V_0 \oplus V_1 \oplus \cdots \oplus V_N,$$

where the V_i are all pairwise inequivalent—that is, the representation of G in $L^2(X)$ is multiplicity-free.

The proof of this theorem is not crucial for the main results, but it is worth remarking that it depends only on the fact that G acts two-point homogeneously on X and as such is a general fact about permutation representations (cf. [W, Chapter 5, section 29]). In this context, a proof follows from the fact that Theorem 3.1 is equivalent to the statement that the *intertwining algebra* of the permutation representation is commutative. (The intertwining algebra is the algebra of linear operators T that commute with the permutation representation ρ—i.e., the set of T such that $T\rho(s) = \rho(s)T$ for all $s \in G$.) To show this commutativity, choose a basis for $L^2(X)$ consisting of "delta functions" or point masses concentrated at single points. For $0 \le k \le N$, define the $|X| \times |X|$ matrices D_k by

$$D_k(x,y) = \begin{cases} 1 & \text{if } d(x,y) = k, \\ 0, & \text{otherwise.} \end{cases} \tag{3.4}$$

Straightforward combinatorial arguments (e.g., [St1, St3]) show that the D_k's commute and span the intertwining algebra, which must then be of dimension $N+1$. Moreover, the algebra is generated by D_1 since the D_k's satisfy the following three-term recurrence [St1, St3],

$$D_1 D_i = c_{i+1} D_{i+1} + a_i D_i + b_{i-1} D_{i-1}, \tag{3.5}$$

where

$$\begin{aligned} c_{i+1} &= |\{z : d(x,z) = 1, d(y,z) = i\}| \quad \text{for any fixed } x, y \text{ with } d(x,y) = i+1, \\ a_i &= |\{z : d(x,z) = 1, d(y,z) = i\}| \quad \text{for any fixed } x, y \text{ with } d(x,y) = i, \\ b_{i-1} &= |\{z : d(x,z) = 1, d(y,z) = i\}| \quad \text{for any fixed } x, y \text{ with } d(x,y) = i-1. \end{aligned}$$

Consequently, D_i is a polynomial in D_1,

$$D_i = p_i(D_1). \tag{3.6}$$

Since D_1 is real symmetric and generates an algebra of dimension $N+1$, it has distinct real nonzero eigenvalues $\{\lambda_0 < \cdots < \lambda_N\}$. Also, since D_1 is in the intertwining algebra for the representation ρ and the intertwining algebra is commutative, the λ_i eigenspaces must be the G-irreducible subspaces.

The importance of Theorem 3.1 is that it shows that in this special case, the isotypic and irreducible decompositions coincide so that the irreducible decomposition is independent of the choice of basis. It is a direct consequence of Theorem 3.1 that in each V_i there exists a unique one-dimensional H-fixed subspace (e.g., see [D, p. 54, Theorem 9]). We choose a basis vector ϕ_i for this subspace by demanding that $\phi_i(x_0) = 1$. Note that this is possible since the previous reference—or Frobenious reciprocity (cf. [S])—shows the existence of some nonzero H-fixed element (hence constant on each of the Ω_k) $\phi_i \in V_i$. Since

$$D_1\phi_i = \lambda_i\phi_i \tag{3.7}$$

and ϕ_i is constant on each Ω_k, the fact that ϕ_i is not identically zero implies that $\phi_i(x_0) \neq 0$. Hence ϕ_i can be normalized so as to assume $\phi_i(x_0) = 1$.

Note that ϕ_i may be viewed as either an H-invariant function on X or an H-biinvariant function on G. As an H-invariant function on X, it is constant on the spheres Ω_k. We call ϕ_i the ith *spherical function.* By counting, we see that the spherical functions give a basis for the H-invariant functions on X.

For distance transitive graphs, the polynomial nature of the spherical functions is derived from the self-same property of the commuting algebra for the representation of G in $L^2(X)$.

As shown in [St1], by evaluating the eigenvalue equation (3.7) at Ω_k, we move recurrence (3.5) to the ϕ_i's:

$$\lambda_i\phi_i(\Omega_k) = \gamma_k\phi_i(\Omega_{k+1}) + \alpha_k\phi_i(\Omega_k) + \beta_k\phi_i(\Omega_{k-1}), \tag{3.8}$$

where for any $x \in \Omega_k$,

$$\begin{aligned}
\gamma_k &= |\{z : z \in \Omega_{k+1} \text{ and } d(x,z) = 1\}|,\\
\alpha_k &= |\{z : z \in \Omega_k \text{ and } d(x,z) = 1\}|, \quad \text{and}\\
\beta_k &= |\{z : z \in \Omega_{k-1} \text{ and } d(x,z) = 1\}|.
\end{aligned}$$

An examination of the combinatorics yields

$$|\Omega_k|\phi_i(\Omega_k) = p_k(\lambda_i). \tag{3.9}$$

The orthogonality relations for the spherical functions take on the form

$$\frac{1}{|X|}\sum_{k=0}^{N}\phi_i(\Omega_k)\phi_j(\Omega_k)|\Omega_k| = \delta_{ij}\frac{1}{\dim(V_j)}, \tag{3.10}$$

where $\phi_i(\Omega_k)$ makes sense since ϕ_i is constant on Ω_k. In addition, we have a "dual orthogonality relation,"

$$\frac{1}{|X|}\sum_{i=0}^{N}\phi_i(\Omega_k)\phi_i(\Omega_j)\dim(V_i) = \delta_{kj}\frac{1}{|\Omega_k|}. \tag{3.11}$$

We summarize this with the following theorem.

THEOREM 3.2. *Let X be a finite distance transitive graph with respect to a group of isometries G. Let*

$$L^2(X) = V_0 \oplus \cdots \oplus V_N$$

be the isotypic and hence irreducible decomposition of $L^2(X)$ so that N is the maximum distance occurring in X. Let ϕ_i be the spherical function for V_i and λ_i as in (3.7) *and Ω_k as in* (3.2). *Then*

$$|\Omega_k|\phi_i(\Omega_k) = p_k(\lambda_i)$$

for some set of orthogonal polynomials $\{p_k(x) \mid 0 \le k \le N\}$ such that p_k is of degree k and the polynomials satisfy a three-term recurrence (3.5).

Remarks. 1. It is worth noting that while the spherical functions ϕ_i are determined by the polynomial functions described above, Theorem 3.2 does not say that $\phi_i(\Omega_k)$ is polynomial in k (i.e., equal to some fixed polynomial evaluated at $N+1$ fixed points). Rather, this is a statement that the dual functions p_k are an orthogonal polynomial system with respect to the weights $\dim(V_i)$, although for many examples this will also be true of the spherical functions (cf. section 4). As a consequence, in general the inverse spherical transform is always a projection onto polynomials and would thus benefit from general results on fast projection onto polynomials. In fact, such an algorithm can then be transposed to obtain an algorithm for the direct transform with the same complexity, whether or not the direct transform is obtained by projection onto polynomials.

2. The existence of spherical functions depended only on the fact that the permutation representation of G on $L^2(G/H)$ was multiplicity free. This is often summarized by saying that (G, H) form a *Gelfand pair*. Gelfand pairs have been much studied of late. See Gross [Gr] for a survey with applications to number theory and Diaconis [D] for applications to statistics and probability as well as an extensive bibliography. Helgason's book [He] gives a thorough introduction to the study of spherical functions for compact and locally compact groups with a full bibliography.

As remarked, the polynomial nature follows from the polynomial relation of the D_i's. This is true in a slightly more general setting than distance transitive graphs. It can be extended to finite two-point homogeneous spaces in which the metric satisfies some technical properties (cf. [St1, p. 90]).

Spherical functions may also be computed by character-theoretic methods. Travis [Tr] generalizes this approach to construct "generalized" spherical functions attached to any pair of characters ψ and χ for representations of a finite group G and subgroup H, respectively.

3. While the existence of the spherical functions depends only on the multiplicity-free nature of the representation, their expression as certain sampled values of orthogonal polynomial sets and consequent relations via the recurrence (3.8) use the integer-valued property of the metric.

4. We should point out that many of the problems and results discussed here may be phrased in the language of association schemes. Bannai and Ito [BI] give a beautiful treatment of this subject. We have not pursued this connection.

3.2. Fast spherical transforms on distance transitive graphs. The terminology is that of section 3.1. In particular, recall that $H < G$ is the isotropy group of a fixed basepoint $x_0 \in X$ so that $L^2(H\backslash G/H)$ is identified with the subspace of $L^2(X)$ of functions constant on spheres around x_0.

THEOREM 3.3. *For distance transitive graphs with maximum distance N, the spherical transform and its inverse can be computed in at most $O(N \log^2 N)$ operations.*

Proof. Let $f \in L^2(H\backslash G/H)$. Then the components of $\widehat{f}$ are

$$\widehat{f}(\phi_i) = \sum_{k=0}^{N} f(\Omega_k)\phi_i(\Omega_k)|\Omega_k| = \sum_{k=0}^{N} f(x_k)p_k(\lambda_i) \tag{3.12}$$

using

$$|\Omega_k|\phi_i(\Omega_k) = p_k(\lambda_i)$$

from section 3.1.

This has the form of polynomial evaluation, or multiplication by the transpose of the generalized Vandermonde matrix associated with the polynomials p_k and the evaluation points λ_i:

$$\begin{pmatrix} \widehat{f}(\phi_0) \\ \widehat{f}(\phi_1) \\ \vdots \\ \widehat{f}(\phi_N) \end{pmatrix} = \begin{pmatrix} p_0(\lambda_0) & p_1(\lambda_0) & \cdots & p_N(\lambda_0) \\ p_0(\lambda_1) & p_1(\lambda_1) & \cdots & p_N(\lambda_1) \\ \vdots & \vdots & \cdots & \vdots \\ p_0(\lambda_N) & p_1(\lambda_N) & \cdots & p_N(\lambda_N) \end{pmatrix} \begin{pmatrix} f(\Omega_0)|\Omega_0| \\ f(\Omega_1)|\Omega_1| \\ \vdots \\ f(\Omega_N)|\Omega_N| \end{pmatrix} = P(\Lambda)^t \mathbf{f}_\Omega.$$

Likewise, the inverse spherical transform can be written in terms of $(P(\Lambda)^t)^t = P(\Lambda)$ itself; by the dual orthogonality equation (3.11),

$$f(\Omega_k) = \frac{1}{|X|} \sum_{i=0}^{N} \widehat{f}(\phi_i)\phi_i(\Omega_k) \dim(V_i).$$

Using equation (3.10), we rewrite this as

$$|\Omega_k| f(\Omega_k) = \frac{|\Omega_k|}{|X|} \sum_{i=0}^{N} \widehat{f}(\phi_i) p_k(\lambda_i) \dim(V_i).$$

Up to scaling, this has the form of projection onto the polynomials p_k, or multiplication by the generalized Vandermonde matrix $P(\Lambda)$. The three-term recurrence relation is already known explicitly; consequently, the methods of section 2 apply directly to this computation. Thus the inverse spherical transform can be done in $O(N \log^2 N)$ operations.

We can also conclude that the transpose problem, the direct spherical transform, is also fast. This follows, for instance, from the results of Bshouty et al. [BKK]. Roughly speaking, they observe that if a straight-line algorithm can compute a matrix product $M \cdot \mathbf{v}$ in time $O(T(n))$ (where M is an $n \times n$ matrix and $\mathbf{v}$ is a column vector), then there exists an algorithm computing the transposed product $M^t\mathbf{v}$ in the same time. They note that any such algorithm may be encoded in a directed graph and in this context the "transposed" algorithm is essentially given by reversing all arrows on the graph.

In our case, this has a concrete interpretation in matrix language. Namely, the inverse spherical transform algorithm amounts to a factorization of the matrix $P(\Lambda)$. The order reversed and transposed factors comprise a factorization of $P(\Lambda)^t$, which

effects the direct transform by matrix multiplication. The individual factors have block structure with Toeplitz blocks, and this does not change upon their transposition. Therefore, the direct transform is computed with the same complexity as the inverse. □

Finally, consider the convolution of two functions $f, g \in L^2(H\backslash G/H)$. Recall that this is simply the convolution over G (cf. equation (3.3)) of H-biinvariant functions which is again H-biinvariant. As such, it makes sense to compute the DST of the convolution. It can be shown that for such functions,

$$|X|\widehat{f \star g}(\phi_i) = \widehat{f}(\phi_i)\widehat{g}(\phi_i),$$

with a quick proof using the multiplicative properties of a Fourier transform on a finite group and the fact that a spherical function is a particular matrix coefficient for the symmetry group (cf. [D, pp. 54–56]). Thus we obtain the following result.

THEOREM 3.4. *Let $f, g \in L^2(H\backslash G/H)$. Given as initial input the spherical transforms $\{\widehat{f}(\phi_i)\}_i$, the function f may be recovered in $O(N \log^2 N)$ operations. The convolution $f \star g$ can be computed in at most $O(N \log^2 N)$ operations. The implied constants here are universal and depend only on the universal constant for the FFT.*

Example 2: *Two particular distance transitive graphs.*

1. *K-sets of an N-set.* This is the collection of size-K subsets $x \subset \{1, 2, \ldots, N\}$, $|x| = K$, with metric $d(x, y) = K - |x \cap y|$, S_N as the symmetry group. The K-sets are made into a graph in the usual way: put edges between those K-sets whose distance is 1. Assuming that $2K < N$, the largest distance is K, occurring for disjoint K-sets. Picking a basepoint K-set x_0, the stabilizer is $\cong S_K \times S_{N-K}$, so we may identify this graph with $S_N/(S_K \times S_{N-K})$.

This is a distance transitive graph of size $\binom{N}{K}$. The weights in the spherical function orthogonality relations are the sizes of the spheres at fixed distances from the basepoint: $|\Omega_j| = \binom{N-K}{j}$. Recall that the spherical functions satisfy

$$|\Omega_j|\phi_i(\Omega_j) = p_j(\lambda_i)$$

for a family of orthogonal polynomials defined on the collection of eigenvalues for the adjacency operator. We saw that the spherical functions are eigenvectors of the adjacency operator and that this provides the three-term recurrence from which the λ_i's and p_j's may be determined:

$$\begin{aligned}\lambda_i p_j(\lambda_i) = j^2 p_{j-1}(\lambda_i) + (K-j)(N-K-j)p_{j+1}(\lambda_i) \\ + [K(N-K) - j^2 - (K-j)(N-K-j)]p_j(\lambda_i).\end{aligned}$$

This is the recurrence for the Eberlein or dual Hahn polynomials. From the case where $j = 1$, we get $\lambda_i = K(N-K) - i(N+1-i)$. We can now compute the spherical functions as

$$\phi_i(\Omega_j) = c \sum_{l=0}^{i} \frac{(N-K-i+1)_l}{(-K)_s} \binom{K-j}{l} \binom{j}{-i-l}.$$

This is the Hahn polynomial $Q_i(j; K-N-1, -K-1, K)$ [KM, St1]. As we have already seen, these are orthogonal polynomials satisfying a three-term recurrence (2.27). The norms can be determined from $\dim V_i = \binom{N}{i} - \binom{N}{i-1}$.

In this case, we have the recurrence relation needed to make the forward spherical transform fast, as discussed in Example 1 of the last section. On the other hand, we

know that in every case we have the recurrence relation for the p_k's needed to make the inverse transform fast.

2. *The hypercube*: The hypercube $\mathbb{Z}_2^N$ has the Hamming metric and symmetries consisting of the hyperoctohedral group, the semidirect product $\mathbb{Z}_2$ wr S_N. This is a distance transitive graph. The three-term recurrence from the adjacency operator eigenequation is

$$\lambda_i p_j(\lambda_i) = j\lambda_i p_{j-1}(\lambda_i) + (N-j)p_{j+1}(\lambda_i),$$

from which we determine the eigenvalues $\lambda_i = N - 2i$ and the spherical functions

$$\phi_i(\Omega_j) = c\sum_{l=0}^{i} \binom{j}{l}\binom{N-j}{i-l}(-1)^{i-l}.$$

Again, these are orthogonal polynomials with respect to weights $|\Omega_j| = \binom{N}{j} = \dim V_j$, known as the Krawtchouk polynomials $K_i(j, 1/2, N)$. This is a particularly nice case in that the dual polynomials and the spherical polynomials are the same up to a constant. Thus the forward spherical transform and its inverse are effectively the same, and can be done fast using the three-term recurrence as before.

4. Computation of isotypic projections. As remarked in section 1, a fast DST algorithm has applications in spectral analysis for data on distance transitive graphs. In this section, we wish to explain this in a little more detail. Diaconis' book [D, especially Chapter 8] is an excellent introduction to these ideas and also gives many pointers to the existing literature. (See [DR] for a more thorough account of the following discussion as well as for other approaches to this problem.)

In general, let G be a finite group acting transitively on a set

$$X = \{x_0, x_1, \ldots, x_n\}.$$

The action of G on X then determines the associated permutation representation ρ of G in $L^2(X)$ given by translation,

$$(\rho(s)f)(x) = f(s^{-1}x).$$

If η and η' are two representations of G, then we will write $\eta \sim \eta'$ if η is equivalent to η'. Recall that the *isotypic decomposition* of $L^2(X)$,

$$L^2(X) = V_0 \oplus \cdots \oplus V_N,$$

is defined by the following:

(1) *Each V_i is G-invariant.*

(2) *If $\rho^{(i)} := \rho\,|_{V_i}$, then*

$$\rho^{(i)} \sim m_i\eta_i,$$

where the η_i's are irreducible representations of G, m_i is some positive integer, and $i \neq j$ implies that $\eta_i \not\sim \eta_j$.

The isotypic decomposition is canonical in the sense that it is independent of the choice of basis for $L^2(X)$.

In appropriate settings, data on a such a finite homogeneous space X is viewed as a vector $f \in L^2(X)$. The relevant statistics then become the projections of f onto the

isotypic components. To state things a bit more sharply, the computational problem is as follows:

Given as input $f = (f(x_0), \dots, f(x_n))$, compute for $i = 0, \dots, N$ the projection of f into the ith isotypic, denoted $f^{(i)} (\in V_i)$, as

$$f^{(i)} = (f^{(i)}(x_0), \dots, f^{(i)}(x_n)).$$

One way to proceed here is via character theory. Let χ_i be the character corresponding to η_i. Then [S, Theorem 2.7],

$$f^{(i)}(x) = \frac{\chi_i(1)}{|G|} \sum_{s \in G} \chi_i(s) f(s^{-1}x). \tag{4.1}$$

This gives a naïve upper bound of $|X||G|$ operations to compute all projections. Note that in the example of the California Lottery of section 1, this would give $49!\binom{49}{6}$ operations, which is beyond the capabilities of any machine.

Careful analysis of this formula permits significant speedups, even in the general case.

THEOREM 4.1 ([DR, Theorem 2.4]). *For any fixed i, the projection onto the ith isotypic can be computed in at most $|X|^2$ operations. Consequently, all projections can be computed in at most $(N+1)|X|^2$ operations.*

Let us now specialize the case of interest, in which $L^2(X)$ has a multiplicity-free decomposition so that the isotypic decomposition is actually an irreducible decomposition. As previously, let H denote the isotropy subgroup of the chosen basepoint x_0 and let $\{s_0 = 1, \dots, s_n\}$ denote a fixed set of coset representatives. Let $\{\phi_i\}_{i=0}^N$ denote the corresponding spherical functions. In this case, the character formula (4.1) can be rewritten as

$$f^{(i)}(x_k) = \frac{|H|}{|G|} \chi_i(1) \sum_{j=0}^{N} f_k(\Omega_j) \phi_i(\Omega_j) |\Omega_j|, \tag{4.2}$$

where

$$f_k(\Omega_j) = \frac{1}{|\Omega_j|} \sum_{x \in \Omega_j} f(s_k^{-1} x). \tag{4.3}$$

The computation of the f_k is a preprocessing of the original data whose complexity will depend on the geometry of X. In any event, this may always be done in at most $|X|^2$ additions.

Finally, using the notation of the previous sections, we rewrite (4.2) as

$$f^{(i)}(x_k) = \frac{|H|}{|G|} \chi_i(1) \widehat{f}_k(\phi_i).$$

Consequently, using the results of section 3, we have the following result.

THEOREM 4.2. *Let X be a distance transitive graph for G with maximum distance N. Then the set of projections $f^{(i)} \in V_i$ $(i = 0, \dots, N)$ may be computed in at most*

$$O(|X|^2 + |X| N \log^2 N)$$

operations.

Remark. In some cases, the projections can also be computed combinatorially using variations of the discrete Radon transform (cf. [D, DR, BDRR]).

5. Final remarks. Of course, distance transitive graphs are not the only source of orthogonal polynomials. Another example closely related to this setting is the construction of orthogonal polynomial systems from group actions on posets [St2]. If P is a ranked poset, then $L^2(P)$ has a natural decomposition into "harmonics." In [St2], Stanton shows that under certain assumptions about the automorphism group G of P, the space of functions on the maximal elements of P gives a multiplicity-free representation of G. Again these functions can be written in terms of discretely sampled orthogonal polynomials.

More generally, one might consider other special function systems satisfying recurrence relations that arise in a continuum setting. Results similar to those of this paper can be obtained, provided that an appropriate sampling theorem is available to reduce the computations to finite ones. Some initial work along this line for the case of the homogeneous space $SO(3)/SO(2)$ may be found in [DrH]. Maslen has recently extended these ideas to more general compact groups [M].

Beyond the example of spectral analysis, we are actively seeking other applications for the techniques presented here. A recent book by Nikiforov, Suslov, and Uvarov [NSU] cites a large number of tantalizing possibilities.

Acknowledgments. We would like to thank the referees for their suggestions following a careful reading of the manuscript. We also thank Peter Kostelec and Doug Warner for their help with the final typesetting.

DOUBLY LOGARITHMIC COMMUNICATION ALGORITHMS FOR OPTICAL-COMMUNICATION PARALLEL COMPUTERS*

LESLIE ANN GOLDBERG†, MARK JERRUM‡, TOM LEIGHTON§, AND SATISH RAO¶

Abstract. In this paper, we consider the problem of interprocessor communication on parallel computers that have optical communication networks. We consider the *completely connected optical-communication parallel computer* (OCPC), which has a completely connected optical network, and also the *mesh-of-optical-buses parallel computer* (MOB-PC), which has a mesh of optical buses as its communication network. The particular communication problem that we study is that of realizing an *h-relation.* In this problem, each processor has at most h messages to send and at most h messages to receive. It is clear that any 1-relation can be realized in one communication step on an OCPC. However, the best previously known p-processor OCPC algorithm for realizing an arbitrary h-relation for $h > 1$ requires $\Theta(h + \log p)$ expected communication steps. (This algorithm is due to Valiant and is based on earlier work of Anderson and Miller.) Valiant's algorithm is optimal only for $h = \Omega(\log p)$, and it is an open question of Geréb-Graus and Tsantilas whether there is a faster algorithm for $h = o(\log p)$. In this paper, we answer this question in the affirmative and we extend the range of optimality by considering the case in which $h \leq \log p$. In particular, we present a $\Theta(h + \log\log p)$-communication-step randomized algorithm that realizes an arbitrary h-relation on a p-processor OCPC. We show that if $h \leq \log p$, then the failure probability can be made as small as $p^{-\alpha}$ for any positive constant α. We use the OCPC algorithm as a subroutine in a $\Theta(h + \log\log p)$-communication-step randomized algorithm that realizes an arbitrary h-relation on a $p \times p$-processor MOB-PC. Once again, we show that if $h \leq \log p$, then the failure probability can be made as small as $p^{-\alpha}$ for any positive constant α.

1. Introduction.

The p-processor *completely connected optical-communication parallel computer* (p-OCPC) consists of p processors, each of which has its own local memory. The p processors can perform local computations and can communicate with each other by message passing. A *computation* on this computer consists of a sequence of *communication steps.* During each communication step, each processor can perform some local computation and then send one message to any other processor. If a given processor is sent one message during a communication step, then it receives this

message successfully, but if it is sent more than one message, then the transmissions are garbled and it does not receive any of the messages.

Eshaghian [Esh88], [Esh91] first studied the computational aspects of parallel architectures with complete optical interconnection networks. The OCPC model is an abstract model of computation which formalizes important properties of such architectures. It was first introduced by Anderson and Miller [AM88] and Eshaghian and Kumar [EK88] and has subsequently been studied by several authors, including Valiant [Val90], Geréb-Graus and Tsantilas [GT92], and Gerbessiotis and Valiant [GV92] (though not always under the name OCPC). The feasibility of the OCPC from an engineering point of view is discussed in [AM88], [GT92], and [Rao92]. See also the references in [McC93].

In the first part of this paper, we study the problem of interprocessor communication on an OCPC. In particular, we study the problem of realizing *h-relations*. This problem arises in both the direct implementation of specific parallel algorithms [AM88], and the simulation of shared-memory models, such as the PRAM, on more realistic distributed-memory models [Val90]. An h-relation [Val90] is a communication problem in which each processor has up to h messages that it wishes to send to other processors (assumed distinct). The destinations of these messages can be arbitrary except that each processor is the destination of at most h messages. The goal is to design a fast p-OCPC algorithm that can realize an arbitrary h-relation. Anderson and Miller [AM88] have observed that an h-relation can easily be realized in h communication steps if all of the processors are given *total* information about the h-relation to be realized.[1] A more interesting (and perhaps more realistic) situation arises if we assume that initially each processor knows about only the messages that it wants to send and the processors learn about the h-relation only by receiving messages from other processors. This is the usual assumption, and it is the one that will be made here.

An OCPC algorithm for realizing h-relations is said to be *direct* if it has the property that the only messages that are exchanged by the processors are the original messages of the h-relation and these messages are sent only to their destinations. In this paper, we prove the following:

1. The expected number of communication steps taken by *any* direct algorithm for realizing h-relations on a p-OCPC is $\Omega(h + \log p)$.

2. An arbitrary h-relation can be realized on a p-OCPC in $\Theta(h + \log\log p)$ communication steps with high probability. (Valiant has shown that an arbitrary h-relation can be realized in $\Theta(h + \log p)$ communication steps, which deals with the case where $h \geq \log p$; our algorithm (see Theorem 1) covers the case of sublogarithmic h.)

It is easy to see that any 1-relation can be realized in one communication step on an OCPC. Anderson and Miller [AM88] were the first to consider the problem of realizing h-relations for $h > 1$. They discovered a direct p-OCPC algorithm that runs for $\Theta(h)$ communication steps and delivers most of the messages in an arbitrary h-relation. In particular, the expected number of messages remaining after Anderson and Miller's algorithm is run is $O(p)$. Anderson and Miller were interested in the special class of h-relations in which each of the messages with a given destination has a unique label ℓ in the range $1 \leq \ell \leq h$. For this class of h-relations, Anderson and Miller also discovered a deterministic $\Theta(h + \log p)$-communication-step algorithm that

[1] To see this, model the communications between the p processors viewed as sources and the p processors viewed as destinations as the edges of a bipartite graph of order $2p$. Since the graph has maximum degree h, it is edge colorable with h colors, which can be interpreted as time steps.

delivers all of the messages in any h-relation that contains only $O(p)$ messages. Thus their algorithms can be combined to obtain an algorithm that realizes an arbitrary h-relation from their special class in $\Theta(h + \log p)$ expected communication steps.

Valiant [Val90] considered the general problem of realizing h-relations for $h > 1$. He discovered a $\Theta(h + \log p)$-expected-communication-step p-OCPC algorithm that realizes an arbitrary h-relation. Valiant's algorithm consists of the first phase of Anderson and Miller's algorithm followed by a second phase which redistributes the remaining $O(p)$ messages using parallel prefix, sorts them, and then sends them to the correct destinations. The second phase of Valiant's algorithm takes $\Theta(h + \log p)$ communication steps.

Prior to this work, Valiant's algorithm was the fastest known OCPC algorithm that can realize an arbitrary h-relation for $h > 1$. It is not direct, however. The fastest known *direct* OCPC algorithm for realizing arbitrary h-relations is due to Geréb-Graus and Tsantilas [GT92] and runs in $\Theta(h + \log p \log\log p)$ expected communication steps. In this paper, we show that every direct OCPC algorithm for realizing h-relations takes $\Omega(h + \log p)$ expected communication steps. Furthermore, we describe a $\Theta(h + \log\log p)$-communication-step p-OCPC algorithm that can realize an arbitrary h-relation and we show that if $h \leq \log p$, then the failure probability can be made as small as $p^{-\alpha}$ for any positive constant α. (The Θ notation does not hide any large constants in the running time of our algorithm.)

In this paper we also consider a model of computation known as the *mesh-of-optical-buses parallel computer* (MOB-PC). The $p \times p$ MOB-PC consists of p^2 processors, organized in a $p \times p$ array. The processors can perform local computations and can communicate with each other by message passing. As in the case of the OCPC, a computation on this computer consists of a sequence of communication steps. During each communication step, each processor can perform some local computation and then send one message. Unlike the OCPC, the MOB-PC has the restriction that the destination of each message must be in the row or the column of its sender. (The reason for considering the MOB-PC is that this restriction makes it much easier to build than a p-OCPC (see [Rao92]).) As in the case of the OCPC, if a given processor is sent one message during a communication step, then it receives this message successfully, but if it is sent more than one message, then the transmissions are garbled and it does not receive any of the messages.

The $p \times p$ mesh of optical buses is a member of a class of networks studied by Wittie [Wit81] and suggested by Dowd as a method for optical interconnects [Dow91]. Rao studied the MOB-PC in [Rao92] and used a result of Leighton and Maggs to show that for $h \geq \log p$, an arbitrary h-relation can be realized on a $p \times p$ MOB-PC in $\theta(h)$ communication steps. In this paper, we describe a $\Theta(h + \log\log p)$-communication-step randomized algorithm that realizes an arbitrary h-relation on a $p \times p$ MOB-PC, and we show that if $h \leq \log p$, then the failure probability can be made as small as $p^{-\alpha}$ for any positive constant α.

The following experiment gives the intuition underlying our lower bound for direct OCPC algorithms and our OCPC algorithm (which is a subroutine in our MOB-PC algorithm). Suppose that two processors P_i and P_j of an OCPC are both trying to send messages to a third processor P_d and that they adopt the following direct strategy. During each communication step, processors P_i and P_j both flip fair coins. If P_i's coin comes up "heads," then P_i sends its message to P_d. Similarly, if P_j's coin comes up "heads," then P_j sends its message to P_d. On any given communication step, P_d has probability $\frac{1}{2}$ of successfully receiving a message. Therefore, the probability

that P_d has not received any messages after t communication steps is 2^{-t}. Now suppose that we use a similar strategy to realize a 2-relation in which each processor is the destination of two messages. After t communication steps, we will expect to have $p\,2^{-t}$ processors that have received no messages at all. Therefore, it will take $\Omega(\log p)$ communication steps to realize the 2-relation.

Intuitively, the reason that so much time is needed is that the events are "too independent." In particular, the fact that most of the other messages are already delivered will not make it easier for P_i and P_j to send their messages to P_d. In order to obtain a sublogarithmic OCPC algorithm, we adopt the following strategy. We divide the set of p destinations into disjoint "target groups." During the first part of our algorithm, we send each message in the h-relation to a randomly chosen processor within the target group containing its destination. As more and more messages are delivered to a given target group, the probability that any remaining message is successfully delivered to the group in one communication step increases. Once all of the messages have been delivered to their target groups, we solve the smaller problem of realizing an h-relation within each target group.

Our OCPC algorithm consists of four procedures. The first three procedures deliver the messages to their target groups and the last procedure realizes smaller h-relations within the target groups.

The methods that we use to deliver messages to target groups rely upon the fact that the number of messages being sent to each group is small compared to the size of the group. The first procedure of our algorithm (the "thinning" procedure) establishes this condition by delivering most of the messages in the h-relation to their final destinations. The thinning procedure is a direct OCPC algorithm and it is based on Anderson and Miller's algorithm. Proving that it satisfies the appropriate conditions requires a probabilistic analysis of dependent events. To do the analysis, we use the "method of bounded differences" [McD89], [Bol88]. Note that Matias and Vishkin's "thinning out" procedure [MV91] is similar to one step of our "thinning" procedure; in their case, just one step suffices since the density of messages is much lower.

After the thinning procedure has terminated the number of messages remaining will be $O(p/(h \log\log p))$ with high probability. The purpose of the second procedure (the "spreading" procedure) is to redistribute these messages so that each sender has at most one message to send. After the spreading procedure terminates, the third procedure delivers the remaining messages to their target groups. The bulk of the messages are delivered using a probabilistic tool called "approximate compaction." After the approximate compaction terminates, the number of messages that have not been delivered to their target groups will be $O(p/\log^2 p)$ with high probability. Each remaining message is copied $\log p$ times and the processors are reallocated so that $\log p$ processors can work together to send each message to its target group. (The approximate compaction technique and the copying technique were first used in PRAM algorithms such as those described in [CDHR89] and in [GM91] and [MV91]. In this work, we require a smaller failure probability for approximate compaction than previous authors because our target groups are only polylogarithmic in size and we need to bound the probability of failure in any group.)

At the end of the third procedure, the communication problem that remains consists of one h-relation within each target group. These h-relations could be realized in $\Theta(h + \log\log p)$ communication steps by simultaneously running the second phase of Valiant's algorithm within each target group, substituting a deterministic EREW

sorting algorithm such as Cole's parallel merge sort (see [Col88]) for the randomized sorting algorithm that Valiant uses.

Our fourth procedure is an alternative algorithm for realizing the h-relations within the target groups. It does not rely on efficient deterministic $O(\log p)$-time EREW sorting and it is therefore likely to be faster in practice. The algorithm is as follows. Each target group is subdivided into disjoint subgroups. Our "thinning," "spreading," and "deliver to target group" procedures are run simultaneously in each target group to deliver the messages in that group to the appropriate subgroups. The communication problem remaining with each subgroup is an h-relation, and this h-relation is realized using the second phase of Valiant's algorithm, in which the sorting is done by Bitonic sort. With high probability, the proportion of target groups for which this strategy delivers all of the messages is at least $1 - 1/\log^c p$ for a sufficiently large constant c. The processors from these target groups are then reallocated and used to help the unsuccessful target groups finish realizing their h-relations. After the processors are reallocated, each unsuccessful target group sorts its messages using an enumeration sort due to Muller and Preparata [MP75] which is fast in practice as well as in theory. The sorted messages are then delivered to their destinations.

The structure of this paper is as follows. In section 2, we describe the OCPC algorithm in detail. We demonstrate that it uses $\Theta(h + \log\log p)$ communication steps, and we prove that if $h \leq \log p$, then the probability that any messages are left undelivered can be made as small as $p^{-\alpha}$ for any positive constant α. In section 3, we give the proof of the lower bound for direct OCPC algorithms. Finally, in section 4, we describe the MOB-PC algorithm. We demonstrate that it uses $\Theta(h + \log\log p)$ communication steps, and we prove that if $h \leq \log p$, then the probability that any messages are left undelivered can be made as small as $p^{-\alpha}$ for any positive constant α.

2. The OCPC algorithm. In this section, we prove the following theorem.

THEOREM 1. *Suppose that $h \leq \log p$. There is a randomized algorithm that realizes an arbitrary h-relation on a p-OCPC in $\theta(h + \log\log p)$ communication steps. The failure probability of the algorithm is $p^{-\alpha}$. The constant $\alpha > 0$ may be chosen arbitrarily.*

Before we can define the OCPC algorithm, we must describe the partition of the set $\{P_1, \ldots, P_p\}$ of processors into disjoint "target groups." The size of each target group will be a polynomial in $\log(p)$. To be precise, let c_1 denote a sufficiently large integer (the size of c_1 will depend upon the failure probability that we wish to obtain) and let k denote $\lceil \log^{c_1} p \rceil$. We will divide the p processors into approximately p/k target groups, each of size about k. To simplify the presentation, we will assume that k divides p[2] and we will define the ℓth target group for ℓ in the range $0 \leq \ell < p/k$ to be the set $\{P_{k\ell}, \ldots, P_{k\ell+k-1}\}$. We will define the target group of any given message to be the target group containing the destination of the message, and we will say that the message is destined for that target group.

The algorithm consists of the following four procedures:

- *Thinning.* At the beginning of the algorithm, the number of messages destined for any given target group may be as high as hk. The goal of the thinning procedure is to deliver most of the messages to their final destinations so that by the end of the procedure the number of undelivered messages destined for any given target group is at most $k/(h\lceil c_2 \log\log p \rceil)$ for a sufficiently large

[2] The case in which k does not divide p presents no real difficulty. In this case, the target groups should be defined in such a way that all but one of the groups has size k and the size of the remaining group is between k and $2k$.

constant c_2. If $h \leq \log p$, then this can be done in $\Theta(h + \log(h) \log\log\log(p))$ steps with probability at least $1 - p^{-\alpha}$, where the constant in the running time depends upon α and c_2.

- *Spreading.* At the end of the thinning procedure, there will be only $O(p/(h \log\log p))$ undelivered messages. However, some senders may have as many as h undelivered messages. The spreading procedure spreads these out so that each sender has at most one to send. This can be done in $\Theta(h + \log\log p)$ communication steps with probability at least $1 - p^{-\alpha}$, where the constant in the running time depends upon α.
- *Deliver to target groups.* This procedure delivers all of the undelivered messages to their target groups. After it terminates, each sender will have at most two undelivered messages to send and the destination of each undelivered message will be within the target group containing its sender. The procedure can be implemented in $\Theta(\log\log p)$ communication steps with probability at least $1 - p^{-\alpha}$, where the constant in the running time depends upon α.
- *Deliver within target groups.* This procedure delivers all messages to their final destinations. It can be implemented deterministically in $\Theta(h + \log\log p)$ steps by running the second phase of Valiant's algorithm twice in each target group. However, this implementation may be slow in practice. In section 2.4, we describe an alternate implementation which runs in $\Theta(h + \log\log p)$ communication steps and succeeds with probability at least $1 - p^{-\alpha}$. (The constant in the running time depends upon α.)

We will use the following tool in the implementation of our algorithm. (For similar tools, see [CDHR89], [GM91], and [MV91].)

DEFINITION 1. *The* (s, β, Δ) approximate compaction problem *is defined as follows. Given*

- *a p-OCPC in which at most s senders each have one message to send and*
- *a set of* βs *receivers which is known to all of the senders,*

deliver all but up to Δ *of the messages to the set of receivers in such a way that each receiver receives at most one message. (During the delivery, messages may only be sent from the original senders to the* βs *receivers.)*

LEMMA 1. *For any positive constant* α*, there is a positive constant* c_2 *such that the* $(s, \lceil c_2 \log\log p \rceil, \Delta)$ *approximate compaction problem can be solved in* $O(\log\log p)$ *communication steps with failure probability at most* $\alpha^{-\sqrt{s}} + s^{-\alpha(\Delta+1)}$.[3]

Using the (s, β, Δ) approximate compaction algorithm, we can accomplish a variety of tasks. For example (following [CDHR89] and [GM91]), we use the algorithm to allocate $\lfloor \log p \rfloor$ processors to each message once the number of undelivered messages is reduced to $p/\lfloor \log p \rfloor^2$. In the proof of Lemma 1, we use Lemma 2 (see below) and the following definition.

DEFINITION 2. *The* (s, β, Δ) approximate collection problem *is defined to be the same as the* (s, β, Δ) *approximate compaction problem except that we remove the requirement that each receiver receives at most one message.*

LEMMA 2. *For any positive constant* α*, there is a positive constant* c_2' *such that the* $(s, 36, \Delta)$ *approximate collection problem can be solved in at most* $\lceil c_2' \log\log p \rceil$ *communication steps with failure probability at most* $\alpha^{-\sqrt{s}} + s^{-\alpha(\Delta+1)}$.

Proof of Lemma 1. Let α be any positive constant and let $c_2 = 36c_2' + 1$, where

[3] In fact, there is a positive constant c_2 such that the (s, c_2, Δ) approximate compaction problem can be solved in $O(\log\log s)$ communication steps with small failure probability, but Lemma 1 is sufficient for our purposes.

c_2' is the constant associated with α in Lemma 2. Suppose that we are given an instance of the $(s, \lceil c_2 \log\log p\rceil, \Delta)$ approximate compaction problem. Partition the set of receivers into $\lceil c_2' \log\log p\rceil$ disjoint sets $R_1, R_2, \ldots$, each of size at least $36s$. Since by Lemma 2 the $(s, 36, \Delta)$ approximate collection problem can be solved in at most $\lceil c_2' \log\log p\rceil$ communication steps with failure probability at most $\alpha^{-\sqrt{s}} + s^{-\alpha(\Delta+1)}$, there is an algorithm with this failure probability that delivers all but up to Δ of the messages to the receivers in R_1 in only $\lceil c_2' \log\log p\rceil$ steps. To solve the $(s, \lceil c_2 \log\log p\rceil, \Delta)$ approximate compaction problem, simply run this algorithm, substituting the set R_i for R_1 on the ith communication step of the algorithm, thus guaranteeing that each receiver receives at most one message. □

Proof of Lemma 2. We say a sender is *active* initially if it contains a message. Our algorithm proceeds in a number of similar communication steps, where in step i each active sender sends its message to a random location in the set of receivers. Each sender that successfully transmitted a message is considered *inactive.*

Let m denote $36s$. We must show that there are at most Δ active messages when the algorithm terminates. We use the following claim.

CLAIM 1. *Let c be a positive integer. If there are at most m/r active senders left at step i, then the probability that there will be $f = \max\{\lceil m/r^{3/2}\rceil, \Delta + 1\}$ or more active senders left at step $i + 2c$ is at most $(2\mathrm{e}/\sqrt{r}\,)^{cf}$.*

We prove Claim 1 by imagining that in a certain step the m/r active senders make their random choice of destination in some fixed order. For there to be f active senders that do not transmit their message, there must be $\lceil f/2\rceil$ times at which a sender chooses the same receiver as one chosen by a previous sender in this order. The probability of choosing the same receiver as a previous sender is at most $(m/r)/m = 1/r$. Thus the probability of $\lceil f/2\rceil$ such events occurring is bounded above by

$$\begin{aligned}
\binom{\lfloor m/r\rfloor}{\lceil f/2\rceil}\left(\frac{1}{r}\right)^{\lceil f/2\rceil} &\le \left(\frac{2em}{rf}\right)^{\lceil f/2\rceil}\left(\frac{1}{r}\right)^{\lceil f/2\rceil} \\
&\le \left(\frac{2em}{r^2 \max\left\{\lceil m/r^{3/2}\rceil,\, \Delta+1\right\}}\right)^{\lceil f/2\rceil} \\
&\le \left(\frac{2em}{r^2(m/r^{3/2})}\right)^{f/2} \\
&\le \left(\frac{2e}{\sqrt{r}}\right)^{f/2}.
\end{aligned}$$

We proceed by computing the probability that f active senders remain after $2c$ steps. It is easy to verify that the probability that f senders remain active after $2c$ steps in our algorithm is less than the probability that f senders remain active if each of the $2c$ successive steps is implemented by sending from all of the processors that were active at the initial step. In this situation, the successive steps are independent; thus the probability that there are f senders that never got a message through on any of the steps is at most the probability above raised to the $2c$th power. This proves Claim 1.

Now we define $r_0 = 36$, $r_j = r_{j-1}^{3/2}$, $f_j = \max\left\{\lceil m/r_j^{3/2}\rceil, \Delta + 1\right\}$, and $t = \min\{j : f_j = \Delta + 1\}$. The algorithm will run for $t + 1$ "supersteps" $0, 1, \ldots, t$, each superstep consisting of $2c$ steps as described above, with c a constant to be chosen later. Observe that the number of supersteps, and hence the total number of steps, is $\mathrm{O}(\log\log s)$ and is therefore $\mathrm{O}(\log\log p)$.

We say that superstep j is *successful* if, starting with at most m/r_j active senders, it finishes with (strictly) fewer than f_j active senders. Note that if supersteps $0, 1, \ldots, j$ are all successful, then the number of active senders remaining at the end of superstep j is strictly less than f_j. If all $t+1$ supersteps are successful, then the number of active senders remaining at the end is at most Δ, as required.

Using Claim 1, we can bound the probability that some superstep fails by

$$\sum_{j=0}^{t} \Big(\frac{2\mathrm{e}}{\sqrt{r_j}}\Big)^{cf_j}.$$

Notice that each term where $r_j \le m^{1/3}$ is at most $(\mathrm{e}/3)^{6c\sqrt{s}}$, and every other term is at most $(16\mathrm{e}^6/(9s))^{c(\Delta+1)/6}$. Thus the probability that *some* superstep fails is at most

$$(t+1)\Big\{\Big(\frac{\mathrm{e}}{3}\Big)^{6c\sqrt{s}} + \Big(\frac{16\mathrm{e}^6}{9s}\Big)^{c(\Delta+1)/6}\Big\}.$$

Observe that $t+1 = \mathrm{O}(\log\log s)$, so if c is chosen to be big enough relative to α, this is at most $\alpha^{-\sqrt{s}} + s^{-\alpha(\Delta+1)}$, as required. □

We proceed by describing the implementation of the various steps of the algorithm.

2.1. Thinning. The thinning procedure is a direct OCPC algorithm which is based on Anderson and Miller's algorithm [AM88]. It consists of $\log h + 1$ phases. Intuitively, the goal of the ith phase is to reduce the problem of realizing an $h/2^{i-1}$-relation to the problem of realizing an $h/2^i$-relation. That is, the ith phase should get so many of the messages delivered that the remaining communication problem is "essentially" an $h/2^i$-relation. After the last phase, the h-relation will be mostly realized, except that there will be a small number (at most $k/(h\lceil c_2 \log\log p\rceil)$) of undelivered messages destined for each target group. (Recall that k denotes $\lceil \log^{c_1} p\rceil$.)

Let c_3 be a sufficiently large constant (depending on c_1 and c_2 and the constant α in the desired failure probability) and let t_i denote $c_3\lceil h/2^{i-1} + \log h + \log\log\log p\rceil$. ($t_i$ denotes the number of communication steps in phase i.) Before phase i, it will be the case that each participating sender has at most $h/2^{i-1}$ undelivered messages to send. During phase i, each participating sender executes the following communication step t_i times:

Choose an integer j uniformly at random from the set $\{1, \ldots, h/2^{i-1}\}$.
If there are at least j undelivered messages to be sent,
send the jth undelivered message to its destination.

After each communication step, there is an acknowledgment step in which every receiver that receives a message sends an acknowledgment back to the sender indicating that the message was delivered successfully. At the end of phase i, any sender that has more than $h/2^i$ undelivered messages left to send stops participating.

We will prove the following theorem.

THEOREM 2. *Suppose that $h \le \log p$. Then with probability at least $1 - p^{-\alpha}$, the number of undelivered messages destined for any given target group is at most $k/(h\lceil c_2 \log\log p\rceil)$ after the thinning procedure terminates.*

In order to prove Theorem 2, we will use the following notation. We will say that a given message is "participating" at any point in time if it is undelivered at that time and its sender is participating. We will say that a receiver is "overloaded" in phase i if at the start of phase i the number of participating messages with that destination

is more than $h/2^{i-1}$. We will say that the receiver becomes overloaded in phase i if it is not overloaded in phases 1 through i but it is overloaded in phase $i+1$. We will say that a sender is "good" in phase i if it does not have a message to send to an overloaded receiver. For every target group T, let $S(T)$ denote the set containing all senders in the h-relation with messages destined for T and let $N(T)$ denote the set containing all destinations of messages from processors in $S(T)$. Finally, let $S(N(T))$ be the set containing all senders with messages destined for members of $N(T)$. (Note that $|S(T)| \leq h\,|T|$, $|N(T)| \leq h^2|T|$, and $|S(N(T))| \leq h^3|T|$.) The theorem follows from the following lemma.

LEMMA 3. *Suppose that $h \leq \log p$. Let i be an arbitrary phase of the thinning procedure and let T be any target group. With probability at least $1 - p^{-}(\alpha+1)$,*

1. *at most $|N(T)|/(h^6\lceil c_2 \log\log p\rceil)$ receivers in $N(T)$ become overloaded in phase i;*
2. *at most $|S(T)|/(h^6\lceil c_2 \log\log p\rceil)$ good senders in $S(T)$ stop participating at the end of phase i.*

Proof of Theorem 2. To see that the theorem follows from Lemma 3, note that the number of target groups is at most p/k and the number of phases is $O(\log h)$, so with probability at least $1 - p^{-\alpha}$, conditions 1 and 2 hold for all phases i and target groups T. Suppose that this is the case and consider any particular target group T. A message that is destined for T will be delivered by the thinning procedure unless either (1) there is a phase in which its sender is not good (in which case the sender could possibly stop participating) or (2) its sender stops participating even though it is good. The number of messages that are destined for T and are not delivered is therefore at most

$$\log(h) \times (h^2|N(T)|/(h^6\lceil c_2 \log\log p\rceil) + h|S(T)|/(h^6\lceil c_2 \log\log p\rceil)).$$

This is at most $k/(h\lceil c_2 \log\log p\rceil)$. □

The proof of Lemma 3 will use the following "independent bounded differences inequality" of McDiarmid [McD89]. (The inequality is a development of the "Azuma martingale inequality"; a similar formulation was also derived by Bollobás as [Bol88].)

THEOREM 3 (McDiarmid). *Let $x_1, \ldots, x_n$ be independent random variables, with x_i taking values in a set A_i for each i. Suppose that the (measurable) function $f : \prod A_i \to \mathbb{R}$ satisfies $|f(\overline{x}) - f(\overline{x}')| \leq c_i$ whenever the vectors $\overline{x}$ and $\overline{x}'$ differ only in the ith coordinate. Let Y be the random variable $f(x_1, \ldots, x_n)$. Then for any $t > 0$,*

$$\Pr\left(|Y - \mathrm{E}(Y)| \geq t\right) \leq 2\exp\left(-2t^2 / \textstyle\sum_{i=1}^{n} c_i^2\right). \qquad \square$$

Proof of Lemma 3. Suppose that $h \leq \log p$, let i be an arbitrary phase of the thinning procedure, and let T be any target group. Let x_a denote the sequence of integers randomly chosen by processor P_a during phase i.

We will start by proving that with probability at least $1 - p^{-(\alpha+2)}$, at most $|N(T)|/(h^6\lceil c_2 \log\log p\rceil)$ receivers in $N(T)$ become overloaded in phase i.

Let $Y = f(\{x_a \mid P_a \in S(N(T))\})$ be the number of receivers in $N(T)$ that become overloaded during phase i. Let R be any receiver in $N(T)$ that is not overloaded in phases 1 through i, and let s_j denote the number of participating messages that are destined for R at the jth communication step of phase i. (Note that these messages are not necessarily *sent* on the jth communication step.) The probability that R receives a message on this step is at least $s_j\,(2^{i-1}/h)\,(1 - 2^{i-1}/h)^{s_j - 1}$. There is a positive constant ρ such that this probability is greater than or equal to ρ for every s_j that

is greater than or equal to $h/2^i$. (Note that R cannot become overloaded in phase i if s_j is ever less than $h/2^i$.) Therefore, the probability that R becomes overloaded is at most

$$\sum_{b=0}^{h/2^i-1} \binom{t_i}{b} \rho^b (1-\rho)^{t_i-b}.$$

Furthermore, as long as c_3 is sufficiently large (i.e., t_i is sufficiently large compared to b), there is a constant $c_4 > 1$ such that the above sum is at most $c_4^{-t_i}$. Therefore, the expected number of processors in $N(T)$ that become overloaded in phase i is at most $|N(T)|\, c_4^{-t_i}$, which is at most $|N(T)|/(2h^6\lceil c_2 \log\log p\rceil)$ as long as c_3 is sufficiently large.

If the value of x_a changes for any a, then Y changes by at most h. Therefore, by the bounded differences inequality of Theorem 3, the probability that Y is greater than $|N(T)|/(h^6\lceil c_2 \log\log p\rceil)$ is at most

$$2\exp(-2\,|N(T)|^2/(4\,h^{12}\,\lceil c_2 \log\log p\rceil^2\,|S(N(T))|\,h^2)).$$

This is at most $p^{-(\alpha+2)}$ as long as the constant c_1 is sufficiently large (i.e., the target groups are sufficiently large). (Here we use the fact that $h \le \log p$.)

We now prove that with probability at least $1 - p^{-(\alpha+2)}$, at most

$$|S(T)|/(h^6\lceil c_2 \log\log p\rceil)$$

good senders in $S(T)$ stop participating at the end of phase i.

Let $Y = f(\{x_a \mid P_a \in S(N(T))\})$ be the number of good senders in $S(T)$ that stop participating at the end of phase i.

Let S be any good sender in $S(T)$ that participates in phase i, and let s_j denote the number of participating messages that S has to send at the jth communication step of phase i. Let $d_{\ell,j}$ denote the number of participating messages at the jth communication step that have the same destination as the ℓth message that S has to send. (Since S is good, each $d_{\ell,j}$ is less than or equal to $h/2^{i-1}$.) The probability that S sends a message successfully on the jth communication step is at least $\sum_{\ell=1}^{s_j}(2^{i-1}/h)\,(1-2^{i-1}/h)^{d_{\ell,j}-1}$. As before, there is a positive constant ρ such that this probability is greater than or equal to ρ for every s_j that is greater than or equal to $h/2^i$. Therefore, the probability that S stops participating is at most

$$\sum_{b=0}^{h/2^i-1} \binom{t_i}{b} \rho^b (1-\rho)^{t_i-b}.$$

As in the proof of the first part of the lemma, we conclude that the expected number of good senders in $S(T)$ that stop participating at the end of phase i is at most $|S(T)|/(2h^6\lceil c_2 \log\log p\rceil)$.

If the value of x_a changes for any a, then Y changes by at most h^2. Therefore, by the bounded differences inequality of Theorem 3, the probability that Y is greater than $|S(T)|/(h^6\lceil c_2 \log\log p\rceil)$ is at most

$$2\exp(-2\,|S(T)|^2/(4\,h^{12}\,\lceil c_2 \log\log p\rceil^2\,|S(N(T))|\,h^4)).$$

This is at most $p^{-(\alpha+2)}$ as long as the constant c_1 is sufficiently large (i.e., the target groups are sufficiently large). (Once again, we use the fact that $h \le \log p$.) □

2.2. Spreading. Let α be any positive constant and let c_2 be the constant associated with α that is defined in Lemma 1. At the end of the thinning procedure, there will be at most $p/(h\lceil c_2 \log\log p\rceil)$ undelivered messages. We wish to spread these out so that each sender has at most one to send. To do this, we observe that there are at most $p/(h\lceil c_2 \log\log p\rceil)$ senders with undelivered messages. Suppose (without loss of generality) that h divides p and partition the set of p receivers into h disjoint sets $R_1, \ldots, R_h$ of size p/h. Perform a $(p/(h\lceil c_2 \log\log p\rceil), \lceil c_2 \log\log p\rceil, 0)$ approximate compaction to send the first message from each sender to a unique processor in R_1. (The probability that this will succeed is at least

$$1 - \alpha^{-\sqrt{p/(h\lceil c_2 \log\log p\rceil)}} - (p/(h\lceil c_2 \log\log p\rceil))^{-\alpha}.)$$

Finally, send the remaining messages to $R_2, \ldots, R_h$ in $\Theta(h)$ communication steps with no contention using the following strategy. If the first message of sender i was sent to the jth cell of R_1 by the approximate compaction, then send the ℓth message of sender i to the jth cell of R_ℓ for $1 < \ell \leq h$.

2.3. Deliver to target groups. Let α be any positive constant and let c_2 be the constant associated with α that is defined in Lemma 1. At the end of the spreading procedure, each sender will have at most one undelivered message to send and each target group will have at most $k/(h\lceil c_2 \log\log p\rceil)$ undelivered messages to receive. (Recall that $k = \lceil \log^{c_1} p\rceil$.) Our goal is to deliver the messages to the target groups. After this procedure terminates, each processor will have at most two undelivered messages to send and the destination of each undelivered message will be within the target group containing its sender.

We have two methods for implementing this procedure in $\Theta(\log\log p)$ communication steps. The simpler method (which we describe here) involves making copies of messages but the other method does not. The simpler of the two methods consists of two phases.

We first describe phase 1. Consider any target group T. At the start of the procedure, there are at most $k/\lceil c_2 \log\log p\rceil$ senders, each of which has one message to send to the target group. Let ℓ denote $\lfloor \log p \rfloor$. We send all but up to k/ℓ^2 of these messages to T in $O(\log\log p)$ steps by doing a $(k/\lceil c_2 \log\log p\rceil, \lceil c_2 \log\log p\rceil, k/\ell^2)$ approximate compaction. We can do this in parallel for each target group, and the probability that it fails for any target group is at most

$$\tfrac{p}{k}(\alpha^{-\sqrt{k/\lceil c_2 \log\log p\rceil}} + (k/\lceil c_2 \log\log p\rceil)^{-\alpha(k/\ell^2+1)}),$$

which is sufficiently small as long as the constant c_1 in the definition of k is sufficiently large.

We will use the phrase "completely undelivered" to describe all messages that were undelivered before phase 1 and were not delivered to their target groups during phase 1. At the end of phase 1, each sender has at most one completely undelivered message to send, each member of each target group has received at most one message, and the number of completely undelivered messages is at most p/ℓ^2. Choose ℓ disjoint sets $R_1, \ldots, R_\ell$ of size $\lfloor p/\ell \rfloor$ from the set of p receivers and let Q_j denote the set consisting of the jth receiver from each of $R_1, \ldots, R_\ell$. Next, send all of the completely undelivered messages to R_1 by performing a $(p/\ell^2, \lceil c_2 \log\log p\rceil, 0)$ approximate compaction. (This fails with probability at most $\alpha^{-\sqrt{p/\ell^2}} + (p/\ell^2)^{-\alpha}$.) Finally (for each j in parallel), the processors in Q_j copy the message received at the jth receiver in R_1

(if there is one) to the other processors in Q_j. (This takes $\Theta(\log\log p)$ communication steps.)

At this point, each completely undelivered message is stored at each of the ℓ processors in Q_j (for some j) and each processor stores at most one completely undelivered message. The following communication step is now performed in parallel by all processors. If the ith processor in Q_j has a completely undelivered message to send, then it chooses an integer uniformly at random from the set $\{\gamma \mid (1 \le \gamma \le k)$ and $(\gamma \bmod \ell = i)\}$ and it sends the message to the γth processor in its target group. The probability that the ith processor in Q_j is unsuccessful is at most $1/\ell$, and this probability is independent of the probability that the other processors in Q_j succeed, so the probability that there is a completely undelivered message that is not delivered at least once to its target group in this communication step is at most $p\ell^{-\ell}$, which is sufficiently small.

For each j, in parallel the processors in Q_j perform parallel prefix to select one of the delivered copies. They then send messages "cancelling" any other copies that were delivered to their target group. This takes $\Theta(\log\log p)$ communication steps. Note that each processor receives at most two messages during the procedure — one in phase 1 and one in phase 2.

2.4. Deliver within target groups. When this procedure begins, each sender has at most two undelivered messages to send and the destination of each undelivered message is within the target group containing its sender. Our goal is to deliver all of the undelivered messages.

This procedure can be implemented deterministically in $\Theta(h + \log\log p)$ steps by running the second phase of Valiant's algorithm [Val90] twice within each target group. The algorithm within each target group is as follows. First, we consider only one undelivered message per sender. These messages are sorted by destination in $\Theta(\log\log p)$ communication steps using an EREW sorting algorithm such as Cole's parallel merge sort [Col88].[4] Then the sorted messages are delivered to their destinations without contention in $\Theta(h)$ communication steps. Next, the process is repeated for the remaining undelivered messages.

In this section, we describe an alternative implementation of the procedure. It does not rely on efficient deterministic $O(\log p)$-time EREW sorting and it is therefore likely to be faster in practice.

The main idea is as follows. We start by subdividing each target group into target subgroups. We then run the "thinning," "spreading," and "deliver to target group" procedures within each target group to deliver the messages to their target subgroups. If these three procedures succeed within a target group, then each sender in the group will have at most two undelivered messages to send and the destination of each undelivered message will be within the target *subgroup* of its sender. We can now run the second phase of Valiant's algorithm twice within each target subgroup to deliver the messages in the target group to their final destinations. Since the subgroups are very small, we can use Bitonic sort (which is fast in practice) to do the sorting. With high probability, the proportion of target groups for which the "thinning," "spreading," or "deliver to target group" procedures fail will be $O(k^{-3})$. We now allocate a group of k^2 extra processors to each of these target groups, and

[4] Valiant uses a randomized parallel sorting algorithm instead of using parallel merge sort. We cannot do that here because we want to be able to claim that (with high probability) the messages are successfully (and quickly) sorted in all of our target groups.

we use these extra processors to sort the messages using a counting sort that is fast in practice as well as in theory.

We now describe the procedure in more detail. The communication problem within each target group can be viewed as the problem of realizing an h-relation on a k-OCPC. Therefore, we can run the "thinning," "spreading," and "deliver to target group" procedures simultaneously *within* each target group. Before we can do that, we must partition each target group into target subgroups. Let the size of the target subgroups be $k' = \lceil \log^{c_5} k \rceil$, where c_5 is a constant that is sufficiently large that the probability that the "thinning," "spreading," and "deliver to target group" procedures fail within a target group is at most k^{-3}. (In order to simplify the presentation, in this section, we will assume that k' divides k. The case in which k' does not divide k is no more difficult—it is simply messier. Similarly, we will assume that k^3 divides p.) After the "deliver to target group" procedure terminates within each target group, run the second phase of Valiant's algorithm twice within each target subgroup, using Bitonic sort to do the sorting. (This takes $\Theta(h + \log^2 k')$ communication steps.) If the "thinning," "spreading," and "deliver to target group" procedures succeeded within a target group then all of its messages are now delivered. (This will happen with probability at least $1 - k^{-3}$.)

We now describe the second part of the procedure — the allocation of extra processors to help target groups that have not finished. Partition the set of target groups into p/k^2 disjoint sets $S_1, \ldots, S_{p/k^2}$. Each set S_ℓ contains k target groups and is called a *target supergroup*. Partition the set of target supergroups into k disjoint sets $\mathcal{C}_1, \ldots, \mathcal{C}_k$. Each set $\mathcal{C}_\ell$ contains p/k^3 target supergroups (and therefore p/k^2 target groups) and is called a *collection* of target supergroups. Note that with probability at least $1 - k \exp(-p/3k^5)$, each collection of target supergroups contains at most $2p/k^5$ unfinished target groups. Suppose that this is the case. Each target group and each target supergroup performs a parallel prefix to determine whether or not it has finished. (This takes $\Theta(\log \log p)$ communication steps.) Next, each processor that is part of an unfinished target group attempts to find a finished target supergroup. In particular, if the processor is the jth member of the target group, then it chooses a target supergroup uniformly at random from $\mathcal{C}_j$ and it sends a message to the first processor in the target supergroup asking whether the target supergroup is finished. The probability that a given member of a given unfinished target group fails to find a finished supergroup is at most $3/k$. (The probability that the supergroup chosen is not finished is at most $2/k^2$ and the probability that the query is sent to the same destination as some other query is at most $2/k$.) Furthermore, the queries from any given target group are independent of each other, so the probability that every processor in a given unfinished target group fails to find a finished supergroup is at most $(3/k)^k$ and the probability that there exists an unfinished target group that fails to find a finished supergroup is at most $p(3/k)^k$, which is sufficiently small. Each unfinished target group then performs a parallel prefix to choose a single finished supergroup.

At this point, each unfinished target group has identified a single finished supergroup containing k^2 processors. Consider the k^2 processors to be organized in a k by k matrix. We now run Valiant's algorithm twice in each unfinished target group. The messages are sorted using Muller and Preparata's algorithm [MP75], which works as follows. The ith processor of the unfinished target group sends its message (if it has one) to all of the processors in the ith row. (This takes $\Theta(\log \log p)$ communication steps.) If the processor in the ith row of the ith column gets a message, then it sends this message to all of the processors in the ith column and the processors in the ith

column perform parallel prefix to determine its rank. (Again, this takes $\Theta(\log\log p)$ communication steps.) Finally (in one communication step), the message with rank i is sent to the ith processor in the unfinished target group.

3. A lower bound for direct OCPC algorithms. The algorithm described in the previous section often sends a message to a processor other than its final destination, i.e., the algorithm is not *direct*. Using a nondirect strategy in a network that allows direct routing may seem strange at first, and one might question its necessity. In this section, we prove a lower bound that demonstrates that any sublogarithmic OCPC algorithm must necessarily use nondirect routing.

THEOREM 4. *Let $\mathcal{A}$ be any direct (randomized) OCPC algorithm that can realize any 2-relation with success probability at least $\frac{1}{2}$. Then there is a 2-relation which $\mathcal{A}$ takes $\Omega(\log p)$ communication steps to realize.*

Proof. Consider any direct randomized OCPC algorithm that runs for $t \leq \lfloor \frac{1}{3}\log p \rfloor$ steps. We shall construct a 2-relation ρ such that the probability that the algorithm successfully realizes ρ is exponentially small (in p). In the 2-relation ρ, each processor has at most one message to send.

Consider a processor P_i that is not itself the destination of any messages and has a single message to send to P_d but is blocked every time it attempts to transmit. Since P_i receives no external stimulus, we can imagine that P_i selects its transmission strategy at random in advance of the first time step. A strategy for P_i to transmit to P_d (under the blocking regime) can be coded as a binary word of length t, where a 1 in position t' indicates that P_i is to attempt to send its message at time step t'.

For convenience, assume that p is divisible by 4. The 2-relation ρ is the union of $p/4$ subrelations, each consisting of a pair of sending processors attempting to send a single message each to a common destination. The $3p/4$ processors in the 2-relation are distinct. The $p/4$ subrelations will be selected sequentially. Note that at any stage, there will be $f \geq p/4$ "free" processors from which the next pair of senders may be selected. To make the selection, first choose a free destination processor P_d. Observe that since the number of possible transmission strategies is 2^t, there must exist a strategy $\sigma \in \{0,1\}^t$ such that the expected number of free senders that choose strategy σ to send to P_d under the blocking regime is at least $f2^{-t}$. Thus there is a free sender, say P_i, that chooses strategy σ with probability at least $2^{-t} \geq p^{-1/3}$ and a different free sender, say P_j, that chooses σ with probability at least

$$(f2^{-t}-1)/(f-1) \geq 2^{-t} - f^{-1} \geq p^{-1/3} - 4p^{-1},$$

which is at least $\frac{1}{2}p^{-1/3}$ for $p \geq 24$. Now add to ρ the subrelation that requires P_i and P_j each to send a single message to P_d.

Note that P_i and P_j select strategies independently, so the probability that they both select σ is at least $\frac{1}{2}p^{-2/3}$; thus the probability that P_i and P_j fail to get rid of their messages is also at least $\frac{1}{2}p^{-2/3}$. Since there are $p/4$ subrelations forming ρ, the probability that ρ is successfully realized is at most $(1-\frac{1}{2}p^{-2/3})^{p/4}$, which is less than $\exp(-p^{1/3}/8)$. □

It may be observed from the proof that a direct algorithm requires a logarithmic number of steps to achieve even inverse polynomial success probability.

4. The MOB-PC algorithm. In this section, we describe a $\theta(h+\log\log p)$-communication-step algorithm that realizes an arbitrary h-relation on a $p \times p$ MOB-PC. We show that if $h \leq \log p$, then the failure probability can be made as small as $p^{-\alpha}$ for any positive constant α.

Since each row and each column of a $p \times p$ MOB-PC is itself a p-OCPC, we start by considering a p-OCPC. As in section 2, we divide the p processors into target groups of size $k = \lceil \log^{c_1} p \rceil$. A *target-group h-relation* is defined to be a communication problem in which each processor has up to h messages that it wishes to send. The destinations of these messages are target groups, and each target group is the destination of at most hk messages. We will use the following lemma.

LEMMA 4. *Suppose that $h \leq \log p$ and let α be any positive constant. Then there is a p-OCPC algorithm that can realize an arbitrary target-group h-relation in $O(h + \log\log p)$ steps with failure probability $3p^{-\alpha}$.*

Proof. Suppose that we are given a target-group h-relation. As in section 2, we will let $S(T)$ denote the set containing all senders that have messages destined for target group T. Let $M(S(T))$ denote the set of messages that are to be sent by these senders. Let each message choose a destination uniformly at random from within its target group. Let $h' = 8eh + \log\log p$ and let $h'' = h'/2$. We will say that a message is *externally bad* with respect to a target group T if the message has the same destination as at least h'' other messages that are not sent from senders in $S(T)$. We will say that a message is *internally bad* with respect to a target group T if it has the same destination as at least h'' other messages that are sent from senders in $S(T)$. We will say that a sender is *initially good* unless one or more of its messages is (externally or internally) bad. We will prove the following claim.

CLAIM 2. *With probability at least $1 - p^{-\alpha}$, every set $S(T)$ contains at most $k/(2h'^2\lceil c_2 \log\log p \rceil)$ senders that are not initially good.*

Suppose that every set $S(T)$ contains at most $k/(2h'^2\lceil c_2 \log\log p \rceil)$ senders that are not initially good and that we start to deliver messages to their destinations by running the thinning procedure from section 2.1 using h' as the value of the variable "h". It is easy to see that we can modify the proof of Lemma 3 to obtain the following. (The following lemma is the same as Lemma 3 except for the factor of 2 in the denominator.)

LEMMA 3′. *Suppose that $h' \leq \log p$. Let i be an arbitrary phase of the thinning procedure and let T be any target group. With probability at least $1 - p^{-(\alpha+1)}$,*

1. *at most $|N(T)|/(2\,h'^6\lceil c_2 \log\log p \rceil)$ receivers in $N(T)$ become overloaded in phase i;*
2. *at most $|S(T)|/(2\,h'^6\lceil c_2 \log\log p \rceil)$ good senders in $S(T)$ stop participating at the end of phase i.*

We conclude that with probability at least $1 - 2p^{-\alpha}$, the number of messages that are not delivered to a given target group is at most the sum of

1. $k/(2h'\lceil c_2 \log\log p \rceil)$ (these messages may not be delivered because their sender is not initially good);
2. $k/(2h'\lceil c_2 \log\log p \rceil)$ (these messages may not be delivered because their sender stops participating or stops being good during the thinning).

We conclude that with probability at least $1 - 2p^{-\alpha}$, the number of undelivered messages destined for any given target group is at most $k/(h'\lceil c_2 \log\log p \rceil)$ after the thinning procedure terminates. Therefore, we can deliver the rest of the messages to their target groups using the "spreading" procedure from section 2.2 and the "deliver to target groups" procedure from section 2.3. In the remainder of this section, it will be important to have our algorithm for realizing target-group h-relations behave symmetrically with respect to the different destinations within a target group. We can achieve this goal by modifying the "deliver to target group" procedure from section 2.3 as follows.

1. In the first part of the procedure, we deliver messages to their target groups using "approximate collection" rather than "approximate compaction."

2. In the second part of the procedure (the part involving copies), the "winner" is chosen uniformly at random (rather than arbitrarily) from amongst the successfully delivered copies.

We now finish the proof of Lemma 4 by proving Claim 2. Let T be any target group. We will show that the probability that $M(S(T))$ contains more than $k/(4h'^2\lceil c_2 \log\log p\rceil)$ externally bad messages is at most $\frac{1}{2}p^{-\alpha}\,(k/p)$. Then we will show that the probability that $M(S(T))$ contains more than $k/(4h'^2\lceil c_2 \log\log p\rceil)$ internally bad messages is at most $\frac{1}{2}p^{-\alpha}\,(k/p)$.

First, we consider externally bad messages. We will say that a processor P is *externally crowded* with respect to a target group T if there are at least h'' messages which are not in $M(S(T))$ and have destination P. A set of b members of a target group are all externally crowded only if at least bh'' messages have destinations in the set. Therefore, the probability that there is a set of b members of a target group that are all externally crowded is at most

$$\binom{p}{k}\binom{k}{b}\binom{kh}{bh''}\left(\frac{b}{k}\right)^{bh''}.$$

We can use Stirling's approximation to show that for $b = k/h''^6$ this quantity is at most $(p/k)2^{-k/h''^5}$. Therefore, with probability at least $1-(p/k)2^{-k/h''^5}$, every target group has at most k/h''^6 processors which are externally crowded with respect to T. Suppose that this is the case. Then the probability that a message in $M(S(T))$ chooses a destination which is externally crowded with respect to T is at most h''^{-6}. Using a Chernoff bound, we see that with probability at least $1-\exp(-|M(S(T))|\,/\,(3\times h''^6))$, at most $2\,|M(S(T))|/h''^6$ messages in $M(S(T))$ choose a destination which is externally crowded with respect to T. Note that as long as p is sufficiently large, $2\,|M(S(T))|/h''^6 \le k/(4h'^2\lceil c_2\log\log p\rceil)$. Also, as long as $|M(S(T))| \ge k/(4h'^2\lceil c_2\log\log p\rceil)$, $h' \le \log p$, and the constant c_1 is sufficiently large, the sum of $(p/k)2^{-k/h''^5}$ and $\exp(-|M(S(T))|\,/\,(3\times h''^6))$ is at most $\frac{1}{2}p^{-\alpha}\,(k/p)$.

We now consider internally bad messages. We start by calculating an upper bound on the probability that a message is internally bad. This probability is at most

$$\sum_{j=h''}^{hk-1}\binom{hk-1}{j}\frac{1}{k^j}\left(1-\frac{1}{k}\right)^{hk-1-j}.$$

We can use Stirling's approximation to show that this sum is $\mathrm{O}(2^{-h''})$. So the expected number of messages in $M(S(T))$ which are internally bad is $\mathrm{O}(|M(S(T))|2^{-h''})$.

Let x_i be a random variable which denotes the destination of the ith message in $M(S(T))$ and let Y be a random variable denoting the number of internally bad messages in $M(S(T))$. (Y is a function of $x_1,\ldots,x_{|M(S(T))|}$.) If we change one of the x_i's, then we change Y by at most $h''+1$. Therefore, by Theorem 3 (the bounded differences inequality),

$$\begin{aligned}&\Pr(Y \ge k/(4h'^2\lceil c_2\log\log p\rceil))\\ &\quad\le 2\exp\left(-2\left(\frac{k}{4h'^2\lceil c_2\log\log p\rceil}-\mathrm{E}(Y)\right)^2\Big/\left(|M(S(T))|\,(h''+1)^2\right)\right).\end{aligned}$$

Since $\mathrm{E}(Y) \leq k/(8{h'}^2\lceil c_2 \log\log p\rceil)$ (for big enough p), the probability is at most

$$2\exp(-k/(32{h'}^4\lceil c_2 \log\log p\rceil^2 h^2(h''+1)^2)).$$

This quantity is at most $\frac{1}{2}p^{-\alpha}\,(k/p)$ as long as c_1 is sufficiently large and h' is at most $\log p$. □

Now that we have proved Lemma 4, we are ready to describe our algorithm for realizing h-relations on a $p \times p$ MOB-PC. We have already observed that each row and each column of a MOB-PC is a p-OCPC. We will divide each row and each column of the MOB-PC into target groups of size k. A *block* of the MOB-PC is defined to be a $k \times k$ sub-MOB-PC in which each row is a row target group of the original MOB-PC and each column is a column target group of the original MOB-PC. We will use the phrase *column of blocks* to refer to a collection of p/k blocks which together make up k columns of the MOB. Finally, we will subdivide each column of blocks into p/k^2 *superblocks* in which each superblock consists of k blocks. (As in section 2.4, we will simplify the presentation by assuming that k^3 divides p. We will also assume that $h \leq \log p$.)

The algorithm has five steps:

1. *On each row:* Each message picks a random row target group and the messages are routed to the target groups.

2. *On each column:* Each message chooses as its immediate destination the column target group that intersects the row of its final destination. The messages are routed to the target groups.

3. *Within each block:* Each message chooses an immediate destination uniformly at random from its row. The messages are routed to their immediate destinations using the OCPC algorithm in each row. Each message that was successfully delivered to its immediate destination chooses as its new immediate destination the processor which is in its column and in the row of its final destination. The messages are routed to their immediate destinations using the OCPC algorithm in each column. If the block contains a message that was not successfully delivered to the row of its final destination, then we say that the block *failed.* Every processor in the block is notified of the failure.

4. If any block of a superblock failed, then we say that the superblock failed. Every processor in the superblock is notified of the failure. Each failed block attempts to allocate a superblock which has not failed from within its column of blocks. After allocating a superblock, the failed block copies all of its messages to each of the blocks in the superblock. Each of these blocks then repeats step 3. If there is a block in the superblock which does not fail, then the first such block copies the (delivered) messages back to the original failed block.

5. *On each row:* Each message is routed to its final destination.

We will conclude the section by considering each of the five steps. For each step, we will discuss the method that is used to implement the step and also the failure probability of the method.

At the beginning of step 1, each processor has at most h messages. Each message then picks a random row target group. Using a Chernoff bound, we see that the probability that a given target group is the destination of more than $2hk$ messages is at most $e^{-hk/3}$, so the probability that there is such a target group is at most $p \times (p/k) \times e^{-hk/3}$, which is at most $p^{-\alpha}$ as long as c_1 is sufficiently large. Suppose that every target group is the destination of at most $2hk$ messages. Then we can use the method described in the proof of Lemma 4 to deliver the messages to their target

groups in $O(h + \log\log p)$ steps. The probability that this method fails is at most $3p^{-\alpha}$ for any positive constant α.

At the beginning of step 2, each processor has at most h_2 messages, where h_2 is h plus the number of time steps used in step 1. If it is also true that every target group is the destination of $O(hk)$ messages in step 2, then we can use the method described in the proof of Lemma 4 to deliver the messages to the target groups in $O(h + \log\log p)$ steps. We will conclude our discussion of step 2 by showing that with high probability each target group is the destination of $O(hk)$ messages.

Let T be any column target group and let C be the column of T. There are at most hkp messages which have final destinations in rows which intersect T. These are the only messages which could be destined for T in step 2. We will refer to them as the set of "potentially relevant" messages. Each potentially relevant message will be destined for T in step 2 if and only if it is delivered to column C in step 1. Therefore, our goal is to prove that with high probability only $O(hk)$ of the potentially relevant messages are delivered to column C in step 1.

We start out by using a Chernoff bound to prove that with probability at least $1 - \exp(-hk^2/3)$, only $2hk^2$ of the potentially relevant messages select target groups that intersect C in step 1. We refer to these messages as "relevant" messages. Our goal is to prove that with high probability only $O(hk)$ of the relevant messages are delivered to column C in step 1.

We will use the following theorem of Hoeffding, which is included in McDiarmid's paper [McD89].

THEOREM 5 (Hoeffding). *Let the random variables $X_1, \ldots, X_p$ be independent, with $0 \le X_i \le 1$ for each i. Let $\overline{X} = \frac{1}{p}\sum_i X_i$ and $\mu = \mathrm{E}[\overline{X}]$. Then for $0 \le t < 1 - \mu$,*

$$\Pr(\overline{X} \ge t + \mu) \le \left[\left[\frac{\mu}{\mu + t}\right]^{\mu+t}\left[\frac{1-\mu}{1-\mu-t}\right]^{1-\mu-t}\right]^{p}. \qquad \square$$

To apply Hoeffding's inequality, let X_i be h_2^{-1} times the number of relevant messages that are delivered to row i of column C in step 1. Observe that $0 \le X_i \le 1$ and that the X_i's are independent. Note that $\overline{X}$ is $(h_2 p)^{-1}$ times the number of relevant messages that are delivered to column C in step 1. Recall that the algorithm for realizing target-group h-relations behaves symmetrically with respect to the destinations forming a particular target group; thus the expected number of relevant messages delivered to column C in step 1 is k^{-1} times the expected number of relevant messages. Therefore, μ is at most $2hk/(h_2 p)$. Let t denote $4hk/(h_2 p)$. Observe that $t \ge 2\mu$ and that $0 \le t < 1 - \mu$. By Hoeffding's inequality, the probability that $\overline{X}$ is at least $6hk/h_2 p$ is at most

$$\left[\left[\frac{\mu}{\mu + t}\right]^{\mu+t}\left[\frac{1-\mu}{1-\mu-t}\right]^{1-\mu-t}\right]^{p} \le 3^{-tp}e^{tp} = e^{-\Omega(tp)}.$$

We conclude that with high probability at most $6hk$ messages are destined for any target group during step 2. In this case, the messages can be delivered in $O(h + \log\log p)$ steps using the method described in the proof of Lemma 4.

At the beginning of step 3, each processor has at most h_3 messages, where h_3 is h plus the number of time steps used in steps 1 and 2. Using a Chernoff bound (as in step 1), we see that with probability at least $1 - p \times (p/k) \times e^{-hk/3}$, each row of

each block is the destination of at most $2hk$ messages in step 3. We now consider each particular block. Following Rao [Rao92], we can use a Chernoff bound to show that with probability at least $1 - k^2 \exp(-h_3/3)$, the communication problem on each row is a $2h_3$ relation. Similarly, with high probability the communication problem on each column is a $2h_3$-relation. Therefore, the probability of failure can be made as small as k^{-3}. The processors in the block use parallel prefix to notify each other of failure. Similarly, the processors in each superblock use parallel prefix to notify each other of failure.

The implementation and analysis of step 4 closely follows that of section 2.4. The probability that there is a failed block that fails to allocate a superblock is at most $(p^2/k^2)(3/k)^k$. The probability that there is a superblock in which every block fails when it repeats step 3 is at most $(p^2/k^3)(1/k^3)^k$.

If steps 1–4 are successful, then at the start of step 5, all of the messages will be in the correct row. Furthermore, there will be at most h_5 messages at any processor, where h_5 is h plus the number of time steps used in steps 1–4. Since the communication problem is an h-relation, each processor will be the destination of at most h messages. Therefore the p-OCPC algorithm described in section 2 can be used to deliver the messages on each row. The probability that this algorithm fails is at most p (the number of rows) multiplied by the probability that the p-OCPC algorithm fails, which is at most $p^{-\alpha}$ for any positive constant α.

In the introduction to this paper, we pointed out that the MOB-PC is easier to build than an OCPC because it restricts the number of processors that a given processor can send to directly. Nevertheless, we have provided an algorithm for realizing h-relations on a MOB-PC which is asymptotically as fast as the fastest known algorithm for realizing h-relations on an OCPC. Similarly, we could define a new machine by replacing each row and each column of a $p \times p$ MOB-PC with a $p^{1/2} \times p^{1/2}$ MOB-PC. Our algorithm could be used recursively to realize h-relations in $O(h + \log\log p)$ steps on the new machine. Clearly, this recursion could be carried out to any constant depth.

THE ROBOT LOCALIZATION PROBLEM*

LEONIDAS J. GUIBAS†, RAJEEV MOTWANI‡, AND PRABHAKAR RAGHAVAN§

Abstract. We consider the following problem: given a simple polygon $\mathcal{P}$ and a star-shaped polygon $\mathcal{V}$, find a point (or the set of points) in $\mathcal{P}$ from which the portion of $\mathcal{P}$ that is visible is translation-congruent to $\mathcal{V}$. The problem arises in the localization of robots equipped with a range finder and a compass—$\mathcal{P}$ is a map of a known environment, $\mathcal{V}$ is the portion visible from the robot's position, and the robot must use this information to determine its position in the map. We give a scheme that preprocesses $\mathcal{P}$ so that any subsequent query $\mathcal{V}$ is answered in optimal time $O(m+\log n+A)$, where m and n are the number of vertices in $\mathcal{V}$ and $\mathcal{P}$ and A is the number of points in $\mathcal{P}$ that are valid answers (the output size). Our technique uses $O(n^5)$ space and preprocessing in the worst case; within certain limits, we can trade off smoothly between the query time and the preprocessing time and space. In the process of solving this problem, we also devise a data structure for output-sensitive determination of the visibility polygon of a query point inside a polygon $\mathcal{P}$. We then consider a variant of the localization problem in which there is a maximum distance to which the robot can "see"—this is motivated by practical considerations, and we outline a similar solution for this case. We finally show that a single localization query $\mathcal{V}$ can be answered in time $O(mn)$ with no preprocessing.

1. Introduction.

We consider the following problem: A robot is at an unknown position in an environment for which it has a map. It "looks" about its position, and based on these observations, it must infer the place (or set of places) in the map where it could be located. This is known as the *localization problem* in robotics [8, 22].

Aside from being an interesting and fundamental geometric problem, this task has several practical applications. As described in [8], localization eliminates the need for complex position-guidance equipment to be built into factories and buildings. Unmanned spacecraft require localization for the following reason [18, 20]: A rover lands on Mars, a map of whose terrain is available to it. It looks about its position and then infers its exact position on the Martian surface. Another application comes from robots that follow a planned path through a scene: the control systems that guide such a robot along the planned path gradually accumulate errors due to mechanical drift. Thus it is desirable to use localization from time to time to verify the actual position of the robot in the map, and apply corrections as necessary to return it to the planned path [22].

We assume that the robot is in an environment such as an office or factory, with flat vertical walls and a flat floor—thus the problem we address is for polygonal workspaces in two dimensions. The subject of this paper is localization using a *range*

finder [19], a device commonly used in real robots [8, 9, 10, 19]. A range finder is a device that emanates a beam (laser or sonic) and determines the distance to the first point of contact with any object in that direction. This is similar to the *finger probe* model [7, 21] studied in computational geometry. In practice, a robot sends out a series of beams spaced at small angular intervals about its position, measuring the distance to points at each of these angles. The discrete "points of contact" are then fitted together to obtain a *visibility polygon* $\mathcal{V}$ with m vertices (in general, the number of beam probes will be much larger than m).

The robot has a map of its environment: a polygon $\mathcal{P}$ (possibly containing holes) having n vertices. We assume that the robot has a compass: its representations of $\mathcal{P}$ and $\mathcal{V}$ have a common reference direction (say north). We wish to solve the following problem: given $\mathcal{P}$ and $\mathcal{V}$, determine all of the points $p \in \mathcal{P}$ such that the visibility polygon of p is translation-congruent to $\mathcal{V}$; see Figure 1.

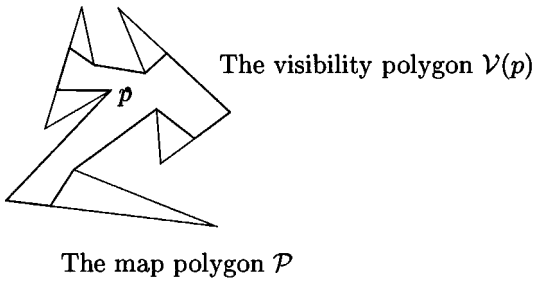

FIG. 1. *The setting for our robot localization problem.*

Because the map is likely to be fixed for a given environment, our main interest is in preprocessing the map so that subsequent queries can be answered quickly. Our main contribution is a scheme for preprocessing a simple polygon $\mathcal{P}$ so that any query $\mathcal{V}$ can be answered in time $O(m + \log n + A)$, where A is the size of the output (the number of places in $\mathcal{P}$ at which the visibility polygon would match $\mathcal{V}$); this query time is the best possible. Our preprocessing takes $O(n^5)$ time and space (section 5). We also exhibit a smooth tradeoff between the query time and the preprocessing cost, within certain limits. In these bounds, n^5 is really $n^4 r$, where r is the number of reflex vertices in $\mathcal{P}$. Better bounds hold for polygons where the number of mutually visible vertices is smaller than $O(n^2)$ and/or which do not have collinear sides.

The development of our scheme involves the study of a fundamental property of simple polygons—the *visibility cell decomposition*—that has several other applications. Sections 2, 3, and 4 study some properties of this decomposition. An interesting application of these ideas is to the construction of a data structure for the output-sensitive determination of the visibility polygon of a query point (see section 6.4). This requires a query time of $O(\log n + m)$ using $O(n^2 r)$ preprocessing and space, where m is the size of the visibility polygon. Once again, we can trade off between the query time and the space requirement.

In section 6, we consider variants of the basic problem. We first describe the effect of holes in the map polygon. Next, we consider a variant motivated by a property of some range finders—that a distance measurement is obtained only if there is a wall within a certain maximum distance D, and otherwise no reading is obtained (indicating only that the distance to the nearest wall is greater than D in that direction). We show how our approach can be modified to deal with this feature without increasing the query time, but with additional preprocessing. We

then address the following question: Given no preprocessing, what is the complexity of answering a single query? We provide an algorithm running in time $O(mn)$ by applying results on ray shooting.

Independently of our work, Bose, Lubiw, and Munro [2] obtained some of the results presented here. In particular, they provided a scheme for preprocessing a simple polygon so as to compute the vertices of the polygon that are visible from a query point in time $O(\log n + m)$ time. The machinery developed for this purpose includes some of the visibility cell decomposition structure theorems described below.

1.1. Overview of our scheme. We now give a brief overview of our scheme to motivate the study of the visibility cell decomposition in sections 2, 3, and 4. We approach the problem by partitioning the map polygon into regions such that within a region, the visibility polygon of any point is roughly the same; in section 2, we call this rough view a *skeleton*. An intuitive definition of the skeleton of $\mathcal{V}$ is that it is a contraction of $\mathcal{V}$ so that the skeleton boundary contains exactly those vertices from $\mathcal{V}$ that can be certified to be vertices of $\mathcal{P}$. We provide a data structure which quickly identifies all of the regions that have the same skeleton as the query $\mathcal{V}$. We then check the candidate regions to see if they contain any points that have exactly the same view as $\mathcal{V}$. Some difficulties that arise are the following:

(a) Due to occlusions by reflex vertices, an edge of the map polygon may have neither or only one of its endpoints visible from a point inside the polygon. Our characterization of a skeleton must cater to these incomplete edges.

(b) If the line segments forming several edges of the polygon are collinear, it is possible that a "window" in the map allows the robot to see only an interior portion of one of these edges. Further, it cannot easily identify which of these collinear edges it sees. The problem is compounded when there are several such windows and collections of collinear edges. In fact, this is one source of complexity in our preprocessing. In the case where the map $\mathcal{P}$ has no collinear edges, the preprocessing space can be improved to $O(n^3 r)$; see section 5.

(c) There can be regions that match the skeleton but contain no point whose visibility polygon is congruent to V. Thus we must still pinpoint those visibility regions (from all of the ones that share this skeleton) that contain a point whose visibility polygon exactly matches $\mathcal{V}$. We must do so in time proportional to A, so we cannot check each candidate region individually. We reduce this problem to a form of point location in a planar subdivision.

2. Visibility polygons and skeletons. Let $\mathcal{P}$ denote a polygon with n sides. We will refer to $\mathcal{P}$ as the *map polygon*. Let P denote the boundary of $\mathcal{P}$. We first assume that $\mathcal{P}$ has no holes, deferring this general case to section 6.1. Henceforth, all polygons will be assumed to be oriented with respect to a common reference direction.

Two points in P are *visible* to each other if the straight line joining them meets P only at these endpoints. The *visibility polygon* $\mathcal{V}(p)$ for any point $p \in \mathcal{P}$ is the polygon consisting of all points in $\mathcal{P}$ that are visible from p. Assume that the number of vertices in $\mathcal{V}(p)$ is m.

Let $V(p)$ denote the boundary of $\mathcal{V}(p)$. Assume that p does not lie on P, and hence it does not lie on $V(p)$. In general, there will be edges and vertices in $V(p)$ which do not coincide with edges and vertices in P. To deal with such cases, we define the notion of spurious edges and vertices. Informally, an edge or a vertex is nonspurious if the view from p provides a guarantee that this edge or vertex is on the boundary of $\mathcal{P}$.

DEFINITION 1. *An edge of* $V(p)$ *is* spurious *if it is collinear with* p.

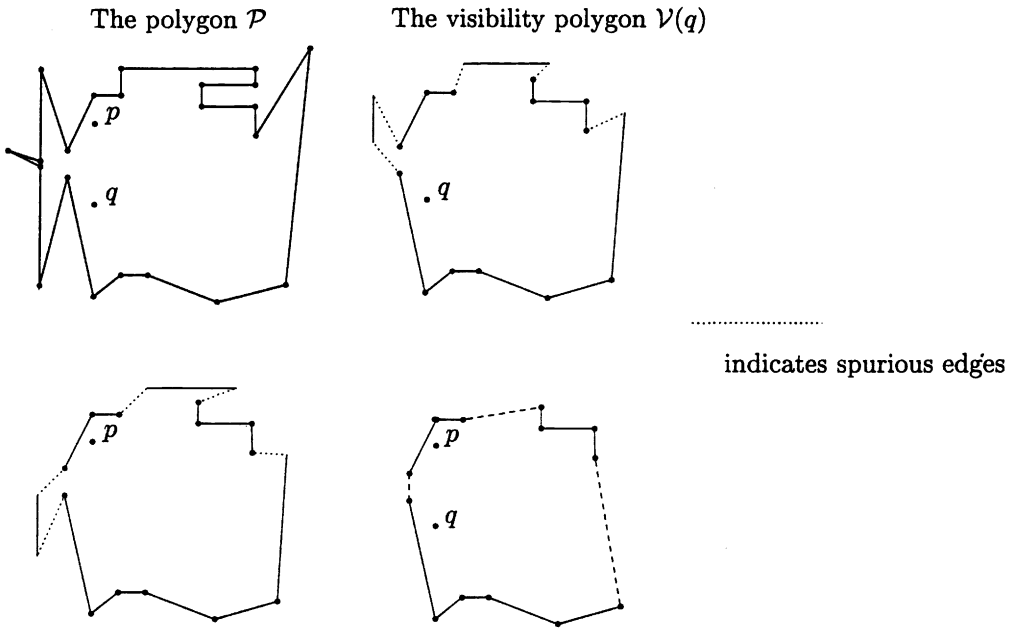

FIG. 2. *Visibility polygons and their skeletons.*

DEFINITION 2. *A vertex $v \in V(p)$ is* spurious *if it lies on a spurious edge $(u, v) \in V(p)$ and the other endpoint u is closer to p.*

Some of these notions are illustrated in Figure 2.

This definition may label as spurious an edge (or a vertex) which actually lies on P. This happens only if that edge is collinear with p. In that case, the closer of the two endpoints of the edge may be visible from p, but it will then block the view of any other point on the edge. Thus, although the edge (u, v) is in $V(p)$, the robot sitting at point p cannot infer this from its localized view. Similarly, the definition of a spurious vertex assumes that if a ray from p goes through vertices u and v of P, in that order, then u is an obstacle to the visibility of v from p. As the next lemma shows, the nonspurious components of $V(p)$ are invariant under any modifications to $\mathcal{P} \setminus \mathcal{V}(p)$. The proof is an easy consequence of the above definitions.

LEMMA 2.1. *An edge e or a vertex v in V is nonspurious if and only for each choice of $\mathcal{P}$ and $p \in \mathcal{P}$ such that $\mathcal{V}(p) = V$, e and v lie on P.*

A *reflex vertex* in P is a vertex which subtends an angle greater than 180^0 inside $\mathcal{P}$. It is the existence of reflex vertices which creates obstacles to viewing the points inside $\mathcal{P}$. Note that a spurious vertex can never be a reflex vertex in $V(p)$.

DEFINITION 3. *A reflex vertex v in $V(p)$ is a* blocking vertex *if at least one edge incident on v in P does not intersect $\mathcal{V}(p)$.*

It is now easy to establish the following lemma.

LEMMA 2.2. *If a vertex in $V(p)$ is a nonblocking reflex vertex, then both its incident edges in $V(p)$ must be nonspurious.*

The next lemma follows from the observation that each spurious edge can be extended to pass through p. Thus no two spurious edges of $V(p)$ can meet each other except at p, and by assumption p does not lie on the boundary of $\mathcal{V}(p)$.

LEMMA 2.3. *No two spurious edges can be adjacent in $V(p)$.*

For each spurious edge, the endpoint closer to p is a blocking reflex vertex and the other endpoint is a spurious vertex.

LEMMA 2.4. *Let $e \in V(p)$ be a nonspurious edge and e' be the edge of P on which it lies. Then e is the only portion of e' visible from p and the edge e is of one of the following three types:*

- full edge: *the endpoints of e are the same as those of e'*;
- half-edge: *one endpoint of e is spurious and the other is an endpoint of e'*;
- partial edge: *both endpoints of e are spurious vertices.*

We now conclude that the spurious vertices and edges in $V(p)$ can occur only in certain specific patterns. Consider a clockwise traversal of $V(p)$ starting with an arbitrary blocking (and therefore reflex) vertex. (If no such vertex exists, then $\mathcal{V}(p) = \mathcal{P}$, trivializing the whole problem, so from now on we assume the existence of such a vertex.) The sequence of vertices seen in this traversal can be decomposed into chains of consecutive nonspurious vertices alternating with chains of consecutive spurious vertices; call this the *vertex chain decomposition* of $V(p)$.

LEMMA 2.5. *The* vertex chain decomposition *of $V(p)$ has the following properties:*

1. *A nonspurious chain can contain blocking vertices only as its endpoints.*
2. *A spurious chain is of length at most* 2.
3. *Consider a spurious chain with only one vertex v. Let x be the last vertex of the preceding chain and y be the first vertex of the succeeding chain. Then one of x and y is a blocking vertex joined to v by a spurious edge, while the other is nonblocking and is joined to v by a half-edge.*
4. *Consider a spurious chain with two vertices u and v, in that order. Let x be the last vertex of the preceding chain and y be the first vertex of the succeeding chain. Then both x and y are blocking vertices with spurious edges going to u and v, respectively, and the edge (u, v) is a partial edge.*

Fix a canonical blocking reflex vertex v_o of $V(p)$ as the *origin* with reference to which we specify all other points. For example, v_o can be the leftmost blocking reflex vertex of $V(p)$. Let $V^*(p)$ be the polygon induced by the nonspurious vertices of $V(p)$ ordered by a clockwise traversal of starting at v_o. In $V^*(p)$, if two adjacent vertices are from the same chain in $V(p)$, then their edge is the same as in $V(p)$, and this must be a nonspurious edge. Otherwise, the two vertices are endpoints of neighboring chains in $V(p)$ and their edge in $V^*(p)$ is a newly introduced *artificial* edge.

Every artificial edge e' of $V^*(p)$ corresponds to some half or partial edge e of $V(p)$. The edge e is one of the edges of $V(p)$ which connect the two chains whose endpoints are the vertices of e'. We will label each artificial edge e' with a characterization of the line on which the corresponding edge e lies. This line characterization will be the coefficients of the linear equation that defines the line containing e, with the origin at v_o.

DEFINITION 4. *The* skeleton *$V^*(p)$ of a visibility polygon $\mathcal{V}(p)$ is the polygon induced by the nonspurious vertices of $V(p)$. Each artificial edge of $V^*(p)$ is labeled with the line equation and the type of the corresponding half- or partial edge.*

The skeleton of a visibility polygon can also be looked upon as a polygon induced by all of the full edges in $V(p)$ such that the chains of edges are tied together by artificial edges. It is important to keep in mind that a skeleton is a *labeled* polygon as described above.

DEFINITION 5. *The* embedding *of a skeleton $V^*(p)$ is a* 1–1 *mapping h from the vertices in the skeleton into the vertices of P such that the following hold:*

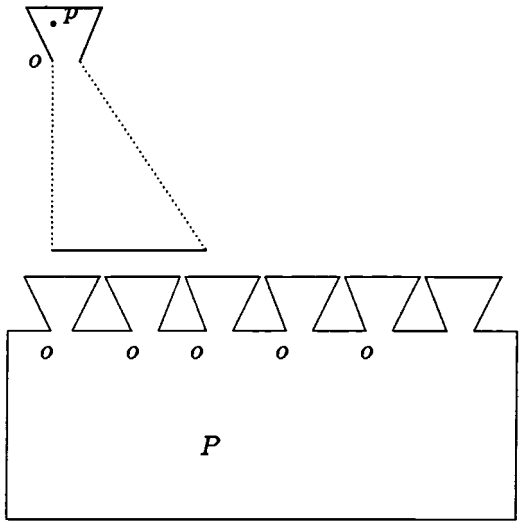

FIG. 3. *A bad case for localization.*

1. *For each vertex v in $V^*(p)$, the location of $h(v)$ relative to $h(v_o)$ is identical to the location of v relative to v_o in $V(p)$.*
2. *There is a full edge between vertices u and v in $V^*(p)$ if and only if there is an edge of P with $h(u)$ and $h(v)$ as endpoints.*
3. *Let l' be the line labeling an artificial edge between vertices u and v in $V^*(p)$. Then there is an edge e of P lying on a line l whose equation (with $h(v_o)$ as origin) is that of l', and there is a point of e visible from both u and v.*

Does $V^*(p)$ have enough information to uniquely determine the point p? Unfortunately not: the information about the endpoints of a half- or partial edge e in $V(p)$ is absent from the labels of the corresponding edge e' in $V^*(p)$. (The reason for this imprecise labeling will become clear later when we describe our search mechanism.) Thus a single embedding may have several candidate edges in P for the edge e. These candidate edges must all be collinear. For instance, in Figure 2, the partial edge on the left visible from p and that visible from q are collinear. Note that the skeletons of p and q come out to be the same.

Let r denote the number of reflex vertices in $\mathcal{P}$.

THEOREM 2.6. *Given a visibility polygon $\mathcal{V}(p)$, its skeleton $V^*(p)$ has at most r embeddings in $\mathcal{P}$ and this bound is best possible.*

Proof. Let us label any embedding h of $V^*(p)$ in $\mathcal{P}$ by the vertex $h(v_o)$, where v_o is the origin vertex in $V^*(p)$. We claim that there can be at most one embedding with the label v for any vertex v in P. This follows from the observation that the location of every vertex in $V^*(p)$ is fixed with reference to the origin vertex. Having specified the location of the origin as being at v immediately fixes the location of every other vertex and thus uniquely determines the embedding h itself.

Since v_o is a reflex vertex, there are at most r distinct labels for the embeddings of $V^*(p)$. It follows that number of distinct embeddings cannot exceed r.

To see that this bound is tight to within constant factors, consider the polygon $\mathcal{P}$ and the visibility polygon $\mathcal{V}(p)$ in Figure 3. It is clear that the origin of $V^*(p)$ can

be mapped to any of the vertices marked with o in P. Clearly, there are $\Theta(r)$ such embeddings. □

The location of the point p is fixed with reference to the origin vertex v_o of $V^*(p)$. Thus the only possible locations of the point p are the (at most r) locations corresponding to the different embeddings of the skeleton. Notice that an embedding of $V^*(p)$ may not correspond to an embedding of $V(p)$, although the converse is always true.

COROLLARY 2.7. *The number of solutions in $\mathcal{P}$ to a localization query $\mathcal{V}$ is at most r.*

3. Visibility cell decomposition. We now describe the subdivision of the map polygon into *visibility cells* such that the points in each cell have essentially the same visibility polygon. The subdivision is created by introducing lines into the interior of the map polygon. Each line partitions $\mathcal{P}$ into two regions, one where a vertex v is not visible due to the obstruction created by vertex u and another region where u cannot block the view of v. Each such line starts at a reflex vertex u and ends at the boundary of $\mathcal{P}$. It is collinear with a vertex v which is either visible from u or adjacent to it in P. This line is said to be *emanating* from v and *anchored* at u.

It is convenient to give each of the interior lines a direction and consider the interior of the map polygon to be dissected by a collection of such rays. A ray determined by vertex v as emanating vertex and vertex u as anchor vertex proceeds *from* u into P *away* from v. It forms the boundary between regions that can locally see v and others that cannot. We will classify this ray as a *left* or *right* ray for v according to whether the obstruction defining the anchor u is to the left or the right of the ray from the point of view of an observer sitting on v and looking along the ray. Note again that a ray starts at the anchor vertex and proceeds away from the emanating vertex.

THEOREM 3.1. *In the visibility cell decomposition of the map polygon $\mathcal{P}$,*

1. *the number of lines introduced in the interior of $\mathcal{P}$ is $O(nr)$, and this bound is the best possible*;
2. *each cell in the decomposition is a convex polygonal region inside $\mathcal{P}$.*

Proof. It easy to see that there are at most $O(nr)$ interior lines in the decomposition since each interior line is generated by a pair of anchor and emanating vertices, and each pair of vertices generates at most two interior lines. It is also quite easy to construct examples where the upper bound is achieved.

For the second part, let $\mathcal{C}$ be a visibility cell which is nonconvex and let w be a reflex vertex on the boundary of $\mathcal{C}$. We first claim that w cannot be a vertex from the boundary of $\mathcal{P}$. Otherwise, the edges incident on w would be extended into interior lines, and these interior lines would subdivide $\mathcal{C}$. On the other hand, no interior vertex can be a reflex vertex for its bordering visibility cells since it is formed by the intersection of two interior lines which start and end at the polygon boundary. This gives a contradiction. □

Since we can have $\Theta(nr)$ lines forming the cell decomposition, an obvious bound on the total complexity of the cells in the decomposition is $O(n^2r^2)$. However, the structure of our problem can be exploited to obtain the following tighter bound.

THEOREM 3.2. *The number of visibility cells in a given map polygon, as well as their total complexity, is $O(n^2r)$, and this bound is best possible.*

Proof. We will show that the number of subdivision vertices is $O(n^2r)$. There are a total of $O(nr)$ rays, and each ray gives rise to one boundary vertex only. Therefore, it suffices to count nonboundary vertices for the asymptotic bound in the theorem.

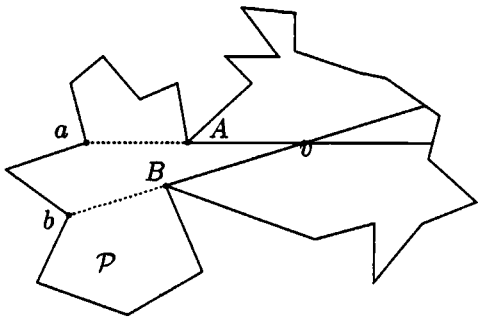

FIG. 4. *A type* 4 *vertex of the visibility decomposition.*

The simplest proof of this theorem consists of considering each of these $O(nr)$ rays separately. Let R be such a ray in the subdivision, anchored at A and emanating from a. Suppose we walk along this ray, starting at A and going away from a. During this walk, there can be at most $2n$ changes in the set of visible vertices. This is because in a simple polygon, once a vertex disappears from view when we walk in the polygon along a straight line, it will never become visible again (otherwise, the occluder in between represents a hole in the polygon). This implies that the ray R has $O(n)$ vertices on it. Since the number of rays is $O(nr)$, we get the desired bound.

However, we now present a more involved proof whose structural aspects will be useful in arguments later on.

Consider a vertex of the subdivision which does not lie on the boundary P. There must be two rays whose intersection gives rise to this vertex v. Let the first ray emanate from the vertex a with the anchor vertex A and the second ray emanate from b with the anchor B. Consider the two lines containing the given rays; they divide the plane into four "quadrants." Notice that if both rays are of the same orientation (i.e., both left or both right), then the corresponding anchors must lie in adjacent quadrants. In the case where the two rays have different orientations, the corresponding anchors lie in either the same quadrant or opposite quadrants.

Label each vertex of the subdivision that does not lie on the boundary of P by the pair of vertices that the two rays determining the vertex emanate from, as well as by the two bits specifying the relative placement of the two anchors in the quadrants defined above. The two bits classify the subdivision vertices into four types. Type 1 vertices are determined by two left rays and have the anchors in adjacent quadrants; type 2 vertices are analogous except that the rays are both of the right orientation. Type 3 vertices have the anchors in the same quadrant, while type 4 vertices have the anchors in opposite quadrants. Figure 4 illustrates a type 4 vertex.

The hardest case to deal with is that of the type 4 vertices—when the two anchors lie in opposite quadrants. Consider a type 4 vertex v determined by two rays, say a ray from a with right anchor A and a ray from b with left anchor B. Suppose we take the portion of the boundary of P from A to B not containing a or b and replace it with the interior segments Av and vB. We have not eliminated any vertices of our subdivision with the same label as v because in the eliminated part of P, at least one of a of b is not visible. In the remaining part of $\mathcal{P}$, there cannot be any other type 4 vertex labeled by a and b which uses either A or B as an anchor for the two rays. Thus there can be at most r vertices with this label. Since the total number of labels

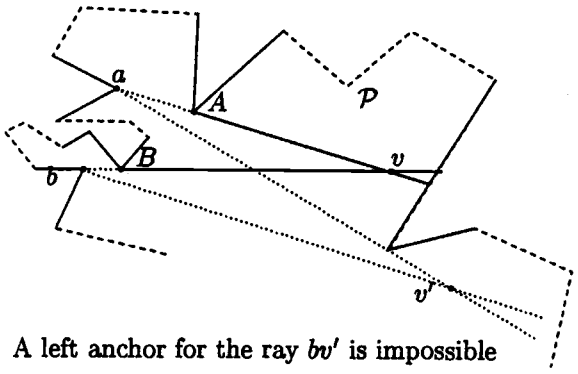

FIG. 5. *Labels with two left anchors are unique.*

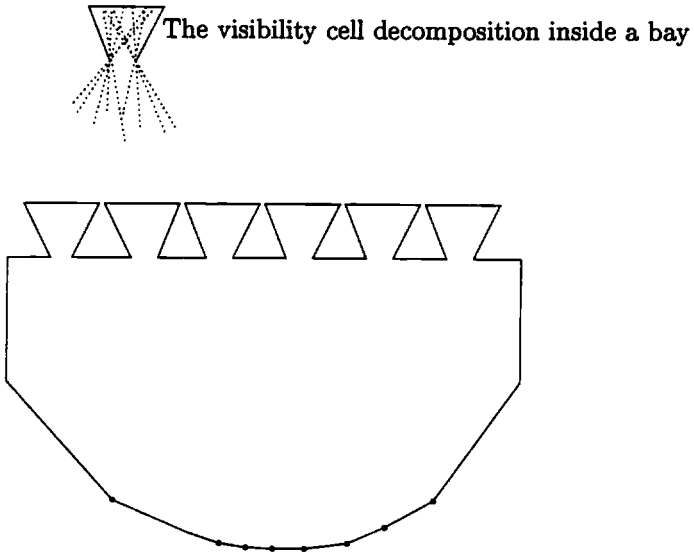

FIG. 6. *A polygon with a large visibility cell decomposition.*

is $O(n^2)$, we have the desired bound.

There are three other cases to consider. In each case, a simple topological argument shows that only a *unique* vertex can possess that label. See, for example, Figure 5, which shows the situation for two left rays. Thus there can be a total of $O(n^2r)$ interior vertices of our subdivision, and so the number of cells is similarly bounded.

For a lower bound, consider a polygon P that has $\Omega(r)$ small bays (each say of three sides) lying roughly along a straight line and facing a convex chain of $\Omega(n)$ sides that is visible from all of them; see Figure 6. Then within each bay, we can get $\Theta(n^2)$ regions corresponding to the visible subchain of the convex chain. This gives a total of $\Theta(n^2r)$ subdivision vertices in total. □

4. Visibility from a cell. We now examine the visibility polygons for all of the points in a particular cell and extract some common features from these views. We must be careful about the assignment of the points on the interior lines to the cells in the decomposition. Consider an interior ray emanating from vertex u and anchored at vertex v. The cells bordering this ray are divided into classes: those which can see u and those which cannot. The boundary edges determined by this ray are assumed to be a part of the latter kind of cells only. Using this rule, each interior vertex gets assigned to a unique cell as well.

The following theorem ties together the notions of a skeleton and a visibility cell.

THEOREM 4.1. *For any visibility cell $\mathcal{C}$ and points $p, q \in \mathcal{C}$, $V^*(p) = V^*(q)$.*

Proof. Consider the straight line joining p and q; call this line l. Clearly, l is totally contained in $\mathcal{C}$, even when p and q are boundary points. Further, no interior line of the decomposition intersects l. Suppose s is the point on l which is the closest to q such that it has a different visibility skeleton than $V^*(q)$.

First, consider the case where $V^*(s)$ and $V^*(q)$ do not have the same underlying polygon, i.e., they have a different set of vertices. Assume without loss of generality that the difference between the two skeletons is that a vertex of P, say x, is visible from s but is not visible from q. Then there must exist a reflex vertex $y \in V^*(q)$ such that it is an obstruction for q viewing x. Then the ray emanating from x and anchored at y must intersect l between s and q, giving a contradiction. Therefore, the underlying polygon for the skeleton is invariant over the entire cell.

Any difference in the skeletons $V^*(q)$ and $V^*(s)$ must then be in the labeling of the edges. It is fairly easy to verify that the locations of full edges and artificial edges must be the same in both cases, as must be the labelings of the artificial edges as corresponding to either half- or partial edges. The difference, if any, must be in the line characterizations that label some artificial edge. In that case, there must exist two edges of P, say e_s and e_q, such that s can see some portion of e_s but cannot see e_q at all, and q can see some portion of e_q but cannot see e_s at all. We then conclude that there is some point between s and q on l which sees a vertex not visible from q. This contradicts the assumption that s was the closest point of l to q which has a different skeleton.

Thus there can be no point s on l which has different visibility skeleton from q. □

This theorem allows us to make the following definition.

DEFINITION 6. *For any visibility cell $\mathcal{C}$, the visibility skeleton of the cell $V^*(\mathcal{C})$ is the common visibility skeleton for all points contained in $\mathcal{C}$.*

The exact choice of an edge e of P for any half- or partial edge is also invariant over the cell, although the portion of e that can be seen varies from point to point in the cell. However, Theorem 4.1 does not guarantee that if two points have the same visibility skeleton, then they are in the same visibility cell. In fact, a visibility skeleton can have r embeddings and could have several distinct visibility cells in its kernel, all with the same skeleton (as was already discussed; see Figure 2). This is because there could be several collinear edges of P that are all candidates for being the half- or partial edge corresponding to a particular artificial edge of the skeleton. If we assume that P contains no collinear edges, then there can be only one relevant visibility cell in the kernel of each embedding of the skeleton.

DEFINITION 7. *The binary relation "$\equiv$" over the visibility cells in the decomposition is such that for any two cells, $\mathcal{C}_1 \equiv \mathcal{C}_2$ if and only if $V^*(\mathcal{C}_1) = V^*(\mathcal{C}_2)$.*

It is easy to verify that this is an equivalence relation over the cells such that each equivalence class of cells is associated with a unique visibility skeleton. Let $\mathcal{E}_i$

for $1 \leq i \leq t$ be the equivalence classes for $\mathcal{P}$, and denote by V_i^* the visibility skeleton of the cells in the ith equivalence class. Also, let e_i denote the total size of all visibility cells in $\mathcal{E}_i$.

Before we embark on explaining our searching data structures, we would like to characterize the complexity of a visibility cell in terms of the complexity of its visibility skeleton. Recall that each side of a cell arises from a ray anchored at an endpoint of an artificial edge.

THEOREM 4.2. *Let $\mathcal{C}$ be a visibility cell whose visibility skeleton has s artificial edges. Then the complexity of $\mathcal{C}$ is $O(s)$.*

Proof. Each side of the polygon $\mathcal{C}$ is determined by a ray anchored at one of the blocking reflex vertices. Each such blocking vertex can have at most two rays which bound $\mathcal{C}$. Since the number of blocking reflex vertices is $O(s)$, the result follows. □

5. Data structures and search algorithms. We now describe the construction of the data structures and algorithms for query processing. In the first step of preprocessing, we compute the visibility cell decomposition of the map polygon and the visibility skeleton for each cell. Each skeleton polygon of size s is represented as an $O(s)$-dimensional real vector. These vectors are stored in a multidimensional search tree, each of whose leaves indexes an equivalence class of cells with the same skeleton. Given $\mathcal{V}(p)$, we extract the visibility skeleton $V^*(p)$ and query this data structure to identify the equivalence class of cells where p must be located. The last and most nontrivial stage of the search is concerned with identifying the possible locations of p within the equivalence class. This reduces to a search problem in a planar subdivision.

5.1. Computing cells and their skeletons. The visibility cells and their skeletons are computed by the following steps: (i) for each reflex vertex, identify the vertices of $\mathcal{P}$ that are visible from it—each such vertex can give rise to a line in the arrangement with one endpoint at that reflex vertex; (ii) compute the arrangement of all of these lines inside $\mathcal{P}$; (iii) compute for each cell in the arrangement the visibility polygon (and hence the skeleton). This last computation can be done in an incremental fashion as we walk along a line of the arrangement; the visibility polygon incurs only one change from one vertex on a line to the next vertex. Let C denote the number of visibility cells and N denote the number of visibility cell vertices; note that C and N are always $O(n^2 r)$.

THEOREM 5.1. *The preprocessing time and space for computing the visibility cell decomposition are $O(nr \log n + nN)$.*

Proof. By standard results in ray shooting in simple polygons [15] and the construction of arrangements via sweepline methods [11], steps (i) and (ii) above can together be completed in $O(nr \log n + N \log n)$ time and $O(nr + N)$ space. To bound the complexity of step (iii), we note that the visibility skeletons of adjacent regions differ in at most a constant number of contiguous edges. Thus we may generate the C visibility skeletons by the following procedure that walks along the lines forming the arrangement. We assume for simplicity of description that there are no degeneracies in the arrangement, i.e., at most two lines intersect at any point of the arrangement except at vertices of $\mathcal{P}$. Assume that every vertex of the arrangement that is not a vertex of $\mathcal{P}$ is labeled by the emanating and anchor vertices of the two lines that intersect to form that vertex.

We first compute the visibility polygons of the r reflex vertices in time $O(nr)$ [14]. Call this set ρ.

We begin at the (reflex) anchor vertex of the first line (call it ℓ) in the arrangement; given ρ, we can in time $O(n)$ obtain the visibility skeleton of the cell of the

arrangement that contains ℓ and its anchor and lies to the right of ℓ. We then walk on the arrangement along ℓ; at each new vertex w of the arrangement, a vertex v of $\mathcal{P}$ either becomes visible or invisible. Indeed, v is the emanating vertex of the other line that intersects ℓ at w. From this we can in $O(n)$ time and space read off and write down the visibility skeleton of the region bounded by line ℓ and vertex w and lying to the right of ℓ. We repeat this for all the lines forming the arrangement, for a total of $O(Nn)$ time and space.

By combining the complexities of all three steps, the result follows. □

Let $\mathcal{R}_i$, $1 \leq i \leq C$, be the regions/cells in the subdivision. Define r_i to be the complexity of $\mathcal{R}_i$, m_i to be the complexity of the $V^*(\mathcal{R}_i)$, and s_i to be the number of blocking vertices in these skeletons. Note that r_i is $O(s_i)$ and that $s_i \leq m_i$.

5.2. Locating the equivalence class. Assume that we have obtained a subdivision of $\mathcal{P}$ into C visibility cells and have computed a visibility polygon for one point in each of the cells. We start by showing how to compute the equivalence classes.

Given a visibility polygon of complexity m, the corresponding skeleton can be computed in $O(m)$ time. We will encode each of the C skeletons as an M-dimensional real vector, where $M = O(m)$. The encoding fixes an origin of the skeleton at a canonical reflex vertex (as described earlier) and specifies the position of every other vertex relative to the origin using $2m$ real numbers. Further, we store the edge labels using another $2m$ components. The ordering of the vertices and edges in the skeleton is specified implicitly by the ordering of the components of the encoding. This entire process takes $O(m)$ time.

A crucial property of the representation is that two cells have the same skeleton if and only if their representations are identical. This motivated the definition of a skeleton and is vital to constructing and searching the equivalence classes.

We first partition the cells according to the number of vertices in their visibility skeletons. Now consider the T_s cells whose skeletons have size s. We construct a multidimensional search tree [17] for the vectors corresponding to the skeleton representations of these cells. These search trees can be constructed in $O(sT_s + T_s \log T_s)$ time and space and support exact match queries in time $O(s + \log T_s)$. The various skeletons whose vector representations are identical will reach the same leaf of this search tree. Thus the leaves are in 1–1 correspondence with the equivalence classes of cells in this collection. (In practice, it would be more efficient to recompute the equivalence search trees using one representative from each equivalence class, after having computed the equivalence classes as above.)

We have at most n different search trees corresponding to the different values of s. Given a query $\mathcal{V}$, we can easily determine which tree to search and thence the correct equivalence class.

THEOREM 5.2. *The t equivalence classes, $\mathcal{E}_i$, can be computed in $O(nN)$ time using the equivalence search trees. The n search trees can all be constructed in $O(nN)$ time and space, and answer queries in time $O(s+\log n)$, where s is the query skeleton size.*

5.3. Searching within an equivalence class. It remains to specify how we search within an equivalence class of visibility cells for all the possible locations of the query point p. We will have one data structure for each of the at most n equivalence classes, associated with the corresponding leaf of the equivalence tree.

We now fix our attention on any one equivalence class $\mathcal{E}_i$. Let V^* be the skeleton corresponding to $\mathcal{E}_i$. Each cell in $\mathcal{E}_i$ can be identified with a distinct embedding of V^*. The cell must lie in the kernel of that embedding. For each embedding, there could be

several cells in the kernel, but these must be disjoint convex polygonal regions. (Recall that there will be only one cell per embedding if P contains no collinear sides.) Let the class $\mathcal{E}_i$ consist of cells from k different embeddings. The complexity of any one cell in $\mathcal{E}_i$ is at most m, the size of $\mathcal{V}(p)$. The following theorem bounds the overall complexity e_i of all the cells in $\mathcal{E}_i$.

THEOREM 5.3. *The total number of cells in any equivalence class $\mathcal{E}_i$, as well as their total complexity e_i, is $O(n^2)$. This bound is best possible.*

It turns out to be much easier to prove a stronger version of Theorem 5.3.

DEFINITION 8. *The class $\mathcal{C}_m$ of cells in the decomposition consists of all cells whose skeletons contain m nonspurious vertices.*

We will show that the total complexity of the cells in the class $\mathcal{C}_m$ is $O(n^2)$. This implies that the total complexity of the cells in an equivalence class is also $O(n^2)$ since these cells must all belong to $\mathcal{C}_m$ for some m.

THEOREM 5.4. *The overall complexity of the cells in $\mathcal{C}_m$ is $O(n^2)$.*

Proof. The longer proof of Theorem 3.2 will prove useful here. Recall that in that proof each vertex of the subdivision was given a label determined by the two rays on which it lies. The label consists of the names of the two emanating map vertices, as well as two bits specifying the layout of the anchor vertices with respect to these rays. There are four types of vertices corresponding to the four possible layouts. There could be as many as n vertices of type 4 which carry the label of a particular pair of map vertices. It is the latter kind of vertices which can be large in number. Overall, there are only $O(n^2)$ vertices which are of types 1–3 or lie on the boundary of the map polygon.

We must now do a careful assignment of the edges and vertices of the subdivision to the visibility cell. The rays determining a vertex create four quadrants, one of which is the region where the two emanating vertices are blocked from view by the anchors. The vertex is assigned to the incident cell which lies in this quadrant. Similarly, each edge lies on a ray on one side of which the emanating vertex is hidden from view by the anchor vertex. The edge is assigned to the adjacent cell which lies on that side of the ray. Thus each edge/vertex is assigned to only one cell, but it still bounds all its neighboring cells.

This assignment of edges and vertices is motivated by our definition of visibility. Consider a ray emanating from v and anchored at w. From the view of any point p on this ray, the vertex v is not visible. Thus in the skeleton $V^*(p)$, there will be a spurious edge from w to v, and v will be considered a spurious vertex.

Now consider the edges which bound the cells in $\mathcal{C}_m$. Some of these edges could be portions of the boundary of the map polygon. There are at most nr rays in the subdivision, and each ray will create one additional subdivision vertex on the boundary P. The number of subdivision edges lying on P cannot exceed the number of subdivision vertices on P, and these are at most $nr + n$ in number. We will ignore all such edges from now on since our goal is to prove a bound of $O(n^2)$.

Consider any particular ray R emanating at the vertex v and anchored at the vertex w. This ray starts at w and proceeds away from v until it hits the boundary P. We will assume that the ray is directed away from v. There may be several subdivision vertices on the ray, besides its endpoints, and this will divide R into a sequence of edges which bound some cells. We will think of these edges as open intervals separated by the vertices on R.

Assume that from the point of view of an observer sitting at v and looking in the direction of the ray, the anchor w lies to the left. We will argue only for the case of such "leftist" rays since the case of the "rightist" rays is similar. Each edge on the

ray will be assigned to the cell lying to its left. However, we will have to count each such edge as contributing to the complexity of both the cell to its right and the cell to its left.

As we trace along the ray from w to the boundary of P, we will traverse the edges on the ray in order. If the cell bounded by an edge (i.e., the cell to its right) is in $\mathcal{C}_m$, then the edge will contribute to the complexity of $\mathcal{C}_m$. Consider the vertices on this ray. Think of the ray as a vertical line which is directed towards the north. Each vertex x on this ray is caused by another ray, call it R', whose anchor may lie to the left or right of R—and this does not really matter. The anchor for R' may lie below it; in this case the vertex is called an *incrementing* vertex. This means that as we cross v, a new vertex comes into view, and this vertex is the emanating vertex for R'. Similarly, a vertex is called *decrementing* if its anchor lies above R'. Upon crossing such a vertex, the emanating vertex falls out of view. The key observation is that a type 4 vertex must be a decrementing vertex, and moreover its anchor must lie to the right of R.

Consider the sequence of edges we see that bound cells (to the right) which are in $\mathcal{C}_m$. Note that since all of these edges are not assigned to the cells to the right, the cells will have v in their skeleton. Thus any two consecutive $\mathcal{C}_m$ edges will be separated by a collection of vertices (including their endpoints) which contains an equal number of incrementing and decrementing vertices. We will label each $\mathcal{C}_m$ edge with the nearest incrementing vertex which lies below it. Since no two $\mathcal{C}_m$ edges are adjacent on R, each such edge gets assigned a unique label except possibly the first such edge on R. The crucial point here is that none of the labels can be a vertex of type 4.

Each vertex can label at most four $\mathcal{C}_m$ edges since it lies on two rays and can be used as a label for at most two $\mathcal{C}_m$ edges on each of these two rays—one each when we are considering the cells to left or to the right of R. Since none of the labels is of type 4, the number of distinct labels is $O(n^2)$. Moreover, the number of unlabeled $\mathcal{C}_m$ edges is at most nr, i.e., one per ray. We conclude that the number of edges contributing to the complexity of cells in $\mathcal{C}_m$ is $O(n^2)$.

It is easy to see that this bound can be reached in the example which proves the tightness of the $O(n^3)$ bound on the complexity of the subdivision. □

Consider any one embedding h of V^* and all of the cells in the kernel of the embedded skeleton which belong to $\mathcal{E}_i$. Let $h(p)$ denote the point in P which has the same location relative to $h(v_o)$ as p has to v_o. The following theorem states that if $h(p)$ lies in one of the cells with skeleton V^*, then $h(p)$ is a valid answer to the query $\mathcal{V}(p)$.

THEOREM 5.5. *Let h be any embedding of $V^*(p)$ and $h(p)$ be the corresponding location of p. Then $\mathcal{V}(h(p)) = \mathcal{V}(p)$ if and only if $V^*(h(p)) = V^*(p)$.*

Proof. Clearly, if $h(p)$ and p have the same visibility polygon, then they have the same skeleton. The nontrivial part is to show that if they have the same skeleton then they have the same visibility polygon.

Since the two points have the same skeleton, all of the nonspurious vertices are identically laid out in the two visibility polygons, as are all the full edges. Now consider any fixed artificial edge e' of their skeleton. Suppose that e' is labeled as being in correspondence with a half-edge. Then in the visibility polygon, there is a spurious edge se which is adjacent to this half-edge. The spurious edge starts at the same reflex vertex in both visibility polygons and is collinear with p. Thus the only difference between the two visibility polygons could be in the location of the spurious vertex where se meets the half edge. However, one endpoint of the half edge

is nonspurious and has the same location in both visibility polygons. Moreover, the line characterization of the half edge is the same in both cases. Therefore, the location of the spurious vertex must also be identical in the two cases.

The other case to be considered is where the artificial edge e' is in correspondence with a partial edge. In this case, there are two spurious edges in the visibility polygon which meet the partial edge. By an argument similar to the one above, it is easy to see that the location of the two spurious vertices must also be identical in the two visibility polygons.

We conclude that the relative location of all the spurious vertices must be identical in $\mathcal{V}(h(p))$ and $\mathcal{V}(p)$, and hence the two polygons must be identical. □

Thus to verify if p could have been in any particular embedding, it suffices to check if $h(p)$ lies in a cell with the same visibility skeleton. Let k denote the total number of valid embeddings. Note that in general each embedding may contain multiple cells with the same visibility skeleton V^*, as we are seeking. Our problem reduces to the following: given a collection of k families of disjoint convex polygons (one for each embedding) of total complexity e, we wish to identify the polygon(s) (if any) where a point q is located. When k is large, searching independently in each embedding's cells would require time at least k, which may be much larger than A (the output size). However, observe that all of the embeddings are congruent and have the same location of p with respect to the origin. The only difference between the embeddings is in the visibility cells therein which have V^* as their skeleton. The cells in different embeddings are possibly totally unrelated to each other.

Our solution is to consider all embeddings at once by overlaying all of their cells into one embedding of the skeleton. Thus with reference to the origin of V^*, we have k collections of convex polygons of total complexity e_i that are overlaid to create a planar subdivision. The problem is now that of performing a point location in this subdivision; each region is labeled by the set of visibility cells that intersect to create it. The overall complexity and time to compute this subdivision is at most $O(e_i^2)$.

Using data structures for point location in planar subdivisions due to Kirkpatrick [16] or Edelsbrunner, Guibas, and Stolfi [12], we can perform point location in time $O(\log n)$ with preprocessing and space $O(e_i^2)$. When we sum over all equivalence classes, our total cost will be

$$O\left(\sum_{i=1}^{t} e_i^2\right) = O\left(n^2 \sum_{i=1}^{t} e_i\right) = O(n^2 N)$$

by Theorem 5.4. In most cases, this will be the dominant preprocessing cost of our final algorithm.

There is actually one more problem to be overcome in implementing this approach: with each region in these subdivisions that we compute, we need to associate a list of the visibility cells whose intersection creates that region. This could blow up the space requirement by as much as another factor of n. To avoid this extra cost, we proceed as follows. Consider a particular subdivision $\mathcal{S}$ obtained by the overlay of congruent visibility skeletons in class $\mathcal{E}_i$ and let $\mathcal{G}$ be the dual graph of that subdivision whose vertices are a set of canonical points, chosen one per region of $\mathcal{S}$. Now double each edge in $\mathcal{G}$ and consider an Eulerian tour τ of this new $\mathcal{G}$ (which must exist since each vertex has even degree and can be computed in linear time in the size of $\mathcal{G}$). Break the tour at some region covered by no cell (e.g., any infinite region of $\mathcal{S}$). The resulting path, τ', can enter and exit each original cell multiple times, but its overall complexity will still be only e_i^2. Each passage of τ' through a cell can be thought of

an interval. Let us construct an interval tree on this collection of e_i^2 known intervals. We can determine the cells covering any point of the path τ' by standard interval-tree searching methods, improved by fractional cascading [6], in total time $O(\log n + A)$, where A is the size of the answer. We can do the same for any point in $\mathcal{S}$ since its coverage will be the same as for the canonical point selected in the region of $\mathcal{S}$ where it falls.

So we finally have our theorem.

THEOREM 5.6. *The localization problem can be solved with preprocessing time and space of* $O(n^2N)$ *and a query time of* $O(m + \log n + A)$.

Note that if we want any one solution, the query time drops to $O(m + \log n)$.

Also, if we assume that P contains no collinear sides, then we can get a better preprocessing bound. Let equivalence class $\mathcal{E}_i$ contain s_i cells of total complexity e_i; each cell must come from a different embedding in this case. The cells are convex, and thus their overlay can have complexity at most $O(s_i e_i)$ and can be computed within the same time bound [1]. Since each s_i is at most r, in this case, the overall space and preprocessing time needed drops to $O(rN)$.

We can also reduce the space in general at the expense of increased query time. Moreover, we can smoothly trade off the query time with the preprocessing time and space.

THEOREM 5.7. *Let* $1 \leq f(n) \leq n$. *The localization problem can solved in* $O(n^2N/f(n))$ *space and preprocessing and query time* $O(m + f(n)\log n + A)$.

Proof. Consider any particular equivalence class $\mathcal{E}_i$. Pick $\gamma = n^2/f(n)$ and consider the embeddings whose complexity is at most γ each. These can be partitioned into groups of embeddings such that each group has complexity roughly γ. The idea is to overlay the cells from the embeddings in a particular group, using a total space of $O(\gamma^2)$ for each such group. The number of such groups cannot exceed $O(n^2/\gamma)$ since the overall complexity of all the embeddings is bounded by $O(n^2)$. The total space required by these groups is $O(n^2\gamma)$. Searching independently in each group's planar subdivision requires time $O(n^2 \log n/\gamma)$.

The embeddings of complexity at least γ each are also searched independently. Their total space requirement is $O(n^2)$. Moreover, since they cannot be more than $O(n^2/\gamma)$ in number, it requires $O(n^2 \log n/\gamma)$ time to search them. Thus our total space requirement for this equivalence class is $O(n^2\gamma)$ and the query time is $O(n^2 \log n/\gamma)$. This implies the desired result. □

The next result is obtained when we perform an independent point location in each distinct embedding.

THEOREM 5.8. *The localization problem can be solved with* $O(nN)$ *space and preprocessing and a query time of* $O(m + r \log n + A)$.

6. Extensions and variants. We briefly outline below how the methods above can be extended to work in a number of additional cases.

6.1. Map polygons with holes. When the map polygon has holes, the size and complexity of the visibility cell decomposition can be higher. In this case, we have a tight bound of $\Theta(n^2r^2)$ on the number of visibility cells. Although we do not have the space to develop this here, we merely mention that when all of the holes are convex, the increase in the number of visibility cells can be bounded in terms of the *number of holes*. This also applies to the increase in the preprocessing and space bounds.

6.2. The limited-range version. We now consider a feature of range finders that arises in practice: they can reliably obtain range readings only up to some

distance D [19]. Beyond this distance, the noise levels are too high to measure the distance, and we learn only that the distance is greater than D. Our approach to preprocessing $\mathcal{P}$ can be modified to work even in this case. The set of points within distance D of an edge of $\mathcal{P}$ is an oval region. Now consider the arrangement of the oval regions defined by all the edges of $\mathcal{P}$; since any two ovals intersect at most at four places, this arrangement partitions the plane into $O(n^2)$ subdivisions. Within each cell of this subdivision, the set of edges of $\mathcal{P}$ that are within distance D is invariant. Intersecting this arrangement with our visibility cell decomposition, we obtain a modified decomposition with the property that in each subdivision, the (redefined) skeletons are the same. Our search process is now applied to this modified decomposition to obtain the same query time.

6.3. The single-shot query problem. Now consider the problem of answering a single query $\mathcal{V}$. Here the cost of any preprocessing must be included in the cost of answering the query. We present an algorithm running in time $O(nm)$ based on some results in ray shooting. Suppose we wish to determine at each vertex of $\mathcal{P}$ where the ray going in a fixed direction first hits $\mathcal{P}$ again. This problem is equivalent to trapezoidalizing $\mathcal{P}$ using lines parallel to the shooting direction. This can be done in linear time [5, 13] given a triangulation of the polygon $\mathcal{P}$. The recent result of Chazelle [4] shows that the triangulation itself can be computed in linear time.

THEOREM 6.1. *Given a map polygon $\mathcal{P}$ and a visibility polygon $\mathcal{V}$, the set of valid locations of p can be determined in time $O(nm)$.*

Proof. First, for each of the $O(m)$ spurious edges in $\mathcal{V}$, we determine the trapezoidalization of $\mathcal{P}$ in the direction of that spurious edge. This requires a total of $O(nm)$ time. Now we try each possible embedding of $\mathcal{V}$ in $\mathcal{P}$, of which there are at most n. In each potential embedding case, we can determine its validity by using the information from the trapezoidalizations queries. Effectively, we are trying to trace a fixed placement of $\mathcal{V}$ in $\mathcal{P}$; we do this by following edges of P and using the trapezoidalizations to implement in constant time ray-shooting queries when we need to walk along a spurious edge of $\mathcal{V}$. Thus the time to verify an embedding is $O(m)$ and the total time is $O(nm)$. □

When the range finder has a limited range D, we can answer a single query in $O(n^2)$ time.

6.4. Visibility query processing. Consider the problem of preprocessing a polygon $\mathcal{P}$ so that a visibility query can be efficiently answered. A visibility query is a point $p \in \mathcal{P}$, and we are required to compute the edges and vertices of P visible from p. An interesting side effect of our results is the construction of an efficient data structure for this problem. The obvious approach is to compute the visibility cell decomposition and store in each cell a modified skeleton for the cell. This new skeleton records the (circular) list of the visible edges and vertices for that cell, which is constant over the cell. A query can now be answered by performing a point location in this cell decomposition. However, this is inefficient in its use of space since we must store the skeletons for each cell separately.

We now sketch an idea for making the space requirement linear in the complexity of the cell decomposition. The idea is to avoid storing the full visibility list at each cell. Instead, at each interior line we store the change in the visibility as we cross it. Borrowing from an idea of Chazelle [3], we actually store the visibility skeleton only at those cells where the visibility is a "local" minimum (i.e., those cells that see less of P than any of their neighbors). These are the cells where crossing any boundary edge leads to additional vertices/edges becoming visible. To compute the visibility in any

cell, we perform a walk to a minimal visibility cell, keeping track of the changes in visibility as we cross interior lines. If we are not at a minimal cell, there is always a cell boundary such that crossing it will cause the number of visible vertices to decrease. The length of the walk cannot exceed the size of the output.

Furthermore, the number of these minimal visibility cells is $O(n^2)$. This is because there cannot be two adjacent type 4 vertices on the boundary of such a minimal cell. One way to see this is to use the analysis in the proof of Theorem 5.4, except that we apply it to edges that bound a minimal visibility cell rather than to edges that bound cells in $\mathcal{C}_m$, as was the goal in that theorem. In particular, consider traversing a ray away from the anchor which (say) lies to the left of the ray; then a minimal cell bounded by an edge e lying on this ray must also lie to the left of the ray. Further, the first endpoint of e that is encountered must be a decrementing vertex (and possibly of type 4), but the second endpoint of e must be incrementing and hence cannot be of type 4. It follows that each minimal cell has at least one vertex not of type 4, and we charge the minimal cell to this vertex. In this fashion, each vertex can be charged at most four times. By recalling that the number of vertices that are not of type 4 is $O(n^2)$, we get the following result.

THEOREM 6.2. *Using $O(n^3)$ space and preprocessing, a visibility query can be answered in time $O(\log n + m)$, where m is the size of the output visibility polygon.*

7. Further work.

- The single-shot problem resembles a classic string-matching problem, and it is likely that an algorithm running in time $o(mn)$ can be devised using techniques from that field.
- We assumed that the robot has a compass and thus $\mathcal{V}$ is oriented with respect to $\mathcal{P}$. What if this assumption were removed?
- In any real-life situation, the data obtained from the sensor is likely to be noisy. How can se solve this problem when we seek only approximate congruence between $\mathcal{V}$ and the visibility polygon of a point in $\mathcal{P}$?
- A hard but natural extension of our problem is to the case of three-dimensional polyhedral terrains. Here the robot's viewing mechanism would be a camera which would deliver two-dimensional images.

A FAST ALGORITHM FOR OPTIMALLY INCREASING THE EDGE CONNECTIVITY*

DALIT NAOR†, DAN GUSFIELD†, AND CHARLES MARTEL†

Abstract. Let $G = (V, E)$ be an undirected, unweighted graph with n nodes, m edges and edge connectivity λ. Given an input parameter δ, the *edge augmentation problem* is to find the smallest set of edges to add to G so that its edge connectivity is increased by δ. In this paper, we present a solution to this problem which runs in $O(\delta^2 nm + \delta^3 n^2 + nF(G))$, where $F(G)$ is the time to perform one maximum flow on G. In fact, our solution gives the optimal augmentation for *every* δ', $1 \leq \delta' \leq \delta$, in the same time bound. By introducing minor modifications to the solution, we can solve the problem without knowing δ in advance, and we can also solve the node-weighted version and the degree-constrained version of the problem. If $\delta = 1$, then our solution is particularly simple; it runs in $O(nm)$ time, and it is a natural generalization of the algorithm in [K. Eswaran and R. E. Tarjan, *SIAM J. Comput.*, 5 (1976), pp. 653–665] for the case where $\lambda + \delta = 2$. We also solve the converse problem in the same time bound: given an input number k, increase the connectivity of G as much as possible by adding at most k edges. Our solution makes extensive use of the structure of particular sets of cuts.

1. Introduction.

Consider an undirected, unweighted graph $G = (V, E)$ with n nodes, m edges, and edge connectivity λ. Given a parameter δ, the *edge augmentation problem* is to find a smallest set of edges to add to G so that its edge connectivity is increased to $(\lambda + \delta) = C$.

The edge augmentation problem is a fundamental problem in graph theory. It has direct applications in the design of reliable networks [14, 15, 16] and indirect applications in problems of statistical data security [19]. More abstractly, the problem is of interest as a demonstration of the algorithmic power that comes from understanding and exploiting subtle graph-theoretic structure. Any solution to this problem must add at least $C - \lambda'$ new edges across any cut of size λ', $\lambda' < C$. Hence to obtain an efficient solution, one must make extensive use (explicitly or implicitly) of the underlying *structure* of the set of cuts of size up to C in G, and one must derive and use this structure efficiently.

In this paper, we give a solution to the edge augmentation problem which runs in $O(\delta^2 nm + \delta^3 n^2) + nF(G)$ time, where $F(G)$ is the time to perform one maximum flow in G. For the case of $\delta = 1$, our solution is particularly simple and runs in $O(nm)$ time. The edge augmentation problem was first shown to be solvable in polynomial time by Watanabe and Nakamura [36], who gave an algorithm that works in $O((\lambda + \delta)^2 n^4((\lambda + \delta)n + m))$ time, and this was improved by Watanabe [35] to

$O((\lambda+\delta)^2 n^3((\lambda+\delta)n+m))$. Cai and Sun [5] also considered the problem and described a solution but did not provide any time analysis. An initial version of our algorithm appeared in [30]. Independently, using a quite different approach, Frank [9] gave an $O(n^5)$ algorithm for the problem which extends to a more general augmentation problem where local connectivities may be prescribed. A new implementation of our algorithm, which uses a poset representation for minimum cuts, was given by [11].

The edge augmentation problem is a particular instance of the general *graph augmentation problem*. This general area was first investigated by Eswaran and Tarjan [7], who gave a polynomial-time algorithm for the problem of augmenting an unweighted graph to make it 2-edge-connected (bridge-connected). In our terminology, this is the special case of $\lambda + \delta = 2$. They also showed that the corresponding weighted case is NP-complete. Later, Fredrickson and JáJá [10] showed that the 2-edge-connected weighted problem remains NP-complete even if the initial graph is a tree and gave an approximation algorithm for the problem. The problem of optimal strong augmentation of a mixed graph (a graph with both undirected and directed edges) was given an efficient solution by Gusfield [17]. Kajitani and Ueno [22] and Ueno, Kajitani, and Wada [34] solved the unweighted problem for all graphs which are trees, directed and undirected (a special case of $\lambda = 1$). Their method is polynomial, but no time bounds are stated explicitly in their papers. Both [36] and [5] deal with the general edge augmentation problem and show its polynomiality. These papers are very long, and the methods described therein are quite involved. The method of Frank [9] solves the edge augmentation problem for both directed and undirected graphs and is based on a different approach. It extends to a more general problem when local connectivities may be prescribed, and it generalizes to a strongly polynomial algorithm. Its extension by [3] applies to mixed graphs. In [11], the directed and undirected versions are considered. All methods allow, and often require, the addition of parallel edges. For the vertex analogue of the problem (i.e. adding edges to increase the vertex connectivity), much less in known; see [7, 32, 37, 20, 21] for results on the special case where $\lambda + \delta = 2$ or 3.

The main result in this paper is a solution to the edge augmentation problem for undirected, unweighted graphs for *any* initial edge connectivity λ and *any* increment δ. Our method is faster than the previous methods: its running time is $O(\delta^2 nm + \delta^3 n^2)$, with an initial cost of $nF(G)$ (when $\delta > 1$), where $F(G)$ is the best time to compute a maximum flow in an unweighted graph. (The best $F(G)$ known is $O(\min\{n^{2/3}m, m^{3/2}\})$ for simple graphs and $O(m^{3/2})$ for multigraphs [8, 2].) This is a considerable improvement over the $O((\lambda + \delta)^2 n^3((\lambda + \delta)n + m))$ method of [35], and when δ is not very large ($\delta < n$), it improves the $O(n^5)$ method of [9]. Our method is also simple and intuitive and allows a self-contained exposition. It can be easily adapted to solve the augmentation problem even without the knowledge of a target increment δ in advance, and yet it produces a solution that is optimal for any intermediate increment. It can therefore be used to solve the converse problem: given a number k, what is the highest connectivity that can be achieved by adding at most k new edges to the graph? It can also be adapted to solve two other variations on the problem which were suggested and first solved by Frank [9]: the node-weighted version and the degree-constrained version. In the node-weighted version, each node x has a weight $cost(x)$; the goal is to find a minimum-weight set of edges that solve the augmentation problem, where the weight of adding an edge (x, y) is $cost(x) + cost(y)$. In the degree-constrained version, each vertex v has an upper bound $g(v)$ on its degree; the task is to solve the augmentation problem subject to the constraint that for every

vertex v, its degree in the final graph does not exceed $g(v)$.

For the case where the increase in connectivity is one ($\delta = 1$), our method is particularly simple, and is a natural generalization of the algorithm of [7] for the 2-edge connectivity case ($\lambda + \delta = 2$). Its running time is $O(nm)$, compared with the $O(\lambda^2 n^3(\lambda + m))$ of [35] or $O(n^5)$ of [9]. Note that $O(nm)$ is also the best time bound, in terms of n and m, for computing the connectivity value alone [31] (also described in [1]), [26]. (Nagamochi and Ibaraki [27] achieved a better bound of $O(m + \min\{\lambda n^2, pn + n^2 \log n\})$ for computing the connectivity, p being the number of pairs of vertices that are connected by an edge; when expressed only in terms of n and m, it reduces to $O(nm)$. Gabow [11] achieved $O(m + \lambda m \log(n^2/m))$.) Hence within the same best time bound for computing just the connectivity value, we can optimally increase the edge connectivity by one. (The implementation of our algorithm in [11], which uses a poset representation of cuts, runs in $O(m + \lambda^2 n \log(n/\lambda))$ for $\delta = 1$ and in $O(m + (\lambda + \delta)^2 n \log n)$ for $\delta > 1$.)

Given the efficiency and simplicity of the solution for $\delta = 1$, a natural approach to the problem of general δ is to successively (and optimally) increase the connectivity by steps of one until connectivity $\lambda + \delta$ is reached. Unfortunately, it is not true that *every* optimal set of edges which increases the connectivity by one can be extended to an optimal solution to increase the connectivity by $\delta > 1$. This approach even fails for $\delta = 2$ and $\lambda = 1$, as demonstrated in Figure 1. The graph G in Figure 1 becomes 3-edge-connected if the edges $\{(1, 11), (2, 12)\}$ are added. G becomes 2-edge-connected if the edge $(6, 8)$ is added (which is an optimal augmentation by one), but then *two* more edges must be added to make G 3-edge-connected (say, $\{(1, 11), (2, 12)\}$). So for the general problem, a less myopic method is needed. Though not every optimal augmentation by one can be extended to an optimal augmentation by $\delta > 1$, it is true that *there exists* an optimal solution for the case where $\delta > 1$ consisting of a sequence of δ augmentations where each augmentation successively increases the connectivity by one using the minimum number of edges. Such a sequence is given in [35] as an improvement over the algorithm in [36]. Our solution also finds such sequence. In fact, the sequence of δ *optimal* augmentations by one found by our algorithm also has the property that it is optimal for *any* intermediate $\delta' \leq \delta$, and hence the target δ need not be specified in advance. In order to construct this sequence, the algorithm needs to select each optimal augmentation by one with the future augmentations "in mind."

The approach employed by our algorithm is similar at its high level to the one used in [36]. It also uses similar results to prove the correctness of the algorithm. See section 4.6 for further discussion. However, we obtain substantially better running times by using a better algorithm for augmenting by one and by improving the time to do successive augmentations. The successive augmentations are sped up by using improved algorithms, data structures, and structural properties of the graph.

A crucial component of our solution is the use of compact structures which implicitly represent various information about sets of cuts. We use three such structures. The first is the Gomory–Hu equivalent flow tree [13], the second is one that we call the extreme-sets tree, and the third is a compact representation of the set of *all* connectivity cuts in a graph, where a connectivity cut is an edge cut of size λ. This representation is described by [6]. The use of this relatively unknown structure (at least in the West) is one of the keys to our faster solution.

This paper is organized as follows. In section 2, we describe the compact representation of the connectivity cuts. Section 3 contains the $O(nm)$-time solution for the

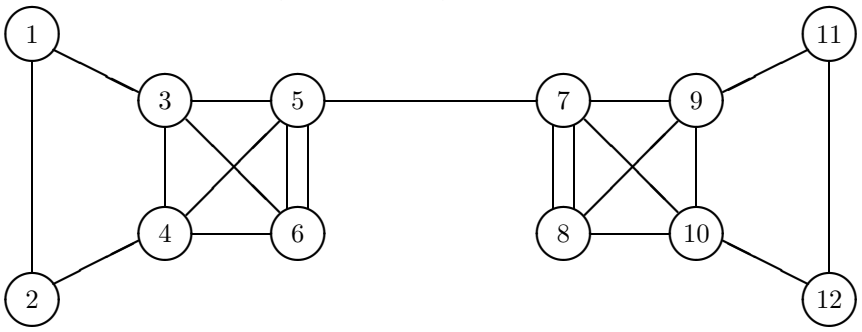

FIG. 1. *An example where an optimal augmentations by one cannot be extended to yield an optimal augmentation by two.*

edge augmentation problem where $\delta = 1$. In section 4, the solution for any δ is given. Section 5 refers to other variations on the problem: the no-target augmentation problem, the node-weighted version, and the degree-constrained problem. Finally, section 6 suggests as open questions a few possible extensions, in particular, the augmentation problem with no parallel edges.

2. Representing all connectivity cuts. We start by describing an elegant, compact representation for the sets of *all* connectivity cuts. In a graph $G = (V, E)$ with n nodes, m edges, and connectivity λ, a *connectivity cut* is a set of λ edges whose removal from the graph disconnects it into two sets of nodes, A and $\overline{A}$. We denote such a cut by $(A, \overline{A})$. The connectivity cut might not be unique; however, there can be only $O(n)$ of them if λ is odd and $O(n^2)$ of them if λ is even (we refer to [6, 23] and, indirectly, [4]).

The set of all connectivity cuts can be compactly represented by a simple edge-weighted graph $\mathcal{H}(G)$ of $O(n)$ nodes and edges [6], and this representation can be constructed in $O(nm)$ time [24] (see also [28, 29]). Each vertex in G maps to exactly one node in $\mathcal{H}(G)$ so that any node in $\mathcal{H}(G)$ corresponds to a subset (possibly empty) of vertices from G. A cut $(S, \overline{S})$ in $\mathcal{H}(G)$ defines a cut $(A, \overline{A})$ in G, where A consists of all the vertices from G that are mapped into nodes of S. Each minimal cut (a cut such that no proper subset of its edges is also a cut) in $\mathcal{H}(G)$ is also a λ-cut (a cut of total edge weight λ) in $\mathcal{H}(G)$, and it corresponds to a connectivity cut in G; each connectivity cut in G corresponds to one or more λ-cuts (or minimal cuts) in $\mathcal{H}(G)$. Hence the minimal cuts in $\mathcal{H}(G)$ compactly represent the connectivity cuts in G.

If λ is odd, then $\mathcal{H}(G)$ is particularly simple—it is a tree, all its edges are of weight λ, and any minimal cut in $\mathcal{H}(G)$ is obtained by removing one of its edges. If λ is even, then $\mathcal{H}(G)$ is called a *cactus*—it can contain cycles, but any two cycles have *at most* a single vertex in common, so no edge is in more than one cycle. Every edge in a cycle is called a *cycle edge* and is given weight $\lambda/2$; every other edge is called a *tree edge* and is given weight λ. Hence minimal cuts in $\mathcal{H}(G)$ are of exactly two types: a cut of the first type is obtained by removing a tree edge, and a cut of the second type is obtained by removing any pair of cycle edges that lie on the same cycle. Every tree is a cactus with no cycles; hence to unify our discussion, we always refer to $\mathcal{H}(G)$ as a cactus. Throughout the paper, we use the term "vertex" to denote a vertex in G and the term "node" to denote a node in $\mathcal{H}(G)$. In Figure 2 we give an example of a graph G with connectivity 4, and its connectivity cuts are represented by $\mathcal{H}(G)$.

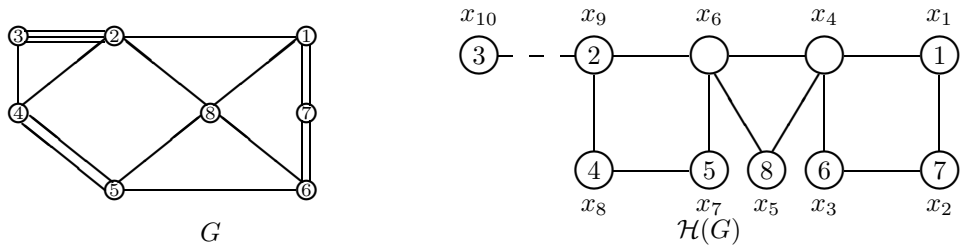

FIG. 2. *A graph G and its cactus representation $\mathcal{H}(G)$ ($\lambda = 4$). The weight of a solid edge in $\mathcal{H}(G)$ is 2, and the weight of a dashed edge is 4.*

3. Increasing connectivity by one. Our solution to the augmentation problem for $\delta = 1$ uses the representation $\mathcal{H}(G)$ and is a natural generalization of the method in [7] for the 2-edge-connectivity augmentation problem ($\lambda + \delta = 2$). To see that our solution generalizes the solution in [7], note that if the graph is originally 1-edge-connected, i.e., $\lambda = 1$, then the representation of all 1-cuts in the graph is well known: it is the tree obtained by contracting each of the 2-edge-connected components into a single node. The augmentation algorithm in [7] finds this representation for the 1-cuts and optimally augments it by one using a depth-first numbering of the tree leaves. Our method finds the cactus representation $\mathcal{H}(G)$ for *any* λ and augments it by one using a depth-first traversal of the cactus that generalizes the one of [7].

DEFINITION. *We say that a node u is a leaf in a cactus if either u is connected by a single tree edge or u is in a cycle and has degree exactly 2. Note that if there are no cycles in the graph, then this is the usual definition of a leaf (in Figure 2, the nodes $x_1, x_2, x_3, x_5, x_7, x_8, x_{10}$ are leaves).*

Let $u_1, \ldots, u_k$ be the leaves of $\mathcal{H}(G)$ and U_i be vertices in G which map to u_i, and let $(U_1, \overline{U_1}), \ldots, (U_k, \overline{U_k})$ be the λ-cuts of G defined by these leaves, i.e., either by the removal of the single incident tree-edge or by the removal of the two incident cycle-edges.

LEMMA 3.1. *If $\mathcal{H}(G)$ has k leaves, then at least $\lceil k/2 \rceil$ edges must be added to increase the connectivity of G by one.*

Proof. First, note that none of the leaves of $\mathcal{H}(G)$ can be empty subsets of vertices from G since otherwise they would not correspond to a λ-cut in G. Hence every u_i defines a λ-cut $(U_i, \overline{U_i})$ in G, so at least one new edge must go across each U_i, $1 \le i \le k$. Since the U_i's are disjoint, a new edge can satisfy at most two of these requirements. Hence at least $\lceil k/2 \rceil$ edges are needed. □

We now show that this bound is achievable. We first need to define a special type of depth-first-search (DFS) traversal in a cactus. This traversal consists of two stages. The first stage assigns different colors to the different simple cycles in the cactus so that all cycle edges of the same cycle are assigned the same color. Since every cycle edge is in exactly one cycle, such a coloring procedure is possible. It can be done efficiently, in $O(n + m)$ time, by adapting any procedure that finds the articulation points in a graph (see, for example, [25, 33]). The second stage is a DFS traversal that starts at an arbitrary node and obeys the following rule: if a node u is visited for the first time via a cycle edge that is colored red (say), then traverse all other edges incident at u *before* traversing the other red edge incident to u. Note that if the graph

has no cycles, then this is the usual DFS tree traversal.

An alternative presentation of the above DFS traversal is as follows: if every tree edge in the cactus is replaced by a pair of parallel edges, then the cactus becomes an Eulerian graph. The DFS traversal essentially finds some Eulerian tour in the graph.

We can now fully describe our solution to the problem of augmenting the connectivity of a graph by one.

ALGORITHM **Aug-1**

(1) Construct $\mathcal{H}(G)$, the representation of all connectivity cuts.

(2) Traverse $\mathcal{H}(G)$ in the modified DFS manner described above and enumerate its leaves $u_1, \ldots, u_k$ in the order in which they are first encountered in the DFS traversal.

(3.a) Form the pairs $\{(U_i, U_{i+\lceil k/2 \rceil}) : 1 \leq i \leq \lfloor k/2 \rfloor\}$, where U_i is the set of vertices from G that map to the leaf u_i of $\mathcal{H}(G)$.

(3.b) For each pair $(U_i, U_{i+\lceil k/2 \rceil})$, $1 \leq i \leq \lfloor k/2 \rfloor$, pick an *arbitrary* vertex from G in U_i and an *arbitrary* vertex from G in $U_{i+\lceil k/2 \rceil}$ and connect them by an edge. If k is odd, then connect some vertex in $U_{\lceil k/2 \rceil}$ to a vertex in an arbitrary different leaf U_j.

Note that the nonuniqueness of the solution comes from step (3.b) since it does not specify *which* vertex from G in U_i and $U_{i+\lceil k/2 \rceil}$ should be connected by the edge. This will be important in the solution for the case where $\delta > 1$. To prove the correctness of the algorithm, we need the following lemma.

LEMMA 3.2. *If the leaves of $\mathcal{H}(G)$ are numbered in the order they are first encountered in the above DFS traversal then, for every λ-cut $(S, \overline{S})$ of $\mathcal{H}(G)$, all the leaves in S have consecutive numbers, and all the leaves in $\overline{S}$ have consecutive numbers (under the definition that 1 succeeds k).*

Proof. Recall the two types of λ-cuts in $\mathcal{H}(G)$. First, suppose that $(S, \overline{S})$ is obtained by the removal of a tree edge of weight λ from $\mathcal{H}(G)$. In this case, the claim follows directly since it is the fundamental property of a DFS leaves enumeration in a tree. Now suppose that $(S, \overline{S})$ is obtained by the removal of two cycle edges (from the same cycle), each of weight $\lambda/2$. Let $c_1, \ldots, c_p$ be the vertices on this cycle, and without loss of generality, suppose that c_1 is the first vertex of this cycle to be visited in the DFS traversal. Then $c_1, \ldots, c_p$ must be visited in either this order or the counterclockwise order since any c_i can be reached from c_1 only via the cycle. Also, our DFS-traversal rule implies that for every c_i, the subgraph that is attached to c_i by edges not from this cycle is traversed *before* c_{i+1}. Hence since $(S, \overline{S})$ splits the cycle into two consecutive parts, the leaves on both sides must have consecutive numbers. ∎

THEOREM 3.3. *Algorithm* **Aug-1** *optimally increases the connectivity of G by one and can be implemented in $O(nm)$ time.*

Proof. We first show that at least one new edge crosses every λ-cut in $\mathcal{H}(G)$ (and thus crosses every λ-cut in G). Let $(S, \overline{S})$ be a λ-cut in $\mathcal{H}(G)$. By Lemma 3.2, the leaves in each side of the cut have consecutive DFS numbers (where 1 succeeds k). Without loss of generality, assume that S contains less than or equal to $k/2$ leaves, and let $u_i \in S$ (S must contain at least one leaf). If $i < \lceil k/2 \rceil$, $u_{i+\lceil k/2 \rceil}$ must lie in $\overline{S}$, so the edge $(u_i, u_{i+\lceil k/2 \rceil})$ crosses it. If $i > \lceil k/2 \rceil$, $u_{i-\lceil k/2 \rceil}$ must lie in $\overline{S}$, so the edge $(u_i, u_{i-\lceil k/2 \rceil})$ crosses it. Finally, if $i = \lceil k/2 \rceil$, the new edge attached to u_i crosses S since it is connected to a leaf different than u_i. Hence the connectivity of the new graph has increased by at least one. This is also an optimal augmentation since by Lemma 3.1, $\lceil k/2 \rceil$ is a lower bound on the number of edges that must be added, and

this method achieves this bound. Since $\mathcal{H}(G)$ can be constructed in $O(nm)$ time and can be traversed in $O(n+m)$ time, the total running time of algorithm **Aug-1** is $O(nm)$. □

Example. Consider the graph G in Figure 2, and apply algorithm **Aug-1** to G. The DFS traversal visits the leaves of $\mathcal{H}(G)$ in the following order: x_1, x_2, x_3, x_5, x_7, x_8, x_{10}. The pairs formed are (x_1, x_7), (x_2, x_8), and (x_3, x_{10}). Since in this example every leaf contains exactly one vertex from G, these pairs immediately translate to the edges $(1,5)$, $(7,4)$, and $(6,3)$. Finally, leaf x_5 is connected to x_1 (this is an arbitrary decision), so the last edge added is $(8,1)$.

4. Increasing connectivity by δ. The method for $\delta > 1$ is considerably more complicated than the solution for the case where $\delta = 1$. Given that a simple solution for the $\delta = 1$ case exists, one approach to the $\delta > 1$ case is to successively augment by one for δ steps by applying algorithm **Aug-1** δ times. We show that this approach *can* yield an optimal solution if some caution is taken at each step of the application. Recall that the method of algorithm **Aug-1**, which augments optimally by one, does not necessarily produce a unique solution: it specifies pairs of leaves in $\mathcal{H}(G)$ that are to be connected by an edge, without suggesting which vertex from G in each leaf should become the endpoint of the edge; hence if the leaf is not a singleton, various choices exist. We take advantage of this "freedom." We show that by looking deeper "inside" these leaves to find cuts of higher values that will have to be augmented later, we can find an optimal solution to the augmentation by one that can be extended to an optimal solution for δ. That is, we make a more "intelligent" choice in step (3.b) of algorithm **Aug-1** when choosing the current solution. By showing that this is possible, we in fact provide another proof to the result of [35] which states that there is an optimal solution to the case where $\delta > 1$ which consists of a sequence of δ optimal solutions to the problem of augmenting by one.

We start with section 4.1, which establishes an obvious lower bound on the number of edges that must be added to augment a graph. Next, in section 4.2, we define a partition, called the *extreme-sets partition*, used to guide the search for an "intelligent" choice at each stage of augmenting by one. Section 4.3 describes the complete algorithm that finds an optimal solution by using the extreme-sets partition together with successive applications of algorithm **Aug-1**. Finally, in sections 4.4 and 4.5, we prove the optimality of the algorithm and its running time.

4.1. The lower bound. We now state a lower bound from [36, 5, 9] on the number of edges that must be added for any increment δ. It is used to prove the optimality of our algorithm. For $U \subset V$, denote by $d(U)$ the number of edges connecting vertices in U and vertices in $V \setminus U$. We call $d(U)$ the *degree* of U.

Let P be any partition of V into disjoint subsets $P_1, \ldots, P_k$. Define $\Phi(P)$, the *edge demand* of P, as $\Phi(P) = \sum_{i=1}^{k} \max\{0\ ,\ (\lambda+\delta) - d(P_i)\}$.

OBSERVATION 4.1. (See [36, 5, 9].) *For any partition P, at least $\lceil \Phi(P)/2 \rceil$ edges must be added to increase the connectivity of G by δ.*

Proof. If for some subset P_i, $d(P_i) < \lambda + \delta$, then at least $(\lambda+\delta) - d(P_i)$ new edges that have one endpoint in P_i and cross $(P_i, \overline{P_i})$ must be added. Since the subsets of P are all disjoint, each edge can satisfy at most two of the requirements. Hence at least $\lceil \Phi(P)/2 \rceil$ edges are needed. □

COROLLARY 4.1 (The lower bound). *The minimum number of edges that must be added to a graph to make it $(\lambda+\delta)$-edge-connected is greater than or equal to $\max_P\{\lceil \Phi(P)/2 \rceil\}$ over all partitions P. Also, any augmentation which for some par-*

tition P makes the graph $\lambda + \delta$ edge-connected by adding $\lceil \Phi(P)/2 \rceil$ edges is optimal.

As shown in [36, 5, 9], this lower bound is achievable. Moreover, the minimum number of edges that are needed equals the ceiling of half of the demand of some partition and hence equals the ceiling of half of the maximum edge demand over all partitions (a min–max relation).

4.2. The extreme-sets partition. We define a partition of the vertices of G, called the *extreme-sets partition*, denoted ES, and later show that the number of edges added by our algorithm always equals $\lceil \Phi(ES)/2 \rceil$, where $\Phi(ES)$ is the edge demand of the partition ES, thus proving that ES has the maximum edge demand over all partitions.

DEFINITION. *A set $U \subset V$ is* k-extreme *if and only if its degree k is* strictly smaller *than the degree of* each *of its proper subsets, i.e., if and only if $d(U) = k$ and for any $W \subset U$, $d(W) > k$.*

LEMMA 4.2. *If X is k-extreme, $Y \neq X$ is l-extreme, and $k \leq l$, then either $Y \subset X$ or X and Y are disjoint.*

Proof. Clearly, $X \not\subset Y$ since otherwise Y is not an extreme set. Suppose that X and Y properly intersect. There can be two cases: either $X \cup Y = V$ or $X \cup Y \subset V$. If $X \cup Y = V$, then $\overline{X} \subset Y$; but $d(\overline{X}) = d(X) = k$ (since the graph is undirected), and $k \leq l$, contradicting the fact that Y is l-extreme. If X and Y properly intersect and $X \cup Y \subset V$, then V is divided into four nonempty quadrants $X \cap Y$, $X \cap \overline{Y}$, $\overline{X} \cap \overline{Y}$, and $\overline{X} \cap Y$. We number them as quadrants 1, 2, 3, and 4, respectively, and denote by d_{ij} the number of edges between quadrant i and quadrant j, $1 < i, j < 4$ ($d_{ij} = d_{ji}$). See Figure 3.

Since X and Y are both extremes, $d(X \cap \overline{Y}) > k$ and $d(\overline{X} \cap Y) > l$, so

$$d(X \cap \overline{Y}) + d(\overline{X} \cap Y) > k + l. \tag{1}$$

Also, $d(X) = k = d_{14} + d_{13} + d_{24} + d_{23}$ and $d(Y) = l = d_{12} + d_{13} + d_{24} + d_{43}$; hence $d_{14} + d_{24} + d_{23} \leq k$ and $d_{12} + d_{24} + d_{43} \leq l$. Note that $d(X \cap \overline{Y}) = d_{21} + d_{24} + d_{23}$ and $d(\overline{X} \cap Y) = d_{14} + d_{24} + d_{34}$, so

$$d(X \cap \overline{Y}) + d(\overline{X} \cap Y) = d_{12} + d_{23} + d_{34} + d_{14} + 2d_{24} \leq k + l, \tag{2}$$

but (2) contradicts (1). In summary, X cannot properly intersect with Y, and $X \not\subset Y$; hence the lemma follows. □

Lemma 4.2 is the key to defining the extreme-sets partition. Define the set of vertices V to be a 0-extreme set, and note that any single vertex u is $d(u)$-extreme, where $d(u)$ is the degree of u. By Lemma 4.2, the collection of extreme sets in G has the property that either any two sets are disjoint or one is contained in the other (a hierarchical structure). Such a collection can be represented by a tree in a natural way. In this tree, every leaf corresponds to a vertex in V, and the root corresponds to the set V; every other node in the tree corresponds to an extreme set, and a node y is an ancestor of another node x if and only if the extreme set associated with node y contains the extreme set associated with node x. We call this tree the *extreme-sets tree*, denoted EST.

Since we have a hierarchical structure of sets, we can now use a definition that was proposed in [36]: for any node x in the extreme-sets tree, let X be the set of vertices in G that correspond to x (the leaves in the subtree rooted at x). Starting at the leaves, for each node x other than the root, recursively define $\Phi(x)$ as the edge

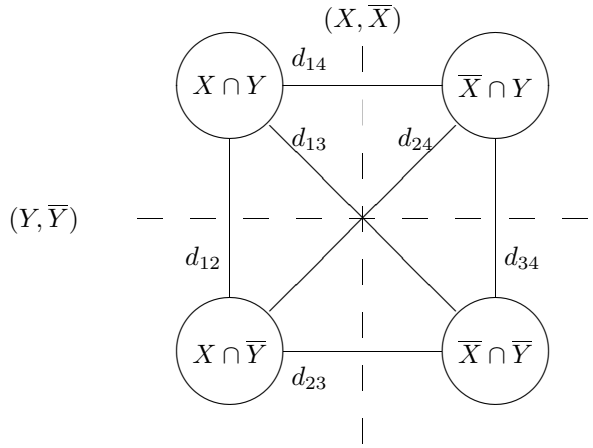

FIG. 3. *The four nonempty quadrants generated by two crossing cuts* $(X, \overline{X})$ *and* $(Y, \overline{Y})$.

demand of x,

$$\Phi(x) = \max \left\{ 0, (\lambda + \delta) - d(X), \sum_{\text{y child of x}} \Phi(y) \right\},$$

and the edge-demand of the root r as $\Phi(r) = \sum_{\text{y child of r}} \Phi(y)$. Intuitively, $\Phi(x)$ is a lower bound on the number of edges that need to be attached to vertices in X in order to increase the connectivity of G by δ; if $d(X) < (\lambda + \delta)$, then at least $(\lambda + \delta) - d(X)$ edges need to be attached to vertices in X, and this argument holds recursively for any subset of X. (The children of x correspond to disjoint subsets of X.)

If r is the root of the extreme-sets tree EST, then the recursive procedure **Find_Part(r)** finds a partition of V into subsets $X_1, \ldots, X_k$ such that the edge demand of this partition equals the edge demand of r. This partition is called the *extreme-sets partition* and is denoted by $ES = X_1, \ldots, X_k$. **Find_Part(r)** finds a set of nodes in the tree as close to the root as possible such that the edge-demand of each node is either zero or (if greater than zero) strictly greater than the sum of the edge demands of its children. Initially, ES is empty.

Find_Part(x)
If x is a leaf, then $ES \leftarrow ES \cup \{X\}$.
Else, for every child y of x,
  If $\Phi(y) = 0$ or $\Phi(y) > \sum_{\text{z child of y}} \Phi(z)$, then $ES \leftarrow ES \cup \{Y\}$
  Else **Find_Part(y)**

Clearly, ES is a partition of V and is uniquely defined by the tree and the edge demands of its nodes. Also, if $ES = \{X_1, \ldots, X_k\}$, then $\Phi(r) = \sum_{i=1}^{k} \max\{0, (\lambda + \delta) - d(X_i)\}$ since if a child y of the root did not contribute its corresponding set Y to the partition ES, then $\Phi(y) = \sum_{\text{z child of y}} \Phi(z)$, and this property holds recursively. Hence $\Phi(ES) = \Phi(r)$.

Figure 4 shows the extreme-sets tree of the graph G depicted in Figure 1. If $\delta = 2$, then $\Phi(x_5) = \Phi(x_6) = \Phi(x_7) = \Phi(x_8) = 0$, $\Phi(x_4) = 0$, $\Phi(x_2) = \Phi(x_3) = 1$, and $\Phi(x_1) = 2$. The left and the parts of the tree are symmetric; hence $\Phi(r) = 4$. The extreme-sets partition is therefore $ES = \{1\}, \{2\}, \{3, 4, 5, 6\}, \{7, 8, 9, 10\}, \{11\}, \{12\}$ and $\Phi(ES) = 4$.

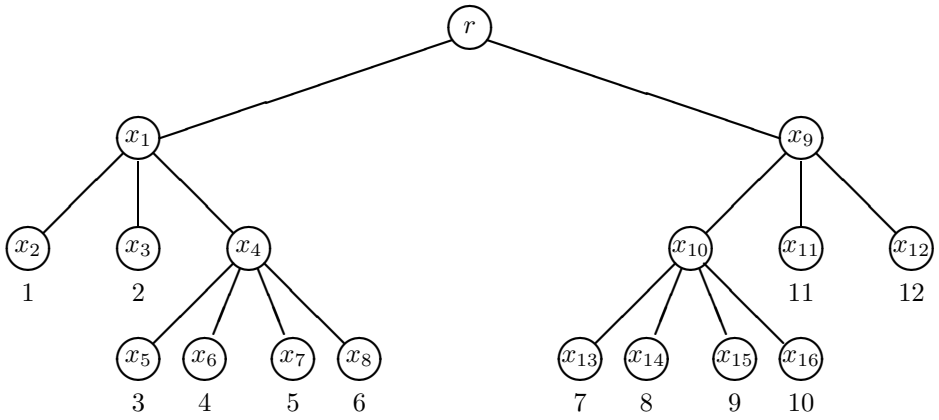

FIG. 4. *The extreme-sets tree of the graph G from Figure* 1.

Extreme sets play an important role in the augmentation problem. First, note that λ-extreme sets are the immediate children of the root of EST and that a set U of vertices in G is λ-extreme if and only if it is a leaf in the representation $\mathcal{H}(G)$. Let the set $U \subset V$ be a leaf in the representation $\mathcal{H}(G)$, and let $(A, \overline{A})$ be any λ-cut such that $A \cap U$ is nonempty. Then $U \subseteq A$ since by the definition of $\mathcal{H}(G)$, any λ-cut that puts some vertex i from U in one of its sides must contain the entire set U in the same side. Hence the degree of a leaf in $\mathcal{H}(G)$ is λ (since $(U, \overline{U})$ is a λ-cut), and the degree of any subset of it is greater than λ since otherwise there will be another λ-cut that is completely contained in it, a contradiction to the above. Recall that the new edges that are added to increase the connectivity of G by one in algorithm **Aug-1** connect only vertices from G that are in some leaf in $\mathcal{H}(G)$. Hence for the case where $\delta = 1$, if the λ-extreme sets are augmented appropriately, then no other cuts have to be augmented. In general, suppose that U is k-extreme and $k < \lambda + \delta$. We can "expect" U to be a leaf in the representation of the augmented graph when the augmented connectivity is k since no subset of it is of degree k or less. This intuitive reasoning will be stated more precisely later.

4.3. The algorithm. The algorithm that optimally augments G by δ works in δ phases. At phase i, $1 \leq i \leq \delta$, a graph G^i is constructed, and its connectivity is $\lambda + i$. As we shall prove, every intermediate graph G^i is an optimal solution for the problem of increasing the connectivity of G by i. At each phase, we basically apply algorithm **Aug-1** (the algorithm that optimally augments by 1) to the graph G^{i-1} and obtain G^i. However, whenever there is more than one optimal way to augment G^i by one, we use the extreme-sets tree EST^i of the graph G^i to make the right choice among the various possibilities. Once EST^i is known, the rule for choosing the right solution is easy to implement.

The following is a high-level description of phases $1, 2, \ldots, \delta$ of the algorithm. Initially, we assume that $G^0 \equiv G$, and that EST^0, the extreme-sets tree for G, is known.

ALGORITHM **Aug-δ**

(1) Repeat steps (1)–(3.a) of algorithm **Aug-1** on the graph G^i, i.e., find its connectivity cuts representation $\mathcal{H}(G^i)$, traverse and enumerate its leaves in the DFS

manner described earlier, and form the pairs of leaves of $\mathcal{H}(G^i)$ that are to be connected by new edges.

(2) The following steps replace step (3.b) in the algorithm **Aug-1**:

(2.a) For each leaf U_a in $\mathcal{H}(G^i)$, find the node u_a in the tree EST^i that corresponds to the set U_a. (U_a is a $(\lambda+i)$-extreme set in G^i, so the node u_a must exist.) Find a node w_a of EST^i in the subtree of u_a, possibly u_a itself, with the following properties: (i) $\Phi(w_a) > 0$; (ii) $\Phi(z) = 0$ for every child z of w_a. (If u_a is a leaf in EST^i, then $w_a \equiv u_a$.)

(2.b) Construct the graph G^{i+1} by adding the following edges to G^i: for any pair (U_a, U_b) of leaves in $\mathcal{H}(G^i)$ that is formed in step (1), pick an arbitrary vertex from G which is a leaf in the subtree of w_a in EST^i and an arbitrary vertex from G which is a leaf in the subtree of w_b in EST^i and connect them by an edge.

(3) Compute the extreme-sets tree EST^{i+1} for the graph G^{i+1} by *updating* EST^i.

Handling the case of an odd number of leaves in $\mathcal{H}(G^i)$. If the number of leaves in $\mathcal{H}(G^i)$ is odd at some phase other than the last one (that is, $i < \delta$), then at the end of step (1), there will be some leaf U_a that participates in two different pairs (i.e., *two* new edges have to be attached to U_a). Note that $\Phi(u_a) \geq 2$ since this is not the very last stage of the algorithm. For this leaf, in step (2.a) we select *two* nodes, w_{a_1} and w_{a_2}, from the subtree of u_a and associate each one with a different pair. Then step (2.b) can be performed as before. w_{a_1} and w_{a_2} are selected as follows: First, find a node w_a in the subtree of u_a such that (i) $\Phi(w_a) \geq 2$ and (ii) $\Phi(z) < 2$ for every child z of w_a. (Since $i < \delta - 1$, $\Phi(u_a) \geq 2$, so this is always possible.) If w_a is a leaf, then define $w_{a_1} \equiv w_a$ and $w_{a_2} \equiv w_a$. Otherwise, let z_1 and z_2 be two children of w_a with the *largest* edge demand among w_a's children: for $j = 1, 2$, find a node w_{a_j} in the subtree of z_j, possibly z_j itself, such that (i) $\Phi(w_{a_j}) > 0$ and (ii) $\Phi(z) = 0$ for every child z of w_{a_j}. This is similar to the rule of (2.a). Note that only three cases are possible: (a) $\Phi(z_1) = 0$, $\Phi(z_2) = 0$; (b) $\Phi(z_1) = 1$, $\Phi(z_2) = 0$; (c) $\Phi(z_1) = 1$, $\Phi(z_2) = 1$. This fact will be important later.

4.4. Optimality of the algorithm.

THEOREM 4.3. *Starting with any graph G and edge connectivity λ, the connectivity of G^δ at the end of algorithm* **Aug-δ** *is $\lambda + \delta$.*

Proof. At each phase i of the algorithm, $1 \leq i \leq \delta$, the set of new edges that are added to G^{i-1} is a set of edges which could have been added by algorithm **Aug-1** when applied to G^{i-1}. Hence the connectivity of the resulting graph G^i has increased by one, so the connectivity of G^δ is $\lambda + \delta$. ∎

THEOREM 4.4. *Let $\Phi(ES^i)$ be the edge demand of the partition ES^i defined by the extreme-sets tree of G^i. The number of edges added by algorithm* **Aug-δ** *is exactly $\lceil \Phi(ES^0)/2 \rceil$.*

Proof. We will show in Theorem 4.9 that if l_i new edges are added at the ith phase of the algorithm, $i = 1, \ldots, \delta - 1$, then $\Phi(ES^i) = \Phi(ES^{i-1}) - 2l_i$. At the last phase, $l_\delta = \lceil \Phi(ES^{\delta-1})/2 \rceil$ since at most one endpoint (the last one) may be added without satisfying a demand. Applying the argument repeatedly, we get that the total number of edges that are added over all phases is $\lceil \Phi(ES^0)/2 \rceil$. ∎

The key to the optimality of algorithm **Aug-δ** is therefore Theorem 4.9, which states that the edge demands of successive extreme sets trees are decreased by the "right" amount, i.e., by twice the number of edges added at each phase. The correctness of this theorem follows from a sequence of lemmas that are also used for the derivation of the running time of the algorithm. We now state and prove these lemmas.

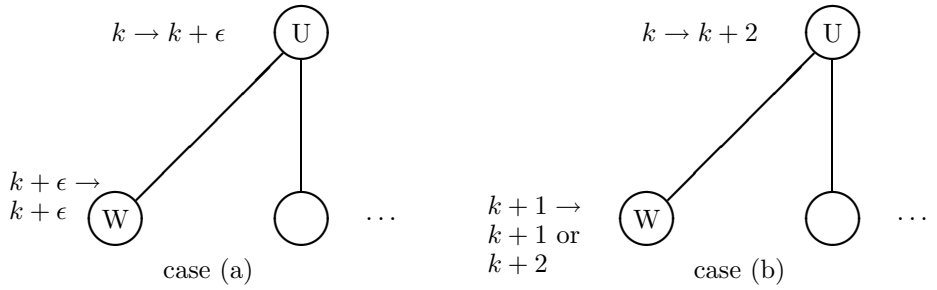

FIG. 5. *Lemma* 4.6; *W and U are represented as nodes in the tree.*

OBSERVATION 4.2. *Every nonextreme set $Z \subset V$ such that $d(Z) = k$ contains a k'-extreme set W, where $k' \leq k$.*

Proof. Z is nonextreme; therefore, it contains a subset $Z' \subset Z$ with $d(Z') \leq k$. If Z' is extreme, then the lemma follows ($W \equiv Z'$); otherwise, repeat this argument on Z'. The process terminates and eventually finds a subset of Z which is also an extreme set since a singleton is by definition an extreme set. □

OBSERVATION 4.3. *If W is an extreme set in G^{i-1}, then at the end of the ith phase of* **Aug-δ**, *the degree of W can increase by at most* 2.

Proof. First, suppose that the number of leaves in $\mathcal{H}(G^{i-1})$ is even. Every leaf in $\mathcal{H}(G^{i-1})$ gets one new endpoint attached to it, so the degree of every $(\lambda + i - 1)$-extreme set in G^{i-1} is increased by one by the end of the ith phase. If W is extreme, then by Lemma 4.2, it can be contained in at most one $(\lambda + i - 1)$-extreme set. If W is not contained in any $(\lambda + i - 1)$-extreme set, then its degree does not change; otherwise, its degree increases by one only if the endpoint of the new edge is also in W, and it remains unchanged otherwise. If the number of leaves in $\mathcal{H}(G^{i-1})$ is odd, then exactly one leaf gets two new endpoints attached to it; the same arguments follow in this case. □

The next two lemmas are cornerstones in the proof of optimality and the time analysis of the algorithm.

LEMMA 4.5. *If U is an extreme set in G^{i+1}, then it must have been an extreme set in G^i.*

LEMMA 4.6. *A set U is k-extreme in G^i but not extreme in G^{i+1} if and only if one of two cases* (*summarized in Figure* 5) *occurs:*

(a) *in G^i there is a $(k+\epsilon)$-extreme set W, $W \subset U$, $\epsilon = 1$ or 2, such that in G^{i+1} the degree of U is $k+\epsilon$, but the degree of W remains $k+\epsilon$.*

(b) *in G^i there is a $(k+1)$-extreme set W, $W \subset U$, such that in G^{i+1} the degree of U is $k+2$, but the degree of W either remains $k+1$ or changes to $k+2$.*

The proofs of these lemmas assume without loss of generality that $i = 0$, and we denote by G and G' the graphs G^0 and G^1, respectively. Also, for $X \subset V$, denote by $d(X)$ and $d'(X)$ the degrees of X in G and G', respectively.

Proof of Lemma 4.5. We show the contraposition of the lemma. That is, we show that if U is nonextreme in G, then U contains a subset $W \subset U$ such that in G', $d'(W) \leq d'(U)$; hence U must remain nonextreme in G'.

Clearly, only new edges that are added to G at the current step may change the degree of U relative to its subsets. Also, if all new edges that are attached to vertices in U are connected *across* U, i.e., their other endpoint is not in U, then the degree of any subset of U can increase by at most the degree increase of U; so U, which is nonextreme in G, remains nonextreme in G'. Therefore, we need consider only the

case where there is at least one new edge (x, y), $x, y \in U$.

Let S be the λ-extreme set that the edge (x, y) crosses such that $d'(S) = d(S)+1$. Recall that a new edge always connects two λ-extremes, and since the degrees of all but one λ-extreme are increased by one, such an S must exist. By the definition of S and U, $S \cap U \neq \emptyset$, and also $U \not\subseteq S$ (since (x, y) crosses S but not U). Hence either $S \subset U$ or S and U properly intersect.

1. $S \subset U$: this is an easy case since S is a subset of U with degree $d'(S) = \lambda + 1$, but $d'(U) \geq \lambda + 1$ (the connectivity of G' is $\lambda + 1$), so U is not extreme in G'.

2. S properly intersects U: again, there are two cases to consider.

2.1. If $S \cup U = V$, then $d'(U \cap \overline{S}) = d'(S) = \lambda + 1$; but $d'(U) \geq \lambda + 1$ and $(U \cap \overline{S}) \subset U$, so U is not extreme in G'.

2.2. If $S \cup U \subset V$, then V is divided into four nonempty quadrants $S \cap U$, $S \cap \overline{U}$, $\overline{S} \cap \overline{U}$, and $\overline{S} \cap U$. We number them as quadrants 1, 2, 3, and 4, respectively, and let d_{ij} be the number of edges between quadrant i and quadrant j, $1 < i, j < 4$ ($d_{ij} = d_{ji}$). See Figure 3, replacing X with S and Y with U.

Since S is an extreme set in G, $d(S \cap \overline{U}) > d(S)$, or

$$\begin{aligned} &d_{21} + d_{23} + d_{24} > d_{14} + d_{13} + d_{42} + d_{23} \\ &\quad \Longrightarrow d_{21} > d_{14} + d_{13}, \end{aligned}$$

which implies that

$$d_{21} > d_{14} - d_{13}$$

since all d_{ij}'s are nonnegative. Adding $(d_{24} + d_{34})$, we get

$$d_{21} + d_{24} + d_{34} > d_{14} - d_{13} + d_{24} + d_{34}$$

or

$$d_{21} + d_{24} + d_{13} + d_{34} > d_{14} + d_{24} + d_{34},$$

that is, $d(U) > d(\overline{S} \cap U)$. Hence $\overline{S} \cap U$ is a subset of U with degree (in G) strictly smaller than U. The only new edges that can make the degree of $\overline{S} \cap U$ greater or equal to the degree of U are the ones that cross $\overline{S} \cap U$ but not U, i.e., edges between $\overline{S} \cap U$ and $S \cap U$. But these edges also cross S, and we know that there is exactly one new edge that crosses S (since $d'(S) = d(S) + 1$). Therefore, there can be at most one new edge between $\overline{S} \cap U$ and $S \cap U$, so $d'(U) \geq d'(\overline{S} \cap U)$. This shows that U is not extreme in G'. □

Proof of Lemma 4.6. Let U be an extreme set in G which is no longer extreme in G' and $d(U) = k$; that is, there exists $Z \subset U$ with $d'(Z) \leq d'(U)$, but since U is extreme in G, $d(Z) > d(U)$. For that to happen, the degree of U must increase; but by Observation 4.3, it can increase by at most 2. Consider all possible cases.

$d'(U) = k + 1$: Since $d(Z) > k$ and $d'(Z) \leq k + 1$, $d(Z) = d'(Z) = k + 1$. ($d(Z)$ was not increased at that phase.) We now show that case (a) of the lemma with $\epsilon = 1$ must hold. If Z itself is a $(k + 1)$-extreme set in G, then we are done; otherwise, by Observation 4.2, Z contains an extreme set W with $d(W) \leq k + 1$. But W is also a subset of U, and U is k-extreme, so $d(W) = k + 1$, and the claim follows.

$d'(U) = k+2$: Since $d(Z) > k$ and $d'(Z) \leq k+2$, either $d(Z) = k+2$ and no new edges are attached to Z or $d(Z) = k + 1$ and zero or one new edges are attached to Z. We now show that either case (a) with $\epsilon = 2$ or case (b) of the lemma must hold.

If $d(Z) = k + 2$ and Z is extreme in G, then case (a) with $\epsilon = 2$ holds; if Z is not extreme, it contains an extreme set W with $d(W) \leq k + 2$. But U is k-extreme and W is also contained in U, so $d(W) = k + 1$ or $d(W) = k + 2$; since no new edges are attached to W, cases (a) or (b) hold. If $d(Z) = k + 1$, then case (b) holds since either Z is extreme or Z contains an extreme set W with $d(W) = k + 1$ in G; in both cases, the degree of the extreme set increases by 0 or 1. □

Constructing EST^{i+1} from EST^i. Lemmas 4.5 and 4.6 show how to obtain EST^{i+1} from EST^i. They show that no new nodes can be created (Lemma 4.5) and that the rule for removing nodes from EST^{i+1} is simple (Lemma 4.6). Given EST^i and the set of new edges that are added at step i, first compute the new degrees of all sets that are tree nodes; then traverse EST^i from the root downwards and look for any degree violation of the form described in Lemma 4.6, namely, either case (a) or (b) in Figure 5. If such a violation is detected at node u of the tree, then u is removed and its children are attached to its parent; this operation is called a *node removal*. The rest of the tree remains the same. Note that all we do is check the degrees of *nodes in the tree*, without considering other subsets of V, and this observation is what makes the (dynamic) computation of successive extreme-sets trees much more efficient than recomputing a new tree at each iteration.

Relating $\Phi(ES^i)$ to $\Phi(ES^{i-1})$. Let T and T' be the extreme-sets trees of G^{i-1} and G^i, respectively, where r and r' are their corresponding roots. Also, for every set $X \subset V$, $d(X)$ and $d'(X)$ are the degrees of X in G^{i-1} and G^i respectively. For a node x in a tree, $\Phi(x)$ is the edge demand of x in G^{i-1} and $\Phi'(x)$ is the edge demand of x in G^i. First, assume that $\Phi(ES^0)$ is even so that *every* new edge satisfies a demand of some extreme set. We will handle the odd case later.

LEMMA 4.7. *If x is a node in T other than the root and ϵ new edges are attached to vertices in X ($\epsilon = 0, 1, 2$), then*

$$\Phi'(x) = \begin{cases} 0 & \text{if } \Phi(x) = 0, \\ \Phi(x) - \epsilon & \text{if } \Phi(x) > 0. \end{cases}$$

Proof. For any node x other than the root, if a new edge is attached to some vertex in X, then its other endpoint is not in X. This is true since a new edge always connects two vertices that belong to two different leaves in $\mathcal{H}(G^{i-1})$, and all the vertices in X belong in the same leaf in $\mathcal{H}(G^{i-1})$. Hence the quantity $\lambda + \delta - d(X)$ decreases by ϵ. This fact is used below.

The lemma is proved by induction on the distance of x from the bottom of the tree. For a leaf x, if $\epsilon = 0, 1$, then the lemma follows immediately since $\Phi(x) = \max\{0, \lambda + \delta - d(X)\}$; if $\epsilon = 2$ for a leaf x, then $\Phi(x) \geq 2$, so the lemma also follows.

For an internal node x, let $y_1, y_2, \ldots$ be its children, so $\Phi(x) = \max\{0, \lambda + \delta - d(X), \sum_i \Phi(y_i)\}$. Clearly, if $\Phi(x) = 0$, then $\Phi'(x) = 0$; otherwise, $\Phi(x) = \max\{\lambda + \delta - d(X), \sum_i \Phi(y_i)\}$.

First, consider the case where only one edge is attached to X ($\epsilon = 1$). If the new edge is attached to a vertex in y_j for some j and $\Phi(y_j) = 0$, then $\sum_i \Phi(y_i) = 0$ (since by the rule of step (2.a), if $\Phi(y_j) = 0$ and $\epsilon = 1$, then the demand of all of y_j's siblings must also be zero). Hence $\Phi(x) = \lambda + \delta - d(X)$ and clearly $\Phi'(x) = \Phi(x) - \epsilon$. Otherwise, if $\Phi(y_j) > 0$, then by the induction hypothesis $\Phi'(y_j) = \Phi(y_j) - \epsilon$, so $\sum_i \Phi'(y_i) = \sum_i \Phi(y_i) - \epsilon$. Combining the two cases, we get that $\Phi'(x) = \max\{\lambda + \delta - d'(X), \sum_i \Phi'(y_i)\} = \Phi(x) - \epsilon$.

Now suppose that *two* edges are attached to X ($\epsilon = 2$). This will happen only if $\Phi(x) \geq 2$. If both edges were attached to vertices in y_j for some j, then it must be that

$\Phi(y_j) \geq 2$, so by induction $\Phi'(x) = \max\{\lambda + \delta - d'(X), \sum_i \Phi'(y_i)\}$. If the edges are attached one to a vertex in y_j and the other to a vertex in y_k for some $j \neq k$ so that $\Phi(y_j) = 1$ but $\Phi(y_k) = 0$ or $\Phi(y_j) = \Phi(y_k) = 0$, then $\sum_{i \neq j,k} \Phi(y_i) = 0$. (Refer to the paragraph following step (3) of algorithm **Aug-δ**.) Therefore, $\Phi(x) = \lambda + \delta - d(X)$, so $\sum_i \Phi'(y_i) = 0$ and $\Phi'(x) = \{\lambda + \delta - d'(X)\} = \Phi(x) - \epsilon$. If $\Phi(y_j) + \Phi(y_k) \geq 2$, then the lemma follows inductively. □

If $\Phi(ES^0)$ is even, then every node x which is an immediate child of the root that gets a new edge attached to it must be a leaf in the cactus. The demand of a cactus leaf is always at least one; moreover, if $\Phi(ES^0)$ is even and two edges are attached to some cactus leaf, then it must be that its demand is at least two. (In fact, the only case where two edges are attached to a cactus leaf but its demand is one is when $\Phi(ES^0)$ is odd and the very last edge is attached.) Hence $\Phi(x) \geq \epsilon$ for every node x which is an immediate child of the root. Therefore, a corollary of Lemma 4.7 is that $\Phi'(r) = \Phi(r) - 2l_i$, where l_i is the number of new edges added by the algorithm at the ith phase. The edge demand of the root is defined as the sum of the demands of its children, and every new endpoint reduces the demand of some child by one; the total decrease in the demand of T is therefore $2l_i$. We now show that the total decrease in the demand of T' is also $2l_i$.

LEMMA 4.8. $\Phi'(r') = \Phi'(r)$.

Proof. T' is obtained from T by a sequence of node-removal operations. Let $\alpha(x) = (\lambda + \delta) - d'(X)$. By Lemma 4.6, x is in T but not in T' if it has a child w (in T) such that $d'(W) \leq d'(X)$, so $\alpha(w) \geq \alpha(x)$. Hence

$$\sum_{y \text{ child of } x \text{ in } T} \Phi'(y) \geq \sum_{y \text{ child of } x \text{ in } T} \alpha(y) \geq \alpha(w) \geq \alpha(x).$$

Since $\Phi'(x) = \max\{\alpha(x), \sum_{y \text{ child of } x} \Phi'(y)\}$ and $\sum_{y \text{ child of } x} \Phi'(y) \geq \alpha(x)$, we get that $\Phi'(x) = \sum_{y \text{ child of } x} \Phi'(y)$. Hence the removal of x from T does not change the edge demand of its parent since x's children are attached to its parent. In general, node removals do not affect the edge demand of any of the remaining nodes, including the root, so $\Phi'(r) = \Phi'(r')$. □

THEOREM 4.9. *Assume that either $\Phi(ES^0)$ is even or we are at any phase $i < \delta$. If $\Phi(ES^i)$ is the edge demand of the partition ES^i defined by the extreme-sets tree of G^i and l_i new edges are added at the ith phase of algorithm* **Aug-δ**, *then $\Phi(ES^i) = \Phi(ES^{i-1}) - 2l_i$.*

Proof. Lemma 4.7 implies that $\Phi'(r) = \Phi(r) - 2l_i$, and by Lemma 4.8, $\Phi'(r) = \Phi'(r')$, so $\Phi'(r') = \Phi(r) - 2l_i$. Since the edge demand of the partition defined by a tree equals the edge demand of its root, the theorem follows. □

Now assume that $\Phi(ES^0)$ is odd. In this case, the very last edge that is added at phase $i = \delta$ does not satisfy a demand of a leaf in the cactus. Hence at that phase, $\Phi(ES^i) = 0$, and $\Phi(ES^{i-1}) + 1 = 2l_i$, so over all phases we have $\Phi(ES^0) + 1 = \sum_i 2l_i$.

4.5. Time analysis of algorithm Aug-δ. Algorithm **Aug-δ** repeatedly applies algorithm **Aug-1** to the graph and maintains the correct extreme-sets tree at each phase. The major issue is therefore the computation of the tree in each phase. In section 4.4, we showed that EST^{i+1} can be obtained from EST^i by a sequence of node-removal operations. A node that needs to be removed is identified by a simple criteria based on the degrees of its children in the tree, namely that the minimum degree of its children is greater than its own degree. Hence EST^{i+1} can be computed from EST^i by two traversals of the tree: the first, a bottom-up traversal, updates the new degrees of the tree nodes, and the minimum degree of the children is propagated

upwards; then in a top-down fashion, if a node is to be removed, its children are attached to its parent. Note that the new degrees need not be recomputed from the graph but only updated, i.e., the addition of an edge (u, v) increases the degree of u and v by one. This information is propagated towards the upper nodes during the tree traversal, so it takes time linear in the size of the tree. The top-down traversal may redirect every edge in the tree exactly once; hence it also takes time linear in the size of the tree. In summary, EST^{i+1} can be obtained from EST^i in linear time (the size of the tree is $O(n)$).

We now show how to compute EST^0. The definition of extreme sets does not lend itself to an efficient computation since it requires the inspection of the degrees of all of its subsets. Fortunately, it turns out that extreme sets are highly structured and closely related to another type of sets, maximal-edge-connected components, which can be found relatively easily.

Define $C(i, j)$ as the minimum cut value between vertices i and j in G. We say that a set U is a *maximal l-edge-connected component* if and only if (i) $l = \min_{i,j \in U} C(i, j)$ and (ii) for any $v \notin U$, $i \in U$, $C(i, v) < l$.

LEMMA 4.10. *Every k-extreme set U ($d(U) = k$) is a maximal l-edge-connected component for some l. (There is no relation between l and k.)*

Proof. Let U be a k-extreme set, let $v \notin U$ and $i \in U$, and define $l = \min_{i,j \in U} C(i, j)$. If $l > k$, then since $(U, \overline{U})$ is a cut that separates v from i for any $v \notin U$ and $i \in U$ and since $d(U) = k < l$, $C(i, v) < l$, so U is a maximal l-edge-connected component. The more difficult case is when $l \leq k$. Define $(X, \overline{X})$ to be some cut of size l that separates two vertices $i, j \in U$. (Such a cut exists since $l = \min_{i,j \in U} C(i, j)$.) Since $X \not\subset U$ (otherwise, U is not k-extreme) yet X splits U, U and X must properly intersect. Also, $X \cup U \neq V$ since otherwise $d(U \cap \overline{X}) = d(X) = l \leq k$, $(U \cap \overline{X}) \subset U$, which contradicts our assumption that U is not k-extreme.

In summary, X and U must properly intersect and their intersection divides V into four nonempty quadrants, $X \cap U$, $X \cap \overline{U}$, $\overline{X} \cap \overline{U}$, and $\overline{X} \cap U$, numbered 1, 2, 3, and 4 respectively. As before, let d_{ij}, $1 \leq i, j \leq 4$, be the number of edges between quadrants i and j. We will now show that $d(\overline{U} \cap X) < l$ and that $d(\overline{U} \cap \overline{X}) < l$. Hence for any $v \notin U$ (v is either in $(\overline{U} \cap X)$ or in $(\overline{U} \cap \overline{X})$), there exists a cut of size $< l$ that separates it from any $i \in U$, so the claim follows.

Note that since U is k-extreme, we have $d(U \cap X) > k$,

$$\begin{aligned} d_{12} + d_{13} + d_{14} > k = d_{12} + d_{13} + d_{42} + d_{43} \\ \Longrightarrow d_{14} > d_{42} + d_{43} \\ \Longrightarrow d_{14} - d_{42} > d_{43} \\ \Longrightarrow d_{14} + d_{42} \geq d_{14} - d_{42} > d_{43}, \end{aligned} \tag{3}$$

and also $d(U \cap \overline{X}) > k$,

$$\begin{aligned} d_{14} + d_{24} + d_{34} > k = d_{12} + d_{13} + d_{42} + d_{43} \\ \Longrightarrow d_{14} > d_{12} + d_{13} \\ \Longrightarrow d_{14} - d_{13} > d_{12} \\ \Longrightarrow d_{14} + d_{13} \geq d_{14} - d_{13} > d_{12}. \end{aligned} \tag{4}$$

Adding $d_{31} + d_{32}$ to both sides of equation (3), we get

$$d(\overline{U} \cap \overline{X}) = d_{34} + d_{31} + d_{32} < d_{14} + d_{42} + d_{31} + d_{32} = d(X) = l,$$

that is, $d(\overline{U} \cap \overline{X}) < l$. Adding $d_{23} + d_{24}$ to equation (4), we get

$$d(\overline{U} \cap X) = d_{12} + d_{23} + d_{24} < d_{14} + d_{13} + d_{23} + d_{24} = d(X) = l,$$

that is, $d(\overline{U} \cap X) < l$. □

A subset U is simply called a *maximal component* if it is a maximal l-edge-connected component for some l. Note that while we have shown that all extreme sets are maximal components, it is *not* the case that all maximal components are extreme sets. Lemma 4.10 is the key to efficiently computing the initial extreme-sets tree EST^0 since maximal components are relatively easy to find. Maximal components form a hierarchical structure that can be represented by a tree, the *MCC tree*, since any two maximal components are either disjoint or contained in one another. This hierarchical structure is implied, for example, by the famous result of Gomory and Hu [13], as explained in the next paragraph. *MCC* is a rooted tree whose leaves are the vertices of G. Each node u in the tree represents a subset $U \subseteq V$ which consists of the leaves in the subtree of the u. u is a node in *MCC* if and only if U is a maximal l-edge-connected component for some l.

One can efficiently compute the *MCC* tree from an equivalent-flow tree of G. An *equivalent-flow tree* is a weighted tree whose vertex set is V, and for any $i, j \in V$, the minimum weight edge on the path from i to j in the tree is the value of the minimum cut between i and j in G. An equivalent-flow tree can be constructed with $n - 1$ max-flow computations [13, 18]. The next procedure finds the *MCC* tree of G from an equivalent-flow tree of G. As it builds *MCC* it keeps at each node u of the tree built so far a *partial* equivalent flow tree T_u (the equivalent flow tree of the vertices in U).

- Initially, *MCC* contains a single node r (root) that corresponds to V, the vertex set of G. V is a λ-maximal edge-connected component. Associate with this node the equivalent-flow tree of the entire graph, T_r.
- Let u be a node in *MCC* that contains more than one vertex from V, $U \subseteq V$ be the set of vertices in u, and T_u be the equivalent-flow tree associated with U. Remove from T_u all edges with the smallest weight, and let $T_{u_1}, T_{u_2}, \ldots$ be the subtrees created as a result of this operation. $U_i \subset U$ is the set of vertices in T_{u_i}. For each subset U_i, create a new tree node u_i that contains vertices U_i, and make it a child of u in *MCC*. U_i is now a k-maximal edge-connected component, where k is the smallest edge weight in the subtree T_{u_i}, and the equivalent-flow tree associated with u_i is T_{u_i}.
- Repeat this process until all tree nodes contain singletons (which are the leaves of *MCC*).

By Lemma 4.10, if U is extreme, then it must be a maximal edge-connected component and hence must appear as a node u in *MCC*. By Observation 4.2, if U is a maximal k-edge-connected component but is *not* extreme, then it must contain an *extreme* set W such that $d(W) \leq d(U)$, so W is also a maximal k'-edge-connected component for some $k' > k$. Therefore, W must appear as a node in the subtree of u in the *MCC* tree and indicates that u and its corresponding set U is not extreme. Note that every leaf in *MCC* is a singleton and hence an extreme set.

In summary, EST^0 is a partial tree of *MCC*, i.e., some of *MCC*'s internal nodes are missing from it. To find and remove these internal nodes, compute the degrees $d(W)$ of all nodes w in *MCC*. Then in a bottom-up fashion, determine for each *internal* node u whether all nodes in its subtree are of degrees greater than $d(U)$; if not, then remove u from the tree and attach its children to u's parent. The resulting tree is EST^0. Since the computation of *MCC* is dominated by the $n - 1$ maximum-flow computations required to construct the equivalent-flow tree and since EST^0 can

be constructed from *MCC* in $O(nm)$ time (the degrees of the tree nodes must be computed), we get the following result.

COROLLARY 4.11. *Let G be a simple graph. The extreme-sets tree EST^0 of G can be computed in $O(nF(G))$ time, where $F(G)$ is the time to compute a single maximum flow in G. Since G is undirected and unweighted, the time to compute EST^0 is $O(m^{3/2}n)$* [8, 2].

The next lemma is an extension of the edge connectivity algorithm of [31] to multigraphs. It also implies that the edge connectivity of an undirected, *edge-weighted* graph is computable in $O(Pm)$ time, where $P = \sum_{v \in V} p(v)$ and $p(v)$ is the maximum capacity of all edges incident at v, provided that the weights are integers. Note that in a simple graph, $P = n$, yielding the original result of [31]. The proof of the lemma is included in Appendix A since it is not directly relevant to the paper.

LEMMA 4.12. *For vertices u and v, let $c(u, v)$ be the number of edges between u and v, and $p(v) = \max_{u \in V}\{c(u, v)\}$. Define $P = \sum_{v \in V} p(v)$. Let m be the number of pairs of vertices which are connected by some edge in G. The edge connectivity of G and its representation $\mathcal{H}(G)$ can be computed in time $O(Pm)$.*

THEOREM 4.13. *For any $\delta > 0$, algorithm* **Aug-δ** *optimally solves the edge augmentation problem in time $O(\delta^2 nm + \delta^3 n^2 + n^{5/3}m)$.*

Proof. Let P', p', and m' be the corresponding values of P, p, and m at the current phase of the algorithm. If the initial graph G is simple, then at the end of algorithm **Aug-δ**, $p'(v) \leq \delta + 1$ for all v. This is because at each iteration, algorithm **Aug-1** adds at most one new edge between a fixed pair of vertices (that is, for some pair u, v, **Aug-1** will never add two or more edges between them). Hence at the end of the algorithm, $P' = \sum_{v \in V} p'(v) \leq n(\delta+1) \leq 2\delta n$. Also, the algorithm adds at most $\delta n/2$ new edges throughout the phases (at most $n/2$ at each phase), so at the end of the algorithm, $m' \leq m + \delta n/2$. By Lemma 4.12, the construction of $\mathcal{H}(G^i)$ at each phase is bounded by $O(P'm') = O(\delta nm + \delta^2 n^2)$, yielding $O(\delta P'm') = O(\delta^2 nm + \delta^3 n^2)$ overall. Computing the initial extreme-sets tree EST^0 requires $O(nF(G))$ time, and EST^i can be computed from EST^{i-1} in $O(n)$ time. Hence we get $O(nF(G)) = O(n^{5/3}m)$ for the initial computation, plus $O(\delta^2 nm + \delta^3 n^2)$ for the computations throughout the phases. ∎

4.6. Relation between algorithm Aug-δ and Watanabe and Nakamura's algorithm. In the presentation of the algorithm in this paper, we have discussed some of its similarities to the algorithm of Watanabe and Nakamura (as presented in [36, 35]). In this section, we elaborate on the similarities and differences between the two approaches.

(i) Watanabe and Nakamura [36] provided the first polynomial algorithm for the general augmentation problem. This algorithm adds an edge at a time and tests (according to a well-defined criteria) that this edge can be extended to an optimal solution. Later, in his technical report, Watanabe [35] proved that the algorithm can be sped up by finding at once a *set* of edges which optimally increase the connectivity by one and which can be extended further.

The main idea employed by our algorithm **Aug-δ** is to extend the simple and efficient approach developed in algorithm **Aug-1** (section 3) in order to solve the general problem of augmentation by δ. Section 4 shows that the idea can be implemented correctly and efficiently.

Hence both approaches find successive optimal augmentations by one until they reach the desired connectivity. However, they differ in the method by which they select an optimal augmentation by one that can be extended further. Moreover, we were

specifically interested in those augmentations by one that can be found by algorithm **Aug-1** via the use of the cactus graph and the DFS enumeration.

(ii) The hierarchical structure of maximal connected components, which we call *MCC* in the paper, is used in both algorithms. However, the *MCC* is *a major component* in the algorithm of Watanabe and Nakamura, whereas in our algorithm it is used only as an auxiliary tool to efficiently construct the main data structure in our algorithm, the *EST* tree (in fact, only to construct EST^0).

Specifically, extreme sets, and the extreme-sets tree, are key objects in our algorithm. (Note that they are not defined or used in [36, 35].) They can be intuitively related to the notion of edge demand, and our algorithm uses them extensively to guide the selection at each phase of our algorithm. Unfortunately, the definition of extreme sets does not lend itself to a practical implementation since it requires testing the degrees of all subsets of a given set. By observing the relationship between extreme sets and maximal connected components (section 4.5), we were able to use the *MCC* tree in order to devise an efficient method to construct the first extreme sets tree EST^0. This relationship also implies that various properties of extreme sets (for example, the one proved in Lemma 4.2) can also be proved indirectly via maximal connected components.

(iii) Finally, at a high level, our proof method resembles the proof method of [36]. Both follow the following steps: (1) use the lower bound observation to derive a lower bound that is implied by some partition; in our case, we use the extreme-sets partition. This is also the first step in the proofs of [9, 5]. For that we use the definition of $\Phi(x)$ which was introduced in [36]. (2) show that the addition of x new edges to the graph decreases this lower bound by x. (3) show that at the end of the algorithm, the connectivity has gone up by the desired amount.

5. Variations on the edge augmentation problem.

5.1. The no-target problem. Suppose that the target connectivity is not known or given in advance; instead, the goal is to augment the graph, possibly several times, so that for any intermediate connectivity, the augmentation is optimal. Our solution can be adapted to solve the augmentation problem even if the target increment δ is not known in advance by introducing a simple modification to step (2.a) of algorithm **Aug-δ**. In both cases, the algorithm first finds the node u_a that corresponds to the set U_a which is a leaf in $\mathcal{H}(G^i)$ and then selects a vertex in U_a to be the endpoint of the new edge. The algorithms differ in the criteria by which this vertex is selected. If the target δ is known in advance, then the vertex in U_a is selected according to criteria $\mathcal{A}$ as follows:

> Start at node u_a. As long as the edge demand of the current node is positive and the current node is not a leaf, pick a child whose *edge demand* is positive and make it the current node. If no such child exists and the current node is not a leaf yet, pick an arbitrary leaf in its subtree.

If the target δ is *not* known, then the vertex in U_a is selected according to criteria $\mathcal{B}$ as follows:

> Start at node u_a. As long as the current node is not a leaf, pick the child with the smallest *degree* and make it the current node.

OBSERVATION 5.1. *Let G be a graph with connectivity λ. For any $\delta \geq 1$, if $K \equiv \lambda + \delta$ and u is a node in the extreme-sets tree, then $\Phi(u) > 0$ if and only if $d(U) < K$.*

Proof. The proof is by induction on the height of the subtree rooted at u. For a leaf u, the claim follows immediately since $\Phi(u) = K - d(U)$. For an internal node u, if $d(U) < K$, then clearly $\Phi(u) \geq K - d(U) > 0$. Now suppose that $\Phi(u) > 0$ but $d(U) \geq K$: for any child w of u, $d(W) \geq d(U) \geq K$ since W is a subset of U and U is an extreme set. Hence by the induction hypothesis, $\Phi(w) = 0$, so $\Phi(u) = \max\{0, K - d(U), \sum_w \Phi(w)\} = 0$, a contradiction. □

THEOREM 5.1. *Criteria $\mathcal{B}$ correctly modifies algorithm* **Aug-δ** *to solve the edge augmentation problem when δ is not known.*

Proof. Suppose that the algorithm is run using criteria $\mathcal{B}$, stops when a connectivity $K = \lambda + \delta$ is reached (for any δ), and adds a set of new edges E'. We show that the algorithm that uses criteria $\mathcal{A}$ and δ as a target could have picked exactly the same set of new edges E'. Since the latter was shown to be correct and optimal, the modified algorithm is also correct and optimal for *any* connectivity value it reaches.

Starting at u_a, follow the path chosen according to criteria $\mathcal{B}$ without knowing δ. Let u be the current node along this path and $w_1, w_2, \ldots$ be its children. Suppose that w_j is the child with the smallest degree among u's children and therefore is picked to be the next node on the path. If $d(w_j) \geq K$, then $d(w_i) \geq K$ for any w_i, so by Observation 5.1, $\Phi(w_i) = 0$ for all i. In that case, according to criteria $\mathcal{A}$, *any* leaf in the subtree of u can be picked; hence the (entire) remaining path chosen by criteria $\mathcal{B}$ could have been chosen by criteria $\mathcal{A}$. If $d(w_j) < K$, then $\Phi(w_j) > 0$; but according to criteria $\mathcal{A}$, any child whose edge demand is positive may be picked, so the choice of w_j is valid in both cases. Hence the entire path could have been picked according to criteria $\mathcal{A}$, so the endpoint of the new edge is properly chosen. This argument applies for any new edge in E'. □

The converse problem. The solution to the problem of increasing the connectivity of G as much as possible by adding at most k edges is now immediate. Apply the modified version of **Aug-δ** using criteria $\mathcal{B}$ (with no δ in mind) until k new edges are used. The connectivity at that point is the solution to the converse problem.

5.2. The node-weighted problem. Frank [9] first formulated and solved the following variant of the edge augmentation problem. Suppose that there is a nonnegative cost $c(v)$ associated with every vertex $v \in V$ and that the cost of adding a new edge (x, y) to G is $c(x) + c(y)$. The goal is to find the minimum-cost set of edges to add to G in order to make it $(\lambda + \delta)$-edge-connected. The solution in [9] was proved using polymatroid theory, and it extends to more general instances of the problem. We now show that algorithm **Aug-δ** can be adapted in a very natural way to optimally solve the node-weighted version of the edge augmentation problem for undirected graphs. Since the edge demand $\Phi(X)$ of any subset of vertices $X \subset V$ must be satisfied, $\lceil \Phi(ES)/2 \rceil$, the lower bound defined by the extreme-sets partition on the *number* of edges that need to be added to G, still holds. We establish a lower bound on the *cost* of the solution to the node-weighted problem and then show how to find a set of edges whose cost equals this lower bound. It will be shown that the minimum node-weighted solution is also optimal with respect to the *number* of edges it adds, i.e., it is the minimum node-weighted solution among all possible solutions that add exactly $\lceil \Phi(ES)/2 \rceil$ new edges.

Let x be a node in the extreme-sets tree, $X \subset V$ be the set of vertices in G that are leaves in the subtree of x, and $\Phi(x)$ be its edge demand. Recursively define $\Psi(x)$, the min-cost edge demand of x, as

$$\Psi(x) = \sum_{y \text{ child of } x} \Psi(y) + \max\left\{0, \left(\lambda + \delta - d(X) - \sum_{y \text{ child of } x} \Phi(y)\right)\right\} C_{\min}(X),$$

where $C_{\min}(X) = \min_{v \in X}\{c(v)\}$ (the minimum node cost among all vertices in X). The min-cost edge demand of the root r is defined as $\Psi(r) = \sum_{y \text{ child of } r} \Psi(y)$. Intuitively, $\Psi(x)$ is a lower bound on the cost of the edges that are "missing" from X: every subset Y of X that requires $\Phi(y)$ edges contributes at least $\Psi(y)$ to the total cost; the rest of the missing edges from X, $\max\{0, (\lambda+\delta-d(X)) - \sum_{y \text{ child of } x} \Phi(y)\}$, may be connected to *any* vertex in X, so they contribute at least $C_{\min}(X)$ per edge. Note that if $c(v) = \alpha$ for every v, then $\Psi(r) = \alpha\Phi(r)$.

Clearly $\Psi(ES)$ is a lower bound on the cost of the optimal solution, where ES is the extreme-sets partition of G. This lower bound can be achieved if the following criteria, criteria $\mathcal{C}$, is employed instead of the original criteria $\mathcal{A}$ in step (2.a) of Algorithm **Aug-δ**:

> Start at node u_a in the tree. As long as the edge demand of the current node is positive and the current node is not a leaf, pick a child whose *edge demand* is *positive*, and make it the current node; otherwise, pick the *minimum-cost* leaf in the subtree of the current node.

Since criteria $\mathcal{C}$ is a restricted version of criteria $\mathcal{A}$, the solution obtained by running **Aug-δ** with criteria $\mathcal{C}$ is also optimal with respect to the number of new edges it adds.

THEOREM 5.2. *Criteria $\mathcal{C}$ correctly modifies algorithm* **Aug-δ** *to solve the node-weighted version of the edge-augmentation problem.*

Proof. We have to show that at each phase $\Psi(ES^i)$ drops by the total cost of the new edges added in that stage. The proof is essentially similar to the one given in section 4.4. The analogue of Lemma 4.7 is that if $c(\epsilon_x)$ is the total cost of the new endpoints attached to X, then $\Psi'(x) = \Psi(x) - c(\epsilon_x)$; to prove the analogue lemma, one needs to observe that in the bottom of the induction, if x is a leaf in T, then $c(\epsilon_x) = \epsilon c(x)$, where ϵ is the *number* of new endpoints attaches to X. The analogue of Lemma 4.8 replaces Φ with Ψ, and the proof is similar. The corollary is that the total cost of the solution is $\Psi(ES)$, and hence it is the minimum-cost solution. ∎

5.3. The degree-constrained problem. We now show that our algorithm can be extended in a natural way to solve another variant of the edge augmentation problem which was first formulated and solved by Frank [9]. Suppose that there are constraints $g(v)$ and $f(v)$ associated with the degree of every vertex $v \in V$. The *degree-constrained augmentation problem* is to add the smallest number of edges to the graph and increase its connectivity by δ, subject to the constraints that the degree of v in the resulting graph does not exceed $g(v)$ and is not below $f(v)$. There is not always a solution to this problem. Frank gave a necessary and sufficient condition for this problem and an $O(n^5)$-time algorithm to solve it. We consider a restricted case of this problem, where only the $g(v)$ is specified, i.e., $f(v) = 0$ for all v, and give a necessary and sufficient condition for the problem to be solvable, expressed in terms of our algorithm. If the condition is met, then a minor addition to algorithm **Aug-δ** produces a solution to the degree-constrained version. The running time of the modified algorithm remains $O(\delta^2 nm + \delta^3 n^2)$. Recall the extreme-sets partition ES defined by the extreme-sets tree EST of G. Clearly, $\lceil \Phi(ES)/2 \rceil$ is a lower bound on the number of edges required to solve the problem.

THEOREM 5.3. *Let $\Phi(x)$ be the edge demand of x, and let $x_1, \ldots, x_r$ be the immediate children of the root of the EST tree. The degree-constrained augmentation problem is solvable if and only if*

1. *for every node x in EST,*

$$\sum_{v \in X} g(v) - d(v) \geq \Phi(x),$$

2. *if $\Phi(ES)$ is odd, then*

$$\sum_{v \in S} g(v) - d(v) \geq \Phi(ES) + 1,$$

where $S = \{v \in X_i, i = 1, \ldots, r | \Phi(x_i) > 0\}$.

Moreover, if the problem is solvable, then the optimal solution adds $\lceil \Phi(ES)/2 \rceil$ new edges.

Proof. If for some $X \subset V$, $\sum_{v \in X}(g(v) - d(v)) < \Phi(x)$, then no solution can satisfy the edge demand of X under the degree constraints, so the necessity of this condition is obvious. Also, if $\Phi(ES)$ is odd, then $\lceil \Phi(ES)/2 \rceil$ edges must be added, so the total degree increment (on all vertices) must be at least $\Phi(ES) + 1$. Since $\Phi(ES) = \sum_{i=1}^{r} \Phi(x_i)$, we get that the allowed amount of degree increment among vertices in $x_1, \ldots, x_r$ must be at least $\Phi(ES) + 1$.

Suppose that condition 1 above initially holds for every node x in EST^0, and consider the first phase of algorithm **Aug-δ**. First, assume that either $\Phi(ES)$ is even or $\Phi(ES)$ is odd and we are not at the last phase of the algorithm. When applying the algorithm, in step (2.a), start at u_a; then repeat following a child whose edge demand is positive until no such child exists. Let x be the current node. Note that $\Phi(x) > 0$ since the addition of every edge, other than the last edge when $\Phi(ES)$ is odd, always satisfies some demand. If x is a leaf, simply pick it to be the endpoint of the new edge; otherwise, instead of picking an arbitrary leaf from the subtree of x, choose a leaf v with $g(v) > d(v)$.

Observe that if x is a leaf, then $g(x) - d(x) \geq \Phi(x) > 0$, so $g(x) > d(x)$, and a new edge can be attached to x. If x is not a leaf, then $\sum_{v \in X}(g(v) - d(v)) \geq \Phi(x) > 0$, so there must be some $v \in X$ with $g(v) > d(v)$, and a new edge can be attached to v. Hence if condition 1 above holds, then the current phase of the (modified) algorithm can be applied without violating the degree constraints. It now needs to be shown that at the end of the current phase, conditions 1 and 2 still hold, i.e., for every node x in the new tree, if $d'(x) = d(x) + \epsilon$ is its new degree, then $\sum_{v \in X}(g(v) - d'(v)) \geq \Phi'(x)$, and also $\sum_{v \in S} g(v) - d'(v) \geq \Phi'(ES) + 1$ if $\Phi(ES)$ is odd. This is true since by Lemma 4.7, if $\Phi(x) > 0$, then
