$$\Phi'(x) = \Phi(x) - \epsilon \leq \left(\sum_{v \in X} g(v) - d(v) \right) - \epsilon = \sum_{v \in X} g(v) - d'(v),$$

which also implies that

$$\Phi'(ES) + 1 = \sum_{i=1}^{r} \Phi'(x_i) + 1 \leq \sum_{v \in S} g(v) - d'(v).$$

Hence if the condition holds initially, then by applying algorithm **Aug-δ** (with the minor addition), the necessary condition is maintained throughout, so the algorithm terminates.

Now consider the last phase of the algorithm when $\Phi(ES)$ is odd. Without loss of generality, let x_i be the root's child for which $\sum_{v \in X_i} g(v) - d(v) \geq \Phi(x_i) + 1$ (condition

2 assures that such an x_i exists). We add the following detail to the last phase of the algorithm: In step (1) of algorithm **Aug-δ**, enumerate the leaves of the cactus by assigning the number 1 to x_i. (x_i is necessarily a leaf in the cactus since it is a child of the root at the last stage.) In addition, attach the last endpoint of the last edge to some vertex $v^* \in X_i$ for which $g(v^*) > d(v^*)$. Note that (i) there must be such $v^* \in X_i$ and (ii) the last endpoint of the last edge can be attached to a vertex in any leaf of the cactus *other than* to a vertex in the $\lceil k/2 \rceil$'s leaf, where $k \geq 2$ is the number of leaves in the cactus. Since v^* is in the first leaf, this requirement is satisfied. Hence condition 2 of the theorem guarantees that the last phase of the algorithm can be completed properly.

The modified algorithm adds $\lceil \Phi(ES)/2 \rceil$ new edges, since it produces a solution which could have been chosen for the unconstrained problem. But since this is also a lower bound on the number of edges needed, the solution is optimal. □

6. Open problems.

The augmentation problem with no parallel edges. No polynomial solution is known for the edge augmentation problem if parallel edges are *not* allowed. (Our algorithm, as well as all previous algorithms, may add parallel edges.) The state of this problem is an interesting question.

Clearly, any λ-edge-connected graph with $\lambda > n - 1$ must have parallel edges. At the other extreme, an unconnected graph can be made 1-edge-connected without adding parallel edges by linking its connected components to a tree of components. Hence if the target connectivity is either 1 or greater than $n - 1$, then the answer is known. For the intermediate values, the following preliminary observations can be made.

If the graph G is either 1- or 2-edge-connected, then many of the known algorithms, such as those of [7, 36, 37], can augment it to be 3-edge-connected by selecting nonparallel edges. This is also true for our solution: if $\lambda = 1, 2$, then any pair of leaves in the cactus which are singletons that are connected by an edge in the graph must also be adjacent in the DFS enumeration; but our algorithm adds edges between only nonconsecutive leaves.

However, this is not true in general, as shown by the following sequence of graphs. For any $3 \leq \lambda \leq n - 1$, define $G_\lambda = (V_\lambda, E_\lambda)$ as follows:

$$V_\lambda = \{a_1, \ldots, a_\lambda, b_1, \ldots, b_\lambda, b_{\lambda+1}, \ldots, b_p\}$$

for $p > \lambda + 1$ and

$$E_\lambda = \{(a_i, a_j) | 1 \leq i < j \leq \lambda\} \cup \{(b_i, b_j) | 1 \leq i < j \leq p\} \cup \{(a_i, b_i) | i = 1, 2, \ldots \lambda\}.$$

That is, G_λ consists of two cliques, one of size λ and the other of size $p > \lambda+1$, together with a set of λ edges *between* the cliques. The edge connectivity of G_λ is λ, and $\mathcal{H}(G_\lambda)$ is a star with an empty node in the middle and leaves $a_1, a_2, \ldots, a_\lambda, \{b_1, \ldots, b_p\}$. The graph G_3 with $p = 5$ is shown in Figure 6. If $\lambda \geq 3$, then any optimal solution that increases the connectivity of G_λ by one (i.e., adds $\lceil \frac{\lambda+1}{2} \rceil$ edges) must add a new edge of the type (a_i, a_j), which already exists in G_λ.

THEOREM 6.1. *Any 0-, 1- or 2-edge-connected graph with ≥ 4 vertices can be optimally augmented to a 3-edge-connected graph without adding parallel edges.*

For any $\lambda \geq 3$, there is a family of λ-edge-connected graphs on n vertices, $n \geq \lambda + 2$, which require the addition of parallel edges when optimally augmenting to a $(\lambda + 1)$-edge-connected graph.

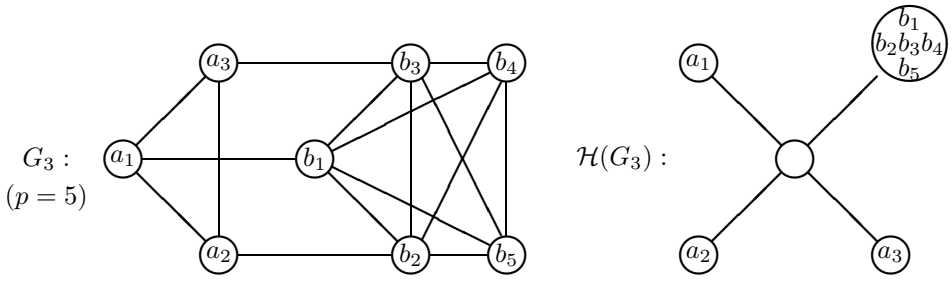

FIG. 6. *An example where an optimal augmentation by one requires parallel edges* (G_3 *with* $p = 5$).

The final lemma characterizes a broad class of graphs which can be optimally augmented by one without parallel edges. Its proof is included in Appendix B.

LEMMA 6.2. *If* λ*, the connectivity of* G*, is smaller than the minimum degree of* G*, then* G *can be augmented by one without parallel edges.*

Appendix A. Finding edge connectivity in a multigraph. The algorithm of [31] finds the edge connectivity of an uncapacitated simple graph in $O(nm)$ time. We now show how to extend the analysis of this algorithm to multigraphs, i.e., graphs with parallel edges. Let m be the number of pairs of vertices which are connected by some edge. Let $p(v)$ be the *maximum* number of parallel edges between v and any one of its neighbors, and define $P = \sum_{v \in V} p(v)$. Then the running time of the algorithm is $O(Pm)$. Note that for simple graphs, $P = n$; hence we obtain the original $O(nm)$. The algorithm of [31] for simple graphs is described and analyzed in [1] (see [12]).

The algorithm of [31]. Let $v_1, \ldots, v_n$ be an arbitrary ordering of the vertices of G. G_i is the graph obtained from G by contracting the set $\{v_1, \ldots, v_i\}$ into a single node called v_0. It is easy to see that if C_i is the minimum cut between v_{i+1} and v_0 in G_i, then λ, the edge connectivity of G, is the smallest of all C_i. The ith phase of the algorithm computes C_i; at the beginning of that phase, any edge of the form (v_0, v_j) in G_i ($v_j \neq v_0$) is assumed to be marked, as well as the vertex v_j.

C_i is computed in two stages. First, all paths of length 1 or 2 from v_{i+1} to v_0, which are called *short paths*, are found and each contributes one unit of flow to C_i. The short paths are found by scanning the adjacency list of v_{i+1}: every edge (v_{i+1}, v_0) is a path of length one; an edge (v_{i+1}, v_j), where v_j is a marked node, followed by a marked edge (v_j, v_0) is a path of length 2. These paths remain untouched. Then all paths of length three or more between v_{i+1} and v_0, which are called the *long paths*, are found. This is done using the original Ford–Fulkerson algorithm by successively building residual graphs while ignoring the edges on the short paths found earlier, finding augmentation paths, and augmenting the flow by one unit for each such path. Observe that since every edge on a short path is connected to either v_0 or v_{i+1}, there is never a need to undo the flow on this edge; it is therefore allowed to ignore these edges in building the residual graphs.

At the end of the computation of C_i, G_{i+1} is constructed: v_{i+1} is contracted with v_0, adjacency lists are updated, and all edges (v_{i+1}, v_j), $v_j \neq v_0$, that participated in some long path are marked (including v_j).

Time analysis for multigraphs. We now extend the analysis in [31] to multigraphs. The short paths in phase i are found by scanning v_{i+1}'s adjacency list. Hence the total time to find all short paths over all phases is $O(C)$, where C is the number of

edges in the graph, since every edge is scanned twice. Similarly, the time to build $G_1, \ldots, G_{n-1}$ and mark the edges and vertices during all phases is $O(C)$. Clearly, $C \leq Pm$. We now show that the time to search for the long paths is bounded by $O(Pm)$.

Suppose that w appears for the first time as the *second* vertex on a *long* path during phase i and that there are x_i such long paths. At the end of that phase, v_{i+1} is contracted with v_0, w becomes adjacent to v_0 from then on, and x_i of its edges are marked. Now suppose that w appears again as the second vertex on some path during phase j, $j > i$. If the number of these paths is not greater than x_i, then they all must be short paths (since they will use the edges that were marked during phase i). If the number of these paths is greater than x_i, then x_i of them must be short, and the remaining x_j paths will be long paths. However, $x_i + x_j$ is bounded by the number of edges between w and v_{j+1} and hence bounded by $p(w)$. This argument can be applied repeatedly, every time w appears as a second vertex on some path, so the total number of long paths that contain w as the second vertex is at most $p(w)$. Therefore, the number of long paths found during the entire algorithm is bounded by P. Since the time to search for a long path is linear in the size of the residual graph, i.e., $O(m)$, the long paths are found in $O(Pm)$.

Appendix B. Augmentation with no parallel edges. We now prove Lemma 6.2, which states that a certain class of graphs can be optimally augmented by one without parallel edges.

LEMMA B.1. *Let G be a graph with no parallel edges and connectivity $\lambda > 1$, and let A, $|A| > 1$, be a leaf in $\mathcal{H}(G)$; that is, A is λ-extreme. There exists a vertex $v \in A$ whose neighbors all belong to A.*

Proof. Since A is λ-extreme, $d(A) = \lambda$ and $d(v) > \lambda$ for any $v \in A$. If $\min(A) = \min_{v \in A}\{d(v)\}$ is the minimum over all degrees of the vertices in A, then $\min(A) > \lambda$. We have

$$\begin{aligned}\lambda|A| < \min(A)|A| &\leq \sum_{v \in A} d(v) \leq d(A) + 2(\#\text{ edges within A}) \\ &= \lambda + 2(\#\text{ edges within A}) \leq \lambda + |A|(|A| - 1)\end{aligned}$$

Hence $\lambda|A| < \lambda + |A|(|A| - 1)$ or $\lambda(|A| - 1) < |A|(|A| - 1)$. Therefore, $|A| > \lambda$ since we assumed that $|A| > 1$. If $|A| > \lambda$, then there must be a vertex $v \in A$ that is connected only to vertices in A since the number of edges going out of A is λ, and this proves the lemma. □

LEMMA B.2. *If λ, the connectivity of G, is smaller than the minimum degree of G, then G can be augmented by one without parallel edges.*

Proof. If λ is smaller than the minimum degree of G, then there are no λ-extreme sets that are singletons. Hence Lemma B.1 assures that any pair of leaves in the cactus $\mathcal{H}(G)$ can be connected by a new edge (i.e., not from the original set of edges). Therefore, algorithm **Aug-1** can always select a set of nonparallel edges that optimally augment G by one. □

Acknowledgments. We would like to thank one of the referees for pointing out the problem with an earlier version of Theorem 5.3. We would also like to thank Prof. Lou Hakimi for preliminary discussions on the augmentation problem.

GRAPH DECOMPOSITION IS NP-COMPLETE: A COMPLETE PROOF OF HOLYER'S CONJECTURE*

DORIT DOR† AND MICHAEL TARSI†

Abstract. An H-decomposition of a graph $G = (V, E)$ is a partition of E into subgraphs isomorphic to H. Given a fixed graph H, the H-decomposition problem is to determine whether an input graph G admits an H-decomposition.

In 1980, Holyer conjectured that H-decomposition is NP-complete whenever H is connected and has three edges or more. Some partial results have been obtained since then. A complete proof of Holyer's conjecture is the content of this paper. The characterization problem of all graphs H for which H-decomposition is NP-complete is hence reduced to graphs where every connected component contains at most two edges.

Key words. graph, decomposition, NP-completeness

1. Introduction.

Given a graph H, the H-decomposition problem is stated as follows: Can the edge set of an input graph G be partitioned into subgraphs isomorphic to H?

Holyer [10] conjectured the NP-completeness [8] of H-decomposition whenever H consists of at least three edges. In that wide form, the conjecture was known to be false (assuming P $\neq$ NP) even before it was stated. Brouwer and Wilson [4] presented a polynomial-time algorithm for the case where H is the union of t disjoint edges ($H = tK_2$). Independently, Alon [1] obtained the same result after the case of $H = 3K_2$ was studied in details by Bialostocki and Roditty [3]. Later, Preisler and Tarsi [15] presented a polynomial algorithm for the union of a single path of two edges and t disjoint edges, $H = P_3 \bigcup tK_2$. The case where $H = P_3 \bigcup K_2$ was solved previously by Favaron, Lonc, and Truszczynski [7]. Recently, Lonc [12] proved the existence of a polynomial-time algorithm for the case where $H = sP_3$ is the union of s vertex disjoint, two-edges-long paths.

In all of the above, polynomial algorithms were found for H-decomposition in which each connected component of H is either a single-edge- or two-edge-long path. This led to a relaxed version of Holyer's conjecture, restricted to graphs H which contain a connected component with three edges or more.

Several partial results in that direction have been obtained during the last decade. Holyer [10], [9] proved his conjecture for ($H =$) complete graphs, for simple paths, and for simple circuits. Leven (unpublished) presented a proof for the case where H is a star (a complete bipartite graph $K_{1,n}$). Cohen and Tarsi [17] generalized those results to a family of graphs which contains the set of all trees. Masuyama and Hakimi [18] proved NP-completeness for all graphs which include a vertex of degree 1.

A related topic is the factorization problem, which is the analogous problem for vertex partition: Determine for a fixed graph H whether an input graph $G = (V, E)$ contains vertex-disjoint subgraphs, isomorphic to H, such that the union of their

vertex sets is V. Kirkpatrick and Hell [11] proved that this problem is NP-complete (NPC) if and only if H contains at least three vertices in a connected component.

The content of this paper is a complete proof of Holyer's conjecture, that is, a proof of the following result.

THEOREM 1.1. *H-decomposition is* NPC *whenever H contains a connected component with three edges or more.*

We conclude this section with some notational remarks.

- Let $G = (V, E)$ be a graph G with vertex set $V = V(G)$ and edge set $E = E(G)$. For another graph $G' = (V, E')$, we use $G - G'$ or $G - E'$ to denote $(V, E - E')$, and for a set V' of vertices, we define $G - V' = (V - V', E - \{e \in E : e \text{ is incident to a vertex of } V'\})$.
- The graph $G = (V, H)$ is *k-connected* if $G - V'$ is connected for any $(k-1)$-element subset V' of V, and it is *k-separable* if it is not $(k+1)$-connected.
- An *H-subgraph* of G is a subgraph of G which is isomorphic to H.
- If G admits an H-decomposition D, then we refer to each graph in D as a *D-part*.
- Let D be an H-decomposition of G and let H' be a D-part. Since H' is an H-subgraph, there exists an isomorphism $f : V(H') \to V(H)$ (select a certain isomorphism if there are more than one). For $v \in V(H') \subseteq V(G)$ and $x \in V(H)$, the relation $x = f(v)$ is denoted by $v = x(H')$. We also say in this case that *v plays the role of x in H'*.

2. Methodological overview. Our proof of Theorem 1.1 is rather long and technical—not to say cumbersome. This section can be read as a stand-alone extended abstract which draws the overall picture without coping with all technical details. Yet it is also an integrated part of the proof, setting the general frame, whereas the following sections fill in the empty squares.

One major difficulty faced in previous attempts to prove Theorem 1.1 lies in its wide nature. Apparently, it is rather easy to custom tailor the necessary machinery for a given graph H. It is a much harder task to design a suit that fits all graphs. For example, if G is H-decomposable, then the degree of each vertex of G is the sum of certain vertex degrees of H. This leads to the following definition of the graph parameter $g(H)$.

DEFINITION 2.1. *Let $H = (V, E)$ be a graph. The greatest common divisor of the degrees $d(x)$ over all vertices $x \in V$ is denoted by $g(H)$.*

Clearly, the set of H-decomposable graphs is reached when $g(H) = 1$, and indeed the graphs H treated in [17] and in [18] all have $g(H) = 1$. For a uniform general proof, a family of simply structured graphs is required, where H-decomposable graphs can be found regardless of the specific graph H at hand. Such a family is merely the set of complete graphs K_n due to the following theorem by Wilson [14], which is considered to be the key theorem of graph-decomposition theory.

WILSON'S THEOREM. *For every graph $H = (V, E)$, the conditions $|E|$ divides $\binom{n}{2}$ and $g(H)$ divides $(n-1)$, which are obviously necessary for the complete graph K_n to be H-decomposable, are also sufficient if n is larger than some constant $n_0(H)$.*

With complete graphs as the basic building blocks, we still use three different main proof schemes, each designed for a certain family of graphs H. It is observed in [17] that if C-decomposition is NPC, where C is a connected component of H, then H-decomposition is also NPC. It then suffices to consider connected graphs H.

Graph decomposition is basically a partition of a set into disjoint subsets taken from a given collection. It seems natural to consider a similar problem, known to be

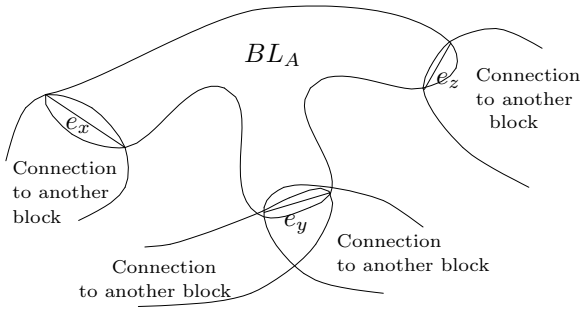

FIG. 1. *A part of* $G_H(I)$ *where* $A = \{x, y, z\}$.

NPC, as a starting point for a polynomial reduction. (H-decomposition is clearly in NP; our task here is to prove NP-hardness.) The problem selected for our first two schemes is the following.

DEFINITION 2.2. *An instance of* k*-XC* (k-eXact Cover) *is a pair* $I = (U, \mathcal{A})$*, where* U *is a finite set and* $\mathcal{A}$ *is a collection of* k*-element subsets of* U*. The* k*-XC problem on* I *is to decide whether there exists a partial collection* $X \subseteq \mathcal{A}$ *of pairwise-disjoint sets such that* $|U| = k \cdot |X|$ *and* $\bigcup_{A \in X} A = U$*.*

For every integer $k \geq 3$, k-XC is known to be NPC (k-dimensional matching is a restricted version of k-XC).

To prove that H-decomposition is NPC, for every instance $I = (U, \mathcal{A})$ of k-XC (for some constant $k \geq 3$), we construct a graph $G_H(I)$ in polynomial time such that H-decomposition of $G(I)$ is equivalent to k-XC on I.

2.1. First scheme: Blocks with isolated boundary edges. Let $I = (U, \mathcal{A})$ be an instance of k-XC. To represent each k-tuple $A \in \mathcal{A}$, we design an "all-or-none" building block. This should be a graph BL_A, which contains k *incidence edges*, $e_1, \ldots, e_k$, each representing the inclusion of an element $x \in U$ in A. Both graphs BL_A and $BL_A - \{e_1, \ldots, e_k\}$ should be H-decomposable.

The graph $G_H(I)$ is formed by merely grouping the blocks together such that every element $x \in U$ is represented by an incidence edge e_x, shared by all blocks BL_A, for which $x \in A$. Other than that, the blocks are vertex disjoint.

An exact cover X of I easily translates into an H-decomposition of $G_H(I)$ as follows: Decompose BL_A for every $A \in X$ and $BL_A - \{e_1, \ldots, e_k\}$ for the other k-tuples A, which are not in X. Since X is an exact cover, given any $x \in U$, the common incidence edge e_x is "used" by one of the blocks and hence an H-decomposition of $G_H(I)$ is indeed formed (see Figure 1).

To meet the "only if" requirement of the reduction, the block should be designed such that any H-decomposition of $G_H(I)$ would impose an H-decomposition on either BL_A or $BL_A - \{e_1, \ldots, e_k\}$ for every $A \in \mathcal{A}$. For clear discussion of that aspect, we introduce some further notation.

DEFINITION 2.3.

- *A* module $M = (V, E, B)$ *is a connected graph on vertex set* V *and edge set* E*, which contains a prespecified subgraph* B*, called its* boundary*. The vertices* (*respectively, edges*) *of* B *are the* boundary vertices (*respectively,* boundary edges) *of* M*. The edges of* $M - B(M)$ *are the* interior edges *of* M *and the* interior vertices *are those incident to no boundary edge.*

- *A* modular extension *of a module M is a graph G which contains M as an induced subgraph such that no edge in $G-M$ is adjacent to an interior vertex of M. We also say in that case that M is a* modular subgraph *of G.*
- *Let G be a modular extension of M. A subgraph T of G which includes an interior edge of M as well as an edge of $G-M$ is called* split *(with respect to M).*

We can use now the new terminology to summarize the scheme as a lemma.

LEMMA 2.1. *H-decomposition is* NP*-complete, if H allows the existence of a* block module *BL_H whose boundary B consists of k vertex-disjoint edges for some integer $k \geq 3$ and it satisfies the following conditions:*

1. *BL_H and $BL_H - B$ are both H-decomposable.*
2. *Any H-decomposition of a modular extension of BL_H contains an H-decomposition of either BL_H or $BL_H - B$.*

It is straightforward to verify that condition 2 indeed provides the "only if" direction to complete the reduction described above. The explicit construction of block modules is presented in section 3.

2.2. Second scheme: Boundary cliques. There exists an inherent flaw in the use of Lemma 2.1 related to the graphic parameter $g(H)$.

An obviously necessary condition for H-decomposability of a graph G is $g(H)|g(G)$. Consequently, if a graph G and a subgraph G' of G are both H-decomposable, then $g(H)|g(G-G')$. Consider the block module BL_H of Lemma 2.1 and its subgraph $BL_H - B$. Both graphs are H-decomposable and the difference between them is the boundary B consisting of vertex-disjoint edges. Clearly, $g(B) = 1$ and hence this scheme is applicable only for graphs H with $g(H) = 1$.

The isolated boundary edges of the first scheme are replaced in the second by m-cliques. The value of m depends on the graph H at hand and is specified in section 4. For reasons that will become clear later, we define $d = m - 1$.

Given an instance $I = (U, \mathcal{A})$ of 3^d-XC, a graph $G_H(I)$ is constructed as follows: For every $A = \{x_1, \ldots, x_{3^d}\} \in \mathcal{A}$, we construct a *grouping* module GR_A, which replaces the block module of the first scheme. The boundary of GR_A consists of 3^d *arms* denoted by $K_1^+, \ldots, K_{3^d}^+$ and 3^d *antiarms* denoted by $K_1^-, \ldots, K_{3^d}^-$. Each arm and each antiarm is an m-clique and they are all vertex disjoint. The module GR_A is built to make both subgraphs $GR_A - \{K_1^+, \ldots, K_{3^d}^+\}$ and $GR_A - \{K_1^-, \ldots, K_{3^d}^-\}$ H-decomposable. For every $x \in U$, let all grouping modules GR_A for which $x \in A$ share a common boundary arm E_x.

The antiarms are taken care of by means of another module, the *r-alternator*, r-A_H. Its boundary consists of r edge-disjoint m-cliques $K^1, \ldots, K^r$, such that the graph obtained by deleting any $r-1$ of them is H-decomposable. We refer to each of these cliques as an *arm* of the alternator.

For each element x included in $A_1, \ldots, A_t$ ($A_i \in \mathcal{A}$), we construct a *t-alternator* AE_x, each arm of which is an antiarm of one of $GR_{A_1}, \ldots, GR_{A_t}$. The graph obtained is $G_H(I)$ (see Figure 2).

Let D_A^- and D_A^+ denote an H-decomposition of $GR_A - \{K_1^+, \ldots, K_{3^d}^+\}$ and $GR_A - \{K_1^-, \ldots, K_{3^d}^-\}$, respectively. An exact cover $X \subset \mathcal{A}$ easily provides an H-decomposition of $G_H(I)$ as follows: Take the union of the decompositions D_A^+ for every $A \in X$ and D_A^- for every $A \notin X$. Consider an element $x \in U$ which belongs to sets $A_1, \ldots, A_t$. Since X is an exact cover, the common arm E_x is covered by exactly one of the $D_{A_i}^+$'s, for which $A_i \in X$ and $t-1$ arms of the t-alternator AE_x are covered, each by a decomposition $D_{A_j}^-$, $A_j \notin X$. The remaining "one-armed alternators" are H-decomposable

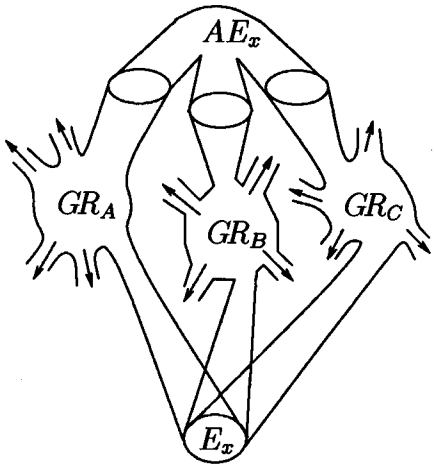

FIG. 2. *A part of* $G_H(I)$ *where* $x \in A, B, C \in \mathcal{A}$.

and thus complete an H-decomposition of $G_H(I)$.

Our construction of the grouping module is based on the existence of the *Holyer graph* $H_{m,3}$, which is defined in [10] (see also section 5), where the following is proven.

LEMMA 2.2. *There are exactly two distinct* K_m*-decompositions of* $H_{m,3}$*:* $K^+ = \{K_i^+\}_{i=1}^{3^{m-1}}$ *and* $K^- = \{K_i^-\}_{i=1}^{3^{m-1}}$*, each consisting of* 3^{m-1} m*-cliques.*

The grouping module GR_A consists of a copy of the Holyer graph $H_{d+1,3}$, where each $(d+1)$-clique in $K^+ = \{K_i^+\}_{i=1}^{3^d}$ and $K^- = \{K_i^-\}_{i=1}^{3^d}$ is an arm of one of $2 \cdot 3^d$ 2-alternator modules. The other $2 \cdot 3^d$ arms of these alternators, 3^d for K^+ and 3^d for K^-, are the *arms* and *antiarms* of GR_A, respectively.

Due to our definition of the alternator and Lemma 2.2, the subgraphs obtained from GR_A by deleting either all of its arms or all of its antiarms are indeed H-decomposable. It remains to assure that any H-decomposition of $G_H(I)$ would impose an exact cover on I. This mission is much more involved and relies on a careful design of the alternator modules, which is left to section 4.

2.3. Third scheme: Triangular graphs. Due to technical reasons that are explicitly stated in section 4.2, our second scheme fails when H is a graph of a certain type, which we call *triangular*. This is basically a triangle, where each of the three edges is replaced by any connected component.

DEFINITION 2.4. *A graph* $G = (V, H)$ *is called triangular by three of its vertices* $v_0, v_1, v_2 \in V$ *if it is the union of three connected components* C_0, C_1, C_2 *and* $V(C_i) \cap V(C_{i+1}) = \{v_i\}$ *for* $i \in \{0, 1, 2\}$*, addition modulo* 3 *(see Figure* 3*).*

Fortunately, Holyer's proof [10] for the case where H is a triangle can be modified to cover all triangular graphs. Holyer's method and its application to triangular graphs is described in section 5.

2.4. Case listing. We conclude this preliminary section with a "checklist" of the various families of graphs for which different versions of the proof are given.

- 3-connected graphs with $g(H) = 1$ are treated in section 3.1.
- 2-connected, 2-separable graphs with $g(H) = 1$ are treated in section 3.2.
- 5-connected graphs with $g(H) > 1$ are treated in section 4.1.

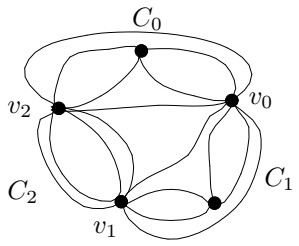

FIG. 3. *A triangular graph.*

- 2-connected, 4-separable, nontriangular graphs with $g(H) > 1$ are treated in section 4.2.
- 1-separable, nontriangular graphs are treated in section 4.3.
- Triangular graphs are treated in section 5.

One can easily verify that the list above indeed covers all connected graphs H. After considering the last two cases in the list, it remains to consider 2-connected, nontriangular graphs. Such graphs with $g(H) = 1$ are treated in the first two cases and graphs with $g(H) > 1$ are treated in the next two. Despite some overlapping, none of the cases is redundant.

3. Explicit construction of BL_H. Block modules which comply with Lemma 2.1 are made up of smaller modules, which we call chains.

DEFINITION 3.1. *A* chain module *related to a connected graph H is a module $C_H = (V, E, B)$ whose boundary contains two edges and which satisfies the following conditions:*

1. *A path in C_H which includes both boundary edges is at least $k+2$ edges long.*
2. *Once either one of the boundary edges is deleted from C_H, the remaining graph is H-decomposable.*
3. *If G is a modular extension of C_H which admits an H-decomposition D, where no D-part includes both boundary edges of C_H, then no D-part is split.*

LEMMA 3.1. *Let H be a connected graph with $k \geq 3$ edges. The H-decomposition problem is* NP*-complete if H allows the existence of a chain module $C_H = (V, E, B)$.*

Proof. A *block module* LB_H is formed of a copy H' of H, every edge of which is a boundary edge of one of k chain modules, which are otherwise vertex disjoint. The other boundary edges of the chains will be denoted by $e_1, \ldots, e_k$ and serve as boundary edges of the block.

We now show that BL_H meets the requirement set in Lemma 2.1.

The graph $LB_H - H'$ is the union of k chains with one boundary edge deleted from each. The same holds for $LB_H - \{e_1, \ldots, e_k\}$. Condition 2 of Definition 3.1 then implies that both LB_H and $LB_H - \{e_1, \ldots, e_k\}$ are H-decomposable, as condition 1 of Lemma 2.1 requires. Let G be a modular extension of LB_H and let D be an H-decomposition of G. Condition 1 of Definition 3.1 makes the boundary edges of a chain too far apart for one H-subgraph to include both of them, and no shortcut in G is possible due to the structure of the block. Then no H-subgraph of G exists which includes both boundary edges of a chain. By condition 3 of Definition 3.1, no D-part is split with respect to any of the chains. By condition 2, the number of edges in a chain is 1 (mod$k$). Consequently, D contains a decomposition of each one of the chain modules with either one of its boundary edges deleted. The only H-subgraph

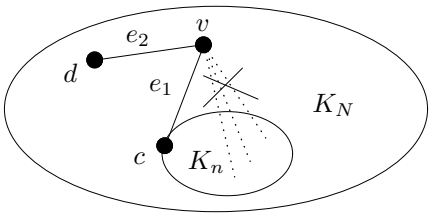

FIG. 4. *The link module.*

which includes an edge of H' with no edge interior to a chain is H' itself. Hence if $H' \in D$, then D contains a decomposition of BL_H. If $H' \notin D$, then a subset of D decomposes $BL_H - \{e_1, \ldots, e_k\}$. Hence condition 2 of Lemma 2.1 is met. □

We proceed by constructing chain modules which satisfy the conditions stated in Definition 3.1. The chain is formed by concatenation of smaller modules, which we call *links*. Each link module includes two boundary edges, the removal of either one of which provides an H-decomposable graph. Several links are chained, each sharing one boundary edge with each neighbor, to form a chain module, where the boundary edges are far apart from each other, as required by condition 1 of Definition 3.1. As pointed out in section 2, this technique is restricted to graphs H where $g(H) = 1$. We assume first that H is 3-connected, which makes condition 3 very easy to meet. The structure of the link module is later modified to fit to the case where H is 2-connected and 2-separable. The case where H is 1-separable is treated in section 4.3 using a different scheme.

3.1. Constructing the chain module where H is 3-connected.

The link module L_H. In accordance with Wilson's theorem, select an integer n such that K_n and K_{n+1} are both H-decomposable. (Notice that $g(H) = 1$ is necessary for the existence of such an n.) Apply Wilson's theorem one more time to choose an integer N such that K_N is K_{n+1}-decomposable. Select a vertex v of the complete graph K_N and delete $n-1$ of the edges incident to v. Also, select c and d, two of the vertices which remain adjacent to v. The graph obtained with boundary edges (v, d) and (v, c) is the link module L_H.

PROPOSITION 3.2. *The subgraph obtained from L_H by deleting either one of its boundary edges $e_1 = (v, c)$, or $e_2 = (v, d)$, is H-decomposable.*

To verify the proposition, start with a K_{n+1}-decomposition D of K_N, where the $(n+1)$-clique, on v, c, and the $n-1$ vertices which then become nonadjacent to v, is a D-part. Once all of the edges incident to v in this clique (including (v, c)) are deleted, the remaining edges form a copy of K_n. Since K_n and K_{n+1} are both H-decomposable, the partition obtained can be refined into an H-decomposition of $L_H - \{(v, c)\}$ (see Figure 4). The same argument holds for $L_H - \{(v, d)\}$.

The chain module C_H. A sequence $(L_1, L_2, \ldots, L_{2k})$ of $2k$ copies of L_H is concatenated into a chain module C_H by means of identifying the edge (v_i, d_i) (that is, the edge (v, d) of L_i) with the edge (c_{i+1}, v_{i+1}) and their corresponding end vertices (v_i with c_{i+1} and d_i with v_{i+1}) for every $1 \le i \le 2k-1$. The two edges (c_1, v_1) and (v_{2k}, d_{2k}) serve as the boundary edges of C_H (see Figure 5).

It remains to show that C_H indeed satisfies the conditions of Definition 3.1. Condition 1 is satisfied since the boundary edges of the chain are located $2k$ links apart

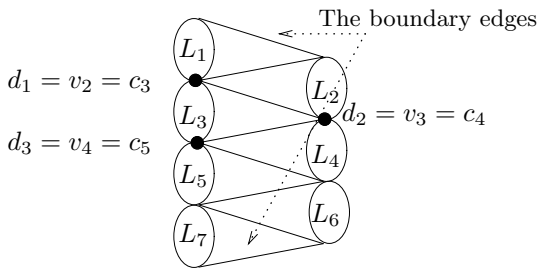

FIG. 5. *The chain module, C_H.*

from each other. Condition 2 is a straightforward corollary of Proposition 3.2. Any split subgraph with at most k edges disconnects at the two end vertices of a boundary edge. The 3-connectivity of H then implies condition 3.

3.2. Constructing the chain where H is 2-connected and 2-separable. 3-connectivity is essential for the last argument. The link module L_H is almost a complete graph, and many copies of any graph H of lower connectivity are split among chains, violating condition 3 of Definition 3.1. To avoid this, we focus on a D-part which includes a boundary edge of a link module. We construct a sparse modified link where the connection of this D-part with the rest of the graph is "minimal." When the modified link module L'_H replaces L_H as the basic brick of a chain, the conditions of Definition 3.1 are met for 2-connected, 2-separable graphs. This mission requires a deeper look into the structure of 2-separable graphs.

DEFINITION 3.2. *A* separating pair (SP) *of a 2-connected graph H is a pair of vertices $\{x, y\} \subset V$ such that the graph $H - \{x, y\} = (V - \{x, y\}, E - \{e | e$ is incident to either x or $y\})$ is not connected. An $\{x, y\}$-component is a subgraph of H induced by the union of $\{x, y\}$ with a connected component of $H - \{x, y\}$. All $\{x, y\}$-components then share vertices x and y (and an edge (x, y) if it exists), and they are otherwise disjoint. An SP-sequence of H is a sequence $(\{x_1, y_1\}, \ldots, \{x_t, y_t\})$ of distinct (not necessarily disjoint) SP's such that all $\{x_j, y_j\}$ for $j > i$ are included in the same $\{x_i, y_i\}$-component.*

The modified link L'_H. Let $H = (V, E)$ be a 2-connected, 2-separable, graph with $g(H) = 1$ and $|E| = k \geq 3$. Let $S = (\{x_1, y_1\}, \ldots, \{x_t, y_t\})$ be an SP-sequence of H of maximum length t. Also, let S be selected such that the degree $d(x_t)$ is minimum among all SP-sequences of length t. From an $\{x_t, y_t\}$-component which does not contain $\{x_{t-1}, y_{t-1}\}$, select a vertex $z \neq y_t$ adjacent to x_t (see Figure 6). In accordance with Proposition 3.2, we start with an H-decomposition D of $L_H - \{(v, c)\}$. Let H_v be the D-part which includes (v, d). Recall that D is formed by decomposing complete graphs and hence no constraint holds regarding the roles of c, d, and v in H_v. We take advantage of this freedom to select $v = x_t(H_v)$, $d = z(H_v)$, and $c \notin V(H_v)$. From H_v we construct $H_{v'}$, a new copy of H, as follows: For every $u \in V(H_v)$ such that $(u, z = d) \notin E(H_v)$, we replace u in H_v by a new vertex u'. That is, every edge (u, w) is deleted and (u', w) is inserted instead. Also, a new vertex v' is added to replace v in $H_{v'}$ in the role of x_t. We define $D' = (D - \{H_v\}) \bigcup \{H_{v'}\}$. The modified link L'_H is the union of all $T \in D'$ and the edge (v', c) with boundary edges (v', c) and (v', d). The H-subgraph $H_{v'}$ is called the *kernel* of L'_H (see Figure 6).

The modified link is meant to satisfy the following stronger version of Proposition 3.2.

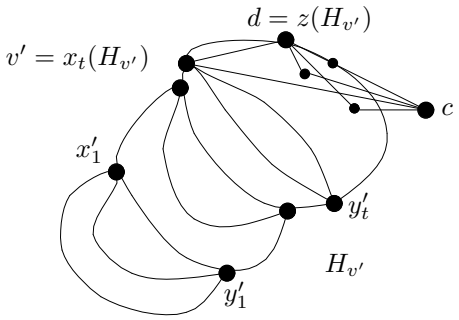

FIG. 6. *The modified link module* L'_H.

PROPOSITION 3.3.

1. *The subgraph obtained from* L'_H *by deleting either one of its boundary edges* (v', c) *or* (v', d) *is* H*-decomposable.*
2. *Let* L *be an* L'_H *modular subgraph of a graph* G*, where either* $\{v', c\}$ *or* $\{v', d\}$ *is an SP of any split* H*-subgraph. If* D *is an* H*-decomposition of* G*, then there exists a* D*-part* $H(L)$ *entirely contained in* L *such that the degree of* $v'(L)$ *in* $L - H(L)$ *is at most* 1.

Proof. Obviously, D' is an H-decomposition of $L'_H - \{(v', c)\}$. Furthermore, the neighborhood of (the set of vertices adjacent to) c in L_H is identical to that of d. The vertex d in H_v plays the role of $z \in V(H)$. The neighbors of this vertex, except for v, were not changed and $c \notin V(H_v)$. Consequently, the neighborhoods of c and d are also identical in L'_H. Thus, switching the roles of c and d in each $T \in D'$, we also obtain an H-decomposition for $L'_H - \{(v', d)\}$. Condition 1 is then satisfied.

Let G and L be as stated in part 2 of Proposition 3.3. Let $H_{v'}$ be the kernel of L and let $S' = (\{x'_1, y'_1\}, \ldots, \{x'_t = v', y'_t\})$ be the copy in $H_{v'}$ of the maximal SP-sequence S as defined above. The modified link is designed to make "most of" its kernel $H_{v'}$ be "separated" from the rest of the link, to which it is connected only through the farthest $\{x_t, y_t\}$-component. Accordingly, the sequence S' is also an SP-sequence of L and of G. Select an edge e from an $\{x'_1, y'_1\}$-component which does not contain the other members of S'. Let $H(L)$ be the D-part which contains e. Clearly, S' is also an SP-sequence of $H(L)$. If $H(L)$ contains an edge out of L, then $\{v'(L), d(L)\}$ or $\{v'(L), c(L)\}$ is an SP of $H(L)$, which can be appended to S' to form a longer SP-sequence—a contradiction. This implies that $H(L) \subset L$. Regarding the degree of $v'(L)$, this vertex belongs to the tth SP of S'. The sequence S was selected to make the degree of x_t minimal. Thus $d(v'(L))$ in $H(L)$ is at least $d(x_t)$ (in H). On the other hand, the degree of $v'(L)$ in L is $d(x_t) + 1$. (It was inserted to replace x_t and then an edge (v', c) was added.) This obviously implies $d(v'(L)) \leq 1$ in $L - H(L)$. □

The chain module C_H, where H is 2-connected and 2-separable, is constructed by the concatenation of $2k$ modified links L'_H exactly as described in the previous subsection for 3-connected graphs. The vertex v of each link is replaced by the vertex v' of the modified link. It remains to verify that the conditions of Lemma 3.1 are met by that construction.

Condition 1 is satisfied since the boundary edges of the chain are located $2k$ modified links apart from each other. Condition 2 is a consequence of part 1 of

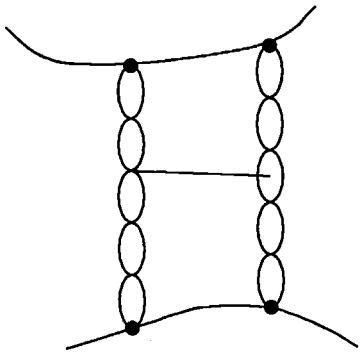

FIG. 7. *The chain module C' after deletion of all $H(L'_i)$'s.*

Proposition 3.3. Let C, G and D be as stated for Condition 3. Considering the structure of a chain, it turns out that an H-subgraph which is split with respect to a modified link, indeed has an SP consisting of the end-vertices of a boundary edge, as required for part 2 of Proposition 3.3. Let C' denote the subgraph obtained from the chain C after the edges of the D-part $H(L_i)$, defined in Proposition 3.3, are deleted from each of the modified links L_i. By Proposition 3.3 at most one of the edges adjacent to v' of each L_i still remains in C'. Two consecutive L_i's share one of these edges and thus at most one such edge remains in all of C'. Thus C' is structured of two 1-separable subgraphs, possibly connected to each other by a single edge. A path between C''s boundary edges passes through at least k articulation points of C' (see Figure 7).

Since H is 2-connected, only one D-part can be partially contained in C'. According to the construction of a chain, the number of edges in C is $1 (\mathrm{mod}\ k)$. This clearly still holds for C'. Hence, there must be a single D-part which contains a single edge of C' and this edge is clearly a boundary edge of C as required.

4. Constructing alternator modules. The link module used in the first scheme has two boundary edges, and an H-decomposable subgraph is obtained when either one of them is deleted. This is impossible, as indicated in section 2.2, when $g(H) > 1$. Instead, we use another module, called a *square*, as the elementary block from which r-alternators are built. The boundary of the square is a 4-cycle such that if either pair of opposite edges is removed, we obtain an H-decomposable graph.

DEFINITION 4.1. *A* square module *related to a graph H is a module $S_H(v_1, v_2, v_3, v_4)$, (abbreviated S_H where no ambiguity is caused) whose boundary is a 4-cycle $B(S_H) = \{e_1 = (v_1, v_2), e_2 = (v_2, v_3), e_3 = (v_3, v_4), e_4 = (v_4, v_1)\}$, and it satisfies the following two conditions:*

1. *Each of $S_H - \{e_1, e_3\}$ and $S_H - \{e_2, e_4\}$ is H-decomposable.*
2. *Every H-decomposition of a modular extension of S_H contains an H-decomposition of either one of the above two subgraphs.*

Square modules are combined to form an r-alternator module $r\text{-}A_H$ as follows.

Let u be a vertex of H for which the degree $d = d(u)$ is maximum. The vertex set of the alternator contains subsets $V^q = \{v_i^q : 0 \le i \le d\}$ for $1 \le q \le r$ and $W = \{w_{i,j} : i \ne j,\ 0 \le i, j \le d\}$. Now construct $r\binom{d+1}{2}$ square modules $S_{i,j}^q = S_H(v_i^q, v_j^q, w_{j,i}, w_{i,j})$ for every $1 \le q \le r$ and $0 \le i < j \le d$. Let the $S_{i,j}^q$'s be vertex disjoint except for the common vertices of the V^q's and W. Also, for each $0 \le i \le d$, construct a copy H_i^-

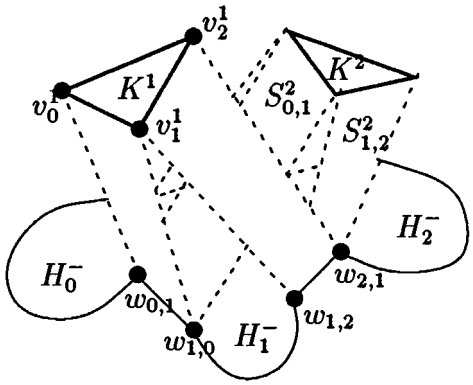

FIG. 8. *The* 2*-alternator module for* $d = 2$.

of $H - \{u\}$, where the d vertices $w_{i,j}, j \neq i$, serve as the d neighbors of the deleted vertex u. We refer to these $(H - \{u\})$-subgraphs as *wings*. Let the vertex sets of the wings otherwise be disjoint from each other and from the V^q's and W. The boundary of r-A_H is induced by $\bigcup_{q=1}^{r} V^q$. The induced $(d+1)$-cliques on each vertex set V^q are denoted by K^q and serve as the arms of the module (see Figure 8).

We first verify that the alternator indeed complies with the scheme described in section 2.2.

PROPOSITION 4.1. *The subgraph obtained from an* r*-alternator by deleting* $r-1$ *of its arms is* H*-decomposable.*

Proof. Select $1 \leq q \leq r$ and delete each of the H-subgraphs induced by $V(H_i^-) \bigcup \{v_i^q\}$ for $0 \leq i \leq d$. Once all of the cliques $K^{q'}$, $q' \neq q$, are also removed, there are altogether two edges deleted from each square $S_{i,j}^q$, which form a complete matching on its boundary. The remaining subgraph is thus H-decomposable by condition 1 of Definition 4.1. □

We now show that the process by which an exact cover on I is translated into an H-decomposition of $G_H(I)$, described in section 2.2, is indeed invertible. Once this is done, the entire scheme is summarized into the existence of square modules.

LEMMA 4.2. *If* H *allows the existence of a square module* (*cf. Definition* 4.1)*, then* H*-decomposition is* NPC.

Proof. Let $G_H(I)$ be the graph whose construction is detailed in section 2.2, and let D be an H-decomposition of $G_H(I)$. Let G' denote the subgraph obtained from $G_H(I)$ after the deletion of the D-parts which cover the interior of all of the square modules $S_{i,j}^q$ in all of the alternator modules which form $G_H(I)$. Applying condition 2 of Definition 4.1, G' is the union of all wings of the alternators involved, with some additional edges incident with the common boundary vertices. It turns out that the degree sequence of the vertices of G' is that of t disjoint copies of H, where t is the total number of wings in $G_H(I)$, which is also the number of parts in an H-decomposition of G', except for some excessive repetition of the maximal degree d. Now focus on the vertices of a wing. Each of them is of degree at most d, which implies that no such vertex is shared between two distinct D-parts; otherwise, there would be too many vertices of certain small degree for t edge-disjoint D-parts. Consequently, for any r-alternator module in $G_H(I)$, each wing is entirely contained in a single D-part, which must be induced by $V(H_i^-) \bigcup \{v_i^q\}$ for some $1 \leq q \leq r$. Again applying condition 2 of Definition 4.1 to the square modules $S_{i,j}^q$ for that specific value of q, it turns out that

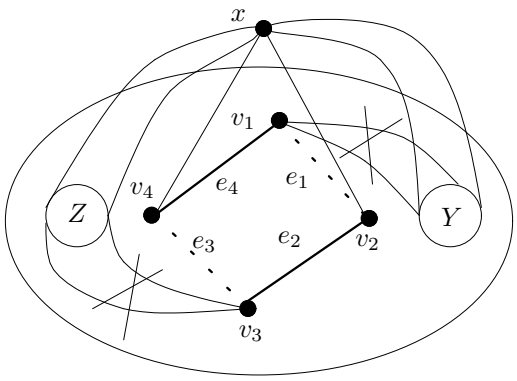

FIG. 9. *The presquare module.*

the same q is used for each $0 \le i \le d$. In particular, if we focus on the 2-alternators of the grouping modules, D provides a K_{d+1}-decomposition of the $H_{d+1,3}$-subgraph of each GR_A. By Lemma 2.2, it is either K^+ or K^-. Therefore, $X = \{A | D_A^+ \subset D\}$ forms a solution for I. □

It now remains to argue that square modules indeed exist. Notice that condition 1 of Definition 4.1 might be met regardless of $g(H)$ because the degrees of vertices in the subgraph obtained do not depend on which one of the two pairs of edges is deleted. However, $g(H) > 1$ appears to be helpful for meeting condition 2, as indicated by the following lemma. (In contrast with condition 2, if $g(H) = 1$, then a D-part may contain two adjacent boundary edges.) This is why our first scheme did not become redundant once the second was developed.

LEMMA 4.3. *If $g(H) > 1$, then condition 2 of Definition 4.1 is a consequence of the apparently weaker requirement:*

$2'$. No D-part of an H-decomposition D of a modular extension of S_H is split.

Proof. Let D be an H-decomposition of a modular extension of $S = S_H(v_1, v_2, v_3, v_4)$. Let D' denote the set of all D-parts which include an interior edge and are hence entirely contained in S if condition $2'$ holds. Clearly, $R = S - \bigcup_{T \in D'} T$ is a subset of $B(S) = \{e_1, e_2, e_3, e_4\}$. Since $g(H) > 1$, the difference between the degrees of a vertex in two unions of disjoint H-subgraphs is either 0 or at least 2. Thus if condition 1 is satisfied, then R is a complete matching on $\{v_1, v_2, v_3, v_4\}$ that is either $R = \{e_1, e_3\}$ or $R = \{e_2, e_4\}$, which is the assertion of condition 2. □

The first step towards establishing the existence of S_H is the following construction of a *presquare* module for any given graph H.

The presquare module PS_H. Let H be any graph. In accordance with Wilson's theorem, select integers n and N such that K_n is H-decomposable and K_N is K_n-decomposable. Make N big enough to allow two vertex-disjoint copies of K_n in a K_n-decomposition of K_N. Select four vertices v_1, v_2, v_3, v_4 of the graph $K_N = (V, E)$ and two sets $Y, Z \subset V$ of $n - 2$ vertices each, disjoint from each other and from $\{v_1, v_2, v_3, v_4\}$. Insert a new vertex $x \notin V$ and define $PS_H(v_1, v_2, v_3, v_4)$ to be

$$(V \cup \{x\}, E - \{(v_1, y), (v_3, z) : y \in Y, z \in Z\} \cup \{(x, u) : u \in Y \cup Z \cup \{v_2, v_4\}\}).$$

Let the boundary $B(PS_H)$ of the module be the 4-cycle $\{e_1 = (v_1, v_2), e_2 = (v_2, v_3), e_3 = (v_3, v_4), e_4 = (v_4, v_1)\}$ (see Figure 9).

The presquare satisfies the first condition of Definition 4.1.

PROPOSITION 4.4. *Each of* $PS_H - \{e_1, e_3\}$ *and* $PS_H - \{e_2, e_4\}$ *is* H*-decomposable.*

To verify the proposition, delete the edges of the two n-cliques induced by $Y \cup \{x, v_2\}$ and by $Z \cup \{x, v_4\}$. If the two edges $e_1 = (v_1, v_2), e_3 = (v_3, v_4)$ are also deleted, then the remaining edges are those of the original K_N from which two n-cliques induced by $Y \cup \{v_1, v_2\}$ and by $Z \cup \{v_3, v_4\}$ are deleted. By the definition of n and N, This remaining graph can be partitioned to complete K_n-decomposition, and hence H-decomposition, of $S_H - \{e_1, e_3\}$. The same argument holds for $S_H - \{e_2, e_4\}$.

The means by which the presquare is used to construct the square module vary as various families of graphs H are considered.

4.1. The square module for 5-connected graphs. If H is 5-connected and $g(H) > 1$, we simply define $S_H = PS_H$. The four boundary vertices of PS_H make any split subgraph 4-separable. The assertion of condition $2'$ of Lemma 4.3 immediately follows.

4.2. Constructing the square module for 2-connected, 4-separable, nontriangular graphs H with $g(H) > 1$. When graphs H of lower connectivity are considered, we face a situation that is analogous to the one we dealt with in section 3.2. Here we take similar measures as we define a modified presquare module PS'_H. The construction here is more complex, and several copies of the modified presquare are required to form one square module. It so happens that the square module obtained fails in meeting the definition if H is either 1-separable or triangular. These two cases are treated separately.

Separating sets of two, three, or four vertices are involved here, and hence some more definitions are required.

DEFINITION 4.2. *A* minimal separating set (MS) *of a graph* $G = (V, E)$ *is a set of vertices* $S \subset V$*, such that* $(G - S) = (V - S, E - \{e : e \text{ is incident to an element of } S\})$ *is not connected and no proper subset of* S *has this property. An* S-component *is a subgraph of* G*, induced by the union of* S *and a connected component of* $G - S$*.*

A k-separating sequence (k-SS) *is a sequence* $Q = \{S_1, S_2, \ldots, S_n\}$ *of distinct MSs of cardinality* $|S_i| \le k$ *such that their cardinalities* $|S_1|, \ldots, |S_n|$ *form a nondecreasing sequence and for every* $1 \le i \le n - 1$*, all* S_j*'s,* $j > i$*, are contained in the same* S_i*-component. Let* $n_j(Q)$ *denote the number of MSs in* Q *which are of cardinality* j*. We define a partial order among* k*-SSs of* G *by* $Q_1 > Q_2$ *if* $n_j(Q_1) > n_j(Q_2)$ *for the smallest* j*, where* $n_j(Q_1) \ne n_j(Q_2)$*. A* maximal k-SS *is maximal with respect to that partial order.*

Let $Q = \{S_1, S_2, \ldots, S_n\}$ *be a* k*-SS of* G*. Let* $C_0(Q, G)$ *denote the union of the* S_1*-components which do not contain* S_2 *and let* $C_n(Q, G)$ *be one of the* S_n*-components which do not contain* S_{n-1}*. (If* $n = 1$*, then* $C_1(Q, G)$ *is any component and* $C_0(Q, G)$ *is the union of all the others.)*

PROPOSITION 4.5. *Let* H *be a subgraph of* G *and* $Q = \{S_1, \ldots, S_n\}$ *be a maximal* k*-SS of* H *such that no edge of* $G - H$ *is incident to any vertex of* $H - C_n(Q, H)$*. If* H' *is an* H*-subgraph of* G *which includes an edge* $e_0 \in C_0(Q, H)$*, then* S *is a (maximal)* k*-SS of* H'*.*

Proof. Since no edge of $G - H$ is incident to $V(H - C_n)$, the sequence Q is also a k-SS of G. Being as big as H, the subgraph H' includes an edge $e_n \in C_n(Q, G)$. The removal of any S_i disconnects e_0 from e_n; hence there exists an MS of H', $S' \subseteq S_i$. We should prove that $S' = S_i$. Take the smallest i for which $S' \subsetneq S_i$. Since H' is isomorphic to H and Q is maximal, S' must equal S_t for some $t < i$ (otherwise,

$(S_1, S_2, \ldots, S', \ldots) > Q)$, that is, $S' = S_t \subsetneq S_i$ for some $t < i$. This is a contradiction since no MS is a proper subset of another. □

The modified presquare module PS'_H. Recalling the construction of PS_H and Proposition 4.4, form an H-decomposition D of $PS_H - \{e_1, e_3\}$, where $e_1 = (v_1, v_2)$ and $e_3 = (v_3, v_4)$. Let $Q = (S_1, \ldots, S_n)$ be a maximal 4-SS, where $S_n = \{x_1, \ldots, x_r\}$, such that $d(x_r)$ is minimum among all maximal 4-SSs. Select a vertex $z \notin S_n$ which is adjacent to x_r in $C_n(Q, H)$.

For the D-part H_{v_1}, which contains the edge (v_1, v_4), select $x_r(H_{v_1}) = v_1$ and $z(H_{v_1}) = v_4$. (No constraint holds regarding the roles of v_1 and v_4 in H_{v_1} since D is formed by decomposing complete graphs.) Also, verify that v_3 is not a vertex of H_{v_1}.

From the D-part H_{v_1}, construct $H_{v'_1}$, a new copy of H as follows: For every $u \in V(H_{v_1})$ such that $(u, z(H_{v_1}) = v_4) \notin E(H_{v_1})$, replace u in H_{v_1} by a new vertex u'. Also, add a new vertex v'_1 to replace v_1 in the role of $x_r(H_{v_1})$.

Similarly, let the role of x_r and z in the D-part H_{v_3}, which includes the edge (v_3, v_2), be played by the vertices v_3 and v_2 in that order. (Note that (v_3, v_2) can be any edge of an n-clique that is vertex disjoint from the clique which includes (v_1, v_4).) Using the same scheme as above, construct $H_{v'_3}$ from the D-part H_{v_3}. Also, add a new vertex v'_3 to replace v_3 in the role of $x_r(H_{v_3})$.

Define $D' = (D - \{H_{v_1}, H_{v_3}\}) \bigcup \{H_{v'_1}, H_{v'_3}\}$ and let PS'_H be the union of all $T \in D'$ and the edges $e'_1 = (v'_1, v_2)$ and $e'_3 = (v'_3, v_4)$. The boundary vertices of PS'_H are v'_1, v_2, v'_3, v_4 and the 4-cycle $e'_1, \ldots, e'_4$ on these vertices, in that order, is the boundary of the module. We refer to that specific copy as $PS'_H(v'_1, v_2, v'_3, v_4)$.

PROPOSITION 4.6. *The modified presquare module satisfies condition* 1 *of Definition* 4.1.

Proof. Obviously, D' is an H-decomposition of $PS'_H - \{e'_1, e'_3\}$. Furthermore, the neighborhood of v_2 in PS_H is identical to that of v_4. The vertex v_4 in H_{v_1} plays the role of $z \in V(H_{v_1})$. The neighbors of v_4, except for v_1, were not changed and v_2 is not a vertex of H_{v_1}. Similarly, the neighbors of v_2, except for v_3, were not changed and v_4 is not a vertex of H_{v_3}. Consequently, the neighborhoods of v_2 and v_4 are also identical in $H_{v'_1}$ and $H_{v'_3}$. Thus switching the roles of v_2 and v_4 in each $T \in D'$, we also obtain an H-decomposition for $PS'_H - \{e'_2, e'_4\}$. □

We are now in a position to prove the following stronger version of Proposition 4.4.

PROPOSITION 4.7. *If G is a modular extension of a modified presquare $PS'_H(v'_1, v_2, v'_3, v_4)$ which admits an H-decomposition D, then there exist two D-parts $H(PS'_H, v'_1)$ and $H(PS'_H, v'_3)$, entirely contained in PS'_H, such that each of the degree of v'_1 and that of v'_3 in $PS'_H - \{H(PS'_H, v'_1), H(PS'_H, v'_3)\}$ is at most* 1.

Proof. Let $Q = (S_1, \ldots, S_n)$ be the maximal 4-SS of the subgraph $H_{v'_1}$ of PS'_H, as defined above. By the construction of $H_{v'_1}$, the sequence Q is also a 4-SS of PS'_H and of G. To verify the proposition, take a D-part H' which includes an edge $e_0 \in C_0(Q, H)$. By Proposition 4.5, Q is a 4-SS of H'. Regarding the degree of v'_1, this vertex belongs to the nth SS of Q, $S_n = \{x_1, \ldots, x_r\}$. The sequence Q was selected to make the degree of x_r the minimum. Thus $d(v'_1)$ in H' is at least $d(x_r)$ (in H). If H' includes any edge out of PS'_H, then the separating 4-set of G, $\{v'_1, v_2, v'_3, v_4\}$, is also a separating 4-set of H' which obviously does not contain S_n (since only v'_1 is included in S_n) and can be appended to Q to form a greater 4-SS-sequence — a contradiction, which implies that $H' \subseteq PS'_H$. The degree of v'_1 in PS'_H is $d(x_r) + 1$. (It was inserted to replace x_r and then an edge e'_1 was added.) Recalling that $d(v'_1)$ in H' is at least $d(x_r)$, H' is the D-part $H(PS'_H, v'_1)$, as the proposition states. The same argument

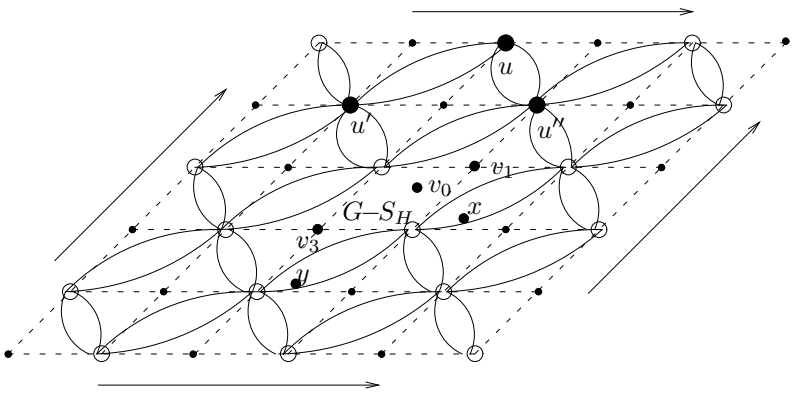

FIG. 10. *G'. The doted grid lines are not edges of the graph and are drawn for reference only. "$\circ$" and "$\bullet$" denote fat and thin vertices, respectively. The vertices x and y can be located in any of the squares surrounding v_1 and v_3.*

can be applied to v_3' to obtain $H(PS_H', v_3')$. □

In light of Proposition 4.7, we refer to the boundary vertices v_1' and v_3' as the *thin* vertices of the modified presquare, and, accordingly, v_2 and v_4 are the *fat* ones.

Constructing the square module S_H. Start with an $m \times m$ (or $(m+1) \times (m+1)$ if m is odd) rectangular grid on the two-dimensional torus. Let one square of the grid be the boundary of S_H and let the vertices of this square be denoted by v_1, v_2, v_3, v_4. Fill all of the other grid squares with copies of PS_H' whose boundaries intersect according to their geometric adjacency. While doing so, make each grid vertex either thin in all of the modified presquares which contain it or fat in all of them. Thus a "thin" "fat" 2-coloring of the grid vertices is induced. Let v_1 and v_3 be colored "thin." The graph obtained is the square module $S_H(v_1, v_2, v_3, v_4)$. A modular extension of S_H can be represented by filling the empty boundary square with $G - S$ (see Figure 10).

LEMMA 4.8. *S_H is a square module* (*cf. Definition* 4.1).

Proof. As a consequence of Propositions 4.6 and 4.7, condition 1 of Definition 4.1 is satisfied by S_H. We now prove that condition $2'$ of Lemma 4.3 is also satisfied.

Let D be an H-decomposition of a modular extension G of S_H. Let G' denote the graph obtained from G by deleting all of the D-parts $H(PS_H', v_1')$ and $H(PS_H', v_3')$, defined in Proposition 4.6, from all the PS_H''s in S_H. As a result of that proposition, each thin grid vertex, except v_1 and v_3, is completely saturated by the above D-parts and is hence isolated in G'. The remainder of each modified presquare is a "diagonal *strip*" connected to the rest of G' by the two fat grid vertices, to which we refer as the *end vertices* of that strip. There might remain a single edge connecting v_1 to an interior vertex x of S_H and one connecting v_3 to an interior vertex y (in addition to many vertices adjacent to v_1 and to v_3 in $G - S_H$).

Let H_0 be an H-subgraph of G' which contains a vertex v_0 of $G - S_H$. Assume that H_0 contains an interior vertex of S_H. As an H-subgraph, H_0 is too small to go around the whole torus. Let u be a grid vertex in H_0 which is furthest (in geometric distance on the torus) from the boundary square. At most two strips lead from u to the boundary and thus either H_0 is 1-separable or it is triangular by u and the other end vertices of the above two strips u' and u'' (see Figure 10). More careful attention should be paid to the case where H_0 is limited to the squares which surround the boundary and includes the edge (v_1, x) (and/or (v_3, y)). A short case analysis shows

that also in that scenario H_0 is either 1-separable or triangular by v_1, x, and a certain grid vertex whose identity depends on the exact location of x. Since H is 2-connected and nontriangular, the above leads to a contradiction and thus condition $2'$ is satisfied. □

4.3. The reduction for 1-separable nontriangular graphs. For a 1-separable graph H, we first select a particular 2-connected component C of H. The graph $H - C$ is called the *tail* of H. Given an instance I of 3^d-XC, we construct $G_C(I)$ and then expand it to obtain $G_H(I)$ by inserting the right number of tails, hanging at each vertex. Being 2-connected, C can replace H in the scheme described in the last section. Yet some minor modifications of the construction of $G_C(I)$ are required to cover the case where $g(C) = 1$. The presquare module is replaced by a structure which we call a new presquare module, NS_H; this is also an expansion of a known module, the modified presquare module, PS'_C.

Careful selection of C assures that an H-decomposition of $G_H(I)$ (and of NS_H) implies a C-decomposition of $G_C(I)$ (and of PS'_C). Finally, we claim that every C-decomposition of $G_C(I)$ indeed implies a solution for I.

This subsection is divided into three parts. In the first part, we define the notion of expansion and describe the new presquare module. In the second part, we show that an H-decomposition of an expanded graph implies a C-decomposition of the original one. We conclude this subsection by showing that C-decomposition of $G_C(I)$ implies a solution for I when $g(C) = 1$. For $g(C) > 1$, this fact was already shown in section 4.2. We start by stating the rules by which the subgraph 2-connected block C is selected.

Let x be a separating vertex of H such that $\{x\}$ is the last MS of a maximal 1-SS and let C be a 2-connected $\{x\}$-component. Choose x and C to make $|E(C)|$ the maximum among all such selections. If such C does not exist, then H contains a vertex of degree 1. NP-completeness for that case is proven in [18].

We are now in a position to define the expanded graph.

Definition 4.3.

- *Let D be an H-decomposition of G and let x and v be vertices of H and G, respectively. We define $N(x, v, D)$ to be the number of D-parts H' for which $x(H') = v$.*
- *Let x be a separating vertex of H and let C be an $\{x\}$-component of H. Let D be a C-decomposition of a graph G. We construct the $\{H, C, D\}$-expansion G' as follows: For each vertex v of G, construct $n(v) = N(x, v, D)$ copies of $H - C$, in which v is identified with x and the other vertices are new. These copies are denoted by $(H - C)_{i,v}$ for $1 \le i \le n(v)$ and $v \in V(G)$. The expanded graph G' is*

$$G' = G \bigcup_{v \in V(G)} \bigcup_{1 \le i \le n(v)} (H - C)_{i,v}.$$

The new presquare module NS_H. Let D be a C-decomposition of PS'_C. We define the new presquare module, $NS_H(D)$, to be an $\{H, C, D\}$-expansion of PS'_C.

In section 4.2, it is shown that the modified presquare module PS'_C satisfies both condition 1 of Definition 4.1 and Proposition 4.7. Moreover, these two conditions are sufficient for constructing a square module that satisfies Definition 4.1. We now show that the definition of NS_H is independent of the selection of D and prove the conditions satisfied by the new presquare module.

LEMMA 4.9.

1. *$PS_C(v_1,\ldots,v_4)-\{e_1,e_3\}$ admits a C-decomposition D_1 such that $N(x,v_2,D_1) = N(x,v_4,D_1)$.*
2. *There exist C-decompositions D_1 and D_2 of $PS'_C - \{e_1,e_3\}$ and $PS'_C - \{e_2,e_4\}$, respectively, such that $N(x,v_2,D_1) = N(x,v_4,D_1) = N(x,v_2,D_2) = N(x,v_4,D_2)$.*
3. *$NS_H = NS_H(D_1) = NS_H(D_2)$ is well defined and satisfies condition 1 of Definition 4.1.*
4. *The new presquare module NS_H satisfies Proposition 4.7 if every H-decomposition of NS_H implies a C-decomposition of a PS'_C subgraph of NS_H.*

Proof.

1. Recall that by its definition, $PS'_C - \{e_1,e_3\}$ is K_N-decomposable for some constant N for which K_N is C-decomposable. The total symmetry of K_N clearly allows the required structure of D_1.
2. Let D_1 be as above and let D_2 be the decomposition obtained from D_1 by switching the roles of v_2 and v_4.
3. Add to each D_i-part ($i = 1,2$) one copy of $H - C$ to obtain an H-decomposition in accordance with condition 1 of Definition 4.1.
4. Since PS'_C satisfies Proposition 4.7, the new presquare module NS_H also satisfies Proposition 4.7 if every H-decomposition of NS_H implies a C-decomposition of a PS'_C-subgraph. □

LEMMA 4.10. *Every H-decomposition of G_H implies a C-decomposition of G_C, where G_H is an $\{H,C,D\}$-expansion of G_C.*

Proof. Let D be an H-decomposition of G_H. If each $\{x\}$-component of H is isomorphic to C, then each D-part is an edge-disjoint union of C-subgraphs. Therefore, assume that not all of the $\{x\}$-components are isomorphic. We wish to prove that for every $D' \in D$, the set $E(D') \bigcap E(G_C)$ is an edge-disjoint union of copies of C. Take any separating vertex $v \in V(G_C) \subset V(G_H)$ and any $\{v\}$-component C' in G_H, which is edge-disjoint from G_C.

Note that C was selected as the end component of a maximal sequence of separating vertices and hence at most one $\{x\}$-component of H is 1-separable. First, assume that C' is 1-separable. Let H' be a D-part that intersects C' and contains a maximal path of separating vertices in C'. Since the size of H' equals the size of H, the vertex v is also a separating vertex of H'. Therefore, H' contains a maximal path of separating vertices in H and hence does not contain any separating vertex from another tail of H. Thus at most one 1-separable component of H is contained in each D-part. Since the number of such components in G_H equals $N = \frac{E(G_H)}{E(H)}$, each 1-separable component of H is contained in exactly one D-part.

The graph $G_H - G_C$ contains N edge-disjoint copies of $H - C$, i.e., N edge-disjoint copies of each 2-connected component of H, except C. Since $E(C)$ was chosen to be maximum, no component of $G_H - G_C$ is shared between more than one D-part. (Otherwise, there will be too many small components.) If we remove all of those components from D, we obtain a C-decomposition of G_C. □

From this presquare module, we construct the modified square module S'_H following the construction for 2-connected, nontriangular H, replacing each PS'_H by a copy of NS_H. Since the new presquare module satisfies both condition 1 of Definition 4.1 and Proposition 4.7, the square obtained satisfies the following conditions:

1. Each of $S'_H - \{e_1,e_3\}$ and $S'_H - \{e_2,e_4\}$ is H-decomposable.
2. No D-part of an H-decomposition D of a modular extension of S'_H is split.

This second condition replaces condition 2 of Definition 4.1 only when $g(C) > 1$. The rest of the proof for nontriangular, 1-separable graphs therefore takes different paths for $g(C) > 1$ and for $g(C) = 1$. Notice that since H is nontriangular, so is C.

The case where $g(C) > 1$. For an instance $I = (U, \mathcal{A})$ of 3^d-XC, construct $G = G_C(I)$ (as defined in section 2.2), replacing each square module by the above modified square S'_H. Let $S(G)$ be the union of all square modules in G. Let D be any C-decomposition of $G_C(I)$ and let $D' = \{P : P \in D, P \not\subset S(G)\}$. Notice that $n(v) = N(z, v, D')$ is independent of D (see section 4.2). Finally, define $G_H(I)$ to be an $\{H, C, D'\}$-expansion of G.

By Lemma 4.10, every H-decomposition of $G_H(I)$ implies a C-decomposition of $G_C(I)$ and hence a solution for the instance I.

The case where $g(C) = 1$. When $g(C) = 1$, we modify the construction of $G_C(I)$. The first step in the construction of the alternator was the selection of a vertex u, for which $d(u)$ was maximum. The selection of u changes when $g(C) = 1$, but otherwise the construction remains the same. Recall that the construction of $G_C(I)$ did not involve any constraints on $d(u)$ and $g(C)$. (The constraints were required only for the correctness proof.)

The graph $G_H(I)$ is therefore, constructed as follows: Select a vertex z in C and let $d = d(z)$. Given an instance $I = (U, \mathcal{A})$ of 3^d-XC, construct $G_{C,z}(I)$ with the following exception: For any 2-alternator module in $G_{C,z}(I)$ and $0 \le i \le d$, let $w_{i,i+1}$ be a "thin" vertex in $S^1_{i,i+1}$ (additions modulo $d+1$) and let $w_{i+1,i}$ be a "thin" vertex in $S^2_{i+1,i}$ (see the discussion in section 4 of the r-alternator module for the definition of $w_{i,j}$ and $S^q_{i,j}$). Similarly to the case where $g(C) > 1$, let $G_H(I)$ be an $\{H, C, D'\}$-expansion of $G_C(I)$.

The validity of the construction follows from Lemma 4.11 and the selection of z.

LEMMA 4.11. *H-decomposition is* NPC *if there exists a vertex z in C such that for every C-decomposition D of $G_{C,z}(I)$, each wing is contained in exactly one D-part.*

Proof. Suppose z is a vertex which satisfies the above and let D be a C-decomposition of $G_{C,z}(I)$. Take any 2-alternator of $G_{C,z}(I)$, $A = 2\text{-}A_C$, and let D_i, $0 \le i \le d$, be the D-parts which are internal to A but not to any square module. Since each wing is contained in exactly one D-part, $V(D_i)$ is $V(H_i^-) \bigcup \{v_i^{q_i}\}$ for some $q_i \in \{1, 2\}$.

We first show that $q = q_0 = \cdots = q_d$. Suppose without loss of generality that $q_0 = 1$. Since $w_{0,1}$ is "thin" in $S^1_{0,1}$ and $w_{1,0}$ is "thin" in $S^2_{1,0}$, the edge $(w_{1,0}, v_1^2)$ is not in D_1 and therefore q_1 also equals 1.

Now take any H-decomposition D of $G_{H,z}(I)$. By Lemma 4.10, D contains a C-decomposition D' of $G_{C,z}(I)$. As seen above, all the 2-alternators are decomposed properly and a solution for I is obtained. □

To complete this section we show how vertex z is selected in order to meet the condition of Lemma 4.11. (For $g(C) > 1$, this condition is a simple corollary of condition 2 of Definition 4.1.)

First, assume that x is adjacent to every vertex in C and select z to be x. Let D be a C-decomposition of $G_C(I)$, which exists by Lemma 4.10, and let D' be the set of D-parts which are not included in any square module. Take any vertex $w = w_{i,j}$. If w plays the role of x in a D'-part, then its vertex set V is included in $\{w_{i,k}, 0 \le k \ne i \le d(x)\} \bigcup \{w_{j,i}\} \bigcup \{v_i^q, q = 1, 2, \ldots\}$. If $w_{j,i} \in V$, then its degree is 1—a contradiction. Therefore, each wing is contained in at least one D'-part and a counting argument shows that it must contain all of the wing. Hence all vertices playing the role of x

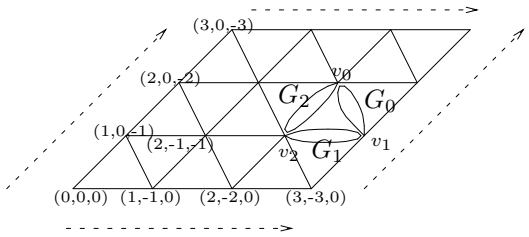

FIG. 11. *$H_{3,3}$ embedded in the (two-dimensional) torus (and modified for M_p).*

are v_i^q's. Since each v_i^q is connected to at most one wing, each wing is contained in exactly one D'-part.

Finally, we can assume that there exists a vertex v in C which is not adjacent to x. In that case, select z to be a vertex whose distance from x is maximal and denote its distance from x by l.

Again, let D' be a C-decomposition of $G_C(I)$ after removing the parts which are included in square modules. Take any D'-part P which contains $x(H_i^-)$. It is easy to see that $x(P)$ is $x(H_i^-)$. Moreover, P contains (entirely) the first $l-1$ levels of the BFS tree of H_i^-, rooted at x. Any vertex in $V(P)\setminus V(H_i^-)$ must be in the lth level of the tree and it must be adjacent to some vertex from the $(l-1)$st level. Since every $w_{j,i}$ is adjacent to exactly one vertex of another wing, each vertex of P which is not in H_i^- is not in any other wing. (Otherwise, C is 1-separable.) Thus each wing is contained in exactly one D'-part.

5. Triangular graphs. This section completes the proof of Theorem 1.1 by proving the following.

LEMMA 5.1. *H-decomposition is* NPC *if H is a triangular graph.*

The proof of Lemma 5.1 is a modification of Holyer's proof for triangles [10], where he presents a polynomial-time reduction of 3SAT to K_3-decomposition.

DEFINITION 5.1. *An instance of* 3SAT *is a set of clauses $C=\{C_1,\dots,C_r\}$ in variables $u_1,\dots,u_s$. Each clause C_i consists of three literals $l_{i,1}$, $l_{i,2}$, and $l_{i,3}$, where a literal $l_{i,j}$ is either a variable u_k or its negation $\overline{u_k}$. The problem is to determine whether C is satisfiable, that is, whether there exists a Boolean assignment to the variables which simultaneously satisfies all of the clauses in C. A clause is satisfied if one or more of its literals has value "true."*

The basic building block used for our reduction is a modified version of the Holyer graph $H_{3,p}$. For every $n\ge 3$ and $p\ge 3$, the Holyer graph is $H_{n,p}=(V_{n,p},E_{n,p})$, where

$$V_{n,p}=\left\{x=(x_1,\dots,x_n)\in\mathbb{Z}_p^n \ :\ \sum_{i=1}^{n}x_i\equiv 0\right\},$$

$$E_{n,p}=\{(x,y):\exists i,j \text{ such that } y_k\equiv x_k \text{ for } k\neq i,j \text{ and } y_i\equiv x_i+1, y_j\equiv x_j-1\},$$

and "$\equiv$" stands for congruence mod p (see Figure 11). Note that $H_{n,p}$ can be regarded as embedded in the $(n-1)$-dimensional torus $T^{n-1}=S^1\times\cdots\times S^1$ and that the local structure of $H_{n,p}$ is the same for each p. ($H_{n,p}$ should not be confused with the H-decomposition subgraph.)

LEMMA 5.2. *The graph $H_{3,p}$ has the following properties:*

1. *The degree of each vertex is* 6.
2. *The largest complete subgraph is a triangle.*

3. *The number of triangles which include each vertex is* 6.
4. *Each edge occurs in exactly two triangles.*
5. *Each two distinct triangles either are edge disjoint or have exactly one edge in common.*
6. *There are exactly two distinct edge partitions of $H_{3,p}$ into K_3's.*

All the above listed facts are trivial for $n = 3$. A proof in the wider frame of general n can be found in [10].

The two K_3 partitions of $H_{3,p}$ will be called "true" and "false" partitions, denoted by *T-partition* and *F-partition*. Two K_3's in $H_{3,p}$ are called neighbors if they have a common edge. Also, define a *patch* to be the subgraph of $H_{3,p}$ consisting of the vertices and edges of a particular K_3 and its neighbors. It is a T-patch if the central K_3 belongs to the T-partition, and it is an F-patch otherwise. Two patches P_1 and P_2 in $H_{3,p}$ are called *noninterfering* if the distance $d(x, y)$ in $H_{3,p}$ between vertices $x \in V(P_1)$ and $y \in V(P_2)$ is always at least 10.

Proof of Lemma 5.1 *for* 2*-connected graphs.* Let H be a 2-connected graph which is triangular by vertices v_0, v_1, and v_2 and components G_0, G_1, and G_2. Select v_0, v_1, v_2 and G_0, G_1, G_2 such that $|E(G_0)|$ is maximum among all possible triangular representations of H.

Let $I = \{C_1, \ldots, C_r\}$ in s variables $u_1, \ldots, u_s$, where each C_i consists of literals $l_{i,1}, l_{i,2}$, and $l_{i,3}$. We construct a graph $G_H(I)$ for which H-decomposition is equivalent to 3SAT on I.

Label each of the vertices of $H_{3,p}$ either v_0, v_1, or v_2 such that the labeling forms a proper 3-coloring and replace every edge (v_i, v_{i+1}) (mod 3) by a copy of the component G_i. Let all of these copies of G_0, G_1, and G_2 be disjoint except for the common original vertices of $H_{3,p}$. In the graph obtained, M_p, we have a copy of H replacing every triangle of $H_{3,p}$. Accordingly, M_p admits T and F H-decompositions and has its T- and F-patches (see Figure 11). Every H-subgraph of M_p obtained from a triangle of $H_{3,p}$ will be referred to as a K_3'.

Take a copy U_i of M_p to represent each variable u_i and copies $C_{l,1}$, $C_{l,2}$, and $C_{l,3}$ of M_p to represent each clause C_l. Join these copies of M_p together as follows: If $l_{i,j}$ is u_k, then identify an F-patch of $C_{i,j}$ with an F-patch of U_k. If $l_{i,j}$ is $\overline{u_k}$, then identify an F-patch of $C_{i,j}$ with a T-patch of U_k. Also, join $C_{i,1}$, $C_{i,2}$, and $C_{i,3}$ for each i by identifying one F-patch from each and then removing the edges of the central K_3'. Choose all patches which occur in a single M_p copy to be noninterfering. The graph obtained is $G_H(I)$.

If C is satisfiable, we partition $G_H(I)$ by partitioning U_k according to the truth of u_k in a satisfying assignment, choosing one "true" literal $l_{i,j}$ for each i and F-partitioning the corresponding $C_{i,j}$. On the other hand, suppose that there exists an H-decomposition D of $G_H(I)$. The maximality of G_0 implies $\{w, z\} \subset \{v_2\} \cup V(G_0)$ for each separating pair $\{w, z\}$ of H such that $w \in V(G_i)$ and $z \in V(G_j)$ $(i \neq j)$.

First, we assume that each of the three components of each K_3' is included in exactly one D-part. Thus it is enough to consider K_3-decompositions of $G_H'(I)$, obtained from $G_H(I)$ by replacing each such component by a simple edge.

Suppose that there is a K_3-decomposition of $G_H'(I)$, and consider a particular copy M of a modified M_p (that is, a copy of $H_{3,p}$) involved in the construction of $G_H(I)$. Take a D-part, say B, which is in M but not near any join. Clearly, the neighbors of B do not belong to D, the neighbors of neighbors of B do belong to D, and so on. Therefore, the edges of M, except perhaps those involved in joins, are all T-partitioned or all F-partitioned. Thus we may say that M is T- or F-partitioned.

Now suppose $l_{i,j}$ is u_k and consider the join between $C_{i,j}$ and U_k. We claim that the edges in the vicinity of this join are K_3-decomposable if and only if at least one of $C_{i,j}$ and U_k is T-partitioned. If (say) $C_{i,j}$ is T-partitioned, this accounts for all of the edges of $C_{i,j}$ near the joining patch except for those of the patch itself. The patch can be regarded as belonging to U_k, which can then be locally partitioned in either way. If, on the other hand, both $C_{i,j}$ and U_k are F-partitioned, a similar argument shows that the edges of the patch not belonging to the central K_3 are forced to belong to the F-partitions of both $C_{i,j}$ and U_k, which is a contradiction. Similarly, if $l_{i,j}$ is $\overline{u_k}$, then either $C_{i,j}$ is F-partitioned or U_k is T-partitioned.

Finally, we show that each of the three components of K_3' is included in exactly one D-part. Let S be the multiset of all SPs of all D-parts and consider one particular K_3', say A, in $G_H(I)$. We show that if a D-part does not include all components of K_3', then the total number of separating pairs in all D-parts (i.e., $|S|$) is too large. Obviously, S contains all SPs included in one of the three components of each K_3' in $G_H(I)$. Therefore, the only SPs which are not guaranteed to be in S are $\{v_2, w\}$, $w \in V(G_0) \setminus \{v_0, v_1\}$ for some K_3'-subgraph of $G_H(I)$. If there is no such SP in H, then a simple counting argument implies that each of the three components of A is contained in exactly one D-part. Hence assume that H contains $n > 2$ separating pairs, $\{v_2, w_1\}, \ldots, \{v_2, w_n\}$ such that $w_i \in G_0$ for $i = 1, \ldots, n$ ($v_0 = w_1$ and $v_1 = w_n$). If more than one D-part intersects the G_0 component of A, then there are more than $\binom{n}{2} + n - 2$ separating pairs in S, more than S could possibly contain. Therefore, G_0 intersects with exactly one D-part and each of G_0, G_1, and G_2 is included in exactly one D-part. □

To complete the proof of Theorem 1.1, we need only prove Lemma 5.1 for 1-separable graphs. H-decomposition of $G_H(I)$ is definitely implied by the satisfiability of I, exactly as described in the last proof. The other direction does not follow since the counting argument is highly dependent on 2-connectivity. To overcome this difficulty, we replace SSs by corresponding SPs. As in section 4.3, we define C, a 2-connected component of H. Lemma 4.10 then implies that H-decomposition of $G_H(I)$ contains a C-decomposition of a subgraph of $G_H(I)$, from which the satisfiability of I follows. □

6. Concluding remarks. The existence and structure of graph decompositions for various pairs (G, H) is a well-established branch of "classical" graph theory (see, e.g., [2] and [16] for a partial list of references), and the natural question regarding the computational complexity of the corresponding decision problems arose long ago. Despite substantial effort devoted to that issue, no general answer has been given until now.

The history of the problem solved by Theorem 1.1 is sketched in the introduction. It seems that the use of Wilson's theorem was the key step toward our general proof. Without it, the problem was settled only for complete graphs and a rather limited family of graphs H, all with $g(H) = 1$. Yet, also with Wilson's theorem at hand, many technical difficulties were tackled along the way.

Notice that our theorem does not completely settle the complexity status of all graph-decomposition problems. However, very recently, after the first version of this paper had already been submitted for publication, we heard that Bryś and Lonc [5] has presented a polynomial time-algorithm to decide H-decomposability whenever H has no component with more than two edges. Their presentation follows many partial results obtained during the last 15 years, most of which are listed in the introduction.

Apparently, graph decomposition presents a pattern which was already observed

in graph coloring, satisfiability, and many other graph-theoretical and combinatorial decision problems. The border between polynomial and NPC problems is crossed once a simple size parameter of the problem changes from 2 to 3. Unlike other combinatorial problems (e.g., graph isomorphism) whose complexity status is an open problem, graph decomposition, being in NPC, does not provide any consequences regarding the general complexity hierarchy. In that sense, our result brings no surprise. It just confirms the expected. It is surprising, however, how complicated the proof turned out to be, in comparison to NP-completeness proofs of other basic graph-theoretical problems. Of course, there might be a much simpler way to get to that result, a way that we — as well as others who have dealt with the problem since the early 1980s—have thus far missed.

THE FOURTH MOMENT METHOD*

BONNIE BERGER†

Abstract. Higher moment analysis has typically been used to upper bound certain functions. In this paper, we introduce a new combinatorial method to *lower bound* the expectation of the absolute value of a random variable X by the expectation of a quartic in X. In the special case where we are looking at the absolute value of a (weighted) sum of $\{-1, +1\}$ unbiased random variables, we achieve tight bounds, using only a fourth moment, for the *total discrepancy* of a set system. Because the fourth moment depends only on 4-wise independence, our bounds will hold over polynomially sized distributions, and so these bounds will be directly applicable in removing randomness to obtain *NC* algorithms. We obtain the first *NC* algorithms for the problems of *total discrepancy, maximum acyclic subgraph, tournament ranking, the Gale–Berlekamp switching game,* and *edge discrepancy.* We show that for most of these applications it is truly *necessary* to consider a fourth moment by exhibiting a 3-wise independent distribution which does not achieve the required bounds. Our method is strong enough to give a new combinatorial bound on tournament ranking.

Key words. removing randomness, set discrepancy, Gayle–Berlekamp switching game, maximum acyclic subgraph

1. Introduction.

In the design of parallel algorithms, randomness can often be used as a resource. Especially for parallel algorithms, however, generating many random bits can be expensive. We would like to be able to reduce the number of random bits that an algorithm needs to guarantee good performance—or even perhaps remove the randomness entirely. The key to the general methodologies for removing randomness from parallel algorithms [14, 17, 1, 18, 5, 3] involves showing that the analysis of the algorithm's good performance depends on *lesser independence.* This will allow us, for constant k-wise independent distributions, for example, to perform an exhaustive search [14, 17, 1] on a polynomially sized sample space.

For a large class of graph-theoretic randomized algorithms, the "goodness" of a particular solution is measured in terms of balance. More precisely, let $\mathcal{A} \subseteq 2^{\Gamma}$, $|\mathcal{A}| = |\Gamma| = n$, be a family of finite sets. Let $Y = \langle Y_1, \ldots, Y_n \rangle \in \{-1, +1\}^n$ be a 2-coloring of the underlying points in Γ (i.e., Y_i is the color of the ith element of Γ). Define $S_i(Y) = \sum_{j \in A_i} Y_j$, where $A_i \subseteq \mathcal{A}$. Then $\mathrm{disc}(Y) = \max_{1 \le i \le n} |S_i(Y)|$. The *set discrepancy* problem is to find a coloring Y such that $\mathrm{disc}(Y)$ is small. There is also a weighted version of the problem. Previous work has focused on upper bounding the expected maximum discrepancy of a set system over n sets; [2, 5, 19] give a good upper bound on the expected maximum discrepancy, using a $O(\log n)$th moment to do so. A good upper bound on the expected maximum discrepancy means that all sets are guaranteed to be nearly balanced, using only $O(\log n)$-wise independence. Since [2, 5, 19] also show how to derandomize algorithms whose analysis depends only on $O(\log n)$-wise independence, they obtain *NC* algorithms for set discrepancy, edge coloring, and lattice approximation.

On the other hand, problems such as tournament ranking take advantage of the fact that there will always be some positive discrepancy in each set. In this paper, we

†Laboratory for Computer Science and Department of Applied Mathematics, Massachusetts Institute of Technology, Cambridge, MA 02139 (bab@theory.lcs.mit.edu).

will be concerned with problems of this type: where a good solution is constructed by taking advantage of probabilistic *imbalance.* We will be interested in the *total discrepancy* of a set system. This is similar to set discrepancy above, except that we want to find a coloring Y such that $\texttt{tot-disc}(Y) = \sum_{i=1}^{n} |S_i(Y)|$ is large. We address the weighted version of this problem in section 3. A good lower bound on the expected *sum* of the discrepancies of the individual sets implies that the expected disparity between wins and losses will be large. To achieve *NC* algorithms for these problems which use randomness to obtain large total discrepancy, we will give such a lower bound based on lesser independent distributions.

We introduce a new combinatorial method to bound the expectation of an absolute value of a random variable X from below by a fourth moment. In the special case where we are looking at the absolute value of a (weighted) sum of $\{-1, +1\}$ unbiased random variables, we achieve a lower bound, using a fourth moment, for the *total discrepancy* of a set system. (It is easy to show that our bound is tight using only a second moment; see Lemma 3.3.) Since a fourth moment requires only 4-wise independence, this will allow us to use parallel derandomization techniques. Our lower bound for total discrepancy will match the previously well-known lower bound which requires n-wise independence [26].

We obtain the first *NC* algorithm for lower bounding total discrepancy, and this in turn will give us the first *NC* algorithms for the *Gale–Berlekamp switching game* and *edge discrepancy.* We also apply our fourth moment inequality to devise the first *NC* approximation algorithm for getting strictly more than half the arcs in the *maximum acyclic subgraph* problem and *tournament ranking.* These problems will be defined later in section 5. Although our algorithms for these problems are discrepancy-like in flavor, dependencies between random variables will prevent us from simply applying our discrepancy lower bounds. Instead, these problems will require a more involved application of our fourth moment method. The maximum acyclic subgraph problem, or its alternate formulation as the *feedback arc set* problem, arises in many applications, including machine-shop scheduling [16], generation of test vectors for circuits [24], register minimization in VLSI design [24], feedback minimization in systems [22], and circuit simulation through functional abstraction [15].

Finally, we show that it is truly *necessary* to consider a fourth moment. We exhibit a discrepancy problem and a 3-wise independent distribution for which we get very small expected total discrepancy. In fact, surprisingly, every point in the sample space of this 3-wise independent distribution yields very small total discrepancy. This shows that for lower bounding total discrepancy, 4-wise independence is both necessary and sufficient.

This threshold behavior for k-wise independence is particularly interesting since it shows that there are natural problems, which need only constant-wise independence but for which Luby's [18] parallel binary search procedure for pairwise and 3-wise independent sample spaces can be proved to be too weak. Parallel binary search techniques can sometimes be preferable to exhaustive search, even over constant-wise independent distributions, because exhaustive search can sometimes blow up the number of processors needed by the algorithm. Therefore, in order to obtain more efficient *NC* algorithms over constant-wise independent distributions, our result shows that we require more powerful methods to perform binary search in parallel, such as those found in [2, 5, 19].

A preliminary version of this paper appeared in [4].

2. The method. In this section, we present a new method for lower bounding the expectation of an absolute value with a fourth moment. Suppose we have an arbitrary random variable S and we are looking for a lower bound on $E[|S|]$. The argument is complicated by the fact that we are taking an expectation of an absolute value. In order to make things more manageable, we might consider S^2 in place of $|S|$. But then the problem arises that if $|S|$ is a little more than its expected value, then the contribution that S^2 makes to its expected value is proportionally much larger. This means that even if the expectation of S^2 is known to be large, we cannot say much about $E[|S|]$. Our solution will be to find a $c > 0$ for which $f(S) = c(S^2 - S^4/q) \leq |S|$ (where $q > 0$). Intuitively, we compensate for S^2 growing large by subtracting off a multiple of S^4, which grows even faster. We show that we can choose our constants c and q so that if $E[f(S)]$ is large, then $E[|S|]$ is large. This notion is captured in the following lemma.

LEMMA 2.1. *For all $X \geq 0$ and for all $q > 0$*

$$X \geq \frac{3\sqrt{3}}{2\sqrt{q}} \left(X^2 - \frac{X^4}{q} \right).$$

Proof. We want to find a c such that $X \geq (1/c\sqrt{q})(X^2 - X^4/q)$. Equivalently, we want a $c \geq (qX - X^3)/q^{3/2}$. If we differentiate the right-hand side of this equation to find the maximum value, we find that it occurs when $X = \sqrt{q/3}$. Plugging in this X, we get that the maximum value is $2/(3\sqrt{3})$. So we can set c to be this constant. Now plugging in for c, we get that

$$X \geq \frac{3\sqrt{3}}{2\sqrt{q}} \left(X^2 - \frac{X^4}{q} \right),$$

as claimed. □

THEOREM 2.2. *For any random variable S and for all $q > 0$,*

$$E[|S|] \geq \frac{3\sqrt{3}}{2\sqrt{q}} \left(E[S^2] - \frac{E[S^4]}{q} \right).$$

Proof. The proof follows from Lemma 2.1 by linearity of expectation. □

A special case of this theorem is particularly interesting, and we give it in the following corollary.

COROLLARY 2.3 (see [9, p. 194]). *For any random variable S,*

$$E[|S|] \geq \frac{E[S^2]^{3/2}}{E[S^4]^{1/2}}.$$

Proof. Plugging $q = 3E[S^4]/E[S^2]$ into Theorem 2.2, we obtain the desired result. Alternatively, Furedi has pointed out that this special-case form of the result can be proved as a consequence of Hölder's inequality [12, p. 140]. □

3. Tight bounds for total discrepancy using 4-wise independence. We are interested in lower bounding the expected total discrepancy of a family of sets using less independence. Weighted total discrepancy is similar to the unweighted case except that for each set $A_i \subseteq \mathcal{A}$, we let $\epsilon_{11}, \ldots, \epsilon_{nn} \in \mathbf{R}^1$ be the weights on its elements, where

[1] We can also extend these methods to obtain similar results for $\epsilon_{ij} \in \mathbf{C}$.

$\epsilon_{ij} = 0$ if $j \notin A_i$, and we define $S_i = S_i(Y) = \epsilon_{i1}Y_1 + \cdots + \epsilon_{in}Y_n$. The *weighted total discrepancy* problem is to find a coloring Y such that $\texttt{wt-tot-disc}(Y) = \sum_{i=1}^{n} |S_i|$ is large.

We apply the fourth moment method as given in section 2 to obtain a tight bound on total discrepancy in the case when the Y_i are chosen 4-wise independently at random. *NC* algorithms resulting from our bounds appear in section 5.2. First, we bound the expected discrepancy of a single set, A, since we can then use linearity of expectation to get a bound on the total discrepancy. Without loss of generality, suppose A has n elements.

LEMMA 3.1. *Let $Y_1, \ldots, Y_n$ be 4-wise independent variables, each being 1 or -1 with equal probability, and let $\epsilon_1, \ldots, \epsilon_n \in \mathbf{R}$. If $S = \epsilon_1 Y_1 + \cdots + \epsilon_n Y_n$, then*

$$E[|S|] \geq \sqrt{\frac{\epsilon_1^2 + \cdots + \epsilon_n^2}{3}}.$$

In the special case of unweighted discrepancy, when $\epsilon_i \in \{-1, +1\}$, then

$$E[|S|] \geq \sqrt{\frac{n}{3}}.$$

Proof. To get a lower bound on $E[|S|]$ using Theorem 2.2, we need to compute $E[S^2]$ and $E[S^4]$.

Before we compute the expected values, let us note the following facts:

1. $E[Y_i^t]$ is 0 when t is odd and 1 when t is even.
2. $E[Y_{i_1} \cdots Y_{i_t}] = E[Y_{i_1}] \cdots E[Y_{i_t}]$ when $t \leq 4$.

For notational convenience, henceforth in this paper, when we sum over an index i, we mean $i = 1, \ldots, n$, and when we sum over indices $i_1, \ldots, i_t$, we assume that they are all different.

Observe that

$$E[S^2] = \sum_i \epsilon_i^2 E[Y_i^2] + \sum_{i \neq i'} \epsilon_i \epsilon_{i'} E[Y_i Y_{i'}] = \sum_i \epsilon_i^2. \tag{3.1}$$

Also, observe that

$$\begin{aligned} E[S^4] &= \sum_i \epsilon_i^4 E[Y_i^4] + 4 \sum_{i,i'} \epsilon_i^3 \epsilon_{i'} E[Y_i^3 Y_{i'}] + 3 \sum_{i,i'} \epsilon_i^2 \epsilon_{i'}^2 E[Y_i^2 Y_{i'}^2] \\ &\quad + 6 \sum_{i,i',i''} \epsilon_i^2 \epsilon_{i'} \epsilon_{i''} E[Y_i^2 Y_{i'} Y_{i''}] + \sum_{i,i',i'',i'''} \epsilon_i \epsilon_{i'} \epsilon_{i''} \epsilon_{i'''} E[Y_i Y_{i'} Y_{i''} Y_{i'''}] \\ &= \sum_i \epsilon_i^4 + 3 \sum_{i,i'} \epsilon_i^2 \epsilon_{i'}^2. \end{aligned} \tag{3.2}$$

Plugging these values for $E[S^2]$ and $E[S^4]$ into Theorem 2.2 and choosing $q = (3\sum_i \epsilon_i^4 + 9\sum_{i,i'} \epsilon_i^2 \epsilon_{i'}^2)/\sum_i \epsilon_i^2$, we get that

$$E[|S|] \geq \frac{3\sqrt{3}}{2\sqrt{\frac{3\left(\sum_i \epsilon_i^4 + 3\sum_{i,i'} \epsilon_i^2 \epsilon_{i'}^2\right)}{\sum_i \epsilon_i^2}}} \left(\sum_i \epsilon_i^2 - \frac{\sum_i \epsilon_i^4 + 3\sum_{i,i'} \epsilon_i^2 \epsilon_{i'}^2}{\frac{3\left(\sum_i \epsilon_i^4 + 3\sum_{i,i'} \epsilon_i^2 \epsilon_{i'}^2\right)}{\sum_i \epsilon_i^2}} \right)$$
$$= \frac{3\sqrt{\sum_i \epsilon_i^2}}{2\sqrt{\sum_i \epsilon_i^4 + 3\sum_{i,i'} \epsilon_i^2 \epsilon_{i'}^2}} \left(\frac{2\sum_i \epsilon_i^2}{3} \right)$$
$$= \frac{(\sum_i \epsilon_i^2)^{3/2}}{(\sum_i \epsilon_i^4 + 3\sum_{i,i'} \epsilon_i^2 \epsilon_{i'}^2)^{1/2}}.$$

Squaring the first and last parts of this equation, we get that

$$E[|S|]^2 \geq \frac{(\sum_i \epsilon_i^2)^3}{\sum_i \epsilon_i^4 + 3\sum_{i,i'} \epsilon_i^2 \epsilon_{i'}^2} = \frac{(\sum_i \epsilon_i^2)(\sum_i \epsilon_i^4 + \sum_{i,i'} \epsilon_i^2 \epsilon_{i'}^2)}{\sum_i \epsilon_i^4 + 3\sum_{i,i'} \epsilon_i^2 \epsilon_{i'}^2} \geq \frac{\sum_i \epsilon_i^2}{3}. \qquad \square$$

By linearity of expectation, we obtain the following theorem, which provides a lower bound on the expected total discrepancy.

THEOREM 3.2. *Let $Y_1, \ldots, Y_n$ be 4-wise independent variables, each being 1 or -1 with equal probability. Then the expected total discrepancy*

$$E\left[\sum_{i=1}^n |S_i|\right] \geq \frac{\sum_{i=1}^n \sqrt{\epsilon_{i1}^2 + \cdots + \epsilon_{in}^2}}{\sqrt{3}}.$$

In the case of complete independence of the Y_i's, it has been shown [26] that the expected total discrepancy $E\left[\sum_{i=1}^n |S_i|\right] \geq \sqrt{2/\pi} \sum_{i=1}^n \sqrt{\epsilon_{i1}^2 + \cdots + \epsilon_{in}^2}$; that is, this gives a constant of $\sqrt{2/\pi}$ versus $1/\sqrt{3}$ in the theorem above.

The bounds in the preceding lemma and theorem are tight up to constant factors, as we show in the following lemma.

LEMMA 3.3. *Let $Y_1, \ldots, Y_n$ be pairwise independent variables, each being 1 or -1 with equal probability, and let $\epsilon_1, \ldots, \epsilon_n \in \mathbf{R}$. If $S = \epsilon_1 Y_1 + \cdots + \epsilon_n Y_n$, then*

$$E[|S|] \leq \sqrt{\epsilon_1^2 + \cdots + \epsilon_n^2}.$$

Proof. The proof follows simply from the fact that $E[X]^2 \leq E[X^2]$ for any random variable X and from the bound in equation (3.1). $\square$

In Theorem 3.2, we showed that the expected total discrepancy is large using only 4-wise independence. In what follows, we will show a slightly stronger result, namely, that the discrepancy is large with positive probability. Our proof will require the following inequality due to Cantelli [23], which achieves a slightly better bound than Chebyshev's inequality.

PROPOSITION 3.4 (Cantelli). *If X is a random variable with mean μ and variance σ^2, then for all $r \geq 0$,*

$$\Pr[X < \mu - r\sigma] \leq \frac{1}{r^2 + 1}.$$

By combining Cantelli's inequality with Lemma 3.1, we can directly show that there exists an $\alpha > 0$ such that $\Pr[|S| \geq \alpha\sqrt{\epsilon_1^2 + \cdots + \epsilon_n^2}]$ is bounded from below

by a constant. However, we can prove a more general result by combining Cantelli's inequality with fourth moment analysis, as in the following lemma.

LEMMA 3.5. *For any random variable S and $0 < \alpha < 1$,*

$$\Pr\left[\,|S| \geq \alpha\sqrt{E[S^2]}\,\right] \;\geq\; \frac{(1-\alpha^2)^2}{(1-\alpha^2)^2 + \frac{E[S^4]}{E[S^2]^2} - 1}.$$

Proof. We apply Cantelli's inequality (Proposition 3.4) to show that

$$\Pr\left[\,|S| \geq \alpha\sqrt{E[S^2]}\,\right] \;=\; \Pr\left[\,S^2 \geq \alpha^2 E[S^2]\,\right] \;\geq\; \frac{r^2}{r^2+1},$$

where $r = (1-\alpha^2)E[S^2]/\sqrt{E[S^4] - E[S^2]^2}$. Simplifying, this yields the desired bound. □

THEOREM 3.6. *Let $Y_1, \ldots, Y_n$ be 4-wise independent variables, each being 1 or -1 with equal probability, let $\epsilon_1, \ldots, \epsilon_n \in \mathbf{R}$, and let $0 < \alpha < 1$. If $S = \epsilon_1 Y_1 + \cdots + \epsilon_n Y_n$, then*

$$\Pr\left[\,|S| \geq \alpha\sqrt{\epsilon_1^2 + \cdots + \epsilon_n^2}\,\right] \;\geq\; \frac{(1-\alpha^2)^2}{(1-\alpha^2)^2 + 2}.$$

Proof. Use Lemma 3.5 and the fact that from equations (3.1) and (3.2), we have that $E[S^2] = \epsilon_1^2 + \cdots + \epsilon_n^2$ and $E[S^4] \leq 3(\epsilon_1^2 + \cdots + \epsilon_n^2)^2$. □

We set $\alpha = 1/\sqrt{3}$ to get the following corollary.

COROLLARY 3.7.

$$\Pr\left[\,|S| \geq \frac{\sqrt{\epsilon_1^2 + \cdots + \epsilon_n^2}}{\sqrt{3}}\,\right] \;\geq\; \frac{2}{11}.$$

We note that Theorem 3.6, when used directly in lower bounding the expected total discrepancy, does not yield as good a constant as we obtained in Theorem 3.2 above, i.e., we get $1/3$ versus the $1/\sqrt{3}$ achieved above. However, Corollary 3.7 will be useful later when we consider the problem of finding a sample point for which a constant fraction of the sets in a set system have large discrepancy.

4. Fourth moments are necessary. We now show that a fourth moment is actually necessary to achieve a lower bound on total discrepancy. We do this by exhibiting a discrepancy problem and a 3-wise independent distribution for which we get very small expected total discrepancy. In fact, every point in the sample space of this 3-wise independent distribution yields very small total discrepancy. Note that this also shows pairwise independence is not sufficient for lower bounding total discrepancy.

Distribution $\mathcal{D}$ (also see [18]) is as follows. Let $n = 2^{l-1}$ and $a_i = \langle i_1, \ldots, i_{l-1}, 1\rangle$, where $\text{bin}(i) = \langle i_1, \ldots, i_{l-1}\rangle$ is the binary expansion of i. Let $\omega = \langle \omega_1, \ldots, \omega_l\rangle$ be picked uniformly from Z_2^l. Define random variables $X_0, \ldots, X_{n-1}$ such that

$$X_i = a_i \cdot \omega.$$

CLAIM 4.1. *Distribution $\mathcal{D}$ is 3-wise independent.*

Proof. It is fairly easy to show (see [2]) that X_{i_1}, X_{i_2}, and X_{i_3} are independent and unbiased iff a_{i_1}, a_{i_2}, and a_{i_3} are linearly independent as vectors over Z_2. Assume that X_{i_1}, X_{i_2}, and X_{i_3} are dependent. Then

$$\alpha_1 a_{i_1} + \alpha_2 a_{i_2} + \alpha_3 a_{i_3} = 0,$$

where $\alpha_1, \alpha_2, \alpha_3 \in Z_2$ are not all 0. Consequently, an even number of α's are 1 (since in distribution $\mathcal{D}$ the last bit of a_i is always 1). In addition, there cannot be exactly two α's that are 1: the a_i's being distinct implies that $a_{i_j} + a_{i_k} \neq 0$. Therefore, $\alpha_1, \alpha_2, \alpha_3 = 0$, which is a contradiction. Thus X_{i_1}, X_{i_2}, and X_{i_3} are independent and unbiased. □

Observe that distribution $\mathcal{D}$ is not 4-wise independent; in particular, X_4, X_5, X_6, and X_7 are dependent since $X_7 = X_4 + X_5 + X_6$.

THEOREM 4.1. *For all $i, j \in \{0, \ldots, n-1\}$, define $\epsilon_{ij} = (-1)^{a_i \cdot a_j}$.*[2] *Let $S_i = \epsilon_{i0} Y_0 + \cdots + \epsilon_{i,n-1} Y_{n-1}$, where $Y_j = (-1)^{X_j}$ and the X_j's are chosen from distribution $\mathcal{D}$. Then for any $X = \langle X_0, \ldots, X_{n-1} \rangle$ in the sample space,*

$$\sum_{i=1}^{n} |S_i| \;=\; n,$$

i.e., the total discrepancy is very small.

Proof. Pick an arbitrary ω. Let $\omega' = \langle \omega_1, \ldots, \omega_{l-1} \rangle$. Note that if $a_j \cdot \omega = 0$, then $Y_j = 1$, and if $a_j \cdot \omega = 1$, then $Y_j = -1$. By definition,

$$\begin{aligned}
\sum_i |S_i| &= \sum_i \left| \sum_j \epsilon_{ij} Y_j \right| \\
&= \sum_i \left| \sum_j (-1)^{a_i \cdot a_j} (-1)^{a_j \cdot \omega} \right| \\
&= \sum_i \left| \sum_j (-1)^{a_j \cdot (a_i + \omega)} \right|.
\end{aligned}$$

Observe that $a_i + \omega$ has a 1 in exactly those positions where a_i and ω differ.

CLAIM 4.2. $\text{bin}(i) = \omega'$ *implies that* $|S_i| = n$.

Proof. Since $\text{bin}(i) = \omega'$ and for all i, $a_{il} = 1$, $a_i + \omega = \vec{0}$ when $\omega_l = 1$ and $\langle 0, \ldots, 0, 1 \rangle$ when $\omega_l = 0$. Then $a_j \cdot (a_i + \omega) = 0$ when $\omega_l = 1$ and 1 when $\omega_l = 0$, which implies that $|S_i| = n$ in either case. □

CLAIM 4.3. *For all i such that* $\text{bin}(i) \neq \omega'$, $|S_i| = 0$.

Proof. Since $\text{bin}(i) \neq \omega'$, a_i and ω differ in at least one position among $1, \ldots, l-1$. Half of the a_j's have an even number of 1's in positions where a_i and ω differ and half of the a_j's have an odd number of 1's in these positions. Hence $|S_i| = 0$. □

By Claims 4.2 and 4.3 and the fact that exactly one i has $\text{bin}(i) = \omega'$, we get that $\sum_i |S_i| = n$, thereby proving the theorem. □

Note that the bound in the theorem is the worst possible because it is always easy to get a total discrepancy of n by making the discrepancy of a single set be n.

As a simple consequence Theorem 4.1, we obtain a very small expected total discrepancy over a 3-wise independent distribution. Note that any cubic will have

[2] The matrix $\{\epsilon_{ij}\}$ is an example of a Hadamard matrix.

the same expected value under any 3-wise independent distribution. Thus as a consequence of Theorem 4.1, there is no cubic that will give a good lower bound on the expected total discrepancy, i.e., there is no analogous "third moment method" for lower bounding total discrepancy. This indicates that there is a threshold of independence where we need to go to 4-wise independence to get an adequate lower bound for total discrepancy. Since Luby [18] could only handle up to 3-wise independence efficiently in parallel, this serves to further motivate the need for the general framework of [5] to remove randomness in the case of more than 3-wise (and up to polylogarithmic) independence.

5. *NC* algorithms.

5.1. Background on removing randomness. For many applications [26, 21, 14, 17, 1, 18, 5, 3], the problem of removing randomness from an algorithm can be solved by finding an $\hat{X} = \langle X_1, \ldots, X_n \rangle$ such that $F(\hat{X}) \geq E[F(X)]$, for some function F which measures the "goodness" of a sample point, and some sample space $\mathcal{S}$ over which the expectation is to be computed. The problem is then how best to find a good sample point (e.g., an $\hat{X}$ such that $F(\hat{X}) \geq E[F(X)]$) in $\mathcal{S}$. If the space of sample points is small (e.g., polynomial), then this can be accomplished by brute force [14, 17, 1]; namely, we could try all points until we get a good one, for one must exist. Although a fully independent sample space is large, polynomial-size sample spaces for 4-wise independent distributions exist.

PROPOSITION 5.1 (see [1]). *For any constant k, there exists a k-wise independent distribution over $X_1, \ldots, X_n$, where the X_i's are unbiased binary random variables, with only $O(n^{\lfloor k/2 \rfloor})$ sample points.*

PROPOSITION 5.2 (see [13, 17, 1]). *For any constant k, there exists a k-wise independent distribution over $X_1, \ldots, X_n$, where the X_i's are uniform in $[0, n-1]$, with only $O(n^k)$ sample points.*

To say that our inequality depends only on 4-wise independence means that it will hold for any 4-wise independent distribution. Therefore, there is an $O(n^4)$ ($O(n^2)$ for unbiased binary random variables) size sample space which we can search exhaustively in *NC* by assigning a processor for each sample point. Notice, however, that we get a blowup in the number of processors, as compared to the *RNC* algorithm, by a factor of the number of sample points.

Alternatively, as long as S is a sum of a polynomial number of functions of at most $\log n$ variables each, we could also use the Berger–Rompel [5] general framework to remove randomness from functions of the form $B(S) = (3\sqrt{3}/(2\sqrt{q}))(S^2 - S^4/q)$, where $q > 0$. This is because raising S to the fourth or second power yields a sum of a polynomial number of functions of at most four times as many variables as before. The general framework can also handle a sum of a polynomial number of functions $B(S)$. Note, however, that the general framework cannot be used to handle functions of the special-case form given in Corollary 2.3.

We discuss the tradeoff between using exhaustive search to derandomize versus the more complicated methods of the general framework of [5] for the specific case of derandomizing total discrepancy in section 5.2 and for the case of maximum acyclic subgraph in section 5.4.2.

5.2. Total discrepancy is in *NC*. Theorem 3.2 immediately gives us an *RNC* algorithm for total discrepancy where if we pick the Y_j's 4-wise independently with

$\{-1,+1\}$ equally likely probability, we get a solution with expected total discrepancy

$$E\left[\sum_{i=1}^{n}|S_i|\right] \;\geq\; \frac{\sum_{i=1}^{n}\sqrt{\epsilon_{i1}^2+\cdots+\epsilon_{in}^2}}{\sqrt{3}}.$$

To get an *NC* algorithm, we can either try all sample points in a 4-wise independent sample space or do parallel binary search, as discussed in section 5.1. Which method is better depends on Δ, the maximum set size.

Trying all sample points has a processor blowup of $O(n^2)$ for each sample point, an additional factor of $O(\Delta)$ processors to sum over the at most Δ elements of each set, and another factor of $O(n)$ processors to sum over the n sets. This gives an *NC* algorithm which uses $O(n^3\Delta)$ processors, runs in $O(\log n)$ time, and returns a solution with total discrepancy

$$\sum_{i=1}^{n}|S_i| \;\geq\; \frac{\sum_{i=1}^{n}\sqrt{\sum_{j\in A_i}\epsilon_{ij}^2}}{\sqrt{3}},$$

which, of course, is equivalent to the lower bound that we got for the *RNC* algorithm.

On the other hand, we could do a parallel binary search, as implemented by the general framework of [5]. Using our fourth moment inequality, the total discrepancy can be expressed as a sum of $O(n\Delta^4)$ functions, each depending on at most four random variables. This gives an *NC* algorithm which uses $O(n\Delta^4)$ processors, runs in $O(\log n)$ time, and returns a solution with the same total discrepancy as exhaustive search.

In summary, if $\Delta \geq n^{2/3}$, exhaustive search is better since it uses fewer processors, and parallel binary search is better otherwise.

Remark. Using 4-wise independence, we can also find in *NC* a single setting of the Y_j's such that the total discrepancy $\sum_{i=1}^{n}|S_i|$ is $\Theta(n^{3/2})$, i.e., this single setting meets both the upper and lower bounds.

Remark. These methods can be extended to get a sample point that has a constant fraction of the individual discrepancies large as well by using methods similar to Corollary 3.7.

5.3. The Gale–Berlekamp switching game and edge discrepancy are in *NC*. Our methods can be applied to get the first *NC* algorithms for the Gale–Berlekamp switching game and the edge discrepancy problem.

In the *Gale–Berlekamp switching game,* we want an algorithm which, given an $n\times n$ matrix of $a_{ij}\in\{-1,+1\}$, outputs an n-vector of $X_i\in\{-1,+1\}$ and an n-vector of $Y_i\in\{-1,+1\}$ so that

$$\sum_{i,j=1}^{n} a_{ij}X_iY_j \;\geq\; cn^{3/2}$$

for some constant $c>0$.

Brown and Spencer [7, 26] gave a deterministic polynomial-time algorithm for this problem (for $c=\sqrt{2/\pi}$) by picking the Y_j's n-wise independently at random and then utilizing the method of conditional probabilities to derandomize. We, on the other hand, will pick the Y_j's 4-wise independently with $\{-1,+1\}$ equally likely probability and then derandomize using parallel methods.

The proof of our algorithm's correctness follows along the same lines of Brown and Spencer's [7, 26] proof for the sequential case.

LEMMA 5.3. *Picking $Y_1, \ldots, Y_n$ 4-wise independently, each 1 or -1 with equal probability, we obtain an RNC algorithm for the Gale–Berlekamp switching game, where $c = 1/\sqrt{3}$ in the solution.*

Proof. Let $R_i = \sum_{j=1}^{n} a_{ij} Y_j$. Set $X_i = 1$ if $R_i \geq 0$ and -1 otherwise. Then

$$E\left[\sum_{i,j=1}^{n} a_{ij} X_i Y_j\right] = E\left[\sum_{i=1}^{n} R_i X_i\right] = E\left[\sum_i |R_i|\right] = E\left[\sum_i \left|\sum_j a_{ij} Y_j\right|\right] \geq \frac{n^{3/2}}{\sqrt{3}}$$

by Theorem 3.2 if we let $\epsilon_{ij} = a_{ij} \in \{-1, +1\}$. □

To get an *NC* algorithm, trying all sample points works best in this case since $\Delta = n$ (see the discussions in sections 5.1 and 5.2). Thus we get the following theorem.

THEOREM 5.4. *There is an NC algorithm for the Gale–Berlekamp switching game which uses $O(n^4)$ processors, runs in $O(\log n)$ time, and returns a solution where $c = 1/\sqrt{3}$.*

Subsequent to our work, a higher-dimensional version of the switching game result was obtained by Tetali [27].

In the *edge discrepancy* problem, we are given an edge coloring $\chi : E \to \{-1, +1\}$ of $K_n = (V, E)$ and we want to find a subset of the vertices $S \subseteq V$ so that

$$\left|\sum_{e \in E_S} \chi(e)\right| \geq cn^{3/2},$$

where E_S are the edges of the subgraph induced by S.

Erdös and Spencer discovered a polynomial-time algorithm for edge discrepancy through a reduction to the Gale–Berlekamp switching game (see [10] and [26, pp. 47–48]). This reduction, which can easily be done in *NC*, in conjunction with Theorem 5.4 gives us the following theorem.

THEOREM 5.5. *There is an* NC *algorithm for the edge discrepancy problem which uses $O(n^4)$ processors, runs in $O(\log n)$ time, and returns a solution where $c = 1/(12\sqrt{3})$.*

5.4. The maximum acyclic subgraph problem and tournament ranking are in *NC*. We can also apply our methods to obtain the first *NC* algorithm that gets strictly greater than half the arcs for the *maximum acyclic subgraph* problem, and *tournament ranking* as a special case. The maximum acyclic subgraph problem is as follows: given a directed graph $G = (V, A)$, where $|V| = n$ and $|A| = m$, find the largest subset of the arcs which does not contain a cycle. This problem is *NP*-complete, so we settle for approximate solutions. (See [6] for more background on the problem.)

Berger and Shor [6] showed how to handle 2-cycles optimally and therefore reduced the problem to finding algorithms for 2-cycle-free graphs. So we henceforth consider only such graphs. Furthermore, they devised randomized and deterministic polynomial-time algorithms and an *RNC* algorithm (which we describe below) and proved that these algorithms find an acyclic subgraph $\hat{A} \subseteq A$ with at least $|A|/2 + \Omega(\sum_{i=1}^{n} \sqrt{\deg(i)})$ arcs, where $\deg(i)$ is the degree of vertex i in G.

Using Theorem 2.2 and a more delicate analysis than we used for lower bounding the discrepancy of a set, we are able to prove that the Berger–Shor *RNC* algorithm

works using 5-wise (versus n-wise in [6]) independence. Then the parallel derandomization techniques can be applied. Moreover, our proof techniques, which utilize the fourth moment method, give the following improved lower bound on the size of the acyclic subgraph returned by our *NC* algorithm:

$$\frac{|A|}{2} - 1 + \frac{\sqrt{6}}{40}\sum_{i=1}^{n}\sqrt{\deg(i)} + \frac{\sqrt{3}}{20}\sum_{i=1}^{n}|d_{\text{out}}(i) - d_{\text{in}}(i)|,$$

where $d_{\text{out}}(i)$ is the out-degree of vertex i in G and $d_{\text{in}}(i)$ is the in-degree of i. This bound is tight, within a constant factor on the low-order terms [6].

We remark that if $\deg(i) = |V| - 1$, for all i, an acyclic subgraph corresponds simply to a tournament ranking. A *tournament ranking* is an ordering of players from "best" to "worst," where we maximize the number of pairs of players A and B for which player A has beaten player B and we have assigned A a higher rank than B. Our acyclic subgraph result generalizes and improves upon the corresponding $|A|/2 + \Omega(\sum_{v\in V}\sqrt{|V|})$ bound for tournaments discovered by Spencer [25, 26]. (A sequential algorithm that achieves this latter bound was first presented in [20].) The improved bound that we get is a natural consequence of our methods, which are constructive.

Let $G = (V, A)$, $|V| \geq 2$, be a tournament. We are able to find in *NC* a ranking of the players so that there are at least

$$\frac{|A|}{2} - 1 + \frac{\sqrt{3}}{40}|V|^{3/2} + \frac{\sqrt{3}}{20}\sum_{i=1}^{n}|d_{\text{out}}(i) - d_{\text{in}}(i)|$$

wins of higher-ranked players over lower ranked ones. Notice that the last term results in an improved ranking when there are players who have an unbalanced number of wins and losses. This bound is tight within a constant factor on the low-order terms for tournaments [8].

5.4.1. An improved *RNC* algorithm which uses 5-wise independence. Berger and Shor [6] gave the following *RNC* approximation algorithm for the maximum acyclic subgraph problem in 2-cycle free graphs. Suppose that we have a processor for each vertex and each arc in G and an incoming and outgoing adjacency list in shared memory. Then once we have assigned a randomized ordering to the vertices of G, we can process all of them in parallel. To produce a randomized ordering, randomly assign each vertex i a rank $r_i \in \{1, \ldots, \sigma\}$, $\sigma \in \mathbf{N}$ (we will discuss possible choices for σ later). When we process a vertex, we will only consider its neighbors with a higher number in the assigned ordering. We will place in the acyclic subgraph $\hat{A}$ either all of the out-arcs to or all of the in-arcs from the higher-numbered neighbors, whichever set is larger. It can easily be seen that this procedure can be handled with a linear number of processors in logarithmic time using standard parallel algorithm and data structure techniques.

However, this randomized algorithm is not in a form to which any of the known parallel derandomization procedures can be applied; its analysis is based on that of its sequential counterpart, whose analysis depends on n-wise independence. Moreover, Greenlaw [11] has shown that if the algorithm is modified to process vertices in order of highest-degree vertex in the remaining graph, then the problem of finding the acyclic subgraph produced by this algorithm is *P-complete.*

In this paper, we will show that if we assign the randomized ordering 5-wise independently (as opposed to n-wise independently), we will be able to obtain an even

better lower bound on $E[|\hat{A}|]$, the expected number of arcs in the acyclic subgraph, than was achieved through the sequential case analysis in [6]. The key point is that we will then be able to derandomize this *RNC* algorithm to get an *NC* algorithm.

For $\langle r_1, \ldots, r_n \rangle \in \{1, \ldots, \sigma\}^n$ chosen from a 5-wise independent distribution, we wish to show that $E[|\hat{A}|]$ is large. It will be convenient for us to define the following random variables. Let Y_{ij} be the indicator random variable for $r_j > r_i$, i.e., Y_{ij} is 1 if $r_j > r_i$ and 0 otherwise. Furthermore, let Z_{ij} be $+Y_{ij}$ if $\langle i, j \rangle \in A$ and $-Y_{ij}$ if $\langle j, i \rangle \in A$. (Note that + and – are fixed by direction.) Let

$$X_i = \left| \sum_{j \in N(i)} Z_{ij} \right|.$$

Intuitively, X_i is the discrepancy, or difference in the number of incoming and outgoing arcs, at the ith vertex when it is processed. Let $d_i = \sum_{j \in N(i)} Y_{ij}$. So d_i is the degree of the ith vertex when it is processed. Let S denote the number of arcs that have both of their endpoints with the same rank. Thus $S = \sum_{<i,j> \in A} s_{ij}$, where s_{ij} is 1 if $r_i = r_j$ and 0 otherwise.

For the purposes of analysis, suppose that the algorithm breaks ties between ranks by a random permutation on all of the ranks once they are chosen. Call this algorithm Aperm and the original algorithm A5wise. Then the sizes of the acyclic subgraphs (i.e., the $|\hat{A}|$'s) produced by the two algorithms will differ by at most the number of arcs connecting nodes of equal rank. Thus the expected difference in the $|\hat{A}|$'s produced by the two algorithms is at most the expected number of arcs connecting nodes of equal rank; in particular, the expected behavior of A5wise is at least the expected behavior of Aperm minus this difference.

More formally, let us first examine the expected behavior of Aperm, that is, the case when all the ranks are distinct. Expanding $|\hat{A}|$ out in terms of the random variables defined above, we get

$$|\hat{A}| = \sum_{i=1}^{n} \left(\frac{d_i}{2} + \frac{X_i}{2} \right) = \frac{1}{2}|A| + \frac{1}{2} \sum_{i=1}^{n} X_i.$$

By linearity of expectation,

$$E[|\hat{A}|] = \frac{1}{2}|A| + \frac{1}{2} \sum_{i=1}^{n} E[X_i]. \tag{5.1}$$

We would now like to prove that $\sum_{i=1}^{n} E[X_i]$ is large. Observe that X_i is the absolute value of a sum of random variables Z_{ij}. So as in section 2, we will bound its expectation from below by a fourth moment. Applying Theorem 2.2, we have that for all $q > 0$, $E[X_i] \geq (3\sqrt{3}/2\sqrt{q})(E[X_i^2] - E[X_i^4]/q)$. We will show that if the r_i's are chosen 5-wise independently in algorithm Aperm,

$$\frac{3\sqrt{3}}{2\sqrt{q_i}} \left(E[X_i^2] - \frac{E[X_i^4]}{q_i} \right) \geq \frac{\sqrt{6}}{20} \sqrt{\deg(i)} + \frac{\sqrt{3}}{10} |d_{\text{out}}(i) - d_{\text{in}}(i)|,$$

where $q_i = \deg(i) + 2(d_{\text{out}}(i) - d_{\text{in}}(i))^2$.

To do this, we need to compute $E[X_i^2]$ and $E[X_i^4]$. The following claim will be helpful.

CLAIM 5.1. *$(X_i)^k$ is a function which is a sum of terms depending on at most $k+1$ ranks r_i each.*

Proof. X_i^k is a polynomial which is a sum of terms depending on k Z_{ij}'s each. It would appear that k Z_{ij}'s are dependent on $2k$ r_i's. However, since each term of k Z_{ij}'s is really dependent on one i and at most k $j \in N(i)$, each term is a function of at most $k+1$ r_i's. □

We can thus use the fact that, although $Y_{ij_1}, Y_{ij_2}, \ldots, Y_{ij_t}$ are not independent, we can still compute their expected product by the following lemma for $t \leq 4$.

LEMMA 5.6. *$E[Y_{ij_1} Y_{ij_2} \cdots Y_{ij_t}] = 1/(t+1)$ when $j_1, j_2, \ldots, j_t$ are all distinct and $t \leq 4$.*

Proof. This is because the product $Y_{ij_1} Y_{ij_2} \cdots Y_{ij_t}$ is 0 except when i has a lower rank than all of $j_1, \ldots, j_t$. We note that if ranks $\langle r_i, r_{j_1}, \ldots, r_{j_t} \rangle$ are chosen from at least a $(t+1)$-wise independent distribution and ties are broken through a random permutation, then all $(t+1)$-tuples of distinct rank values are equally likely. Then by symmetry, since each of $r_i, r_{j_1}, \ldots, r_{j_t}$ is equally likely to be the least element, only $1/(t+1)$ has r_i least. □

Before we compute $E[X_i^2]$ and $E[X_i^4]$, let us give some useful definitions. Let $B = \{\langle i, j \rangle \in A\}$ and $C = \{\langle j, i \rangle \in A\}$. Let $b = d_{\text{out}}(i) = |B|$ and $c = d_{\text{in}}(i) = |C|$. Let $z = b+c$ and $x = |b-c|$. Let $B_k = \{(j_1, \ldots, j_k) | j_1, \ldots, j_k \in B \text{ all distinct}\}$ and let $C_k = \{(j_1, \ldots, j_k) | j_1, \ldots, j_k \in C \text{ all distinct}\}$. Let $\beta = \sum_{j \in B} Y_{ij}$ and $\gamma = \sum_{j \in C} Y_{ij}$. Without loss of generality, we assume that $b \geq c$.

LEMMA 5.7. *$E[X_i^2] = z/6 + x^2/3$.*

Proof. Observe that

$$E[X_i^2] = E[(\beta - \gamma)^2] = E[\beta^2 - 2\beta\gamma + \gamma^2].$$

We will compute this term by term using linearity of expectation. First,

$$E[\beta^2] = \sum_{j \in B} E[Y_{ij}^2] + \sum_{(j,j') \in B_2} E[Y_{ij} Y_{ij'}] = \sum_{j \in B} E[Y_{ij}] + \sum_{(j,j') \in B_2} E[Y_{ij} Y_{ij'}] = b\frac{1}{2} + (b^2 - b)\frac{1}{3}$$

by Lemma 5.6. By symmetry,

$$E[\gamma^2] = c\frac{1}{2} + (c^2 - c)\frac{1}{3}.$$

Also,

$$E[-2\beta\gamma] = -2 \sum_{j \in B} \sum_{j' \in C} E[Y_{ij} Y_{ij'}] = -2bc\frac{1}{3}.$$

Combining all terms,

$$E[X_i^2] = \frac{1}{6}(b+c) + \frac{1}{3}(b-c)^2 = \frac{1}{6}z + \frac{1}{3}x^2. \qquad \square$$

LEMMA 5.8. *$E[X_i^4] = (1/30)(z + 2x^2)(3z + 3x^2 - 1)$.*

Proof. Observe that

$$E[X_i^4] = E[(\beta - \gamma)^4] = E[\beta^4 - 4\beta^3\gamma + 6\beta^2\gamma^2 - 4\beta\gamma^3 + \gamma^4].$$

We will likewise compute this term by term using linearity of expectation. First,

$$\begin{aligned}E[\beta^4] &= \sum_{j\in B} E[Y_{ij}^4] + \binom{4}{1}\sum_{(j,j')\in B_2} E[Y_{ij}^3 Y_{ij'}] + 3\sum_{(j,j')\in B_2} E[Y_{ij}^2 Y_{ij'}^2] \\ &\quad + \binom{4}{2}\sum_{(j,j',j'')\in B_3} E[Y_{ij}^2 Y_{ij'} Y_{ij''}] + \sum_{(j,j',j'',j''')\in B_4} E[Y_{ij}Y_{ij'}Y_{ij''}Y_{ij'''}] \\ &= b\frac{1}{2} + \binom{4}{1}b(b-1)\frac{1}{3} + 3b(b-1)\frac{1}{3} + \binom{4}{2}b(b-1)(b-2)\frac{1}{4} \\ &\quad + b(b-1)(b-2)(b-3)\frac{1}{5}.\end{aligned}$$

By symmetry,

$$\begin{aligned}E[\gamma^4] &= c\frac{1}{2} + \binom{4}{1}c(c-1)\frac{1}{3} + 3c(c-1)\frac{1}{3} + \binom{4}{2}c(c-1)(c-2)\frac{1}{4} \\ &\quad + c(c-1)(c-2)(c-3)\frac{1}{5}.\end{aligned}$$

Next,

$$\begin{aligned}E[-4\beta^3\gamma] &= -4\left[\sum_{j\in B}\sum_{j'''\in C} E[Y_{ij}^3 Y_{ij'''}] + \binom{3}{2}\sum_{(j,j')\in B_2}\sum_{j'''\in C} E[Y_{ij}^2 Y_{ij'}Y_{ij'''}]\right. \\ &\quad \left. + \sum_{(j,j',j'')\in B_3}\sum_{j'''\in C} E[Y_{ij}Y_{ij'}Y_{ij''}Y_{ij'''}]\right] \\ &= -4\left[bc\frac{1}{3} + \binom{3}{2}b(b-1)c\frac{1}{4} + b(b-1)(b-2)c\frac{1}{5}\right].\end{aligned}$$

By symmetry,

$$E[-4\beta\gamma^3] \;=\; -4\left[bc\frac{1}{3} + \binom{3}{2}bc(c-1)\frac{1}{4} + bc(c-1)(c-2)\frac{1}{5}\right].$$

Also,

$$\begin{aligned}E[6\beta^2\gamma^2] &= 6\left[\sum_{j\in B}\sum_{j''\in C} E[Y_{ij}^2 Y_{ij''}^2] + \sum_{j\in B}\sum_{(j'',j''')\in C_2} E[Y_{ij}^2 Y_{ij''}Y_{ij'''}]\right. \\ &\quad \left. + \sum_{(j,j')\in B_2}\sum_{j''\in C} E[Y_{ij}Y_{ij'}Y_{ij''}^2] + \sum_{(j,j')\in B_2}\sum_{(j'',j''')\in C_2} E[Y_{ij}Y_{ij'}Y_{ij''}Y_{ij'''}]\right] \\ &= 6\left[bc\frac{1}{3} + bc(c-1)\frac{1}{4} + b(b-1)c\frac{1}{4} + b(b-1)c(c-1)\frac{1}{5}\right].\end{aligned}$$

Combining all terms,

$$\begin{aligned}E[X_i^4] &= \frac{(b-c)^4}{5} - \frac{(b-c)^2}{15} + \frac{3(b-c)^2(b+c)}{10} + \frac{(b+c)^2}{10} - \frac{b+c}{30} \\ &= \frac{x^4}{5} - \frac{x^2}{15} + \frac{3x^2 z}{10} + \frac{z^2}{10} - \frac{z}{30} \\ &= \frac{(z+2x^2)(3z+3x^2-1)}{30}.\end{aligned}$$

□

By Lemmas 5.7 and 5.8, when $q = z + 2x^2$,

$$\frac{3\sqrt{3}}{2\sqrt{q}}\left(E[X_i^2] - \frac{E[X_i^4]}{q}\right) \geq \frac{\sqrt{6}}{20}\sqrt{z} + \frac{\sqrt{3}}{10}\,x.$$

This fact and Theorem 2.2 imply that

$$E[X_i] \geq \frac{\sqrt{6}}{20}\sqrt{z} + \frac{\sqrt{3}}{10}\,x.$$

This implies

$$\sum_{i=1}^{n} E[X_i] \geq \frac{\sqrt{6}}{20}\sum_{i=1}^{n}\sqrt{\deg(i)} + \frac{\sqrt{3}}{10}\sum_{i=1}^{n}|d_{\text{out}}(i) - d_{\text{in}}(i)|.$$

Therefore, plugging the above equation into equation (5.1), we have for algorithm Aperm that

$$E[|\hat{A}|] \geq \frac{|A|}{2} + \frac{\sqrt{6}}{40}\sum_{i=1}^{n}\sqrt{\deg(i)} + \frac{\sqrt{3}}{20}\sum_{i=1}^{n}|d_{\text{out}}(i) - d_{\text{in}}(i)|. \tag{5.2}$$

Now let us consider the expected behavior of the actual algorithm A5wise since we do not really have access to an algorithm that produces truly random permutations. Recall from the discussion above that $E[|\hat{A}|]$ for A5wise is at least $E[|\hat{A}|]$ for Aperm minus the expected number of arcs with equal rank (i.e., $E[S]$). Therefore, from equation (5.2) and this fact, we have shown for algorithm A5wise that

$$E[|\hat{A}|] \geq \frac{1}{2}|A| - E[S] + \frac{1}{2}\sum_{i=1}^{n} E[X_i].$$

We already lower bounded equation (5.1) in equation (5.2), so all that remains is to upper bound $E[S]$, which is achieved by the following lemma.

Lemma 5.9. $E[S] \leq |A|/\sigma$.

Proof. For any pairwise independent distribution, $E[s_{ij}] = 1/\sigma$. □

We have succeeded in proving the following theorem for A5wise.

Theorem 5.10. *For $\langle r_1, \ldots, r_n\rangle \in \{1, \ldots, \sigma\}^n$ chosen from a 5-wise independent distribution, the expected size of the acyclic subgraph found by the RNC algorithm is*

$$E[|\hat{A}|] \geq \frac{|A|}{2} - \frac{|A|}{\sigma} + \frac{\sqrt{6}}{40}\sum_{i=1}^{n}\sqrt{\deg(i)} + \frac{\sqrt{3}}{20}\sum_{i=1}^{n}|d_{\text{out}}(i) - d_{\text{in}}(i)|.$$

Observe that the larger we make σ, the better the lower bound we get on the expected size of our acyclic subgraph. However, in terms of asymptotics, $\sigma \geq 16\sqrt{\Delta}$, where Δ is the maximum degree of any vertex in the graph, suffices (since the second term is then dominated by the third). This will be useful in the next section since we will see that there is a tradeoff between the bound we achieve on $|\hat{A}|$ and the number of processors, or running time, we get when we derandomize.

Corollary 5.11. *For $\langle r_1, \ldots, r_n\rangle \in \{1, \ldots, 16\sqrt{\Delta}\}^n$ chosen from a 5-wise independent distribution,*

$$E[|\hat{A}|] \geq \frac{|A|}{2} + \Omega\left(\sum_{i=1}^{n}\sqrt{\deg(i)} + \sum_{i=1}^{n}|d_{\text{out}}(i) - d_{\text{in}}(i)|\right).$$

5.4.2. The *NC* algorithm. We can derandomize the algorithm of the previous section in parallel. Since that randomized algorithm obtained a large acyclic subgraph using 5-wise independence, we can derandomize by simply trying all sample points of a 5-wise independent distribution, or, as we will show, we can use the techniques of [5] to do a parallel binary search. While the former approach is simpler, in this case, the latter requires fewer processors.

Before we describe either of these approaches, it will be convenient to define a benefit function [14, 18]

$$B(W) \;=\; \frac{1}{2}|A| - S + \frac{3\sqrt{3}}{4}\sum_{i=1}^{n}\frac{1}{\sqrt{q_i}}\left(X_i^2 - \frac{X_i^4}{q_i}\right),$$

where $W = \langle r_1, \ldots, r_n\rangle \in \{1, \ldots, \sigma\}^n$ and $q_i = \deg(i) + (d_{\text{out}}(i) - d_{\text{in}}(i))^2$. By the analysis leading to the proof of Theorem 5.10, we know that $E[B(W)]$ for W chosen over a 5-wise independent distribution is large.

We can therefore try all sample points W in a 5-wise independent distribution to find a W such that $B(W) \geq E[B(W)]$. This would require one processor for each sample point, of which there are $O(n^5 + \sigma^5)$. If we pick $\sigma = n$, we get a large acyclic subgraph, but we may need $O(n^5)$ processors.

Alternatively, we can do a binary search in parallel to obtain the following theorem. Recall that $\Delta = \max_{1\leq i\leq n}\deg(i)$.

THEOREM 5.12. *There is an NC algorithm for maximum acyclic subgraph which uses $O(n\Delta^4)$ processors, runs in $O(\log^2 n \log\sigma)$ time, and produces an acyclic subgraph $\hat{A}$ of size*

$$|\hat{A}| \;\geq\; \frac{|A|}{2} \;-\; \frac{|A|}{\sigma} \;+\; \frac{\sqrt{6}}{40}\sum_{i=1}^{n}\sqrt{\deg(i)} \;+\; \frac{\sqrt{3}}{20}\sum_{i=1}^{n}|d_{\text{out}}(i) - d_{\text{in}}(i)|.$$

Proof. To find a good W, we apply one of the basic approaches for handling multivalues given in [5] to the problem at hand. We have 5-wise independent multivalued random variables $W = \langle r_1, \ldots, r_n\rangle$, where $\text{bin}(r_k) = r_{k1}r_{k2}\cdots r_{kl}$ ($r_{kt} \in \{0, 1\}$ and $l = \lceil\log\sigma\rceil$); in other words, W can be thought of as an $n \times l$ Boolean matrix that has the r_k's as its rows. We compute the r_k's bit by bit, setting the tth bit of all of the r_k's simultaneously. Let $U^{(t)}$ be the tth column of W once all of the bits in the column are set. Similarly, $U_k^{(t)} = r_{kt}$ once its bit is set. At step t, we will show below how to compute the tth bit of all the r_k's, $U^{(t)}$ such that

$$\begin{aligned} &E[B(W)|r_{kj} = U_k^{(j)} \text{ for } 1\leq k\leq n,\ 1\leq j\leq t] \\ &\quad\geq E[B(W)|r_{kj} = U_k^{(j)} \text{ for } 1\leq k\leq n,\ 1\leq j\leq t-1]. \end{aligned}$$

In other words, find a setting for the tth bits of the r_k's such that the expected benefit from setting the first t bits of the r_k's is at least the expected benefit from setting the first $t-1$ bits of the r_k's. If we let

$$F^{(t)}(U^{(t)}) = E[B(W)|r_{kj} = U_k^{(j)} \text{ for } 1\leq k\leq n,\ 1\leq j\leq t],$$

then the above is equivalent to finding a $U^{(t)}$ with $F^{(t)}(U^{(t)}) \geq E[F^{(t)}(U^{(t)})]$.

A simple inductive argument then shows that for all t,

$$E[B(W)|r_{kj} = U_k^{(j)} \text{ for } 1\leq k\leq n,\ 1\leq j\leq t] \geq E[B(W)].$$

It follows that letting W be such that $r_{kj} = U_k^{(j)}$ for all k and j implies that $B(W) \geq E[B(W)]$.

To find a setting of $U^{(t)}$ such that $F^{(t)}(U^{(t)}) \geq E[F^{(t)}(U^{(t)})]$, we utilize the method given in [5] for binary searching a distribution with n 5-wise independent 0/1 random variables. This works as follows. We construct an $n \times O(\log n)$ matrix M whose rows are 5-wise linearly independent. It was shown that for a randomly chosen vector $\omega \in \{0,1\}^{O(\log n)}$, taking the matrix–vector product of $M\omega$ produces an X which consists of n 5-wise independent 0/1 random variables. By setting ω one bit at a time so that the expected benefit of X, given the settings of ω to that point, is always nondecreasing, it is possible to get a setting for X such that the benefit of X is at least the expected benefit of X.

It remains to show how to compute the expected benefit from setting the first t bits of the r_k's, given a partial setting of ω. First, let us define some terms. From Claim 5.1, we know that our benefit function $B(W)$ is a sum of terms depending on at most five ranks r_k each. Let $\alpha = \{ij_1, \ldots, ij_\tau\}$, where $\tau \in [1,4]$ and $j_1, \ldots, j_\tau$ are all distinct, be the indices of the arcs involved in such a term. Recall that Y_{ij} is the indicator random variable for $r_j > r_i$ and s_{ij} is the indicator random variable for $r_i = r_j$. Then $B(W)$ is a sum of $O(n\Delta^4)$ functions $g_\alpha(W) = Y_{ij_1}Y_{ij_2}\cdots Y_{ij_\tau}$ and $O(n\Delta)$ functions $s_{ij}(W) = I\{r_i = r_j\}$, each depending on at most five r_k's each. Note that g_α is the indicator function for $Y_{ij_1}Y_{ij_2}\cdots Y_{ij_\tau}$, i.e., g_α is 1 if r_i is the minimum among $r_i, r_{j_1}, \ldots, r_{j_\tau}$ and 0 otherwise.

Let

$$f_\alpha^{(t)}(U^{(t)}) = E[g_\alpha(W) | r_{kj} = U_k^{(j)} \text{ for } 1 \leq k \leq n,\ 1 \leq j \leq t],$$

which is the expectation that r_i is minimum among $r_{j1}, \ldots, r_{jt}$, given that the first t bits of the r_k's are specified. Let

$$f_{ij}^{(t)}(U^{(t)}) = E[s_{ij}(W) | r_{kj} = U_k^{(j)} \text{ for } 1 \leq k \leq n,\ 1 \leq j \leq t],$$

which is the expectation that the first t bits of the r_k's are specified. This allows us to write $F^{(t)}(U^{(t)})$ as a sum of $O(n\Delta^4)$ functions $f_\alpha^{(t)}$ and $f_{ij}^{(t)}$, each depending on at most five ranks r_{kt}. Assuming that, given $U^{(1)}, \ldots, U^{(t-1)}$, we can construct functions $f_\alpha^{(t)}$ and $f_{ij}^{(t)}$, given a partial setting of ω, we can compute $F^{(t)}(U^{(t)})$ given the partial setting of ω. We then choose the bit of ω that was set so as to maximize $F^{(t)}(U^{(t)})$. After all bits of ω have been set in this way, we have found a $U^{(t)}$ such that $F^{(t)}(U^{(t)}) \geq E[F^{(t)}(U^{(t)})]$.

We now show how to construct, for any t and for any settings of the first $t-1$ bits $U^{(1)}, \ldots, U^{(t-1)}$, the functions $f_\alpha^{(t)}(U^{(t)})$ given a partial setting of ω. Given term α, the $(t-1)$-bit prefix of each rank $r_i, r_{j_1}, \ldots, r_{j_\tau}$, and partial information on the tth bit of each of these ranks, $f_\alpha^{(t)}$ is the probability that r_i is the minimum rank among $r_i, r_{j_1}, \ldots, r_{j_\tau}$. To calculate $f_\alpha^{(t)}$, we sort the ranks of term α into groups of those that have a strictly smaller t-bit prefix than r_i (group Γ_1), those that have the same t-bit prefix as r_i (group Γ_2), and those that have a strictly larger t-bit prefix than r_i (group Γ_3). If $|\Gamma_1| > 0$, then $f_\alpha^{(t)} = 0$. Otherwise, we focus on those ranks with the same t-bit prefix because only these are in contention for the minimum rank value.

Again for the purposes of analysis, we utilize algorithm Aperm, which we specified to perform a random permutation of those ranks that are equal upon setting the last (i.e., the lth) bit of the ranks. We will analyze what happens to algorithm Aperm

up to the permutation (i.e., the bits of the lth column are set but the identical ranks have not been permuted yet). Intuitively, we do this because we cannot derandomize $O(n!)$ possibilities.

By way of example, suppose we have five ranks involved in the g_α term. There are 2^5 different ways to set the tth bits for these ranks. For each setting of the five bits, we have a collection of ranks whose leading order $t-1$ bits are the same. We have partial information on their tth bit (from the partial setting of ω) but no information on their remaining bits (i.e., they are completely random). For each possible setting of the five bits, we want to know the probability of that r_i is the minimum rank:

$$\begin{aligned}&\Pr[r_i \text{ is min} \mid \text{partial info on } \omega]\\ &= \sum_{32 \text{ settings}} (\Pr[\text{get that setting} \mid \text{partial info on } \omega] \cdot \Pr[r_i \text{ is min} \mid \text{get that setting}]).\end{aligned}$$

Calculating $\Pr[r_i \text{ is min} \mid \text{get that setting}]$ merely requires a table lookup: it is 0 or $1/((\#$ of identical ranks including setting of tth bit)$+1)$ since all of the ranks are assumed to be distinct for algorithm Aperm.

To calculate $\Pr[\text{get that setting} \mid \text{partial info on } \omega]$, assume without loss of generality that we have a five-row matrix M' such that all the rows are independent. We are setting the bits of a $l' = O(\log n)$ bit vector ω one at a time. Some of ω's values have been set, let us say t', and the rest are random. We want to know the probability that when we plug in the remaining $l'-t'$ unfixed values into vector ω, the five bits of the ranks will get the specified setting. This probability can be calculated by solving a linear system of equations with $l'-t'$ unknowns. Suppose u is the dimension of the solution space. Then the probability is $2^u/2^{l'-t'} = 2^{u-l'+t'}$. The solution to the system of equations can be computed quickly since M' is of size $5 \times O(\log n)$ and ω is of size $\log n$, so it can be done sequentially in NC.

Next, we show how to construct, for any t and for any settings of the first $t-1$ bits $U^{(1)}, \ldots, U^{(t-1)}$, the functions $f_{ij}^{(t)}(U^{(t)})$ given a partial setting of ω. Note that the indicator s_{ij} is only for the part of the algorithm up to the random permutation. As with $f_\alpha^{(t)}$, to compute $f_{ij}^{(t)}$, we first show how to compute

$$E[s_{ij}(W) | r_{kj} = U_k^{(j)} \text{ for } 1 \le k \le n,\ 1 \le j \le t];$$

it then suffices to plug in the given $U^{(1)}, \ldots, U^{(t-1)}$ and every possible setting of the variables $\{U_k^{(t)} | k \in \{i,j\}\}$ to construct $f_{ij}^{(t)}$.

Given arc $\langle i,j \rangle$ and the first t bits of ranks r_i and r_j, $f_{ij}^{(t)}$ is the probability that $r_i = r_j$. Clearly, if r_i and r_j have different t-bit prefixes, then $f_{ij}^{(t)} = 0$. Otherwise,

$$\begin{aligned}f_{ij}^{(t)} &= \Pr[r_i = r_j | r_i \text{ and } r_j \text{ have same } t\text{-bit prefix}]\\ &= \frac{1}{2^{l-t}}.\end{aligned}$$

Now we want to argue that the above procedure finds a sample point W (i.e., a collection of ranks) for which $|\hat{A}|$ is large. For any collection of ranks, the following is true:

$$|\hat{A}| = \sum_{i=1}^{n} \left(\frac{d_i}{2} + \frac{X_i}{2} \right) = \frac{1}{2}|A| - \frac{1}{2}S + \frac{1}{2}\sum_{i=1}^{n} X_i. \tag{5.3}$$

Note that the sum over all d_i is equivalent to $|A| - S$ since S arcs are not processed, and each processed arc is counted only once. In particular, let us suppose that equation (5.3) applies to the collection of 5-wise independent ranks obtained before the final random permutation is performed by algorithm APERM. S is then the number of arcs with equal rank at this point. By the discussion in the preceding section, the $\sum_i X_i$ for these ranks is at least $\sum_i X_i - S$ for the collection of ranks produced by any final permutation. The number of arcs we get for the acyclic subgraph $|\hat{A}|$ when the sample point W is derived by the above process is at least

$$\begin{aligned}
&\frac{1}{2}|A| - \frac{1}{2}S + \frac{1}{2}\sum_{i=1}^{n} X_i \\
&\qquad \text{(where } X_i \text{ is derived from 5-wise independent distribution for } r_k\text{'s)} \\
&\geq \frac{1}{2}|A| - \frac{1}{2}S + \frac{1}{2}\sum_{i=1}^{n}(E[X_i] - S) \\
&\qquad \text{(where } E[X_i] \text{ is derived from tie-breaking } r_k\text{'s by a random permutation)} \\
&= \frac{1}{2}|A| - S + \frac{1}{2}\sum_{i=1}^{n} E[X_i] \\
&\geq \frac{1}{2}|A| - S + \frac{3\sqrt{3}}{4}\sum_{i=1}^{n}\frac{1}{\sqrt{q_i}}\left(E[X_i^2] - \frac{E[X_i^4]}{q_i}\right),
\end{aligned}$$

for $q_i = \deg(i) + 2(d_{\text{out}}(i) - d_{\text{in}}(i))^2$ (by Theorem 2.2). The latter part of the equation is the expected benefit $E[B(W)]$. (S was fixed after the 5-wise independent ranks were determined.)

Thus we have selected a sample point that achieves at least the expected benefit up to the random permutation that is left. The expected benefit was computed to be large in the previous section (see Theorem 5.10). By the fact that for each column of M, we deal with at most $O(n\Delta^4)$ terms and by the running-time analysis in [5], we have achieved the desired Theorem 5.12. □

COROLLARY 5.13. *There is an NC algorithm for maximum acyclic subgraph which uses $O(n\Delta^4)$ processors, runs in $O(\log^3 n)$ time, and produces an acyclic subgraph of size*

$$|\hat{A}| \;\geq\; \frac{|A|}{2} \;+\; \Omega\left(\sum_{i=1}^{n}\sqrt{\deg(i)} \;+\; \sum_{i=1}^{n}|d_{\text{out}}(i) - d_{\text{in}}(i)|\right).$$

In the case where $\deg(i) = |V| - 1$, Theorem 5.12 and Corollary 5.13 imply *NC* algorithms and analogous lower bounds for tournament ranking.

Acknowledgments. I am happy to thank Lenore Cowen, Dan Kleitman, Tom Leighton, and John Rompel for helpful discussions. Thanks to Prof. Dudley for helpful references. Also, thanks to Joel Spencer for suggesting the title and pointing out that the lower bound on discrepancy could be immediately applied to get an *NC* algorithm for the switching game.

TESTING SHARED MEMORIES*

PHILLIP B. GIBBONS† AND EPHRAIM KORACH‡

Abstract. Sequential consistency is the most widely used correctness condition for multiprocessor memory systems. This paper studies the problem of testing shared-memory multiprocessors to determine if they are indeed providing a sequentially consistent memory. It presents the first formal study of this problem, which has applications to testing new memory system designs and realizations, providing run-time fault tolerance, and detecting bugs in parallel programs.

A series of results are presented for testing an execution of a shared memory under various scenarios, comparing sequential consistency with linearizability, another well-known correctness condition. Linearizability imposes additional restrictions on the shared memory, beyond that of sequential consistency; these restrictions are shown to be useful in testing such memories.

Key words. sequential consistency, linearizability, multiprocessors, shared memory, testing, NP-completeness

1. Introduction.

Shared-memory multiprocessors typically promise application and system programmers some high-level view of the memory system. High-level correctness conditions such as sequential consistency [26] provide a conceptually simple framework for programming parallel machines. In a *sequentially consistent* memory, each execution is indistinguishable (by the processors) from an execution of a (very fast) serial memory in which only one read or write occurs at a time, in an order consistent with the respective sequences of reads and writes at the individual processors [26, 3]. Sequential consistency is the most widely used correctness condition for multiprocessor memory systems.

A memory system promising sequential consistency may fail to provide it for a number of reasons. First, high-performance shared-memory multiprocessors (cf. [5, 7, 12, 27]) employ a variety of techniques to improve their memory system performance (e.g., buffering, pipelining, caching, multiple paths to memory, parallel access to memory banks); these serve to distance the implementation from the sequential consistency abstraction. Subtle design errors can occur in the memory system architecture or in the supporting compilers due to the complexity of the design and the difficulty in reasoning about asynchronous, concurrent systems. Second, various hardware components may fail; such failures are more common in parallel machines due to the multitude of components devoted to providing the large shared-memory system. Third, certain implementations used in practice provide only an approximation to sequential consistency, e.g., *processor consistency*, as a tradeoff for improved performance [16]. Fourth, shared-memory multiprocessors may support *release consistency* [16, 21], which provides a sequentially consistent memory (only) for programs that are free of data races. (A *data race* occurs when two or more processors access the same location, with at least one writing, without intervening synchronization.) The memory system may fail to provide sequential consistency if the program contains data races.

In this paper, we study the problem of testing shared-memory multiprocessors to determine if they are indeed providing a sequentially consistent memory. We focus on the basic problem of testing whether the memory system provided sequential consistency for a given execution of a parallel program. For the given execution, the test provides certification of the consistency or inconsistency of the memory system during that execution, providing useful feedback whenever the memory system is suspect or the program may contain data races, as discussed above. The test can also be used as a building block in testing new memory system designs and realizations by verifying each execution in a suite of test executions.

This paper provides a formal and systematic study of the complexity of testing the correctness of an execution of a shared memory based on the reads and writes observed by the individual processors. We define the problem *verifying sequential consistency of shared-memory executions* (VSC) and prove that it is an NP-complete problem. This motivates the study of various restrictions on the problem to further characterize its complexity. Some of the variants that we consider are also motivated by their potential utility in testing executions of existing parallel machines.

We compare results obtained for testing for sequential consistency with results obtained for testing for linearizability, another well-known correctness condition. In a *linearizable* shared memory, each execution is indistinguishable from an execution of a serial memory, in which each read or write occurs at a distinct point in time between when it is issued by the processor and when the system acknowledges its completion [22]. We define the problem *verifying linearizability of shared-memory executions* (VL) and show that the additional restrictions imposed by linearizability beyond that of sequential consistency are quite useful in testing such memories. In particular, we present $O(n \log n)$-time algorithms for several variants of the VL problem whose corresponding VSC variants are NP-complete.

In an independent work, Wing and Gong [34] defined and studied the problem of testing and verifying linearizability for arbitrary shared data structures (e.g., a FIFO queue with push and pop operations). They developed a simulation environment for testing implementations (written using a C-Threads package) of shared data structures, using as a building block a procedure for verifying individual executions. This procedure uses a greedy algorithm that runs in exponential time; for this reason, Wing and Gong suggested testing implementations by verifying many, short executions (at most several hundred operations each). They also point out that the general problem they consider is NP-complete. Finally, they presented specifications, implementations, and proofs of correctness (i.e., linearizability) for a number of shared data structures. In contrast to their work, we focus specifically on shared memories, consider both sequential consistency and linearizability, and present fast algorithms for several important variants of these testing problems.

Other related previous work includes work on devising a suite of simple programs to help test whether the memory system is providing sequential consistency or a weaker correctness condition [11], work on detecting violations of sequential consistency within the memory system itself [14, 15], work on testing the serializability of database transactions [31], work on detecting data races (e.g., [2, 23, 28, 29]), work on proving that weak memory systems provide sequential consistency for programs that are free of data races (e.g., [1, 20, 21]), work on testing uniprocessor memories [9], work on algorithms for testing data structures on uniprocessors (e.g., [10]), work on verifying specific properties of cache-coherence protocols (e.g., [32] and the references therein), work on computing with faulty shared memories [4], work on de-

termining minimal ordering constraints needed to preserve sequential consistency [33], and work on comparing implementations of sequential consistency versus linearizability (e.g., [8]). However, none of this work addresses the general testing questions considered in this paper.

1.1. The testing problems. During an execution of a parallel program on a given multiprocessor, processors request to read or write particular shared-memory locations as dictated by the program, and the memory system responds to each request with a return value or acknowledgment. Associated with each processor is a total order on its shared-memory operations, denoted its *program order*. Associated with each read operation, $read(a, d, t_1, t_2)$, issued by a processor are the address a of the shared-memory location read, the value d returned for the read, the time t_1 the read was issued, and the time t_2 of the response. Likewise, associated with each write operation, $write(a, d, t_1, t_2)$, issued by a processor are the address a of the shared-memory location written, the value d written, the time t_1 the write was issued, and the time t_2 of the response. The times t_1 and t_2 define an interval of time for an operation: t_1 is the *start-of-interval* time for the operation and t_2 is the *end-of-interval* time for the operation.

We consider testing procedures in which for each processor we are given its sequence of shared-memory operations. Our goal is to determine whether or not the sequences can be interleaved as required by the correctness condition. For example, both sequential consistency and linearizability require that in the interleaved sequence, each read operation returned the value that was written by the last preceding write to the same location (the usual read/write semantics).

Sequential consistency. Sequential consistency is based on respecting the program orders and the read/write semantics, while ignoring the start-of-interval and end-of-interval times. We define the *verifying sequential consistency of shared-memory executions* (VSC) problem as follows.

VERIFYING SEQUENTIAL CONSISTENCY OF SHARED-MEMORY EXECUTIONS

INSTANCE: Variable set A, value set D, finite collection of nonempty sequences $S_1, \ldots, S_p$, each consisting of a finite set of memory operations of the form "$read(a, d)$" or "$write(a, d)$," where $a \in A, d \in D$.

QUESTION: Is there a sequence S, an interleaving of $S_1, \ldots, S_p$, such that for each $read(a, d)$ in S, there is a preceding $write(a, d)$ in S with no other $write(a, d')$ between the two?

We denote such a sequence S as a *legal schedule* for the instance; such a schedule certifies that the memory system provided sequential consistency for the execution corresponding to the instance. If there is no legal schedule, then the memory system failed to provide sequential consistency.

Figure 1 depicts a positive instance of the VSC problem. Figure 2 depicts a negative instance.

Linearizability. In contrast, linearizability adds the further constraint that the schedule S must respect the time intervals for the operations. We define the *verifying linearizability of shared-memory executions* (VL) problem as follows.

VERIFYING LINEARIZABILITY OF SHARED-MEMORY EXECUTIONS

INSTANCE: Variable set A, value set D, finite collection of nonempty sequences $S_1, \ldots, S_p$, each consisting of a finite set of memory operations of the form "$read(a, d, t_1, t_2)$" or "$write(a, d, t_1, t_2)$," where $a \in A$, $d \in D$, and t_1 and t_2 are positive rationals, $t_1 < t_2$, defining

$$S_1: \quad write(a,0), write(b,1), read(a,1).$$
$$S_2: \quad read(b,1), write(a,1), write(c,0).$$

FIG. 1. *A positive instance of the VSC problem. In fact, there are two different legal schedules:* $write(a,0)$, $write(b,1)$, $read(b,1)$, $write(a,1)$, $read(a,1)$, $write(c,0)$ *and* $write(a,0)$, $write(b,1)$, $read(b,1)$, $write(a,1)$, $write(c,0)$, $read(a,1)$.

$$S_1: \quad write(a,0), write(a,1), write(b,1).$$
$$S_2: \quad read(b,1), read(a,0).$$

FIG. 2. *A negative instance of the VSC problem. It is not possible to merge* S_1 *and* S_2 *into a legal schedule. For example, in the schedule* $write(a,0)$, $write(a,1)$, $write(b,1)$, $read(b,1)$, $read(a,0)$, *the operation* $write(a,1)$ *is between* $write(a,0)$ *and* $read(a,0)$. *Although* $write(a,1)$ *is an unread write, its existence makes this a negative instance.*

an interval of time such that all intervals in an individual sequence are pairwise disjoint, and t_1 and t_2 are unique rationals in the overall instance.

QUESTION: Is there an assignment of a distinct time to each operation such that

1. each time is within the interval associated with the operation;
2. for each $read(a,d,\tau_1,\tau_2)$, there is a $write(a,d,t_1,t_2)$ assigned an earlier time, with no other $write(a,d',t_1',t_2')$ assigned a time between the two?

Such a time assignment defines a *legal schedule* S that totally orders the operations in the instance. The memory system provided linearizability for the execution corresponding to the instance if and only if there is a legal schedule.

As in the VSC problem, a legal schedule is an interleaving of the individual processor sequences. Thus any linearizable execution is also sequentially consistent. However, as shown below, not all sequentially consistent executions are linearizable.

Figure 3 depicts a positive instance of the VL problem. Thus if the start-of-interval and end-of-interval times are removed from the instance, it is necessarily a positive instance of the VSC problem. Figure 4 depicts a negative instance of the VL problem; this particular instance corresponds to a positive instance of the VSC problem.

For both the VSC and VL problems, the formalization assumes that each variable (i.e., each shared-memory location) must be written before it is read; generalizations to handle reads of the initial state of memory are straightforward. A schedule has a *reads-from violation* if it has a read operation such that either there is no preceding write operation with the same address and value or there is an intervening write operation with the same address but a different value; such a schedule is not legal.

1.2. Results in this paper. Table 1 highlights and compares our main results for the VSC and VL problems. Both problems are NP-complete, as indicated in the table. Three restricted versions of the two problems are studied: bounding the number of operations in each processor sequence, bounding the number of locations in the instance, and bounding the number of processors. A "w.l.o.g." in Table 1

$$S_1: \quad write(a,1,1,3), write(b,1,4,6), write(c,1,7,8).$$
$$S_2: \quad read(b,1,2,5), read(a,1,9,10).$$

FIG. 3. *A positive instance of the VL problem. There are many possible legal time assignments, each of which schedules the write of a, then the write of b, then the read of b, then the write of c, and finally the read of a. If the start-of-interval and end-of-interval times are removed from the instance, we have a positive instance of the VSC problem.*

$$S_1: \quad write(a,0,1,2), read(a,0,5,6).$$
$$S_2: \quad write(a,1,3,4).$$

FIG. 4. *A negative instance of the VL problem. Since the write of value* 1 *must be assigned a time between the write of value* 0 *and the read of value* 0*, there is no legal VL schedule. However, the schedule* $write(a,0)$*,* $read(a,0)$*,* $write(a,1)$ *is a legal VSC schedule.*

indicates that the complexity of the problem is not affected by the given restriction. In addition, we define and study four important variants on the VSC and VL problems; these variants differ in the additional information provided as input, as detailed in section 4. Perhaps somewhat surprisingly, the VSC problem is NP-complete for all but one of the variants considered, in contrast with the results obtained for the VL problem. We also show how our algorithmic results can be extended to handle atomic read–modify–write operations, with no asymptotic penalty.

Our algorithms have small constants and hence are suitable for testing real shared memories (see [17, 19] for implementation details).

Since this is the first paper to study these problems systematically, a number of our NP-completeness results are obtained using somewhat standard techniques. For more interesting constructions, we refer the reader particularly to Theorems 4.3, 4.11, 3.5, and 2.7 of this paper.

The combinatorial questions that arise in studying these testing problems are interesting due to the asymmetry between reads and writes, and the fact that the constraints on legal schedules imposed by reads and writes to the same location cannot be represented as a partial order.

Outline of the paper. The remainder of this paper is organized as follows. Section 2 presents our results for the VSC problem, showing the problem is NP-complete, even with only two operations per processor, only two locations, or only three processors. These results are contrasted with results for the serializability problem for database transactions. Section 3 presents our results for the VL problem, showing that the problem is NP-complete even with only one operation per processor and only one location and, on the other hand, presenting an $O(n \log n)$-time algorithm when the number of processors is fixed. Section 4 presents our results for four variants of the VSC and VL problems that provide additional information as input, specifically, a read-mapping, write-order, read&write only, and conflict-order. It also presents our extensions to handle atomic read-modify-write operations.

Preliminary versions of this work appeared in [18, 19].

2. Verifying sequential consistency. We begin this section with a proof that the VSC problem is NP-complete, even with only two operations per processor (section 2.1). Then the VSC problem is shown to be NP-complete with only two locations

TABLE 1
A summary of the main results of this paper.

variant	*VSC result*	*VL result*
general problem	NP-complete	NP-complete
2 operations per proc	NP-complete	w.l.o.g.
2 locations	NP-complete	w.l.o.g.
3 processors	NP-complete	$O(n \log n)$
read-mapping	NP-complete	$O(n \log n)$
write-order	NP-complete	$O(n \log n)$
read&write only	NP-complete	NP-complete
conflict-order	$O(n \log n)$	$O(n \log n)$

(section 2.2) or only three processors (section 2.3). We conclude this section with some comparisons between the VSC problem (and the results obtained) and the serializability problem for database transactions (section 2.4).

2.1. The VSC problem is NP-complete. The VSC problem is in NP since given a schedule of the reads/writes in the processor sequences, we can test that the schedule is consistent with the processor sequences and does not have reads-from violations, in linear time in one pass through the schedule, simulating the operations.

THEOREM 2.1. *The VSC problem, restricted to instances in which each sequence contains at most two memory operations and each variable occurs in at most two write operations, is* NP*-complete.*

Proof. We use a reduction from the 3-Satisfiability (3SAT) problem [13]. Consider a 3SAT instance $\mathcal{F}$ with n variables, $v_1, \ldots, v_n$, and m clauses, $C_1, \ldots, C_m$. We use the notation $(v_i, S(v_i))$ to represent either the variable v_i (when $S(v_i) = \mathsf{T}$) or its complement $\overline{v}_i$ (when $S(v_i) = \mathsf{F}$) in a clause.

To reduce 3SAT to VSC, techniques are needed for simulating an OR and an AND, as well as an assignment of variables that remains in effect until the formula is evaluated. We observe that in all legal schedules, the following must hold:

1. The second operation in a processor sequence must not precede the first.
2. A read operation must not precede the first write operation with the same address and value.
3. A second write operation to an address, writing a different value than the first such write, must not precede any read operation of the first write (in order to avoid a reads-from violation).

Thus assignment to variable v_i can be simulated using the following four sequences, V_i^1, V_i^2, V_i^3, and V_i^4 (listed in columns):

$$\begin{array}{cccc} \underline{V_i^1} & \underline{V_i^2} & \underline{V_i^3} & \underline{V_i^4} \\ W(v_i, \mathsf{T}) & R(x,1) & W(v_i, \mathsf{F}) & R(x,1) \\ & R(v_i, \mathsf{T}) & & R(v_i, \mathsf{F}) \end{array},$$

where a write $W(x,1)$ (shown below) occurs only after the satisfiability of $\mathcal{F}$ has been simulated. Then both writes to v_i cannot occur before $W(x,1)$; this ensures that the initial assignment to each v_i must remain in effect until the satisfiability of $\mathcal{F}$ has been simulated.

An OR is simulated by having two writes to the same location of the same value: a read can be scheduled after either write. For each clause $C_j = (v_p, S(v_p)) \vee (v_q, S(v_q)) \vee$

V_1^1	V_1^2	V_1^3	V_1^4				
$W(v_1,\mathsf{T})$	$R(x,1)$	$W(v_1,\mathsf{F})$	$R(x,1)$				
	$R(v_1,\mathsf{T})$		$R(v_1,\mathsf{F})$	C_1^1	C_1^2	C_1^3	C_1^4
				$R(v_1,\mathsf{T})$	$R(v_3,\mathsf{F})$	$R(v_4,\mathsf{T})$	$R(d_1,\mathsf{T})$
V_2^1	V_2^2	V_2^3	V_2^4	$W(d_1,\mathsf{T})$	$W(d_1,\mathsf{T})$	$W(c_1,\mathsf{T})$	$W(c_1,\mathsf{T})$
$W(v_2,\mathsf{T})$	$R(x,1)$	$W(v_2,\mathsf{F})$	$R(x,1)$				
	$R(v_2,\mathsf{T})$		$R(v_2,\mathsf{F})$	C_2^1	C_2^2	C_2^3	C_2^4
				$R(v_1,\mathsf{F})$	$R(v_2,\mathsf{F})$	$R(v_4,\mathsf{T})$	$R(d_2,\mathsf{T})$
V_3^1	V_3^2	V_3^3	V_3^4	$W(d_2,\mathsf{T})$	$W(d_2,\mathsf{T})$	$W(c_2,\mathsf{T})$	$W(c_2,\mathsf{T})$
$W(v_3,\mathsf{T})$	$R(x,1)$	$W(v_3,\mathsf{F})$	$R(x,1)$				
	$R(v_3,\mathsf{T})$		$R(v_3,\mathsf{F})$	A^0	A^1	A^2	
				$W(x,0)$	$R(c_1,\mathsf{T})$	$R(c_2,\mathsf{T})$

$W(v_4,\mathsf{T})$	$R(x,1)$	$W(v_4,\mathsf{F})$	$R(x,1)$				
	$R(v_4,\mathsf{T})$		$R(v_4,\mathsf{F})$				

FIG. 5. *An example of the construction for transforming a* 3SAT *instance to a VSC instance in which each processor sequence has at most two operations and each address is written at most twice. Shown here are the sequences obtained for the* 3SAT *instance* $(v_1 \vee \overline{v}_3 \vee v_4) \wedge (\overline{v}_1 \vee \overline{v}_2 \vee v_4)$.

$(v_r, S(v_r))$, we have four sequences C_j^1, C_j^2, C_j^3, and C_j^4:

C_j^1	C_j^2	C_j^3	C_j^4
$R(v_p, S(v_p))$	$R(v_q, S(v_q))$	$R(v_r, S(v_r))$	$R(d_j,\mathsf{T})$
$W(d_j,\mathsf{T})$	$W(d_j,\mathsf{T})$	$W(c_j,\mathsf{T})$	$W(c_j,\mathsf{T})$

.

Four sequences, as opposed to three, are used in this construction since we are permitted at most two writes to a location. By observations 1 and 2 above, this ensures that the location c_j is not set to T unless clause C_j is satisfied by the guessed truth assignment.

Finally, the AND of the clauses is simulated by the following $m+1$ sequences, $A^0, A^1, \ldots, A^m$:

A^0	A^1	A^2	$\cdots$	A^m
$W(x,0)$	$R(c_1,\mathsf{T})$	$R(c_2,\mathsf{T})$		$R(c_m,\mathsf{T})$
$W(x,1)$	$R(x,0)$	$R(x,0)$		$R(x,0)$

.

The leftmost sequence ensures that $W(x,1)$ is the "second" write to its address. Thus by observation 3 above, x is not set to 1 unless all clauses have been satisfied by the guessed assignment.

This construction uses $4n+5m+1$ sequences and $n+2m+1$ distinct addresses. An example is given in Figure 5.

LEMMA 2.2. *Let $\mathcal{F}$ be an instance of a* 3SAT *problem, and let $\mathcal{V}$ be the instance of the VSC problem constructed as described above. Then $\mathcal{V}$ is a positive instance if and only if $\mathcal{F}$ is satisfiable.*

Proof. Suppose $\mathcal{F}$ is satisfiable. We will construct a schedule in which, for each i, the first write to v_i scheduled corresponds to the satisfying truth assignment. Let $T(v_1), \ldots, T(v_n)$, where $T(v_i) \in \{\mathsf{T}, \mathsf{F}\}$, be a satisfying assignment for $\mathcal{F}$. We construct the following schedule for $\mathcal{V}$:

1. first, $W(v_1, T(v_1)), \ldots, W(v_n, T(v_n))$;

2. then for $j = 1, 2, \ldots, m$, all sequences C_j^t whose read is $R(v_k, T(v_k))$ for some k, followed by C_j^4 if either C_j^1 or C_j^2 has been scheduled;
3. then $W(x, 0)$ from A^0, followed by the sequences A^1 to A^m, followed by $W(x, 1)$ from A^0;
4. then for $i = 1, 2, \ldots, n$, if $T(v_i) = \mathsf{T}$, the sequences V_i^2, V_i^3, and V_i^4; otherwise, if $T(v_i) = \mathsf{F}$, the sequences V_i^4, V_i^1, and V_i^2;
5. finally, for $j = 1, 2, \ldots, m$, any remaining sequences C_j^1, C_j^2, or C_j^3, followed by C_j^4 if it has yet to be scheduled.

The reader may verify that this is a legal schedule.

Conversely, suppose $\mathcal{V}$ is a positive VSC instance. If S is a legal schedule for $\mathcal{V}$, then the first value written to each v_i will be our satisfying assignment. We show that any unsatisfied clause corresponds to a cycle in S; a contradiction. For $i = 1, 2, \ldots, n$, let $T(v_i) = \mathsf{T}$ if $W(v_i, \mathsf{T})$ is before $W(v_i, \mathsf{F})$ in S; otherwise, let $T(v_i) = \mathsf{F}$. Suppose $T(v_1), \ldots, T(v_n)$ is *not* a satisfying assignment for $\mathcal{F}$, and let

$$C_k = (v_p, S(v_p)) \vee (v_q, S(v_q)) \vee (v_r, S(v_r))$$

be an unsatisfied clause. Let $\neg S(v_p)$, $\neg S(v_q)$, and $\neg S(v_r)$ denote the complement of $S(v_p)$, $S(v_q)$, and $S(v_r)$, respectively. Since C_k is not satisfied, $W(v_p, \neg S(v_p))$ is before $W(v_p, S(v_p))$, $W(v_q, \neg S(v_q))$ is before $W(v_q, S(v_q))$, and $W(v_r, \neg S(v_r))$ is before $W(v_r, S(v_r))$ in S. Since there are no reads-from violations in S and only two writes to v_p, all of the $R(v_p, \neg S(v_p))$ operations are before any of the $R(v_p, S(v_p))$ operations in S; similarly for v_q and v_r. Since S is a legal schedule, some $W(c_k, \mathsf{T})$ precedes the $R(c_k, \mathsf{T})$ in A^k, which precedes $W(x, 1)$, which precedes all $R(x, 1)$, including the one that precedes $R(v_p, \neg S(v_p))$, which as argued above precedes the $R(v_p, S(v_p))$ from C_k^1, which precedes the $W(d_k, \mathsf{T})$ on C_k^1. Likewise for v_q, some $W(c_k, \mathsf{T})$ precedes the $W(d_k, \mathsf{T})$ on C_k^2. One of these $W(d_k, \mathsf{T})$'s must precede the $R(d_k, \mathsf{T})$ on C_k^4 which precedes the $W(c_k, \mathsf{T})$ on C_k^4. A similar argument for v_r shows that some $W(c_k, \mathsf{T})$ also precedes $W(c_k, \mathsf{T})$ on C_k^3. This is a contradiction since only C_k^3 and C_k^4 contain $W(c_k, \mathsf{T})$. □

Since the above transformation can be done in polynomial time, Theorem 2.1 is proved. □

Note that instances with only one memory operation per processor can be solved by simply checking that there exists a write operation with the same address and value as each read operation.

We also observe that instances with long processor sequences can always be transformed to equivalent instances with at most three memory operations per processor.

OBSERVATION 2.3. *There is a linear-time reduction from the VSC problem with p sequences, n operations, and k variables to the VSC problem with n sequences, $O(n)$ operations, and $k + 1$ variables such that each sequence contains at most three operations.*

Proof. Let α be an address not in the original instance. For $i = 1, \ldots, p$, we replace the ith sequence in the instance, $s_1^{(i)}, s_2^{(i)}, \ldots, s_{m_i}^{(i)}$, with the following m_i sequences:

$$\begin{array}{ccccc} s_1^{(i)} & R(\alpha, x_1^{(i)}) & \cdots & R(\alpha, x_{m_i-2}^{(i)}) & R(\alpha, x_{m_i-1}^{(i)}) \\ W(\alpha, x_1^{(i)}) & s_2^{(i)} & & s_{m_i-1}^{(i)} & s_{m_i}^{(i)} \\ & W(\alpha, x_2^{(i)}) & & W(\alpha, x_{m_i-1}^{(i)}) & \end{array},$$

where $\forall i, j, i', j'$, $x_j^{(i)} = x_{j'}^{(i')}$ if and only if $i = i'$ and $j = j'$. There are a total of $\sum_{i=1}^{p}(3m_i - 2) = 3n - 2p$ operations. Since each new data value is unique, the

operations in the ith sequence of the original instance appear in sequence order in any legal schedule of the constructed instance. The reader may verify that this constructed instance is a positive instance if and only if the original instance is a positive instance. □

2.2. The VSC problem with two locations. We show that the VSC problem is NP-complete even when only two locations are used.

THEOREM 2.4. *The VSC problem restricted to instances with only two variables is* NP*-complete.*

Proof. Our reduction from 3SAT is depicted in Figure 6. We use two variables, a and b. Variable a is used to select a truth setting. The writes to a in the first sequence set instance variables to *true*; the writes to a in the second sequence set instance variables to *false*. For each instance variable, the second such write establishes the truth setting. Variable b is used to ensure that exactly one assignment is selected per instance variable by forcing both writes to a for this instance variable to be scheduled before any writes to a for the next instance variable.

The three sequences for a clause C_j begin with two reads, corresponding to a particular literal in the clause. The first read can be scheduled only after the variable's truth setting has been established; the second read can then be scheduled if the assignment to the variable matches the assignment needed for the clause.

The final write in the first sequence together with the first read in the third sequence ensure that all of the first and second sequences must be scheduled before any of the third sequence. The $2n$ writes at the end of the third sequence are used to clean up the remaining reads after the satisfiability of the 3SAT instance has been simulated. The reads in the third sequence demand that for each clause, at least one of the writes is scheduled prior to the cleanup: in order to schedule the $R(b, 2n + j)$ operation, we must first schedule a $W(b, 2n+j)$ operation on behalf of clause C_j. This in turn requires that the two reads to a in some sequence for C_j be scheduled prior to the cleanup, and this is possible only if that particular literal in C_j is satisfied.

LEMMA 2.5. *Let $\mathcal{F}$ be an instance of a* 3SAT *problem, and let $\mathcal{V}$ be the instance of the VSC problem constructed as described above. Then $\mathcal{V}$ is a positive instance if and only if $\mathcal{F}$ is satisfiable.*

Proof. Suppose $\mathcal{F}$ is satisfiable. We will construct a schedule in which, for each v_i, the latter of $W(a, \mathsf{T}_i)$ and $W(a, \mathsf{F}_i)$ scheduled corresponds to the satisfying truth assignment. Let $T(v_1), \ldots, T(v_n)$ be a satisfying assignment for $\mathcal{F}$, where $T(v_i) \in \{\mathsf{T}, \mathsf{F}\}$. We construct the following schedule for $\mathcal{V}$:

1. Repeat the following for $i = 1, 2, \ldots, n$: Consider group i. If $T(v_i) = \mathsf{T}$, schedule $W(a, \mathsf{F}_i)$, then $W(a, \mathsf{T}_i)$. Otherwise, schedule $W(a, \mathsf{T}_i)$, then $W(a, \mathsf{F}_i)$. Next, schedule $W(b, 2i-1)$, $R(b, 2i-1)$, $W(b, 2i)$. Then schedule all $R(b, 2i)$ operations. If $T(v_i) = \mathsf{T}$, schedule all $R(a, \mathsf{T}_i)$ operations. Otherwise, schedule all $R(a, \mathsf{F}_i)$ operations.
2. Schedule $W(a, \alpha)$, $W(b, \beta)$, $R(b, \beta)$.
3. Repeat the following for $p = 1, 2, \ldots, m$: Schedule any $W(b, 2n+p)$ for which both reads above it have been scheduled. Since each clause of $\mathcal{F}$ is satisfied, at least one such write can be scheduled. Then schedule $R(b, 2n + p)$.
4. Finally, we schedule the cleanup writes together with all unscheduled reads in the $3m$ clause sequences. At the very end, schedule all remaining writes to b in these clause sequences.

The reader may verify that this is a legal schedule.

Conversely, suppose $\mathcal{V}$ is a positive instance. If S is a legal schedule for $\mathcal{V}$, then

First, we have the following three sequences:

$W(a, \mathsf{T}_1)$	$W(a, \mathsf{F}_1)$	$R(b, \beta)$
$W(b, 1)$	$R(b, 1)$	$R(b, 2n+1)$
$R(b, 2)$	$W(b, 2)$	$R(b, 2n+2)$
$W(a, \mathsf{T}_2)$	$W(a, \mathsf{F}_2)$	:
$W(b, 3)$	$R(b, 3)$	$R(b, 2n+m)$
$R(b, 4)$	$W(b, 4)$	$W(a, \mathsf{T}_1)$
:	:	$W(a, \mathsf{F}_1)$
$W(a, \mathsf{T}_n)$	$W(a, \mathsf{F}_n)$	$W(a, \mathsf{T}_2)$
$W(b, 2n-1)$	$R(b, 2n-1)$	$W(a, \mathsf{F}_2)$
$R(b, 2n)$	$W(b, 2n)$	:
$W(a, \alpha)$		$W(a, \mathsf{T}_n)$
$W(b, \beta)$		$W(a, \mathsf{F}_n)$

Then for each clause C_j, say $C_j = v_p \vee \overline{v}_q \vee v_r$, we have the following three sequences:

$R(b, 2p)$	$R(b, 2q)$	$R(b, 2r)$
$R(a, \mathsf{T}_p)$	$R(a, \mathsf{F}_q)$	$R(a, \mathsf{T}_r)$
$W(b, 2n+j)$	$W(b, 2n+j)$	$W(b, 2n+j)$

FIG. 6. *Transforming an instance of* 3SAT *to an instance of VSC with just two locations, a and b. There are n variables, $v_1, \ldots, v_n$, and m clauses, $C_1, \ldots, C_m$ in the* 3SAT *instance. We construct a VSC instance with $3m+3$ sequences. $W(a, d)$ designates a write to location a of the value d; $R(a, d)$ designates a read from location a of the value d. Some data values are expressed as arithmetic expressions, e.g., $2n+m$, $2n+j$, $2p$, $2q$, and $2r$, indicating a value that is the result of evaluating the expression using the values of n, m, j, p, q, and r appropriate to the overall instance, the particular clause, or the particular variable.*

let $\mathcal{T}$ be the truth assignment corresponding to, for each v_i, the latter of $W(a, \mathsf{T}_i)$ and $W(a, \mathsf{F}_i)$ (from the first two sequences) scheduled. Let $S = S_1 S_2 S_3$, where S_1 is the prefix of S up to and including $W(b, \beta)$ and S_3 is the suffix of S starting with $W(a, \mathsf{T}_1)$ from the cleanup. All operations in the first two sequences are in S_1, but none of the last sequence is in S_1. Since the value of b is β at the end of S_1 and any writes to b not in S_1 write values in $[2n+1..2n+m]$, all of the reads of b in the clause sequences are in S_1.

Consider a clause C_p and its three sequences. If none of the three reads to a in these sequences are in S_1, then since the value of a is α at the end of S_1, all must be in S_3. But therefore all of the writes $W(b, 2n+p)$ are also in S_3. However, $R(b, 2n+p)$ must be in S_2, a contradiction. Consider a literal v_i in C_p (the case of $\overline{v}_i$ is symmetric). Since any $R(b, 2i)$ must be after the $W(b, 2i)$, which in turn must be after $W(b, 2i-1)$, this implies that $R(a, \mathsf{T}_i)$ must be after both $W(a, \mathsf{T}_i)$ and $W(a, \mathsf{F}_i)$. Therefore, in the three sequences of C_p, at least one of the reads to a in S_1 must read the value written by the second of these two writes. It follows that C_p is satisfied by T. □

Since the above transformation can be done in polynomial time, Theorem 2.4 follows. □

A simple modification of the previous construction shows that the VSC problem is NP-complete even when both the number of locations and the number of operations per sequence are small constants.

COROLLARY 2.6. *The VSC problem restricted to instances with only two variables is* NP*-complete, even if each sequence contains at most three memory operations.*

Proof. Since we are restricted to only two variables, the general reduction of Observation 2.3 cannot be applied. Instead, we divide the first sequence in Figure 6, with its $3n+2$ operations, into $n+1$ sequences, one with the first two operations only (i.e., creating the sequence $W(a, \mathsf{T}_1)$, $W(b, 1)$), and the remaining n with subsequent sets of three operations. We divide the second sequence in Figure 6, with its $3n$ operations, into n sequences of three operations each. Finally, we replace the last sequence in Figure 6, with its $2n + m + 1$ operations, with the following $m + n$ sequences of three operations each: the sequence $R(b, \beta)$, $R(b, 2n + 1)$, $W(a, \alpha_2)$; for $i = 2, \ldots, m - 1$, the sequence $R(a, \alpha_i)$, $R(b, 2n + i)$, $W(a, \alpha_{i+1})$; the sequence $R(a, \alpha_m)$, $R(b, 2n + m)$, $W(b, \beta_2)$; and finally, for $i = 1, \ldots, n$, the sequence $R(b, \beta_2)$, $W(a, \mathsf{T}_i)$, $W(a, \mathsf{F}_i)$. The reader may verify that this new construction is a positive instance if and only if the construction in Figure 6 is a positive instance. Thus the corollary follows from the proof of Theorem 2.4. □

2.3. The VSC problem for three processors. Many multiprocessors have only a small number of processors, e.g., 8, 16, or 32. We have shown that the VSC problem with $O(n)$ processors is NP-complete; in this section, we show that the VSC problem with just three processors is still NP-complete.

The previous NP-completeness proofs in this paper use a disjoint set of processors for each clause; some also use a disjoint set of processors for each variable. The difficulty in proving an NP-completeness result for a small fixed number of processors is that we do not have as much freedom to schedule operations in an arbitrary order, since the total order on operations at a processor must be respected by any legal schedule. Since processors are a scarce resource, care must be taken to ensure that the construction permits steady progress through each processor sequence, unless the intent is to construct a negative instance. In particular, for each read operation r, there is a corresponding write operation that can be scheduled closely after the operation preceding r at its processor.

Our reduction is from POSITIVE ONE-IN-THREE 3SAT, a variant of 3SAT in which no clause contains a negated literal and we seek a truth assignment such that each clause has exactly one true literal (and hence two false literals). This problem is known to be NP-complete [13]. We construct the instance of the VSC problem, using three processors, depicted in Figure 7.

The idea behind this construction is that the desired truth assignment is the second scheduled write to each v_i. Any legal schedule proceeds in stages, enforced by the seven-operation construction marked $(*)$. For each clause, each of the three processors is satisfied by a particular one-in-three assignment. The subtle part of the construction are the writes marked $(**)$. For any of the three ways to satisfy this clause, this construction frees up the other two processors (by negating variables), yet returns all variables to their original setting (for the next clause). Conversely, for any assignment that does not satisfy this clause, there is no legal scheduling of the operations in this stage.

THEOREM 2.7. *The VSC problem restricted to three processors is* NP*-complete.*

Proof. Let $\mathcal{F}$ be an instance of a POSITIVE ONE-IN-THREE 3SAT problem, and let $\mathcal{V}$ be the instance of the VSC problem constructed as depicted in Figure 7. We will show that $\mathcal{V}$ is a positive instance if and only if $\mathcal{F}$ is a positive instance.

Suppose $\mathcal{F}$ is one-in-three satisfiable. We will construct a schedule in which, for each i, the second write to v_i scheduled corresponds to the satisfying truth assignment.

$\underline{P1}$	$\underline{P2}$	$\underline{P3}$	
$W(v_1, \mathsf{T})$	$W(v_1, \mathsf{F})$		
$\cdots$	$\cdots$		
$W(v_n, \mathsf{T})$	$W(v_n, \mathsf{F})$

$R(v_{r_m}, \mathsf{F})$	$R(v_{p_m}, \mathsf{F})$	$R(v_{q_m}, \mathsf{F})$	(C_m)
$W(v_{p_m}, \mathsf{F})$	$W(v_{q_m}, \mathsf{F})$	$W(v_{r_m}, \mathsf{F})$	$(**)$
$W(v_{q_m}, \mathsf{T})$	$W(v_{r_m}, \mathsf{T})$	$W(v_{p_m}, \mathsf{T})$	$(**)$

FIG. 7. *Transforming an instance of* POSITIVE ONE-IN-THREE 3SAT *to an instance of VSC. There are* n *variables,* $v_1, \ldots, v_n$, *and* m *clauses,* $C_1, \ldots, C_m$, *where* $C_i = (v_{p_i}, \mathsf{T}) \vee (v_{q_i}, \mathsf{T}) \vee (v_{r_i}, \mathsf{T})$, *for* p_i, q_i, *and* $r_i \in \{1, 2, \ldots, n\}$.

Let $T(v_1), \ldots, T(v_n)$, where $T(v_i) \in \{\mathsf{T}, \mathsf{F}\}$, be a satisfying assignment for $\mathcal{F}$. We construct the following schedule for $\mathcal{V}$:

1. First, for $i = 1, 2, \ldots, n$, the pair $W(v_i, \mathsf{T})$, $W(v_i, \mathsf{F})$ if $T(v_i) = \mathsf{F}$, or the pair $W(v_i, \mathsf{F})$, $W(v_i, \mathsf{T})$ if $T(v_i) = \mathsf{T}$;
2. then $W(z, 1)$, $W(z, 2)$, $R(z, 1)$, $R(z, 2)$, $W(z, 3)$, $R(z, 3)$, $R(z, 3)$.
3. Since clause $C_1 = (v_{p_1}, \mathsf{T}) \vee (v_{q_1}, \mathsf{T}) \vee (v_{r_1}, \mathsf{T})$ is satisfied by a one-in-three assignment, exactly one of the following is true: (1) $T(v_{p_1}) = \mathsf{T}$, $T(v_{q_1}) = \mathsf{F}$, and $T(v_{r_1}) = \mathsf{F}$; (2) $T(v_{p_1}) = \mathsf{F}$, $T(v_{q_1}) = \mathsf{T}$, and $T(v_{r_1}) = \mathsf{F}$; or (3) $T(v_{p_1}) = \mathsf{F}$, $T(v_{q_1}) = \mathsf{F}$, and $T(v_{r_1}) = \mathsf{T}$. Suppose the first case holds (the other cases follow by symmetry). Schedule $R(v_{p_1}, \mathsf{T})$, $R(v_{q_1}, \mathsf{F})$, $R(v_{r_1}, \mathsf{F})$, $W(v_{p_1}, \mathsf{F})$, and $W(v_{q_1}, \mathsf{T})$ from $P1$; then $R(v_{q_1}, \mathsf{T})$, $R(v_{r_1}, \mathsf{F})$, $R(v_{p_1}, \mathsf{F})$, $W(v_{q_1}, \mathsf{F})$, and $W(v_{r_1}, \mathsf{T})$ from $P2$; then $R(v_{r_1}, \mathsf{T})$, $R(v_{p_1}, \mathsf{F})$, $R(v_{q_1}, \mathsf{F})$, $W(v_{r_1}, \mathsf{F})$, and $W(v_{p_1}, \mathsf{T})$ from $P3$. Note that at this point, the current "value" of each v_i is the same as it was before this step of the construction.
4. Repeat the construction of the previous two steps for clauses $C_2, \ldots, C_m$ in an analogous manner.

The reader may verify that this is a legal schedule.

Conversely, suppose $\mathcal{V}$ is a positive VSC instance. If S is a legal schedule for $\mathcal{V}$, then the second value written to each v_i will be our satisfying assignment. For $i = 1, 2, \ldots, n$, let $T(v_i) = \mathsf{T}$ if the first $W(v_i, \mathsf{F})$ from $P1$ precedes in S the first $W(v_i, \mathsf{T})$ from $P2$; otherwise, let $T(v_i) = \mathsf{F}$. A simple induction establishes that any prefix S_j of S ending in $W(z, 3j)$, $j = 1, \ldots, m$, contains precisely the following

events: all events in the prefix of $P1$ ending in $W(z, 3j-2)$, all events in the prefix of $P2$ ending in $W(z, 3j-1)$, and all events in the prefix of $P3$ ending in $W(z, 3j)$.

For $j = 1, \ldots, m$, consider the operations in $P1$, $P2$, and $P3$ in S immediately following S_j:

$$\begin{array}{lll} R(z,3j) & R(z,3j) & \\ R(v_{p_j},\mathsf{T}) & R(v_{q_j},\mathsf{T}) & R(v_{r_j},\mathsf{T}) \\ R(v_{q_j},\mathsf{F}) & R(v_{r_j},\mathsf{F}) & R(v_{p_j},\mathsf{F}) \\ R(v_{r_j},\mathsf{F}) & R(v_{p_j},\mathsf{F}) & R(v_{q_j},\mathsf{F}) \end{array} .$$

Due to these reads, it is not possible to extend S_j to a legal schedule unless the current "value" of exactly one of v_{p_j}, v_{q_j}, and v_{r_j} is T. Assume that v_{p_j} is T, while v_{q_j} and v_{r_j} are F. A careful inspection of the operations for C_j reveals that the following is a subsequence of S_{j+1} after S_j: $R(v_{p_j},\mathsf{T})$, $R(v_{q_j},\mathsf{F})$, $R(v_{r_j},\mathsf{F})$, $W(v_{p_j},\mathsf{F})$, $W(v_{q_j},\mathsf{T})$ (all from $P1$), $R(v_{q_j},\mathsf{T})$, $R(v_{r_j},\mathsf{F})$, $R(v_{p_j},\mathsf{F})$, $W(v_{q_j},\mathsf{F})$, $W(v_{r_j},\mathsf{T})$ (from $P2$), $R(v_{r_j},\mathsf{T})$, $R(v_{p_j},\mathsf{F})$, $R(v_{q_j},\mathsf{F})$, $W(v_{r_j},\mathsf{F})$, $W(v_{p_j},\mathsf{T})$ (from $P3$). This subsequence may be interleaved with the remaining operations in $S_{j+1} - S_j$, namely, $R(z,3j)$, $R(z,3j)$, $W(z,3j+1)$, $W(z,3j+2)$, $R(z,3j+1)$, $R(z,3j+2)$, and $W(z,3(j+1))$. By symmetry, these properties also hold in the case where v_{q_j} is T, while v_{r_j} and v_{p_j} are F, or the case where v_{r_j} is T, while v_{p_j} and v_{q_j} are F.

We claim that for $i = 1, \ldots, n$ and $j = 1, \ldots, m$, the "value" of v_i through S_j is $T(v_i)$. This is established via a simple induction, where the base case, $j = 1$, holds by definition. Moreover, by the characterization of S_{j+1} of the previous paragraph, it follows by inspection that for $i = 1, \ldots, n$, the "value" of v_i through S_{j+1} is the same as through S_j.

It follows that $T(v_1), \ldots, T(v_n)$ is a satisfying one-in-three assignment for each clause in $\mathcal{F}$, and hence $\mathcal{F}$ is one-in-three satisfiable. □

The construction depicted in Figure 7 uses only $n+1$ locations. Alternatively, it can be modified to have each location assume at most two values.

2.4. Comparison with serializability. The VSC problem is reminiscent of the serializability problem for database transactions. The most similar variant is that of view serializability. In the *view serializability* problem [31], we are given a *history* H, i.e., a total order on a set of reads and writes, where each read or write is associated with a particular database transaction, and each read or write contains an address but not a value. Each read is assumed to read from the last preceding write in H to the same address. The task is to determine if there is a total order on the *transactions* that preserves this mapping of reads to writes. The view serializability problem is NP-complete [31].

The VSC problem differs from the view serializability problem in at least four ways. First, in the VSC problem, legal schedules may interleave operations from different processors: the sequence of operations at a processor must be in order but need not be consecutive in a legal schedule. For example, the instance in Figure 1 is a positive VSC instance, but a negative instance for view serializability: both $S = S_1S_2$ and $S = S_2S_1$ have reads-from violations. Second, the *input* to a view serializability problem, a consistent total order of the reads and writes, is the desired *output* of the VSC problem. Third, when a database system is correctly enforcing serializability, each transaction that is not aborted will view an unchanged database during the course of its operations. Thus a single read of an address suffices to learn the value in that location for the duration of the transaction, and in general, it may be assumed that within each transaction, there is at most one read and one write to each location.

These restrictions are not appropriate for the VSC problem since communicating processors exchange values by writing and reading memory. Fourth, the VSC problem does not provide a mapping of reads to writes that must be preserved. However, in section 4, we will consider a variant of the VSC problem (the VSC-read problem) in which the input includes such a mapping, and a legal schedule must preserve this mapping.

For the VSC problem, we observe that the ability to interleave input sequences is not all that helpful unless the number of processors is bounded. Specifically, the construction in Observation 2.3 converts any VSC instance into one in which there is a legal schedule if and only if there is a legal schedule such that each processor sequence is a consecutive subsequence of the schedule. Thus the VSC problem is NP-complete even when interleaving is not permitted. On the other hand, if the number of processors is bounded, then interleaving is quite powerful. Whereas the VSC problem with three processors is NP-complete, there is a trivial linear-time algorithm for serializability when the number of transactions is restricted to a constant k: with k "processors," there are only a constant number, $k!$, of possible serializations to check.

3. Verifying linearizability. In this section, we present results for testing linearizability. We begin with some preliminary remarks in section 3.1, including an efficient reduction from the VL problem to the VSC problem. In section 3.2, we show that the VL problem is NP-complete. (The NP-completeness proof together with the reduction can be used for an alternative proof of Corollary 2.6.) Then in section 3.3, we present a polynomial-time algorithm for the VL problem with $O(\log n)$ processors.

3.1. Preliminaries. As discussed in section 1, linearizability is more restrictive than sequential consistency, in that a legal schedule must respect the time intervals for the operations. This added constraint makes implementations of linearizability provably slower than implementations of sequential consistency [8]. In the interest of memory system performance, shared-memory multiprocessors such as the Kendall Square KSR1 [12] support sequential consistency instead of linearizability. On the other hand, linearizability has the advantage over sequential consistency that each address, or, more generally, each shared data object, can be considered in isolation. Herlihy and Wing [22] proved that a system is linearizable if and only if each object in the system is linearizable. Thus linearizable objects can be implemented, verified, and executed independently. In this paper, we use the following implication of the Herlihy and Wing theorem.

FACT 3.1. *$\mathcal{V}$ is a positive instance of the VL problem if and only if, for each address a, the subinstance of $\mathcal{V}$ comprised solely of the operations on a is a positive instance.*

Thus as indicated in Table 1, we can assume without loss of generality that a VL instance has but a single location. This assumption does not alter the complexity of the problem: if $f(n)$ is the running time on an instance of size n, then since $f(n) \geq n$, $f(n) = f(\sum_{i=1}^{k} n_i) \geq \sum_{i=1}^{k} f(n_i)$, where $n_1, \ldots, n_k$ are the respective sizes of the subinstances on each of the k locations.

Note as well that if the number of processors is not bounded, then we can also assume without loss of generality that a VL instance has but a single operation per processor, as indicated in Table 1. This follows since the intervals for operations by a single processor do not overlap, so the total order between them is enforced whether or not they are considered to be part of the same processor sequence.

A VL instance can be reduced to a VSC instance that uses additional operations that reflect the scheduling constraints defined by the start-of-interval and end-of-interval times. Specifically, we have the following reduction from the VL problem to the VSC problem.

THEOREM 3.2. *There is an $O(n \log n)$-time reduction from the VL problem with n operations and k variables to k instances of the VSC problem with two variables, at most three memory operations per sequence, and a total of $O(n)$ operations over all instances.*

Proof. By Fact 3.1, it suffices to construct distinct VSC instances for each of the k variables in the VL instance. Consider one such variable, a, and let $\mathcal{V}$ be the subinstance comprised of the operations on a, with n_a operations. Let $t_1, t_2, \ldots, t_{n_a}$ be the end-of-interval times in $\mathcal{V}$ in increasing order. We construct the following VSC instance $\mathcal{V}'$ using two types of sequences. For each operation $read(a, d, t_i, t_j)$ or $write(a, d, t_i, t_j)$ in $\mathcal{V}$, we have in $\mathcal{V}'$ the following type I sequence: (1) $read(b, \tau)$, where τ is the largest end-of-interval time in $\mathcal{V}$ less than t_i (if any); (2) $read(a, d)$ or $write(a, d)$; and (3) $write(b, t_j)$. In addition, for each end-of-interval time t_j, $j < n_a$, we have a type II sequence (1) $read(b, t_j)$, (2) $read(b, t_{j+1})$. Clearly, $\mathcal{V}'$ is a VSC instance with two variables, at most three memory operations per sequence, and $O(n_a)$ operations. We will show that the operations on b encode the scheduling constraints defined by the start-of-interval and end-of-interval times.

We begin by showing that if two operations have nonoverlapping intervals in $\mathcal{V}$, then the order between them is respected by any legal schedule for $\mathcal{V}'$.

LEMMA 3.3. *Consider any two operations π_i and π_j in $\mathcal{V}$ and the corresponding operations π_i' and π_j' in $\mathcal{V}'$. If the end-of-interval time for π_i is less than the start-of-interval time for π_j, then π_i' precedes π_j' in any legal schedule for $\mathcal{V}'$.*

Proof. Let S' be a legal schedule for $\mathcal{V}'$. Consider the subsequence S_r' of S' of all $read(b, t)$ operations in $\mathcal{V}'$. Since there is exactly one $write(b, t)$ operation for each end-of-interval t, all $read(b, t)$ operations for the given t are consecutive in S_r' and follow this $write(b, t)$ operation in S'. Moreover, due to the type II sequences, the $read(b, t)$ operations in S_r' are in nondecreasing order of t. If the end-of-interval time t_i for π_i is less than the start-of-interval time t_j for π_j, then there is a $read(b, t_k)$ operation preceding π_j' in a type I sequence such that $t_k \geq t_i$. It follows that π_i' precedes $write(b, t_i)$ precedes $read(b, t_i)$ precedes $read(b, t_k)$ precedes π_j' in S'. ∎

We now prove the correctness of our construction.

LEMMA 3.4. *$\mathcal{V}'$ is a positive VSC instance if and only if $\mathcal{V}$ is a positive VL instance.*

Proof. Suppose $\mathcal{V}$ is a positive VL instance, and let A be an assignment of times for a legal schedule for $\mathcal{V}$. For each operation π' in $\mathcal{V}'$, define $A'(\pi')$ as follows:

1. If π' is an operation on a, then $A'(\pi') = A(\pi)$, where π is the corresponding operation in $\mathcal{V}$.
2. If π' is an operation on b with data value t, then $A'(\pi') = t$.

Let S be a sequence of the operations in $\mathcal{V}'$ in nondecreasing order according to A' such that among operations with the same A' value, the operation on a (if any) precedes the write operation on b precedes any read operations on b. We claim that S is a legal schedule for $\mathcal{V}'$. First, observe that any type II sequence appears in order in S. Moreover, consider the type I sequence constructed for an operation $\pi = read(a, d, t_1, t_2)$ or $write(a, d, t_1, t_2)$ in $\mathcal{V}$: $read(b, \tau)$ (if any), $\pi' = read(a, d)$ or $write(a, d)$, and $write(b, t_2)$. By construction and since A corresponds to a legal

schedule,

$$\tau < t_1 \leq A(\pi) = A'(\pi') \leq t_2,$$

and hence the type I sequence also appears in order in S. Thus S is an interleaving of the individual sequences. Second, there are no reads-from violations on a since the order of operations on a corresponds to a legal schedule for $\mathcal{V}$. Moreover, there are no reads-from violations on b since for each $read(b, \tau)$ operation, τ is an end-of-interval time, and hence a $write(b, \tau)$ operation is the last preceding write operation in S.

Conversely, suppose $\mathcal{V}'$ is a positive VSC instance, and let S' be a legal schedule for $\mathcal{V}'$. Let $S'_a = \pi'_1, \pi'_2, \ldots, \pi'_{n_a}$ be the subsequence of S' comprised of the operations on a. Let $S_a = \pi_1, \pi_2, \ldots, \pi_{n_a}$ be the corresponding operations in $\mathcal{V}$. Since S' is legal, there are no reads-from violations in S_a. Let ϵ_0 be the minimum difference between any pair of times (start-of-interval or end-of-interval) in $\mathcal{V}$; let $\epsilon = \epsilon_0/n$. We assign times to operations in S_a inductively as follows. The first operation π_1 is assigned a time equal to its start-of-interval time. For $k = 2, \ldots, n_a$, the operation π_k in S_a is assigned a time equal to the maximum of its start-of-interval time and ϵ greater than the time assigned to π_{k-1}. We claim that even in this latter case, the time assigned to π_k is within its interval. To see this, let π_i, $1 \leq i < k$, be the last operation preceding π_k in S_a that is assigned a time equal to its respective start-of-interval time t_i. The time assigned to π_k is $t_i + (k-i)\epsilon$. Since π'_i precedes π'_k in S', it follows by Lemma 3.3 that the start-of-interval time for π_i is less than the end-of-interval time for π_k by at least ϵ_0. Thus since

$$t_i + (k-i)\epsilon < t_i + n\epsilon = t_i + \epsilon_0,$$

the time assigned to π_k is within its interval. □

As the reader may verify, this transformation can be done in $O(n \log n)$ time. Theorem 3.2 follows. □

3.2. The VL problem is NP-complete. In this section, we prove the NP-completeness of the VL problem by a reduction from the Satisfiability problem (SAT) [13]. By Fact 3.1, it is necessary to consider a reduction based on a single location. The VL problem is in NP since given an assignment of times, we can test in polynomial time that each operation is assigned a time within its interval and that the schedule defined by the assignment has no reads-from violations.

THEOREM 3.5. *The VL problem is* NP*-complete.*

Proof. Consider an instance $\mathcal{F}$ of SAT with n variables, $v_1, v_2, \ldots, v_n$, and m clauses, $C_1, C_2, \ldots, C_m$. Without loss of generality, assume that each variable and its negation appear in at least one clause, but not the same clause, and that there are no repeated variables in a clause. We construct an instance of the VL problem with at most $5nm + 4n + m$ operations, corresponding to $\mathcal{F}$. To simplify the description, the construction has multiple operations sharing the same start-of-interval or end-of-interval times; these ties can be broken arbitrarily to ensure unique time values. In particular, we use only integral times in our simplified description, with at most $m + 2$ intervals sharing the same start or end time, so unique positive rationals can be readily selected to break any ties.

Figure 8 depicts an example construction. For each clause C_j, $j = 1, \ldots, m$, we have a $read(a, c_j, 1, 3n{+}1)$ operation, denoted the *clause read* for C_j. For each variable v_i, $i = 1, \ldots, n$, assignment to v_i is simulated using two operations: $write(a, i, 3i - 1, 3i)$ and $write(a, \bar{\imath}, 3i - 1, 3i)$.

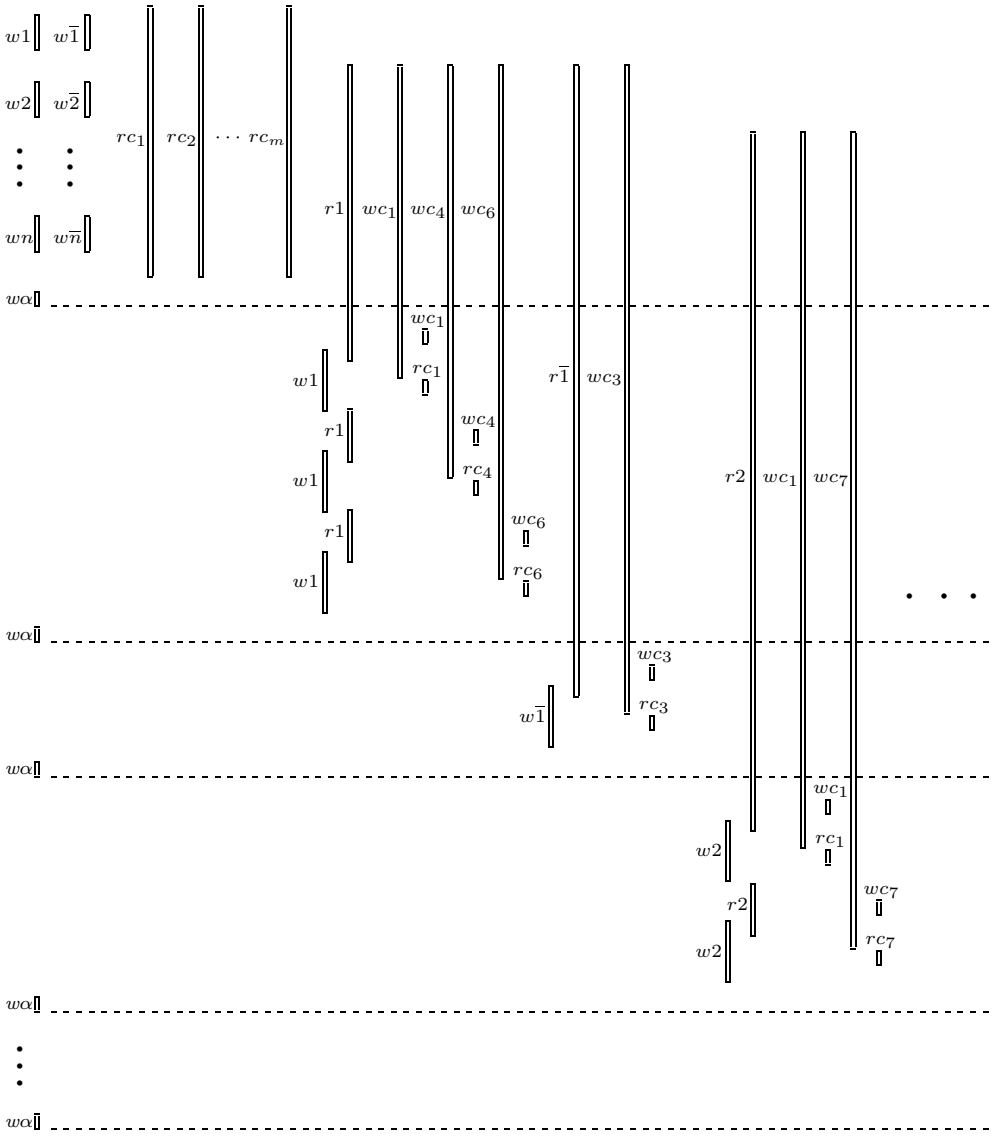

FIG. 8. *Transforming an instance of* SAT *to an instance of VL with a single location. There are* n *variables,* $v_1, \ldots, v_n$*, and* m *clauses,* $C_1, \ldots, C_m$*. The full construction has at most* $5nm+4n+m$ *operations. Here the literal* v_1 *appears in exactly clauses* C_1*,* C_4*, and* C_6*, the literal* $\overline{v}_1$ *appears in clause* C_3 *only, the literal* v_2 *appears in exactly clauses* C_1 *and* C_7*, and so forth. Every column corresponds to a processor sequence. Vertical boxes depict the intervals of time for the respective read* (r) *or write* (w) *operations to the single location; time progresses from top to bottom in the figure. The number or symbol following each* r *or* w *indicates the value read or written.*

We have $2n$ write operations, used to partition the problem into $2n$ phases, one for each literal, as follows. Consider $i = 1, \ldots, n$. Let m_i ($m_{\overline{i}}$) be the number of clauses containing the literal v_i ($\overline{v}_i$, respectively). By assumption, $m_i > 0$, $m_{\overline{i}} > 0$, and $m_i + m_{\overline{i}} \leq m$. Let $\Delta_i = (7m+4)(i-1) + 3n + 3$ and let $\Delta_{\overline{i}} = \Delta_i + 7m_i + 2$. There is a $write(a, \alpha, \Delta_i - 1, \Delta_i)$ and a $write(a, \alpha, \Delta_{\overline{i}} - 1, \Delta_{\overline{i}})$.

There is a set of operations for each literal v_i, denoted the *group* of operations for i. For $i = 1, \ldots, n$, if $C_{i_1}, C_{i_2}, \ldots, C_{i_{m_i}}$ are the clauses containing the literal v_i, we have the following $5m_i$ intervals. First, for C_{i_1}, we have

- $ri^{(1)} = read(a, i, 3i + 1, \Delta_i + 4)$,
- $wi^{(1)} = write(a, i, \Delta_i + 3, \Delta_i + 7)$,
- $wc_{i_1}^{(1)} = write(a, c_{i_1}, 3i + 1, \Delta_i + 5)$,
- $wc_{i_1}^{(2)} = write(a, c_{i_1}, \Delta_i + 1, \Delta_i + 2)$,
- $rc_{i_1} = read(a, c_{i_1}, \Delta_i + 5, \Delta_i + 6)$.

Then for C_{i_k}, $k = 2, \ldots, m_i$, we have

- $ri^{(k)} = read(a, i, \Delta_i + 7(k-1), \Delta_i + 7(k-1) + 4)$,
- $wi^{(k)} = write(a, i, \Delta_i + 7(k-1) + 3, \Delta_i + 7(k-1) + 7)$,
- $wc_{i_k}^{(1)} = write(a, c_{i_k}, 3i + 1, \Delta_i + 7(k-1) + 5)$,
- $wc_{i_k}^{(2)} = write(a, c_{i_k}, \Delta_i + 7(k-1) + 1, \Delta_i + 7(k-1) + 2)$,
- $rc_{i_k} = read(a, c_{i_k}, \Delta_i + 7(k-1) + 5, \Delta_i + 7(k-1) + 6)$.

The operations $wc_{i_1}^{(1)}, wc_{i_2}^{(1)}, \ldots, wc_{i_{m_i}}^{(1)}$ are denoted the *clause writes* for v_i.

Likewise, there is a set of operations for each literal $\overline{v}_i$, denoted the *group* of operations for $\bar{\imath}$. For $i = 1, \ldots, n$, if $C_{\bar{i}_1}, C_{\bar{i}_2}, \ldots, C_{\bar{i}_{m_{\bar{i}}}}$ are the clauses containing the literal $\overline{v}_i$, we have the $5m_{\bar{i}}$ intervals obtained from the previous definition by replacing $\Delta_{\bar{\imath}}$ with Δ_{i+1} and leaving "$3i + 1$" unchanged but otherwise replacing i with $\bar{\imath}$ throughout.

This completes the construction.

The idea behind the construction is the following. Consider a variable v_1, and refer to Figure 8. Recall that all reads and writes are to the same location. Both $w1$ and $w\overline{1}$ on the left must be scheduled before any $r1$ or $r\overline{1}$; the second write scheduled corresponds to the truth assignment. If $w1$ is scheduled second, then the first $r1$ can be scheduled, followed by the clause writes wc_1, wc_4, and wc_6 for v_1. If all clauses can be satisfied by the truth setting, then the set of all clause writes will ensure that all m clause reads can be scheduled during their common interval. Consider the three $w1$ operations and the two $r1$ operations below the first dashed line, together with the $r1$ operation that crosses this line. Since the crossing $r1$ has been scheduled, the two $r1$ operations below the line can pair up with the first two $w1$ operations; this in turn permits the rc_1 (below the line) to be paired with the wc_1 directly above it. On the other hand, if $w\overline{1}$ had been scheduled second instead, then the first $w1$ is paired with the crossing $r1$. Hence the first $w1$ is scheduled between the intervals for the wc_1 and the rc_1 below the line; this implies that a clause write wc_1 is needed below the line. For this reason, all clause writes for a literal not in the truth assignment must be scheduled below the first dashed line. It follows that all clause reads can be scheduled if and only if we have a satisfying truth assignment.

LEMMA 3.6. *Let $\mathcal{F}$ be an instance of a* SAT *problem, and let $\mathcal{V}$ be the instance of the VL problem constructed as described above. Then $\mathcal{V}$ is a positive instance if and only if $\mathcal{F}$ is satisfiable.*

Proof. Suppose $\mathcal{F}$ is satisfiable. We will construct a schedule in which, for each v_i, the latter of $write(a, i, 3i - 1, 3i)$ and $write(a, \bar{\imath}, 3i - 1, 3i)$ scheduled corresponds to the satisfying truth assignment. Let $T(v_1), \ldots, T(v_n)$, where $T(v_i) \in \{\mathsf{T}, \mathsf{F}\}$, be a satisfying assignment for $\mathcal{F}$. We construct the following schedule for $\mathcal{V}$:

1. Repeat the following for $i = 1, 2, \ldots, n$:
   If $T(v_i) = \mathsf{T}$, schedule $write(a, \bar{\imath}, 3i - 1, 3i)$ at time $3i - 1$, then $write(a, i, 3i - 1, 3i)$ at time $3i$. Consider the $5m_i$ operations in the group for i, together with

the m_i corresponding clause reads, $read(a, c_{i_1}, 1, 3n+1)$ through $read(a, c_{i_{m_i}}, 1, 3n+1)$. Schedule $ri^{(1)} = read(a, i, 3i+1, \Delta_i+4)$ at time $3i+1$. Then after time $3i+1$ and before time $3i+2$, for $k = 1, \ldots, m_i$, schedule each of m_i clause writes paired with any unscheduled, corresponding clause reads: $wc_{i_k}^{(1)} = write(a, c_{i_k}, 3i+1, \Delta_i + 7(k-1) + 5)$ followed by, if it has not yet been scheduled, $read(a, c_{i_k}, 1, 3n+1)$.

The case where $T(v_i) = \mathsf{F}$ is symmetric, and left to the reader.

2. Since $T(v_1), \ldots, T(v_n)$ is a satisfying assignment for $\mathcal{F}$, all clause reads have been scheduled by this point. Schedule $write(a, \alpha, \Delta_1 - 1, \Delta_1)$ at time Δ_1.
3. Repeat the following for $i = 1, 2, \ldots, n$:
   If $T(v_i) = \mathsf{T}$, consider the $4m_i - 1$ unscheduled operations in group i and the $5\overline{m}_i$ unscheduled operations in group $\bar{\imath}$:
   (a) Schedule $wc_{i_1}^{(2)}$ at time $\Delta_i + 2$, then rc_{i_1} at time $\Delta_i + 5$, then $wi^{(1)}$ at time $\Delta_i + 7$.
   (b) Then repeat for $k = 2, \ldots, m_i$: Schedule $ri^{(k)}$ at time $\Delta_i + 7(k-1) + 1$, then $wc_{i_k}^{(2)}$ at time $\Delta_i + 7(k-1) + 2$, then rc_{i_k} at time $\Delta_i + 7(k-1) + 5$, and finally $wi^{(k)}$ at time $\Delta_i + 7(k-1) + 7$.
   (c) This completes group i. Schedule $write(a, \alpha, \Delta_{\bar{\imath}} - 1, \Delta_{\bar{\imath}})$ at time $\Delta_{\bar{\imath}}$.
   (d) Schedule $wc_{\bar{\imath}_1}^{(2)}$ at time $\Delta_{\bar{\imath}} + 1$, then $w\bar{\imath}^{(1)}$ at time $\Delta_{\bar{\imath}} + 3$, then $r\bar{\imath}^{(1)}$ at time $\Delta_{\bar{\imath}} + 4$, then $wc_{\bar{\imath}_1}^{(1)}$ at time $\Delta_{\bar{\imath}} + 5$, and finally $rc_{\bar{\imath}_1}$ at time $\Delta_{\bar{\imath}} + 6$.
   (e) Then repeat for $k = 2, \ldots, m_{\bar{\imath}}$: Schedule $wc_{\bar{\imath}_k}^{(2)}$ at time $\Delta_{\bar{\imath}} + 7(k-1) + 1$, then $w\bar{\imath}^{(k)}$ at time $\Delta_{\bar{\imath}} + 7(k-1) + 3$, then $r\bar{\imath}^{(k)}$ at time $\Delta_{\bar{\imath}} + 7(k-1) + 4$, then $wc_{\bar{\imath}_k}^{(1)}$ at time $\Delta_{\bar{\imath}} + 7(k-1) + 5$, and finally $rc_{\bar{\imath}_k}$ at time $\Delta_{\bar{\imath}} + 7(k-1) + 6$.
   (f) This completes group $\bar{\imath}$. Schedule $write(a, \alpha, \Delta_{i+1} - 1, \Delta_{i+1})$ at time Δ_{i+1}.

   The case where $T(v_i) = \mathsf{F}$ is symmetric and left to the reader.

The reader may verify that this is a legal schedule.

Conversely, suppose $\mathcal{V}$ is a positive instance. If $\mathcal{S}$ is a legal schedule for $\mathcal{V}$, then let $\mathcal{T}$ be the truth assignment defined as follows: for each v_i, if $write(a, \bar{\imath}, 3i-1, 3i)$ precedes $write(a, i, 3i-1, 3i)$ in $\mathcal{S}$, then $\mathcal{T}(v_i) = \mathsf{T}$; otherwise, $\mathcal{T}(v_i) = \mathsf{F}$.

We observe the following for $i = 1, \ldots, n$: Both $write(a, i, 3i-1, 3i)$ and $write(a, \bar{\imath}, 3i-1, 3i)$ precede both $ri^{(1)}$ and $r\bar{\imath}^{(1)}$ in $\mathcal{S}$. Thus if $\mathcal{T}(v_i) = \mathsf{F}$, then while $r\bar{\imath}^{(1)}$ may be scheduled in $\mathcal{S}$ prior to time $3i+3$, $ri^{(1)}$ cannot be. The $ri^{(1)}$ operation must be scheduled after the only other operation that writes i prior to the end of its interval, namely $wi^{(1)}$. Hence $wc_{i_1}^{(2)}$ precedes $wi^{(1)}$ precedes $ri^{(1)}$ precedes rc_{i_1}. But this implies that for $k = 2, \ldots, m_i$, $wc_{i_k}^{(2)}$ precedes $wi^{(k)}$ precedes $ri^{(k)}$ precedes rc_{i_k}. The case where $\mathcal{T}(v_i) = \mathsf{T}$ is symmetric.

Suppose $\mathcal{T}$ does not satisfy a clause C_j. Consider the literals in C_j sorted by their index, and let x be the number of literals in C_j. For $k = 1, \ldots, x$, define $j_k \in \{1, \bar{1}, 2, \bar{2}, \ldots, n, \bar{n}\}$ such that $j_k = i$ (or $\bar{\imath}$) if and only if v_i ($\overline{v}_i$, respectively) is the kth literal in C_j. We claim that all writes of c_j are scheduled in $\mathcal{S}$ after Δ_1. The proof is by induction on decreasing k. Consider the last rc_j in $\mathcal{S}$, in group j_x. Due to the argument given in the preceding paragraph, there is only one write of c_j that could have been scheduled so as to be read by the rc_j: the sole write of c_j in group j_x whose interval is not strictly after Δ_{j_x}. Assume inductively that all writes of c_j from groups j_{k+1} to j_x are scheduled after $\Delta_{j_{k+1}}$. Thus due to the argument given in the preceding paragraph, there is only one write of c_j that could have been scheduled so

as to be read by the rc_j: the sole write of c_j in group j_k whose interval is not strictly after Δ_{j_k}. The claim follows by induction.

Since there are no writes of c_j in $\mathcal{S}$ until after $\Delta_1 = 3n + 3$, but the clause read $read(a, c_j, 1, 3n + 1)$ must be scheduled before Δ_1, $\mathcal{S}$ is not a legal schedule, a contradiction.

Hence $\mathcal{T}$ is a satisfying assignment for $\mathcal{F}$. □

Since the above transformation can be done in polynomial time, Theorem 3.5 follows. □

3.3. The VL problem with few processors. In this section, we describe a polynomial-time algorithm for the VL problem when the number of processors (i.e., sequences) is bounded. Recall that if two operations have nonoverlapping intervals, their order in any legal schedule is predetermined. Thus since we can consider each address in isolation, the number of possible schedules grows with the number of overlapping intervals for operations on that address. The specific result we obtain is the following.

THEOREM 3.7. *The VL problem restricted to instances such that at any time t, there are at most k operations on the same address whose intervals contain t, can be solved in $O(n2^{O(k)} + n \log n)$ time.*

Proof. We consider each address x in isolation. Let S_x be the set of operations on x. Let $t_0 > 0$ be the earliest start-of-interval time and t_∞ be the latest end-of-interval time for an operation in S_x. To simplify the discussion that follows, we augment S_x with two additional writes to x: Let $S'_x = S_x \cup \{write(x, \delta, t_0/3, t_0/2), write(x, \delta, t_\infty + 1, t_\infty + 2)\}$, where δ is a value not appearing in S_x. For each address, we may assume without loss of generality that there are only k processors.

Let G_x be a leveled acyclic digraph, with one level for each operation in S'_x, in order of increasing end-of-interval times, and at most $k2^{k-1}$ vertices per level, as follows. We identify each level by the finishing time t of its corresponding operation α_t. There are at most $k - 1$ additional operations in S'_x with intervals containing t; these may or may not be assigned times greater than t. Consider all possible subsets of these operations; there are at most 2^{k-1} of them. Each vertex at level i specifies one of these subsets, plus a last write to x. The vertex represents a prefix of a schedule of the operations in S'_x, namely, a schedule in which the operations in the subset as well as all operations with start-of-interval times after t are assigned times later than t, and the last write assigned a time no later than t is indicated. Since for a given subset there are at most k possible choices of a last write, we have at most $k2^{k-1}$ nodes. The first level consists of a single node, with last write $write(x, \delta, t_0/3, t_0/2)$; the last level consists of a single node, with last write $write(x, \delta, t_\infty + 1, t_\infty + 2)$.

The edges of G_x are defined as follows. Consider two consecutive levels t and t', and let α and α' be the operations with end-of-interval times t and t', respectively. All intervals, other than α's, that contain time t must contain t'. Consider two vertices in G_x, v at level t and v' at level t'. There is an edge between v and v' if the following conditions hold:

1. Every interval containing both t and t' that was assigned a time no later than t, according to v, is also assigned a time no later than t', according to v'.
2. Let A be the set of operations with intervals containing t' (including possibly α') that were assigned a time later than t (either they do not contain t or they contain t but were assigned a time later than t, according to v) but were assigned a time no later than t', according to v'. Every read in A must either read the value of the last write in v or has a corresponding write of the same value in A. Moreover, the last write in v' must either be in the set A or, if

there are no writes in A, the same last write as in v.

Note that the operations in A can be safely scheduled without reads-from violations in the interval between the last start-of-interval time in A and t'. It follows that there is a directed edge from v to v' if and only if there is a schedule consistent with both v and v'. This leads to the following claim, whose proof is left to the reader.

CLAIM 3.8. *We have a positive VL instance if and only if there is a source-to-sink path in G_x for each address x.*

To construct the graphs for each address, first we sort the operations by address, and within an address, by their starting and finishing times (each operation appears twice in this sorted sequence). Then we test for each pair of vertices on consecutive levels whether a directed edge should be between them. Next, we test for a source-to-sink path in each G_x using depth-first search. If we have a positive instance, we assign times to the operations based on the information in the vertices visited along the source-to-sink paths. Each G_x can be constructed and searched in $O(n_x 2^{O(k)})$ time, where n_x is the number of operations in S_x. Thus the total running time is $O(n \log n + n2^{O(k)})$. □

Since with k processors there can be at most k overlapping intervals, Theorem 3.7 implies, for instance, the following two corollaries.

COROLLARY 3.9. *There is an $O(n \log n)$-time algorithm for the VL problem with any fixed number of processors.*

COROLLARY 3.10. *There is a polynomial-time algorithm for the VL problem with $O(\log n)$ processors.*

4. Providing additional input information. In the previous sections, we have considered the basic VSC and VL problems, in which the only constraints on legal schedules arise from (1) either the order of operations at a processor or the time intervals, and (2) the fact that some write operation with the same address and value must precede each read operation, with no intervening write with the same address but a different value. In this section, we consider variants of the VSC and VL problems in which the input provides additional information on either the pairing of reads to particular writes (section 4.1), the order of writes to a location (section 4.2), the old value overwritten by each write (section 4.3), or the order of all conflicting operations to a location (section 4.4). As shown in Table 1, this additional information helps in some cases, but not in others. We also show how our algorithmic results can be extended to handle atomic read-modify-write operations, with no asymptotic penalty (section 4.5).

Each of the variants considered in this section is motivated by practical considerations in existing multiprocessors. For further details, we refer the reader to [17, 19].

We require that the additional information provided by the memory system as input in these variants be respected in any legal schedule. What happens if the additional information provided is incorrect? If there are anomalies in the additional information, e.g., a read is paired with a write with a different address, we detect this and report a negative instance. If the additional information is incorrect such that a positive instance (ignoring the information) becomes a negative instance, we report a negative instance: there is clearly something wrong with the memory system. The most important property that we require, however, is that the testing procedure must never be persuaded by incorrect (or even correct) additional information that an execution was sequentially consistent or linearizable when in fact it was not. Conversely, if both the execution and the additional information were correct, the testing procedure must report a positive instance.

4.1. Providing the read-mapping. In the basic VSC and VL problems, whenever there are multiple writes with the same address and value, there may be ambiguity as to which of the writes is to be paired with a given read of the same address and value. The question addressed in this section is as follows: If for each read there is no ambiguity as to with which write it is to be paired, do the VSC and VL problems remain NP-complete?

We define the *VSC-read* and *VL-read* problems, in which for each read operation, it is known precisely which write was responsible for the value read; a legal schedule must respect this relation. (A schedule S respects the relation if and only if, for each read in S, the write to which it is mapped is the last preceding write in S with the same address.) The function mapping each read to the responsible write is called a *read-mapping*. A schedule that does not respect the read-mapping has a *reads-from violation*.

VSC-read. We will show that the VSC-read problem is NP-complete by a reduction from view serializability. Recall that in the *view serializability* problem, we are given a *history* H, i.e., a total order on a set of reads and writes, where each read or write is associated with a particular database transaction, and each read or write contains an address but not a value. Each read is assumed to read from the last preceding write in H to the same address. The task is to determine if there is a total order on the *transactions* that preserves the read-mapping in H.

THEOREM 4.1. *The VSC-read problem restricted to instances in which each sequence contains at most three memory operations is* NP*-complete.*

Proof. We begin by showing a reduction to the VSC-read problem with no restrictions on the number of operations in a sequence. Given a history H, an instance of a view serializability problem, we construct an instance of the VSC-read problem as follows. Let α be an address not in H. Let S_i' be the sequence of operations in H for transaction i, where each write operation in a transaction is assigned a unique value to write, and each read operation is assigned the value of the last previous write in H to the same address. Let $S_i = W(\alpha, i)S_i'R(\alpha, i)$ for all transactions i. This construction ensures that all operations in S_i must be scheduled consecutively in any legal schedule: any schedule that interleaves operations from different S_i's must violate the reads-from mapping for α. It follows that we have a positive VSC-read instance if and only if H is view serializable.

To complete the theorem, we note that Observation 2.3 can be adapted to the VSC-read problem by simply adding the read-mapping. □

VL-read. We now turn to the VL-read problem and show that, in contrast to the VSC-read problem, there is an $O(n \log n)$-time algorithm for this problem.

THEOREM 4.2. *There is an $O(n \log n)$-time algorithm for the VL-read problem.*

Proof. We sort the input by address, and within an address, by start-of-interval and end-of-interval times. We check to see that each read is mapped to a write operation with the same address and value; otherwise, we have a negative instance. Consider each address separately. Define a *cluster* to be a write w and the set R of reads mapped to the write. The write w must be assigned a time earlier than that of any read in R. Thus the start-of-interval time for w must be earlier than the end-of-interval time for any read in R; otherwise, we have a negative instance. Any legal time assignment defines an interval for a cluster from the time assigned to w to the time assigned to the last read in R; only operations in this cluster can be scheduled during this time interval. Define a *zone* for a cluster to be the interval from the earliest end-of-interval time for an operation in the cluster to the latest start-of-interval time

for an operation in the cluster. In the normal scenario, the former is earlier than the latter, and we have a *forward* zone; otherwise, we have a *backward* zone. For any legal time assignment, the interval of time for a cluster with a forward zone must contain that zone. Therefore, if two forward zones overlap, we have a negative instance.

For a cluster with a backward zone, the backward zone is the intersection of the individual operation intervals for operations in the cluster. Thus all operations in a cluster can be safely scheduled in *any* subinterval of the zone of positive length. Moreover, one can see that the interval of time for the cluster in any legal time assignment must intersect its backward zone. It follows that if a backward zone is contained within the forward zone for some other cluster, we have a negative instance.

Finally, if none of the illegal configurations described above occurs, we have a positive instance. Let ϵ_0 be the minimum difference between any pair of times in the instance. Augment each forward zone by $\epsilon_0/3$ before and after the zone. Then the operations in forward zone clusters are safely scheduled within their respective augmented zones, and the operations in backward zone clusters are safely scheduled outside all augmented forward zones using nonoverlapping subintervals: for each cluster, w is scheduled at the start of the augmented zone or subinterval, and then the operations in R are scheduled in order of start-of-interval times. The reader may verify that this is a legal schedule.

The final legal schedule is obtained by merging the individual schedules for each address. After the initial sorting, the algorithm runs in linear time. □

4.2. Providing the write-order. A second source of ambiguity in the basic VSC and VL problems is that there may be multiple writes to the same location by different processors. The question addressed in this section is as follows: If for each location there is no ambiguity as to the order of writes to the location, do the VSC and VL problems remain NP-complete?

We define the *VSC-write* and *VL-write* problems, in which for each shared-memory location, a total order on the write operations to the location is known; a legal schedule must respect this *write-order* relation.

VSC-write. We show that the VSC-write problem is NP-complete. In fact, we prove that the VSC problem is NP-complete even when each location is written to by only a single processor, yielding the following stronger result.

THEOREM 4.3. *The VSC and VSC-write problems restricted to instances in which each location is written to by only a single processor are* NP*-complete.*

Proof. Our reduction from 3SAT is depicted in Figure 9. The construction consists of operations used to select a truth assignment and then to test each clause. We use the $W(ok)$ operation in the first sequence to signal when all clauses have been tested and it is time to clean up so that the set of operations not used in testing the particular assignment may be safely scheduled if and only if the assignment satisfied the 3SAT instance. Note that for each location, all writes to that location appear in the same sequence. Thus for the VSC-write problem, the write-order is implied by the order of the individual sequences.

In all three NP-completeness proofs of section 2, the constructions have, for each variable, two writes to the same location such that the order between the two writes determines the truth setting for the variable. Here the order on two such writes is predetermined by the order in which they appear in their processor sequence. Hence we use two writes to *different* locations, which must somehow be coupled so that only one setting of the 3SAT variable occurs prior to the cleanup. The first interesting part of the construction, then, is the four sequences for each variable.

First, we have the following three sequences:

$W(a_1, 1)$	$W(b_1, 1)$	$W(c_1, 1)$
$W(a_1, 2)$	$W(b_1, 2)$	$W(c_1, 2)$
$W(a_2, 1)$	$W(b_2, 1)$	$W(c_2, 1)$
$W(a_2, 2)$	$W(b_2, 2)$	$W(c_2, 2)$
:	:	:
$W(a_m, 1)$	$W(b_m, 1)$	$W(c_m, 1)$
$W(a_m, 2)$	$W(b_m, 2)$	$W(c_m, 2)$
$R(f_1)$	$W(f_1)$	$W(f_2)$
$R(f_2)$		
$W(ok)$	$R(ok)$	$R(ok)$
$W(a_1, 1)$	$W(b_1, 1)$	$W(c_1, 1)$
$W(a_2, 1)$	$W(b_2, 1)$	$W(c_2, 1)$
:	:	:
$W(a_m, 1)$	$W(b_m, 1)$	$W(c_m, 1)$

Then for each variable v_i, $i = 1, 2, \ldots, n$, we have the following four sequences:

$W(y_i, 1)$	$W(z_i, 1)$	$R(y_i, 2)$	$R(z_i, 2)$
$W(y_i, 2)$	$W(z_i, 2)$	$R(z_i, 1)$	$R(y_i, 1)$
$W(y_i, 1)$	$W(z_i, 1)$	$W(v_i)$	$W(\overline{v}_i)$
		$R(ok)$	$R(ok)$
		$R(y_i, 2)$	$R(z_i, 2)$

Finally, for each clause $C_j = \lambda_{j,1} \vee \lambda_{j,2} \vee \lambda_{j,3}$, $j = 1, 2, \ldots, m$, where $\lambda_{j,1}$, $\lambda_{j,2}$, and $\lambda_{j,3}$ denote literals from $\{v_1, \ldots, v_n, \overline{v}_1, \ldots, \overline{v}_n\}$, we have the following three sequences:

$R(\lambda_{j,1})$	$R(\lambda_{j,2})$	$R(\lambda_{j,3})$
$R(b_j, 1)$	$R(c_j, 1)$	$R(a_j, 1)$
$R(a_j, 2)$	$R(b_j, 2)$	$R(c_j, 2)$

FIG. 9. *Transforming an instance of* 3SAT *with n variables and m clauses to an instance of VSC with $4n + 3m + 3$ sequences and locations, such that each location is written to by only a single processor. For locations that are written to only once in the entire construction, we omit the data field in the write and the reads for that location.*

We begin by proving the following lemma about these four sequences.

LEMMA 4.4. *Consider the four sequences for a variable v_i, together with an additional sequence comprised solely of a $W(ok)$ operation. Then we have the following:*

1. *There exists a legal schedule for these sequences such that $W(v_i)$ precedes $W(ok)$ precedes $W(\overline{v}_i)$.*
2. *There exists a legal schedule for these sequences such that $W(\overline{v}_i)$ precedes $W(ok)$ precedes $W(v_i)$.*
3. *There exists no legal schedule for these sequences such that both $W(v_i)$ and $W(\overline{v}_i)$ precede $W(ok)$.*

Proof. For claim 1, the reader may verify that the following is a legal schedule: $W(y_i, 1)$, $W(y_i, 2)$, $R(y_i, 2)$, $W(z_i, 1)$, $R(z_i, 1)$, $W(v_i)$, $W(ok)$, $R(ok)$, $R(y_i, 2)$, $W(z_i, 2)$, $R(z_i, 2)$, $W(y_i, 1)$, $R(y_i, 1)$, $W(\overline{v}_i)$, $R(ok)$, $R(z_i, 2)$, $W(z_i, 1)$. Claim 2 follows by symmetry. As for claim 3, suppose both did precede $W(ok)$ in a legal schedule S.

Let $S = S_1S_2$, where S_1 is the prefix of S up to and including the $W(ok)$ operation. Then the first $R(y_i, 2)$ and the first $R(z_i, 2)$ are in S_1. By symmetry, assume without loss of generality that the former precedes the latter in S_1. Then it can be seen that the first $W(y_i, 1)$ precedes $W(y_i, 2)$ which precedes $R(y_i, 1)$ in S_1. So to avoid a reads-from violation, $W(y_i, 2)$ must precede the second $W(y_i, 1)$ which must precede $R(y_i, 1)$ in S_1. But since the second $R(y_i, 2)$ is in S_2 and there are no other $W(y_i, 2)$ operations to schedule after the $R(y_i, 1)$ operation, S is not a legal schedule, and we have a contradiction. □

Likewise, in the previous construction, we simulate an OR using three writes with the same address and value, any one of which signals that a clause has been satisfied by the truth assignment. Here the order on any such writes is predetermined, and hence this approach for simulating an OR does not work. The second interesting part of the construction, then, is how the first three sequences together with all the clause sequences accurately test each clause.

Consider the jth clause C_j and its three sequences, say S_1, S_2, and S_3. There is a row in the first three sequences in which writes to a_j, b_j, and c_j set the values of these locations to 1, followed by a row in which writes to these same locations set the values to 2. These six operations must be scheduled prior to the cleanup. If C_j is satisfied, then for at least one of S_1, S_2, or S_3, the entire sequence can be scheduled prior to the cleanup. On the other hand, if C_j is not satisfied, then all operations in S_1, S_2, and S_3 remain to be scheduled during the cleanup. The second reads in S_1, S_2, and S_3 read the value 1; thus before the first such read, e.g., $R(c_j, 1)$, can be scheduled, we must schedule the appropriate write of 1, $W(c_j, 1)$, during the cleanup. But then for that particular location c_j, the read of 2 remains to be scheduled, and yet the value cannot be reset to 2.

LEMMA 4.5. *Let $\mathcal{F}$ be an instance of the* 3SAT *problem, and let $\mathcal{V}$ be the instance of the VSC-write problem constructed as depicted in Figure* 9. *Then $\mathcal{V}$ is a positive instance if and only if $\mathcal{F}$ is satisfiable.*

Proof. Suppose $\mathcal{F}$ is satisfiable, and let $\mathcal{T}$ be a satisfying assignment for $\mathcal{F}$. We construct the following schedule for $\mathcal{V}$:

1. For each variable v_i set to true (respectively, false) by $\mathcal{T}$, schedule operations in the four sequences for v_i according to claim 1 (respectively, claim 2) of Lemma 4.4, up to but not including the $W(ok)$ added by the lemma.
2. For each clause C_j in turn, schedule as follows: First, schedule one of the reads that agrees with $\mathcal{T}$. This leaves two reads in the same sequence, say $R(c_j, 1)$ and $R(b_j, 2)$, if the second of the sequences for C_j agrees with $\mathcal{T}$. Schedule the first $W(a_j, 1)$, the first $W(b_j, 1)$, and the first $W(c_j, 1)$ (in a row in the figure), then the read $R(c_j, 1)$. Then schedule $W(a_j, 2)$, $W(b_j, 2)$, $W(c_j, 2)$, and $R(b_j, 2)$.
3. Schedule $W(f_1)$, $R(f_1)$, $W(f_2)$, $R(f_2)$, and $W(ok)$. Then schedule the two $R(ok)$ operations (from the same sequences as the $W(f_1)$ and $W(f_2)$).
4. For each variable v_i set to true (respectively, false) by $\mathcal{T}$, schedule all remaining operations in the four sequences for v_i according to claim 1 (respectively, claim 2) of Lemma 4.4 after the $W(ok)$ added by the lemma.
5. At this point, both $W(v_i)$ and $W(\overline{v}_i)$ have been scheduled, so all remaining $R(v_i)$ and $R(\overline{v}_i)$ operations can safely be scheduled next.
6. For each clause C_j in turn, schedule as follows: There are two pairs of unscheduled reads in the sequences for C_j, say $R(b_j, 1)$ followed by $R(a_j, 2)$ and $R(a_j, 1)$ followed by $R(c_j, 2)$ (if the pair $R(c_j, 1)$ and $R(b_j, 2)$ were the ones

scheduled above). Note that the last writes to a_j, b_j, and c_j scheduled each wrote the value 2. Schedule the second $W(b_j, 1)$, then $R(b_j, 1)$, then $R(a_j, 2)$. Then schedule the second $W(a_j, 1)$, then $R(a_j, 1)$, then $R(c_j, 2)$, and finally the second $W(c_j, 1)$.

The reader may verify that this is a legal schedule.

Conversely, suppose $\mathcal{V}$ is a positive instance, and let S be a legal schedule for $\mathcal{V}$. Let $S = S_1 S_2$, where S_1 is the prefix of S up to and including $W(ok)$ and S_2 is the remaining suffix of S. We observe that the claims of Lemma 4.4 apply to S since, outside of $W(v_i)$, $W(\overline{v}_i)$, and $R(ok)$, the four sequences for each v_i contain addresses appearing only in these four sequences. Let $\mathcal{T}$ be the partial truth assignment such that for each v_i, v_i is set to true if $W(v_i)$ is in S_1, v_i is set to false if $W(\overline{v}_i)$ is in S_1, and v_i is not set otherwise. (It follows from claim 3 of Lemma 4.4 that no variable is set to both true and false.) We claim that the partial truth assignment $\mathcal{T}$ satisfies $\mathcal{F}$. Suppose not, and let C_j be an unsatisfied clause. Since for each of the three sequences for C_j, the first read cannot be in S_1, then the last two reads in each such sequence are in S_2. Moreover, the last write to a_j, b_j, and c_j in S_1 wrote the value 2. By symmetry, assume without loss of generality that $R(a_j, 1)$ precedes both $R(b_j, 1)$ and $R(c_j, 1)$ in S_2. Then the second $W(a_j, 1)$ precedes $R(a_j, 1)$, to avoid a reads-from violation, which precedes $R(b_j, 1)$ which precedes $R(a_j, 2)$ in S_2. Since there is no $W(a_j, 2)$ in between the $W(a_j, 1)$ and the $R(a_j, 2)$ in S_2, S is not a legal schedule, a contradiction. Therefore, all clauses are satisfied by T. □

Since the above transformation can be done in polynomial time, Theorem 4.3 follows. □

VL-write. We now turn to the VL-write problem, and show that, in contrast to the VSC-write problem, there is an $O(n \log n)$-time algorithm for this problem.

THEOREM 4.6. *There is an $O(n \log n)$-time algorithm for the VL-write problem.*

Proof. Let $\mathcal{V}$ be an instance of the VL-write problem. We sort the instance by address and, within each address, by start-of-interval and end-of-interval times. We check to see that each write is included only in the write-order for its address; otherwise, we have a negative instance.

Consider the set of operations S on an address a in $\mathcal{V}$. Let $w_1, w_2, \ldots, w_m$ be the sequence of writes to address a as ordered by the write-order. The algorithm proceeds in rounds. We begin with all operations in S unscheduled and maintain the invariant that all the start-of-interval times for scheduled operations are less than all the end-of-interval times of unscheduled operations. At round i, if the start-of-interval time for w_i is greater than the end-of-interval time for an unscheduled operation, then we have a negative instance and halt. Otherwise, schedule w_i. Then greedily schedule, in order of increasing start-of-interval times, all unscheduled reads of the same value whose start-of-interval times are less than the end-of-interval time for all unscheduled operations. Continue on to the next round.

If any reads remain unscheduled after round m, then we have a negative instance and halt. Otherwise, a legal assignment of times for the operations in S is obtained inductively as follows. Let ϵ_0 be the minimum difference between any pair of times (start-of-interval or end-of-interval) in $\mathcal{V}$; let $\epsilon = \epsilon_0/n$. The first operation scheduled, w_1, is assigned a time equal to its start-of-interval time. Each subsequent operation is assigned a time equal to the maximum of its start-of-interval time and ϵ greater than the time assigned to the previous scheduled operation.

We now show that this greedy algorithm finds a legal schedule of S if and only if one exists. The schedule produced by the algorithm is legal since it contains all of

the operations in S, the write-order is respected, the last write scheduled prior to a read has the same value, and all operations are assigned times within their intervals. To see that this last condition holds, consider an operation π that is assigned a time greater than its start-of-interval time. Let π' be the last operation prior to π that is assigned a time equal to its respective start-of-interval time t'. Since π' is scheduled before π, t' is less than the end-of-interval time for π. Thus π is assigned a time less than $t' + \epsilon_0$ and hence within its interval.

Conversely, assume that there is a legal schedule of S. Suppose that the greedy algorithm completes $j \leq m$ rounds. For $i = 1, \ldots, j$, we claim that the set of operations S_i in the greedy schedule prior to w_i is a superset of the set of operations scheduled prior to w_i in any legal schedule of S. The proof is by induction, with a trivial basis since w_1 is the first operation in any legal schedule. Assume that the claim is true for $i-1$. Consider a legal schedule of S, and let S'_i be the set of operations prior to w_i in the schedule. Suppose there is an operation α in S'_i that is not in S_i. Since the order on writes is fixed, S'_i and S_i contain the same writes, as do S'_{i-1} and S_{i-1}. It follows from the inductive assumption that α is a read of the value written by w_{i-1}. Since α is not in S_i, there must be an operation not in S_i whose end-of-interval time is less than the start-of-interval time for α such that the operation is a read of a different value. Since α is in S'_i but reads a different value, it must be in S'_{i-1}. But then by the inductive assumption, it is in S_{i-1}, a contradiction.

From this claim, we see that any unscheduled operation in S_j will be scheduled after w_j in any legal schedule, and hence its end-of-interval time is greater than the start-of-interval time for w_j. Moreover, the set of reads not in S_m is a subset of the set of reads scheduled after w_m in any legal schedule. It follows that the algorithm successfully completes all m rounds and finds a legal schedule of S.

If for all addresses, the algorithm succeeds in finding a legal schedule, we have a positive instance. The final legal schedule for $\mathcal{V}$ is obtained by merging the individual schedules for each address. □

4.3. Read&write only. In the VSC-write and VL-write problems, the input provides a mapping from each write to the previous write on the same address (if any). In this section, we consider the complexity of the VSC and VL problems when for each write, the input provides not the identity of the previous write but only its value.

We view the memory operations as atomic read–modify–write operations. Accordingly, we define a *read&write*$(a, d_{old} : d_{new}, t_1, t_2)$ operation, where $a \in A$ is the address, $d_{old} \in D$ is the old value (returned by the read), and $d_{new} \in D$ is the new value written. A legal schedule must respect this pairing of old and new values: each *read&write*$(a, d_{old} : d_{new}, t_1, t_2)$ operation must be preceded by an operation that writes d_{old} to a with no intervening operation that writes a different value to a. As before, the start-of-interval time t_1 and end-of-interval time t_2 are needed for the VL problem but not the VSC problem. In the VSC and VL problems with *read&write only*, all operations are *read&write* operations; in this context, a *read* is simply a *read&write* that does not alter the value.

Note that the relationship between the VSC-write/VL-write problems and the VSC/VL problems with read&write only is analogous to the relationship between the VSC-read/VL-read problems and the basic VSC/VL problems, namely, the distinction between providing the identity of the previous write versus providing only the value of the previous write.

VSC with read&write only. We show that the VSC problem with read&write only is NP-complete, even under two restrictive scenarios.

By Theorem 4.3, the VSC problem restricted to instances in which each location is written to by only a single processor is NP-complete. In such instances, each write can be replaced with the appropriate read&write operation, yielding the following corollary.

COROLLARY 4.7. *The VSC problem with read&write only restricted to instances in which each location is written to by only a single processor is* NP*-complete.*

We next observe that instances with long processor sequences can always be transformed to equivalent instances with at most two memory operations per processor.

OBSERVATION 4.8. *There is a linear-time reduction from the VSC problem with read&write only with p sequences, n operations, and k variables to the VSC problem with read&write only with at most n sequences, $O(n)$ operations, and k variables such that each sequence contains at most two operations.*

Proof. For $i = 1, 2, \ldots, p$, consider the ith sequence in the instance, $S_i = rw(a_1, d_1 : d'_1)$, $rw(a_2, d_2 : d'_2)$, ..., $rw(a_{m_i}, d_{m_i} : d'_{m_i})$, where $a_1, \ldots, a_{m_i}$, $d_1, \ldots, d_{m_i}$, $d'_1, \ldots, d'_{m_i}$ are not necessarily distinct. When S_i has more than two memory operations (i.e., $m_i > 2$), the construction splits each operation $rw(a_j, d_j : d'_j)$ in S_i, other than the first and the last operation, into a pair of operations to the same address: $rw(a_j, d_j : x^{(i)}_{j-1})$ and $rw(a_j, x^{(i)}_{j-1} : d'_j)$. In particular, we replace S_i with the following $m_i - 1$ replacement sequences for S_i:

$$\begin{array}{cccccc} rw(a_1, d_1 : d'_1) & rw(a_2, x^{(i)}_1 : d'_2) & rw(a_3, x^{(i)}_2 : d'_3) & \cdots & rw(a_{m_i-1}, x^{(i)}_{m_i-2} : d'_{m_i-1}) \\ rw(a_2, d_2 : x^{(i)}_1) & rw(a_3, d_3 : x^{(i)}_2) & rw(a_4, d_4 : x^{(i)}_3) & & rw(a_{m_i}, d_{m_i} : d'_{m_i}) \end{array},$$

where $\forall i, j, i', j'$, $x^{(i)}_j = x^{(i')}_{j'}$ if and only if $i = i'$ and $j = j'$.

The idea behind this construction is as follows. Consider the pairs of operations in the constructed instance. Since each new data value is unique, then in any legal schedule of the constructed instance, no operation to the same address can be scheduled between a pair, and no operation from the same replacement sequences can be scheduled between a pair. This in turn will imply that any legal schedule can be reordered to obtain a new legal schedule in which the two operations in any pair are consecutive. Then considering each pair as being replaced by its original operation, we have a legal schedule of the original instance.

The reader may verify that this constructed instance is a positive instance if and only if the original instance is a positive instance. □

We now show that the VSC problem with read&write only is NP-complete even when there is only a single variable and at most two operations per sequence.

THEOREM 4.9. *The VSC problem with read&write only restricted to instances with one variable and at most two memory operations per sequence is* NP*-complete.*

Proof. We show the reduction for sequences with many operations; this can be transformed to sequences with at most two operations each by applying Observation 4.8. Given a 3SAT instance $\mathcal{F}$ with n variables and m clauses, we construct the following VSC instance $\mathcal{V}$. First, we have the following $2n + 1$ sequences, A, $V_1, V'_1, \ldots, V_n, V'_n$, where $\perp$ is the initial value of a, the literal v_1 is in clauses $\{c_2, c_3, \ldots, c_m\}$, the literal $\overline{v}_1$ is in clauses $\{c_4, c_6, \ldots, c_9\}$,..., the literal v_n is in

clauses $\{c_4, c_5, \ldots, c_8\}$, and the literal $\overline{v}_n$ is in clauses $\{c_1, c_6, \ldots, c_m\}$:

$\underline{A}$	$\underline{V_1}$	$\underline{V_1'}$	$\cdots$	$\underline{V_n}$	$\underline{V_n'}$
$rw(a, \perp : 1)$	$rw(a, 1 : c_2)$	$rw(a, 1 : c_4)$		$rw(a, n : c_4)$	$rw(a, n : c_1)$
$rw(a, 1' : 2)$	$rw(a, c_2 : c_3)$	$rw(a, c_4 : c_6)$		$rw(a, c_4 : c_5)$	$rw(a, c_1 : c_6)$
$rw(a, 2' : 3)$	:	:		:	:
:	$rw(a, c_m : 1')$	$rw(a, c_9 : 1')$		$rw(a, c_8 : n')$	$rw(a, c_m : n')$
$rw(a, (n-1)' : n)$					

In addition, we have the following $m + 1$ sequences, A', $C_1, C_2, \ldots, C_m$:

$\underline{A'}$	$\underline{C_1}$	$\underline{C_2}$	$\cdots$	$\underline{C_m}$
$rw(a, c_m' : 1)$	$rw(a, c_1 : c_1)$	$rw(a, c_2 : c_2)$		$rw(a, c_m : c_m)$
$rw(a, 1' : 2)$	$rw(a, n' : c_1')$	$rw(a, c_1' : c_2')$		$rw(a, c_{m-1}' : c_m')$
$rw(a, 2' : 3)$				
:				
$rw(a, (n-1)' : n)$				

LEMMA 4.10. *Let $\mathcal{F}$ be an instance of the* 3SAT *problem, and let $\mathcal{V}$ be the instance of the VSC problem with read&write only constructed as defined above. Then $\mathcal{V}$ is a positive instance if and only if $\mathcal{F}$ is satisfiable.*

Proof. Suppose $\mathcal{F}$ is satisfiable. Let $T(v_1), \ldots, T(v_n)$ be a satisfying assignment for $\mathcal{F}$, where $T(v_i) \in \{\mathsf{T}, \mathsf{F}\}$. We construct the following schedule for $\mathcal{V}$:

1. first, $rw(a, \perp : 1)$ (or $rw(\perp : 1)$; from now on we shall omit the variable "a"); this is the first operation in A;
2. then if $T(v_1) = \mathsf{T}$, all of the operations in V_1, interleaved with *clause read* operations, as explained below, and followed by the second operation in A, $rw(1' : 2)$; otherwise, if $T(v_1) = \mathsf{F}$, all of the operations in V_1', interleaved with *clause read* operations, as explained below, and followed by the second operation in A.
3. For $i = 2, 3, \ldots, n$, repeat the previous step: If $T(v_i) = \mathsf{T}$ ($T(v_i) = \mathsf{F}$), schedule all of the operations in V_i (respectively, V_i'), interleaved with *clause read* operations, as explained below, and followed by, for $i < n$, the $(i+1)$th operation in A, $rw(i' : i + 1)$.
4. The first operation in each sequence C_j is denoted the *clause read* for clause c_j. Since T satisfies $\mathcal{F}$, then each clause c_j is satisfied by some $T(v_i)$, and therefore when the corresponding V_i or V_i' was scheduled, an operation of the form $rw(x : c_j)$ for some value x was in that sequence; the clause read for c_j is scheduled immediately after the first such operation $rw(x : c_j)$.
5. Next, we schedule $rw(n' : c_1')$, $rw(c_1' : c_2'), \ldots, rw(c_{m-1}' : c_m')$, followed by $rw(c_{m'} : 1)$ (the first operation in A').
6. Finally, repeat the following for $i = 1, 2, \ldots, n$: If $T(v_i) = \mathsf{F}$ ($T(v_i) = \mathsf{T}$), schedule all of the operations in V_i (respectively, V_i'), followed by, for $i < n$, the $(i+1)$th operation in A': $rw(i' : i + 1)$.

The reader may verify that this is a legal schedule.

Conversely, suppose $\mathcal{V}$ is a positive instance and let S be a legal schedule for $\mathcal{V}$. For $i = 1, \ldots, n$, let the first operation in S from either V_i or V_i' be denoted the *variable read* operation for v_i and the sequence V_i or V_i' containing v_i be denoted the *variable read sequence*. Let the sequence V_i or V_i' that is not the variable read sequence for v_i be denoted the *cleanup read sequence* and its first operation be denoted the *cleanup read*. Consider the truth assignment T defined as follows: For each $i = 1, \ldots, n$,

$T(v_i) = \mathsf{T}$ if V_i is the variable read sequence for v_i and $T(v_i) = \mathsf{F}$ otherwise. Note that by the construction, operations in a variable read sequence only write values c_j for clauses satisfied by T. We will show that T is a satisfying assignment for $\mathcal{F}$.

Suppose there is a clause c_j not satisfied by T, and consider the clause read for c_j: $rw(c_j : c_j)$. Let $S = \sigma_1 rw(c_j : c_j)\sigma_2$. We claim that $rw(c'_m : 1)$ and hence all of A' is in σ_2. To see this, first observe that since the values $c'_1, c'_2, \ldots, c'_m$ are read by exactly one operation and written by exactly one operation, the sequence $rw(n' : c'_1)$, $rw(c'_1 : c'_2), \ldots, rw(c'_{m-1} : c'_m)$, $rw(c'_m : 1)$ is a consecutive subsequence of S. Since the second operation in C_j is in this subsequence and in σ_2, then $rw(c'_m : 1)$ is in σ_2 as well. Thus all of A' is in σ_2, and hence at most one operation that writes i, $i = 1, \ldots, n$, is in σ_1.

Since among the two operations that read i, the variable read precedes the cleanup read, it follows that the cleanup read and hence the cleanup read sequence is in σ_2 for all v_i. The last operation in σ_1 must write c_j and thus must be in a variable read sequence. Thus, as observed above, c_j is satisfied by T, a contradiction.

The lemma follows. □

Since the above transformation can be done in polynomial time, Theorem 4.9 follows. □

VL with read&write only. We show that the VL problem with read&write only is NP-complete. This contrasts with the $O(n \log n)$-time algorithm for the VL-write problem.

THEOREM 4.11. *The VL problem with read&write only is* NP*-complete.*

Proof. With only read&write operations, a more careful construction is needed than the one shown in Figure 8 that relies on writes whose old values are not predetermined. Each new value to be written must serve as the old value for the next write (recall that there is but a single location), giving us less flexibility in the construction. Nevertheless, we show below how to overcome this difficulty to obtain a construction with the desired properties.

Our reduction is again from SAT. Consider an instance $\mathcal{F}$ of SAT with n variables, $v_1, v_2, \ldots, v_n$, and m clauses, $C_1, C_2, \ldots, C_m$. Without loss of generality, assume that each variable and its negation appear in at least one clause, but not the same clause, and that there are no repeated variables in a clause. We construct an instance of the VL problem with at most $5nm + 10n + m + 1$ operations, corresponding to $\mathcal{F}$. To simplify the description, we have multiple intervals with common start times or end times; these ties can be broken arbitrarily to ensure unique time values.

Figure 10 depicts an example construction. First, there is an initial read&write operation: *read&write*$(a, \perp : 0, 1, 2)$. Then for each clause C_j, $j = 1, \ldots, m$, we have a *read&write*$(a, c_j : c_j, 3, 5n + 4)$ operation, denoted the *clause read* for C_j.

For $i = 1, \ldots, n$, let m_i (respectively, $m_{\bar{i}}$) be the number of clauses containing the literal v_i (respectively, $\overline{v_i}$). By assumption, $m_i > 0$, $m_{\bar{i}} > 0$, and $m_i + m_{\bar{i}} \leq m$. For $i = 1, \ldots, n+1$, let $\Delta_i = (7m+4)(i-1)+5n+4$. For $i = 1, \ldots, n$, let $\Delta_{\bar{i}} = \Delta_i + 7m_i + 2$.

For each variable v_i, assignment to v_i is simulated using six operations:

- *read&write*$(a, 0 : i, 5i, 5i + 1)$,
- *read&write*$(a, 0 : \bar{i}, 5i, 5i + 1)$,
- *read&write*$(a, \hat{i} : 0, 5i, 5i + 1)$,
- *read&write*$(a, \hat{i} : 0, 5i + 3, 5i + 4)$,
- *read&write*$(a, i : \hat{i}, 5i, \Delta_i - 1)$,
- *read&write*$(a, \bar{i} : \hat{i}, 5i, \Delta_{\bar{i}} - 1)$.

There is a set of operations for each literal v_i, denoted the *group* of operations

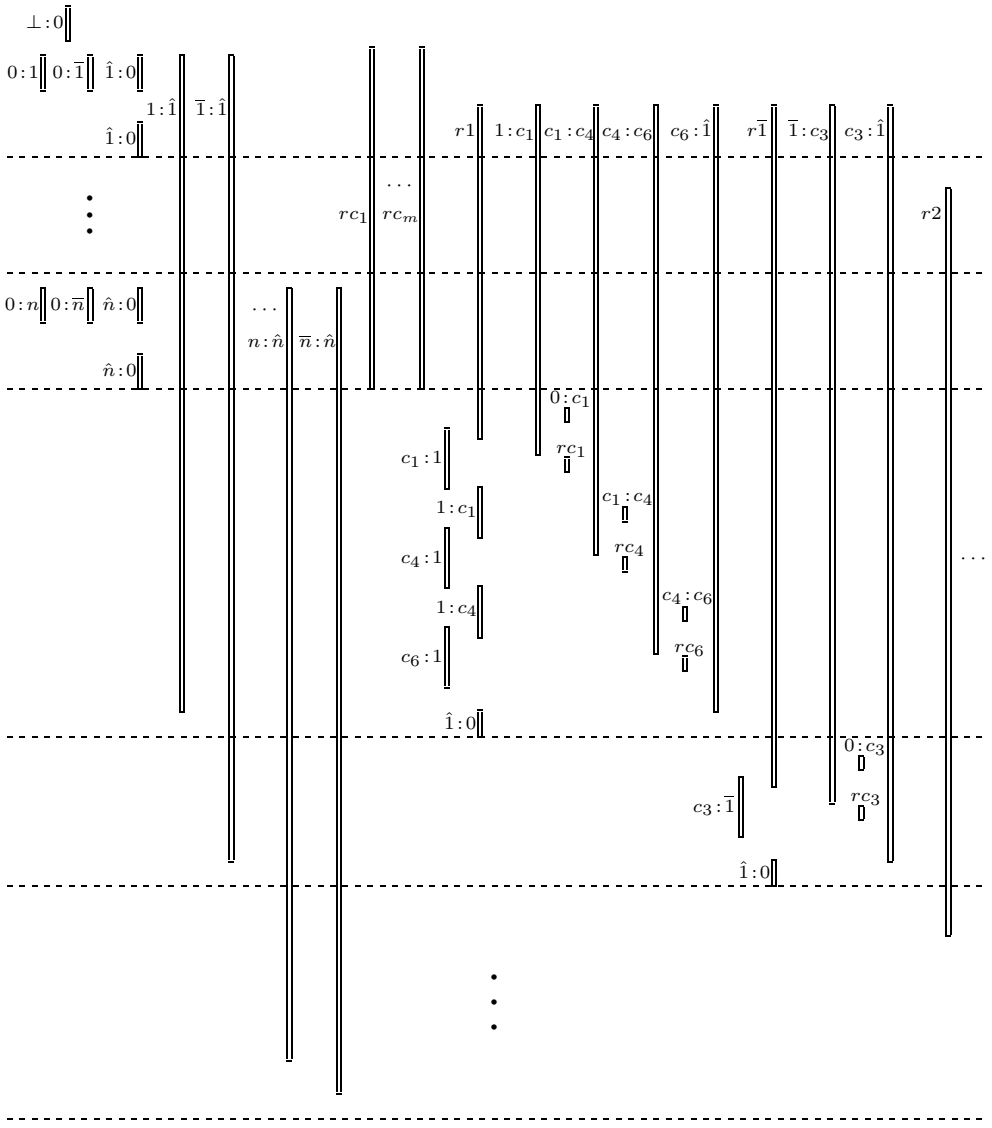

FIG. 10. *Transforming an instance of* SAT *to an instance of VL with a single location such that all memory operations are read&write operations. There are n variables, $v_1, \ldots, v_n$, and m clauses, $C_1, \ldots, C_m$. The full construction has at most $5nm + 10n + m + 1$ operations. Here the literal v_1 appears in exactly clauses C_1, C_4, and C_6, the literal $\overline{v}_1$ appears in clause C_3 only, and so forth. Every column corresponds to a processor. Vertical boxes depict the intervals of time for the respective read&write operations to the single location; time progresses from top to bottom in the figure. A read&write operation with old value d and new value d' is denoted $d:d'$; the case where $d = d'$ is denoted simply rd. The set of values used is $\{0, 1, \overline{1}, \hat{1}, 2, \overline{2}, \hat{2}, \ldots, n, \overline{n}, \hat{n}, c_1, c_2, \ldots, c_m\}$. The first read&write necessarily reads the initial value in memory, which we denote $\perp$, before writing a new value (i.e., 0).*

for i. For $i = 1, \ldots, n$, if $C_{i_1}, C_{i_2}, \ldots, C_{i_{m_i}}$ are the clauses containing the literal v_i, we have the following $5m_i + 2$ intervals. First, for C_{i_1}, we have

- *read&write*$(a, i\!:\!i, 5i+2, \Delta_i+4)$,
- *read&write*$(a, i\!:\!c_{i_1}, 5i+2, \Delta_i+5)$,
- *read&write*$(a, 0\!:\!c_{i_1}, \Delta_i+1, \Delta_i+2)$,
- *read&write*$(a, c_{i_1}\!:\!c_{i_1}, \Delta_i+5, \Delta_i+6)$,
- *read&write*$(a, c_{i_1}\!:\!i, \Delta_i+3, \Delta_i+7)$.

Then for C_{i_k}, $k = 2, \ldots, m_i$, we have

- *read&write*$(a, i\!:\!c_{i_{k-1}}, \Delta_i+7(k-1), \Delta_i+7(k-1)+4)$,
- *read&write*$(a, c_{i_{k-1}}\!:\!c_{i_k}, 5i+2, \Delta_i+7(k-1)+5)$,
- *read&write*$(a, c_{i_{k-1}}\!:\!c_{i_k}, \Delta_i+7(k-1)+1, \Delta_i+7(k-1)+2)$,
- *read&write*$(a, c_{i_k}\!:\!c_{i_k}, \Delta_i+7(k-1)+5, \Delta_i+7(k-1)+6)$,
- *read&write*$(a, c_{i_k}\!:\!i, \Delta_i+7(k-1)+3, \Delta_i+7k)$.

Finally, we have *read&write*$(a, c_{i_{m_i}}\!:\!\hat{\imath}, 5i+2, \Delta_{\bar{\imath}}-1)$ and *read&write*$(a, \hat{\imath}\!:\!0, \Delta_{\bar{\imath}}-1, \Delta_{\bar{\imath}})$.

Likewise, there is a set of operations for each literal $\overline{v_i}$, denoted the *group* of operations for $\bar{\imath}$. For $i = 1, \ldots, n$, if $C_{\bar{i}_1}, C_{\bar{i}_2}, \ldots, C_{\bar{i}_{m_{\bar{i}}}}$ are the clauses containing the literal $\overline{v_i}$, we have the $5m_{\bar{\imath}} + 2$ intervals obtained from the previous definition by replacing $\Delta_{\bar{\imath}}$ with Δ_{i+1} and leaving "$5i+2$" unchanged but otherwise replacing i with $\bar{\imath}$ throughout.

This completes the construction.

We show below that for any satisfying truth assignment, there is a legal schedule for the instance constructed. As an example, consider a satisfying assignment that sets v_1 to true, and refer to Figure 10. In this case, a legal schedule begins: $\perp : 0$, then $0 : \overline{1}$, then $\overline{1} : \hat{1}$, then the first $\hat{1} : 0$, then $0 : 1$, then $r1$, then $1 : c_1$ (immediately to the right of $r1$ in the figure), then the clause read rc_1, then $c_1 : c_4$, then the clause read rc_4 (not shown), then $c_4 : c_6$, then the clause read rc_6 (not shown), then $c_6 : \hat{1}$, and then the second $\hat{1} : 0$. The schedule continues with operations for $v_2, v_3, \ldots, v_n$ until the second $\hat{n} : 0$ is scheduled. Then the remaining (cleanup) operations for v_1 are scheduled as follows: $0 : c_1$ (in the figure, just below the third dashed line from the top), then rc_1, then $c_1 : 1$, then the $1 : c_1$ to its right, then the $c_1 : c_4$ to its right, then the rc_4 below it, then $c_4 : 1$, then $1 : c_4$, then the $c_4 : c_6$ to its right, then the rc_6 below it, then $c_6 : 1$, then $1 : \hat{1}$, and then the $\hat{1} : 0$ just above the fourth dashed line; then $0 : c_3$, then $c_3 : \overline{1}$, then $r\overline{1}$, then $\overline{1} : c_3$, then rc_3, then $c_3 : \hat{1}$, and then the $\hat{1} : 0$ just above the fifth dashed line. The schedule continues with cleanup operations for $v_2, v_3, \ldots, v_n$ until all operations have been scheduled.

LEMMA 4.12. *Let $\mathcal{F}$ be an instance of a* SAT *problem, and let $\mathcal{V}$ be the instance of the VL problem with read&write operations constructed as described above. Then $\mathcal{V}$ is a positive instance if and only if $\mathcal{F}$ is satisfiable.*

Proof. Suppose $\mathcal{F}$ is satisfiable, and let $\mathcal{T}$ be a satisfying truth assignment for $\mathcal{F}$. We construct the following schedule for $\mathcal{V}$. When there is no ambiguity, we use the notation "$d_1 : d_2$" to denote a read&write operation to address a with old value d_1 and new value d_2; the case where $d_1 = d_2$ is denoted simply "rd_1." We show the order in which events are scheduled; an assignment of distinct, valid times to operations is left to the reader. The schedule is as follows:

1. First, schedule $\perp : 0$.
2. Repeat the following for $i = 1, 2, \ldots, n$:
   If v_i is set to true by $\mathcal{T}$, schedule $0 : \bar{\imath}$, then $\bar{\imath} : \hat{\imath}$, then *read&write*$(a, \hat{\imath} : 0, 5i, 5i+1)$, then $0 : i$, and then ri. Schedule $i : c_{i_1}$, followed by—if it has not already been scheduled—the clause read rc_j, where $j = i_1$. Then repeat

for $k = 2, \ldots, m_i$: schedule *read&write*$(a, c_{i_{k-1}} : c_{i_k}, 5i + 2, \Delta_i + 7(k-1) + 5)$, followed by—if it has not already been scheduled—the clause read rc_j, where $j = i_k$. Finally, schedule $c_{i_{m_i}} : \hat{\imath}$, then *read&write*$(a, \hat{\imath} : 0, 5i + 3, 5i + 4)$.

The case where v_i is set to false by $\mathcal{T}$ is symmetric and left to the reader.

3. Since $\mathcal{T}$ is a satisfying assignment for $\mathcal{F}$, all clause reads have been scheduled by this point. Note also that all the above operations can be scheduled prior to time Δ_1.

   Repeat the following for $i = 1, 2, \ldots, n$:

   If v_i is set to true by $\mathcal{T}$, consider the $4m_i$ unscheduled operations in group i, together with the unscheduled $i : \hat{\imath}$, and finally the $5m_{\bar{\imath}} + 2$ (unscheduled) operations in group $\bar{\imath}$:

   (a) Schedule $0 : c_{i_1}$, then rc_{i_1}, then $c_{i_1} : i$.

   (b) Then repeat for $k = 2, \ldots, m_i$: Schedule $i : c_{i_{k-1}}$, then the unscheduled $c_{i_{k-1}} : c_{i_k}$, then rc_{i_k}, and then $c_{i_k} : i$.

   (c) Schedule the unscheduled $i : \hat{\imath}$, then schedule *read&write*$(a, \hat{\imath} : 0, \Delta_{\bar{\imath}} - 1, \Delta_{\bar{\imath}})$ to complete group i.

   (d) Next, schedule $0 : c_{\bar{\imath}_1}$, then $c_{\bar{\imath}_1} : \bar{\imath}$, then $r\bar{\imath}$, then $\bar{\imath} : c_{\bar{\imath}_1}$, and then $rc_{\bar{\imath}_1}$.

   (e) Then repeat for $k = 2, \ldots, m_{\bar{\imath}}$: Schedule *read&write*$(a, c_{\bar{\imath}_{k-1}} : c_{\bar{\imath}_k}, \Delta_{\bar{\imath}} + 7(k-1) + 1, \Delta_{\bar{\imath}} + 7(k-1) + 2)$, then $c_{\bar{\imath}_k} : \bar{\imath}$, then $\bar{\imath} : c_{\bar{\imath}_{k-1}}$, then the unscheduled $c_{\bar{\imath}_{k-1}} : c_{\bar{\imath}_k}$, and then $rc_{\bar{\imath}_k}$.

   (f) Finally, to complete group $\bar{\imath}$, schedule $c_{\bar{\imath}_{m_{\bar{\imath}}}} : \hat{\imath}$ and then *read&write*$(a, \hat{\imath} : 0, \Delta_{i+1} - 1, \Delta_{i+1})$.

   The case where v_i is set to false by $\mathcal{T}$ is symmetric and left to the reader.

The reader may verify that this is a legal schedule.

The proof of the converse, i.e., if $\mathcal{V}$ is a positive instance, then $\mathcal{F}$ is satisfiable, parallels the proof given in Lemma 3.6 and is left to the reader. □

Since the above transformation can be done in polynomial time, Theorem 4.11 follows. □

4.4. Providing the conflict-order. Two operations on the same location *conflict* if at least one is a write. In the *VSC-conflict* and *VL-conflict* problems, both a read-mapping and a write-order are known, implying that all conflicting operations are ordered; a legal schedule must respect this *conflict-order* relation.

VSC-conflict. There is a simple $O(n \log n)$-time algorithm for the VSC-conflict problem. Thus although providing either the read-mapping or the write-order is NP-complete, providing both yields a fast algorithm.

THEOREM 4.13. *There is an $O(n \log n)$-time algorithm for the VSC-conflict problem.*

Proof. Sort the VSC-conflict instance by address. We check to see that each read is mapped to a write operation with the same address and value and that each write is included only in the write-order for its address; otherwise, we have a negative instance. Construct a graph G with a vertex for each operation in the instance. Add an edge between a vertex u and a vertex v if u immediately precedes v in some processor sequence. In addition, add edges from each write to all reads mapped to it and from the write and these reads to the next write in its write-order. The graph G has n vertices and $O(n)$ edges.

The reader may verify that if G has a directed cycle, we have a negative instance. Otherwise, we have a positive instance, and any topological sort of G yields a legal schedule. □

VL-conflict. An $O(n \log n)$-time algorithm for the VL-conflict problem follows as a corollary to Theorems 3.2 and 4.13.

COROLLARY 4.14. *There is an $O(n \log n)$-time algorithm for the VL-conflict problem.*

4.5. Atomic read–modify–write. We conclude this section by showing how the algorithmic results of this paper can be extended to handle atomic read–modify–write operations at no asymptotic penalty. The input consists of three types of memory operations: reads, writes, and read&writes. The read&write operations are included in both the domain and range of any read-mapping, as well as ordered by any write-order (in which case the value read must match the value written by the previous write).

Few processors. We first consider the scenario where the number of processors is bounded.

THEOREM 4.15. *The VL problem with read, write, and read&write operations, restricted to instances such that at any time t, there are at most k operations on the same address whose intervals contain t, can be solved in $O(n2^{O(k)} + n \log n)$ time.*

Proof. The proof parallels the proof of Theorem 3.7, with the following modification of the algorithm to handle the possible presence of read&write operations. Namely, condition 2 for including an edge between a vertex v and a vertex v' on consecutive levels of the graph defines a set A of operations that must be assigned times after the last write ω designated by v and before any writes not in A. With only reads and writes, it sufficed to test whether each read in A read either the value of the last write designated by v or the value of some write in A. With read&write operations, however, we cannot have, for example, the set A consist of two operations that each read the designated last write and write a new value. We use the following test instead. Consider a multigraph H consisting of a vertex for every value occurring in $A \cup \{\omega\}$, plus an extra dummy vertex z. Each read&write operation in A that reads a value d and writes a value d' defines a directed edge in H from the vertex for d to the vertex for d'. Each write operation defines a directed edge from z to the vertex for the value written. Each read operation defines a self-loop at the vertex for the value read. There is a directed edge from z to the vertex for the value written by ω. Then for each vertex y in H whose in-degree exceeds its out-degree by $j > 0$, we have j directed dummy edges in H from y to z.

LEMMA 4.16. *The set of operations in A can be safely scheduled if and only if H has an Eulerian circuit.*

Proof. If H has an Eulerian circuit, then consider the sequence S of operations defined by an Eulerian circuit that begins with the edge for ω. Then the schedule obtained from S by removing ω and all dummy edges contains all of A and has no reads-from violations. Conversely, if there is no Eulerian circuit, then either H has a vertex x whose out-degree exceeds its in-degree or it has a nonempty set of vertices not reachable from z. In the former case, note that $x \neq z$ since by construction the in-degree of z is necessarily at least as large as its out-degree. Moreover, since any vertex with an outgoing dummy edge has the same in-degree as out-degree, all edges incident to x correspond to operations in $A \cup \{\omega\}$. Hence there are more operations that read and modify x's value than there are operations that write it. It follows that any schedule of A will have a reads-from violation. In the latter case, any schedule of A will have a reads-from violation at the first scheduled operation from the unreachable set. □

We construct H and check to see that all vertices are reachable from z and have the same in-degree as out-degree in time linear in the size of A. Finally, consider the last write, ω', designated by v', which like ω may be either a write or a read&write. The final condition required for adding an edge from v to v' is that either ω' is in A and writes a value whose vertex in H has an outgoing dummy edge or, if there are no writes or read&writes in A, $\omega' = \omega$. □

Theorem 4.15 implies, for instance, the following corollary.

COROLLARY 4.17. *There is an $O(n \log n)$-time algorithm for the VL problem with read, write, and read&write operations and any fixed number of processors.*

Read-mapping. If a read-mapping is provided, then we have the following corollary to Theorem 4.2.

COROLLARY 4.18. *There is an $O(n \log n)$-time algorithm for the VL-read problem with read, write, and read&write operations.*

Proof. We modify the algorithm in Theorem 4.2 to handle read&write operations by simply replacing the use of *clusters* in that algorithm with *cluster sequences*, as defined below. Observe that at most one read&write operation can be mapped by the read-mapping to a single write or read&write; otherwise, we have a negative instance. Define a *cluster sequence*, $S = w_1, R_1, w_2, R_2, \ldots, w_k, R_k$, $k \geq 1$, to be a sequence of alternating operations and sets such that w_1 is an ordinary write operation, $w_2, \ldots, w_k$ are read&write operations with w_i mapped to w_{i-1} for $i = 2, \ldots, k$, there is no read&write operation mapped to w_k, and R_i is the set of ordinary reads mapped to w_i for $i = 1, \ldots, k$. Any legal schedule assigns w_1 an earlier time than any read in R_1, which is assigned an earlier time than w_2, and so on. Thus the start-of-interval time for an operation must be earlier than the end-of-interval time for any operation that is ordered after it in its cluster sequence; otherwise, we have a negative instance. A legal assignment of times defines an interval for a cluster sequence, from the time assigned to w_1 to the time assigned to the last read in R_k; only operations in this cluster sequence can be scheduled during this time interval. The algorithm and proof continue as in Theorem 4.2. □

Write-order and conflict-order. Since the old value on writes provides no additional information once a write-order is provided, we have the following corollary to Theorems 4.6 and 4.13 and Corollary 4.14.

COROLLARY 4.19. *There are $O(n \log n)$-time algorithms for the VL-write, VSC-conflict, and VL-conflict problems with read, write, and read&write operations.*

5. Conclusions. This paper provides the first formal and systematic study of the complexity of testing the correctness of an execution of a shared memory, based on the reads and writes observed by the individual processors. We define two combinatorial problems: the *verifying sequential consistency of shared-memory executions* (VSC) problem for testing for sequential consistency, and the *verifying linearizability of shared-memory executions* (VL) problem for testing for linearizability. We show that the VSC problem is NP-complete even when the number of processors, locations, or operations per processor is bounded. Moreover, the problem remains NP-complete even when additional information is provided, such as the pairing of reads to particular writes, the order of writes to a location, or the old value overwritten by each write. However, if the order of all conflicting operations to a location is provided, we obtain an $O(n \log n)$-time algorithm. Linearizability, in contrast, is more restrictive than sequential consistency, and our results show that these additional restrictions can be quite useful in testing for linearizability. In particular, we present $O(n \log n)$-time algorithms for several variants of the VL problem whose corresponding VSC variants

are NP-complete. On the other hand, we show that the VL problem is NP-complete even when given the old value overwritten by each write operation.

Efficient testing algorithms can be used by machine designers, system software writers, application programmers, and naïve users whenever doubt arises as to whether all aspects of the memory system are functioning properly. In [17, 19], we present approaches to implementing testing procedures on real multiprocessors or their simulators. In particular, we devise schemes for collecting the additional information needed for the read-mapping, write-order, old value on writes, or conflict-order. We also describe algorithms for heuristic testing of several processors at a time. The results in [17, 19] demonstrate interesting tradeoffs between the speed, accuracy, and obtrusiveness of various testing procedures.

We have presented several $O(n \log n)$-time algorithms; after sorting, these run in linear time. Depending on the assumptions made on the form of the input, one could apply integer sorting to obtain linear time bounds for these algorithms.

In this paper, we consider read, write, and read–modify–write operations. This is extended in [17, 19], where we also consider the load-reserved (a.k.a. load-linked, load-locked) and store-conditional operations [24] appearing in many recent architectures. More generally, one can consider testing shared memories that support various data structures, such as priority queues.

Finally, correctness conditions other than linearizability and sequential consistency can be considered. A number of correctness conditions from the domain of database transactions have been previously studied (e.g., [6, 25, 30]). It would be interesting to develop a general theory encompassing a wide range of correctness conditions so that tradeoffs between the generality of a correctness condition and its complexity may be better understood.

Acknowledgments. We thank Michael Merritt and Robert Cypher for discussions related to this work. We acknowledge the helpful comments of an anonymous referee.

POLYNOMIAL METHODS FOR SEPARABLE CONVEX OPTIMIZATION IN UNIMODULAR LINEAR SPACES WITH APPLICATIONS*

ALEXANDER V. KARZANOV† AND S. THOMAS MCCORMICK‡

Abstract. We consider the problem of minimizing a separable convex objective function over the linear space given by a system $Mx = 0$ with M a totally unimodular matrix. In particular, this generalizes the usual minimum linear cost circulation and cocirculation problems in a network and the problems of determining the Euclidean distance from a point to the perfect bipartite matching polytope and the feasible flows polyhedron.

We first show that the idea of minimum mean cycle canceling originally worked out for linear cost circulations by Goldberg and Tarjan [*J. Assoc. Comput. Mach.*, 36 (1989), pp. 873–886.] and extended to some other problems [T. R. Ervolina and S. T. McCormick, *Discrete Appl. Math*, 46 (1993), pp. 133–165], [A. Frank and A. V. Karzanov, Technical Report RR 895-M, Laboratoire ARTEMIS IMAG, Université Joseph Fourier, Grenoble, France, 1992], [T. Ibaraki, A. V. Karzanov, and H. Nagamochi, private communication, 1993], [M. Hadjiat, Technical Report, Groupe Intelligence Artificielle, Faculté des Sciences de Luminy, Marseille, France, 1994] can be generalized to give a combinatorial method with geometric convergence for our problem. We also generalize the computationally more efficient cancel-and-tighten method.

We then consider objective functions that are piecewise linear, pure and piecewise quadratic, or piecewise mixed linear and quadratic, and we show how both methods can be implemented to find exact solutions in polynomial time (strongly polynomial in the piecewise linear case). These implementations are then further specialized for finding circulations and cocirculations in a network.

We finish by showing how to extend our methods to find optimal integer solutions, to linear spaces of larger fractionality, and to the case when the objective functions are given by approximate oracles.

Key words. separable convex optimization, unimodular linear spaces, min mean canceling, network flows

1. Introduction.

A *circulation* in a digraph $G = (V, E)$ is a vector $x \in \mathbb{R}^E$ satisfying the *conservation* condition

$$\sum_{k:(k,i)\in E} x_{ki} - \sum_{j:(i,j)\in E} x_{ij} = 0 \quad \text{for all } i \in V.$$

A vector $\pi \in \mathbb{R}^V$ of *node potentials* induces a *cocirculation* (or potential difference, or tension) $\Delta\pi \in \mathbb{R}^E$ in G defined by

$$\Delta\pi(i,j) = \pi_j - \pi_i \quad \text{for } (i,j) \in E.$$

Suppose that for each $e \in E$ we are given an *objective* function $w_e : \mathbb{R} \to \mathbb{R}$ which is convex. Consider the problem of minimizing the separable *total objective* function, defined as

$$w(x) = \sum_{e \in E} w_e(x_e), \tag{1}$$

over the set $\mathcal{C}$ of circulations in G and consider a similar problem for the set $\mathcal{C}^\perp$ of cocirculations in G. This framework includes many special problems on circulations and cocirculations. The most popular is the classical *minimum linear cost circulation problem* (briefly, the *linear circulation problem*): given lower and upper arc bounds $l, u \in \mathbb{R}^E$ with $l \le u$ and arc costs $c \in \mathbb{R}^E$, find $x \in \mathcal{C}$ that minimizes $\sum_{e \in E} c_e x_e$ subject to $l_e \le x_e \le u_e$, $e \in E$. This is reduced to the above "unconstrained" problem by defining for $e \in E$

$$w_e(r) = \begin{cases} c_e u_e + \alpha(r - u_e) & \text{if } r > u_e, \\ c_e r & \text{if } l_e \le r \le u_e, \\ c_e l_e + \alpha(l_e - r) & \text{if } r < l_e, \end{cases} \tag{2}$$

where α is a sufficiently large positive number. (We could also just set $w_e(x_e) = +\infty$ when x_e is outside the bounds.) Thus we obtain a special case of separable piecewise linear objective function w; see Figure 1. In the case of the *minimum linear cost cocirculation problem* (briefly, *linear cocirculation problem*), let a^+ (a^-) denote the vector of positive parts (negative parts) of vector a, i.e., the vector with ith component $\max\{a_i, 0\}$ ($\max\{-a_i, 0\}$). Then the dual objective function can be written as

$$\max_\pi \{l^T(\bar{c}^\pi)^+ - u^T(\bar{c}^\pi)^-\} \tag{3}$$

(see [8]), where $\bar{c}^\pi_e = c_e - \Delta\pi_e$ is the vector of reduced costs. Equation (3) shows that the classic dual circulation (cocirculation) objective is the piecewise linear function shown in Figure 2.

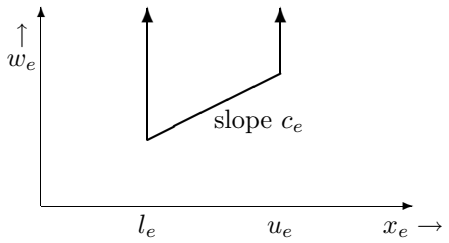

FIG. 1. *The arc objective function for the classic linear circulation problem with lower bound l_e, upper bound u_e, and cost c_e.*

It is tempting to further generalize this model by allowing demands at nodes, by putting convex penalties on violations of conservation, or by putting convex costs on the node potentials, etc. However, all of these generalizations can be handled by adjoining a new node 0 to the network, along with arcs from 0 to every other node. These new arcs can then carry demands, conservation violations, or node potentials. Thus we do not really lose any generality by considering only the simpler model.

Among the many approaches to solving the linear circulation problem (see, e.g., Ahuja, Magnanti, and Orlin [1] for a survey), one strongly polynomial method is especially simple, namely, the minimum mean cycle canceling method due to Goldberg

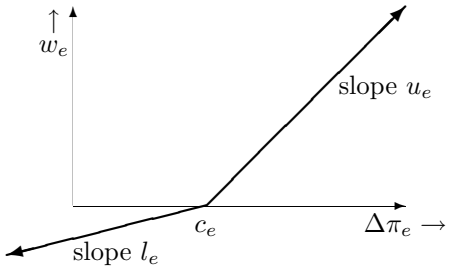

FIG. 2. *The arc objective function for the classic linear cocirculation problem with lower bound l_e, upper bound u_e, and cost c_e.*

and Tarjan [5]. Its ideas inspired a number of polynomial and strongly polynomial algorithms for other problems, such as the linear cocirculation problem [2], determining the Euclidean distances to certain polyhedra [4, 12], and the min-cost cocirculation (tension) problem [7]. (However, it appears that it does not work well for submodular flow problems; see [20].)

The first purpose of the present paper is to show that the "minimum mean canceling method" can be unified and generalized to solve a wide class of problems. We generalize it in two directions at once: to deal with separable convex objectives as in (1); and to arbitrary unimodular linear spaces L (i.e., the solution set of system $Mx = 0$ with a totally unimodular matrix M). The sets of circulations and cocirculations of a digraph are special cases of such an L. The method we develop is combinatorial and has geometric dual convergence in terms of the ℓ_1-distance of the current vector of partial (left and right) derivatives to an optimal dual vector.

There is a faster version of the minimum mean cycle canceling method for the linear circulation problem, the "cancel-and-tighten method" [5, 2]. We show that this also can be generalized to our generic case to give a method whose dual convergence is at essentially the same geometric rate but which has much faster iterations than our first method.

This paper considers several specializations and two generalizations of our general model by varying the form of the objective functions and the type of linear space. An overview of the various cases and their running times is given in the next section, with details in sections 3–12. Two generalizations go beyond our model: our methods can solve problems where the variables are restricted to be integer (see section 12) and problems whose constraint matrices are not totally unimodular but have "bounded fractionality" (see section 10). We also consider practical implications of duality for these problems in section 11 and the accuracy attainable by our methods when the objective functions are represented by approximate oracles in section 13.

Polynomial algorithms for the circulation problem with nonlinear separable costs based on capacity scaling were designed by Florian [3] and Minoux [23, 24]. In particular, [24] gives a polynomial algorithm for finding an optimal integer-valued circulation in a network with quadratic costs; this algorithm was speeded up and extended to general convex costs in [1, Chapter 14]. Our methods do not require any scaling, are as fast, and work with the problem in a more combinatorial way.

Hochbaum and Shanthikumar [11] gave a polynomial method for separable convex minimization over a linear space which is also based on capacity scaling. Their method involves solving linear programs where each original variable gets replicated $4n$ times (n is the number of original variables). By contrast, our methods work in the space

of original variables at all times and appear to be faster in general. For the case of separable convex circulation problems on networks, the Hochbaum–Shanthikumar algorithm can be specialized into a practical algorithm [10, 1], with about the same running time as our method (see section 2).

On the other hand, our methods assume the existence of a stronger oracle than what is assumed in [11]. That is, our oracle (O) (ii) in section 3 essentially assumes that we can do root-finding for the derivatives of the objective functions, whereas [11] assumes only an evaluation oracle. There are well-developed methods for root-finding, so our oracle is reasonable in practice. However, in theory, as [10] points out, there is a lower bound on root-finding even for square roots with the floor operation that is not strongly polynomial [17], and this shows that our oracle cannot be simulated with a strongly polynomial number of calls to an evaluation oracle.

In the general case, our methods depend on having an efficient procedure for solving various linear programs (LPs) over L. Such LPs can be solved in strongly polynomial time, e.g., by Tardos's version [32] of the ellipsoid method. For circulations and cocirculations on networks, we use fast combinatorial algorithms in place of solving LPs.

There are many applications for convex separable cost circulations; see [1, Chapter 14]. Many of these applications involve piecewise quadratic and/or linear objective functions. However, our method should be useful also for more general nonlinear problems. An example of this comes from applications to queuing networks where modelers are interested in the arc congestion function $w_e(x_e) = a_e x_e/(u_e - x_e)$ on the interval $[0, u_e)$ (see, e.g., [16]).

Applications for cocirculations are rarer, but they do arise. The best known example is the dual to the minimum-cost network flow problem, as discussed above. Chapter 7F of [30] contains several other more general applications of cocirculations. A more nonlinear application is to traffic flow equilibrium in congested cities, where the cocirculation represents differences in timings of traffic lights; see Hassin [9]. This application is not convex, but perhaps our methods could be used as a heuristic for quickly finding local optima. Our cocirculation methods should be also useful in PERT networks, where there are often nonlinear penalties for the elapsed time (time difference) for the task represented by an arc.

An example of a problem that is not unimodular is the well-known fractional b-matching problem (see, e.g., [6]). Such problems have the node-edge incidence matrix of an undirected graph as the essential part of their coefficient matrix. This problem turns out to have fractionality 2, which is certainly bounded, so the extension of our methods in section 10 will give strongly polynomial algorithms for this problem.

A more significant nonunimodular application arises when we add a new set of linear constraints $d^i x = 0$, $i = 1, \dots, p$, to the unimodular system $Mx = 0$, where all entries d^i_j are integers and the sum of their absolute values is at most a fixed number k. For example, in a network, we could add the equalities $x_e = x_{e'}$ for $k/2$ pairs of arcs $\{e, e'\}$ in the network. Then 2^k (which is constant because k is fixed) is an upper bound on any subdeterminant of the resulting matrix and so also on the fractionality of the problem. Thus our methods are again polynomial.

2. An overview of the results. Let L be a subspace of the Euclidean space $\mathbb{R}^E$ with coordinates indexed by the elements of a set E, and let $L^\perp$ be the orthogonal complement of L. We study the unconstrained (within L) optimization problem

(4) find $x \in L$ such that $w(x) = \sum_{e \in E} w_e(x_e)$ is as small as possible,

where each w_e is convex. We may assume that L contains a nonzero point; otherwise, the problem is trivial. We also assume that (4) has a *finite* optimal solution x. This assumption can be checked by solving two linear programs, one which computes an $x \in L$ satisfying any bounds implicit in the w_e's and another which computes an $h \in L^\perp$ that satisfies any dual bounds (see [30]).

We now impose the important restriction that L is a *unimodular space* given by a totally unimodular matrix M with n rows and m columns (the columns correspond to the elements of E, so $|E| = m$ also). We assume w.l.o.g. that M has full row rank n, so we can permute and partition the columns of M as $(B \quad N)$, where B is $n \times n$ and nonsingular. Since pivoting preserves total unimodularity, the matrix $(I \quad B^{-1}N)$ gives an alternative unimodular representation of L.

Now the $(m-n) \times m$ matrix $K = ((B^{-1}N)^T \quad -I)$ clearly has full row rank and is totally unimodular, and it is easy to check that $\{h \in \mathbb{R}^E : Kh = 0\}$ is exactly $L^\perp$. Thus $L^\perp$ is a unimodular linear space which is represented by matrix K. For convenience, we will often call the vectors in L ($L^\perp$) *circulations* (*cocirculations*).

A nonzero vector $\xi \in L$ ($\xi \in L^\perp$) whose support $\text{supp}(\xi) = \{e \in E : \xi_e \neq 0\}$ is inclusionwise minimal is said to be a *cycle* (resp. *cocycle*) of L. Since a positive multiple of a cycle essentially defines the same cycle, we will henceforth assume that a cycle is the canonical representative of this class that is integral with no common divisors. Then a unimodular linear system is distinguished by the fact that all of its cycles (and cocycles) are $(0, \pm 1)$ vectors. The *size* of a cycle or cocycle is its number of nonzero components. Key parameters for us will be ϕ ($\phi^\perp$), the maximum size of a cycle (resp. cocycle), and ρ ($\rho^\perp$), one plus the rank of M (resp. K); clearly, $\phi \leq \rho = n+1$ and $\phi^\perp \leq \rho^\perp = m-n+1$.

Example. Let $\mathcal{D} = (V, E)$ be a digraph with node-arc incidence matrix M. Then M is totally unimodular and $L = \{x \in \mathbb{R}^E : Mx = 0\}$ is the set of circulations for $\mathcal{D}$. The set of cycles for this L is exactly the set of simple circuits (with possible forward and backward arcs) in $\mathcal{D}$, and the set of co-cycles is exactly the set of simple cuts (with possible forward and backward arcs) in $\mathcal{D}$. The dual space $L^\perp$ is the space of cocirculations. Conversely, if M is instead a matrix whose rows are the incidence vectors of a circuit basis, then M is again totally unimodular and $L = \{x \in \mathbb{R}^E : Mx = 0\}$ is the set of cocirculations for $\mathcal{D}$. The set of cycles for this L is exactly the set of simple cuts in $\mathcal{D}$, and the set of co-cycles is exactly the set of simple circuits in $\mathcal{D}$. The dual space $L^\perp$ is the space of circulations.

Our first algorithm will find a cycle ξ such that updating the current x along ξ by step length α via $x := x + \alpha\xi$ will decrease the objective value. The cost of cycle ξ w.r.t. x is the local change in objective value from this change. A minimum mean cycle is a cycle whose cost per nonzero component is minimum. The min mean canceling method (MMCM) chooses a min mean cycle with an appropriate step length at each iteration. Section 3 will show that MMCM is a polynomial-time algorithm, but its time bounds are not impressive. One reason is that it is slow (but polynomial) to compute min mean cycles. Another is that it takes $O(\rho^\perp)$ MMCM iterations to achieve a relatively modest reduction in its measure of convergence.

We propose a second method, called *cancel-and-tighten*, that overcomes both of these problems. Section 5 shows that a single cancel-and-tighten iteration achieves essentially the same reduction in the convergence parameter that takes $O(\rho^\perp)$ MMCM iterations, without the need to compute any min mean cycles.

We shall consider various special and general cases of problem (4). First, consider the objective functions w_e. In the piecewise linear and/or quadratic case, we use C

to represent the largest number among the data. More precisely, when the w_e's are all piecewise linear with integer slopes, then C denotes the absolutely largest finite slope. When the w_e's are piecewise mixed linear and quadratic with all coefficients of all pieces and all breakpoints integer, then C denotes the absolutely largest finite number among all these data. We look at the cases where for all $e \in E$, we have the following:

1. The w_e's are *general*, i.e., they have no special properties other than convexity. In this case, we shall assume that we have some initial bound β on the "deviation" of an initial solution from optimality and that we want to get a final solution whose "deviation" is at most ε, in a sense to be made precise in section 3.

2. The w_e's are piecewise linear, with all slopes integral.

3. The w_e's are again piecewise linear, but the slopes may be general. Define B as the number of linear pieces in all of the w_e's; note that $O(B)$ pieces of data are needed to represent such a set of w_e's, so B can legitimately appear in a strongly polynomial bound. Cases 2 and 3 are dealt with in section 6.

4. The w_e's are piecewise quadratic with all data integral.

5. The w_e are piecewise mixed linear and quadratic with all data integral. Cases 4 and 5 are dealt with in section 7.

6. The w_e's are general, but we are looking for an optimal *integral* solution. This case actually concerns constraints, not objectives, but it is dealt with in section 12 by transforming it to the case of piecewise linear objectives.

Now consider a generalization and some specializations of the space L:

a. We generalize by allowing L to be any linear space represented by a rational matrix. We measure the deviation of L ($L^\perp$) from unimodularity by its *fractionality* q ($q^\perp$), which is the absolutely largest component of any cycle of L ($L^\perp$) when it is scaled to have all integral components with no common divisors. Thus unimodular spaces have fractionality $q = q^\perp = 1$. Case a is dealt with in section 10.

b. This is the standard unimodular case, which is dealt with in section 3.

c. Here we specialize to the case where L is the space of circulations of a network.

d. Here we specialize to the case where L is the space of cocirculations of a network. Cases c and d are dealt with in section 8.

The running-time bounds of our methods will involve the parameters ϕ, $\phi^\perp$, ρ, and $\rho^\perp$. In most instances, we will use the upper bounds $\phi \le \rho \le O(n)$ and $\phi^\perp \le \rho^\perp \le O(m-n) \le O(m)$. However, there are some situations where our sharper bounds are useful. For example, if $\mathcal{D}$ is a bipartite network with n_1 left nodes and n_2 right nodes, where $n_1 \ll n_2$, then $\phi = O(n_1)$. As another example, if $m = n + O(\sqrt{n})$, then $\rho^\perp = O(\sqrt{n})$.

In order to express running time of algorithms for computing min mean cycles below, we need two more definitions. Let $LP_q(n, m)$ denote the time to solve an $n \times m$ linear program over a space of fractionality q, and let $MC(n, m)$ denote the time to find a min cut separating two given nodes in a network with n nodes and m arcs.

THEOREM 2.1. *The numbers of iterations and running times per iteration for MMCM and cancel-and-tighten under the above assumptions about the objective functions and constraints are as given in Table* 1 *below. The bounds in row* 1 *are for approximate solutions, and the bounds in the other rows are for finding exact solutions.*

We now give a "proof" of Theorem 2.1 that outlines the main ideas behind its bounds, while leaving the harder technical details for later sections.

TABLE 1

Table of main results. Abbreviations PWL, PWQ, and PWLQ stand for "piecewise linear," "piecewise quadratic," and "piecewise mixed linear and quadratic," respectively. C+T stands for "cancel-and-tighten."

Type of Objective	Type of Constraints			
	(a) Fractionality q	(b) Unimodular	(c) Network Circulation	(d) Network Cocirculation

Proof. The convergence proof for MMCM depends on analyzing $\lambda(x)$, the negative of the min mean cycle value w.r.t. the current point x. Lemma 3.4 shows that $\rho^\perp$ iterations of MMCM suffice to reduce $\lambda(x)$ by a factor of at most $(1 - 1/2\phi)$. Since

$$(1 - 1/2\phi)^{2\phi \log(\beta/\varepsilon)} < \varepsilon/\beta,$$

$O(\rho^\perp \phi \log(\beta/\varepsilon))$ MMCM iteration reduce $\lambda(x)$ from its initial value of at most β to a final value below ε. This is the result in box 1b of Table 1, and all other MMCM results follow from this.

To get the results in row 2 for MMCM with piecewise linear objectives with integral slopes, section 6 shows that $\lambda(x) \leq C$ for any feasible initial x, and Lemma 6.1 shows that if $\lambda(x) < 1/\phi$, then x is optimal. Thus the bounds in row 2 result from substituting C for β and ϕ for $1/\varepsilon$ in the row 1 bounds.

The results in row 4 for MMCM with piecewise quadratic objectives and integral data are derived similarly. Section 7 shows that we can choose an initial x with $\lambda(x) = O(C^{m+1})$ and that if we reduce $\lambda(x)$ below $1/(2C^{2m}\phi)$, then we can round x

to an optimal x using continued fractions (see [31]). Thus here $\log(\beta/\varepsilon) = O(m \log C)$.

The results in row 3 for MMCM with piecewise linear objectives and general slopes are slightly more complicated. Section 4 defines *reduced costs*, which are closely related to $\lambda(x)$; in fact, Corollary 4.2 and Lemma 4.3 show that $-\lambda(x)$ and the most negative reduced cost differ by a factor of at most ϕ. For piecewise linear objectives, there are at most B different values that reduced costs can take. By the same reasoning as for row 1, $O(\rho^{\perp}\phi \log \phi)$ MMCM iterations suffice to reduce $\lambda(x)$ by a factor of at least ϕ. By Corollary 4.2 and Lemma 4.3, this must cause a decrease in the most negative reduced cost. But this can happen at most B times. Finally, Lemma 11 from [28] applies here to remove the factor of $\log \phi$ from the iteration bounds.

The results in row 5 for MMCM with piecewise mixed linear and quadratic objectives follow the ideas for the piecewise quadratic case. Using the same ideas and number of iterations, we can compute the exact values of optimal x_e's that are located in "quadratic parts" of the objective functions. We are left with a piecewise linear problem with at most two pieces per element, which we can solve in the same number of iterations as in row 3 where $B = O(m)$. Thus these bounds are the sums of the bounds in row 3 and row 4.

The results in row 6 for MMCM (aside from column a) restricted to integral solutions start by noting that an equivalent problem results if we replace the w_e's with their piecewise linear approximations with breakpoints at all integers. Thus we effectively have instances with piecewise linear objectives (with possibly an unbounded number of pieces) with integral breakpoints and general slopes. We now apply the duality results from section 11, which say that when we dualize, the objective functions for the dual are piecewise linear, now with integral slopes and general breakpoints. Then the bounds from row 2 applied to the dual can be used with the parameters for L and $L^{\perp}$ interchanged.

The convergence proof for cancel-and-tighten in section 5 depends on analyzing $\overline{\lambda}$, an upper bound on $\lambda(x)$. Lemma 5.2 shows that one iteration of cancel-and-tighten reduces $\overline{\lambda}$ by a factor of at most $(1 - 1/2\rho)$. Then the same reasoning as in row 1 of MMCM gives the iteration bound in box 1b for cancel-and-tighten.

Rows 2–6 in Table 1 for cancel-and-tighten are obtained in the same way as the corresponding rows for MMCM, except that the trick from [28] does not apply to cancel-and-tighten in row 3.

We turn now to the columns of Table 1. Column a deals with linear spaces of fractionality q. Section 10 shows that essentially the same proofs go through except that the factor $(1 - 1/2\phi)$ of Lemma 3.4 is replaced by the factor $(1 - 1/(2q\phi))$ in Lemma 10.1. This leads to an extra factor of $O(q)$ in all of the bounds in column (a), except for the subcase asking for integral optimal solutions (box 6a). This problem is NP hard even for $q = 2$ since a special case of this is finding a maximum independent set (stable set) in a graph. It can be shown that there exists an optimal solution to the continuous relaxation of the linearized problem here with the denominators of all components bounded by Q, the least common multiple of all cycle vectors. For example, for the independent set problem, $q = Q = 2$. This would then lead to $O(\rho^{\perp} q^{\perp} \log(\phi^{\perp} QC))$ iterations to solve the continuous relaxation for MMCM and $O(\rho\phi^{\perp} q^{\perp} \log(\phi^{\perp} QC))$ iterations for cancel-and-tighten.

Columns c and d deal with linear spaces coming from networks with n nodes and m arcs. Column c deals with network circulation problems, and its bounds come from replacing ϕ and ρ by n and $\rho^{\perp}$ by m. Column d deals with network cocirculation problems, and its bounds come from replacing ϕ and ρ by m and $\rho^{\perp}$ by n.

Finally, we consider the two row 7's, the time per iteration rows. Section 9 gives a general algorithm for computing min mean cycles by solving linear programs, which is a refinement of a general method in [15]. The bound in MMCM box 7a comes from Theorem 9.2, and MMCM box 7b just sets $q = 1$ in this bound. MMCM box 7c gives the current fastest weakly and strongly polynomial bounds for computing a min mean cycle in a network (which dominates the time per iteration for MMCM); the top bound is from [26, 18] and the bottom one from [14]. MMCM box 7d does the same for computing a max mean cut in a network; the top bound is from [27], and the bottom bound is from [13, 18, 27].

The bounds in the cancel-and-tighten time-per-iteration row are implicit in section 5 in columns a and b and are covered explicitly in section 8 in columns c and d. To get the strongly polynomial bounds in cancel-and-tighten row 3, it is necessary to intersperse an iteration using an exact min mean cycle from time to time. Section 5 shows that it is possible to amortize the time for these (expensive) iterations over the remaining (cheaper) iterations. □

Note that when we specialize our general methods to piecewise linear objective functions on networks (rows 2 and 3, columns c and d times row 7), when we set $B = O(m)$ (as would be the case for classic linear circulation and cocirculation problems), they have the same time bounds as the best bounds in [5, 2]. Thus, despite being considerably generalized, our methods do not sacrifice any efficiency.

Taking the product of cancel-and-tighten box 6c with its time-per-iteration box 7d (we must use box 7d instead of 7c since we dualize when solving integer problems), we get a bound of $O(m \log(nC)(m + n \log n))$ total time for cancel-and-tighten for circulations in networks with general objectives and integer restrictions. This is roughly the same as the bound of $O(m \log C(m + n \log n))$ for an algorithm for the same problem in [1, Chapter 14]; see also [10].

Note that for problems with fractionality q, there is a factor of $O(q)$ more iterations, and each iteration takes a factor of $O(q^2)$ more time. Nevertheless, if q is bounded by a polynomial in $|E|$, the whole algorithm is still polynomial. For the fractional b-matching problem $q = 2$ and for the second example in the introduction, $q \leq 2^k$ for k fixed, so our methods are polynomial in both cases.

3. The minimum mean canceling method. In what follows, we utilize some well-known facts in convex analysis, linear algebra, and optimization; for references, see, e.g., Rockafellar [29] or Schrijver [31].

The convexity of w_e ensures the existence of the *right derivative*, denoted by $c_e^{\vdash}(r)$, and the *left derivative*, $c_e^{\dashv}(r)$, at every $r \in \mathbb{R}$. Note that $c_e^{\dashv}(r) < c_e^{\vdash}(r)$ is possible at a *breakpoint*. The interval $[c_e^{\dashv}(r), c_e^{\vdash}(r)]$ is known as the *subdifferential* of $w_e(r)$, and an $h \in [c_e^{\dashv}(r), c_e^{\vdash}(r)]$ is called a *subgradient* of w_e at r; see [29]. We refer to $c_e^{\vdash}(r)$ and $c_e^{\dashv}(r)$ as the *left (local) cost* and *right (local) cost* of e at r, respectively. Because of the convexity of w_e,

$$\text{if } r < r', \quad \text{then } c_e^{\dashv}(r) \leq c_e^{\vdash}(r) \leq c_e^{\dashv}(r') \leq c_e^{\vdash}(r'); \tag{5}$$

in particular, both $c_e^{\dashv}(r)$ and $c_e^{\vdash}(r)$ are monotone nondecreasing in r. The convexity of w_e implies that

$$\text{for any } r \in \mathbb{R}, \quad c_e^{\vdash} \text{ is continuous at } r \text{ in the set } [r, \infty) \text{ and } c_e^{\dashv} \text{ is continuous at } r \text{ in } (-\infty, r]. \tag{6}$$

It will be enough for us to assume that w_e is given by an *oracle* which

(O) (i) when given a point $r \in \mathbb{R}$ will return the costs $c_e^{\vdash}(r)$ and $c_e^{\dashv}(r)$;
(ii) when given a "slope" $p \in \mathbb{R}$ will return a point r with $c_e^{\dashv}(r) \le p \le c_e^{\vdash}(r)$.

In the case of piecewise linear or quadratic functions, (O) (i) and (ii) reduce to a simple linear or binary search, followed by solving a one-variable linear equation. Even for more complicated objectives such as the application to queuing networks [16], it is usually easy to compute both parts of (O) in practice.

We recall that any nonzero point (resp. any integral point) $x \in L$ is a nonnegative (resp. nonnegative integer) combination $\alpha_1\xi^1 + \cdots + \alpha_k\xi^k$ of $k \le |E|$ cycles $\xi^1, \ldots, \xi^k \in L$; moreover, these ξ^i's may be chosen so that

$$\xi_e^i \xi_e^j \ge 0 \quad \text{for } i, j = 1, \ldots, k \text{ and } e \in E. \tag{7}$$

This is called a *conformal decomposition* of x.

In what follows, we associate a $(0, \pm 1)$-vector ξ in $\mathbb{R}^E$ with the pair $F_\xi = (A_\xi, B_\xi)$, where $A_\xi = \{e : \xi_e = 1\}$ and $B_\xi = \{e : \xi_e = -1\}$. If ξ is a cycle (resp. cocycle) of L, we call F_ξ a *cycle* (resp. *cocycle*) also; the set of such F_ξ's is denoted by $\mathcal{F}$ (resp. $\mathcal{F}^\perp$). Define $|F|$, the *size* of F, as $|A| + |B|$.

For a function $f : S \to \mathbb{R}$ and a subset $S' \subseteq S$, we use $f(S')$ to denote $\sum(f_e : e \in S')$. Also, when it is not confusing, for a fixed point $x \in L$ and a cycle $F = (A, B)$, we denote $\sum_{e \in A} c_e^{\vdash}(x_e)$ by $c^{\vdash}(A)$ and denote $\sum_{e \in B} c_e^{\dashv}(x_e)$ by $c^{\dashv}(B)$.

Suppose that we have a cycle $F = (A, B)$ and a circulation $x \in L$ and we want to "augment x around F," i.e., increase x by an amount $\varepsilon > 0$ on the elements of A and decrease x by ε on the elements of B. Then the local change in objective function value per unit of ε is $c^{\vdash}(A) - c^{\dashv}(B)$, the *cost of* F *at* x, denoted by $c(x, F)$. We say that F is a *negative cycle* at x if $c(x, F) < 0$. The *mean cost* of F at x is $\overline{c}(x, F) := c(x, F)/|F|$. We say that F is a *minimum mean cycle* if $\overline{c}(x, F)$ is as small as possible. Define

$$\lambda(x) = \max\{0, -\min_{F \in \mathcal{F}} \overline{c}(x, F)\}. \tag{8}$$

If $\lambda(x)$ is positive, it is called the *absolute minimum mean value* for x.

The following lemma gives an optimality criterion for (4).

LEMMA 3.1. *Point $x \in L$ is an optimal solution to* (4) *if and only if there are no negative cycles at x or, equivalently, if $\lambda(x) = 0$.*

This lemma can be derived from general optimality theorems in convex programming, but to make our description self-contained, we prove it directly. Let $x \in L$. Suppose that $\overline{c}(x, F) = -\lambda < 0$ for some $F = (A, B) \in \mathcal{F}$. Then push a small amount $\varepsilon > 0$ around F to get $x' \in L$ with $w(x') < w(x)$, thus proving that x is not optimal. More precisely, we set

$$x'_e = \begin{cases} x_e + \varepsilon & \text{for } e \in A, \\ x_e - \varepsilon & \text{for } e \in B, \\ x_e & \text{otherwise,} \end{cases} \tag{9}$$

where $\varepsilon > 0$ is chosen so that $\delta_e(\varepsilon) := c_e^{\vdash}(x_e + \varepsilon) - c_e^{\vdash}(x_e) < \lambda$ for each $e \in A$ and $\delta_e(\varepsilon) := c_e^{\dashv}(x_e) - c_e^{\dashv}(x_e - \varepsilon) < \lambda$ for each $e \in B$. Such an ε exists because of (6). Since $c^{\vdash}$ and $c^{\dashv}$ are monotone, $w_e(x'_e) - w_e(x_e)$ is at most $\varepsilon c_e^{\vdash}(x_e) + \varepsilon\delta_e(\varepsilon)$ for $e \in A$ and at most $-\varepsilon c_e^{\dashv}(x_e) + \varepsilon\delta_e(\varepsilon)$ for $e \in B$, whence

$$w(x') - w(x) \le \varepsilon c(x, F) + \sum_{e \in A \cup B} \varepsilon\delta_e(\varepsilon) < \varepsilon c(x, F) + \varepsilon\lambda|F| = 0.$$

This proves the "only if" part of Lemma 3.1. The "if" part will follow from the next lemma. Given a circulation x and a cocirculation h, the *positive reduced cost* of element e is $c_e^{\vdash}(x_e) - h_e$ and its *negative reduced cost* is $h_e - c_e^{\dashv}(x_e)$. The next lemma characterizes $-\lambda(x)$ as being the largest possible lower bound on reduced costs when h varies over all vectors in $L^{\perp}$.

LEMMA 3.2. *A real λ is an upper bound on $\lambda(x)$ if and only if there exists $h \in L^{\perp}$ such that the reduced costs satisfy*

$$c_e^{\vdash}(x_e) - h_e \geq -\lambda \quad \text{and} \quad h_e - c_e^{\dashv}(x_e) \geq -\lambda \quad \text{for all } e \in E. \tag{10}$$

Moreover, if $\lambda = \lambda(x) > 0$, $F = (A, B)$ is a minimum mean cycle, and $h \in L^{\perp}$ satisfies (10)*, then $c_e^{\vdash}(x_e) - h_e = -\lambda$ for all $e \in A$ and $h_e - c_e^{\dashv}(x_e) = -\lambda$ for all $e \in B$.*

Proof. Let $\mathbb{1}$ denote a vector of ones, and consider the following optimization problem:

$$\begin{aligned} \min(c^{\vdash}x^+ - c^{\dashv}x^-)/(\mathbb{1}x^+ + \mathbb{1}x^-) \\ \text{s.t.} \quad M(x^+ - x^-) = 0, \\ x^+, x^- \geq 0. \end{aligned} \tag{11}$$

If (11) has an optimal solution, then it also has an optimal (x^+, x^-) with minimal support, which must then be a min mean cycle. Since (11) is homogeneous, it does not hurt to normalize by requiring that the denominator equals 1. Therefore, the problem remains the same if we delete the denominator to get the LP

$$\begin{aligned} \min c^{\vdash}x^+ - c^{\dashv}x^- \\ \text{s.t.} \quad M(x^+ - x^-) = 0, \\ \mathbb{1}x^+ + \mathbb{1}x^- = 1, \\ x^+, x^- \geq 0, \end{aligned} \tag{12}$$

with dual

$$\begin{aligned} \max \delta \\ \text{s.t.} \quad \pi M + \delta\mathbb{1} \leq c^{\vdash}, \\ -\pi M + \delta\mathbb{1} \leq -c^{\dashv}, \\ \pi, \delta \text{ free}. \end{aligned} \tag{13}$$

Note that since π is free, πM is an arbitrary vector h in $L^{\perp}$. Thus we can rewrite (13) as

$$\begin{aligned} \max \delta \\ \text{s.t.} \quad \delta\mathbb{1} \leq c^{\vdash} - h, \\ \delta\mathbb{1} \leq h - c^{\dashv}, \\ Kh = 0, \\ \delta \text{ free}. \end{aligned} \tag{14}$$

Dual LP (14) is asking for the largest (least negative) value of δ that satisfies (10). Then the first part of the lemma follows from LP duality.

For the second part, if F is a minimum mean cycle with, say, $c_e^{\vdash} - h_e > -\lambda(x)$ for some element in A, then since (10) is true for all elements of F, we would have $\bar{c}(x, F) > -\lambda$, contradicting that $\lambda = \lambda(x)$. □

From Lemma 3.2, we now derive the "if" part of Lemma 3.1. Suppose that $x^* \in L$ admits no negative cycles, i.e., $\lambda(x^*) = 0$. Then (10) yields

$$c_e^{\dashv}(x_e^*) \le h_e \le c_e^{\vdash}(x_e^*) \quad \text{for each } e \in E. \tag{15}$$

We show that (15) implies the optimality of x^*, i.e., $w(x) \ge w(x^*)$ holds for any $x \in L$. Since w is convex and any point in L is a nonnegative combination of cycles, it suffices to prove this for $x = x^* + \xi$, where ξ is a cycle of L. Let $F_\xi = (A, B)$. If $e \in A$, we have $x_e = x_e^* + 1$ and $c_e^{\vdash}(x_e) \ge c_e^{\vdash}(x_e^*)$, whence $w_e(x_e) - w_e(x_e^*) \ge c_e^{\vdash}(x_e^*)(x_e - x_e^*) = c_e^{\vdash}(x_e^*)$. If $e \in B$, we have $x_e = x_e^* - 1$ and $c_e^{\dashv}(x_e) \le c_e^{\dashv}(x_e^*)$, whence $w_e(x_e) - w_e(x_e^*) \ge -c_e^{\dashv}(x_e^*)$. Therefore,

$$w(x) - w(x^*) \ge \sum_{e \in A} c_e^{\vdash}(x_e^*) - \sum_{e \in B} c_e^{\dashv}(x_e^*) \ge h(A) - h(B) = h\xi = 0,$$

as required.

Lemma 3.2 is crucial for our MMCM. We assume that there is a procedure available to solve the following auxiliary problem (AP); algorithms for solving (AP) are discussed in section 9.

(AP): Given $x \in L$, find $\lambda = \lambda(x)$, and if $\lambda > 0$, find a minimum mean cycle $F = (A, B)$ at x and $h \in L^{\perp}$ satisfying (10).

MMCM starts with any reasonable $x \in L$ and computes $\lambda = \lambda(x)$. If $\lambda = 0$, stop since x is optimal (by Lemma 3.1). Otherwise ($\lambda > 0$), find F and h as in (AP). For each element $e \in F$, use answer (ii) of oracle (O) for w_e to compute the local step length ε_e as an increment Δ s.t.

$$\begin{cases} c_e^{\dashv}(x_e + \Delta) \le c_e^{\vdash}(x_e) + \lambda = h_e \le c_e^{\vdash}(x_e + \Delta) & \text{if } e \in A, \\ c_e^{\dashv}(x_e - \Delta) \le c_e^{\dashv}(x_e) - \lambda = h_e \le c_e^{\vdash}(x_e - \Delta) & \text{if } e \in B \end{cases} \tag{16}$$

(the equalities come from the second part of Lemma 3.2); clearly, $\varepsilon_e > 0$. The overall step length ε is $\min\{\varepsilon_e : e \in A \cup B\}$. That is, we increase ε until the first time a reduced cost (w.r.t. h) in F becomes nonnegative. Now push ε around F forming x' as in (9), and make x' the new current point x in L. Continue until λ is "small enough."

We claim that this method converges geometrically in λ. We show this using two lemmas. The first is similar to a lemma in Goldberg and Tarjan [5], and the second is similar to a lemma in Frank and Karzanov [4] with an improvement generalizing a result in Radzik and Goldberg [28]. Note that (16) and (5) imply that

$$\begin{aligned} &c_e^{\vdash}(x_e) \le c_e^{\dashv}(x'_e) \le c_e^{\vdash}(x_e) + \lambda \quad \text{for } e \in A, \\ &c_e^{\dashv}(x_e) \ge c_e^{\vdash}(x'_e) \ge c_e^{\dashv}(x_e) - \lambda \quad \text{for } e \in B. \end{aligned} \tag{17}$$

LEMMA 3.3. *If x' is obtained from x at an iteration, then $\lambda(x') \le \lambda(x)$.*

Proof. Let $h \in L^{\perp}$ be a cocirculation proving the optimality of $\lambda = \lambda(x)$, i.e., h is as in Lemma 3.2. By Lemma 3.2, it is enough to show that (10) holds for $c^{\vdash}(x')$ and $c^{\dashv}(x')$.

Since x' and x coincide outside F, it suffices to examine only elements in the minimum mean cycle $F = (A, B)$ at x that is chosen at the iteration. For $e \in A$, the inequality

$$c_e^{\vdash}(x'_e) \ge c_e^{\vdash}(x_e)$$

(since $x'_e > x_e$) together with (10) implies

$$c_e^{\vdash}(x'_e) \geq h_e - \lambda,$$

and the inequality

$$c_e^{\dashv}(x'_e) \leq c_e^{\vdash}(x_e) + \lambda$$

(by (17)) together with the equality $c_e^{\vdash}(x_e) = h_e - \lambda$ (by Lemma 3.2) implies

$$-c_e^{\dashv}(x'_e) \geq -c_e^{\vdash}(x_e) - \lambda = -h_e + \lambda - \lambda > -h_e - \lambda,$$

as required. The proof for $e \in B$ is similar. □

For the next lemma, we superscript everything by the iteration number.

LEMMA 3.4. *After every $\rho^{\perp}$ iterations, $\lambda = \lambda(x)$ decreases by a factor of at most $(1 - 1/2\phi)$, i.e., $\lambda^{i+\rho^{\perp}} \leq \lambda^i(1 - 1/2\phi)$.*

Proof. Fix $h := h^i \in L^{\perp}$ proving the optimality of $\lambda = \lambda(x^i)$, and consider iterations $i, i+1, \ldots, i+\rho^{\perp}$. For each $j = i, \ldots, i+\rho^{\perp}$, call $e \in E$ *positively* (*negatively*) *close to* h if $c_e^{\vdash}(x_e^j) - h_e \geq -\lambda/2$ (resp. $h_e - c_e^{\dashv}(x_e^j) \geq -\lambda/2$), and otherwise call it positively (negatively) *far from* h. Note that $c_e^{\vdash}(x_e) - c_e^{\dashv}(x_e) \geq 0$ implies that e cannot be positively and negatively far from h at the same time. The proof rests on the following two claims.

CLAIM 1. *If for all $k = i, \ldots, j-1$ the chosen cycle $F^k = (A^k, B^k)$ is such that each $e \in A^k$ is positively far from h and each $e \in B^k$ is negatively far from h, then $c_e^{\vdash}(x_e^j) - h_e \geq -\lambda$ and $h_e - c_e^{\dashv}(x_e^j) \geq -\lambda$ for all $e \in E$.*

Proof. The proof is by induction on j. Then $c_e^{\vdash}(x_e^j) \geq c_e^{\vdash}(x_e^{j-1}) \geq h_e - \lambda$ for $e \in E - B^{j-1}$ and $-c_e^{\dashv}(x_e^j) \geq -c_e^{\dashv}(x_e^{j-1}) \geq -h_e - \lambda$ for $e \in E - A^{j-1}$. Consider the remaining two cases. For $e \in A^{j-1}$, we have $c_e^{\dashv}(x_e^j) \leq c_e^{\vdash}(x_e^{j-1}) + \lambda^{j-1}$ (by (17)) and $c_e^{\vdash}(x_e^{j-1}) < h_e - \lambda/2$ (since e is positively far from h). Putting these inequalities together yields $c_e^{\dashv}(x_e^j) < h_e - \lambda/2 + \lambda^{j-1} < h_e + \lambda^{j-1}$, whence $-c_e^{\dashv}(x_e^j) > -h_e - \lambda^{j-1} \geq -h_e - \lambda$ (since $\lambda^{j-1} \leq \lambda$ by Lemma 3.3). The case for $e \in B^{j-1}$ is similar. □

We say that an element e in a cycle $F = (A, B) \in \mathcal{F}$ (i.e., $e \in A \cup B$) is close (far) if e is positively close (far) whenever $e \in A$ and negatively close (far) whenever $e \in B$.

CLAIM 2. *There is some iteration j ($i < j \leq i+\rho^{\perp}$) such that either* (i) $\lambda^j < \lambda/2$, *or* (ii) F^j *includes an element close to* h.

Proof. Suppose that for $j = 1, \ldots, i + \rho^{\perp} - 1$, no iteration j satisfies (i), i.e., $\lambda^j \geq \lambda/2$, and suppose that all iterations up to and including j have all elements of their cycles far from h so that Claim 1 applies. Denote by P (resp. N) the current set of elements positively (resp. negatively) close to h, and let $C = P \cap N$. By the *rank* of C, we mean the rank of the submatrix of K induced by the columns corresponding to elements of C (recall that K is a matrix representing $L^{\perp}$, with rank $\rho^{\perp} - 1$). We shall show that each iteration j increases the rank of C by at least one. This implies that after iteration $i + \rho^{\perp} - 1$, C meets the support of every cycle $\xi \in L$. Therefore, the cycle $F^{i+\rho^{\perp}}$ must include some element of C, proving (ii).

First, we show that if $e \in E$ belongs to P (resp. N) before iteration j, then e remains in P (resp. N) after the iteration. Consider a positively close e (the proof is similar for a negatively close e). Now e could become positively far only if $c_e^{\vdash}(x_e)$ decreased, which implies that $e \in B^j$. But then e is negatively far from h at iteration j, i.e., $-c_e^{\dashv}(x_e^j) < -h_e - \lambda/2$. This together with $c_e^{\vdash}(x_e^{j+1}) \geq c_e^{\dashv}(x_e^j) - \lambda^j$ (by (17))

yields $c_e^{\vdash}(x_e^{j+1}) > h_e + \lambda/2 - \lambda^j \geq h_e - \lambda/2$ so that e is not positively far from h after iteration j. Thus each of the sets P, N, and C is monotone nondecreasing.

Next, we show that there is at least one element e in F^j such that iteration j makes e close (recall that all elements in F^j are far). Lemma 3.3 says that $\lambda^j \leq \lambda$. By the choice of ε^j, either (a) A^j contains e with $c_e^{\vdash}(x_e^{j+1}) \geq c_e^{\vdash}(x_e^j) + \lambda^j$ or (b) B^j contains e with $c_e^{\dashv}(x_e^{j+1}) \leq c_e^{\dashv}(x_e^j) - \lambda^j$. Suppose that (a) takes place (case (b) is similar). Then (using Claim 1 for j) we get

$$c_e^{\vdash}(x_e^{j+1}) \geq c_e^{\vdash}(x_e^j) + \lambda^j \geq h_e - \lambda + \lambda^j \geq h_e - \lambda/2.$$

Thus iteration j adds this e as a new element to C.

Finally, we show that adding this e increases the rank of C. Suppose to the contrary that the rank of the set C at the beginning of iteration j equals the rank of $C \cup \{e\}$. Then a minimal vector $\xi' \in L^{\perp}$ proving the dependence of e on C corresponds to a cocycle, and $e \in \mathrm{supp}(\xi')$. Let $\xi \in L$ be the vector corresponding to F^j. Since $\xi\xi' = 0$ and $\xi_e\xi'_e \neq 0$, there exists another element $e' \neq e$ in both F^j and $\mathrm{supp}(\xi')$. But e is the only element of $\mathrm{supp}(\xi')$ not in C, so $e' \in C \cap F^j$. But each element of F^j was far at the beginning of iteration j, a contradiction. □

We may assume that $\lambda^j \geq \lambda/2$ for $j = i, \ldots, i + \phi^{\perp}$; otherwise, Lemma 3.3 shows that we are already done. Thus there must be an iteration j satisfying Claim 2(ii), i.e., with either (a) A^j containing an element u positively close to h or (b) B^j containing an element u' negatively close to h. Consider the smallest j with this property and assume that (a) takes place (case (b) is similar). Using Claim 1, we have

$$\begin{aligned} c(x^j, F^j) &= c(x^j, F^j) - h(A^j) + h(B^j) \\ &= \sum_{e \in A^j - \{u\}} (c_e^{\vdash}(x_e^j) - h_e) + (c_u^{\vdash}(x_u^j) - h_u) + \sum_{e \in B^j} (h_e - c_e^{\dashv}(x_e^j)) \\ &\geq -\lambda(|A^j| - 1) - \lambda/2 - \lambda|B^j| = -\lambda|F^j| + \lambda/2, \end{aligned}$$

whence $\lambda^j \leq \lambda(1 - 1/2\phi)$. □

This establishes MMCM box 1b in Table 1.

4. Cost distance and dual and primal convergence. Since $\lambda(x)$ is the best possible lower bound on reduced costs over all $h \in L^{\perp}$, it is a measure of dual convergence. However, it remains unclear whether this fact forces fast convergence of the current point x to an optimal point. Here we introduce another, closely related measure of the quality of the current point x which will enable us to show fast convergence of x to an optimal point for some special cases of w and to compute exact optimal solutions in sections 6 and 7.

Given $x \in L$ and $h \in L^{\perp}$, for each $e \in E$, define

$$\langle x_e, h_e \rangle = \begin{cases} h_e - c_e^{\vdash}(x_e) & \text{if } c_e^{\vdash}(x_e) < h_e, \\ c_e^{\dashv}(x_e) - h_e & \text{if } c_e^{\dashv}(x_e) > h_e, \\ 0 & \text{if } c_e^{\dashv}(x_e) \leq h_e \leq c_e^{\vdash}(x_e), \end{cases} \tag{18}$$

and then define

$$\langle x, h \rangle = \max_{e \in E} \langle x_e, h_e \rangle. \tag{19}$$

That is, $\langle x, h \rangle$ is the absolute value of the most negative reduced cost for x and h. Clearly, $\langle x, h \rangle \geq 0$, and if $\langle x, h \rangle = 0$, then x is optimal since (18) turns into (15). We call $\langle x, h \rangle$ the *cost distance* from x to h.

LEMMA 4.1. *Let x^* be an optimal solution to* (4) *and $h^* \in L^\perp$ prove its optimality, i.e., x^* and h^* satisfy* (15). *Let $x \in L$ and suppose that $\delta = \langle x, h^* \rangle > 0$. Then there exists a cycle $F \in \mathcal{F}$ whose cost $c(x, F)$ is at most $-\delta$.*

Proof. Let $u \in E$ be an element with $\langle x_u, h^*_u \rangle = \delta$. Then $x_u \neq x^*_u$ (otherwise, $\delta = 0$). Suppose for definiteness that $x_u < x^*_u$ (the reverse case is similar). Represent $z = x^* - x$ as $z = \alpha_1 \xi^1 + \cdots + \alpha_k \xi^k$, where $\alpha_1, \ldots, \alpha_k > 0$ and $\xi^1, \ldots, \xi^k$ are cycles of L satisfying (7). Since $z_u > 0$, there is ξ^i with $\xi^i_u = 1$; let $F = (A, B) \in \mathcal{F}$ correspond to ξ^i. Then $u \in A$, and from (7), it follows that

$$x^*_e > x_e \text{ for } e \in A \quad \text{and} \quad x^*_e < x_e \text{ for } e \in B.$$

By (5) and (15), $c^{\vdash}_e(x_e) \leq c^{\dashv}_e(x^*_e) \leq h^*_e$ for $e \in A$ and $c^{\dashv}_e(x_e) \geq c^{\vdash}_e(x^*_e) \geq h^*_e$ for $e \in B$. Also $c^{\vdash}_u(x_u) = h^*_u - \delta$. Thus

$$c(x, F) = \sum_{e \in A} c^{\vdash}_e(x_e) - \sum_{e \in B} c^{\dashv}_e(x_e) \leq -\delta + h^*(A) - h^*(B) = -\delta,$$

as required. □

COROLLARY 4.2. $\langle x, h^* \rangle \leq \phi \lambda(x)$.

Proof. If $\langle x, h^* \rangle > \phi \lambda(x)$, Lemma 4.1 shows that there is a cycle F with $c(x, F) < -\phi \lambda(x)$. But then $-\lambda(x) \leq \overline{c}(x, F) < -\phi \lambda(x)/|F| \leq -\lambda(x)$ (since $|F| \leq \phi$), a contradiction. □

In section 6, we will also need to bound $\lambda(x)$ by $\langle x, h^* \rangle$ on the other side.

LEMMA 4.3. $\lambda(x) \leq \langle x, h^* \rangle$.

Proof. Recall that $\lambda(x)$ is the minimum $\lambda \geq 0$ such that there is an $h \in L^\perp$ satisfying (10). Since h^* is one such h, we have

$$\lambda(x) \leq \max_e \max\{h^* - c^{\vdash}_e(x_e), c^{\dashv}_e(x_e) - h^*, 0\} = \langle x, h^* \rangle . \qquad \square$$

If we replace each $w_e(r)$ by $w'_e(r) = k w_e(r/k)$ for an integer $k > 1$, then the right cost $c'^{\vdash}$ for w' satisfies $c'^{\vdash}_e(kr) = c^{\vdash}_e(r)$, and similarly for the left cost $c'^{\dashv}$. Thus if we define $x' = kx$ and $x'^* = kx^*$, then x'^* is optimal for the problem with w', while h^* remains optimal for w'. Therefore, $\langle x', h^* \rangle = \langle x, h^* \rangle$, whereas the ℓ_∞-distance between x' and x'^* has increased by a factor of k. This makes it seem as if cost distance is of limited utility in measuring primal convergence.

However, cost distance is indeed a useful measure of primal convergence for an important class of functions w. We say that w_e is *fast growing* (f.g.) *with speed* α ($\alpha > 0$) in an interval σ of $\mathbb{R}$ if for any $r, r' \in \sigma$, $r < r'$, we have $c^{\dashv}_e(r') - c^{\vdash}_e(r) \geq \alpha(r' - r)$ (this is related to the concept of *strong convexity* in [25, Chapter 7]). For example, the quadratic function $w_e(r) = ar^2 + br + d$ ($a > 0$) is f.g. with $\alpha = 2a$ in $(-\infty, \infty)$. Other examples of f.g. functions are piecewise quadratic, cubic, and exponential functions. If w_e is f.g. for all $e \in E$, we say that w is fast growing, and its speed is defined to be the smallest speed of any w_e.

LEMMA 4.4. *If w_e is f.g. with speed α in an interval σ and both the current value x_e and optimal value x^*_e are in σ, then $|x_e - x^*_e| \leq \alpha^{-1} \langle x_e, h^*_e \rangle$.*

Proof. Assume that $x_e < x^*_e$ (the reverse case is similar) so that $\langle x_e, h^*_e \rangle = h^*_e - c^{\vdash}_e(x_e)$. Then w_e f.g. means that $x^*_e - x_e \leq \alpha^{-1}(c^{\dashv}_e(x^*_e) - c^{\vdash}_e(x_e))$. But the optimality of x^* and h^* implies that $h^* \geq c^{\dashv}_e(x^*_e)$ (by (15)). Plugging this into the bound on $x^*_e - x_e$ and using the value for $\langle x_e, h^*_e \rangle$ give the result. □

5. A faster method: Cancel-and-tighten. MMCM can take up to $\rho^{\perp}$ iterations to reduce $\lambda(x)$ by the factor $(1-1/2\phi)$ (these bounds can be tight; see [28]). It is reasonable to ask if there is a faster way to achieve the same reduction, particularly since both [5] and [2] give "cancel-and-tighten" algorithms which do this in the cases of circulations and cocirculations in networks.

The outline of our faster method is that the first half of each iteration is a *cancel* step that improves a primal x, and the second half is a *tighten* step that improves a dual h. The cancel step iteratively "cancels" (augments x around, in the sense of (9)) cycles whose elements are restricted to be sufficiently far away from the optimality condition (15). When no such cycles remain, we can compute a direction d in which to move our current dual estimate h that guarantees a $(1-1/2\rho)$ decrease (which is almost as good as the $(1-1/2\phi)$ decrease in MMCM). Thus our speedup comes from two sources: First, we do not have to compute minimum mean cycles, but rather we may cancel any sufficiently far cycles. Second, we get a decrease after only one iteration of cancel-and-tighten, rather than $\rho^{\perp}$ iterations of MMCM.

Instead of computing a min mean cycle to find the exact value of $\lambda(x)$, we keep a dual vector $h \in L^{\perp}$ that approximately satisfies the optimality condition (15) with x. We define $\overline{\lambda}$ as the absolute value of the most negative reduced cost w.r.t. h (i.e., $\overline{\lambda} = \langle x, h\rangle$), so that $\overline{\lambda}$ is an upper bound on $\lambda(x)$. By Lemma 3.2, h proves that $\overline{\lambda}$ is a valid upper bound via satisfying

$$c_e^{\vdash}(x_e) - h_e \geq -\overline{\lambda} \quad \text{and} \quad h_e - c_e^{\dashv}(x_e) \geq -\overline{\lambda} \quad \text{for all } e \in E. \tag{20}$$

We try to improve x and h by decreasing the gap between the costs and h. Define the subset $P^{\text{far}} \subseteq E$ (resp. $N^{\text{far}} \subseteq E$) consisting of elements that are positively (resp. negatively) far from h as defined in the proof of Lemma 3.4 (using $\overline{\lambda}$ in place of $\lambda(x)$), and define $E^{\text{far}} = P^{\text{far}} \cup N^{\text{far}}$.

Call a cycle $F = (A, B)$ with $A \subseteq P^{\text{far}}$ and $B \subseteq N^{\text{far}}$ a *far cycle*. The cancel step consists of finding and canceling far cycles until no more exist. Define $C = E - (P^{\text{far}} \cup N^{\text{far}})$ as the set of elements close to h. Then at each inner iteration of the cancel step, we find a minimal-support nonzero solution to the system

$$\begin{aligned} Mz &= 0, \\ z_e &\geq 0 \quad \text{for } e \in P^{\text{far}}, \\ &\leq 0 \quad \text{for } e \in N^{\text{far}}, \\ &= 0 \quad \text{for } e \in C. \end{aligned} \tag{21}$$

System (21) can be solved using linear programming techniques.

The computation of the step length ε for a far cycle $F = (A, B)$ found by solving (21) resembles (16) but is a bit different since the gaps between the costs and h_e's do not all have the same value $-\lambda$ here. Again using (O) (ii) for w_e, we compute

$$\varepsilon_e = \text{an increment } \Delta \text{ s.t.} \begin{cases} c_e^{\dashv}(x_e + \Delta) \leq h_e \leq c_e^{\vdash}(x_e + \Delta) & \text{if } e \in A, \\ c_e^{\dashv}(x_e - \Delta) \leq h_e \leq c_e^{\vdash}(x_e - \Delta) & \text{if } e \in B \end{cases} \tag{22}$$

and the overall step length $\varepsilon = \min\{\varepsilon_e : e \in A \cup B\}$. Then $\varepsilon > 0$.

LEMMA 5.1. *A cancel step preserves* (20) *and uses at most* $\rho^{\perp}$ *iterations, each canceling a far cycle.*

Proof. Since we are canceling cycles consisting only of elements far from h, Claim 1 in the proof of Lemma 3.4 shows that we cannot create any elements violating (20).

Furthermore, the proof of Claim 2 shows that we cannot create any new elements far from h either. Comparing (16) with (22) in the case where $e \in P^{\text{far}}$ (the other case is similar), since $h_e = c_e^{\vdash}(x_e) + (h_e - c_e^{\vdash}(x_e))$ for element e in (22), we are effectively using $h_e - c_e^{\vdash}(x_e)$ for the λ in (16); since $h_e - c_e^{\vdash}(x_e) > \overline{\lambda}/2$, case (i) of Claim 2 cannot hold. Thus $|P^{\text{far}}|$ and $|N^{\text{far}}|$ are monotone nonincreasing.

At least one element in each far cycle canceled (namely, an element determining ε) must become close to h and so drop out of P^{far} or N^{far}. In the same way as in the proof of Claim 2, each such newly close element must increase the rank of the submatrix of K induced by the elements close to h, and hence we can cancel at most $\rho^{\perp}$ cycles before no more far cycles exist. □

It might seem that canceling $\rho^{\perp}$ far cycles might be as much work as canceling $\rho^{\perp}$ min mean cycles, but for the specializations to networks in section 8, the total work to cancel the far cycles in one cancel can be done much faster than even one min mean cycle computation. Even in the general case, solving (21) for a far cycle is much faster than finding a min mean cycle.

The tighten step now looks for a *sufficiently improving direction*, which is a vector $d \in \mathbb{R}^E$ that satisfies the following conditions:

[A] d is an integral vector in $L^{\perp}$.
[B] For all e, $|d_e| \leq \rho - 1$.
[C] For all $e \in P^{\text{far}}$, $d_e \geq +1$.
[D] For all $e \in N^{\text{far}}$, $d_e \leq -1$.

LEMMA 5.2. *If d is a sufficiently improving direction and we replace h by $h' := h - (\overline{\lambda}/2\rho)d$, then $\overline{\lambda}$ is reduced to at most $\overline{\lambda}' := (1 - 1/2\rho)\overline{\lambda}$, i.e., (20) holds for h' and $\overline{\lambda}'$.*

Proof. By [A], $h' \in L^{\perp}$.

Suppose that e is not positively far from h. Then by [B],

$$\begin{aligned} c_e^{\vdash}(x_e) - h'_e &= c_e^{\vdash}(x_e) - h_e + d_e\overline{\lambda}/2\rho \\ &\geq c_e^{\vdash}(x_e) - h_e - (\rho - 1)\overline{\lambda}/2\rho \\ &= c_e^{\vdash}(x_e) - h_e - \overline{\lambda}/2 + \overline{\lambda}/2\rho. \end{aligned}$$

Since $c_e^{\vdash}(x_e) - h_e \geq -\overline{\lambda}/2$ for such an e, we have that this e satisfies (20) in the positive direction for h' and $\overline{\lambda}'$. The negative direction for the case where e is not negatively far from h is similar.

By [C], if $e \in P^{\text{far}}$, then

$$\begin{aligned} c_e^{\vdash}(x_e) - h'_e &= c_e^{\vdash}(x_e) - (h_e - d_e\overline{\lambda}/2\rho) \\ &\geq c_e^{\vdash}(x_e) - h_e + \overline{\lambda}/2\rho. \end{aligned}$$

Since e satisfied (20) in the positive direction for h and $\overline{\lambda}$, it also satisfies (20) in the positive direction for h' and $\overline{\lambda}'$. The negative direction for the case where $e \in N^{\text{far}}$ is similar. □

Lemma 5.2 shows that moving a distance of $\overline{\lambda}/2\rho$ in a sufficiently improving direction reduces $\overline{\lambda}$ by a factor of at least $(1 - 1/2\rho)$, as desired. To finish specifying the tighten step, it remains only to show how to (efficiently) compute a sufficiently improving direction.

Note that when the cancel step is done, system (21) has $z = 0$ as its only feasible solution. In particular, for each $u \in E^{\text{far}}$, there is no far cycle containing u. The following shows that there is a cocycle D^u with corresponding incidence vector ξ^u proving this fact.

LEMMA 5.3. *An element $u \in E^{\text{far}}$ is contained in no far cycle if and only if there is a cocycle $\xi^u \in L^\perp$ such that $\xi^u_u \neq 0$, $\xi^u_e \geq 0$ for all $e \in P^{\text{far}}$, and $\xi^u_e \leq 0$ for all $e \in N^{\text{far}}$.*

Proof. Applying Farkas' lemma to (21) with the additional constraint $z_u = 1$ or $z_u = -1$, we observe that u is in no far cycle if and only if there is a vector $\xi = y^T M$ feasible to

$$\begin{aligned} &\xi_e \geq 0 \quad \text{for } e \in P^{\text{far}}, \\ &\xi_e \leq 0 \quad \text{for } e \in N^{\text{far}}, \\ &\xi_u \neq 0. \end{aligned} \tag{23}$$

Now if (23) has a solution in $L^\perp$ then it has a solution that is a cocycle ξ^u. Conversely, if ξ^u as in the lemma exists then it satisfies (23), thus proving (by Farkas' lemma) that no far cycle contains u. □

Now the tighten step can compute d as follows. Find a subset B^{far} of E^{far} such that $\{\xi^u : u \in B^{\text{far}}\}$ forms a basis for $\{\xi^u : u \in E^{\text{far}}\}$. Then define d to be $\sum_{u \in B^{\text{far}}} \xi^u$.

LEMMA 5.4. *This d is a sufficiently improving direction.*

Proof. Since d is a sum of incidence vectors of cocycles, d certainly satisfies [A].

The dimension of the subspace of $L^\perp$ spanned by $\{\xi^e : u \in E^{\text{far}}\}$ (i.e., the cardinality of B^{far}) is at most the dimension of $L^\perp$, which is $\rho - 1$. This proves [B].

Consider $e \in E^{\text{far}}$. By Lemma 5.3, for all $u \in E^{\text{far}}$, $\xi^u_e \geq 0$ if $e \in P^{\text{far}}$ and $\xi^u_e \leq 0$ if $e \in N^{\text{far}}$. Furthermore, for the vector ξ^e, we have $\xi^e_e \neq 0$. Now since $\{\xi^u : u \in B^{\text{far}}\}$ generates all of $\{\xi^{e'} : e' \in E^{\text{far}}\}$, there must be at least one $u \in B^{\text{far}}$ such that $\xi^u_e \neq 0$. By Lemma 5.3, every such ξ^u_e must have the same sign as ξ^e_e. This proves [C] and [D]. □

In practice, to construct a sufficiently improving direction d efficiently, it suffices to find a basic feasible solution of the linear program obtained by adding to (23) the constraints $-\rho + 1 \leq \xi_e \leq \rho - 1$ $(e \in E)$, $\xi_e \geq 1$ $(e \in P^{\text{far}})$, and $\xi_e \leq -1$ $(e \in N^{\text{far}})$.

This establishes cancel-and-tighten box 1b in Table 1.

6. (Strongly) polynomial bounds on computing exact solutions with piecewise linear costs. Note that if we start with an integral x^0 (often $x^0 = 0$ will work), then with integral breakpoints, the algorithm will always maintain an integral solution. Thus with integral breakpoints, we can guarantee an integer optimal solution. We use x^* (resp. h^*) to denote an optimal circulation (resp. cocirculation).

Note that piecewise linear functions are not f.g. in the sense of section 4. Thus we will need to develop different techniques for proving that our methods can find exact optimal solutions.

6.1. A polynomial bound with integral slopes. We assume that all slopes are integral in this subsection. We borrow an optimality characterization from [5] that depends directly on $\lambda(x)$ and not on $\langle x, h^* \rangle$.

LEMMA 6.1. *In the piecewise linear case with integral slopes, if $\lambda(x) < 1/\phi$, then x is exactly optimal.*

Proof. Let $h \in L^\perp$ be a dual vector proving that $\lambda(x) < 1/\phi$. Then Lemma 3.2 says that the reduced cost of every element in cycle $F = (A, B)$ is more than $-1/\phi$. This implies that $c(x, F) = (c^\vdash - h)(A) + (h - c^\dashv)(B) > -|F|/\phi \geq -1$. But $c(x, F)$ is an integer, so it must be nonnegative. Thus by Lemma 3.1, x is optimal. □

Let x^0 denote our initial circulation. Each finite $c^\dashv_e(x^0_e)$ and $c^\vdash_e(x^0_e)$ will be equal to one of the $O(B)$ possible slopes so that $\lambda(x^0)$ and $\overline{\lambda}$ are at most C. This together with Lemma 6.1 establishes both row 2's in Table 1.

6.2. A strongly polynomial bound for general slopes. The proof of strong polynomiality for the case of linear network flow in [5] seems not to work when some w_e's have more than two breakpoints. However, the alternative proof below (which has the same flavor as a proof that [28] uses for the case of networks) is just as strong as the ones given for special cases in [5, 2, 7] since we will be able to derive exactly the same bounds on running time for those special cases in section 8. At the same time, this proof is somewhat simpler than the proofs in [5, 2, 7].

We use the very close relationship between $\lambda(x)$ and $\langle x, h^* \rangle$ given by Corollary 4.2 and Lemma 4.3, which say that neither number can get very far from the other. Each $c_e^{\vdash}(x_e)$ and $c_e^{\dashv}(x_e)$ equals one of the only $O(B)$ slopes, and we may assume that h^* stays fixed throughout the algorithm. Thus by (18) and (19), $\langle x, h^* \rangle$ always equals $h_e^* - c_e^{\vdash}(x_e)$, $c_e^{\dashv}(x_e) - h_e^*$, or 0 for some element e. Therefore, there are only $O(B)$ different values that $\langle x, h^* \rangle$ can take, a strongly polynomial number.

THEOREM 6.2. *In the piecewise linear case, MMCM requires $O(B\rho^{\perp}\phi \log \phi)$ iterations to compute an exact optimal circulation.*

Proof. Define a *big iteration* as a sequence of iterations that reduce $\lambda(x)$ by a factor of more than $1/\phi$. As argued in the proof of Theorem 2.1, a big iteration consists of $O(\rho^{\perp}\phi \log \phi)$ min mean cycle cancellations. Let x be our point before a big iteration and x' be the point after a big iteration. Then

$$\begin{aligned} \langle x', h^* \rangle &\le \phi\lambda(x') && \text{(by Corollary 4.2)} \\ &< \lambda(x) && \text{(by the definition of big iteration)} \\ &\le \langle x, h^* \rangle && \text{(by Lemma 4.3).} \end{aligned} \tag{24}$$

This shows that $\langle x, h^* \rangle$ strictly decreased during the big iteration. Thus after at most B big iterations, $\langle x, h^* \rangle$ has decreased B times, and its only possible remaining value is $\langle x, h^* \rangle = 0$, implying that x is optimal. □

The argument in Theorem 6.2 does not work for cancel-and-tighten because Lemma 4.3 might not be true for $\overline{\lambda}$ (but Corollary 4.2 *is* true with $\overline{\lambda}$ in place of $\lambda(x)$). That is, there is nothing in cancel-and-tighten to force $\overline{\lambda}$ to take large downwards steps, even when this is possible due to $\langle x, h^* \rangle$ becoming smaller than an optimal reduced cost. However, we can use an idea from [5] and at the beginning of every big iteration, we use a min mean cycle computation to replace $\overline{\lambda}$ by the exact value of $\lambda(x)$. Then (24) becomes true, and the rest of the proof of Theorem 6.2 goes through as before. In applications to networks, the (slow) min mean cycle iterations can be amortized over the (fast) tighten-step iterations so as to not slow down the fast asymptotic running time of cancel-and-tighten; see section 8.

7. Polynomial bounds on computing exact solutions with quadratic and linear costs and integer data. For this case, we assume that for each $e \in E$ the function w_e consists of a sequence of functions $f_e^i = a_e^i x_e^2 + b_e^i x_e + d_e^i$, $i = 1, \ldots, k_e$, where each f_e^i is defined on the interval between the breakpoints p_e^{i-1} and p_e^i ($p_e^{i-1} < p_e^i$); so $p_e^0 = -\infty$, $p_e^{k_e} = \infty$, and $f_e^i(p_e^i) = f_e^{i+1}(p_e^i)$. We assume that all a_e^i, b_e^i, and d_e^i are integers with $a_e^i \ge 0$ and that each finite p_e^i is an integer. If $a_e^i = 0$, then this piece is linear; otherwise, it is quadratic. Thus we have the case of *piecewise mixed linear and quadratic* costs. If all a_e^i are positive, then we have *piecewise quadratic* costs. Slightly redefine C to be the maximum number among all $4a_e^i$, $2|b_e^i|$, and (finite) $2|p_e^i|$ ($e \in E$).

If x_e^* is interior to piece i, define the bounds $p_e = p_e^{i-1}$ and $p_e' = p_e^i$ and force h_e to be the derivative of f_e^i by defining its bounds as $g_e = g_e' = 2a_e^i x_e + b_e^i$. If instead

$x_e^* = p_e^i$, then set $p_e = p'_e = p_e^i$ and set $g_e = c_e^{\dashv}(p_e^i)$ and $g'_e = c_e^{\vdash}(p_e^i)$. Then any x and h feasible to the following linear system must be optimal:

$$\begin{aligned} Mx &= 0, \\ Kh &= 0, \\ p_e \le x_e \le p'_e, &\quad e \in E, \\ g_e \le h_e \le g'_e, &\quad e \in E. \end{aligned} \tag{25}$$

It can be seen that the absolute value of any subdeterminant of the matrix combining all constraints in (25) is at most C^m, where $m = |E|$. This implies the following.

LEMMA 7.1. *In the piecewise mixed linear and quadratic case, there are optimal solutions x^* and h^* such that every component x_e^* of x^* and every component h_e^* of h^* is a rational with numerator and denominator at most C^m.*

We will also need a bound on the cost distance $\langle x^0, h^* \rangle$ between an initial x^0 and an optimal h^*. We can feasibly choose $x^0 = 0$. Each h_e^* is bounded above by $2a_e^i x_e^* + b_e^i$ for some i. By Lemma 7.1, each $x_e^* \le C^m$, so $\langle x^0, h^* \rangle = O(C^{m+1})$, and by Lemma 4.3, $\beta = \lambda(x^0) \le O(C^{m+1})$. Our goal will be to reduce $\langle x, h^* \rangle$ below $1/(2C^{2m})$; by Corollary 4.2, to do this it suffices to reduce $\lambda(x)$ below $\varepsilon = 1/(2\phi C^{2m})$. The running time bounds involve $\log(\beta/\varepsilon)$, which is $O(m \log C)$ since $\phi = o(C^{2m})$.

7.1. The piecewise quadratic case. Since w is strictly convex in this case, problem (4) has a unique optimal solution x^*. Thus if we reduce $|x_e - x_e^*|$ below $1/(2C^{2m})$, then there is a unique rational closest to x_e with denominator at most C^m, and by Lemma 7.1, this rational must be x_e^*. Furthermore, x_e can be efficiently rounded to x_e^* using standard continued fractions techniques [31]. Defining α to be the minimum of $2a_e^i$ among all e and i, each w_e is f.g. with speed α. Therefore, by Lemma 4.4, it suffices to decrease $\langle x_e, h_e^* \rangle$ (which is an upper bound on $\alpha|x_e - x_e^*|$) below $\alpha/(2C^{2m})$. This establishes both row 4's of Table 1.

7.2. The piecewise mixed linear and quadratic case. This case differs from the previous one because the w_e need not be f.g. when some pieces f_e^i are linear.

Our strategy is to run the algorithm long enough to be able to round the elements x_e whose x_e^*'s fall into quadratic pieces as above. After we fix x_e to be x_e^* on such pieces, we are left with a piecewise linear problem where each element has at most two pieces with finite slope, which we can solve in strongly polynomial time as in section 6.

More precisely, let $x \in L$ be any circulation. We say that e is a *quadratic element* of x if (i) x_e is interior to a quadratic piece, (ii) x_e equals a breakpoint between two quadratic pieces, or (iii) x_e equals a breakpoint between a quadratic piece and a linear piece with arbitrarily large slope representing a lower or upper bound; otherwise, e is a *linear element* of x. Define $\Delta = 1/C^m$ and redefine α to be the minimum of $2a_e^i$ over quadratic pieces.

Now run the algorithm in "phase 1" until $\langle x, h^* \rangle < \Delta^2/2$, so we can use continued fractions to round each x_e to a unique x'_e with denominator at most C^m. The next lemma will show that whenever e is a quadratic element of x', then we can set $x_e^* = x'_e$ without loss of optimality. Furthermore, it will show that when e is a linear element of x', we can constrain x_e^* to be in one of the at most two linear pieces adjacent to x'_e, and so we can complete x^* by solving a piecewise linear "phase 2."

LEMMA 7.2. *If element e is quadratic for x'_e, then $x'_e = x_e^*$. If x'_e is interior to a linear piece f_e^i, then every optimal x_e^* is in f_e^i's piece. If x'_e equals the breakpoint*

p_e^i between linear pieces f_e^{i-1} and f_e^i, then every optimal x_e^* is in f_e^{i-1}'s piece or f_e^i's piece. If x'_e equals the breakpoint p_e^i between a linear piece and a quadratic piece, then every optimal x_e^* is in the linear piece.

Proof. Suppose that e is quadratic for x'_e, and let x_e^* and h_e^* come from optimal solutions with denominators at most C^m as in Lemma 7.1. If $x_e^* > x'_e$ (the reverse case is similar), then $x_e^* - x'_e \geq \Delta^2$. Since $|x'_e - x_e| < \Delta^2/2$, we get $x_e^* - x_e \geq \Delta^2/2$. If x'_e is interior to a quadratic piece, let f_e^i be that quadratic piece; otherwise, x'_e equals a breakpoint, say p_e^{i-1}, and we may assume that f_e^i is quadratic. Then $h_e^* \geq 2a_e^i x_e^* + b_e^i$. But now, since $c_e^{\vdash}(x_e) \leq \max\{2a_e^i x_e + b_e^i, 2a_e^i x'_e + b_e^i\}$, we have $\Delta^2/2 > \langle x_e, h_e^* \rangle \geq 2a_e^i(\Delta^2/2)$, a contradiction. Thus we must have $x'_e = x_e^*$ so that e is quadratic for this x_e^* and so for all optimal solutions.

If x'_e is interior to linear piece f_e^i with slope b_e^i, then x_e must also be interior to f_e^i. Thus $\langle x_e, h_e^* \rangle < \Delta^2/2$ implies that

$$|b_e^i - h_e^*| < \Delta^2/2. \tag{26}$$

If there is an optimal x^* with corresponding h^*, where x_e^* does not belong to f_e^i, then by Lemma 7.1 we may assume that there is such a solution with denominators at most $1/\Delta$. If x_e^* is in the interior of a linear piece with slope $b_e^j = h_e^*$, then $|b_e^i - b_e^j| = |b_e^i - h_e^*| \geq 1$, contradicting (26). Otherwise, x_e^* is either interior to a quadratic piece or at a breakpoint nonadjacent to f_e^i. In either case, since x_e^* is outside of f_e^i's interval by at least $\Delta^2/2$, h_e^* must differ from b_e^i by more than $\Delta^2/2$, again contradicting (26). Thus x_e^* is in f_e^i's interval, forcing every optimal solution to use f_e^i's interval.

The remaining two cases have proofs much like the previous case. □

Now we have our algorithm: If e is quadratic for x', then we can fix $x_e^* = x'_e$. Otherwise, we use one of the three linear cases in Lemma 7.2 to constrain x_e to lie in either in a single linear piece or the union of two adjacent linear pieces. This establishes both row 5's of Table 1.

Many applications of piecewise mixed linear and quadratic costs do not need to solve the piecewise linear second phase. For example, if the only piecewise linear parts are bounds (as in [4, 12]), then all elements are quadratic for every solution, so the optimal solution will be fully determined after the first phase. Alternatively, if there is only one linear piece per element, then the second phase can be solved more simply as just a linear feasibility problem with bounds over L.

8. Implementations for networks. We assume that the digraph $G = (V, E)$ has n nodes and $m = |E|$ arcs so that the maximum size of a circuit is $O(n)$ and the maximum size of a cut is $O(m)$. Note that an initial circulation satisfying any bounds implicit in the arc cost functions can be computed with one max flow, and similarly an initial cocirculation can be computed with one shortest path [1]. Thus it is easy to initialize the algorithms and to verify that optimal solutions exist.

8.1. Network circulation algorithms. We consider how to implement cancel-and-tighten for circulations. Make an auxiliary graph consisting of the arcs in P^{far} and the reverses of the arcs in N^{far} so that far cycles are directed cycles. We then adapt a trick from [5] for the classic linear circulation problem. It develops an algorithm based on dynamic trees for the problem of canceling all cycles consisting solely of negative reduced-cost augmentable (admissible) arcs. The key of an arc in its method is the residual capacity of the arc in this direction. Instead, choose the number ε_e defined in (22) for every arc e far from h. Once the method finds and cancels a cycle, it then

cuts all arcs that are no longer augmentable out of the data structure. We apparently need to cut out all arcs that become close to h, but instead we relax our concept of the cancel step a bit. Note that the proof of Claim 1 remains true even if each cycle contains elements satisfying only that $c_e^{\vdash}(x_e) - h_e \le 0$ (for forward elements) or $h_e - c_e^{\dashv}(x_e) \le 0$ (for backwards elements). Thus we can cut out only arcs whose reduced costs become 0; this may cause some arcs that become newly close to h to stay in the dynamic trees and so participate in some future cancellation, but this will not cause a violation of (20). Furthermore, the proof of Claim 2 shows that no new arcs far from h can be created. Since each cancellation cuts at least one arc of the auxiliary graph out of the dynamic trees, we still get the $O(m)$ bound on the number of cancellations. Thus in the same way as in [5], this method takes only $O(m \log n)$ time.

When the cancel step is done, the auxiliary graph is acyclic, so an acyclic node labeling l exists. The label differences $\Delta l_{ij} := l_j - l_i$ form a sufficiently improving direction d for the tighten step and can be computed in linear time [5]. Thus one round of cancel-and-tighten costs $O(m \log n)$ time, which is a lot smaller than the time to compute even one min mean cycle.

Now consider the piecewise linear case from section 6. If we want to use cancel-and-tighten for circulations in networks in the piecewise linear case and we want to achieve the strongly polynomial bound of row 3 in Table 1, we are required to substitute a $O(mn)$ [14] min mean cycle computation once every $O(n \log n)$ tighten steps. Since $O(n \log)$ tighten steps cost $O(mn \log^2 n) > O(mn)$ time, this does not affect our cancel-and-tighten time bound. This establishes column c of Table 1.

8.2. Network cocirculation algorithms. We now consider how to implement cancel-and-tighten for cocirculations. Make an auxiliary graph containing the arcs in P^{far} and the reverses of the arcs in N^{far}, with the ε_e from (22) as lengths, together with both the forward and reverses of arcs close to h with length 0. Then a far cycle is a cut whose forward arcs all have positive lengths. We then adapt a trick from [2] for the classic linear cocirculation problem. Select an arbitrary node r as a source and compute shortest-path distances from r to every other node. Update x by these shortest-path distances, which effectively cancels all far cycles (cuts) with r on the source side. Then do the same thing with all arcs reversed to cancel far cycles with r on the sink side. This takes $O(m + n \log n)$ time.

Since no cut with all forward arcs positive remains after the cancel step, we can find a set of circuits such that each arc in E^{far} gets covered at least once in the proper orientation, and such a circuit cover can be computed in linear time [2]. The sum of the incidence vectors of these circuits is a sufficiently improving direction d for the tighten step. Thus one round of cancel-and-tighten costs $O(m + n \log n)$ time, which is a lot smaller than the time to compute even one min mean cut.

Now consider the piecewise linear case from section 6. If we want to use cancel-and-tighten for cocirculations in networks in the piecewise linear case and we want to achieve the strongly polynomial bound of row 3 in Table 1, we are required to substitute a $O(nMC(n, m))$ min mean cut computation once every $O(m \log n)$ tighten steps [27]. However, $O(m \log n)$ tighten steps cost $O(m \log n(m+n \log n)) < O(nMC(n, m))$ time, which would affect our cancel-and-tighten time bound. However, an idea of Radzik quoted in [2] allows the same strongly polynomial bound to hold even with a weaker *semiexact* min mean cut computation that costs only $O(MC(n, m))$ time. This can now be amortized without loss of efficiency; see [2] for details.

9. How to compute minimum mean cycles. We now explain how to solve the auxiliary problem (AP) in strongly polynomial time for an arbitrary unimodular linear space L. There exist general methods for computing min mean values under various assumptions; see Karzanov [15], Megiddo [21, 22], or Radzik [27]. None of the approaches in [21, 22, 27] seems to yield a strongly polynomial algorithm for (AP); we know of no algorithm for unimodular linear programming that is "linear" in the sense required by Megiddo's methods, and Radzik's method does not even apply to finding min mean circuits in networks.

We assume that L is explicitly given via a system $Mx = 0$ with a totally unimodular $n \times m$ matrix M whose columns are indexed by elements of a set E. We can get a strongly polynomial algorithm by directly solving the linear program (12) using the version of the ellipsoid algorithm developed by Tardos [32]. This depends on realizing that, although the LP is not totally unimodular, the size of its matrix in binary notation is $O(mn)$.

An algorithm that is more combinatorial is derived from the general method in [15] that enables us to reduce (AP) to solving $O(\rho\phi)$ linear programs with totally unimodular constraint matrices. This method will also allow us to solve (AP) for systems which are not totally unimodular.

Recall from the proof of Lemma 3.2 that (AP) is equivalent to solving problem (11). It is clear that (11) is, in turn, a special case of the following problem. Suppose that L' is a (not necessarily unimodular) linear subspace of $\mathbb{R}^{E'}$ given by a system $M'y = 0$ with an integer $n' \times m'$ matrix M' ($m' = |E'|$). Consider the cone $\mathcal{K} = L' \cap \mathbb{R}^{E'}_+ = \{y \in L' : y \geq 0\}$. Let $|y|$ denote the ℓ_1-norm $\sum_{e \in E'} |y_e|$, and for $y \in \mathcal{K} - \{0\}$, define the min mean value of y as $\nu_d(y) = dy/|y|$. Then, given a vector $d \in \mathbb{R}^{E'} - \{0\}$, the *minimum mean problem* (MMP) for $\mathcal{K}$ and d is to compute

$$\nu^* := \nu^*_d := \min_{y \in \mathcal{K} - \{0\}} \nu_d(y)$$

as well as a minimizing y.

An integer vector $y \in \mathcal{K} - \{0\}$ is called *elementary*, or a *cycle*, if $y = y' + y''$ is impossible for any two integral vectors $y', y'' \in \mathcal{K} - \{0\}$. We say that the maximum $q = q(\mathcal{K})$ of y_e's among all elementary vectors y and $e \in E'$ is the *fractionality* of $\mathcal{K}$. (Clearly, q does not exceed the maximum absolute value of a subdeterminant of M'.) Problem (AP) for L with $q > 1$ will be used in the next section. Clearly, there is an optimal solution to the MMP which is an elementary vector. Computationally, given any optimal solution y^* to the MMP, standard linear algebra techniques can extract an optimal cycle from y^*.

For $y \in \mathbb{R}^{E'}$, let $S(y) = \mathrm{supp}(y)$ and let $S^+(y)$, $S^-(y)$, and $S^0(y)$ denote the sets of $e \in E'$ with y_e positive, negative, and zero, respectively. We assume that every $e \in E'$ is contained in the support of at least one cycle in $\mathcal{K}$; otherwise, we could delete e from E'. Each iteration of the algorithm for the MMP transforms the current objective vector d by adding to it a vector $h \in (L')^\perp$ and possibly by shifting d by a constant $\delta \in \mathbb{R}$ (i.e., setting $d_e := d_e + \delta$ for all $e \in E'$). Clearly, the former operation does not change $\nu_d(y)$ for any $y \in \mathcal{K}$, while the latter one increases it by δ (and therefore increases ν^* to $\nu^* + \delta$). At the beginning of the algorithm, we shift the initial d by a sufficiently large negative r in order to ensure that the inequality $\nu^*_d \leq 0$ holds. We maintain $\nu^*_d \leq 0$ throughout the algorithm.

Recall that d^+ denotes the positive part of the current d. At an iteration, an element $u \in E'$ with $d_u < 0$ is fixed, and we solve the following pair of dual linear

programs:

$$\min\{d^+y \,:\, y \in \mathcal{K},\ y_u = 1\} \tag{27}$$

and

$$\max\{h_u \,:\, h \in (L')^\perp,\ \ h_e \geq -d^+_e \ \text{ for } \ e \in E' - \{u\}\}. \tag{28}$$

To see that (27) and (28) are dual LPs, rewrite (27) as $\min\{d^+y \,:\, M'y = 0,\ y \geq 0,\ y_u = 1\}$, let the dual vector for the constraints $M'y = 0$ be γ, and let the dual scalar for $y_u = 1$ be σ. Then if we define $h = -\gamma M'$, we must have $h \in (L')^\perp$ (since the rows of M' are a basis of $(L')^\perp$), and it is clear (since $d^+_u = 0$) that $h_u = \sigma$ at optimality in the dual of (27).

By the above assumption, there is a cycle whose support contains u; thus (27) has a feasible solution. Since the objective value of (27) is bounded below by zero, (27) has an optimal solution. When feasible solutions y and h to (27) and (28) are optimal, then the following (complementary slackness) condition holds:

$$\text{for any } \ e \in E' - \{u\}, \quad d^+_e + h_e > 0 \ \text{ implies } \ y_e = 0. \tag{29}$$

Let y and h be optimal, and define $\widehat{d} = d + h$. If $\widehat{d}_u \geq 0$, we finish the iteration with the new objective vector $d' = \widehat{d}$. If instead $\widehat{d}_u < 0$, we in addition shift $\widehat{d}$ by $\delta := -\widehat{d}y/|y|$, and the resulting vector d' becomes the new objective vector. In the latter case, we also keep y as a possible candidate for being an optimal solution of the original (and each intermediate) problem; set $y^* := y$. Then $d'y^* = 0$.

From (29), we observe that

$$\text{for } \ e \in S(y) - \{u\}, \quad \widehat{d}_e = \begin{cases} 0 & \text{if } d_e \geq 0, \\ d_e & \text{if } d_e < 0. \end{cases} \tag{30}$$

Since y is nonnegative, (30) implies

$$\widehat{d}y \leq \widehat{d}_u y_u = \widehat{d}_u; \tag{31}$$

hence $\delta > 0$ (in case $\widehat{d}_u < 0$). Note also that (30) together with $h_u = d^+y \geq 0$ (since $d^+ \geq 0$ and $y \geq 0$) and $\delta > 0$ preserves the following monotone property (in both cases):

$$S^-(d') \subseteq S^-(d); \qquad \text{and } d'_e \geq d_e \quad \text{for any } e \in S^-(d'). \tag{32}$$

The algorithm finishes if the iteration results in d' with $d'_e \geq 0$ for all $e \in E'$, i.e., $S^-(d') = \emptyset$. Then for the y^* obtained at the last iteration when a shift of d occurs, we have $d'y^* \geq 0$. On the other hand, after that iteration, the current d was transformed only by adding vectors from $L^\perp$, which does not change the inner product of d and y^*. Hence $d'y^* = 0$ (so $d'_e = 0$ for all $e \in S(y^*)$). This and $\nu^*_{d'} \geq 0$ (as $d' \geq 0$) yield that y^* is an optimal solution to the original MMP.

We say that the iteration is *big* if $S^-(d')$ is strictly contained in $S^-(d)$ and *small* otherwise. The number of big iterations does not exceed $N = |S^-(d^0)|$ for the d^0 obtained by the initial shift of the original objective vector. So we have to estimate the number of consecutive small iterations. We impose the additional rule that the same element u is fixed throughout consecutive small iterations. Suppose that the current and the next iterations are small. Let y', h', and d' be the corresponding

objects found at the next iteration. Note that by the definition of small iterations, $S^-(d) = S^-(d')$ so that $Q := Q(d) := S^+(d) \cup S^0(d)$ is independent of d during this sequence of small iterations.

LEMMA 9.1. $y(Q) > y'(Q)$.

Proof. Obviously, $d'_e \geq \delta$ for each $e \in Q$, and (30) implies that $d'_e = \delta$ for $e \in S(y) \cap Q$. This and $d'y = 0$ give

$$d'_u = d'_u y_u \geq \sum(d'_e y_e \,:\, e \in S^-(d)) = -\sum(d'_e y_e \,:\, e \in Q) = -\delta y(Q). \tag{33}$$

On the other hand, we have $\widehat{d}'_u = d'_u + h'_u < 0$ (since the second iteration is small), so

$$-d'_u > h'_u = (d')^+ y' \geq \delta y'(Q) \tag{34}$$

(using LP strong duality for the second iteration and the fact that $d'_e \geq \delta$ for $e \in Q$). Comparing (33) and (34) yields $\delta y(Q) > \delta y'(Q)$, and the result follows because $\delta > 0$. □

Note that the preliminary shift of the original d can be chosen so that the above number N is at most ρ (the rank of M'; since $M' = (M \quad -M)$ in our application, we use the same ρ and ϕ for both M and M'). Indeed, let $p_1 < p_2 < \cdots < p_k$ be all the different values of d_e, $e \in E'$, and let $X_i = \{e \in E \,:\, d_e \leq p_i\}$. Solving the corresponding LP problems, find the minimum i such that X_i contains the support of some nonzero vector of $\mathcal{K}$. Shift d by $-p_i$. This makes the elements of X_{i-1} $(X_i - X_{i-1})$ be of negative (resp. zero) value, and therefore there is $y \in \mathcal{K} - \{0\}$ with $\nu_d(y) \leq 0$. Clearly, we have $N = |X_{i-1}| \leq \rho$.

THEOREM 9.2. *The number of iterations of the algorithm is at most* $\rho \min\{q^2\phi, \eta\}$, *where* η *is the number of elementary vectors in* $\mathcal{K}$. *In particular, if* q *is bounded by a polynomial in* $|E'|$ *and a strongly polynomial algorithm is used to solve* (27) *and* (28), *then this algorithm is strongly polynomial for the MMP.*

Proof. Consider two consecutive small iterations as in Lemma 9.1. As we noted, there must be extreme optimal solutions y and y' to (27) in these iterations. By Lemma 9.1, $y(Q) > y'(Q)$, so the number of consecutive small iterations does not exceed the number of distinct values of $z(Q)$ for extreme vectors z of $\mathcal{K}$ with $z_u = 1$. But if z' is an integral extreme vector of $\mathcal{K}$, then $z'(Q)$ is an integer between 1 and $q\phi$, and there are at most q ways to normalize z' to z so that $z_u = 1$. Thus there can be at most $\min\{q^2\phi, \eta\}$ values for $x(Q)$. Now the result follows from the fact that the number of big iterations is at most ρ. □

For the original function d and the final function d^*, we have $d^* = d + h^* + \delta^* \mathbb{1}_{E'}$, where δ^* is the total shift and h^* is the sum of solutions to (28) over the iterations. Since d^* is nonnegative and $d^*_e = 0$ for any $e \in S(y^*)$,

$$d_e + h^*_e \begin{cases} = -\delta^* & \text{for } e \in S(y^*), \\ \geq -\delta^* & \text{otherwise.} \end{cases} \tag{35}$$

In particular, $\nu^*_d = -\delta^*$. (Note also that (35) proves the equality $\nu^*_d = \max_{h \in (L')^\perp} \min_{e \in E'}(d_e + h_e)$.)

10. The methods for linear spaces of bigger fractionality. We now generalize the method developed in section 3 to linear spaces $L \subseteq \mathbb{R}^E$ given by system $Mx = 0$ when M is not totally unimodular. We briefly describe how to do this, emphasizing only the places where significant differences exist between this case and section 3.

The cost at x of a cycle ξ is defined as

$$c(x,\xi) = \sum\{c_e^{\vdash}(x_e)\xi_e \ : \ e \in S^+(\xi)\} + \sum\{c_e^{\dashv}(x_e)\xi_e \ : \ e \in S^-(\xi)\},$$

and its mean cost $\overline{c}(x,\xi)$ is $c(x,\xi)/|\xi|$ ($S^+(\xi)$ and $S^-(\xi)$ are as defined in the previous section). Then ξ is a minimum mean cycle at x if $\overline{c}(x,\xi)$ is as small as possible, and $\lambda(x)$ is defined to be $\max\{0, -\overline{c}(x,\xi)\}$, where ξ is a minimum mean cycle.

Lemmas 3.1 and 3.2 remain true in this case. MMCM is generalized as follows. For the current $x \in L$, we solve the analogue of the auxiliary problem (AP) to compute $\lambda = \lambda(x)$ and, if $\lambda > 0$, to find a minimum mean cycle ξ of L at x and $h \in L^{\perp}$ satisfying (10). If $\lambda > 0$, we "push $\varepsilon > 0$ around ξ," i.e. transform x into the new current point $x' \in L$ defined as $x' = x + \varepsilon\xi$ (cf. (9)). To compute the step length ε, we first compute the local step lengths ε_e as an increment Δ such that (cf. (16))

$$\begin{cases} c_e^{\dashv}(x_e + \Delta\xi_e) \le c_e^{\vdash}(x_e) + \lambda = h_e \le c_e^{\vdash}(x_e + \Delta\xi_e) & \text{if } e \in S^+(\xi), \\ c_e^{\dashv}(x_e - \Delta\xi_e) \le c_e^{\dashv}(x_e) - \lambda = h_e \le c_e^{\vdash}(x_e - \Delta\xi_e) & \text{if } e \in S^-(\xi), \end{cases}$$

and then $\varepsilon = \min\{\varepsilon_e \ : \ e \in S^+(\xi) \cup S^-(\xi)\}$.

In this case, Lemma 3.3 has essentially the same proof, while Lemma 3.4 should be modified as follows.

LEMMA 10.1. *After every $\rho^{\perp}$ iterations, $\lambda = \lambda(x)$ decreases by a factor of at most $(1 - 1/(2\phi q))$.*

Proof. The proof is similar to that of Lemma 3.4. The only nontrivial point that needs some reproving is when, at some iteration j ($i < j \le i + \rho^{\perp}$), for the chosen cycle ξ^j, there is an element $u \in \mathrm{supp}(\xi^j)$ close to h, and for all $e \in S^+(\xi^j) - \{u\}$ (resp. $e \in S^-(\xi^j) - \{u\}$), we have $c_e^{\vdash} - h_e \ge -\lambda$ (resp. $h_e - c_e^{\dashv} \ge -\lambda$); for simplicity, we replace $c_e^{\vdash}(x_e^j)$ and $c_e^{\dashv}(x_e^j)$ by $c_e^{\vdash}$ and $c_e^{\dashv}$ here. For definiteness, let u be positively close to h. Then

$$\begin{aligned} c(x^j,\xi^j) &= c(x^j,\xi^j) - h\xi^j \\ &= \sum_{e \in S^+(\xi^j) - \{u\}} (c_e^{\vdash} - h_e)\xi_e^j + (c_e^{\vdash} - h_u)\xi_u^j - \sum_{e \in S^-(\xi^j)} (h_e - c_e^{\dashv})\xi_e^j \\ &\ge -\lambda \sum_{e \in S^+(\xi^j) - \{u\}} \xi_e^j \ - \ \frac{1}{2}\lambda\xi_u^j \ + \lambda \sum_{e \in S^-(\xi^j)} \xi_e^j \\ &= -\lambda|\xi^j| + \frac{1}{2}\lambda\xi_u^j \ge -\lambda|\xi^j| + \lambda/2, \end{aligned}$$

whence $-\lambda^j = \overline{c}(x,\xi^j) \ge -\lambda + \lambda/2|\xi^j| \ge -\lambda(1 - 1/2\phi q)$ (since $|\xi^j| \le \phi q$), and the result follows. □

This establishes column a of Table 1.

11. Duality and practical implementations. Throughout our methods, we have liberally used dual vectors $h \in L^{\perp}$, and we computed optimal dual vectors h^*. There is a well-developed theory of duality in convex optimization that shows that not only is h^* optimal in the sense of proving x^*'s optimality via (15), but h^* is the optimal solution of a related optimization problem dual to (4). The form of this problem is

$$\min_{h \in L^{\perp}} \sum_{e \in E} v_e(h_e), \tag{36}$$

where each v_e is the *convex conjugate* of the corresponding w_e (see, e.g., Rockafellar [30], who would say that we have a dual pair of monotropic programming problems).

Suppose that w_e is piecewise linear. Then v_e is also piecewise linear, the breakpoints of v_e are the slopes of w_e, and the slopes of v_e are the breakpoints of w_e. For example, the convex conjugate of the cost function for linear circulations in networks in Figure 1 is the function for linear cocirculations in networks in Figure 2. Similarly, w_e is piecewise mixed linear and quadratic if and only if v_e is piecewise mixed linear and quadratic.

Since we get h^* solving (36) for free when we solve the primal problem (4), if we want to compute x^*, we have the luxury of being free to either solve the primal problem (4) and get x^* directly or solve the dual problem (36) and get x^* as the optimal set of dual variables for (36). This free choice has some practical implications because (although the primal and dual problems are in theory completely symmetric) in practice it may be easier to solve one than the other.

We focus on solving circulation and cocirculation problems in networks. The number of MMCM iterations is $O(mn \log(\beta/\varepsilon))$ for both cases (MMCM boxes 1c and 1d in Table 1). However, the time per iteration (which is dominated by the min mean cycle computation) is, up to log factors, $O(mn)$ for circulations and $O(mn^2)$ for cocirculations using strongly polynomial algorithms, and $O(\sqrt{n}m)$ for circulations and $O(mn)$ for cocirculations using polynomial algorithms under the similarity assumption (namely, that $C = O(n^{O(1)})$; see [1]). Thus it is clearly better to use MMCM on the circulation version of the problem when we have a choice.

For the faster cancel-and-tighten method, the work per iteration is the same up to log factors: $O(m)$ for both circulations and cocirculations. However, the number of iterations is $O(n \log(\beta/\varepsilon))$ for circulations but $O(m \log(\beta/\varepsilon))$ for cocirculations (cancel-and-tighten boxes 1c and 1d of Table 1). In the piecewise linear case, the iteration bound for circulations is $O(\min\{n \log(nC), Bn \log n\})$, and for cocirculations it is $O(\min\{m \log(nC), Bm \log n\})$ (cancel-and-tighten boxes in rows 2 and 3, columns c and d of Table 1). Thus in both cases, solving the circulation version of the problem instead of the cocirculation version will result in a speedup by a factor of roughly $O(m/n)$.

Thus we conclude that when finding an optimal cocirculation in a network, it should be faster to dualize the problem and solve the circulation version of the problem instead. An experimental implementation of the cocirculation methods from [2] (a special case of our methods) in [19] proved to be very slow, confirming our recommendation.

12. Solving integer problems. For some applications it is more realistic to consider problems where the decision variables are restricted to be integers; see, e.g., [24] or [1, Chapter 14]. We show here how to adapt our methods to this restriction.

Formally, we want to solve the following problem:

(37) Find an integral $x \in L$ such that $w(x) = \sum_{e \in E} w_e(x_e)$ is as small as possible.

Define $\widehat{w}_e(x_e)$ so that it matches the value of $w_e(x_e)$ whenever x_e is integral and is linear between consecutive integers, so the $\widehat{w}_e$'s are piecewise linear. It is equivalent to solve (4) using the $\widehat{w}_e$'s and solve (37) with the w_e's. We would like to use the versions of our methods adapted for piecewise linear costs to solve (4) using the $\widehat{w}_e$'s. Unfortunately, the number of pieces in all of the $\widehat{w}_e$'s might be unbounded, so we cannot use the strongly polynomial bound. Also, the $\widehat{w}_e$'s have integral breakpoints

but general slopes, just the reverse of what Lemma 6.1 requires. However, we can (implicitly) dualize the problem to get a problem over the dual space $L^\perp$ with objectives $\widehat{v}_e$, the convex conjugates of the $\widehat{w}_e$ (see section 11). Recall from section 11 that the $\widehat{v}_e$'s are also piecewise linear and have integer slopes, so Lemma 6.1 *does* apply to the dual problem.

To make this work, we need to be able to simulate an oracle for $\widehat{v}_e$ from the given oracle for w_e. For (O) (i), we are given r and want to find $\widehat{c}_e^{\dashv}(r)$ and $\widehat{c}_e^{\vdash}(r)$, where the $\widehat{c}_e$'s are the left and right costs at r w.r.t. $\widehat{v}_e$. We use (O) (ii) for w_e to find a p such that $c_e^{\dashv}(p) \le r \le c_e^{\vdash}(p)$. Set $k = \lceil p \rceil$ and compute the slope of $\widehat{w}_e$ between $k-1$ and k as $w_e(k) - w_e(k-1)$. If $w_e(k) - w_e(k-1) \le r$, then $\widehat{c}_e^{\vdash}(r) = k$; otherwise, it equals $k-1$. Similarly, if $w_e(k) - w_e(k-1) > r$, then $\widehat{c}_e^{\dashv}(r) = k$; otherwise, it equals $k-1$.

For (O) (ii), we are given p and want to find r such that $\widehat{c}_e^{\dashv}(r) \le p \le \widehat{c}_e^{\vdash}(r)$. Since $\widehat{v}_e$ is piecewise linear, such an r always exists which is a breakpoint of $\widehat{v}_e$. Then the two slopes adjacent to this breakpoint r are $\widehat{c}_e^{\dashv}(r)$ and $\widehat{c}_e^{\vdash}(r)$. Redualizing back to the primal and remembering that dualizing interchanges slopes and breakpoints, we want to find a slope r of $\widehat{w}_e$ whose adjacent breakpoints $a = \widehat{c}_e^{\dashv}(r)$ and $b = \widehat{c}_e^{\vdash}(r)$ bracket p. But breakpoints of $\widehat{w}_e$ are just all of the integers, so $a = \lfloor p \rfloor$, $b = \lceil p \rceil$ (if p is an integer, set $b = p+1$ instead), and so r is the linear approximation of the slope between these breakpoints, namely $w_e(b) - w_e(a)$.

Note that duality reverses the roles of the two parts of the oracle: We use (O) (i) for w_e to simulate (O) (ii) for $\widehat{v}_e$, and we use (O) (ii) for w_e to simulate (O) (i) for $\widehat{v}_e$. This allows us to simulate an oracle for $\widehat{v}_e$ using only $O(1)$ calls to the oracle for w_e. Otherwise, we run our algorithm as before (using matrix K in place of matrix M). This yields the bounds in both row 6's of Table 1.

13. The methods for problems with approximate oracles. In the case where some w_e's are general convex functions, it may not be possible to exactly represent $c_e^{\vdash}$ and $c_e^{\dashv}$ in a finite word length, leading to an *evaluation error* δ_e. Similarly, an exact solution to (O) (ii) may be transcendental and/or it might not be easy to solve the equation $w_e'(r) = p$ exactly (which is roughly what (O) (ii) requires). Then (O) (ii) might be implemented as a numerical root-finding procedure with some known error, leading to a *root-finding error* δ_r. We now use the convention that symbols for approximate quantities are the same symbols as the exact quantities with tildes added. We now assume that we have an oracle that

($\tilde{\text{O}}$) (i) when given a "point" $r \in \mathbb{R}$ will return costs $\widetilde{c}_e^{\vdash}(r)$ and $\widetilde{c}_e^{\dashv}(r)$ satisfying $|\widetilde{c}_e^{\vdash}(r) - c_e^{\vdash}(r)| \le \delta_e$ and $|\widetilde{c}_e^{\dashv}(r) - c_e^{\dashv}(r)| \le \delta_e$;

(ii) when given a "scalar" $p \in \mathbb{R}$ will return a point $\widetilde{r}$ with $c_e^{\dashv}(\widetilde{r}) - \delta_r \le p \le c_e^{\vdash}(\widetilde{r}) + \delta_r$ (so $\widetilde{c}_e^{\dashv}(\widetilde{r}) - \delta_e - \delta_r \le p \le \widetilde{c}_e^{\vdash}(\widetilde{r}) + \delta_e + \delta_r$).

The first consequence of these errors is that $\widetilde{\lambda}(x)$, the approximate min mean cycle value that we compute w.r.t. $\widetilde{c}_e^{\vdash}$ and $\widetilde{c}_e^{\dashv}$, will not exactly equal $\lambda(x)$. However, since $\widetilde{c}_e^{\vdash}$ and $\widetilde{c}_e^{\dashv}$ differ from $c_e^{\vdash}$ and $c_e^{\dashv}$ by at most δ_e per element, it is easy to see that $\widetilde{\lambda}(x)$ satisfies

$$|\lambda(x) - \widetilde{\lambda}(x)| \le \delta_e. \tag{38}$$

A quick scan of Lemmas 3.3 and 3.4 (the key lemmas proving polynomial convergence) shows that our arguments there all have a slack of at least $\lambda/2$ in them, except for the argument in Claim 2 that no new element far from h can be created. We want to claim that whenever $\widetilde{\lambda}(x)$ is large enough w.r.t. δ_e and δ_r, the arguments in those lemmas will still hold true with the approximate data $\widetilde{c}_e^{\vdash}$, $\widetilde{c}_e^{\dashv}$, and $\widetilde{\lambda}(x)$ substituted

for $c_e^{\vdash}$, $c_e^{\dashv}$, and $\lambda(x)$. The argument in Claim 2 depends on knowing that for some e (superscripting by iteration number)

$$\begin{aligned} &\widetilde{c}_e^{\vdash}(x_e^j) + \widetilde{\lambda}^j \le \widetilde{c}_e^{\vdash}(x_e^{j+1}) \quad \text{if } e \in A^j \qquad \text{and} \\ &\widetilde{c}_e^{\dashv}(x_e^j) - \widetilde{\lambda}^j \ge \widetilde{c}_e^{\dashv}(x_e^{j+1}) \quad \text{if } e \in B^j, \end{aligned} \tag{39}$$

but ($\tilde{\text{O}}$) (ii) might cause these inequalities to be violated by as much as $\delta := \delta_e + \delta_r$. We can fix this and obtain an easy analysis of the approximate oracle case by slightly increasing our local step length ε_e from (16) to now be an increment Δ such that

$$\begin{cases} \widetilde{c}_e^{\dashv}(x_e + \Delta) - \delta \le \widetilde{c}_e^{\vdash}(x_e) + \widetilde{\lambda} + \delta \le \widetilde{c}_e^{\vdash}(x_e + \Delta) + \delta & \text{if } e \in A, \\ \widetilde{c}_e^{\dashv}(x_e - \Delta) - \delta \le \widetilde{c}_e^{\dashv}(x_e) - \widetilde{\lambda} - \delta \le \widetilde{c}_e^{\vdash}(x_e - \Delta) + \delta & \text{if } e \in B. \end{cases} \tag{40}$$

That is, we call ($\tilde{\text{O}}$) (ii) with $p = \widetilde{c}_e^{\vdash}(x_e) + \widetilde{\lambda} + \delta_e + \delta_r$ when $e \in A$ and $p = \widetilde{c}_e^{\dashv}(x_e) - \widetilde{\lambda} - \delta_e - \delta_r$ when $e \in B$. Since $x_e^{j+1} = x_e^j + \Delta$ for an e achieving the minimum ε_e, this ensures that (39) will hold for this e.

There are two factors that limit how much we can reduce $\widetilde{\lambda}(x)$ before the inaccuracies catch up with us: (i) the maximum error in a $c_e^{\vdash}$ or $c_e^{\dashv}$, namely δ_e, can be at most the slack in the arguments in Lemmas 3.3 and 3.4, namely $\widetilde{\lambda}(x)/2$; and (ii) the increment in reduced cost, namely $\widetilde{\lambda}(x) + \delta_e + \delta_r$, plus the maximum error in $c_e^{\vdash}$ and $c_e^{\dashv}$, namely δ_e, must be smaller than $\widetilde{\lambda} + \widetilde{\lambda}/2$ to ensure that we do not make a positively far element negatively far or vice versa. Now (i) gives the bound $\widetilde{\lambda}(x) > 2\delta_e$ and (ii) gives $\widetilde{\lambda}(x) \ge 2\delta_r + 2\delta_e$. That is, we must have

$$\widetilde{\lambda}(x) \ge 2\delta_e + 2\delta_r. \tag{41}$$

Now, as long as $\widetilde{\lambda}(x)$ satisfies (41), and since we contrived (40) to make (39) true, the whole analysis of Lemmas 3.3 and 3.4 becomes true with $\widetilde{c}_e^{\vdash}$, $\widetilde{c}_e^{\dashv}$, and $\widetilde{\lambda}(x)$ in place of $c_e^{\vdash}$, $c_e^{\dashv}$, and $\lambda(x)$. In particular, this shows that $\widetilde{\lambda}(x)$ will geometrically decrease. Once the algorithm has driven $\widetilde{\lambda}(x)$ down to $2\delta_e + 2\delta_r$, (38) says that $\lambda(x) \le 3\delta_e + 2\delta_r$. This estimate can be used with the cost distance defined in section 4 and the bounds based on it developed in section 7 to get a bound on how close x is to an optimal solution.

These arguments suggest that when ($\tilde{\text{O}}$) (ii) is implemented as a root-finding procedure with an error estimate available at each iteration, then it will be faster to run the root-finder only until the current error in its root, δ_r', is small enough so that $\widetilde{\lambda}(x) - 2\delta_r' > 2\delta_e$.

The same sort of analysis can be pushed through for the cancel-and-tighten method. All of this shows that even with an approximate oracle, our methods can obtain an answer whose accuracy is close to the accuracy of the underlying evaluation and root-finding machinery.

Acknowledgments. We thank the referees for suggesting improvements to this paper and Maurice Queyranne for pointing out an error in an earlier version.

ALGORITHMS FOR THE CERTIFIED WRITE-ALL PROBLEM*

RICHARD J. ANDERSON† AND HEATHER WOLL‡

Abstract. In this paper, we prove new upper bounds on the complexity of the certified write-all problem with respect to an adaptive adversary. Our strongest result is that for any $\epsilon > 0$, there exists an $O(p^{1+\epsilon})$ work algorithm for the p-processor p-memory cell write-all. We also give a randomized $O(p^2 \log p)$ work algorithm for a p-processor p^2-memory cell write-all.

Key words. certified write-all problem, asynchronous computation, synchronization primitives, adversary models

AMS subject classifications. 68Q10, 68Q22

PII. S0097539794319126

1. Introduction.

A fundamental problem in asynchronous computation is to have p processors set n memory cells to a fixed value, and then signal the completion of the task. This problem is important in its own right as well as for capturing the difficulty of other problems in asynchronous computation such as the step-by-step simulation of a synchronous computation on an asynchronous machine.

Formally, the input to the certified write-all problem is an array $B[1. . n]$ and a variable c. The variables are all initialized to 0. The problem is to set all the variables to 1, with the restriction that c cannot be set to 1 until all the $B[i]$'s are guaranteed to be 1. We have p processors available. We assume a fully asynchronous model, where processors read and write to a global memory.

Each processor issues a stream of read and write instructions. A computation is an interleaving of these instructions. We are interested in worst case asynchronous computation, so we consider the interleaving which maximizes the cost of the computation. A common way to view this is to assume that an all powerful (or adaptive) adversary constructs the interleaving sequence.

We use the *work* measure as the cost of the algorithm. The work of the algorithm is the total number of instructions executed up until the point that the problem is solved.

The write-all problem was introduced by Kanellakis and Shvartsman [KS92] who gave an $O(p \log^2 p)$ work upper bound for a p-processor, p-cell write-all algorithm under the fail-stop model. Martel, Subramonian, and Park [MSP90] gave an $O(p)$ work bound for an $\frac{p}{\log p \log^* p}$-processor, p-cell write-all algorithm under a weaker adversary model than considered here. Martel's algorithm was randomized and assumed that the adversary must set the instruction interleaving prior to viewing the random numbers. The write-all problem for the general (adaptive) adversary model was previously considered by Buss et al. [BKRS96]. They gave an algorithm with $O(p^{\log_2 3})$ work ($\log_2 3 \approx 1.59$). Our algorithm can be viewed as an extension of their method. They also established an $\Omega(p \log p)$ work lower bound for the write-all problem.

2. Block write algorithm. In the write-all problem, we must write to n memory cells using p processors. The difficulty is that an adversary controls the order in which the processors execute. The adversary can cause all processors to halt except for one. This means that a processor must write to all memory cells when the other processors appear to have stopped. To avoid using $\Omega(np)$ work, processors must detect when other processors have written to regions of memory.

One method for reducing the work is to have the processors perform *block writes*. The memory is divided into blocks $B_1, \ldots, B_k$, each of size b. Each block B_i has an associated completion bit b_i. A block write to B_i is done by first reading b_i, and if b_i is 0, writing to the memory cells of B_i and then setting b_i to 1. In other words, B_i is written to only if the completion bit is not set when the write begins. If the processors perform block writes in the same order, then the adversary can cause $\Omega(pn)$ work by having the processors execute in lock step. However, if the processors perform block writes in different orders, then the worst case work can be reduced. For example, suppose that there are two processors P_1 and P_2 and two blocks B_1 and B_2. P_1 does block writes in the order B_1, B_2, and P_2 does block writes in the order B_2, B_1. Either $b_2 = 1$ when P_1 reaches B_2, or $b_1 = 1$ when P_2 reach B_1. This means that the amount of work is at most $\frac{3}{2}n + 7$ instead of $2n$. (The "+7" comes from reading and writing completion bits.) All of our algorithms are based upon using this idea to limit the amount of duplicated work.

The block write algorithm has each processor perform block writes to all cells. The order of the block writes is governed by a different permutation for each processor. A processor with permutation $\pi = \pi_1, \ldots, \pi_k$ performs the block writes in the order $B_{\pi_1}, \ldots, B_{\pi_k}$. We discuss how to analyze the performance of this algorithm and how to pick the permutations to use. We also generalize the algorithm to work with hierarchies of blocks to get different performance bounds.

The adversary chooses an interleaving of the instruction streams to maximize the amount of work. We can summarize this order by looking at the order in which the completion bits are set to 1. For a fixed interleaving of instructions, there is a permutation $\alpha = \alpha_1, \ldots, \alpha_k$ such that the assignments to the completion bits occur in the order $b_{\alpha_1}, \ldots, b_{\alpha_k}$.

A processor *succeeds* on a block write if the completion bit is zero when the write starts, so that the processor writes to the cells of the block. We want to be able to compute the maximum number of successful block writes for a processor, given the processor's permutation π and the adversaries interleaving α. A processor maximizes its number of successful block writes by having the writes occur as early as possible in the interleaving sequence subject to the constraint that they are consistent with α. For example, suppose $\pi = (4, 3, 1, 5, 2, 6)$ and $\alpha = (3, 4, 6, 1, 2, 5)$. The processor can succeed in its writes to blocks B_4, B_1, and B_5. In general, a processor can succeed in its write to block B_{π_i}, if the blocks $B_{\pi_1}, \ldots, B_{\pi_{i-1}}$ are completed before B_{π_i} according the to permutation α. This means that π_i occurs in α after $\pi_1, \ldots, \pi_{i-1}$. The permutation α^{-1} gives the position of i in the permutation α, so the permutation $\alpha^{-1}\pi$ gives the position of π_i in α.[1] In the example, $\alpha^{-1} = (4, 5, 1, 2, 6, 3)$ and $\alpha^{-1}\pi = (2, 1, 4, 6, 5, 3)$. If π_i occurs after $\pi_1, \ldots, \pi_{i-1}$, this means that $(\alpha^{-1}\pi)_i > (\alpha^{-1}\pi)_1, \ldots, (\alpha^{-1}\pi)_i > (\alpha^{-1}\pi)_{i-1}$, so i is a *left-to-right maxima* of $\alpha^{-1}\pi$. This result is summarized in the following lemma.

LEMMA 2.1. *Suppose that a processor performs its block writes in the order* $B_{\pi_1}, \ldots, B_{\pi_k}$ *and the adversary causes the completion bits to be written in the order*

[1] For permutations A and B, the composition permutation AB is defined $(AB)_i = A_{B_i}$.

$b_{\alpha_1}, \ldots, b_{\alpha_k}$. *The maximum number of successful block writes for the processor is bounded by the number of left-to-right maxima in* $\alpha^{-1}\pi$. □

We shall now turn our attention to bounding the number of left-to-right maxima in a set of permutations before returning to the write-all algorithms.

3. Contention of permutations. We define the *contention* of a set of permutations in order to quantify the worst case work that an adversary can cause. This allows us to express our bounds in terms of a simple combinatorial quantity. In this section, we assume that permutations are over the set $\{1, \ldots, n\}$ unless we say otherwise. A *random permutation* is a permutation which has been chosen uniformly from the set of all permutations of $\{1, \ldots, n\}$, and a *set of random permutations* is a set of independently chosen random permutations. The harmonic series is $H_n = \sum_{j=1}^{n} \frac{1}{j}$. This quantity occurs in our bounds on contention of permutations. The value of H_n is very close to the natural logarithm, satisfying the bound $\ln n \leq H_n \leq \ln n + 1$.

Let $\pi = \pi_1, \ldots, \pi_n$ be a permutation. We say π_i is a *left-to-right maxima* if $\pi_i > \pi_k$ for $k < i$. It is well known that the expected number of left-to-right maxima in a random permutation is H_n [Knu73]. We need a bound on the expected number of left-to-right maxima in a set of n random permutations.

We use $LR(\pi)$ to denote the number of left-to-right maxima in a permutation π and $LR(S)$ to denote the total number of left-to-right maxima in a set S of permutations, so $LR(S) = \sum_{\pi \in S} LR(\pi)$.

We begin with a lemma which can be used to analyze the distribution of $LR(\pi)$ when π is a random permutation.

LEMMA 3.1. *Suppose* $\pi = \pi_1, \ldots, \pi_n$ *is a random permutation. For* $1 \leq i \leq n$, *let* $X_i = 1$ *if* π_i *is a left-to-right maxima and* $X_i = 0$ *otherwise. The random variables* $X_1, \ldots, X_n$ *are independent random variables with* $\text{Prob}[X_i = 1] = \frac{1}{i}$.

Proof. The proof is by induction. The key to the proof is to generate random permutations by an algorithm which converts a random permutation on $\{1, \ldots, n-1\}$ into a random permutation on $\{1, \ldots, n\}$ without changing the values of $X_1, \ldots, X_{n-1}$.

Our method for generating a random permutation is as follows:

1. Construct a random permutation $\pi' = \pi'_1, \ldots, \pi'_{n-1}$ on $\{1, \ldots, n-1\}$.
2. Choose a random value r from $\{1, \ldots, n\}$. Let $\pi_n = r$. For $i < n$, let $\pi_i = \pi'_i$ if $\pi'_i < r$ and $\pi_i = \pi'_i + 1$ if $\pi'_i \geq r$.

π_n is a left-to-right maxima if and only if $r = n$, so $\text{Prob}[X_n = 1] = \frac{1}{n}$. This holds for any permutation π', so there is no conditioning between the $X_1, \ldots, X_{n-1}$ and X_n, so the random variables are independent. □

It follows from Lemma 3.1 that if S is a set of n random permutations, then the expected size of $LR(S)$ is nH_n. We need to show that it is very unlikely for $LR(S)$ to be larger than cnH_n for some c. Our proof relies on a "Chernoff bound" due to Raghavan. We restate his result here for completeness.

LEMMA 3.2 (Raghavan). *Let* $X_1, X_2, \ldots, X_r$ *be a sequence of independent Bernoulli trials and let* $\Psi = X_1 + X_2 + \cdots + X_r$. *Suppose* $\text{Exp}[\Psi] = m$. *For* $\delta > 0$,

$$\text{Prob}[\Psi > (1+\delta)m] < \left(\frac{e^{\delta}}{(1+\delta)^{(1+\delta)}} \right)^{m}.$$

Proof. See [Rag88, Theorem 1]. □

LEMMA 3.3. *Let* S *be a set of* n *random permutations. The probability that* $LR(S) > 3nH_n$ *is at most* $\frac{1}{2^n n!}$.

Proof. Let $S = \{\pi^1, \ldots, \pi^n\}$ be a set of random permutations. If $n \leq 3$ the result is trivial, so we assume $n \geq 4$. Let X_{ij} be a random variable that is one if π^i_j is a left-to-right maximum in π^i and zero otherwise. The key observation for the proof is that this is a set of independent random variables. It is clear that random variables which correspond to different permutations are independent, and Lemma 3.1 shows that random variables associated with the same permutation are also independent.

Let $\Psi = \sum_i \sum_j X_{ij}$. Since $\text{Prob}[X_{ij} = 1] = \frac{1}{p-j+1}$, we have $\text{Exp}[\Psi] = nH_n$. Applying Lemma 3.2 with $\delta = 2$

$$\text{Prob}[\Psi > 3n \ln n] < \left(\frac{e^2}{3^3}\right)^{nH_n} < \left(\frac{1}{e}\right)^{nH_n} \leq \left(\frac{1}{e}\right)^{n \ln n} = \frac{1}{n^n} < \frac{1}{2^n n!}.$$

(We use the assumption that $n \geq 4$ in the last inequality.) □

For permutations π and α, the contention of π with respect to α (denoted $\text{Cont}(\pi, \alpha)$) is defined to be $LR(\alpha^{-1}\pi)$. For a set S of permutations and a permutation α, the contention of S with respect to α is defined $\text{Cont}(S, \alpha) = \sum_{\pi \in S} \text{Cont}(\pi, \alpha)$. The maximum contention of S is $\text{Cont}(S) = \max_\alpha \text{Cont}(S, \alpha)$. We will show that there exists a set S of n permutations with $\text{Cont}(S) \leq 3nH_n$. First, we show that Lemma 3.3 applies, and then we prove the theorem using a probabilistic argument.

LEMMA 3.4. *Let α be a fixed permutation and S a set of n random permutations. The probability that* $\text{Cont}(S, \alpha) > 3nH_n$ *is at most* $\frac{1}{2^n n!}$.

Proof. The set of permutations $S' = \{\alpha^{-1}\pi \mid \pi \in S\}$ is a random set of permutations since multiplication by a fixed permutation can be viewed as a one-to-one mapping. Lemma 3.3 applies directly to give the result. □

We now prove that there exists a set of permutations with low contention. Our proof is based on the probabilistic method pioneered by Erdös [ES74], where we show the existence of a set with a certain property by showing that a random set has the property with probability greater than zero.

THEOREM 3.5. *Let S be a random set of n permutations. The probability that* $\text{Cont}(S) > 3nH_n$ *is at most* $\frac{1}{2^n}$.

Proof. We say that a set S of n permutations is *bad* for a permutation α if $\text{Cont}(S, \alpha) > 3nH_n$. By Lemma 3.4 the probability that a random set of n permutations is bad for a fixed α is less than $\frac{1}{2^n n!}$. Summing over all permutations α shows that with probability less than $\frac{1}{2^n}$, a random set of n permutations is bad for some α. □

COROLLARY 3.6. *There exists a set of S permutations with* $\text{Cont}(S) \leq 3nH_n$.

4. Randomized algorithms for the write-all problem. We use the results of the previous sections to derive several write-all algorithms. The algorithms differ in their ratios of processors to memory locations. The algorithms perform block writes in an order given by a random set of permutations. The following lemma relates the amount of work to the contention.

LEMMA 4.1. *Let $S = \pi^1, \ldots, \pi^p$ be a set of permutations on $1, \ldots, p$. Suppose that processor j performs its block writes in the order $B_{\pi^j_1}, \ldots, B_{\pi^j_p}$. The number of successful block writes is at most* $\text{Cont}(S)$.

Proof. If the adversary fixes the order of writes to $b_1, \ldots, b_p$ to the permutation α, then Lemma 2.1 says that the number of successful block writes for processor j is at most $\text{Cont}(\pi^j, \alpha)$. If we sum over all processors, the number of successful block writes for interleaving α is at most $\text{Cont}(S, \alpha)$. Hence, $\text{Cont}(S)$ is an upper bound on the number of successful block writes. □

Our first algorithm is for the case $n = p^2$, so we want to write to p^2 memory locations using p processors. In this case, we use the block write algorithm described in section 2. The memory is divided into p blocks of size p. A set $S = \{\pi^1, \ldots, \pi^p\}$ of random permutations on $\{1, \ldots, p\}$ is constructed. The code for processor j follows.

```
BlockWriteI
  for i := 1 to p
    k := π_i^j;
    if b_k = 0
      write B_k;
      b_k := 1;
```

By Lemma 4.1 the number of successful block writes is bounded by $3pH_p$ with probability $1 - \frac{1}{2^p}$. Each processor does $O(p)$ additional work in testing completion bits, so the total work is $O(p^2 \log p)$ with high probability.

To improve the result, we would like to decrease the number of memory cells per processor yet still maintain efficiency. We give another randomized algorithm which reduces the block size to $\sqrt{p}$. We do this by generalizing the *BlockWrite*I algorithm to use a two-level hierarchy of blocks. The *big* blocks are $B_1, \ldots, B_{\sqrt{p}}$ with completion bits $b_1, \ldots, b_{\sqrt{p}}$. Block B_i is divided into *small* blocks $B_{i1}, \ldots, B_{i\sqrt{p}}$ with completion bits $b_{i1}, \ldots, b_{i\sqrt{p}}$. The big blocks have size p and the small blocks have size $\sqrt{p}$. The processors are numbered P_{ij} for $1 \le i, j \le \sqrt{p}$. We uses a set of $\sqrt{p}$ random permutation $S = \pi^1, \ldots, \pi^{\sqrt{p}}$ over $\{1, \ldots, \sqrt{p}\}$.

The code for processor P_{ij} follows.

```
BlockWriteII
  for k := 1 to √p
    s := π_k^i;
    if b_s = 0
      for l := 1 to √p
        t := π_l^j;
        if b_st = 0
          write B_st;
          b_st := 1;
      b_s := 1;
```

LEMMA 4.2. *For a random choice of permutations, the algorithm BlockWrite*II *has* $O(p^{3/2} \log^2 p)$ *work with probability at least* $1 - \frac{1}{2^{\sqrt{p}}}$.

Proof. We divide the processors into groups $G_i = \{P_{i1}, \ldots, \mathcal{P}_{i\sqrt{p}}\}$. A group G_i *succeeds* in a block write to B_k if at least one processor in the group succeeds. By considering permutations of writes to $b_1, \ldots, b_{\sqrt{p}}$, Lemma 4.1 implies that the number of successful group writes is at most $\mathrm{Cont}(S)$.

When group G_i has a successful write to B_k, we make the pessimistic assumption that all processors in the group succeed. Lemma 4.1 now implies that the number of successful writes by processors in G_i to the small blocks in $B_{k1}, \ldots, B_{k\sqrt{p}}$ is at most $\mathrm{Cont}(S)$, and the associated work is $O(\sqrt{p}\mathrm{Cont}(S) + p)$. Putting these two together, we get a work bound of $\sqrt{p}\mathrm{Cont}^2(S) + p\mathrm{Cont}(S)$. Theorem 3.5 implies that this is $O(p^{3/2} \log^2)$ with probability at least $1 - \frac{1}{2^{\sqrt{p}}}$. □

5. Deterministic algorithm for the write-all problem. We can adapt the ideas used in the randomized algorithm to get a deterministic algorithm. The only use of randomness is that we do not know how to construct a set of permutations with low contention, so we rely on using a random set, which has low contention with

overwhelming probability. In our deterministic algorithm we increase the number of levels of recursion. As the number of levels of recursion increases, the size of the permutations decreases. When we reduce the size of the permutations used to a constant q, we claim that we can find a good set in constant time by a brute force search. The brute force algorithm tests every set of q permutations by evaluating the set's contention with respect to all permutations. This takes $O(\binom{q!}{q} q! q^2 \log q)$ time, which is a constant.

We show that for any $\epsilon > 0$ there exists a deterministic p processor algorithm for writing to p-memory cells that takes $O(p^{1+\epsilon})$ work. Suppose $p = q^d$ for integers q and d. We view the computation as taking place on a q-ary tree of height d. Each internal node of the tree contains a single bit, which corresponds to the completion bit of a block, and the leaf nodes contain the memory cells. We use a set $S = \{\pi^1, \ldots, \pi^q\}$ of permutations over $\{1, \ldots, q\}$ with $\text{Cont}(S) \leq 3qH_q$. The existence of such a set is guaranteed by Corollary 3.6. When a processor is at a node, it visits the children of that node in an order given by a permutation of S. We label the processors with distinct strings of length d over the alphabet $\{1, \ldots, q\}$. Each processor chooses a permutation to use for all of the nodes at a particular level of the tree. The choice of permutation is based upon the label of the processor. The processor labeled $q_1 \cdots q_d$ considers the children of a node on level l in the order given by π^{q_l}.

We give the code for the recursive algorithm *BlockWrite*III. The blocks are labeled B^l_α where α is a string of length l over $\{1, \ldots, q\}$, and the completion bits are labeled b^l_α. The algorithm assigns 1's to all of the blocks B^d_α. We give the code for the processor $q_1 \cdots q_d$. The initial call is *BlockWrite*III$(0, \lambda)$.

```
BlockWriteIII(l, α)
  if l = d then
    B^l_α := 1
  else
    for i := 1 to q do
      t := π^{q_l}_i;
      if b^{l+1}_α = 0
        BlockWriteIII(l + 1, αt);
        b^{l+1}_{αt} := 1;
```

Since each processor will write to all of the cells in the absence of other processors, it is easy to see that the algorithm solves the write-all problem. We now establish the work bound. We divide the processors into groups, with the groups indexed by strings over $\{1, \ldots, q\}$. For β, a string of length l, the group G^l_β is the set of all processors whose name has as a prefix the string β. We say that G^l_β has a *successful* write to B^l_α if some processor in G^l_β makes a call to *BlockWrite*III(l, α). The next lemma is the key to the performance analysis.

LEMMA 5.1. *If G^l_β has a successful write to B^l_α, then there are at most* $\text{Cont}(S)$ *pairs s and t where $G^{l+1}_{\beta s}$ has a successful write to $B^{l+1}_{\alpha t}$.*

Proof. Suppose that G^l_β has a successful write to B^l_α. Assume that every processor in G^l_β is successful in writing to B^l_α. A processor in $G^{l+1}_{\beta s}$ reads and writes $b^{l+1}_{\alpha 1}, \ldots, b^{l+1}_{\alpha q}$ in the order given by π^s. This is precisely the situation covered in Lemma 4.1, so the number of pairs of s and t where $G^{l+1}_{\beta s}$ has a successful write to $B^{l+1}_{\alpha t}$ is at most $\text{Cont}(S)$. ∎

We can now prove the main theorem. We refer to a successful write of G^l_β to B^l_α as a write on level l.

THEOREM 5.2. *For every $\epsilon > 0$, there exists a deterministic $O(p^{1+\epsilon})$ work algorithm for the p-processor, p-memory cell certified write-all.*

Proof. It follows Lemma 5.1 that the number of successful writes to level l is at most $(\mathrm{Cont}(S))^l$. Each successful write on level l can be performed by $\frac{p}{q^l}$ processors, so the work W is bounded by

$$W \le c \sum_{l=0}^{\log_q p} \frac{p}{q^l} (\mathrm{Cont}(S))^l \le cp \sum_{l=0}^{\log_q p} (3H_q)^l < cp(c' \log q)^{\log_q p}$$

for some constants c and c'. Manipulating logarithms we have

$$\log[(c' \log q)^{\log_q p}] = \log_q p \log\log q^{c'} = \log p \log\log q^{c'} / \log q.$$

So

$$W \le cp^{1+\log\log q^{c'}/\log q}.$$

Since $\log\log q^c / \log q \to 0$, for any $\epsilon > 0$ we can find a q such that $W \le p^{1+\epsilon}$. ∎

COMPUTATIONAL MODELING FOR GENETIC SPLICING SYSTEMS*

SAM MYO KIM†

Abstract. A genetic splicing system involves DNA molecules mixed with enzymes and a ligase that allow the molecules to be cleaved and recombined to produce other molecules in addition to the original ones. Recently, using formal language theory, several researchers have investigated the string properties of DNA molecules that may potentially arise from the original set of molecules under the effect of the given restriction enzymes.

This paper introduces an algorithm which, given a splicing system whose initial set of strings is regular, constructs a finite state automaton that recognizes the set of DNA molecules spliced by the system. This algorithm solves the open problem of constructing such an automaton and shows a direct approach to the proof of regularity of spliced languages.

Key words. finite state automata, languages, genetic splicing, DNA molecules

1. Introduction.

Genetic splicing is one of the most popular techniques in the field of genetic engineering. It involves restriction enzymes and DNA molecules. Restriction enzymes are endodeoxyribonucleases that recognize specific nucleotide sequences in double-stranded DNA and cleave both strands of the double helix. In molecular biology each double-stranded DNA molecule is represented in terms of paired symbols from four alphabet A, T, C, and G, which denote adenine, cytocine, guanine, and thymine, respectively. The pairs are A/T, T/A, G/C, and C/G. In [5], Head used formal language theory for the study of the potential effect of a set of restriction enzymes and a ligase that allow a set of DNA molecules to be cleaved and reassociated to produce further molecules. He introduced a new generative formalism called a splicing system as an abstract model for such a biological setting and analyzed the associated languages.

The effect of a restriction enzyme is to cut the molecule into two pieces at a specific pattern of the molecule which is defined by the enzyme involved. For example, consider the effect of enzyme *EcoRI* represented by the pair of strings

GAATTC
CTTAAG

on a small hypothetical DNA molecule represented by the pair of strings

....GCTACTAGAATTCGCGCTA....
....CGATGATCTTAAGCGCGAT.... .

The enzyme works on the molecule by finding a substring pair identical to the enzyme, indicated by the underlines. The enzyme cuts this molecule into two staggered pieces

† Department of Computer Engineering, Kyungpook National University, Taegu, Korea (kims@bh.kyungpook.ac.kr).

Notice that G/C on the left piece (in this notation G is from the top string of the piece and C from the bottom string) and C/G on the right are not involved in the cut. However, they are needed for finding the right pattern and the cut that takes place. Enzymes are classified into two groups depending on where the overhangs occur. In the above example, the left piece has the overhang on the lower half of the strand and the right piece on the top half.

There are enzymes which cut the other way. For example, enzyme *HhaI*

GCGC
CGCG

will cut the above molecule as follows.

....GCTACTAGAATTCGCG CTA....
....CGATGATCTTAAGC GCGAT.... .

The staggered ends of a DNA molecule recombine with others if they match. For example, if there exists the following piece cut from some other molecule

AATTACATT....
TGTAA....

then by combining with the first half of the fragments cut by *EcoRI*, the following DNA molecule can be formed.

....GCTACTAGAATTACATT....
....CGATGATCTTAATGTAA.... .

In [5], it was proved that if the initial set of DNA strings is finite, the strings generated by the system are strictly locally testable [5], and if the initial set is regular, the set of strings generated is also regular [1]. In [2] an algorithm was presented which, given a splicing system, constructs an automaton which recognizes the language of the splicing system. This algorithm works only for the class of permanent splicing systems. It has been an open problem to develop a more powerful algorithm that does not require the permanence property of splicing systems.

We solve this open problem by introducing an algorithm which uses the so-called monomialization technique that we have developed based on the concept of input memory span of [7]. Given a splicing system with its initial set of strings given in terms of the finite state transition graph of an automaton that recognizes the set, our algorithm constructs an automaton that recognizes the set of strings generated by the system. This paper also shows constructive proofs of the strict locality in [5] and the regularity in [1] of the spliced languages.

Section 2 describes a formal definition of genetic splicing systems which abstracts the above biological concept, investigates the language generated by a splicing system, and introduces lemmas that will be used in sections 4 and 5. Section 3 develops useful concepts and related lemmas concerning finite state transition graphs that will be used in sections 4 and 5 together with the ones developed in section 2. Section 4 introduces an algorithm which constructs an automaton for a given splicing system and analyzes its output. Section 5 proves the main theorems of the paper and, finally, section 6 gives some concluding remarks.

2. Splicing systems. This section formally defines splicing systems, which were first introduced in [5], and develops some lemmas that will be used in sections 4 and 5.

DEFINITION 2.1 (see [5]). *A* splicing system *is a quadruple* $S = (A, I, B, C)$, *where*

A: *a finite alphabet,*

I: *a set of initial strings in* A^*, *and*

B, C: finite sets of triples (u, x, v), $u, x, v \in A^*$.

Note that the size of I can be infinite. The sets B and C are called *left-hand patterns* and *right-hand patterns*, respectively. A substring uxv in a string over the alphabet A is called *left-hand site* if (u, x, v) is a left-hand pattern and *right-hand site* if (u, x, v) is a right-hand pattern. String x is called the *crossing* of the site uxv. In this paper we will use u, x, and v, and their subscript symbols to denote patterns and sites. For a string $wuxvz$ with a site uxv, we call wux the *left half* of $wuxvz$ with respect to site uxv, and xvz the *right half* of $wuxvz$ with respect to site uxv. We assume that for each string in I there are an unbounded number of copies available whenever they are needed for splicing. In the biological sense, we may assume that alphabet A consists of the four symbols each representing one of the four paired symbols $A/T, T/A, G/C$, and C/G, and B and C represent, respectively, the two types of enzymes depending on the locations of the overhangs.

DEFINITION 2.2. *For a splicing system $S = (A, I, B, C)$, by $L(S)$ we denote the set of strings generated by S which is formally defined as follows.*

(1) $I \subseteq L(S)$.
(2) *If $w_1u_1xv_1z_1$ and $w_2u_2xv_2z_2$ are in $L(S)$, and u_1xv_1 and u_2xv_2 are sites of the same hand, then $w_1u_1xv_2z_2$ and $w_2u_2xv_1z_1$ are also in $L(S)$.*

A language L is *splicing language* if there exists a splicing system S which generates L. In part (2) of the above definition, string $w_1u_1xv_2z_2$ is produced by splicing $w_1u_1xv_1z_1$ and $w_2u_2xv_2z_2$ on sites u_1xv_1 and u_2xv_2, respectively. Notice that $w_1u_1xv_2z_2$ is formed by writing the left half of $w_1u_1xv_1z_1$ w.r.t $u_1x_1v_1$ followed by the right half of $w_2u_2xv_2z_2$ w.r.t. u_2xv_2 with the crossing x overlapped. We will denote this operation as follows:

$$w_1\underline{u_1xv_1}z_1 \not\vdash w_2\underline{u_2xv_2}z_2 = w_1u_1xv_2z_2.$$

Notice that spliced sites are underlined. In the literature the following two classes of splicing systems have been studied, in particular, for their language properties and characterizations in terms of finite state automata.

DEFINITION 2.3 (see [2]). *A splicing system $S = (A, I, B, C)$ is* permanent *if, for each pair of strings $w_1u_1xv_1z_1$ and $w_2u_2xv_2z_2$ in A^* with sites u_1xv_1 and u_2xv_2 of the same hand, it has the following property: if y is a substring of w_1u_1x (respectively, xv_2z_2) that is the crossing of a site in $w_1u_1xv_1z_1$ (respectively, $w_2u_2xv_2z_2$), then this same substring y of $w_1u_1xv_2z_2$* is *the crossing of a site in $w_1u_1xv_2z_2$.*

Notice that the substring y must exist either in w_1u_1x of $w_1u_1xv_1z_1$ or in xv_2z_2 of $w_2u_2xv_2z_2$.

DEFINITION 2.4 (see [5]). *A* persistent *splicing system is defined as Definition* 2.3 *with the word* "is" *occurring in boldface replaced by* "contains an occurrence of."

Clearly, permanence implies persistence. To help the reader understand the above two definitions, consider the following operation of a splicing system:

$$w_1\underline{u_1xv_1}z_1 \not\vdash w_2\underline{u_2xv_2}z_2 = w_1u_1xv_2z_2.$$

Since x is a substring in w_1u_1x that is the crossing of a site in $w_1u_1xv_1z_1$, if the system is permanent, then the same x in $w_1u_1xv_2z_2$ is the crossing of a site in $w_1u_1xv_2z_2$. If the system is persistent, the same x contains an occurrence of the crossing of a site in $w_1u_1xv_2z_2$. In other words, $w_1u_1xv_2z_2$ contains a site whose crossing is contained in the substring x. Now, suppose that $w_1u_1xv_2z_2 = w_3u_3x_3v_3z_3$ such that $u_3x_3v_3$

is a site and the crossing x is contained in $x_3v_3z_3$. Consider the following splicing operation:

$$w_4\underline{u_4x_3v_4}z_4 \not\vdash w_3\underline{u_3x_3v_3}z_3 = w_4u_4x_3v_3z_3.$$

The substring x, which is contained in $x_3v_3z_3$, also exists in $w_4u_4x_3v_3z_3$ and, hence, the same x should have the crossing of a site. Now, we investigate some interesting splicing operations and introduce several lemmas that will be used in section 5. We need the following well-known theorem (e.g., [4, p.7]).

THEOREM 2.5. *Let $\alpha, \gamma \in A^+$ and $\beta \in A^*$ such that $\alpha\beta = \beta\gamma$. Then there exist $\alpha_1, \alpha_2 \in A^*$ and $p \geq 0$ such that $\alpha = \alpha_1\alpha_2$, $\gamma = \alpha_2\alpha_1$, and $\beta = \alpha^p\alpha_1 = \alpha_1\gamma^p$.*

Note that $p = \lfloor |\beta|/|\alpha| \rfloor$ and $|\alpha_1| = |\beta| \bmod |\alpha|$.

LEMMA 2.6. *Let $\alpha, \beta, \gamma \in A^+$ such that $\alpha\beta = \beta\gamma$. Then, for all $k > |\beta|$, string β is a substring of both α^k and γ^k.*

Proof. By Theorem 2.5 there are $\alpha_1, \alpha_2 \in A^*$ such that $\alpha = \alpha_1\alpha_2$ and $\beta = \alpha^p\alpha_1 = \alpha_1\gamma^p$, where $p = \lfloor |\beta|/|\alpha| \rfloor \geq |\beta|$. Clearly, $\alpha^{p+1} = \alpha^p\alpha_1\alpha_2 = \beta\alpha_2$ and $\gamma^{p+1} = \alpha_2\alpha_1\gamma^p = \alpha_2\beta$. □

LEMMA 2.7. *Let $w_1, w_2, w_3 \in L(S)$ of a splicing system $S = (A, I, B, C)$ such that for some sites uxv, $u_1x_1v_1$, and $u_2x_2v_2$,*

$$w_1 = w_{11}uxvz_1 = w_{12}u_1x_1v_1y_1z_1,$$
$$w_2 = w_{21}uxvy_0z_2 = w_{22}u_2x_2v_2y_2y_0z_2, \text{ and}$$
$$w_3 = w_{31}u_1x_1v_1y_1z_3 = w_{32}u_2x_2v_2y_2y_0z_3,$$

where $w_{ij}, z_1, z_2, z_3 \in A^*$ and $y_0 \in A^+$. Then $w_{11}uxv(y_0)^+z_2 \subseteq L(S)$.

Proof. We prove the lemma by showing that $w_{11}uxv(y_0)^kz_2 \in L(S)$, for all $k \geq 1$, by induction. The following splicing operation shows that $w_{11}uxv(y_0)^kz_2 \in L(S)$ for $k = 1$:

$$w_{11}\underline{uxv}z_1 \not\vdash w_{21}\underline{uxv}y_0z_2 = w_{11}uxvy_0z_2.$$

Suppose that $w_{11}uxv(y_0)^iz_2 \in L(S)$ for all $i < k$. We have $w_{11}uxv(y_0)^iz_2 = w_{12}u_1x_1v_1y_1(y_0)^iz_2$. The following sequence of splicing produces $w_{11}uxv(y_0)^{i+1}z_2$:

(1) $w_{31}\underline{u_1x_1v_1}y_1z_3 \not\vdash w_{12}\underline{u_1x_1v_1}y_1(y_0)^iz_2 = w_{31}u_1x_1v_1y_1(y_0)^iz_2$
$= w_{32}u_2x_2v_2y_2y_0(y_0)^iz_2$,

(2) $w_{22}\underline{u_2x_2v_2}y_2y_0z_2 \not\vdash w_{32}\underline{u_2x_2v_2}y_2y_0(y_0)^iz_2 = w_{22}u_2x_2v_2y_2y_0(y_0)^iz_2$
$= w_{21}uxvy_0(y_0)^iz_2$,

(3) $w_{11}\underline{uxv}z_1 \not\vdash w_{21}\underline{uxv}y_0(y_0)^iz_2 = w_{11}uxvy_0(y_0)^iz_2 = w_{11}uxv(y_0)^{i+1}z_2$. □

If we choose $w_1 = w_2 = w_3$, $z_1 = z_2 = z_3$, and $uxv = u_1x_1v_1y_1 = u_2x_2v_2y_2$ in Lemma 2.7, we get $w_{11} = w_{12} = w_{31}$ and $w_{21} = w_{22} = w_{32}$, and the first two expressions of the lemma become redundant. For this simple case of the lemma we present the following corollary.

COROLLARY 2.8. *Let $w \in L(S)$ of a splicing system. If $w = w_1uxvz = w_2uxvy_0z$, for some $w_1, w_2, z \in A^*$, $y_0 \in A^+$ and a site uxv, then $w_1uxv(y_0)^*z \subseteq L(S)$.*

LEMMA 2.9. *Let $w_1, w_2, w_3 \in L(S)$ of a splicing system S that satisfies the condition of Lemma 2.7 above. Then there exists a constant c such that for all $k \geq c$, the string $(y_0)^k$ contains the site uxv.*

Proof. Conditions (1), (2), and (3) of Lemma 2.7 implies that strings w_1, w_2, and w_3 can be superposed as shown in Figure 1. In the figure, heavy vertical lines indicate exact positions and others can vary. It is easy to see that the longest string among $uxvy_0$, $u_2x_2v_2y_2y_0$, $u_1x_1v_1y_1$, and uxv has the others as suffixes. The figure shows the case in which $u_2x_2v_2y_2y_0$ is the longest.

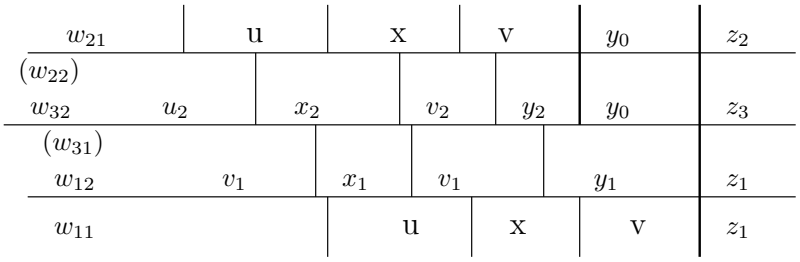

FIG. 1. *Superposing w_1, w_2, and w_3 for Lemma* 2.9.

Whichever the case, we have $zuxv = uxvy_0$ for some $z \in A^+$. By Lemma 2.6 with $\beta = uxv$ and $\gamma = y_0$, string ${y_0}^k$ contains the site uxv for all $k > |uxv|$. □

LEMMA 2.10. *Let $w_1, w_2, w_3 \in L(S)$ of a splicing system $S = (A, I, B, C)$ such that*

$$w_1 = w_{11}uxvz_1 = w_{12}u_1x_1v_1y_1vz_1,$$
$$w_2 = w_{21}u'xv'y_0z_2 = w_{22}u_2x_2v_2y_2y_0z_2, \text{ and}$$
$$w_3 = w_{31}u_1x_1v_1y_1z_3 = w_{32}u_2x_2v_2y_2y_0z_3,$$

for some $w_{ij}, z_1, z_2, z_3 \in A^*$ and $y_0 \in A^*$, where uxv and $u'xv'$ are sites of the same hand, and $u_1x_1v_1$ and $u_2x_2v_2$ are arbitrary sites. Then $w_{11}ux(v'y_0)^+z_2 \subseteq L(S)$.

Proof. Notice that $w_{11}ux = w_{12}u_1x_1v_1y_1$, $w_{21}u'xv' = w_{22}u_2x_2v_2y_2$, and $w_{31}u_1x_1v_1y_1 = w_{32}u_2x_2v_2y_2y_0$. We will prove the lemma by showing that $w_{11}ux(v'y_0)^kz_2 \in L(S)$ for all $k \geq 1$. The following splicing operation shows that $w_{11}ux(v'y_0)^kz_2 \in L(S)$ for $k = 1$:

$$w_{11}\underline{uxv}z_1 \not\vdash w_{21}\underline{u'xv'}y_0z_2 = w_{11}uxv'y_0z_2.$$

For $k > 1$, suppose that $w_{11}ux(v'y_0)^iz_2 \in L(S)$ for all $i < k$. Then by the property of w_1, we have

$$w_{11}ux(v'y_0)^iz_2 = w_{12}u_1x_1v_1y_1(v'y_0)^iz_2.$$

We can produce $w_{11}ux(v'y_0)^{i+1}z_2$ by the following sequence of splicing operations:

(1) $w_{31}\underline{u_1x_1v_1}y_1z_3 \not\vdash w_{12}\underline{u_1x_1v_1}y_1(v'y_0)^iz_2 = w_{31}u_1x_1v_1y_1(v'y_0)^iz_2$
$= w_{32}u_2x_2v_2y_2y_0(v'y_0)^iz_2,$

(2) $w_{22}\underline{u_2x_2v_2}y_2y_0z_2 \not\vdash w_{32}\underline{u_2x_2v_2}y_2y_0(v'y_0)^iz_2 = w_{22}u_2x_2v_2y_2y_0(v'y_0)^iz_2$
$= w_{21}u'xv'y_0(v'y_0)^iz_2,$

(3) $w_{11}\underline{uxv}z_1 \not\vdash w_{21}\underline{u'xv'}y_0(v'y_0)^iz_2 = w_{11}uxv'y_0(v'y_0)^iz_2$
$= w_{11}ux(v'y_0)^{i+1}z_2.$ □

In Lemma 2.10 if $w_1 = w_2 = w_3$, $vz_1 = z_2 = z_3$, $ux = u_1x_1v_1y_1$, and $u'xv' = u_2x_2v_2y_2$, the first two expressions become redundant. For this simple case of the lemma we present the following corollary.

COROLLARY 2.11. *Let $w \in L(S)$ of a splicing system S such that $w = w_1uxvz = w_2u'xv'y_0vz$ for some $w_1, w_2, z \in A^*$ and sites uxv and $u'xv'$ of the same hand. Then $w_1ux(v'y_0)^*vz \subseteq L(S)$.*

LEMMA 2.12. *Let $w_1, w_2, w_3 \in L(S)$ of a splicing system S that satisfies the condition of Lemma* 2.10 *above. If S is persistent, there exists a constant c such that for all $k \geq c$ the string $(v'y_0)^k$ contains a site.*

Proof. It suffices to show that x is a substring of $(v'y_0)^k$. As for the proof of Lemma 2.9, we can superpose w_1, w_2, and w_3 as shown in Figure 2, which implies

$zx = xv'y_0$ for some $z \in A^+$. By Lemma 2.6 with $\gamma = v'y_0$ and $\beta = x$, string x is a substring of $(v'y_0)^k$ for all $k > |v'y_0|$. □

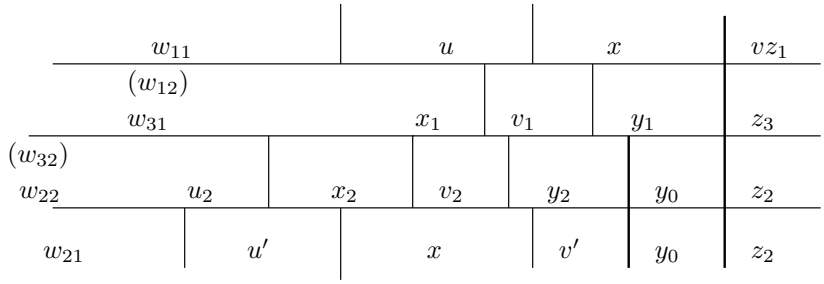

FIG. 2. *Superposing w_1, w_2, and w_3 for Lemma* 2.12.

3. Automata and input memory spans. This section investigates finite state transition graphs and develops some concepts and lemmas that will be used in sections 4 and 5 for constructing an automaton which recognizes the language of a given splicing system. In this paper we use the notation of [9] for the automaton $M = (Q, A, \delta, q_{st}, F)$. The automata that our algorithm constructs is nondeterministic. Thus, $\delta(p, x) \subseteq Q$, for a state $p \in Q$ and string $x \in A^*$. We write $q \in \delta(p, x)$ to refer to a sequence of transitions in response to the input string x beginning at p and ending at q. (Note that q_{st} designates the start state of an automaton.) By a graph we mean the state transition graph of the automaton, which is an edge-labeled directed graph. Following the convention we allow an edge to have more than one label. We assume that every state is reachable from the start state, and from every state an accepting state is reachable. Hence, the graph does not have dead states.

A *path* is a sequence of, possibly repeating, states $q_0 q_1 \dots q_n$ such that there is a directed edge from q_i to q_{i+1}, $0 \le i < n$. An *accepting path* is a path which starts from the start state and ends in an accepting state. A *span* is a string of symbols collected along a path one symbol from each edge. Notice that there can be more than one span on a path because more than one symbol can be assigned on an edge. If $q \in \delta(p, x)$, there is a path from p to q which has span x. An *accepting span* is a span of an accepting path. By A^k ($A^{\le k}$), we denote the set of strings of length k ($\le k$) over the alphabet A. By $L(G)$ we denote the set of accepting spans in state transition graph G, i.e., the language of the automaton represented by graph G. We need the following definition which was introduced in [7].

DEFINITION 3.1 (input memory span). *Let $M = (Q, A, \delta, q_{st}, F)$ be an automaton. A string w is an input memory span (IMS) of state q if there is a state p such that $q \in \delta(p, w)$. For a state $q \in Q$ and a nonnegative integer k, the set of input memory spans of order k of state q, denoted by $IMS(q, k)$, is defined as follows:*

$$IMS(q,k) = \{x \mid x \in A^k, q \in \delta(q_{st}, wx), w \in A^*\} \bigcup \{x \mid x \in A^{<k}, q \in \delta(q_{st}, x)\}.$$

We can prove that this definition is equivalent to the statement of the following lemma which is used for computing $IMS(q, k)$ of all states q of a given automaton as shown in Figure 3. We leave the proof of the lemma for the reader.

LEMMA 3.2. *Let q be a state of an automaton $M = (Q, A, \delta, q_{st}, F)$; then $IMS(q, k)$ can be defined as follows.*

(1) *$IMS(q, 0) = \{\epsilon\}$ and, for all $k \ge 0$, $\epsilon \in IMS(q_{st}, k)$.*

(2) *For $k > 0$, $a \in A$ and $x \in A^*$ $xa \in IMS(q,k)$, if and only if there exists $p \in Q$ such that $x \in IMS(p, k-1)$ and $q \in \delta(p,a)$.*

Procedure Compute_IMS(G, k)
(//G is a finite state transition graph which is defined as $G = (A, Q, \delta, q_{st}, F)$.
This procedure computes IMS of order k of all states in G. //)
for each state $q \in Q$ let $IMS(q, 0) = \{\epsilon\}$;
for $i = 1$ to k **do**
for each state $q \in Q$ **do**
if q is the start state **then** let $IMS(q, i) = \{\epsilon\}$
else let $IMS(q, i) = \emptyset$;
for $i = 1$ to k **do**
begin
for each state $q \in Q$ **do**
if $q \in \delta(p, a)$, for some $p \in Q$ and $a \in A$, **then**
for each $x \in IMS(p, i-1)$ put xa in $IMS(q, i)$;
end;

FIG. 3. *Algorithm for computing IMS.*

DEFINITION 3.3 (monomial state, monomial automaton). *A state q is monomial with respect to string x, if $x \notin IMS(q, |x|)$ or x is the only IMS of length $\leq |x|$ of q, i.e., $\{x\} = IMS(q, |x|)$. An automaton is monomial w.r.t. string x if every state of the automaton is monomial w.r.t. x. An automaton is monomial of order k if every state of the automaton is monomial w.r.t. every string of length k.*

If a state q of an automaton is not monomial w.r.t. a string x, we can transform the automaton to an equivalent one such that the state is monomial w.r.t. x. Appendix A shows an algorithm for monomializing a state transition graph G w.r.t. a string x. (For now, ignore statements 5 and 11 which are for algorithm $SPLICE$ in Appendix B to block splitting "merged" transitions. We will be back to this later in section 4.)

The basic idea is state splitting. Let $x = a_1 a_2 \dots a_n$, $n \geq 1$, and $x_i = a_1 a_2 \dots a_i$, with $x_0 = \epsilon$. By definition, the graph G is monomial w.r.t. the null string ϵ. Suppose that G is monomial w.r.t. string x_i, $i < n$. If a state q is not monomial w.r.t. a string $x_i a_{i+1}$, then the algorithm splits q into two equivalent states, say q_1 and q_2, such that $IMS(q_1, i+1) = \{x_i a_{i+1}\}$ and $x_i a_{i+1} \notin IMS(q_2, i+1)$. Figure 4 shows an example of monomializing a graph w.r.t. string *aaaa*. Notice that state q in part (a) of the figure, which is not monomial w.r.t. string *aaaa*, is split into two together with its ancestors along the path (of shaded nodes) which has span *aaaa*.

LEMMA 3.4. *Let M be an automaton with n states and alphabet size c. Automaton M can be monomialized to order k by increasing the number of states to no more than nc^{k+1}.*

Proof. By Definition 3.1, for a state q, we have

$$|IMS(q,k)| \leq c^k + c^{k-1} + \cdots + c^0 = \frac{c^{k+1} - 1}{c - 1} \leq c^{k+1}.$$

Hence, by splitting each state into no more than c^{k+1} equivalent states we can monomialize the automaton to order k. The resulting automaton will have no more than nc^{k+1} states. □

DEFINITION 3.5 (see [8]). *For a string $x \in A^*$ and a nonnegative integer k, define*

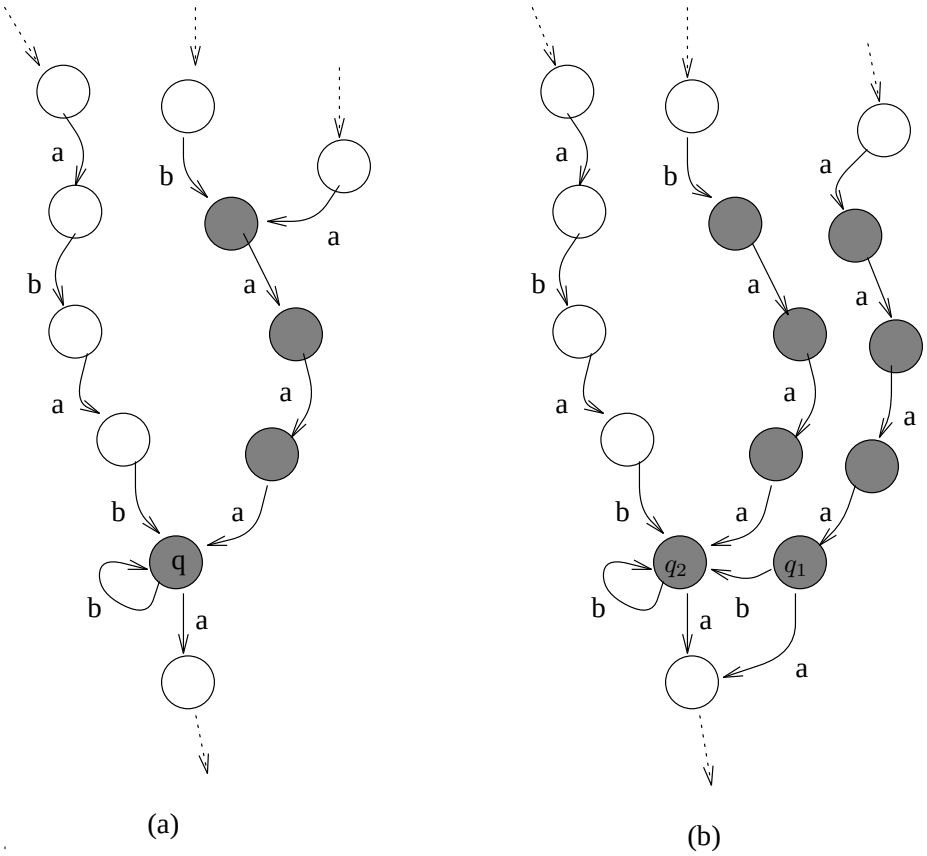

FIG. 4. *Monomializing state q w.r.t. string aaaa.*

$f_k(x)$*: the prefix of* x *of length* k*,*
$t_k(x)$*: the suffix of* x *of length* k*, and*
I_{k+1}*: the set of all substrings of* x *of length* $k+1$*.*

A language $L \subseteq A^*$ *is* $(k+1)$*-testable in strict sense* ($(k+1)$*-LTSS*) *if and only if there exists finite sets* α*,* β*, and* γ *such that*

$$x \in L \Longleftrightarrow (f_k(x) \in \alpha) \bigwedge (t_k(x) \in \gamma) \bigwedge (I_{k+1}(x) \subseteq \beta).$$

A language is strictly locally testable (or locally testable in the strict sense, or LTSS) if it is $(k+1)$*-LTSS for some* $k \geq 0$*.*

In other words, a language is $LTSS$ if its membership of a string x can be decided by inspecting the substrings of x of some constant length. It is irrelevant to the order of appearance of the substrings and other global properties of the string. An automaton is $LTSS$ if its language is $LTSS$. Theorem 3.6 below shows a simple necessary and sufficient condition that the state transition graph of a reduced deterministic finite automaton should have if it is $LTSS$.

In [5], it is shown that the languages generated by persistent splicing systems are strictly locally testable if the initial set I is finite. This proof was based on an algebraic property of locally testable languages. In section 5 we will give another proof of this fact by showing that the automaton constructed in section 4 is strictly

locally testable. For the proof we use the following property of the state transition graphs of strictly locally testable automata that we introduced in [6].

THEOREM 3.6 (see [6]). *Let $M = (Q, A, \delta, q_{st}, F)$ be a deterministic finite state automaton which is reduced. The language $L(M)$ is LTSS if and only if there is no pair of distinct states $p, q \in Q$ which are not dead state and $w \in A^+$ such that $\delta(p, w) = p$ and $\delta(q, w) = q$.*

In other words, an automaton is not $LTSS$ if its state transition graph has two distinct looping paths with the same span. For example, Figure 5(a) shows an automaton which violates Theorem 2.5 in two cases: one is $\delta(r, 0) = r$ and $\delta(q, 0) = q$, and the other is $\delta(p, 011) = p$ and $\delta(q, 011) = q$. The automaton in Figure 5(b) is $LTSS$.

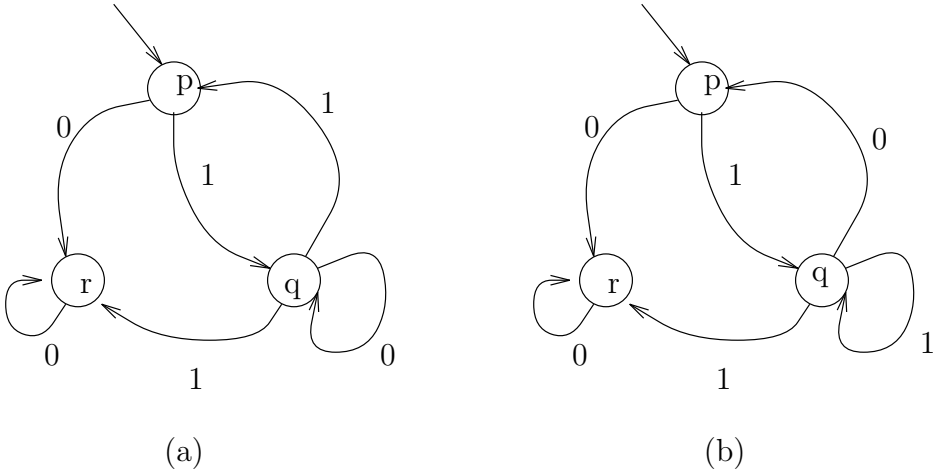

FIG. 5. (a) *An automaton which is not LTSS*; (b) *an LTSS automaton.*

If the state transition graph of a nondeterministic automaton does not have two identical looping paths, then it is $LTSS$ because its reduced deterministic version of the state transition graph will also have no such looping paths as we now prove.

LEMMA 3.7. *Let $M = (Q, A, \delta, q_{st}, F)$ be a nondeterministic automaton having the property that, for all $p, q \in Q$ and a string $x \in A^+$, if $p \in \delta(p, x)$ and $q \in \delta(q, x)$, then $p = q$. Then the language $L(M)$ is LTSS.*

Proof. Let $n = |Q|$. Assuming the hypothesis of the lemma, we note that, for all $w_1, w_2 \in A^*$ and $y \in A^+$ such that both $\delta(q_{st}, w_1 y^n)$ and $\delta(q_{st}, w_2 y^n)$ are defined, string $w_1 y^i w_3 \in L(M)$ if and only if $w_2 y^i w_3 \in L(M)$ for all $i \geq n$.

Let $M' = (Q', A, \delta', q'_{st}, F')$ be the reduced deterministic version of M. For a pair of nondead states $p', q' \in Q'$ and $y \in A^+$, suppose that $\delta'(p', y) = p'$ and $\delta'(q', y) = q'$. Let $w_1, w_2 \in A^*$ such that $\delta(q'_{st}, w_1) = p'$ and $\delta(q'_{st}, w_2) = q'$. In the nondeterministic automaton M, both $\delta(q_{st}, w_1 y^n)$ and $\delta(q_{st}, w_2 y^n)$ should be defined. Hence, for all $w_3 \in A^*$ and $i \geq n$, string $w_1 y^i w_3 \in L(M)$ if and only if $w_2 y^i w_3 \in L(M)$. It follows that string $w_1 y^i w_3 \in L(M')$ if and only if $w_2 y^i w_3 \in L(M')$, which implies that, for all $w_3 \in A^*$, $\delta(p', w_3)$ is in an accepting state if and only if $\delta(q', w_3)$ is. This implies that $p' = q'$. By Theorem 3.6, $L(M)$ is $LTSS$. ∎

We can easily extend Lemma 3.7 as follows.

LEMMA 3.8. *Let $M = (Q, A, \delta, q_{st}, F)$ be a nondeterministic automaton. The language $L(M)$ is LTSS if for every pair of identical looping paths corresponding to $p \in \delta(p, w)$ and $q \in \delta(q, w)$, for some $p, q \in Q$ and $w \in A^+$ in the transition graph,*

the looping paths have a common state r such that $r \in \delta(p, w_1)$ and $r \in \delta(q, w_1)$ for some prefix w_1 of w.

Proof. Let $w = w_1 w_2$. Since $r \in \delta(r, w_2 w_1)$, the two looping paths can be merged into a single looping path without affecting the language of the automaton. Let M' be the resulting automaton. By Lemma 3.7 $L(M')$ is $LTSS$. □

4. Constructing an automaton for a splicing system. This section describes an algorithm *CONSTRUCT* which, given a splicing system $S = (A, I, B, C)$, constructs the finite state transition graph of an automaton whose language is $L(S)$. Appendix B shows a high level description of the algorithm. We assume that I is regular which is given in terms of the finite state transition graph G of an automaton which recognizes I. Graph G is iteratively modified by subroutine *SPLICE* which merges and links certain states until no such modifications are possible.

Let G_i, $i \geq 1$, be the graph that results from ith iteration of the algorithm with $G_0 = G$. For each pattern (u, x, v), subroutine $SPLICE$ modifies G_i in three major steps in each iteration: state monomialization and merging in step I, linking in step II, and state collapsing in step III. In steps I(1) and I(2) the algorithm monomializes graph G w.r.t. uxv using algorithm $Monomialize$ in Appendix A which was described in section 3. Note that by statements 5 and 11 of the algorithm, if a state q has incoming transitions which are marked as "merged" by step I-5 of algorithm $SPLICE$, those "merged" transitions are kept merged either in q_1 or q_2 depending on whether q_1 has a marked incoming transition or not. Figure 6 shows what will happen if the graph in Figure 5 is monomialized w.r.t. string *aaaa* with both of the incoming transitions (thick edges) to the dark-colored state marked as "merged."

For a pattern (u, x, v) of system S, let $Q(uxv)$ denote the set of states p whose IMS of length $|uxv|$ contains uxv, i.e., $uxv \in IMS(p, |uxv|)$, after the monomialization step. Let $Q(ux, v)$ denote the set of states q such that $ux \in IMS(q, |ux|)$ and $r \in \delta(q, v)$ for a state $r \in Q(uxv)$. In step I the algorithm finds $Q(uxv)$ and $Q(ux, v)$ for each pattern (u, x, v) and merges all states in $Q(uxv)$ into a single state, which we will denote by $MQ(uxv)$, and marks all converged transitions as "merged" (by step I(5)). These "merged" transitions will be kept merged on a common state throughout the computation.

In step II the algorithm constructs a link with span v' from every state in $Q(ux, v)$ to state $MQ(u'xv')$ for every pattern (u', x, v') of the same hand with the same crossing as that of pattern (u, x, v). We call states in $Q(ux, v)$ *link sources* and the state $MQ(u'xv')$ *link destination*. Note that links are not marked as "merged", though they end at a merged state. Figure 7 illustrates merging and linking operations for sites uxv and $u'xv'$, where highlighted nodes are merged states whose incoming transitions corresponding to the solid edges will be marked as "merged."

Step III collapses equivalent states that meet certain conditions. This step is needed to guarantee that the graph does not grow indefinitely. We will go back to this step for further details after Lemma 4.4.

Figure 8 shows an example of constructing an automaton which recognizes the language generated by splicing system $S = (A, I, B, C)$, where $A = \{a, b\}$, $I = \{baa, aaba, bb\}$, $B = \{(b, a, a), (a, a, b), (ba, b, a), (\epsilon, b, b)\}$, and $C = \emptyset$. Part (a) of the figure is the state transition graph which recognizes I, part (b) is the result of processing sites (b, a, a) and (a, a, b), and part (c) is the final graph after processing sites (ba, b, a) and (ϵ, b, b). Notice that the highlighted state in part (b) is split into two in part (c) by monomialization step. We leave it for the reader to show that the language of the automaton is $L(S) = \{baa, aaba, bb, aaa, baba, babb, ba\}$.

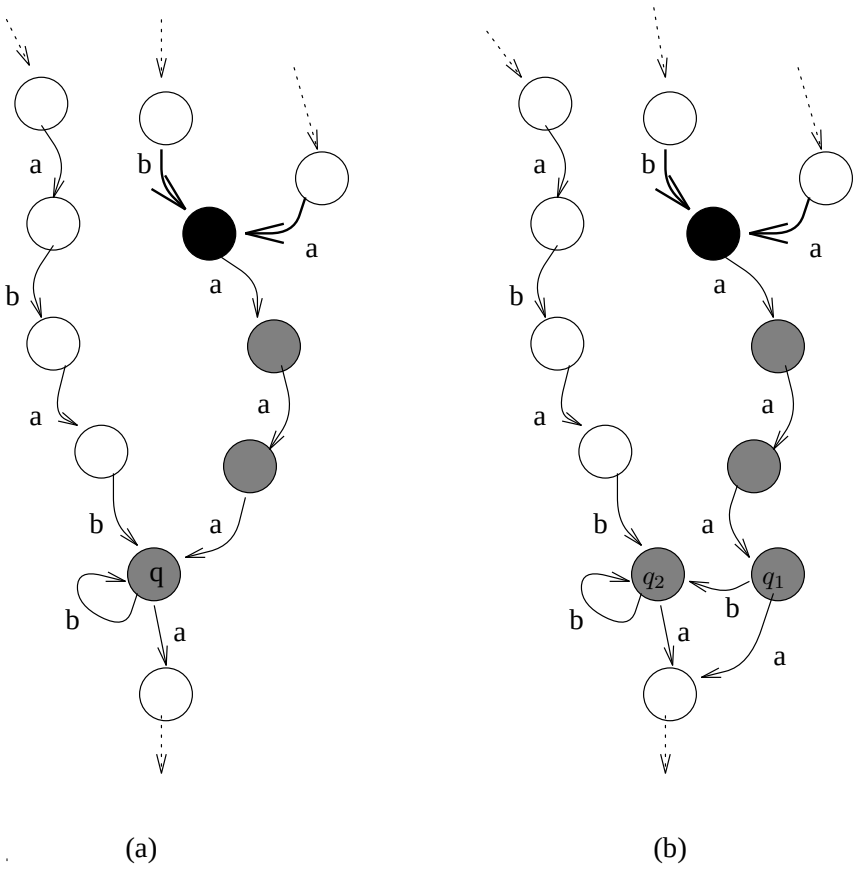

FIG. 6. *State splitting to monomialize state q w.r.t. aaaa.*

Now, we study algorithm $CONSTRUCT$ and develop several lemmas that will be used in section 5 where we will prove that if G is the output of the algorithm then $L(G) = L(S)$. We first present the main theorem of this section which proves that algorithm $CONSTRUCT$ terminates under the presumption of finiteness of G_i, which will be ascertained by Lemma 4.7.

THEOREM 4.1. *If the size of the graph G_i is finite for all $i \geq 0$, then there exists a k such that $L(G_k) = L(G_{k+1})$ and algorithm $CONSTRUCT$ terminates after $(k+1)$st iteration.*

Proof. Suppose that the algorithm does not terminate. This implies that during each iteration subroutine $SPLICE$ finds $|Q(uxv)| > 1$ for some pattern (u, x, v). Since the size of the automaton is finite, it should be that $G_i = G_j$, for some $j > i \geq 0$, possibly with different labels on states. Suppose that in jth iteration it was found that $|Q(uxv)| > 1$, and all the states in $Q(uxv)$ have been merged into one state by step I(5) of algorithm $SPLICE$. Then, in ith iteration, the same states in $Q(uxv)$ should have been merged into a state with all the converged transitions to that state marked as "merged" by step I(5) of algorithm $SPLICE$. Since "merged" transitions to a state are kept in a common state (by statements 5 and 11 of algorithm *Monomialize*), algorithm $SPLICE$ should have $|Q(uxv)| = 1$ in jth iteration. We are in a contradiction. It follows that in jth iteration every nonempty set $Q(uxv)$

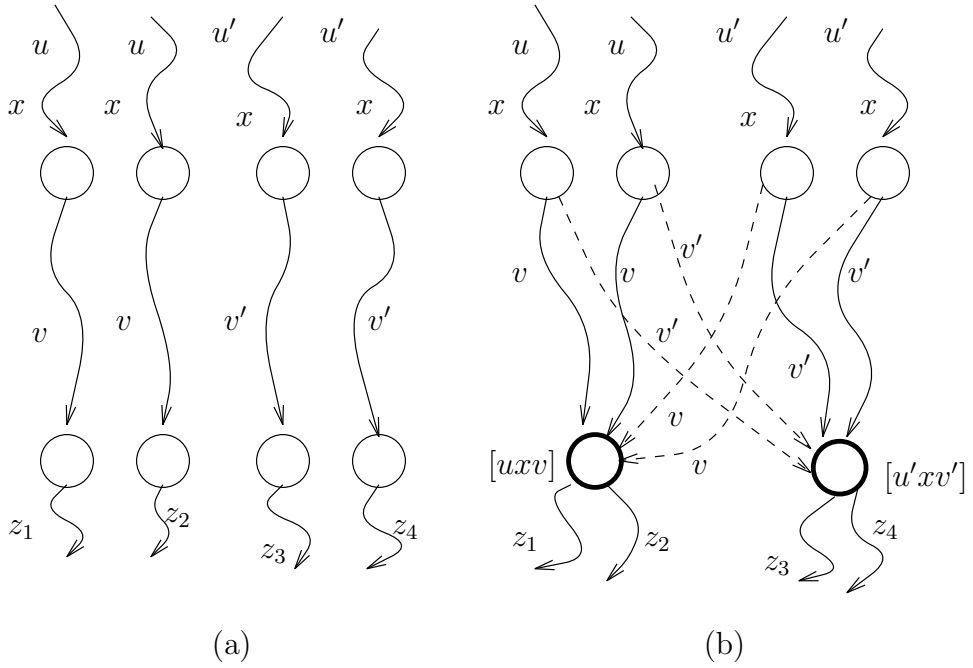

FIG. 7. *Merging and linking.*

should have only one element whose incoming transitions have been merged in previous iteration. No state merging or linking will occur in this iteration and the graph does not change, causing the algorithm to terminate in the next iteration. We take $i = k$ for the theorem. □

For a string w, by $SF(w)$ we denote the set of suffixes of w. Let p and q be two states. By I_{pq} we denote the set of spans which start from p and end at q. By F_p and T_p we, respectively, denote the set of spans that start from q_{st} and end in p and the set of spans that start from p and end at an accepting state. Formally,

$F_p = \{w \mid w \in A^*, p \in \delta(q_{st}, w)\}$,
$T_p = \{w \mid w \in A^*, r \in \delta(p, w), r \in F\}$,
$I_{pq} = \{w \mid w \in A^*, q \in \delta(p, w)\}$.

LEMMA 4.2. *Let p be a state in $Q(uxv)$ which is not monomial w.r.t. a site uxv after the monomialization step (i.e., step* (I-2)*) of algorithm SPLICE. For every span $w \in F_p$, if $uxv \notin SF(w)$, then there exists a span $\hat{w} \in F_p$ which satisfies the following conditions:*

(a) *$uxv \in SF(\hat{w})$,*
(b) *$w = w_1u'x'v'y$ and $\hat{w} = \hat{w}_1u'x'v'y$, for some $w_1, \hat{w}_1, y \in A^*$ and a site $u'x'v'$, such that $w_1u'x'v', \hat{w}_1u'x'v' \in F_r$, for a state r.*

Proof. If there is no string $\hat{w}$ that satisfies condition (a), then $uxv \notin IMS(p, |uxv|)$ and state p is monomial w.r.t. uxv by Definition 3.3. We are in a contradiction. Suppose that w and $\hat{w}$ do not satisfy condition (b) of the lemma. Then by algorithm *Monomialize*, state r and all its descendents up to p along the path corresponding to $p \in \delta(r, y)$ should have been split, with p split into two equivalent states p_1 and p_2 which are monomial w.r.t. string uxv. It follows that no such state p can be in $Q(uxv)$ that is not monomial w.r.t. string uxv. Again, we are in a contradiction. □

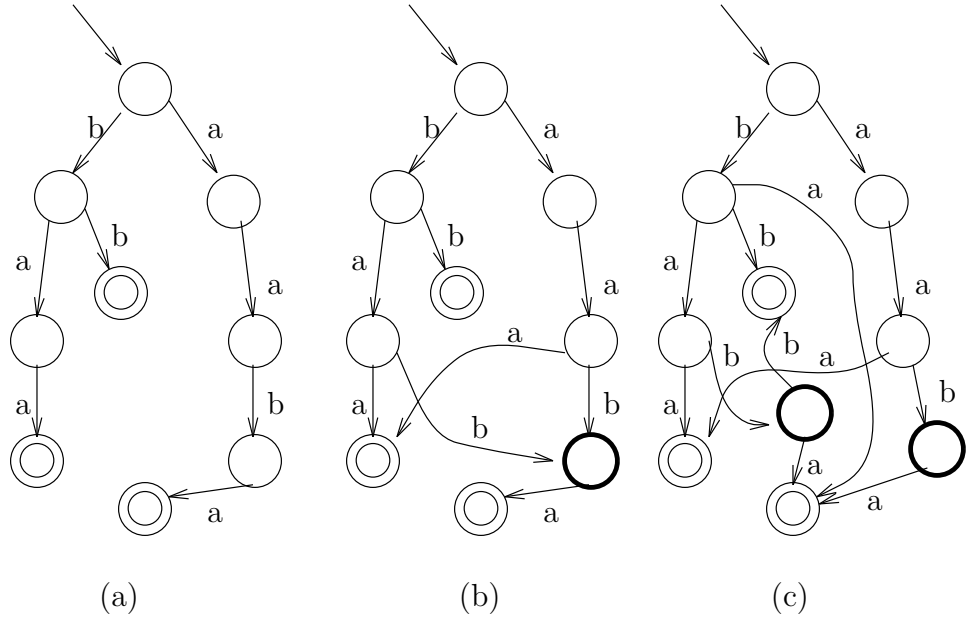

FIG. 8. *Constructing an automaton for* $S = (A, I, B, C)$, *where* $A = \{a, b\}$, $I = \{baa, aaba, bb\}$, $B = \{(b, a, a), (a, a, b), (ba, b, a), (\epsilon, b, b)\}$ *and* $C = \emptyset$.

Actually, condition (b) of Lemma 4.2 implies that both of the last transitions of $r \in \delta(q_{st}, w_1u'x'v')$ and $r \in \delta(q_{st}, \hat{w}_1u'x'v')$ have mark "merged" given by algorithm $SPLICE$ when it computed $Q(u'x'v')$ and merged the set into a state. Consequently, monomializing the graph w.r.t. string uxv, algorithm *Monomialize* should have kept both of these marked transitions merged at state r. (Recall statements 5 and 11 of algorithm *Monomialize* and Figure 6.) Similarly, the following lemma holds.

LEMMA 4.3. *Let* p *be a state in* $Q(ux, v)$ *which is not monomial w.r.t.* ux *after the monomialization step (i.e., step* I(2)*) of algorithm* $SPLICE$ *for site* uxv. *For every span* $w \in F_p$, *if* $ux \notin SF(w)$, *then there exists a span* $\hat{w} \in F_p$, *not necessarily distinct from* w, *which satisfies the following conditions:*

(a) $ux \in SF(\hat{w})$,
(b) $w = w_1u'x'v'y$ *and* $\hat{w} = \hat{w}_1u'x'v'y$, *for some* $w_1, \hat{w}_1, y \in A^*$ *and a site* $u'x'v'$, *such that both* $w_1u'x'v', \hat{w}_1u'x'v' \in F_r$, *for a state* r.

Clearly, if w is an accepting span of G_i, it will remain as an accepting span, possibly of a different path, after monomialization and merging in step I, linking in step II, and link merging in step III. Hence, we have the following.

LEMMA 4.4. *For a string* $w \in A^*$, *if* $w \in L(G_i)$, *then* $w \in L(G_{i+1})$.

Now, we are ready to show that the size of graph G_i is bounded by some constant factor of the size of the input G_0. By Lemma 3.4, monomializing G_0 increases its size by no more than a constant factor. Clearly, merging does not increase the graph size. Linking introduces new paths and consequently increases the graph size. If one of the states on the links becomes a link source which in turn introduces new links, recursively inducing an unbounded number of links, the graph may grow unbounded and the algorithm will not terminate. Figure 9(a) illustrates this possibility, where the highlighted node is a link destination $MQ(u_0xv_0)$, and link sources in $Q(u_1x, v_1)$ are labeled by $[u_1x]$. (In the figure only one link with span v_0 is shown from each link

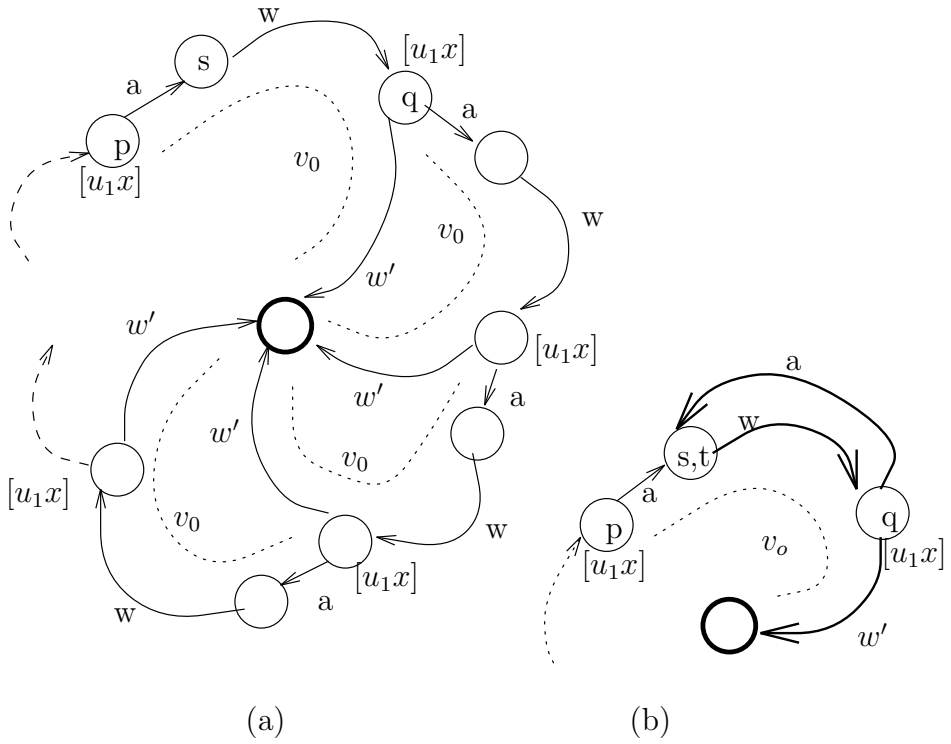

FIG. 9. *Link recurrence and link merging.*

source to the link destination.)

We solve this problem by merging those links whose link sources have the same input memory spans of order equal to the length of the longest site of the system. Part (b) of Figure 9 illustrates the result of this merging operation on part (a) of the figure.

Let $p, q \in Q(u_1x, v_1)$ and $r = MQ(u_0xv_0)$ in G_i, and in step II the algorithm has put links with span v_0 from p to r and q to r. Let s and t be the first states on these links as shown in Figure 9(a). (Note that in the figure $v_0 = aww'$, where a, w, w' are, respectively, the spans on p to s, s to q, and q to r paths.) If we can show that s and t are equivalent in the output graph of algorithm CONSTRUCT, we can merge them and their successors pairwise.

Notice that if neither s nor t is an ancestor of the other, they are equivalent in G_i. However, if a state on either p to r link or q to r link (not both) is later merged into (or linked to) other state, s and t can no longer be equivalent. This is possible because the states on p to r link may have different input memory spans from those of states on q to r link. If t is a descendant of s on identical links that will be recursively generated an unbounded number of times as shown in Figure 9(a), we can also merge s and t and their successors pairwise because $T_s = T_t = w(aw)^*w'T_r$. The following lemma formally presents this idea, which is implemented by step III of algorithm *SPLICE*.

LEMMA 4.5. *Let $r = MQ(u_0xv_0)$ and $p, q \in Q(u_1x, v_1)$ for some sites u_0xv_0 and u_1xv_1 of the same hand. Let k be the length of the longest possible site of the system. If $IMS(p, k) = IMS(q, k)$, then we can merge the two links from p to r and from q*

to r, excluding p and q, into a single link without affecting the language of the output graph from algorithm CONSTRUCT.

Proof. Let $ps_0s_1 \dots s_n$ be p to r link and $qt_0t_1 \dots t_n$ be q to t link, where $s_n = t_n = r$. Since $IMS(p,k) = IMS(q,k)$, for a site $u'x'v'$, state s_i is in $Q(u'x', v')$ if and only if t_i is in $Q(u'x', v')$, and s_i is in $Q(u'x'v')$ if and only if t_i is in $Q(u'x'v')$. Hence, if s_i is merged into (or linked to) a state, t_i will be merged into (or linked to) the same state. States s_i and t_i remain equivalent throughout the computation. We can merge the two links by collapsing s_i and t_i pairwise, for all i, $0 \le i \le n$, without affecting the language of the graph. □

LEMMA 4.6. *If I is given in terms of a finite state transition graph G_0, then, for every $i \ge 0$, the number of linking states in G_i is finite.*

Proof. Let $c = |A|$, and let k_1 and k_2, respectively, be the length of the longest possible site of the splicing system and the length of the longest link. After step III no two separate links exist from a pair of link sources p and q which are linked to the same destination with the property that $IMS(p, k_1) = IMS(q, k_1)$. Let $\mu = c^{k_1+1}$, which is the largest possible size of the set of IMS of a state (recall the proof of Lemma 3.4). There are no more than 2^μ different sets of input memory spans of length $\le k_1 + 1$. Hence, there are no more than 2^μ separate links in G_i that link to the same merged state. There are no more than $k_2 - 1$ states on a link, and at most $|B| + |C|$ merged states exist in G_i. It follows that G_i has $(k_2 - 1)(|B| + |C|)2^\mu$ linking states, which is finite. □

LEMMA 4.7. *If I is given in terms of a finite state transition graph G_0, then G_i is finite for all $i \ge 0$.*

Proof. By Lemma 3.4 monomializing G_0 increases the graph size by no more than a constant factor of the graph size. By Lemma 4.6, the total number of states introduced by linking is also no more than a constant factor of the given graph size. If a link is introduced from a link source p to a link destination q, the IMS of q and its descendents may change, and, consequently, monomialization during the subsequent iterations of the algorithm may increase the number of states. However, monomialization introduces no more than k_1 states per link introduced, where k_1 is the maximum site length of the system. Since the number of links is finite, throughout the computation, the number of states introduced by monomialization is also finite. □

5. Characterization theorem. This section proves a characterization of genetic splicing systems in terms of an automaton by showing that for a given splicing system S, the automaton generated by algorithm $CONSTRUCT$ recognizes the language $L(S)$. In particular, we prove the following three main theorems of the paper.

THEOREM 5.1. *Let G be the output graph from algorithm CONSTRUCT for a splicing system $S = (A, I, B, C)$ with I given in terms of the state transition graph of an automaton whose language is I. Then $L(G) = L(S)$.*

Proof. Lemmas 5.9 and 5.10 will, respectively, prove that $L(G) \subseteq L(S)$ and $L(S) \subseteq L(G)$. □

Since I is given in terms of the finite state transition graph of an automaton whose language is I, Theorem 5.1 implies a constructive proof of the following theorem which was proved in [1] using alphabetic dominos.

THEOREM 5.2. *Let $S = (A, I, B, C)$ be a splicing system. If I is regular, so is $L(S)$.*

THEOREM 5.3. *Let $S = (A, I, B, C)$ be a splicing system with finite I. If S is persistent, then $L(S)$ is LTSS.*

Proof. We defer the proof till we prove Lemma 5.11.

To prove Theorem 5.1, we first investigate how each step of algorithm $SPLICE$ affects the language $L(G_i)$. The algorithm has four operations that may affect the language: monomialization (step I(2)), state merging (step I(5)), linking (step II(2)), and link merging (step III). State monomialization and link merging do not affect the language because the one splits a state into equivalent states and the other merges equivalent states that will remain equivalent throughout the computation. By the following two lemmas we shall investigate the effect of state merging and linking operations.

LEMMA 5.4. *For a pattern (u, x, v) of a splicing system S, let G' be the resulting graph after merging the states in $Q(uxv)$ of a graph G to a single state $MQ(uxv)$ in step* I(5) *of algorithm $SPLICE$. If $L(G) \subseteq L(S)$, then $L(G') \subseteq L(S)$.*

Proof. Let $p, q \in Q(uxv)$. Clearly, all accepting spans that are introduced by merging p and q are in the following set $(F_p + F_q)(I_{pq} + I_{qp})^*(T_p + T_q)$. (Recall the notation of F_p, T_p, and Ipq from section 4.) No other spans are affected by the operation. Hence, for the proof it is enough to show the following:

$$(F_p + F_q)(I_{pq} + I_{qp})^*(T_p + T_q) \subseteq L(S).$$

Let $w \in F_p$, $w' \in F_q$, $z \in T_p$, $z' \in T_q$, and $y_k y_{k-1} \dots y_1 \in (I_{pq} + I_{qp})^*$, for some $k \geq 0$, where y_i is either in I_{pq} or in I_{qp}. Let $Y_{ki} = y_k y_{k-1} \dots y_i$, $Y_{ii} = y_i$, and $Y_{0i} = \epsilon$. For the proof it is enough to show that, for all $k \geq 0$,

$$(w + w')Y_{k1}(z + z') \subseteq L(S).$$

We show this by induction on k. Since $p \in Q(uxv)$, by Lemma 4.2, for every $w \in F_p$, if $uxv \notin SF(w)$, there exists $\hat{w} \in F_p$ such that $uxv \in SF(\hat{w})$, $\hat{w} = \hat{w}_1 u_1 x_1 v_1 y$ and $w = w_1 u_1 x_1 v_1 y$ for some $\hat{w}_1, w_1, y \in A^*$ and a site $u_1 x_1 v_1$. The same property holds for every string $w' \in F_q$.

For any pair of strings $w \in F_p$ and $w' \in F_q$, find $\hat{w} \in F_p$ and $\hat{w}' \in F_q$ such that $uxv \in SF(\hat{w})$, $uxv \in SF(\hat{w}')$, $w = w_1 u_1 x_1 v_1 y$, $\hat{w} = \hat{w}_1 u_1 x_1 v_1 y$, $w' = w'_2 u_2 x_2 v_2 y'$, and $\hat{w}' = \hat{w}'_1 u_1 x_1 v_1 y$. Since $wz, \hat{w}z, w'z', \hat{w}'z' \in L(G)$, by the hypothesis of the lemma we have $wz, \hat{w}z, w'z', \hat{w}'z' \in L(S)$. With $\hat{w}z = \hat{w}_0 uxvz$ and $\hat{w}'z' = \hat{w}'_0 uxvz'$, the system generates $\hat{w}z'$ and $\hat{w}'z$ as follows:

$$\hat{w}_0 \underline{uxv} z \not\rightarrow \hat{w}'_0 \underline{uxv} z' = \hat{w}_0 uxvz' = \hat{w}z',$$

$$\hat{w}'_0 \underline{uxv} z' \not\rightarrow \hat{w}_0 \underline{uxv} z = \hat{w}'_0 uxvz = \hat{w}'z.$$

It follows that

$$(\hat{w} + \hat{w}')(z + z') \subseteq L(S).$$

With $wz = w_1 u_1 x_1 v_1 yz$ and $\hat{w}(z + z') = \hat{w}_1 u_1 x_1 v_1 y(z + z')$, the system generates all strings in $w(z + z')$ as follows:

$$w_1 \underline{u_1 x_1 v_1} yz \not\rightarrow \hat{w}_1 \underline{u_1 x_1 v_1} y(z + z') = w_1 u_1 x_1 v_1 y(z + z') = w(z + z').$$

Likewise, with $w'z = w'_1 u_2 x_2 v_2 y'z$ and $\hat{w}'(z + z') = \hat{w}'_1 u_2 x_2 v_2 y'(z + z')$ the system produces $w'(z + z')$ as follows:

$$w'_1 u_2 x_2 v_2 y' z \not\rightarrow \hat{w}'_1 u_2 x_2 v_2 y'(z + z') = w'_1 u_2 x_2 v_2 y(z + z') = w'(z + z').$$

It follows that for all $w \in F_p$, $w' \in F_q$, $z \in T_p$, and $z' \in T_q$,

$$(w + w')(z + z') = (w + w')Y_{01}(z + z') \subseteq L(S).$$

Now, suppose that $(w + w')Y_{i1}(z + z') \subseteq L(S)$, for all i, $0 \leq i < k$. If $y_{i+1} \in I_{pq}$, clearly, $wy_{i+1} \in F_q$ and hence, by Lemma 4.2 there exists $\hat{w}' \in F_q$ such that $uxv \in SF(\hat{w}')$, $wy_{i+1} = w_{i+1}u_1x_1v_1y$ and $\hat{w}' = \hat{w}'_1u_1x_1v_1y$, for some $w_{i+1}, \hat{w}'_1, y \in A^*$ and a site $u_1x_1v_1$. Since $wy_{i+1}z' \in L(G)$, by the hypothesis of the lemma we have $wy_{i+1}z' \in L(S)$. By the induction hypothesis we have $\hat{w}'Y_{i1}(z + z') \subseteq L(S)$. With $wy_{i+1}z' = w_{i+1}u_1x_1v_1yz'$ and $\hat{w}'Y_{i1}(z + z') = \hat{w}'_1u_1x_1v_1yY_{i1}(z + z')$ the system generates all strings in $wY_{(i+1)1}(z + z')$ as follows:

$$\begin{aligned} &w_{i+1}\underline{u_1x_1v_1}yz' \not\rightarrow \hat{w}'_1\underline{u_1x_1v_1}yY_{i1}(z + z') \\ &\quad = w_{i+1}u_1x_1v_1yY_{i1}(z + z') = wy_{i+1}Y_{i1}(z + z') = wY_{(i+1)1}(z + z'). \end{aligned}$$

If $y_{i+1} \in I_{qp}$, then $w'y_{i+1} \in F_p$ and $w'y_{i+1}z \in L(G)$. Applying the same argument above with the roles of p and q (and w and w') interchanged, we can show that the system generates $w'Y_{(i+1)1}(z + z')$. It follows that

$$(w + w')Y_{(i+1)1}(z + z') \subseteq L(S),$$

which implies that $(w + w')Y_{k1}(z + z') \subseteq L(S)$ for all $k \geq 0$. □

Lemma 5.4 is concerned with one merging operation in step I(5) of the algorithm. Obviously, we can extend the lemma for a sequence of merging operations as follows.

LEMMA 5.5. *Let G' be the resulting graph when step* I *of algorithm SPLICE completes its merging operation on G for all sites. If $G \subseteq L(S)$, then $L(G') \subseteq L(S)$.*

LEMMA 5.6. *For two distinct patterns of the same hand (u, x, v) and $(u'xv')$, which have the same crossing, let $p \in Q(ux, v)$ and $q = MQ(u'xv')$ in a graph G. Let G' be the graph that is constructed from G by linking a path from p to q with span v' in step* II *of algorithm SPLICE. If $L(G) \subseteq L(S)$, then $L(G') \subseteq L(S)$.*

Proof. Let $r = MQ(uxv)$. Figure 10 illustrates the effect of the linking operation. We first consider the case $I_{qp} = \emptyset$. Clearly, adding p to q path with span v' in G will result in adding the set $F_pv'T_q$ to $L(G)$. Let $w \in F_p$ and $z' \in T_q$. We will show that $wv'z' \in L(S)$. Let $z \in T_r$ and $\hat{w}' \in F_q$ such that $\hat{w}' = \hat{w'}_0u'xv'$. Notice that, since q is a merged state, such $\hat{w'}$ exists by Lemma 4.2. Since $wvz, \hat{w}'z' \in L(G)$, by the hypothesis of the lemma we have $wvz, \hat{w}'z' \in L(S)$. Since $p \in Q(ux, v)$, by Lemma 4.3, there exists $\hat{w} \in F_p$ such that $ux \in SF(\hat{w})$ (i.e., $\hat{w} = w_0ux$ for some $w_0 \in A^*$), $w = w_1u_1x_1v_1y$ and $\hat{w} = \hat{w}_1u_1x_1v_1y$ for some $w_1, \hat{w}_1, y \in A^*$ and a site $u_1x_1v_1$. Since $\hat{w}vz \in L(G)$, we have $\hat{w}vz \in L(S)$.

With $\hat{w}vz = \hat{w}_0uxvz$ and $\hat{w}'z' = \hat{w}'_0u'xv'z'$ the system produces $\hat{w}v'z'$ as follows:

$$\hat{w}_0\underline{uxv}z \not\rightarrow \hat{w}'_0\underline{u'xv'}z' = \hat{w}_0uxv'z' = \hat{w}v'z'.$$

With $\hat{w}v'z' = \hat{w}_1u_1x_1v_1yv'z'$ and $wz = w_1u_1x_1v_1yz$, the system generates $w_1u_1x_1v_1yv'z' = wv'z'$ as follows:

$$w_1\underline{u_1x_1v_1}yz \not\rightarrow \hat{w}_1\underline{u_1x_1v_1}yv'z' = w_1u_1x_1v_1yv'z' = wv'z'.$$

It follows that $F_pv'T_q \subseteq L(S)$, which implies $L(G') \subseteq L(S)$.

Now, suppose that $I_{qp} \neq \emptyset$. Adding a p to q link induces a cycle as Figure 10 shows. For the proof we examine how the set of strings in $F_pT_p + F_qT_q$ will be affected

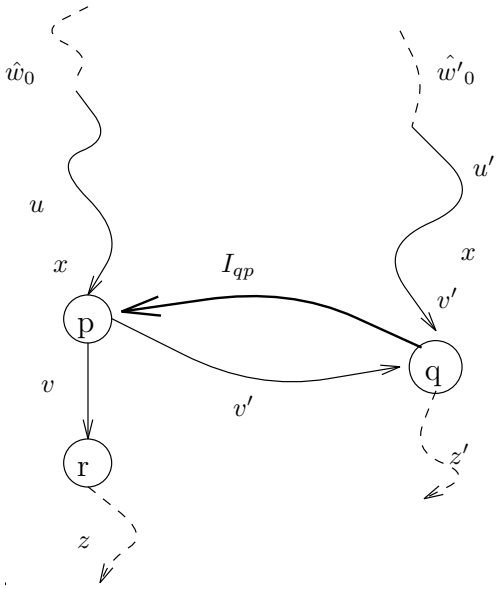

FIG. 10. *Linking from p to q with span v′.*

when the algorithm adds p to q path with span v'. Notice that F_pT_p is the set of accepting spans in G that start with a string in F_p, and F_qT_q is the set of accepting spans that start with a string in F_q. The set of spans in G' that start from q and end in an accepting state is

$$T_q + I_{qp}(v'I_{qp})^*(vT_r + (v' + I_{pq})T_q).$$

Notice that $I_{qp}(v'I_{qp})^*$ denotes all spans that start from q and end in p. The second term of the above expression denotes the set of strings that start with a span in I_{qp} and end with a span in either in T_r or T_q. Let

$$R = I_{qp}(v'I_{qp})^*(vT_r + (v' + I_{pq})T_q).$$

In $L(G')$, the set of accepting spans which start with a string in F_q is $F_q(T_q + R)$, and the set of accepting spans which start with a string in F_p is $F_p(T_p + (I_{pq} + v')R)$. So, for the proof of the lemma it is enough to show that

$$F_q(T_q + R) + F_p(T_p + (I_{pq} + v')R \subseteq L(S).$$

Since $F_qT_q + F_pT_p \subseteq L(S)$ by the hypothesis of the lemma, we only need to show that

$$F_qR + F_p(I_{pq} + v')R \subseteq L(S).$$

We show this in two parts: $F_qR \subseteq L(S)$ and $F_p(I_{pq} + v')R \subseteq L(S)$.

Part I. Proof of $F_qR = F_qI_{qp}(v'I_{qp})^*(vT_r + (v' + I_{pq})T_q) \subseteq L(S)$. Let $w' \in F_q$, $y_0 \in I_{qp}$, $z \in T_r$, $z' \in T_q$ and $t \in v' + I_{pq}$. Let $Y_{k1} = v'y_kv'y_{k-1} \dots v'y_1 \in (v'I_{qp})^*$, $k \geq 0$, where $Y_{ii} = v'y_i$ and $Y_{0i} = \epsilon$, for all i, $1 \leq i \leq k$. For the proof it is enough to show the following:

$$w'y_0Y_{k1}(vz + tz') \subseteq L(S).$$

Since $w'y_0vz \in L(G)$, by the hypothesis of the lemma we have $w'y_0vz \in L(S)$. Since $w'y_0 \in F_p$ and $p \in Q(ux, v)$, by Lemma 4.3 there exists $\hat{w} \in F_p$ such that $ux \in SF(\hat{w})$, $\hat{w} = \hat{w}_1u_1x_1v_1y$, and $w'y_0 = w'_1u_1x_1v_1y$ for some $\hat{w}_1, w'_1, y \in A^*$ and a site $u_1x_1v_1$. Since $\hat{w}vz \in L(G)$, we have $\hat{w}vz \in L(S)$. Find $\hat{w}' \in F_q$ such that $u'xv' \in SF(\hat{w}')$. Since $\hat{w}'z' \in L(G)$, we have $\hat{w}'z' \in L(S)$ by the hypothesis of the lemma.

Splicing $\hat{w}vz = \hat{w}_0uxvz$ and $\hat{w}'z' = \hat{w}'_0u'xv'z'$ the system generates $\hat{w}v'z'$ as follows:

$$\hat{w}_0\underline{uxv}z \not\rightarrow \hat{w}'_0\underline{u'xv'}z' = \hat{w}_0uxv'z' = \hat{w}v'z'.$$

Let $y' \in I_{pq}$. Then $\hat{w}y'z' \in L(G)$ and by the hypothesis of the lemma $\hat{w}y'z' \in L(S)$. For an arbitrary $t \in v' + I_{pq}$, we know that $\hat{w}tz' \in L(S)$. With $\hat{w}tz' = \hat{w}_1u_1x_1v_1ytz'$ and $w'y_0vz = w'_1u_1x_1v_1yvz$, the system generates $w'y_0tz'$ as follows:

$$w'_1u_1x_1v_1yvz \not\rightarrow \hat{w}_1u_1x_1v_1ytz' = w'_1u_1x_1v_1ytz' = w'y_0tz'.$$

Since $w'y_0vz \in L(S)$, we have proved that

$$w'y_0(vz + tz') = w'y_0Y_{01}(vz + tz') \subseteq L(S).$$

Now, suppose that $w'y_0Y_{i1}(vz+tz') \subseteq L(S)$, for some i, $0 \leq i < k$. For the proof of Part I, we will show that $w'y_0Y_{(i+1)1}(vz + tz') \subseteq L(S)$.

Since y_0 is an arbitrary string in I_{qp}, obviously, $w'y_{i+1}Y_{i1}(vz+tz') \subseteq L(S)$. Since $w'y_0 \in F_p$, by Lemma 4.3 there exists $\hat{w} \in F_p$ such that $ux \in SF(\hat{w})$, $\hat{w} = \hat{w}_1u_1x_1v_1y$, and $w'y_0 = w'_1u_1x_1v_1y$ for some $\hat{w}_1, w'_1, y \in A^*$ and a site $u_1x_1v_1$.

Let $\hat{w}'$ be a string in F_q such that $u'xv' \in SF(\hat{w}')$. Clearly, $\hat{w}'y_{i+1}Y_{i1}(vz+tz') \subseteq L(S)$. Since $\hat{w}vz \in L(G)$, by the hypothesis of the lemma we have $\hat{w}vz \in L(S)$. Since $\hat{w}vz = \hat{w}_0uxvz$ and $\hat{w}'y_{i+1}Y_{i1}(vz + tz') = \hat{w}'_0u'xv'y_{i+1}Y_{i1}(vz + tz')$, the system produces $\hat{w}v'y_{i+1}Y_{i1}(vz + tz')$ by the following operation:

$$\hat{w}_0\underline{uxv}z \not\rightarrow \hat{w}'_0\underline{u'xv'}y_{i+1}Y_{i1}(vz+tz') = \hat{w}_0uxv'y_{i+1}Y_{i1}(vz+tz') = \hat{w}v'y_{i+1}Y_{i1}(vz+tz').$$

With $w'y_0vz = w'_1u_1x_1v_1yvz$ and $\hat{w}v'y_{i+1}Y_{i1}(vz+tz') = \hat{w}_1u_1x_1v_1yv'y_{i+1}Y_{i1}(vz+tz')$, finally the system produces $w'y_0Y_{(i+1)1}(vz + tz')$ by the following splicing operation:

$$w'_1\underline{u_1x_1v_1}yvz \not\rightarrow \hat{w}_1\underline{u_1x_1v_1}yv'y_{i+1}Y_{i1}(vz + tz')$$

$$= w'_1u_1x_1v_1yv'y_{i+1}Y_{i1}(vz + tz') = w'y_0Y_{(i+1)1}(vz + tz').$$

It follows that $w'y_0Y_{k1}(vz + tz') \subseteq L(S)$, for all $w' \in F_q$, $y_0 \in I_{qp}$, $z \in T_r$, $z' \in T_q$, $t \in v' + I_{pq}$, and $Y_{k1} \in (v'I_{qp})^*$. This implies that $F_qR \subseteq L(S)$.

Part II. Proof of $F_p(I_{pq}+v')R \subseteq L(S)$. Obviously, $F_pI_{pq} \subseteq F_q$. Since $F_qR \subseteq L(S)$ from Part I of the proof, we have $F_pI_{pq}R \subseteq L(S)$. Hence, for the proof it is enough to show that $F_pv'R \subseteq L(S)$. Let $w \in F_p$. We will show that $wv'R \subseteq L(S)$. Since $wvz \in L(G)$, we have $wvz \in L(S)$ by the hypothesis of the lemma. Find $\hat{w}' \in F_q$ such that $u'xv' \in SF(\hat{w}')$. From Part I we know that $\hat{w}'R \subseteq L(S)$.

If $ux \in SF(w)$, then since $wvz = w_0uxvz$ and $\hat{w}'R = \hat{w}'_0u'xv'R$, the system produces $w_0uxv'R = wv'R$ by

$$w_0\underline{uxv}z \not\rightarrow \hat{w}'_0\underline{u'xv'}R = w_0uxv'R = wv'R.$$

If $ux \notin SF(w)$, then by Lemma 4.3 there exists $\hat{w} \in F_p$ such that $ux \in SF(\hat{w})$, $\hat{w} = \hat{w}_1 u_1 x_1 v_1 y$, and $w = w_1 u_1 x_1 v_1 y$ for some $\hat{w}_1, w_1, y \in A^*$ and a site $u_1 x_1 v_1$. Since $\hat{w}vz \in L(G)$, we have $\hat{w}vz \in L(S)$. Since $\hat{w}vz = \hat{w}_0 uxvz$, the system produces all strings in $\hat{w}v'R$ as follows:

$$\hat{w}_0 \underline{uxv} z \vdash \hat{w}'_0 \underline{u'xv'} R = \hat{w}_0 uxv'R = \hat{w}v'R.$$

Finally, since $\hat{w}v'R = \hat{w}_1 u_1 x_1 v_1 y v'R$ and $wvz = w_1 u_1 x_1 v_1 y vz$, the system generates all strings in $wv'R$ by the following operation:

$$w_1 \underline{u_1 x_1 v_1} yvz \vdash \hat{w}_1 \underline{u_1 x_1 v_1} yv'R = w_1 u_1 x_1 v_1 yv'R = wv'R.$$

It follows that $F_p v'R \subseteq L(S)$. □

Lemma 5.6 is concerned with one linking operation in step II. As for the merging operation, we can extend this lemma for a sequence of linking operations.

LEMMA 5.7. *Let G' be the resulting graph processed by step* II *of algorithm SPLICE with graph G. If $L(G) \subseteq L(S)$, then $L(G') \subseteq L(S)$.*

Step III, which merges links, actually merges states that will remain equivalent throughout the computation as it was shown by Lemma 4.5. Since Step III does not change the language, we have the following.

LEMMA 5.8. *Let G' be the resulting graph processed by step* III *of algorithm SPLICE with graph G. If $L(G) \subseteq L(S)$, then $L(G') \subseteq L(S)$.*

Now, we are ready to present the two lemmas that prove Theorem 5.1.

LEMMA 5.9. *Let G be the output graph from algorithm CONSTRUCT for a splicing system $S = (A, I, B, C)$ with I given in terms of the state transition graph of an automaton whose language is I. Then $L(G) \subseteq L(S)$.*

Proof. By Lemma 4.4, if w is in $L(G_i)$, it is also in $L(G_{i+1})$. Clearly, $L(G_0) = I$. Since by definition $I \subseteq L(S)$, we have $L(G_0) \subseteq L(S)$. By Theorem 4.1 algorithm *CONSTRUCT* terminates after some finite nth iteration. Thus we have $G = G_n$. Suppose that $L(G_i) \subseteq L(S)$ for all $i < n$. By Lemmas 5.5, 5.7, and 5.8 we know that $L(G_{i+1}) \subseteq L(S)$, which implies that $L(G) \subseteq L(S)$. □

LEMMA 5.10. *$L(S) \subseteq L(G)$ for the same G and S of Lemma* 5.9.

Proof. Suppose $L(S) - L(G) \neq \emptyset$. Since $L(S)$ is spliced starting with I and $I \subseteq L(S) \bigcap L(G)$, there should be a string $w \in L(S) - L(G)$ that is generated by splicing with some strings in $L(S) \bigcap L(G)$. Let $w = w_0 x_1 w_1 x_2 w_2 \dots x_k w_k$, for some $k \geq 1$, such that x_i, $1 \leq i \leq k$ is a crossing of a pattern. (Notice that x_i is a crossing that is not necessarily embedded in a site.) This implies that $L(G)$ should have strings $w_0 x_1 z_0$, $y_1 x_1 w_1 x_2 z_1$, $y_2 x_2 w_2 x_3 z_2, \dots, y_k x_k w_k$, for some $y_i, z_j \in A^*$, $1 \leq i \leq k$, $0 \leq j \leq k-1$, such that, for each i, the two x_i's that appear in each pair of adjacent strings in the sequence are crossings which are embedded in sites of the same hand. Let $u_i x_i v_i$ and $u'_i x_i v'_i$ be those two sites that have crossing x_i.

Since $w_0 x_1 z_0, y_1 x_1 w_1 x_2 z_1 \in L(G)$, algorithm *SPLICE* should have added an accepting span $w_0 x_1 w_1 x_2 z_1$ in step I or II of the algorithm when it processed the site whose crossing is x_1. Since the graph has two spans $w_0 x_1 w_1 x_2 z_1$ and $y_2 x_2 w_2 x_3 z_2$, the algorithm should have added an accepting span $w_0 x_1 w_1 x_2 w_2 x_3 z_2$ in step I or step II of the algorithm when it processed crossing x_2, and so on. Finally, the algorithm should have added an accepting span $w_0 x_1 w_1 x_2 w_2 \dots x_k w_k$, which is w. It follows that $w \in L(G)$, a contradiction. □

In [5], it was shown that if I is finite set, $L(S)$ is strictly locally testable. We prove the same result by showing that the reduced deterministic version of M does

not have two nondead states p and q such that $\delta(p,w)=p$ and $\delta(q,w)=q$, for any $w\in A^+$, which is a necessary and sufficient condition that a reduced deterministic finite automaton must satisfy to be strictly locally testable [6]. For the proof we need the following lemma.

LEMMA 5.11. *Let y be a span of a cycle in G_i. If the system S is persistent and $|I|$ is finite, there is a constant c such that, for all $k\geq c$, string y^k contains a site.*

Proof. If $|I|$ is finite, graph G_0 has no cycle. Clearly, during the computation a new cycle will be introduced either by merging, linking, or link collapsing. More specifically, a cycle will be introduced only when there exist two states p and q such that p is an ancestor of q and either one of the following conditions is satisfied. Let uxv and $u'xv'$ be sites of the same hand and let k be the length of the longest site.

(1) $p,q\in Q(uxv)$.
(2) $p=MQ(u'xv')$ and $q\in Q(ux,v)$.
(3) $p,q\in Q(ux,v)$ such that $IMS(p,k)=IMS(q,k)$ and there exists $r=MQ(u'xv')$.

If condition (1) is satisfied, a cycle will be introduced when p and q are merged in step I of the algorithm. If condition (2) is satisfied, step II will create a cycle when it constructs a link from q to p with span v'. If condition (3) is satisfied, step III will create a cycle when it collapses the two links from p to r and from q to r, both with span v'.

Case (1). $p,q\in Q(uxv)$. Let $y_0\in I_{pq}$. Step I of the algorithm merges p and q and creates a cyclic with span y_0. Let $w_3\in F_p$. Since $p\ inQ(uxv)$, by Lemma 4.2 there exists $w_2\in F_p$ such that $w_2=w_{21}uxv=w_{22}u_2x_2v_2y_2$ and $w_3=w_{32}u_2x_2v_2y_2$. Since $w_3y_0\in F_q$, again by Lemma 4.2 there exists $w_1\in F_q$ such that $w_1=w_{11}uxv=w_{12}u_1x_1v_1y_1$ and $w_3y_0=w_{31}u_1x_1v_1y_1$. Let $z\in T_q$. We have three accepting spans w_1z, w_2y_0z, and w_3y_0z that have the following properties.

$$w_1z=w_{11}uxvz=w_{12}u_1x_1v_1y_1z,$$
$$w_2y_0z=w_{21}uxvy_0z=w_{22}u_2x_2v_2y_2y_0z, \text{ and}$$
$$w_3y_0z=w_{31}u_1x_1v_1y_1z=w_{31}u_2x_2v_2y_2y_0z.$$

By Theorem 5.1, $w_1z,w_2y_0z,w_3y_0z\in L(S)$. By Lemmas 2.7 and 2.9, there exists a constant c such that for all $k\geq c$, the string $(y_0)^k$ has a site.

Case (2). $p=MQ(u'xv')$ and $q\in Q(ux,v)$. Let $y_0\in I_{pq}$. Linking q to p with span v' in step II, the algorithm creates a cycle with span $v'y_0$. Let $w_3\in F_p$. Since $p\in Q(u'xv')$, by Lemma 4.2 there exists $w_2\in F_p$ such that $w_2=w_{21}u'xv'=w_{22}u_2x_2v_2y_2$ and $w_3=w_{32}u_2x_2v_2y_2$. Since $w_3y_0\in F_q$, by Lemma 4.3 there exists $w_1\in F_q$ such that $w_1=w_{11}ux=w_{12}u_1x_1v_1y_1$ and $w_3y_0=w_{31}u_1x_1v_1y_1$. Let $r=MQ(uxv)$ and $r\in T_r$. We have accepting spans w_1vz, w_2y_0vz, and w_3y_0vz that have the following property:

$$w_1vz=w_{11}uxvz=w_{12}u_1x_1v_1y_1vz,$$
$$w_2y_0vz=w_{21}u'xv'y_0vz=w_{22}u_2x_2v_2y_2y_0vz, \text{ and}$$
$$w_3y_0vz=w_{31}u_1x_1v_1y_1vz=w_{31}u_2x_2v_2y_2y_0vz.$$

By Theorem 5.1, $w_1vz,w_2y_0vz,w_3y_0vz\in L(S)$, and by Lemmas 2.10 and 2.12 there exists a constant c such that for all $k\geq c$, the string $(v'y_0)^k$ contains a site.

Case (3). $p,q\in Q(ux,v)$ such that $IMS(p,k)=IMS(q,k)$ and there exists $r=MQ(u'xv')$. Let s and t, respectively, be the first states of the links from p to r and from q to r with span v' that have been introduced by step II. Let a be the label on the q to t transition, which is the first symbol of v'. Clearly, p to s transition has the same label a. Let $w\in I_{sq}$. Then, collapsing states s and t introduces a loop with span aw. We will show that there is a constant c such that $(aw)^k$ contains a site for

all $k > c$. Obviously, $aw \in I_{pq}$. We will actually show that for any $y_0 \in I_{pq}$, string ${y_0}^k$ contains a site.

Let $w_1 \in F_p$. We have $w_1 y_0 \in F_q$. Suppose that q is not monomial w.r.t. ux. By Lemma 4.3, we have $w_1 y_0 = w_{12} u_1 x_1 v_1 y_1$ for some $w_{12}, y_1 \in A^*$ and a site $u_1 x_1 v_1$. (Notice that $|ux| > |u_1 x_1 v_1 y_1|$. Otherwise, q should be monomial *w.r.t.* ux.) Since $IMS(p,k) = IMS(q,k)$, state p is also not monomial *w.r.t.* ux and $w_1 = w_{11} u_1 x_1 v_1 y_1$. Let $z_1 \in T_q$. String $w_1 y_0 z_1$ is an accepting span, and we have $w_1 y_0 z_1 = w_{11} u_1 x_1 v_1 y_1 y_0 z_1 = w_{12} u_1 x_1 v_1 y_1 z_1$. Since $|y_0| \geq 1$, we have $u_1 x_1 v_1 y_1 y_0 = z u_1 x_1 v_1 y_1$ for some $z \in A^+$. By Theorem 5.1, $w_1 y_0 z_1 \in L(S)$, and by Corollary 2.8, $w_{11} u_1 x_1 v_1 y_1 (y_0)^+ z_1 \subseteq L(S)$. By Lemma 2.9, there exists a constant c such that for all $k \geq c$ the string $(y_0)^k$ has a site.

Now, suppose that q is monomial w.r.t. ux. We have $w_1 y_0 v \in F_r$. Let $z_1 \in T_r$. Then $w_1 y_0 v z_1$ is an accepting span. Since $IMS(p,k) = IMS(q,k)$, state p is also monomial w.r.t. ux. Hence, we have $w_1 y_0 v' z_1 = w_{11} uxy_0 v' z_1 = w_{11} zuxv' z_1$ for some $z_1 \in A^+$. Since $uxy_0 = zux$, by Lemma 2.6 there is a constant c such that ${y_0}^k$ contains ux, for all $k \geq c$. By the property of persistence there should be a constant $c' \geq c$ such that for all $k \geq c'$, ${y_0}^k$ has a site. ∎

Now, we are ready to prove Theorem 5.3.

Proof. Let G be the output of algorithm *CONSTRUCT*. To prove that $L(G)$ is strictly locally testable, we show that the reduced deterministic version of G satisfies Theorem 2.5. Suppose that the graph has a pair of states p and q such that $\delta(p,w) = p$ and $\delta(q,w) = q$ for some $y \in A^+$. Let C_p and C_q denote the cycles, respectively, corresponding to $\delta(p,w) = p$ and $\delta(q,w) = q$. By Lemma 5.11, there is a constant c such that for all $k \geq c$, the string w^k has a site, say uxv. This implies that C_p and C_q have states p' and q', respectively, such that $p', q' \in Q(uxv)$. States p' and q' should have been merged into a state $r = MQ(uxv)$ by step I(5) of algorithm *SPLICE*. State r belongs to both of the cycles C_p and C_q, and $r \in \delta(r, w_2 w_1)$, for some w_1 and w_2 such that $w = w_1 w_2$. By Lemma 3.8 the language $L(G)$ is $LTSS$. ∎

6. Concluding remarks. We have introduced an algorithm, which, given a splicing system with its initial set of strings given in terms of the state transition graph of an automaton that recognizes the set, constructs an automaton that recognizes the language generated by the system. This solves the open problem in [2]. With the construction we could show that if the system is persistent, the splicing language is $LTSS$. This result also shows a constructive proof of regularity of splicing languages when I is regular, which was proven in [1] by using an algebraic system called alphabetic dominos.

The algorithm in [2] works for permanent splicing systems. Recently, one of the reviewers commented that this algorithm had been extended to the class of so-called twist-free splicing systems [3]. A pair of distinct patterns (u,x,v) and (w,y,z) are twisted if there is another pair of patterns (u',x,v') and (w',y,z') such that either one of the following conditions are satisfied.

(a) For some $u_1 \in A^+$ such that $ux = u_1 u_2$, either one of u_1 and w' is suffix of the other, and either one of u_2 and z is prefix of the other.

(b) For some $z_2 \in A^+$ such that $z = z_1 z_2$, either one of z_2 and v' is prefix of the other, and either one of z_1 and ux is suffix of the other.

A splicing system is twist free if it has no pair of twisted patterns. Twist freeness implies both permanence and persistence. If a splicing system has a pair of twisted patterns, a site can be destroyed. The splicing system in Figure 8 has one twisted pair (ba, b, a) and (b, a, a). Our algorithm solves the problem of twisted patterns by

monomializing the graph as shown in the figure (see the split states highlighted).

We can think of multihanded splicing systems $S = (A, I, H_1, H_2, \ldots, H_n)$, a generalization of the two-handed splicing model. Our algorithm and the main results can be easily extended to such a generalization.

The automata that our algorithm constructs are nondeterministic like the other algorithms introduced in [2] and [3]. It would be challenging to develop a practical algorithm that can construct a deterministic automaton for a given splicing system. There is considerable room for improvement in our algorithm. For the improvement we may note that, in biology, sites are almost always 4, 6, or 8 bps long, and most sites consist of reverse palindromes. Can we use these properties for more efficient construction? Is the algorithm practical for such data? Can we improve it?

Appendix A.

procedure $Monomialize(G, x)$
(//This algorithm monomializes the finite state transition graph G of an automaton $M = (Q, A, \delta, q_{st}, F)$ w.r.t. string $x \in A^+$. It is assumed that the automaton, which is nondeterministic, has no ϵ transition.

The algorithm uses two subroutines $Split1(G, q, q_1, q_2, c)$ and $Split2(G, q, q_1, q_2, c)$. Given a state q which is not monomial w.r.t. symbol c, algorithm $Split1(G, q, q_1, q_2, c)$, splits q into two equivalent states q_1 and q_2 and makes them monomial w.r.t. symbol c such that $IMS(q_1, 1) = \{c\}$ and $c \notin IMS(q_2, 1)$. Given G which is monomial w.r.t. a string $x \in A^+$ and a state q which is not monomial w.r.t. xc, $Split2(G, q, q_1, q_2, c)$ splits q into two equivalent states q_1 and q_2 and monomializes them w.r.t. string xc such that $IMS(q_1, |xc|) = \{xc\}$ and $xc \notin IMS(q_2, |xc|)$. Statements 5 and 11 are for algorithm $SPLICE$ in Appendix B to block splitting transitions marked as "merged." //)

FAST MANAGEMENT OF PERMUTATION GROUPS I*

LÁSZLÓ BABAI†, EUGENE M. LUKS‡, AND ÁKOS SERESS§

Abstract. We present new algorithms for permutation group manipulation. Our methods result in an improvement of nearly an order of magnitude in the worst-case analysis for the fundamental problems of finding strong generating sets and testing membership. The normal structure of the group is brought into play even for such elementary issues. An essential element is the recognition of large alternating composition factors of the given group and subsequent extension of the permutation domain to display the natural action of these alternating groups. Further new features include a novel fast handling of alternating groups and the sifting of defining relations in order to link these and other analyzed factors with the rest of the group. The analysis of the algorithm depends on the classification of finite simple groups. In a sequel to this paper, using an enhancement of the present method, we shall achieve a further order of magnitude improvement.

Key words. permutation group algorithm, strong generating set

1. Introduction.

Since the size of a permutation group G on n letters can be exponential in n, it is customary, for computational purposes, to specify G by a small list of generators. However, the succinctness of such a representation raises the issue of whether we can deal effectively with the groups that we can specify. Can one, for example, find the order of G and test membership in G without enumerating all of its elements?

In fact, in the late sixties, Sims developed efficient algorithms for permutation group manipulation [Si70]. These included the key notion of a *strong generating set* (SGS) which is the underlying concept in essentially all polynomial-time algorithms in computational group theory. Given a chain $G = G_0 \geq G_1 \geq \cdots \geq G_m = 1$ of subgroups of G, an SGS with respect to this chain is a set $T \subset G$ such that $T \cap G_i$ generates G_i for each i. Sims's algorithm uses the point stabilizer chain; that is, G_i is the pointwise stabilizer of the first i points of the permutation domain.

While Sims's methods for constructing an SGS have been widely used in computational group theory since their inception, the question of their asymptotic efficiency was not resolved until 1980. Furst, Hopcroft, and Luks [FHL] observed that a version of Sims's algorithm runs in polynomial time, namely $O(n^6 + sn^2)$ steps, where s is the number of generators given for G. Subsequently, Knuth [Kn] and Jerrum [Je82], [Je86] gave variants with running time $O(n^5 + sn^2)$. All of these algorithms rest on the most elementary group theory.

Since Knuth's note of 1981 (a preliminary version of [Kn]) and Jerrum's 1982 paper, the $O(n^5)$ bound has achieved notoriety and is generally believed to be the best that can be obtained via Sims's approach alone (cf. Remark 2.13). The main result of this paper is the improvement of the worst case bound by nearly one order of magnitude.

THEOREM 1.1. *Given a permutation group G by a list S of generators, $|S| = s$, the following problems can be solved in $O(n^4 \log^{c_1} n + sn^2)$ time.*

(a) *Find a set of strong generators.*

(b) *Find the order of G.*

(c) *Test membership of any permutation in G. Additional tests cost only $O(n^2)$ each.*

(d) *Find the pointwise stabilizer of a subset of the permutation domain.*

(e) *Construct a generator-relation presentation $\langle X|R\rangle$ of G in which $|X| = O(n \log^{c_2} n)$ and $|R| = O(n^2 \log^{c_3} n)$.*

In order to avoid long timing expressions as in Theorem 1.1 and concentrate on the essential part of the improvements, we introduce a "soft version" of the big-O notation. For two functions $f(n), g(n)$, we write $f(n) = O^{\sim}(g(n))$ if $f(n) \leq Cg(n) \log^c n$ (c, C are positive constants). Thus the time bound for basic permutation group manipulation in Theorem 1.1 is $O^{\sim}(n^4 + sn^2)$. We do not try, at this time, to minimize the exponent of $\log n$. Straightforward estimates give $c_1 = 7, c_2 = 2$, and $c_3 = 4$.

The new algorithms are not merely improved versions of previous SGS constructions. All of those predecessors construct an SGS with respect to the chain of point stabilizer subgroups. A key departure from the traditional approach is the use of another sort of subgroup tower, one which is not easily observable solely in terms of the action on the original permutation domain. Its very specification subsumes knowledge of the group structure. We construct an SGS with respect to a subgroup chain $G = G_0 \geq G_1 \geq \cdots \geq G_m = 1$ such that each G_i is *normal* in G and the factor groups G_i/G_{i+1} are either products of isomorphic alternating groups or subgroups of products of small primitive groups ("small" in this context means of order $n^{c \log n}$).

Naive divide-and-conquer of the permutation domain provides some normal subgroups of G in the kernels of induced actions on orbits or blocks of imprimitivity; the new machinery comes into play precisely when such decomposition bottoms out. The structure of large primitive groups allows an augmentation of the domain that readmits naive decomposition. This idea is part of the NC-procedure developed for the same problem [BLS87]. However, the sequential algorithm cannot be viewed as the sequential implementation of the parallel one. Even a knowledgeable implementation of the relevant part of parallel ideas would require $O^{\sim}(n^6)$ at best.

The timing analysis depends on the classification of finite simple groups via information on the order of primitive permutation groups whose socle is not the product of alternating groups. We remark, however, that there is an *elementary* version of the algorithm breaking the $O(n^5)$ barrier. Instead of the classification, we may use Babai's bound [Ba] on the order of uniprimitive groups and Pyber's recent bound [Py] on the order of doubly transitive groups to obtain an $O^{\sim}(n^{4.5})$ algorithm. In fact, the elementary algorithm is simpler in the sense that we do not have to detect alternating groups in socles of primitive groups involved in G (unless the primitive group itself is alternating or symmetric in its natural action on blocks of imprimitivity of G). Both Babai's and Pyber's results are within a logarithmic factor (in the exponent) from optimal; the loss in running time is due to the fact that we do not have elementary

estimates for the order of primitive groups with nonalternating-type socle. We sketch the elementary version in section 9.

We mention two further aspects which are important differences from previous methods. Exploiting the normality of subgroups in the new subgroup chain, we first obtain only normal generators, i.e., generators whose normal closure is the given subgroup. Another difference is the novel handling of full symmetric and alternating groups. We formulate the latter result as a separate theorem.

THEOREM 1.2. *From a given list of generators of the symmetric or alternating group, one can construct an SGS with respect to the chain of point stabilizer subgroups in* $O^{\sim}(n^3 + sn^2)$ *time. (The term "construct" refers to the operations of taking products and powers of permutations.) Moreover, there is a Las Vegas algorithm achieving the same goal in* $O^{\sim}(n^2 + sn)$ *expected running time.*

A random algorithm is Las Vegas if it never returns incorrect answers. We require that the SGS is constructed from the given generators via permutation multiplications since we apply this result when the symmetric group is involved in a larger permutation group G and acts on blocks of imprimitivity of G. We can guarantee that a given permutation from the symmetric group belongs to G only if it is constructed by the aforementioned operations.

We remark that the *random subproduct method*, originally developed to prove the random part of Theorem 1.2, was substantially extended by Babai, Cooperman, Finkelstein, Luks, and Seress [BCFLS91], [BCFLS95] to yield an elementary Monte Carlo algorithm for the basic tasks mentioned in Theorem 1.1 which runs in $O(n^3 \log^4 n + sn \log n)$ time. (A Monte Carlo algorithm may return a wrong answer with a fixed but arbitrarily small probability.)

In a sequel to this paper, we shall extend our method to achieve a further order of magnitude improvement in the running time.

THEOREM 1.3 (see [BLS]). *Given a permutation group* G *by a list* S *of generators,* $|S| = s$*, the following problems can be solved in* $O^{\sim}(sn^3)$ *time:*

(a) *All items listed in Theorem* 1.1.

(b) *Finding a composition series of* G.

Let us remark that the length of the input is $\Theta(sn)$ so this is an $O^{\sim}(n^3)$ algorithm as a function of the input length. For the more complicated task of computing a composition series, Theorem 1.3 gives an improvement of *five* orders of magnitude from Luks's original algorithm [Lu87]. This result requires a deeper probe into the structure of primitive groups with different types of socle, in the spirit of the O'Nan–Scott theorem [Sc], [Cam].

Like the method of this paper, the $O^{\sim}(sn^3)$ algorithm examines the primitive groups involved in G and locates the large alternating composition factors. It differs in its handling of the nonalternating part of G and a reduction of the number of "normal generators" for consecutive groups in the normal series. Specifically, the arguments in sections 6 and 7 are improved. A part of these results appeared in [BLS93].

As presented in sections 3–8, our $O^{\sim}(n^4)$ algorithm requires $O^{\sim}(n^3 + sn^2)$ memory. In section 9 we indicate how to decrease the memory requirement to $O^{\sim}(n^2 + sn)$. Also, without loss in time efficiency, the algorithm can output Jerrum's compressed data structure [Je86] for an SGS with respect to the point stabilizer subgroup chain; this requires only $O(n^2)$ space and supports membership testing in $O(n^2)$ time per test.

At this point, our emphasis is on the theoretical improvement realized by our

algorithm. Practical computations often deal with so-called *small-base groups*, i.e., families of groups satisfying $\log|G| < \log^c n$ for some fixed constant c. For small-base group inputs, the traditional algorithms run in $O^{\sim}(n^2)$ time and our method becomes essentially a version of the traditional approach. The attention given to the small-base case is, in part, due to the fact that interesting permutation representations of the nonalternating simple groups tend to have a small base. However, it is also the case that it has often been impractical to deal with large-base groups. Thus, aspects of the new methods should be important in practice where there is a need to deal with groups where $\log|G|$ is, say, proportional to n and when hardware is improved to allow the usage of $\Theta(n^2)$ memory for n in the tens of thousands.

2. Definitions and preliminaries. We refer to any standard text, e.g. [Ha], for basic facts about groups. For permutation group concepts we refer to [Wi] and [Cam]. We mention two sources of information on the classification of finite simple groups [Go], [Car], but no knowledge of these works is required. Cameron [Cam] gives a fine survey of all the consequences of the simple groups classification relevant to our work.

2.1. Group theory. We write $H \leq G$ if H is a subgroup of G and $H \triangleleft G$ if H is a normal subgroup of G.

LEMMA 2.1 (see [Ha, p. 96]). *Let $H \leq G$ and assume S is a set of generators of G and R is a complete set of right coset representatives of G mod H. Then the set*

$$\{\rho\sigma\rho_1^{-1} : \rho, \rho_1 \in R, \sigma \in S, \rho\sigma\rho_1^{-1} \in H\}$$

generates H.

The generators described here are called *Schreier generators* of H; their number is $|S||G:H|$ (these are not necessarily distinct).

For $Q \subset G$, the *normal closure* $\langle Q^G\rangle$ of Q in G is the smallest normal subgroup of G containing Q. More generally, for $K \leq G$, $\langle Q^K\rangle$ is the smallest subgroup of G containing Q and normalized by K. We say Q is a set of *normal generators* for H if $H = \langle Q^G\rangle$. For $\tau, \sigma \in G$, τ^σ denotes the *conjugate* $\sigma^{-1}\tau\sigma$. A group $G \neq 1$ is called *simple* if it has no nontrivial normal subgroups. We call G *semisimple* if it is the direct product of simple groups. If these simple groups are isomorphic then G is *characteristically simple*. A *composition series* of G is any series $1 = G_r \triangleleft \cdots \triangleleft G_1 \triangleleft G_0 = G$ where the quotients G_{i-1}/G_i are simple; these quotients are the *composition factors*. The group G is *solvable* if all composition factors of G are cyclic. We need the following well-known fact (see, e.g., [Sc]).

PROPOSITION 2.2. *Let H be a subgroup of the semisimple group $G = \prod_{i=1}^m T_i$ such that all T_i are simple nonabelian and H projects onto each factor. Then H is direct product of "diagonal" subgroups; more precisely, the T_i can be arranged into blocks of isomorphic groups so that, after a suitable renumbering of the factors,*

$$H = \mathrm{Diag}(T_1 \times \cdots \times T_{k_1}) \times \cdots \times \mathrm{Diag}(T_{k_{r-1}+1} \times \cdots \times T_{k_r}).$$

In other words, having identified the groups in each block, H consists precisely of the elements of the form

$$(\alpha_1, \ldots, \alpha_1), \ldots, (\alpha_r, \ldots, \alpha_r).$$

The *socle* of G is the subgroup generated by all minimal normal subgroups and is denoted by $\mathrm{Soc}(G)$. The socle is semisimple.

The *automorphism group* of G is denoted by $\mathrm{Aut}(G)$. Every element $g \in G$ induces an *inner automorphism* $x \mapsto g^{-1}xg$. The group of inner automorphisms, $\mathrm{Inn}(G)$, is normal in $\mathrm{Aut}(G)$. The factor group $\mathrm{Out}(G) = \mathrm{Aut}(G)/\mathrm{Inn}(G)$ is the *outer automorphism group*. One of the classification-dependent results required by our algorithm analysis is the so-called Schreier conjecture.

THEOREM 2.3 (Schreier conjecture). *The outer automorphism group of a finite simple group is solvable.*

2.2. Permutation groups. The group of all permutations of an n-element set A is denoted $\mathrm{Sym}(A)$, or $\mathrm{Sym}(n)$ if the specific set is unessential. Subgroups of $\mathrm{Sym}(n)$ are the *permutation groups* of *degree* n. The *even* permutations of A form the *alternating group* $\mathrm{Alt}(A)$ (or $\mathrm{Alt}(n)$). We refer to $\mathrm{Sym}(A)$ and $\mathrm{Alt}(A)$ as the *giants*. These two families of groups require special treatment in most algorithms (see sections 5 and 8).

The *support* $\mathrm{supp}(\pi)$ of $\pi \in \mathrm{Sym}(A)$ consists of those elements of A actually displaced by π, i.e., $\{a \in A : a^\pi \neq a\}$. The *degree* of π is $\deg(\pi) = |\mathrm{supp}(\pi)|$.

We say that G *acts on* A if a homomorphism $G \to \mathrm{Sym}(A)$ is given. This action is *faithful* if its kernel is the identity. The *orbit* of $a \in A$ under G is the set of images $\{a^\gamma : \gamma \in G\}$. G is *transitive* on A if there is only one orbit. We say G is t*-transitive* if the action of G induced on the set of ordered t-tuples of distinct elements of A is transitive ($t \leq n$). The maximum such t is the *degree of transitivity* of G. The degree of transitivity of the giants is $\geq n - 2$.

THEOREM 2.4. *If G is 2-transitive and $|G| \geq n^{2+\log n}$ then G is giant.*

This is an immediate consequence of the classification of doubly transitive groups, which is essentially due to Curtis, Kantor, and Seitz [CKS]. Their work is based on detailed knowledge of the finite simple group classification. For the list of doubly transitive groups, see, e.g., [Cam].

Actually, we could use a weaker version of Theorem 2.4, with no loss in the asymptotic analysis of running time. The following result has a strikingly simple, elementary proof.

THEOREM 2.5 (see [Py]). *There exists an explicitly computable constant c such that if G is 2-transitive and $|G| \geq n^{c \log^2 n}$ then G is giant.*

2.3. Orbits, orbitals, blocks, stabilizers. If G acts on A, the orbits of the induced (componentwise) G-action on $A \times A$ are called *orbitals* [Si67]. The *stabilizer* of $x \in A$ is the subgroup $G_x = \{\gamma \in G : x^\gamma = x\}$. If G is transitive on A then there is a bijection between the orbitals of G and the orbits of G_x. For an orbital Θ of G and $x \in A$, the (out)neighbors of x in the (di)graph (A, Θ) form the orbit $\Theta(x) = \{y | (x, y) \in \Theta\}$ of the stabilizer G_x. For $B \subset A$, we use G_B for the *pointwise stabilizer* $\bigcap_{x \in B} G_x$ of B, and $G_{\{B\}}$ for the setwise stabilizer $\{\gamma \in G : B^\gamma = B\}$ of B. If $B \subset A$ is stabilized by G, then we denote by G^B the restriction of G to B, so that $G^B \leq \mathrm{Sym}(B)$. Then, $G(B) = G^B_{\{B\}}$ denotes the image of the action of the setwise stabilizer of B on B.

If G is transitive on A and $G_x = 1$ for some (any) $x \in A$, then G is said to be *regular*. If G is transitive and $D \subseteq A$, D is called a *block* (for G) if for all $\gamma \in G$, either $D^\gamma = D$ or $D^\gamma \cap D = \emptyset$, and G is called *primitive* if no nontrivial blocks exist. (Trivial blocks have 0, 1, or $|A|$ elements.) If D is a block then the set of images of D is called a *block system* and an action of G is induced on the block system. The block system is *minimal* if that action is primitive.

For section 4, we need the following elementary results on the structure of primitive groups. They all follow from the O'Nan–Scott theorem [Sc] (cf. [Cam], [Lu87]).

THEOREM 2.6. *Let $G \leq \mathrm{Sym}(A)$ be primitive. If $\mathrm{Soc}(G)$ is abelian then $n = p^d$ for some prime p, A can be identified with the d-space over $GF(p)$ and (via this identification) $G \leq \mathrm{AGL}(d,p)$, the group of affine transformations of A, and $\mathrm{Soc}(G) \cong \mathbf{Z}_p^d$ is the group of translations of A.*

THEOREM 2.7. *Let $G \leq \mathrm{Sym}(A)$ be primitive. Then*

$$\mathrm{Soc}(G) = T_1 \times \cdots \times T_d$$

where the T_i are isomorphic simple groups. If $\mathrm{Soc}(G)$ is nonabelian then G contains a normal subgroup N such that

(a) $\mathrm{Soc}(G) \leq N \leq \mathrm{Aut}(T_1) \times \cdots \times \mathrm{Aut}(T_d)$;

(b) *G/N is a subgroup of S_d;*

(c) $n \geq 5^d$.

In the particular case that the isomorphic T_i are alternating groups, we say that G is of *alternating type*.

THEOREM 2.8. *Let $G \leq \mathrm{Sym}(A)$ be primitive. If G has more than one minimal normal subgroup then G has precisely two minimal normal subgroups, each of order $|A|$.*

2.4. Primitive groups of Cameron type. A remarkable class of primitive groups of alternating type is obtained as follows.

First we define a class of imprimitive groups. Let B be a set of k elements, $k \geq 5$, and $1 \leq s < k/2$. Let $C = rB = B_1 \dot\cup \cdots \dot\cup B_r$ denote the disjoint union of r copies of B. An *s-transversal* of C is a subset $X \subset C$ such that $|X \cap B_i| = s$ for $i = 1, \ldots, r$. Let A denote the set of s-transversals and let $n = |A| = \binom{k}{s}^r$. The *wreath product* $W(B,r) = \mathrm{Sym}(B) \wr S_r \leq \mathrm{Sym}(C)$ consists of all permutations of C that respect the partition $\{B_i\}$. Clearly,

$$\mathrm{Soc}(W(B,r)) = \mathrm{Alt}(B_1) \times \cdots \times \mathrm{Alt}(B_r).$$

Now let $W(B,r) \geq G \geq \mathrm{Soc}(W(B,r))$ and assume G acts transitively on the set of blocks $\{B_i\}$. Under these conditions, the action of G on A is *primitive* (and alternating type, since $\mathrm{Soc}(G) = \mathrm{Soc}(W(B,r))$). We say that the primitive groups obtained this way are of *Cameron type*.

THEOREM 2.9 (see [Li]). *If G is a primitive group of degree n and order $> n^{9 \log n}$ then G is of Cameron type.*

This is the third consequence of the simple groups classification that we require. The name "Cameron type" acknowledges the first version of Theorem 2.9 by Cameron [Cam], who formulated the lower bound as $> n^{c \log n}$, without explicit determination of the constant $c = 9$. For large n, c approaches 1. We remark that the actual value of c plays no role in the algorithms; their analysis depends only on the existence of c.

2.5. Cameron schemes. For application in section 4, we introduce a combinatorial structure associated with the action of $W(B,r)$ on A. Let A, B, C be as above. For an s-transversal $X \in A$, let $X_i = X \cap B_i$. For $X, Y \in A$, let $d_i = |X_i \cap Y_i|$ and let $f_1 \leq f_2 \leq \cdots \leq f_r$ be the sorted sequence $\{d_i\}$. We call $(f_1, \ldots, f_r)$ the *intersection pattern* of X and Y. Let us partition $A \times A$ according to intersection patterns: $A \times A = R_0 \cup \cdots \cup R_N$. We call the system $C(n,k,s,r) = (A; R_0, \ldots, R_N)$ the *Cameron scheme* with parameters (n,k,s,r). This is a particular *association scheme*

[Bos], [Del], [MS]; it includes the Hamming schemes ($s = 1$) and the Johnson schemes ($r = 1$) as particular cases. The scheme can be thought of as a coloring of the edges of the complete graph on n vertices (including self-loops); we refer to the R_i as *color classes*.

It is clear that each group of Cameron type acts on a Cameron scheme. In fact, the color classes are precisely the orbitals of the action of $W(B, r)$ on A. It may, however, happen that the color classes split under the action of a Cameron-type group $G \le W(B, r)$. In a key subroutine, NATURAL_ACTION, we recover the imprimitive action of G on $C = rB$ using the orbital structure of the primitive G-action on A, thereby reducing the Cameron-type groups to imprimitive groups with a block system of $r \le \log n / \log 5$ blocks, with giants acting on each block.

Some elementary observations about the orbital structure will be useful in this computation. Let Σ_i be the color class corresponding to the intersection pattern $(s - i, s, \dots, s)$ and Φ to $(0, 0, \dots, 0)$.

LEMMA 2.10. *Let G be a Cameron-type group acting on the points A of a Cameron scheme $C(n, k, s, r)$ and suppose $k \ge 2rs^2$. Then the following hold.*

(a) *Σ_1 is the second smallest orbital of G.*

(b) *Φ is the largest orbital of G.*

Proof. We note first that Σ_i $(0 \le i \le s)$ and Φ are orbitals of G; i.e., they do not split. For Φ this follows from the fact that $G \ge \mathrm{Alt}(k)^r$. For Σ_i we need in addition that the stabilizer of any $a \in A$ acts transitively on the set of blocks $\{B_i\}$.

Proof of (a): Fix $x \in A$ and consider an orbital Θ. We have to prove that $|\Sigma_1(x)| < |\Theta(x)|$ for any Θ other than Σ_1 and the diagonal Σ_0 (the diagonal is the *smallest* orbital). Observe, since $k \ge 2s^2$, that $\binom{k-s}{s} \ge s(k - s)$ with strict inequality when $s > 1$.

For $s \ge i > 1$,

$$|\Sigma_i(x)| = r\binom{s}{s-i}\binom{k-s}{i} > rs(k-s) = |\Sigma_1(x)|.$$

Assume now that Θ is contained in the color class with intersection pattern $(i_1, i_2, \dots)$ where $i_1 \le i_2 < s$; let $(x, y) \in \Theta$. Just counting the images of y under the stabilizer of x in $\mathrm{Alt}(k)^r$ we obtain

$$|\Theta(x)| \ge \binom{s}{i_1}\binom{k-s}{s-i_1}\binom{s}{i_2}\binom{k-s}{s-i_2}$$

$$\ge s^2(k-s)^2 > rs(k-s),$$

the final inequality using $k \ge 2r$.

Proof of (b): We have to prove that Φ is the largest color class in the Cameron scheme. (Note that G plays no role here.)

We use the fact that, for $1 \le i \le s$,

$$r\binom{k-s}{s-i}\binom{s}{i} < \binom{k-s}{s}.$$

To see this, note that $k \geq \max\{2rs^2, 2s+1\}$ implies $k - 2s + 1 > rs^2$, so that

$$\frac{\binom{k-s}{s}}{\binom{k-s}{s-i}} = \prod_{j=0}^{i-1} \frac{k-2s+i-j}{s-j} > \prod_{j=0}^{i-1} \frac{rs^2}{s-j} \geq rs^i \geq r\binom{s}{i}.$$

Now let the color class Θ have intersection pattern $(0^{r_0}, \ldots, s^{r_s})$. (The exponents denote multiplicities.) Then

$$|\Theta(x)| = \binom{r}{r_0, r_1, \ldots, r_s} \prod_{i=0}^{s} \binom{k-s}{s-i}^{r_i} \binom{s}{i}^{r_i}$$

$$< \binom{r}{r_0, r_1, \ldots, r_s} \binom{k-s}{s}^{r} \frac{1}{r^{r-r_0}} < \binom{k-s}{s}^{r} = |\Phi(x)|. \qquad \square$$

2.6. Strong generators. In our algorithms, permutation groups are input and output via sets of generators. A standard tool for permutation group computation is an SGS [Si70]. An SGS with respect to the subgroup chain $G = G_0 \geq G_1 \geq \cdots \geq G_m = 1$ is a set $T \subset G$ such that $T \cap G_i$ generates G_i for all i.

Let C_i be a set of (right) coset representatives for G_{i-1} mod G_i, $i = 1, 2, \ldots, m$. Then any $\alpha \in G$ has a unique factorization $\alpha = \rho_m \cdots \rho_2 \rho_1$ with $\rho_i \in C_i$. An SGS T is computationally effective if, for any $\alpha \in G_{i-1}$, there are fast procedures for determining the coset of G_i to which α belongs and constructing a representative for this coset from T.

We construct an SGS with respect to a subgroup chain $G = G_0 \geq G_1 \geq \cdots \geq G_m = 1$ such that each G_i is normal in G and the factor groups G_{i-1}/G_i are either subgroups of direct products of small primitive groups ("small levels") or direct products of alternating groups ("alternating levels"). To achieve the effectiveness mentioned above, we, in fact, construct an SGS with respect to a refinement $G = H_0 \geq H_1 \geq \cdots \geq H_{m'} = 1$ of the subgroup chain $G = G_0 \geq G_1 \geq \cdots \geq G_m = 1$. Namely, we construct a permutation representation for each G_{i-1} with kernel G_i. The refinement between G_{i-1} and G_i is a pointwise stabilizer chain in this representation. The advantage of a pointwise stabilizer chain is that it is easy to recognize the coset to which a given permutation belongs: given $\alpha \in H$, its coset $H_x\alpha$ is determined by x^α.

If a pointwise stabilizer chain is long, it requires too much time and storage to store all coset representatives at each level. Hence, in alternating groups, we use the following Jerrum-style [Je86] compact SGS. Suppose that $K \cong \mathrm{Alt}(m)$ and K acts naturally on a set $B = \{x_1, \ldots, x_m\}$ with K_i the pointwise stabilizer of $\{x_1, \ldots, x_i\}$. Let the set T consist of the permutations $\pi_1, \pi_2, \ldots, \pi_{m-1}$ satisfying the following properties. For all $1 \leq k \leq m-2$, π_k fixes pointwise $x_1, \ldots, x_{k-1}$ and π_{m-1} fixes pointwise $x_1, \ldots, x_{m-3}$. Moreover, $x_k^{\pi_k} = x_{k+1}$ for $k = 1, 2, \ldots, m-2$ and $x_{m-2}^{\pi_{m-1}} = x_m$. Suppose we store just the products $\mu_i = \pi_1\pi_2\cdots\pi_i$ for $i \leq m-2$ and $\mu_{m-1} = \pi_1\pi_2\cdots\pi_{m-3}\pi_{m-1}$. Then $\{\mu_{i-1}^{-1}\mu_j : i-1 \leq j \leq m-1\}$ is a complete set of coset representatives for K_i in K_{i-1}. Thus, any coset representative within the chain can be obtained with one multiplication. (We use the term *multiplication* for the evaluation of $\alpha^{-1}\beta$ as well as $\alpha\beta$; clearly the timings are the same.)

It is useful to observe that an SGS for a factor group G/N, lifted to G and appended to an SGS for N, gives an SGS for G. With an abuse of language, we call a subset $C \subset G$ a set of strong generators of G/N if C is a lifting of such a set. Suppose $\alpha \in G$ is factored according to a fixed SGS of G/N, that is, $\bar{\alpha} = \bar{\rho}_l \cdots \bar{\rho}_2 \bar{\rho}_1$, where the bar signifies the image mod N. Then $\nu = \alpha(\rho_l \cdots \rho_1)^{-1} \in N$ and we call ν the *siftee* of α into N. The following notion plays an important role in reducing the number of generators we use for N. If $C \subset G$ is an SGS for G/N and $S^* \subset G$ is a set of generators for G/N such that $C \subset \langle S^* \rangle$ (in G, not only in G/N), then we say that S^* is *compatible* with C.

2.7. Sims's algorithm. Sims's algorithm for constructing strong generators has been formulated for the case when G_i is the stabilizer of the first i points of the permutation domain. An efficient version of Sims's method has been analyzed by Knuth [Kn]. In this subsection, we describe a slight extension of the latter version.

We consider the action of $G = \langle Q \rangle \leq \mathrm{Sym}(A)$ on the set $C = \{1, 2, \ldots, m\}$. Let G_i be the pointwise stabilizer of $\{1, 2, \ldots, i\}$,

$$G = G_0 \geq G_1 \geq \cdots \geq G_m = N,$$

where N is the kernel of the G-action on C. Our objective is to find an SGS of G/N.

During the procedure, we maintain lists T_i, $i = -1, 0, \ldots, m-1$ and R_i, $i = 0, 1, \ldots, m$, where R_i is a not-necessarily-complete list of right coset representatives of G_{i-1} mod G_i; and $T_i \subseteq G_i$ such that $\langle T_i \rangle \supseteq \bigcup_{j \geq i+1} R_j$. The lists $T_{-1} := Q$ and $R_0 := \{1\}$ do not change during the procedure; all other lists may sometimes be augmented. Each time T_i is augmented, the group $\langle T_i \rangle^C$ increases.

We employ the following SIFT routine which attempts to factor $\pi \in G_k$ (k is part of the input) over the current partial coset lists. If it does not succeed then it inserts a new coset representative in the appropriate R_{j+1}, updates the T_i, $k+1 \leq i \leq j$, and sets $k := j$. In any case, at the conclusion of SIFT, $\pi \in N R_m R_{m-1} \cdots R_{k+1}$.

procedure SIFT$(\pi, C, k, \{T_i\}, \{R_i\})$
Initialize: $\sigma := \pi$, $j := k$.
    while $j \leq m-1$ **and** $\sigma \neq 1$ **do**
        if $\sigma \in G_{j+1}\alpha$ for some $\alpha \in R_{j+1}$
            then set $\sigma := \sigma\alpha^{-1}$ and $j := j+1$
            else
                begin
                    add σ to R_{j+1};
                    add σ to T_l, $l = k+1, \ldots, j$;
                    $k := j$;
                end ;
end (SIFT).

The main procedure is the following.

procedure PERMREP(Q, C)
INPUT: (Q, C) as above.
OUTPUT: $\{T_i\}, \{R_i\}$.
Initialize: $k := -1$, $T_{-1} := Q$,
        $T_i := \emptyset$ for $0 \leq i \leq m-1$, $R_i := \{1\}$, for $0 \leq i \leq m$.
    while $k \geq -1$ **do**
        begin

```
        while R_{k+1} × T_k not exhausted do
            begin
                select next (ρ, τ) in R_{k+1} × T_k;
                SIFT(ρτ, C, k, {T_i}, {R_i});
            end ;
        k := k − 1
        end
end (PERMREP).
```

Note that the intention is to put the elements of each $R_{k+1} \times T_k$ in a queue as such elements are created (by augmentation of R_{k+1} and/or T_k), ensuring that each $(\rho, \tau) \in R_{k+1} \times T_k$ is selected exactly once in the lifetime of the procedure.

The following proposition is just a reformulation of Sims's basic observations.

PROPOSITION 2.11. *When procedure PERMREP(Q, C) terminates, R_i is a complete set of coset representatives for G_{i-1} mod G_i and $\langle T_i \rangle^C = G_i^C$ for $0 \le i \le m$.*

Proof. Recall that N denotes the kernel of the G-action on C. As a result of having sifted $R_i T_{i-1}$, we know $R_i T_{i-1} \subseteq N R_m R_{m-1} \cdots R_i$ for $0 \le i \le m$. We have also maintained the properties $T_i \subseteq G_i$, $\bigcup_{j \ge i+1} R_j \subseteq \langle T_i \rangle$, and the elements of R_i represent distinct cosets mod G_i.

Since $Q = R_0 T_{-1} \subseteq N R_m \cdots R_1 \subseteq N\langle T_0 \rangle$, $G = N\langle T_0 \rangle$. Suppose, for any i that $G_i = N\langle T_i \rangle$; then $R_{i+1} T_i \subseteq N R_m R_{m-1} \cdots R_{i+1} \subseteq N\langle T_{i+1} \rangle R_{i+1}$, whence $G_i \subseteq N R_{i+1} \langle T_i \rangle \subseteq N\langle T_{i+1} \rangle R_{i+1}$. It follows that $G_i = N\langle T_i \rangle = N G_{i+1} R_{i+1}$ and $G_{i+1} = N\langle T_{i+1} \rangle$. □

We use the following easy facts about PERMREP(Q, C). We set $n = |A|$ and assume $n \ge m = |C|$. Therefore, the cost of each group operation is $O(n)$. Let $t = \max\{|G_{i-1}^C : G_i^C| : 1 \le i \le m\}$; note that $t \le m$. Also, $\log |G^C|$ is an upper bound on the length of subgroup chains in G^C so there are $\le \log |G^C|$ indices i such that $G_i \ne G_{i+1}$. In particular, the cost of each sift is $O(n \log |G^C|)$ and each T_i is increased $\le \log |G^C|$ times. From this, we obtain the following estimates.

THEOREM 2.12. (a) *Let $|Q| = q$. The running time of PERMREP(Q, C) is $O(n \log |G^C|(q + t \log^2 |G^C|))$; in particular, if $|G^C| \le \exp(\log^c n) = \exp(O^\sim(1))$ then the running time is $O^\sim(n(q + t))$.*

(b) *At any moment during the execution of the algorithm, $|T_{k-1}| \le 1 + \sum_{j=k}^m \log |R_j|$.*

Remark 2.13. The $O(n^5)$ bottleneck that is inherent to all versions of Sims's method [Si70], [FHL], [Je86], [Kn] can be appreciated in the context of PERMREP (take $C = A$ and $N = 1$). These methods rely on the construction of generators for the groups in the pointwise stabilizer chain, using Schreier's construction of subgroup generators. (In PERMREP, Schreier generators enter in the sifting of $R_{k+1} T_k$, since the sift of $\rho\tau$ begins with finding $\rho_1 \in R_{k+1}$ such that $\rho\tau\rho_1^{-1} \in G_{k+1}$.) In general, $|R_{k+1}|$, $|T_k|$ and the number of groups in the chain can each be $\Omega(n)$ so there may be $\Omega(n^3)$ elements to sift and a sift may cost $\Omega(n^2)$. In fact, Knuth discusses a class of groups in which the *average* behavior of such methods is $\Theta(n^5)$.

As in [FHL], a slight modification of PERMREP provides normal closures. The addition to the previous procedure is that we have to add conjugates of generators to the generating set until we get a group closed for conjugation. We again consider group actions.

The situation is the following: $G = \langle S \rangle \le \mathrm{Sym}(A)$ and $\langle Q \rangle \le \mathrm{Sym}(A)$ act on C. The output consists of sets of coset representatives $\{R_i\}$ and sets of generators of the stabilizer chain over C for $H := \langle Q^G \rangle$. For sets of permutations T and S, T^S denotes

the set of conjugates $\{\tau^\sigma : \tau \in T, \sigma \in S\}$.

procedure NORMCL(Q, C, S)
INPUT: (Q, C, S) as above.
OUTPUT: $\{T_i\}, \{R_i\}$.
    PERMREP(Q, C);
    $T^* := \emptyset$;
    repeat
        $k := -1$, $T_{-1} := (T_0 \setminus T^*)^S$, $T^* := T_0$;
        while $k \geq -1$ **do**
            begin
                while $R_{k+1} \times T_k$ not exhausted **do**
                    begin
                        select next $(\rho, \tau) \in R_{k+1} \times T_k$;
                        SIFT$(\rho\tau, C, k, \{T_i\}, \{R_i\})$;
                    end ;
                $k := k - 1$
            end
    until $T_0 = T^*$
end (NORMCL).

The proof of correctness and the timing of this algorithm is similar to that of PERMREP (with H playing the role of G in the estimates). Let $t = \max\{|H_{i-1}^C : H_i^C| : 1 \leq i \leq m\}$.

PROPOSITION 2.14. *When procedure NORMCL(Q, C, S) terminates, the R_i form complete sets of coset representatives for H, and $\langle T_i \rangle^C = H_i^C$.*

THEOREM 2.15. *Let $s = |S|$, $q = |Q|$. The running time of NORMCL(Q, C, S) is $O(n \log |H^C|(q + s \log |H^C| + t \log^2 |H^C|))$; in particular, if $|H^C| \leq \exp(\log^c n) = \exp(O^\sim(1))$ then the running time is $O^\sim(n(q + s + t))$.*

2.8. Structure forest, structure domain. It is natural in dealing with permutation groups, whether theoretically or in computational settings, to use the orbit structure in a problem decomposition. Further combinatorial divide-and-conquer is available in the imprimitivity structure of transitive groups. For computational purposes, it is convenient to provide an extension of the permutation domain that both reflects and guides the flow of control in such procedures. Specifically, a *structure forest* (SF) for a permutation group $G \leq \mathrm{Sym}(A)$ is a forest of rooted trees on which G acts as automorphisms fixing the roots, such that the leaves form the permutation domain A, and, denoting by $G(v)$ the permutation group induced on the children of node v by G_v (the stabilizer of v), each $G(v)$ is primitive. Thus, in particular, there is exactly one tree per orbit in A, and it is not possible to insert intermediate levels in that tree, with nontrivial branching, and remain consistent with the G action on the tree.

To reflect the flow of control in our procedure (e.g., treating orbits sequentially) we suppose that the trees of the SF are stacked vertically and enumerate the resulting "levels." Hence, the root of the first tree comprises level 0, its leaves comprise level h, where h is the height of this tree, the root of the second tree comprises level $h + 1$, etc.

The divide-and-conquer offered by the SF alone does not suffice for our methods. To achieve a finer decomposition, we need to delve into the primitive groups themselves; specifically, for "large" groups, we use the forced relations between the nature

of the socle and that of the permutation domain.

The first and principal stage creates an *extended structure forest* (ESF). For this, the SF is augmented at nodes v where $G(v)$ is a "large" group, i.e., of order $> \exp(\log^c n)$. At such places, we are assured that $G(v)$ is, in fact, a Cameron-type group with $\mathrm{Soc}(G(v)) \cong \mathrm{Alt}(k)^r$. Such $G(v)$ has a natural imprimitive representation on a set B of size kr, and we can build a structure forest (in fact, a tree) $T(v)$ on B for $G(v)$. Our algorithm constructs the trees $T(v)$ so that the leaves of $T(v)$ correspond to certain subsets of the children of $G(v)$. In particular, we need only do the work of constructing $T(v)$ at one node v at each level of the SF, using the action of G to copy the trees to other nodes at the same level. As a result, the permutation action of each element of G naturally extends to the ESF. We consider the trees $T(v)$ appended to the SF to be placed *entirely between levels of the initial forest*. Having so situated the $T(v)$, we delete the edges between v and its children in the original forest. Thus, edges, where they exist, in the ESF only traverse consecutive levels. It is important to note, however, that $G(v)$ acts faithfully on the leaves of $T(v)$, so that the subgroup of G that fixes all the leaves at this level also fixes all the nodes at the level of the children of v in the SF.

We now continue to use $G(v)$ to denote the (primitive) permutation group induced by G_v on the set of children of the node v of the ESF. (In context, it is clear which $G(v)$ is intended when we specify the ambient graph.) Thus, in the ESF, $G(v)$ is either a "small" group (of order $< \exp(\log^c n)$) or a giant. Furthermore, the groups at a given level are isomorphic, in fact, conjugate under the action of G; accordingly, we can talk about *small group levels* and *giant levels* in the ESF.

A second refinement is used to restrict the giant levels to be alternating. Consider a node v of the ESF where $G(v)$ is a full symmetric group $\mathrm{Sym}(C(v))$ on the children $C(v)$ of v. At each such node, we append a small tree consisting of the root v and two leaves, say v_L and v_R (for "left" and "right"), which are inserted at a new level between v and $C(v)$. Again, we sever the links from v to $C(v)$, but we now connect both v_L and v_R to all points in $C(v)$. We need to extend the action of G to the new intermediate level. This may be done by fixing any orderings of the $C(v)$, relative to which the actions of $\gamma \in G$ can be viewed as inducing even or odd permutations; if γ induces an "even" mapping of $C(v)$ to $C(w)$ then $v_L^\gamma = w_L$ and $v_R^\gamma = w_R$, else $v_L^\gamma = w_R$ and $v_R^\gamma = w_L$. We call the resulting structure D a *structure domain* (SD) for G.

For a node $v \in D$, we continue to denote the children of v, that is, the neighbors at next level by $C(v)$ and the action of G_v on $C(v)$ by $G(v)$.

We summarize some important properties of this structure. A structure domain for $G \leq \mathrm{Sym}(A)$ is a graph $D = (V, E)$ such that the following hold.

(i) $A \subseteq V$ and $|V| = O(n)$, where $n = |A|$.

(ii) The action of G extends to $\mathrm{Aut}(D)$.

(iii) The orbits of G in V, called "levels," are ordered, $L_0, L_1, \ldots, L_m$, and $E \subseteq \bigcup_{i=0}^{m-1}(L_i \times L_{i+1})$.

(iv) If $E \cap (L_i \times L_{i+1}) = \emptyset$, then $G_{L_i} \leq G_{L_{i+1}}$.

(v) If $E \cap (L_i \times L_{i+1}) \neq \emptyset$, then, letting $G(v)$ denote the action of G_v on the neighbors $C(v)$ in L_{i+1} of $v \in L_i$, it follows that $G(v)$ is either a "small" group or $\mathrm{Alt}(C(v))$.

Let $G_0 = G$ and, for $i \geq 1$, let G_i be the kernel of the action of G_{i-1} on L_i. Then the normal series

$$G = G_0 \geq G_1 \geq \cdots \geq G_m = 1$$

is the chain forecast in the introduction and in section 2.6. Instances of (iv) suggest that the chain is not strictly decreasing (and one can have equality of successive groups even when the induced bipartite graph is nontrivial), but it is convenient to allow this occasional duplication. Note, however, that (v) implies, when $G_{i+1} < G_i$, that G_i/G_{i+1} is either a product of isomorphic alternating groups or a subgroup of the product of isomorphic small primitive groups. The fact that, in the former case, G_{i-1}/G_i is actually isomorphic to a product of alternating groups (not only a subgroup) follows from Proposition 2.2.

Informally, we say the SD consists of *small group levels* and *alternating levels*.

3. Organization of the algorithm. In this section, we outline our main algorithm. Suppose that $G = \langle S \rangle \leq \mathrm{Sym}(A)$ is given, $|A| = n$. We construct a chain of normal subgroups $G = G_0 \geq G_1 \geq \cdots \geq G_m = 1$ and, for each $1 \leq i \leq m$, a permutation representation of G_{i-1} on a set L_i such that

(i) G_i is the kernel of the action of G_{i-1} on L_i;

(ii) G_{i-1}/G_i is either a subgroup of a direct product of small primitive groups ("small" in this context means of order $< \exp(9 \log^2 n \log\log n)$) or $G_{i-1}/G_i \cong \mathrm{Alt}(k)^r$ for some k, r.

The normal subgroup G_i is defined to be the pointwise stabilizer of the first i levels in a structure domain (see section 2.8). However, we have to *construct* generators for the G_i. We do this successively for $i = 0, 1, \ldots, m-1$. We construct an SGS T_i for G/G_i and *normal generators* N_i for G_i, i.e., group elements whose normal closure (in G) is G_i.

Suppose we have constructed T_{i-1} and N_{i-1}. We start to take the normal closure of N_{i-1} in G until the known part of the normal closure generates G_{i-1}/G_i. We confirm this by examining the action of G_{i-1} on L_i. Then we obtain T_i by appending an SGS for G_{i-1}/G_i to T_{i-1}. For this, if G_{i-1}/G_i corresponds to a small group level then we add complete sets of coset representatives from the point stabilizer chain on L_i to T_{i-1} (we do ensure that the total number of saved coset representatives in the entire subgroup chain is only $O(n \log^2 n)$); if G_{i-1}/G_i is the product of alternating groups then we add Jerrum-style compact SGS (cf. section 2.6) for each of these alternating groups to T_{i-1}. We also obtain a presentation for G_{i-1}/G_i, which, along with presentations for earlier quotients, facilitates a construction of normal generators N_i for G_i. Thus we proceed to the next value of i.

We emphasize that generators for G_i (not only normal generators) are available only when the entire algorithm is finished.

During the algorithm, we work with various permutation representations of subgroups of G. If a procedure performs group operations, we may either need the result in the current representation only (*local* operation) or in the original representation as well (*global* operation). An example of a purely local operation is the determination of whether the stabilizer of a node v in the SF acts as a Cameron-type group on its children. To this end, it is enough to perform group operations in $G(v)$ and the action of G_v on other nodes of the SF is irrelevant. All operations not explicitly labelled "local" are understood to be global. Since the sum of sizes of all the induced permutation representations remains $O(n)$, the cost of elementary group operations remains $O(n)$.

Main Algorithm.
INPUT: a set S of generators for $G \leq \mathrm{Sym}(A)$, $|S| = s$.
Step 1. Construct a structure forest and choose a representative v in each orbit of the SF. For all such v, construct Schreier generators for G_v.

Step 2. For these representatives, use NATURAL_ACTION to decide whether $G(v)$ is a "large group" and, if so, construct new action and corresponding structure tree $T(v)$.
Step 3. Append a copy of $T(v)$ to all nodes in the orbit v^G, deleting the connections of v to its children in the SF, thus obtaining an ESF. Extend the G-action of generators to the ESF. Inserting new levels at giant symmetric nodes, obtain the SD. Henceforth, compute the effect of any global operation on the entire SD. Compute the node stabilizers G_w as in Step 1 for representatives of G-orbits of the SD.
Step 4. For each node v representing an alternating level in the SD, construct an SGS for $G(v)$.

Step 5. **for** $i := 1$ to m **do**
construct SGS for G_{i-1}/G_i
store a *compatible* generating set S_{i-1} of size $O^\sim(|L_i|)$ for G_{i-1}/G_i
(* cf. section 2.6 *)
construct normal generators for G_i
end (MAIN ALGORITHM).

LEMMA 3.1. (a) *A structure forest can be computed in* $O(sn^2)$ *time.* (b) *Generators of* G_v *for representatives of the* G*-orbits of the SF can be constructed in* $O(sn^2)$ *time.*

Proof. (a) According to Atkinson [At], a structure forest can be computed as efficiently as orbits and minimal blocks of imprimitivity, i.e., in $O(sn^2)$ time.

(b) The action of the group generators on the orbit v^G of a node v in the SF naturally defines a graph on v^G. Choosing a spanning tree in this graph and computing the product of generators along the paths from v in this tree, group elements which carry v to the other nodes of its orbit can be computed in $O(|v^G|n + |v^G|s)$ time. We obtain generators for G_v (and, at the same time, for $G(v)$) via Lemma 2.1; thus G_v is generated by $O(|v^G|s)$ elements and the cost of computing each is $O(n)$. The result follows since the sum of the $|v^G|$ over orbit representatives v is the number of nodes in the SF. □

Steps 2 and 3 will be analyzed in section 4. We present a novel method for constructing an SGS for the giants in section 5. Section 6 relates group presentations (in terms of generators and relations) to the construction of normal generators. By the results of section 4, the factor groups G_{i-1}/G_i in Step 5 are either subgroups of products of "small" groups or products of alternating groups. We handle the first case in section 7, utilizing NORMCL (cf. section 2.7). For the second case, we give an efficient implementation of Luks's "noncommutative linear algebra" [Lu86] in section 8. Finally, in section 9, we present a version of the algorithm with decreased memory requirement and wrap up the proof of Theorem 1.1.

4. Reducing large to giant. The purpose of this section is to classify primitive groups as "large" and "small." Large groups turn out to be groups of Cameron type, and we construct their "natural" (often imprimitive) action with giants acting on each block and a small group permuting the blocks. Thereby most algorithmic problems are reduced to consideration of giants and small groups.

Our objective is achieved by the subroutine NATURAL_ACTION. This procedure is a slight refinement of the one under the same name in [BLS87]. The procedure involves a global variable n, the degree of the permutation group which is the input of the full algorithm. However, we execute group multiplications only on the set where the group under the current investigation acts primitively (local operations, cf.

section 3).

First, we describe a simple procedure to test whether or not a permutation group is a giant.

procedure TEST_GIANT(G)
INPUT: a 2-transitive group $G = \langle Q \rangle \leq \mathrm{Sym}(C)$, $|C| = m$.
Begin executing PERMREP(Q, C)
if $|\{i : |R_i| \neq 1\}| \geq 2\log m + \log^2 m$ ($*$ we use the notation of section 2.7. $*$)
then stop PERMREP(Q, C); **output** "giant" and **halt**
else output "small group" and **halt**
end (TEST_GIANT).

When reading the following pseudocode, it is useful to review the notation of sections 2.4 and 2.5 and keep in mind that NATURAL_ACTION was designed to handle Cameron-type groups, when $m = \binom{k}{s}^r$ and the underlying set A corresponds to s-transversals in rB for some set B of size k. In that scenario, Γ and Δ correspond to the sets of pairs of s-transversals with intersection pattern $(s-1, s, \ldots, s)$ and $(0, 0, \ldots, 0)$, respectively. The primary aim of the procedure is to construct a subset of A corresponding to the s-transversals containing a fixed point in rB. Such a set is constructed as $C(x, y)$ below, where x, y are s-transversals with intersection pattern $(s-1, s, \ldots, s)$ and $C(x, y)$ consists of all s-transversals containing the unique point in x that is not covered by y. The subset $C(x, y)$ has kr distinct images under G, corresponding to the points of rB. We compute this set D of images in two phases, first constructing in $D(x)$ only the rs images corresponding to the points of x. This and other checks on the sizes of newly constructed objects allow early termination in the case when G is not a large group.

procedure NATURAL_ACTION(Q)
INPUT: a primitive group $G = \langle Q \rangle \leq \mathrm{Sym}(A)$, where $m := |A| \leq n$.
Step 1. **if** $m \leq 3\log^2 n$
then output "small group" and **halt**
Step 2. **if** G is 2-transitive
then TEST_GIANT(G); ($*$ procedure will halt there $*$)
Step 3. Compute the orbitals (G-orbits on $A \times A$);
$\Gamma :=$ the second smallest orbital;
($*$ The smallest orbital is the diagonal. $*$)
$\Delta : D$ the largest orbital.
Fix $x \in A$;
if $|\Gamma(x)| > 2\sqrt{m}\log m$
then output "small group" and **halt**
For each $w \in A$ construct $\alpha(w) \in G$ such that $x^{\alpha(w)} = w$.
Construct Schreier generators for G_x.
Fix $y \in \Gamma(x)$. For each $y' \in \Gamma(x)$ compute some $\beta(y') \in G_x$ such that $y^{\beta(y')} = y'$.
Compute the sets

$$B(x, y) = \Delta(y) - \Delta(x);$$
$$C(x, y) = A - \bigcup_{z \in B(x,y)} \Delta(z).$$

Let $D(x) = \{C(x, y)^{\beta(y')} : y' \in \Gamma(x)\}$.
if $|D(x)| > \log m$
then output "small group" and **halt**

Let $D = \bigcup_{w \in A} D(x)^{\alpha(w)}$.
if $|D| > 2\sqrt{m} \log m$
then output "small group" and **halt**
Step 4. Consider G-action on D. ($*$ This action exists and it is transitive. $*$)
Select a system $\{E_1, \ldots, E_t\}$ of minimal-size (but nonsingleton) imprimitivity blocks
($* \bigcup_i E_i = D *$).
if $q := |E_i| > 4 \log\ n$ **and** $G(E_1)$:=the stabilizer of E_1 restricted to E_1 is 2-transitive
and TEST_GIANT($G(E_1)$) returns message "giant"
then output ("large group, faithfully acting on D";
the G-action on D;
a structure tree for the G-action on D)
else output "small group"
halt
end (NATURAL_ACTION).

We say that G *fails the large groups test* if output is "small group." Otherwise G is said to *pass the large groups test*.

4.1. Correctness of the subroutine NATURAL_ACTION.

LEMMA 4.1. *If TEST_GIANT(G) outputs "giant" then G is a giant. If the output is "small group" then $|G| < m^{2+\log m}$.*

Proof. It is proved by Theorem 2.4. □

The following result justifies the term "small groups" and provides additional information about large groups.

THEOREM 4.2. (1) *If NATURAL_ACTION outputs "giant" then G is a giant.*

(2) *If NATURAL_ACTION outputs "large group" then G acts faithfully on D and the stabilizer of each block E_i restricted to E_i contains* $\mathrm{Alt}(E_i)$.

(3) *If NATURAL_ACTION outputs "small group" then*

$$|G| < \exp(9 \log^2 n\ \log\log n).$$

Statement (1) is obviously correct. For (2) we need a lemma.

LEMMA 4.3. *For $p \neq r$ primes, the order of a Sylow r-subgroup of the linear group* $\mathrm{GL}(d, p)$ *is less than p^{2d}.*

Proof. This result is implicit in [Lu82, Lemma 3.6]. □

COROLLARY 4.4. *For $q \geq 4d \log p$, the order of* $\mathrm{Alt}(q)$ *does not divide the order of the affine linear group* $\mathrm{AGL}(d, p)$.

Proof. Let $r = 3$ if $p = 2$ and let $r = 2$ otherwise. The result follows from Lemma 4.3 (except for the two easy cases $p = 2, d \leq 3$). □

Proof of Theorem 4.2*, part* (2). We show that the alternating groups constructed by the procedure are in the socle of G and G has a unique minimal normal subgroup. These facts imply that the G-action on D has a trivial kernel. We say that the group H is *involved* in the group K if $H \cong L/M$ for some $M \triangleleft K, M \leq L \leq K$. If a simple group H is involved in K then clearly H is involved in a composition factor of K.

We may assume G is not a giant. Let K be the kernel of the G-action on D. The stabilizer of E_1 restricted to E_1 passed TEST_GIANT, whence it contains $\mathrm{Alt}(q)$, $q := |E_1|$. As the G-action on the set of blocks is transitive, the same holds for each E_i. Also, it follows that $\mathrm{Alt}(q)$ is involved in G/K.

If $\mathrm{Soc}(G)$ is abelian then, by Theorem 2.6, $m = p^d$ for some prime p and $G \leq \mathrm{AGL}(d, p)$. But, $d \log p = \log\ m \leq \log\ n \leq q/4$ and therefore, by Corollary 4.4, the order of $\mathrm{Alt}(q)$ does not divide $|G|$. Thus this case cannot occur. Hence $\mathrm{Soc}(G)$

is nonabelian and the results stated in Theorem 2.7 apply. We use the notation of Theorem 2.7 and refer to $N \triangleleft G$ established there.

First we show that $\mathrm{Alt}(q)$ is not involved in $G/\mathrm{Soc}(G)$. Indeed, otherwise $\mathrm{Alt}(q)$ must be involved either in G/N or in $N/\mathrm{Soc}(G)$. The first case is impossible because $G/N \leq S_d$ (Theorem 2.7(b)) and $d \leq \log\ m/\log\ 5 < q/8$ (Theorem 2.7(c)). In the second case, $\mathrm{Alt}(q)$ is involved in $N/\mathrm{Soc}(G) \leq \mathrm{Out}(T)^d$, a solvable group by the Schreier conjecture (Theorem 2.3), again a contradiction.

It follows now that $\mathrm{Alt}(q)$ is involved in $\mathrm{Soc}(G)$ and $K \not\geq \mathrm{Soc}(G)$. Now $\mathrm{Soc}(G)$ must be the unique minimal normal subgroup for otherwise, by Theorem 2.8, we have a contradiction:

$$n^2 \geq m^2 = |\mathrm{Soc}(G)| \geq |\mathrm{Alt}(q)| = q!/2 > 2^q \geq n^4.$$

It follows that K contains no minimal normal subgroup, whence $K = 1$. □

Proof of Theorem 4.2*, part* (3). Assume the order of $|G|$ exceeds the stated bound. We must show that at no point will "small group" be falsely announced. This would not happen in Step 1, for $m \leq 3\log^2 n$ implies $|G| \leq m! < (3\log^2 n)^{3\log^2 n}$. If G is 2-transitive then the Step 2 call to TEST_GIANT will correctly halt with that revelation (by Theorem 2.4).

By Theorem 2.9, G is of Cameron type and A can be identified with the set of points of a Cameron scheme $C(m, k, s, r)$, and we may assume that $rs > 1$; that is, G is not a giant. Of course, the parameters and the identification are not known a priori. We prove that Step 3 of NATURAL_ACTION correctly recovers this structure with D corresponding to rB, E_i to B_i (so $q = k$), and the parameter k satisfies $k > 4\log n$. (We use the letters r, k, B_i, $C = rB = B_1 \cup \cdots \cup B_r$ to mean what they do in section 2.5. We call the action of G on C "natural." Recall that each $a \in A$ corresponds to an s-transversal $T(a) \subset rB$.)

We take note of some inequalities satisfied by the parameters of this $C(m, k, s, r)$. Since $m = \binom{k}{s}^r \geq (k/s)^{rs} \geq 2^{rs}$,

$$rs \leq \log m. \tag{4.1}$$

Since $rs > 1$, we have $m \geq \binom{k}{2}$ which implies

$$k < 2\sqrt{m}. \tag{4.2}$$

Also,

$$k > 4\log n; \tag{4.3}$$

otherwise, $|G| \leq (k!)^r r! \leq k^{kr} r! \leq m^k r! \leq n^{4\log n}(\log n)! < \exp(9\log^2 n\ \log\log\ n)$. Finally,

$$k \geq 2rs^2; \tag{4.4}$$

otherwise, using (4.1), we have $|G| \leq (k!)^r r! < (2rs^2)^{2r^2s^2} r! < (2\log^2 n)^{2\log^2 n}(\log\ n)!$ $< \exp(9\log^2 n\ \log\log\ n)$.

We claim now that the G-action on D is similar to the natural G-action on C. For $b \in rB$, let $U(b) = \{u \in A | b \in T(u)\}$. We need to show that that $D = \{U(b) | b \in rB\}$. By (4.4) and Lemma 2.10, $\Gamma = \Sigma_1$ and $\Delta = \Phi$. Thus, for any $y \in \Gamma(x)$, the set $T(x) - T(y)$ is a singleton $\{b(x, y)\}$. Now, a simple inspection of the Cameron scheme,

using that $k > 3s$ (by (4.4) since $rs > 1$), shows that $C(x, y) = U(b(x, y))$. The result follows since G acts transitively on C.

The identification of the E_i with the B_i follows because the latter are the unique minimal-size blocks in the natural action of G. Finally, (4.1), (4.2), and (4.3) ensure that the cardinality tests on that $\Gamma(x), D(x), D, E_i$ in Steps 3 and 4 do not cause terminal output "small group." □

4.2. Time complexity of the subroutine NATURAL_ACTION.

LEMMA 4.5. *Suppose $G = \langle Q \rangle$ acts on an m-set, and $|Q| = q$. Then TEST_GIANT(G) runs in $O^{\sim}(m^2 + qm)$ time.*

Proof. We work with $O^{\sim}(1)$ coset representative sets R_i each of size $2 \leq |R_i| \leq m$, and, by Theorem 2.12(b), $O^{\sim}(1)$ sets of generators T_i of size $O^{\sim}(1)$. Hence the sifting of products of the form $\rho\tau$, $\rho \in R_i, \tau \in T_{i-1}$ for some i costs $O^{\sim}(m^2)$; in addition, we may have to sift the elements of Q. □

THEOREM 4.6. *Suppose $G = \langle Q \rangle$ acts on an m-set, and $|Q| = q$. Then NATURAL_ACTION(Q) runs in $O^{\sim}(qm^2)$ time.*

Proof. Testing 2-transitivity takes $O(m^2q)$ time. Hence, by Lemma 4.5, Step 2 can be executed in $O^{\sim}(m^2q)$. Finding the orbitals requires $O(m^2q)$ steps. The (local) computation of $\{\alpha(w) : w \in A\}$ requires $O^{\sim}(m^2 + qm)$ time. The number of Schreier generators is qm; they are found in $O(m^2q)$ time. $O^{\sim}(qm^{3/2})$ steps suffice to find the $\beta(y')$. $C(x, y)$ can be determined in $O(m^2)$ time. We compute $D(x)$ in $O^{\sim}(m^2)$. Finally, D is also obtained in $O^{\sim}(m^2)$. Thus Step 3 requires $O^{\sim}(m^2q)$ total time.

The action of any $\phi \in Q$ on D can be found in $O^{\sim}(m^{3/2})$. The structure tree is computed in $O^{\sim}(mq)$, and, since $r = O^{\sim}(1)$, generators for the stabilizers of orbit-representatives on the new tree can be computed in $O^{\sim}(qm)$ time. Finally, we call TEST_GIANT on a set of size $O^{\sim}(\sqrt{m})$, with $O^{\sim}(q)$ generators, requiring $O^{\sim}(m + q\sqrt{m})$ time. Thus the time complexity of Step 4 is $O^{\sim}(mq + m^{3/2})$. □

COROLLARY 4.7. *Step 2 of the main algorithm runs in $O^{\sim}(sn^2)$ time.*

Proof. We apply NATURAL_ACTION to the action $G(v)$ of the point stabilizer G_v on the children of v for certain nodes v of the structure forest (one node from each level of each tree). Denoting by q_v the number of (Schreier) generators for G_v and by m_v the number of children of v, $\sum_v (q_v m_v) = O(sn)$. □

4.3. Extending the structure forest.

PROPOSITION 4.8. *Step 3 of the main algorithm runs in $O^{\sim}(sn^2)$ time.*

Proof. Suppose that a node v is the representative of an orbit in the original SF, v has m children, and NATURAL_ACTION appended a tree $T(v)$ to v. The vertices of $T(v)$ are subsets of the children of v; hence the group elements carrying v to the other nodes of its orbit v^G, computed in Step 1, naturally define a copy of $T(v)$ appended to the other nodes in v^G. These copies of $T(v)$ can be obtained in $O^{\sim}(m^{3/2}|v^G|)$ and the action of any $\sigma \in G$ can be extended to the appended trees within the same time bound. Hence the action of σ on the entire ESF can be computed in $O^{\sim}(n^{3/2})$. The extension to the SD is straightforward and in time $O(n)$. Finally, as in Lemma 3.1(b), generators of G_v for representatives of G-orbits of the SD can be constructed in $O(sn^2)$ time. □

5. Constructing strong generators for a giant. The purpose of this section is to construct a Jerrum-style compact SGS for the giants. Recall that the "giants" are the symmetric and alternating groups in their natural action. The Jerrum-style compact SGS for $G = \mathrm{Sym}(C)$ acting on the set $C = \{x_1, x_2, \ldots, x_m\}$ consists of $m-1$ permutations $\pi_1, \pi_2, \ldots, \pi_{m-1}$ such that for all $1 \leq k \leq m-1$, π_k fixes $x_1, \ldots, x_{k-1}$

and $x_k^{\pi_k} = x_{k+1}$. For $G = \mathrm{Alt}(C)$, the SGS contains $\pi_1, \pi_2, \ldots, \pi_{m-2}$ as above while π_{m-1} fixes $x_1, \ldots, x_{m-3}$ and $x_{m-2}^{\pi_{m-1}} = x_m$.

We require that the strong generators are constructed from the given generators of the giant by the following *legal operations: multiplication, inversion, and taking powers of permutations*. The reason for this constraint is that the procedure is applied to the case when $G(v)$, the action of the stabilizer of node v on the children in the structure domain, is an alternating group. In this case, although we know a priori that some $\sigma \in G(v)$ acts on the children as, e.g., a given 3-cycle, no such permutation can be guaranteed to belong to the input group unless it has been constructed, by way of legal operations, from the generators of $G(v)$. In this application, all group operations are global; i.e., we perform them on all points in the SD.

5.1. Construction of a 3-cycle. The essence of the procedure is the construction of a 3-cycle. Once a 3-cycle ρ is constructed, an SGS can be obtained easily by taking appropriate conjugates of ρ.

We note that a byproduct of the procedure yields a simple, elementary proof of the old result, known to Jordan (1895) [Jo] (and vastly surpassed by Theorem 2.4) that the only $c \log^2 n / \log \log n$ -fold transitive permutation groups are the giants [BS87]. It also yields an $\exp(\sqrt{n \ln n}(1 + o(1)))$ upper bound on the diameter of any Cayley graph of the giants [BS88].

Our goal is achieved by the procedure THREE_CYCLE. As a preprocessing phase, we determine and store the first $\log n$ primes. (The global variable n is the degree of the permutation group which is the input of the entire algorithm; we assume that n is sufficiently large.) We denote the ith prime by p_i and the product of the first i primes by $p(i)$.

Also, we need the following definitions. For $\pi \in \mathrm{Sym}(C)$, let us call a subset B of $\mathrm{supp}(\pi)$ *independent* with respect to π if $B \cap B^\pi = \emptyset$. The *commutator* of $\pi, \tau \in \mathrm{Sym}(C)$ is $[\pi, \tau] = \pi\tau\pi^{-1}\tau^{-1}$.

The procedure THREE_CYCLE uses the subroutine ORBITALS. Given generators for some $G \leq \mathrm{Sym}(C)$, $|C| = m$, ORBITALS returns $O(\log m)$ generators for a subgroup $H \leq G$ with the same orbitals as G. In particular, if G is a giant then ORBITALS returns $O(\log m)$ generators for a 2-transitive subgroup. The idea is the following. Suppose that generators for some $H \leq G$ are already defined but the orbital structures of the two groups are different. We fix an ordering of the generators $P = \{\tau_1, \ldots, \tau_k\}$ of G, and, for each H-orbital Δ which is not an orbital of G, we find the last element of P which moves Δ. Then we add a product of the form $\tau_1^{\varepsilon_1}\tau_2^{\varepsilon_2}\cdots\tau_k^{\varepsilon_k}$ to the generators of H where each $\varepsilon_i \in \{0, 1\}$ and ε_j is chosen such that $\tau_1^{\varepsilon_1}\tau_2^{\varepsilon_2}\cdots\tau_j^{\varepsilon_j}$ moves at least half of the H-orbitals Δ for which τ_j was the last generator moving Δ. This is a deterministic version of the *random subproduct method*, which we describe in section 5.4.

procedure ORBITALS(P, C, R)
INPUT:$G = \langle P \rangle \leq \mathrm{Sym}(C)$, $|C| = m$, $P = \{\tau_1, \ldots, \tau_k\}$.
OUTPUT: Generators R for some $H \leq G$ with same orbitals as G, $|R| = O(\log m)$.
Initialize: compute orbitals $O_1, \ldots, O_p$ of G; $R = \emptyset$
repeat
    compute orbitals $\{\Delta_i : i \in I\}$ of $\langle R \rangle$
    for all $\Delta_i \notin \{O_1, \ldots, O_p\}$, compute
        $\mathrm{last}(\Delta_i) := \max\{j : \Delta_i^{\tau_j} \neq \Delta_i\}$
    $\sigma := 1$ ($*$ start constructing new element of R $*$)

for $j := 1$ to k **do**
if $|\{\Delta_i : \text{last}(\Delta_i) = j, \Delta_i^\sigma = \Delta_i\}| > |\{\Delta_i : \text{last}(\Delta_i) = j, \Delta_i^\sigma \neq \Delta_i\}|$
then $\sigma := \sigma\tau_j$
$R := R \cup \{\sigma\}$
until orbitals of G = orbitals of $\langle R\rangle$
end (ORBITALS).

Steps 1–3 in the next procedure can be viewed as a preprocessing phase in which we construct the first $\log^2 n$ coset representative sets in the stabilizer chain of a giant G. With these coset representative sets in hand, it is easy matter to construct a permutation $\tau \in G$ that has a prescribed effect on an arbitrary subset of size $\log^2 n$ (cf. Lemma 5.2). Such constructed elements are useful in a computation that replaces a given element λ by one with significantly smaller support. For an appropriately designed τ, $\lambda_1 = [\lambda, \tau]$ contains cycles of prime length for a lot of different primes. An underlying idea then is that one of these primes does not divide most of the cycle lengths in λ_1. Taking an appropriate power of λ_1, we can kill all cycles whose length was not divisible by that prime and we get a permutation with smaller support. Iterating the process, we obtain a 3-cycle.

procedure THREE_CYCLE(Q)
INPUT: $G = \langle Q\rangle$ acting on $C = \{x_1, x_2, \ldots, x_m\}$; $m > 3\log^2 n$, G^C is a giant.
OUTPUT: An SGS, constructed from Q (using legal operations only).
Step 1. Begin PERMREP(Q, C);
stop PERMREP(Q, C) when $|\{i : i > \log^2 n, |R_i| \neq 1\}| = 2\log n + \log^2 n$.
Let R be a collection of nontrivial coset representatives such that
$|R \cap R_i| = 1$ for all $i > \log^2 n$, $|R_i| \neq 1$.
Step 2. ORBITALS(Q, C, Q_0).
Step 3. **for** $i := 1$ to $\log^2 n$ **do**
Let $G(i-1) := \langle Q_{i-1} \cup R\rangle$.
Construct coset representatives D_i for $G(i-1)^C$ mod $G(i-1)^C_{x_i}$
($*$ $G(i-1)^C_{x_i}$ is the stabilizer of x_i in $G(i-1)^C$. $*$)
Construct Schreier generators Q_i^* for $G(i-1)^C_{x_i}$.
ORBITALS(Q_i^*, C, Q_i).
Step 4. Compute $f(m), g(m)$, where $f(m) := \min\{\{\}r : p(r) > m^4\}$, and $g(m) := \sum_{i=1}^{f(m)} p_i$.
Step 5. Let λ be any $\neq 1$ element of G.
while $\deg(\lambda) > \log^2 n$ **do**
Choose $B \subset \text{supp}(\lambda), |B| = g(m)$ such that B is independent.
Construct $\tau \in G$ such that τ fixes pointwise B^λ and
$\tau|_B$ consists of cycles of length $p_1, p_2, \ldots, p_{f(m)}$.
$\lambda_1 := [\lambda, \tau]$.
For all $i \leq f(m)$, compute $m(i) :=$ the product of all cycle lengths in λ_1
which are not divisible by p_i.
Choose $i \leq f(m)$ such that $2 \leq \deg(\lambda_1^{m(i)}) < \deg(\lambda)/2$.
Let $\lambda := \lambda_1^{m(i)}$ for this i.
end
Step 6. Construct $\rho \in G$ such that ρ fixes exactly $\deg(\lambda) - 1$ points in $\text{supp}(\lambda)$.
Let $\sigma = [\lambda, \rho]$. ($*$ σ is a 3-cycle $*$)
Step 7. Take conjugates of σ to obtain an SGS for $\text{Alt}(C)$.
If $G^C = \text{Sym}(C)$ then sift an odd permutation to obtain an SGS for G^C.

output the SGS for G^C.
end (THREE_CYCLE).

5.2. Correctness of the subroutine THREE_CYCLE.

LEMMA 5.1. *For each* $1 \le i \le \log^2 n$, $\langle Q_i^* \rangle^{C \setminus \{x_1,\ldots,x_i\}}$ *contains* $\mathrm{Alt}(C \setminus \{x_1,\ldots,x_i\})$.

Proof. It is proved by Theorem 2.4. □

LEMMA 5.2. *Given any* $D \subset C, |D| = d \le \log^2 n$, *and an injection* $f : D \to C$, *it is possible to construct* $\tau \in G$ *such that* $\tau|_D = f$, *and* τ *is a* $2d$*-long product of elements of* $\bigcup_{i=1}^{\log^2 n} D_i$.

Proof. By Lemma 5.1, for all $i \le \log^2 n$ $D_i = \{\alpha(i,j) | i \le j \le m\}$, where $\alpha(i,j)$ fixes $x_1, x_2, \ldots, x_{i-1}$ and moves x_i to x_j. For any distinct $a_1, \ldots, a_d \in C$, let us define recursively $\pi(a_1,\ldots,a_d) = \rho\alpha(d, a_d^\rho)^{-1}$, where $\rho = \pi(a_1,\ldots,a_{d-1})$. Then, for $i \le d$ we have $a_i^{\pi(a_1,\ldots,a_d)} = i$. Let now $D = \{l_1,\ldots,l_d\}$. Then $\tau = \pi(l_1,\ldots,l_d)\pi(f(l_1),\ldots,f(l_d))^{-1}$ is appropriate. □

PROPOSITION 5.3. $f(m) = O(\frac{\log\ m}{\log\ \log\ m})$ *and* $g(m) = O(\frac{\log^2 m}{\log\ \log\ m})$.

Proof. It is proved by the prime number theorem [HW]. □

COROLLARY 5.4. $f(m) = O(\log n)$ *and* $g(m) = O(log^2 n)$.

The following is easily verified.

LEMMA 5.5. *Let* $\pi, \tau \in \mathrm{Sym}(C)$. *Assume that* B *is an independent set with respect to* π *and* $\tau|_{B^\pi}$ *is the identity. Then* $[\pi,\tau]|_B = \tau^{-1}|_B$.

LEMMA 5.6. *Let* $\pi \in \mathrm{Sym}(m)$, $k = \deg(\pi)$. *Suppose* π *contains cycles of each prime length* p_i, $i \le r = f(m)$. *Let* $m(i)$ *be the product of all cycle lengths occurring in* π *which are not divisible by* p_i. *Then* $2 \le \deg(\pi^{m(i)}) < k/4$ *for some* $i \le r$.

Proof. Let $K = \mathrm{supp}(\pi)$. For each $x \in K$, let us consider the set $P(x)$ of those primes p_i dividing the length of the π-cycle through x. Clearly, the product of these primes is $\le k$.

Let $n(i)$ denote the number of points x such that $p_i \in P(x)$. Let us estimate the weighted average W of the $n(i)$ with weights $\log\ p_i$. Recall that the sum of the weights is $\sum \log\ p_i > \log(m^4) = 4 \log\ m$; therefore,

$$W < \sum_{x \in K} \sum_{p_i \in P(x)} \log\ p_i/(4 \log\ m)$$

$$\le (k \log\ k)/(4 \log\ m) \le k/4.$$

We thus infer that $n(i) < k/4$ for some $i \le r$. Clearly, $\pi^{m(i)}$ is not the identity and it fixes all but $n(i)$ points. □

THEOREM 5.7. *The output of THREE_CYCLE*(Q) *is an SGS for* G.

Proof. By Lemma 5.1, Step 3 constructs the first $\log^2 n$ coset-representative sets for a giant. By Corollary 5.4, we can choose independent sets of size $g(m)$ from permutations of degree $> \log^2 n$. By Lemma 5.2, we are able to construct the permutations τ, ρ required in Step 5 and 6. By Lemma 5.5, $\lambda_1|_B$ has the same cycle structure as $\tau|_B$; moreover, $\deg(\lambda_1) \le \deg(\lambda) + \deg(\tau\lambda^{-1}\tau^{-1}) = 2\deg(\lambda)$. Hence, by Lemma 5.6, we can choose $i \le r$ such that $2 \le \deg(\lambda_1^{m(i)}) < \deg(\lambda)/2$. In Step 6, we compute the commutator of two permutations whose supports intersect in exactly one point, whence the commutator is a 3-cycle. Finally, we can obtain permutations which conjugate σ into elements of an SGS by Lemma 5.2. □

5.3. Time complexity of THREE_CYCLE.

LEMMA 5.8. *ORBITALS(P, C, R) runs in $O^\sim(|P||C|^2 + |P|n)$ time.*

Proof. The orbitals of G can be computed in $O(|P||C|^2)$ time. One execution of the repeat loop costs $O^\sim(|R||C|^2)$ for the computation of the orbitals of $\langle R\rangle$, plus $O(|P||C|^2)$ for the computation of the function $\text{last}(\Delta_i)$, plus $O(|C|^2)$ for checking the images Δ_i^σ, plus $O(|P|n)$ for group multiplications to compute σ. The key observation is that we execute the repeat loop only $O(\log|C|)$ times since, at each execution, the new σ increases at least half of the orbitals Δ_i for which the function $\text{last}(\Delta_i)$ is defined. Therefore, after l executions of the repeat loop, the number of "bad" Δ_i's is $\le |C|^2(3/4)^l$. □

LEMMA 5.9. *Suppose that the sum of the different positive integers b_i is $\le m$. Then $\prod b_i \le \exp(O^\sim(\sqrt{m}))$.*

Proof. Choose $b_1 < b_2 < \cdots$ such that $\prod b_i$ is maximal. Then $b_1 \le 4$, for otherwise substituting b_1 by 2 and $b_1 - 2$ the product would increase. Also, for any i, $b_{i+1} - b_i \le 2$; otherwise the product would increase by substituting $b_i + 1$ and $b_{i+1} - 1$ for b_i and b_{i+1}. Moreover, $b_{i+1} = b_i + 2$ for at most one i: if $b_{i+1} \ge b_i + 2$ and $b_{j+1} \ge b_j + 2$ for some $i < j$ then by substituting b_i by $b_i + 1$ and b_{j+1} by $b_{j+1} - 1$ the product would increase. Thus the b_i comprise an initial segment of the natural numbers with the possible omission of 1, 2, 3 and one other number. If $\max\{b_i\} = x$, then $m \ge \sum b_i \ge x(x+1) - 1 - 2 - 3 - (x-1)$, which implies $x \le 2 + \sqrt{2m}$. We have then $\prod b_i < x! = \exp(O^\sim(\sqrt{m}))$. □

THEOREM 5.10. *Suppose that $|Q| = q$ and $\langle Q\rangle^C$ is a giant. Then THREE_CYCLE(Q) constructs an SGS for $\langle Q\rangle^C$ in $O^\sim(qn + mn + m^2q + m^3)$ time.*

Proof. By the prime number theorem, the $\log n$th prime is $O(\log n \log\log n)$; hence the preprocessing phase requires $O^\sim(1)$ time. By Theorem 2.12(b) and the argument already used at the analysis of TEST_GIANT (cf. Lemma 4.5), Step 1 runs in $O^\sim(qn + mn)$. By Lemma 5.8, Step 2 requires $O^\sim(m^2q + qn)$ time and the output Q_0 satisfies $|Q_0| = O(\log m)$. We execute the loop of Step 3 $O^\sim(1)$ times. The coset representative set D_i is obtained in $O(mn)$. The Schreier generators are constructed in $O^\sim(mn)$ time and their number is $|Q_i^*| \le m|Q_{i-1}| = O^\sim(m)$. Using Lemma 5.8 again, Q_i is computed in $O^\sim(m^3 + mn)$; hence the total time requirement of Step 3 is $O^\sim(mn + m^3)$. Step 4 runs in $O^\sim(1)$. Since we decrease the degree of λ at least by a factor 2, the loop of Step 5 is executed $O^\sim(1)$ times. By Lemma 5.2, τ, whence λ_1, is obtained in $O^\sim(n)$. By Lemma 5.9, $m(i)$ is a $\le O^\sim(\sqrt{m})$-digit number; thus, for all $i \le r$, $m(i)$ can be computed in $O^\sim(m)$ time [SS], and $\lambda_1^{m(i)}$ can be constructed in $O^\sim(n\sqrt{m})$. (For all x in the permutation domain, we have to divide $m(i)$ by the length of the cycle through x.) Hence Step 5 requires $O^\sim(n\sqrt{m})$ time. Step 6 runs in $O^\sim(n)$. Finally, by Lemma 5.2, Step 7 requires $O^\sim(mn)$ time. □

COROLLARY 5.11. *Step 4 of the main algorithm runs in $O^\sim(n^3 + sn^2)$ total time.*

Proof. We apply THREE_CYCLE to the action of the stabilizer of some nodes v on the children of v in the SD. As in the proof of Corollary 4.7, denoting by q_v the number of (Schreier) generators for G_v and by m_v the number of children of v, $\sum_v (q_v m_v) = O(sn)$. □

5.4. Las Vegas speedup of THREE_CYCLE. In this section we present a randomized version of THREE_CYCLE with $O^\sim((q+m)n)$ running time. As indicated in the proof of Theorem 5.10, calls to the subroutine ORBITALS were the only parts of the procedure THREE_CYCLE not executable within this tighter time bound. ORBITALS is accelerated by using random subproducts of generators.

DEFINITION 5.12. *Let $G = \langle \tau_1, \tau_2, \ldots, \tau_k \rangle$. A random subproduct of the generators $\tau_1, \ldots, \tau_k$ is an instance of the product $\tau_1^{\varepsilon_1}\tau_2^{\varepsilon_2}\cdots\tau_k^{\varepsilon_k}$ where the ε_i are independent,* 0-1 *valued random variables with* $\mathrm{Prob}(\varepsilon_i = 0) = \mathrm{Prob}(\varepsilon_i = 1) = 1/2$.

The key observation is that a random subproduct of the generators is just as likely to increase an orbital of a subgroup $H \leq G$ as the deterministically constructed element σ in ORBITALS. We make this observation more precise in the following lemma.

LEMMA 5.13. *Let $G = \langle \tau_1, \tau_2, \ldots, \tau_k \rangle \leq \mathrm{Sym}(m)$. Then the expected number of random subproducts of the generators $\tau_1, \ldots, \tau_k$ which generate a subgroup H with the same orbitals as G is $c \log m$.*

Proof. Let H_t be the subgroup generated by the first t random subproducts and let $\sigma = \tau_1^{\varepsilon_1}\tau_2^{\varepsilon_2}\cdots\tau_k^{\varepsilon_k}$ be the $(t+1)$st random subproduct. Let $\{\Delta_i : i \in I\}$ be the orbitals of H_t which are not orbitals in G. For an arbitrary Δ_i, let $l = \mathrm{last}(\Delta_i) = \max\{j : \Delta_i^{\tau_j} \neq \Delta_i\}$. Then

$$\begin{aligned}
\mathrm{Prob}(\Delta_i^{\sigma} \neq \Delta_i) &= \mathrm{Prob}(\Delta_i^{\tau_1^{\varepsilon_1}\cdots\tau_l^{\varepsilon_l}} \neq \Delta_i) \\
&\geq \mathrm{Prob}(\varepsilon_l = 1 | \Delta_i^{\tau_1^{\varepsilon_1}\cdots\tau_l^{\varepsilon_{l-1}}} = \Delta_i)\mathrm{Prob}(\Delta_i^{\tau_1^{\varepsilon_1}\cdots\tau_l^{\varepsilon_{l-1}}} = \Delta_i) \\
&\quad + \mathrm{Prob}(\varepsilon_l = 0 | \Delta_i^{\tau_1^{\varepsilon_1}\cdots\tau_l^{\varepsilon_{l-1}}} \neq \Delta_i)\mathrm{Prob}(\Delta_i^{\tau_1^{\varepsilon_1}\cdots\tau_l^{\varepsilon_{l-1}}} \neq \Delta_i) \\
&= 1/2.
\end{aligned}$$

Hence, with probability $\geq 1/2$, σ enlarges each "bad" orbital of H_t. A standard argument shows that after taking t random subproducts the expected number of "bad" orbitals is $\leq m^2(3/4)^t$. □

The speedup of THREE_CYCLE is straightforward: instead of calling ORBITALS, we take $O(\log m)$ random subproducts of generators. The procedure is Las Vegas since we can check in $O^{\sim}(m^2)$ time whether these random subproducts generate a 2-transitive group.

Chronologically, the idea of random subproducts preceded the subroutine ORBITALS (cf. [BLS88]). Random subproducts are useful far beyond the scope of this paper; for example, in [BCFLS91], [BCFLS95], augmented with other ideas, they provide a $O^{\sim}(n^3)$ *elementary* Monte Carlo SGS construction.

6. Descending the structure domain: Traversing levels. In the previous sections, we discussed the first four (preparatory) steps of the main algorithm. We constructed an extension of the original permutation domain, called the SD, and an ordered partition of the SD such that the pointwise stabilizer G_i of the first i sets is normal in G. The algorithm proceeds by constructing an SGS for successive G_i mod G_{i+1} and finding *normal generators* for G_{i+1} (that is, generators of subgroup whose normal closure in G is G_{i+1}). We describe the construction of these elements through a process of *normal sifting*, which relies on knowledge of presentations for the quotients G_i/G_{i+1}. Our time bounds depend critically on the number of normal generators obtained and, to that end, we indicate how we form concise presentations.

Recall that a *presentation* of a group G is a pair $\langle X \mid \mathcal{R} \rangle$, in which X is a set and $\mathcal{R} \subseteq \mathcal{F}(X)$ ($\mathcal{F}(X)$ denotes the free group on X) such that there is an epimorphism $\phi : \mathcal{F}(X) \to G$ with kernel $\langle \mathcal{R}^{\mathcal{F}(X)} \rangle$. We shall say that the presentation is *induced by* ϕ; in the algorithmic application of presentations, it is typically necessary to specify ϕ along with X and $\mathcal{R}$. The elements of $\mathcal{R}$ are called *relators*.

6.1. Normal sifting. Let

$$G = G_0 \geq G_1 \geq \cdots \geq G_m = N \tag{6.1}$$

be a chain of normal subgroups of G. Let $S_i \subset G_i$ generate G_i mod G_{i+1}, i.e., $G_i = \langle S_i \rangle G_{i+1}$ $(i \leq m-1)$. We call the collection $\{S_i : 0 \leq i \leq m-1\}$ a system of *chain generators* of the series (6.1).

Suppose that

$$G_i/G_{i+1} = \langle X_i \mid \mathcal{R}_i \rangle \tag{6.2}$$

is a presentation of G_i/G_{i+1} induced by $\phi : X_i \to G_i/G_{i+1}$. We say that $S_i \subseteq G_i$ *corresponds* to this presentation if the natural map $G_i \to G_i/G_{i+1}$ yields a bijection $S_i \to \phi(X_i)$. Then, for $w(X_i) \in \mathcal{R}_i$, substitution of S_i for X_i yields an element $w(S_i) \in G_{i+1}$.

Assume that the subgroup chain

$$G = H_0 \geq H_1 \geq \cdots \geq H_f = N \tag{6.3}$$

is a refinement of (6.1): $G_i = H_{j_i}$ $(0 = j_0 < j_1 < \cdots < j_m = f)$. Assume further that a set C_j of right coset representatives of H_{j-1} mod H_j is given for each j, $1 \leq j \leq f$ such that for $j_i + 1 \leq j \leq j_{i+1}$, we have $C_j \subset \langle S_i \rangle$. Such a system will be called *compatible* with the given system $\{S_i\}$ of chain generators of (6.1). Given an element of $g \in G$, we can sift it down along the chain $\{H_j\}$ to obtain a siftee, a member of N. This defines the map sift: $G \to N$.

THEOREM 6.1 (normal sift theorem). *Assume a series of normal subgroups* (6.1) *of the group $G = \langle S \rangle$ is given along with chain generators $\{S_i \mid 0 \leq i \leq m-1\}$ which correspond to presentations* (6.2) *of the factors. Assume a refinement* (6.3) *of* (6.1) *is given along with coset representatives, compatible with the given chain generators. Let Q denote the set of the following elements:*

(a) *S (the set of generators of G);*

(b) *$g^{-1}hg$ for $g \in S$ and $h \in S_i$, $1 \leq i \leq m-1$;*

(c) *$w_i(S_i)$ for all $w_i \in \mathcal{R}_i$, $0 \leq i \leq m-1$.*

Then $N = \langle \mathrm{sift}(Q)^G \rangle$.

Proof. Let $H = \langle \mathrm{sift}(Q)^G \rangle$. Set $\bar{G} = G/H$ and let $\phi : G \to \bar{G}$ be the natural homomorphism. Clearly, $H \leq N$, and therefore $|\bar{G}| \geq |G/N|$. We have to prove that equality holds here. For any subset $U \subset G$, we use $\bar{U}$ to denote $\phi(U)$.

Let $H_i = \langle S_i, S_{i+1}, \ldots, S_{m-1} \rangle$. $(H_m = 1.)$

1. $\bar{H}_0 = \bar{G}$, because $\mathrm{sift}(S) \subset H$ by (a).

2. $\bar{H}_i \triangleleft \bar{G}$, because $\mathrm{sift}(S_i^S) \subset H$ by (b).

3. $|\bar{H}_i/\bar{H}_{i+1}| \leq |G_i/G_{i+1}|$, because $w_i(\bar{S}_i) \in \bar{H}_{i+1}$ for $w_i \in \mathcal{R}_i$ by (c).

It follows that $|\bar{G}| = |\bar{H}_0/\bar{H}_1| \cdots |\bar{H}_{m-1}/\bar{H}_m| \leq |G_0/G_1| \cdots |G_{m-1}/G_m| = |G/N|$. □

6.2. Presentations. The normal sift theorem is applied each time our descent of the structure domain finishes a level. There, we are dealing with quotients G_i/G_{i+1} that act faithfully on L_{i+1}, the $(i+1)$st level of the SD. For our time bounds, we need to ensure that $|\mathcal{R}_i| = O^{\sim}(|L_{i+1}|^2)$.

For a full alternating group, $\mathrm{Alt}(q)$, there is a concise set of at most q relations [Car], cf. [CM, p. 67]. We quote Carmichael's presentation of $\mathrm{Alt}(q)$.

THEOREM 6.2 (see [Car]). *Fix $q \geq 4$. Let $X = \{x, y\}$. Let*

$$\mathcal{R}_{\mathrm{Car}} = \{y^{q-2}, x^3, (yx)^q\} \cup \{(xy^{-k}xy^k)^2 \mid 1 \leq k \leq (q-3)/2\}$$

if q is odd, and

$$\mathcal{R}_{\mathrm{Car}} = \{y^{q-2}, x^3, (yx)^{q-1}\} \cup \{(x^{(-1)^k} y^{-k} x y^k)^2 \mid 1 \le k \le (q-2)/2\}$$

if q is even. Then $\langle X \mid \mathcal{R}_{\mathrm{Car}} \rangle$ is a presentation of $\mathrm{Alt}(q)$.

This extends easily to a presentation of direct products of alternating groups, the situation we uncover at alternating levels of the SD. We use a Carmichael presentation, with a pair of generators, for each factor and enter the relators (commutators) that ensure that the pairs of generators commute.

For the small-group levels, we recall an elementary construction of presentations. Suppose that, for $1 \le j \le f$, C_j is a complete set of right coset representatives for $H_{j-1} \bmod H_j$, where

$$G = H_0 \ge H_1 \ge \cdots \ge H_f = 1.$$

For each $\gamma \in \bigcup_{j=1}^{f} C_j$, associate a symbol x_γ and let X be the collection of these symbols. For any $j \ge k$ and $1 \ne \sigma \in C_j$, $1 \ne \tau \in C_k$,

$$\sigma\tau = \gamma_f \cdots \gamma_{j+1}\gamma_j, \text{ for unique } \gamma_p \in C_p,\ j \le p \le f.$$

Let $w_{\sigma,\tau}$ be the word $x_\tau^{-1} x_\sigma^{-1} x_{\gamma_f} \cdots x_{\gamma_{j+1}} x_{\gamma_j}$ and let $\mathcal{R}$ be the collection of all such words. Then $\langle X \mid \mathcal{R} \rangle$ is a presentation of H.

Let $H = G_i/G_{i+1}$ be a small-level group acting on L_{i+1}, $|L_{i+1}| = m$. Coset representatives in the point stabilizer chain for H are available via PERMREP (Proposition 2.11). We know, however, that H is contained in a direct product of isomorphic primitive groups, this direct product acting as a "small" group on each of its, say r, orbits each of size m/r. Any such orbit includes at most $O^\sim(1)$ points where the point stabilizer chain for H decreases, i.e., where $|C_i| \ne 1$. Furthermore $|C_i| \le m/r$ for all i. It follows that $|X| = O^\sim(m)$ and $|\mathcal{R}| = O^\sim(m^2)$.

7. Descending the structure domain: Small group levels. By the results of section 4, the group $G(w)$ (the action of the stabilizer of the node w in the structure domain on the children of w), is either an alternating or a small group. (A small group is of order $< \exp(9 \log^2 n \log\log n)$.) Moreover, for $w, w' \in L_i$ these groups are isomorphic. We call L_i an *alternating level* if $G(w)$ is alternating for $w \in L_i$, and a *small group level* in the other case. Our objective in this section is to get past a small group level L_{i-1}. Suppose that we have constructed an SGS for G/G_{i-1} and normal generators Q^{i-1} for G_{i-1}. We proceed to constructing an SGS for G_{i-1}/G_i and normal generators Q^i for G_i.

The routine NORMCL(Q^{i-1}, L_i, S) gives us the SGS. A presentation for G_{i-1}/G_i is obtained according to section 6.2, and then normal generators for G_i are constructed according to Theorem 6.1.

Timing analysis for NORMCL. Let $L_{i-1} := \{w_1, w_2, \ldots, w_r\}$, and denote by B_j the children of w_j. Then $L_i = \bigcup_{1 \le j \le r} B_j$ and $|(G_{i-1})^{L_i}| = \exp(O^\sim(|L_{i-1}|))$. Moreover, since G_{i-1} stabilizes L_{i-1} pointwise, $t := \max(|(G_{i-1})_j^{L_i} : (G_{i-1})_{j+1}^{L_i}|) \le |L_i|/r$. (Recall that $(G_{i-1})_j^{L_i}$ denotes the jth subgroup in the pointwise stabilizer chain in the group G_{i-1} acting on the set L_i.) Therefore, by Theorem 2.15, the running time of NORMCL(Q^{i-1}, L_i, S) is $O^\sim\big(|L_{i-1}|n(|Q^{i-1}| + s|L_{i-1}| + |L_i||L_{i-1}|)\big)$.

Number of normal generators obtained. There are $O^\sim(|L_i|)$ coset representatives, so $|Q^i| \le |Q^{i-1}| + O^\sim(s|L_i| + |L_i|^2)$.

Finally we observe that the time to sift each normal generator into G_i is $O^\sim(n|L_{i-1}|)$.

Remark 7.1. If $s > n$ then we may apply NORMCL(Q^{i-1}, L_i, S^*) with $S^* := \bigcup_{j<i-1} S^j$. Since S^* is a set of compatible generators for G/G_{i-1} and Q^{i-1} contains the siftees of S into G_{i-1}, $\langle S\rangle = \langle S^*, Q^{i-1}\rangle$ and $\langle Q^{i-1}\rangle^{\langle S^*\rangle} = \langle Q^{i-1}\rangle^G$. This change improves the timing and the bound on the number of generators, replacing s by n in both expressions.

8. Descending the structure domain: Alternating levels. Suppose that we have constructed an SGS for G/G_{i-1} in Step 5 of the main algorithm and L_{i-1} is an alternating level. In this section, we describe a method to obtain an SGS for G_{i-1}/G_i and normal generators for G_i.

First, we introduce some notation. Let v be a representative node at level L_{i-1}. Level L_i can be partitioned into $L_i = B_1 \dot\cup B_2 \dot\cup \cdots \dot\cup B_r$, $|B_j| = m > 3\log^2 n$ for all j such that for each $w \in L_{i-1}$ the children of w comprise one of the B_j and the point stabilizer G_w acts as $\mathrm{Alt}(B_j)$ on this B_j. We may suppose that B_1 contains the children of v. While computing Schreier generators for G_v, the algorithm constructed $\alpha_2, \ldots, \alpha_r \in G$ such that $B_1^{\alpha_j} = B_j$. We denote by Q^{i-1} the set of normal generators for G_{i-1} constructed by the algorithm and by S the generators of G. Finally, for $\pi \in G_{i-1}$, $\mathrm{length}(\pi) := |\{j : \pi|_{B_j} \neq 1\}|$.

If all elements of Q^{i-1} act trivially on L_i, then $G_i = G_{i-1}$ and there is nothing to do. If there exists $\rho \in Q^{i-1}$ acting nontrivially on $B_{j'}$ for some $j' \leq r$, then, since G_{i-1} contains all conjugates of ρ, G_{i-1} acts as $\mathrm{Alt}(B_{j'})$ on $B_{j'}$; moreover, conjugating by $\alpha_2, \ldots, \alpha_r$ we see that $G_{i-1}^{B_j} = \mathrm{Alt}(B_j)$ for all $j \leq r$. Hence, by Proposition 2.2, G_{i-1}/G_i is isomorphic to $\mathrm{Alt}(m)^k$ for some k. We give an efficient version of Luks's "noncommutative linear algebra" to determine which coordinates of $\prod_{j\leq r} \mathrm{Alt}(B_j)$ are *linked* in the diagonal subgroups. We note that because of the transitive G-action on $\{B_1, \ldots, B_r\}$, the number of $\mathrm{Alt}(B_j)$'s is the same in each linked collection.

8.1. The procedure GIANT_CLOSURE. In Step 4 of the main algorithm, we computed an SGS $P_v \subseteq G$ for $G(v)$, the action of G_v on B_1. However, the elements of P_v are not necessarily in G_{i-1} (that is, they do not necessarily fix *all* nodes at level $i-1$). Here we describe a subroutine which computes an SGS $R \subseteq G_{i-1}$ for $\mathrm{Alt}(B_1)$ given P_v and given an element of G_{i-1} acting nontrivially on B_1.

More precisely, with additional applications in mind, we consider the following situation. The setwise stabilizer $G_{\{C\}}$ of a group G acts on a set C, $|C| \geq 8$, as $\mathrm{Alt}(C)$. The input to GIANT_CLOSURE is $P \subseteq G_{\{C\}}$ such that P is an SGS in this action, and $\rho \in G_{\{C\}}$. The output is R, an SGS for $\mathrm{Alt}(C)$, such that $R \subseteq \langle \rho^{\langle P\rangle}\rangle$; i.e., R is generated by conjugates of ρ by the elements of $\langle P\rangle$. Moreover, we require that there are $\tau, \sigma \in \langle \rho^{\langle P\rangle}\rangle$ such that $w(\tau, \sigma) = 1$ for $w(x, y) \in \mathcal{R}_{\mathrm{Car}}$ (see Theorem 6.2), and $R \subseteq \langle \tau, \sigma\rangle$.

If $C = \{1, 2, \ldots, m\}$, m even then $\tau = (1\ 2\ 3)$, $\sigma = (1\ 2)(3\ 4\ \ldots\ m-1\ m)$ satisfy the relations in Theorem 6.2. If m is odd then we can choose $\tau = (1\ 2\ 3)$, $\sigma = (3\ 4\ \ldots\ m-1\ m)$.

procedure GIANT_CLOSURE$(G, C, \rho, P, R, \tau, \sigma)$
INPUT:C, P, ρ as specified above.
OUTPUT: R, τ, σ.
Step 1. Let $\gamma_1 \in \langle P\rangle$ such that $\gamma_1|_C$ is a 3-cycle not commuting with $\rho|_C$. Compute $\rho_1 = [\rho, \gamma_1]$. $(*\ \deg(\rho_1|_C) \leq 6\ *)$ Take $\gamma_2 \in \langle P\rangle$ such that $|\mathrm{supp}(\rho_1|_C) \cap \mathrm{supp}(\gamma_2|_C)| = 1$. Compute $\rho_2 = [\rho_1, \gamma_2]$. $(*\ \rho_2|_C$ is a 3-cycle $*)$
Step 2. Conjugating ρ_2 with appropriate elements of $\langle P\rangle$, obtain permutations

$\pi_1, \pi_2, \ldots, \pi_{m-2}$ such that $\pi_i|_C = (i\ i+1\ i+2)$. $(*\ \pi_1, \pi_2, \ldots, \pi_{m-2}, \pi_{m-2}^2$ is an SGS for $\mathrm{Alt}(C)\ *)$.
Step 3. Compute τ, σ as specified before the procedure as a product of the π_i's.
Step 4. If m is odd then compute $\sigma\tau$. $(*\ \sigma\tau|_C = (1\ 2\ \ldots\ m-1\ m)\ *)$ R consists of τ and its conjugates by the powers of $\sigma\tau$.

If m is even then compute $\sigma\tau^2$ and $\tau\sigma^{-1}\tau\sigma$. $(*\ \sigma\tau^2|_C = (2\ 3\ \ldots\ m-1\ m)$ and $\tau\sigma^{-1}\tau\sigma|_C = (2\ 3\ 4)\ *)$ R consists of τ, $\tau\sigma^{-1}\tau\sigma$, and the conjugates of $\tau\sigma^{-1}\tau\sigma$ by the powers of $\sigma\tau^2$.
end (GIANT_CLOSURE).

PROPOSITION 8.1. *If group operations in G require $O(n)$ time then GIANT_CLOSURE$(G, C, \rho, P, R, \tau, \sigma)$ computes an SGS for* $\mathrm{Alt}(C)$ *in $O(mn)$.*

Proof. The correctness of the procedure is obvious. Given an SGS for $\mathrm{Alt}(C)$, any element of $\mathrm{Alt}(C)$ can be constructed from it by $O(m)$ group multiplications. Therefore, Steps 1 and 3 require $O(mn)$ time. By Lemma 5.2, a permutation with three prescribed positions can be constructed in $O(n)$ time so Step 2 also runs in $O(mn)$. Finally, we notice that using the result of the conjugation by the previous power of $\sigma\tau$ (or $\sigma\tau^2$), all conjugates in Step 4 can be computed with $O(m)$ group operations. □

8.2. The procedure GIANT_LINK. We obtain an SGS for G_{i-1}/G_i by applying the procedure GIANT_LINK. We use the notation introduced at the beginning of section 8 for the input; the output will be an SGS T and a set S^{i-1} of compatible generators for G_{i-1}/G_i and a set Q^i of normal generators for G_i.

If two coordinates $j, j' \le r$ are not linked in a diagonal action then there exists $\pi \in G_{i-1}$ such that $\pi|_{B_j} \neq 1$ and $\pi|_{B_{j'}} = 1$. In this case, we say that π *witnesses the separation of j from j'*. Note that possession of a witness to the separation of j from j' does not imply possession of a witness to the reverse separation, even though we know that one exists.

GIANT_LINK uses the subroutine GIANT_SEPARATE. The input is an SGS $R_j \subset G_{i-1}$ for $G_{i-1}^{B_j} \cong \mathrm{Alt}(B_j)$ and $\pi_1, \pi_2 \in G_{i-1}$ such that $\pi_l|_{B_j} \neq 1$ for $l = 1, 2$. The output is a single $\pi \in G_{i-1}$ such that, for any coordinate j', if either π_1 or π_2 witnesses the separation of j from j', then π also witnesses this separation.

procedure GIANT_SEPARATE(R_j, π_1, π_2, π)
INPUT:R_j, π_1, π_2 as specified above.
OUTPUT: π.
  if $\pi_1|_{B_j}, \pi_2|_{B_j}$ do not commute
    then $\pi := [\pi_1, \pi_2]$
    else take $\rho \in \langle R_j \rangle$ such that $\pi_1|_{B_j}, \rho^{-1}\pi_2\rho|_{B_j}$ do not commute
      $\pi := [\pi_1, \rho^{-1}\pi_2\rho]$
end (GIANT_SEPARATE).

PROPOSITION 8.2. *GIANT_SEPARATE computes the witness π in $O(n)$ time.*

Proof. The only nontrivial point is that an appropriate $\rho \in \langle R_j \rangle$ can be constructed in $O(n)$ time. If $\pi_1|_{B_j}$ has a fixed point, say $x^{\pi_1} = x$, then conjugate π_2 such that $x^{\rho^{-1}\pi_2\rho} = y$ for some y with $y^{\pi_1} \neq y$. If $\pi_1|_{B_j}$ does not have a fixed point then choose four different points $x, y, z, u \in B_j$ such that $x^{\pi_1} = y$ and $z^{\pi_1} = u$. Conjugate π_2 such that $y^{\rho^{-1}\pi_2\rho} = u$ and $x^{\rho^{-1}\pi_2\rho} \neq z$. Since we described the value of ρ at ≤ 4 points, such ρ can be obtained in $O(n)$ time by Lemma 5.2. Note that $\pi_2|_{B_{j'}} = 1$ implies $\rho^{-1}\pi_2\rho|_{B_{j'}} = 1$. □

In the first three steps of GIANT_LINK, we compute a subgroup of G_{i-1} which acts as the full alternating group on each B_j. In Step 4, we obtain witnesses for all pairs not linked by this subgroup and then compute a single witness for each B_j. In the loop described in Steps 5–7, we obtain additional elements of the subgroup G_{i-1} (until we have a collection that fully generates G_{i-1}/G_i). First, in Step 5, until the linked collections have the same length, we conjugate the shortest collection into all positions, necessarily breaking up some links in the longer collections. Step 7 ensures that we have done all the link breaking that is implied by the subgroup at hand and, if so, that the subgroup is normalized (mod G_i) by G; failure of either test produces a new witness to separation in Step 7, and the loop is repeated. If the tests are passed, we can specify Q^i (Step 8).

procedure GIANT_LINK$(L_i, Q^{i-1}, S, P_v, \{\alpha_2, \ldots, \alpha_r\}, Q^i, S^{i-1}, T)$
INPUT: $L_i = B_1 \dot\cup \cdots \dot\cup B_r, Q^{i-1}, S, P_v, \{\alpha_2, \ldots, \alpha_r\}$ as specified above.
OUTPUT: Q^i, S^{i-1}, T.
Step 1. take $\rho \in Q^{i-1}$, $\rho|_{B_j} \neq 1$ for some j; Compute $\rho_1 := \alpha_j \rho \alpha_j^{-1}$.
Step 2. GIANT_CLOSURE$(G, B_1, \rho_1, P_v, R_1, \tau_1, \sigma_1)$.
Step 3. **for** $j := 2$ to r **do**
compute $R_j := \alpha_j^{-1} R_1 \alpha_j, \sigma_j := \alpha_j^{-1}\sigma_1\alpha_j$, $\tau_j := \alpha_j^{-1}\tau_1\alpha_j$, and $\rho_j := \alpha_j^{-1}\rho_1\alpha_j$.
Step 4. **for** $j := 1$ to r **do**
Collect the following elements of G_{i-1} in a set Σ:
the siftees of $Q^{i-1} \cup \{\sigma_{j'}, \tau_{j'} : 1 \le j' \le r\}$ through R_j
$w(\tau_j, \sigma_j)$ for all $w(x, y) \in \mathcal{R}_{\mathrm{Car}}$ ($*$ see Theorem 6.2 $*$)
for $\sigma \in \Sigma$ **do**
for all coordinates j' for which σ witnesses the separation of j' from j but this separation is not witnessed by the current $\rho_{j'}$ **do**
GIANT_SEPARATE$(R_{j'}, \rho_{j'}, \sigma, \rho_{j'})$.
Step 5. **while** there exist j, j' with length$(\rho_j) \neq$ length$(\rho_{j'})$ **do**
take ρ_j with minimal length
for $j' := 1$ to r **do**
GIANT_SEPARATE$(R_{j'}, \rho_{j'}, \alpha_{j'}^{-1}\alpha_j\rho_j\alpha_j^{-1}\alpha_{j'}, \rho_{j'})$
if the lengths of all $\rho_{j'}$, $1 \le j' \le r$, are equal **and**
there exist j', j'' such that $\rho_{j''}$ witnesses a separation of j' (from some j''') that is *not* witnessed by $\rho_{j'}$
then for one such pair j', j''
GIANT_SEPARATE$(R_{j'}, \rho_{j'}, \rho_{j''}, \rho_{j'})$.
Step 6. **for** $j := 1$ to r **do**
GIANT_CLOSURE$(G, B_j, \rho_j, R_j, R_j, \tau_j, \sigma_j)$.
Step 7. **for** $j := 1$ to r **do**
Collect the following elements of G_{i-1} in a set Σ:
the siftees of $Q^{i-1} \cup \{\sigma_{j'}, \tau_{j'} : 1 \le j' \le r\}$ through R_j
$w(\tau_j, \sigma_j)$ for all $w(x, y) \in \mathcal{R}_{\mathrm{Car}}$
the siftees of $\{\sigma_{j'}^{\alpha}, \tau_{j'}^{\alpha} : \alpha \in S, 1 \le j' \le r\}$ through R_j
for $\sigma \in \Sigma$ **do**
for all coordinates j' for which σ witnesses the separation of j' from j but this separation is not witnessed by the current $\rho_{j'}$ **do**
GIANT_SEPARATE$(R_{j'}, \rho_{j'}, \sigma, \rho_{j'})$
if any of the ρ_j were changed in this step **then goto** Step 5.

Step 8. Let $J \subseteq \{1, 2, \ldots, r\}$ consist of a representative j from each linked collection of coordinates.
output $S^{i-1} := \{\tau_j, \sigma_j : j \in J\}$;
output $T := \bigcup\{R_j : j \in J\}$;
collect in Q^i the following elements of G_i:
the siftees of Q^{i-1} through the SGS T
for all distinct $j, j' \in J$, the commutators $[\sigma_j, \tau_{j'}], [\sigma_j, \sigma_{j'}], [\tau_j, \tau_{j'}]$, $[\tau_j, \sigma_{j'}]$
for all $j \in J$, $w(\tau_j, \sigma_j)$ for all $w(x, y) \in \mathcal{R}_{\mathrm{Car}}$
the siftees of $\{\alpha^{-1}\tau_j\alpha, \alpha^{-1}\sigma_j\alpha : \tau_j, \sigma_j \in S^{i-1}, \alpha \in S\}$ through the SGS T;
output Q^i.
end (GIANT_LINK).

8.3. Correctness and time requirement of GIANT_LINK.

THEOREM 8.3. *The outputs T, S^{i-1} of GIANT_LINK are, respectively, an SGS and a set of compatible generators for G_{i-1}/G_i. The collection Q^i is a set of normal generators for G_i.*

Proof. We first claim that after the execution of Step 4, for all $1 \le j \le r$, ρ_j witnesses the separation of j form any j' that is implied by the group $H = \langle Q^{i-1} \cup \{\tau_j, \sigma_j : 1 \le j \le r\}\rangle$. The claim follows from Theorem 6.1 with $G := H, N := H_{B_j}$ and $m := 1$ (because normal generators for the kernel of the action on B_j suffice to witness possible separations of any j' from j). Thus, in particular, the distinct classes $\mathcal{C}_j = \{j' \mid \rho_j|_{B_{j'}} \neq 1\}$, $1 \le j \le r$ partition $\{1, \ldots, r\}$.

When we emerge from Step 5, the distinct classes among the $\mathcal{C}_j$ are again disjoint (a nontrivial intersection would be picked up by the last **if** statement, which would reduce the length of $\rho_{j'}$ for some j' in the intersection) and they now have the same size.

In Step 7, if the sifting of Q^{i-1}, $\sigma_{j'}, \tau_{j'}$ and the elements $w(\tau_j, \sigma_j)$ witness no new separations, then we know that the ρ_j, $1 \le j \le r$, witness all separations implied by elements of the group $H = \langle Q^{i-1} \cup \{\tau_j, \sigma_j : 1 \le j \le r\}\rangle$ (by the argument for Step 4). Furthermore, we know that H acts on L_i as a direct product of alternating groups, exactly one alternating group in each still-linked class of coordinates. If so, the successful sifting of the collection of $\sigma_{j'}^{\alpha}, \tau_{j'}^{\alpha}$ guarantees that H is invariant (mod G_i) under the action of G.

The claims about T and S^{i-1} are now clear. The fact that Q^i is a set of normal generators of G_i then follows from Theorem 6.1 (with the chain of normal subgroups $G = G_0 \ge G_1 \ge \cdots \ge G_{i-1} \ge G_i = N$). □

THEOREM 8.4. *Let $s = |S|$. Then GIANT_LINK$(L_i, Q^{i-1}, S, P_v, \{\alpha_2, \ldots, \alpha_r\}, Q^i, S^{i-1}, T)$ runs in time $O^{\sim}(|Q^{i-1}||L_i|n + s|L_i|^2 n)$ and $|Q^i| \le |Q^{i-1}| + O(s|L_i| + |L_i|^2)$.*

Proof. In Step 1, we can pick an appropriate ρ in $O(|Q^{i-1}|rm)$ and ρ_1 is computed in $O(n)$ time. By Proposition 8.1, Step 2 requires $O(mn)$ time and Step 3 can be executed in $O(rmn)$.

In Step 4, we sift $|Q^{i-1}| + 2r$ elements through r SGS's, requiring $O(|Q^{r-1}|rmn + r^2mn)$ total time; moreover, we compute $O(rm)$ defining relations, in $O(rmn)$ total time. Altogether for all $1 \le j \le r$ we place $O(|Q^{i-1}|r + r^2)$ elements into Σ; for each of these, $O(mr)$ time suffices to check whether it breaks some new links. The total cost of calls of the subroutine GIANT_SEPARATE in Step 4 is at most $O(r^2n)$ since for each pair j, j' we call GIANT_SEPARATE at most once. Hence the total cost of

Step 4 (using that $r \leq n$) is $O(|Q^{r-1}|rmn + r^2mn)$.

We enter the **while** loop of Step 5 at most r times since the minimum length of ρ_j decreases at each call. (Within the **while** loop, the length of each $\rho_{j'}$ decreases at least to the previous minimum.) Hence calls of GIANT_SEPARATE in Step 5 cost $O(r^2n)$. The **if** statement can also be executed within this time bound, since all we have to check is whether the sets $\mathcal{C}_j$ (see the proof of Theorem 8.3) define a partition of $\{1, 2, \ldots, r\}$.

Each time Step 6 is executed, all the ρ_j are of the same length. The length in any round is necessarily a divisor of the length in the previous round, so Step 6 is executed $\leq \log r$ times. By Proposition 8.1, one execution costs $O(mrn)$.

Step 7 is executed always after Step 6, i.e., $\leq \log r$ times, and one execution is similar to Step 4 with the additional sifting of $O(sr)$ conjugates (by S) through the r SGS's for a total timing of $O(|Q^{r-1}|rmn + sr^2mn)$.

Finally, Step 8 runs in $O(|Q^{i-1}|mrn + r^2n + srmn)$. Only the term $O(srmn)$ (instead of $O(sr^2mn)$) requires additional explanation: each conjugate $\alpha^{-1}\tau_j\alpha$, $\alpha \in S$ acts nontrivially in only one of the linked collections of alternating groups so sifting costs only $O(mn)$. Noting that $|L_i| = mr$, the proof is complete. □

Remark 8.5. If $s > n$ then we may use the set $S^* = \bigcup_{j<i-1} S^j$ instead of S as input of GIANT_LINK, replacing the term s by n in both the running time and number of generators created. Correctness is proved by the argument in Remark 7.1.

9. Proof of the main results. In this section, we finish the proof of Theorem 1.1 and sketch two other versions of the algorithm: one with reduced memory requirement (and same time efficiency as the original) and an elementary version with $O^{\sim}(n^{4.5})$ running time.

9.1. Proof of Theorem 1.1. The algorithm described in sections 3–8 computed an SGS for the input group $G = \langle S \rangle \leq \mathrm{Sym}(n)$, $|S| = s$; we have to analyze the running time.

By Lemma 3.1, Corollary 4.7, Proposition 4.8, and Corollary 5.11, the first four steps of the main algorithm run within $O^{\sim}(n^3 + sn^2)$. By the analysis in section 7 and Theorem 8.4, the number of normal generators created while processing level L_{i-1} is $O^{\sim}(s|L_i| + |L_i|^2)$ (in addition to the $|Q^{i-1}|$ normal generators for G_{i-1}). Hence $|Q^i| = O^{\sim}(n^2 + sn)$ for all i and, by section 7 and Theorem 8.4, Step 5 runs in $O^{\sim}(n^4 + sn^3)$.

If the $O^{\sim}(sn^3)$ term becomes dominant, i.e., $s > n$, then we modify the procedure according to Remarks 7.1, 8.5, and the running time drops down to $O^{\sim}(n^4 + sn^2)$. Finally, if sn^2 dominates n^4, i.e., $s > n^2$, then we begin the algorithm by reducing the number of generators to $O(n^2)$ in $O(sn^2)$ time. This can be achieved by sifting the elements of S into (the originally empty) coset representative table with respect to the point stabilizer chain of the permutation domain (cf. procedure SIFT in section 2.7). In any case, we can achieve the claimed $O(n^4 \log^c n + sn^2)$ running time with no logarithmic factors multiplying sn^2.

We turn to the proof of claims (b)–(e) in Theorem 1.1. The order of G is easily computed as the product of sizes of coset representative sets. Although the SGS constructed by the algorithm can be used directly for membership testing by extending the action of a candidate permutation to the SD and there is a method to compute pointwise set stabilizers from it (developed for the parallel procedure in [BLS87]), it is easier to use a result of Brown, Finkelstein, and Purdom [BFP]. They provide an $O(n^3)$ base-change algorithm for converting strong generating sets with respect

to point stabilizer chains along different orderings of the permutation domain. The base-change algorithm outputs the SGS in Jerrum's compact format.

Finally, we observe that the normal sift theorem (Theorem 6.1) essentially provides the scheme for proving (e). Note that, with the descent of the SD complete, the chain generators generate G, so we may assume $S = \bigcup_i S_i$. We associate a symbol x_π to every element π of S and let X denote the collection of these. Each coset representative $\rho \in R_j$ (see notation and discussion preceding the theorem) is representable as a word in S and there is a corresponding word $w(\rho)$ in X. The elements to be sifted in Theorem 6.1 (a),(b),(c) are given as words in S, and so each τ corresponds naturally to a word $w'(\tau)$ in X. Sifting τ can be interpreted as expressing τ canonically as a word $\rho_1 \cdots \rho_l$. From each such sift we derive a relation $w'(\tau)^{-1} w(\rho_1) \cdots w(\rho_l)$ and denote the collection of these by $\mathcal{R}$. Then $\langle X \mid \mathcal{R} \rangle$ is a presentation of G.

9.2. Reducing the memory requirement. The algorithm, as presented in sections 3–8, requires $O^\sim(n^3 + sn^2)$ space. Here we indicate how to reduce the memory requirement to $O^\sim(n^2 + sn)$.

The first four steps of the main algorithm run within this tighter bound. The problem arises because of the top-down approach in Step 5 since, eventually, we accumulate $O^\sim(n^2 + sn)$ normal generators. On the other hand, the SGS we build occupies only $O^\sim(n^2)$ space. The solution is to build the output SGS T simultaneously on all levels. We call T *up-to-date* on level i if $\langle T \cap G_j \rangle$ is a normal subgroup of G for all $j \geq i$. We work always at the lowest level (i.e., greatest index i) which is not up-to-date.

We start executing Step 5 at level 0 as before. The difference is that working on level i, whenever the algorithm produces a normal generator ψ for G_{i+1}, we sift ψ *immediately* into the SGS already constructed. If ψ factors completely then it can be discarded; if it has a nontrivial siftee on some lower level j then we suspend the execution on level i and jump down to level j.

On small levels, we execute exactly the same steps as in the original algorithm (possibly interrupted by some computations on lower levels). On alternating levels, we may execute GIANT_LINK $O(\log n)$ times, discovering smaller and smaller linked collections of subgroups. There are no more than $O(\log n)$ executions since the lengths of linked collections are divisors of each other. This extra work may add a $\log n$ factor to a lower-order term in the running time.

9.3. An elementary version. Two elementary estimates on the order of primitive groups enable us to break the $O(n^5)$ barrier by an elementary, $O^\sim(n^{4.5})$ algorithm. One of them is Pyber's estimate (cf. Theorem 2.5) on the order of nongiant 2-transitive groups and the other one is due to Babai.

THEOREM 9.1 (see [Ba]). *Let $G \leq \mathrm{Sym}(n)$ be primitive; G is not a giant. Then $|G| \leq \exp(O^\sim(\sqrt{n}))$.*

ELEMENTARY ALGORITHM.
INPUT: a set S of generators for $G \leq \mathrm{Sym}(A)$, $|S| = s$.
Step 1. Construct an SF and choose a representative v in each orbit of the SF. For all such v, construct Schreier generators for G_v.
Step 2. For these representatives, use TEST_GIANT to decide whether $G(v)$ is a giant.
By inserting new levels after symmetric levels, obtain the SD. Compute the node stabilizers G_w as in Step 1 for representatives of G-orbits of the SD. Let $(L_0, L_1, \ldots, L_m)$ be the levels of the SD.

Step 3. For each node v representing an alternating level in the SD, construct an SGS for $G(v)$.

Step 4. **for** $i := 1$ to m **do**
if L_{i-1} is an alternating level
then construct SGS for G_{i-1}/G_i, normal generators for G_i as in section 8
else construct SGS for G_{i-1}/G_i, normal generators for G_i as in section 7

end (ELEMENTARY ALGORITHM).

We have to modify the stopping condition in TEST_GIANT and in the first step of THREE_CYCLE to accommodate the weaker bound in Theorem 2.5. This change adds only a logarithmic factor to a low-order term in the running time. Since NATURAL_ACTION is eliminated from this algorithm, correctness is elementary. However, primitive groups on small levels may be of the size allowed in Theorem 9.1, adding a factor $\sqrt{n}$ in the analysis of section 7.

Acknowledgment. We are indebted to the referees for their careful work and for suggestions to improve the presentation.

PARAMETERIZED DUPLICATION IN STRINGS: ALGORITHMS AND AN APPLICATION TO SOFTWARE MAINTENANCE*

BRENDA S. BAKER†

Abstract. As an aid in software maintenance, it would be useful to be able to track down duplication in large software systems efficiently. Duplication in code is often in the form of sections of code that are the same except for a systematic change of parameters such as identifiers and constants. To model such parameterized duplication in code, this paper introduces the notions of parameterized strings and parameterized matches of parameterized strings. A data structure called a parameterized suffix tree is defined to aid in searching for parameterized matches. For fixed alphabets, algorithms are given to construct a parameterized suffix tree in linear time and to find all maximal parameterized matches over a threshold length in a parameterized p-string in time linear in the size of the input plus the number of matches reported. The algorithms have been implemented, and experimental results show that they perform well on C code.

Key words. string matching, pattern matching, duplication

1. Introduction.

In a large ongoing systems project, introduction of new features and code maintenance by large staffs of programmers may result in code that includes many duplicated sections. Such duplication still occurs even though it has long been known that copying code may make the code larger, more complex, and more difficult to maintain. For example, when a new feature is introduced, rather than risk breaking a working feature by making a major revision, a programmer might choose to leave the old section of code untouched, and to add another slightly modified copy of it for the new feature. A bug fix might also be handled by copying and modifying the code, for example, if the original programmer omitted handling of special cases. The copies might be further copied and modified as time goes on. With time, the amount of duplication in a system can become substantial and can complicate maintenance.

While some of the duplication in a software system may involve sections of code that are identical, much of the duplication involves sections of code that are not identical, but are the same except for a systematic change of parameters such as identifiers and constants. For example, each occurrence of *first*, *last*, 0, and *fun* in one section may be replaced by *init*, *final*, 1, and *g*, respectively, in the other section; this kind of correspondence between sections of code is called a *parameterized match* [Bak1]. [Bak1] describes a program *dup* that finds all maximal parameterized matches over a threshold length in C code; application of *dup* to a million-line subsystem of a production system revealed that 21% of the lines were involved in parameterized matches of at least 30 lines (excluding comments and white space).

This paper formalizes the notion of parameterized matches for code in terms of *parameterized strings*, or *p-strings*, which are strings over two alphabets: an alphabet of constant symbols and an alphabet of parameter symbols. Two parameterized

strings are a *parameterized match*, or *p-match*, if they are the same except for a one-to-one correspondence between the parameter symbols occurring in them. For example, *axbxyazyx* and *aubuvaxvu* are a p-match where the one-to-one correspondence maps the x, y, and z of the first p-string into the u, v, and x, respectively, of the second p-string.

For use in searching p-strings, we define a new data structure called a *parameterized suffix tree*, or *p-suffix tree*. We show that a p-suffix tree can be built in time and space $O(n)$, where n is the length of the input, if the alphabets are fixed. Given a pattern p-string P of length m and a text p-string T of length n over fixed alphabets, a p-suffix tree for T can be used to determine in $O(n+m)$ time and $O(n)$ space whether P has a p-match in T. An algorithm is given that finds all maximal p-matches over a threshold length in a p-string S in time $O(n+r)$, where n is the length of the input and r is the number of matches reported, by searching a p-suffix tree constructed for S. The algorithms for constructing p-suffix trees and for reporting all maximal p-matches over a threshold length have been implemented. Experiments show that the program performs well on C code input.

The algorithms in this paper improve upon the somewhat ad hoc method of finding parameterized matches in *dup*. The parameterized-matching algorithm implemented in *dup* operates as follows: it transforms all parameter candidates such as identifiers and constants to the same symbol P, finds exact matches in the transformed code, and then checks the exact matches for possible parameterized matches; the worst-case running time is not a function of the size of the input and number of p-matches, or even of the size of the input and the total length of the p-matches. In some cases, as many as 99% of the exact matches found do not correspond to parameterized matches.

P-suffix trees are a generalization of suffix trees for strings [McC, Ukk, We], but are more dynamic in that each access to an input symbol requires a transformation based on the depth in the tree. The algorithm described here for building p-suffix trees is based on the McCreight algorithm for building suffix trees [McC]; however, the original algorithm and the concept of suffix links used in it must be modified to allow for the dynamic way in which p-strings are handled and the failure of a key property of strings to generalize for p-strings. The algorithm for finding all maximal p-matches over a threshold length is a generalization of the suffix-tree-based algorithm implemented in *dup* for finding all exact matches over threshold length in strings [Bak1, Bak2]; again, the generalization is not straightforward because of the dynamic nature of p-suffix trees.

The generalization of suffix trees to p-strings is related to Giancarlo's generalization of suffix trees to L-strings [G] in that both have to deal with the failure of the same key property of strings to generalize. In other respects, L-strings and p-strings behave differently, because L-strings do not obey the restricted form of this property that can be proved for p-strings. Consequently, the linear bounds obtainable for constructing p-suffix trees with fixed alphabets do not appear to be obtainable for constructing L-suffix trees for L-strings.

Four other methods have been attempted for finding duplication in code: (1) string pattern matching has been applied to strings encoding the call graph and statistics about characteristics such as use of operators to detect student plagiarism [Ja]; (2) signal processing techniques combined with a graphical user interface have been used to find approximate duplication by eye [CH]; (3) exhaustive search was used on parse trees to identify identical subtrees or subtrees related by change of

parameter, but was found to be unsuccessful because of time and space usage [Jo]; and (4) data flow analysis and safe approximation techniques have been proposed as a basis for comparing program components in a restricted programming language [Ho].

Parameterized matching is reminiscent of unification [GeN], where the goal is to determine whether two expressions can be made equivalent via substitutions for variables, but unification differs in three ways from our problem: the domain is expressions (terms) rather than strings, terms (rather than just variables) are substituted for variables, and there is no notion of matching just parts of terms.

A parameterized match is a kind of approximate match, but is very different from the standard definition in which two strings are an approximate match if they are within a specified edit distance (number of insertions, deletions, or substitutions) from each other, as studied, for example, in [CL, GG]. Even exact or approximate matches to regular expressions [Aho, MM, WM] do not involve any notion of relating repeated occurrences of corresponding (but different) symbols.

The UNIX grep pattern-matching program and ed editor [KP] allow a pattern to be a restricted regular expression with backreferencing to refer to parts of the text matching earlier parts of the pattern, as described in [Aho]. This problem is NP-complete [Aho], and the algorithms implemented are undocumented, but are based on backtracking and do not correctly implement the definitions [Hu92]. The grep/ed usage of backreferencing is not comparable with our definitions: in our terminology, they have no way of requiring that distinct parameters should match different substrings, while we have no way of allowing them to match the same substrings. These programs also do not address the problem of finding all duplication over a threshold length.

The paper is organized as follows. Section 2 defines parameterized strings, parameterized matches, and parameterized suffix trees, and shows how parameterized suffix trees can be used for parameterized pattern matching. The algorithm for constructing a parameterized suffix tree is given in section 3. Section 4 gives the algorithm for reporting all parameterized matches over a threshold length in a p-string. An implementation of the algorithms and some experimental results from applying them to C code are described in section 5. Section 6 discusses time bounds for the algorithms for variable alphabets and directions for further research.

2. Parameterized strings, parameterized matches, and parameterized suffix trees. In this section, we introduce parameterized strings, parameterized matches, and parameterized suffix trees (p-suffix trees), and show how parameterized suffix trees can be used for parameterized pattern matching. We assume a RAM model of computation with the uniform cost criterion [AHU].

Throughout, Σ will be a fixed finite alphabet of constant symbols and Π will be a fixed finite alphabet of parameter symbols; i.e., the sizes of Σ and Π are $O(1)$. We assume that Σ and Π are disjoint from each other and the set of nonnegative integers, that symbols are ordered and can be compared in constant time, and that symbols of Π can be used to index into an array in constant time.

DEFINITION. *A string of symbols in* $(\Sigma \cup \Pi)^*$ *is called a* parameterized string *or* p-string. *Two p-strings are a* parameterized match, *or* p-match, *if one p-string can be transformed into the other by renaming the parameters via a one-to-one function whose domain is the set of parameter symbols occurring in one p-string and whose range is the set of parameter symbols occurring in the other p-string.*

For example, if x, y, and v are parameter symbols and a, b, and c are constant symbols, then $S_1 = axaybxycby$ and $S_2 = ayavbyvcbv$ are a p-match, where x and y of S_1 and renamed as y and v, respectively, in S_2.

Determining whether two entire p-strings are a p-match is straightforward, as follows. Scan the two p-strings left to right, while constructing a table giving the one-to-one correspondence, to see if any mismatches are found between symbols. In addition to mismatches in length, mismatches can be between different non-parameters, between a parameter and a non-parameter, or between two parameters, at least one of which has already been made to correspond to a different parameter. Given our definitions, checking for mismatches can be done in time linear in input length n and space $O(|\Pi|)$, by constructing a table for the one-to-one correspondence. Unfortunately, this approach does not conveniently generalize to pattern matching.

Instead, we use a procedure *prev*, that chains together occurrences of the same parameter, to obtain a string in $(\Sigma \cup \mathrm{N})^*$, where N is the set of nonnegative integers. For each parameter, the leftmost occurrence is represented by a 0, and each successive occurrence is represented by the difference in position compared to the previous occurrence. A number representing such a difference in position is called a *parameter pointer*. For example, if u, v, x, and y are parameter symbols and a and b are constant symbols, then $prev(abuvabuvu) = ab00ab442 = prev(abxyabxyx)$. (Each parameter pointer is a single digit here.)

Since symbols of Π can be used to index into a table, computation of *prev* can be done in time linear in input length and space linear in $|\Pi|$ by means of a table containing the position of last occurrence of each parameter symbol encountered. Proving the following proposition is straightforward from the definitions.

PROPOSITION 1. *P-strings S and $\overline{S}$ are a p-match if and only if $prev(S) = prev(\overline{S})$.*

DEFINITION. *Define the ith p-suffix of a p-string $S = b_1 b_2 \dots b_n$ to be $psuffix(S, i) = prev(b_i b_{i+1} \dots b_n)$. Define $prefix(S, i, j) = prev(b_i b_{i+1} \dots b_j)$, for $i \le j$. Define $prefix(S, i, j)$ to be the empty string if $j < i$.*

Note that a symbol of $prev(S)$ corresponds to a different value in $\mathrm{psuffix}(S, i)$ if it is a parameter pointer that points to a position before i. For example, if $prev(S) = a0a2ab3$, then $psuffix(S, 3) = a0ab3$. It is easily seen that $prefix(S, i, j)$ is the prefix of length $j - i + 1$ of $psuffix(S, i)$.

The following proposition follows directly from the definitions and Proposition 1.

PROPOSITION 2. *If P is a p-string pattern and T is a p-string text, P has a p-match starting at position i of T iff $prev(P) = prefix(T, i, i + |P| - 1)$.*

We also note that the value of the jth symbol of $psuffix(S, i)$ can be computed in constant time from j and the corresponding $(j + i - 1)$st symbol b of $prev(S)$. We let f be this function; the value of f is as follows.

DEFINITION. *For $b \in \Sigma \cup \mathrm{N}$, if b if a nonnegative integer larger than $j - 1$, $f(b, j) = 0$; otherwise $f(b, j) = b$.*

Our strategy is to generalize suffix trees in p-strings based on Proposition 2 and the function f. First, we briefly review suffix trees.

Suppose that Σ is an alphabet and $S = a_1 a_2 \dots a_n$ is a string, where each $a_i \in \Sigma$. For each i, $1 \le i \le n$, the substring $a_i \dots a_n$ is a *suffix* of the input. Without loss of generality, we assume that the last symbol a_n is a unique endmarker; consequently, no suffix is the prefix of another suffix. A suffix tree is a compacted trie (multiway Patricia trie) over the alphabet $\Sigma \cup N$ representing the suffixes of the input string [McC]. A suffix tree is shown in Figure 1. Each arc of the tree is labelled with a nonempty substring of the input, each internal (nonleaf) vertex has degree at least two, and, for each internal vertex, the arcs to its children have labels beginning with distinct symbols. For each leaf, the concatenation of the labels on the path from the

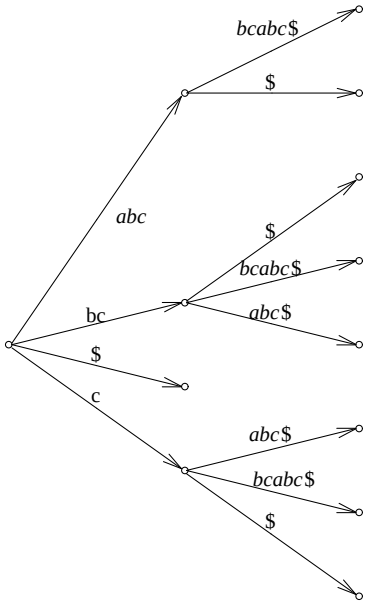

FIG. 1. *A suffix tree for the string abcbcabc* $.

root to the leaf is a distinct suffix of S. Each vertex other than a leaf has at least two children. Since the number of internal vertices is less than the number of leaves, the number of vertices is at most $2n$. Because no suffix is a prefix of another suffix, there is a one-to-one correspondence between the leaves and the suffixes.

The generalization of suffix trees to p-suffixes of a p-string gives us p-suffix trees, defined as follows.

DEFINITION. *If S is a p-string that ends with a unique endmarker in Σ, a* parameterized suffix tree*, or* p-suffix tree*, for S is a compacted trie* (*multiway Patricia trie*) *that stores the p-suffixes of S.*

Each are in a p-suffix tree for S represents a nonempty substring of a p-suffix of S; each internal vertex has degree at least two; and the arcs from an internal vertex to its children have labels beginning with distinct first symbols. For each leaf, the concatenation of the labels on the path from the root to the leaf is a p-suffix of S. Since S ends with a unique endmarker, no p-suffix of S is the prefix of another p-suffix of S, and consequently, each p-suffix of S is the concatenation of the labels on a path from the root to a leaf. Thus, there is a one-to-one correspondence between leaves and p-suffixes of S, and the number of vertices in S is linear in $|S|$. Arcs are oriented from the root toward the leaves, so that arcs leaving a vertex point toward its children.

Example. Let $S = xbyyxbx\$$, where x and y are parameter symbols and b and \$ are constant symbols, so that $prev(S) = 0b014b2\$$. (All parameter pointers are single digits here.) The p-suffixes to be encoded in the tree are $0b014b2\$$, $b010b2\$$, $010b2\$$, $00b2\$$, $0b2\$$, $b0\$$, $0\$$, and \$. Notice that the parameter pointers change to 0 as the preceding part of the string is shortened. The p-suffix tree for S is shown in Figure 2.

DEFINITION. *For each vertex ν, the* pathstring *of ν is the concatenation of the labels on the path from the root to ν, and ν is the* locus *of its pathstring. The length of the pathstring of ν is the* pathlength *of ν.*

In order for the p-suffix tree to be stored in space linear in input length, arc labels

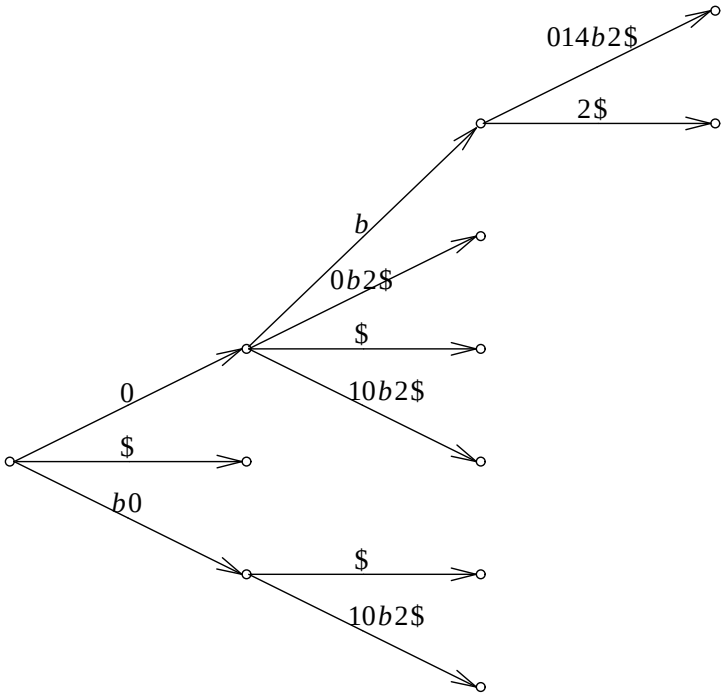

FIG. 2. *A* p-*suffix tree for the* p-*string* $S = xbyyxbx\$$, *where* $\Sigma = \{b, \$\}$ *and* $\Pi = \{x, y\}$.

are calculated dynamically as follows. We assume that $prev(S)$ has been computed and stored in an array. For each vertex ν other than the root, we store the pathlength $plen(\nu)$, an index $firstpos(\nu)$ into the input to specify the starting position of the label of the arc from its parent, and the length $arclen(\nu)$ of this arc. If a label symbol is at pathlength j from the root and corresponds to index k into the input, its value in the label is $f(b, j)$, where b is the kth symbol of $prev(S)$, and f is as defined above; extracting this value takes constant time.

Because up to n symbols of N can be used even when Π is fixed, it might seem that the number of children of each internal vertex is $O(n)$. However, this number is bounded by $|\Sigma| + |\Pi|$, for the following reason. The pathstring of any vertex ν contains parameter pointers representing at most $|\Pi|$ distinct chains of parameters, and the first symbol of an arc to a child must either be a symbol of Σ, a 0 (implying that at most $|\Pi| - 1$ chains appear in the pathstring of ν), or a nonnegative integer pointing to the last element of one of these chains.

For fixed alphabets, linked lists can be used to store the arcs, as far as the theoretical time bounds are concerned; in practice, for large alphabets, hashing would be used, as suggested by McCreight [McC].

Thanks to Proposition 2, searching the p-suffix tree of a text p-string $T\$$ for a pattern p-string P is straightforward: follow the path determined by successive symbols of $prev(P)$ from the root downward in the p-suffix tree for $T\$$ to see if $prev(P)$ is identical to the first part of some p-suffix of T. This search can be accomplished in time $O(|P|)$. The actual matching positions can be calculated from the descendant leaves. Thus, we obtain the following result.

THEOREM 1. *Given p-strings* P *and* T *over fixed alphabets,* $prev(T)$, *and a p-*

suffix tree for T\$, where \$ is a unique endmarker, whether P has a p-match with a substring of T can be determined in time $O(|P|)$ and space $O(|T|)$. All positions of T at which P has a p-match can be found in time $O(|P| + k)$ and space $O(|T|)$, if there are k such positions.

In the next section, we will show that for fixed alphabets, a p-suffix tree can be built in time and space linear in the input length. Consequently, given p-strings P and T, whether P has a p-match with a substring of T can be determined in time $O(|P| + |T|)$ and space $O(|T|)$, and all positions of T at which P has a p-match can be found in time $O(|P| + |T| + k) = O(|P| + |T|)$ and space $O(|T|)$.

3. Building a p-suffix tree. In this section, an algorithm is given for constructing a p-suffix tree. We would like to imitate McCreight's algorithm for building suffix trees as much as possible; however, some basic changes must be made because of the difference between strings and p-strings.

Some useful properties. Strings have the following two trivial properties:

(1) Common Prefix Property. For $a, b \in \Sigma$ and $S, T \in \Sigma^*$, if $aS = bT$, then $S = T$.
(2) Distinct Right Context Property. Suppose $aS = bT$ and $aSc \neq bTd$, where $a, b, c, d \in \Sigma$ and $S, T \in \Sigma^*$. Then $Sc \neq Td$.

These two properties make it possible to augment a suffix tree with pointers called *suffix links*. If an internal vertex has pathstring $a\alpha$, where a is a symbol and α is a string, its suffix link points to an internal vertex with pathstring α; in addition, the suffix link for the root points to the root. The definition of suffix links depends on the two properties in the following way. The existence of an internal vertex with pathstring $a\alpha$ implies there are two distinct strings sharing prefix $a\alpha$. The Common Prefix Property guarantees that stripping off the initial a from the two strings results in strings sharing an initial prefix α, and the Distinct Right Context Property implies that no longer prefix is shared, which in turn guarantees the existence of an internal vertex with pathstring α. Suffix links are useful both for building a suffix tree [McC] and for pattern matching in space proportional to the size of the pattern [CL].

The Common Prefix Property generalizes to p-strings, but unfortunately the Distinct Right Context Property does not.

LEMMA 1 (Common Prefix Property for p-strings). *If $a, b \in \Sigma \cup \Pi$ and S and T are p-strings such that $prev(aS) = prev(bT)$, then $prev(S) = prev(T)$.*

Proof. Observe that $prev(S)$ is different from $prev(aS)$ only in the deletion of the first symbol and in the changing of a parameter pointer pointing to the first position in $prev(aS)$ to a 0, if such a parameter pointer exists, and similarly for $prev(T)$ and $prev(bT)$. By equality of $prev(aS)$ and $prev(bT)$, such parameter pointers, if they exist, must be in the same position in these two p-strings. □

We would like to be able to generalize the Distinct Right Context Property to p-strings as follows: if $prev(aS) = prev(bT)$ and $prev(aSc) \neq prev(bTd)$, then $prev(Sc) \neq prev(Td)$, where $a, b, c, d \in \Sigma \cup \Pi$ and S and T are p-strings. Unfortunately, this is false, because *prev* turns nonnegative integers into 0's as the front end of the string is chopped off. For example, suppose $S = xabxyabz$, with $\Sigma = \{a, b\}$ and $\Pi = \{x, y, z\}$. Then $prev(xabx) = 0ab3$ and $prev(yabz) = 0ab0$, which have a common prefix of $0ab$, but $prev(abx) = ab0 = prev(abz)$, and the distinctness of the right contexts of $0ab$ is lost.

The best we can do is the following restricted form of the Distinct Right Context Property.

LEMMA 2 (Restricted Distinct Right Context Property for p-strings). *Suppose* $prev(aS) = prev(bT)$ *and* $prev(aSc) \neq prev(bTd)$, *where* S *and* T *are p-strings of length* k *and* $a, b, c, d \in \Sigma \cup \Pi$. *If* $prev(Sc) = prev(Td)$, *then the last symbol of one of* $prev(aSc)$, $prev(bTd)$ *is* $k+1$, *while the last symbol of the other is* 0.

Proof. Obviously, $prev(aSc)$ and $prev(bTd)$ differ only at their last symbol. Suppose $prev(Sc) = prev(Td)$. If the common last symbol is a nonzero parameter pointer or is in Σ, then the corresponding symbols in $prev(aSc)$ and $prev(bTd)$ also have a common value ν, implying that $prev(aSc) = prev(aS)\nu = prev(aT)\nu = prev(aTd)$, a contradiction. The only other possibility is that the last symbols of $prev(Sc)$ and $prev(Td)$ are zero, and the last symbols of $prev(aSc)$ and $prev(bTd)$ are parameter pointers in $\{0, k+1\}$. They can't both be zero or both be $k+1$, since $prev(aSc) \neq prev(bTd)$. □

Overview of McCreight's algorithm. McCreight's algorithm for building suffix trees inserts suffixes in stages, where Stage i inserts suffix i (the suffix starting at position i of the input), for $i = 1, 2, \ldots, n$ (from left to right). Define $head_i$ to be the longest prefix of the ith suffix of S that is also a prefix of the jth suffix of S for some $j < i$. The path for suffix i in the tree coincides with an existing path up to $|head_i|$ symbols; in Stage i, the algorithm inserts a new vertex hd_i at that point, if no vertex exists there already, and gives it a child that is a leaf whose pathstring is suffix i.

Suffix links are McCreight's key to turning this idea into an efficient algorithm. A suffix link for a vertex with pathstring $a\alpha$, where a is a symbol and α is a string, points to the vertex with pathstring α (which must exist because of the Common Prefix Property and Distinct Right Context Property); the suffix link for the root points to the root. Suppose Stage $i-1$ found that $head_{i-1}$ was $a\alpha$, where a is a symbol and α a p-string. Then $head_i$ will be at least as long as $|\alpha|$ because of the Common Prefix Property. In Stage i, if the suffix link is already defined for the vertex with pathstring $a\alpha$, there is no need to trace the common prefix α from the root; the processing can jump directly from the vertex with pathstring $a\alpha$ to the vertex with pathstring α via a suffix link. From that point, scanning can continue downward to find the desired location of hd_i.

Unfortunately, the suffix links are constructed dynamically, and the desired suffix link may not actually be defined until after it would be most useful in Stage i. McCreight's algorithm gets around this obstacle as follows. In Stage i, it uses the best suffix link available, namely that of the parent of the desired vertex, and follows a path downward in the tree while *rescanning* part of the input, up to a pathlength of $|\alpha|$. Fortunately, we know what symbols of the input were already scanned, just not where to go in the tree; thus, only the first symbol of each arc needs to be rescanned. If no vertex exists at this point (with pathlength $|\alpha|$), a new vertex hd_i is inserted, the missing suffix link is set to point to hd_i, and a leaf is created to represent suffix i. If a vertex does exist already at this point, the missing suffix link is set to it, and the *scanning* phase continues along the path corresponding to suffix i until the next symbol is not available in the tree; at this point, the algorithm creates an internal vertex hd_i if necessary, and a leaf to represent suffix i. (This explanation skips over some of the details of the algorithm.)

Our algorithm. We would like to generalize McCreight's algorithm to p-suffix trees. Unfortunately, we cannot generally define a suffix link for a vertex with pathstring $prev(aS)$ to point to a vertex with pathstring $prev(S)$, because that vertex may not exist due to the failure of the Distinct Right Context Property for p-strings.

We can, however, define a modified suffix link, called a *contracted suffix link*. For a vertex with pathstring $prev(aS)$, the contracted suffix link points to the best available vertex, namely the one whose pathstring is the *contracted locus* of $prev(S)$, by the following definition.

DEFINITION. *For $\alpha \in (\Sigma \cup \mathrm{N})^*$, the* contracted locus *of α is the vertex whose pathstring is the longest prefix of α of all vertices in the tree.*

The contracted locus of α must exist because the empty string is a prefix of every string, and the root is the locus of the empty string.

The contracted locus of a pathstring may change as vertices are added to the p-suffix tree. Thus many contracted suffix links may need to be reset. But the following algorithm uses lazy evaluation; i.e., a contracted suffix link is reset only when it needs to be evaluated.

DEFINITION. *For a p-string S and $i \geq 1$, define $head_i(S)$ as the longest prefix of $psuffix(S, i)$ that is also a prefix of $psuffix(S, j)$ for some $j < i$. Define $head_0$ to be the empty string.*

LEMMA 3. *If $head_{i-1}(S) = prefix(S, i-1, s)$, where $i - 1 \leq s$, then $head_i(S) = prefix(S, i, t)$ for some $t \geq s$.*

Proof. By definition of $head_{i-1}$, there is some $j < i - 1$ such that $head_{i-1}(S)$ is a prefix of $psuffix(S, j)$ as well as of $psuffix(S, i-1)$. Since $|head_{i-1}(S)| = s - i + 2$, the first $s - i + 1$ symbols of $psuffix(S, j+1)$ and $psuffix(S, i)$ must be the same by the Common Prefix Property. The result follows by definition of *head*. □

The construction of p-suffix trees follows the organization of McCreight's original algorithm [McC] as much as possible; modifications are needed to allow for updating out-of-date contracted suffix links and the extra searching resulting from out-of-date contracted suffix links. The values of *plen*, *firstpos*, and *arclen* are stored for the vertices as described earlier. In addition, for each vertex ν, the contracted suffix link $CSL(\nu)$ is stored, and if ν is not the root, a pointer to its parent $parent(\nu)$ is stored.

Let S be the p-string for which the p-suffix tree is to be constructed; we assume that S ends in a unique endmarker in Σ, and $P = prev(S)$ has already been constructed in linear time and space as described in the previous section. The main procedure of the algorithm, called *lazy*, is given in Figure 3; additional procedures, *prescan*, *rescan*, and *scan*, called by *lazy* are described in the text. The ith iteration of the main loop of *lazy* will be referred to as Stage i and inserts the ith p-suffix into the tree.

The tree is initialized to a root, with $CSL(root) = root$ and $oldhd = root$. We will prove the algorithm correct inductively by means of the following properties, which we will show must hold for Stage i, $i \geq 1$.

P1: At the beginning of stage i, $CSL(\nu)$ has been set for the root and for every internal vertex ν except possibly for *oldhd*, which is the locus of $head_{i-1}$; $CSL(root)$ points to *root*, and for a vertex ν other than the root, if $CSL(\nu)$ is defined and the pathstring of ν is $prefix(S, j, k)$, where $j \leq k$, $CSL(\nu)$ points to a vertex whose pathstring is $prefix(S, j+1, t)$ for some t, $j \leq t \leq k$.

P2: At the end of Stage i, the tree is a compacted trie for the first i p-suffixes.

The goals in Stage i are to set $CSL(oldhd)$, to find or create hd, the locus of $head_i$, and to create a new leaf as the locus for $psuffix(S, i)$. Along the way, the contracted suffix link for $parent(oldhd)$ may be updated. In the following discussion, we assume that P1 and P2 held up to the start of Stage i.

If *oldhd* is the root, $CSL(oldhd)$ is already set to the root, and is up-to-date; the algorithm proceeds to call *scan*, described below.

```
/*index(i,len) translates a tree pathlength len into an index
into prev(S) for Stage i */
#define index(i,len) i-1+len
#define FP(i,j)          f(P[i],j)

lazy() {
   int i,short;
   VERTEX c,d,hd,oldhd,start;
   create a tree consisting of a root;
   oldhd=root;
   CSL(oldhd)=root;
   for (i=1;i<=n;++i) { /* Stage i */
      if (oldhd == root) hd=scan(root,child(root,S(0,i)),0,i,i);
      else {
         if (CSL(oldhd) is defined)
           start = CSL(oldhd);
         else
           start = CSL(parent(oldhd)) = prescan(parent(oldhd),i);
         pgoal=plen(oldhd)-1;   /* pgoal = |prefix(S,i,s)| */
         c=rescan(start,pgoal,i); /*contracted locus of prefix(S,i,s) */
         short = pgoal-plen(c);
         /*compare next transformed symbol of prev(S) to corresponding
                symbol on the appropriate arc out of c */
         d=child(c,f(plen(c),index(i,plen(c)+1)));
         if ((d is defined) and (short>0) and
            (FP(index(i,pgoal+1),pgoal)!= FP(firstpos(d)+short,pgoal) {
            create a new vertex hd between c and d
              with arclen(hd) = short and firstpos(hd)=i-1+pgoal;
            CSL(oldhd) = hd;
            }
         else  {
              CSL(oldhd) = c;
              hd = scan(c,d,short,index(i,pgoal+1),i);
            }
         }
      }
      add a new leaf lf as a child of hd, with firstpos(lf)=i+plen(hd),
          arclen(hd)=n-i-plen(hd)-1; /*  locus of psuffix(i) */
      oldhd=hd;
   }
}
```

FIG. 3. *The main procedure for the algorithm for constructing p-suffix trees.*

So suppose *oldhd* is not the root. For $s = plen(oldhd) + i - 2$, $head_{i-1} = prefix(S, i-1, s)$. $CSL(oldhd)$ must be set to the contracted locus of $prefix(S, i, s)$. Fortunately, $prefix(S, i, s)$ is guaranteed to be a prefix of some pathstring already existing in the tree. This follows from the definition of $head_{i-1}$ and the Common Prefix Property.

Initially, *lazy* looks for a vertex *start* that is an ancestor of the contracted locus of $prefix(S, i, s)$. If $CSL(oldhd)$ is already defined (although possibly out of date), by property P1, $CSL(oldhd)$ can be used as *start*. Otherwise *lazy* begins by updating $CSL(parent(oldhd))$ and sets *start* to its updated value. This updated value is found by calling $prescan(parent(oldhd), i)$ and will be the contracted locus of $prefix(S, i, r)$ for some $r < s$.

If $parent(oldhd)$ is the root, $prescan(parent(oldhd), i)$ returns the root. Otherwise, it follows the path of $prefix(S, i, s)$ downward in the tree from the vertex pointed to by $CSL(parent(oldhd))$. It needs to check only the first symbol of each arc label since $prefix(S, i, r)$ is a prefix of $prefix(S, i, s)$, which we showed to be a prefix of some pathstring in the tree. It finds the contracted locus by not exceeding the desired pathlength, $plen(parent(oldhd)) - 1$.

Once *start* has been set, *lazy* finds the current contracted locus c of $prefix(S, i, s)$ by calling a function $rescan(start, pgoal, i)$, where $pgoal = plen(oldhd) - 1$. Now, *rescan* scans downward from *start* following the path of $prefix(S, i, s)$. Like *prescan*, *rescan* checks only the first symbol of each arc label because $prefix(S, i, s)$ is known to be a prefix of some pathstring in the tree. The contracted locus of $prefix(S, i, s)$ is found by not exceeding the desired pathlength, *pgoal*; the contracted locus is *short* symbols above where the locus of $prefix(S, i, s)$ would be (if it existed), for some $short \geq 0$.

While c is currently the contracted locus of $prefix(S, i, s)$, it may no longer be so at the end of the stage if a new vertex is created as the locus of $head_i$. By Lemma 3, for some $t \geq s$, $head_i = prefix(S, i, t)$, but the value of t is not yet known. The only case in which c will not be the contracted locus of $prefix(S, i, s)$ at the end of the stage is when $short > 0$ and $t = s$. If $short > 0$, whether $t = s$ is determined by checking the $(short + 1)$st transformed symbol on the arc from c to the appropriate child d.

Thus the algorithm proceeds as follows. If $short > 0$ and $t = s$, a new vertex is created as the locus hd of $head_i$ and $CSL(oldhd)$ is made to point to it. Otherwise, the algorithm sets $CSL(oldhd)$ to c and sets hd to the vertex returned by $scan(c, d, short, i + pgoal, i)$.

$Scan(c, d, short, j, i)$ begins just after the $(short)$th symbol on the arc into d (or at c if $short = 0$) and the jth input symbol and scans downward in the tree along the path determined by $psuffix(S, i)$ until the next transformed input symbol is not available in the tree. At this point, *scan* creates a new vertex as the locus of $head_i$, if none exists already, and returns it.

Finally, a new arc is added from the locus hd of $head_i = prefix(S, i, t)$ to a new leaf, which is the locus of $psuffix(S, i)$.

Property P1 holds initially when the tree is initialized to just the root. In Stage i, the algorithm sets $CSL(oldhd)$ to the contracted locus for $prefix(S, i, s)$, implying P1 holds for $oldhd$, and care is taken to ensure that P1 still holds for $parent(oldhd)$ if its contracted suffix link was reset. No other contracted suffix links were changed. Hence, if P1 held at the beginning of this stage, it still holds at the end of the stage.

Property P2 holds at the beginning when the tree is initialized to just the root, and for $i > 1$, by the induction hypothesis, property P2 holds at the end of Stage $i - 1$. Either the locus of $head_i$ is created in Stage i by *lazy* because $short > 0$ and $t = s$, or it is created by *scan*. In either case, it is made the child of the old contracted locus of $head_i$ in the tree. Therefore, property P2 holds at the end of Stage i.

By induction, properties P1 and P2 hold for all stages. For $i = n$, P2 implies that the tree is a compacted trie for all the p-suffixes of S. Thus, the above algorithm constructs a p-suffix tree for S.

Analysis.

THEOREM 2. *Let Σ and Π be fixed finite disjoint alphabets. Given a p-string $S \in (\Sigma \cup \Pi)^*$ ending in a unique endmarker in Σ, a p-suffix tree can be constructed for S in time $O(n)$ and space $O(n)$, where n is the length of S.*

Proof. Since correctness of the algorithm was shown above and linearity of space was shown when p-suffix trees were defined in section 2, it only remains to analyze the running time. The proof is more complicated than that for McCreight's algorithm because of the parameter pointers and the use of contracted loci. In McCreight's algorithm, of the input symbols rescanned in a single stage, only the last can be rescanned again later, implying that the time for rescanning is linear in the length of the string. In our case, the failure of the Distinct Right Context Property and the resulting use of contracted loci mean that from one stage to the next, rescanning can back up in the input and rescan again a sequence of symbols already rescanned, but at most a number proportional to $|\Pi|$ in any stage, for a total of $O(|\Pi|n)$ rescanning steps. Prescanning, not needed in McCreight's algorithm, also can recheck symbols already checked previously, but again at most a number proportional to $|\Pi|n$. The result will follow from our assumption that $|\Pi|$ is $O(1)$.

First we observe that *scan* uses $O(n)$ time over all stages, because in each stage, *scan* is called at most once and scans at most one symbol scanned in an earlier stage, and $|\Sigma|$ and $|\Pi|$ are $O(1)$.

Next, we analyze the work required for prescanning.

Call a contracted suffix link *good* if it is for the root or if it is from ν to $\overline{\nu}$, where the pathlength of $\overline{\nu}$ is one less than the pathlength of ν. Otherwise, it is *bad*. By the Restricted Distinct Right Context Property, when a vertex is first given a bad suffix link, it has exactly two arcs, one whose label begins with 0 and one whose label begins with the pathlength of the vertex.

Let $BAD(y)$ be the set of vertices ν that have had contracted suffix links pointing to proper ancestors of y at the start of Stage i and whose contracted suffix links are reset to point to y or a descendant of y after y is created. Every prescanning step that checks the first symbol on an outarc of y is due to a distinct member of $BAD(y)$.

At the start of Stage i, every vertex in $BAD(y)$ still has exactly two outarcs, one whose label begins with 0 and one whose label begins with the pathlength of the vertex, since otherwise the vertex would have been given a good contracted suffix link already. We claim that all vertices of $BAD(y)$ lie in a single path in the tree at the start of Stage i and that the path corresponding to $BAD(y)$ goes along the arcs whose labels begin with a parameter pointer 0.

For suppose that vertices of $BAD(y)$ include w_b and w_c, where neither is an ancestor of the other. Let z be their lowest common ancestor. Since any pathstring can have at most one parameter pointer to the first symbol, by the definition of *prev*, z has two arcs whose labels begin with symbols we will call b and c, respectively, where b and c are not parameter pointers to the first symbols in the pathstrings and $b \neq c$. Without loss of generality, suppose the arc whose label begins with c was created second. By the Restricted Distinct Right Context Property, in the stage after the second arc was created, z received a good contracted suffix link to a vertex u, with arcs whose labels begin with b and c, respectively. Since all internal vertices descended from the arc of z whose label begins with c get their contracted suffix links created after u is created (by construction), w_c has a bad contracted suffix link pointing to u or to a descendant of u through the arc whose label begins with c. By the definition of $BAD(y)$, the contracted suffix link of w_c points strictly above y at the start of Stage i but to y or below y after y is created, and consequently y is a descendant of u through the arc whose label begins with c. But then the $(|u|+1)$st symbol of the pathstring of y is c, whereas by the definition of w_b, it must be b, contradicting the membership of w_b in $BAD(y)$. Therefore, either w_b or w_c must be an ancestor of the other.

Moreover, at each vertex ν (other than the one farthest from the root) in $BAD(y)$, the path follows the outarc whose label begins with 0. The path cannot follow the arc whose label begins with a parameter pointer to the first symbol in the pathstring, because each vertex of $BAD(y)$ has an outarc whose label begins with a parameter pointer to the first symbol in the pathstring, and a pathstring can have at most one such parameter pointer by definition of *prev*.

Since the number of 0's in a pathstring is at most $|\Pi|$, $BAD(y)$ contains at most $|\Pi|$ vertices. Therefore, vertices created before y account for at most $|\Pi|$ symbols prescanned because of y. The only other prescanning steps involving y are those in which prescanning begins at y for vertices whose bad contracted suffix links point directly at y; there are at most n such steps.

There are at most n prescanning steps that can be allocated to the first symbol prescanned in each stage. Over all vertices y, there are at most $|\Pi|n$ additional prescanning steps. Since $|\Sigma|$ and $|\Pi|$ are $O(1)$, each step takes $O(1)$ time, and the total time for prescanning is $O(n)$.

Finally, we analyze the time required for rescanning.

An argument similar to the prescanning argument shows that the number of symbols rescanned in resetting an out-of-date *CSL*(*oldhd*) is $O(|\Pi|n) = O(n)$ over all stages.

Next, we consider rescanning for stages in which *CSL*(*oldhd*) is initially undefined. We will show that, in successive stages, rescanning can back up in the input and rescan sections of input already rescanned, but it cannot back up past symbols already rescanned whose transformed value is not 0. More precisely, suppose that the kth symbol of $prev(S)$ is rescanned in Stage i after having been previously rescanned, $k > i$ (the kth symbol is not the first symbol in the label of an outarc from the root), and the transformed value in this rescanning is not 0. We will show that this symbol must be the first symbol rescanned in Stage i.

The transformed value is the first symbol in the label of an outarc of the locus of $prefix(S, i, k-1)$ and is either a symbol in Σ or an integer between 1 and $k-i$. Also, $k \leq s$, where *oldhd* is the locus of $prefix(S, i-1, s)$, or the kth symbol of $prev(S)$ would not be rescanned. Let j be the number of the last stage in which this symbol was rescanned or scanned. In Stage j, the transformed value of the kth symbol was the same, because of the definition of f and the fact that this symbol was deeper in the tree in Stage j than in Stage i. In Stage j, the kth symbol of $prev(S)$ corresponds to the first symbol on an arc of an internal vertex. Therefore, for some q, $prefix(S, j, k-1) = prefix(S, q, q+k-j-1)$ but $prefix(S, j, k) \neq prefix(S, q, q+k-j)$, and the last symbol of $prefix(S, j, k)$ is either a symbol in Σ or an integer between 1 and $k-i < k-j$. Therefore, by the Common Prefix Property and Restricted Distinct Right Context Property, the locus of $prefix(S, j+1, k-1) = prefix(S, q+1, q+k-j-1)$ exists at the end of Stage $j+1$. Moreover, this argument can be applied inductively to show that the locus of $prefix(S, i-1, k-1)$ exists at the end of Stage $i-1$. Consequently, $k-1 \leq r < s$, where $parent(oldhd)$ is the locus of $prefix(S, i-1, r)$. But the contracted locus of $prefix(S, i, r)$ cannot be any closer to the root than the locus of $prefix(S, i, k-1)$. We conclude that the kth symbol of $prev(S)$ must be the first symbol rescanned in Stage i.

We have shown that other than the first symbol rescanned in each stage, only symbols transformed into 0's can have been rescanned previously. Since the number of 0's in any pathstring is at most $|\Pi|$, each stage rescans at most $|\Pi| + 1$ symbols already rescanned previously. Over all stages, there are at most n rescannings of

symbols for the first time. Since $|\Pi|$ and $|\Sigma|$ are $O(1)$, $O(|\Pi|n) = O(n)$ symbols are rescanned and the time for rescanning each symbol is $O(1)$. Thus, the total time spent on rescanning over all stages is $O(n)$.

From above, scanning, prescanning, and rescanning use $O(n)$ time over all stages. Since the time used by *lazy* outside of these procedures is also $O(n)$, the result follows. □

4. An algorithm for finding all maximal p-matches over a threshold length. This section defines maximal p-matches and gives algorithms for finding all maximal p-matches over threshold length in a p-string.

DEFINITION. *For a p-string S, define S_i to be its ith symbol, for $1 \le i \le |S|$, and $S_{i,j} = S_i \dots S_j$, for $1 \le i \le j \le |S|$.*

Let S be a p-string of length n. If $S_{i,i+k}$ and $S_{j,j+k}$ are a p-match, where $1 \le k < n$ and $1 \le i,\ j \le n-k$, we denote it by $(i, j, k+1)$ or (equivalently) $(j, i, k+1)$, i.e., by the two starting positions and the length of the p-match. Define S_{n+1} to be an endmarker \$ that does not occur in S, and S_0 to be a beginning marker that also does not occur in S, with $S_0 \neq \$$.

DEFINITION. *Suppose $S_{i,i+k}$ and $S_{j,j+k}$ are a p-match, where $1 \le i \le i+k \le n$ and $1 \le j \le j+k \le n$. We say this p-match is* left-extensible *if $S_{i-1,i+k}$ and $S_{j-1,j+k}$ are a p-match, and* right-extensible *if $S_{i,i+k+1}$ and $S_{j,j+k+1}$ are a p-match. If it is neither left-extensible nor right-extensible and is not the trivial p-match $(1, 1, n)$, we say it is a* maximal *p-match.*

LEMMA 4. *If (i, j, k) is a maximal p-match, then this p-match cannot be extended in any amount in either or both directions; i.e., there are no $r, s \ge 0$ with at least one of r, s nonzero such that $(i-r, j-r, r+k+s)$ is a p-match.*

Proof. If two p-strings p-match, and they are truncated on the right (left) by the same amount, the resulting p-strings will still p-match. Therefore, if there is a p-match that is more than one symbol longer in either direction, there will also be a p-match that is exactly one symbol longer, contradicting the nonextensibility of the p-match. □

Maximal p-matches for p-strings include as a subcase maximal matches for strings. It was shown in [Bak2] that the maximal match relation is not an equivalence relation, because it is not transitive. For example, consider the string *adbdadb*. The triple (2, 4, 1) represents the maximal match between the first two *d*'s. Similarly, the triple (4, 6, 1) represents the maximal match between the last two *d*'s. However, the first and last *d*'s are not a maximal match; they are part of the longer maximal match (1, 5, 3). Thus, maximal p-matches are also not an equivalence relation, and an algorithm to report all maximal p-matches over a threshold length must report pairs of p-substrings rather than equivalence classes of p-strings.

In [Bak2], a suffix-tree-based algorithm was given to find all maximal matching substrings over a threshold length in a string. We would like to generalize that algorithm to p-suffix trees and p-strings. The algorithm for strings was based on two facts: each pathstring in a suffix tree represents one or more matches that are not right-extensible, and whether the p-matches are left-extensible can be determined by checking the symbol to the left of the matching substrings.

For p-suffix trees, it is also true that each pathstring represents one or more p-matches that are not right-extensible. However, checking whether the p-matches are left-extensible is more complicated.

Suppose $S_{i,i+k}$ and $S_{j,j+k}$ are a p-match. If S_{i-1} and S_{j-1} are both in Π, the first symbols of $prev(S_{i-1,i+k})$ and $prev(S_{j-1,j+k})$ will both be 0. Nevertheless, it may

happen that $S_{i-1,i+k}$ and $S_{j-1,j+k}$ are not a p-match. The reason is that for some $r \leq k$, the rth symbols of $prev(S_{i,i+k})$ and $prev(S_{j,j+k})$ may both be 0, but S_{i+r-1} may be the next occurrence of S_{i-1}, while S_{j+r-1} may be the first occurrence of some parameter other than S_{j-1}, so these symbols cannot correspond under renaming in $S_{i-1,i+k}$ and $S_{j,j+k}$. For example, consider $S_{i-1,i+k} = xabcx$ and $S_{j-1,j+k} = yabcz$, where x, y, and z are parameters. Then $prev(abcx) = abc0 = prev(abcz)$, but $prev(xabcx) = 0abc3$ while $prev(yabcz) = 0abc0$. This is the failure of the Distinct Right Context Property in a different guise.

It would be convenient to have a way to determine left-extensibility just by checking the positions to the left. Our solution is to construct another string, $A = (prev(S^r))^r$, where the superscript r represents reversal; in A, the parameters are turned into forward references rather than back references as before. Note that A can be constructed in time and space linear in $|S|$ by scanning $prev(S)$, replacing each parameter by a 0, and then replacing each such 0 pointed to by a parameter pointer by the value of the parameter pointer. Let $A_0 = S_0$ (the unique beginning-marker). The following proposition shows that by applying a transform function to each left context, we need check only the left context positions for equality.

LEMMA 5. *Let $i, j, k > 0$ and $i \neq j$. A p-match (i, j, k) is left-extensible iff $f(A_{i-1}, k+1) = f(A_{j-1}, k+1)$.*

Proof. The proof is trivial if at least one of the symbols A_{i-1} and A_{j-1} is in Σ. So, consider the case where both are parameters.

If (i, j, k) is left-extensible, $(i-1, j-1, k+1)$ is a p-match and S_{i-1} occurs in $S_{i,i+k-1}$ iff S_{j-1} occurs in the corresponding positions of $S_{j,j+k-1}$. If these symbols do occur, then

$$f(A_{i-1}, k+1) = f(A_{j-1}, k+1) > 0,$$

while if they don't occur, then

$$f(A_{i-1}, k+1) = f(A_{j-1}, k+1) = 0.$$

Now, suppose (i, j, k) is a p-match and $f(A_{i-1}, k+1) = f(A_{j-1}, k+1) = r$. If $r = 0$, then the initial symbols are both parameter symbols that don't occur in the rest of the p-strings, and the p-match is left-extensible. If $r > 0$, then the initial symbols are the same as the parameter r symbols to the right, and the one to one correspondence between parameter symbols for (i, j, k) also implies that $(i-1, j-1, k+1)$ is a p-match and (i, j, k) is left-extensible. □

The algorithm for finding all maximal p-matches over a threshold length will be based on p-suffix trees augmented by lists of the following forms.

DEFINITION. *A* plist *is a list of integers, and a* clist *is a list of plists.*

An integer i in a plist will represent the ith p-suffix. Each plist will be constructed so that all of its member elements correspond to p-suffixes with the same transformed left context. The intent is to construct a clist for each vertex ν to represent the descendant leaves of ν, sorted by transformed left context in A.

For strings, the algorithm recurses over a suffix tree as follows [Bak2]. For each leaf L, it creates a clist containing a single plist with one index corresponding to the suffix represented by the leaf. At each internal vertex, after constructing the clists for the children, the algorithm sorts the information represented by the clists of the children into a new clist. The sorting is accomplished by processing the children from left to right and merging their information into a new clist. At the same time, any longest p-matches that are found are reported.

The following example illustrates the operation of the string algorithm at a vertex ν. Suppose we represent a plist with positions $p_1, p_2, \ldots, p_k$ and left context σ by $\sigma : p_1, p_2, \ldots, p_k$. If the first child of ν has a clist containing plists a:35,72,46, b:43,7, and c:25, the second child has a clist consisting of plists a:66,2 and c:56, and the third child has a clist consisting of plists b:64,31 and c:82,13,59, where a, b, $c \in \Sigma$, then the clist constructed for the parent, ν, will be a:35,72,46,66,2, b:43,7,64,31, and c:25,56,82,13,59.

For strings, this algorithmic structure is adequate [Bak2]. For p-strings, an extra step must be performed, because the transformed left context of a plist may change from nonzero to zero when it is transformed with respect to a smaller number. For example, if the transformed left context is 35 when evaluated with respect to the pathlength 38 of a child, and the parent has pathlength 32, then the transformed left context will be 0 when transformed with respect to the pathlength of the parent.

Thus, a clist that is sorted by left context for a child may contain more than one plist with left context 0 when the left contexts are evaluated with respect to the parent. Thus, after a clist is constructed for a child c of a vertex ν, the clist is scanned for any plists corresponding to left contexts of 0 when transformed with respect to the pathlength of ν, and such plists are merged into a single plist.

Figure 4 gives the three procedures needed to perform this algorithm for a threshold t: *pdup*, *concatz*, and *pcombine*. The main procedure is *pdup*, which recurses over the p-suffix tree. For each internal vertex, *pdup* calls *pcombine*, which sorts and combines the plists produced for the children, and applies *concatz* to handle the special case where a nonzero value of a transformed left context changes to a zero value. The concatenations of plists, which are not described explicitly, are done via pointers rather than by copying; by maintaining pointers to the beginning and end of each plist, each concatenation is done in $O(1)$ time. For conciseness, the following definitions are assumed in the pseudocode.

DEFINITION. *For a leaf L, the starting position of the p-suffix corresponding to L is $start(L) = firstpos(L) + arclen(L) - plen(L)$. For an integer i, define $LCA(i)$ to be A_{i-1}. For a plist of pl, define $LCA(pl)$ to be A_{i-1}, where the first element of pl is i.*

Thus, for a vertex ν, $f(LCA(pl), plen(\nu)+1)$ is the transformed left context used for pl while processing vertex ν.

THEOREM 3. *Given a p-string S of length n over fixed alphabets Σ and Π and a positive integer t, all p-matches of length at least t in S can be found in time $O(n+r)$ and space $O(n)$, where r is the number of matches reported.*

Proof. Construct the p-suffix tree T for $S\$$, where \$ is an endmarker that doesn't occur in S, using linear time by Theorem 2. Then, call $pdup(root(T), t)$, where *pdup* is given in Figure 4.

We claim that the algorithm correctly merges the clists of the children at each vertex ν, transforming the left context values as required by the pathlength of ν, and reporting exactly the longest p-matches over threshold length. A formal proof would be by induction on the depth of ν; details are left to the interested reader.

Now, we need to analyze the time and space bounds for the algorithm. The time spent on linear searches of clists and plists in *pcombine* and *concatz* is dominated by the number of steps spent on cross-products. Two cross-products of clists are performed in *pcombine*. We partition the work into *same-work*, namely, the steps required when the transformed left contexts are the same, and *different-work*, namely, the steps required when the transformed left contexts are different. We bound the amount of same-work and different-work as follows.

```
/*f is defined in Section 2 */
clist pcombine(clist cl1, clist cl2, int len, int t) {
   plist pl1, pl2;
   clist outputlist;
   if (len < t) return (NULL);
   for each plist pl1 of cl1 and each plist pl2 of cl2
      if (f(LCA(pl1),len+1) ≠ f(LCA(pl2),len+1))
         for every p1 in pl1 and every p2 in pl2
           report a maximal match (p1, p2, len);
   /*construct outputlist */
   for each plist pl1 of cl1 and each plist pl2 of cl2
      if (f(LCA(pl1), len+1) == f(LCA(pl2),len+1)) {
         include in outputlist the plist obtained by concatenating
           pl2 to pl1;
        mark pl1 and pl2 as used;
      }
   for each plist pl1 of cl1 that is not marked used
      include pl1 in outputlist;
   for each plist pl2 of cl2 that is not marked used
      include pl2 in outputlist;
   remove marks from all plists in outputlist;
   return outputlist;
}
clist concatz(clist cl, int len) {
   scan cl and concatenate all plists pl for which f(LCA(pl), len+1)=0
      into one plist while leaving others unchanged
}

clist pdup(vertex v, int t) {
   clist cl;
   if (v is a leaf) return a clist containing one plist
      consisting of start(ν);
   cl = NULL;
   for each child s of v
      cl = pcombine(cl, concatz(pdup(s,t),plen(v)),plen(v),t);
   return cl;
}
```

FIG. 4. *The algorithm pdup for reporting all maximal p-matches of length at least t.*

By examining the second cross-product of clists, where plists are merged, it is easy to see that the same-work done at vertex ν is linear in the number of new links created in combining plists, and consequently, the amount of same-work performed over all vertices is linear in the sum of the lengths of the plists for the root, and is consequently linear in n.

At each step in the first cross-product with distinct transformed left contexts, a maximal p-match is reported for each pair of positions in the cross-product of the plists. Therefore, the amount of time spent over all vertices on different-work in the two cross-products of clists is linear in r. □

5. Implementation and experiments. This section describes an application of the p-suffix tree to finding parameterized duplication in C code. The algorithms *lazy* and *pdup* have been implemented in a C program running under UNIX. The sets Σ and Π are disjoint sets of integers, varying with the input. For each line of C code, the lexical analyzer turns tokens such as identifiers and constants (but not keywords or operators) into integer parameter symbols, generates a new version of

TABLE 1
Data for lazy *on three subsystems.*

Number of lines	Number of symbols	$\|\Sigma\|$	$\|\Pi\|$	Number of symbols prescanned	Number of symbols rescanned	Time for *lazy* in seconds
35233	112146	2406	6761	60730	27371	4.97
101874	320947	3992	11718	176690	74149	15.06
158579	517415	8808	24168	271069	121202	25.91

the line in which each such token is replaced by a "P," and obtains an integer in Σ corresponding to the transformed line. Thus, each line of input corresponds to one symbol of Σ and zero or more symbols of Π (in the order in which the corresponding tokens occur in the line). Since Σ and Π can be very large, accessing the children of each vertex is accomplished by hashing rather than by linked lists in *lazy*. How to do this was suggested by McCreight [McC]. However, since *pdup* requires being able to scan successive children of each vertex, which cannot easily be done with the hashing method, the outarcs of each vertex are converted into linked lists for running *pdup*; the transformation is done in time linear in input length.

The program was applied to code from three different subsystems of a production system. The experiments were run on one processor of an SGI machine with eight 33 MHz R3000 processors, data and instruction caches of 64 Kbytes, a secondary data cache size of 256 Kbytes, and main memory size of 256 Mbytes.

Table 1 gives the data related to *lazy*. The first four columns give the data for the input subsystems: the number of lines (including comments and white space), the length of the resulting p-string, the size of Σ, and the size of Π. The last three columns give the running time for *lazy*, (not including the lexical analysis), the number of symbols prescanned, and the number of symbols rescanned.

The proof of Theorem 2 suggests that, in the worst case, the number of steps executed for prescanning and rescanning might be proportional to $|\Pi|$ times the length of the input. Since $|\Pi|$ is not constant in our application, and could be in principle proportional to n, the running time could be quadratic rather than linear in n. Table 1 shows that this blowup was not observed in the experiments: in each case, the number of symbols prescanned and the number of symbols rescanned were less than the length of the input. The question of why this blowup was not observed is partially answered by looking at the maximum number of prescannings and rescannings in any stage. For the largest subsystem, the maximum number of prescannings in any stage was 6, and for the other two, it was 3; for the largest subsystem, the maximum number of rescannings in any stage was 99, for the second largest, it was 33, and for the smallest, it was 16. Either the bound of $|\Pi|n$ steps is not tight, or the input from code does not generate worst-case behavior. In any case, we conclude that *lazy* runs fast even with large alphabets and large input.

Table 2 gives data regarding running times of *pdup* and running times of the whole program (including lexical analysis and *lazy*) on the three subsystems, with a threshold length of 75, which is a value which would be reasonable for the application. The times given for *pdup* include the time for transforming the arc representation from hashing into linked lists and the time for running *pdup*. Note that with a threshold of 75, the number of p-matches reported is much less than input length; hence the running time of *pdup* is dominated by the part of the algorithm linear in input length. With a threshold of 10 for the largest subsystem, with p-string length of 517415, *pdup*

TABLE 2
Running times for pdup *and for the whole program.*

Threshold length	Number of lines	Number of symbols	Number of matches	*pdup* time in seconds	Total time in seconds
75	35233	112146	512	4.28	27.48
75	101874	320947	3837	15.14	69.64
75	158579	517415	16088	26.06	111.33

reports 5017926 maximal p-matches and takes 467 seconds, and the whole program takes 555 seconds.

6. Discussion. The theorems in this paper were stated in terms of fixed alphabets, but in the application, as described in the last section, the alphabets are not fixed. It is interesting to examine further the worst-case time bounds in the case of variable alphabets.

The construction of A from $prev(S)$ takes time linear in $|S|$ even for variable alphabets, and in *pdup*, arcs are only accessed sequentially. Thus, for variable alphabets, once the p-suffix tree is constructed for a p-string S, the time to report all maximal p-matches over a threshold length in S is $O(n + r)$, where n is the input length and r is the number of p-matches reported.

On the other hand, as mentioned in the previous section, the bounds proved for constructing a p-suffix tree do depend on alphabet size: the proof of Theorem 2 shows that the number of symbols prescanned and rescanned when running *lazy* on input of length n is bounded by $O(n|\Pi|)$. If arcs are stored in a balanced tree scheme with $O(\log(|\Sigma| + |\Pi|))$ access time, then *lazy* constructs a p-suffix tree in worst-case time $O(n(|\Pi| \log(|\Sigma| + |\Pi|)))$. As discussed in the last section, these bounds may not be tight.

The author is continuing work on p-suffix trees, some of which will be described in [Bak3]. As a step in improving the worst-case bounds for variable alphabets, [Bak3] will show that a p-suffix tree for a p-string S of length n can be constructed in $O(n \log n)$ time and $O(n)$ space if Σ and Π can vary. However, that algorithm is not practical, since it relies on complicated auxiliary data structures.

An issue regarding the choice of problem statement is that reporting all maximal p-matches over a threshold length does not necessarily result in a natural analysis of certain kinds of duplication. For example, a structure of $(abc)^4$ will be reported as one p-match of length 3, one of length 6, and one of length 9 (with the matching p-strings overlapping). It could be that some other set of definitions would enable a more natural analysis of the structure of duplication.

A related issue regarding the choice of definitions is the issue of how the amount of output relates to the amount of information it conveys. Tufte has stressed in his beautiful book [Tu] on the visual display of data that it is important to maximize the data-ink ratio. The same principle should apply to how much output is reported by algorithms. In the case of duplication, if there are c copies of the same p-string, then a natural way to report them would be by listing c starting positions and the p-string; however, because the p-match relationship is not an equivalence relation, they could in general be part of $c(c-1)/2$ distinct maximal p-matches, and under the maximal p-match definition, these must be reported separately. It is not obvious what definitions would enable reporting a minimal amount of information in each case, in a way easily understandable to the user of the program.

Acknowledgments. The author would like to thank Raffaele Giancarlo for helpful discussions relating to this work, and William Chang for providing an implementation of McCreight's algorithm that was modified to implement `lazy`.

THE MAXIMUM LATENCY AND IDENTIFICATION OF POSITIVE BOOLEAN FUNCTIONS*

KAZUHISA MAKINO† AND TOSHIHIDE IBARAKI‡

Abstract. Consider the problem of identifying $\min T(f)$ and $\max F(f)$ of a positive (i.e., monotone) Boolean function f by using membership queries only, where $\min T(f)$ ($\max F(f)$) denotes the set of minimal true vectors (maximal false vectors) of f. It is known that an incrementally polynomial algorithm exists if and only if there is a polynomial time algorithm to check the existence of an unknown vector u for given sets $MT \subseteq \min T(f)$ and $MF \subseteq \max F(f)$; that is, $u \in \{0,1\}^n \setminus (\{v \mid v \geq w \text{ for some } w \in MT\} \cup \{v \mid v \leq w \text{ for some } w \in MF\})$. This paper introduces a measure for the difficulty to find an unknown vector, which is called the maximum latency. If the maximum latency is constant, then an unknown vector can be found in polynomial time and there is an incrementally polynomial algorithm for identification. Several subclasses of positive functions are shown to have constant maximum latency, e.g., 2-monotonic positive functions, Δ-partial positive threshold functions, and matroid functions, while the class of general positive functions has $\lfloor n/4 \rfloor + 1$ maximum latency and the class of positive k-DNF functions has $\Omega(\sqrt{n})$ maximum latency.

1. Introduction.

Consider the problem of identifying $T(f)$ (set of true vectors) and $F(f)$ (set of false vectors) of a given Boolean function (or a function in short) f by asking membership queries to an oracle whether $f(u) = 0$ or 1 holds for some selected vectors u [6]. In the terminology of computational learning theory [1, 2, 28], this is the exact learning of a Boolean theory f by membership queries only. It is also a process of forming a theory that explains a certain phenomenon by collecting positive and negative data (in the sense of causing and not causing that phenomenon) [12]. In particular, we are interested in the case where f is known to be positive, i.e., monotone. If f is a positive function, $T(f)$ and $F(f)$ can be compactly represented by $\min T(f)$ (set of minimal true vectors) and $\max F(f)$ (set of maximal false vectors). Therefore our problem is stated as follows.

PROBLEM IDENTIFICATION.

Input: A membership oracle for a positive function f.

Output: $\min T(f)$ and $\max F(f)$.

The complexity of this type of enumeration algorithm is usually measured in its length of input and output. An algorithm to enumerate items $a_1, a_2, \ldots, a_p$ is called *incrementally polynomial* [19, 21] (i) if it iterates the following procedure for $i = 1, 2, \ldots, p$: output the ith item a_i from the knowledge of its input and items $a_1, a_2, \ldots, a_{i-1}$ generated by then and (ii) if the time required for the ith iteration

is polynomial in the input length and the sizes of $a_1, a_2, \ldots, a_{i-1}$. If an algorithm is incrementally polynomial, it also satisfies the criterion of *polynomial total time* [19] (i.e., polynomial time in the length of input and output).

Now let MT and MF respectively denote the partial knowledge of $\min T(f)$ and $\max F(f)$ currently at hand, i.e.,

$$MT \subseteq \min T(f) \text{ and } MF \subseteq \max F(f). \tag{1}$$

Define

$$T(MT) = \{v \mid v \geq w \text{ for some } w \in MT\},$$
$$F(MF) = \{v \mid v \leq w \text{ for some } w \in MF\}.$$

By assumption (1), $T(MT) \subseteq T(f)$ and $F(MF) \subseteq F(f)$, and hence

$$T(MT) \cap F(MF) = \emptyset$$

holds. A vector u is called *unknown* if

$$u \in \{0,1\}^n \setminus (T(MT) \cup F(MF)),$$

since it is not known at the current stage whether u is a true vector or a false vector of f. If there is no unknown vector, then $T(MT) \cup F(MF) = \{0,1\}^n$ holds, i.e., $MT = \min T(f)$ and $MF = \max F(f)$ hold for some positive function f.

The general procedure of identifying a positive function f can be described as follows.

Algorithm IDENTIFY.

Input: A membership oracle for a positive function f.

Output: $\min T(f)$ and $\max F(f)$.

1. Start with appropriate sets MT ($\subseteq \min T(f)$) and MF ($\subseteq \max F(f)$).

2. Test if $T(MT) \cup F(MF) = \{0,1\}^n$ holds. If so, output MT and MF, and halt. Otherwise, find an unknown vector u and go to 3.

3. Ask an oracle if $f(u) = 1$ or $f(u) = 0$. If $f(u) = 1$, then compute a new minimal true vector y such that $y \leq u$ and let $MT := MT \cup \{y\}$. On the other hand, if $f(u) = 0$, compute a new maximal false vector y such that $y \geq u$ and let $MF := MF \cup \{y\}$. Return to 2.

The crucial part of this algorithm is in step 2, i.e., to solve the following problem, where a set of vectors M is *incomparable* if any pair of vectors v and w in M satisfies $v \not\geq w$ and $w \not\geq v$.

Problem EQ.

Input: Incomparable sets MT, MF ($\subseteq \{0,1\}^n$) such that $T(MT) \cap F(MF) = \emptyset$.

Question: Does $T(MT) \cup F(MF) = \{0,1\}^n$ (i.e., no unknown vector) hold?

In case of $MT, MF = \emptyset$, problem EQ is obviously polynomially solvable, since all vectors u are unknown. Hence in the following, we assume $MT \cup MF \neq \emptyset$ in step 1. If problem EQ can be solved in polynomial time, it is known that an unknown vector in step 2 can be found in polynomial time [6] and that computing a minimal true vector or a maximal false vector y from an unknown vector u in step 3 can also be done in polynomial time [1, 6, 15, 28]. Therefore, an incrementally polynomial algorithm exists if problem EQ can be solved in polynomial time. The converse direction is also known [6], and hence an incrementally polynomial algorithm exists if and only if problem EQ can be solved in polynomial time. As noted in [6], problem

EQ is polynomially equivalent to many other interesting problems encountered in various fields such as hypergraph theory [13], theory of coteries (used in distributed systems) [16, 18], artificial intelligence [27], and Boolean theory [5]. Unfortunately, the complexity of these problems is still open [6, 13, 19], though the recent result by M. Fredman and L. Khachiyan [14] shows that it is unlikely that the problem is NP-hard.

We comment here that there is a wide spectrum of research on the exact learning of Boolean functions. Many of these studies, however, are based on the model of using both membership and equivalence queries. Using such a model, N. H. Bshouty [9] showed that any Boolean function (not necessarily positive) is polynomially learnable either as DNF (disjunctive normal form) or CNF (conjunctive normal form).

In order to investigate the complexity of problem EQ, we introduce in this paper the concept of maximum latency, which is a complexity measure for finding an unknown vector. If the maximum latency is constant, then problem EQ can be solved in polynomial time, though the converse is not generally true. Based on the result by V. K. Korobkov and T. L. Reznik [20], it is noted in section 3 that the maximum latency of general positive functions is $\lfloor n/4 \rfloor + 1$. However, several special classes of positive functions are found in section 4 to have constant maximum latency, e.g., classes of (i) 2-monotonic positive functions [4, 7, 8, 11, 25, 26] (ii) Δ-partial positive threshold functions [25], (iii) k-degree positive threshold functions, (iv) matroid functions [3, 10], and (v) k-tight positive functions. For these classes of positive functions, therefore, there are incrementally polynomial identification algorithms. Finally, it is shown in section 5 that the class of positive k-DNF functions has maximum latency not less than $\Omega(\sqrt{n})$, even though it is known [13] that problem EQ can be solved in polynomial time for this class of functions.

The last result indicates that the concept of maximum latency is not always sufficient to distinguish polynomially solvable cases from those not solvable in polynomial time. However, it is also evident that the maximum latency is a powerful tool to find polynomially solvable special cases.

2. Definitions and basic properties. A *Boolean function*, or a *function* in short, is a mapping $f : \{0,1\}^n \mapsto \{0,1\}$, where $v \in \{0,1\}^n$ is called a *Boolean vector* (a *vector* in short). If $f(v) = 1$ (resp., 0), then v is called a *true* (resp., *false*) vector of f. The set of all true vectors (resp., false vectors) is denoted by $T(f)$ (resp., $F(f)$). Two special functions with $T(f) = \emptyset$ and $F(f) = \emptyset$ are, respectively, denoted by $f = \bot$ and $f = \top$. A function f is *positive* if $v \leq w$ always implies $f(v) \leq f(w)$. A positive function is also called *monotone*.[1] A true vector v of f is *minimal* if there is no other true vector w such that $w < v$, and let $\min T(f)$ denote the set of all minimal true vectors of f. A *maximal* false vector is symmetrically defined and $\max F(f)$ denotes the set of all maximal false vectors of f.

If functions f and h satisfy $h(a) \leq f(a)$ for all $a \in \{0,1\}^n$, then we denote $h \leq f$. If $h \leq f$ and there exists a vector a satisfying $h(a) = 0$ and $f(a) = 1$, we denote $h < f$. The variables $x_1, x_2, \ldots, x_n$ and their complements $\bar{x}_1, \bar{x}_2, \ldots, \bar{x}_n$ are called *literals*. A *term* (resp., *clause*) is a conjunction (resp., disjunction) of literals such that at most one of x_i and $\bar{x}_i$ appears for each variable. A term t (resp., clause C) is called an *implicant* (resp., *implicate*) of a function f if $t \leq f$ (resp. $C \geq f$). An implicant t (resp., implicate C) of a function is called *prime* if there is no implicant

[1] The name "monotone" may be more familiar to people in theoretical computer science than "positive." However, in this paper we use "positive" to avoid confusion, since such names as 1-monomonic (or unate) and 2-monotonic used in threshold logic do not exclude nonpositive functions.

$t' > t$ (resp., no implicate $C' < C$). A DNF (resp., CNF) is a disjunction of terms (resp., conjunction of clauses).

If f is positive, it is known that f has (i) the unique DNF consisting of all prime implicants and (ii) the unique CNF consisting of all prime implicates. There is one-to-one correspondence between prime implicants (resp., prime implicates) and minimal true vectors (resp., maximal false vectors). For example, a positive function $f = x_1x_2 \vee x_2x_3x_4 = x_2(x_1 \vee x_3)(x_1 \vee x_4)$ has prime implicants x_1x_2 and $x_2x_3x_4$, which respectively correspond to minimal true vectors (1100) and (0111), and prime implicates x_2, $(x_1 \vee x_3)$, and $(x_1 \vee x_4)$, which respectively correspond to maximal false vectors (1011), (0101), and (0110). In other words, the input length to describe a positive function f is $O(n|\min T(f)|)$ (resp., $O(n|\max F(f)|)$) if it is represented by DNF (resp., CNF).

Sets $\min T(f)$ and $\max F(f)$, respectively, define $T(f)$ and $F(f)$ by

$$T(f) = \{v \mid v \geq a \text{ for some } a \in \min T(f)\},$$
$$F(f) = \{v \mid v \leq b \text{ for some } b \in \max F(f)\}.$$

DEFINITION 2.1. *Given incomparable sets MT, MF ($\subseteq \{0,1\}^n$) such that $MT \cup MF \neq \emptyset$ and $T(MT) \cap F(MF) = \emptyset$, the partial function g is defined by*

$$g(v) = \begin{cases} 1, & v \in T(MT), \\ 0, & v \in F(MF), \\ \textit{unknown}, & \textit{otherwise}. \end{cases}$$

If MT and MF of g satisfy $MT \subseteq \min T(f)$ and $MF \subseteq \max F(f)$ for some (complete) positive function f, then g is called a partial function of f. *The set of unknown vectors of g is denoted by $U(g)$, i.e.,*

$$U(g) = \{0,1\}^n \setminus (T(MT) \cup F(MF)).$$

The k-neighborhood of g (defined by MT and MF) is given by

$$N_k(g) = \{v \mid \| v - a \| \leq k \text{ for some } a \in MT \cup MF\},$$

where $\| w \|$ denotes $\sum_{i=1}^{n} |w_i|$; i.e., $N_k(g)$ is the set of all vectors within Hamming distance k of $MT \cup MF$. The latency *of g, $\lambda(g)$, is defined by the integer k satisfying*

$$N_{k-1}(g) \cap U(g) = \emptyset \quad \textit{and} \quad N_k(g) \cap U(g) \neq \emptyset.$$

As a special case, if $U(g) = \emptyset$, i.e., $g = f$, then $\lambda(g)$ is defined to be 0. $\lambda(g)$ is equivalently given by

$$\lambda(g) = \min\{\| u - a \| \mid a \in MT \cup MF, u \in U(g)\}.$$

Example 2.2. Let $f = x_1x_3 \vee x_2x_4$, i.e.,

$$\min T(f) = \{1010, 0101\},$$
$$\max F(f) = \{0011, 0110, 1001, 1100\},$$

and let g be a partial function defined by

$$MT = \{1010, 0101\},$$
$$MF = \{0011, 0110, 1001\}.$$

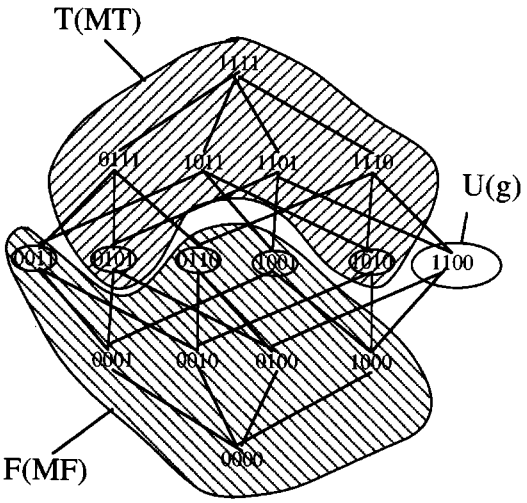

FIG. 1. *The partial function g of Example* 2.2.

Then the set of unknown vectors is

$$U(g) = \{1100\},$$

and we obtain $\lambda(g) = 2$ (see Figure 1).

DEFINITION 2.3. *Let C_X be a subclass of positive functions. $C_X(n)$ denotes the set of functions in C_X with n variables. For $C_X(n)$, the* maximum latency *is defined by*

$$\Lambda_X(n) = \max\{\lambda(g) \mid g \text{ is a partial function of } f \in C_X(n)\}.$$

If g is a partial function of $f \in C_X(n)$, then by definition there is no unknown vector if $N_{\Lambda_X(n)}(g) \cap U(g) = \emptyset$. That is, in order to find an unknown vector, we need only to search $\Lambda_X(n)$-neighborhood of g. Therefore, if a positive function f of n variables is known to belong to class $C_X(n)$, step 2 of Algorithm IDENTIFY can be executed as follows.

2. Test if $N_{\Lambda_X(n)}(g) \subseteq T(MT) \cup F(MF)$, where g is the partial function defined by MT and MF. If so, output MT and MF, and halt. Otherwise, find an unknown vector $u \in N_{\Lambda_X(n)}(g) \setminus (T(MT) \cup F(MF))$ and go to 3.

The test of $N_{\Lambda_X(n)}(g) \subseteq T(MT) \cup F(MF)$ can be accomplished by checking if $v \geq a$ for some $a \in MT$ or $v \leq b$ for some $b \in MF$, for every $v \in N_{\Lambda_X(n)}(g)$. This computation takes at most

$$n(|MT| + |MF|)\,|N_{\Lambda_X(n)}(g)| \leq n(|MT| + |MF|)^2\, n^{\Lambda_X(n)}$$

time. Therefore, we have the next result.

THEOREM 2.4. *Let g, defined by MT and MF, be a partial function of $f \in C_X(n)$. If $\Lambda_X(n)$ is constant, then an unknown vector can be found in polynomial time in n and $|MT| + |MF|$. (Therefore, in this case, there is an incrementally polynomial algorithm to identify $f \in C_X(n)$.)*

3. Maximum latency of general positive functions. Let

C_P: class of all positive functions.

It was shown by V. K. Korobkov and T. L. Reznik [20] that $\Lambda_P(n) \leq \lfloor n/4 \rfloor + 1$ for all n, and that $\Lambda_P(n) \geq \lfloor n/4 \rfloor + 1$ for $n = 4k$. Similar results were independently obtained in [22]. We complement these results by showing the next lemma. For a vector $v \in \{0,1\}^n$, use the notations $ON(v) = \{j \mid v_j = 1,\ j = 1,2,\ldots,n\}$ and $OFF(v) = \{j \mid v_j = 0,\ j = 1,2,\ldots,n\}$.

LEMMA 3.1. *$\Lambda_P(n) \geq \lfloor n/4 \rfloor + 1$ for all positive integers n.*

Proof. For $n = 1,2,3$, it is clear that $\Lambda_P(n) = \lfloor n/4 \rfloor + 1 = 1$. We show $\Lambda_P(n) \geq \lfloor n/4 \rfloor + 1$ for $n \geq 4$ by providing an example of g with $\lambda(g) = \lfloor n/4 \rfloor + 1$. In this example (MT, MF), there is exactly one unknown vector u. Hence, there is a vector $v \in MT$ (resp., $v \in MF$) such that $v \leq u + e_i$ (resp., $v \geq u - e_i$) for every $i \in OFF(u)$ (resp., $i \in ON(u)$), where e_i denotes the unit vector whose ith component is 1. MT and MF are constructed in such a way that all vectors $v \in MT \cup MF$ are used for the above purpose and satisfy $\| v - u \| \geq \lfloor n/4 \rfloor + 1$.

(1) $n = 4k$ $(k \geq 1)$: Define a $2k \times 4k$ matrix

$$X = \left(\begin{array}{cc|c} J_k & O & \\ \hline O & J_k & I_{2k} \end{array}\right)$$

and a $(k^2 + 2k) \times 4k$ matrix

$$Y = \left(\begin{array}{c|cc} Q & \multicolumn{2}{c}{J_{k^2 \times 2k}} \\ \hline J_{2k} - I_{2k} & \begin{array}{c|c} J_k & O \\ \hline O & J_k \end{array} & \end{array}\right),$$

where J_i is the $i \times i$ matrix whose elements are all 1's, $J_{i \times j}$ is the $i \times j$ matrix whose elements are all 1's, I_i is the $i \times i$ identity matrix, O is the $k \times k$ zero matrix, and Q is the $k^2 \times 2k$ matrix defined by

$$Q = \left(\begin{array}{ccccc|c} 0 & 1 & \ldots & \ldots & 1 & \\ 0 & 1 & \ldots & \ldots & 1 & \\ \multicolumn{5}{c|}{\ldots\ldots\ldots\ldots\ldots} & J_k - I_k \\ 0 & 1 & \ldots & \ldots & 1 & \\ \hline 1 & 0 & 1 & \ldots & 1 & \\ \multicolumn{5}{c|}{\ldots\ldots\ldots\ldots\ldots} & J_k - I_k \\ 1 & 0 & 1 & \ldots & 1 & \\ \hline \multicolumn{5}{c|}{\ldots\ldots\ldots\ldots\ldots} & \ldots \\ \hline 1 & \ldots & \ldots & 1 & 0 & \\ \multicolumn{5}{c|}{\ldots\ldots\ldots\ldots\ldots} & J_k - I_k \\ 1 & \ldots & \ldots & 1 & 0 & \end{array}\right) \begin{array}{l} \left.\vphantom{\begin{array}{c}a\\a\\a\\a\end{array}}\right\} k \\ \left.\vphantom{\begin{array}{c}a\\a\\a\\a\end{array}}\right\} k. \\ \vdots \\ \left.\vphantom{\begin{array}{c}a\\a\\a\\a\end{array}}\right\} k \end{array}$$

A partial function g is then defined by $MT = \{x^{(j)} \mid j = 1,2,\ldots,2k\}$ and $MF = \{y^{(j)} \mid j = 1,2,\ldots,k^2 + 2k\}$, where $x^{(j)}$ is the jth row of X and $y^{(j)}$ is the jth row of Y. Furthermore, let

$$u = (\underbrace{1,1,\ldots,1}_{2k},\underbrace{0,0,\ldots,0}_{2k}).$$

It is clear that $T(MT) \cap F(MF) = \emptyset$ and $u \notin T(MT) \cup F(MF)$; i.e., u is an unknown vector. Furthermore, $u - e_i \in F(MF)$ for every $i \in ON(u)$ and $u + e_i \in T(MT)$ for every $i \in OFF(u)$, where e_i denotes the unit vector whose ith component is 1. Consider the positive function f satisfying $\min T(f) = MT$. Then it is not difficult to see that $\max F(f) = \{u\} \cup MF$ by using a relation

$$\max F(f) = \{\bar{v} \mid v \in \min T(f^d)\},$$

where f^d is the dual of f. Therefore, $T(MT) \cup F(MF) \cup \{u\} = \{0,1\}^n$; i.e., u is the only unknown vector. Finally, $\| x^{(j)} - u \| = k + 1 > k$ for every j $(1 \le j \le 2k)$, $\| y^{(j)} - u \| = 2k + 2 > k$ for every j $(1 \le j \le k^2)$, and $\| y^{(j)} - u \| = k + 1 > k$ for every j $(k^2 < j \le k^2 + 2k)$. This proves that $N_k(g) \cap U(g) = \emptyset$ and $N_{k+1}(g) \cap U(g) \neq \emptyset$.

(2) $n = 4k + \alpha$ $(k \ge 1,\ 1 \le \alpha \le 3)$: Define a $2k \times (4k + \alpha)$ matrix

$$X = \left(\begin{array}{c|c|c|c} J_k & O & I_{2k} & J_{2k \times \alpha} \\ \hline O & J_k & & \end{array} \right)$$

and a $(k^2 + 2k + \alpha) \times (4k + \alpha)$ matrix

$$Y = \left(\begin{array}{c|c|c} Q & \begin{array}{c|c} J_k & O \\ \hline O & J_k \end{array} & J_{(k^2+2k) \times \alpha} \\ \hline J_{2k} - I_{2k} & & \\ \hline J_{\alpha \times 4k} & & J_\alpha - I_\alpha \end{array} \right).$$

Define a partial function g by $MT = \{x^{(j)} \mid j = 1, 2, \ldots, 2k\}$ and $MF = \{y^{(j)} \mid j = 1, 2, \ldots, k^2 + 2k + \alpha\}$. Furthermore, let

$$u = (\underbrace{1, 1, \ldots, 1}_{2k}, \underbrace{0, 0, \ldots, 0}_{2k}, \underbrace{1, 1, \ldots, 1}_{\alpha}).$$

Similarly to case (1), it can be shown that $U(g) = \{u\}$, and $N_k(g) \cap U(g) = \emptyset$ and $N_{k+1}(g) \cap U(g) \neq \emptyset$ for $k = \lfloor n/4 \rfloor$. □

In Example 2.2, it is easy to see that g is the partial function constructed for $k = 1$ in the proof (1) of the above lemma.

THEOREM 3.2. *Class C_P satisfies*

$$\Lambda_P(n) = \lfloor n/4 \rfloor + 1.$$

Proof. Combine the result in [20] and Lemma 3.1. □

4. Restricted classes of positive functions with constant maximum latencies. In this section, we find some restricted classes of positive functions with constant maximum latency, which are important in practice and theory (e.g.,[2, 13, 25]). As stated in Theorem 2.4, functions in these classes can be identified by incrementally polynomial algorithms.

4.1. 2-monotonic positive functions. An assignment A of binary values 0 or 1 to k variables $x_{i_1}, x_{i_2}, \ldots, x_{i_k}$ is called a *k-assignment* and is denoted by

$$A = (x_{i_1} \leftarrow a_1, x_{i_2} \leftarrow a_2, \ldots, x_{i_k} \leftarrow a_k),$$

where each of $a_1, a_2, \ldots, a_k$ is either 1 or 0. Let the complement of A, denoted by $\bar{A}$, represent the assignment obtained from A by complementing all the 1's and 0's in A. When a function f of n variables and a k-assignment A are given,

$$f_A = f_{(x_{i_1} \leftarrow a_1,\, x_{i_2} \leftarrow a_2, \ldots, x_{i_k} \leftarrow a_k)}$$

denotes the function of $(n-k)$ variables obtained by fixing variables $x_{i_1}, x_{i_2}, \ldots, x_{i_k}$ as specified by A.

Let f be a function of n variables. If either $f_A \leq f_{\bar{A}}$ or $f_A \geq f_{\bar{A}}$ holds for every k-assignment A, then f is said to be *k-comparable*. If f is k-comparable for every k such that $1 \leq k \leq m$, then f is said to be *m-monotonic*. (For more detailed discussion on these topics, see [25] for example.) In particular, f is 1-monotonic if $f_{(x_i \leftarrow 1)} \geq f_{(x_i \leftarrow 0)}$ or $f_{(x_i \leftarrow 1)} \leq f_{(x_i \leftarrow 0)}$ holds for any $i \in \{1, 2, \ldots, n\}$. A 1-monotonic function is also called a *unate* function. A positive function is precisely a 1-monotonic function f for which $f_{(x_i \leftarrow 1)} \geq f_{(x_i \leftarrow 0)}$ holds for all i.

Now consider a 2-assignment $A = (x_i \leftarrow 1, x_j \leftarrow 0)$. If

$$f_A \geq f_{\bar{A}} \ \text{(resp., } f_A > f_{\bar{A}}\text{)}$$

holds, this is denoted by $x_i \succeq_f x_j$ (resp., $x_i \succ_f x_j$). Variables x_i and x_j are said to be *comparable* if either $x_i \succeq_f x_j$ or $x_i \preceq_f x_j$ holds. When $x_i \succeq_f x_j$ and $x_i \preceq_f x_j$ hold simultaneously, it is denoted as $x_i \approx_f x_j$. If f is 2-monotonic, this binary relation $\succeq_f$ over the set of variables is known to be a total preorder (i.e., reflexive, transitive, and comparable) [25]. A 2-monotonic positive function f of n variables is called *regular* if

$$x_1 \succeq_f x_2 \succeq_f \cdots \succeq_f x_n.$$

Any 2-monotonic positive function becomes regular by permuting variables.

The 2-monotonicity was originally introduced in conjunction with threshold functions (e.g., [25]), where a positive function f is *threshold* if there exist $n+1$ nonnegative real numbers $w_1, w_2, \ldots, w_n$ and t such that

$$f(x) = \begin{cases} 1 & \text{if } \sum w_i x_i \geq t, \\ 0 & \text{if } \sum w_i x_i < t. \end{cases}$$

As $w_i \geq w_j$ implies $x_i \succeq_f x_j$ and $w_i = w_j$ implies $x_i \approx_f x_j$, a threshold function is always 2-monotonic, although the converse is not true [25]. Let

C_{2M}: class of 2-monotonic positive functions,
C_{TH}: class of positive threshold functions.

THEOREM 4.1. *Class C_{2M} satisfies*

$$\Lambda_{2M}(n) = 1.$$

Proof. Assume that a 2-monotonic positive function f is regular without loss of generality and that g is a partial function of f defined by MT and MF. Assume that $N_1(g) \cap U(g) = \emptyset$ and $U(g) \neq \emptyset$ (i.e., $\Lambda_{2M}(n) > 1$). Take a $u \in \max U(g)$, where $\max U(g)$ is the set of maximal unknown vectors (i.e., $u + e_j \in T(MT)$ for all $j \in OFF(u)$). Let $j = \max\{i \mid i \in OFF(u)\}$. Since $u + e_j \in T(MT)$, there exists an $a \in MT$ such that $a \leq u + e_j$. Note that $a_j = 1$ holds since otherwise $a \leq u$, contradicting $u \in U(g)$. Then $a - e_j \in F(MF)$ by the assumption $N_1(g) \cap U(g) = \emptyset$. Therefore, there exists a $b \in MF$ such that $b \geq a - e_j$. This b satisfies $b_j = 0$ since otherwise $b \geq a$, a contradiction. For any $l \in OFF(u) \setminus \{j\}$,

$$a - e_j + e_l \in T(f) \subseteq T(MT) \cup U(g)$$

by regularity of f, and hence $b \not\geq a - e_j + e_l$, i.e., $b_l = 0$ for all $l \in OFF(u)$ and hence $b \leq u$. (i) If $b = u$, then $u \in F(MF)$, which is a contradiction. (ii) If $b < u$, then $u \in T(MT)$ by $N_1(g) \cap U(g) = \emptyset$, which is also a contradiction. □

Since the complexity of problem IDENTIFICATION is still open, E. Boros et al. [7, 8] considered the following restricted problem.

PROBLEM IDENTIFICATION-2M.

Input: A membership oracle for a positive function f.

Output: If f is 2-monotonic, then $\min T(f)$ and $\max F(f)$; otherwise, "no."

Two algorithms were proposed therein; one uses $O(n^3m)$ time and $O(n^3m)$ queries, while the other uses $O(nm^2+n^2m)$ time and $O(nm)$ queries, where $m = |\min T(f)| + |\max F(f)|$. Based on the concept of maximum latency, we could recently construct a new algorithm for IDENTIFICATION-2M, which uses $O(n^2m)$ time and $O(n^2m)$ queries [24]. Since $m \gg n$ can be expected in usual cases, this is an improvement over the previous two algorithms.

COROLLARY 4.2. *Class C_{TH} satisfies*

$$\Lambda_{TH}(n) = 1.$$

4.2. Δ-partial positive threshold functions.

DEFINITION 4.3 (see [25]). *A positive function f is called Δ-partial threshold if f is represented by*

$$f(x) = \begin{cases} 1 & \text{if } \sum w_i x_i \geq t + \alpha, \\ 0 & \text{if } \sum w_i x_i < t - \alpha, \\ 0 \text{ or } 1 & \text{otherwise,} \end{cases}$$

where $w_i\,(i = 1, 2, \ldots, n)$, t and Δ are nonnegative real numbers, and

$$\alpha = \Delta w_{\min},$$

where $w_{\min} = \min_i w_i$. Associated with these $w_i\,(i = 1, 2, \ldots, n)$ and t, define the threshold function h *by*

$$h(x) = \begin{cases} 1 & \text{if } \sum w_i x_i \geq t, \\ 0 & \text{if } \sum w_i x_i < t. \end{cases}$$

Then the above f is called a Δ-partial threshold function of h.

In the above definition of f, the value $f(x)$ in the case of "otherwise" can be determined arbitrary, provided that the resulting f is positive.

Example 4.4. Let h be a threshold function represented by

$$h(x) = \begin{cases} 1 & \text{if } 2x_1 + x_2 + x_3 + x_4 \geq 3, \\ 0 & \text{if } 2x_1 + x_2 + x_3 + x_4 < 3, \end{cases}$$

i.e., $h = x_1x_2 \vee x_1x_3 \vee x_1x_4 \vee x_2x_3x_4$, and

$$\min T(h) = \{1100, 1010, 1001, 0111\},$$
$$\max F(h) = \{0011, 0101, 0110, 1000\}.$$

Consider $f = x_1x_2 \vee x_1x_3 \vee x_2x_4$, i.e.,

$$\min T(f) = \{1100, 1010, 0101\},$$
$$\max F(f) = \{0011, 0110, 1001\}.$$

This f is a 1-partial threshold function of h represented by

$$f(x) = \begin{cases} 1 & \text{if } 2x_1 + x_2 + x_3 + x_4 \geq 4, \\ 0 & \text{if } 2x_1 + x_2 + x_3 + x_4 < 2, \\ 0 \text{ or } 1 & \text{otherwise,} \end{cases}$$

where $\alpha = \min_i w_i = 1$.

Let

$C_{\Delta PTH}$: class of Δ-partial positive threshold functions.

THEOREM 4.5. *Class $C_{\Delta PTH}$ satisfies*

$$\Lambda_{\Delta PTH}(n) \leq \lceil \Delta \rceil + 1.$$

Proof. Let f be a Δ-partial threshold function of a threshold function h. We assume $w_1 \geq w_2 \geq \cdots \geq w_n$ without loss of generality. Assuming that g is a partial function of f defined by MT and MF such that $N_{\lceil \Delta \rceil + 1}(g) \cap U(g) = \emptyset$ and $U(g) \neq \emptyset$, we derive a contradiction. Take a $u \in \max U(g)$, and let $j = \max\{i \mid i \in OFF(u)\}$. There exists an $a \in MT$ such that $a \leq u + e_j$. Since $\| u - a \| \geq \lceil \Delta \rceil + 2$ by assumption, $\| u - (a - e_j) \| \geq \lceil \Delta \rceil + 1$ holds, i.e., $|ON(u) \setminus ON(a)| \geq \lceil \Delta \rceil + 1$. Let

$$c^{(1)} = a - e_j + \sum_{l=1}^{\lceil \Delta \rceil} e_{i_l},$$

where i_l, $l = 1, 2, \ldots, \lceil \Delta \rceil$, are arbitrary $\lceil \Delta \rceil$ indices in $ON(u) \setminus ON(a)$. Note that $c^{(1)} \notin U(g)$ (i.e., $c^{(1)} \in T(MT) \cup F(MF)$) because $a \in MT$, $\| a - c^{(1)} \| = \lceil \Delta \rceil + 1$, and, by assumption, $\| x - y \| \geq \lceil \Delta \rceil + 2$ for any pair of $x \in MT$ and $y \in U(g)$. If $c^{(1)} \in T(MT)$, then $u \in T(MT)$ holds since $u \geq c^{(1)}$, which is a contradiction. If $c^{(1)} \in F(MF)$, then there exists a $b^{(1)} \in MF$ such that $b^{(1)} \geq c^{(1)}$. (i) If $b^{(1)} \geq u$, then $u \in F(MF)$, which is a contradiction. (ii) If $b^{(1)} < u$, then $b^{(1)} \in MF$ and $N_{\lceil \Delta \rceil + 1}(g) \cap U(g) = \emptyset$ imply $b^{(1)} + e_i \in T(MT)$ for any $i \in OFF(b^{(1)}) \cap ON(u)$. Since $u \geq b^{(1)} + e_i$, this means $u \in T(MT)$, which is a contradiction. (iii) Otherwise (i.e., $b^{(1)}$ and u are incomparable), $|ON(b^{(1)}) \setminus ON(u)| \neq \emptyset$ holds. We consider the following two cases.

Case 1. $a \in MT \cap T(h)$: Take a $p \in ON(b^{(1)}) \setminus ON(u)$. Then

$$\begin{aligned} \sum w_i c_i^{(1)} + w_p &= \sum w_i a_i - w_j + \sum_{l=1}^{\lceil \Delta \rceil} w_{i_l} + w_p \\ &\geq t + \alpha + (w_p - w_j) \\ &\geq t + \alpha \quad (\text{by } w_p \geq w_j). \end{aligned}$$

Therefore, $c^{(1)} + e_p \in T(f)$, a contradiction to $c^{(1)} + e_p \leq b^{(1)} \in MF$.

Case 2. $a \in MT \cap F(h)$: Let $ON(b^{(1)}) \setminus ON(u) = \{p_1, p_2, \ldots, p_s\}$. If $s \geq \lceil \Delta \rceil + 1$, then

$$\begin{aligned} \sum w_i b_i^{(1)} &\geq \sum w_i c_i^{(1)} + \sum_{l=1}^{s} w_{p_l} \\ &= \sum w_i a_i - w_j + \sum_{l=1}^{\lceil \Delta \rceil} w_{i_l} + \sum_{l=1}^{s} w_{p_l}. \end{aligned} \tag{2}$$

Since we have $\sum w_i a_i \geq t - \alpha$ (by $a \in MT \cap F(h)$), $\sum_{l=1}^{\lceil \Delta \rceil} w_{i_l} \geq \Delta w_{\min} = \alpha$, and

$$\begin{aligned}\sum_{l=1}^{s} w_{p_l} &= w_{p_1} + \sum_{l=2}^{s} w_{p_l} \\ &\geq w_{p_1} + \alpha \quad (\text{by } \ s \geq \lceil \Delta \rceil + 1),\end{aligned}$$

the right-hand side of (2) is at least

$$\begin{aligned}(t-\alpha) - w_j + \alpha + (w_{p_1} + \alpha) &\geq t + \alpha + (w_{p_1} - w_j) \\ &\geq t + \alpha \quad (\text{by } \ w_{p_1} \geq w_j).\end{aligned}$$

This implies $b^{(1)} \in T(f)$, which is a contradiction. Therefore, we conclude $s \leq \lceil \Delta \rceil$. Now, $u \geq b^{(1)} - \sum_{l=1}^{s} e_{p_l}$ implies $u > b^{(1)} - \sum_{l=1}^{s} e_{p_l}$ since $N_{\lceil \Delta \rceil + 1}(g) \cap U(g) = \emptyset$. In other words, there exists a $p' \in ON(u) \setminus ON(b^{(1)})$. Define

$$c^{(2)} = b^{(1)} - \sum_{l=1}^{s} e_{p_l} + e_{p'} \ (\in T(MT) \cup F(MF) \quad \text{by } \ \| \, b^{(1)} - c^{(2)} \, \| \leq \lceil \Delta \rceil + 1).$$

Then $c^{(2)} > c^{(1)}$ since $b^{(1)} - \sum_{l=1}^{s} e_{p_l} \geq c^{(1)}$. If $c^{(2)} \in T(MT)$, then $u \in T(MT)$ holds since $u \geq c^{(2)}$, which is a contradiction. If $c^{(2)} \in F(MF)$, then there exists a $b^{(2)} \in MF$ such that $b^{(2)} \geq c^{(2)}$. (i) If $b^{(2)} \geq u$, then $u \in F(MF)$, a contradiction. (ii) If $b^{(2)} < u$, then similar to the case $b^{(1)} < u$, $u \in T(MT)$, a contradiction. (iii) Otherwise (i.e., $b^{(2)}$ and u are incomparable),

$$ON(b^{(2)}) \setminus ON(u) = \{q_1, q_2, \ldots, q_r\} \text{ and } 0 < r \leq \lceil \Delta \rceil$$

can be shown in a manner similar to $b^{(1)}$. Then define

$$c^{(3)} = b^{(2)} - \sum_{l=1}^{r} e_{q_l} + e_{q'} \in T(MT) \cup F(MF),$$

where $q' \in ON(u) \setminus ON(b^{(2)})$. Then $c^{(3)} > c^{(2)}$ holds since $b^{(2)} - \sum_{l=1}^{r} e_{q_l} \geq c^{(2)}$.

However, this procedure cannot be continued indefinitely, since

$$c^{(1)} < c^{(2)} < c^{(3)} < \cdots < u$$

and the distance between u and $c^{(1)}$ is finite, and it completes the proof. □

As an example, we construct a partial function g of $f \in C_{\Delta PTH}$ of Example 4.4 by

$$\begin{aligned}MT &= \min T(f) - \{1100\} = \{1010, 0101\}, \\ MF &= \max F(f) = \{0011, 0110, 1001\}.\end{aligned} \tag{3}$$

In this case, $U(g) = \{1100\}$ and $\lambda(g) = \lceil 1 \rceil + 1 = 2$.

4.3. *k*-degree positive threshold functions.

DEFINITION 4.6. *A function f is called a* k-degree positive threshold function *if*

$$f(x) = \begin{cases} 1 & \text{if } \sum w_i x_i + \sum_{i_1 < i_2} w_{i_1 i_2} x_{i_1} x_{i_2} + \cdots + \sum_{i_1 < \cdots < i_k} w_{i_1 \ldots i_k} x_{i_1} \ldots x_{i_k} \geq t, \\ 0 & \text{otherwise,} \end{cases}$$

where all weights $w_{i_1 i_2 \cdots i_{k'}}$ $(1 \leq k' \leq k)$ and threshold t are nonnegative.

Example 4.7. Let f be a 2-degree threshold function represented by

$$f(x) = \begin{cases} 1 & \text{if } 5x_1 + 5x_2 + 3x_3 + 3x_4 + x_1x_3 + x_2x_4 \geq 9, \\ 0 & \text{otherwise.} \end{cases}$$

Then $f = x_1x_2 \vee x_1x_3 \vee x_2x_4$, and

$$\begin{aligned} &\min T(f) = \{1100, 1010, 0101\}, \\ &\max F(f) = \{0011, 0110, 1001\}. \end{aligned}$$

Note that a 1-degree threshold function is simply a threshold function. In the following, we show that, if the sum of higher terms

$$\sum_{i_1<i_2} w_{i_1i_2} + \sum_{i_1<i_2<i_3} w_{i_1i_2i_3} + \cdots + \sum_{i_1<\cdots<i_k} w_{i_1\ldots i_k}$$

is relatively small (i.e., higher terms are used only to perturb linear terms), so is the maximum latency.

LEMMA 4.8. *If a k-degree positive threshold function f satisfies*

$$2\Delta w_{\min} \geq \sum_{l=2}^{k} \binom{n}{l} \max_{i_1<i_2<\cdots<i_l} w_{i_1i_2\ldots i_l},$$

where $w_{\min} = \min_i w_i$, then f is a Δ-partial positive threshold function.

Proof. Let f be represented by

$$f(x) = \begin{cases} 1 \text{ if } \sum w_ix_i + \sum_{i_1<i_2} w_{i_1i_2}x_{i_1}x_{i_2} + \cdots + \sum_{i_1<\cdots<i_k} w_{i_1\ldots i_k}x_{i_1}\ldots x_{i_k} \geq t, \\ 0 \text{ otherwise,} \end{cases}$$

and let h be the threshold function represented by

$$h(x) = \begin{cases} 1 & \text{if } \sum w_ix_i \geq t - \alpha, \\ 0 & \text{if } \sum w_ix_i < t - \alpha, \end{cases}$$

where $\alpha = \Delta w_{\min}$. We show that f is represented by

$$f(x) = \begin{cases} 1 & \text{if } \sum w_ix_i \geq t, \\ 0 & \text{if } \sum w_ix_i < t - 2\alpha, \\ 0 \text{ or } 1 & \text{otherwise,} \end{cases}$$

which implies that $f \in C_{\Delta PTH}$.

(i) If $\sum w_ix_i \geq t$, then it is trivial that $f(x) = 1$ since all weights $w_{i_1i_2\cdots i_{k'}}$ $(1 \leq k' \leq k)$ are nonnegative.

(ii) If $\sum w_ix_i < t - 2\alpha$, then

$$\begin{aligned} \sum w_ix_i + \sum_{i_1<i_2} w_{i_1i_2}x_{i_1}x_{i_2} + \cdots + \sum_{i_1<\cdots<i_k} w_{i_1\ldots i_k}x_{i_1}\ldots x_{i_k} \\ &< t - 2\alpha + \sum_{l} \binom{n}{l} \max_{i_1<i_2<\cdots<i_l} w_{i_1i_2\ldots i_l} \\ &< t - 2\alpha + 2\alpha = t, \end{aligned}$$

i.e., $f(x) = 0$. □

In Example 4.7, since

$$2\Delta w_{\min} = 6\Delta \geq \binom{4}{2} \max_{i_1<i_2} w_{i_1 i_2} = 6$$

holds for $\Delta = 1$, f is 1-partial threshold. In fact, with $t = 6$ and $\alpha = \Delta w_{\min} = 3$, f can be represented by

$$f(x) = \begin{cases} 1 & \text{if } 5x_1 + 5x_2 + 3x_3 + 3x_4 \geq 9, \\ 0 & \text{if } 5x_1 + 5x_2 + 3x_3 + 3x_4 < 3, \\ 0 \text{ or } 1 & \text{otherwise.} \end{cases}$$

Combining Lemma 4.8 with Theorem 4.5, we establish the next theorem.

THEOREM 4.9. *For the class of k-degree positive threshold functions, which satisfy*

$$2\Delta w_{\min} \geq \sum_{l=2}^{k} \binom{n}{l} \max_{i_1<i_2<\cdots<i_l} w_{i_1 i_2 \ldots i_l},$$

its maximum latency is not greater than $\lceil \Delta \rceil + 1$.

As an example, let us construct a partial function g of f of Example 4.7 by using MT and MF of (3). In this case, we have $U(g) = \{1100\}$ and $\lambda(g) = \lceil 1 \rceil + 1 = 2$.

4.4. Matroid functions.

DEFINITION 4.10. *A positive function f is called a* matroid *function if for each $v, w \in \min T(f)$ and each $i \in ON(v) \setminus ON(w)$ there exists a $j \in ON(w) \setminus ON(v)$ such that $v - e_i + e_j \in \min T(f)$.*

In other words, for a matroid function f of n variables, $M = (E, \mathcal{F})$ forms a *matroid* [29], where $E = \{1, 2, \ldots, n\}$ and $\mathcal{F} = \{ON(v) \mid v \leq a \text{ for some } a \in \min T(f)\}$. Minimal true vectors of f correspond to the *bases* of matroid M. Let

$$C_{MAT}: \quad \text{class of matroid functions.}$$

From the definition of a matroid function, there exists a nonnegative integer $r\,(\leq n)$ such that $|ON(a)| = r$ for every $a \in \min T(f)$. This r is called the *rank* of f. Matroid functions provide a very rich class of examples [3], including the following example of spanning tree functions [3, 10]. For an undirected graph $G = (V, E)$ where $E = \{1, 2, \ldots n\}$, f is called a *spanning tree function* of G if it is given by

$$f(v) = \begin{cases} 1 \text{ if } G_v = (V, ON(v)) \text{ is connected,} \\ 0 \text{ if } G_v = (V, ON(v)) \text{ is disconnected.} \end{cases}$$

For any $a \in \min T(f)$, $ON(a)$ is a *spanning tree* of G and for any $b \in \max F(f)$, $OFF(b)$ is a *minimal cut* of G. The rank of spanning tree function is $r = |V| - 1$.

First, we derive a lower bound on Λ_{MAT}.

LEMMA 4.11. *Class C_{MAT} of matroid functions satisfies*

$$\Lambda_{MAT}(n) = 1 \quad \textit{if } n = 1, 2, 3,$$
$$\Lambda_{MAT}(n) \geq 2 \quad \textit{if } n \geq 4.$$

Proof. For $n = 1, 2, 3$, it is clear by examining all matroid functions that $\Lambda_{MAT}(n) = 1$. For $n \geq 4$, we provide an example of g with $\lambda(g) = 2$. Consider a spanning tree function f of Figure 2.

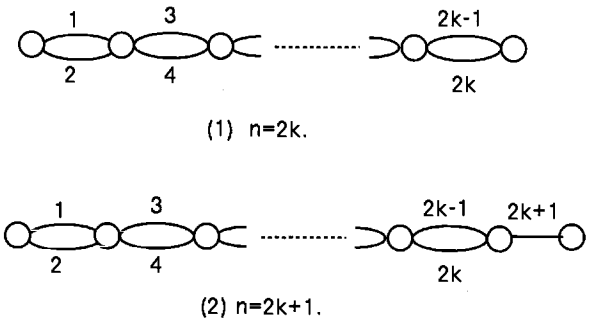

FIG. 2. *The graph g of the proof of Lemma* 4.11.

(1) $n = 2k$ $(k \geq 2)$: Let

$$\min T(f) = \{a \mid |ON(a) \cap \{2j-1, 2j\}| = 1 \quad \text{for all } j = 1, 2, \ldots, k\},$$
$$\max F(f) = \{b \mid OFF(b) = \{2j-1, 2j\} \quad \text{for some } j = 1, 2, \ldots, k\}.$$

Then we construct a partial function g of f by

$$MT = \min T(f) - \{u\},$$
$$MF = \max F(f),$$

where $u = (0101\cdots01)$. For any j, $u + e_{2j-1} \geq u + e_{2j-1} - e_{2j} \in MT$, and hence $u + e_{2j-1} \in T(MT)$. Similarly, $u - e_{2j} \in F(MF)$ for any j. Therefore, $T(MT) \cup F(MF) \cup \{u\} = \{0,1\}^n$. For every $a \in MT$, $\| a \| = \| u \| = k$ and $a \neq u$ imply $\| u - a \| \geq 2$. For every $b \in MF$, we have $u \not\leq b$. Furthermore, $\| b \| = n - 2$ and $\| u \| = k$ imply $u \not\geq b$ and

$$\| u - b \| \geq 2.$$

Therefore, we obtain $\lambda(g) \geq 2$.

(2) $n = 2k + 1$ $(k \geq 2)$: Let

$$\min T(f) = \{a \mid 2k+1 \in ON(a) \text{ and } |ON(a) \cup \{2j-1, 2j\}| = 1 \text{ for all } j = 1, 2, \ldots, k\},$$
$$\max F(f) = \{b \mid OFF(b) = \{2j-1, 2j\} \text{ for some } j = 1, 2, \ldots, k\} \cup \{11\cdots10\},$$

and construct a partial function g of f by

$$MT = \min T(f) - \{0101\cdots011\}$$
$$MF = \max F(f).$$

Then $U(g) = \{0101\cdots011\}$. The rest is similar to case (1), and we have $\lambda(g) \geq 2$. □

Example 4.12. For $n = 4$, the above construction gives $f = x_1x_3 \vee x_1x_4 \vee x_2x_3 \vee x_2x_4$, i.e.,

$$\min T(f) = \{1010, 1001, 0110, 0101\},$$
$$\max F(f) = \{0011, 1100\}$$

and

$$MT = \min T(f) - \{0101\} = \{1010, 1001, 0110\},$$
$$MF = \max F(f) = \{0011, 1100\},$$
$$U(g) = \{0101\}.$$

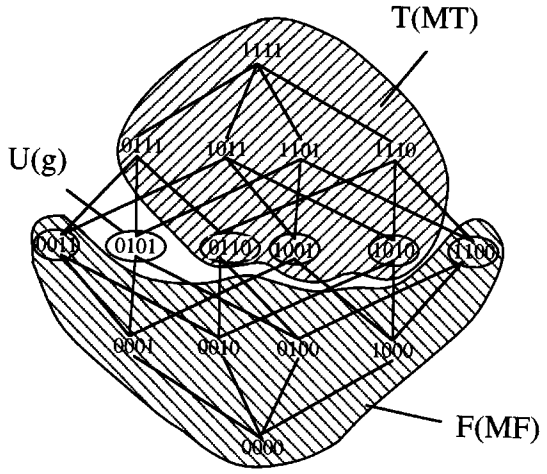

FIG. 3. *The partial function g of Example* 4.12.

The result is illustrated in Figure 3. The latency $\lambda(g)$ is obviously equal to 2.

Next, we consider an upper bound on Λ_{MAT}.

LEMMA 4.13. *Let f be a matroid function. If a partial function g of f defined by MT and MF satisfies $N_2(g) \cap U(g) = \emptyset$, then $MT = \min T(f)$.*

Proof. Note that $MT \cup MF \neq \emptyset$ holds by the definition of a partial function g. First assume $MT = \emptyset$. Then $MF \neq \emptyset$ and we let $b \in MF$. If $OFF(b) = \emptyset$ (i.e., $b = (1, 1, \ldots, 1)$), then $MT = \min T(f) = \emptyset$, which completes the proof. Otherwise, $b + e_j \in T(MT)$ holds for any $j \in OFF(b)$, since $b + e_j \in N_1(g)$ and $N_2(g) \cap U(g) = \emptyset$. This means $MT \neq \emptyset$, a contradiction. Hence in the following, we consider the case of $MT \neq \emptyset$. Assume that there exists a $v \in \min T(f) \setminus MT$. Take an $a^{(1)} \in MT$ and let $k = |ON(a^{(1)}) \setminus ON(v)|$. If $k = 1$, then $\| v - a^{(1)} \| = 2$ since $|ON(v)| = |ON(a^{(1)})| = r$, where r is the rank of f, which is a contradiction. If $k > 1$, there exists $a^{(2)} = a^{(1)} - e_i + e_j \in \min T(f)$ where $i \in ON(a^{(1)}) \setminus ON(v)$ and $j \in ON(v) \setminus ON(a^{(1)})$, since f is a matroid function. Then $\| a^{(2)} - a^{(1)} \| = 2$, and hence $a^{(2)} \in MT$ and $|ON(a^{(2)}) \setminus ON(v)| = k - 1$. By repeating this procedure, we obtain $a^{(1)}, a^{(2)}, \ldots, a^{(k-1)}, a^{(k)} \in MT$ such that $|ON(a^{(k)}) \setminus ON(v)| = 1$, a contradiction. □

After showing the next lemma, we show a sufficient condition to have $MF = \max F(f)$.

LEMMA 4.14. *If f is a matroid function, then for every $a \in \min T(f)$ and every $j \in ON(a)$, there exists exactly one $b \in \max F(f)$ such that $b \geq a - e_j$.*

Proof. See [29], for example. □

LEMMA 4.15. *Let f be a matroid function. If a partial function g of f defined by $MT = \min T(f)$ and some MF satisfies $N_1(g) \cap U(g) = \emptyset$, then $MF = \max F(f)$. That is, $f = g$ (i.e., $\lambda(g) = 0$).*

Proof. Assume that there exists a $v \in \max F(f) \setminus MF$. For any $j \in OFF(v)$, there exists an $a \in MT$ such that $a \leq v + e_j$, and there exists a $b \in MF$ such that $b \geq a - e_j$. Then Lemma 4.14 implies that $v = b$, a contradiction. □

LEMMA 4.16. *If g is a partial function of a matroid function f, then $\lambda(g) \leq 2$.*

Proof. It follows from Lemma 4.13 and Lemma 4.15. □

THEOREM 4.17. *Class C_{MAT} of matroid functions satisfies*

$$\Lambda_{MAT}(n) = \begin{cases} 1, & n = 1, 2, 3, \\ 2, & n \geq 4. \end{cases}$$

Proof. It follows from Lemma 4.11 and Lemma 4.16. □

In fact, it is known [21] that learning $\min T(f)$ of a matroid function f with only a membership oracle can be done in polynomial time in n and $|\min T(f)|$. Since Lemma 4.14 indicates that $|\max F(f)| \leq n|\min T(f)|$, we can show a similar result by our algorithm that uses the maximum latency.

4.5. *k*-tight positive functions.

DEFINITION 4.18. *A positive function f is called* k-tight *for a positive integer k if it satisfies*

$$\max\{\| a-b \| \mid a \in \min T(f), b \in \max F(f) \text{ and } a-e_j \leq b \text{ for some } j \in ON(a)\} \leq k.$$

Let

C_{kTI}: class of k-tight positive functions.

Note that the condition $a - e_j \leq b$ for $a \in \min T(f)$ and $b \in \max F(f)$ is equivalent to the condition $b + e_j \geq a$. Let us imagine $\min T(f)$ and $\max F(f)$ as the bottoms of ravines and the peaks of mountains, respectively. Then k-tightness of f implies that the height difference between a mountain peak and the bottoms of its surrounding ravines is at most k. This means that the ground is locally smooth, even though some mountains may be very high.

For example, a positive threshold function with $w_{\max} \leq k w_{\min}$ is always k-tight, where $w_{\max} = \max_i w_i$ and $w_{\min} = \min_i w_i$, since for any $a \in \min T(f)$, $j \in ON(a)$, and $i_l \in OFF(a)$ $(l = 1, 2, \ldots, k)$,

$$\begin{aligned} \sum_{i=1}^{n} w_i a_i - w_j + \sum_{l=1}^{k} w_{i_l} &\geq \sum w_i a_i - w_{\max} + k w_{\min} \\ &\geq \sum w_i a_i \ \geq \ t, \end{aligned}$$

i.e., $a - e_j + \sum_{l=1}^{k} e_{i_l} \in T(f)$.

To introduce other types of k-tight functions, define the *rank* of a set $S \subseteq \{0,1\}^n$ by $r(S) = \max\{\| x \| \mid x \in S\}$ and the *antirank* by $ar(S) = \min\{\| x \| \mid x \in S\}$, respectively.

THEOREM 4.19. *A positive function f satisfying one of the following conditions is k-tight.*

(i) $|r(\max F(f)) - ar(\min T(f))| \leq k - 2$.
(ii) $ar(\min T(f)) \geq n - k + 1$.
(iii) $r(\max F(f)) \leq k - 1$.

Proof. (i) For any $a \in \min T(f)$ and $b \in \max F(f)$, $| \| b \| - \| a \| | \leq k - 2$. If $a - e_j \leq b$, then $\| b - a \| \leq k$ holds.

Conditions (ii) and (iii) are similar to (i). □

These types of functions are discussed in [13] and other papers.

LEMMA 4.20. *For a positive function f, define an undirected bipartite graph $G_f = (\min T(f), \max F(f), E)$, where $E = \{(a, b) \mid a \in \min T(f), b \in \max F(f)$ and $a - e_j \leq b$ for some $j \in ON(a)\}$. Then this G_f is connected.*

Proof. We proceed by induction on $|\min T(f)|$. For $|\min T(f)| = 0, 1$, it is trivially true. Assume that the lemma holds for all $|\min T(f)| \leq k$ but does not hold for $|\min T(f)| = k+1$, i.e., G_f is not connected. Let $\min T(f) = \{a^{(1)}, a^{(2)}, \ldots, a^{(k)}, a^{(k+1)}\}$, V_1 be the connected component of G_f that includes $a^{(1)}$ and $V_2 = V - V_1$, where V is the set of all nodes in G_f.

First, we show $V_1 \cap \min T(f) \neq \{a^{(1)}\}$. Take a $b \in \max F(f)$ such that $b \geq a^{(1)} - e_j$ for $j \in ON(a^{(1)})$. Then $b_j = 0$, since otherwise $b \geq a^{(1)}$, a contradiction, and hence $\| b \| \leq n-1$. If $\| b \| = n-1$, then $b + e_j = (1, 1, \ldots, 1)$ and $a^{(i)} \leq b + e_j$ for all $a^{(i)} \in \min T(f)$, i.e., $V_1 \cap \min T(f) = \min T(f)$. Otherwise, i.e., $\| b \| < n-1$, there exists an $a' \in \min T(f)$ such that $a' \leq b + e_i$ for some $i \in OFF(b) \setminus \{j\}$. Then $a'_j = 0$ by $a' \leq b + e_i$ and $b_j = 0$. Therefore, $a' \neq a^{(1)}$ and $\{a^{(1)}, a'\} \subseteq V_1 \cap \min T(f)$.

Second, we show $V_2 \cap \min T(f) \neq \emptyset$. If $V_2 \cap \min T(f) = \emptyset$ (i.e., $\min T(f) \subseteq V_1$), then $\max F(f) \subseteq V_1$ holds since for any $b \in \max F(f)$, there exist $j \in OFF(b)$ and $a \in \min T(f)$ such that $a \leq b + e_j$. This contradicts the assumption that G_f is not connected.

Now, define f' by $\min T(f') = \{a^{(2)}, a^{(3)}, \ldots, a^{(k+1)}\}$, and let

$$S = \{b \in \max F(f') \mid b \geq a^{(1)}\}.$$

Then

$$\begin{aligned} \min T(f') \cup \{a^{(1)}\} &= \min T(f), \\ \max F(f') \setminus S &\subseteq \max F(f), \end{aligned}$$

and hence

$$S = (\min T(f') \cup \max F(f')) \setminus (\min T(f) \cup \max F(f)). \tag{4}$$

There is no path from each $a^{(p)} \in V_1 \cap (\min T(f) \setminus \{a^{(1)}\})$ to any $a^{(q)} \in V_2 \cap \min T(f)$ in G_f. However, by the induction hypothesis, these $a^{(p)}$ and $a^{(q)}$ are connected in $G_{f'}$. That is, by property (4), there are $a^{(p)} \in V_1 \cap (\min T(f) \setminus \{a^{(1)}\})$, $a^{(q)} \in V_2 \cap \min T(f)$, and $c \in S$ such that c is adjacent to $a^{(p)}$ and $a^{(q)}$ in $G_{f'}$. We then show that there is a $b \in \max F(f)$ such that b is adjacent to $a^{(1)}$ and $a^{(q)}$ in G_f, which leads to a contradiction. Take a $j \in ON(a^{(1)}) \setminus ON(a^{(q)})$ arbitrarily. Then $c - e_j \in F(f)$ since $\min T(f) \cap \{v \mid v \leq c\} = \{a^{(1)}\}$. Therefore, there exists a $b \in \max F(f)$ such that $b \geq c - e_j$. Since $a^{(1)} - e_j \leq c - e_j \leq b$, this b is adjacent to $a^{(1)}$ in G_f. Moreover, $a^{(q)} - e_i \leq c$ for some $i \in ON(a^{(q)})$, since c is adjacent to $a^{(q)}$ on $G_{f'}$. Hence, $a^{(q)} - e_i \leq c - e_j$ by $a^{(q)}_j = 0$. Therefore, $a^{(q)} - e_i \leq b$, i.e., b is adjacent to $a^{(q)}$. ∎

THEOREM 4.21. *Class C_{kTI} of k-tight positive functions satisfies*

$$\Lambda_{kTI}(n) \leq k.$$

Proof. Assuming that g is a partial function of $f \in C_{kTI}$, defined by MT and MF, such that $N_k(g) \cap U(g) = \emptyset$ and $U(g) \neq \emptyset$, we derive a contradiction. Since $U(g) \neq \emptyset$, there exists a $u \in (\min T(f) \cup \max F(f)) \cap U(g)$. We assume $u \in \min T(f) \cap U(g)$ without loss of generality, and let $T_1 = \{u\}$ and $F_1 = \emptyset$. If there exists some $j \in ON(u)$ such that $u - e_j \in F(MF)$, then there exists a $b \in MF$ such that $b \geq u - e_j$. $\| u - b \| \leq k$ holds since f is k-tight, and hence $u \in N_k(g) \cap U(g)$, which is a contradiction. Therefore, $u - e_j \in U(g)$ holds for all $j \in ON(u)$; i.e., $F_2 = \{b \in \max F(f) \mid b \geq u - e_j$ for some $u \in T_1$ and $j \in ON(u)\}$ satisfies $F_2 \subseteq U(g)$. If $b + e_i \in T(MT)$ for some $b \in F_2$ and $i \in OFF(b)$, then some $a \in MT$ satisfies $a \leq b + e_j$

and $\| a - b \| \leq k$, i.e., $b \in N_k(g) \cap U(g)$, a contradiction. Therefore, $T_2 \subseteq U(g)$, where $T_2 = \{a \in \min T(f) | a \leq u + e_j$ for some $u \in F_2$ and $j \in OFF(u)\}$. We can indefinitely continue this procedure, which generates $T_1 \subseteq T_2 \subseteq \cdots \subseteq U(g)$ and $F_1 \subseteq F_2 \subseteq \cdots \subseteq U(g)$, where F_{i+1} ($\subseteq \max F(f)$) is the set of vertices adjacent to T_i in G_f, and T_{i+1} ($\subseteq \min T(f)$) is the set of vertices adjacent to F_{i+1} in G_f. By Lemma 4.20, we obtain $T_l = \min T(f)$ and $F_l = \max F(f)$ for a sufficient large l. This is a contradiction to $MT \cup MF \neq \emptyset$. □

COROLLARY 4.22. (i) *For the class of positive functions f satisfying $|r(\max F(f)) - ar(\min T(f))| \leq k$, its maximum latency is not greater than $k + 2$.*

(ii) *For the class of positive functions f satisfying $ar(\min T(f)) \geq n - k$, its maximum latency is not greater than $k + 1$.*

(iii) *For the class of positive functions f satisfying $r(\max F(f)) \leq k$, its maximum latency is not greater than $k + 1$.*

Proof. Combine Theorems 4.19 and 4.21. □

5. Positive *k*-DNF functions.

DEFINITION 5.1. *A positive function f which satisfies*

$$r(\min T(f)) \leq k$$

is called a positive k-DNF function*, where DNF stands for disjunctive normal form.*

Let

$$C_{kDNF}: \quad \text{class of positive } k\text{-DNF functions.}$$

The next theorem shows that the maximum latency cannot be constant for this class, though there is an incrementally polynomial identification algorithm [13].

THEOREM 5.2. *Class C_{kDNF} satisfies*

$$\Lambda_{kDNF}(n) \geq \begin{cases} 1, & k = 1, \\ (k-1)\left\lfloor \sqrt{\frac{n}{(k-1)}} \right\rfloor - k + 2, & k \geq 2, \end{cases}$$

for $n \geq 4(k-1)$.

Proof. For $k = 1$, it is clear that $\Lambda_{1DNF}(n) \geq 1$. For $k \geq 2$, we provide an example of g with $\lambda(g) = (k-1)\lfloor \sqrt{\frac{n}{(k-1)}} \rfloor - k + 2$ for $n \geq 4(k-1)$. Let $\alpha = \lfloor \sqrt{\frac{n}{(k-1)}} \rfloor$, where α satisfies $\alpha \geq 2$. Then

$$\sqrt{\frac{n}{(k-1)}} \geq \alpha, \quad \text{i.e., } n \geq \alpha^2(k-1).$$

Therefore, let $n = \alpha^2(k-1) + \beta$, where β is a nonnegative integer. Now define a $\alpha(\alpha-1)(k-1) \times n$ matrix

$$X = \left(\begin{array}{ccc} Q & \left| I_{\alpha(\alpha-1)(k-1)} \right| & O_{\alpha(\alpha-1)(k-1)\times\beta} \end{array} \right),$$

where Q is the $\alpha(\alpha-1)(k-1) \times \alpha(k-1)$ matrix

$$Q = \begin{array}{c} \overbrace{}^{k-1}\overbrace{}^{k-1}\overbrace{}^{k-1}\quad\overbrace{}^{k-1} \\ \left(\begin{array}{cccc} 11\cdots1 & 00\cdots0 & \cdots & 00\cdots0 \\ 11\cdots1 & 00\cdots0 & \cdots & 00\cdots0 \\ \cdots\cdots & \cdots\cdots & \cdots & \cdots\cdots \\ 11\cdots1 & 00\cdots0 & \cdots & 00\cdots0 \\ \hline 00\cdots0 & 11\cdots1 & \cdots & 00\cdots0 \\ \cdots\cdots & \cdots\cdots & \cdots & \cdots\cdots \\ 00\cdots0 & 11\cdots1 & \cdots & 00\cdots0 \\ \hline \cdots\cdots & \cdots\cdots & \cdots & \cdots\cdots \\ \hline 00\cdots0 & 00\cdots0 & \cdots & 11\cdots1 \\ \cdots\cdots & \cdots\cdots & \cdots & \cdots\cdots \\ 00\cdots0 & 00\cdots0 & \cdots & 11\cdots1 \end{array}\right) \end{array} \begin{array}{l} \left.\phantom{\begin{array}{c}a\\a\\a\\a\end{array}}\right\} (\alpha-1)(k-1) \\ \left.\phantom{\begin{array}{c}a\\a\\a\end{array}}\right\} (\alpha-1)(k-1), \\ \vdots \\ \left.\phantom{\begin{array}{c}a\\a\\a\end{array}}\right\} (\alpha-1)(k-1) \end{array}$$

I_j is the $j \times j$ identity matrix, and $O_{i\times j}$ is the $i \times j$ zero matrix. Define f by

$$\min T(f) = (\text{the set of rows of matrix } X)$$

and a partial function g of f by $MT = \min T(f)$ and $MF = \max F(f) \setminus \{u\}$, where

$$u = (\underbrace{1,1,\ldots,1}_{\alpha(k-1)}, \underbrace{0,0,\ldots,0}_{\alpha(\alpha-1)(k-1)}, \underbrace{1,1,\ldots,1}_{\beta}).$$

Then $u + e_j \in T(MT)$ for any $j \in OFF(u)$ since $u \in \max F(f)$ and $MT = \min T(f)$. Moreover, $u - e_j \in F(MF)$ for any $j \in \{1,2,\ldots,\alpha(k-1)\}$ and $u - \sum_{j\in S} e_j \notin F(MF)$, where $S = \{n-\beta+1, n-\beta+2, \ldots, n\}$. In other words,

$$U(g) = \{\ (\underbrace{1,1,\ldots,1}_{\alpha(k-1)}, \underbrace{0,0,\ldots,0}_{\alpha(\alpha-1)(k-1)}, \underbrace{*,*,\ldots,*}_{\beta})\ \},$$

where $*$ stands for 0 or 1. It is not difficult to see that $\| a - w \| \geq (\alpha-1)(k-1)+1$ for every $a \in MT$ and $w \in U(g)$ and $\| b - w \| \geq (\alpha-1)(k-1)+1$ for every $b \in MF$ and $w \in U(g)$. Therefore, its latency is

$$\lambda(g) = (\alpha-1)(k-1)+1 = (k-1)\left\lfloor \sqrt{\frac{n}{(k-1)}} \right\rfloor - k + 2. \qquad \square$$

We note that the f and g of Example 2.2 satisfy the above conditions with $n = 4$ and $k = 2$.

6. Conclusion. The problem of identifying a positive Boolean function f has an incrementally polynomial algorithm if and only if problem EQ can be solved in polynomial time [6]. In this paper, we introduced the maximum latency as a measure for the difficulty to find an unknown vector. If the maximum latency is constant, then EQ can be solved in polynomial time. It turned out that the maximum latency of general positive functions is $\lfloor n/4 \rfloor + 1$, but several subclasses of positive functions have constant maximum latency. Such subclasses include classes of (i) 2-monotonic positive functions, (ii) Δ-partial positive threshold functions, (iii) k-degree positive threshold

functions, (iv) matroid functions, and (v) k-tight positive functions. Finally, it is shown that the class of positive k-DNF functions has maximum latency not less than $O(\sqrt{n})$, even though it is known [13] that problem EQ can be solved in polynomial time for this class of functions.

The last result indicates that the concept of maximum latency is not always sufficient to distinguish polynomially solvable cases from those not solvable in polynomial time. However, it is also evident that the maximum latency is a powerful tool to find polynomially solvable special cases.

Acknowledgments. The authors are grateful to the valuable comments given by H. Nagamochi and the other members of their laboratory, and to the information on [20] provided by T. Hegedus of Comenius University, Slovakia. The authors also appreciate the comments given by two anonymous reviewers, which helped improve the readability of this paper.

AN EXPANDER-BASED APPROACH TO GEOMETRIC OPTIMIZATION*

MATTHEW J. KATZ† AND MICHA SHARIR‡

Abstract. We present a new approach to problems in geometric optimization that are traditionally solved using the parametric-searching technique of Megiddo [*J. ACM*, 30 (1983), pp. 852–865]. Our new approach is based on expander graphs and range-searching techniques. It is conceptually simpler, has more explicit geometric flavor, and does not require parallelization or randomization. In certain cases, our approach yields algorithms that are asymptotically faster than those currently known (e.g., the second and third problems below) by incorporating into our (basic) technique a subtechnique that is equivalent to (though much more flexible than) Cole's technique for speeding up parametric searching [*J. ACM*, 34 (1987), pp. 200–208]. We exemplify the technique on three main problems—the *slope selection* problem, the planar *distance selection* problem, and the planar *two-line center* problem. For the first problem we develop an $O(n \log^3 n)$ solution, which, although suboptimal, is very simple. The other two problems are more typical examples of our approach. Our solutions have running time $O(n^{4/3} \log^2 n)$ and $O(n^2 \log^4 n)$, respectively, slightly better than the previous respective solutions of [Agarwal et al., *Algorithmica*, 9 (1993), pp. 495–514], [Agarwal and Sharir, *Algorithmica*, 11 (1994), pp. 185–195]. We also briefly mention two other problems that can be solved efficiently by our technique.

In solving these problems, we also obtain some auxiliary results concerning batched range searching, where the ranges are congruent discs or annuli. For example, we show that it is possible to compute deterministically a compact representation of the set of all point-disc incidences among a set of n congruent discs and a set of m points in the plane in time $O((m^{2/3}n^{2/3} + m + n) \log n)$, again slightly better than what was previously known.

Key words. expander graphs, geometric optimization, slope selection, computational geometry, parametric searching, range searching, facility location

1. Introduction.

More than 10 years ago, Megiddo [34] proposed the ingenious technique of *parametric searching* for efficiently solving a variety of optimization problems. The technique has recently been applied to many problems in geometric optimization, thus demonstrating its power and versatility (see [2, 3, 4, 6, 7, 12, 18, 20, 37] for some of these applications).

The general idea behind parametric searching is that we are given a "decision problem" $P(\lambda)$ that depends on a real parameter λ, and we seek an optimal value λ^* of λ, where a certain extremal condition is satisfied. For example, in the *slope selection* problem, we are given n lines in the plane and an integer k, and we want to find the kth leftmost vertex of the arrangement of the lines. The corresponding decision problem $P(\lambda)$ is to determine whether the number of vertices of the arrangement to the left of or on the vertical line $x = \lambda$ is smaller than, equal to, or larger than k, and the

optimal λ^* is the abscissa of the vertical line that passes through the kth leftmost vertex.

We assume that an "oracle" procedure $A(\lambda)$ that solves the decision problem is available; that is, it can determine whether a given value of λ is smaller than, equal to, or larger than the desired optimal λ^*. Our goal is to run some sort of binary search over λ, using $A(\lambda)$ as a discriminating procedure, until λ^* is found. The problem is that the number of critical values of λ where the output of $A(\lambda)$ might change is often too large, so we cannot afford to generate all of them. (In the slope selection problem, these critical values are the abscissae of the vertices of the arrangement, so there are quadratically many such values. The oracle for this problem simply has to count the number of vertices lying to the left of a vertical line $x = \lambda$, which can easily be done in time $O(n \log n)$ using a standard inversion-counting procedure; see, e.g., [18].)

The parametric-searching technique generates, in an implicit manner, only a small subset of these critical values which is guaranteed to include λ^*. It does so by running a generic parallel version of the oracle $A(\lambda)$; that is, it runs such a parallel procedure without knowing the value of λ, with the intention of simulating its execution at the unknown λ^*. Whenever it needs to resolve, in a single parallel step, a batch of comparisons whose outcome depends on λ, it computes the critical values where any of these comparisons changes its outcome and runs a binary search to locate λ^* among these values, using the (explicit) oracle $A(\lambda)$. This determines the outcome of all comparisons of the current batch, and the next parallel step can be executed. Each parallel step generates further restrictions on the range where λ^* must lie, and at the end of execution this range must essentially shrink to a singleton, thus yielding λ^*. The parallel version of the generic algorithm ensures that the algorithm executes only a small number of (expensive) oracle calls. We refer the reader to [7, 34, 37] for more detailed expositions of the method.

In spite of its power and versatility, parametric searching suffers from several disadvantages. First, it relies crucially on the availability of a parallel version of the oracle procedure, which is not always easy to obtain. Admittedly, this parallel version is simulated sequentially, so we can develop it in the rather loose comparison-based model of Valiant [38], but still it is often a major hurdle in the application of parametric searching. In addition, the parallel algorithm is often much more complicated than its sequential counterpart, and the need to run it generically tends to make its implementation extremely complicated. Second, the behavior of parametric searching is rather mysterious and highly nonintuitive. On one hand, this is where the beauty of the method lies, but it also makes the method difficult to follow, and makes the execution of the algorithm appear to be rather erratic, performing comparisons that are guided by some mysterious rule and that by magic manage to converge on the right value of λ^*. This feeling is more acute in geometric applications of parametric searching, where one would like to have a geometric interpretation that will provide a more explicit explanation and prediction of the behavior of the algorithm, and where such an interpretation is often lacking.

Recently, Chazelle et al. [12] proposed an alternative approach to parametric searching in geometric optimization. Their approach is based on epsilon nets and on recent related partitioning techniques (called *cuttings*). They applied it to the slope selection problem and obtained an $O(n \log^2 n)$ (deterministic) solution. Their solution is conceptually much simpler than the previous optimal $O(n \log n)$ solution of Cole et al. [18]. Moreover, it can be made optimal by replacing the oracle calls by calls to the approximating oracle of [18] (this observation was missed in [12]). It seems that

the approach of [12] can be applied to other geometric problems, although this still remains to be worked out.

Another alternative approach to parametric searching was recently proposed by Dillencourt, Mount, and Netanyahu [19] and by Matoušek [28, 29]. This approach is based on randomization and yields efficient and fairly simple algorithms. For example, in the slope selection problem, it generates a small number of random critical values of λ and locates λ^* among these values. Then it generates a new set of random values of λ from the restricted range where λ^* is now known to lie and again locates λ^* among these new values, and continues in this manner until λ^* is found. In the case of slope selection, the algorithm of [28] has expected running time $O(n \log n)$. Matoušek comments in [28] on possible extensions of his technique to other geometric problems, such as those studied in this paper.

In this paper we propose a different alternative approach to parametric searching in geometric optimization and demonstrate its applicability to the slope selection problem; to the *distance selection* problem, where we are given n points in the plane and an integer k, and we want to find the kth smallest distance between the given points; and to the *two-line center* problem, where we are given n points in the plane and want to find the smallest width r so that all the points can be covered by the union of two strips of width r. Agarwal et al. [2] present a randomized solution to the distance selection problem, based on parametric searching, that runs in expected time $O(n^{4/3} \log^{8/3} n)$. Their solution can be made deterministic using more involved techniques [1]. Another deterministic solution, which also runs in time $O(n^{4/3} \log^{8/3} n)$, was recently given by Goodrich [21]. Here we give an improved $O(n^{4/3} \log^2 n)$ solution. Agarwal and Sharir [6] present a deterministic $O(n^2 \log^5 n)$ algorithm for the two-line center problem, which is based on parametric searching. Here we give an improved $O(n^2 \log^4 n)$ algorithm for this problem.[1] We also briefly mention two more problems for which our approach yields efficient solutions. These problems are as follows.

(i) The *two-center* problem: Given n points in the plane, find the smallest radius r so that all the points can be covered by the union of two discs of radius r.

(ii) The *minimum output rate* problem: Given consecutive time intervals $T_1, \ldots, T_n$ and input rates $I_1, \ldots, I_n$ (where I_j is the input rate during the jth time interval) and a buffer size B, find the minimum output rate R^* required to assure that the buffer does not overflow; see [35] for more details.

We present an $O(n^2 \log^3 n)$ solution to the first problem; the same asymptotic running time was achieved by Agarwal and Sharir [6] using parametric searching. The second problem was solved by Megiddo, Naor, and Anderson [35], who gave an $O(n \log n \log\log n)$ deterministic solution and a randomized solution with expected running time $O(n \log n)$, both using parametric searching. We give a geometric interpretation of the problem and derive a deterministic $O(n \log^3 n)$ solution and a randomized solution (which is based on a different approach) with expected running time $O(n \log n)$, which we believe to be simpler than the solution of [35].

[1] There have been recent developments, after the original submission of this paper, in regard to the solution of the two-line center problem. Glozman, Kedem, and Shpitalnik [*On some geometric selection and optimization problems via sorted matrices*, Proc. Workshop on Algorithms and Data Structures, Lecture Notes in Comput. Sci. 995, Springer-Verlag, Berlin, 1995, pp. 26–37] give another algorithm with running time $O(n^2 \log^4 n)$, and Jaromczyk and Kowaluk [*The two-line center problem from a polar view: A new algorithm and data structure*, Proc. Workshop on Algorithms and Data Structures, Lecture Notes in Comput. Sci. 955, Springer-Verlag, Berlin, 1995, pp. 13–25] give an improved $O(n^2 \log^2 n)$ solution.

Our approach is based on *expander graphs* that are constructed on certain subsets of the input objects. Since expanders can be constructed in an explicit deterministic manner (see, e.g., [9]), our technique is deterministic. It is conceptually rather simple, does not require parallelization, and has a very clear geometric interpretation. In addition, it avoids performing some of the generic comparisons that are performed in standard parametric-searching applications (such as [2]), which change their outcome at roots of rather high-degree polynomials. Its analysis relies on a simple and known property of expanders, which loosely states that for any pair of sufficiently large sets of vertices, the expander contains sufficiently many edges between them. There are only a few applications of expanders to geometric problems, such as the recent application of expanders to parallel linear programming [8]. We hope that our study will lead to further geometric applications of expanders.

As an exemplification of our technique, the slope selection problem is perhaps not ideal, in the sense that (what we regard as) the elegant and simple algorithm that is given below is suboptimal and runs in time $O(n \log^3 n)$ (which is, by the way, the same running time yielded by the basic parametric-searching method, without the improvements of [17] and of [18]). To improve it, one must develop additional technical tricks that have little to do with the basic method. (In a companion paper [25], we do present an alternative $O(n \log n)$ algorithm, which is also based on expanders.)

The solution to the distance selection problem is a much more typical exemplification of our technique and also demonstrates the general applicability of the technique. Roughly speaking, the algorithm runs in $O(\log n)$ stages. Each stage produces a further restricted range where the kth smallest distance is known to lie, with the additional property that the jth range I_j contains at most $O(n^2\rho^j)$ distances among the given points for some constant $\rho < 1$. The jth stage begins by generating a compact representation of the set of all pairs of points whose distances lie in I_{j-1}. This is done by performing batched range searching with appropriate annuli centered at the given points. This yields a collection of complete bipartite graphs $\{M_t \times P_t\}_t$, where for each t the distance between every point in M_t and every point in P_t lies in I_{j-1}. Next we replace each such bipartite graph by an expander G_t. We associate with each edge of these expanders the distance between the two points that it connects. Since the total number of edges of these graphs is relatively small, we can afford to run a binary search (using the oracle) to locate the desired kth smallest distance in the list of the distances associated with these edges. This search produces the next interval I_j and the whole procedure is repeated.

The analysis of the algorithm, namely, the proof that the numbers of distances in the ranges I_j keep decreasing geometrically, is somewhat intricate and relies on the property of expanders mentioned above and on certain properties of range searching via geometric partitioning.

We enhance our basic technique (as described above) by a subtechnique. The enhanced technique yields, in certain cases, algorithms that are asymptotically faster that those previously known (e.g., our algorithms for the distance selection problem and for the two-line center problem). The subtechnique is in some sense equivalent to Cole's technique for speeding up standard parametric searching [17], although the context in which it is applied is rather different (and considerably more general). In both approaches, the number of (expensive) oracle calls is reduced, so that only a constant (rather than logarithmic) number of calls are made in each stage of the algorithm. For Cole's improvement to apply, the generic parallel algorithm must run on a sorting network (or satisfy similar restrictive conditions), whereas our improvement

is much more flexible and can be applied in fairly general settings.

We also obtain some results concerning *batched range searching*, which we use in the algorithm for the distance selection problem. These results, we believe, are of independent interest. Loosely speaking, each stage of our algorithms begins with a range I where λ^* is known to lie and aims to shrink this range further. To do so, the algorithm performs range searching to obtain, in compact form, all pairs (or triples, etc.) of the data objects, whose "comparisons" generate critical values of λ that fall in I. Once all these interactions have been found, we replace them by certain expander graphs and use only the critical values generated by the edges of those graphs for the oracle-guided binary search. In this setting all the relevant range-searching queries are known in advance, so we can perform all of them using *batched range searching*; this technique, when carefully implemented, can perform better than standard range searching. For example, given n congruent discs and m points in the plane, we compute a compact representation of the set of all point-disc incidences in time $O((m^{2/3}n^{2/3} + m + n)\log n)$, slightly better than what was previously known.

The paper is organized as follows. In section 2 we briefly review expander graphs and their basic properties. In section 3 we obtain some results concerning batched range searching. (The contents of this section are not directly related to the main topic of this paper, so this section may be skipped in a first reading, if so desired.) Sections 4, 5, and 6 present, respectively, our solutions to the distance selection problem, the two-line center problem, and the slope selection problem. In section 7 we briefly mention two more problems for which our approach yields efficient algorithms. We conclude the paper in section 8 with a discussion of the potential of our technique and with some open problems and suggestions for further research.

2. Expanders and their properties.

DEFINITION 2.1. *A graph $G = (V, E)$ is an (n, d, c) expander if it has n vertices, its degree is d, and for every set of vertices $W \subset V$ of cardinality $|W| \leq n/2$, $|N(W)| \geq c|W|$, where $N(W)$ is the set of vertices in $V \setminus W$ that are connected to W by an edge of G.*

The following property is proved in [9, Chap. 9, Corollary 2.2].

LEMMA 2.2. *If G is a d-regular graph with n vertices and λ is the second largest eigenvalue of the adjacency matrix of G, then G is an (n, d, c) expander with $c = (d - \lambda)/2d$.*

Thus, if λ is much smaller than d (which is the largest eigenvalue of the adjacency matrix of G), then G is a good expander.

Lubotzky, Phillips, and Sarnak [26] (and independently Margulis [27]) have given an explicit and very simple description of a d-regular graph G with n vertices, for which $\lambda \leq 2\sqrt{d-1}$, for any $d = p + 1$ and $n = q + 1$, where p and q are primes congruent to 1 modulo 4. These graphs actually have the stronger property that all their eigenvalues (except d) have *absolute* value at most $2\sqrt{d-1}$. We will refer to such graphs as *LPS-expanders*.

From the description in [26] it follows that, whenever d is a constant, an LPS-expander of degree d with n vertices can be constructed deterministically in $O(n)$ time.

The following lemma, which is the main property of LPS-expanders that we will need in this paper, is proved in [9, Chap. 9, Corollary 2.5].

LEMMA 2.3. *Let $G = (V, E)$ be a d-regular graph with n vertices. Assume the absolute value of all its eigenvalues, but the largest is at most λ. Then, for every two sets of vertices A and B of respective cardinalities a and b, we have $|e(A, B) - abd/n| \leq$*

$\lambda\sqrt{ab}$, *where* $e(A, B)$ *is the number of edges of* G *connecting a vertex of* A *with a vertex of* B.

COROLLARY 2.4. *If* A *and* B *are two sets of vertices of respective cardinalities* a *and* b *such that* $e(A, B) = 0$, *then* $ab \leq 4n^2/d$.

Proof. The previous lemma and the fact that $\lambda < 2\sqrt{d}$ imply that if $ab > 4n^2/d$, then $e(A, B) \geq abd/n - 2\sqrt{abd} > 0$, as is easily verified. This contradiction completes the proof. □

COROLLARY 2.5. *If* A *and* B *are two sets of vertices of respective cardinalities* a *and* b *such that* $e(A, B) < 3n$, *then* $ab < 9n^2/d$.

Proof. The previous lemma and the fact that $\lambda < 2\sqrt{d}$ imply that if $ab \geq 9n^2/d$, then $e(A, B) \geq abd/n - 2\sqrt{abd} \geq 3n$, as is easily verified. □

3. Batched range searching. We next describe how to perform efficiently the batched range searching required in step 1 of the distance selection algorithm presented in section 4. For simplicity of presentation, we describe the method for the case where the ranges are congruent discs rather than annuli, but the technique works equally well for congruent annuli. The technique is reminiscent of the approach of Clarkson et al. [15]; it is a result of independent interest, and we hope that it will also find other applications.

Let $C = \{c_1, \ldots, c_n\}$ be a set of n congruent circles, and let $P = \{p_1, \ldots, p_m\}$ be a set of m points in the plane. We wish to compute a compact representation of the set Z of all pairs of the form (c_i, p_j), where $c_i \in C$, $p_j \in P$, and p_j lies inside c_i. The representation we are interested in is a collection of complete pairwise edge-disjoint bipartite subgraphs of $C \times P$, that is, pairs of the form (C_t, P_t), where $C_t \subseteq C$, $P_t \subseteq P$, the sets $C_t \times P_t$ are pairwise disjoint, and $Z = \bigcup_t C_t \times P_t$.

We first consider the following problem. Let C be a set of n circles in the plane. We wish to preprocess C so that, given a query point p, the set of circles of C containing p in their interior can be found quickly. The following theorem is due to Agarwal. Here the circles of C do not have to be congruent.

THEOREM 3.1. *Let* C *be a set of* n *circles in the plane. One can construct, in* $O(n^2 \log n)$ *time, a data structure that uses* $O(n^2 \log n)$ *space, so that the set of circles containing a query point in their interior can be reported in* $O(\log n)$ *time as a collection of* $O(\log n)$ *pairwise disjoint "canonical" (prestored) sets.*

This data structure is constructed as follows. Form the arrangement $\mathcal{A}(C)$ of the circles in C, and let G be the dual graph of $\mathcal{A}(C)$; the nodes of G are the faces of $\mathcal{A}(C)$ and its edges connect pairs of faces adjacent along an edge of $\mathcal{A}(C)$. Compute a spanning tree of G and duplicate each edge of the tree to obtain an Eulerian tour π of G; the tour may visit a face of $\mathcal{A}(C)$ any number of times, but the overall number of its edges is clearly $O(n^2)$ (see Figure 1). Now fix a circle $c \in C$ and mark all the edges of π that cross c (i.e., are dual to an edge of $\mathcal{A}(C)$ contained in c). There are only $O(n)$ such edges in π since there are only $O(n)$ edges in $\mathcal{A}(C)$ that are contained in c and each of them is crossed by π at most twice (once in each direction). These (marked) edges partition π into subsequences, so that the union of cells of $\mathcal{A}(C)$ in a single subsequence is either fully contained inside c or lies fully outside c. The total number of such subsequences, over all circles in C, is only $O(n^2)$. We now build a balanced segment tree T over the nodes of π, in their order along π, and represent each circle c by the collection of sequences of faces of $\mathcal{A}(C)$ that are interior to c, as just constructed, viewing each such subsequence as a "segment" of π. We store each of these "segments," for each circle $c \in C$, at $O(\log n)$ nodes of T in a standard fashion (see Figure 2). The desired data structure consists of the resulting segment tree T

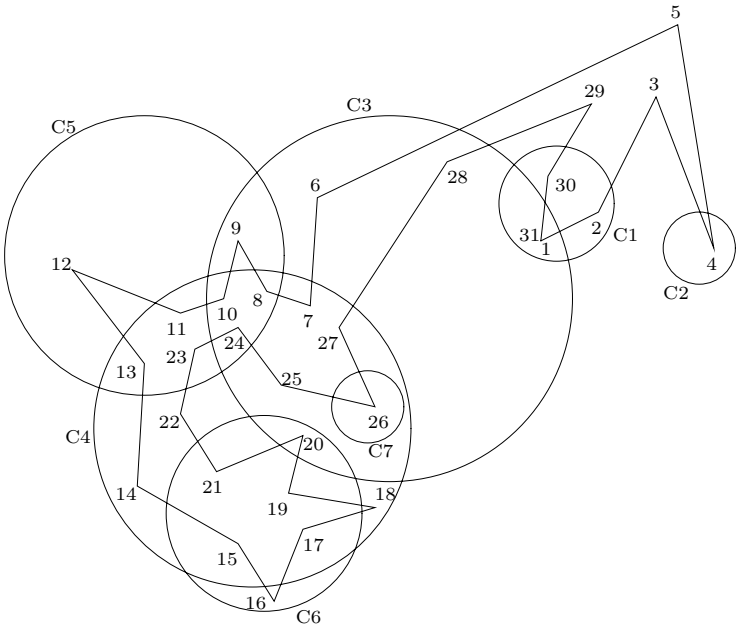

FIG. 1. *An Eulerian path in an arrangement of circles.*

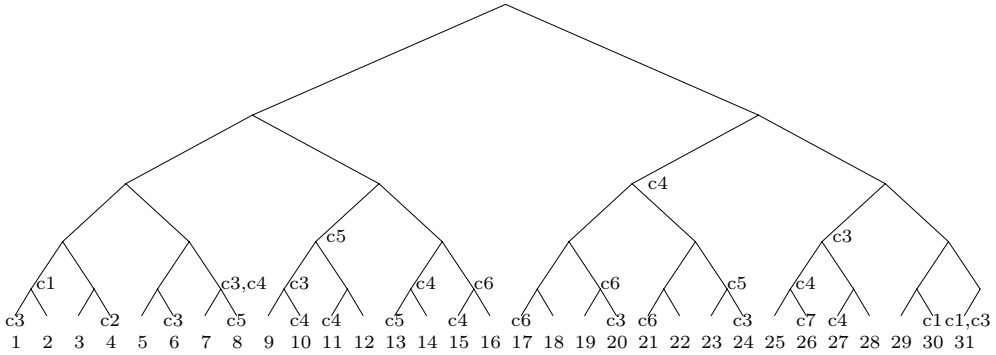

FIG. 2. *The corresponding segment tree.*

plus an efficient point location structure for $\mathcal{A}(C)$, where, in addition, each face of $\mathcal{A}(C)$ points to some leaf of T (that is, to a node of π) that is equal to it. It is easily checked that the data structure requires $O(n^2 \log n)$ space and can be constructed in time $O(n^2 \log n)$.

Next, given a query point p, we locate the face f of $\mathcal{A}(C)$ containing p, access the leaf of T to which f points, construct the path of T from this leaf to the root of T, and report the sets of circles stored at each of the $O(\log n)$ nodes along that path. It is easily seen that each circle containing p appears in exactly one of these sets, which implies the correctness of the query.

We now return to our original problem of computing a compact representation of the set Z of all point-circle containments, for a set C of n congruent circles and a set P of m points in the plane, as defined above. We first describe a "base" solution

to this problem, which is less efficient than our final algorithm, but is required as a subroutine in that algorithm.

We distinguish between two cases. Assume first that $n \leq m^{1/2}$. Construct the data structure of Theorem 3.1 for the collection C of n circles and perform m queries in it, one query for each point $p \in P$; we store p at each node along the path of the segment tree traced by the query. After completing the m queries, we produce the output by traversing all the nodes of the tree and by reporting, for each node t, the complete bipartite graph formed between the set C_t of circles stored at t and the set P_t of points stored at t (if either of these sets is empty, we ignore t). We thus obtain a collection of $O(m)$ complete edge-disjoint bipartite graphs $C_t \times P_t$, with

$$\sum_t |P_t|,\ \sum_t |C_t| = O(m \log n) = O(m \log m).$$

The total cost of the algorithm is

$$O(n^2 \log n + m \log n) = O(m \log n) = O(m \log m).$$

Now consider the case where $n > m^{1/2}$. Partition C into $\lceil \frac{n}{m^{1/2}} \rceil$ subsets of size at most $\lceil m^{1/2} \rceil$ each and construct the data structure of Theorem 3.1 for each of these subsets separately. Now for each $p \in P$ perform $\lceil \frac{n}{m^{1/2}} \rceil$ separate queries, one in each of these data structures. As in the former case, we defer the reporting until all the queries have been processed. The cost of the preprocessing is thus

$$\frac{n}{m^{1/2}} O((m^{1/2})^2 \log m^{1/2}) = O(nm^{1/2} \log m),$$

and the cost of the queries is

$$m \frac{n}{m^{1/2}} O(\log m^{1/2}) = O(nm^{1/2} \log m).$$

After all queries are performed, we traverse all the trees to obtain a collection of

$$\frac{n}{m^{1/2}} O(m) = O(nm^{1/2})$$

complete edge-disjoint bipartite graphs $C_t \times P_t$, as above, with

$$\sum_t |P_t|,\ \sum_t |C_t| = \frac{n}{m^{1/2}} O(m \log m) = O(nm^{1/2} \log m).$$

We next combine both cases and, for technical reasons required by our analysis, also interchange the roles of points and circles (which is possible since the circles are congruent, so a circle c_i contains a point p_j if and only if the circle congruent to c_i and centered at p_j contains the center of c_i) to obtain the following intermediate result.

THEOREM 3.2. *Let C be a set of n congruent circles, and let P be a set of m points in the plane. One can compute the set of pairs of the form (c, p), where $p \in P$, $c \in C$, and p lies inside c, as a collection of complete edge-disjoint bipartite graphs $\{C_t \times P_t\}_t$ in $O((mn^{1/2} + n) \log n)$ space and time. The number of graphs obtained is $O(mn^{1/2} + n)$, and we have $\sum_t |P_t|, \sum_t |C_t| = O((mn^{1/2} + n) \log n)$. Each such point-circle containment pair appears in exactly one of these graphs.*

Next we fix some parameter $1 \leq r \leq n$ (not necessarily a constant) and compute a $(1/r)$-*cutting* for C. That is, we partition the plane into $k = O(r^2)$ cells $\Delta_1, \ldots, \Delta_k$,

each of constant description complexity, so that each cell is intersected by at most n/r circles. This can be done in $O(nr)$ deterministic time, as in [11, 30]. Within this time bound we can also obtain for each cell Δ_i the set C_i of circles crossing Δ_i.

Let $P_i = P \cap \Delta_i$ and $m_i = |P_i|$. Clearly $\sum_{i=1}^{k} m_i = m$. We can compute the sets $P_1, \ldots, P_k$ using $O(r^2 + m)$ space and $O((r^2 + m) \log r)$ time (by preprocessing the above cutting for efficient point location and then by performing m queries with the points of P).

We obtain Z as the disjoint union of two subsets Z_1 and Z_2. The set Z_1 (resp., Z_2) consists of all pairs $(c, p) \in Z$ such that c intersects (resp., fully contains) the cell of the cutting in which p lies. Our final representation will consist of a compact representation of Z_1 and a compact representation of Z_2.

We first compute a compact representation of the set Z_1. The above cutting induces k subproblems, one for each cell of the cutting. In the ith subproblem we must consider the interaction between m_i points and at most n/r congruent circles. According to Theorem 3.2, this can be solved in $O((m_i(n/r)^{1/2} + n/r) \log(n/r))$ time and space. Thus all the k subproblems can be solved in a total of

$$\sum_{i=1}^{k} O((m_i(n/r)^{1/2} + n/r) \log(n/r)) = O((m(n/r)^{1/2} + nr) \log(n/r))$$

time and space. As a result, we obtain a collection of complete edge-disjoint bipartite graphs $C_t \times P_t$, so that the number of graphs is

$$O(m(n/r)^{1/2} + nr)$$

and

$$\sum_t |P_t|, \ \sum_t |C_t| = O((m(n/r)^{1/2} + nr) \log(n/r)).$$

Now we show how to compute a compact representation of the set Z_2. We compute an Eulerian path π of the dual graph of the cutting. The length of π is $O(r^2)$ (and it can be computed in $O(r^2)$ time), and each edge of the cutting is crossed at most twice by the path (once in each direction). Next we associate with each circle $c \in C$ the set of maximal intervals along the path such that for each node in such an interval, its corresponding cell is fully contained in c. We claim that the total number of such intervals, over all circles, is only $O(nr)$. To see this, observe that each such interval I can be charged to a pair (c, w), where c is the relevant circle and w is the node of π that follows I; note that c necessarily crosses the cell Δ of the cutting that w represents. Since each such Δ is crossed by at most n/r circles and π has only $O(r^2)$ nodes, the total number of intervals is at most $O(nr)$.

This argument also implies that we can find all these intervals in time $O(nr \log r)$: for each circle $c \in C$ mark all the nodes of π whose associated cell of the cutting is crossed by c (such a cell may correspond to many nodes of π, and we mark all of them). We next sort all the marked nodes along π and obtain the desired intervals as those nonempty "gaps" between consecutive pairs of marked nodes, which are fully contained in c. We repeat this for each $c \in C$, and the preceding arguments imply that the overall cost of this procedure is $O(nr \log r)$.

Now build a balanced segment tree T over the nodes of π, as above. The construction takes $O(r^2 + nr \log r)$ time and space. We next perform $O(r^2)$ queries, one for each cell of the cutting. (As above, each cell is mapped to only one leaf of T,

even though other leaves may represent the same cell, and the query only traces the path in T from that leaf to the root. The preceding arguments justify this strategy.) The queries take a total of $O(r^2 \log r)$ time. Again, we defer the reporting until all queries are processed and then report, for each node t of T, the complete bipartite graph formed between the circles stored at t and the union $\bigcup P_i$ over all cells Δ_i whose queries have reached t. This yields a collection of $O(r^2)$ complete edge-disjoint bipartite graphs $C_t \times P_t$, with $\sum_t |P_t|$, $\sum_t |C_t| = O(nr \log r)$.

Combining all the preceding steps, we see that the cost of the entire computation is dominated by $O((m(n/r)^{1/2} + nr) \log n)$. If we choose $r = \frac{m^{2/3}}{n^{1/3}}$, we obtain the following summary result.

THEOREM 3.3. *Let C be a set of n congruent circles and P be a set of m points in the plane. One can compute the set of pairs of the form (c, p), where $p \in P$, $c \in C$, and p lies inside c, as a collection $\{C_t \times P_t\}_t$ of complete edge-disjoint bipartite graphs in $O((m^{2/3}n^{2/3} + m + n) \log n)$ time and space. The number of graphs obtained is $O(m^{2/3}n^{2/3} + m + n)$, and we have $\sum_t |P_t|$, $\sum_t |C_t| = O((m^{2/3}n^{2/3} + m + n) \log n)$. Each such point-circle containment pair appears in exactly one of these graphs.*

Remark 1. As a special case, we also obtain the oracle for our distance selection algorithm (see section 4), which has to compute the number of pairs (c, p), where p lies in c. The resulting algorithm thus takes $O((m^{2/3}n^{2/3} + m + n) \log n)$ time and $O(m^{2/3}n^{2/3} + m + n)$ space.

Remark 2. We also obtain an efficient solution to the following problem: given n congruent circles of radius r in the plane, count the number of (resp., report in a compact form all the) intersecting pairs. (Take as the set of points P the set of centers of the given circles, and let the set C consist of circles of radius $2r$ about these centers.) The resulting algorithm thus takes $O(n^{4/3} \log n)$ time and $O(n^{4/3})$ (resp., $O(n^{4/3} \log n)$) space.

Theorem 3.3 and the first remark above can also easily be applied to the case where our ranges are congruent annuli rather than circles. We omit here the easy details.

THEOREM 3.4. *Let M be a set of n congruent annuli and P be a set of m points in the plane. One can compute the set of pairs of the form (A, p), where $p \in P$, $A \in M$, and p lies inside A, as a collection $\{M_t \times P_t\}_t$ of complete edge-disjoint bipartite graphs in $O((m^{2/3}n^{2/3} + m + n) \log n)$ time and space. The number of graphs obtained is $O(m^{2/3}n^{2/3} + m + n)$, and we have $\sum_t |P_t|$, $\sum_t |M_t| = O((m^{2/3}n^{2/3} + m + n) \log n)$. Each such point-annulus containment pair appears in exactly one of these graphs.*

4. Selecting distances in the plane. In this section we present our technique as applied to the distance selection problem. Let $P = \{p_1, \ldots, p_n\}$ be a given set of n points in the plane in general position, and let k be a given integer in the range $[1, \binom{n}{2}]$. The problem is to find the kth smallest distance among the points of P. The algorithm proceeds in stages; the jth stage produces an interval $I_j = (\alpha_j, \beta_j)$, so that the kth smallest distance among the points of P is known to lie in that interval, and the total number of distances among the points of P that lie in I_j is at most $O(n^2 \rho^j)$ for some constant parameter $\rho < 1$. Thus, after logarithmically many stages, we are left with a sufficiently small number of distances, from which it will be easy to retrieve the desired distance. Initially, we have $I_0 = (0, \infty)$.

For clarity of exposition, we first describe an initial version of the algorithm, which does not yet employ our Cole-like improvement. In this version, the number of calls to the oracle in each stage is $O(\log n)$. Since the number of stages is $O(\log n)$ and each oracle call takes $O(n^{4/3} \log n)$, the complexity of the entire algorithm is $O(n^{4/3} \log^3 n)$.

Afterwards we will obtain an improved version by applying our Cole-like technique to step 4 of each stage (see below). This will reduce the number of calls to the oracle to only $O(1)$ per stage and thus improve the complexity of the entire algorithm by a logarithmic factor.

An initial version: The jth stage proceeds as follows.

1. For $i = 1, \ldots, n$, let A_i denote the annulus centered at p_i and having radii α_{j-1} and β_{j-1}. Let M denote the set of these annuli. We perform batched range searching with the sets M and P, using the technique described in section 3, whose results are summarized in Theorem 3.4. This batched range searching thus takes time and space $O(n^{4/3} \log n)$, and its output consists of a collection of $O(n^{4/3})$ complete bipartite graphs $\{M_t \times P_t\}_t$, where $\sum_t |P_t|, \sum_t |M_t| = O(n^{4/3} \log n)$. Note also that $\sum_t |P_t| \cdot |M_t|$ is twice the number of pairs of points of P whose distance lies between α_{j-1} and β_{j-1}, and is thus $O(n^2 \rho^{j-1})$ by assumption. If this number is sufficiently small, we simply examine all edges of these graphs and select the desired distance, terminating the algorithm. (For this we need to know the number k_0 of pairs of points at distance $\leq \alpha_{j-1}$; our desired distance is then the $(k-k_0)$th smallest distance represented in the above bipartite graph collection. We obtain k_0 as in Remark 1 following Theorem 3.3.)
2. Replace each complete bipartite graph $M_t \times P_t$ by the following smaller graph G_t. Put $m_t = |M_t|$ and $n_t = |P_t|$. Partition M_t into $k = \lfloor \frac{m_t}{n_t} \rfloor$ subsets, $M_{t1}, \ldots, M_{tk}$, so that each subset, with the possible exception of the last one M_{tk}, has exactly n_t elements, and M_{tk} has between n_t and $2n_t - 1$ elements. For each $i \leq k$, construct a d-regular LPS-expander graph G_{ti} on the vertex set $M_{ti} \cup P_t$. Let G_t be the union of all these graphs. Assuming d to be a constant, the number of edges of G_t is clearly $O(|M_t| + |P_t|)$. Thus the total number of edges of all the graphs G_t is proportional to $\sum_t O(|M_t| + |P_t|) = O(n^{4/3} \log n)$.
3. Each edge (A, p) of G_t that connects a node representing an annulus with a node representing a point is associated with the distance between p and the center of A. (All other edges of G_t are ignored.) Let L be the list of all these edge distances, over all graphs G_t, sorted in increasing order. The length of L is $O(n^{4/3} \log n)$.
4. Now run a binary search over L, using as an oracle, for each $\lambda \in L$, a counting variant of the batched range-searching procedure of section 3, involving the set P of points and the set of circles of radius λ centered at the points of P. As shown in section 3, the cost of an oracle call is also $O(n^{4/3} \log n)$. This yields a new interval $I_j = (\alpha_j, \beta_j)$ where the kth smallest distance is known to lie. Note that the interval I_j has the property that it contains no distance induced by any edge of any of the graphs G_t.
5. We now repeat the whole procedure with the new interval I_j.

Once the algorithm terminates, its correctness is easy to prove. The main step in the analysis is to establish the invariant concerning the number of distances that lie in each interval I_j, thereby showing that the algorithm does indeed terminate and that it takes only $O(\log n)$ stages to do so.

Fix one of the pairs (M_t, P_t) obtained by the partitioning procedure of step 1. Let M_{ti} be one of the subsets of M_t in the partition of step 2. Replace each annulus A in M_{ti} by another annulus A' with the same center as A but with radii α_j and β_j (see Figure 3); let M'_{ti} denote the resulting set of annuli. Compute (only for the purpose of

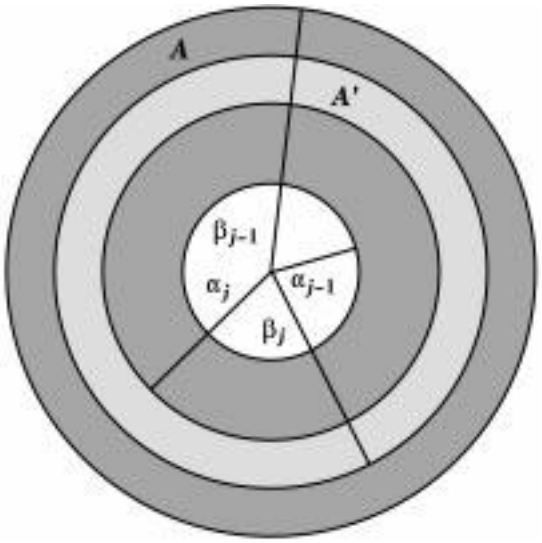

FIG. 3. *The concentric annuli A and A'.*

analysis) a $1/r$-cutting for the set M'_{ti} of size $O(r^2)$. That is, fix some parameter r and partition the plane into $k = O(r^2)$ cells, $\Delta_1, \ldots, \Delta_k$, so that each cell is intersected by at most $|M'_{ti}|/r$ of the circles bounding the annuli of M'_{ti}. (Actually, for our analysis, it is sufficient to assume that for some constant $c > 0$, a $1/r$-cutting of size $O(r^c)$ can be computed.)

For each $u = 1, \ldots, k$, let $P_t^{(u)}$ denote the set of points in P_t that lie inside Δ_u, let $K_{ti}^{'(u)}$ denote the set of annuli in M'_{ti} that fully contain Δ_u, and let $L_{ti}^{'(u)}$ denote the set of annuli in M'_{ti} that have a bounding circle that crosses Δ_u. It is clear that the number D_{ti} of distances between centers of annuli in M'_{ti} and points in P_t that lie in I_j satisfies

$$D_{ti} \leq \sum_u |L_{ti}^{'(u)}| \cdot |P_t^{(u)}| + \sum_u |K_{ti}^{'(u)}| \cdot |P_t^{(u)}|.$$

Since, for each u, we have $|L_{ti}^{'(u)}| \leq |M'_{ti}|/r = |M_{ti}|/r$, and since $\sum_u |P_t^{(u)}| = |P_t|$, it follows that

$$\sum_u |L_{ti}^{'(u)}| \cdot |P_t^{(u)}| = O\left(\frac{|M_{ti}| \cdot |P_t|}{r}\right).$$

Next consider the second sum $\sum_u |K_{ti}^{'(u)}| \cdot |P_t^{(u)}|$. Since, for each $A' \in K_{ti}^{'(u)}$ and each $p \in P_t^{(u)}$, the distance between p and the center of A' is in I_j, and since the corresponding expander G_{ti} has no edge whose distance lies in I_j, it follows that G_{ti} contains no edge connecting between $K_{ti}^{'(u)}$ (or, more precisely, the original annuli in M_{ti} corresponding to the annuli of $K_{ti}^{'(u)}$) and $P_t^{(u)}$. Hence, by Corollary 2.4, it follows that

$$|K_{ti}^{'(u)}| \cdot |P_t^{(u)}| \leq \frac{4(|M_{ti}| + |P_t|)^2}{d}.$$

Since there are only $O(r^2)$ cells, it follows that the corresponding sum satisfies

$$\sum_u |K_{ti}^{'(u)}| \cdot |P_t^{(u)}| = O\left(\frac{r^2(|M_{ti}| + |P_t|)^2}{d}\right).$$

Hence,

$$D_{ti} = O\left(\frac{r^2(|M_{ti}| + |P_t|)^2}{d}\right) + O\left(\frac{|M_{ti}| \cdot |P_t|}{r}\right).$$

Recall that $|P_t| \leq |M_{ti}| < 2|P_t|$, which is easily seen to imply that $(|M_{ti}| + |P_t|)^2 \leq 5|M_{ti}| \cdot |P_t|$. Hence,

$$D_{ti} = O\left(|M_{ti}| \cdot |P_t| \cdot \left[\frac{r^2}{d} + \frac{1}{r}\right]\right).$$

If we now choose $r = d^{1/3}$ and ρ to be appropriately proportional to $1/d^{\frac{1}{3}}$, then we have, for each of these pairs,

$$D_{ti} \leq \rho |M_{ti}| \cdot |P_t|.$$

Hence, summing up all these inequalities, we conclude that the total number of distances between the points of P that fall in I_j is at most ρ times the number of these distances within I_{j-1}. This establishes the desired invariant, thus completing the analysis of the algorithm, and yielding the following intermediate result.

LEMMA 4.1. *The above algorithm computes the kth smallest distance among n points in the plane in (deterministic) time* $O(n^{4/3} \log^3 n)$.

An improved version: We now apply our Cole-like improvement to step 4 of each stage of the algorithm. This will reduce the number of oracle calls in a single stage of the algorithm to only a constant and will improve the complexity of the algorithm by a logarithmic factor. To this end, we replace step 4 above by the following.

4. Let W be the number of pairs of points of P whose distance lies in I_{j-1}; that is, $W = 1/2 \sum_t |P_t| \cdot |M_t|$. We assume that $W \geq 8$; otherwise, we can simply check the constant number of distances in I_{j-1} and select out of them the desired distance. We assign a weight to each distance in L, so that the weight of each of the at most $(|P_t| + |M_{ti}|)d/2$ distances induced by the edges of an expander G_{ti} is $|P_t||M_{ti}|/(|P_t| + |M_{ti}|)$ (recall that some of these expander edges do not induce a distance; see step 3 of the algorithm). The total weight of the distances in L is

$$\leq \sum_{t,i} (|P_t| + |M_{ti}|) \frac{d}{2} \cdot \frac{|P_t||M_{ti}|}{|P_t| + |M_{ti}|} = \frac{d}{2} \sum_{t,i} |P_t| \cdot |M_{ti}| = Wd,$$

and, using the fact that $|P_t| \leq |M_{ti}|$, the weight of any single distance in L is

$$\frac{|P_t||M_{ti}|}{|P_t| + |M_{ti}|} < |P_t| \leq \sqrt{|P_t| \cdot |M_{ti}|} \leq \sqrt{2W} \leq \frac{W}{2},$$

since we have assumed that $W \geq 8$. Partition the list L into at most $2d$ intervals, each of weight at most W and at least $W/2$, and perform at most $\log(2d) = O(1)$ oracle calls to obtain the interval I_j that contains the desired distance. (Note that there is no need to sort L for the binary search; instead,

one may use repeated weighted-median findings on appropriate portions of L, which take a total time linear in the size of L.) Below we show that although now I_j is not necessarily defined by two consecutive values in L, the number of distances between the points of P that lie in I_j is still only ρ times the number of these distances within I_{j-1} for some constant $\rho < 1$.

It remains to show that, after the above change, it is still true that the number of distances that lie in the interval I_j is only $O(n^2\rho^j)$ for some constant $\rho < 1$. The analysis below is similar to the analysis for the basic version. The main difference is that we use Corollary 2.5 instead of Corollary 2.4.

As above, fix one of the pairs (M_t, P_t) obtained by the partitioning procedure of step 1 and let M_{ti} be one of the subsets of M_t in the partition of step 2. Suppose first that the corresponding expander graph G_{ti} contains at least $3(|P_t| + |M_{ti}|)$ edges whose distances lie in I_j. Then, by definition, G_{ti} contributes at least $3|P_t| \cdot |M_{ti}|$ to the total weight of edges whose distances lie in I_j. Since, by construction, this total weight is at most W, we conclude that $\sum_{t,i} |P_t| \cdot |M_{ti}|$, over all t, i for which G_{ti} has the above property, is at most $W/3$.

Thus we only need to consider graphs G_{ti} that have fewer than $3(|P_t| + |M_{ti}|)$ edges whose distances lie in I_j. Let M'_{ti} be the corresponding set of new annuli, as above, and compute (only for the purpose of analysis) a $1/r$-cutting of M'_{ti}, as above, to obtain the sets $P_t^{(u)}$, $K_{ti}^{'(u)}$, and $L_{ti}^{'(u)}$, $u = 1, \ldots, r$. As above, the number D_{ti} of distances between centers of annuli in M'_{ti} and points in P_t that lie in I_j satisfies

$$D_{ti} \leq \sum_u |L_{ti}^{'(u)}| \cdot |P_t^{(u)}| + \sum_u |K_{ti}^{'(u)}| \cdot |P_t^{(u)}| = O\left(\frac{|M_{ti}| \cdot |P_t|}{r}\right) + \sum_u |K_{ti}^{'(u)}| \cdot |P_t^{(u)}|.$$

Next consider the sum $\sum_u |K_{ti}^{'(u)}| \cdot |P_t^{(u)}|$. Since, for each $A' \in K_{ti}^{'(u)}$ and each $p \in P_t^{(u)}$, the distance between p and the center of A' is in I_j, and since the corresponding expander G_{ti} has fewer than $3(|P_t| + |M_{ti}|)$ edges whose distances lie in I_j, it follows that G_{ti} contains fewer than $3(|P_t| + |M_{ti}|)$ edges connecting between $K_{ti}^{'(u)}$ (or, more precisely, the original annuli in M_{ti} corresponding to the annuli of $K_{ti}^{'(u)}$) and $P_t^{(u)}$. Hence, by Corollary 2.5, it follows that

$$|K_{ti}^{'(u)}| \cdot |P_t^{(u)}| \leq \frac{9(|M_{ti}| + |P_t|)^2}{d}.$$

Thus we can repeat the analysis given above, with the only difference that the constants of proportionality are now larger, to conclude that, for an appropriate constant $\rho = O(1/d^{\frac{1}{3}})$, we have $D_{ti} \leq \rho |M_{ti}| \cdot |P_t|$. Hence, summing up all these inequalities and adding the contribution of expanders G_{ti} with many edges whose distances fall in I_j, we conclude that the total number of distances between the points of P that fall in I_j is at most $(\rho + \frac{1}{6})$ times the number of these distances within I_{j-1}. The factor $(\rho + \frac{1}{6})$ is smaller than 1 if we choose d sufficiently large. This establishes the desired invariant and thus completes the analysis of the algorithm. Since both the range-searching procedure and the oracle procedure cost $O(n^{4/3} \log n)$, the total running time of the above algorithm is $O(n^{4/3} \log^2 n)$. To summarize, we have shown the following theorem.

THEOREM 4.2. *The improved algorithm computes the kth smallest distance among n points in the plane in (deterministic) time* $O(n^{4/3} \log^2 n)$.

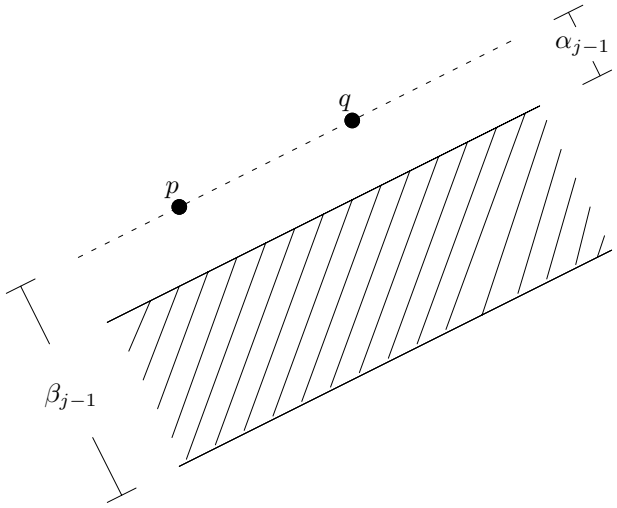

FIG. 4. *The strip $A^r_{p,q}$ defined by p and q.*

5. The two-line center problem. In this section we apply our new technique to obtain an improved algorithm for the two-line center problem. Let P be a given set of n points in the plane in general position. The problem is to find two strips whose union contains P, so that the larger width w^* of the two strips is as small as possible. Note that w^* is determined by three points of P—two points defining one of the borders of the wider strip and the third point defining the opposite border. We use the algorithm of Agarwal and Sharir [6], whose running time is $O(n^2 \log^3 n)$, for the appropriate decision problem: given a value $w > 0$, determine whether $w^* < w$, $w^* > w$, or $w^* = w$.

The main algorithm proceeds in stages; the jth stage produces an interval $I_j = (\alpha_j, \beta_j)$, so that w^* is known to lie in that interval, and the total number of strips defined by triples of points in P whose width lies in I_j is at most $O(n^3\rho^j)$ for some constant parameter $\rho < 1$. Thus, after logarithmically many stages, we are left with a sufficiently small number of widths, from which it will be easy to retrieve the desired width. Initially, we have $I_0 = (0, \infty)$. The jth stage proceeds as follows.

1. For each pair of points $p, q \in P$, draw the open strip $A^r_{p,q}$ of width $\beta_{j-1} - \alpha_{j-1}$, whose borders are parallel to the line passing through p and q and lie to the right of this line at distances α_{j-1} and β_{j-1}, respectively (see Figure 4). Let $A^l_{p,q}$ denote the strip symmetric to $A^r_{p,q}$ with respect to the line through p and q. (We note that, for $p_1, p_2, p_3 \in P$, we have $p_3 \in A^r_{p_1,p_2}$ (resp., $p_3 \in A^l_{p_1,p_2}$) if and only if the width of the strip defined by $(\{p_1, p_2\}, p_3)$ (i.e., defined by the line through p_1 and p_2 and the line parallel to it through p_3) lies in $(\alpha_{j-1}, \beta_{j-1})$ and the center line of this strip lies to the right (resp., to the left) of p_1p_2.) Let M denote the set of these $n(n-1)$ strips. Perform $n(n-1)$ batched range-searching queries on the set P with these strips. Using standard techniques, such as those of [31], [32], or [13], we can perform these queries so that the output consists of a collection of pairs (M_t, P_t), where, for each t, P_t is a subset of P, M_t is a subset of M, for each $p \in P_t$ and each $A \in M_t$ we have $p \in A$, and each such containment is obtained in exactly one

pair $M_t \times P_t$. Moreover, using an approach similar to that of [32], one can show that the number of pairs is at most $O(n^2)$, $\sum_t |P_t| = O(n^2)$, $\sum_t |M_t| = O(n^2 \log^2 n)$ and the batched range searching takes time $O(n^2 \log^2 n)$. Note also that $\sum_t |P_t| \cdot |M_t|$ is equal to the number of strips with width between α_{j-1} and β_{j-1} that are defined by triples of points of P, and is thus $O(n^3 \rho^{j-1})$ by assumption. If this number is sufficiently small, we find the desired width by examining all the relevant strips, in increasing width order, and stop.

2. For each pair (M_t, P_t), construct a graph G_t exactly as in step 2 of the preceding algorithm. Here the total number of edges of all the graphs G_t is proportional to $\sum_t O(|M_t| + |P_t|) = O(n^2 \log^2 n)$.
3. Each edge (A, p) of G_t is associated with the width of the strip spanned by the two points defining A and the point p. Let L be the list of all these edge values, over all graphs G_t, sorted in increasing order. The length of L is $O(n^2 \log^2 n)$. (As above, only some of the edges of G_t are used to form L.)
4. Now run a binary search over L, using the oracle of [6], to obtain a new interval $I_j = (\alpha_j, \beta_j)$ where w^* is known to lie. As in section 4, we make only a constant number of oracle calls, employing a weighing scheme similar to that used above, with obvious and straightforward modifications. (As in the preceding algorithm, there is no need to actually sort L for the binary search.)
5. We now repeat the whole procedure with the new interval I_j.

Once the algorithm terminates, its correctness is easy to establish. Using an analysis similar to that of the preceding section (which we therefore omit), one easily shows that the algorithm does indeed terminate and that it takes only $O(\log n)$ stages to do so. The running time of the algorithm is thus $O(\log n)$ times the cost of a single stage, and that cost is dominated by the cost of an oracle call, which is $O(n^2 \log^3 n)$ [6]. Thus we have the following theorem.

THEOREM 5.1. *The above algorithm solves the two-line center problem in (deterministic) time* $O(n^2 \log^4 n)$.

Remark. Note that if the oracle of [6] could be improved, say by a logarithmic factor, the complexity of the above algorithm would improve to $O(n^2 \log^3 n)$. We leave this as an open problem for further research.

6. Slope selection. In this section we consider the slope selection problem and develop an algorithm that is very similar to those obtained in the preceding sections. Let $\mathcal{L} = \{\ell_1, \ldots, \ell_n\}$ be a given collection of n lines in the plane in general position, and let $1 \le k \le \binom{n}{2}$ be an integer. We want to find the kth leftmost vertex v_k of the arrangement $\mathcal{A}(\mathcal{L})$ of $\mathcal{L}$. As in the preceding section, the algorithm proceeds in $O(\log n)$ stages; the jth stage produces a vertical slab $\sigma_j = (\alpha_j, \beta_j)$ (this is a shorthand notation for $\alpha_j < x < \beta_j$), so that v_k is known to lie in σ_j, and the total number of vertices of $\mathcal{A}(\mathcal{L})$ within σ_j is at most $O(n^2 \rho^j)$ for some constant parameter $\rho < 1$. Initially, we have $\sigma_0 = (-\infty, \infty)$ (that is, the entire plane).

The jth stage proceeds as follows.

1. For a line ℓ, let $\xi(\ell)$, $\eta(\ell)$ denote the y-coordinates of the intercepts of ℓ with the left and right borders of σ_{j-1}, respectively. Note that two lines ℓ and ℓ' intersect within σ_{j-1} if and only if either
   (i) $\xi(\ell) < \xi(\ell')$ and $\eta(\ell) > \eta(\ell')$ or
   (ii) $\xi(\ell) > \xi(\ell')$ and $\eta(\ell) < \eta(\ell')$.
   In other words, we can map each line ℓ_i to the point $\ell_i^* = (\xi(\ell_i), \eta(\ell_i))$ in a dual plane, so that, given any query line ℓ, the set of lines of $\mathcal{L}$ that intersect ℓ

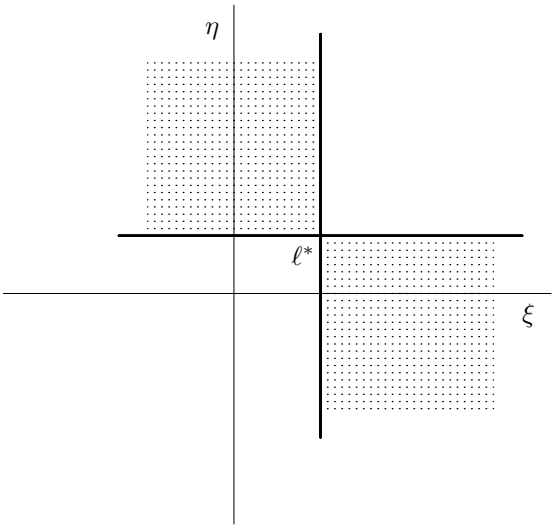

FIG. 5. *The two quadrant ranges defined by ℓ.*

within σ_{j-1} is the (set dual to the) output of the following pair of *orthogonal range-searching queries* (see Figure 5):

$$\{\ell_i^* \quad | \quad \xi(\ell_i) < \xi(\ell),\ \eta(\ell_i) > \eta(\ell)\},$$

$$\{\ell_i^* \quad | \quad \xi(\ell_i) > \xi(\ell),\ \eta(\ell_i) < \eta(\ell)\}.$$

To perform such range-searching queries, we use the standard two-dimensional *range tree* data structure. As is well known, we can perform our $2n$ quadrant range queries in this structure, so that each query takes $O(\log^2 n)$ time and returns its output as the disjoint union of $O(\log^2 n)$ canonical subsets. Thus we obtain a collection of pairs $(\mathcal{K}_t, \mathcal{L}_t)$ of subsets of $\mathcal{L}$ (where each $\mathcal{L}_t$ is some canonical set and $\mathcal{K}_t$ is the set of queries associated with it) that satisfy the following properties.

(i) For each t, every line $\ell \in \mathcal{K}_t$ intersects every line $\ell' \in \mathcal{L}_t$ within σ_{j-1}.
(ii) For each pair of lines ℓ, ℓ' of $\mathcal{L}$ that intersect within σ_{j-1}, there exists a unique t such that $\ell \in \mathcal{K}_t$, $\ell' \in \mathcal{L}_t$.
(iii) $\sum_t |\mathcal{L}_t|, \sum_t |\mathcal{K}_t| = O(n \log^2 n)$.

Properties (i) and (ii) imply that the total number of vertices of $\mathcal{A}(\mathcal{L})$ within σ_{j-1} is at most $\sum_t |\mathcal{L}_t| \cdot |\mathcal{K}_t|$.

2. For each pair $(\mathcal{K}_t, \mathcal{L}_t)$, construct a graph G_t in the same manner as in the preceding sections. The total number of edges of all the graphs G_t is proportional to $\sum_t O(|\mathcal{K}_t| + |\mathcal{L}_t|) = O(n \log^2 n)$.
3. Each edge (ℓ, ℓ') of G_t, with $\ell \in \mathcal{K}_t, \ell' \in \mathcal{L}_t$, is associated with the vertex of $\mathcal{A}(\mathcal{L})$ formed by the intersection of ℓ and ℓ'. Let L be the list of all these vertices, over all graphs G_t, sorted in the order of increasing x-coordinates. The length of L is $O(n \log^2 n)$.
4. Now run a binary search over L, using the inversion-counting oracle mentioned in the introduction, to obtain a new slab $\sigma_j = (\alpha_j, \beta_j)$ where the kth leftmost

vertex v_k is known to lie. Note that the slab σ_j has the property that it contains no vertex associated with any edge of any of the graphs G_t. (As in the preceding sections, there is no need to sort L, and the repeated median findings that are used instead take only linear time in $|L|$.)

5. We now repeat the whole procedure with the new slab σ_j until we obtain a slab that contains only a single vertex, and then we terminate the algorithm and report that vertex.

Once the algorithm terminates, its correctness is easy to establish (under the assumption of general position). The analysis, showing that the algorithm does indeed terminate and that it takes only $O(\log n)$ stages to do so, is similar to that given in the preceding sections. Specifically, fix one of the pairs $(\mathcal{K}_t, \mathcal{L}_t)$ obtained by the range-searching procedure of step 1. Let $\mathcal{K}_{ti}$ be one of the subsets of $\mathcal{K}_t$ in the partition of step 2. Consider a modified dual plane, obtained by replacing the ξ and η coordinates by the respective intercepts ξ', η' of lines along the left and right borders of the new slab σ_j. We fix some parameter r, to be determined shortly, and apply (only for the purpose of analysis) the following partitioning of the new dual plane. The plane is partitioned into r vertical slabs, so that each slab contains $|\mathcal{L}_t|/r$ points dual to lines in $\mathcal{L}_t$, and then each slab is partitioned, by horizontal cuts, into r rectangles, each containing $|\mathcal{L}_t|/r^2$ dual points. For each line $\ell \in \mathcal{K}_{ti}$, consider the pair of quadrants

$$Q_1(\ell) = \{\xi < \xi'(\ell),\ \eta > \eta'(\ell)\},$$

$$Q_2(\ell) = \{\xi > \xi'(\ell),\ \eta < \eta'(\ell)\}.$$

For each of the resulting quadrants Q, there are at most $2r$ rectangles of the partitioning that are crossed by the boundary of Q; each other rectangle is either fully contained within Q or lies fully outside Q.

For each $u = 1, \ldots, r$, let R_u denote the uth rectangle of the partitioning, let $\mathcal{L}_t^{(u)}$ denote the set of lines of $\mathcal{L}_t$ whose dual points fall in R_u, let $\mathcal{Q}_{ti}^{'(u)}$ denote the set of lines of $\mathcal{K}_{ti}$ whose associated quadrants fully contain R_u, and let $\mathcal{Q}_{ti}^{''(u)}$ denote the set of lines of $\mathcal{K}_{ti}$ whose associated quadrants are such that their boundary crosses R_u. It is clear that the number D_{ti} of intersection points between lines in $\mathcal{L}_t$ and lines in $\mathcal{K}_{ti}$ that lie in σ_j satisfies

$$D_{ti} \le \sum_u |\mathcal{Q}_{ti}^{'(u)}| \cdot |\mathcal{L}_t^{(u)}| + \sum_u |\mathcal{Q}_{ti}^{''(u)}| \cdot |\mathcal{L}_t^{(u)}|.$$

By the property of "small crossing number" that our partition has, it follows that $\sum_u |\mathcal{Q}_{ti}^{''(u)}| = O(|\mathcal{K}_{ti}|r)$, so

$$\sum_u |\mathcal{Q}_{ti}^{''(u)}| \cdot |\mathcal{L}_t^{(u)}| = O\left(\frac{|\mathcal{K}_{ti}| \cdot |\mathcal{L}_t|}{r}\right).$$

Next consider the other sum $\sum_u |\mathcal{Q}_{ti}^{'(u)}| \cdot |\mathcal{L}_t^{(u)}|$. Since, for each line $\ell' \in \mathcal{Q}_{ti}^{'(u)}$ and each line $\ell \in \mathcal{L}_t^{(u)}$, the intersection point between ℓ and ℓ' lies in σ_j, and since the corresponding expander G_{ti} has no edge whose corresponding intersection point lies in σ_j, it follows that G_{ti} contains no edge connecting between $\mathcal{Q}_{ti}^{'(u)}$ and $\mathcal{L}_t^{(u)}$. Hence, by Corollary 2.4, it follows that

$$|\mathcal{Q}_{ti}^{'(u)}| \cdot |\mathcal{L}_t^{(u)}| \le \frac{4(|\mathcal{K}_{ti}| + |\mathcal{L}_t|)^2}{d}.$$

Since there are only r^2 indices u, it follows that the corresponding sum satisfies

$$\sum_u |\mathcal{Q}_{ti}^{'(u)}| \cdot |\mathcal{L}_t^{(u)}| \leq \frac{4r^2(|\mathcal{K}_{ti}| + |\mathcal{L}_t|)^2}{d}.$$

Hence, as in the preceding sections,

$$\begin{aligned} D_{ti} &= \frac{4r^2(|\mathcal{K}_{ti}| + |\mathcal{L}_t|)^2}{d} + O\left(\frac{|\mathcal{K}_{ti}| \cdot |\mathcal{L}_t|}{r}\right) \\ &= O\left(|\mathcal{K}_{ti}| \cdot |\mathcal{L}_t| \cdot \left[\frac{r^2}{d} + \frac{1}{r}\right]\right). \end{aligned}$$

If we now choose $r = d^{1/3}$ and ρ to be appropriately proportional to $1/d^{\frac{1}{3}}$, then we have, for each of these pairs, $D_{ti} \leq \rho|\mathcal{K}_{ti}| \cdot |\mathcal{L}_t|$, and, summing up all these inequalities, we conclude that the total number of vertices of $\mathcal{A}(\mathcal{L})$ that fall in σ_j is at most ρ times the number of these vertices within σ_{j-1}. This establishes the desired invariant, thus completing the analysis of the algorithm, and yielding the following summary result.

THEOREM 6.1. *The above algorithm computes the kth leftmost vertex in an arrangement of n lines in the plane in (deterministic) time* $O(n \log^3 n)$.

Remark. We have not used here the Cole-like improvement, since it does not improve the overall running time of the algorithm; see a discussion concerning this issue in the concluding section.

7. Other applications. In this section we briefly mention two other problems for which our approach yields efficient algorithms that are comparable with the corresponding known algorithms, which are based on parametric searching.

7.1. The two-center problem. In this subsection we present an algorithm for the planar two-center problem, defined as follows. Let P be a given set of n points in the plane in general position. We wish to find two closed discs whose union contains P, so that the larger radius r^* of the two discs is as small as possible. Note that r^* is determined either by a pair of points of P, in which case r^* is half the distance between these points, or by a triple of points of P, in which case r^* is the radius of the circumcircle of the triangle spanned by these points. We use the recent algorithm of Hershberger [23] (see also [6, 24]), whose running time is $O(n^2)$, for the corresponding decision problem: given a value $r > 0$, determine whether $r^* < r$, $r^* > r$, or $r^* = r$. We begin our algorithm with a preliminary stage in which we perform a binary search for r^* among the $\binom{n}{2}$ half-distances determined by pairs of points in P. The complexity of this stage is $O(n^2 \log n)$, and at its end we have either found r^* (if r^* is determined by a pair of points in P) or obtained an open interval (α_0, β_0) such that r^* is known to lie in this interval and none of the half-distances determined by pairs of points in P is in (α_0, β_0).

The main algorithm is very similar to the algorithm of section 5 for the two-line center problem. We therefore describe only the range-searching part of the jth stage.

For each pair of points $p, q \in P$, at distance less than $2\beta_{j-1}$, draw the two open discs $C_{p,q}^r, D_{p,q}^r$ of respective radii α_{j-1} and β_{j-1}, whose centers lie to the right of the segment pq and whose bounding circles pass through p and q. Let $L_{p,q}^r$ denote the symmetric difference of these two discs. Let $L_{p,q}^l$ denote the symmetric difference of the two discs with the same radii whose centers lie to the left of pq and whose bounding circles pass through p and q. We will refer to ranges like $L_{p,q}^r$ and $L_{p,q}^l$ as *double lunes* (see Figure 6). Note that, for $p_1, p_2, p_3 \in P$, we have $p_3 \in L_{p_1,p_2}^r$

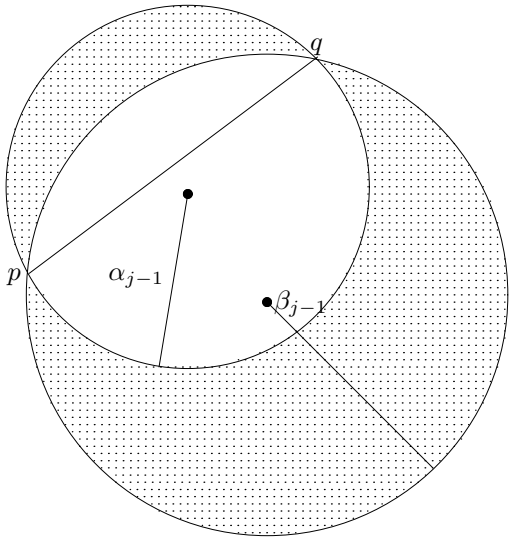

FIG. 6. *The double lune $L^r_{p,q}$ defined by p and q.*

(resp., $p_3 \in L^l_{p_1,p_2}$) if and only if the radius of the circumcircle of p_1, p_2, p_3 lies in $(\alpha_{j-1}, \beta_{j-1})$, and the center of this circle lies to the right (resp., to the left) of p_1p_2. We thus must compute the collection of all pairs of the form $(L^x_{p_1,p_2}, p_3)$, where x stands for either r or l and where p_3 lies in the double lune $L^x_{p_1,p_2}$, and represent it as a collection of complete bipartite graphs as in the previous examples. We distinguish among four types of such pairs, according to whether x is r or l and whether p_3 lies in $C^x_{p_1,p_2} - D^x_{p_1,p_2}$ or in $D^x_{p_1,p_2} - C^x_{p_1,p_2}$. Each type is handled separately. We will show how to compute the collection of all pairs of the form $(L^r_{p_1,p_2}, p_3)$, where p_3 lies in $C^r_{p_1,p_2} - D^r_{p_1,p_2}$; the other three types are computed in a similar and symmetric fashion.

Let $\mathcal{C}^r$ (resp., $\mathcal{D}^r$) denote the set of discs $C^r_{p,q}$ (resp., $D^r_{p,q}$), and let A denote the set of discs of radius α_{j-1} centered at the points of P. We construct a $(1/n)$-cutting for the set A, using the hierarchical decomposition technique of Chazelle [11], appropriately adapted to the case of circles. We retain the tree $\mathcal{T}$ that is obtained in the construction, where the nodes of the kth level of the tree represent the cells of the cutting at the kth level in the hierarchy (this is a $(1/r_0^k)$-cutting of A for some constant r_0). We denote the set of centers of the discs of $\mathcal{C}^r$ by $\overline{\mathcal{C}^r}$. We perform $\binom{n}{2}$ point-location queries in the final cutting, with the points of $\overline{\mathcal{C}^r}$, in batched mode; each query is performed by searching with the query point through an appropriate path of $\mathcal{T}$, so it takes $O(\log n)$ time, for a total of $O(n^2 \log n)$ time for all queries. At each node v of $\mathcal{T}$, excluding the root, we obtain a pair $(A_v, \overline{\mathcal{C}^r_v})$ of sets, where $A_v \subseteq A$ is the set of discs whose bounding circles cross the cell associated with the parent of v and which fully contain the cell associated with v, and where $\overline{\mathcal{C}^r_v} \subseteq \overline{\mathcal{C}^r}$ is the set of query points passing through v, i.e., lying within the cell associated with v. Note that $\sum_v |A_v|$, over all nodes v of $\mathcal{T}$, is $O(n^2)$ and that $\sum_v |\overline{\mathcal{C}^r_v}|$, over all nodes v at a fixed level of $\mathcal{T}$, is $O(n^2)$. For each node v we obtain the following subproblem: denote by $\mathcal{D}^r_v$ the subset of $\mathcal{D}^r$ that corresponds to the subset $\overline{\mathcal{C}^r_v}$, that is, the set of discs $D^r_{p_1,p_2}$, where the centers of the corresponding discs $C^r_{p_1,p_2}$ belong to $\overline{\mathcal{C}^r_v}$. Denote by $P_v \subseteq P$

the set of centers of the discs of A_v. We want to report, in compact form, all pairs $(D^r_{p_1,p_2}, p_3)$, where $D^r_{p_1,p_2} \in \mathcal{D}^r_v$ and $p_3 \in P_v$ such that p_3 does not lie in the interior of $D^r_{p_1,p_2}$. Put $|\overline{\mathcal{C}^r_v}| = m_v$ and $|A_v| = n_v$.

We now apply the algorithm of Theorem 3.1 to each of these subproblems. This requires a few (simple and straightforward) modifications because here we are interested in points lying in the *exterior* of the given discs; we omit the easy details. We can thus report the desired pairs, for the subproblem at a node v, in time and storage $O(n_v^2 \log n_v + m_v \log n_v)$ (for this, we need to interchange the roles of discs and points). The overall cost of the computation at all the nodes of the kth level of the tree is

$$O(s_k(n/r_0^{k-1})^2 \log(n/r_0^{k-1})) + \sum_{v \text{ at level } k} O(m_v \log(n/r_0^{k-1}))$$
$$= O(s_k(n/r_0^{k-1})^2 \log n + n^2 \log n),$$

where s_k is the size of the kth level cutting. Since the construction of [11] ensures that $s_k \le r_0^{2(k+1)}$, assuming that r_0 is sufficiently large, it follows that the cost of the computations at the nodes of the kth level of the tree is $O(r_0^4 n^2 \log n) = O(n^2 \log n)$. Thus, summing over all nodes of the tree, we get that the total cost of a single application of the range-searching step, as well as the overall size of the bipartite graphs that it produces, is $O(n^2 \log^2 n)$. This completes the description of the range-searching stage, and the rest of the algorithm remains essentially as in the previous examples. The total running time of the algorithm is thus $O(n^2 \log^3 n)$, matching the running time of the best previous algorithm of [6]. (Note that here we do not need to apply our Cole-like improvement because we can afford to perform $O(\log n)$ oracle calls per stage without increasing the overall running time.)

7.2. The minimum output rate problem. In this subsection we present algorithms for the *minimum output rate* problem: given consecutive time intervals $T_1, \ldots, T_n$, input rates $I_1, \ldots, I_n$ (where I_j is the input rate during the jth time interval), and a buffer size B, find the minimum output rate R^* required to assure that the buffer does not overflow. This problem was defined and solved by Megiddo, Naor, and Anderson [35], who give an $O(n \log n \log\log n)$ deterministic algorithm and an $O(n \log n)$ randomized algorithm, both based on parametric searching. Let $a_i \equiv T_i I_i$ denote the total amount of data received during the ith interval, for $i = 1, \ldots, n$, and define a set H of $\binom{n}{2} + n$ lines of negative slope in the plane:

$$l_{i,j} = (a_i + \cdots + a_j) - (T_i + \cdots + T_j)x, \quad 1 \le i \le j \le n.$$

Megiddo, Naor, and Anderson prove that the desired rate R^* is equal to the x-coordinate of the intersection point of the upper envelope of H and the horizontal line at height B, which we denote by l. That is, it is equal to the x-coordinate of the rightmost intersection point of the lines of H with l (see Figure 7).

Given some value x_0, we would like to compute a compact representation of the lines intersecting l to the right of x_0. Define (as in [35]) $W_i = W_i(x_0) = \sum_{k=1}^{i}(a_k - T_k x_0)$, $i = 1, \ldots, n$, and $W_0 = 0$. (The values $W_1, \ldots, W_n$ can be computed in $O(n)$ time by computing the auxiliary values $U_i = \sum_{k=1}^{i} a_k$ and $V_i = \sum_{k=1}^{i} T_k x_0$, $i = 1, \ldots, n$.) Note that the line $l_{i,j}$ intersects l to the right of x_0 if and only if it intersects the vertical line through x_0 above l, that is, if and only if $W_j - W_{i-1} > B$. We compute a compact representation of the pairs (i, j), $0 \le i < j \le n$, such that $W_j - W_i > B$, as follows. Map the value W_i to the point $(i, W_i - B)$, $i = 0, \ldots, n$,

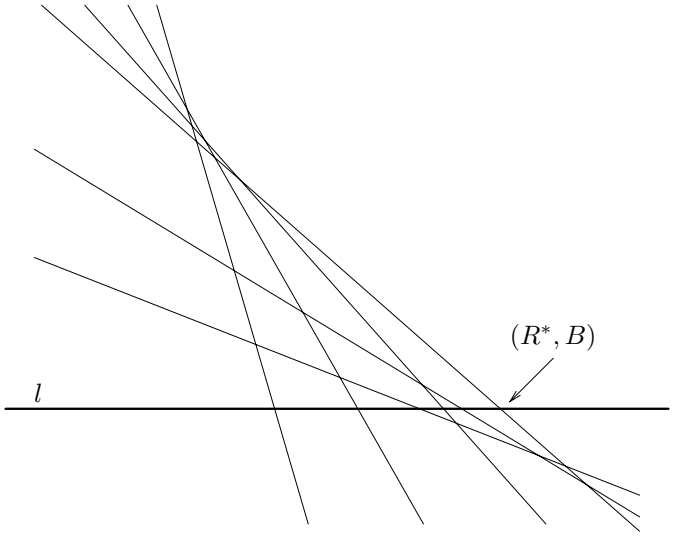

FIG. 7. *The minimum output rate problem in geometric setting.*

and let P denote the resulting set of points. Note that for any fixed index i, the set of pairs (i, j) with $W_j - W_i > B$ is determined by the set of points of P lying in the (open) northeast quadrant whose apex is the point (i, W_i). Thus we preprocess the points in P for efficient quadrant range searching. We can actually perform n batched queries to obtain in total time $O(n \log^2 n)$ the desired set of pairs as a collection of $O(n \log^2 n)$ complete bipartite graphs with vertex sets of total size $O(n \log^2 n)$.

The above simple method to compute a compact representation for the set of lines of H intersecting l to the right of some given x-value gives rise to a simple, expander-based $O(n \log^3 n)$ deterministic algorithm for the minimum output rate problem. We omit here the details, which are very similar to those in earlier sections.

We also note that the above method gives rise to an $O(n \log n)$ randomized algorithm, which we believe to be simpler than the one presented in [35]. We describe it here, even though it is not within the scope of this paper, since it is very simple and short (it also resembles the algorithms considered in [36]). Pick a random sample of size $O(n \log n)$ from the set H. (A random line can be chosen by picking randomly two indices i and j.) We regard the sample as a random sample of the intersection points of the lines of H with the line l. It is easy to show that, with high probability, the number of intersection points between any two consecutive sample points (alternatively, the number of intersection points to the left of the leftmost sample point or to the right of the rightmost sample point) is less than cn for some constant c. Let x_0 be the rightmost point in the sample. Below we describe a simple procedure for reporting the k intersection points to the right of x_0 in time $O(n \log n + k)$. By the above remark, the expected running time of this procedure is only $O(n \log n)$. After applying this procedure, we select the rightmost intersection point from the linear number of points that were output. The x-coordinate of this point is the desired R^*.

The reporting of the required intersections is equivalent to the reporting of all pairs (i, j) for which $i < j$ and $W_j - W_i > B$. We do this in stages. In the jth stage, for $j = 0, \ldots, n$, we report all pairs (i, j) such that $i < j$ and $W_j - W_i > B$. At the beginning of the jth stage the values $W_0, \ldots, W_{j-1}$ are already stored in some

balanced binary search tree (which is empty initially). We search in this tree with the value $W_j - B$ and report all pairs (i, j) such that W_i is smaller than $W_j - B$. Next we insert the value W_j into the tree and proceed to the next stage. The cost of the jth stage is clearly $O(\log n + k_j)$, where k_j is the number of pairs reported in this stage, implying a total reporting cost of $O(n \log n + k)$, as claimed.

8. Conclusion. In this paper we have proposed a new approach to geometric optimization problems which is based on expander graphs combined with range-searching techniques and have demonstrated its applicability to several specific problems, including the slope selection problem, the distance selection problem, and the two-line center problem. Our approach can be used instead of the parametric-searching technique or instead of randomized approaches of the sort suggested in [19, 28, 29]. It yields deterministic and rather simple algorithms, avoids the parallelization that is required in parametric searching, and also avoids some of the more complex generic comparisons that standard parametric-searching algorithms tend to generate.

How general is our technique? Roughly speaking, it works well when the critical values of the problem, through which we want to run a binary search, are obtained by interaction between pairs (or triples, or any fixed-size tuples) of the input objects. Rather than constructing all such critical values, we construct expanders on certain subsets of the data items and use their edges to retrieve only a small subset of critical values, thus speeding up the algorithm considerably. The cost of the algorithm is generally dominated by two terms: (i) $O(\log n)$ times the cost of the binary search oracle and (ii) $O(\log n)$ times the cost of the batched range searching that is performed at each stage of the algorithm. Often these two costs are similar, up to a polylogarithmic factor, and then our solution tends to be (more or less) as efficient as the solutions obtained by the previous methods. In fact, part (i) of the cost of our technique is at least as fast as the cost of the other (parametric-searching or randomized) approaches, and can be faster in cases where Cole's improvement cannot be applied in the parametric-searching solution. Inspecting the three main examples given above, we see that (a) in the slope selection problem the range-searching part was the bottleneck (so that we didn't even have to apply our Cole-like improvement); (b) in the two-line center problem the oracle cost was the bottleneck (so we didn't have to use a particularly fast batched range-searching technique); (c) only in the distance selection problem do the two parts of the cost balance each other.

To see what kinds of limitations and/or challenges are imposed by our technique, consider the problem of computing the diameter of a set P of n points in 3-space. The oracle for this problem is rather efficient [10] and can be implemented in deterministic $O(n \log n)$ time (see also [12], [33], and [16]). However, the range searching that seems to be required here is much more expensive: we are given the n points of P and n ranges, each being the exterior of a ball of some fixed radius centered at a point of P, and we want to perform these range-searching queries in batch mode. This seems to be much more expensive than an oracle call (the only techniques we are aware of require time close to $O(n^{4/3})$), so the naive application of our technique seems to be much less efficient than previous solutions. We pose it as an open problem to find an alternative and more efficient range-searching setting for this problem which will make our technique yield a solution with close-to-linear running time. Intuitively, the oracle is so efficient here because it exploits the delicate combinatorial property that the intersection of n congruent balls in 3-space has only linear complexity. So far we seem to lose this property when applying the range searching mentioned above. The

irony is that our approach does not need the oracle at all: assuming all the critical values are induced by expander edges, these values are distances between pairs of points of P, so the diameter must clearly be at least the largest of these values, so no binary search and thus no oracle calls are required.

We finally note that our approach could also be applied to other, nongeometric optimization problems, provided that the search for the optimal value of the parameter can be guided by an appropriate range-searching mechanism, for which the underlying range space has finite VC dimension (see [14, 22] for details). However, we will not elaborate on this possibility; rather, we leave it as another open problem to explore.

Acknowledgments. We wish to thank Noga Alon for several helpful discussions that provided valuable information concerning expanders and their applications, and Pankaj Agarwal for helpful discussions and suggestions concerning the range-searching technique of section 3.

Introduction to Special Section on Quantum Computation

The rapid evolution of computers in the half century since their invention has resulted in dramatically smaller and faster computers. However, from a computational point of view, all these computers look alike; for example, they are built out of simple logic gates. A fundamental thesis of computer science---the modern form of the Church--Turing thesis---asserts that this is inevitable in a deep sense. Any computer can be simulated with at most a polynomial factor slowdown by a probabilistic Turing machine. Quantum computation poses the first credible challenge to this thesis. It goes back to a suggestion by Feynman [4], who pointed out that there appears to be no efficient way of simulating a quantum mechanical system on a computer, and suggested that, perhaps, a computer based on quantum physical principles might be able to carry out the simulation efficiently. Two formal models for quantum computers---the quantum Turing machine [2] and quantum computational networks [3] ---were defined by Deutsch.

The first three papers in this issue describe efficient quantum algorithms for computational tasks that we do not know how to solve classically. In "Quantum Complexity Theory," Bernstein and Vazirani give the first formal evidence that quantum computers violate the modern form of the Church--Turing thesis. They show that a certain problem---the recursive Fourier sampling problem---can be solved in polynomial time on a quantum Turing machine, but relative to an oracle, requires superpolynomial time on a classical probabilistic Turing machine. Simon, in the paper "On the Power of Quantum Computation" introduces a fundamental projection technique and uses it to design an efficient quantum algorithm to determine whether a certain type of function is 2-1 or 1-1. He further shows that, relative to an oracle, this problem requires exponential time on a classical probabilistic Turing machine. In the paper "Polynomial-Time Algorithms for Prime Factorization and Discrete Logarithms on a Quantum Computer," Shor gives remarkable polynomial time quantum algorithms for two of the most famous problems in computer science: factoring and discrete log. Since the computational hardness of these problems is the basis of several famous cryptosystems, Shor's paper very dramatically underlines the power of quantum computers.

To understand the computational power of quantum computers, it is helpful to consider a quantum mechanical system of n particles, each of which can be in one of two states, labeled $|0\rangle$ and $|1\rangle$. If this were a classical system, then its instantaneous state could be described by n bits. However, in quantum physics, the system is allowed to be in a linear superposition of configurations, and indeed the instantaneous state of the system is described by a unit vector in the 2^n dimensional vector space, whose basis vectors correspond to all the 2^n classical configurations. Therefore, to describe the instantaneous state of the system, we must specify 2^n complex numbers. Nature must update 2^n complex numbers at each instant to evolve the system in time. This is an extraordinary amount of effort, since even for $n = 200$, 2^n is larger than estimates of the number of elementary particles in the visible universe.

Nonetheless, there are limits to the power of quantum computers. In "Strengths and Weaknesses of Quantum Computing," Bennett, Bernstein, Brassard, and Vazirani show that, relative to a random oracle, with probability 1, the class *NP* cannot be solved on a quantum Turing machine in time $o(2^{n/2})$. This bound is tight, since recent work of Grover [5] has shown how to accept any language in *NP* in time $O(2^{n/2})$ on a quantum Turing machine.

Quantum computers are necessarily time reversible. Indeed, Bennett's work [1] on reversible computation inspired early work on quantum computation that preceded Feynman's paper [4]. The reversibility requirement makes it quite complex to implement even basic computational primitives such as looping or composition. In "Quantum Complexity Theory," Bernstein and Vazirani show how to implement quantum programming primitives and give a construction for an efficient universal quantum Turing machine. The structure of the universal quantum Turing machine is quite simple: it consists of a deterministic Turing machine with a single "quantum coin flip." In "Quantum Computability," Adleman, DeMarrais, and Huang greatly simplify this further by showing that a very simple type of coin flip is sufficient---a rotation by an angle θ such that $\sin\theta = 3/5$.

Making quantum computers robust against noise and decoherence is an important and challenging problem. In "Stabilization of Quantum Computations by Symmetrization," Barenco, Berthiaume, Deutsch, Ekert, Jozsa, and Macchiavello show how to use the quantum watchdog effect to stabilize a quantum computation against noise. Their method is based on running several copies of the quantum computer in parallel and projecting its state into the symmetric subspace at frequent intervals. They show that the quantum watchdog effect results in the suppression of errors that lie outside the symmetric subspace.

Quantum computation touches upon the foundations of both computer science and quantum physics. It is not unlikely that the issues raised by quantum computation will stimulate further research into the foundations of quantum physics.

I wish to express my gratitude to several people who made this special section possible. Oded Goldreich acted as editor for two of the papers in the issue and dealt with them with his characteristic efficiency and judgment. The editorial staff at SIAM, most notably Lisa Dougherty, Beth Gallagher, Deidre Wunderlich, and Sam Young, were extremely helpful, patient, and resourceful. Finally, I would like to thank a number of referees whose careful and timely reviews were critical to putting together this issue.

QUANTUM COMPLEXITY THEORY*

ETHAN BERNSTEIN† AND UMESH VAZIRANI‡

Abstract. In this paper we study quantum computation from a complexity theoretic viewpoint. Our first result is the existence of an efficient universal quantum Turing machine in Deutsch's model of a quantum Turing machine (QTM) [Proc. Roy. Soc. London Ser. A, 400 (1985), pp. 97–117]. This construction is substantially more complicated than the corresponding construction for classical Turing machines (TMs); in fact, even simple primitives such as looping, branching, and composition are not straightforward in the context of quantum Turing machines. We establish how these familiar primitives can be implemented and introduce some new, purely quantum mechanical primitives, such as changing the computational basis and carrying out an arbitrary unitary transformation of polynomially bounded dimension.

We also consider the precision to which the transition amplitudes of a quantum Turing machine need to be specified. We prove that $O(\log T)$ bits of precision suffice to support a T step computation. This justifies the claim that the quantum Turing machine model should be regarded as a discrete model of computation and not an analog one.

We give the first formal evidence that quantum Turing machines violate the modern (complexity theoretic) formulation of the Church–Turing thesis. We show the existence of a problem, relative to an oracle, that can be solved in polynomial time on a quantum Turing machine, but requires superpolynomial time on a bounded-error probabilistic Turing machine, and thus not in the class **BPP**. The class **BQP** of languages that are efficiently decidable (with small error-probability) on a quantum Turing machine satisfies $\mathbf{BPP} \subseteq \mathbf{BQP} \subseteq \mathbf{P}^{\sharp\mathbf{P}}$. Therefore, there is no possibility of giving a mathematical proof that quantum Turing machines are more powerful than classical probabilistic Turing machines (in the unrelativized setting) unless there is a major breakthrough in complexity theory.

1. Introduction.

Just as the theory of computability has its foundations in the Church–Turing thesis, computational complexity theory rests upon a modern strengthening of this thesis, which asserts that any "reasonable" model of computation can be *efficiently* simulated on a probabilistic Turing machine (an efficient simulation is one whose running time is bounded by some polynomial in the running time of the simulated machine). Here, we take reasonable to mean in principle physically realizable. Some models of computation, though interesting for other reasons, do not meet this criterion. For example, it is clear that computers that operate on arbitrary length words in unit time or that exactly compute with infinite precision real numbers are not realizable. It has been argued that the TM (actually, the polynomial time equivalent cellular automaton model) is the inevitable choice once we assume that we can implement only finite precision computational primitives. Given the widespread belief that $\mathbf{NP} \not\subseteq \mathbf{BPP}$, this would seem to put a wide range of im-

portant computational problems (the **NP**-hard problems) well beyond the capability of computers.

However, the TM fails to capture all physically realizable computing devices for a fundamental reason: the TM is based on a classical physics model of the universe, whereas current physical theory asserts that the universe is quantum physical. Can we get inherently new kinds of (discrete) computing devices based on quantum physics? Early work on the computational possibilities of quantum physics [6] asked the opposite question: does quantum mechanics' insistence on unitary evolution restrict the class of efficiently computable problems? They concluded that as far as deterministic computation is concerned, the only additional constraint imposed by quantum mechanics is that the computation must be reversible, and therefore by Bennett's [7] work it follows that quantum computers are at least as powerful as classical computers. The issue of the extra computational power of quantum mechanics over probabilistic computers was first raised by Feynman [25] in 1982. In that paper, Feynman pointed out a very curious problem: the natural simulation of a quantum physical system on a probabilistic TM requires an exponential slowdown. Moreover, it is unclear how to carry out the simulation more efficiently. In view of Feynman's observation, we must re-examine the foundations of computational complexity theory, and the complexity-theoretic form of the Church–Turing thesis, and study the computational power of computing devices based on quantum physics.

A precise model of a quantum physical computer—hereafter referred to as the QTM—was formulated by Deutsch [20]. There are two ways of thinking about quantum computers. One way that may appeal to computer scientists is to think of a quantum TM as a quantum physical analogue of a probabilistic TM—it has an infinite tape and a transition function, and the actions of the machine are local and completely specified by this transition function. Unlike probabilistic TMs, QTMs allow branching with complex "probability amplitudes" but impose the further requirement that the machine's evolution be time reversible. This view is elaborated in section 3.2. Another way is to view a quantum computer as effecting a transformation in a space of complex superpositions of configurations. Quantum physics requires that this transformation be unitary. A quantum algorithm may then be regarded as the decomposition of a unitary transformation into a product of unitary transformations, each of which makes only simple local changes. This view is elaborated on in section 3.3. Both formulations play an important role in the study of quantum computation.

One important concern is whether QTMs are really analog devices, since they involve complex transition amplitudes. It is instructive to examine the analogous question for probabilistic TMs. There, one might worry that probabilistic machines are not discrete and therefore not "reasonable," since they allow transition probabilities to be real numbers. However, there is extensive work showing that probabilistic computation can be carried out in a such a way that it is so insensitive to the transition probabilities that they can be allowed to vary arbitrarily in a large range [34, 44, 47]. In this paper, we show in a similar sense that QTMs are discrete devices: the transition amplitudes need only be accurate to $O(\log T)$ bits of precision to support T steps of computation. As Lipton [30] pointed out, it is crucial that the number of bits is $O(\log T)$ and not $O(T)$ (as it was in an early version of this paper), since k bits of precision require pinning down the transition amplitude to one part in 2^k. Since the transition amplitude is some physical quantity such as the angle of a polarizer or the

length of a π pulse, we must not assume that we can specify it to better than one part in some polynomial in T, and therefore the precision must be $O(\log T)$.

Another basic question one may ask is whether it is possible to define the notion of a general purpose quantum computer. In the classical case, this question is answered affirmatively by showing that there is an efficient universal TM. In this paper, we prove that there is an efficient QTM. When given as input the specification of an arbitrary QTM M, an input x to M, a time bound T, and an accuracy ϵ, the universal machine produces a superposition whose Euclidean distance from the time T superposition of M on x is at most ϵ. Moreover, the simulation time is bounded by a polynomial in T, $|x|$, and $\frac{1}{\epsilon}$. Deutsch [20] gave a different construction of a universal QTM. The simulation overhead in Deutsch's construction is exponential in T (the issue Deutsch was interested in was computability, not computational complexity). The structure of the efficient universal QTM constructed in this paper is very simple. It is just a deterministic TM with a single type of quantum operation—a quantum coin flip (an operation that performs a rotation on a single bit). The existence of this simple universal QTM has a bearing on the physical realizability of QTMs in general, since it establishes that it is sufficient to physically realize a simple quantum operation on a single bit (in addition to maintaining coherence and carrying out deterministic operations, of course). Adleman, DeMarrais, and Huang [1] and Solovay and Yao [40] have further clarified this point by showing that quantum coin flips with amplitudes $\frac{3}{5}$ and $\frac{4}{5}$ are sufficient for universal quantum computation.

Quantum computation is necessarily time reversible, since quantum physics requires unitary evolution. This makes it quite complicated to correctly implement even simple primitives such as looping, branching, and composition. These are described in section 4.2. In addition, we also require programming primitives, such as changing the computational basis, which are purely quantum mechanical. These are described in section 5.1. Another important primitive is the ability to carry out any specified unitary transformation of polynomial dimension to a specified degree of accuracy. In section 6 we show how to build a QTM that implements this primitive. Finally, all these pieces are put together in section 7 to construct the universal QTM.

We can still ask whether the QTM is the most general model for a computing device based on quantum physics. One approach to arguing affirmatively is to consider various other reasonable models and to show that the QTM can efficiently simulate each of them. An earlier version of this work [11] left open the question of whether standard variants of a QTM, such as machines with multiple tapes or with modified tape access, are more powerful than the basic model. Yao [46] showed that these models are polynomially equivalent to the basic model, as are quantum circuits (which were introduced in [21]). The efficiency of Yao's simulation has been improved in [10] to show that the simulation overhead is a polynomial with degree independent of the number of tapes. Arguably, the full computational power of quantum physics for discrete systems is captured by the quantum analogue of a cellular automaton. It is still an open question whether a quantum cellular automaton might be more powerful than a QTM (there is also an issue about the correct definition of a quantum cellular automaton). The difficulty has to do with decomposing a unitary transformation that represents many overlapping sites of activity into a product of simple, local unitary transformations. This problem has been solved in the special case of linearly bounded quantum cellular automata [24, 45].

Finally, several researchers have explored the computational power of QTMs. Early work by Deutsch and Jozsa [22] showed how to exploit some inherently quan-

tum mechanical features of QTMs. Their results, in conjunction with subsequent results by Berthiaume and Brassard [12, 13], established the existence of oracles under which there are computational problems that QTMs can solve in polynomial time with certainty, whereas if we require a classical probabilistic TM to produce the correct answer with certainty, then it must take exponential time on some inputs. On the other hand, these computational problems are in **BPP**—the class of problems that can be solved in polynomial time by probabilistic TMs that are allowed to give the wrong answer with small probability. Since **BPP** is widely considered the class of efficiently computable problems, these results left open the question of whether quantum computers are more powerful than classical computers.

In this paper, we give the first formal evidence that quantum Turing machines violate the modern form of the Church–Turing thesis by showing that, relative to an oracle, there is a problem that can be solved in polynomial time on a quantum Turing machine, but cannot be solved in $n^{o(\log n)}$ time on a probabilistic Turing machine with any fixed error probability $< 1/2$. A detailed discussion about the implications of these oracle results is in the introduction of section 8.4. Simon [39] subsequently strengthened our result in the time parameter by proving the existence of an oracle relative to which a certain problem can be solved in polynomial time on a quantum Turing machine, but cannot be solved in less than $2^{n/2}$ steps on a probabilistic Turing machine (Simon's problem is in $\mathbf{NP} \cap \mathbf{co}$–$\mathbf{NP}$ and therefore does not address the nondeterminism issue). More importantly, Simon's paper also introduced an important new technique which was one of the ingredients in a remarkable result proved subsequently by Shor [37]. Shor gave polynomial time quantum algorithms for the factoring and discrete log problems. These two problems have been well studied, and their presumed intractability forms the basis of much of modern cryptography. These results have injected a greater sense of urgency into the actual implementation of a quantum computer. The class **BQP** of languages that are efficiently decidable (with small error-probability) on a quantum Turing machine satisfies $\mathbf{BPP} \subseteq \mathbf{BQP} \subseteq \mathbf{P}^{\#\mathbf{P}}$. This rules out the possibility of giving a mathematical proof that quantum Turing machines are more powerful than classical probabilistic Turing machines (in the unrelativized setting) unless there is a major breakthrough in complexity theory.

It is natural to ask whether QTMs can solve every problem in NP in polynomial time. Bennett, Bernstein, Brassard, and Vazirani [9] give evidence showing the limitations of QTMs. They show that relative to an oracle chosen uniformly at random, with probability 1, the class **NP** cannot be solved on a QTM in time $o(2^{n/2})$. They also show that relative to a permutation oracle chosen uniformly at random, with probability 1, the class $\mathbf{NP} \cap \mathbf{co}$–$\mathbf{NP}$ cannot be solved on a QTM in time $o(2^{n/3})$. The former bound is tight since recent work of Grover [28] shows how to accept the class **NP** relative to any oracle on a quantum computer in time $O(2^{n/2})$.

Several designs have been proposed for realizing quantum computers [17, 23, 31]. A number of authors have argued that there are fundamental problems in building quantum computers, most notably the effects of the decoherence of quantum superpositions or the entanglement of the system with the environment [14, 18, 29, 35, 42]. Very recently, there has been a sequence of important results showing how to implement quantum error-correcting codes and also how to use these codes to make quantum algorithms (quite) robust against the effects of decoherence [16, 38].

Quantum computation touches upon the foundations of both computer science and quantum physics. The nature of quantum physics was clarified by the Einstein–Podolsky–Rosen paradox and Bell's inequalities (discussed in [25]), which demonstrate

the difference between its statistical properties and those of any "classical" model. The computational differences between quantum and classical physics are if anything more striking and can be expected to offer new insights into the nature of quantum physics. For example, one might naively argue that it is impossible to experimentally verify the exponentially large size of the Hilbert space associated with a discrete quantum system, since any observation leads to a collapse of its superposition. However, an experiment demonstrating the exponential speedup offered by quantum computation over classical computation would establish that something like the exponentially large Hilbert space must exist. Finally, it is important, as Feynman pointed out [25], to clarify the computational overhead required to simulate a quantum mechanical system. The simple form of the universal QTM constructed here—the fact that it has only a single nontrivial quantum operation defined on a single bit—suggests that even very simple quantum mechanical systems are capable of universal quantum computation and are therefore hard to simulate on classical computers.

This paper is organized as follows. Section 2 introduces some of the mathematical machinery and notation we will use. In section 3 we introduce the QTM as a natural extension of classical probabilistic TMs. We also show that QTMs need not be specified with an unreasonable amount of precision. In sections 4 and 5 we demonstrate the basic constructions which will allow us to build up large, complicated QTMs in subsequent sections. Many actions which are quite easy for classical machines, such as completing a partially specified machine, running one machine after another, or repeating the operation of a machine a given number of times, will require nontrivial constructions for QTMs. In section 6, we show how to build a single QTM which can carry out any unitary transformation which is provided as input. Then, in section 7, we use this simulation of unitary transformations to build a universal quantum computer. Finally, in section 8 we give our results, both positive and negative, on the power of QTMs.

2. Preliminaries. Let $\mathbf{C}$ denote the field of complex numbers. For $\alpha \in \mathbf{C}$, we denote by α^* its complex conjugate.

Let V be a vector space over $\mathbf{C}$. An inner product over V is a complex function $(\cdot,\cdot)$ defined on $V \times V$ which satisfies the following.

1. $\forall x \in V, (x,x) \geq 0$. Moreover $(x,x) = 0$ iff $x = 0$.
2. $\forall x, y, z \in V, (\alpha x + \beta y, z) = \alpha(x,z) + \beta(y,z)$.
3. $\forall x, y \in V, (x,y) = (y,x)^*$.

The inner product yields a norm given by $\|x\| = (x,x)^{1/2}$. In addition to the triangle inequality $\|x+y\| \leq \|x\| + \|y\|$, the norm also satisfies the Schwarz inequality $\|(x,y)\| \leq \|x\|\|y\|$.

An *inner-product space* is a vector space V together with an inner product $(\cdot,\cdot)$.

An inner-product space $\mathcal{H}$ over $\mathbf{C}$ is a *Hilbert space* if it is complete under the induced norm, where $\mathcal{H}$ is complete if every Cauchy sequence converges. For example, if $\{x_n\}$ is a sequence with $x_n \in \mathcal{H}$ such that $\lim_{n,m\to\infty} \|x_n - x_m\| = 0$, then there is an x in $\mathcal{H}$ with $\lim_{n\to\infty} \|x_n - x\| = 0$.

Given any inner-product space V, each vector $x \in V$ defines a linear functional $x^* : V \to \mathbf{C}$, where $x^*(y) = (x,y)$. The set of such linear functionals is also an inner-product space and will be referred to as the *vector dual* of V and denoted V^*. In the case that V is a Hilbert space, V^* is called the *dual* of V and is the set of all continuous linear functionals on V, and the dual space V^* is also a Hilbert space.

In Dirac's notation, a vector from an inner-product space V is identified using the "ket" notation $|\ \rangle$, with some symbol(s) placed inside to distinguish that vector

from all others. We denote elements of the dual space using the "bra" notation $\langle\ |$. Thus the dual of $|\phi\rangle$ is $\langle\phi|$, and the inner product of vectors $|\psi\rangle$ and $|\phi\rangle$, which is the same as the result of applying functional $\langle\psi|$ to the vector $|\phi\rangle$, is denoted by $\langle\psi|\phi\rangle$.

Let U be a linear operator on V. In Dirac's notation, we denote the result of applying U to $|\phi\rangle$ as $U|\phi\rangle$. U also acts as a linear operator on the dual space V^* mapping each linear functional $\langle\phi|$ of the dual space to the linear functional which applies U followed by $\langle\phi|$. We denote the result of applying U to $\langle\phi|$ by $\langle\phi|U$.

For any inner-product space V, we can consider the usual vector space basis or Hamel basis $\{|\theta_i\rangle\}_{i\in I}$. Every vector $|\phi\rangle \in V$ can be expressed as a finite linear combination of basis vectors. In the case that $\||\theta_i\rangle\| = 1$ and $(\langle\theta_i|, |\theta_j\rangle) = 0$ for $i \neq j$, we refer to the basis as an orthonormal basis. With respect to an orthonormal basis, we can write each vector $|\phi\rangle \in V$ as $|\phi\rangle = \sum_{i\in I} \alpha_i|\theta_i\rangle$, where $\alpha_i = \langle\theta_i|\phi\rangle$. Similarly each dual vector $\langle\phi| \in V^*$ can be written as $\langle\phi| = \sum_{i\in I} \beta_i\langle\theta_i|$, where $\alpha_i = \langle\phi|\theta_i\rangle$. Thus each element $|\phi\rangle \in V$ can be thought of as a column vector of the α_i's, and each element $\langle\phi| \in V$ can be thought of as a row vector of the β_i's. Similarly each linear operator U may be represented by the set of *matrix elements* $\{\langle\theta_i|U|\theta_j\rangle\}_{i,j\in I}$, arranged in a "square" matrix with rows and columns both indexed by I. Then, the "column" of U with index i is the vector $U|\theta_i\rangle$, and the "row" of U with index i is the dual vector $\langle\theta_i|U$.

For a Hilbert space $\mathcal{H}$, $\{|\theta_i\rangle\}_{i\in I}$ is a *Hilbert space basis* for $\mathcal{H}$ if it is a maximal set of orthonormal vectors in $\mathcal{H}$. Every vector $|\phi\rangle \in \mathcal{H}$ can be expressed as the limit of a sequence of vectors, each of which can be expressed as a finite linear combination of basis vectors.

Given a linear operator U in an inner product space, if there is a linear operator U^* which satisfies $\langle U^*\phi|\psi\rangle = \langle\phi|U\psi\rangle$ for all ϕ, ψ, then U^* is called the *adjoint* or *Hermitian conjugate* of U. If a linear operator in an inner product space has an adjoint, it is unique. The adjoint of a linear operator in a Hilbert space or in a finite-dimensional inner product space always exists. It is easy to see that if the adjoints of U_1 and U_2 exist, then $(U_1 + U_2)^* = U_1^* + U_2^*$ and $(U_1U_2)^* = U_2^*U_1^*$. An operator U is called *Hermitian* or *self-adjoint* if it is its own adjoint ($U^* = U$). The linear operator U is called *unitary* if its adjoint exists and satisfies $U^*U = UU^* = I$.

If we represent linear operators as "square" matrices indexed over an orthonormal basis, then U^* is represented by the conjugate transpose of U. So, in Dirac's notation we have the convenient identity $\langle\phi|U^*|\psi\rangle = (\langle\psi|U|\phi\rangle)^*$.

Recall that if the inner-product space V is the tensor product of two inner-product spaces V_1, V_2, then for each pair of vectors $|\phi_1\rangle \in V_1, |\phi_2\rangle \in V_2$ there is an associated tensor product $|\phi_1\rangle \otimes |\phi_2\rangle$ in V. In Dirac's notation, we denote $|\phi_1\rangle \otimes |\phi_2\rangle$ as $|\phi_1\rangle|\phi_2\rangle$.

The *norm* of U is defined as $\|U\| = \sup_{\||x\rangle\|=1} \|U|x\rangle\|$. A linear operator is called *bounded* if $\|U\|$ is finite. We will freely use the following standard facts about bounded linear operators:

$$\text{if } U^* \text{ exists then } \|U^*\| = \|U\|, \tag{2.1}$$

$$\|U_1U_2\| \leq \|U_1\|\|U_2\|, \tag{2.2}$$

$$\|U_1\| - \|U_2\| \leq \|U_1 + U_2\| \leq \|U_1\| + \|U_2\|. \tag{2.3}$$

Notice that a unitary operator U must satisfy $\|U\| = 1$. We will often use the following fact which tells us that if we approximate a series of unitary transformations with other unitary transformations, the error increases only additively.

FACT 2.1. *If U_1, U_1', U_2, U_2' are unitary transformations on an inner-product space, then*

$$\|U_1'U_2' - U_1U_2\| \;\leq\; \|U_1' - U_1\| + \|U_2' - U_2\|.$$

This fact follows from statements (2.3) and (2.2) above, since

$$\begin{aligned} \|U_1'U_2' - U_1U_2\| &\leq \|U_1'U_2' - U_1U_2'\| \;+\; \|U_1U_2' - U_1U_2\| \\ &\leq \|U_1' - U_1\|\|U_2'\| \;+\; \|U_1\|\|U_2' - U_2\|. \end{aligned}$$

2.1. Miscellaneous notation. If d is a direction $\in \{L, R\}$, then $\bar{d}$ is the opposite of d.

Given two probability distributions $\mathcal{P}_1$ and $\mathcal{P}_2$ over the same domain I, the *total variation distance* between $\mathcal{P}_1$ and $\mathcal{P}_2$ is equal to $\frac{1}{2}\sum_{i\in I}|\mathcal{P}_1(i) - \mathcal{P}_2(i)|$.

We will refer to the cardinality of a set S as $\mathrm{card}(S)$ and the length of a string x as $|x|$.

3. QTMs.

3.1. A physics-like view of randomized computation. Before we formally define a QTM, we introduce the necessary terminology in the familiar setting of probabilistic computation. As a bonus, we will be able to precisely locate the point of departure in the definition of a QTM.

Quantum mechanics makes a distinction between a system's evolution and its measurement. In the absence of measurement, the time evolution of a probabilistic TM can be described by a sequence of probability distributions. The distribution at each step gives the likelihood of each possible configuration of the machine. We can also think of the probabilistic TM as specifying an infinite-dimensional stochastic matrix[1] M whose rows and columns are indexed by configurations. Each column of this matrix gives the distribution resulting from the corresponding configuration after a single step of the machine. If we represent the probability distribution at one time step by a vector $|v\rangle$, then the distribution at the next step is given by the product $M|v\rangle$. In quantum physics terminology, we call the distribution at each step a "linear superposition" of configurations, and we call the coefficient of each configuration (its probability) its "amplitude." The stochastic matrix is referred to as the "time evolution operator."

Three comments are in order. First, not every stochastic matrix has an associated probabilistic TM. Stochastic matrices obtained from probabilistic TM are finitely specified and map each configuration by making only local changes to it. Second, the support of the superposition can be exponential in the running time of the machine. Third, we need to constrain the entries allowed in the transition function of our probabilistic TM. Otherwise, it is possible to smuggle hard-to-compute quantities into the transition amplitudes, for instance by letting the ith bit indicate whether the ith deterministic TM halts on a blank tape. A common restriction is to allow amplitudes only from the set $\{0, \frac{1}{2}, 1\}$. More generally, we might allow any real number in the interval $[0, 1]$ which can be computed by some deterministic algorithm to within any desired 2^{-n} in time polynomial in n. It is easily shown that the first possibility is computationally no more restrictive than the second.

[1] Recall that a matrix is stochastic if it has nonnegative real entries that sum to 1 in each column.

Returning to the evolution of the probabilistic TM, when we observe the machine after some number of steps, we do not see the linear superposition (probability distribution) but just a sample from it. If we "observe" the entire machine, then we see a configuration sampled at random according to the superposition. The same holds if we observe just a part of the machine. In this case, the superposition "collapses" to one that corresponds to the probability distribution conditioned on the value observed. By the linearity of the law of alternatives,[2] the mere act of making observations at times earlier than t does not change the probability for each outcome in an observation at time t. So, even though the unobserved superposition may have support that grows exponentially with running time, we need only keep track of a constant amount of information when simulating a probabilistic TM which is observed at each step. The computational possibilities of quantum physics arise out of the fact that observing a quantum system changes its later behavior.

3.2. Defining a QTM. Our model of randomized computation is already surprisingly close to Deutsch's model of a QTM. The major change that is required is that in quantum physics, the amplitudes in a system's linear superposition and the matrix elements in a system's time evolution operator are allowed to be complex numbers rather than just positive reals. When an observation is made, the probability associated with each configuration is not the configuration's amplitude in the superposition, but rather the squared magnitude of its amplitude. So instead of always having a linear superposition whose entries sum to 1, we will now always have a linear superposition whose Euclidean length is 1. This means that QTMs must be defined so that their time evolution preserves the Euclidean length of superpositions.

Making these changes to our model, we arrive at the following definitions.

For completeness, let us recall the definition of a deterministic TM. There are many standard variations to the definition of a deterministic TM, none of which affect their computational power. In this paper we will make our choices consistent with those in Deutsch's paper [20]: we consider TMs with a two-way infinite tape and a single tape head which must move left or right one square on each step. We also give standard definitions for interpreting the input, output, and running time of a deterministic TM. Note that although we usually restrict our discussion to TMs with tape head movements $\{L, R\}$, we will sometimes consider *generalized* TMs with tape head movements $\{L, N, R\}$ (where N means no head movement).

DEFINITION 3.1. *A* deterministic TM *is defined by a triplet* (Σ, Q, δ)*, where* Σ *is a finite alphabet with an identified blank symbol* $\#$*,* Q *is a finite set of states with an identified initial state* q_0 *and final state* $q_f \neq q_0$*, and* δ*, the* deterministic transition function*, is a function*

$$\delta \ : \ Q \times \Sigma \rightarrow \Sigma \times Q \times \{L, R\}.$$

The TM has a two-way infinite tape of cells indexed by $\mathbf{Z}$ *and a single read/write tape head that moves along the tape.*

A configuration *or* instantaneous description *of the TM is a complete description of the contents of the tape, the location of the tape head, and the state* $q \in Q$ *of the finite control. At any time only a finite number of tape cells may contain nonblank symbols.*

[2] The law of alternatives says exactly that the probability of an event A doesn't change if we first check to see whether event B has happened, $P(A) = P(A|B)P(B) + P(A|\overline{B})P(\overline{B})$.

For any configuration c of TM M, the successor configuration c' is defined by applying the transition function to the current state q and currently scanned symbol σ in the obvious way. We write $c \to_M c'$ to denote that c' follows from c in one step.

By convention, we require that the initial configuration *of M to satisfies the following conditions: the tape head is in cell 0, called the* start cell*, and the machine is in state q_0. An initial configuration has* input $x \in (\Sigma - \#)^*$ *if x is written on the tape in positions $0, 1, 2, \ldots$, and all other tape cells are blank. The TM* halts *on input x if it eventually enters the final state q_f. The number of steps a TM takes to halt on input x is its* running time *on input x. If a TM halts then its* output *is the string in Σ^* consisting of those tape contents from the leftmost nonblank symbol to the rightmost nonblank symbol, or the empty string if the entire tape is blank. A TM which halts on all inputs therefore computes a function from $(\Sigma - \#)^*$ to Σ^*.*

We now give a slightly modified version of the definition of a QTM provided by Deutsch [20]. As in the case of probabilistic TM, we must limit the transition amplitudes to efficiently computable numbers. Adleman, DeMarrais, and Huang [1] and Solovay and Yao [40] have separately shown that further restricting QTMs to rational amplitudes does not reduce their computational power. In fact, they have shown that the set of amplitudes $\{0, \pm\frac{3}{5}, \pm\frac{4}{5}, 1\}$ are sufficient to construct a universal QTM. We give a definition of the computation of a QTM with a particular string as input, but we defer discussing what it means for a QTM to halt or give output until section 3.5. Again, we will usually restrict our discussion to QTMs with tape head movements $\{L, R\}$ but will sometimes consider "generalized" QTMs with tape head movements $\{L, N, R\}$. As we pointed out in the introduction, unlike in the case of deterministic TMs, these choices do make a greater difference in the case of QTMs. This point is also discussed later in the paper.

DEFINITION 3.2. *Call $\tilde{\mathbf{C}}$ the set consisting of $\alpha \in \mathbf{C}$ such that there is a deterministic algorithm that computes the real and imaginary parts of α to within 2^{-n} in time polynomial in n.*

A QTM M is defined by a triplet (Σ, Q, δ), where Σ is a finite alphabet with an identified blank symbol $\#$, Q is a finite set of states with an identified initial state q_0 and final state $q_f \neq q_0$, and δ, the quantum transition function*, is a function*

$$\delta \quad : \quad Q \times \Sigma \to \tilde{\mathbf{C}}^{\Sigma \times Q \times \{L,R\}}.$$

The QTM has a two-way infinite tape of cells indexed by $\mathbf{Z}$ and a single read/write tape head that moves along the tape. We define configurations, initial configurations, and final configurations exactly as for deterministic TMs.

Let $\mathcal{S}$ be the inner-product space of finite complex linear combinations of configurations of M with the Euclidean norm. We call each element $\phi \in \mathcal{S}$ a superposition *of M. The QTM M defines a linear operator $U_M : \mathcal{S} \to \mathcal{S}$, called the* time evolution operator *of M, as follows: if M starts in configuration c with current state p and scanned symbol σ, then after one step M will be in superposition of configurations $\psi = \sum_i \alpha_i c_i$, where each nonzero α_i corresponds to a transition $\delta(p, \sigma, \tau, q, d)$, and c_i is the new configuration that results from applying this transition to c. Extending this map to the entire space $\mathcal{S}$ through linearity gives the linear time evolution operator U_M.*

Note that we defined $\mathcal{S}$ by giving an orthonormal basis for it: namely, the configurations of M. In terms of this standard basis, each superposition $\psi \in \mathcal{S}$ may be represented as a vector of complex numbers indexed by configurations. The time evolution operator U_M may be represented by the (countable dimensional) "square"

matrix with columns and rows indexed by configurations where the matrix element from column c and row c' gives the amplitude with which configuration c leads to configuration c' in a single step of M.

For convenience, we will overload notation and use the expression $\delta(p, \sigma, \tau, q, d)$ to denote the amplitude in $\delta(p, \sigma)$ of $|\tau\rangle|q\rangle|d\rangle$.

The next definition provides an extremely important condition that QTMs must satisfy to be consistent with quantum physics. We have introduced this condition in the form stated below for expository purposes. As we shall see later (in section 3.3), there are other equivalent formulations of this condition that are more familiar to quantum physics.

DEFINITION 3.3. *We will say that M is* well formed *if its time evolution operator U_M preserves Euclidean length.*

Wellformedness is a necessary condition for a QTM to be consistent with quantum physics. As we shall see in the next subsection, wellformedness is equivalent to unitary time evolution, which is a fundamental requirement of quantum physics.

Next, we define the rules for observing the QTM M. For those familiar with quantum mechanics, we should state that the definition below restricts the measurements to be in the computational basis of $\mathcal{S}$. This is because the actual basis in which the measurement is performed must be efficiently computable, and therefore we may, without loss of generality, perform the rotation to that basis during the computation itself.

DEFINITION 3.4. *When QTM M in superposition $\psi = \sum_i \alpha_i c_i$ is observed or measured, configuration c_i is seen with probability $|\alpha|^2$. Moreover, the superposition of M is updated to $\psi' = c_i$.*

We may also perform a partial measurement*, say only on the first cell of the tape. In this case, suppose that the first cell may contain the values* 0 *or* 1*, and suppose the superposition was $\psi = \sum_i \alpha 0_i c0_i + \sum_i \alpha 1_i c1_i$, where the $c0_i$ are those configurations that have a* 0 *in the first cell, and $c1_i$ are those configurations that have a* 1 *in the first cell. Measuring the first cell results in $\Pr[0] = \sum_i |\alpha 0_i|^2$. Moreover, if a* 0 *is observed, the new superposition is given by $\frac{1}{\sqrt{\Pr[0]}} \sum_i \alpha 0_i c0_i$, i.e., the part of the superposition consistent with the answer, with amplitudes scaled to give a unit vector.*

Note that the wellformedness condition on a QTM simply says that the time evolution operator of a QTM must satisfy the condition that in each successive superposition, the sum of the probabilities of all possible configurations must be 1.

Notice that a QTM differs from a classical TM in that the "user" has decisions beyond just choosing an input. A priori it is not clear whether multiple observations might increase the power of QTMs This point is discussed in more detail in [10], and there it is shown that one may assume without loss of generality that the QTM is only observed once. Therefore in this paper we shall make simplifying assumptions about the measurement of the final result of the QTM. The fact that these assumptions do not result in any loss of generality follows from the results in [10].

In general, the "output" of a QTM is a sample from a probability distribution. We can regard two QTMs as functionally equivalent, for practical purposes, if their output distributions are sufficiently close to each other. A formal definition of what it means for one QTM to simulate another is also given in [10]. As in the case of classical TMs, the formal definition is quite unwieldy. In the actual constructions, it will be easy to see in what sense they are simulations. Therefore we will not replicate the formal definitions from [10] here. We give a more informal definition below.

DEFINITION 3.5. *We say that QTM M' simulates M with slowdown f with accuracy ϵ if the following holds: let $\mathcal{D}$ be a distribution such that observing M on input x after T steps produces a sample from $\mathcal{D}$. Let $\mathcal{D}'$ be a distribution such that observing M' on input x after $f(T)$ steps produces a sample from $\mathcal{D}'$. Then we say that M' simulates M with accuracy ϵ if $|\mathcal{D} - \mathcal{D}'| \leq \epsilon$.*

We will sometimes find it convenient to measure the accuracy of a simulation by calculating the Euclidean distance between the target superposition and the superposition achieved by the simulation. The following shows that the variation distance between the resulting distributions is at most four times this Euclidean distance.

LEMMA 3.6. *Let $\phi, \psi \in \mathcal{S}$ such that $\|\phi\| = \|\psi\| = 1$, and $\|\phi - \psi\| \leq \epsilon$. Then the total variation distance between the probability distributions resulting from measurements of ϕ and ψ is at most 4ϵ.*

Proof. Let $\phi = \sum_i \alpha_i |i\rangle$ and $\psi = \sum_i \beta_i |i\rangle$. Observing ϕ gives each $|i\rangle$ with probability $|\alpha_i|^2$, while observing ψ gives each $|i\rangle$ with probability $|\beta_i|^2$. Let $\pi = \phi - \psi = \sum_i (\alpha_i - \beta_i)|i\rangle$. Then the latter probability $|\beta_i|^2$ can be expressed as

$$\beta_i \beta_i^* = (\alpha_i + \gamma_i)(\alpha_i + \gamma_i)^* = |\alpha_i|^2 + |\gamma_i|^2 + \alpha_i \gamma_i^* + \gamma_i \alpha_i^*.$$

Therefore, the total variation distance between these two distributions is at most

$$\sum_i \|\gamma_i\|^2 + |\alpha_i \gamma_i^*| + |\gamma_i \alpha_i^*| \leq \sum_i |\gamma_i|^2 + \langle \gamma || \alpha \rangle + \langle \alpha || \gamma \rangle \leq \epsilon^2 + 2\|\alpha\|\|\gamma\| \leq \epsilon^2 + 2\epsilon.$$

Finally, note that since we have unit superpositions, we must have $\epsilon \leq 2$. ∎

3.3. Quantum computing as a unitary transformation. In the preceding sections, we introduced QTMs as extensions of the notion of probabilistic TMs. We stated there that a QTM is well formed if it preserves the norm of the superpositions. In this section, we explore a different, and extremely useful, alternative view of QTMs: in terms of properties of the time evolution operator. We prove that a QTM is well formed iff its time evolution is unitary. Indeed unitary time evolution is a fundamental constraint imposed by quantum mechanics, and we chose to state the wellformedness condition in the last section mainly for expository purposes.

Understanding unitary evolution from an intuitive point of view is quite important to comprehending the computational possibilities of quantum mechanics. Let us explore this in the setting of a quantum mechanical system that consists of n parts, each of which can be in one of two states labeled $|0\rangle$ and $|1\rangle$ (these could be n particles, each with a spin state). If this were a classical system, then at any given instant it would be in a single configuration which could be described by n bits. However, in quantum physics, the system is allowed to be in a linear superposition of configurations, and indeed the instantaneous state of the system is described by a unit vector in the 2^n-dimensional vector space, whose basis vectors correspond to all the 2^n configurations. Therefore, to describe the instantaneous state of the system, we must specify 2^n complex numbers. The implications of this are quite extraordinary: even for a small system consisting of 200 particles, nature must keep track of 2^{200} complex numbers just to "remember" its instantaneous state. Moreover, it must update these numbers at each instant to evolve the system in time. This is an extravagant amount of effort, since 2^{200} is larger than the standard estimates on the number of particles in the visible universe. So if nature puts in such extravagant amounts of effort to evolve even a tiny system at the level of quantum mechanics, it would make sense that we should design our computers to take advantage of this.

However, unitary evolution and the rules for measurement in quantum mechanics place significant constraints on how these features can be exploited for computational purposes. One of the basic primitives that allows these features to be exploited while respecting the unitarity constraints is the discrete fourier transform—this is described in more detail in section 8.4. Here we consider some very simple cases: one interesting phenomenon supported by unitary evolution is the interference of computational paths. In a probabilistic computation the probability of moving from one configuration to another is the sum of the probabilities of each possible path from the former to the latter. The same is true of the probability amplitudes in quantum computation but not necessarily of the probabilities of observations. Consider, for example, applying the transformation

$$U = \begin{pmatrix} \frac{1}{\sqrt{2}} & \frac{1}{\sqrt{2}} \\ \frac{1}{\sqrt{2}} & -\frac{1}{\sqrt{2}} \end{pmatrix}$$

twice in sequence to the same tape cell which at first contains the symbol 0. If we observe the cell after the first application of U, we see either symbol with probability $\frac{1}{2}$. If we then observe after applying U a second time, the symbols are again equally likely. However, since U^2 is the identity, if we only observe at the end, we see a 0 with probability 1. So, even though there are two computational paths that lead from the initial 0 to a final symbol 1, they interfere destructively cancelling each other out. The two paths leading to a 0 interfere constructively so that even though both have probability $\frac{1}{4}$, when we observe twice we have probability 1 of reaching 0 if we observe only once. Such a boosting of probabilities, by an exponential factor, lies at the heart of the QTM's advantage over a probabilistic TM in solving the Fourier sampling problem.

Another constraint inherent in computation using unitary transformations is reversibility. We show in section 4.2 that for any QTM M there is a corresponding QTM M^R, whose time evolution operator is the conjugate transpose of the time evolution operator of M, and therefore undoes the actions of M. Sections 3.5 and 4.1 are devoted to defining the machinery to deal with this feature of QTMs.

We prove below in Appendix A that a QTM is well formed if its time evolution operator is unitary. This establishes that our definition (which did not mention unitary evolution for expository purposes) does satisfy the fundamental constraint imposed by quantum mechanics—unitary evolution. Actually one could still ask why this is consistent with quantum mechanics, since the space $\mathcal{S}$ of *finite* linear combinations of configurations is not a Hilbert space since it is not complete. To see that this doesn't present a problem, notice that $\mathcal{S}$ is a dense subset of the Hilbert space $\mathcal{H}$ of all (not just finite) linear combinations of configurations. Moreover, any unitary operator U on $\mathcal{S}$ has a unique extension $\hat{U}$ to $\mathcal{H}$; and $\hat{U}$ is unitary and its inverse is $\hat{U}^*$. The proof is quite simple. Let $\hat{U}$ and $\hat{U}^*$ be the continuous extensions of U and U^* to $\mathcal{H}$. Let $x, y \in \mathcal{H}$. Then there are sequences $\{x_n\}, \{y_n\} \in \mathcal{S}$ such that $x_n \to x$ and $y_n \to y$. Moreover, for all n, $(Ux_n, y_n) = (x_n, U^* y_n)$. Taking limits, we get that $(\hat{U}x, y) = (x, \hat{U}^* y)$, as desired.

As an aside, we should briefly mention that another resolution of this issue is achieved by following Feynman [26], who suggested that if we use a quantum mechanical system with Hamiltonian $U + U^*$, then the resulting system has a local, time invariant Hamiltonian. It is easy to probabilistically recover the computation of the original system from the computation of the new one.

It is interesting to note that the following theorem would not be true if we defined QTMs using a one-way infinite tape. In that case, the trivial QTM which always moves its tape head right would be well formed, but its time evolution would not be unitary since its start configuration could not be reached from any other configuration.

THEOREM A.5. *A QTM is well formed iff its time evolution operator is unitary.*

3.4. Precision required in a QTM. One important concern is whether QTMs are really analog devices, since they involve complex transition amplitudes. The issue here is how accurately these transition amplitudes must be specified to ensure that the correctness of the computation is not compromised. In an earlier version of this paper, we showed that $T^{O(1)}$ bits of precision are sufficient to correctly carry out T steps of computation to within accuracy ϵ for any constant ϵ. Lipton [30] pointed out that for the device to be regarded as a discrete device, we must require that its transition amplitudes be specified to at most one part in $T^{O(1)}$ (as opposed to accurate to within $T^{O(1)}$ bits of precision). This is because the transition amplitude represents some physical quantity such as the angle of a polarizer or the length of a π pulse, and we must not assume that we can specify it to better than one part in some polynomial in T, and therefore the number of bits of precision must be $O(\log T)$. This is exactly what we proved shortly after Lipton's observation, and we present that proof in this section.

The next theorem shows that because of the unitary time evolution errors in the superposition made over a sequence of steps will, in the worst case, only add.

THEOREM 3.7. *Let U be the time evolution operator of a QTM M and $T > 0$. If $|\phi_0\rangle, |\tilde{\phi}_0\rangle, \ldots, |\phi_T\rangle, |\tilde{\phi}_T\rangle$ are superpositions of U such that*

$$\| |\phi_i\rangle - |\tilde{\phi}_i\rangle \| \ \leq \ \epsilon,$$

$$|\phi_i\rangle \ = \ U|\tilde{\phi}_{i-1}\rangle,$$

then $\| |\tilde{\phi}_T\rangle - U^T|\phi_0\rangle \| \leq T\epsilon$.

Proof. Let $|\psi_i\rangle = |\tilde{\phi}_i\rangle - |\phi_i\rangle$. Then we have

$$|\tilde{\phi}_T\rangle \ = \ U^T|\phi_0\rangle + U^T|\psi_0\rangle + U^{T-1}|\psi_1\rangle + \cdots + |\psi_T\rangle$$

The theorem follows by the triangle inequality since U is unitary and $\| |\psi_i\rangle \| \leq \epsilon$. □

DEFINITION 3.8. *We say that QTMs M and M' are* ϵ-close *if they have the same state set and alphabet and if the difference between each pair of corresponding transition amplitudes has magnitude at most ϵ. Note that M and M' can be ϵ-close even if one or both are not well formed.*

The following theorem shows that two QTMs which are close in the above sense give rise to time evolution operators which are close to each other, even if the QTMs are not well formed. As a simple consequence, the time evolution operator of a QTM is always bounded, even if the QTM is not well formed.

THEOREM 3.9. *If QTMs M and M' with alphabet Σ and state set Q are ϵ-close, then the difference in their time evolutions has norm at most* 2 $\text{card}(\Sigma)\ \text{card}(Q)\epsilon$. *Moreover, this statement holds even if one or both of the machines are not well formed.*

Proof. Let QTMs M and M' with alphabet Σ and state set Q be given which are ϵ-close. Let U be the time evolution of M, and let U' be the time evolution of M'.

Now, consider any unit length superposition of configurations $|\phi\rangle = \sum_j \alpha_j |c_j\rangle$. Then we can express the difference in the machines' operations on $|\phi\rangle$ as follows:

$$U|\phi\rangle - U'|\phi\rangle = \sum_j \left(\sum_{i \in P(j)} (\lambda_{i,j} - \lambda'_{i,j})\alpha_i \right) |c_j\rangle,$$

where $P(j)$ is the set of i such that configuration c_i can lead to c_j in a single step of M or M' and where $\lambda_{i,j}$ and $\lambda'_{i,j}$ are the amplitudes with which c_i leads to c_j in M and M'.

Applying the triangle inequality and the fact that the square of the sum of n reals is at most n times the sum of their squares, we have

$$\begin{aligned} \|U|\phi\rangle - U'|\phi\rangle\|^2 &= \sum_j \left| \sum_{i \in P(j)} (\lambda_{i,j} - \lambda'_{i,j})\alpha_i \right|^2 \\ &\leq \sum_j 2 \text{ card}(\Sigma) \text{ card}(Q) \sum_{i \in P(j)} \left| (\lambda_{i,j} - \lambda'_{i,j})\alpha_i \right|^2. \end{aligned}$$

Then since M and M' are ϵ-close, we have

$$\begin{aligned} \sum_j 2 \text{ card}(\Sigma) \text{ card}(Q) \sum_{i \in P(j)} & \left| (\lambda_{i,j} - \lambda'_{i,j})\alpha_i \right|^2 \\ &= 2 \text{ card}(\Sigma) \text{ card}(Q) \sum_j \sum_{i \in P(j)} \left| \lambda_{i,j} - \lambda'_{i,j} \right|^2 |\alpha_i|^2 \\ &\leq 2 \text{ card}(\Sigma) \text{ card}(Q) \epsilon^2 \sum_j \sum_{i \in P(j)} |\alpha_i|^2. \end{aligned}$$

Finally since for any configuration c_j, there are at most $2 \text{ card}(\Sigma) \text{ card}(Q)$ configurations that can lead to c_j in a single step, we have

$$\begin{aligned} 2 \text{ card}(\Sigma) \text{ card}(Q) \epsilon^2 \sum_j \sum_{i \in P(j)} |\alpha_i|^2 &\leq 4 \text{ card}(\Sigma)^2 \text{ card}(Q)^2 \epsilon^2 \sum_i |\alpha_i|^2 \\ &= 4 \text{ card}(\Sigma)^2 \text{ card}(Q)^2 \epsilon^2. \end{aligned}$$

Therefore, for any unit length superposition $|\phi\rangle$

$$\|(U - U')|\phi\rangle\| \leq 2 \text{ card}(\Sigma) \text{ card}(Q) \epsilon. \qquad \square$$

The following corollary shows that $O(\log T)$ bits of precision are sufficient in the transition amplitudes to simulate T steps of a QTM to within accuracy ϵ for any constant ϵ.

COROLLARY 3.10. *Let $M = (\Sigma, Q, \delta)$ be a well-formed QTM, and let M' be a QTM which is $\frac{\epsilon}{24 \text{ card}(\Sigma) \text{ card}(Q) T}$-close to M, where $\epsilon > 0$. Then M' simulates M for time T with accuracy ϵ. Moreover, this statement holds even if M' is not well formed.*

Proof. Let $b = \frac{1}{24 \text{ card}(\Sigma) \text{ card}(Q) T}$. Without loss of generality, we further assume $\epsilon < \frac{1}{2}$.

Consider running M and M' with the same initial superposition. Since M is well formed, by Theorem A.5, its time evolution operator U is unitary. By Theorem 3.9 the time evolution operator of M', U' is within $\delta = \frac{\epsilon}{12T}$ of U.

Applying U' can always be expressed as applying U and then adding a perturbation of length at most δ times the length of the current superposition. So, the length of the superposition of U' at time t is at most $(1 + \delta)^t$. Since $\delta \leq \frac{1}{T}$, this length is at most e. Therefore, appealing to Theorem 3.7 above, the difference between the superpositions of M and M' at time T is a superposition of norm at most $3\delta T \leq \frac{\epsilon}{4}$. Finally, Lemma 3.6 tells us that observing M' at time T gives a sample from a distribution which is within total variation distance ϵ of the distributions sampled from by observing M at time T. $\square$

3.5. Input/output conventions for QTMs. Timing is crucial to the operation of a QTM, because computational paths can only interfere if they take the same number of time steps. Equally important are the position of the tape head and alignment of the tape contents. In this subsection, we introduce several input/output conventions on QTMs and deterministic TMs which will help us maintain these relationships while manipulating and combining machines.

We would like to think of our QTMs as finishing their computation when they reach the final state q_f. However, it is unclear how we should regard a machine that reaches a superposition in which some configurations are in state q_f but others are not. We try to avoid such difficulties by saying that a QTM halts on a particular input if it reaches a superposition consisting entirely of configurations in state q_f.

DEFINITION 3.11. *A* final configuration *of a QTM is any configuration in state q_f. If when QTM M is run with input x, at time T the superposition contains only final configurations, and at any time less than T the superposition contains no final configuration, then M* halts *with* running time T *on input x. The superposition of M at time T is called the* final superposition *of M run on input x. A polynomial-time QTM is a well-formed QTM, which on every input x halts in time polynomial in the length of x.*

We would like to define the output of a QTM which halts as the superposition of the tape contents of the configurations in the machine's final superposition. However, we must be careful to note the position of the tape head and the alignment relative to the start cell in each configuration since these details determine whether later paths interfere. Recall that the output string of a final configuration of a TM is its tape contents from the leftmost nonblank symbol to the rightmost nonblank symbol. This means that giving an output string leaves unspecified the alignment of this string on the tape and the location of the tape head to be identified. When describing the input/output behavior of a QTM we will sometimes describe this additional information. When we do not, the additional information will be clear from context. For example, we will often build machines in which all final configurations have the output string beginning in the start cell with the tape head scanning its first symbol.

DEFINITION 3.12. *A QTM is called* well behaved *if it halts on all input strings in a final superposition where each configuration has the tape head in the same cell. If this cell is always the start cell, we call the machine* stationary. *Similarly, a deterministic TM is called stationary if it halts on all inputs with its tape head back in the start cell.*

To simplify our constructions, we will often build QTMs and then combine them in simple ways, like running one after the other or iterating one a varying number of times. To do so we must be able to add new transitions into the initial state q_0 of a machine. However, since there may already be transitions into q_0, the resulting machine may not be reversible. But, we can certainly redirect the transitions out of the final state q_f of a reversible TM or a well-behaved QTM without affecting its behavior. Note that for a well-formed QTM, if q_f always leads back to q_0, then there can be no more transitions into q_0. In that case, redirecting the transitions out of q_f will allow us to add new ones into q_0 without violating reversibility. We will say that a machine with this property is in *normal form.* Note that a well-behaved QTM in normal form always halts before using any transition out of q_f and therefore also before using any transition into q_0. This means that altering these transitions will not alter the relevant part of the machine's computation. For simplicity, we arbitrarily

define normal form QTMs to step right and leave the tape unchanged as they go from state q_f to q_0.

DEFINITION 3.13. *A QTM or deterministic TM $M = (\Sigma, Q, \delta)$ is in* normal form *if*

$$\forall \sigma \in \Sigma \quad \delta(q_f, \sigma) = |\sigma\rangle|q_0\rangle|R\rangle.$$

We will need to consider QTMs with the special property that any particular state can be entered while the machine's tape head steps in only one direction. Though not all QTMs are "unidirectional," we will show that any QTM can be efficiently simulated by one that is. Unidirectionality will be a critical concept in reversing a QTM, in completing a partially described QTM, and in building our universal QTM. We further describe the advantages of unidirectional machines after Theorem 5.3 in section 5.2.

DEFINITION 3.14. *A QTM $M = (\Sigma, Q, \delta)$ is called* unidirectional *if each state can be entered from only one direction: in other words, if $\delta(p_1, \sigma_1, \tau_1, q, d_1)$ and $\delta(p_2, \sigma_2, \tau_2, q, d_2)$ are both nonzero, then $d_1 = d_2$.*

Finally, we will find it convenient to use the common tool of thinking of the tape of a QTM or deterministic TM as consisting of several tracks.

DEFINITION 3.15. *A* multitrack *TM with k tracks is a TM whose alphabet Σ is of the form $\Sigma_1 \times \Sigma_2 \times \cdots \times \Sigma_k$ with a special blank symbol $\#$ in each Σ_i so that the blank in Σ is $(\#, \ldots, \#)$. We specify the input by specifying the string on each "track" and optionally by specifying the alignment of the contents of the tracks. So, a TM run on input $x_1; x_2; \ldots; x_k \in \Pi_{i=1}^{k} (\Sigma_i - \#)^*$ is started in the (superposition consisting only of the) initial configuration with the nonblank portion of the ith coordinate of the tape containing the string x_i starting in the start cell. More generally, on input $x_1|y_1; x_2|y_1; \ldots; x_k|y_k$ with $x_i, y_i \in \Sigma_i^*$ the nonblank portion of the ith track is $x_i y_i$ aligned so that the first symbol of each y_i is in the start cell. Also, input $x_1; x_2; \ldots; x_k$ with $x_{l+1}, \ldots, x_k = \epsilon$ is abbreviated as $x_1; x_2; \ldots; x_l$.*

4. Programming a QTM. In this section we explore the fundamentals of building up a QTM from several simpler QTMs. Implementing basic programming primitives such as looping, branching, and reversing, a computation is straightforward for deterministic TMs. However, these constructions are more difficult for QTMs because one must be very careful to maintain reversibility. In fact, the same difficulties arise when building reversible deterministic TMs. However, building up reversible TMs out of simpler reversible TMs has never been necessary. This is because Bennett [7] showed how to efficiently simulate any deterministic TM with one which is reversible. So, one can build a reversible TM by first building the desired computation with a nonreversible machine and then by using Bennett's construction. None of the constructions in this section make any special use of the quantum nature of QTMs, and in fact all techniques used are the same as those required to make the analogous construction for reversible TMs.

We will show in this section that reversible TMs are a special case of QTMs. So, as Deutsch [20] noted, Bennett's result allows any desired deterministic computation to be carried out on a QTM. However, Bennett's result is not sufficient to allow us to use deterministic computations when building up QTMs, because the different computation paths of a QTM will only interfere properly provided that they take exactly the same number of steps. We will therefore carry out a modified version of Bennett's construction to show that any deterministic computation can be carried out

by a reversible TM whose running time depends only on the length of its input. Then, different computation paths of a QTM will take the same number of steps provided that they carry out the same deterministic computation on inputs of the same length.

4.1. Reversible TMs.

DEFINITION 4.1. *A* reversible TM *is a deterministic TM for which each configuration has at most one predecessor.*

Note that we have altered the definition of a reversible TM from the one used by Bennett [7, 8], so that our reversible TMs are a special case of our QTMs. First, we have restricted our reversible TM to move its head only left and right, instead of also allowing it to stay still. Second, we insist that the transition function δ be a complete function rather than a partial function. Finally, we consider only reversible TMs with a single tape, though Bennett worked with multitape machines.

THEOREM 4.2. *Any reversible TM is also a well-formed QTM.*

Proof. The transition function δ of a deterministic TM maps the current state and symbol to an update triple. If we think of it as instead giving the unit superposition with amplitude 1 for that triple and 0 elsewhere, then δ is also a quantum transition function and we have a QTM. The time evolution matrix corresponding to this QTM contains only the entries 1 and 0. Since Corollary B.2 proven below in Appendix B tells us that each configuration of a reversible TM has exactly one predecessor, this matrix must be a permutation matrix. If the TM is reversible then there must be at most one 1 in each row. Therefore, any superposition of configurations $\sum_i \alpha_i |c_i\rangle$ is mapped by this time evolution matrix to some other superposition of configurations $\sum_i \alpha_i |c'_i\rangle$. So, the time evolution preserves length, and the QTM is well formed. □

Previous work of Bennett shows that reversible machines can efficiently simulate deterministic TMs. Of course, if a deterministic TM computes a function which is not one-to-one, then no reversible machine can simulate it exactly. Bennett [7] showed that a generalized reversible TM can do the next best thing, which is to take any input x and compute $x; M(x)$, where $M(x)$ is the output of M on input x. He also showed that if a deterministic TM computes a function which is one-to-one, then there is a generalized reversible TM that computes the same function. For both constructions, he used a multitape TM and also suggested how the simulation could be carried out using only a single-tape machine. Morita, Shirasaki, and Gono [33] use Bennett's ideas and some further techniques to show that any deterministic TM can be simulated by a generalized reversible TM with a two symbol alphabet.

We will give a slightly different simulation of a deterministic TM with a reversible machine that preserves an important timing property.

First, we describe why timing is critical. In later sections, we will build QTMs with interesting and complex interference patterns. However, two computational paths can only interfere if they reach the same configuration at the same time. We will often want paths to interfere which run much of the same computation but with different inputs. We can only be sure they interfere if we know that these computations can be carried out in exactly the same running time. We therefore want to show that any function computable in deterministic polynomial time can be computed by a polynomial time reversible TM in such a way that the running time of the latter is determined entirely by the length of its input. Then, provided that all computation paths carry out the same deterministic algorithms on the inputs of the same length, they will all take exactly the same number of steps.

We prove the following theorem in Appendix B on page 1465 using ideas from the constructions of Bennett and Morita, Shirasaki, and Gono.

THEOREM 4.3 (synchronization theorem). *If f is a function mapping strings to strings which can be computed in deterministic polynomial time and such that the length of $f(x)$ depends only on the length of x, then there is a polynomial time, stationary, normal form reversible TM which given input x, produces output $x; f(x)$, and whose running time depends only on the length of x.*

If f is a function from strings to strings such that both f and f^{-1} can be computed in deterministic polynomial time and such that the length of $f(x)$ depends only on the length of x, then there is a polynomial time, stationary, normal form reversible TM which given input x, produces output $f(x)$, and whose running time depends only on the length of x.

4.2. Programming primitives. We now show how to carry out several programming primitives reversibly. The branching, reversal, and looping lemmas will be used frequently in subsequent sections.

The proofs of the following two lemmas are straightforward and are omitted. However, they will be quite useful as we build complicated machines, since they allow us to build a series of simpler machines while ignoring the contents of tracks not currently being used.

LEMMA 4.4. *Given any QTM (reversible TM) $M = (\Sigma, Q, \delta)$ and any set Σ', there is a QTM (reversible TM) $M' = (\Sigma \times \Sigma', Q, \delta')$ such that M' behaves exactly as M while leaving its second track unchanged.*

LEMMA 4.5. *Given any QTM (reversible TM) $M = (\Sigma_1 \times \cdots \times \Sigma_k, Q, \delta)$ and permutation $\pi : [1, k] \to [1, k]$, there is a QTM (reversible TM) $M' = (\Sigma_{\pi(1)} \times \cdots \times \Sigma_{\pi(k)}, Q, \delta')$ such that the M' behaves exactly as M except that its tracks are permuted according to π.*

The following two lemmas are also straightforward, but stating them separately makes Lemma 4.8 below easy to prove. The first deals with swapping transitions of states in a QTM. We can swap the outgoing transitions of states p_1 and p_2 for transition function δ by defining $\delta'(p_1, \sigma) = \delta(p_2, \sigma)$, $\delta'(p_2, \sigma) = \delta(p_1, \sigma)$, and $\delta'(p, \sigma) = \delta(p, \sigma)$ for $p \neq p_1, p_2$. Similarly, we can swap the incoming transitions of states q_1 and q_2 by defining $\delta'(p, \sigma, \tau, q_1, d) = \delta(p, \sigma, \tau, q_2, d)$, $\delta'(p, \sigma, \tau, q_2, d) = \delta(p, \sigma, \tau, q_1, d)$, and $\delta'(p, \sigma, \tau, q, d) = \delta(p, \sigma, \tau, q, d)$ for $q \neq q_1, q_2$.

LEMMA 4.6. *If M is a well-formed QTM (reversible TM), then swapping the incoming or outgoing transitions between a pair of states in M gives another well-formed QTM (reversible TM).*

LEMMA 4.7. *Let $M_1 = (\Sigma, Q_1, \delta_1)$ and $M_2 = (\Sigma, Q_2, \delta_2)$ be two well-formed QTMs (reversible TMs) with the same alphabet and disjoint state sets. Then the union of the two machines, $M = (\Sigma, Q_1 \cup Q_2, \delta_1 \cup \delta_2)$, with arbitrarily chosen start state $q_0 \in Q_1 \cup Q_2$, is also a well-formed QTM (reversible TM).*

Using the two preceding lemmas, we can insert one machine in place of a state in another. When we perform such an insertion, the computations of the two machines might disturb each other. However, sometimes this can easily be seen not to be the case. For example, in the insertion used by the dovetailing lemma below, we will insert one machine for the final state of a well-behaved QTM, so that the computation of the original machine has been completed before the inserted machine begins. In the rest of the insertions we carry out, the two machines will operate on different tracks, so the only possible disturbance involves the position of the tape head.

LEMMA 4.8. *If M_1 and M_2 are normal form QTMs (reversible TMs) with the same alphabet and q is a state of M_1, then there is a normal form QTM M which acts as M_1 except that each time it would enter state q, it instead runs machine M_2.*

Proof. Let M_1 and M_2 be as stated with initial and final states $q_{1,0}, q_{2,0}, q_{1,f}, q_{2,f}$, and with q a state of M_1.

Then we can construct the desired machine M as follows. First, take the union of M_1 and M_2 according to Lemma 4.7 on page 1428 and make the start state $q_{1,0}$ if $q \neq q_{1,0}$ and $q_{2,0}$ otherwise, and make the final state $q_{1,f}$ if $q \neq q_{1,f}$ and $q_{2,f}$ otherwise. Then, according to Lemma 4.6, swap the incoming transitions of q and $q_{2,0}$ and the outgoing transitions of q and $q_{2,f}$ to get the well-formed machine M.

Since M_1 is in normal form, the final state of M leads back to its initial state no matter whether q is the initial state of M_1, the final state of M_1, or neither. □

Next, we show how to take two machines and form a third by "dovetailing" one onto the end of the other. Notice that when we dovetail QTMs, the second QTM will be started with the final superposition of the first machine as its input superposition. If the second machine has differing running times for various strings in this superposition, then the dovetailed machine might not halt even though the two original machines were well behaved. Therefore, a QTM built by dovetailing two well-behaved QTMs may not itself be well behaved.

LEMMA 4.9 (dovetailing lemma). *If M_1 and M_2 are well-behaved, normal form QTMs (reversible TMs) with the same alphabet, then there is a normal form QTM (reversible TM) M which carries out the computation of M_1 followed by the computation of M_2.*

Proof. Let M_1 and M_2 be well-behaved, normal form QTMs (reversible TMs) with the same alphabet and with start states and final states $q_{1,0}, q_{2,0}, q_{1,f}, q_{2,f}$.

To construct M, we simply insert M_2 for the final state of M_1 using Lemma 4.8 on page 1428.

To complete the proof we need to show that M carries out the computation of M_1 followed by that of M_2.

To see this, first recall that since M_1 and M_2 are in normal form, the only transitions into $q_{1,0}$ and $q_{2,0}$ are from $q_{1,f}$ and $q_{2,f}$, respectively. This means that no transitions in M_1 have been changed except for those into or out of state $q_{1,f}$. Therefore, since M_1 is well behaved and does not prematurely enter state $q_{1,f}$, the machine M, when started in state $q_{1,0}$, will compute exactly as M_1 until M_1 would halt. At that point M will instead reach a superposition with all configurations in state $q_{2,0}$. Then, since no transitions in M_2 have been changed except for those into or out of $q_{2,f}$, M will proceed exactly as if M_2 had been started in the superposition of outputs computed by M_1. □

Now we show how to build a conditional branch around two existing QTMs or reversible TMs. The branching machine will run one of the two machines on its first track input, depending on its second track input. Since a TM can have only one final state, we must rejoin the two branches at the end. We can join reversibly if we write back out the bit that determined which machine was used. The construction will simply build a reversible TM that accomplishes the desired branching and rejoining and then insert the two machines for states in this branching machine.

LEMMA 4.10 (branching lemma). *If M_1 and M_2 are well-behaved, normal form QTMs (reversible TMs) with the same alphabet, then there is a well-behaved, normal form QTM (reversible TM) M such that if the second track is empty, M runs M_1 on its first track and leaves its second track empty, and if the second track has a* 1 *in the start cell (and all other cells blank), M runs M_2 on its first track and leaves the* 1 *where its tape head ends up. In either case, M takes exactly four more time steps than the appropriate M_i.*

Proof. Let M_1 and M_2 be well-behaved, normal form QTMs (reversible TMs) with the same alphabet.

Then we can construct the desired QTM as follows. We will show how to build a stationary, normal form reversible TM BR which always takes four time steps and leaves its input unchanged, always has a superposition consisting of a single configuration, and has two states q_1 and q_2 with the following properties. If BR is run with a 1 in the start cell and blanks elsewhere, then BR visits q_1 once with a blank tape and with its tape head in the start cell and doesn't visit q_2 at all. Similarly, if BR is run with a blank tape, then BR visits q_2 once with a blank tape and with its tape head in the start cell and doesn't visit q_1 at all. Then if we extend M_1 and M_2 to have a second track with the alphabet of BR, extend BR to have a first track with the common alphabet of M_1 and M_2, and insert M_1 for state q_1 and M_2 for state q_2 in BR, we will have the desired QTM M.

We complete the construction by exhibiting the reversible TM BR. The machine enters state q_1' or q_2' depending on whether the start cell contains a 1 and steps left and enters the corresponding q_1 or q_2 while stepping back right. Then it enters state q_3 while stepping left and state q_f while stepping back right.

So, we let BR have alphabet $\{\#, 1\}$, state set $\{q_0, q_1, q_1', q_2, q_2', q_3, q_f\}$, and transition function defined by the following table

	$\#$	1
q_0	$\#, q_2', L$	$\#, q_1', L$
q_1'	$\#, q_1, R$	
q_2'	$\#, q_2, R$	
q_1	$1, q_3, L$	
q_2	$\#, q_3, L$	
q_3	$\#, q_f, R$	
q_f	$\#, q_0, R$	$1, q_0, R$

It can be verified that the transition function of BR is one-to-one and that it can enter each state while moving in only one direction. Therefore, appealing to Corollary B.3 on page 1466 it can be completed to give a reversible TM. □

Finally, we show how to take a unidirectional QTM or reversible TM and build its reverse. Two computational paths of a QTM will interfere only if they reach configurations that do not differ in any way. This means that when building a QTM we must be careful to erase any information that might differ along paths which we want to interfere. We will therefore sometimes use this lemma when constructing a QTM to allow us to completely erase an intermediate computation.

Since the time evolution of a well-formed QTM is unitary, we could reverse a QTM by applying the unitary inverse of its time evolution. However, this transformation is not the time evolution of a QTM since it acts on a configuration by changing tape symbols to the left and right of the tape head. However, since each state in a unidirectional QTM can be entered while moving in only one direction, we can reverse the head movements one step ahead of the reversal of the tape and state. Then, the reversal will have its tape head in the proper cell each time a symbol must be changed.

DEFINITION 4.11. *If QTMs M_1 and M_2 have the same alphabet, then we say that* M_2 reverses *the computation of M_1 if identifying the final state of M_1 with the initial state of M_2 and the initial state of M_1 with the final state of M_2 gives the following. For any input x on which M_1 halts, if c_x and ϕ_x are the initial configuration and final superposition of M_1 on input x, then M_2 halts on initial superposition ϕ_x with final superposition consisting entirely of configuration c_x.*

LEMMA 4.12 (reversal lemma). *If M is a normal form, reversible TM or unidirectional QTM, then there is a normal form, reversible TM or QTM M' that reverses the computation of M while taking two extra time steps.*

Proof. We will prove the lemma for normal form, unidirectional QTMs, but the same argument proves the lemma for normal form reversible TMs.

Let $M = (\Sigma, Q, \delta)$ be a normal form, unidirectional QTM with initial and final states q_0 and q_f, and for each $q \in Q$ let d_q be the direction which M must move while entering state q. Then, we define a bijection π on the set of configurations of M as follows. For configuration c in state q, let $\pi(c)$ be the configuration derived from c by moving the tape head one square in direction $\bar{d}_q$ (the opposite of direction d_q). Since the set of superpositions of the form $|c\rangle$ give an orthonormal basis for the space of superpositions of M, we can extend π to act as a linear operator on this space of superpositions by defining $\pi|c\rangle = |\pi c\rangle$. It is easy to see that π is a unitary transformation on the space of superpositions on M.

Our new machine M' will have the same alphabet as M and state set given by Q together with new initial and final states q'_0 and q'_f. The following three statements suffice to prove that M' reverses the computation of M while taking two extra time steps.

1. If c is a final configuration of M and c' is the configuration c with state q_f replaced by state q'_0, then a single step of M' takes superposition $|c'\rangle$ to superposition $\pi(|c\rangle)$.

2. If a single step of M takes superposition $|\phi_1\rangle$ to superposition $|\phi_2\rangle$, where $|\phi_2\rangle$ has no support on a configuration in state q_0, then a single step of M' takes superposition $\pi(|\phi_2\rangle)$ to superposition $\pi(|\phi_1\rangle)$.

3. If c is an initial configuration of M and c' is the configuration c with state q_0 replaced by state q'_f, then a single step of M' takes superposition $\pi(|c\rangle)$ to superposition $|c'\rangle$.

To see this, let x be an input on which M halts, and let $|\phi_1\rangle, \ldots, |\phi_n\rangle$ be the sequence of superpositions of M on input x, so that $|\phi_1\rangle = |c_x\rangle$ where c_x is the initial superposition of M on x and $|\phi_n\rangle$ has support only on final configurations of M. Then, since the time evolution operator of M is linear, statement 1 tells us that if we form the initial configuration $|\phi'_n\rangle$ of M' by replacing each state q_f in the $|\phi_n\rangle$ with state q'_0, then M' takes $|\phi'_n\rangle$ to $\pi(|\phi_n\rangle)$ in a single step. Since M is in normal form, none of $|\phi_2\rangle, \ldots, |\phi_n\rangle$ have support on any superposition in state q_0. Therefore, statement 2 tells us that the next n steps of M' lead to superpositions $\pi(|\phi_{n-1}\rangle), \ldots, \pi(|\phi_1\rangle)$. Finally, statement 3 tells us that a single step of M' maps superposition $\pi(|c_x\rangle)$ to superposition $|c'_x\rangle$.

We define the transition function δ' to give a well-formed M' satisfying these three statements with the following transition rules.

1. $\delta'(q'_0, \sigma) = |\sigma\rangle|q_f\rangle|\bar{d}_{q_f}\rangle$.
2. For each $q \in Q - q_0$ and each $\tau \in \Sigma$,

$$\delta'(q, \tau) = \sum_{p,\sigma} \delta(p, \sigma, \tau, q, d_q)^* |\sigma\rangle|p\rangle|\bar{d}_p\rangle.$$

3. $\delta'(q_0, \sigma) = |\sigma\rangle|q'_f\rangle|d_{q_0}\rangle$.
4. $\delta'(q'_f, \sigma) = |\sigma\rangle|q'_0\rangle|R\rangle$.

The first and third rules can easily be seen to ensure statements 1 and 3. The second rule can be seen to ensure statement 2 as follows: Since M is in normal form, it maps a superposition $|\phi_1\rangle$ to a superposition $|\phi_2\rangle$ with no support on any

configuration in state q_0 if and only if $|\phi_1\rangle$ has no support on any configurations in state q_f. Therefore, the time evolution of M defines a unitary transformation from the space $\mathcal{S}_1$ of superpositions of configurations in states from the set $Q_1 = Q - q_f$ to the space of superpositions $\mathcal{S}_2$ of configurations in states from the set $Q_2 = Q - q_0$. This fact also tells us that the second rule above defines a linear transformation from space $\mathcal{S}_2$ back to space $\mathcal{S}_1$. Moreover, if M takes configuration c_1 with a state from Q_1 with amplitude α to configuration c_2 with a state from Q_2, then M' takes configuration $\pi(c_2)$ to configuration $\pi(c_1)$ with amplitude α^*. Therefore, the time evolution of M' on space $\mathcal{S}_2$ is the composition of π and its inverse around the conjugate transpose of the time evolution of M. Since this conjugate transpose must also be unitary, the second rule above actually gives a unitary transformation from the space $\mathcal{S}_2$ to the space $\mathcal{S}_1$ which satisfies statement 2 above.

Since M' is clearly in normal form, we complete the proof by showing that M' is well formed. To see this, just note that each of the four rules defines a unitary transformation to one of a set of four mutually orthogonal subspaces of the spaces of superpositions of M'. □

The synchronization theorem will allow us to take an existing QTM and put it inside a loop so that the machine can be run any specified number of times.

Building a reversible machine that loops indefinitely is trivial. However, if we want to loop some finite number of times, we need to carefully construct a reversible entrance and exit. As with the branching lemma above, the construction will proceed by building a reversible TM that accomplishes the desired looping and then inserting the QTM for a particular state in this looping machine. However, there are several difficulties. First, in this construction, as opposed to the branching construction, the reversible TM leaves an intermediate computation written on its tape while the QTM runs. This means that inserting a nonstationary QTM would destroy the proper functioning of the reversible TM. Second, even if we insert a stationary QTM, the second (and any subsequent) time the QTM is run, it may be started in superposition on inputs of different lengths and hence may not halt. Therefore, there is no general statement we are able to make about the behavior of the machine once the insertion is carried out. Instead, we describe here the reversible looping TM constructed in Appendix C on page 1470 and argue about specific QTMs resulting from this machine when they are constructed.

LEMMA 4.13 (looping lemma). *There is a stationary, normal form, reversible TM M and a constant c with the following properties. On input any positive integer k written in binary, M runs for time $O(k \log^c k)$ and halts with its tape unchanged. Moreover, M has a special state q^* such that on input k, M visits state q^* exactly k times, each time with its tape head back in the start cell.*

5. Changing the basis of a QTM's computation. In this section we introduce a fundamentally quantum mechanical feature of quantum computation, namely changing the computational basis during the evolution of a QTM. In particular, we will find it useful to change to a new orthonormal basis for the transition function in the middle of the computation—each state in the new state set is a linear combination of states from the original machine.

This will allow us to simulate a general QTM with one that is unidirectional. It will also allow us to prove that any partially defined quantum transition function which preserves length can be extended to give a well-formed QTM.

We start by showing how to change the basis of the states of a QTM. Then we give a set of conditions for a quantum transition function that is necessary and sufficient

for a QTM to be well formed. The last of these conditions, called separability, will allow us to construct a basis of the states of a QTM which will allow us to prove the unidirection and completion lemmas below.

5.1. The change of basis. If we take a well-formed QTM and choose a new orthonormal basis for the space of superpositions of its states, then translating its transition function into this new basis will give another well-formed QTM that evolves just as the first under the change of basis. Note that in this construction the new QTM has the same time evolution operator as the original machine. However, the states of the new machine differ from those of the old. This change of basis will allow us to prove Lemmas 5.5 and 5.7 below.

LEMMA 5.1. *Given a QTM $M = (\Sigma, Q, \delta)$ and a set of vectors B from $\tilde{C}^Q$ which forms an orthonormal basis for $\mathbf{C}^Q$, there is a QTM $M' = (\Sigma, B, \delta')$ which evolves exactly as M under a change of basis from Q to B.*

Proof. Let $M = (\Sigma, Q, \delta)$ be a QTM, and let B be an orthonormal basis for $\mathbf{C}^Q$.

Since B is an orthonormal basis, this establishes a unitary transformation from the space of superpositions of states in Q to the space of superpositions of states in B. Specifically, for each $p \in Q$ we have the mapping

$$|p\rangle \to \sum_{v \in B} \langle p||v\rangle \ |v\rangle.$$

Similarly, we have a unitary transformation from the space of superpositions of configurations with states in Q to the space of configurations with states in B. In this second transformation, a configuration with state p is mapped to the superposition of configurations, where the corresponding configuration with state v appears with amplitude $\langle p||v\rangle$.

Let us see what the time evolution of M should look like under this change of basis. In M a configuration in state p reading a σ evolves in a single time step to the superposition of configurations corresponding to the superposition $\delta(p, \sigma)$:

$$\delta(p, \sigma) = \sum_{\tau, q, d} \delta(p, \sigma, \tau, q, d) \ |\tau\rangle|q\rangle|d\rangle.$$

With the change of basis, the superposition on the right-hand side will instead be

$$\sum_{\tau, v, d} \left(\sum_{q} \langle q|v\rangle \ \delta(p, \sigma, \tau, q, d) \right) |\tau\rangle|v\rangle|d\rangle.$$

Now, since the state symbol pair $|v\rangle|\sigma\rangle$ in M' corresponds to the superposition

$$\sum_{p} \langle v|p\rangle \ |p\rangle|\sigma\rangle$$

in M, we should have in M'

$$\delta'(v, \sigma) = \sum_{p} \langle v|p\rangle \left(\sum_{\tau, v', d} \left(\sum_{q} \langle q|v'\rangle \ \delta(p, \sigma, \tau, q, d) \right) \right) |\tau\rangle|v'\rangle|d\rangle.$$

Therefore, M' will behave exactly as M under the change of basis if we define δ' by saying that for each $v, \sigma \in B \times \Sigma$,

$$\delta'(v, \sigma) = \sum_{\tau, v', d} \left(\sum_{p, q} \langle v|p\rangle \ \langle q|v'\rangle \ \delta(p, \sigma, \tau, q, d) \right) |\tau\rangle|v'\rangle|d\rangle.$$

Since the vectors in B are contained in $\tilde{C}^Q$, each amplitude of δ' is contained in $\tilde{C}$.

Finally, note that the time evolution of M' must preserve Euclidean length since it is exactly the time evolution of the well-formed M under the change of basis. □

5.2. Local conditions for QTM wellformedness. In our discussion of reversible TMs in Appendix B we find properties of a deterministic transition function which are necessary and sufficient for it to be reversible. Similarly, our next theorem gives three properties of a quantum transition function which together are necessary and sufficient for it to be well formed. The first property ensures that the time evolution operator preserves length when applied to any particular configuration. Adding the second ensures that the time evolution preserves the length of superpositions of configurations with their tape head in the same cell. The third property, which concerns "restricted" update superpositions, handles superpositions of configurations with tape heads in differing locations. This third property will be of critical use in the constructions of Lemmas 5.5 and 5.7 below.

DEFINITION 5.2. *We will also refer to the superposition of states*

$$\sum_{q \in Q} \delta(p, \sigma, \tau, q, d)|q\rangle$$

resulting from restricting $\delta(p, \sigma)$ to those pieces writing symbol τ and moving in direction d as a direction d-going restricted superposition*, denoted by $\delta(p, \sigma|\tau, d)$.*

THEOREM 5.3. *A QTM $M = (\Sigma, Q, \delta)$ is well formed iff the following conditions hold:*

unit length

$$\forall\ p, \sigma\ \in\ Q \times \Sigma \quad \|\delta(p, \sigma)\| = 1,$$

orthogonality

$$\forall\ (p_1, \sigma_1) \neq (p_2, \sigma_2)\ \in\ Q \times \Sigma \quad \delta(p_1, \sigma_1) \cdot \delta(p_2, \sigma_2) = 0,$$

separability

$$\forall\ (p_1, \sigma_1, \tau_1), (p_2, \sigma_2, \tau_2)\ \in\ Q \times \Sigma \times \Sigma \quad \delta(p_1, \sigma_1|\tau_1, L) \cdot \delta(p_2, \sigma_2|\tau_2, R) = 0.$$

Proof. Let U be the time evolution of a proposed QTM $M = (\Sigma, Q, \delta)$. We know M is well formed iff U^* exists and U^*U gives the identity or, equivalently, iff the columns of U have unit length and are mutually orthogonal. Clearly, the first condition specifies exactly that each column has unit length. In general, configurations whose tapes differ in a cell not under either of their heads, or whose tape heads are not either in the same cell or exactly two cells apart, cannot yield the same configuration in a single step. Therefore, such pairs of columns are guaranteed to be orthogonal, and we need only consider pairs of configurations for which this is not the case. The second condition specifies the orthogonality of pairs of columns for configurations that differ only in that one is in state p_1 reading σ_1 while the other is in state p_2 reading σ_2.

Finally, we must consider pairs of configurations with their tape heads two cells apart. Such pairs can only interfere in a single step if they differ at most in their states and in the symbol written in these cells. The third condition specifies the orthogonality of pairs of columns for configurations which are identical except that the second has its tape head two cells to the left, is in state p_2 instead of p_1, has a σ_2

instead of a τ_2 in the cell under its tape head, and has a τ_1 instead of a σ_1 two cells to the left. □

Now consider again unidirectional QTMs, those in which each state can be entered while moving in only one direction. When we considered this property for deterministic TMs, it meant that when looking at a deterministic transition function δ, we could ignore the direction update and think of δ as giving a bijection from the current state and tape symbol to the new symbol and state. Here, if δ is a unidirectional quantum transition function, then it certainly satisfies the separability condition since no left-going and right-going restricted superpositions have a state in common. Moreover, update triples will always share the same direction if they share the same state. Therefore, a unidirectional δ is well formed iff, ignoring the direction update, δ gives a unitary transformation from superpositions of current state and tape symbol to superpositions of new symbol and state.

5.3. Unidirection and completion lemmas. The separability condition of Theorem 5.3 allows us to simulate any QTM with a unidirectional QTM by applying a change of basis. The same change of basis will also allow us to complete any partially specified quantum transition function which preserves length.

It is straightforward to simulate a deterministic TM with one which is unidirectional. Simply split each state q into two states q_r and q_l, both of which are given the same transitions that q had, and then edit the transition function so that transitions moving right into q enter q_r and transitions moving left into q enter q_l. The resulting machine is clearly not reversible since the transition function operates the same on each pair of states q_r, q_l.

To simplify the unidirection construction, we first show how to interleave a series of quantum transition functions.

LEMMA 5.4. *Given k state sets $Q_0, \ldots, Q_{k-1}, Q_k = Q_0$ and k transition functions each mapping from one state set to the next*

$$\delta_i : Q_i \times \Sigma \to \tilde{\mathbf{C}}^{\Sigma \times Q_{i+1} \times \{L,R\}}$$

such that each δ_i preserves length, there is a well-formed QTM M with state set $\bigcup_i (Q_i, i)$ which alternates stepping according to each of the k transition functions.

Proof. Suppose we have k state sets transition functions as stated above. Then we let M be the QTM with the same alphabet, with state set given by the union of the individual state sets $\bigcup_i (Q_i, i)$, and with transition function according to the δ_i,

$$\delta((p,i),\sigma) = \sum_{\tau,q,d} \delta_i(p,\sigma,\tau,q,d)|\tau\rangle|q, i+1\rangle|d\rangle.$$

Clearly, the machine M alternates stepping according to $\delta_0, \ldots, \delta_{k-1}$. It is also easy to see that the time evolution of M preserves length. If $|\phi\rangle$ is a superposition of configurations with squared length α_i in the subspace with configurations with states from Q_i, then δ maps ϕ to a superposition with squared length α_i in the subspace with configurations with states from Q_{i+1}. □

LEMMA 5.5 (unidirection lemma). *Any QTM M is simulated, with slowdown by a factor of 5, by a unidirectional QTM M'. Furthermore, if M is well behaved and in normal form, then so is M'.*

Proof. The key idea is that the separability condition of a well-formed QTM allows a change of basis to a state set in which each state can be entered from only one direction.

The separability condition says that

$$\forall\ (p_1,\sigma_1,\tau_1),(p_2,\sigma_2,\tau_2)\ \in\ Q\times\Sigma\times\Sigma,$$

$$\delta(p_1,\sigma_1|\tau_1,L)\cdot\delta(p_2,\sigma_2|\tau_2,R)=0.$$

This means that we can split $\mathbf{C}^Q$ into mutually orthogonal subspaces $\mathbf{C}_L$ and $\mathbf{C}_R$ such that $span(\mathbf{C}_L,\mathbf{C}_R)=\mathbf{C}^Q$ and

$$\forall\ (p_1,\sigma_1,\tau_1)\in\ Q\times\Sigma\times\Sigma,$$

$$\delta(p_1,\sigma_1|\tau_1,d)\in\mathbf{C}_d.$$

Now, as shown in Lemma 5.1 above, under a change of basis from state set Q to state set B the new transition function is defined by

$$\delta'(v,\sigma,\tau,v',d)=\sum_{p,q}\langle v|p\rangle\langle q|v'\rangle\delta(p,\sigma,\tau,q,d).$$

So, choose orthonormal bases B_L and B_R for the spaces $\mathbf{C}_L$ and $\mathbf{C}_R$ and let $M'=(\Sigma,B_L\cup B_R,\delta')$ be the QTM constructed according to Lemma 5.1 which evolves exactly as M under a change of basis from state set Q to state set $B=B_L\cup B_R$. Then any state in M' can be entered in only one direction. To see this, first note that since $\delta(p,\sigma|\tau,d)\in B_d$ and $v=\sum_q\langle v|q\rangle|q\rangle$, the separability condition implies that for $v\in B_{\overline{d}}$,

$$\sum_q\delta(p,\sigma,\tau,q,d)\langle v|q\rangle^*=0.$$

Therefore, for any $v,\sigma,\tau,v'\in B\times\Sigma\times\Sigma\times B_{\overline{d}}$,

$$\delta'(v,\sigma,\tau,v',d)=\sum_{p,q}\langle v|p\rangle\langle q|v'\rangle\delta(p,\sigma,\tau,q,d)$$

$$=\sum_p\langle v|p\rangle\sum_q\langle q|v'\rangle\delta(p,\sigma,\tau,q,d)=0.$$

Therefore, any state in B can be entered while traveling in only one direction.

Unfortunately, this new QTM M' might not be able to simulate M. The problem is that the start state and final state of M might correspond under the change of basis isomorphism to superpositions of states in M', meaning that we would be unable to define the necessary start and final states for M'. To fix this problem, we use five time steps to simulate each step of M and interleave the five transition functions using Lemma 5.4 on page 1435.

1. Step right leaving the tape and state unchanged:

$$\delta_0(p,\sigma)=|\sigma\rangle|p\rangle|R\rangle.$$

2. Change basis from Q to B while stepping left:

$$\delta_1(p,\sigma)=\sum_{b\in B}\langle p|b\rangle|\sigma\rangle|b\rangle|L\rangle.$$

3. M' carries out a step of the computation of M. So, δ_2 is just the quantum transition function δ' from QTM M' constructed above.

4. Change basis back from B to Q while stepping left:

$$\delta_3(b,\sigma) = \sum_{p\in Q} \langle b|p\rangle|\sigma\rangle|p\rangle|L\rangle.$$

5. Step right leaving the tape and state unchanged:

$$\delta_4(p,\sigma) = |\sigma\rangle|p\rangle|R\rangle.$$

If we construct QTM M' with state set $(Q\times\{0,1,4\}\cup(B\times\{2,3\})$ using Lemma 5.4 on page 1435 and let M' have start and final states $(q_0,0)$ and $(q_f,0)$, then M' simulates M with slowdown by a factor of 5.

Next, we must show that each of the five transition functions obeys the well-formedness conditions and hence according to Lemma 5.4 that the interleaved machine is well formed.

The transition function $\delta_2 = \delta'$ certainly obeys the wellformedness conditions since M' is a well formed QTM. Also, δ_0 and δ_4 obey the three wellformedness conditions since they are deterministic and reversible. Finally, the transition functions δ_1 and δ_3 satisfy the unit length and orthogonality conditions since they implement a change of basis, and they obey the separability condition since they only move in one direction.

Finally, we must show that if M is well-behaved and in normal form, then we can make M' well behaved and in normal form.

So, suppose M is well behaved and in normal form. Then there is a T such that at time T the superposition includes only configurations in state q_f with the tape head back in the start cell, and at any time less than T the superposition contains no configuration in state q_f. But this means that when M' is run on input x, the superposition at time $5T$ includes only configurations in state $(q_f,0)$ with the tape head back in the start cell, and the superposition at any time less than $5T$ contains no configuration in state $(q_f,0)$. Therefore, M' is also well behaved.

Then for any input x there is a T such that M enters a series of $T-1$ superpositions of configurations all with states in $Q-\{q_0,q_f\}$ and then enters a superposition of configurations all in state q_f with the tape head back in the start cell. Therefore, on input x, M' enters a series of $5T-1$ superpositions of configurations all with states in $Q'-\{(q_f,0),(q_0,4)\}$ and then enters a superposition of configurations all in state $(q_f,0)$ with the tape head back in the start cell. Therefore, M' is well behaved. Also, swapping the outgoing transitions of $(q_f,0)$ and $(q_0,4)$, which puts M' in normal form, will not change the computation of M' on any input x. □

When we construct a QTM, we will often only be concerned with a subset of its transitions. Luckily, any partially defined transition function that preserves length can be extended to give a well-formed QTM.

DEFINITION 5.6. *A QTM M whose quantum transition function δ' is only defined for a subset $S\subseteq Q\times\Sigma$ is called a* partial *QTM. If the defined entries of δ' satisfy the three conditions of Theorem* 5.3 *on page* 1434 *then M is called a* well-formed partial *QTM.*

LEMMA 5.7 (completion lemma). *Suppose M is a well-formed partial QTM with quantum transition function δ. Then there is a well-formed QTM M' with the same state set and alphabet whose quantum transition function δ' agrees with δ wherever the latter is defined.*

Proof. We noted above that a unidirectional quantum transition function is well formed iff, ignoring the direction update, it gives a unitary transformation from superpositions of current state and tape symbol to superpositions of new symbol and state. So if our partial QTM is unidirectional, then we can easily fill in the undefined entries of δ by extending the set of update superpositions of δ to an orthonormal basis for the space of superpositions of new symbol and state.

For a general δ, we can use the technique of Lemma 5.1 on page 1433 to change the basis of δ away from Q so that each state can be entered while moving in only one direction, extend the transition function, and then rotate back to the basis Q.

We can formalize this as follows: let $M = (\Sigma, Q, \delta)$ be a well-formed partial QTM with δ defined on the subset $S \subseteq Q \times \Sigma$. Denote by $\overline{S}$ the complement of S in $Q \times \Sigma$.

As in the proof of the unidirection lemma above, the separability condition allows us to partition $\mathbf{C}^Q$ into mutually orthogonal subspaces $\mathbf{C}_L$ and $\mathbf{C}_R$ such that $span(\mathbf{C}_L, \mathbf{C}_R) = \mathbf{C}^Q$ and

$$\forall\ (p_1, \sigma_1, \tau_1) \in\ S \times \Sigma,$$

$$\delta(p_1, \sigma_1 | \tau_1, d) \in \mathbf{C}_d.$$

Then, we choose orthonormal bases B_L and B_R for $\mathbf{C}_L$ and $\mathbf{C}_R$ and consider the unitary transformation from superpositions of configurations with states in Q to the space of configurations with states in $B = B_L \cup B_R$, where any configuration with state p is mapped to the superposition of configurations where the corresponding configuration with state v appears with amplitude $\langle p|v\rangle$.

If we call δ' the partial function δ followed by this unitary change of basis, then we have

$$\delta'(p, \sigma) = \sum_{\tau, v, d} \left(\sum_q \langle q|v\rangle \delta(p, \sigma, \tau, q, d) \right) |\tau\rangle |v\rangle |d\rangle.$$

Since δ preserves length and δ' is δ followed by a unitary transformation, δ' also preserves length.

But now δ' can enter any state in B while moving in only one direction. To see this, first note that since $\delta(p, \sigma; \tau, d) \in B_d$ and $v = \sum_q \langle v|q\rangle |q\rangle$, the separability condition implies that for $v \in B_{\overline{d}}$,

$$\sum_q \delta(p, \sigma, \tau, q, d) \langle v|q\rangle^* = 0.$$

Therefore, for any $p, \sigma, \tau, v \in S \times \Sigma \times B_{\overline{d}}$,

$$\delta'(p, \sigma, \tau, v, d) = \sum_q \langle q|v\rangle \delta(p, \sigma, \tau, q,) = 0.$$

Therefore, any state in B can be entered while traveling in only one direction.

Then, since the direction is implied by the new state, we can think of δ' as mapping the current state and symbol to a superposition of new symbol and state. Since δ' preserves length, the set $\delta'(S)$ is a set of orthonormal vectors, and we can expand this set to an orthonormal basis of the space of superpositions of new symbol and state. Adding the appropriate direction updates and assigning these new vectors arbitrarily to $\delta'(\bar{S})$, we have a completely defined δ' that preserves length. Therefore, assigning $\delta(\bar{S})$ as $\delta'(\bar{S})$ followed by the inverse of the basis transformation gives a completion for δ that preserves length. ∎

6. An efficient QTM implementing any given unitary transformation. Suppose that the tape head of a QTM is confined to a region consisting of k contiguous tape cells (the tape is blank outside this region). Then the time evolution of the QTM can be described by a d-dimensional unitary transformation, where $d = k\text{card}(Q)\text{card}(\Sigma)^k$. In this section we show conversely that there is a QTM that, given any d-dimensional unitary transformation as input, carries out that transformation (on a region of its tape). To make this claim precise we must say how the d-dimensional unitary transformation is specified. We assume that an approximation to the unitary transformation is specified by a $d \times d$ complex matrix whose entries are approximations to the entries of the actual unitary matrix corresponding to the desired transformation. We show in Theorem 6.11 on page 1447 that there is a QTM that, on input ϵ and a d-dimensional transformation which is within distance $\frac{\epsilon}{2(10\sqrt{d})^d}$ of a unitary transformation, carries out a transformation which is an ϵ approximation to the desired unitary transformation. Moreover, the running time of the QTM is bounded by a polynomial in d and $\frac{1}{\epsilon}$.

In a single step, a QTM can map a single configuration into a superposition of a bounded number of configurations. Therefore, in order to carry out an (approximation to an) arbitrary unitary transformation on a QTM, we show how to approximate it by a product of simple unitary transformations—each such simple transformation acts as the identity in all but two dimensions. We then show that there is a particular simple unitary transformation such that any given simple transformation can be expressed as a product of permutation matrices and powers of this fixed simple matrix. Finally, we put it all together and show how to design a single QTM that carries out an arbitrary unitary transformation—this QTM is deterministic except for a single kind of quantum coin flip.

The decomposition of an arbitrary unitary transformation into a product of simple unitary transformations is similar to work carried out by Deutsch [21]. Deutsch's work, although phrased in terms of quantum computation networks, can be viewed as showing that a d-dimensional unitary transformation can be decomposed into a product of transformations where each applies a particular unitary transformation to three dimensions and acts as the identity elsewhere. We must consider here several issues of efficiency not addressed by Deutsch. First, we are concerned that the decomposition contains a number of transformations which is polynomial in the dimension of the unitary transformation and in the desired accuracy. Second, we desire that the decomposition can itself be efficiently computed given the desired unitary transformation as input. For more recent work on the efficient simulation of a unitary transformation by a quantum computation network see [5] and the references therein.

6.1. Measuring errors in approximated transformations. In this section, we will deal with operators (linear transformations) on finite-dimensional Hilbert spaces. It is often convenient to fix an orthonormal basis for the Hilbert space and describe the operator by a finite matrix with respect to the chosen basis. Let $e_1, \ldots, e_d$ be an orthonormal basis for Hilbert space $\mathcal{H} = \mathbf{C}^d$. Then we can represent an operator U on $\mathcal{H}$ by a $d \times d$ complex matrix M, whose i,jth entry $m_{i,j}$ is (Ue_j, e_i). The ith row of the matrix M is given by ${e_i}^T M$, and we will denote it by M_i. We denote by ${M_i}^*$ the conjugate transpose of M_i. The jth column of M is given by Me_j. U^*, the adjoint of U, is represented by the $d \times d$ matrix M^*. M is unitary iff $MM^* = M^*M = I$. It follows that if M is unitary then the rows (and columns) of M are orthonormal.

Recall that for a bounded linear operator U on a Hilbert space $\mathcal{H}$, the norm of U is defined as

$$|U| \;=\; \sup_{\|x\|=1} |Ux|.$$

If we represent U by the matrix M, then we can define the norm of the matrix M to be same as the norm of U. Thus, since we're working in a finite-dimensional space,

$$\|M\| \;=\; \max_{\|v\|=1} \|Mv\|.$$

FACT 6.1. *If U is unitary, then $\|U\| = \|U^*\| = 1$.*

Proof. $\forall x \in \mathcal{H}$, $\|Ux\|^2 = (Ux, Ux) = (x, U^*Ux) = (x, x) = \|x\|^2$. Therefore, $\|U\| = 1$, and similar reasoning shows $\|U^*\| = 1$. □

We will find it useful to keep track of how far our approximations are from being unitary. We will use the following simple measure of a transformation's distance from being unitary.

DEFINITION 6.2. *A bounded linear operator U is called* ϵ-close to unitary *if there is a unitary operator $\tilde{U}$ such that $\|U - \tilde{U}\| \leq \epsilon$. If we represent U by the matrix M, then we can equivalently say that M is* ϵ-close to unitary *if there is a unitary matrix $\tilde{M}$ such that $\|M - \tilde{M}\| \leq \epsilon$.*

Notice that, appealing to statement (2.3) in section 2 if U is ϵ-close to unitary, then $1 - \epsilon \leq \|U\| \leq 1 + \epsilon$. However, the converse is not true. For example the linear transformation $\left(\begin{smallmatrix} 1 & 0 \\ 0 & 0 \end{smallmatrix}\right)$ has norm 1, but is 1 away from unitary.

Next, we show that if M is close to unitary, then the rows of M are close to unit length and will be close to orthogonal.

LEMMA 6.3. *If a d-dimensional complex matrix M is ϵ-close to unitary, then*

$$1 - \epsilon \leq \|M_i\| \;\leq\; 1 + \epsilon, \tag{6.1}$$

$$\forall i \neq j, \quad \|M_i M_j{}^*\| \leq 2\epsilon + 3\epsilon^2. \tag{6.2}$$

Proof. Let $\tilde{M}$ be the unitary matrix such that $\|M - \tilde{M}\| \leq \epsilon$. Let $N = M - \tilde{M}$. Then we know that for each i, $\|\tilde{M}_i\| = 1$ and $\|N_i\| \leq \epsilon$.

So, for any i, we have $M_i = N_i + \tilde{M}_i$. Therefore, $1 - \epsilon \leq \|M_i\| \leq 1 + \epsilon$.

Next, since $\tilde{M}$ is unitary, it follows that for $i \neq j$, $\tilde{M}_i \tilde{M}_j^* = 0$. Therefore, $(M_i - N_i)(M_j^* - N_j^*) = 0$. Expanding this as a sum of four terms, we get

$$M_i M_j^* = M_i N_j^* + N_i M_j^* - N_i N_j^*.$$

Since $\|M\| \leq 1 + \epsilon$ and $\|N\| \leq \epsilon$, the Schwarz inequality tells us that $\|M_i N_j^*\| \leq (1 + \epsilon)\epsilon$, $\|N_i M_j^*\| \leq \epsilon(1 + \epsilon)$, and $\|N_i N_j^*\| \leq \epsilon^2$. Using the triangle inequality we conclude that $\|M_i M_j^*\| \leq 2(1 + \epsilon)\epsilon + \epsilon^2$. Therefore, $\|M_i M_j{}^*\| \leq 2\epsilon + 3\epsilon^2$. □

We will also use the following standard fact that a matrix with small entries must have small norm.

LEMMA 6.4. *If M is a d-dimensional square complex matrix such that $|m_{i,j}| \leq \epsilon$ for all i, j, then $\|M\| \leq d\epsilon$.*

Proof. If each entry of M has magnitude at most ϵ, then clearly each row M_i of M must have norm at most $\sqrt{d}\epsilon$. So, if v is a d-dimensional column vector with $|v| = 1$, we must have

$$\|Mv\|^2 = \sum_i \|M_i v\|^2 \leq \sum_i d\epsilon^2 = d^2\epsilon^2,$$

where the inequality follows from the Schwarz inequality. Therefore, $\|M\| \leq d\epsilon$. □

6.2. Decomposing a unitary transformation. We now describe a class of exceedingly simple unitary transformations which we will be able to carry out using a single QTM. These "near-trivial" transformations either apply a phase shift in one dimension or apply a rotation between two dimensions, while acting as the identity otherwise.

DEFINITION 6.5. *A $d \times d$ unitary matrix M is* near trivial *if it satisfies one of the following two conditions.*

1. *M is the identity except that one of its diagonal entries is $e^{i\theta}$ for some $\theta \in [0, 2\pi]$. For example, $\exists j\ m_{j,j} = e^{i\theta}\ \forall k \neq j\ m_{k,k} = 1$, and $\forall k \neq l\ m_{k,l} = 0$.*

2. *M is the identity except that the submatrix in one pair of distinct dimensions j and k is the rotation by some angle $\theta \in [0, 2\pi] : \left(\begin{smallmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{smallmatrix}\right)$. So, as a transformation M is near trivial if there exists θ and $i \neq j$ such that $Me_i = (\cos\theta)e_i + (\sin\theta)e_j$, $Me_j = -(\sin\theta)e_i + (\cos\theta)e_j$, and $\forall k \neq i, j\ Me_k = e_k$.*

We call a transformation which satisfies statement 1 a near-trivial phase shift*, and we call a transformation which satisfies Statement 2 a* near-trivial rotation.

We will write a near-trivial matrix M in the following way. If M is a phase shift of $e^{i\theta}$ in dimension j, then we will write down $[j, j, \theta]$ and if M is a rotation of angle θ between dimensions j and k we will write down $[j, k, \theta]$. This convention guarantees that the matrix that we are specifying is a near-trivial matrix and therefore a unitary matrix, *even if* for precision reasons we write down an approximation to the matrix that we really wish to specify. This feature will substantially simplify our error analyses.

Before we show how to use near-trivial transformations to carry out an arbitrary unitary transformation, we first show how to use them to map any particular vector to a desired target direction.

LEMMA 6.6. *There is a deterministic algorithm which on input a vector $v \in \mathbf{C}^d$ and a bound $\epsilon > 0$ computes near-trivial matrices $U_1, \ldots, U_{2d-1}$ such that*

$$\|U_1 \cdots U_{2d-1} v \ - \ \|v\| e_1\| \leq \epsilon,$$

where e_1 is the unit vector in the first coordinate direction. The running time of the algorithm is bounded by a polynomial in d, $\log \frac{1}{\epsilon}$ and the length of the input.

Proof. First, we use d phase shifts to map v into the space $\mathbb{R}^d$. We therefore want to apply the phase shift $\frac{v_i^*}{\|v_i\|}$ to each dimension i with $v_i \neq 0$. So, we let P_i be the near-trivial matrix which applies to dimension i the phase shift by angle ϕ_i, where $\phi_i = 0$ if $v_i = 0$ and otherwise $\phi_i = 2\pi - \cos^{-1} \frac{\mathrm{Re}(v_i)}{\|v_i\|}$ or $\cos^{-1} \frac{\mathrm{Re}(v_i)}{\|v_i\|}$ depending whether $\mathrm{Im}(v_i)$ is positive or negative. Then $P_1 \cdots P_d v$ is the vector with ith coordinate $\|v_i\|$.

Next, we use $d-1$ rotations to move all of the weight of the vector into dimension 1. So, we let R_i be the near-trivial matrix which applies the rotation by angle θ_i to dimensions i and $i+1$, where

$$\theta_i = \cos^{-1} \frac{\|v_i\|}{\sqrt{\sum_{j=i}^{d} \|v_j\|^2}}$$

if the sum in the denominator is not 0 and $\theta_i = 0$ otherwise. Then

$$R_1 \cdots R_{d-1} P_1 \cdots P_d v = \|v\| e_1.$$

Now, instead of producing these values ϕ_i, θ_i exactly, we can compute, in time polynomial in d and $\log \frac{1}{\epsilon}$ and the length of the input, values ϕ_i' and θ_i' which are

within $\delta = \frac{\epsilon}{(2d-1)\|v\|}$ of the desired values. Call P_i' and R_i' the near-trivial matrices corresponding to P_i and R_i but using these approximations. Then, since the distance between points at angle θ and θ' on the unit circle in the real plane is at most $|\theta - \theta'|$,

$$\|R_i - R_i'\| \leq \delta.$$

Thinking of the same inequality on the unit circle in the complex plane, we have

$$\|P_i - P_i'\| \leq \delta.$$

Finally, since each matrix P_i, P_i', R_i, R_i' is unitary, Fact 2.1 on page 1417 gives us

$$\|R_1' \cdots R_{d-1}' P_1' \cdots P_d' \ - \ R_1 \cdots R_{d-1} P_1 \cdots P_d\| \leq (2d-1)\delta$$

and therefore

$$\|R_1' \cdots R_{d-1}' P_1' \cdots P_d' v \ - \ \|v\| e_1\| \leq (2d-1)\delta\|v\| = \epsilon. \qquad \square$$

We now show how the ability to map a particular vector to a desired target direction allows us to approximate an arbitrary unitary transformation.

THEOREM 6.7. *There is a deterministic algorithm running in time polynomial in d and $\log 1/\epsilon$ and the length of the input which when given as input U, ϵ where $\epsilon > 0$ and U is a $d \times d$ complex matrix which is $\frac{\epsilon}{2(10\sqrt{d})^d}$-close to unitary, computes d-dimensional near-trivial matrices $U_1, \ldots, U_n$, with n polynomial in d such that $\|U \ - \ U_n \cdots U_1\| \leq \epsilon$.*

Proof. First we introduce notation to simplify the proof. Let U be a $d \times d$ complex matrix. Then we say U is *k-simple* if its first k rows and columns are the same as those of the d-dimensional identity. Notice that the product of two $d \times d$ k-simple matrices is also k-simple.

If U were d-simple, we would have $U = I$ and the desired computation would be trivial. In general, the U which our algorithm must approximate will not even be 1-simple. So, our algorithm will proceed through d phases such that during the ith phase the remaining problem is reduced to approximating a matrix which is $i+1$-simple.

Suppose we start to approximate a k-simple U with a series of near-trivial matrices with the product V. Then to approximate U we would still need to produce a series of near-trivial matrices whose product W satisfies $W \approx UV^*$. To reduce the problem we must therefore compute near-trivial matrices whose product V is such that UV^* is close to being $k+1$-simple. We can accomplish this by using the algorithm of Lemma 6.6 above.

So, let U be given which is k-simple and is δ-close to unitary, and let Z be the lower right $d-k \times d-k$ submatrix of Z. We invoke the procedure of Lemma 6.6 on inputs Z_1^T (the vector corresponding to the first row of Z) and δ. The output is a sequence of $d-k$-dimensional near trivial matrices $V_1, \ldots, V_{2d-2k-1}$ such that their product $V = V_1 \times \cdots \times V_{2d-2k-1}$ has the property that $\|VZ_1^T - \|Z_1\| e_1\| \leq \delta$.

Now suppose that we extend V and the V_i back to d-dimensional, k-simple matrices, and we let $W = UV^*$. Then clearly V is unitary and V and W are k-simple. In fact, since V is unitary and U is δ-close to unitary, W is also δ-close to unitary. Moreover, W is close to being $k+1$-simple as desired. We will show below that the $k+1$st row of W satisfies $\|W_{k+1} - e_{k+1}^T\| \leq 2\delta$ and that the entries of the $k+1$st column of W satisfy $\|w_{j,k+1}\| \leq 6\delta$ for $j \neq k+1$.

So, let X be the $d \times d$, $k+1$-simple matrix such that

$$x_{1,1} = 1,\ x_{j,1} = 0 \text{ for } j \neq 1,\ x_{1,j} = 0 \text{ for } j \neq 1,\ x_{j,l} = w_{j,l} \text{ for } j, l > l+1.$$

It follows from our bounds on the norm of the first row of W and on the entries of the first column of W that $\|W - X\| \leq 2\delta + 6\sqrt{d}\delta$. Since W is δ-close to unitary, we can then conclude that X is $3\delta + 6\sqrt{d}\delta$-close to unitary.

Unfortunately, we cannot compute the entries of $W = UV^*$ exactly. Instead, appealing to Lemma 6.4 on page 1440, we compute them to within $\frac{\delta}{d}$ to obtain a matrix $\hat{W}$ such that $\|\hat{W} - W\| \leq \delta$. Let's use the entries of $\hat{W}$ to define matrix $\hat{X}$ analogous to X. Using the triangle inequality, it is easy to see that $\|W - \hat{X}\| \leq 3\delta + 6\sqrt{d}\delta$ and $\hat{X}$ is $4\delta + 6\sqrt{d}\delta$-close to unitary. If we are willing to incur an error of $\|W - \hat{X}\| \leq 3\delta + 6\sqrt{d}\delta$, then we are left with the problem of approximating the $k+1$-simple $\hat{X}$ by a product of near-trivial matrices. Therefore, we have reduced the problem of approximating the k-simple matrix U by near-trivial matrices to the problem of approximating the $k+1$-simple matrix $\hat{X}$ by near-trivial matrices while incurring two sources of error:

1. an error of $\|W - \hat{X}\| \leq 3\delta + 6\sqrt{d}\delta$, since we are approximating $\hat{X}$ instead of W;
2. the new matrix $\hat{X}$ is only $4\delta + 6\sqrt{d}\delta$-close to unitary.

Let $\delta' = 10\sqrt{d}\delta$. Clearly δ' is an upper bound on both sources of error cited above. Therefore, the total error in the approximation is just $\sum_{j=1}^{d} (10\sqrt{d})^j \delta \leq 2(10\sqrt{d})^d \delta$. The last inequality follows since $10\sqrt{d} \geq 2$, and therefore the sum can be bounded by a geometric series. Therefore, the total error in the approximation is bounded by ϵ, since by assumption U is δ-close to unitary for $\delta = \frac{\epsilon}{2(10\sqrt{d})^d}$.

It is easy to see that this algorithm runs in time polynomial in d and $\log \frac{1}{\epsilon}$. Our algorithm consists of d iterations of first calling the algorithm from Lemma 6.6 on page 1441 to compute V and then computing the matrix $\hat{X}$. Since the each iteration takes time polynomial in d and $\log \frac{(10\sqrt{d})^d}{\epsilon}$, these d calls take a total time polynomial in d and $\log \frac{1}{\epsilon}$.

Finally, we show as required that the $k+1$st row of W satisfies $\|W_{k+1} - e_{k+1}^T\| \leq 2\delta$ and that the entries of the $k+1$st column of W satisfy $\|w_{j,k+1}\| \leq 6\delta$ for $j \neq k+1$. To see this, first recall that the lower dimension V satisfies $\|VZ_1^T - \|Z_1\|e_1\| \leq \delta$, where Z_1 is the first row of the lower right $k \times k$ submatrix of U. Therefore, the higher dimension V satisfies $\|VU_{k+1}^T - \|U_{k+1}\|e_{k+1}\| \leq \delta$. Then, since $1-\delta \leq \|U_{k+1}\| \leq 1+\delta$, it follows that $\|VU_{k+1}^T - e_{k+1}\| \leq 2\delta$. Therefore, the $k+1$st row of W satisfies $\|W_{k+1} - e_{k+1}^T\| \leq 2\delta$.

Next, we will show that this implies that the entries of the $k+1$st column of W satisfy $\|w_{j,k+1}\| \leq 6\delta$ for $j \neq k+1$. To see this, first notice that since V is unitary and U is delta close to unitary, W is also δ-close to unitary. This means that by statement (6.2) of Lemma 6.3 on page 1440, $\left|W_{k+1} W_j^*\right| \leq 2\delta + 3\delta^2$. Now let us use the condition $\|W_{k+1} - e_{k+1}^T\| \leq 2\delta$. This implies that $|w_{k+1,k+1}| \geq 1 - 2\delta$. Also, let us denote by $\hat{W}_j$ the $d-1$-dimensional row vector arrived at by dropping $w_{j,k+1}$ from W_j. Then the condition that W_{k+1} is close to e_{k+1}^T also implies that $\|\hat{W_{k+1}}\| \leq 2\delta$. Also, the fact that W is δ-close to unitary implies that $\|\hat{W}_j\| \leq 1 + \delta$. Putting all this together, we have $2\delta + 3\delta^2 \geq |W_{k+1} W_j^*| = |w_{k+1,k+1} w_{j,k+1}^* + \hat{W_{k+1}} \hat{W_j}^*| \geq |w_{k+1,k+1} w_{j,k+1}^*| - |\hat{W_{k+1}} \hat{W_j}^*|$. Therefore, $|w_{k+1,k+1} w_{j,k+1}^*| \leq 2\delta + 3\delta^2 + |\hat{W_{k+1}} \hat{W_j}^*| \leq 2\delta + 3\delta^2 + 2\delta(1+\delta) \leq 4\delta + 5\delta^2$. Therefore, $|w_{j,k+1}| \leq \frac{4\delta + 5\delta^2}{1-2\delta}$. Finally, since we may assume that $\delta \leq \frac{1}{10}$, we have $|w_{j,k+1}| \leq 6\delta$. □

6.3. Carrying out near-trivial transformations. In this section, we show how to construct a single QTM that can carry out, at least approximately, any specified near-trivial transformation. Since a near-trivial transformation can apply an arbitrary rotation, either between two dimensions or in the phase of a single dimension, we must first show how a fixed rotation can be used to efficiently approximate an arbitrary rotation. Note that a single copy of this fixed rotation gives the only "nonclassical" amplitudes (those other than $0, 1$) in the transition function of the universal QTM constructed below. See Adleman, DeMarrais, and Huang [1] and Solovay and Yao [40] for the constructions of universal QTMs whose amplitudes are restricted to a small set of rationals.

LEMMA 6.8. *Let* $\mathcal{R} = 2\pi \sum_{i=1}^{\infty} 2^{-2^i}$. *Then there is a deterministic algorithm taking time polynomial in* $\log \frac{1}{\epsilon}$ *and the length of the input which on input* θ, ϵ *with* $\theta \in [0, 2\pi]$ *and* $\epsilon > 0$ *produces integer output* k *bounded by a polynomial in* $\frac{1}{\epsilon}$ *such that*

$$|k\mathcal{R} - \theta| \bmod 2\pi \ \leq \ \epsilon.$$

Proof. First, we describe a procedure for computing such a k.

Start by calculating n, a power of 2, such that $\epsilon > \frac{2\pi}{2^{n-1}}$. Next, approximate $\frac{\theta}{2\pi}$ as a fraction with denominator 2^n. In other words, find an integer $m \in [1, 2^n]$ such that

$$\left| \frac{\theta}{2\pi} - \frac{m}{2^n} \right| \leq \frac{1}{2^n}.$$

Then we can let $k = m2^n$ because

$$\begin{aligned} m2^n\mathcal{R} \bmod 2\pi &= \left(2\pi m \sum_{i=1}^{\infty} 2^{n-2^i} \right) \bmod 2\pi \\ &= \left(2\pi m \sum_{i=\log n+1}^{\infty} 2^{n-2^i} \right) \bmod 2\pi \\ &= \left(\frac{2\pi m}{2^n} + 2\pi m \sum_{i=\log n+2}^{\infty} 2^{n-2^i} \right) \bmod 2\pi \end{aligned}$$

and since

$$\begin{aligned} m \sum_{i=\log n+2}^{\infty} 2^{n-2^i} &\leq m2^{n-4n+1} \\ &\leq 2^{n-3n+1} \\ &\leq 2^{-2n+1} \end{aligned}$$

we have

$$\begin{aligned} |m2^n\mathcal{R} - \theta| \bmod 2\pi &\leq \left| m2^n\mathcal{R} - \frac{2\pi m}{2^n} \right| \bmod 2\pi \ + \ \left| \frac{2\pi m}{2^n} - \theta \right| \\ &\leq \frac{2\pi}{2^{2n-1}} + \frac{2\pi}{2^n} \\ &< \frac{2\pi}{2^{n-1}} \\ &< \epsilon. \qquad \square \end{aligned}$$

At this point it should be clear that a single QTM can carry out any sequence of near-trivial transformations to any desired accuracy ϵ. We formalize this notion below by showing that there is a QTM that accepts as input the descriptions of a sequence of near-trivial transformations and an error bound ϵ and applies an ϵ approximation of the product of these transformations on any given superposition. The formalization is quite tedious, and the reader is encouraged to skip the rest of the subsection if the above statement is convincing.

Below, we give a formal definition of what it means for a QTM to carry out a transformation.

DEFINITION 6.9. *Let $\Sigma \cup \#$ be the alphabet of the first track of QTM M. Let $\mathcal{V}$ be the complex vector space of superpositions of k length strings over Σ. Let U be a linear transformation on $\mathcal{V}$, and let x_U be a string that encodes U (perhaps approximately). We say that x_U* causes *M to carry out the k cell transformation U with accuracy ϵ in time T if for every $|\phi\rangle \in \mathcal{V}$, on input $|\phi\rangle|x_U\rangle|\epsilon\rangle$, M halts in exactly T steps with its tape head back in the start cell and with final superposition $(U'|\phi\rangle)|x\rangle$, where U' is a unitary transformation on $\mathcal{V}$ such that $\|U - U'\| \leq \epsilon$. Moreover, for a family A of transformations, we say that M carries out these transformations in polynomial time if T is bounded by a polynomial in $\frac{1}{\epsilon}$ and the length of the input.*

In the case that A contains transformations that are not unitary, we say that M carries out *the set of transformations A with* closeness factor *c if for any $\epsilon > 0$ and any $U \in A$ which is $c\epsilon$-close to unitary, there is a unitary transformation U' with $\|U' - U\| \leq \epsilon$ such that $|x_U\rangle|\epsilon\rangle$ causes M to carry out the transformation U' in time which is polynomial in $\frac{1}{\epsilon}$ and the length of its input.*

Recall that a near-trivial transformation written as x, y, θ calls for a rotation between dimensions x and y of angle θ if $x \neq y$ and a phase shift of $e^{i\theta}$ to dimension x otherwise. So, we want to build a stationary, normal form QTM that takes as input $w; x, y, \theta; \epsilon$ and transforms w according to the near-trivial transformation described by x, y, θ with accuracy ϵ. We also need this QTM's running time to depend only on the length of w but not its value. If this is the case then the machine will also halt on an initial superposition of the form $|\phi\rangle|x, y, \theta\rangle|\epsilon\rangle$ where $|\phi\rangle$ is a superposition of equal-length strings w.

LEMMA 6.10. *There is a stationary, normal form QTM M with first track alphabet $\{\#, 0, 1\}$ that carries out the set of near-trivial transformations on its first track in polynomial time.*

Proof. Using the encoding x, y, θ for near-trivial transformations described above in section 6.2, we will show how to construct QTMs M_1 and M_2 with first track alphabet $\{\#, 0, 1\}$ such that M_1 carries out the set of near-trivial rotations on its first track in polynomial time, and M_2 carries out the set of near-trivial phase shifts on its first track in polynomial time. Using the branching lemma (page 1429) on these two machines, we can construct a QTM that behaves correctly provided there is an extra track containing a 1 when $x = y$ and we have a phase shift to perform, and containing a 0 when $x \neq y$ and we have a rotation to perform. We can then construct the desired QTM M by dovetailing before and after with machines that compute and erase this extra bit based on x, y. The synchronization theorem lets us construct two such stationary, normal form QTMs whose running times depend only on the lengths of x and y. Therefore, this additional computation will not disturb the synchronization of the computation.

Next, we show how to construct the QTM M_1 to carry out near-trivial rotations.

It is easy to construct a QTM which on input b applies a rotation by angle θ between $|0\rangle$ and $|1\rangle$, while leaving b alone if $b = \#$. But Lemma 6.8 above tells us that we can achieve any rotation by applying the single rotation $\mathcal{R}$ at most a polynomial number of times. Therefore, the following five-step process will allow us to apply a near-trivial rotation. We must be careful that when we apply the rotation, the two computational paths with $b \in \{0, 1\}$ differ only in b since otherwise they will not interfere.

1. Calculate k such that $k\,\mathcal{R}\mathrm{mod}\,2\pi \in [\theta - \epsilon, \theta + \epsilon]$.
2. Transform w, x, y into b, x, y, z, where $b = 0$ if $w = x$, $b = 1$ if $w = y$ and $w \neq x$, and $b = \#$ otherwise and where $z = w$ if $b = \#$ and z is the empty string otherwise.
3. Run the rotation applying machine k times on the first bit of z.
4. Reverse step 2 transforming $\#, x, y, w$ with $w \neq x, y$ into w, x, y, transforming $0, x, y$ into x, x, y, and transforming $1, x, y$ with $x \neq y$ into y, x, y.
5. Reverse step 1 erasing k.

We build the desired QTM M by constructing a QTM for each of these five steps and then dovetailing them together.

First, notice that the length of the desired output of steps 1, 2, 4, and 5 can be computed just from the length of the input. Therefore, using Lemma 6.8 from page 1444 and the synchronization theorem from page 1428, we can build polynomial time, stationary, normal form QTMs for steps 1, 2, 4, and 5 which run in time that depend on the lengths of w, x, y but not their particular values.

To complete the construction we must build a machine for the rotation with these same properties. The stationary, normal form QTM R with alphabet $\{\#, 0, 1\}$, state set $\{q_0, q_1, q_f\}$, and transition function defined by

	$\#$	0	1
q_0	$\|\#\rangle\|q_1\rangle\|L\rangle$	$\cos\mathcal{R}\|0\rangle\|q_1\rangle\|L\rangle$ $+\sin\mathcal{R}\|1\rangle\|q_1\rangle\|L\rangle$	$-\sin\mathcal{R}\|0\rangle\|q_1\rangle\|L\rangle$ $+\cos\mathcal{R}\|1\rangle\|q_1\rangle\|L\rangle$
q_1	$\|\#\rangle\|q_f\rangle\|R\rangle$		
q_f	$\|\#\rangle\|q_0\rangle\|R\rangle$	$\|0\rangle\|q_0\rangle\|R\rangle$	$\|1\rangle\|q_0\rangle\|R\rangle$

runs for constant time and applies rotation $\mathcal{R}$ between start cell contents $|0\rangle$ and $|1\rangle$ while leaving other inputs unchanged. Inserting R for the special state in the reversible TM from the looping lemma, we can construct a normal form QTM which applies rotation $k\mathcal{R}$ between inputs $|0, k\rangle$ and $|1, k\rangle$ while leaving input $|\#w, k\rangle$ unchanged. Since the machine we loop on is stationary and takes constant time regardless of its input, the resulting looping machine is stationary and takes time depending only on k.

Finally, with appropriate use of Lemmas 4.4 and 4.5 on page 1428 we can dovetail these five stationary, normal form QTMs to achieve a stationary, normal form QTM M that implements the desired computation. Since, the phase application machine run in time which is independent of w, x, and y, and the other four run in time which depends only on the length of w, x, and y, the running time of M depends on the length of w, x, and y but not on their particular values. Therefore, it halts with the proper output not only if run on an input with a single string w but also if run on an initial superposition with different strings w and with the same near-trivial transformation and ϵ.

The QTM M_2 to carry out near-trivial phase shifts is the same as M_1 except that we replace the transition function of the simple QTM which applies a phase shift

rotation by angle $\mathcal{R}$ as follows giving a stationary QTM which applies phase shift $e^{i\mathcal{R}}$ if b is a 0 and phase shift 1 otherwise.

	#	0	1
q_0	$\|\#\rangle\|q_1\rangle\|L\rangle$	$e^{i\mathcal{R}}\|0\rangle\|q_1\rangle\|L\rangle$	$\|1\rangle\|q_1\rangle\|L\rangle$
q_1	$\|\#\rangle\|q_f\rangle\|R\rangle$		
q_f	$\|\#\rangle\|q_0\rangle\|R\rangle$	$\|0\rangle\|q_0\rangle\|R\rangle$	$\|1\rangle\|q_0\rangle\|R\rangle$

The proof that this gives the desired M_2 is identical to the proof for M_1 and is omitted. □

6.4. Carrying out a unitary transformation on a QTM. Now that we can approximate a unitary transformation by a product of near-trivial transformations, and we have a QTM to carry out the latter, we can build a QTM to apply an approximation of a given unitary transformation.

THEOREM 6.11 (unitary transformation theorem). *There is a stationary, normal form QTM M with first track alphabet $\{\#, 0, 1\}$ that carries out the set of all transformations on its first track in polynomial time with required closeness factor $\frac{1}{2(10\sqrt{d})^d}$ for transformations of dimension d.*

Proof. Given an $\epsilon > 0$ and a transformation U of dimension $d = 2^k$, which is $\frac{\epsilon}{2(10\sqrt{d})^d}$-close to unitary, we can carry out U to within ϵ on the first k cells of the first track using the following steps.

1. Calculate and write on clean tracks $\frac{\epsilon}{2n}$ and a list of near-trivial $U_1, \ldots, U_n$ such that $\|U - U_n \cdots U_1\| \leq \frac{\epsilon}{2}$ and such that n is polynomial in 2^k.
2. Apply the list of transformations $U_1, \ldots, U_n$, each to within $\frac{\epsilon}{2n}$.
3. Erase $U_1, \ldots, U_n$ and $\frac{\epsilon}{2n}$.

We can construct a QTM to accomplish these steps as follows. First, using Theorem 6.7 on page 1442 and the synchronization theorem on page 1428, we can build polynomial time, stationary, normal form QTMs for steps 1 and 3 that run in time, which depend only on U and ϵ. Finally, we can build a stationary, normal form QTM to accomplish step 2 in time, which is polynomial in 2^k, and $\frac{1}{\epsilon}$ as follows. We have a stationary, normal form QTM constructed in Lemma 6.10 on page 1445 to apply any specified near-trivial transformation to within a given bound ϵ. We dovetail this with a machine, constructed using the synchronization theorem on page 1428, that rotates U_1 around to the end of the list of transformations. Since the resulting QTM is stationary and takes time that depends only on ϵ and the U_i, we can insert it for the special state in the machine of the looping lemma to give the desired QTM for step 2.

With the appropriate use of Lemmas 4.4 and 4.5 on page 1428, dovetailing the QTMs for these three steps gives the desired M'. Since the running times of the three QTMs are independent of the contents of the first track, so is the running time of M'. Finally, notice that when we run M' we apply to the first k cells of the first track, we apply a unitary transformation U' with

$$\|U' - U\| \leq \|U' - U_n \cdots U_1\| + \|U_n \cdots U_1 - U\| \leq n\frac{\epsilon}{2n} + \frac{\epsilon}{2} \leq \epsilon$$

as desired. □

7. Constructing a universal QTM. A universal QTM must inevitably decompose one step of the simulated machine using many simple steps. A step of the

simulated QTM is a mapping from the computational basis to a new orthonormal basis. A single step of the universal QTM can only map some of the computational basis vectors to their desired destinations. In general this partial transformation will not be unitary, because the destination vectors will not be orthogonal to the computational bases which have not yet been operated on. The key construction that enables us to achieve a unitary decomposition is the unidirection lemma. Applying this lemma, we get a QTM whose mapping of the computational basis has the following property: there is a decomposition of the space into subspaces of constant dimension such that each subspace gets mapped onto another.

More specifically, we saw in the previous section that we can construct a QTM that carries out to a close approximation any specified unitary transformation. On the other hand, we have also noted that the transition function of a unidirectional QTM specifies a unitary transformation from superpositions of current state and tape symbol to superpositions of new symbol and state. This means a unidirectional QTM can be simulated by repeatedly applying this fixed-dimensional unitary transformation followed by the reversible deterministic transformation that moves the simulated tape head according to the new state. So, our universal machine will first convert its input to a unidirectional QTM using the construction of the unidirection lemma and then simulate this new QTM by repeatedly applying this unitary transformation and reversible deterministic transformation.

Since we wish to construct a single machine that can simulate every QTM, we must build it in such a way that every QTM can be provided as input. Much of the definition of a QTM is easily encoded: we can write down the size of the alphabet Σ, with the first symbol assumed to be the blank symbol, and we can write down the size of the state set Q, with the first state assumed to be the start state. To complete the specification, we need to describe the transition function δ by giving the $2\ \mathrm{card}(\Sigma)^2\ \mathrm{card}(Q)^2$ amplitudes of the form $\delta(i_1, i_2, i_3, i_4, d)$. If we had restricted the definition of a QTM to include only machines with rational transition amplitudes, then we could write down each amplitude explicitly as the ratio of two integers. However, we have instead restricted the definition of a QTM to include only those machines with amplitudes in $\tilde{\mathbf{C}}$, which means that for each amplitude there is a deterministic algorithm which computes the amplitude's real and imaginary parts to within 2^{-n} in time polynomial in n. We will therefore specify δ by giving a deterministic algorithm that computes each transition amplitude to within 2^{-n} in time polynomial in n.

Since the universal QTM that we will construct returns its tape head to the start cell after simulating each step of the desired machine, it will incur a slowdown which is (at least) linear in T. We conjecture that with more care a universal QTM can be constructed whose slowdown is only polylogarithmic in T.

THEOREM 7.1. *There is a normal form QTM $\mathcal{M}$ such that for any well-formed QTM M, any $\epsilon > 0$, and any T, $\mathcal{M}$ can simulate M with accuracy ϵ for T steps with slowdown polynomial in T and $\frac{1}{\epsilon}$.*

Proof. As described above, our approach will be first to use the construction of the unidirection lemma to build a unidirectional QTM M', which simulates M with slowdown by a factor of 5, and then to simulate M'. We will first describe the simulation of M' and then return to describe the easily computable preprocessing that needs to be carried out.

So, suppose $M = (\Sigma, Q, \delta)$ is a unidirectional QTM that we wish to simulate on our universal QTM.

We start by reviewing the standard technique of representing the configuration of a target TM on the tape of a universal TM. We will use one track of the tape of our universal QTM to simulate the current configuration of M. Since the alphabet and state set of M could have any fixed size, we will use a series of $\log\ \mathrm{card}(Q \times \Sigma)$ cells of our tape, referred to as a "supercell," to simulate each cell of M. Each supercell holds a pair of integers p, σ, where $\sigma \in [1, \mathrm{card}(\Sigma)]$ represents the contents of the corresponding cell of M, and $p \in [0, \mathrm{card}(Q)]$ represents the state of M if its tape head is scanning the corresponding cell and $p = 0$ otherwise. Since the tape head of M can only move distance T away from the start cell in time T, we only need supercells for the $2T + 1$ cells at the center of M's tape (and we place markers to denote the ends).

Now we know that if we ignore the update direction, then δ gives a unitary transformation U of dimension $d = \mathrm{card}(Q \times \Sigma)$ from superpositions of current state and tape symbol to superpositions of new state and symbol. So, we can properly update the superposition on the simulation tracks if we first apply U to the current state and symbol of M and then move the new state specification left or right one supercell according to the direction in which that state of M can be entered.

We will therefore build a QTM $STEP$ that carries out one step of the simulation as follows. In addition to the simulation track, this machine is provided as input a desired accuracy γ, a specification of U (which is guaranteed to be $\frac{\gamma}{2(10\sqrt{d})^d}$-close to the unitary), and a string $s \in \{0,1\}^{\mathrm{card}(Q)}$, which gives the direction in which each state of M can be entered. The machine $STEP$ operates as follows.

1. Transfer the current state and symbol $p; \sigma$ to empty workspace near the start cell, leaving a special marker in their places.
2. Apply U to $p; \sigma$ to within γ, transforming $p; \sigma$ into a superposition of new state and symbol $q; \tau$.
3. Reverse step 1, transferring q, τ back to the marked, empty supercell (and emptying the workspace).
4. Transfer the state specification q one supercell to the right or left depending whether the qth bit of s is a 0 or 1.

Using the synchronization theorem on page 1428, we can construct stationary, normal form QTMs for steps 1, 3, and 4 that take time which is polynomial in T and (for a fixed M) depend only on T. Step 2 can be carried out in time polynomial in $\mathrm{card}(\Sigma), \mathrm{card}(Q)$, and γ with the unitary transformation applying QTM constructed in the unitary transformation theorem. With appropriate use of Lemmas 4.4 and 4.5 on page 1428, dovetailing these four normal form QTMs gives us the desired normal form QTM $STEP$.

Since each of the four QTMs takes time that depends (for a fixed M) only on T and ϵ, so does $STEP$. Therefore, if we insert $STEP$ for the special state in the reversible TM constructed in the looping lemma and provide additional input T, the resulting QTM $STEP'$ will halt after time polynomial in T and $\frac{1}{\epsilon}$ after simulating T steps of M with accuracy $T\epsilon$.

Finally, we construct the desired universal QTM $\mathcal{M}$ by dovetailing $STEP'$ after a QTM which carries out the necessary preprocessing. In general, the universal machine must simulate QTMs that are not unidirectional. So, the preprocessing for desired QTM M, desired input x, and desired simulation accuracy ϵ consists of first carrying out the construction of the unidirection lemma to build a unidirectional QTM M'

which simulates M with slowdown by a factor of 5.[3] The following inputs are then computed for $STEP'$:

1. the proper $2T+1$ supercell representation of the initial configuration of M' with input x,
2. the d-dimensional transformation U for M' with each entry written to accuracy $\frac{\epsilon}{40T(10\sqrt{d})^{d+2}}$,
3. the string of directions s for M',
4. the desired number of simulation steps $5T$ and the desired accuracy $\gamma = \frac{\epsilon}{40T}$.

It can be verified that each of these inputs to $\mathcal{M}$ can be computed in deterministic time which is polynomial in T, $\frac{1}{\epsilon}$, and the length of the input. If the transformation U is computed to the specified accuracy, the transformation actually provided to $STEP$ will be within $\frac{\epsilon}{40T(10\sqrt{d})^d}$ of the desired unitary U and therefore will be $\frac{\epsilon}{40T(10\sqrt{d^d})}$-close to unitary as required for the operation of $STEP$. So, each time $STEP$ runs with accuracy $\frac{\epsilon}{40T}$, it will have applied a unitary transformation which is within $\frac{\epsilon}{20T}$ of U. Therefore, after $5T$ runs of $STEP$, we will have applied a unitary transformation which is within $\frac{\epsilon}{4}$ of the $5T$ step transformation of M'. This means that observing the simulation track of $\mathcal{M}$ after it has been completed will give a sample from a distribution which is within total variation distance ϵ of the distribution sampled by observing M on input x at time T. □

8. The computational power of QTMs. In this section, we explore the computational power of QTMs from a complexity theoretic point of view. It is natural to define quantum analogues of classical complexity classes [13]. In classical complexity theory, **BPP** is regarded as the class of all languages that is efficiently computable on a classical computer. The quantum analogue of BPP—BQP (bounded-error quantum polynomial time)—should similarly be regarded as the class of all languages that is efficiently computable on a QTM.

8.1. Accepting languages with QTMs.

DEFINITION 8.1. *Let M be a stationary, normal form, multitrack QTM M whose last track has alphabet $\{\#, 0, 1\}$. If we run M with string x on the first track and the empty string elsewhere, wait until M halts,*[4] *and then observe the last track of the start cell, we will see a* 1 *with some probability p. We will say that M* accepts *x with probability p and* rejects *x with probability $1-p$.*

Consider any language $\mathcal{L} \subseteq (\Sigma - \#)^*$.

We say that QTM M exactly accepts *the $\mathcal{L}$ if M accepts every string $x \in \mathcal{L}$ with probability* 1 *and rejects every string $x \in (\Sigma - \#)^* - \mathcal{L}$ with probability* 1.

We define the class **EQP** (exact *or* error-free quantum polynomial time) *as the set of languages which are exactly accepted by some polynomial time QTM. More generally, we define the class* **EQTime** $(T(n))$ *as the set of languages which are exactly accepted by some QTM whose running time on any input of length n is bounded by $T(n)$.*

A QTM accepts *the language $\mathcal{L} \subseteq (\Sigma - \#)^*$* with probability *$p$ if M accepts with probability at least p every string $x \in \mathcal{L}$ and rejects with probability at least p every string $x \in (\Sigma - \#)^* - \mathcal{L}$. We define the class* **BQP** *as the set of languages that are*

[3] Note that the transition function of M' is again specified with a deterministic algorithm, which depends on the algorithm for the transition function of M.

[4] This can be accomplished by performing a measurement to check whether the machine is in the final state q_f. Making this partial measurement does not have any other effect on the computation of the QTM.

accepted with probability $\frac{2}{3}$ *by some polynomial time QTM. More generally, we define the class* $\mathbf{BQTime}(T(n))$ *as the set of languages that are accepted with probability* $\frac{2}{3}$ *by some QTM whose running time on any input of length* n *is bounded by* $T(n)$.

The limitation of considering only stationary, normal form QTMs in these definitions is easily seen to not limit the computational power by appealing to the stationary, normal form universal QTM constructed in Theorem 7.1 on page 1448.

8.2. Upper and lower bounds on the power of QTMs. Clearly $\mathbf{EQP} \subseteq \mathbf{BQP}$. Since reversible TMs are a special case of QTMs, Bennett's results imply that $\mathbf{P} \subseteq \mathbf{EQP}$ and $\mathbf{BPP} \subseteq \mathbf{BQP}$. We include these two simple proofs for completeness.

THEOREM 8.2. $\mathbf{P} \subseteq \mathbf{EQP}$.

Proof. Let $\mathcal{L}$ be a language in $\mathbf{P}$. Then there is some polynomial time deterministic algorithm that on input x produces output 1 if $x \in \mathcal{L}$ and 0 otherwise. Appealing to the synchronization theorem on page 1428, there is therefore a stationary, normal form QTM running in polynomial time which on input x produces output $x;1$ if $x \in \mathcal{L}$ and $x;0$ otherwise. This is an $\mathbf{EQP}$ machine accepting $\mathcal{L}$. ∎

THEOREM 8.3. $\mathbf{BPP} \subseteq \mathbf{BQP}$.

Proof. Let $\mathcal{L}$ be a language in $\mathbf{BPP}$. Then there must be a polynomial $p(n)$ and a polynomial time deterministic TM M with $0,1$ output which satisfy the following. For any string x of length n, if we call S_x the set of $2^{p(n)}$ bits computed by M on the inputs $x;y$ with $y \in \{0,1\}^{p(n)}$, then the proportion of 1's in S_x is at least $\frac{2}{3}$ when $x \in \mathcal{L}$ and at most $\frac{1}{3}$ otherwise. We can use a QTM to decide whether a string x is in the language $\mathcal{L}$ by first breaking into a superposition split equally among all $|x\rangle|y\rangle$ and then running this deterministic algorithm.

First, we dovetail a stationary, normal form QTM that takes input x to output $x;0^{p(n)}$ with a stationary, normal form QTM constructed as in Theorem 8.8 below which applies a Fourier transform to the contents of its second track. This gives us a stationary, normal form QTM which on input x produces the superposition $\sum_{y\in\{0,1\}^{p(n)}} \frac{1}{2^{p(n)/2}}|x\rangle|y\rangle$. Dovetailing this with a synchronized, normal form version of M built according to the synchronization theorem on page 1428 gives a polynomial time QTM which on input x produces a final superposition

$$\sum_{y\in\{0,1\}^{p(n)}} \frac{1}{2^{p(n)/2}}|x\rangle|y\rangle|M(x;y)\rangle.$$

Since the proportion of 1's in S_x is at least $\frac{2}{3}$ if $x \in \mathcal{L}$ and at most $\frac{1}{3}$ otherwise, observing the bit on the third track will give the proper classification for string x with probability at least $\frac{2}{3}$. Therefore, this is a $\mathbf{BQP}$ machine accepting the language $\mathcal{L}$. ∎

Clearly $\mathbf{BQP}$ is in exponential time. The next result gives the first nontrivial upper bound on $\mathbf{BQP}$.

THEOREM 8.4. $\mathbf{BQP} \subseteq \mathbf{PSPACE}$.

Proof. Let $M = (\Sigma, Q, \delta)$ be a $\mathbf{BQP}$ machine with running time $p(n)$.

According to Theorem 3.9 on page 1423, any QTM M' which is

$$\frac{\epsilon}{24\ \mathrm{card}(\Sigma)\ \mathrm{card}(Q)p(n)}\text{-close}$$

to M will simulate M for $p(n)$ steps with accuracy ϵ. If we simulate M with accuracy $\frac{1}{12}$, then the success probability will still be at least $\frac{7}{12}$. Therefore, we need only work

with the QTM M' where each transition amplitude from M is computed to its first $\log(288\ \mathrm{card}(\Sigma)\ \mathrm{card}(Q)p(n))$ bits.

Now the amplitude of any particular configuration at time T is the sum of the amplitudes of each possible computational path of M' of length T from the start configuration to the desired configuration. The amplitude of each such path can be computed exactly in polynomial time. So, if we maintain a stack of at most $p(n)$ intermediate configurations we can carry out a depth-first search of the computational tree to calculate the amplitude of any particular configuration using only polynomial space (but exponential time).

Finally, we can determine whether a string x of length n is accepted by M by computing the sum of squared magnitudes at time $p(n)$ of all configurations that M' can reach that have a 1 in the start cell and comparing this sum to $\frac{7}{12}$. Clearly the only reachable "accepting" configurations of M' are those with a 1 in the start cell and blanks in all but the $2p(n)$ cells within distance $p(n)$ of the start cell. So, using only polynomial space, we can step through all of these configurations computing a running sum of the their squared magnitudes. □

Following Valiant's suggestion [43], the upper bound can be further improved to $\mathbf{P}^{\sharp\mathbf{P}}$. This proof can be simplified by using a theorem from [9] that shows how any **BQP** machine can be turned into a "clean" version M that on input x produces a final superposition with almost all of its weight on $x; M(x)$ where $M(x)$ is a 1 if M accepts x and a 0 otherwise. This means we need only estimate the amplitude of this one configuration in the final superposition of M.

Now, the amplitude of a single configuration can be broken down into not only the sum of the amplitudes of all of the computational paths that reach it but also into the sum of positive real contributions, the sum of negative real contributions, the sum of positive imaginary contributions, and the sum of negative imaginary contributions. We will show that each of these four pieces can be computed using a $\sharp\mathbf{P}$ machine.

Recall that $\sharp\mathbf{P}$ is the set of functions f mapping strings to integers for which there exists a polynomial $p(n)$ and a language $\mathcal{L} \in \mathbf{P}$ such that for any string x, the value $f(x)$ is the number of strings y of length $p(|x|)$ for which xy is contained in $\mathcal{L}$.

THEOREM 8.5. *If the language $\mathcal{L}$ is contained in the class* $\mathbf{BQTime}(T(n))$ *with $T(n) > n$, with $T(n)$ time constructible, then for any $\epsilon > 0$ there is a QTM M' which accepts $\mathcal{L}$ with probability $1 - \epsilon$ and has the following property. When run on input x of length n, M' runs for time bounded by $cT(n)$, where c is a polynomial in $\log \frac{1}{\epsilon}$ and produces a final superposition in which $|x\rangle|\mathcal{L}(x)\rangle$, with $\mathcal{L}(x) = 1$ if $x \in \mathcal{L}$ and 0 otherwise, has squared magnitude at least $1 - \epsilon$.*

THEOREM 8.6. $\mathbf{BQP} \subseteq \mathbf{P}^{\sharp\mathbf{P}}$.

Proof. Let $M = (\Sigma, Q, \delta)$ be a **BQP** machine with observation time $p(n)$. Appealing to Theorem 8.5 above, we can conclude without loss of generality that M is a "clean **BQP** machine." For example, on any input x at time $p(|x|)$, the squared magnitude of the final configuration with output $x; M(x)$ is at least $\frac{2}{3}$.

Now as above, we will appeal to Theorem 3.9 on page 1423 which tells us that if we work with the QTM M', where each amplitude of M is computed to its first $b = \log(288\ \mathrm{card}(\Sigma)\ \mathrm{card}(Q)p(n))$ bits, and we run M' on input x, then the squared magnitude at time $p(|x|)$ of the final configuration with output $x; M(x)$ will be at least $\frac{7}{12}$.

We will carry out the proof by showing how to use an oracle for the class $\sharp\mathbf{P}$ to efficiently compute with error magnitude less than $\frac{1}{36}$ the amplitude of the final configuration $x; 1$ of M' at time T. Since the true amplitude has magnitude at most

1, the squared magnitude of this approximated amplitude must be within $\frac{1}{12}$ of the squared magnitude of the true amplitude. To see this, just note that if α is the true amplitude and $\|\alpha' - \alpha\| < \frac{1}{36}$, then

$$\left| \|\alpha\|^2 - \|\alpha'\|^2 \right| \leq \|\alpha' - \alpha\|^2 + 2\|\alpha\|\|\alpha' - \alpha\| \leq \frac{1}{36}\left(2 + \frac{1}{36}\right) < \frac{1}{12}.$$

Since the success probability of M' is at least $\frac{7}{12}$, comparing the squared magnitude of this approximated amplitude to $\frac{1}{2}$ lets us correctly classify the string x.

We will now show how to approximate the amplitude described above. First, notice that the amplitude of a configuration at time T is the sum of the amplitudes of each computational path of length T from the start configuration to the desired configuration. The amplitude of any particular path is the product of the amplitudes in the transition function of M' used in each step along the path. Since each amplitude consists of a real part and an imaginary part, we can think of this product as consisting of the sum of 2^T terms each of which is either purely real or purely imaginary. So, the amplitude of the desired configuration at time T is the sum of these 2^T terms over each path. We will break this sum into four pieces, the sum of the positive real terms, the sum of the negative real terms, the sum of the positive imaginary terms, and the sum of the negative imaginary terms, and we will compute each to within error magnitude less than $\frac{1}{144}$ with the aid of a $\sharp\mathbf{P}$ algorithm. Taking the difference of the first two and the last two will then give us the amplitude of the desired configuration to within an error of magnitude at most $\frac{1}{36}$ as desired.

We can compute the sum of the positive real contributions for all paths as follows. Suppose for some fixed constant c which is polynomial in T we are given the following three inputs, all of length polynomial in T: a specification of a T step computational path p of M', a specification t of one of the 2^T terms, and an integer w between 0 and 2^{cT}. Then it is easy to see that we could decide in deterministic time polynomial in T whether p is really a path from the start configuration of M on x to the desired final configuration, whether the term t is real and positive, and whether the tth term of the amplitude for path p is greater than $w/2^{cT}$. If we fix a path p and term t satisfying these constraints, then the number of w for which this algorithm accepts, divided by 2^{cT}, is within $1/2^{cT}$ of the value of the tth for path p. So, if we fix only a path p satisfying these constraints, then the number of t, w for which the algorithm accepts, divided by 2^{cT}, is within $1/2^{(c-1)T}$ of the sum of the positive real terms for path p. Therefore, the number of p, t, w for which the algorithm accepts, divided by 2^{cT}, is within $N/2^{(c-1)T}$ of the sum of all of the positive real terms of all of the T step paths of M' from the start configuration to the desired configuration. Since there are at most $2\text{card}(\Sigma)\text{card}(Q)$ possible successors for any configuration in a legal path of M, choosing $c > 1 + \frac{\log 144}{T} + \frac{2\text{card}(\Sigma)\text{card}(Q)\log T}{T}$ gives $N/2^{(c-1)T} < \frac{1}{144}$ as desired. Similar reasoning gives $\mathbf{P}^{\sharp\mathbf{P}}$ algorithms for approximating each of the remaining three sums of terms. □

8.3. Oracle QTMs. In this subsection and the next, we will assume without loss of generality that the TM alphabet for each track is $\{0, 1, \#\}$. Initially all tracks are blank except that the input track contains the actual input surrounded by blanks. We will use Σ to denote $\{0, 1\}$.

In the classical setting, an oracle may be described informally as a device for evaluating some Boolean function $f : \Sigma^* \to \Sigma$, on arbitrary arguments, at unit cost per evaluation. This allows us to formulate questions such as, "if f were efficiently computable by a TM, which other functions (or languages) could be efficiently computed

by TMs?" In this section we define oracle QTMs so that the equivalent question can be asked in the quantum setting.

An oracle QTM has a special *query track* on which the machine will place its questions for the oracle. Oracle QTMs have two distinguished internal states: a prequery state q_q and a postquery state q_a. A query is executed whenever the machine enters the prequery state with a single (nonempty) block of nonblank cells on the query track.[5] Assume that the nonblank region on the query tape is in state $|x \cdot b\rangle$ when the prequery state is entered, where $x \in \Sigma^*$, $b \in \Sigma$, and "$\cdot$" denotes concatenation. Let f be the Boolean function computed by the oracle. The result of the oracle call is that the state of the query tape becomes $|x \cdot b \oplus f(x)\rangle$, where "$\oplus$" denotes the exclusive-or (addition modulo 2), after which the machine's internal control passes to the postquery state. Except for the query tape and internal control, other parts of the oracle QTM do not change during the query. If the target bit $|b\rangle$ was supplied in initial state $|0\rangle$, then its final state will be $|f(x)\rangle$, just as in a classical oracle machine. Conversely, if the target bit is already in state $|f(x)\rangle$, calling the oracle will reset it to $|0\rangle$, a process known as "uncomputing," which is essential for proper interference to take place.

The power of quantum computers comes from their ability to follow a coherent superposition of computation paths. Similarly, oracle QTMs derive great power from the ability to perform superpositions of queries. For example, an oracle for Boolean function f might be called when the query tape is in state $|\psi, 0\rangle = \sum_x \alpha_x |x, 0\rangle$, where α_x are complex coefficients, corresponding to an arbitrary superposition of queries with a constant $|0\rangle$ in the target bit. In this case, after the query, the query string will be left in the entangled state $\sum_x \alpha_x |x, f(x)\rangle$.

That the above definition of oracle QTMs yields unitary evolutions is self-evident if we restrict ourselves to machines that are well formed in other respects, in particular evolving unitarily as they enter the prequery state and leave the postquery state.

Let us define $\mathbf{BQTime}\,(T(n))^O$ as the sets of languages accepted with probability at least $\frac{2}{3}$ by some oracle QTM M^O whose running time is bounded by $T(n)$. This bound on the running time applies to each individual input, not just on the average. Notice that whether or not M^O is a **BQP**-machine might depend upon the oracle O; thus M^O might be a **BQP**-machine while $M^{O'}$ might not be one.

We have carefully defined oracle QTMs so that the same technique used to reverse a QTM in the reversal lemma can also be used to reverse an oracle QTM.

LEMMA 8.7. *If M is a normal form, unidirectional oracle QTM, then there is a normal form oracle QTM M' such that for any oracle O, M'^O reverses the computation of M^O while taking two extra time steps.*

Proof. Let $M = (\Sigma, Q, \delta)$ be a normal form, unidirectional oracle QTM with initial and final states q_0 and q_f and with query states $q_q \neq q_f$ and q_a. We construct M' from M exactly as in the proof of the reversal lemma. We further give M' the same query states q_q, q_a as M but with roles reversed. Since M is in normal form, and $q_q \neq q_f$, we must have $q_a \neq q_0$. Recall that the transition function of M' is defined so that for $q \neq q_0$

$$\delta'(q, \tau) = \sum_{p,\sigma} \delta(p, \sigma, \tau, q, d_q)^* |\sigma\rangle |p\rangle |\hat{d}_p\rangle.$$

[5] Since a QTM must be careful to avoid leaving around intermediate computations on its tape, requiring that the query track contains only the query string, adds no further difficulty to the construction of oracle QTMs.

Therefore, since state q_q always leads to state q_a in M, state q_a always leads to state q_q in M'. Therefore, M' is an oracle QTM.

Next, note that since the tape head position is irrelevant for the functioning of the oracle, the operation of the oracle in M'^O reverses the operation of the oracle in M^O. Finally, the same argument used in the reversal lemma can be used again here to prove that M'^O is well formed and that M'^O reverses the computation of M^O while taking two extra time steps. □

The above definition of a quantum oracle for an arbitrary Boolean function will suffice for the purposes of the present paper, but the ability of quantum computers to perform general unitary transformations suggests a broader definition, which may be useful in other contexts. For example, oracles that perform more general, non-Boolean unitary operations have been considered in computational learning theory [15] and have been used to obtain large separations [32] between quantum and classical relativized complexity classes. See [9] for a discussion of more general definitions of oracle quantum computing.

8.4. Fourier sampling and the power of QTMs. In this section we give evidence that QTMs are more powerful than bounded-error probabilistic TMs. We define the recursive Fourier sampling problem which on input the program for a Boolean function takes on value 0 or 1. We show that the recursive Fourier sampling problem is in **BQP**. On the other hand, we prove that if the Boolean function is specified by an oracle, then the recursive Fourier sampling problem is not in $\mathbf{BQTime}(n^{o(\log n)})$. This result provided the first evidence that QTMs are more powerful than classical probabilistic TMs with bounded error probability [11].

One could ask what the relevance of these oracle results is, in view of the non-relativizing results on probabilistically checkable proofs [36, 3]. Moreover, Arora, Impagliazzo, and Vazirani [2] make the case that the fact that the **P** versus **NP** question relativizes does not imply that the question "cannot be resolved by current techniques in complexity theory." On the other hand, in our oracle results (and also in the subsequent results of [39]), the key property of oracles that is exploited is their black-box nature, and for the reasons sketched below, these results did indeed provide strong evidence that $\mathbf{BQP} \neq \mathbf{BPP}$ (of course, the later results of [36] gave even stronger evidence). This is because if one assumes that $\mathbf{P} \neq \mathbf{NP}$ and the existence of one-way functions (both these hypotheses are unproven but widely believed by complexity theorists), it is also reasonable to assume that, in general, it is impossible to (efficiently) figure out the function computed by a program by just looking at its text (i.e., without explicitly running it on various inputs). Such a program would have to be treated as a black box. Of course, such assumptions cannot be made if the question at hand is whether $\mathbf{P} \stackrel{?}{=} \mathbf{NP}$.

Fourier sampling. Consider the vector space of complex-valued functions $f : Z_2^n \to \mathbf{C}$. There is a natural inner product on this space given by

$$(f, g) = \sum_{x \in Z_2^n} f(x) g(x)^*.$$

The standard orthonormal basis for the vector space is the set of delta functions $\delta_y : Z_2^n \to \mathbf{C}$, given by $\delta_y(y) = 1$ and $\delta_y(x) = 0$ for $x \neq y$. Expressing a function in this basis is equivalent to specifying its values at each point in the domain. The characters of the group Z_2^n yield a different orthonormal basis consisting of the parity basis functions $\chi_s : Z_2^n \to \mathbf{C}$, given by $\chi_s(x) = \frac{-1^{s \cdot x}}{2^{n/2}}$, where $s \cdot x = \sum_{i=1}^n s_i x_i$. Given

any function $f : Z_2^n \to \mathbf{C}$, we may write it in the new parity basis as $f = \sum_s \hat{f}(s)\chi_s$, where $\hat{f} : Z_2^n \to \mathbf{C}$ is given by $\hat{f}(s) = (f, \chi_s)$. The function $\hat{f}$ is called the discrete Fourier transform or Hadamard transform of f. Here the latter name refers to the fact that the linear transformation that maps a function f to its Fourier transform $\hat{f}$ is the Hadamard matrix $\mathcal{H}_n$. Clearly this transformation is unitary, since it is just effecting a change of basis from one orthonormal basis (the delta function basis) to another (the parity function basis). It follows that $\sum_x |f(x)|^2 = \sum_s |\hat{f}(s)|^2$.

Moreover, the discrete Fourier transform on Z_2^n can be written as the Kronecker product of the transform on each of n copies of Z_2—the transform in that case is given by the matrix

$$\begin{pmatrix} \frac{1}{\sqrt{2}} & \frac{1}{\sqrt{2}} \\ \frac{1}{\sqrt{2}} & -\frac{1}{\sqrt{2}} \end{pmatrix}.$$

This fact can be used to write a simple and efficient QTM that affects the discrete Fourier transformation in the following sense: suppose the QTM has tape alphabet $\{0, 1, \#\}$ and the cells initially that have only n tape contain nonblank symbols. Then we can express the initial superposition as $\sum_{x\in\{0,1\}^n} f(x)|x\rangle$, where $f(x)$ is the amplitude of the configuration with x in the nonblank cells. Then there is a QTM that affects the Fourier transformation by applying the above transform on each of the n bits in the n nonblank cells. This takes $O(n)$ steps and results in the final configuration $\sum_{s\in\{0,1\}^n} \hat{f}(s)|s\rangle$ (Theorem 8.8 below). Notice that this Fourier transformation is taking place over a vector space of dimension 2^n. On the other hand, the result of the Fourier transform $\hat{f}$ resides in the amplitudes of the quantum superposition and is thus not directly accessible. We can, however, perform a measurement on the n nonblank tape cells to obtain a sample from the probability distribution P such that $P[s] = |\hat{f}(s)|^2$. We shall refer to this operation as Fourier sampling. As we shall see, this is a very powerful operation. The reason is that each value $\hat{f}(s)$ depends upon all the (exponentially many values) of f, and it does not seem possible to anticipate which values of s will have large probability (constructive interference) without actually carrying out an exponential search.

Given a Boolean function $g : Z_2^n \to \{1, -1\}$, we may define a function $f : Z_2^n \to \mathbf{C}$ of norm 1 by letting $f(x) = \frac{g(x)}{2^{n/2}}$. Following Deutsch and Jozsa [22], if g is a polynomial time computable function, there is a QTM that produces the superposition $\sum_{x\in\{0,1\}^n} g(x)|x\rangle$ in time polynomial in n. Combining this with the Fourier sampling operation above, we get a polynomial time QTM that samples from a certain distribution related to the given polynomial time computable function g (Theorem 8.9 below). We shall call this composite operation Fourier sampling with respect to g.

THEOREM 8.8. *There is a normal form QTM which when run on an initial superposition of n-bit strings $|\phi\rangle$ halts in time $2n + 4$ with its tape head back in the start cell and produces final superposition $\mathcal{H}_n|\phi\rangle$.*

Proof. We can construct the desired machine using the alphabet $\{\#, 0, 1\}$ and the set of states $\{q_0, q_a, q_b, q_c, q_f\}$. The machine will operate as follows when started with a string of length n as input. In state q_0, the machine steps right and left and enters state q_b. In state q_b, the machine steps right along the input string until it reaches the # at the end and enters state q_c stepping back left to the string's last symbol. During this rightward scan, the machine applies the transformation

$$\begin{pmatrix} \frac{1}{\sqrt{2}} & \frac{1}{\sqrt{2}} \\ \frac{1}{\sqrt{2}} & -\frac{1}{\sqrt{2}} \end{pmatrix}$$

to the bit in each cell. In state q_c, the machine steps left until it reaches the # to the left of the start cell, at which point it steps back right and halts. The following gives the quantum transition function of the desired machine.

	#	0	1
q_0		$\|0\rangle\|q_a\rangle\|R\rangle$	$\|1\rangle\|q_a\rangle\|R\rangle$
q_a	$\|\#\rangle\|q_b\rangle\|L\rangle$		
q_b	$\|\#\rangle\|q_c\rangle\|L\rangle$	$\frac{1}{\sqrt{2}}\|0\rangle\|q_b\rangle\|R\rangle + \frac{1}{\sqrt{2}}\|1\rangle\|q_b\rangle\|R\rangle$	$\frac{1}{\sqrt{2}}\|0\rangle\|q_b\rangle\|R\rangle - \frac{1}{\sqrt{2}}\|1\rangle\|q_b\rangle\|R\rangle$
q_c	$\|\#\rangle\|q_f\rangle\|L\rangle$	$\|0\rangle\|q_c\rangle\|L\rangle$	$\|1\rangle\|q_c\rangle\|L\rangle$
q_f	$\|\#\rangle\|q_0\rangle\|R\rangle$	$\|0\rangle\|q_0\rangle\|R\rangle$	$\|1\rangle\|q_0\rangle\|R\rangle$

It is can be easily verified that the completion lemma can be used to extend this machine to a well-formed QTM and that this machine has the desired behavior described above. □

THEOREM 8.9. *For every polynomial time computable function $g : \{0,1\}^n \to \{-1,1\}$, there is a polynomial time, stationary QTM where observing the final superposition on input 0^n gives each n-bit string s with probability $|\hat{f}(s)|^2$, where $f(x) = \frac{g(x)}{2^{n/2}}$.*

Proof. We build a QTM to carry out the following steps.

1. Apply a Fourier transform to 0^n to produce $\sum_{i\in\{0,1\}^n} \frac{1}{2^{n/2}}|i\rangle$.
2. Compute f to produce $\sum_{i\in\{0,1\}^n} \frac{1}{2^{n/2}}|i\rangle|f(i)\rangle$.
3. Apply a phase-applying machine to produce $\sum_{i\in\{0,1\}^n} \frac{1}{2^{n/2}}f(i)|i\rangle|f(i)\rangle$.
4. Apply the reverse of the machine in step 2 to produce $\sum_{i\in\{0,1\}^n} \frac{1}{2^{n/2}}f(i)|i\rangle$.
5. Apply another Fourier transform to produce $\sum_{i\in\{0,1\}^n} \frac{1}{2^{n/2}}\hat{f}(s)|s\rangle$ as desired.

We have already constructed above the Fourier transform machine for steps 1 and 5. Since f can be computed in deterministic polynomial time, the synchronization theorem on page 1428 lets us construct polynomial time QTMs for steps 2 and 4 which take input $|i\rangle$ to output $|i\rangle|f(i)\rangle$ and vice versa, with running time independent of the particular value of i.

Finally, we can apply phase according to $f(i)$ in step 3 by extending to two tracks the stationary, normal form QTM with alphabet $\{\#, -1, 1\}$ defined by

	#	-1	1
q_0	$\|\#\rangle\|q_1\rangle\|R\rangle$	$-\|-1\rangle\|q_1\rangle\|R\rangle$	$\|1\rangle\|q_1\rangle\|R\rangle$
q_1	$\|\#\rangle\|q_f\rangle\|L\rangle$	$\|-1\rangle\|q_f\rangle\|L\rangle$	$\|1\rangle\|q_f\rangle\|L\rangle$
q_f	$\|\#\rangle\|q_0\rangle\|R\rangle$	$\|-1\rangle\|q_0\rangle\|R\rangle$	$\|1\rangle\|q_0\rangle\|R\rangle$

Dovetailing these five stationary, normal form QTMs gives the desired machine. □

Remarkably, this quantum algorithm performs Fourier sampling with respect to f while calling the algorithm for f only twice. To see more clearly why this is remarkable, consider the special case of the sampling problem where the function f is one of the (unnormalized) parity functions. Suppose f corresponds to the parity function χ_k; i.e., $f(i) = (-1)^{i\cdot k}$, where $i, k \in \{0,1\}^n$. Then the result of Fourier sampling with respect to f is always k. Let us call this promise problem the parity problem: on input a program that computes f where f is an (unnormalized) parity function, determine k. Notice that the QTM for Fourier sampling extracts n bits of information (the value of k) using just two invocations of the subroutine for computing Boolean function f. It is not hard to show that if f is specified by an oracle, then in a probabilistic setting, extracting n bits of information must require at least n invocations of the Boolean function. We now show how to amplify this advantage of quantum computers over

probabilistic computers by defining a recursive version of the parity problem: the recursive Fourier sampling problem.

To ready this problem for recursion, we first need to turn the parity problem into a problem with range $\{-1, 1\}$. This is easily done by adding a second function g and requiring the answer $g(k)$ rather than k itself.

Now, we will make the problem recursive. For each problem instance of size n, we will replace the 2^n values of f with 2^n independent recursive subproblems of size $\frac{n}{2}$, and so on, stopping the recursion with function calls at the bottom. Since a QTM needs only two calls to f to solve the parity problem, it will be able to solve an instance of the recursive problem of size n recursively in time $T(n)$, where

$$T(n) \;\leq\; poly(n) + 4T\left(\frac{n}{2}\right) \qquad \Longrightarrow \qquad T(n) \leq poly(n).$$

However, since a PTM needs n calls to f to solve the parity problem, the straightforward recursive solution to the recursive problem on a PTM will require time $T(n)$, where

$$T(n) \;\geq\; nT\left(\frac{n}{2}\right) \qquad \Longrightarrow \qquad T(n) \;\geq\; n^{\log n}.$$

To allow us to prove a separation between quantum and classical machines, we will replace the functions with an oracle. For any "legal" oracle O, any oracle satisfying some special constraints to be described below, we will define the language $\mathcal{R}_O$. We will show that there is a QTM which, given access to any legal oracle O, accepts $\mathcal{R}_O$ in time $O(n \log n)$ with success probability 1 but that there is a legal oracle O such that $\mathcal{R}_O$ is not contained in $\mathbf{BPTime}\left(n^{o(\log n)}\right)^O$.

Our language will consist of strings from $\{0, 1\}^*$ with length a power of 2. We will call all such strings *candidates*. The decision whether a candidate x is contained in the language will depend on a recursive tree. If candidate x has length n, then it will have $2^{n/2}$ children in the tree, and in general a node at level $l \geq 0$ (counting from the bottom with leaves at level -1 for convenience) will have 2^{2^l} children. So, the root of the tree for a candidate x of length n is identified by the string x, its $2^{n/2}$ children are each identified by a string $x\$x_1$ where $x_1 \in \{0, 1\}^{n/2}$, and, in general, a descendent in the tree at level l is identified by a string of the form $x\$x_1\$x_2\$ \ldots \$x_m$ with $|x| = n, |x_1| = \frac{n}{2}, \ldots, |x_m| = 2^{l+1}$. Notice that any string of this form for some n a power of 2 and $l \in [0, \log n - 1]$ defines a node in some tree. So, we will consider oracles O which map queries over the alphabet $\{0, 1, \$\}$ to answers $\{-1, +1\}$, and we will use each such oracle O to define a function V_O that gives each node a value $\{-1, +1\}$. The language $\mathcal{R}_O$ will contain exactly those candidates x for which $V_O(x) = 1$.

We will define V_O for leaves (level 0 nodes) based directly on the oracle O. So, if x is a leaf, then we let $V_O(x) = O(x)$.

We will define V_O for all other nodes by looking at the answer of O to a particular query which is chosen depending on the values of V_O for its children. Consider node x at level $l \geq 0$. We will insist that the oracle O be such that there is some $k_x \in \{0, 1\}^{2^l}$ such that the children of x all have values determined by their parity with k_x

$$\forall y \in \{0, 1\}^{2^l}, \quad V_O(x\$y) = (-1)^{y \cdot k_x},$$

and we will then give $V_O(x)$ the value $O(x\$k_x)$. We will say that the oracle O is *legal* if this process allows us to successfully define V_O for all nodes whose level is ≥ 0. Any

query of the form $x\$k$ with x a node at level $l \geq 0$ and $k \in \{0,1\}^{2^l}$, or of the form x with x a leaf, is called a *query at node* x. A query which is located in the same recursive tree as node x, but not in the subtree rooted at x, is called *outside of* x. Notice that for any candidate x, the values of V_O at nodes in the tree rooted at x and the decision whether x is in $\mathcal{R}_O$ all depend only on the answers of queries located at nodes in the tree rooted at x.

THEOREM 8.10. *There is an oracle QTM M such that for every legal oracle O, M^O runs in polynomial time and accepts the language $\mathcal{R}_O$ with probability* 1.

Proof. We have built the language $\mathcal{R}_O$ so that it can be accepted efficiently using a recursive quantum algorithm. To avoid working through the details required to implement a recursive algorithm reversibly, we will instead implement the algorithm with a machine that writes down an iteration that "unwraps" the desired recursion. Then the looping lemma will let us build a QTM to carry out this iteration.

First consider the recursive algorithm to compute V_O for a node x. If x is a leaf, then the value $V_O(x)$ can be found by querying the string $x\$$. If x is a node at level $l \geq 0$, then calculate V_O as follows.

1. Split into an equal superposition of the 2^{2^l} children of x.
2. Recursively compute V_O for these children in superposition.
3. Apply phase to each child given by that child's value V_O.
4. Reverse the computation of step 2 to erase the value V_O.
5. Apply the Fourier transform converting the superposition of children of x into a superposition consisting entirely of the single string k_x.
6. Query $x\$k_x$ to find the value V_O for x.
7. Reverse steps 1–5 to erase k_x (leaving only x and $V_O(x)$).

Notice that the number of steps required in the iteration obeys the recursion discussed above and hence is polynomial in the length of x. So, we can use the synchronization theorem on page 1428 to construct a polynomial time QTM which, for any particular x, writes a list of the steps which must be carried out. Therefore, we complete the proof by constructing a polynomial time QTM to carry out any such list of steps.

Since our algorithm requires us to recursively run both the algorithm and its reverse, we need to see how to handle each step and its reverse. Before we start, we will fill out the node x to a description of a leaf by adding strings of 0's. Then, steps 1 and 5 at level $l \geq 0$ just require applying the Fourier transform QTM to the 2^l bit string at level l in the current node description. Since the Fourier transform is its own reverse, the same machine also reverses steps 1 and 5. Step 3 is handled by the phase-applying machine already constructed above as part of the Fourier sampling QTM in Theorem 8.9. Again, the transformation in step 3 is its own reverse, so the same machine can be used to reverse step 3. Step 6 and its reverse can be handled by a reversible TM that copies the relevant part of the current node description, queries the oracle, and then returns the node description from the query tape. Notice that each of these machines takes time which depends only on the length of its input.

Since we have stationary, normal form QTMs to handle each step at level l and its reverse in time bounded by a polynomial in 2^l, we can use the branching lemma to construct a stationary, normal form QTM to carry out any specified step of the computation. Dovetailing with a machine which rotates the first step in the list to the end and inserting the resulting machine into the reversible TM of the looping lemma gives the desired QTM. □

Computing the function V_O takes time $\Omega(n^{\log n})$ even for a probabilistic computer that is allowed a bounded probability of error. We can see this with the following intuition. First, consider asking some set of queries of a legal O that determine the value of V_O for a node x described by the string $x_1\$ \dots \$x_m$ at level l. There are two ways that the asked queries might fix the value at x. The first is that the queries outside of the subtree rooted at x might be enough to fix V_O for x. If this happens, we say that $V_O(x)$ is *fixed by constraint*. An example of this is that if we asked all of the queries in the subtrees rooted at all of the siblings of x, then we have fixed V_O for all of the siblings, thereby fixing the string k such that $V_O(x_1\$ \dots \$x_m\$y)$ equals $(-1)^{y \cdot k}$.

The only other way that the value of the node x might be fixed is the following. If the queries fix the value of V_O for some of the children of x then this will restrict the possible values for the string k_x such that $V_O(x\$y)$ always equals $(-1)^{y \oplus k_x}$ and such that $V_O(x) = O(x\$k_x)$. If the query $x\$k_x$ for each possible k_x has been asked and all have the same answers, then this fixes the value V_O at x. If the query $x\$k_x$ for the correct k_x has been asked, then we call x a *hit*.

Now notice that fixing the values of a set of children of a level l node x restricts the value of k_x to a set of $2^{2^l - c}$ possibilities, where c is the maximum size of a linearly independent subset of the children whose values are fixed. This can be used to prove that it takes $n \cdot \frac{n}{2} \cdots 1 = n^{\Omega(\log n)}$.

However, this intuition is not yet enough since we are interested in arguing against a probabilistic TM rather than a deterministic TM. So, we will argue not just that it takes $n^{\Omega(\log n)}$ queries to fix the value of a candidate of length n but that if fewer than $n^{\Omega(\log n)}$ queries are fixed, then choosing a random legal oracle consistent with those queries gives to a candidate of length n the value 1 with probability extremely close to $\frac{1}{2}$. This will give the desired result. To see this, call the set of queries actually asked and the answers given to those queries a *run* of the probabilistic TM. We will have shown that if we take any run on a candidate of length n with fewer than $n^{\Omega(\log n)}$ queries, then the probability that a random legal oracle agreeing with the run assigns to x the value 1 is extremely close to $\frac{1}{2}$. This means that a probabilistic TM whose running time is $n^{o(\log n/2)}$ will fail with probability 1 to accept $\mathcal{R}_O$ for a random legal oracle O.

DEFINITION 8.11. *A* run of size k *is defined as a pair* S, f *where* S *is a set of* k *query strings and* f *is map from* S *to* $\{0,1\}$ *such that there is at least one legal oracle agreeing with* f.

Let r *be a run, let* y *be a node at level* $l \geq 2$, *and let* O *be a legal oracle at and below* y *which agrees with* r. *Then* O *determines the string* k_y *for which* $V_O(y) = O(y\$k_y)$. *If* $y\$k_y$ *is a query in* r, *then we say* O makes y a hit for r. *Suppressing the dependency on* r *in the notation, we define* $P(y)$ *as the probability that* y *is a hit for* r *when we choose a legal oracle at and below* y *uniformly at random from the set of all such oracles at and below* y *which agree with* r. *Similarly, for* x *an ancestor of* y, *we define* $P_x(y)$ *as the probability that* y *is a hit when a legal oracle is chosen at and below* x *uniformly at random from the set of all oracles at and below* x *which agree with* r.

LEMMA 8.12. $P_x(y) \leq 2P(y)$.

Proof. Let S be the set of legal oracles at and below y which agree with r. We can write S as the disjoint union of S_h and S_n, where the former is the set of those oracles in S that make y a hit for r. Further splitting S_h and S_n according to the value $V_O(y)$, we can write S as the disjoint union of four sets $S_{h+}, S_{h-}, S_{n+}, S_{n-}$.

Using this notation, we have $P(y) = \frac{\text{card}(S_h)}{\text{card}(S_h)+\text{card}(S_n)}$. It is easy to see that, since the oracles in S_n do not make y a hit for r, $\text{card}(S_{n+}) = \text{card}(S_{n-}) = \frac{\text{card}(S_n)}{2}$.

Next consider the set T of all legal oracles defined at and below x, but outside y, which agree with r. Each oracle $O \in T$ determines by constraint the value $V_O(y)$ but leaves the string k_y completely undetermined. If we again write T as the disjoint union of T_+ and T_- according to the constrained value $V_O(y)$, we notice that the set of legal oracles at and below x is exactly $(T_+ \times S_+) \cup (T_- \times S_-)$. So, we have

$$\begin{aligned} P_x(y) &= \frac{\text{card}(T_+)\text{card}(S_{h+}) + \text{card}(T_-)\text{card}(S_{h-})}{\text{card}(T_+)\text{card}(S_+) + \text{card}(T_-)\text{card}(S_-)} \\ &= \frac{\text{card}(T_+)\text{card}(S_{h+}) + \text{card}(T_-)\text{card}(S_{h-})}{\text{card}(T_+)\text{card}(S_{h+}) + \text{card}(T_-)\text{card}(S_{h-}) + \text{card}(T)\text{card}(S_n)/2}. \end{aligned}$$

Without loss of generality, let $\text{card}(T_+) \geq \text{card}(T_-)$. Then since $\frac{n}{n+c}$ with $c, n > 0$ increases with n, we have

$$\begin{aligned} P_x(y) &\leq \frac{\text{card}(T_+)\text{card}(S_h)}{\text{card}(T_+)\text{card}(S_h) + \text{card}(T)\text{card}(S_n)/2} \\ &\leq \frac{\text{card}(T_+)\text{card}(S_h)}{\text{card}(T_+)\text{card}(S_h) + \text{card}(T_+)\text{card}(S_n)/2} \\ &= \frac{2\text{card}(S_h)}{2\text{card}(S_h) + \text{card}(S_n)} \;\leq\; 2P(y). \qquad \square \end{aligned}$$

For a positive integer n, we define $\gamma(n) = n(\frac{n}{2}) \cdots 1$. Notice that $\gamma(n) > n^{(\log n)/2}$.

THEOREM 8.13. *Suppose r is a run, y is a node at level $l \geq 2$ with q queries from r at or below y, and x is an ancestor of y. Then $P_x(y) \leq \frac{q}{\gamma(n/4)}$ where $n = 2^l$.*

Proof. We prove the theorem by induction on l.

So, fix a run r and a node y at level 2 with q queries from r at or below y. If $q = 0$, y can never be a hit. So, certainly the probability that y is a hit is at most q as desired.

Next, we perform the inductive step. So, assume the theorem holds true for any r and y at level less than l with $l \geq 2$. Then, fix a run r and a node y at level l with q queries from r at or below y. Let $n = 2^l$. We will show that $P(y) \leq \frac{q}{2\gamma(n/4)}$, and then the theorem will follow from Lemma 8.12. So, for the remainder of the proof, all probabilities are taken over the choice of a legal oracle at and below y uniformly at random from the set of all those legal oracles at and below y which agree with r.

Now, suppose that q' of the q queries are actually at y. Clearly, if we condition on there being no hits among the children of y, then k_y will be chosen uniformly among all n-bit strings, and hence the probability y is a hit would be $\frac{q'}{2^n}$. If we instead condition on there being exactly c hits among the 2^n children of y, then the probability that y is a hit must be at most $\frac{q'}{2^{n-c}}$. Therefore, the probability y is a hit is bounded above by the sum of $\frac{q'}{2^{n/2}}$ and the probability that at least $\frac{n}{2}$ of the children of y are hits.

Now consider any child z of y. Applying the inductive hypothesis with y and z taking the roles of x and y, we know that if r has q_z queries at and below z, then $P_y(z) \leq \frac{q_z}{\gamma(n/8)}$. Therefore the *expected* number of hits among the children of y is at most $\frac{(q-q')}{\gamma(n/8)}$. This means that the probability that at least $\frac{n}{2}$ of the children of y are

hits is at most

$$\frac{(q-q')}{\gamma(n/8)n/2} \;=\; \frac{(q-q')}{2\gamma(n/4)}.$$

Therefore,

$$P(y) \;\leq\; \frac{q-q'}{2\gamma(n/4)} + \frac{q'}{2^{n/2}} \;\leq\; \frac{q}{2\gamma(n/4)}$$

since $2\gamma(\frac{n}{4}) < 2^{n/2}$ for $n > 4$. □

COROLLARY 8.14. *For any $T(n)$ which is $n^{o(\log n)}$ relative to a random legal oracle O, with probability 1, $\mathcal{R}_O$ is not contained in* $\mathbf{BPTime}(T(n))$.

Proof. Fix $T(n)$ which is $n^{o(\log n)}$.

We will show that for any probabilistic TM M, when we pick a random legal oracle O, with probability 1, M^O either fails to run in time $cn^{o(\log n)}$ or it fails to accept $\mathcal{R}_O$ with error probability bounded by $\frac{1}{3}$. Then since there are a countable number of probabilistic TMs and the intersection of a countable number of probability 1 events still has probability 1, we conclude that with probability 1, $\mathcal{R}_O$ is not contained in $\mathbf{BPTime}(n^{o(\log n)})$.

We prove the corollary by showing that, for large enough n, the probability that M^O runs in time greater than $T(n)$ or has error greater than $\frac{1}{3}$ on input 0^n is at least $\frac{1}{8}$ for every way of fixing the oracle answers for trees other than the tree rooted at 0^n. The probability is taken over the random choices of the oracle for the tree rooted at 0^n.

Arbitrarily fix a legal behavior for O on all trees other than the one rooted at 0^n. Then consider picking a legal behavior for O for the tree rooted at 0^n uniformly at random and run M^O on input 0^n. We can classify runs of M^O on input 0^n based on the run r that lists the queries the machines asks and the answers it receives. If we take all probabilities over both the randomness in M and the choice of oracle O, then the probability that M^O correctly classifies 0^n in time $T(n)$ is

$$\sum_r \Pr[r]\Pr[\text{correct} \mid r],$$

where $\Pr[r]$ is the probability of run r, where $\Pr[\text{correct} \mid r]$ is the probability the answer is correct given run r, and where r ranges over all runs with at most $T(n)$ queries. Theorem 8.13 tells us that if we condition on any run r with fewer than $\frac{1}{12}\gamma(\frac{n}{4})$ queries, then the probability 0^n is a hit is less than $\frac{1}{12}$. This means that the probability the algorithm correctly classifies 0^n, conditioned on any particular run r with fewer than $\frac{1}{12}\gamma(\frac{n}{4})$ queries, is at most $\frac{7}{12}$. Therefore, for n large enough that $T(n)$ is less than $\frac{1}{12}\gamma(n)$, the probability M^O correctly classifies 0^n in time $T(n)$ is at most $\frac{7}{12}$. So, for sufficiently large n, when we choose O, then with probability at least $\frac{1}{8}$ M^O either fails to run in time $T(n)$ or has success probability less than $\frac{2}{3}$ on input 0^n. □

Appendix A. A QTM is well formed iff its time evolution is unitary. First, we note that the time evolution operator of a QTM always exists. Note that this is true even if the QTM is not well formed.

LEMMA A.1. *If M is a QTM with time evolution operator U, then U has an adjoint operator U^* in the inner-product space of superpositions of the machine M.*

Proof. Let M be a QTM with time evolution operator U. Then the adjoint of U is the operator U' and is the operator whose matrix element in any pair of dimensions i, j is the complex conjugate of the matrix element of U in dimensions j, i. The operator U' defined in this fashion still maps all superpositions to other superpositions (= finite linear combinations of configurations), since any particular configuration of M can be reached with nonzero weight from only a finite number of other configurations. It is also easy to see that for any superpositions ϕ, ψ,

$$\langle U'\phi|\psi\rangle = \langle\phi|U\psi\rangle$$

as desired. □

We include the proofs of the following standard facts for completeness. We will use them in the proof of the theorem below.

FACT A.2. *If U is a linear operator on an inner-product space V and U^* exists, then U preserves norm iff $U^*U = I$.*

Proof. For any $x \in V$, the square of the norm of Ux is $(Ux, Ux) = (x, U^*Ux)$. It clearly follows that if $U^*U = I$, then U preserves norm. For the converse, let $B = U^*U - I$. Since U preserves norm, for every $x \in V$, $(x, U^*Ux) = (x, x)$. Therefore, for every $x \in V$, $(x, Bx) = 0$. It follows that $B = 0$ and therefore $U^*U = I$. □

This further implies the following useful fact.

FACT A.3. *Suppose U is an linear operator in an inner-product space V and U^* exists. Then*

$$\forall x \in V \quad \|Ux\| = \|x\| \qquad \leftrightarrow \qquad \forall x, y \in V \quad (Ux, Uy) = (x, y).$$

Proof. Since $\|Ux\| = \|x\| \leftrightarrow (Ux, Ux) = (x, x)$, one direction follows by substituting $x = y$. For the other direction, if U preserves norm then by Fact A.2, $U^*U = I$. Therefore, $(Ux, Uy) = (x, U^*Uy) = (x, y)$. □

We need to establish one additional fact about norm-preserving operators before we can prove our theorem.

FACT A.4. *Let V be a countable inner-product space, and let $\{|i\rangle\}_{i\in I}$ be an orthonormal basis for V. If U is a norm-preserving linear operator on V and U^* exists, then $\forall i \in I$ $\|U^*|i\rangle\| \leq 1$. Moreover, if $\forall i \in I$ $\|U^*|i\rangle\| = 1$ then U is unitary.*

Proof. Since U preserves norm, $\|UU^*|i\rangle\| = \|U^*|i\rangle\|$. But the projection of $UU^*|i\rangle$ on $|i\rangle$ has norm $|\langle i|UU^*|i\rangle| = \|U^*|i\rangle\|^2$. Therefore $\|U^*|i\rangle\| \geq \|U^*|i\rangle\|^2$, and therefore $\|U^*|i\rangle\| \leq 1$.

Moreover, if $\|U^*|i\rangle\| = 1$, then, since U is norm preserving, $\|UU^*|i\rangle\| = 1$. On the other hand, the projection of $UU^*|i\rangle$ on $|i\rangle$ has norm $\|U^*|i\rangle\|^2 = 1$. It follows that for $j \neq i$, the projection of $UU^*|i\rangle$ on $|j\rangle$ must have norm 0. Thus $|\langle j|UU^*|i\rangle| = 0$. It follows that $UU^* = I$. □

If V is finite dimensional, then $U^*U = I$ implies $UU^* = I$, and therefore an operator is norm preserving if and only if it is unitary. However, if $\mathcal{H}$ is infinite dimensional, then $U^*U = I$ does not imply $UU^* = I$.[6] Nevertheless, the time evolution operators of QTMs have a special structure, and in fact these two conditions are equivalent for the time evolution operator of a QTM.

THEOREM A.5. *A QTM is well formed iff its time evolution operator is unitary.*

Proof. Let U be the norm preserving time evolution operator of a well-formed QTM $M = (\Sigma, Q, \delta)$. Consider the standard orthonormal basis for the superpositions

[6] Consider, for example, the space of finite complex linear combinations of positive integers and the linear operator which maps $|i\rangle$ to $|i + 1\rangle$.

of M given by the set of vectors $|c\rangle$, where c ranges over all configurations of M (as always, $|c\rangle$ is the superposition with amplitude 1 for configuration c and 0 elsewhere). We may express the action of U with respect to this standard basis by a countable dimensional matrix whose c, c'th entry $u_{c,c'} = \langle c'|U|c\rangle$. This matrix has some special properties. First, each row and column of the matrix has only a finite number of nonzero entries. Second, there are only finitely many different types of rows, where two rows are of the same type if their entries are just permutations of each other. We shall show that each row of the matrix has norm 1, and therefore by Fact A.4 above U is unitary. To do so we will identify a set of n columns of the matrix (for arbitrarily large n) and restrict attention to the finite matrix consisting of all the chosen rows and all columns with nonzero entries in these rows. Let this matrix be the $m \times n$ matrix B. By construction, B satisfies two properties: (1) it is almost square; $\frac{m}{n} \leq 1 + \epsilon$ for arbitrarily small ϵ. (2) There is a constant a such that each distinct row type of the infinite matrix occurs at least $\frac{m}{a}$ times among the rows of B.

Now the sum of the squared norms of the rows of B is equal to the sum of the squared norms of the columns. The latter quantity is just n (since the columns of the infinite matrix are orthonormal by Fact A.2 above). If we assume that some row of the infinite matrix has norm $1 - \delta$ for $\delta > 0$, then we can choose n sufficiently large and ϵ sufficiently small so that the sum of the squared norms of the rows is at most $m(1 - \frac{1}{a}) + m/a(1 - \delta) \leq m - m\delta/a \leq n + n\epsilon - n\delta/a < n$. This gives the required contradiction, and therefore all rows of the infinite matrix have norm 1 and, therefore, by Fact A.4 U is unitary.

To construct the finite matrix B let $k > 2$ and fix some contiguous set of k cells on the tape. Consider the set of all configurations S such that the tape head is located within these k cells and such that the tape is blank outside of these k cells. It is easy to see that the number of such configurations $n = k \operatorname{card}(\Sigma)^k \operatorname{card}(Q)$. The columns indexed by configurations in S are used to define the finite matrix B referred to above. The nonzero entries in these columns are restricted to rows indexed by configurations in S together with rows indexed by configurations where the tape head is in the cell immediately to the left or right of the k special cells, and such that the tape is blank outside of these $k + 1$ cells. The number of these additional configurations over and above S is at most $2 \operatorname{card}(\Sigma)^{k+1} \operatorname{card}(Q)$. Therefore, $m = n(1 + 2/k\operatorname{card}(\Sigma))$. For any $\epsilon > 0$, we can choose k large enough such that $m \leq n(1 + \epsilon)$.

Recall that a row of the infinite matrix (corresponding to the operator U) is indexed by configurations. We say that a configuration c is of type $q, \sigma_1, \sigma_2, \sigma_3$ if c is in state $q \in Q$ and the three adjacent tape cells centered about the tape head contain the three symbols $\sigma_1, \sigma_2, \sigma_3 \in \Sigma$. The entries of a row indexed by c must be a permutation of the entries of a row indexed by any configuration c' of the same type as c. This is because a transition of the QTM M depends only on the state of M and the symbol under the tape head and since the tape head moves to an adjacent cell during a transition. Moreover, any configuration d that yields configuration c with nonzero amplitude as a result of a single step must have tape contents identical to those of c in all but these three cells. It follows that there are only a finite number of such configurations d, and the row indexed by c can have only a finite number of nonzero entries. A similar argument shows that each column has only a finite number of nonzero entries.

Now for given $q, \sigma_1, \sigma_2, \sigma_3$ consider the rows of the finite matrix B indexed by configurations of type $q, \sigma_1, \sigma_2, \sigma_3$ and such that the tape head is located at one of the $k - 2$ nonborder cells. Then $|T| = (k - 2)\operatorname{card}(\Sigma)^{k-3}$. Each row of B indexed

by a configuration $c \in T$ has the property that if d is any configuration that yields c with nonzero amplitude in a single step, then $d \in S$. Therefore, the row indexed by c in the finite matrix B has the same nonzero entries as the row indexed by c in the infinite matrix. Therefore, it makes sense to say that row c of B is of the same type as row c of the infinite matrix. Finally, the rows of each type constitute a fraction at least $|T|/m$ of all rows of B. Substituting the bounds from above, we get that this fraction is at least $\frac{(k-2)\mathrm{card}(\Sigma)^{k-3}}{k\ \mathrm{card}(\Sigma)^k\ \mathrm{card}(Q)(1+2/k\mathrm{card}(\Sigma))}$. Since $k \geq 4$, this is at least $\frac{1}{a}$ for constant $a = 2\mathrm{card}(\Sigma)^3\mathrm{card}(Q)(1 + 1/2\mathrm{card}(\Sigma))$. This establishes all the properties of the matrix B used in the proof above. □

Appendix B. Reversible TMs are as powerful as deterministic TM. In this appendix, we prove the synchronization theorem of section 4.1.

We begin with a few simple facts about reversible TMs. We give necessary and sufficient conditions for a deterministic TM to be reversible, and we show that, just as for QTMs, a partially defined reversible TM can always be completed to give a well-formed reversible TM. We also give, as an aside, an easy proof that reversible TMs can efficiently simulate reversible, generalized TMs.

THEOREM B.1. *A TM or generalized TM M is reversible iff both of the following two conditions hold.*

1. *Each state of M can be entered while moving in only one direction. In other words, if $\delta(p_1, \sigma_1) = (\tau_1, q, d_1)$ and $\delta(p_2, \sigma_2) = (\tau_2, q, d_2)$ then $d_1 = d_2$.*
2. *The transition function δ is one-to-one when direction is ignored.*

Proof. First we show that these two conditions imply reversibility.

Suppose $M = (\Sigma, Q, \delta)$ is a TM or generalized TM satisfying these two conditions. Then, the following procedure lets us take any configuration of M and compute its predecessor if it has one. First, since each state can be entered while moving in only one direction, the state of the configuration tells us in which cell the tape head must have been in the previous configuration. Looking at this cell, we can see what tape symbol was written in the last step. Then, since δ is one-to-one we know the update rule, if any, that was used on the previous step, allowing us to reconstruct the previous configuration.

Next, we show that the first property is necessary for reversibility. So, for example, consider a TM or generalized TM $M = (\Sigma, Q, \delta)$ such that $\delta(p_1, \sigma_1) = (\tau_1, q, L)$ and $\delta(p_2, \sigma_2) = (\tau_2, q, R)$. Then, we can easily construct two configurations which lead to the same next configuration: let c_1 be any configuration where the machine is in state p_1 reading a σ_1 and where the symbol two cells to the left of the tape head is a τ_2, and let c_2 be identical to c_1 except that the σ_1 and τ_2 are changed to τ_1 and σ_2, the machine is in state p_2, and the tape head is two cells further left. Therefore, M is not reversible. Since similar arguments apply for each pair of distinct directions, the first condition in the theorem must be necessary for reversibility.

Finally, we show that the second condition is also necessary for reversibility. Suppose that $M = (\Sigma, Q, \delta)$ is a TM or generalized TM with $\delta(p_1, \sigma_1) = \delta(p_2, \sigma_2)$. Then, any pair of configurations which differ only in the state and symbol under the tape head, where one has (p_1, σ_1) and the other (p_2, σ_2), lead to the same next configuration, and again M is not reversible. □

COROLLARY B.2. *If M is a reversible TM, then every configuration of M has exactly one predecessor.*

Proof. Let $M = (\Sigma, Q, \delta)$ be a reversible TM. By the definition of reversibility, each configuration of M has at most one predecessor.

So, let c be a configuration of M in state q. Theorem B.1 tells us that M can enter state q while moving its tape head in only one direction d_q. Since Theorem B.1 tells us that, ignoring direction, δ is one-to-one, taking the inverse of δ on the state q and the symbol in direction $\bar{d}_q$ tells us how to transform c into its predecessor. □

COROLLARY B.3. *If δ is a partial function from $Q \times \Sigma$ to $\Sigma \times Q \times \{L, R\}$ satisfying the two conditions of Theorem* B.1*, then δ can be extended to a total function that still satisfies Theorem* B.1*.*

Proof. Suppose δ is a partial function from $Q \times \Sigma$ to $\Sigma \times Q \times \{L, R\}$ that satisfies the properties of Theorem B.1. Then, for each $q \in Q$ let d_q be the one direction, if any, in which q can be entered, and let d_q be (arbitrarily) L otherwise. Then we can fill in undefined values of δ with as yet unused triples of the form (τ, q, d_q) so as to maintain the conditions of Theorem B.1. Since the number of such triples is $\text{card}(\Sigma)\ \text{card}(Q)$, there will be exactly enough to fully define δ. □

THEOREM B.4. *If M is a generalized reversible TM, then there is a reversible TM M' that simulates M with slowdown at most* 2*.*

Proof. The idea is to replace any transition that has the tape head stand still with two transitions. The first updates the tape and moves to the right, remembering which state it should enter. The second steps back to the left and enters the desired state.

So, if $M = (\Sigma, Q, \delta)$ is a generalized reversible TM then we let M' be identical to M except that for each state q with a transition of the form $\delta(p, \sigma) = (\tau, q, N)$ we add a new state q' and we also add a new transition rule $\delta(q', \sigma) = \sigma, q, L$ for each $\sigma \in \Sigma$. Finally, we replace each transition $\delta(p, \sigma) = (\tau, q, N)$ with the transition $\delta(p, \sigma) = (\tau, q', R)$. Clearly M' simulates M with slowdown by a factor of at most 2.

To complete the proof, we need to show that M' is also reversible.

So, consider a configuration c of M'. We need to show that c has at most one predecessor. If c is in state $q \in Q$ and M enters q moving left or right, then the transitions into q in M' are identical to those in M and therefore since M is reversible, c has at most one predecessor in M'. Similarly, if c is in one of the new states q' then the transitions into q' in M' are exactly the same as those into q in M, except that the tape head moves right instead of staying still. So, again the reversibility of M implies that c has at most one predecessor. Finally, suppose c is in state $q \in Q$, where M enters q while standing still. Then, Theorem B.1 tells us that all transitions in M that enter q have direction N. Therefore, all of them have been removed, and the only transitions entering q in M' are the new ones of the form $\delta(q', \sigma) = \sigma, q, L$. Again, this means that c can have only one predecessor. □

We will prove the synchronization theorem in the following way. Using ideas from the constructions of Bennett [7] and Morita, Shirasaki, and Gono [33], we will show that given any deterministic TM M there is a reversible multitrack TM which on input x produces output $x; M(x)$, and whose running time depends only on the sequence of head movements of M on input x. Then, since any deterministic computation can be simulated efficiently by an "oblivious" machine whose head movements depend only on the length of its input, we will be able to construct the desired "synchronized" reversible TM.

The idea of Bennett's simulation is to run the target machine, keeping a history to maintain reversibility. Then the output can be copied and the simulation run backward so that the history is exactly erased while the input is recovered. Since the target tape head moves back and forth, while the history steadily grows, Bennett uses a multitape TM for the simulation.

The idea of Morita, Shirasaki, and Gono's simulation is to use a simulation tape with several tracks, some of which are used to simulate the tape of the desired machine and some of which are used to keep the history. Provided that the machine can move reversibly between the current head position of the target machine and the end of the history, it can carry out Bennett's simulation with a quadratic slowdown. Morita, Shirasaki, and Gono work with TMs with one-way infinite tapes so that the simulating machine can move between the simulation and the history by moving left to the end of the tape and then searching back toward the right. In our simulation, we write down history for every step the target machine takes, rather than just the nonreversible steps. This means that the end of the history will always be further right than the simulation, allowing us to work with two-way infinite tapes. Also, we use reversible TMs that can only move their head in the directions $\{L, R\}$ rather than the generalized reversible TMs used by Bennett, Morita, Shirasaki, and Gono.

DEFINITION B.5. *A deterministic TM is* oblivious *if its running time and the position of its tape head at each time step depend only on the length of its input.*

In carrying out our single tape Bennett constructions we will find it useful to first build simple reversible TMs to copy a string from one track to another and to exchange the strings on two tracks. We will copy strings delimited by blanks in the single tape Bennett construction but will copy strings with other delimiters in a later section.

LEMMA B.6. *For any alphabet Σ, there is a normal form, reversible TM M with alphabet $\Sigma \times \Sigma$ with the following property. When run on input $x; y$ M runs for $2\max(|x|, |y|) + 4$ steps, returns the tape head to the start cell, and outputs $y; x$.*

Proof. We let M have alphabet $\Sigma \times \Sigma$, state set $\{q_0, q_1, q_2, q_3, q_f\}$, and transition function defined by

	$(\#, \#)$	other (σ_1, σ_2)
q_0	$(\#, \#), q_1, L$	$(\sigma_1, \sigma_2), q_1, L$
q_1	$(\#, \#), q_2, R$	
q_2	$(\#, \#), q_3, L$	$(\sigma_2, \sigma_1), q_2, R$
q_3	$(\#, \#), q_f, R$	$(\sigma_1, \sigma_2), q_3, L$
q_f	$(\#, \#), q_0, R$	$(\sigma_1, \sigma_2), q_0, R$

Since each state in M can be entered in only one direction and its transition function is one-to-one, M is reversible. Also, it can be verified that M performs the desired computation in the stated number of steps. □

LEMMA B.7. *For any alphabet Σ, there is a normal form, reversible TM M with alphabet $\Sigma \times \Sigma$ with the following property. When run on input x, M outputs $x; x$, and when run on input $x; x$ it outputs x. In either case, M runs for $2|x| + 4$ steps and leaves the tape head back in the start cell.*

Proof. We let M have alphabet $\Sigma \times \Sigma$, state set $\{q_0, q_1, q_2, q_3, q_f\}$, and transition function defined by the following where each transition is duplicated for each nonblank $\sigma \in \Sigma$:

	$(\#, \#)$	$(\sigma, \#)$	(σ, σ)
q_0	$(\#, \#), q_1, L$	$(\sigma, \#), q_1, L$	$(\sigma, \sigma), q_1, L$
q_1	$(\#, \#), q_2, R$		
q_2	$(\#, \#), q_3, L$	$(\sigma, \sigma), q_2, R$	$(\sigma, \#), q_2, R$
q_3	$(\#, \#), q_f, R$	$(\sigma, \#), q_3, L$	$(\sigma, \sigma), q_3, L$
q_f	$(\#, \#), q_0, R$	$(\sigma, \#), q_0, R$	$(\sigma, \sigma), q_0, R$

Since each state in M can be entered in only one direction and its transition function is one-to-one, M can be extended to a reversible TM. Also, it can be verified that M performs the desired computation in the stated number of steps. □

THEOREM B.8. *Let M be an oblivious deterministic TM which on any input x produces output $M(x)$, with no embedded blanks, with its tape head back in the start cell, and with $M(x)$ beginning in the start cell. Then there is a reversible TM M' which on input x produces output $x; M(x)$ and on input $x; M(x)$ produces output x. In both cases, M' halts with its tape head back in the start cell and takes time which depends only on the lengths of x and $M(x)$ and which is bounded by a quadratic polynomial in the running time of M on input x.*

Proof. Let $M = (\Sigma, Q, \delta)$ be an oblivious deterministic TM as stated in the theorem and let q_0, q_f be the initial and final states of M.

The simulation will run in three stages.

1. M' will simulate M maintaining a history to make the simulation reversible.
2. M' will copy its first track, as shown in Lemma B.7.
3. M' runs the reverse of the simulation of M erasing the history while restoring the input.

We will construct a normal form reversible TM for each of the three stages and then dovetail them together.

Each of our machines will be a four-track TM with the same alphabet. The first track, with alphabet $\Sigma_1 = \Sigma$, will be used to simulate the tape of M. The second track, with alphabet $\Sigma_2 = \{\#, 1\}$, will be used to store a single 1 locating the tape head of M. The third track, with alphabet $\Sigma_3 = \{\#, \$\} \cup (Q \times \Sigma)$, will be used to write down a list of the transitions taken by M, starting with the marker \$. This \$ will help us find the start cell when we enter and leave the copying phase. The fourth track, with alphabet $\Sigma_4 = \Sigma$, will be used to write the output of M.

In describing the first machine, we will give a partial list of transitions obeying the conditions of Theorem B.1 and then appeal to Corollary B.3. Our machines will usually only be reading and writing one track at a time. So, for convenience we will list a transition with one or more occurrences of the symbols of the form v_i and v_i' to stand for all possible transitions with v_i replaced by a symbol from the appropriate Σ_i other than the special marker \$, and with v_i' replaced by a symbol from Σ_i other than \$ and #.

The first phase of the simulation will be handled by the machine M_1 with state set given by the union of sets Q, $Q \times Q \times \Sigma \times [1,4]$, $Q \times [5,7]$, and $\{q_a, q_b\}$. Its start state will be q_a and the final state q_f.

The transitions of M_1 are defined as follows. First, we mark the position of the tape head of M in the start cell, mark the start of the history in cell 1, and enter state q_0.

$$\begin{array}{llcll} q_a, & (v_1, \#, \#, v_4) & \rightarrow & (v_1, 1, \#, v_4), & q_b, \quad R, \\ q_b, & (v_1, \#, \#, v_4) & \rightarrow & (v_1, \#, \$, v_4), & q_0, \quad R. \end{array}$$

Then, for each pair p, σ with $p \neq q_f$ and with transition $\delta(p, \sigma) = (\tau, q, d)$ in M we include transitions to go from state p to state q updating the simulated tape of M while adding (p, σ) to the end of the history. We first carry out the update of the simulated tape, remembering the transition taken, and then move to the end of the history to deposit the information on the transition. If we are in the middle of the history, we reach the end of the history by walking right until we hit a blank. However, if we are to the left of the history, then we must first walk right over blanks until we reach the start of the history.

$$
\begin{array}{cccccc}
p, & (\sigma,1,v_3,v_4) & \to & (\tau,\#,v_3,v_4), & (q,p,\sigma,1), & d \\
(q,p,\sigma,1), & (v_1,\#,\$,v_4) & \to & (v_1,1,\$,v_4), & (q,p,\sigma,3), & R \\
(q,p,\sigma,1), & (v_1,\#,v_3',v_4) & \to & (v_1,1,v_3',v_4), & (q,p,\sigma,3), & R \\
(q,p,\sigma,1), & (v_1,\#,\#,v_4) & \to & (v_1,1,\#,v_4), & (q,p,\sigma,2), & R \\
(q,p,\sigma,2), & (v_1,\#,\#,v_4) & \to & (v_1,\#,\#,v_4), & (q,p,\sigma,2), & R \\
(q,p,\sigma,2), & (v_1,\#,\$,v_4) & \to & (v_1,\#,\$,v_4), & (q,p,\sigma,3), & R \\
(q,p,\sigma,3), & (v_1,\#,v_3',v_4) & \to & (v_1,\#,v_3',v_4), & (q,p,\sigma,3), & R \\
(q,p,\sigma,3), & (v_1,\#,\#,v_4) & \to & (v_1,\#,(p,\sigma),v_4), & (q,4), & R
\end{array}
$$

When the machine reaches state $(q,4)$ it is standing on the first blank after the end of the history. So, for each state $q \in Q$, we include transitions to move from the end of the history back left to the head position of M. We enter our walk-left state $(q,5)$ while writing a # on the history tape. So, to maintain reversibility, we must enter a second left-walking state $(q,6)$ to look for the tape head marker past the left end of the history. When we reach the tape head position, we step left and right entering state q.

$$
\begin{array}{cccccc}
(q,4), & (v_1,\#,\#,v_4) & \to & (v_1,\#,\#,v_4), & (q,5), & L \\
(q,5), & (v_1,\#,v_3',v_4) & \to & (v_1,\#,v_3',v_4), & (q,5), & L \\
(q,5), & (v_1,\#,\$,v_4) & \to & (v_1,\#,\$,v_4), & (q,6), & L \\
(q,5), & (v_1,1,v_3',v_4) & \to & (v_1,1,v_3',v_4), & (q,7), & L \\
(q,5), & (v_1,1,\$,v_4) & \to & (v_1,1,\$,v_4), & (q,7), & L \\
(q,6), & (v_1,\#,\#,v_4) & \to & (v_1,\#,\#,v_4), & (q,6), & L \\
(q,6), & (v_1,1,\#,v_4) & \to & (v_1,1,\#,v_4), & (q,7), & L \\
(q,7), & (v_1,v_2,v_3,v_4) & \to & (v_1,v_2,v_3,v_4), & q, & R
\end{array}
$$

Finally, we put M_1 in normal form by including the transition

$$q_f, \quad \sigma \quad \to \quad \sigma, \quad q_a, \quad R$$

for each σ in the simulation alphabet.

It can be verified that each state can be entered in only one direction using the above transitions, and relying on the fact that M is in normal form, and we don't simulate its transitions from q_f back to q_0, it can also be verified that the partial transition function described is one-to-one. Therefore, Corollary B.3 says that we can extend these transitions to give a reversible TM M_1. Notice also that the operation of M_1 is independent of the contents of the fourth track and that it leaves these contents unaltered.

For the second and third machines, we simply use the copying machine constructed in Lemma B.7 above, and the reverse of M_1 constructed using Lemma 4.12 on page 1431. Since M_1 operated independently of the fourth track, so will its reversal. Therefore, dovetailing these three TMs gives a reversible TM M', which on input x produces output $x;\epsilon;\epsilon;M(x)$ with its tape head back in the start cell, and on input $x;\epsilon;\epsilon;M(x)$ produces output x.

Notice that the time required by M_1 to simulate a step of M is bounded by a polynomial in the running time of M and depends only on the current head position of M, the direction M moves in the step, and how many steps have already been carried out. Therefore, the running time of the first phase of M' depends only on the series of head movements of M. In fact, since M is oblivious, this running time

depends only the length of x. The same is true of the third phase of M', since the reversal of M_1 takes exactly two extra time steps. Finally, the running time of the copying machine depends only on the length of $M(x)$. Therefore, the running time of M' on input x depends only on the lengths of x and $M(x)$ and is bounded by a quadratic polynomial in the running time of M on x. □

THEOREM B.9. *Let M_1 be an oblivious deterministic TM which on any input x produces output $M_1(x)$, with no embedded blanks, with its tape head back in the start cell, with $M_1(x)$ beginning in the start cell, and such that the length of $M_1(x)$ depends only on the length of x. Let M_2 be an oblivious deterministic TM with the same alphabet as M_1 which on any input $M_1(x)$ produces output x, with its tape head back in the start cell, and with x beginning in the start cell. Then there is a reversible TM M' which on input x produces output $M_1(x)$. Moreover, M' on input x halts with its tape head back in the start cell, and takes time which depends only on the length of x and which is bounded by a polynomial in the running time of M_1 on input x and the running time of M_2 on $M_1(x)$.*

Proof. Let M_1 and M_2 be as stated in the theorem with the common alphabet Σ.

Then the idea to construct the desired M' is first to run M_1 to compute $x; M(x)$, then to run an exchange routine to produce $M(x); x$ and finally to run M_2 to erase the string x, where each of the three phases starts and ends with the tape head in the start cell. Using the construction in Theorem B.8, we build normal form, reversible TMs to accomplish the first and third phases in times which depend only on the lengths of x and $M_1(x)$ and are bounded by a polynomial in the running times of M_1 on input x and M_2 on input $M_1(x)$. In Lemma B.6 on page 1467 we have already constructed a reversible TM that performs the exchange in time depending only on the lengths of the two strings. Dovetailing these three machines gives the desired M. □

Since any function computable in deterministic polynomial time can be computed in polynomial time by an oblivious generalized deterministic TM, Theorems B.8 and B.9 together with Theorem 4.2 give us the following.

THEOREM 4.3 (synchronization theorem). *If f is a function mapping strings to strings which can be computed in deterministic polynomial time and such that the length of $f(x)$ depends only on the length of x, then there is a polynomial time, stationary, normal form QTM which given input x, produces output $x; f(x)$, and whose running time depends only on the length of x.*

If f is a function from strings to strings such that both f and f^{-1} can be computed in deterministic polynomial time and such that the length of $f(x)$ depends only on the length of x, then there is a polynomial time, stationary, normal form QTM, which, given input x, produces output $f(x)$, and whose running time depends only on the length of x.

Appendix C. A reversible looping TM. We prove here the looping lemma from section 4.2.

LEMMA 4.13 (looping lemma). *There is a stationary, normal form, reversible TM M and a constant c with the following properties. On input any positive integer k written in binary, M runs for time $O(k \log^c k)$ and halts with its tape unchanged. Moreover, M has a special state q^* such that on input k, M visits state q^* exactly k times, each time with its tape head back in the start cell.*

Proof. As mentioned above in section 4.2, the difficulty is to construct a loop with a reversible entrance and exit. We accomplish this as follows. Using the synchronization theorem, we can build three-track stationary, normal form, reversible TM $M_1 = (\Sigma, Q, \delta)$ running in time polynomial in $\log k$ that on input $b; x; k$ where

$b \in \{0,1\}$ outputs $b'; x+1; k$ where b' is the opposite of b if $x = 0$ or $k-1$ (but not both) and $b' = b$ otherwise. Calling the initial and final states of this machine q_0, q_f, we construct a reversible M_2 that loops on machine M_1 as follows. We will give M_2 new initial and final states q_a, q_z and ensure that it has the following three properties.

1. Started in state q_a with a 0 on the first track, M_2 steps left and back right, changing the 0 to a 1, and entering state q_0.
2. When in state q_f with a 0 on the first track, M_2 steps left and back right into state q_0.
3. When in state q_f with a 1 on the first track, M_2 steps left and back right, changing the 1 to a 0, and halts.

So, on input $0;0;k$ M_2 will step left and right into state q_0, changing the tape contents to $1;0;k$. Then machine M_1 will run for the first time changing $1;0;k$ to $0;1;k$ and halting in state q_f. Whenever M_2 is in state q_f with a 0 on the first track, it reenters q_0 to run M_2 again. So, machine M_2 will run $k-1$ more times until it finally produces $1;k;k$. At that point, M_2 changes the tape contents to $0;k;k$ and halts. So on input $0;0;k$, M_2 visits state q_f exactly k times, each time with its tape head back in the start cell. This means we can construct the desired M by identifying q_f as q^* and dovetailing M_2 before and after with reversible TMs, constructed using the synchronization theorem, to transform k to $0;0;k$ and $0;k;k$ back to k.

We complete the proof by constructing a normal form, reversible M_2 that satisfies the three properties above. We give M_2 the same alphabet as M_1 and additional states q_a, q_b, q_y, q_z. The transition function for M_2 is the same as that of M_1 for states in $Q - q_f$ and otherwise depends only on the first track (leaving the others unchanged) and is given by the following table

	#	0	1
q_a		$(1, q_b, L)$	
q_b	$(\#, q_0, R)$		
q_f		$(0, q_b, L)$	$(0, q_y, L)$
q_y	$(\#, q_z, R)$		
q_z	$(\#, q_a, R)$	$(0, q_a, R)$	$(1, q_a, R)$

It is easy to see that M_2 is normal form and satisfies the three properties stated above. Moreover, since M_1 is reversible and obeys the two conditions of Theorem B.1, it can be verified that the transition function of M_2 also obeys the two conditions of Theorem B.1. Therefore, according to Theorem B.3, the transition function of M_2 can be completed giving a reversible TM. □

ON THE POWER OF QUANTUM COMPUTATION*

DANIEL R. SIMON†

Abstract. The quantum model of computation is a model, analogous to the probabilistic Turing machine (PTM), in which the normal laws of chance are replaced by those obeyed by particles on a quantum mechanical scale, rather than the rules familiar to us from the macroscopic world. We present here a problem of distinguishing between two fairly natural classes of functions, which can provably be solved exponentially faster in the quantum model than in the classical probabilistic one, when the function is given as an oracle drawn equiprobably from the uniform distribution on either class. We thus offer compelling evidence that the quantum model may have significantly more complexity theoretic power than the PTM. In fact, drawing on this work, Shor has recently developed remarkable new quantum polynomial-time algorithms for the discrete logarithm and integer factoring problems.

Key words. quantum computation, complexity theory, oracles

1. Introduction.

You have nothing to do but mention the quantum theory, and people will take your voice for the voice of science, and believe anything.

—Bernard Shaw, *Geneva* (1938)

The suggestion that the computational power of quantum mechanical processes might be beyond that of traditional computation models was first raised by Feynman [Fey82]. Benioff [Beni82] had already determined that such processes were at least as powerful as Turing machines (TMs); Feynman asked in turn whether such quantum processes could in general be efficiently simulated on a traditional computer. He also identified some reasons why the task appears difficult and pointed out that a "quantum computer" might be imagined that could perform such simulations efficiently. His ideas were elaborated on by Deutsch [Deu85], who proposed that such machines, using quantum mechanical processes, might be able to perform computations that "classical" computing devices (those that do not exploit quantum mechanical effects) can only perform very inefficiently. To that end, he developed a (theoretically) physically realizable model for the "quantum computer" that he conjectured might be more efficient than a classical TM for certain types of computations.

Since the construction of such a computer is beyond the realm of present technology, and would require overcoming a number of daunting practical barriers, it is worth asking first whether the proposed model even theoretically offers any substantial computational benefits over the classical TM model. The first hint of such a possibility was given by Deutsch and Jozsa [DJ92], who presented a simple "promise problem" that can be solved efficiently without error on Deutsch's quantum computer but that requires exhaustive search to solve deterministically without error in a classical setting. Berthiaume and Brassard [BB92] recast this problem in complexity theoretic

terms, constructing an oracle relative to which the quantum computer is exponentially more efficient than any classical (zero-error) PTM. In [BB93], they exhibited a similar separation for nondeterministic (zero-error) TMs.

Unfortunately, the problems explored in [BB92, BB93] are all efficiently solved by a (classical) PTM with exponentially small error probability. However, Bernstein and Vazirani [BV93] subsequently constructed an oracle which produces a superpolynomial relativized separation between the quantum and (classical) probabilistic models. They also gave the first efficient construction of a universal quantum computer which can simulate any quantum computer (as defined by Deutsch, subject to a slight constraint later removed in [Yao93]) with only polynomial overhead (Deutsch's universal quantum computer was subject to exponential slowdown).

In this paper,[1] we present an expected polynomial-time algorithm for a quantum computer that distinguishes between two reasonably natural classes of polynomial-time computable functions. This task appears computationally difficult in the classical setting; in particular, if the function is supplied as an oracle, then distinguishing (with nonnegligible probability) between a random function from one class and a random member of the other would take exponential time for a classical PTM. (A direct consequence is an oracle which produces an exponential relativized gap between the quantum and classical probabilistic models.) Recently Shor [Sho94], drawing on the general approach presented here and using a number of ingenious new techniques, has constructed quantum polynomial-time algorithms for the discrete logarithm and integer factoring problems.

2. The quantum computation model.

2.1. Classical probability versus the quantum model. We can represent a (classical) probabilistic computation on a TM as a leveled tree, as follows: each node corresponds to a state of the machine (i.e., a configuration), and each level represents a step of the computation. The root corresponds to the machine's starting configuration, and each other node corresponds to a different configuration reachable with nonzero probability, in one computation step, from the configuration represented by its parent node. Each edge, directed from parent to child, is associated with the probability that the computation follows that edge to the child node's configuration once reaching the parent node's configuration. Obviously, configurations may be duplicated across a single level of the tree, as children of different parents, as well as appear on different levels of the tree; nevertheless we represent each such appearance by a separate node. Also, we say that any such computation tree is *well defined*, meaning that the probabilities on the edges emanating from a parent node, and the configurations associated with its children, are strictly a function of the configuration associated with the parent node, regardless of the node's position in the tree.

Of course, this tree must necessarily conform not only to the constraints set by the definition of the TM whose computation it represents but also to the laws of probability. For example, the probability of following a particular path from the root to a node is simply the product of the probabilities along its edges. Hence we can associate a probability with each node, corresponding to the probability that that node is reached in the computation, and equal to the product of the probabilities assigned to the edges in the path leading to it from the root. Moreover, the probability that a particular configuration is reached at a certain step i in the computation is simply the sum of the probabilities of all the nodes corresponding to that configuration at

[1] An earlier version of this paper appears in [Sim94].

level i in the tree. (For example, the probability of a particular final configuration is the sum of the probabilities of all leaf nodes corresponding to that configuration.) Finally, the sum of the probabilities of all the configurations at any level of the tree must always be 1, regardless of the starting configuration. A necessary and sufficient condition for a well-defined computation tree to always satisfy this constraint is that the sum of the probabilities on edges leaving any single node always be 1.

A familiar equivalent representation of our well-defined computation, of course, is the Markov chain, in which a vector of probabilities for each possible configuration at a given step is multiplied by a fixed matrix to obtain the vector of probabilities of each configuration at the next step. For example, a space-$S(n)$-bounded computation can be represented by a Markov process with $2^{O(S(n))}$ states. Such a process can always be translated into a PTM, as long as (a) it never takes one configuration to another with nonzero probability unless the second can be obtained from the first via a single TM operation (i.e., changing the control state, and/or changing the contents of the cell under the tape head, and/or moving the head position by one cell); and (b) it assigns probabilities to new configurations consistently for any set of original configurations in which the control state and the contents of the cell under the tape head are identical. We say that processes with this property are *local*; obviously, the computation of any PTM can be represented as a computation tree which is not only well defined but also local.

A computation on a quantum Turing machine (QTM) (as described in [Deu85]) can be represented by a similar tree, but the laws of quantum mechanics require that we make some adjustments to it. Instead of a probability, each edge is associated with an *amplitude.* (In general, an amplitude is a complex number with magnitude at most 1, but it is shown in [BV93] that it is sufficient for complexity theoretic purposes to consider only real amplitudes in the interval $[-1, 1]$.) As before, the amplitude of a node is simply the product of the amplitudes of the edges on the path from the root to that node. The amplitude of a particular configuration at any step in the computation is simply the sum of the amplitudes of all nodes corresponding to that configuration at the level in the tree corresponding to that step. In the vector–matrix representation corresponding to the classical Markov process, a quantum computation step corresponds to multiplying the vector of amplitudes of all possible configurations at the current step by a fixed matrix to obtain the vector representing the amplitude of each configuration in the next step.

Now, the probability of a configuration at any step is the *square* of its amplitude. For example, the probability of a particular final configuration is the square of the sum (*not* the sum of the squares) of the amplitudes of all leaf nodes corresponding to that configuration. This way of calculating probability has some remarkable consequences; for instance, a particular configuration c could correspond to two leaf nodes with amplitudes α and $-\alpha$, respectively, and the probability of c being the final configuration would therefore be zero. Yet the parent nodes of these two nodes might both have nonzero probability. In fact, the computation would produce c with probability α^2 if only the configuration of *one* of the leaf nodes were in some way different. Similarly, if both leaf nodes had amplitude α, then the probability of c being the final configuration would be, not $2\alpha^2$, but rather $4\alpha^2$—that is, more than twice the probability we would obtain if either of the nodes corresponded to a different configuration. This mutual influence between different branches of the computation is called *interference*, and it is the reason why quantum computation is conjectured to be more powerful, in a complexity theoretic sense, than classical probabilistic computation. (It also means that probability is a rather abstract notion for a nonleaf node, with little intuitive

connection to the ultimate probability of any particular computation result.)

However, even a quantum computation tree must obey the property that the sum of the probabilities of configurations at any level must always equal 1. The choice of amplitudes on the edges leading from a node to its children must therefore be restricted so as to ensure that this condition is always obeyed, regardless of the starting configuration. Now, it turns out that it is *not* sufficient simply to require that for each node the sum of the squares of the amplitudes on edges leading to its children be 1. In fact, even *deterministic* ("classical") computation steps, in which a single outgoing edge to a single child has amplitude 1, can violate this constraint by causing previously different configurations in different branches of the tree to become identical. Such an event might change the pattern of interference, thereby altering the sum of the probabilities of the configurations.

Computation steps which never violate this constraint are called *unitary*, because they are equivalent to multiplying the vector of amplitudes of all possible configurations by a unitary matrix. (Recall that a unitary matrix is one whose inverse is its conjugate transpose; when we restrict ourselves to real amplitudes, such a matrix becomes orthogonal—that is, equal to the inverse of its transpose.) A QTM must always execute unitary steps; for instance, its deterministic steps must be *reversible*, in the sense that the preceding configuration can always be determined given the current one. (This restriction eliminates the aforementioned problem of distinct configurations suddenly becoming identical.) To be unitary, nonclassical steps must also be reversible, in the sense that some unitary (nonclassical) step "undoes" the step. Such "unflipping" of quantum coins is made possible by the counterintuitive effects of interference, which can cause alternative branches to cancel each other out, leaving the remaining ones (possibly all leading to an identical outcome) certain.

The QTM model of computation described here is simply a PTM in which the rules described above replace those of classical probability. (A more formal definition of an essentially equivalent QTM model can be found in [BV93].) Just as the computation tree of a classical probabilistic computation is always well defined and local, with probabilities always summing to 1, the computation tree of a quantum computation is always well defined, local, and unitary. At each step, the amplitudes of possible next configurations are determined by the amplitudes of possible current configurations, according to a fixed, local, unitary transformation representable by a matrix analogous to the stochastic matrix of a Markov process.

It is important to note that the standard equivalent characterization of a classical probabilistic computation tree, in which a deterministic machine simply reads a tape containing prewritten outcomes of independent fair coin tosses, does not appear to have a counterpart in the quantum model. It is true that an efficient universal QTM was shown in [BV93] to require only a fixed, standard set of amplitudes for all its nonclassical steps. However, the reversibility condition guarantees that no new interference will be introduced once those steps have been completed (say, after all the "quantum coins" have been tossed), and any remaining computation will thus be unable to exploit quantum effects. Hence the classical and nonclassical parts of the quantum computation tree cannot be "teased apart," as can the deterministic and probabilistic parts of a classical computation tree, and we must always keep an entire tree in mind when we deal with quantum computation, rather than assuming we can just follow a particular (deterministic) branch after some point. We therefore refer to a quantum computation as resulting, at any one step, in a *superposition* of all the branches of its tree simultaneously.

2.2. Notation and an example. It is useful to have a notation to denote superpositions (that is, entire levels of a computation tree). We say that at any step i, the computation is in a superposition of all the configurations $|c_1\rangle, \ldots, |c_k\rangle$ corresponding to nodes that appear in level i of the tree representing the computation, each $|c_j\rangle$ having amplitude α_j. (Borrowing quantum mechanics notation, we distinguish symbols representing configurations from those representing amplitudes by placing $|\rangle$ brackets around configuration symbols.) An abbreviated notation for this superposition is $\sum_j \alpha_j |c_j\rangle$; as we shall see, the suggestive addition/summation notation for superpositions is quite appropriate. A simple example of a unitary quantum step is the quantum "fair coin flip" performed upon a single bit. It is represented by the following matrix M:

$$\frac{1}{\sqrt{2}} \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix}.$$

M acts on 2-element column vectors whose top and bottom entries represent the amplitudes of the states $|0\rangle$ and $|1\rangle$, respectively. A bit in state $|0\rangle$ is transformed by M into a superposition of $|0\rangle$ and $|1\rangle$, both with amplitude $1/\sqrt{2}$. Similarly, a bit in state $|1\rangle$ is transformed into a superposition of $|0\rangle$ and $|1\rangle$ with amplitude of magnitude $1/\sqrt{2}$ in each case, but with the sign, or *phase* of the amplitude of $|1\rangle$ being negative. In other words, the state $|0\rangle$ is transformed into $(1/\sqrt{2})|0\rangle + (1/\sqrt{2})|1\rangle$, and $|1\rangle$ becomes $(1/\sqrt{2})|0\rangle + (-1/\sqrt{2})|1\rangle$.

It turns out that this transformation is its own inverse. For example, performing it a second time on a bit that was originally in state $|0\rangle$ produces $(1/\sqrt{2})((1/\sqrt{2})|0\rangle + (1/\sqrt{2})|1\rangle) + (1/\sqrt{2})((1/\sqrt{2})|0\rangle + (-1/\sqrt{2})|1\rangle)$. Collecting like terms in this expression (here we see the aptness of the addition/summation notation) allows us to obtain the amplitude of each distinct configuration, which in this case is 1 for $|0\rangle$ and 0 for $|1\rangle$. Similarly, performing this same transformation twice on the initial configuration $|1\rangle$ gives us $|1\rangle$ (with amplitude 1, and hence probability 1) again.

In a system of n bits, with 2^n possible configurations, we can perform such a transformation on each bit independently in sequence. The matrices representing these transformations will be of dimension $2^n \times 2^n$, of course; their rows, each corresponding to a different configuration, will each have two nonzero entries, taken from either the top or bottom row of M. Their columns will similarly have two nonzero entries each, taken from either the left or right column of M. Also, they will all be unitary, since they each represent a local, unitary transformation.

The result of performing these n different transformations in sequence will be a superposition of all possible n-bit strings. The amplitude of each string at the end of the n transformations will have magnitude $2^{-n/2}$. As the transformations are applied in turn, the phase of a resulting configuration is changed when a bit that was previously a 1 remains a 1 after the transformation is performed. Hence, the phase of the amplitude of string x is determined by the parity of the dot product of the original configuration string and x. More precisely, if the string w is the original configuration, then performing the product transformation composed of these n transformations in sequence will result in the superposition

$$2^{-n/2} \sum_x (-1)^{w \cdot x} |x\rangle.$$

This product transformation was introduced in [DJ92] and is referred to in [BV93] as the Fourier transformation F.

3. Using quantum computation.

3.1. Problem: Is a function invariant under some xor-mask? Suppose we are given a function $f : \{0,1\}^n \to \{0,1\}^m$, with $m \geq n$, and we are promised that either f is one-to-one, or there exists a nontrivial n-bit string s such that for any pair of distinct inputs x and x', $f(x)$ and $f(x')$ are equal if and only if the bits of x and x' differ in exactly those positions where the bits of s are 1. We wish to determine which of these conditions holds for f, and, in the second case, to find s.

DEFINITION 3.1. *Given a function $f : \{0,1\}^n \to \{0,1\}^m$, with $m \geq n$, the* xor-mask invariance *of f ($XMI(f)$) is*

- *s, if there exists a nontrivial string s of length n such that $\forall x \neq x'(f(x) = f(x') \Leftrightarrow x' = x \oplus s)$, where $\oplus$ denotes bitwise exclusive-or*;
- *0^n, if f is one-to-one*; *and*
- *undefined otherwise.*

THEOREM 3.2. *There exists an algorithm for a QTM which computes $XMI(f)$ (if it is defined), with zero error probability, in expected time $O(nT_f(n) + G(n))$, where $T_f(n)$ is the time required to compute f on inputs of size n, and $G(n)$ is the time required to solve an $n \times n$ linear system of equations over $\mathcal{Z}_2$.*

Proof. The algorithm is very simple, consisting essentially of (an expected) $O(n)$ repetitions of the following routine.

Routine **Fourier-twice**

1. Perform the transformation F described above on a string of n zeros, producing $2^{-n/2} \sum_x |x\rangle$.
2. Compute $f(x)$, concatenating the answer to x, thus producing $2^{-n/2} \sum_x |(x, f(x))\rangle$.
3. Perform F on x, producing $2^{-n} \sum_y \sum_x (-1)^{x \cdot y} |(y, f(x))\rangle$.

End **Fourier-twice**

Note that the (deterministic) computation of $(x, f(x))$ from x in time $T_f(n)$ in step 2 can always be made reversible (and hence unitary) at the cost of only a constant factor in the number of computation steps. This is due to a result obtained independently by Lecerf [Lec63] and Bennett [Benn73].

Suppose f is one-to-one. Then after each performance of **Fourier-twice**, all the possible configurations $|(y, f(x))\rangle$ in the superposition will be distinct, and their amplitudes will therefore all be 2^{-n}, up to phase. Their probabilities will therefore each be 2^{-2n}, and k independent repetitions of **Fourier-twice** will thus yield k configurations each distributed uniformly and independently over configurations of the form $|(y, f(x))\rangle$.

Now suppose that there is some s such that $\forall x \neq x'(f(x) = f(x') \Leftrightarrow x' = x \oplus s)$. Then for each y and x, the configurations $|(y, f(x))\rangle$ and $|(y, f(x \oplus s))\rangle$ are identical, and the amplitude $\alpha(x, y)$ of this configuration will be $2^{-n}((-1)^{x \cdot y} + (-1)^{(x \oplus s) \cdot y})$. Note that if $y \cdot s \equiv 0 \pmod 2$, then $x \cdot y \equiv (x \oplus s) \cdot y \pmod 2$, and $\alpha(x, y) = 2^{-n+1}$; otherwise $\alpha(x, y) = 0$. Thus k independent repetitions of **Fourier-twice** will yield k configurations distributed uniformly and independently over configurations of the form $|(y, f(x))\rangle$ such that $y \cdot s \equiv 0 \pmod 2$.

In both cases, after an expected $O(n)$ repetitions of **Fourier-twice**, sufficiently many linearly independent values of y will have been collected that the nontrivial string s^* whose dot product with each is even is uniquely determined. s^* can then easily be obtained by solving the linear system of equations defined by these values of y. (Once the solution space is constrained to one d imension in $(\mathcal{Z}_2)^n$, it will yield

exactly two solutions, one of which is nontrivial.) In the second case, this string s^* must be the s we are looking for, since we know that $y \cdot s \equiv 0 \pmod 2$ for each y generated in the second case. On the other hand, in the first case, where f is one-to-one, s^* will simply be a random string. Hence, evaluation of, say, $f(0^n)$ and $f(s^*)$ will reveal whether we have found the true s (in the second case) or simply selected a random string (in the first case). □

If we allow a bounded error probability, we can use essentially the same algorithm to solve slightly less constrained promise problems. For example, in the case where f is one-to-one, the outputs of n/ϵ repetitions of **Fourier-twice** (for constants $\epsilon < 1$) will with probability $1 - 2^{O(n)}$ contain a basis for $(\mathcal{Z}_2)^n$. On the other hand, if there exists an s such that for a fraction at least $1 - \epsilon/n$ of possible choices of x, $f(x) = f(x \oplus s)$, then the outputs of n/ϵ repetitions of **Fourier-twice** will still all satisfy $y \cdot s \equiv 0 \pmod 2$, with constant probability, regardless of any other properties of f. Hence we can efficiently distinguish between these two classes of function (for appropriate ϵ) on a quantum computer with negligible error probability.

3.2. Relativized hardness of our problem. Now, in a relativized setting, suppose that an oracle is equiprobably either an oracle uniformly distributed among permutations on n-bit values or an oracle uniformly distributed among those two-to-one functions f for which there exists a unique nontrivial s such that $f(x)$ always equals $f(x \oplus s)$. Then a classical probabilistic oracle TM would require exponentially many oracle queries to successfully distinguish the two cases with probability nonnegligibly greater than $1/2$.

THEOREM 3.3. *Let O be an oracle constructed as follows: for each n, a random n-bit string $s(n)$ and a random bit $b(n)$ are uniformly chosen from $\{0,1\}^n$ and $\{0,1\}$, respectively. If $b(n) = 0$, then the function $f_n : \{0,1\}^n \to \{0,1\}^n$ chosen for O to compute on n-bit queries is a random function uniformly distributed over permutations on $\{0,1\}^n$; otherwise, it is a random function uniformly distributed over two-to-one functions such that $f_n(x) = f_n(x \oplus s(n))$ for all x, where $\oplus$ denotes bitwise exclusive-or. Then any PTM that queries O no more than $2^{n/4}$ times cannot correctly guess $b(n)$ with probability greater than $(1/2) + 2^{-n/2}$, over choices made in the construction of O.*

Proof. Consider any such PTM M. We say that M's choice of the first k queries is *good* for n if M queries O at two n-bit input values whose exclusive or is $s(n)$. If M makes a good choice of $2^{n/4}$ queries for n, then the distribution on answers given by O differs depending on $b(n)$; otherwise, the distributions are identical (i.e., random, uniformly distributed distinct values for each distinct query). Since the probability that M guesses $b(n)$ is only greater than $1/2$ when its choices are good for n, this probability is also bounded above by $1/2 + \delta$, where δ is the probability that M's queries are good for n. Hence, we need only calculate a bound on δ to obtain a bound on M's probability of guessing $b(n)$.

Note that the probability that M's first k queries are good for n is equal to the sum of the conditional probabilities, for each of the queries, that M's queries up to and including that query are good for n, given that the previous ones were not. Note also that given a particular fixed sequence of j queries (and their answers) which is not good for n, the conditional distribution on $s(n)$ (over choices made in constructing O) is uniform over the elements of $\{0,1\}^n$ for which those j queries are still not good for n. (This is because all such possible sequences are equally likely for any $s(n)$, and there are equally many such sequences regardless of $s(n)$.) For example, if the j queries are such that their pairwise bitwise exclusive-ors are all distinct, then $s(n)$ is

conditionally distributed uniformly over the $2^n - j(j-1)/2$ possible values for which the sequence of queries is still not good for n.

Now, consider M's kth oracle query to O, assuming that M's first $k-1$ queries were not good for n. This kth query is completely determined by O's answers to the first $k-1$ queries and by M's probabilistic choices; we will call it q. The probability (over choices made in constructing O) that O's answer to q is the same as its answer to (a distinct) one of the $k-1$ previous queries (and hence that M's first k queries are good for n) is at most $k/(2^n - (k-2)(k-1)/2)$, since there are at most k choices of $s(n)$ (which was uniformly chosen from $\{0,1\}^n$) for which such a "collision" occurs, and $s(n)$ is conditionally distributed uniformly over all but the (at most) $(k-1)(k-2)/2$ values for which M's first $k-1$ queries is not good. Hence, for any sequence of $j = 2^{n/4}$ queries, the probability that it is good for n is at most $\sum_{k=1}^{j}(k/(2^n-(k-2)(k-1)/2)) \leq \sum_{k=1}^{j}(k/(j^4-j^2)) \leq (j^2+j)/(2(j^4-j^2)) \leq 2^{-n/2}$ (for $n \geq 1$). It follows that M cannot estimate $b(n)$ with probability better than $(1/2) + 2^{-n/2}$. □

We can also use Theorem 3.3 to prove the existence of a specific oracle relative to which there is an exponential gap (in terms of classical computing time) between BPP and its quantum analogue, BQP (defined in the natural way; see [BV93]). Let E be the (countable) set of classical oracle PTMs making at most $2^{n/4}$ queries on input 1^n. We say that $M \in E$ *solves* an oracle O generated as in the above theorem if for infinitely many n, M computes $b(n)$, with error bounded away from $1/2$ by some constant, on input 1^n. Theorem 3.3 tells us that for any M, the probability that M solves an O so chosen is 0. Since E is countable, an oracle O so generated will therefore with probability 1 be solved by no $M \in E$. Hence with probability 1 the language $\{1^n | b(n) = 1\}$, for $b(n)$ chosen as in Theorem 3.3, cannot be accepted with error bounded away from $1/2$ by any $M \in E$.

THEOREM 3.4. *There exist an oracle O and constant ϵ relative to which $BQP \not\subseteq PTIME(2^{\epsilon n})$ (with two-sided error).*

4. Conclusion. Since any quantum computer running in polynomial time can be fairly easily simulated in $PSPACE$, as was pointed out in [BV93], we are unlikely to be able to prove anytime soon that BQP is larger than P. However, Shor [Sho94] has recently made a huge advance toward establishing the complexity-theoretic advantage of the quantum model compared to the classical one, by giving quantum polynomial-time algorithms for two well-known presumed-hard problems: computing discrete logarithms modulo an arbitrary prime and factoring integers. His algorithms follow the very rough outline of the ones presented here, but with many additional sophistications that allow them to work over the field $\mathcal{Z}_p^*$ (for primes p such that $p-1$ is smooth) rather than $(\mathcal{Z}_2)^n$, and to extract much more than a single bit of information per iteration. A logical next step might be to try to separate BPP and BQP based on a more general complexity-theoretic assumption such as $P \neq NP$ or the existence of one-way functions. Alternatively, it may be possible to prove limits to the advantages of quantum computation through simulation results of some kind. (In [BBBV94], for example, oracle methods are used to give evidence that $NP \not\subseteq BQP$. On the other hand, Grover [Gro96] has recently shown that for NP-complete decision problems, the associated search problem with solutions of size n can be solved probabilistically, with bounded error, in time $2^{n/2}$ on a quantum computer—i.e., more efficiently than any known classical probabilistic algorithm.)

Another natural question regarding the model is whether the "fair quantum coin flip" suffices as a universal nonclassical step, the way its classical counterpart, the

fair coin flip, suffices as a universal (classical) probabilistic step. Recent work in this direction (see, for instance, [DiV95], [BBCD95]) has shown that there are many choices of a single nonclassical operation that will in fact suffice in simulating quantum computations which use arbitrary feasible quantum operations; however, it is not known whether the "fair quantum coin flip" is one such choice.

Another issue is that of alternative models of quantum computation. Yao [Yao93] has presented a quantum circuit model (following [Deu89]) and proven it equivalent to the QTM. In contrast, it is not yet known whether a quantum cellular automaton is equivalent or more powerful (see [DST96]). Still other distinct quantum-based computational models may exist, as well. For example, any unitary "evolution" matrix describing a quantum computation (in any model) is related (by Schrodinger's equation) to a corresponding Hermitian "Hamiltonian" matrix which describes the same process. There is also a natural notion of locality for Hamiltonians—but evolution matrices and their associated Hamiltonians are not necessarily both local or both nonlocal. It is therefore unclear whether even the definition of BQP (for QTMs or for any other model) is the same for operator-based and Hamiltonian-based encodings. (Feynman has shown, in [Fey86], that the Hamiltonian-based model is at least as powerful as the unitary operator-based one; whether the reverse is true is not known.)

Beyond the question of models is the matter of their implementation. For example, any physical realization of a quantum computer would necessarily be subject to some error; exact superpositions would end up being represented by approximations just as deterministic discrete computations and random coin flips are approximated in modern computers using analog quantities such as voltages. Considerable work has been done on the feasibility of resiliently simulating true randomness with "approximate randomness" (see, for example, [VV85], [CG88]); similar work is necessary to determine if computation using approximations of quantum superpositions can be made comparably resilient. Recent work by Shor [Sho96] on quantum error-correcting codes has made progress toward this goal, showing that errors conforming to a certain restrictive model can in fact be corrected. However, it is not known how well that model covers the types of error likely to be encountered in a practical quantum computer. Resolution of these and other theoretical issues would be a crucial step toward understanding both the utility and the ultimate feasibility of implementing a quantum computer.

Acknowledgments. Many thanks to Charles Bennett, Ethan Bernstein, Gilles Brassard, Jeroen van de Graaf, Richard Jozsa, and Dominic Mayers for valuable insights and helpful discussion.

POLYNOMIAL-TIME ALGORITHMS FOR PRIME FACTORIZATION AND DISCRETE LOGARITHMS ON A QUANTUM COMPUTER*

PETER W. SHOR†

Abstract. A digital computer is generally believed to be an efficient universal computing device; that is, it is believed able to simulate any physical computing device with an increase in computation time by at most a polynomial factor. This may not be true when quantum mechanics is taken into consideration. This paper considers factoring integers and finding discrete logarithms, two problems which are generally thought to be hard on a classical computer and which have been used as the basis of several proposed cryptosystems. Efficient randomized algorithms are given for these two problems on a hypothetical quantum computer. These algorithms take a number of steps polynomial in the input size, e.g., the number of digits of the integer to be factored.

1. Introduction.

One of the first results in the mathematics of computation, which underlies the subsequent development of much of theoretical computer science, was the distinction between computable and noncomputable functions shown in papers of Church [1936], Post [1936], and Turing [1936]. The observation that several apparently different definitions of what it meant for a function to be computable yielded the same set of computable functions led to the proposal of Church's thesis, which says that all computing devices can be simulated by a Turing machine. This thesis greatly simplifies the study of computation, since it reduces the potential field of study from any of an infinite number of potential computing devices to Turing machines. Church's thesis is not a mathematical theorem; to make it one would require a precise mathematical description of a computing device. Such a description, however, would leave open the possibility of some practical computing device which did not satisfy this precise mathematical description and thus would make the resulting theorem weaker than Church's original thesis.

With the development of practical computers, it became apparent that the distinction between computable and noncomputable functions was much too coarse; computer scientists are now interested in the exact efficiency with which specific functions can be computed. This exact efficiency, on the other hand, was found to be too precise a quantity to work with easily. The generally accepted compromise between coarseness and precision distinguishes efficiently from inefficiently computable functions by whether the length of the computation scales polynomially or superpolynomially with the input size. The class of problems which can be solved by algorithms having a number of steps polynomial in the input size is known as P.

For this classification to make sense, it must be machine independent. That is, the question of whether a function is computable in polynomial time must be independent

of the type of computing device used. This corresponds to the following quantitative version of Church's thesis, which has been called the "strong Church's thesis" by Vergis, Steiglitz, and Dickinson [1986] and which makes up half of the "invariance thesis" of van Emde Boas [1990].

THESIS 1.1 (quantitative Church's thesis). *Any physical computing device can be simulated by a Turing machine in a number of steps polynomial in the resources used by the computing device.*

Readers who are not comfortable with Turing machines may think instead of digital computers having an amount of memory that grows linearly with the length of the computation, as these two classes of computing machines can efficiently simulate each other. In statements of this thesis, the Turing machine is sometimes augmented with a random number generator, as it has not yet been determined whether there are pseudorandom number generators which can efficiently simulate truly random number generators for all purposes.

There are two escape clauses in the above thesis. One of these is the word "physical." Researchers have produced machine models that violate the above quantitative Church's thesis, but most of these have been ruled out by some reason for why they are not physical, that is, why they could not be built and made to work. The other escape clause in the above thesis is the word "resources," the meaning of which is not completely specified above. There are generally two resources which limit the ability of digital computers to solve large problems: time (computational steps) and space (memory). There are more resources pertinent to analog computation; some proposed analog machines that seem able to solve NP-complete problems in polynomial time have required exponentially precise parts or an exponential amount of energy. (See Vergis, Steiglitz, and Dickinson [1986] and Steiglitz [1988]; this issue is also implicit in the papers of Canny and Reif [1987] and Choi, Sellen, and Yap [1995] on three-dimensional shortest paths.)

For quantum computation, in addition to space and time there is also a third potentially important resource: precision. For a quantum computer to work, at least in any currently envisioned implementation, it must be able to make changes in the quantum states of objects (e.g., atoms, photons, or nuclear spins). These changes can clearly not be perfectly accurate but must contain some small amount of inherent imprecision. If this imprecision is constant (i.e., it does not depend on the size of the input), then it is not known how to compute any functions in polynomial time on a quantum computer that cannot also be computed in polynomial time on a classical computer with a random number generator[1]. However, if we let the precision grow polynomially in the input size (so the number of *bits* of precision grows logarithmically in the input size), we appear to obtain a more powerful type of computer. Allowing the same polynomial growth in precision does not appear to confer extra computing power to classical mechanics, although allowing exponential growth in precision may [Hartmanis and Simon 1974; Vergis, Steiglitz, and Dickinson 1986].

As far as we know, what precision is possible in quantum state manipulation is dictated not by fundamental physical laws but by the properties of the materials from which and the architecture with which a quantum computer is built. It is currently not clear which architectures, if any, will give high precision, and what this precision will be. If the precision of a quantum computer is large enough to make it more powerful

[1] Note added in proof. This is no longer true. See Aharonov and Ben-Or [Proc. 29th Annual ACM Symposium on Theory of Computing, ACM, New York, 1997, pp. 176–188]; Gottesman, Evslin, Kakade, and Preskill [manuscript, 1997]; Kitaev [manuscript, 1997], Knill, Laflamme, and Zurek [LANL e-print quant-ph/9702058, Los Alamos National Laboratories, Los Alamos, NM, 1997].

than a classical computer, then in order to understand its potential it is important to think of precision as a resource that can vary. Treating the precision as a large constant (even though it is almost certain to be constant for any given machine) would be comparable to treating a classical digital computer as a finite automaton—since any given computer has a fixed amount of memory, this view is technically correct; however, it is not particularly useful.

Because of the remarkable effectiveness of our mathematical models of computation, computer scientists have tended to forget that computation is dependent on the laws of physics. This can be seen in the statement of the quantitative Church's thesis in van Emde Boas [1990], where the word "physical" in the above phrasing is replaced by the word "reasonable." It is difficult to imagine any definition of "reasonable" in this context which does not mean "physically realizable," i.e., that this computing machine could actually be built and would work.

Computer scientists have become convinced of the truth of the quantitative Church's thesis through the failure of all proposed counterexamples. Most of these proposed counterexamples have been based on the laws of classical mechanics; however, the universe is in reality quantum mechanical. Quantum mechanical objects often behave quite differently from how our intuition, based on classical mechanics, tells us they should. It thus seems plausible that the natural computing power of classical mechanics corresponds to that of Turing machines,[2] while the natural computing power of quantum mechanics might be greater.

The first person to look at the interaction between computation and quantum mechanics appears to have been Benioff [1980, 1982a, 1982b]. Although he did not ask whether quantum mechanics conferred extra power to computation, he showed that reversible unitary evolution was sufficient to realize the computational power of a Turing machine, thus showing that quantum mechanics is computationally at least as powerful as classical computers. This work was fundamental in making later investigation of quantum computers possible.

Feynman [1982, 1986] seems to have been the first to suggest that quantum mechanics might be computationally more powerful than Turing machines. He gave arguments as to why quantum mechanics is intrinsically computationally expensive to simulate on a classical computer. He also raised the possibility of using a computer based on quantum mechanical principles to avoid this problem, thus implicitly asking the converse question, "By using quantum mechanics in a computer can you compute more efficiently than on a classical computer?" The first to ask this question explicitly was Deutsch [1985, 1989]. In order to study this question, he defined both quantum Turing machines and quantum circuits and investigated some of their properties.

The question of whether using quantum mechanics in a computer allows one to obtain more computational power was more recently addressed by Deutsch and Jozsa [1992] and Berthiaume and Brassard [1992, 1994]. These papers showed that there are problems which quantum computers can quickly solve exactly, but that classical computers can only solve quickly with high probability and the aid of a random number generator. However, these papers did not show how to solve any problem in quantum polynomial time that was not already known to be solvable in polynomial time with the aid of a random number generator, allowing a small

[2]See Vergis, Steiglitz, and Dickinson [1986], Steiglitz [1988], and Rubel [1989]. I believe that this question has not yet been settled and is worthy of further investigation. In particular, turbulence seems a good candidate for a counterexample to the quantitative Church's thesis because the nontrivial dynamics on many length scales appear to make it difficult to simulate on a classical computer.

probability of error; this is the characterization of the complexity class BPP (bounded error probability probabilistic polynomial time), which is widely viewed as the class of efficiently solvable problems.

Further work on this problem was stimulated by Bernstein and Vazirani [1993]. One of the results contained in their paper was an oracle problem (that is, a problem involving a "black box" subroutine that the computer is allowed to perform but for which no code is accessible) which can be done in polynomial time on a quantum Turing machine but which requires superpolynomial time on a classical computer. This result was improved by Simon [1994], who gave a much simpler construction of an oracle problem which takes polynomial time on a quantum computer but requires *exponential* time on a classical computer. Indeed, while Bernstein and Vaziarni's problem appears contrived, Simon's problem looks quite natural. Simon's algorithm inspired the work presented in this paper.

Two number theory problems which have been studied extensively but for which no polynomial-time algorithms have yet been discovered are finding discrete logarithms and factoring integers [Pomerance 1987, Gordon 1993, Lenstra and Lenstra 1993, Adleman and McCurley 1994]. These problems are so widely believed to be hard that several cryptosystems based on their difficulty have been proposed, including the widely used RSA public key cryptosystem developed by Rivest, Shamir, and Adleman [1978]. We show that these problems can be solved in polynomial time on a quantum computer with a small probability of error.

Currently, nobody knows how to build a quantum computer, although it seems as though it might be possible within the laws of quantum mechanics. Some suggestions have been made as to possible designs for such computers [Teich, Obermayer, and Mahler 1988; Lloyd 1993, 1994; Cirac and Zoller 1995; DiVincenzo 1995; Sleator and Weinfurter 1995; Barenco et al. 1995b; Chuang and Yamomoto 1995], but there will be substantial difficulty in building any of these [Landauer 1995, 1997; Unruh 1995; Chuang et al. 1995; Palma, Suominen, and Ekert 1996]. The most difficult obstacles appear to involve the decoherence of quantum superpositions through the interaction of the computer with the environment, and the implementation of quantum state transformations with enough precision to give accurate results after many computation steps. Both of these obstacles become more difficult as the size of the computer grows, so it may turn out to be possible to build small quantum computers, while scaling up to machines large enough to do interesting computations may present fundamental difficulties.

Even if no useful quantum computer is ever built, this research does illuminate the problem of simulating quantum mechanics on a classical computer. Any method of doing this for an arbitrary Hamiltonian would necessarily be able to simulate a quantum computer. Thus, any general method for simulating quantum mechanics with at most a polynomial slowdown would lead to a polynomial-time algorithm for factoring.

The rest of this paper is organized as follows. In section 2, we introduce the model of quantum computation, the *quantum gate array,* that we use in the rest of the paper. In sections 3 and 4, we explain two subroutines that are used in our algorithms: reversible modular exponentiation in section 3 and quantum Fourier transforms in section 4. In section 5, we give our algorithm for prime factorization, and in section 6, we give our algorithm for extracting discrete logarithms. In section 7, we give a brief discussion of the practicality of quantum computation and suggest possible directions for further work.

2. Quantum computation. In this section we give a brief introduction to quantum computation, emphasizing the properties that we will use. We will describe only *quantum gate arrays,* or *quantum acyclic circuits,* which are analogous to acyclic circuits in classical computer science. This model was originally studied by Yao [1993] and is closely related to the quantum computational networks discussed by Deutsch [1989]. For other models of quantum computers, see references on quantum Turing machines [Deutsch 1985; Bernstein and Vazirani 1993; Yao 1993] and quantum cellular automata [Feynman 1986; Margolus 1986, 1990; Lloyd 1993; Biafore 1994]. If they are allowed a small probability of error, quantum Turing machines and quantum gate arrays can compute the same functions in polynomial time [Yao 1993]. This may also be true for the various models of quantum cellular automata, but it has not yet been proved. This gives evidence that the class of functions computable in quantum polynomial time with a small probability of error is robust in that it does not depend on the exact architecture of a quantum computer. By analogy with the classical class BPP, this class is called BQP (bounded error probability quantum polynomial time).

Consider a system with n components, each of which can have two states. Whereas in classical physics, a complete description of the state of this system requires only n bits, in quantum physics, a complete description of the state of this system requires $2^n - 1$ complex numbers. To be more precise, the state of the quantum system is a point in a 2^n-dimensional vector space. For each of the 2^n possible classical positions of the components, there is a basis state of this vector space which we represent, for example, by $|011\cdots0\rangle$ meaning that the first bit is 0, the second bit is 1, and so on. Here, the *ket* notation $|x\rangle$ means that x is a (pure) quantum state. (Mixed states will not be discussed in this paper, and thus we do not define them; see a quantum theory book such as Peres [1993] for their definition.) The *Hilbert space* associated with this quantum system is the complex vector space with these 2^n states as basis vectors, and the state of the system at any time is represented by a unit-length vector in this Hilbert space. As multiplying this state vector by a unit-length complex phase does not change any behavior of the state, we need only $2^n - 1$ complex numbers to completely describe the state. We represent this superposition of states by

$$\sum_{i=0}^{2^n-1} a_i|S_i\rangle, \tag{2.1}$$

where the amplitudes a_i are complex numbers such that $\sum_i |a_i|^2 = 1$ and each $|S_i\rangle$ is a basis vector of the Hilbert space. If the machine is measured (with respect to this basis) at any particular step, the probability of seeing basis state $|S_i\rangle$ is $|a_i|^2$; however, measuring the state of the machine projects this state to the observed basis vector $|S_i\rangle$. Thus, looking at the machine during the computation will invalidate the rest of the computation. General quantum mechanical measurements, i.e., POVMs (positive operator valued measurement, see [Peres 1993]), can be considerably more complicated than the case of projection onto the canonical basis to which we restrict ourselves in this paper. This does not greatly restrict our model of computation, since measurements in other reasonable bases, as well as other local measurements, can be simulated by first using quantum computation to perform a change of basis and then performing a measurement in the canonical basis.

In order to use a physical system for computation, we must be able to change the state of the system. The laws of quantum mechanics permit only unitary transformations of state vectors. A unitary matrix is one whose conjugate transpose is equal to

its inverse, and requiring state transformations to be represented by unitary matrices ensures that summing the probability over all possible outcomes yields 1. The definition of quantum circuits (and quantum Turing machines) allows only *local* unitary transformations—that is, unitary transformations on a fixed number of bits. This is physically justified because, given a general unitary transformation on n bits, it is not clear how one could efficiently implement it physically, whereas two-bit transformations can at least in theory be implemented by relatively simple physical systems [Cirac and Zoller 1995; DiVincenzo 1995; Sleator and Weinfurter 1995; Chuang and Yamomoto 1995]. While general n-bit transformations can always be built out of two-bit transformations [DiVincenzo 1995; Sleator and Weinfurter 1995; Lloyd 1995; Deutsch, Barenco, and Ekert 1995], the number required will often be exponential in n [Barenco et al. 1995a]. Thus, the set of two-bit transformations form a set of building blocks for quantum circuits in a manner analogous to the way a universal set of classical gates (such as the AND, OR, and NOT gates) form a set of building blocks for classical circuits. In fact, for a universal set of quantum gates, it is sufficient to take all one-bit gates and a single type of two-bit gate, the controlled NOT gate (also called the XOR or parity gate), which negates the second bit if and only if the first bit is 1.

Perhaps an example will be informative at this point. A quantum gate can be expressed as a truth table: for each input basis vector we need to give the output of the gate. One such gate is

$$\begin{aligned} &|00\rangle \to |00\rangle, \\ &|01\rangle \to |01\rangle, \\ &|10\rangle \to \tfrac{1}{\sqrt{2}}(|10\rangle + |11\rangle), \\ &|11\rangle \to \tfrac{1}{\sqrt{2}}(|10\rangle - |11\rangle). \end{aligned} \tag{2.2}$$

Not all truth tables correspond to physically feasible quantum gates, as many truth tables will not give rise to unitary transformations.

The same gate can also be represented as a matrix. The rows correspond to input basis vectors. The columns correspond to output basis vectors. The (i, j) entry gives, when the ith basis vector is input to the gate, the coefficient of the jth basis vector in the corresponding output of the gate. The truth table above would then correspond to the following matrix:

$$\begin{array}{c|cccc} & |00\rangle & |01\rangle & |10\rangle & |11\rangle \\ \hline |00\rangle & 1 & 0 & 0 & 0 \\ |01\rangle & 0 & 1 & 0 & 0 \\ |10\rangle & 0 & 0 & \frac{1}{\sqrt{2}} & \frac{1}{\sqrt{2}} \\ |11\rangle & 0 & 0 & \frac{1}{\sqrt{2}} & -\frac{1}{\sqrt{2}} \end{array}. \tag{2.3}$$

A quantum gate is feasible if and only if the corresponding matrix is unitary, i.e., its inverse is its conjugate transpose.

Suppose that our machine is in the superposition of states

$$\tfrac{1}{\sqrt{2}}|10\rangle - \tfrac{1}{\sqrt{2}}|11\rangle \tag{2.4}$$

and we apply the unitary transformation represented by (2.2) and (2.3) to this state. The resulting output will be the result of multiplying the vector (2.4) by the matrix (2.3). The machine will thus go to the superposition of states

$$\tfrac{1}{2}\left(|10\rangle + |11\rangle\right) - \tfrac{1}{2}\left(|10\rangle - |11\rangle\right) \;=\; |11\rangle. \tag{2.5}$$

This example shows the potential effects of interference on quantum computation. Had we started with either the state $|10\rangle$ or the state $|11\rangle$, there would have been a chance of observing the state $|10\rangle$ after the application of the gate (2.3). However, when we start with a superposition of these two states, the probability amplitudes for the state $|10\rangle$ cancel, and we have no possibility of observing $|10\rangle$ after the application of the gate. Notice that the output of the gate would have been $|10\rangle$ instead of $|11\rangle$ had we started with the superposition of states

$$\frac{1}{\sqrt{2}}|10\rangle + \frac{1}{\sqrt{2}}|11\rangle, \tag{2.6}$$

which has the same probabilities of being in any particular configuration if it is observed as does the superposition (2.4).

If we apply a gate to only two bits of a longer vector (now our circuit must have more than two wires), for each basis vector we apply the transformation given by the gate's truth table to the two bits on which the gate is operating, and leave the other bits alone. This corresponds to multiplying the whole state by the tensor product of the gate matrix on those two bits with the identity matrix on the remaining bits. For example, applying the transformation represented by (2.2) and (2.3) to the first two bits of the basis vector $|110\rangle$ yields the vector $\frac{1}{\sqrt{2}}(|100\rangle - |110\rangle)$.

A quantum gate array is a set of quantum gates with logical "wires" connecting their inputs and outputs. The input to the gate array, possibly along with extra work bits that are initially set to 0, is fed through a sequence of quantum gates. The values of the bits are observed after the last quantum gate, and these values are the output. This model is analogous to classical acyclic circuits in theoretical computer science, and was previously studied by Yao [1993]. As in the classical case, in order to compare quantum gate arrays with quantum Turing machines, we need to make the gate arrays a *uniform* complexity class. In other words, because we use a different gate array for each size of input, we need to keep the designer of the gate arrays from hiding noncomputable (or hard to compute) information in the arrangement of the gates. To make quantum gate arrays uniform, we must add two requirements to the definition of gate arrays. The first is the standard uniformity requirement that the design of the gate array be produced by a polynomial-time (classical) computation. The second uniformity requirement should be a standard part of the definition of analog complexity classes; however, since analog complexity classes have not been as widely studied, this requirement is not well known. The requirement is that the entries in the unitary matrices describing the gates must be computable numbers. Specifically, the first $\log n$ bits of each entry should be classically computable in time polynomial in n [Solovay 1995]. This keeps noncomputable (or hard to compute) information from being hidden in the bits of the amplitudes of the quantum gates.

3. Reversible logic and modular exponentiation. The definition of quantum gate arrays gives rise to completely reversible computation. That is, knowing the quantum state on the wires leading out of a gate tells uniquely what the quantum state must have been on the wires leading into that gate. This is a reflection of the fact that, despite the macroscopic arrow of time, the laws of physics appear to be completely reversible. This would seem to imply that anything built with the laws of physics must be completely reversible; however, classical computers get around this by dissipating energy and thus making their computations thermodynamically irreversible. This appears impossible to do for quantum computers because superpositions of quantum states need to be maintained throughout the computation. Thus, quantum computers necessarily have to use reversible computation. This imposes

extra costs when doing classical computations on a quantum computer, which can be necessary in subroutines of quantum computations.

Because of the reversibility of quantum computation, a deterministic computation is performable on a quantum computer only if it is reversible. Luckily, it has already been shown that any deterministic computation can be made reversible [Lecerf 1963; Bennett 1973]. In fact, reversible classical gate arrays (or reversible acyclic circuits) have been studied. Much like the result that any classical computation can be done using NAND gates, there are also universal gates for reversible computation. Two of these are Toffoli gates [Toffoli 1980] and Fredkin gates [Fredkin and Toffoli 1982]; these are illustrated in Table 3.1.

The Toffoli gate is just a doubly controlled NOT, i.e., the last bit is negated if and only if the first two bits are 1. In a Toffoli gate, if the third input bit is set to 1, then the third output bit is the NAND of the first two input bits. Since NAND is a universal gate for classical gate arrays, this shows that the Toffoli gate is universal. In a Fredkin gate, the last two bits are swapped if the first bit is 0, and left untouched if the first bit is 1. For a Fredkin gate, if the third input bit is set to 0, the second output bit is the AND of the first two input bits; and if the last two input bits are set to 0 and 1 respectively, the second output bit is the NOT of the first input bit. Thus, both AND and NOT gates are realizable using Fredkin gates, showing that the Fredkin gate is universal.

From results on reversible computation [Lecerf 1963, Bennett 1973], we can efficiently compute any polynomial time function $F(x)$ as long as we keep the input x in the computer. We do this by adapting the method for computing the function F nonreversibly. These results can easily be extended to work for gate arrays [Toffoli 1980; Fredkin and Toffoli 1982]. When AND, OR, or NOT gates are changed to Fredkin or Toffoli gates, one obtains both additional input bits, which must be preset to specified values, and additional output bits, which contain the information needed to reverse the computation. While the additional input bits do not present difficulties in designing quantum computers, the additional output bits do, because unless they are all reset to 0, they will affect the interference patterns in quantum computation. Bennett's method for resetting these bits to 0 is shown in the top half of Table 3.2. A nonreversible gate array may thus be turned into a reversible gate array as follows. First, duplicate the input bits as many times as necessary (since each input bit could be used more than once by the gate array). Next, keeping one copy of the input around, use Toffoli and Fredkin gates to simulate nonreversible gates, putting the extra output bits into the RECORD register. These extra output bits preserve enough of a record of the operations to enable the computation of the gate array to be

TABLE 3.2
Bennett's method for making a computation reversible.

reversed. Once the output $F(x)$ has been computed, copy it into a register that has been preset to zero, and then undo the computation to erase both the first OUTPUT register and the RECORD register.

To erase x and replace it with $F(x)$, in addition to a polynomial-time algorithm for F, we also need a polynomial-time algorithm for computing x from $F(x)$; i.e., we need that F is one-to-one and that both F and F^{-1} are polynomial-time computable. The method for this computation is given in the whole of Table 3.2. There are two stages to this computation. The first is the same as before, taking x to $(x, F(x))$. For the second stage, shown in the bottom half of Table 3.2, note that if we have a method to compute F^{-1} nonreversibly in polynomial time, we can use the same technique to reversibly map $F(x)$ to $(F(x), F^{-1}(F(x))) = (F(x), x)$. However, since this is a reversible computation, we can reverse it to go from $(x, F(x))$ to $F(x)$. Put together, these two stages take x to $F(x)$.

The above discussion shows that computations can be made reversible for only a constant factor cost in time, but the above method uses as much space as it does time. If the classical computation requires much less space than time, then making it reversible in this manner will result in a large increase in the space required. There are methods that do not use as much space, but use more time, to make computations reversible [Bennett 1989, Levine and Sherman 1990]. While there is no general method that does not cause an increase in either space or time, specific algorithms can sometimes be made reversible without paying a large penalty in either space or time; at the end of this section we will show how to do this for modular exponentiation, which is a subroutine necessary for quantum factoring.

The bottleneck in the quantum factoring algorithm—i.e., the piece of the factoring algorithm that consumes the most time and space—is modular exponentiation. The modular exponentiation problem is, given n, x, and r, find $x^r \pmod n$. The best classical method for doing this is to repeatedly square of $x \pmod n$ to get $x^{2^i} \pmod n$ for $i \leq \log_2 r$, and then multiply a subset of these powers $(\text{mod } n)$ to get $x^r \pmod n$. If we are working with l-bit numbers, this requires $O(l)$ squarings and multiplications of l-bit numbers $(\text{mod } n)$. Asymptotically, the best classical result for gate arrays for multiplication is the Schönhage–Strassen algorithm [Schönhage and Strassen 1971, Knuth 1981, Schönhage 1982]. This gives a gate array for integer multiplication that uses $O(l \log l \log\log l)$ gates to multiply two l-bit numbers. Thus, asymptotically, modular exponentiation requires $O(l^2 \log l \log\log l)$ time. Making this reversible would naïvely cost the same amount in space; however, one can reuse the space used in the repeated squaring part of the algorithm, and thus reduce the amount of space needed to essentially that required for multiplying two l-bit numbers; one simple method for reducing this space (although not the most versatile one) will be given later in this section. Thus, modular exponentiation can be done in $O(l^2 \log l \log\log l)$ time and $O(l \log l \log\log l)$ space.

While the Schönhage–Strassen algorithm is the best multiplication algorithm discovered to date for large l, it does not scale well for small l. For small numbers, the best gate arrays for multiplication essentially use elementary-school longhand multiplication in binary. This method requires $O(l^2)$ time to multiply two l-bit numbers, and thus modular exponentiation requires $O(l^3)$ time with this method. These gate arrays can be made reversible, however, using only $O(l)$ space.

We now give the method for constructing a reversible gate array that takes only $O(l)$ space and $O(l^3)$ time to compute $(a, x^a \pmod n)$ from a, where a, x, and n are l-bit numbers and x and n are relatively prime. This case, where x and n are relatively prime, is sufficient for our factoring and discrete logarithm algorithms. A detailed analysis of essentially this method, giving an exact number of quantum gates sufficient for factoring, was performed by Beckman et al. [1996].

The basic building block used is a gate array that takes b as input and outputs $b + c \pmod n$. Note that here b is the gate array's input but c and n are built into the structure of the gate array. Since addition $(\bmod n)$ is computable in $O(\log n)$ time classically, this reversible gate array can be made with only $O(\log n)$ gates and $O(\log n)$ work bits using the techniques explained earlier in this section.

The technique we use for computing $x^a \pmod n$ is essentially the same as the classical method. First, by repeated squaring we compute $x^{2^i} \pmod n$ for all $i < l$. Then, to obtain $x^a \pmod n$ we multiply the powers $x^{2^i} \pmod n$, where 2^i appears in the binary expansion of a. In our algorithm for factoring n, we need only to compute $x^a \pmod n$, where a is in a superposition of states but x is some fixed integer. This makes things much easier, because we can use a reversible gate array where a is input but where x and n are built into the structure of the gate array. Thus, we can use the algorithm described by the following pseudocode; here a_i represents the ith bit of a in binary, where the bits are indexed from right to left and the rightmost bit of a is a_0.

```
power := 1
for i = 0 to l−1
    if ( a_i == 1 ) then
        power := power * x^(2^i)   (mod n)
    endif
endfor
```

The variable a is left unchanged by the code and $x^a \pmod n$ is output as the variable *power*. Thus, this code takes the pair of values $(a, 1)$ to $(a, x^a \pmod n)$.

This pseudocode can easily be turned into a gate array; the only hard part of this is the fourth line, where we multiply the variable *power* by $x^{2^i} \pmod n$; to do this we need to use a fairly complicated gate array as a subroutine. Recall that $x^{2^i} \pmod n$ can be computed classically and then built into the structure of the gate array. Thus, to implement this line, we need a reversible gate array that takes b as input and gives $bc \pmod n$ as output, where the structure of the gate array can depend on c and n. Of course, this step can only be reversible if $\gcd(c, n) = 1$—i.e., if c and n have no common factors—as otherwise two distinct values of b will be mapped to the same value of $bc \pmod n$. Fortunately, x and n being relatively prime in modular exponentiation implies that c and n are relatively prime in this subroutine.

We will show how to build this gate array in two stages. The first stage is directly analogous to exponentiation by repeated multiplication; we obtain multiplication from repeated addition $(\bmod n)$. Pseudocode for this stage is as follows.

```
result := 0
for i = 0 to l−1
    if ( b_i == 1 ) then
        result := result + 2^i c  (mod n)
    endif
endfor
```

Again, $2^i c \pmod n$ can be precomputed and built into the structure of the gate array.

The above pseudocode takes b as input and gives $(b, bc \pmod n)$ as output. To get the desired result, we now need to erase b. Recall that $\gcd(c, n) = 1$, so there is a $c^{-1} \pmod n$ with $c\,c^{-1} \equiv 1 \pmod n$. Multiplication by this c^{-1} could be used to reversibly take $bc \pmod n$ to $(bc \pmod n, bcc^{-1} \pmod n) = (bc \pmod n, b)$. This is just the reverse of the operation we want, and since we are working with reversible computing, we can turn this operation around to erase b. The pseudocode for this follows.

```
for i = 0 to l−1
    if ( result_i == 1 ) then
        b := b − 2^i c^{-1}  (mod n)
    endif
endfor
```

As before, $result_i$ is the ith bit of *result*.

Note that at this stage of the computation, b should be 0. However, we did not set b directly to zero, as this would not have been a reversible operation and thus impossible on a quantum computer, but instead we did a relatively complicated sequence of operations which ended with $b = 0$ and which in fact depended on multiplication being a group (mod n). At this point, then, we could do something somewhat sneaky: we could measure b to see if it actually is 0. If it is not, we know that there has been an error somewhere in the quantum computation, i.e., that the results are worthless and we should stop the computer and start over again. However, if we do find that b is 0, then we know (because we just observed it) that it is now exactly 0. This measurement thus may bring the quantum computation back on track in that any amplitude that b had for being nonzero has been eliminated. Further, because the probability that we observe a state is proportional to the square of the amplitude of that state, doing the modular exponentiation and measuring b every time that we know it should be 0 may result in a higher probability of overall success than the same computation done without the repeated measurements of b. This is the *quantum watchdog* (or *quantum Zeno*) effect [Peres 1993], and whether it is applicable in this setting depends on the error model for our quantum circuits. The argument above does not actually show that repeated measurement of b is indeed beneficial, because there is a cost (in time, if nothing else) of measuring b. Before this is implemented, then, it should be checked with analysis or experiment that the benefit of such measurements exceeds their cost. In general, I believe that partial measurements such as this one are a promising way of trying to stabilize quantum computations.

Currently, Schönhage–Strassen is the algorithm of choice for multiplying very large numbers, and longhand multiplication is the algorithm of choice for small numbers. There are also multiplication algorithms which have asymptotic efficiencies between these two algorithms and which are superior for intermediate length numbers [Karatsuba and Ofman 1962; Knuth 1981; Schönhage, Grotefeld, and Vetter 1994]. It is not clear which algorithms are best for which size numbers. While this is known to

some extent for classical computation [Schönhage, Grotefeld, and Vetter 1994], using data on which algorithms work better on classical computers could be misleading for two reasons. First, classical computers need not be reversible, and the cost of making an algorithm reversible depends on the algorithm. Second, existing computers generally have multiplication for 32- or 64-bit numbers built into their hardware, and this tends to increase the optimal changeover points. To further confuse matters, some multiplication algorithms can take better advantage of hardwired multiplication than others. In order to program quantum computers most efficiently, work thus needs to be done on the best way of implementing elementary arithmetic operations on quantum computers. One tantalizing fact is that the Schönhage–Strassen fast multiplication algorithm uses the fast Fourier transform, which is also the basis for all the fast algorithms on quantum computers discovered to date. It is thus tempting to speculate that integer multiplication itself might be speeded up by a quantum algorithm; if possible, this would result in a somewhat faster asymptotic bound for factoring on a quantum computer, and indeed could even make breaking RSA on a quantum computer asymptotically faster than encrypting with RSA on a classical computer.

4. Quantum Fourier transforms. Since quantum computation deals with unitary transformations, it is helpful to know how to build certain useful unitary transformations. In this section we give a technique for constructing in polynomial time on quantum computers one particular unitary transformation, which is essentially a discrete Fourier transform. This transformation will be given as a matrix, with both rows and columns indexed by states. These states correspond to binary representations of integers on the computer; in particular, the rows and columns will be indexed beginning with 0 unless otherwise specified.

This transformation is as follows. Consider a number a with $0 \le a < q$ for some q. We will perform the transformation that takes the state $|a\rangle$ to the state

$$\frac{1}{q^{1/2}} \sum_{c=0}^{q-1} |c\rangle \exp(2\pi i ac/q). \tag{4.1}$$

That is, we apply the unitary matrix whose (a, c) entry is $\frac{1}{q^{1/2}} \exp(2\pi i ac/q)$. This Fourier transform is at the heart of our algorithms, and we call this matrix A_q.

In our factoring and discrete logarithm algorithms, we will use A_q for q of exponential size (i.e., the number of bits of q grows polynomially with the length of our input). We must thus show how this transformation can be done in time polynomial in the number of bits of q. In this paper, we give a simple construction for A_q when q is a power of 2 that was discovered independently by Coppersmith [1994] and Deutsch [see Ekert and Jozsa 1996]. This construction is essentially the standard fast Fourier transform (FFT) algorithm [Knuth 1981] adapted for a quantum computer; the following description of it follows that of Ekert and Jozsa [1996]. In the earlier version of this paper [Shor 1994], we gave a construction for A_q when q was in the special class of smooth numbers having only small prime power factors. In fact, Cleve [1994] has shown how to construct A_q for all smooth numbers q whose prime factors are at most $O(\log n)$.

Take $q = 2^l$, and let us represent an integer a in binary as $|a_{l-1}a_{l-2}\dots a_0\rangle$. For the quantum Fourier transform A_q, we need only to use two types of quantum gates.

These gates are R_j, which operates on the jth bit of the quantum computer:

$$R_j = \begin{array}{c|cc} & |0\rangle & |1\rangle \\ |0\rangle & \frac{1}{\sqrt{2}} & \frac{1}{\sqrt{2}} \\ |1\rangle & \frac{1}{\sqrt{2}} & -\frac{1}{\sqrt{2}} \end{array}, \tag{4.2}$$

and $S_{j,k}$, which operates on the bits in positions j and k with $j < k$:

$$S_{j,k} = \begin{array}{c|cccc} & |00\rangle & |01\rangle & |10\rangle & |11\rangle \\ |00\rangle & 1 & 0 & 0 & 0 \\ |01\rangle & 0 & 1 & 0 & 0 \\ |10\rangle & 0 & 0 & 1 & 0 \\ |11\rangle & 0 & 0 & 0 & e^{i\theta_{k-j}} \end{array}, \tag{4.3}$$

where $\theta_{k-j} = \pi/2^{k-j}$. To perform a quantum Fourier transform, we apply the matrices in the order (from left to right)

$$R_{l-1}\, S_{l-2,l-1}\, R_{l-2}\, S_{l-3,l-1}\, S_{l-3,l-2}\, R_{l-3} \ldots R_1\, S_{0,l-1}\, S_{0,l-2} \ldots S_{0,2}\, S_{0,1}\, R_0; \tag{4.4}$$

that is, we apply the gates R_j in reverse order from R_{l-1} to R_0, and between R_{j+1} and R_j we apply all the gates $S_{j,k}$ where $k > j$. For example, on 3 bits, the matrices would be applied in the order $R_2 S_{1,2} R_1 S_{0,2} S_{0,1} R_0$. To take the Fourier transform A_q when $q = 2^l$, we thus need to use $l(l-1)/2$ quantum gates.

Applying this sequence of transformations will result in a quantum state $\frac{1}{q^{1/2}} \sum_b \exp(2\pi iac/q)|b\rangle$, where b is the bit-reversal of c, i.e., the binary number obtained by reading the bits of c from right to left. Thus, to obtain the actual quantum Fourier transform, we need either to do further computation to reverse the bits of $|b\rangle$ to obtain $|c\rangle$, or to leave these bits in place and read them in reverse order; either alternative is easy to implement.

To show that this operation actually performs a quantum Fourier transform, consider the amplitude of going from $|a\rangle = |a_{l-1} \ldots a_0\rangle$ to $|b\rangle = |b_{l-1} \ldots b_0\rangle$. First, the factors of $1/\sqrt{2}$ in the R matrices multiply to produce a factor of $1/q^{1/2}$ overall; thus we need only worry about the $\exp(2\pi iac/q)$ phase factor in the expression (4.1). The matrices $S_{j,k}$ do not change the values of any bits, but merely change their phases. There is thus only one way to switch the jth bit from a_j to b_j, and that is to use the appropriate entry in the matrix R_j. This entry adds π to the phase if the bits a_j and b_j are both 1, and leaves it unchanged otherwise. Further, the matrix $S_{j,k}$ adds $\pi/2^{k-j}$ to the phase if a_j and b_k are both 1 and leaves it unchanged otherwise. Thus, the phase on the path from $|a\rangle$ to $|b\rangle$ is

$$\sum_{0 \le j < l} \pi a_j b_j + \sum_{0 \le j < k < l} \frac{\pi}{2^{k-j}} a_j b_k. \tag{4.5}$$

This expression can be rewritten as

$$\sum_{0 \le j \le k < l} \frac{\pi}{2^{k-j}} a_j b_k. \tag{4.6}$$

Since c is the bit-reversal of b, this expression can be further rewritten as

$$\sum_{0 \le j \le k < l} \frac{\pi}{2^{k-j}} a_j c_{l-1-k}. \tag{4.7}$$

Making the substitution $l-k-1$ for k in this sum, we obtain

$$\sum_{0\le j+k<l} 2\pi \frac{2^j 2^k}{2^l} a_j c_k. \tag{4.8}$$

Now, since adding multiples of 2π do not affect the phase, we obtain the same phase if we sum over all j and k less than l, obtaining

$$\sum_{j,k=0}^{l-1} 2\pi \frac{2^j 2^k}{2^l} a_j c_k = \frac{2\pi}{2^l} \sum_{j=0}^{l-1} 2^j a_j \sum_{k=0}^{l-1} 2^k c_k, \tag{4.9}$$

where the last equality follows from the distributive law of multiplication. Now, $q = 2^l$ and

$$a = \sum_{j=0}^{l-1} 2^j a_j, \qquad c = \sum_{k=0}^{l-1} 2^k c_k, \tag{4.10}$$

so the expression (4.9) is equal to $2\pi ac/q$, which is the phase for the amplitude $|a\rangle \to |c\rangle$ in the transformation (4.1).

When $k-j$ is large in the gate $S_{j,k}$ in (4.3), we are multiplying by a very small phase factor. This would be very difficult to do accurately physically, and thus it would be somewhat disturbing if this were necessary for quantum computation. In fact, Coppersmith [1994] has shown that one can use an approximate Fourier transform that ignores these tiny phase factors but which approximates the Fourier transform closely enough that it can also be used for factoring. In fact, this technique reduces the number of quantum gates needed for the (approximate) Fourier transform considerably, as it leaves out most of the gates $S_{j,k}$.

Recently, Griffiths and Niu [1996] have shown that this Fourier transform can be carried out using only one-bit gates and measurements of single bits. Both of these operations are potentially easier to implement in a physical system than two-bit gates. The use of two-bit gates, however, is still required during the modular exponentiation step of the factoring and discrete logarithm algorithms.

5. Prime factorization. It has been known since before Euclid that every integer n is uniquely decomposable into a product of primes. For nearly as long, mathematicians have been interested in the question of how to factor a number into this product of primes. It was only in the 1970s, however, that researchers applied the paradigms of theoretical computer science to number theory, and looked at the asymptotic running times of factoring algorithms [Adleman 1994]. This has resulted in a great improvement in the efficiency of factoring algorithms. Currently the best factoring algorithm, both asymptotically and in practice, is the number field sieve [Lenstra et al. 1990, Lenstra and Lenstra 1993], which in order to factor an integer n takes asymptotic running time $\exp(c(\log n)^{1/3}(\log\log n)^{2/3})$ for some constant c. Since the input n is only $\log n$ bits in length, this algorithm is an exponential-time algorithm. Our quantum factoring algorithm takes asymptotically $O((\log n)^2(\log\log n)(\log\log\log n))$ steps on a quantum computer, along with a polynomial (in $\log n$) amount of post-processing time on a classical computer that is used to convert the output of the quantum computer to factors of n. While this post-processing could in principle be done on a quantum computer, there is no reason not to use a classical computer for this step.

Instead of giving a quantum computer algorithm for factoring n directly, we give a quantum computer algorithm for finding the order r of an element x in the multiplicative group (mod n); that is, the least integer r such that $x^r \equiv 1 \pmod{n}$. It is known that using randomization, factorization can be reduced to finding the order of an element [Miller 1976]; we now briefly give this reduction.

To find a factor of an odd number n, given a method for computing the order r of x, choose a random $x \pmod{n}$, find its order r, and compute $\gcd(x^{r/2} - 1, n)$. Here, $\gcd(a, b)$ is the greatest common divisor of a and b, i.e., the largest integer that divides both a and b. The Euclidean algorithm [Knuth 1981] can be used to compute $\gcd(a, b)$ in polynomial time. Since $(x^{r/2} - 1)(x^{r/2} + 1) = x^r - 1 \equiv 0 \pmod{n}$, the numbers $\gcd(x^{r/2} + 1, n)$ and $\gcd(x^{r/2} - 1, n)$ will be two factors of n. This procedure fails only if r is odd, in which case $r/2$ is not integral, or if $x^{r/2} \equiv -1 \pmod{n}$, in which case the procedure yields the trivial factors 1 and n. Using this criterion, it can be shown that this procedure, when applied to a random $x \pmod{n}$, yields a nontrivial factor of n with probability at least $1 - 1/2^{k-1}$, where k is the number of distinct odd prime factors of n. A brief sketch of the proof of this result follows.

Suppose that $n = \prod_{i=1}^{k} p_i^{\alpha_i}$ is the prime factorization of n. Let r_i be the order of $x \pmod{p_i^{\alpha_i}}$. Then r is the least common multiple of all the r_i. Consider the largest power of 2 dividing each r_i. The algorithm only fails if all of these powers of 2 agree: if they are all 1, then r is odd and $r/2$ does not exist; if they are all equal and larger than 1, then $x^{r/2} \equiv -1 \pmod{p_i^{\alpha_i}}$ for every i, so $x^{r/2} \equiv -1 \pmod{n}$. By the Chinese remainder theorem [Knuth 1981; Hardy and Wright 1979, Theorem 121], choosing an $x \pmod{n}$ at random is the same as choosing for each i a number $x_i \pmod{p_i^{\alpha_i}}$ at random, where $x \equiv x_i \pmod{p_i^{\alpha_i}}$. The multiplicative group $(\text{mod } p^{\alpha})$ for any odd prime power p^{α} is cyclic [Knuth 1981], so for the odd prime power $p_i^{\alpha_i}$, the probability is at most $1/2$ of choosing an x_i having a particular power of 2 as the largest divisor of its order r_i. Thus each of these powers of 2 has at most a 50% probability of agreeing with the previous ones, so all k of them agree with probability at most $1/2^{k-1}$. There is thus at least a $1 - 1/2^{k-1}$ probability that the x we choose is good. This argument shows the scheme will work as long as n is odd and not a prime power; finding a factor of even numbers and of prime powers can be done efficiently with classical methods.

We now describe the algorithm for finding the order of $x \pmod{n}$ on a quantum computer. This algorithm will use two quantum registers which hold integers represented in binary. There will also be some amount of workspace. This workspace gets reset to 0 after each subroutine of our algorithm, so we will not include it when we write down the state of our machine.

Given x and n, to find the order of x, i.e., the least r such that $x^r \equiv 1 \pmod{n}$, we do the following. First, we find q, the power of 2 with $n^2 \le q < 2n^2$. We will not include n, x, or q when we write down the state of our machine, because we never change these values. In a quantum gate array we need not even keep these values in memory, as they can be built into the structure of the gate array.

Next, we put the first register in the uniform superposition of states representing numbers $a \pmod{q}$. This leaves our machine in state

$$\frac{1}{q^{1/2}} \sum_{a=0}^{q-1} |a\rangle|0\rangle. \tag{5.1}$$

This step is relatively easy, since all it entails is putting each bit in the first register into the superposition $\frac{1}{\sqrt{2}}(|0\rangle + |1\rangle)$.

Next, we compute $x^a \pmod{n}$ in the second register as described in section 3.

Since we keep a in the first register this can be done reversibly. This leaves our machine in the state

$$\frac{1}{q^{1/2}} \sum_{a=0}^{q-1} |a\rangle |x^a \pmod{n}\rangle. \tag{5.2}$$

We then perform our Fourier transform A_q on the first register, as described in section 4, mapping $|a\rangle$ to

$$\frac{1}{q^{1/2}} \sum_{c=0}^{q-1} \exp(2\pi i ac/q)|c\rangle. \tag{5.3}$$

That is, we apply the unitary matrix with the (a, c) entry equal to $\frac{1}{q^{1/2}} \exp(2\pi iac/q)$. This leaves our machine in state

$$\frac{1}{q} \sum_{a=0}^{q-1} \sum_{c=0}^{q-1} \exp(2\pi iac/q)|c\rangle |x^a \pmod{n}\rangle. \tag{5.4}$$

Finally, we observe the machine. It would be sufficient to observe solely the value of $|c\rangle$ in the first register, but for clarity we will assume that we observe both $|c\rangle$ and $|x^a \pmod{n}\rangle$. We now compute the probability that our machine ends in a particular state $|c, x^k \pmod{n}\rangle$, where we may assume $0 \le k < r$. Summing over all possible ways to reach the state $|c, x^k \pmod{n}\rangle$, we find that this probability is

$$\left| \frac{1}{q} \sum_{a:\, x^a \equiv x^k} \exp(2\pi iac/q) \right|^2, \tag{5.5}$$

where the sum is over all a, $0 \le a < q$, such that $x^a \equiv x^k \pmod{n}$. Because the order of x is r, this sum is over all a satisfying $a \equiv k \pmod{r}$. Writing $a = br + k$, we find that the above probability is

$$\left| \frac{1}{q} \sum_{b=0}^{\lfloor (q-k-1)/r \rfloor} \exp(2\pi i(br + k)c/q) \right|^2. \tag{5.6}$$

We can ignore the term of $\exp(2\pi ikc/q)$, as it can be factored out of the sum and has magnitude 1. We can also replace rc with $\{rc\}_q$, where $\{rc\}_q$ is the residue which is congruent to $rc \pmod{q}$ and is in the range $-q/2 < \{rc\}_q \le q/2$. This leaves us with the expression

$$\left| \frac{1}{q} \sum_{b=0}^{\lfloor (q-k-1)/r \rfloor} \exp(2\pi ib\{rc\}_q/q) \right|^2. \tag{5.7}$$

We will now show that if $\{rc\}_q$ is small enough, all the amplitudes in this sum will be in nearly the same direction, i.e., have close to the same phase, and thus make the sum large. Turning the sum into an integral, we obtain

$$\frac{1}{q} \int_0^{\lfloor (q-k-1)/r \rfloor} \exp(2\pi ib\{rc\}_q/q)db + O\left(\frac{\lfloor (q-k-1)/r \rfloor}{q} \left(\exp(2\pi i\{rc\}_q/q) - 1 \right) \right). \tag{5.8}$$

If $|\{rc\}_q| \leq r/2$, the error term in the above expression is easily seen to be bounded by $O(1/q)$. We now show that if $|\{rc\}_q| \leq r/2$, the above integral is large, so the probability of obtaining a state $|c, x^k \pmod n\rangle$ is large. Note that this condition depends only on c and is independent of k. Substituting $u = rb/q$ in the above integral, we get

$$\frac{1}{r}\int_0^{\lfloor (q-k-1)/r \rfloor r/q} \exp\left(2\pi i \frac{\{rc\}_q}{r} u\right) du. \tag{5.9}$$

Since $k < r$, approximating the upper limit of integration by 1 results in only a $O(1/q)$ error in the above expression. If we do this, we obtain the integral

$$\frac{1}{r}\int_0^{1} \exp\left(2\pi i \frac{\{rc\}_q}{r} u\right) du. \tag{5.10}$$

Letting $\{rc\}_q/r$ vary between $-\frac{1}{2}$ and $\frac{1}{2}$, the absolute magnitude of the integral (5.10) is easily seen to be minimized when $\{rc\}_q/r = \pm\frac{1}{2}$, in which case the absolute value of expression (5.10) is $2/(\pi r)$. The square of this quantity is a lower bound on the probability that we see any particular state $|c, x^k \pmod n\rangle$ with $\{rc\}_q \leq r/2$; this probability is thus asymptotically bounded below by $4/(\pi^2 r^2)$, and so is at least $1/3r^2$ for sufficiently large n.

The probability of seeing a given state $|c, x^k \pmod n\rangle$ will thus be at least $1/3r^2$ if

$$\frac{-r}{2} \leq \{rc\}_q \leq \frac{r}{2}, \tag{5.11}$$

i.e., if there is a d such that

$$\frac{-r}{2} \leq rc - dq \leq \frac{r}{2}. \tag{5.12}$$

Dividing by rq and rearranging the terms give

$$\left|\frac{c}{q} - \frac{d}{r}\right| \leq \frac{1}{2q}. \tag{5.13}$$

We know c and q. Because $q > n^2$, there is at most one fraction d/r with $r < n$ that satisfies the above inequality. Thus, we can obtain the fraction d/r in lowest terms by rounding c/q to the nearest fraction having a denominator smaller than n. This fraction can be found in polynomial time by using a continued fraction expansion of c/q, which finds all the best approximations of c/q by fractions [Knuth 1981; Hardy and Wright 1979, Chapter X].

The exact probabilities as given by (5.7) for an example case with $r = 10$ and $q = 256$ are plotted in Fig. 5.1. For example, the value $r = 10$ could occur when factoring 33 if x were chosen to be 5. Here q is taken smaller than 33^2 so as to make the values of c in the plot distinguishable; this does not change the functional structure of $\mathrm{P}(c)$. Note that with high probability the observed value of c is near an integral multiple of $q/r = 256/10$.

If we have the fraction d/r in lowest terms, and if d happens to be relatively prime to r, this will give us r. We will now count the number of states $|c, x^k \pmod n\rangle$ which enable us to compute r in this way. There are $\phi(r)$ possible values of d relatively prime to r, where ϕ is Euler's totient function [Knuth 1981; Hardy and Wright 1979,

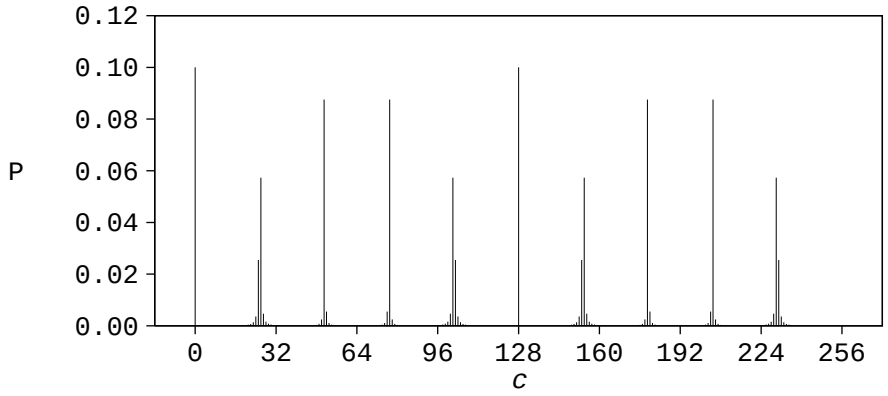

FIG. 5.1. *The probability* P *of observing values of* c *between* 0 *and* 255*, given* $q = 256$ *and* $r = 10$.

section 5.5]. Each of these fractions d/r is close to one fraction c/q with $|c/q - d/r| \leq 1/2q$. There are also r possible values for x^k, since r is the order of x. Thus, there are $r\phi(r)$ states $|c, x^k \pmod n\rangle$ which would enable us to obtain r. Since each of these states occurs with probability at least $1/3r^2$, we obtain r with probability at least $\phi(r)/3r$. Using the theorem that $\phi(r)/r > \delta/\log\log r$ for some constant δ [Hardy and Wright 1979, Theorem 328], this shows that we find r at least a $\delta/\log\log r$ fraction of the time, so by repeating this experiment only $O(\log\log r)$ times, we are assured of a high probability of success.

In practice, assuming that quantum computation is more expensive than classical computation, it would be worthwhile to alter the above algorithm so as to perform less quantum computation and more postprocessing. First, if the observed state is $|c\rangle$, it would be wise to also try numbers close to c such as $c \pm 1, c \pm 2, \ldots$, since these also have a reasonable chance of being close to a fraction qd/r. Second, if $c/q \approx d/r$ where d and r have a common factor, this factor is likely to be small. Thus, if the observed value of c/q is rounded off to d'/r' in lowest terms, for a candidate r one should consider not only r' but also its small multiples $2r', 3r', \ldots$, to see if these are the actual order of x. Although the first technique will only reduce the expected number of trials required to find r by a constant factor, the second technique will reduce the expected number of trials for the hardest n from $O(\log\log n)$ to $O(1)$ if the first $(\log n)^{1+\epsilon}$ multiples of r' are considered [Odylzko 1995]. A third technique, if two candidates for r—say, r_1 and r_2—have been found, is to test the least common multiple of r_1 and r_2 as a candidate r. This third technique is also able to reduce the expected number of trials to a constant [Knill 1995] and will work in some cases where the first two techniques fail.

Note that in this algorithm for determining the order of an element, we did not use many of the properties of multiplication (mod n). In fact, if we have a permutation f mapping the set $\{0, 1, 2, \ldots, n-1\}$ into itself such that its kth iterate, $f^{(k)}(a)$, is computable in time polynomial in $\log n$ and $\log k$, the same algorithm will be able to find the order of an element a under f, i.e., the minimum r such that $f^{(r)}(a) = a$.

6. Discrete logarithms. For every prime p, the multiplicative group (mod p) is cyclic, that is, there are generators g such that $1, g, g^2, \ldots, g^{p-2}$ comprise all the nonzero residues (mod p) [Hardy and Wright 1979, Theorem 111; Knuth 1981]. Suppose that we are given a prime p and such a generator g. The *discrete logarithm* of

a number x with respect to p and g is the integer r with $0 \leq r < p-1$ such that $g^r \equiv x \pmod{p}$. The fastest algorithm known for finding discrete logarithms modulo arbitrary primes p is Gordon's [1993] adaptation of the number field sieve, which runs in time $\exp(O(\log p)^{1/3}(\log\log p)^{2/3})$. We show how to find discrete logarithms on a quantum computer using two modular exponentiations and two quantum Fourier transforms.

This algorithm will use three quantum registers. We first find q a power of 2 such that q is close to p, i.e., with $p < q < 2p$. Next, we put the first two registers in our quantum computer in the uniform superposition of all $|a\rangle$ and $|b\rangle \pmod{p-1}$. One way to do this in quantum polynomial time is to put the register in a uniform superposition of all the numbers from 0 to $q-1$, use quantum computation to test whether the number is less than p, and restart the algorithm if the results of this test are unfavorable. We next compute $g^a x^{-b} \pmod{p}$ in the third register. This leaves our machine in the state

$$\frac{1}{p-1}\sum_{a=0}^{p-2}\sum_{b=0}^{p-2}|a,b,g^a x^{-b} \pmod{p}\rangle. \tag{6.1}$$

As before, we use the Fourier transform A_q to send $|a\rangle \to |c\rangle$ and $|b\rangle \to |d\rangle$ with probability amplitude $\frac{1}{q}\exp(2\pi i(ac+bd)/q)$. That is, we take the state $|a,b\rangle$ to the state

$$\frac{1}{q}\sum_{c=0}^{q-1}\sum_{d=0}^{q-1}\exp\left(\frac{2\pi i}{q}(ac+bd)\right)|c,d\rangle. \tag{6.2}$$

This leaves our quantum computer in the state

$$\frac{1}{(p-1)q}\sum_{a,b=0}^{p-2}\sum_{c,d=0}^{q-1}\exp\left(\frac{2\pi i}{q}(ac+bd)\right)|c,d,g^a x^{-b} \pmod{p}\rangle. \tag{6.3}$$

Finally, we observe the state of the quantum computer.

The probability of observing a state $|c,d,y\rangle$ with $y \equiv g^k \pmod{p}$ is

$$\left|\frac{1}{(p-1)q}\sum_{\substack{a,b\\ a-rb\equiv k}}\exp\left(\frac{2\pi i}{q}(ac+bd)\right)\right|^2, \tag{6.4}$$

where the sum is over all (a,b) such that $a - rb \equiv k \pmod{p-1}$. Note that we now have two moduli to deal with, $p-1$ and q. While this makes keeping track of things more confusing, it does not pose serious problems. We now use the relation

$$a = br + k - (p-1)\left\lfloor\frac{br+k}{p-1}\right\rfloor \tag{6.5}$$

and substitute (6.5) in the expression (6.4) to obtain the amplitude on $|c,d,g^k \pmod{p}\rangle$, which is

$$\frac{1}{(p-1)q}\sum_{b=0}^{p-2}\exp\left(\frac{2\pi i}{q}\left(brc+kc+bd-c(p-1)\left\lfloor\frac{br+k}{p-1}\right\rfloor\right)\right). \tag{6.6}$$

The square of the absolute value of this amplitude is the probability of observing the state $|c, d, g^k \pmod p\rangle$. We will now analyze the expression (6.6). First, a factor of $\exp(2\pi ikc/q)$ can be taken out of all the terms and ignored, because it does not change the probability. Next, we split the exponent into two parts and factor out b to obtain

$$\frac{1}{(p-1)q}\sum_{b=0}^{p-2}\exp\left(\frac{2\pi i}{q}bT\right)\exp\left(\frac{2\pi i}{q}V\right), \tag{6.7}$$

where

$$T = rc + d - \frac{r}{p-1}\{c(p-1)\}_q, \tag{6.8}$$

and

$$V = \left(\frac{br}{p-1} - \left\lfloor\frac{br+k}{p-1}\right\rfloor\right)\{c(p-1)\}_q. \tag{6.9}$$

Here by $\{z\}_q$ we mean the residue of $z \pmod q$ with $-q/2 < \{z\}_q \le q/2$, as in (5.7).

We now classify possible outputs (observed states) of the quantum computer as "good" or "bad." We will show that if we get enough good outputs, then we will likely be able to deduce r, and that furthermore, the chance of getting a good output is constant. The idea is that if

$$\left|\{T\}_q\right| = \left|rc + d - \frac{r}{p-1}\{c(p-1)\}_q - jq\right| \le \frac{1}{2}, \tag{6.10}$$

where j is the closest integer to T/q, then as b varies between 0 and $p-2$, the phase of the first exponential term in (6.7) only varies over at most half of the unit circle. Further, if

$$|\{c(p-1)\}_q| \le q/12, \tag{6.11}$$

then $|V|$ is always at most $q/12$, so the phase of the second exponential term in (6.7) never is farther than $\exp(\pi i/6)$ from 1. If conditions (6.10) and (6.11) both hold, we will say that an output is good. We will show that if both conditions hold, then the contribution to the probability from the corresponding term is significant. Furthermore, both conditions will hold with constant probability, and a reasonable sample of c's for which condition (6.10) holds will allow us to deduce r.

We now give a lower bound on the probability of each good output, i.e., an output that satisfies conditions (6.10) and (6.11). We know that as b ranges from 0 to $p-2$, the phase of $\exp(2\pi ibT/q)$ ranges from 0 to $2\pi iW$ where

$$W = \frac{p-2}{q}\left(rc + d - \frac{r}{p-1}\{c(p-1)\}_q - jq\right). \tag{6.12}$$

It follows from (6.10) that $|W| \le (p-2)/(2q) \le 1/2$. Thus, the component of the amplitude of the first exponential in the summand of (6.7) in the direction

$$\exp(\pi iW) \tag{6.13}$$

is at least $\cos(2\pi(W/2 - Wb/(p-2)))$, where $2\pi(W/2 - Wb/(p-2))$ is between $-\frac{\pi}{2}$ and $\frac{\pi}{2}$. By condition (6.11), the phase can vary by at most $\pi i/6$ due to the second

exponential $\exp(2\pi iV/q)$. Applying this variation in the manner that minimizes the component in the direction (6.13), we get that the component in this direction is at least

$$\cos\left(2\pi\,|W/2 - Wb/(p-2)| + \frac{\pi}{6}\right). \tag{6.14}$$

Thus we get that the absolute value of the amplitude (6.7) is at least

$$\frac{1}{(p-1)q}\sum_{b=0}^{p-2}\cos\left(2\pi\,|W/2 - Wb/(p-2)| + \frac{\pi}{6}\right). \tag{6.15}$$

Replacing this sum with an integral, we get that the absolute value of this amplitude is at least

$$\frac{2}{q}\int_0^{1/2}\cos\left(\frac{\pi}{6} + 2\pi|W|u\right)du \;+\; O\left(\frac{W}{pq}\right). \tag{6.16}$$

From condition (6.10), $|W| \le \frac{1}{2}$, so the error term is $O(\frac{1}{pq})$. As W varies between $-\frac{1}{2}$ and $\frac{1}{2}$, the integral (6.16) is minimized when $|W| = \frac{1}{2}$. Thus, the probability of arriving at a state $|c, d, y\rangle$ that satisfies both conditions (6.10) and (6.11) is at least

$$\left(\frac{1}{q}\frac{2}{\pi}\int_{\pi/6}^{2\pi/3}\cos u\;du\right)^2, \tag{6.17}$$

or at least $.054/q^2 > 1/(20q^2)$.

We will now count the number of pairs (c, d) satisfying conditions (6.10) and (6.11). The number of pairs (c, d) such that (6.10) holds is exactly the number of possible c's, since for every c there is exactly one d such that (6.10) holds. Unless $\gcd(p-1, q)$ is large, the number of c's for which (6.11) holds is approximately $q/6$, and even if it is large, this number is at least $q/12$. Thus, there are at least $q/12$ pairs (c, d) satisfying both conditions. Multiplying by $p-1$, which is the number of possible y's, gives approximately $pq/12$ good states $|c, d, y\rangle$. Combining this calculation with the lower bound $1/(20q^2)$ on the probability of observing each good state gives us that the probability of observing some good state is at least $p/(240q)$, or at least $1/480$ (since $q < 2p$). Note that each good c has a probability of at least $(p-1)/(20q^2) \ge 1/(40q)$ of being observed, since there $p-1$ values of y and one value of d with which c can make a good state $|c, d, y\rangle$.

We now want to recover r from a pair c, d such that

$$-\frac{1}{2q} \le \frac{d}{q} + r\left(\frac{c(p-1) - \{c(p-1)\}_q}{(p-1)q}\right) \le \frac{1}{2q} \pmod 1, \tag{6.18}$$

where this equation was obtained from condition (6.10) by dividing by q. The first thing to notice is that the multiplier on r is a fraction with denominator $p-1$, since q evenly divides $c(p-1) - \{c(p-1)\}_q$. Thus, we need only round d/q off to the nearest multiple of $1/(p-1)$ and divide (mod $p-1$) by the integer

$$c' = \frac{c(p-1) - \{c(p-1)\}_q}{q} \tag{6.19}$$

to find a candidate r. To show that the quantum calculation need only be repeated a polynomial number of times to find the correct r requires only a few more details.

The problem is that we cannot divide by a number c' which is not relatively prime to $p-1$.

For the discrete log algorithm, we do not know that all possible values of c' are generated with reasonable likelihood; we only know this about one-twelfth of them. This additional difficulty makes the next step harder than the corresponding step in the algorithm for factoring. If we knew the remainder of r modulo all prime powers dividing $p-1$, we could use the Chinese remainder theorem to recover r in polynomial time. We will only be able to prove that we can find this remainder for primes larger than 18, but with a little extra work we will still be able to recover r.

Recall that each good (c,d) pair is generated with probability at least $1/(20q^2)$, and that at least one-twelfth of the possible c's are in a good (c,d) pair. From (6.19), it follows that these c's are mapped from c/q to $c'/(p-1)$ by rounding to the nearest integral multiple of $1/(p-1)$. Further, the good c's are exactly those in which c/q is close to $c'/(p-1)$. Thus, each good c corresponds with exactly one c'. We would like to show that for any prime power $p_i^{\alpha_i}$ dividing $p-1$, a random good c' is unlikely to contain p_i. If we are willing to accept a large constant for our algorithm, we can just ignore the prime powers under 18; if we know r modulo all prime powers over 18, we can try all possible residues for primes under 18 with only a (large) constant factor increase in running time. Because at least one-twelfth of the c's were in a good (c,d) pair, at least one-twelfth of the c''s are good. Thus, for a prime power $p_i^{\alpha_i}$, a random good c' is divisible by $p_i^{\alpha_i}$ with probability at most $12/p_i^{\alpha_i}$. If we have t good c''s, the probability of having a prime power over 18 that divides all of them is therefore at most

$$\sum_{18<p_i^{\alpha_i}\,|\,(p-1)} \left(\frac{12}{p_i^{\alpha_i}}\right)^t, \tag{6.20}$$

where $a|b$ means that a evenly divides b, so the sum is over all prime powers greater than 18 that divide $p-1$. This sum (over all integers >18) converges for $t=2$, and goes down by at least a factor of $2/3$ for each further increase of t by 1; thus for some constant t it is less than $1/2$.

Recall that each good c' is obtained with probability at least $1/(40q)$ from any experiment. Since there are $q/12$ good c''s, after $480t$ experiments, we are likely to obtain a sample of t good c''s chosen equally likely from all good c''s. Thus, we will be able to find a set of c''s such that all prime powers $p_i^{\alpha_i} > 20$ dividing $p-1$ are relatively prime to at least one of these c''s. To obtain a polynomial time algorithm, all one need do is try all possible sets of c''s of size t; in practice, one would use an algorithm to find sets of c''s with large common factors. This set gives the residue of r for all primes larger than 18. For each prime p_i less than 18, we have at most 18 possibilities for the residue modulo $p_i^{\alpha_i}$, where α_i is the exponent on prime p_i in the prime factorization of $p-1$. We can thus try all possibilities for residues modulo powers of primes less than 18: for each possibility we can calculate the corresponding r using the Chinese remainder theorem and then check to see whether it is the desired discrete logarithm.

If one were to actually program this algorithm there are many ways in which the efficiency could be increased over the efficiency shown in this paper. For example, the estimate for the number of good c''s is likely too low, especially since weaker conditions than (6.10) and (6.11) should suffice. This means that the number of times the experiment need be run could be reduced. It also seems improbable that the distribution of bad values of c' would have any relationship to primes under 18;

if this is true, we need not treat small prime powers separately.

This algorithm does not use very many properties of Z_p, so we can use the same algorithm to find discrete logarithms over other fields such as Z_{p^α}, as long as the field has a cyclic multiplicative group. All we need is that we know the order of the generator, and that we can multiply and take inverses of elements in polynomial time. The order of the generator could in fact be computed using the quantum order-finding algorithm given in section 5 of this paper. Boneh and Lipton [1995] have generalized the algorithm so as to be able to find discrete logarithms when the group is abelian but not cyclic.

7. Comments and open problems. It is currently believed that the most difficult aspect of building an actual quantum computer will be dealing with the problems of imprecision and decoherence. It was shown by Bernstein and Vazirani [1993] that the quantum gates need only have precision $O(1/t)$ in order to have a reasonable probability of completing t steps of quantum computation; that is, there is a c such that if the amplitudes in the unitary matrices representing the quantum gates are all perturbed by at most c/t, the quantum computer will still have a reasonable chance of producing the desired output. Similarly, the decoherence needs to be only polynomially small in t in order to have a reasonable probability of completing t steps of computation successfully. This holds not only for the simple model of decoherence where each bit has a fixed probability of decohering at each time step, but also for more complicated models of decoherence which are derived from fundamental quantum mechanical considerations [Unruh 1995; Palma, Suominen, and Ekert 1996; Chuang et al. 1995]. However, building quantum computers with high enough precision and low enough decoherence to accurately perform long computations may present formidable difficulties to experimental physicists. In classical computers, error probabilities can be reduced not only through hardware but also through software, by the use of redundancy and error-correcting codes. The most obvious method of using redundancy in quantum computers is ruled out by the theorem that quantum bits cannot be cloned [Peres 1993, section 9-4], but this argument does not rule out more complicated ways of reducing inaccuracy or decoherence using software. In fact, some progress in the direction of reducing inaccuracy [Berthiaume, Deutsch, and Jozsa 1994] and decoherence [Shor 1995] has already been made. The result of Bennett et al. [1996] that quantum bits can be faithfully transmitted over a noisy quantum channel gives further hope that quantum computations can similarly be faithfully carried out using noisy quantum bits and noisy quantum gates.

Discrete logarithms and factoring are not in themselves widely useful problems. They have become useful only because they have been found to be crucial for public-key cryptography, and this application is in turn possible only because they have been presumed to be difficult. This is also true of the generalizations of Boneh and Lipton [1995] of these algorithms. If the only uses of quantum computation remain discrete logarithms and factoring, it will likely become a special-purpose technique whose only *raison d'être* is to thwart public key cryptosystems. However, there may be other hard problems which could be solved asymptotically faster with quantum computers. In particular, of interesting problems not known to be NP-complete, the problem of finding a short vector in a lattice [Adleman 1994, Adleman and McCurley 1994] seems as if it might potentially be amenable to solution by a quantum computer.

In the history of computer science, however, most important problems have turned out to be either polynomial-time or NP-complete. Thus quantum computers will likely not become widely useful unless they can solve NP-complete problems. Solving NP-

complete problems efficiently is a Holy Grail of theoretical computer science which very few people expect to be possible on a classical computer. Finding polynomial-time algorithms for solving these problems on a quantum computer would be a momentous discovery. There are some weak indications that quantum computers are not powerful enough to solve NP-complete problems [Bennett et al. 1997], but I do not believe that this potentiality should be ruled out as yet.

Acknowledgments. I would like to thank Jeff Lagarias for finding and fixing a critical error in the first version of the discrete log algorithm. I would also like to thank him, David Applegate, Charlie Bennett, Gilles Brassard, Andrew Odlyzko, Dan Simon, Bob Solovay, Umesh Vazirani, and correspondents too numerous to list, for productive discussions, for corrections to and improvements of early drafts of this paper, and for pointers to the literature.

STRENGTHS AND WEAKNESSES OF QUANTUM COMPUTING*

CHARLES H. BENNETT†, ETHAN BERNSTEIN‡, GILLES BRASSARD§, AND UMESH VAZIRANI¶

Abstract. Recently a great deal of attention has been focused on quantum computation following a sequence of results [Bernstein and Vazirani, in *Proc. 25th Annual ACM Symposium Theory Comput.*, 1993, pp. 11–20, *SIAM J. Comput.,* 26 (1997), pp. 1411–1473], [Simon, in *Proc. 35th Annual IEEE Symposium Foundations Comput. Sci.*, 1994, pp. 116–123, *SIAM J. Comput.,* 26 (1997), pp. 1474–1483], [Shor, in *Proc. 35th Annual IEEE Symposium Foundations Comput. Sci.*, 1994, pp. 124–134] suggesting that quantum computers are more powerful than classical probabilistic computers. Following Shor's result that factoring and the extraction of discrete logarithms are both solvable in quantum polynomial time, it is natural to ask whether all of **NP** can be efficiently solved in quantum polynomial time. In this paper, we address this question by proving that relative to an oracle chosen uniformly at random with probability 1 the class **NP** cannot be solved on a quantum Turing machine (QTM) in time $o(2^{n/2})$. We also show that relative to a permutation oracle chosen uniformly at random with probability 1 the class $\mathbf{NP} \cap \mathbf{co\text{-}NP}$ cannot be solved on a QTM in time $o(2^{n/3})$. The former bound is tight since recent work of Grover [in *Proc. 28th Annual ACM Symposium Theory Comput.*, 1996] shows how to accept the class **NP** relative to any oracle on a quantum computer in time $O(2^{n/2})$.

Key words. quantum Turing machines, oracle quantum Turing machines, quantum polynomial time

1. Introduction.

Quantum computational complexity is an exciting new area that touches upon the foundations of both theoretical computer science and quantum physics. In the early eighties, Feynman [12] pointed out that straightforward simulations of quantum mechanics on a classical computer appear to require a simulation overhead that is exponential in the size of the system and the simulated time; he asked whether this is inherent, and whether it is possible to design a universal quantum computer. Deutsch [9] defined a general model of quantum computation—the QTM. Bernstein and Vazirani [4] proved that there is an efficient universal QTM. Yao [17] extended this by proving that quantum circuits (introduced by Deutsch [10]) are polynomially equivalent to QTMs.

The computational power of QTMs has been explored by several researchers. Early work by Deutsch and Jozsa [11] showed how to exploit some inherently quantum mechanical features of QTMs. Their results, in conjunction with subsequent results by Berthiaume and Brassard [5, 6], established the existence of oracles under which there are computational problems that QTMs can solve in polynomial

time with certainty; whereas if we require a classical probabilistic Turing machine to produce the correct answer with certainty, then it must take exponential time on some inputs. On the other hand, these computational problems are in **BPP**[1] relative to the same oracle and are therefore efficiently solvable in the classical sense. The quantum analogue of the class **BPP** is the class **BQP**[2] [5]. Bernstein and Vazirani [4] proved that **BPP** $\subseteq$ **BQP** $\subseteq$ **PSPACE**, thus establishing that it will not be possible to conclusively prove that **BQP** $\neq$ **BPP** without resolving the major open problem **P** $\stackrel{?}{=}$ **PSPACE**. They also gave the first evidence that **BQP** $\neq$ **BPP** (polynomial-time QTMs are more powerful than polynomial-time probabilistic Turing machines) by proving the existence of an oracle relative to which there are problems in **BQP** that cannot be solved with small error probability by probabilistic machines restricted to running in $n^{o(\log n)}$ steps. Since **BPP** is regarded as the class of all "efficiently computable" languages (computational problems), this provided evidence that quantum computers are inherently more powerful than classical computers in a model-independent way. Simon [16] strengthened this evidence by proving the existence of an oracle relative to which **BQP** cannot even be simulated by probabilistic machines allowed to run for $2^{n/2}$ steps. In addition, Simon's paper also introduced an important new technique which was one of the ingredients in a remarkable result proved subsequently by Shor [15]. Shor gave polynomial-time quantum algorithms for the factoring and discrete logarithm problems. These two problems have been well studied, and their presumed intractability forms the basis of much of modern cryptography. In view of these results, it is natural to ask whether **NP** $\subseteq$ **BQP**; i.e., can quantum computers solve **NP**-complete problems in polynomial time?

In this paper, we address this question by proving that relative to an oracle chosen uniformly at random [3], with probability 1, the class **NP** cannot be solved on a QTM in time $o(2^{n/2})$. We also show that relative to a permutation oracle chosen uniformly at random, with probability 1, the class **NP** $\cap$ **co-NP** cannot be solved on a QTM in time $o(2^{n/3})$. The former bound is tight since recent work of Grover [13] shows how to accept the class **NP** relative to any oracle on a quantum computer in time $O(2^{n/2})$. See [7] for a detailed analysis of Grover's algorithm.

What is the relevance of these oracle results? We should emphasize that they do not rule out the possibility that **NP** $\subseteq$ **BQP**. What these results do establish is that there is no black-box approach to solving **NP**-complete problems by using some uniquely quantum-mechanical features of QTMs. That this was a real possibility is clear from Grover's [13] result, which gives a black-box approach to solving **NP**-complete problems in square-root as much time as is required classically.

One way to think of an oracle is as a special subroutine call whose invocation only costs unit time. In the context of QTMs, subroutine calls pose a special problem that has no classical counterpart. The problem is that the subroutine must not leave around any bits beyond its computed answer, because, otherwise, computational paths with different residual information do not interfere. This is easily achieved for deterministic subroutines since any classical deterministic computation can be carried out reversibly so that only the input and the answer remain. However, this leaves open the more

[1] **BPP** is the class of decision problems (languages) that can be solved in polynomial time by probabilistic Turing machines with error probability bounded by 1/3 (for all inputs). Using standard boosting techniques, the error probability can then be made exponentially small in k by iterating the algorithm k times and returning the majority answer.

[2] **BQP** is the class of decision problems (languages) that can be solved in polynomial time by QTMs with error probability bounded by 1/3 (for all inputs)—see [4] for a formal definition. We prove in section 4 that, as is the case with **BPP**, the error probability of **BQP** machines can be made exponentially small.

general question of whether a **BQP** machine can be used as a subroutine. Our final result in this paper is to show how any **BQP** machine can be modified into a *tidy* **BQP** machine whose final superposition consists almost entirely of a tape configuration containing just the input and the single bit answer. Since these tidy **BQP** machines can be safely used as subroutines, this allows us to show that $\mathbf{BQP}^{\mathbf{BQP}} = \mathbf{BQP}$. The result also justifies the definition of oracle quantum machines that we now give.

2. Oracle QTMs. In this section and the next, we shall assume without loss of generality that the Turing machine alphabet (for each track or tape) is $\{0, 1, \#\}$, where "#" denotes the blank symbol. Initially all tapes are blank except that the input tape contains the actual input surrounded by blanks. We shall use Σ to denote $\{0, 1\}$.

In the classical setting, an oracle may be described informally as a device for evaluating some Boolean function $A : \Sigma^* \to \Sigma$ on arbitrary arguments at unit cost per evaluation. This allows us to formulate questions such as, "If A were efficiently computable by a Turing machine, which other functions (or languages) could be efficiently computed by Turing machines?" In the quantum setting, an equivalent question can be asked, provided we define oracle QTMs appropriately, which we do in this section, and provided bounded-error QTMs can be composed, which we show in section 4.

An oracle QTM has a special *query tape* (or track), all of whose cells are blank except for a single block of nonblank cells. In a well-formed oracle QTM, the Turing machine rules may allow this region to grow and shrink but prevent it from fragmenting into noncontiguous blocks.[3] Oracle QTMs have two distinguished internal states: a prequery state q_q and a postquery state q_a. A query is executed whenever the machine enters the prequery state. If the query string is empty, a no-op occurs, and the machine passes directly to the postquery state with no change. If the query string is nonempty, it can be written in the form $x \circ b$ where $x \in \Sigma^*$, $b \in \Sigma$, and "$\circ$" denotes concatenation. In that case, the result of a call on oracle A is that internal control passes to the postquery state while the contents of the query tape changes from $|x \circ b\rangle$ to $|x \circ (b \oplus A(x))\rangle$, where "$\oplus$" denotes the exclusive-or (addition modulo 2). Except for the query tape and internal control, other parts of the oracle QTM do not change during the query. If the target bit $|b\rangle$ is supplied in initial state $|0\rangle$, then its final state will be $|A(x)\rangle$, just as in a classical oracle machine. Conversely, if the target bit is already in state $|A(x)\rangle$, calling the oracle will reset it to $|0\rangle$. This ability to "uncompute" will often prove essential to allow proper interference among computation paths to take place. Using this fact, it is also easy to see that the above definition of oracle QTMs yields unitary evolutions if we restrict ourselves to machines that are well formed in other respects, in particular evolving unitarily as they enter the prequery state and leave the postquery state.

The power of quantum computers comes from their ability to follow a coherent superposition of computation paths. Similarly oracle quantum machines derive great power from the ability to perform superpositions of queries. For example, oracle A might be called when the query tape is in state $|\psi \circ 0\rangle = \sum_x \alpha_x |x \circ 0\rangle$, where α_x are complex coefficients, corresponding to an arbitrary superposition of queries with a constant $|0\rangle$ in the target bit. In this case, after the query, the query string will be left in the entangled state $\sum_x \alpha_x |x \circ A(x)\rangle$. It is also useful to be able to put the target bit b into a superposition. For example, the conditional phase inversion used in Grover's algorithm can be achieved by performing queries with the target bit b in the nonclassical superposition $\beta = (|0\rangle - |1\rangle)/\sqrt{2}$. It can readily be verified that an

[3] This restriction can be made without loss of generality and it can be verified syntactically by allowing only machines that make sure they do not break the rule before writing on the query tape.

oracle call with the query tape in state $x \circ \beta$ leaves the entire machine state, including the query tape, unchanged if $A(x) = 0$, and leaves the entire state unchanged while introducing a phase factor -1 if $A(x) = 1$.

It is often convenient to think of a Boolean oracle as defining a length-preserving function on Σ^*. This is easily accomplished by interpreting the oracle answer on the pair (x, i) as the ith bit of the function value. The pair (x, i) is encoded as a binary string using any standard pairing function. A *permutation oracle* is an oracle which, when interpreted as a length-preserving function, acts for each $n \geq 0$ as a permutation on Σ^n. Henceforth, when no confusion may arise, we shall use $A(x)$ to denote the length-preserving function associated with oracle A rather than the Boolean function that gives rise to it.

Let us define $\mathbf{BQTime}(T(n))^A$ as the sets of languages accepted with probability at least $2/3$ by some oracle QTM M^A whose running time is bounded by $T(n)$. This bound on the running time applies to each individual input, not just on the average. Notice that whether or not M^A is a **BQP**-machine might depend upon the oracle A—thus M^A might be a **BQP**-machine while M^B might not be one.

Note: The above definition of a quantum oracle for an arbitrary Boolean function will suffice for the purposes of the present paper, but the ability of quantum computers to perform general unitary transformations suggests a broader definition, which may be useful in other contexts. For example, oracles that perform more general, non-Boolean unitary operations have been considered in computational learning theory [8] and for hiding information against classical queries [14].

Most broadly, a quantum oracle may be defined as a device that, when called, applies a fixed unitary transformation U to the current contents $|z\rangle$ of the query tape, replacing it by $U|z\rangle$. Such an oracle U must be defined on a countably infinite-dimensional Hilbert space, such as that spanned by the binary basis vectors $|\epsilon\rangle, |0\rangle, |1\rangle, |00\rangle, |01\rangle, |10\rangle, |11\rangle, |000\rangle, \ldots$, where ϵ denotes the empty string. Clearly, the use of such general unitary oracles still yields unitary evolution for well-formed oracle QTMs. Naturally, these oracles can map inputs onto superpositions of outputs, and vice versa, and they need not even be length preserving. However, in order to obey the dictum that a single machine cycle ought not to make infinite changes in the tape, one might require that $U|z\rangle$ have amplitude zero on all but finitely many basis vectors. (One could even insist on a uniform and effective version of the above restriction.) Another natural restriction one may wish to impose upon U is that it be an involution, $U^2 = I$, so that the effect of an oracle call can be undone by a further call on the same oracle. Again this may be crucial to allow proper interference to take place. Note that the special case of unitary transformation considered in this paper, which corresponds to evaluating a classical Boolean function, is an involution.

3. On the difficulty of simulating nondeterminism on QTMs. The computational power of QTMs lies in their ability to maintain and compute with exponentially large superpositions. It is tempting to try to use this "exponential parallelism" to simulate nondeterminism. However, there are inherent constraints on the scope of this parallelism, which are imposed by the formalism of quantum mechanics.[4] In this section, we explore some of these constraints.

[4] There is a superficial similarity between this exponential parallelism in quantum computation and the fact that probabilistic computations yield probability distributions over exponentially large domains. The difference is that in the probabilistic case, the computational path is chosen by making a sequence of random choices—one for each step. In the quantum-mechanical case, it is possible for several computational paths to interfere destructively, and therefore it is necessary to keep track of the entire superposition at each step to accurately simulate the system.

To see why quantum interference can speed up **NP** problems quadratically but not exponentially, consider the problem of distinguishing the empty oracle ($\forall_x A(x) = 0$) from an oracle containing a single random unknown string y of known length n (i.e., $A(y) = 1$, but $\forall_{x \neq y} A(x) = 0$). We require that the computer never answer yes on an empty oracle and seek to maximize its "success probability" of answering yes on a nonempty oracle. A classical computer can do no better than to query distinct n-bit strings at random, giving a success probability $1/2^n$ after one query and $k/2^n$ after k queries. How can a quantum computer do better, while respecting the rule that its overall evolution be unitary and, in a computation with a nonempty oracle, all computation paths querying empty locations evolve exactly as they would for an empty oracle? A direct quantum analogue of the classical algorithm would start in an equally weighted superposition of 2^n computation paths, query a different string on each path, and finally collapse the superposition by asking whether the query had found the nonempty location. This yields a success probability $1/2^n$, the same as the classical computer. However, this is not the best way to exploit quantum parallelism. Our goal should be to maximize the separation between the state vector $|\psi_k\rangle$ after k interactions with an empty oracle and the state vector $|\psi_k(y)\rangle$ after k interactions with an oracle nonempty at an unknown location y. Starting with a uniform superposition

$$|\psi_0\rangle = \frac{1}{\sqrt{2^n}} \sum_x |x\rangle,$$

it is easily seen that the separation after one query is maximized by a unitary evolution to

$$|\psi_1(y)\rangle = \frac{1}{\sqrt{2^n}} \sum_x (-1)^{\delta_{x,y}} |x\rangle = |\psi_0\rangle - \frac{2}{\sqrt{2^n}} |y\rangle.$$

This is a phase inversion of the term corresponding to the nonempty location. By testing whether the postquery state agrees with $|\psi_0\rangle$ we obtain a success probability

$$1 - |\langle \psi_0 | \psi_1(y) \rangle|^2 \approx 4/2^n$$

approximately four times better than the classical value. Thus, if we are allowed only one query, quantum parallelism gives a modest improvement but is still overwhelmingly likely to fail because the state vector after interaction with a nonempty oracle is almost the same as after interaction with an empty oracle. The only way of producing a large difference after one query would be to concentrate much of the initial superposition in the y term before the query, which cannot be done because that location is unknown.

Having achieved the maximum separation after one query, how best can that separation be increased by subsequent queries? Various strategies can be imagined, but a good one (called "inversion about the average" by Grover [13]) is to perform an oracle-independent unitary transformation so as to change the phase difference into an amplitude difference, leaving the y term with the same sign as all the other terms but a magnitude approximately threefold larger. Subsequent phase-inverting interactions with the oracle, alternating with oracle-independent phase-to-amplitude conversions, cause the distance between $|\psi_0\rangle$ and $|\psi_k(y)\rangle$ to grow linearly with k, approximately as $2k/\sqrt{2^n}$ when $k \leq \sqrt{N}/2$. This results in a quadratic growth of the success probability, approximately as $4k^2/2^n$ for small k. The proof of Theorem 3.5 shows that this approach is essentially optimal; no quantum algorithm can gain more than this quadratic factor in success probability compared with classical algorithms when attempting to answer **NP**-type questions formulated relative to a random oracle.

3.1. Lower bounds on quantum search. We will sometimes find it convenient to measure the accuracy of a simulation by calculating the Euclidean distance[5] between the target and simulation superpositions. The following theorem from [4] shows that the simulation accuracy is at most four times worse than this Euclidean distance.

THEOREM 3.1. *If two unit-length superpositions are within Euclidean distance ε, then observing the two superpositions gives samples from distributions which are within total variation distance*[6] *at most 4ε.*

DEFINITION 3.2. *Let $|\phi_i\rangle$ be the superposition of M^A on input x at time i. We denote by $q_y(|\phi_i\rangle)$ the sum of squared magnitudes in $|\phi_i\rangle$ of configurations of M which are querying the oracle on string y. We refer to $q_y(|\phi_i\rangle)$ as the* query magnitude of y *in $|\phi_i\rangle$.*

THEOREM 3.3. *Let $|\phi_i\rangle$ be the superposition of M^A on input x at time i. Let $\varepsilon > 0$. Let $F \subseteq [0, T-1] \times \Sigma^*$ be a set of time-string pairs such that $\sum_{(i,y)\in F} q_y(|\phi_i\rangle) \leq \frac{\varepsilon^2}{T}$. Now suppose the answer to each query $(i, y) \in F$ is modified to some arbitrary fixed $a_{i,y}$ (these answers need not be consistent with an oracle). Let $|\phi'_i\rangle$ be the time i superposition of M on input x with oracle A modified as stated above. Then $||\phi_T\rangle - |\phi'_T\rangle| \leq \varepsilon$.*

Proof. Let U be the unitary time evolution operator of M^A. Let A_i denote an oracle such that if $(i, y) \in F$ then $A_i(y) = a_{i,y}$ and if $(i, y) \notin F$ then $A_i(y) = A(y)$. Let U_i be the unitary time evolution operator of M^{A_i}. Let $|\phi_i\rangle$ be the superposition of M^A on input x at time i. We define $|E_i\rangle$ to be the error in the ith step caused by replacing the oracle A with A_i. Then

$$|E_i\rangle = U_i|\phi_i\rangle - U|\phi_i\rangle.$$

So we have

$$|\phi_T\rangle = U|\phi_{T-1}\rangle = U_{T-1}|\phi_{T-1}\rangle + |E_{T-1}\rangle = \cdots = U_{T-1}\cdots U_0|\phi_0\rangle + \sum_{i=0}^{T-1} U_{T-1}\cdots U_{i+1}|E_i\rangle.$$

Since all of the U_i are unitary, $|U_{T-1}\cdots U_i|E_i\rangle| = ||E_i\rangle|$.

The sum of squared magnitudes of all of the E_i is equal to $2\sum_{(i,y)\in F} q_y(|\phi_i\rangle)$ and therefore at most $\frac{\varepsilon^2}{T}$. In the worst case, the $U_{T-1}\cdots U_i|E_i\rangle$'s could interfere constructively; however, the squared magnitude of their sum is at most T times the sum of their squared magnitudes, i.e., ε^2. Therefore $||\phi_T\rangle - |\phi'_T\rangle| \leq \varepsilon$. □

COROLLARY 3.4. *Let A be an oracle over alphabet Σ. For $y \in \Sigma^*$, let A_y be any oracle such that $\forall x \neq y\ A_y(x) = A(x)$. Let $|\phi_i\rangle$ be the time i superposition of M^A on input x and $|\phi_i\rangle^{(y)}$ be the time i superposition of M^{A_y} on input x. Then for every $\varepsilon > 0$ there is a set S of cardinality at most $\frac{2T^2}{\varepsilon^2}$ such that $\forall y \notin S \left||\phi_T\rangle - |\phi_T\rangle^{(y)}\right| \leq \varepsilon$.*

Proof. Since each $|\phi_t\rangle$ has unit length, $\sum_{i=0}^{T-1}\sum_y q_y(|\phi_i\rangle) \leq T$. Let S be the set of strings y such that $\sum_{i=0}^{T-1} q_y(|\phi_i\rangle) \geq \frac{\varepsilon^2}{2T}$. Clearly $\text{card}(S) \leq \frac{2T^2}{\varepsilon^2}$.

If $y \notin S$ then $\sum_{i=0}^{T-1} q_y(|\phi_i\rangle) < \frac{\varepsilon^2}{2T}$. Therefore, by Theorem 3.3 $\forall y \notin S \left||\phi_i\rangle - |\phi_i\rangle^{(y)}\right| \leq \varepsilon$. □

THEOREM 3.5. *For any $T(n)$ which is $o(2^{n/2})$ relative to a random oracle with probability* 1, **BQTime**$(T(n))$ *does not contain* **NP**.

[5] The Euclidean distance between $|\phi\rangle = \sum_x \alpha_x|x\rangle$ and $|\psi\rangle = \sum_x \beta|x\rangle$ is defined as $\left(\sum_x |\alpha_x - \beta_x|^2\right)^{1/2}$.

[6] The total variation distance between two distributions $\mathcal{D}$ and $\mathcal{D}'$ is $\sum_x |\mathcal{D}(x) - \mathcal{D}'(x)|$.

Proof. Recall from section 2 that an oracle can be thought of as a length-preserving function; this is what we mean below by $A(x)$. Let $\mathcal{L}_A = \{y : \exists x\, A(x) = y\}$. Clearly, this language is contained in $\mathbf{NP}^A$. Let $T(n) = o(2^{n/2})$. We show that for any bounded-error oracle QTM M^A running in time at most $T(n)$, with probability 1, M^A does not accept the language $\mathcal{L}_A$. The probability is taken over the choice of a random length-preserving oracle A. Then, since there are a countable number of QTMs and the intersection of a countable number of probability 1 events still has probability 1, we conclude that with probability 1 no bounded error oracle QTM accepts $\mathcal{L}_A$ in time bounded by $T(n)$.

Since $T(n) = o(2^{n/2})$, we can pick n large enough so that $T(n) \leq \frac{2^{n/2}}{20}$. We will show that the probability that M gives the wrong answer on input 1^n is at least $1/8$ for every way of fixing the oracle answers on inputs of length not equal to n. The probability is taken over the random choices of the oracle for inputs of length n.

Let us fix an arbitrary length-preserving function from strings of lengths other than n over alphabet Σ. Let $\mathcal{C}$ denote the set of oracles consistent with this arbitrary function. Let $\mathcal{A}$ be the set of oracles in $\mathcal{C}$ such that 1^n has no inverse (does not belong to $\mathcal{L}_A$). If the oracle answers to length n strings are chosen uniformly at random, then the probability that the oracle is in $\mathcal{A}$ is at least $1/4$. This is because the probability that 1^n has no inverse is $(\frac{2^n-1}{2^n})^{2^n}$ which is at least $1/4$ (for n sufficiently large). Let $\mathcal{B}$ be the set of oracles in $\mathcal{C}$ such that 1^n has a unique inverse. As above, the probability that a randomly chosen oracle is in $\mathcal{B}$ is $(\frac{2^n-1}{2^n})^{2^n-1}$ which is at least $1/e$.

Given an oracle A in $\mathcal{A}$, we can modify its answer on any single input, say y, to 1^n and therefore get an oracle A_y in $\mathcal{B}$. We will show that for most choices of y, the acceptance probability of M^A on input 1^n is almost equal to the acceptance probability of M^{A_y} on input 1^n. On the other hand, M^A must reject 1^n and M^{A_y} must accept 1^n. Therefore M cannot accept both $\mathcal{L}_A$ and $\mathcal{L}_{A_y}$. By working through the details more carefully, it is easy to show that M fails on input 1^n with probability at least $1/8$ when the oracle is a uniformly random function on strings of length n and is an arbitrary function on all other strings.

Let A_y be the oracle such that $A_y(y) = 1^n$ and $\forall z \neq y\ A_y(z) = A(z)$. By Corollary 3.4 there is a set S of at most $338T^2(n)$ strings such that the difference between the $T(n)$th superposition of M^{A_y} on input 1^n and M^A on input 1^n has norm at most $1/13$. Using Theorem 3.1 we can conclude that the difference between the acceptance probabilities of M^{A_y} on input 1^n and M^A on input 1^n is at most $1/13 \times 4 < 1/3$. Since M^{A_y} should accept 1^n with probability at least $2/3$ and M^A should reject 1^n with probability at least $2/3$, we can conclude that M fails to accept either $\mathcal{L}_A$ or $\mathcal{L}_{A_y}$.

So, each oracle $A \in \mathcal{A}$ for which M correctly decides whether $1^n \in \mathcal{L}_A$ can, by changing a single answer of A to 1^n, be mapped to at least $(2^n - \mathrm{card}(S)) \geq 2^{n-1}$ different oracles $A_f \in \mathcal{B}$ for which M fails to correctly decide whether $1^n \in \mathcal{L}_{A_f}$. Moreover, any particular $A_f \in \mathcal{B}$ is the image under this mapping of at most $2^n - 1$ oracles $A \in \mathcal{A}$, since where it now answers 1^n, it must have given one of the $2^n - 1$ other possible answers. Therefore, the number of oracles in $\mathcal{B}$ for which M fails must be at least $1/2$ the number of oracles in $\mathcal{A}$ for which M succeeds. So, calling a the number of oracles in $\mathcal{A}$ for which M fails, M must fail for at least $a + 1/2(\mathrm{card}(\mathcal{A}) - a)$ oracles. Therefore M fails to correctly decide whether $1^n \in \mathcal{L}_A$ with probability at least $(1/2)P[\mathcal{A}] \geq 1/8$.

It is easy to conclude that M decides membership in $\mathcal{L}_A$ with probability 0 for a uniformly chosen oracle A. □

Note: Theorem 3.3 and its Corollary 3.4 isolate the constraints on "quantum parallelism" imposed by unitary evolution. The rest of the proof of the above theorem is similar in spirit to standard techniques used to separate **BPP** from **NP** relative to a random oracle [3]. For example, these techniques can be used to show that, relative to a random oracle A, no classical probabilistic machine can recognize $\mathcal{L}_A$ in time $o(2^n)$. However, quantum machines can recognize this language quadratically faster, in time $O(\sqrt{2^n})$, using Grover's algorithm [13]. This explains why a substantial modification of the standard technique was required to prove the above theorem.

The next result about $\mathbf{NP} \cap \mathbf{co\text{-}NP}$ relative to a random permutation oracle requires a more subtle argument; ideally we would like to apply Theorem 3.3 after asserting that the total query magnitude with which $A^{-1}(1^n)$ is probed is small. However, this is precisely what we are trying to prove in the first place.

THEOREM 3.6. *For any $T(n)$ which is $o(2^{n/3})$, relative to a random permutation oracle, with probability* 1, $\mathbf{BQTime}(T(n))$ *does not contain* $\mathbf{NP} \cap \mathbf{co\text{-}NP}$.

Proof. For any permutation oracle A, let $\mathcal{L}_A = \{y :$ first bit of $A^{-1}(y)$ is $1\}$. Clearly, this language is contained in $(\mathbf{NP} \cap \mathbf{co\text{-}NP})^A$. Let $T(n) = o(2^{n/3})$. We show that for any bounded-error oracle QTM M^A running in time at most $T(n)$, with probability 1, M^A does not accept the language $\mathcal{L}_A$. The probability is taken over the choice of a random permutation oracle A. Then, since there are a countable number of QTMs and the intersection of a countable number of probability 1 events still has probability 1, we conclude that with probability 1, no bounded error oracle QTM accepts $\mathcal{L}_A$ in time bounded by $T(n)$.

Since $T(n) = o(2^{n/3})$, we can pick n large enough so that $T(n) \leq \frac{2^{n/3}}{100}$. We will show that the probability that M gives the wrong answer on input 1^n is at least $1/8$ for every way of fixing the oracle answers on inputs of length not equal to n. The probability is taken over the random choices of the permutation oracle for inputs of length n.

Consider the following method of defining random permutations on $\{0,1\}^n$: let $x_0, x_1, \ldots, x_{T+1}$ be a sequence of strings chosen uniformly at random in $\{0,1\}^n$. Pick π_0 uniformly at random among permutations such that $\pi(x_0) = 1^n$. Let $\pi_i = \pi_{i-1} \cdot \tau$, where τ is the transposition (x_{i-1}, x_i), i.e., $\pi_i(x_i) = \pi_{i-1}(x_{i-1})$ and $\pi_i(x_{i-1}) = \pi_{i-1}(x_i)$. Clearly each π_i is a random permutation on $\{0,1\}^n$.

Consider a sequence of permutation oracles A_i such that $A_i(y) = A_j(y)$ if $y \notin \{0,1\}^n$ and $A_i(y) = \pi_i(y)$ if $y \in \{0,1\}^n$. Denote by $|\phi_i\rangle$ the time i superposition of $M^{A_{T(n)}}$ on input 1^n, and by $|\phi_i'\rangle$ the time i superposition of $M^{A_{T(n)-1}}$ on input 1^n. By construction, with probability exactly $1/2$, the string 1^n is a member of exactly one of the two languages $L_{A_{T(n)}}$ and $L_{A_{T(n)-1}}$. We will show that $E[\left||\phi_{T(n)}\rangle - |\phi'_{T(n)}\rangle\right|] \leq 1/50$. Here the expectation is taken over the random choice of the oracles. By Markov's bound, $P[\left||\phi_{T(n)}\rangle - |\phi'_{T(n)}\rangle\right| \leq 2/25] \geq 3/4$. Applying Theorem 3.1 we conclude that if $\left||\phi_{T(n)}\rangle - |\phi'_{T(n)}\rangle\right| \leq 2/25$, then the acceptance probability of $M^{A_{T(n)}}$ and $M^{A_{T(n)-1}}$ differ by at most $8/25 < 1/3$, and hence either both machines accept input 1^n or both reject that input. Therefore $M^{A_{T(n)}}$ and $M^{A_{T(n)-1}}$ give the same answers on input 1^n with probability at least $3/4$. By construction, the probability that the string 1^n belongs to exactly one of the two languages $L_{A_{T(n)}}$ and $L_{A_{T(n)-1}}$ is equal to $P[$first bit of $x_{T(n)-1} \neq$ first bit of $x_{T(n)}] = 1/2$. Therefore, we can conclude that with probability at least $1/4$, either $M^{A_{T(n)}}$ or $M^{A_{T(n)-1}}$ gives the wrong answer on input 1^n. Since each of $A_{T(n)}$ and $A_{T(n)-1}$ are chosen from the same distribution,

we can conclude that $M^{A_{T(n)}}$ gives the wrong answer on input 1^n with probability at least 1/8.

To bound $E[\left\||\phi_{T(n)}\rangle - |\phi'_{T(n)}\rangle\right\|]$, we show that $|\phi_{T(n)}\rangle$ and $|\phi'_{T(n)}\rangle$ are each close to a certain superposition $|\psi_{T(n)}\rangle$. To define this superposition, run M on input 1^n with a different oracle on each step; on step i, use A_i to answer the oracle queries. Denote by $|\psi_i\rangle$, the time i superposition that results. Consider the set of time-string pairs $S = \{(i, x_j) : \ j \geq i, \ 0 \leq i \leq T\}$. It is easily checked that the oracle queries in the computation described above and those of $M^{A_{T(n)}}$ and $M^{A_{T(n)+1}}$ differ only on the set S. We claim that the expected query magnitude of any pair in the set is at most $1/2^n$, since for $j \geq i$ we may think of x_j as having been randomly chosen during step j, *after* the superposition of oracle queries to be performed has already been written on the oracle tape. Let α be the sum of the query magnitudes for time-string pairs in S. Then

$$E[\alpha] \leq \text{card}(S)/2^n = \binom{T(n)+1}{2}/2^n \leq \frac{T(n)^2}{2^n}$$

for $T(n) \geq 4$. Let ε be a random variable such that $\alpha = \varepsilon^2/2T(n)$. Then by Theorem 3.3, $\left\||\phi\rangle - |\phi_{T(n)}\rangle\right\| \leq \varepsilon$ and $\left\||\phi\rangle - |\phi'_{T(n)}\rangle\right\| \leq \varepsilon$. We showed above that

$$E[\varepsilon^2/T(n)] = E[\alpha] \leq \frac{T(n)^2}{2^n}.$$

But $E[\varepsilon/\sqrt{2T(n)}]^2 \leq E[\varepsilon^2/2T(n)]$. Therefore,

$$\begin{aligned} E[\varepsilon] &= \sqrt{2T(n)}E[\varepsilon/\sqrt{2T(n)}] \leq \sqrt{2T(n)E[\varepsilon^2/2T(n)]} \leq \sqrt{2T(n)\frac{T(n)^2}{2^n}} \\ &\leq \sqrt{\frac{2}{100^3}} < 1/100. \end{aligned}$$

Therefore $E[\left\||\phi\rangle - |\phi_{T(n)}\rangle\right\|] \leq E[\varepsilon] < 1/100$ and $E[\left\||\phi\rangle - |\phi'_{T(n)}\rangle\right\|] \leq E[\varepsilon] < 1/100$. It follows that $E[\left\||\phi_{T(n)}\rangle - |\phi'_{T(n)}\rangle\right\|] < 1/50$.

Finally, it is easy to conclude that M decides membership in $\mathcal{L}_A$ with probability 0 for a uniformly random permutation oracle A. □

Note: In view of Grover's algorithm [13], we know that the constant "1/2" in the statement of Theorem 3.5 cannot be improved. On the other hand, there is no evidence that the constant "1/3" in the statement of Theorem 3.6 is fundamental. It may well be that Theorem 3.6 would still hold (albeit not its current proof) with 1/2 substituted for 1/3.

COROLLARY 3.7. *Relative to a random permutation oracle, with probability* 1, *there exists a* quantum one-way permutation. *Given the oracle, this permutation can be computed efficiently even with a classical deterministic machine, yet it requires exponential time to invert even on a quantum machine.*

Proof. Given an arbitrary permutation oracle A for which A^{-1} can be computed in time $o(2^{n/3})$ on a QTM, it is just as easy to decide $\mathcal{L}_A$ as defined in the proof of Theorem 3.6. It follows from that proof that this happens with probability 0 when A is a uniformly random permutation oracle. □

4. Using a bounded-error QTM as a subroutine. The notion of a subroutine call or an oracle invocation provides a simple and useful abstraction in the context of classical computation. Before making this abstraction in the context of quantum computation, there are some subtle considerations that must be thought through. For example, if the subroutine computes the function f, we would like to think of an invocation of the subroutine on the string x as magically writing $f(x)$ in some designated spot (actually xoring it to ensure unitarity). In the context of quantum algorithms, this abstraction is only valid if the subroutine cleans up all traces of its intermediate calculations and leaves just the final answer on the tape. This is because if the subroutine is invoked on a superposition of x's, then different values of x would result in different scratch work on the tape and would prevent these different computational paths from interfering. Since erasing is not a unitary operation, the scratch work cannot, in general, be erased postfacto. In the special case where f can be efficiently computed deterministically, it is easy to design the subroutine so that it reversibly erases the scratch work—simply compute $f(x)$, copy $f(x)$ into safe storage, and then uncompute $f(x)$ to get rid of the scratch work [2]. However, in the case that f is computed by a **BQP** machine, the situation is more complicated. This is because only some of the computational paths of the machine lead to the correct answer $f(x)$, and therefore if we copy $f(x)$ into safe storage and then uncompute $f(x)$, computational paths with different values of $f(x)$ will no longer interfere with each other, and we will not reverse the first phase of the computation. We show, nonetheless, that if we boost the success probability of the **BQP** machine before copying $f(x)$ into safe storage and uncomputing $f(x)$, then most of the weight of the final superposition has a clean tape with only the input x and the answer $f(x)$. Since such tidy **BQP** machines can be safely used as subroutines, this allows us to show that $\mathbf{BQP}^{\mathbf{BQP}} = \mathbf{BQP}$. The result also justifies our definition of oracle quantum machines.

The correctness of the boosting procedure is proved in Theorems 4.13 and 4.14. The proof follows the same outline as in the classical case, except that we have to be much more careful in simple programming constructs such as looping, etc. We therefore borrow the machinery developed in [4] for this purpose and present the statements of the relevant lemmas and theorems in the first part of this section. The main new contribution in this section is in the proofs of Theorems 4.13 and 4.14. The reader may therefore wish to skip directly ahead to these proofs.

4.1. Some programming primitives for QTMs. In this subsection, we present several definitions, lemmas and theorems from [4].

Recall that a QTM M is defined by a triplet (Σ, Q, δ) where Σ is a finite alphabet with an identified blank symbol $\#$, Q is a finite set of states with an identified initial state q_0 and final state $q_f \neq q_0$, and δ, the *quantum transition function*, is a function

$$\delta \;:\; Q \times \Sigma \rightarrow \tilde{\mathbf{C}}^{\Sigma \times Q \times \{L,R\}}$$

where $\tilde{\mathbf{C}}$ is the set of complex numbers whose real and imaginary parts can be approximated to within 2^{-n} in time polynomial in n.

DEFINITION 4.1. *A* final configuration *of a QTM is any configuration in state q_f. If when QTM M is run with input x, at time T the superposition contains only final configurations and at any time less than T the superposition contains no final configuration, then M* halts *with* running time T *on input x. The superposition of M at time T is called the* final superposition *of M run on input x. A polynomial-time QTM is a well-formed QTM which on every input x halts in time polynomial in the length of x.*

DEFINITION 4.2. *A QTM M is called* well behaved *if it halts on all input strings in a final superposition where each configuration has the tape head in the same cell. If this cell is always the start cell, we call the QTM* stationary.

We will say that a QTM M is in *normal form* if all transitions from the distinguished state q_f lead to the distinguished state q_0, the symbol in the scanned cell is left unchanged, and the head moves right, say. We formally state the following definition.

DEFINITION 4.3. *A QTM $M = (\Sigma, Q, \delta)$ is in* normal form *if*

$$\forall \sigma \in \Sigma \quad \delta(q_f, \sigma) = |\sigma\rangle|q_0\rangle|R\rangle.$$

THEOREM 4.4. *If f is a function mapping strings to strings which can be computed in deterministic polynomial time and such that the length of $f(x)$ depends only on the length of x, then there is a polynomial-time, stationary, normal form QTM which, given input x, produces output $x; f(x)$ and whose running time depends only on the length of x.*

If f is a one-to-one function from strings to strings such that both f and f^{-1} can be computed in deterministic polynomial time, and such that the length of $f(x)$ depends only on the length of x, then there is a polynomial-time, stationary, normal form QTM which, given input x, produces output $f(x)$ and whose running time depends only on the length of x.

DEFINITION 4.5. *A* multitrack *Turing machine with k tracks is a Turing machine whose alphabet Σ is of the form $\Sigma_1 \times \Sigma_2 \times \cdots \times \Sigma_k$ with a special blank symbol $\#$ in each Σ_i so that the blank in Σ is $(\#, \ldots, \#)$. We specify the input by specifying the string on each "track" (separated by ";"), and optionally by specifying the alignment of the contents of the tracks.*

LEMMA 4.6. *Given any QTM $M = (\Sigma, Q, \delta)$ and any set Σ', there is a QTM $M' = (\Sigma \times \Sigma', Q, \delta')$ such that M' behaves exactly like M while leaving its second track unchanged.*

LEMMA 4.7. *Given any QTM $M = (\Sigma_1 \times \cdots \times \Sigma_k, Q, \delta)$ and permutation $\pi : [1, k] \to [1, k]$, there is a QTM $M' = (\Sigma_{\pi(1)} \times \cdots \times \Sigma_{\pi(k)}, Q, \delta')$ such that the M' behaves exactly as M except that its tracks are permuted according to π.*

LEMMA 4.8. *If M_1 and M_2 are well-behaved, normal form QTMs with the same alphabet, then there is a normal form QTM M which carries out the computation of M_1 followed by the computation of M_2.*

LEMMA 4.9. *Suppose that M is a well-behaved, normal form QTM. Then there is a normal form QTM M' such that on input $x; k$ with $k > 0$, the machine M' runs M for k iterations on its first track.*

DEFINITION 4.10. *If QTMs M_1 and M_2 have the same alphabet, then we say that M_2* reverses *the computation of M_1 if the following holds: for any input x on which M_1 halts, let c_x and ϕ_x be the initial configuration and final superposition of M_1 on input x. Then M_2 on input the superposition ϕ_x, halts with final superposition consisting entirely of configuration c_x. Note that for M_2 to reverse M_1, the final state of M_2 must be equal to the initial state of M_1 and vice versa.*

LEMMA 4.11. *If M is a normal form QTM which halts on all inputs, then there is a normal form QTM M' that reverses the computation of M with slowdown by a factor of* 5.

Finally, recall the definition of the class **BQP**.

DEFINITION 4.12. *Let M be a stationary, normal form, multitrack QTM M whose last track has alphabet $\{\#, 0, 1\}$. We say that M accepts x if it halts with a* 1 *in the last track of the start cell. Otherwise, we say that M rejects x.*

A QTM accepts *the language* $\mathcal{L} \subseteq (\Sigma - \#)^*$ with probability p *if* M *accepts with probability at least* p *every string* $x \in \mathcal{L}$ *and rejects with probability at least* p *every string* $x \in (\Sigma - \#)^* - \mathcal{L}$. *We define the class* **BQP** (bounded-error quantum polynomial time) *as the set of languages which are accepted with probability* $2/3$ *by some polynomial-time QTM. More generally, we define the class* $\mathbf{BQTime}(T(n))$ *as the set of languages which are accepted with probability* $2/3$ *by some QTM whose running time on any input of length* n *is bounded by* $T(n)$.

4.2. Boosting and subroutine calls.

THEOREM 4.13. *If QTM* M *accepts language* $\mathcal{L}$ *with probability* $2/3$ *in time* $T(n) > n$, *with* $T(n)$ *time constructible, then for any* $\varepsilon > 0$ *there is a QTM* M' *which accepts* $\mathcal{L}$ *with probability* $1 - \varepsilon$ *in time* $cT(n)$ *where* c *is polynomial in* $\log 1/\varepsilon$ *but independent of* n.

Proof. Let M be a stationary QTM which accepts the language $\mathcal{L}$ in time $T(n)$.

We will build a machine that runs k independent copies of M and then takes the majority vote of the k answers. On any input x, M will have some final superposition of strings $\sum_i \alpha_i |x_i\rangle$. If we call A the set of i for which x_i has the correct answer $M(x)$ then $\sum_{i \in A} |\alpha_i|^2 \geq 2/3$. Now running M on separate copies of its input k times will produce $\sum_{i_1,\ldots,i_k} \alpha_{i_1} \cdots \alpha_{i_k} |x_{i_1}\rangle \cdots |x_{i_k}\rangle$. Then the probability of seeing $|x_{i_1}\rangle \cdots |x_{i_k}\rangle$ such that the majority have the correct answer $M(x)$ is the sum of $|\alpha_{i_1}|^2 \cdots |\alpha_{i_k}|^2$ such that the majority of $i_1, \ldots, i_k$ lie in A. But this is just like taking the majority of k independent coin flips each with probability at least $2/3$ of heads. Therefore, there is some constant b such that when $k = b \log 1/\varepsilon$, the probability of seeing the correct answer will be at least $1 - \varepsilon$.

So, we will build a machine to carry out the following steps.

1. Compute $n = T(|x|)$.
2. Write out k copies of the input x spaced out with $2n$ blank cells in between, and write down k and n on other tracks.
3. Loop k times on a machine that runs M and then steps n times to the right.
4. Calculate the majority of the k answers and write it back in the start cell.

We construct the desired QTM by building a QTM for each of these four steps and then dovetailing them together.

Since steps 1, 2, and 4 require easily computable functions whose output length depends only on k and the length of x, we can carry them out using well-behaved, normal form QTMs, constructed using Theorem 4.4, whose running times also depend only on k and the length of x.

So, we complete the proof by constructing a QTM to run the given machine k times. First, using Theorem 4.4 we can construct a stationary, normal form QTM which drags the integers k and n one square to the right on its work track. If we add a single step right to the end of this QTM and apply Lemma 4.9, we can build a well-behaved, normal form QTM moves which n squares to the right, dragging k and n along with it. Dovetailing this machine after M and then applying Lemma 4.9 gives a normal form QTM that runs M on each of the k copies of the input. Finally, we can dovetail with a machine to return with k and n to the start cell by using Lemma 4.9 two more times around a QTM which carries k and n one step to the left. □

The extra information on the output tape of a QTM can be erased by copying the desired output to another track and then running the reverse of the QTM. If the output is the same in every configuration in the final superposition, then this reversal will exactly recover the input. Unfortunately, if the output differs in different con-

figurations, then saving the output will prevent these configurations from interfering when the machine is reversed, and the input will not be recovered. We show that the output is the same in most of the final superpositions; then the reversal must lead us close to the input.

THEOREM 4.14. *If the language $\mathcal{L}$ is contained in the class* $\mathbf{BQTime}(T(n))$, *with $T(n) > n$ and $T(n)$ time constructible, then for any $\varepsilon > 0$ there is a QTM M' which accepts $\mathcal{L}$ with probability $1 - \varepsilon$ and has the following property. When run on input x of length n, M' runs for time bounded by $cT(n)$, where c is a polynomial in $\log 1/\varepsilon$, and produces a final superposition in which $|x\rangle|\mathcal{L}(x)\rangle$ with $\mathcal{L}(x) = 1$ if $x \in \mathcal{L}$ and 0 otherwise has squared magnitude at least $1 - \varepsilon$.*

Proof. Let $M = (\Sigma, Q, \delta)$ be a stationary, normal form QTM which accepts language $\mathcal{L}$ in time bounded by $T(n)$.

According to Theorem 4.13, at the expense of a slowdown by factor which is polynomial in $\log 1/\varepsilon$ but independent of n, we can assume that M accepts $\mathcal{L}$ with probability $1 - \varepsilon/2$ on every input.

Then we can construct the desired M' by running M, copying the answer to another track, and then running the reverse of M. The copy is easily accomplished with a simple two-step machine that steps left and back right while writing the answer on a clean track. Using Lemma 4.11, we can construct a normal form QTM M^R which reverses M. Finally, with appropriate use of Lemmas 4.6 and 4.7, we can construct the desired stationary QTM M' by dovetailing machines M and M^R around the copying machine.

To see that this M' has the desired properties, consider running M' on input x of length n. M' will first run M on x producing some final superposition of configurations $\sum_y \alpha_y|y\rangle$ of M on input x. Then it will write a 0 or 1 in the extra track of the start cell of each configuration, and run M^R on this superposition $|\phi\rangle = \sum_y \alpha_y|y\rangle|b_y\rangle$. If we were to instead run M^R on the superposition $|\phi'\rangle = \sum_y \alpha_y|y\rangle|M(x)\rangle$ we would after $T(n)$ steps have the superposition consisting entirely of the final configuration with output $x; M(x)$. Clearly, $\langle\phi|\phi'\rangle$ is real, and since M has success probability at least $1 - \varepsilon/2$, $\langle\phi|\phi'\rangle \geq \sqrt{1-\varepsilon}$. Therefore, since the time evolution of M^R is unitary and hence preserves the inner product, the final superposition of M' must have an inner product with $|x\rangle|M(x)\rangle$ which is real and at least $1 - \varepsilon/2$. Therefore, the squared magnitude in the final superposition of M' of the final configuration with output $x; M(x)$ must be at least $(1 - \varepsilon/2)^2 \geq 1 - \varepsilon$. ∎

COROLLARY 4.15. $\mathbf{BQP}^{\mathbf{BQP}} = \mathbf{BQP}$.

Acknowledgment. We wish to thank Bob Solovay for several useful discussions.

QUANTUM COMPUTABILITY*

LEONARD M. ADLEMAN†, JONATHAN DEMARRAIS†, AND MING-DEH A. HUANG†

Abstract. In this paper some theoretical and (potentially) practical aspects of quantum computing are considered. Using the tools of transcendental number theory it is demonstrated that quantum Turing machines (QTM) with rational amplitudes are sufficient to define the class of bounded error quantum polynomial time (BQP) introduced by Bernstein and Vazirani [*Proc. 25th ACM Symposium on Theory of Computation*, 1993, pp. 11–20, *SIAM J. Comput.,* 26 (1997), pp. 1411–1473]. On the other hand, if quantum Turing machines are allowed unrestricted amplitudes (i.e., arbitrary complex amplitudes), then the corresponding BQP class has uncountable cardinality and contains sets of all Turing degrees. In contrast, allowing unrestricted amplitudes does not increase the power of computation for error-free quantum polynomial time (EQP). Moreover, with unrestricted amplitudes, BQP is not equal to EQP. The relationship between quantum complexity classes and classical complexity classes is also investigated. It is shown that when quantum Turing machines are restricted to have transition amplitudes which are algebraic numbers, BQP, EQP, and nondeterministic quantum polynomial time (NQP) are all contained in PP, hence in $P^{\#P}$ and PSPACE. A potentially practical issue of designing "machine independent" quantum programs is also addressed. A single ("almost universal") quantum algorithm based on Shor's method for factoring integers is developed which would run correctly on almost all quantum computers, even if the underlying unitary transformations are unknown to the programmer and the device builder.

Key words. quantum Turing machines, quantum complexity classes

1. Introduction.

In 1982, Feynman [F] considered computers based on quantum mechanical principles and speculated about the existence of a universal quantum simulator analogous to a universal Turing machine. That work was followed by a sequence of important papers by Deutsch [D1, D2], Deutch and Jouzsa [DJ], Bernstein and Vazirani [BV], and others which brought the topic to a state of development suitable for rigorous investigation [Y, Si]. Recently, the topic garnered great attention when Shor [Sh] argued that integer factoring (and the discrete logarithm problem) could be solved in polynomial time on a quantum machine. More formally, Shor asserted that a problem polynomial time equivalent to integer factoring was in the class BQP defined by Bernstein and Vazirani [BV]. Since much of public key cryptography is dependent on the difficulty of factoring and discrete logarithms, the existence of these machines could have a profound effect on cryptography. It is not yet known whether these machines can be built in practice.

In this paper we study some of the theoretical and (potentially) practical aspects of quantum computing. In addition to the class BQP, the classes EQP and NQP, the analogues of the classes P and NP, are also investigated.

The results in [BV] demonstrated that when considering BQP[1] one could restrict attention to QTMs which use rotations by the angle $R = 2\pi \sum_{i=1}^{\infty} 2^{-2^i}$. In this paper, the tools of transcendental number theory are used to demonstrate that, rather than R, the angle θ such that $\cos(\theta) = 3/5$ and $\sin(\theta) = 4/5$ is sufficient (the same result

[1] $BQP_{poly(1/\epsilon)}$ to be precise; see section 2.

has been announced by Solovay [So]). As a result, when considering BQP, one can restrict one's attention to QTMs with rational amplitudes.

We also address an issue concerning implementation of quantum computation. Building a physical device on which to run quantum algorithms apparently requires selecting from the physical universe a set of unitary transformations (e.g., rotations) which will be used as "primitive" operations. It is unclear to what extent the builder of such a device can choose or even know with arbitrary accuracy which unitary transformations have been selected. We show that a single ("almost universal") quantum algorithm based on Shor's result would run correctly on almost all devices (i.e., the set of unacceptable rotations has Lebesgue measure 0)—even if the underlying unitary transformations are unknown to the programmer and the device builder.

Whereas QTMs with rational amplitudes are sufficient for investigating BQP, it is of theoretical interest to understand the power of QTMs with no restrictions on the amplitudes allowed. It is shown that when QTMs are allowed "unrestricted" amplitudes (i.e., arbitrary complex amplitudes), the class of sets which are decidable with bounded error in polynomial time has uncountable cardinality and contains sets of all Turing degrees. In contrast, allowing unrestricted amplitudes does not increase the power of computation for the EQP class. In fact, it is shown that if a set is accepted in EQP by a QTM with unrestricted amplitudes, it is also accepted in EQP by a QTM with amplitudes that are (real) algebraic numbers. It is also shown that, with unrestricted amplitudes, BQP is not equal to EQP.

The relationship between quantum complexity classes and classical complexity classes is also investigated. It is shown that when QTMs are restricted to have transition amplitudes which are algebraic numbers, BQP, EQP, and NQP are all contained in PP, hence in $\mathrm{P}^{\#\mathrm{P}}$ and PSPACE. Finally, let EQP_θ consist of the sets in EQP accepted by QTMs equipped with a single primitive rotation by angle θ. It is demonstrated that for θ such that $\cos(\theta)$ is transcendental, $\mathrm{EQP}_\theta = \mathrm{P}$, in particular assuming $\cos(R)$ is transcendental, $\mathrm{EQP}_R = \mathrm{P}$.

2. Definitions and results. As defined in [BV], a QTM M is a Turing machine where each tuple specifying a transition is assigned an *amplitude* which is a complex number. As in [BV], we assume that M has no stationary transition. The transition function δ of M maps each transition tuple to its amplitude. It induces a linear map, called the *time evolution operator* of M, on the infinite-dimensional linear space $\mathcal{H}$ which has the set of all configurations as an orthonormal basis. A vector in $\mathcal{H}$ is a *superposition of configuration*. Thus, if, for example, $C_1, \ldots, C_m$ are the configurations M can reach in one step from a configuration C under δ, with amplitudes $a_1, \ldots, a_m$, then the time evolution operator maps C to $a_1C_1 + \cdots + a_mC_m$. A QTM M is *well formed* if its time evolution operator preserves the L_2-norm.[2]

Later we will have the need to refer to subsets of QTMs with restricted amplitudes. We introduce notation to facilitate this.

Given any field K, we define QTM_K to be the subset of QTMs whose amplitudes (i.e., the range of δ) are all in K. Examples include $\mathrm{QTM}_{\mathbf{C}}$, $\mathrm{QTM}_{\mathbf{R}}$, $\mathrm{QTM}_{\bar{\mathbf{Q}}}$, and $\mathrm{QTM}_{\mathbf{Q}}$. We will write QTM to refer to $\mathrm{QTM}_{\mathbf{C}}$.

According to [BV], one can assume without loss of generality that the amplitudes of δ are all real and that M enters any particular state from one direction. One can therefore define the local matrix $Ł_\delta$ whose columns are indexed by pairs of current state and symbol and rows by pairs of new state and symbol; and the entry

[2] A probabilistic Turing machine is in fact a Turing machine with a transition function δ whose amplitudes are restricted to 0,1 and 1/2 and whose time evolution operator preserves the L_1-norm.

corresponding to a column and a row is the amplitude for the associated transition.

If $\theta \in \mathbf{R}_{\geq 0}^{<2\pi}$, then we will define QTM_θ, to be the subset of QTM M whose local matrix is block diagonal (up to permutations of rows and columns) with each block either 1, -1, or 2 by 2 of the form

$$\begin{matrix} \cos(\theta) & -\sin(\theta) \\ \sin(\theta) & \cos(\theta). \end{matrix}$$

Note that the 2×2 block represents rotation by angle θ. The universal QTM constructed by Bernstein and Vazirani [BV], for example, belongs to QTM_R, where $R = 2\pi \sum_{i=1}^{\infty} 2^{-2^i}$. We will also call this class QTM_{BV}. Another example is QTM_π, which consists of deterministic Turing machines with all entries either $0, \pm 1$.

On occasion we will use an ad hoc notation. For example, M is in $\mathrm{QTM}_{poly(1/\epsilon)}$ iff there exist an $f \in \mathbf{Z}[x]$ and a deterministic algorithm which, on input $1/\epsilon$, where $\epsilon \in \mathbf{Q}_{>0}^{<1}$, approximates all transition amplitudes of M within ϵ in $f(1/\epsilon)$ time.[3]

If Q_1 and Q_2 are subsets of QTM, then we will write $Q_1 \preceq Q_2$ iff for all $\epsilon \in \mathbf{Q}_{>0}^{<1}$, for all machines $M_1 \in Q_1$, there exists a machine $M_2 \in Q_2$ such that M_2 simulates M_1 to within ϵ with at most a polynomial slowdown, in the sense of [BV].[4] We use $\prec$, $\succ$, and $\asymp$ in the expected ways. For example, $\mathrm{QTM}_{\mathbf{C}} \asymp \mathrm{QTM}_{\mathbf{R}}$ as was shown by Bernstein and Vazirani [BV].

The classes BQP and EQP are due to Bernstein and Vazirani [BV]. The next definitions define restricted notions of BQP and EQP.

In this paper, $||$ denotes length in binary, except in section 3 where it denotes absolute value.

DEFINITION 2.1. *For all $T \subseteq$ QTM, for all $S \subseteq \mathbf{N}$, $S \in \mathrm{BQP}_T$ iff there exists an $f \in \mathbf{Z}[x]$ and an $M \in T$ such that, for all $x \in \mathbf{N}$,*

$x \in S \Rightarrow$ for input x, M accepts with probability greater than $2/3$ after $f(|x|)$ steps;

$x \in \overline{S} \Rightarrow$ for input x, M rejects with probability greater than $2/3$ after $f(|x|)$ steps.

DEFINITION 2.2. *For all $T \subseteq$ QTM, for all $S \subseteq \mathbf{N}$, $S \in \mathrm{EQP}_T$ iff there exists an $f \in \mathbf{Z}[x]$ and an $M \in T$ such that, for all $x \in \mathbf{N}$,*

$x \in S \Rightarrow$ for input x, M accepts with probability 1 after $f(|x|)$ steps;

$x \in \overline{S} \Rightarrow$ for input x, M rejects with probability 1 after $f(|x|)$ steps.

DEFINITION 2.3. *For all $T \subseteq$ QTM, for all $S \subseteq \mathbf{N}$, $S \in \mathrm{NQP}_T$ iff there exists an $f \in \mathbf{Z}[x]$ and an $M \in T$ such that, for all $x \in \mathbf{N}$,*

$x \in S \Rightarrow$ for input x, M accepts with positive probability after $f(|x|)$ steps;

$x \in \overline{S} \Rightarrow$ for input x, M accepts with probability 0 after $f(|x|)$ steps.

For convenience, for all fields K, when T=QTM_K, we will write BQP_K or EQP_K. For all $\theta \in \mathbf{R}_{\geq 0}^{<2\pi}$, when $T = \mathrm{QTM}_\theta$, we will write BQP_θ or EQP_θ. Similarly, when T=$\mathrm{QTM}_{poly(1/\epsilon)}$, we will write $\mathrm{BQP}_{poly(1/\epsilon)}$.

2.1. Results. Let $T_1, T_2 \subseteq$QTM . Then $T_1 \preceq T_2$ implies that $\mathrm{BQP}_{T_1} \subseteq \mathrm{BQP}_{T_2}$. (This is not merely an observation but requires a short proof which will not be given here.) The results in [BV] imply that $\mathrm{QTM}_{poly(1/\epsilon)} \preceq \mathrm{QTM}_R$, and since R is approximable in polynomial time within ϵ, it follows that $\mathrm{BQP}_{poly(1/\epsilon)} = \mathrm{BQP}_R$. Consequently, rotation by angle R serves as a universal primitive for $\mathrm{BQP}_{poly(1/\epsilon)}$. It is

[3] One can define $\mathrm{QTM}_{rpoly(1/\epsilon)}$ as above, but where instead of a deterministic algorithm a "probabilistic" one is used.

[4] That is, suppose in t steps M_1 produces, on input x, a superposition of configuration ϕ_1. Then in time polynomial in $1/\epsilon$ and t, M_2 produces, on the same input x, a superposition of configuration ϕ_2 such that the L_2-norm of $\phi_1 - \phi_2$ is less than ϵ.

natural to ask if R can be replaced by other angles, particularly an angle θ with rational $\cos(\theta)$ and $\sin(\theta)$. We show that for all angles θ in a set S of Lebesgue measure 1, $\mathrm{QTM}_R \preceq \mathrm{QTM}_\theta$, consequently any such θ can replace R as a universal angle. In particular the angle θ with $\cos(\theta) = 3/5$ is in S; hence, $\mathrm{BQP}_{poly(1/\epsilon)} = \mathrm{BQP}_{\mathbf{Q}}$. These results are presented in section 3.

The proof technique for the fact that $\mathrm{QTM}_R \preceq \mathrm{QTM}_\theta$ for all $\theta \in S$ can be applied to construct a program based on Shor's factoring algorithm which works universally for all QTM_θ with $\theta \in S$. This makes it possible to write a single program for a quantum computer without knowing the primitive rotation used by the machine. This is discussed in section 4.

The next set of results addresses the following question: would unrestricted amplitudes for transition functions increase the power of quantum computation? It is shown in section 5 that $\mathrm{BQP}_{\mathbf{C}}$ contains sets of arbitrary Turing degrees, hence undecidable sets in particular. In contrast, it is shown in section 6 that $\mathrm{EQP}_{\mathbf{C}} = \mathrm{EQP}_{\bar{\mathbf{Q}}}$. Moreover, $\mathrm{BQP}_{poly(1/\epsilon)}$, $\mathrm{EQP}_{\bar{\mathbf{Q}}}$, and $\mathrm{NQP}_{\bar{\mathbf{Q}}}$ are all contained in PP, hence in $\mathrm{P}^{\#\mathrm{P}}$ and PSPACE. As a result, $\mathrm{BQP}_{\mathbf{C}} \neq \mathrm{EQP}_{\mathbf{C}}$. The proofs for these equalities explore algebraic geometric structures underlying the EQP and NQP classes. The techniques also yield the following result: for angles θ with $\cos\theta$ transcendental, $\mathrm{EQP}_\theta = \mathrm{P}$. In particular, assuming $\cos(R)$ is transcendental, $\mathrm{EQP}_R = \mathrm{P}$.

3. $\mathbf{QTM_Q \asymp QTM_{BV}}$.

THEOREM 3.1. $\mathrm{QTM}_{BV} \asymp \mathrm{QTM}_{\mathbf{Q}} \asymp \mathrm{QTM}_{\bar{\mathbf{Q}}} \asymp \mathrm{QTM}_{poly(1/\epsilon)}$.

COROLLARY 3.2. $\mathrm{BQP}_{BV} = \mathrm{BQP}_{\mathbf{Q}} = \mathrm{BQP}_{\bar{\mathbf{Q}}} = \mathrm{BQP}_{poly(1/\epsilon)}$.

Essentially the same result has been announced by Solovay [So].

It can be easily demonstrated that $\mathrm{QTM}_{\mathbf{Q}} \preceq \mathrm{QTM}_{\bar{\mathbf{Q}}} \preceq \mathrm{QTM}_{poly(1/\epsilon)}$, and it follows from results on approximations [BV, BBBV] that $\mathrm{QTM}_{poly(1/\epsilon)} \preceq \mathrm{QTM}_{BV}$. Hence, Theorem 3.1 will follow from establishing that $\mathrm{QTM}_{BV} \preceq \mathrm{QTM}_\theta$ for some θ with rational $\cos\theta$ and $\sin\theta$. More generally, one would like to understand for what angles θ, $\mathrm{QTM}_{BV} \preceq \mathrm{QTM}_\theta$. The following theorem provides an answer.

THEOREM 3.3. *For all* $\theta \in \mathbf{R}_{\geq 0}^{<2\pi}$ *if either*

(a) $\theta/2\pi$ *is not rational and not Liouville*;

(b) $\theta/2\pi \in \bar{\mathbf{Q}} - \mathbf{Q}$;

(c) $e^{i\theta} \in \bar{\mathbf{Q}}$ *and* $e^{i\theta}$ *not a root of unity*;

(d) $\cos(\theta), \sin(\theta) \in \mathbf{Q} - \{0\}$;

(e) $\cos(\theta) = 3/5, \sin(\theta) = 4/5$;

then $\mathrm{QTM}_{BV} \preceq \mathrm{QTM}_\theta$.

Thus Theorem 3.1 follows from (e) of Theorem 3.3. It will be shown that (b)–(e) of Theorem 3.3 are actually subcases of (a). We also recall for Theorem 3.3 that (see, e.g., [Ni, B]) a real number ξ is a *Liouville number* if for every positive integer m there is a distinct rational number h_m/k_m with $k_m > 1$ such that $|\xi - h_m/k_m| < (k_m)^{-m}$.

COROLLARY 3.4. *For almost all* $\theta \in \mathbf{R}_{\geq 0}^{<2\pi}$, $\mathrm{QTM}_{BV} \preceq \mathrm{QTM}_\theta$, *where "almost all" means* $S = \{\theta | \theta \in \mathbf{R}_{\geq 0}^{<2\pi}$ *and* $\mathrm{QTM}_{BV} \preceq \mathrm{QTM}_\theta\}$ *has Lebesgue measure* 1.

Corollary 3.4 follows from Theorem 3.3 and the fact that the set of Liouville numbers has Lebesgue measure 0 (see, e.g., [B, p. 86]).

To prove Theorem 3.3 we will need the following lemma.

LEMMA 3.5. *For all* $\theta \in \mathbf{R}$ *with* $\theta/(2\pi)$ *not rational and not Liouville, there exists an* $f \in \mathbf{Z}[X]$ *such that for all* $\gamma \in \mathbf{R}$ *and all* $\epsilon \in \mathbf{R}_{>0}^{<1}$ *there exist* $x \in \mathbf{Z}_{\geq 0}$ *and* $w \in \mathbf{Z}$ *such that* $|x\theta - 2\pi w - \gamma| < \epsilon$ *and* $x < f(1/\epsilon)$.

Proof of Lemma 3.5. Given any irrational α and any positive integer n, there exist integers h and k with $0 < k \leq n$ such that $|k\alpha - h| < 1/n$ (see Theorem 4.2 of

[Ni, p. 44]). Since $\theta/2\pi$ is irrational, if $n = \lceil 2\pi/\epsilon \rceil$, then there exist $h, k \in \mathbf{Z}$ with $0 < k \leq n$ such that $|(k\theta/(2\pi)) - h| < 1/n$ or, equivalently, $|k\theta - 2\pi h| < 2\pi/n \leq \epsilon$.

Since $\theta/2\pi$ is not Liouville and not rational, there exists an $m \in \mathbf{Z}_{>0}$ such that for all $h', k' \in \mathbf{Z}$ with $k' > 1$, $|(\theta/(2\pi)) - h'/k'| \geq 1/k'^m$, and therefore $|k'\theta - 2\pi h'| \geq 2\pi/k'^{m-1}$. Hence $2\pi/k^{m-1} \leq |k\theta - 2\pi h| < \epsilon$.

Let $\beta = \gamma + 2\pi y'$ such that $y' \in \mathbf{Z}$, $-2\pi < \beta < 2\pi$, and $\beta/(k\theta - 2\pi h) \geq 0$. Let $x' = \lceil \beta/(k\theta - 2\pi h) \rceil$. Let $x = x'k$, and $y = x'h$, then $|x\theta - 2\pi y - \beta| = |(k\theta - 2\pi h)x' - \beta| < |(k\theta - 2\pi h)((\beta/(k\theta - 2\pi h)) + 1) - \beta| = |k\theta - 2\pi h| < \epsilon$. Also $|x'| < |\beta/(k\theta - 2\pi h)| + 1 \leq (|\beta|/|k\theta - 2\pi h|) + 1 \leq (|\beta|/(2\pi/k^{m-1})) + 1 < k^{m-1} + 1$ since $|\beta| < 2\pi$. Hence $|x| = x'k < k^m + k$, and since $k \leq n = \lceil 2\pi/\epsilon \rceil$, if $f = 8^m X^m + 8X$, then $x < f(1/\epsilon)$. Let $w = y + y'$, then $|x\theta - 2\pi w - \gamma| = |x\theta - 2\pi y - 2\pi y' - \gamma| = |x\theta - 2\pi y - \beta| < \epsilon$ as required. □

Remark. When $\theta, \gamma \in \mathbf{R}_{>0}^{<2\pi}$, then it follows easily from the lemma that $|w| \leq x + 2$.

The proof which follows demonstrates the capacity of a quantum computer to obtain an approximation to its intrinsic angle through experimentation. This capacity will also play an important role in the subsequent section on almost universal quantum programs.

Proof of Theorem 3.3(a). Given an $M \in \mathrm{QTM}_{BV}$ and $\epsilon \in \mathbf{Q}_{>0}^{<1}$, we will construct an $M' \in \mathrm{QTM}_\theta$ such that M' simulates M with accuracy ϵ and slowdown polynomial in $1/\epsilon$ and time t. The QTM M' will determine a natural number a such that $a\theta$ approximates the angle $R = 2\pi \sum_{i=1}^{\infty} 2^{-2^i}$ used by machines in QTM_{BV}. Once a is determined, M' simulates M by replacing each R-transition with a sequence of a θ-transitions.

In order to determine the number a, M' needs to compute an accurate enough rational approximation $\hat{\theta}$ of its underlying angle θ. Unlike R, the angle θ will not in general be easy to approximate deterministically. However, it is possible to have the QTM compute its own internal angle up to reflection about the x-axis and y-axis with arbitrary accuracy. That is, it is possible to compute approximations to $|\sin(\theta)|$ and $|\cos(\theta)|$. From these approximations an angle $\hat{\theta}$ which approximates θ can be determined. The correct $\hat{\theta}$ (of the four which are consistent with the approximated $|\sin(\theta)|$ and $|\cos(\theta)|$) depends on the quadrant that θ is in; however, in this existence proof, we may assume that this is known. For convenience, we will proceed under the assumption that θ is in the first quadrant. The other cases are handled in a similar manner.

Consider the following procedure that can be implemented on a machine in QTM_θ. On input $n, m \in \mathbf{Z}_{>0}$,

(i) begin with n, m on the tape;

(ii) place m^2n^2 0's on the tape, and for each 0 do a quantum step such that the symbol stays the same with probability $\cos^2(\theta)$ and becomes a 1 with probability $\sin^2(\theta)$;

(iii) observe the bits after the quantum flips and record the ratio r of the number of 0's to m^2n^2;

(iv) output $\hat{\theta} \in \mathbf{Q}$ such that $|\hat{\theta} - \theta'| < 1/n$, where $\theta' = \arccos(\sqrt{r})$.

In the above procedure, the number of 0's follows the binomial distribution with mean $\mu = m^2n^2\cos^2(\theta)$ and standard deviation $\sigma = mn\cos(\theta)\sin(\theta)$. From Chebyshev's inequality it follows that with probability at least $1 - 1/m^2$,

$$\left|r - \cos^2(\theta)\right| = |\cos^2(\theta') - \cos^2(\theta)| < m\sigma/m^2n^2 = \sin(2\theta)/2n < 1/2n.$$

Hence the ratio r approximates $\cos^2(\theta)$ better and better with increasing n. When n is large enough so that the recorded $r = \cos^2(\theta')$ is greater than $2/n$, we have $\cos^2(\theta) >$

$\cos^2(\theta') - 1/2n > 1/n$, and it also follows that $\cos^2(\theta') > \cos^2(\theta) - 1/2n > \cos^2(\theta)/2$. Since θ is in the first quadrant, it follows that $\cos(\theta') > \cos(\theta)/\sqrt{2}$. A similar argument shows that $\sin(\theta') > \sin(\theta)/\sqrt{2}$. Moreover if ψ is an angle between θ and θ', then $\cos(\psi) > \cos(\theta)/\sqrt{2}$ and $\sin(\psi) > \sin(\theta)/\sqrt{2}$; hence $2\sin(\psi)\cos(\psi) > \sin(\theta)\cos(\theta)$. By the mean value theorem,

$$|\theta - \theta'| = |\cos^2(\theta) - \cos^2(\theta')|/2\sin(\psi)\cos(\psi)$$

for some ψ between θ and θ'. It follows that

$$|\theta - \theta'| < |\cos^2(\theta) - \cos^2(\theta')|/\sin(\theta)\cos(\theta) < 1/n.$$

Hence

$$|\theta - \hat{\theta}| \leq |\theta - \theta'| + |\hat{\theta} - \theta'| < 2/n.$$

Consequently the probability that $|\theta - \hat{\theta}| < 2/n$ is at least $1 - 1/m^2$.

We will choose m so that $m > 1/\epsilon$. Let $\delta = \frac{\epsilon}{6t}$. We will run the above procedure on input m and increasing value of n, until the following conditions are met:

(a) the recorded number $r > 2/n$;

(b) there are integers a, b with $0 \leq a, |b| < (n\delta)/6$ such that $|a\hat{\theta} - b2\hat{\pi} - \hat{R}| < 2\delta$, where $\hat{R}, \hat{\pi} \in \mathbf{Q}$ such that $|R - \hat{R}| < \delta/3$ and $|2\pi - 2\hat{\pi}| < 1/n$.

Let f be the polynomial in Lemma 3.5 for θ. We argue that the condition (b) will be met before n exceeds $\frac{6(f(1/\delta)+2)}{\delta}$, which is polynomial in t and $1/\epsilon$.

Indeed let $n = \frac{6(f(1/\delta)+2)}{\delta}$. Then Lemma 3.5 implies the existence of a, b with $0 \leq a, |b| < f(1/\delta) + 2 = (n\delta)/6$ such that $|a\theta - b2\pi - R| < \delta$. With such a and b, $|a||\theta - \hat{\theta}|$, $|b||2\pi - 2\hat{\pi}|$, and $|R - \hat{R}|$ are all bounded by $\delta/3$. Since $|a\hat{\theta} - b2\hat{\pi} - \hat{R}| \leq |a\theta - b2\pi - R| + |a||\theta - \hat{\theta}| + |b||2\pi - 2\hat{\pi}| + |R - \hat{R}|$, it follows that $|a\hat{\theta} - b2\hat{\pi} - \hat{R}| < 2\delta$ as required.

With the computed $\hat{\theta}$ and a, b, we have

$$|a\theta - b2\pi - R| \leq |a\hat{\theta} - b2\hat{\pi} - \hat{R}| + |a||\theta - \hat{\theta}| + |b||2\pi - 2\hat{\pi}| + |R - \hat{R}| < 3\delta.$$

Hence rotation by the angle θ a times approximates rotation by angle R to within $3\delta = \epsilon/(2t)$.

Now on input x, M' can simulate M on input x by replacing each R-transition with a sequence of a θ-transitions appropriately.

Finally, the following argument adapted from [BBBV] (see also [BV]) shows that the superposition of configurations produced by M in t steps is approximated by M' within ϵ after the t steps of M are all simulated.

Let $\{C_1, C_2, ...\}$ be the set of configurations and $\mathcal{H}$ be the space of superpositions of configurations of M. Let U be the time evolution operator of M. Let $\hat{U}$ be the linear map on $\mathcal{H}$ determined by the local matrix which is obtained from the local matrix of M by replacing each 2×2 block representing rotation by angle R with a 2×2 block representing rotation by angle $a\theta$. Suppose at a certain time that ϕ is the superposition of configurations that M has. Then $U^t\phi$ is the superposition of configurations M arrives at after t steps, and $\hat{U}^t\phi$ is the superposition of configurations M' arrives at after simulating these t steps of M. Hence it suffices to show that $\|\hat{U}^t\phi - U^t\phi\| < \epsilon$, for all $\phi \in \mathcal{H}$ with $\|\phi\| = 1$, where $\| \|$ denotes the L_2-norm.

First we show that $\|\hat{U}\phi - U\phi\|^2 < \epsilon^2/t^2$. To see this, let $I(i)$ be the set of C_j such that there is a transition from C_j to C_i with nonzero amplitude; let $E(i)$ be the set

of C_j such that there is a transition from C_i to C_j with nonzero amplitude. Since the local matrix is block diagonal with each block of size at most 2×2, the cardinality of $I(i)$ and $E(i)$ are bounded by 2. Let $UC_i = \sum_j \alpha_{ij} C_j$ and $\hat{U}C_i = \sum_j \hat{\alpha}_{ij} C_j$. Then $|\alpha_{ij} - \hat{\alpha}_{ij}| < \Delta$ where $\Delta = 3\delta = \epsilon/(2t)$. Let $\phi = \sum_j \beta_j C_j$ be of L_2-norm equal to 1. Then

$$U\phi = \sum_i \left(\sum_{j \in I(i)} \alpha_{ji} \beta_j \right) C_i;$$

hence

$$\begin{aligned} \|\hat{U}\phi - U\phi\|^2 = \sum_i \left| \sum_{j \in I(i)} (\hat{\alpha}_{ji} - \alpha_{ji}) \beta_j \right|^2 &\leq \sum_i |I(i)| \sum_{j \in I(i)} |(\hat{\alpha}_{ji} - \alpha_{ji}) \beta_j|^2 \\ &< 2\Delta^2 \sum_i \sum_{j \in I(i)} \beta_j^2 = 2\Delta^2 \sum_j |E(j)| \beta_j^2 \leq 4\Delta^2 \sum_j \beta_j^2 = 4\Delta^2 = \epsilon^2/t^2. \end{aligned}$$

It is easy to see by induction that

$$\hat{U}^t \phi - U^t \phi = \sum_{i=1}^{t} \hat{U}^{t-i} E_i,$$

where $E_i = \hat{U}U^{i-1}\phi - U^i\phi$. Since $U^{i-1}\phi$ is of L_2-norm equal to 1,

$$\|E_i\|^2 = \|\hat{U}(U^{i-1}\phi) - U(U^{i-1}\phi)\|^2 \leq \epsilon^2/t^2.$$

So

$$\|\hat{U}^t \phi - U^t \phi\|^2 = \left\| \sum_{i=1}^{t} \hat{U}^{t-i} E_i \right\|^2 \leq t \sum_{i=1}^{t} \|\hat{U}^{t-i} E_i\|^2 = t \sum_{i=1}^{t} \|E_i\|^2 < \epsilon^2. \qquad \square$$

For the proof of Theorem 3.3(b)–(e), we need a lemma and proof which were generously provided to us by Harold Stark.

LEMMA 3.6. *For all $\theta \in \mathbf{R}_{>0}^{<2\pi}$, if $e^{i\theta} \in \bar{\mathbf{Q}}$ and $e^{i\theta}$ is not a root of unity, then $\theta/(2\pi)$ is not Liouville.*

Note that if θ satisfies the conditions in Lemma 3.6, then $\theta/(2\pi)$ is also not rational. Lemma 3.6 is a consequence of the next theorem which follows from results of Feldman [Fe].

THEOREM 3.7. *For all $a = \cos(b) + i\sin(b) = \exp(ib) \in \bar{\mathbf{Q}}$, with a not a root of unity, there exists a $C, N \in \mathbf{Z}_{>0}$ such that for all $p \in \mathbf{Z}$, $q \in \mathbf{Z}_{>1}$, $|p2\log(-1) - q\log(a)| > Cq^{-N}$, where C and N depend only on a and on the choice of the branch of logarithms used.*

Since $e^{i\theta}$ is algebraic and not a root of unity, by choosing the branch of logarithm such that $2\log(-1) = 2\pi i$, and $\log(e^{i\theta}) = i\theta$, we have that for all $p \in \mathbf{Z}$, $q \in \mathbf{Z}_{>1}$, $|p2\pi i - qi\theta| = |p2\pi - q\theta| > Cq^{-N}$. Hence $|\theta/2\pi - p/q| > C/(2\pi q^{N+1})$ from which it follows that $\theta/2\pi$ is not Liouville. This proves Lemma 3.6. $\square$

Proof of Theorem 3.3(b)–(e). (b) follows from (a) since Liouville numbers are transcendental (see, e.g., [Ni, p. 92]). (c) follows from (a) and Lemma 3.6. (d) follows from (c) and the fact that the only roots of unity with rational real and imaginary parts are 1 and i. Finally, (e) follows from (d). $\square$

4. Almost universal quantum programs. Shor's quantum factoring method is of interest for purely mathematical reasons. However, it is unclear whether devices can be built which will actually implement Shor's method. It follows from the previous section that apparently it is enough to build a device capable of a rotation θ with $\cos(\theta) = 3/5$. But can such a device be built? To what extent can a device builder choose the angles of rotations which will be provided? To what accuracy can the device builder or the programmer know the angles of rotation inherent in the device? It turns out that these questions may be irrelevant and that one can write a single "program" which will factor with high probability on virtually any device which can be built.

This is done essentially as indicated in the proof of Theorem 3.3. One starts with a program for Shor's method which will factor with high probability on a device with rotation by the angle θ with $\cos(\theta) = 3/5$ as primitive. One then writes a new "almost universal program" which will, in the manner described in the proof of Theorem 3.3, calculate "on line" a sufficiently accurate estimation of whatever angle of rotation γ the underlying physical device provides and then use that estimate to simulate the original program with sufficient accuracy to insure factoring. Since the estimate of γ is only unique up to the sign of $\cos(\gamma)$ and $\sin(\gamma)$, we will simultaneously run all four possible approximations; however, this will neither increase the running time significantly nor decrease the probability of a successful factorization substantially. It follows from Corollary 3.4 that the "almost universal program" will factor with high probability on all but those devices with an angle of rotation in a set of Lebesgue measure 0.

5. Unrestricted quantum computation. We have demonstrated that restricting attention to quantum machines with rational amplitudes is sufficient to define the class BQP. However, it is of theoretical interest to understand the power of "unrestricted" quantum computation. In this section, it is shown that $\mathrm{BQP}_{\mathbf{C}}$ has sets of all possible Turing degrees.

THEOREM 5.1. *For all $S \subseteq \mathbf{N}$, there exists an $S' \subseteq \mathbf{N}$ such that*

1. *$S \equiv_T S'$ (Turing equivalent);*
2. *$S' \in \mathrm{BQP}_{\mathbf{C}}$.*

Proof. Throughout this proof, for all $x \in \mathbf{N}$, $|x|$ will denote the length of x. Let $S \subseteq \mathbf{N}$ and let $H : \mathbf{N} \to \{1, -1\}$ be such that for all $x \in \mathbf{N}$, $H(x) = 1$ if $x \in S$, $H(x) = -1$ if $x \in \overline{S}$. Let $S' \subseteq \mathbf{N}$ such that for all $x \in \mathbf{N}$, $x \in S'$ if and only if $H(i+1) = 1$ where i is the greatest integer such that $8^i \leq |x|$. It is clear from the definition that S and S' are Turing equivalent.

Let $\theta = 2\pi(\sum_{x=1}^{\infty} H(x)/8^x)$. Then $\theta \in \mathbf{R}$ (i.e., the series converges).

Let M be a QTM which on input $x \in \mathbf{N}$.

1. Calculate the greatest l such that $l \leq |x|$ and $l = 8^i$ for some $i \in \mathbf{N}$.
2. Place a 0 on the tape.
3. Perform l rotations by the angle θ on this tape location followed by a single rotation by the angle $\pi/4$, so that the amplitude of the configuration with 0 on the tape is $\cos(l\theta + \pi/4)$, and the amplitude with 1 on the tape is $\sin(l\theta + \pi/4)$. This is done in a manner similar to the method used by Bernstein and Vazirani [BV].
4. Output 0 or 1 based on the value of the given tape location. If the output is 1, the machine accepts, and if the output is 0, the machine rejects.

It is clear from the algorithm that for all $x \in \mathbf{N}$, the number of steps taken by M on input x is polynomially bounded in $|x|$.

After the third step of the algorithm, the configuration that corresponds to an output of 0 has amplitude $\cos(l\theta + \pi/4)$, and the configuration that corresponds to

an output of 1 has amplitude $\sin(l\theta + \pi/4)$ for the greatest l such that $l \leq |x|$ and l is power of 8. Let $l = 8^i$. Then

$$l\theta = 2\pi(H(1)8^{i-1} + H(2)8^{i-2} + \cdots + H(i) + H(i+1)/8 + H(i+2)/8^2 + \cdots).$$

Let $k = \pi/4 + l\theta \bmod 2\pi$. If $H(i+1) = 1$, then $\pi/2 - \pi/28 \leq k \leq \pi/2 + \pi/28$, in this case $\sin^2(\pi/4 + l\theta) > 0.98$; hence the input x is accepted with probability greater than 0.98. On the other hand if $H(i+1) = -1$, then $-\pi/28 \leq k \leq \pi/28$, in this case $\cos^2(\pi/4 + l\theta) > 0.98$; hence x is rejected with probability greater than 0.98. Therefore M accepts S' in $\mathrm{BQP}_{\mathbf{C}}$ and the theorem follows. □

Since there are uncountably many subsets of N and each Turing class can contain at most countably many subsets of N (since there are only this many TM), it follows that $\mathrm{BQP}_{\mathbf{C}}$ has uncountable cardinality. From this it follows that $\mathrm{BQP}_{\mathbf{Q}}$ (which clearly has countable cardinality) is a proper subset of $\mathrm{BQP}_{\mathbf{C}}$. From this in turn (see section 2) it follows that $\mathrm{QTM}_{\mathbf{Q}} \prec \mathrm{QTM}_{\mathbf{C}}$ and not $\mathrm{QTM}_{\mathbf{Q}} \succeq \mathrm{QTM}_{\mathbf{C}}$.

6. EQP and NQP. Let M be a QTM with transition function δ. Following [BV] we can assume without loss of generality that δ is a real-valued function.

Suppose there are N tuples $T_1, \ldots, T_N$ in the domain of δ. Let $v = (v_1, \ldots, v_N)$ where $v_i = \delta(T_i)$, the amplitude of δ on transition T_i, for $i = 1, \ldots, N$. We shall call v the *amplitude vector* of δ.

Replacing v by $x = (x_1, \ldots, x_N)$, where x_i are distinct complex variables, we obtain a "symbolic" QTM $M(x)$. By assigning a vector $u \in \mathbf{C}^N$ to x we obtain a QTM denoted by $M(u)$, in particular, $M = M(v)$. The QTMs obtained in this way have transition functions with the same domain, the same set of configurations, hence the same space of superpositions of configurations. They are distinguished by having different amplitude vectors associated with the transition function.

For $u \in \mathbf{R}^N$, $M(u)$ is well formed iff u satisfies a finite set of polynomial equations which can be obtained as follows.

Let $A(x)$ denote the infinite-dimensional matrix representing the (symbolic) time evolution operator of $M(x)$, the linear map induced by δ, on the infinite-dimensional space of superpositions of configurations [BV] with respect to the basis consisting of the whole set of configurations of $M(x)$. The rows and columns of $A(x)$ are labelled by the set of configurations. If upon applying the ith transition, a configuration C yields C', then x_i will be the entry corresponding to column labelled by C and the row labelled by C'. If no such transition exists, the corresponding entry will be 0. Thus each entry of $A(x)$ is one of the variables $x_1, \ldots, x_N$, and for all $u = (u_1, \ldots, u_N) \in \mathbf{R}^N$, by substituting x_i with u_i for $i = 1, \ldots, N$, we obtain the time evolution matrix $A(u)$ for $M(u)$. For all $i, j \in \mathbf{Z}_{>0}$, let $P_{ij}(x)$ denote the dot product of the ith and jth columns of $A(x)$. Then since each column of $A(x)$ has at most N nonzero entries, P_{ij} is the sum of at most N monomials in $x_1, \ldots, x_N$ of degree 2. In particular the set of P_{ij} is finite.

By [BV], $M(u)$ is well formed iff $A(u)^*A(u) = A(u)A(u)^* = I$, where $A(u)^*$ denotes the transpose conjugate of $A(u)$. Since u is real, $A(u)^*$ is just the transpose of $A(u)$. Hence $M(u)$ is well formed iff for all i, j, if $i \neq j$, then $P_{ij}(u) = 0$; if $i = j$, then $P_{ij}(u) = 1$. Hence let J_W be the set of polynomials P_{ij} for $i \neq j$ and $1 - P_{ii}$ for all i. Then $M(u)$ is well formed iff u is a zero to all polynomials in J_W. Note that J_W is finite since the set of P_{ij} is finite.

As will be demonstrated below, whether $M(u)$ accepts or rejects an input with probability 1 can also be characterized algebraically.

For all $i \in \mathbf{Z}_{>0}$, let $A^i(x)$ denote the product of $A(x)$ by itself i times. We note that each entry in $A^i(x)$ is a polynomial (possibly 0) in $\mathbf{Z}[X]$. Let α be an input string.

Let C_α be the initial configuration of $M(x)$ (hence of M and for all $u \in \mathbf{R}^N$, of $M(u)$) on input α. Then for all configurations C, for all $t \in \mathbf{Z}_{>0}$, we denote by $amp_{\alpha,t,C}$ the polynomial which is in the entry of $A^t(x)$ corresponding to the column labelled by C_α and the row labelled by C. For all $u \in \mathbf{C}^N$, $amp_{\alpha,t,C}(u)$ is the amplitude for C at time t on input α to $M(u)$.

Let $\mathcal{C}_A$ denote the set of accepting configurations and $\mathcal{C}_R = \mathcal{C} - \mathcal{C}_A$ the set of rejecting configurations. Suppose $u \in \mathbf{R}^N$, and assuming $M(u)$ is well formed, then an input α is accepted at time t with probability 1 iff

$$\sum_{C \in \mathcal{C}_R} |amp_{\alpha,t,C}(u)|^2 = \sum_{C \in \mathcal{C}_R} amp^2_{\alpha,t,C}(u) = 0,$$

iff $amp_{\alpha,t,C}(u) = 0$ for all $C \in \mathcal{C}_R$. Hence let

$$J_A(t,\alpha) = \{amp_{\alpha,t,C} : C \in \mathcal{C}_R\}.$$

Then $M(u)$ accepts α at time t with probability 1 iff u is a zero of all polynomials in $J_A(t,\alpha)$. Similarly, let

$$J_R(t,\alpha) = \{amp_{\alpha,t,C} : C \in \mathcal{C}_A\}.$$

Then $M(u)$ rejects α with probability 1 iff u is a zero of all polynomials in $J_R(t,\alpha)$.

Let L be a language over the input alphabet of M. Let p be a polynomial function where $p(n)$ is a positive integer for all $n \in \mathbf{Z}_{>0}$. For all inputs α, let $t_\alpha = p(n)$ where n is the length of α. Let

$$J(p,L) = J_W \cup_{\alpha \in L} J_A(t_\alpha,\alpha) \cup_{\alpha \notin L} J_R(t_\alpha,\alpha).$$

From the discussion above we see that for all $u \in \mathbf{R}^N$, $M(u)$ is well formed and accepts L in EQP at time $p(n)$ iff u is a zero of all polynomials in $J(p,L)$.

We recall the following proposition.

PROPOSITION 6.1. *Let I be an ideal in $\mathbf{Q}[x_1,\ldots,x_N]$. If the polynomials in I have a common zero in $\mathbf{R}^N$, then they have a common zero in $(\bar{\mathbf{Q}} \cap \mathbf{R})^N$.*

The proposition follows immediately from Tarski's theorem (see, e.g., [J, p. 323]), noting the fact that I is finitely generated and that both $\mathbf{R}$ and $\bar{\mathbf{Q}} \cap \mathbf{R}$ are real closed fields. It is a direct consequence of the mathematical principle implied by Tarski's theorem that any elementary sentence of algebra which is true in one real closed field is true in every real closed field.

Suppose L is accepted by $M = M(v)$ in EQP at time $p(n)$. Then v is a real zero of polynomials in the ideal I of $\mathbf{Q}[x_1,\ldots,x_N]$ generated by $J(p,L)$. From Proposition 6.1 it follows that the polynomials in I also have a common zero $u \in (\bar{\mathbf{Q}} \cap \mathbf{R})^N$. Since u is a zero of all polynomials in $J(p,L)$, it follows that $M(u)$ is well formed and accepts L in EQP at time $p(n)$.

Hence we have the following.

THEOREM 6.2. $\mathrm{EQP}_{\mathbf{C}} = \mathrm{EQP}_{\bar{\mathbf{Q}} \cap \mathbf{R}}$.

Finally, we give two results which relate quantum complexity classes to classical complexity classes.

THEOREM 6.3. *For all $\theta \in \mathbf{R}^{<2\pi}_{\geq 0}$ such that $\cos\theta$ is transcendental,* $\mathrm{EQP}_\theta = \mathrm{P}$. *In particular assuming $\cos(R)$ is transcendental,* $\mathrm{EQP}_R = \mathrm{P}$.

Proof. Let $M \in \mathrm{EQP}_\theta$ with amplitude vector $v = (v_1,\ldots,v_N) \in \mathbf{R}^N$. Then v_i is 0, ± 1, $\pm\cos\theta$, or $\pm\sin\theta$. Suppose $v_i \in \{0,\pm 1\}$ for all i. Since the time evolution

operator of M preserves the L_2-norm, there is at most one transition tuple with amplitude ± 1 for every pair of current state and symbol. Hence M is deterministic.

Suppose on the other hand that v contains some transcendental coordinates. Let L be accepted by M in EQP at time $p(n)$ for some polynomial p. Let $x = (x_1, \ldots, x_N)$. Form the symbolic QTM $M(x)$ and the set of polynomials $J(p, L)$ as before. Then for $u \in \mathbf{R}^N$, $M(u)$ is well formed and accepts L in EQP at time $p(n)$ iff u is a common zero of all polynomials in $J(p, L)$. Let s and t be variables and $u(s, t)$ be the N-vector obtained from x as follows: for all i, replace x_i by v_i if v_i is 0 or ± 1, replace x_i by $\pm s$ if $v_i = \pm \cos\theta$, and replace x_i by $\pm t$ if $v_i = \pm \sin\theta$. Let $J'(p, L) \subset \mathbf{Q}[s, t]$ be obtained from $J(p, L)$ by specializing each polynomial $F(x)$ in $J(p, L)$ to $F(u(s, t))$. Then for all $a, b \in \mathbf{R}$, $M(u(a, b))$ accepts L in EQP at time $p(n)$ iff a, b is a common zero of all polynomials in $J'(p, L)$. In particular we note that $v = u(\cos\theta, \sin\theta)$ and that $(\cos\theta, \sin\theta)$ is a common zero of all polynomials in $J'(p, L)$. Since $(\cos\theta, \sin\theta)$ is generic for the curve $s^2 + t^2 = 1$, it follows that every polynomial in $J'(p, L)$ is in the ideal generated by $s^2 + t^2 - 1$. But since $(1, 0)$ is a zero of $s^2 + t^2 - 1$, it follows that $(1, 0)$ is also a zero of all polynomials in $J'(p, L)$. This implies that $M(u(1, 0))$ accepts L in EQP. As $u(1, 0) \in \{0, \pm 1\}^N$, $M(u(1, 0))$ is deterministic as observed before, and the theorem follows. □

THEOREM 6.4. $\mathrm{BQP}_{poly(1/\epsilon)}, \mathrm{EQP}_{\mathbf{C}}, \mathrm{NQP}_{\bar{\mathbf{Q}} \cap \mathbf{R}} \subseteq \mathrm{PP} \subseteq \mathrm{P}^{\#\mathrm{P}}$.

From Theorems 5.1 and 6.4 we have the following.

COROLLARY 6.5. $\mathrm{BQP}_{\mathbf{C}} \neq \mathrm{EQP}_{\mathbf{C}}$.

We remark that the result $\mathrm{BQP}_{poly(1/\epsilon)} \subseteq \mathrm{P}^{\#\mathrm{P}}$ was first announced by Valiant (see [BV]). The rest of this section is devoted to the proof of Theorem 6.4. We begin by deriving some additional facts about QTMs with real algebraic amplitudes.

Let M be a QTM with real algebraic amplitude; that is, $M \in \mathrm{QTM}_{\bar{\mathbf{Q}} \cap \mathbf{R}}$. Let the local matrix L_δ of M be an $n \times m$ matrix with $\lambda_{i,j}$ as the entry corresponding to the ith row and jth column for $1 \leq i \leq n$ and $1 \leq j \leq m$. Let K be the field generated by all $\lambda_{i,j}$ over $\mathbf{Q}$. Let D be the degree of K over $\mathbf{Q}$. Then $K = \mathbf{Q}[\beta]$ for some $\beta \in \bar{\mathbf{Q}} \cap \mathbf{R}$, and the irreducible polynomial for β over $\mathbf{Q}$ is of degree D. We will call K the *field of amplitudes* for M.

For all $i, j, k \in \mathbf{Z},\ 1 \leq i \leq n,\ 1 \leq j \leq m,\ 0 \leq k \leq D-1$, let $r_{i,j,k} \in \mathbf{Q}$ be the values such that $\lambda_{i,j} = \sum_{k=0}^{D-1} r_{i,j,k}\beta^k$. For all $i, j, k \in \mathbf{Z},\ 0 \leq i \leq D-1,\ 0 \leq j \leq D-1,\ 0 \leq k \leq D-1$, let $s_{i,j,k} \in \mathbf{Q}$ be the values such that $\beta^i\beta^j = \sum_{k=0}^{D-1} s_{i,j,k}\beta^k$. Let $d_1 \in \mathbf{Z}$ be a common denominator of the $r_{i,j,k}$ and $d_2 \in \mathbf{Z}$ be a common denominator of the $s_{i,j,k}$. These values will be used below.

Let $\mathcal{C}$ be the set of all possible configurations of the machine M. Consider running machine M for t steps on input α. We can define a path of length t for input α leading to configuration C as a sequence of t configurations $\langle C_0, C_1, C_2, \ldots, C_t\rangle$ such that C_0 corresponds to the initial configuration for input α, $C_t = C$, and C_{i+1} can be reached from C_i with one step of the machine (including 0 amplitude moves) for $0 \leq i \leq t-1$. Let $P_{\alpha,t,C}$ be the set of paths of length t for input α leading to configuration C. For all paths $p = \langle C_0, C_1, \ldots, C_t\rangle$, there is an associated amplitude $\rho_p = \prod_{k=0}^{t-1} \lambda_{i_{p,k},j_{p,k}}$ where $i_{p,k}$ and $j_{p,k}$ are the row and column in the local matrix that correspond to moving from configuration C_k to configuration C_{k+1}. Let $d_t = d_1^t d_2^{t-1}$, and let $a_{p,i} \in \mathbf{Q}$ be the values such that $\rho_p = \sum_{i=0}^{D-1}(a_{p,i}/d_t)\beta^i$. The following lemma shows that the $a_{p,i}$'s are integers.

LEMMA 6.6. *There exists a $g \in \mathbf{Z}$ such that for all input strings α, for all configurations $C \in \mathcal{C}$, for all $t \in \mathbf{Z}_{>0}$, for all $p \in P_{\alpha,t,C}$, for all $i \in \mathbf{Z}_{\geq 0}^{<D}$, $a_{p,i} \in \mathbf{Z}$, and $abs(a_{p,i}) \leq g^t$.*

Proof of Lemma 6.6.

$$\rho_p = \prod_{k=0}^{t-1} \lambda_{i_{p,k},j_{p,k}} = \prod_{k=0}^{t-1} \sum_{l=0}^{D-1} r_{i_{p,k},j_{p,k},l}\beta^l = \sum_{0\le l_0,\ldots,l_{t-1}\le D-1} \prod_{k=0}^{t-1} r_{i_{p,k},j_{p,k},l_k} \prod_{k=0}^{t-1} \beta^{l_k}.$$

Since d_1 is the common denominator of the $r_{i,j,k}$, d_1^t will be a common denominator of any product of t $r_{i,j,k}$'s. Since d_2 is a common denominator of the $s_{i,j,k}$'s, it is possible to show by induction that d_2^{t-1} is a common denominator of the product of t β^i's. Hence $d_t = d_1^t d_2^{t-1}$ is a common denominator of the sum above and for all paths p and $i \in \mathbf{Z}_0^{D-1}$, $a_{p,i} \in \mathbf{Z}$.

Let

$$m_1 = \max\{abs(r_{i,j,k}) \mid 0 \le i \le n, 0 \le j \le m, 0 \le k \le D-1\}$$

and

$$m_2 = \max\{abs(s_{i,j,k}) \mid 0 \le i,j,k \le D-1\}.$$

Then it can also be shown from the above equation that

$$abs(a_{p,i}) \le d_t D^t m_1^t D^{t-1} m_2^{t-1}.$$

Hence there exists a $g \in \mathbf{Z}$ such that $abs(a_{p,i}) < g^t$. □

We summarize the constants that we have associated with a QTM M with real algebraic amplitudes. Let $K = \mathbf{Q}[\beta] \subseteq \bar{Q} \cap \mathbf{R}$ be the field of amplitudes for M. Let the local matrix of M be an $n \times m$ matrix with $\lambda_{i,j}$ as the (i,j)th entry. Then

$D = D(M)$ be the degree of K over $\mathbf{Q}$;

$d_1 = d_1(M)$ is the least natural number such that $\lambda_{i,j} \in \frac{1}{d_1}\mathbf{Z}[\beta]$ for all i,j with $1 \le i \le n$, $1 \le j \le m$;

$d_2 = d_2(M)$ is the least natural number such that $\beta^i\beta^j \in (1/d_2)\mathbf{Z}[\beta]$ for all i,j with $1 \le i,j \le D$;

$g = g(M)$ is the least natural number determined in Lemma 6.6 such that for all $\alpha \in \mathbf{N}$ and all $t \in \mathbf{Z}_{>0}$ and for all paths p of t steps on input α, the amplitude ρ_p associated with p has the form $\rho_p = \sum_{i=0}^{D-1}(a_{p,i}/d_t)\beta^i$, where $d_t = d_1^t d_2^{t-1}$, $a_{p,i} \in \mathbf{Z}$, and $abs(a_{p,i}) \le g^t$ for all i.

LEMMA 6.7. *For all inputs α, for all $t \in \mathbf{Z}_{>0}$, the following hold.*

1. *If α is accepted in time t with probability* 0, *then*

$$\sum_{i=0}^{D-1} \sum_{C\in\mathcal{C}_\mathcal{A}} \left(\sum_{p\in P_{\alpha,t,C}} a_{p,i} \right)^2 = 0.$$

2. *If α is accepted in time t with probability > 0, then*

$$\sum_{i=0}^{D-1} \sum_{C\in\mathcal{C}_\mathcal{A}} \left(\sum_{p\in P_{\alpha,t,C}} a_{p,i} \right)^2 > 0.$$

Proof of Lemma 6.7. For all configurations, $C \in \mathcal{C}$, for all $t \in \mathbf{Z}_{>0}$, for input strings α, then

$$amp_{\alpha,t,C}(u) = \sum_{p\in P_{\alpha,t,C}} \rho_p = \sum_{p\in P_{\alpha,t,C}} \sum_{i=0}^{D-1} (a_{p_i}/d_t)\beta^i.$$

Switching the sums we get

$$amp_{\alpha,t,C}(u) = \sum_{i=0}^{D-1} \left(\left(\sum_{p \in P_{\alpha,t,C}} a_{p,i} \right) / d_t \right) \beta^i.$$

For all inputs α and $t \in \mathbf{Z}_{>0}$, if input α is accepted in time t with probability 0, then

$$\sum_{C \in \mathcal{C}_A} amp^2_{\alpha,t,C}(u) = 0,$$

and for all $C \in \mathcal{C}_A$, $amp_{\alpha,t,C}(u) = 0$. Hence, for all $i \in \mathbf{Z}_{\geq 0}^{<D}$, $\sum_{p \in P_{\alpha,t,C}} a_{p,i} = 0$, and therefore

$$\sum_{i=0}^{D-1} \sum_{C \in \mathcal{C}_\mathcal{A}} \left(\sum_{p \in P_{\alpha,t,C}} a_{p,i} \right)^2 = 0,$$

which proves case 1.

For all inputs α and $t \in \mathbf{Z}_{>0}$, if input α is accepted in time t with probability > 0, then

$$\sum_{C \in \mathcal{C}_A} amp^2_{\alpha,t,C}(u) > 0,$$

so there exists a $C \in \mathcal{C}_A$ such that $amp_{\alpha,t,C}(u) \neq 0$, which implies that there exists an $i \in \mathbf{Z}_{\geq 0}^{<D}$ such that $\sum_{p \in P_{\alpha,t,C}} a_{p,i} \neq 0$, and, therefore,

$$\sum_{i=0}^{D} \sum_{C \in \mathcal{C}_\mathcal{A}} \left(\sum_{p \in P_{\alpha,t,C}} a_{p.i} \right)^2 > 0,$$

which proves case 2. □

Theorem 6.4 will be proved by the three lemmas given below.

LEMMA 6.8. $\mathrm{NQP}_{\bar{\mathbf{Q}} \cap \mathbf{R}} \subseteq \mathrm{PP} \subseteq \mathrm{P}^{\#\mathrm{P}}$.

Proof of Lemma 6.8. For all $S \subseteq \mathbf{N}$ such that $S \in \mathrm{NQP}_{\bar{\mathbf{Q}} \cap \mathbf{R}}$, we will show that there exists a nondeterministic Turing machine M' that for all $x \in \mathbf{N}$ the following hold:

if $x \in S$, then M' on input x says "yes" on more than 1/2 its paths;

if $x \in \overline{S}$, then M' on input x says "no" on more than 1/2 its paths.

It will follow that $S \in \mathrm{PP}$ and hence $\mathrm{NQP}_{\bar{\mathbf{Q}} \cap \mathbf{R}} \subseteq \mathrm{PP} \subseteq \mathrm{P}^{\#\mathrm{P}}$.

From the definition of $\mathrm{NQP}_{\bar{\mathbf{Q}} \cap \mathbf{R}}$, there exist a $c \in \mathbf{N}_{>0}$ and an M membership $\mathrm{QTM}_{\bar{\mathbf{Q}} \cap \mathbf{R}}$ such that for all $x \in \mathbf{N}$ the following hold:

$x \in S \rightarrow$ after $|x|^c$ steps M on input x accepts with probability > 0;

$x \in \overline{S} \rightarrow$ after $|x|^c$ steps M on input x rejects with probability 0.

Let $K = \mathbf{Q}[\beta] \subseteq \bar{Q} \cap \mathbf{R}$ be the field of amplitudes for M. Let $n = n(M)$, $D = D(M)$, $d_1 = d_1(M)$, $d_2 = d_2(M)$, and $g = g(M)$ be the constants associated with M as defined before.

We observe that for all $x \in \mathbf{N}$, for all $t \in \mathbf{Z}_{>0}$, a path $< C_0, \ldots, C_t >$ of M of length t on input x can be specified by a natural number $P < n^t$ as follows. Write $P = \sum_{i=0}^{t-1} m_i n^i$ with $0 \leq m_i \leq n-1$. Inductively for $i = 0, \ldots, t-1$, from C_i one

chooses the $(m_i + 1)$st entry from the corresponding column in the local matrix for transition to determine the next configuration C_{i+1}. We shall identify P with the path determined by it on input x, and let ρ_P denote the amplitude associated with P. Let $d_t = d_1^t d_2^{t-1}$. Then from Lemma 6.6, $\rho_P = \sum_{i=0}^{D-1} (a_{P,i}/d_t)\beta^i$, where $a_{P,i} \in \mathbf{Z}$, and $abs(a_{P,i}) \leq g^t$ for all i. We will call $a_{P,i}$ the *ith integral coefficient* of ρ_P for $i = 0, \ldots, D-1$.

Let M' on input x proceed as follows.

1. Compute $t = |x|^c$.

2. Guess seven numbers $\langle P_1, G_1, P_2, G_2, E, i, F\rangle$ ("$\langle$" denotes any "reasonable" pairing function) where $P_1, P_2 \in \mathbf{Z}_{\geq 0}^{\leq n^t}$, $G_1, G_2 \in \mathbf{Z}_{\geq 0}^{\leq g^t+1}$, E, F are 0 or 1 and $i \in \mathbf{Z}_{\geq 0}^{<D}$.

3. Use P_1 to choose a path of length t for M on input x. Compute the configuration C_1, which results along this path, and $a_{P_1,i}$, the ith integral coefficient of the amplitude ρ_{P_1} associated with P_1. Similarly, use P_2 to choose a second path of length t for M on input x, and compute C_2 and $a_{P_2,i}$.

4. (trivial guesses)

(i) If $C_1 \neq C_2$, then output "yes" if $E = 0$ and "no" if $E = 1$.

(ii) If $C_1 \in \mathcal{C}_{\mathcal{R}}$, then output "yes" if $E = 0$ and "no" if $E = 1$, except when $P_1 = P_2 = E = i = F = 0$ and $G_1 = G_2 = g^t + 1$.

(iii) If $G_1 \geq abs(a_{P_1,i})$ or $G_2 \geq abs(a_{P_2,i})$, then output "yes" if $E = 1$ and "no" if $E = 0$, except when $P_1 = P_2 = E = i = F = 0$ and $G_1 = G_2 = g^t + 1$.

5. Else (nontrivial guesses)

(i) If $P_1 = P_2 = E = i = F = 0$ and $G_1 = G_2 = g^t + 1$, output "no."

(ii) If $a_{P_1,i}$ and $a_{P_2,i}$ have the same sign, then output "yes."

(iii) If $a_{P_1,i}$ and $a_{P_2,i}$ have opposite signs, then output "no."

Any path with $G_1 = g^t + 1$ or $G_2 = g^t + 1$ is trivial since $G_1 \geq abs(a_{P_1,i})$ or $G_2 \geq abs(a_{P_2,i})$, respectively, except for the special case when $P_1 = P_2 = E = i = F = 0$ and $G_1 = G_2 = g^t + 1$. The number of trivial guesses plus this additional special guess give two more "no" outputs than "yes" outputs.

For all configurations $C \in \mathcal{C}_{\mathcal{A}}$ which can be reached with t steps of M (including transitions that have amplitude of 0), for all $P_1, P_2 \in P_{x,t,C}$, for all $i \in \mathbf{Z}_{\geq 0}^{<D}$, for all $G_1 \in \mathbf{Z}_{\geq 0}^{<abs(a_{P_1,i})}$, for all $G_2 \in \mathbf{Z}_{\geq 0}^{<abs(a_{P_2,i})}$, the guess is nontrivial. In all other cases (except one) the guess will be trivial.

If we count the number of "yes" outputs minus the number of "no" outputs we get

$$\left(4 \sum_{C \in \mathcal{C}_{\mathcal{A}}} \sum_{i=0}^{D-1} \sum_{P_1 \in P_{x,t,C}} \sum_{P_2 \in P_{x,t,C}} a_{P_1,i} a_{P_2,i}\right) - 2,$$

since for a fixed set of paths P_1, P_2 leading to the same configuration, there are $abs(a_{P_1,i} a_{P_2,i})$ sets of pairs G_1, G_2 for each value of E and F.

The above equation can be rewritten as

$$\left(4 \sum_{C \in \mathcal{C}_{\mathcal{A}}} \sum_{i=0}^{D-1} \left(\sum_{p \in P_{x,t,C}} a_{p,i}\right)^2\right) - 2.$$

If $x \in S$ then x is accepted with positive probability, so from part 2 of Lemma 6.7 the sum is greater than 0, and there are more "yes" outputs than "no" outputs.

If $x \in \overline{S}$ then x is accepted with probability 0, so from part 1 of Lemma 6.7 this sum is -2 and there are more "no" outputs than "yes" outputs. □

LEMMA 6.9. $\mathrm{EQP}_{\mathbf{C}} \subseteq \mathrm{PP} \subseteq \mathrm{P}^{\#\mathrm{P}}$.

Proof of Lemma 6.9. By Theorem 6.2, $\mathrm{EQP}_{\mathbf{C}} = \mathrm{EQP}_{\bar{\mathbf{Q}} \cap \mathbf{R}}$. Since $\mathrm{EQP}_K \subseteq \mathrm{NQP}_K$ for any field K, it follows from Lemma 6.8 that

$$\mathrm{EQP}_{\mathbf{C}} = \mathrm{EQP}_{\bar{\mathbf{Q}} \cap \mathbf{R}} \subseteq \mathrm{NQP}_{\bar{\mathbf{Q}} \cap \mathbf{R}} \subseteq \mathrm{PP} \subseteq \mathrm{P}^{\#\mathrm{P}}. \qquad \square$$

LEMMA 6.10. $\mathrm{BQP}_{poly(1/\epsilon)} \subseteq \mathrm{PP} \subseteq \mathrm{P}^{\#\mathrm{P}}$.

Proof of Lemma 6.10. From section 3, $\mathrm{BQP}_{poly(1/\epsilon)} = \mathrm{BQP}_\theta$, where $\cos(\theta) = 3/5$.

For all $S \subseteq \mathbf{N}$ such that $S \in \mathrm{BQP}_\theta$, we will show that there exists a nondeterministic Turing machine M' that for all $x \in \mathbf{N}$ the following hold:

if $x \in S$, then M' on input x says "yes" on more than $1/2$ its paths;

if $x \in \overline{S}$, then M' on input x says "no" on more than $1/2$ its paths.

It will follow that $S \in \mathrm{PP}$ and hence $\mathrm{BQP}_{poly(1/\epsilon)} = BQP_\theta \subseteq \mathrm{PP} \subseteq \mathrm{P}^{\#\mathrm{P}}$.

From the definition of BQP_θ, there exists a $c \in \mathbf{N}_{>0}$ and M a QTM_θ such that for all $x \in \mathbf{N}$ the following hold:

$x \in S \rightarrow$ after $|x|^c$ steps M on input x accepts with probability $> 2/3$,

$x \in \overline{S} \rightarrow$ after $|x|^c$ steps M on input x rejects with probability $> 2/3$.

Let $n = n(M)$, $D = D(M)$, $d_1 = d_1(M)$, $d_2 = d_2(M)$, and $g = g(M)$ be the constants associated with M as defined before.

Let M' on input x proceed as follows.

1. Compute $t = |x|^c$.

2. Guess five numbers $\langle P_1, G_1, P_2, G_2, E \rangle$ ("$\langle$" denotes any "reasonable" pairing function) where $P_1, P_2 \in \mathbf{Z}_{\geq 0}^{\leq n^t}$, $G_1, G_2 \in \mathbf{Z}_{\geq 0}^{\leq g^t}$, and E is 0 or 1.

3. Use P_1 to choose a path of length t for M on input x. Compute the configuration C_1, which results along this path, and $a_{P_1,i}$, the ith integral coefficient of the amplitude ρ_{P_1} associated with P_1. Similarly, use P_2 to choose a second path of length t for M on input x, and compute C_2 and $a_{P_2,i}$.

4. (trivial guesses)

(i) If $C_1 \neq C_2$, then output "yes" if $E = 0$ and "no" if $E = 1$.

(ii) If $G_1 \geq abs(a_{P_1,0})$ or $G_2 \geq abs(a_{P_2,0})$, then output "yes" if $E = 0$ and "no" if $E = 1$.

5. Else (nontrivial guesses)

(i) If $a_{P_1,0}$ and $a_{P_2,0}$ have the same sign, then output "yes" if C_1 is an accept configuration and "no" if C_1 is a reject configuration.

(ii) If $a_{P_1,0}$ and $a_{P_2,0}$ have opposite signs, then output "yes" if C_1 is a reject configuration and "no" if C_1 is an accept configuration.

Since the entries in the local matrix are rational, the degree of $K = \mathbf{Q}$ equals 1, and so

$$amp_{\alpha,t,C}(u) = \sum_{p \in P_{\alpha,t,C}} a_{p,0}/d_t.$$

Again all the trivial paths have equal "yes" and "no" results.

For all configurations $C \in \mathcal{C}$ which can be reached with t steps of M (including transitions that have amplitude of 0), for all $P_1, P_2 \in P_{x,t,C}$, for all $G_1 \in \mathbf{Z}_{\geq 0}^{<abs(a_{P_1,0})}$, for all $G_2 \in \mathbf{Z}_{\geq 0}^{<abs(a_{P_2,0})}$, the guess is nontrivial. In all other cases the guess will be trivial.

If we count the number of "yes" outputs minus the number of "no" outputs we get

$$2\left(\sum_{C\in\mathcal{C}_{\mathcal{A}}}\sum_{P_1\in P_{x,t,C}}\sum_{P_2\in P_{x,t,C}}a_{P_1,0}a_{P_2,0}-\sum_{C\in\mathcal{C}_{\mathcal{R}}}\sum_{P_1\in P_{x,t,C}}\sum_{P_2\in P_{x,t,C}}a_{P_1,0}a_{P_2,0}\right),$$

since for a fixed set of paths P_1, P_2 leading to the same configuration, there are $abs(a_{P_1,0}a_{P_2,0})$ sets of pairs G_1, G_2 for each value of E.

The above equation can be rewritten as

$$2\left(\sum_{C\in\mathcal{C}_{\mathcal{A}}}\left(\sum_{p\in P_{x,t,C}}a_{p,i}\right)^2-\sum_{C\in\mathcal{C}_{\mathcal{R}}}\left(\sum_{p\in P_{x,t,C}}a_{p,i}\right)^2\right)$$

$$=2d_t^2\left(\sum_{C\in\mathcal{C}_{\mathcal{A}}}\left(amp^2_{\alpha,t,C}(u)\right)-\sum_{C\in\mathcal{C}_{\mathcal{R}}}\left(amp^2_{\alpha,t,C}(u)\right)\right).$$

If $x \in S$, then x is accepted with probability greater than $2/3$ and rejected with probability less than $1/3$ and so the above sum is greater than 0, giving more paths in M' with a "yes" result than a "no" result.

If $x \in \overline{S}$, then x is rejected with probability greater than $2/3$ and accepted with probability less than $1/3$ and so the above sum is less than 0, giving more paths in M' with a "no" result than a "yes" result.

This concludes the proof of Lemma 6.10 and therefore Theorem 6.4. □

7. Discussion. If one is concerned about minimizing (or precisely calculating) the polynomial slowdown in the approximations implicit in Theorem 3.3, then more recent results of Baker and others on transcendental numbers may be useful. Angles θ with $\theta/2\pi \in \bar{\mathbf{Q}} - \mathbf{Q}$ may be particularly good in this regard.

There are many unsettled issues and open questions involving quantum computation. For example, letting K be a field, is $\mathrm{BQP}_K = \mathrm{EQP}_K$? We have shown that $\mathrm{BQP}_{\mathbf{C}} \neq \mathrm{EQP}_{\mathbf{C}}$. It seems unlikely that $\mathrm{BQP}_{\mathbf{Q}} = \mathrm{EQP}_{\mathbf{Q}}$.

One can ask whether $\mathrm{NQP}_K = \mathrm{EQP}_K$, an analogue of the $NP = P$ question.

One can consider the relationship between classical classes and quantum classes. For example does EQP=P? We suspect not, but since EQP$\subseteq$ PSPACE, a yes answer would not be entirely out of the question. Does $\mathrm{BQP}_{\mathbf{Q}}$=BPP?

One can generalize the notion of a "classical" probabilistic Turing machine to allow for amplitudes in $\mathbf{C}$ and consider the relationship between natural classes on a classical probabilistic Turing machine and on a quantum machine. For example, is it the case that $\mathrm{BQP}_{\mathbf{C}} = \mathrm{BPP}_{\mathbf{C}}$ (when BPP_K is appropriately defined)? Does $\mathrm{BQP}_{\mathbf{Q}} = \mathrm{BPP}_{\mathbf{Q}}$? An affirmative answer would inform us that the power of quantum computation is not found in the use of the L_2-norm but rather in the use of general (possibly negative) amplitudes.

One can ask similar questions for QTM_θ rather than QTM_K. For example, let θ and θ' have cos = 3/5 and 5/12, respectively. Then $\mathrm{QTM}_\theta \asymp \mathrm{QTM}_{\theta'}$ and hence $\mathrm{BQP}_\theta = \mathrm{BQP}_{\theta'}$; however, does $\mathrm{EQP}_\theta = \mathrm{EQP}_{\theta'}$? If $\theta/2\pi \notin \mathbf{Q}$, does EQP_θ =P?

To what extent would demonstrating relationships between various complexity classes over various fields (or with various angles) have implications similar to those which arise when relationships between classical classes are demonstrated with respect to an oracle?

One could consider very general notions of machines (amplitudes in $\mathbf{C}$, arbitrary norms, for example). Would an investigation of these shed light on the basic open problems of computational complexity?

On a more concrete level, is the "shortest vector in a lattice" problem in $\mathrm{BQP}_{\mathbf{Q}}$ (this has been asked by numerous researchers)? Is primality in $\mathrm{EQP}_{\mathbf{C}}$? Is primality in $\mathrm{EQP}_{\mathbf{Q}}$? Can integers be multiplied in linear time on a QTM?

Acknowledgments. We thank Harold Stark for providing us with Lemma 3.6, Charles Bennett for contributing to our understanding of methods of approximating θ used in the proof of Theorem 3.3, and Don Coppersmith for enlightening comments regarding a previous version of this paper. Finally, we thank the anonymous referees for bringing Proposition 6.1 to our attention, for pointing out a mistake in an earlier version, and for many valuable comments.

STABILIZATION OF QUANTUM COMPUTATIONS BY SYMMETRIZATION *

ADRIANO BARENCO†, ANDRÉ BERTHIAUME‡, DAVID DEUTSCH§, ARTUR EKERT¶, RICHARD JOZSA‖, AND CHIARA MACCHIAVELLO**

Abstract. We propose a method for the stabilization of quantum computations (including quantum state storage). The method is based on the operation of projection into $\mathcal{SYM}$, the symmetric subspace of the full state space of R redundant copies of the computer. We describe an efficient algorithm and quantum network effecting $\mathcal{SYM}$–projection and discuss the stabilizing effect of the proposed method in the context of unitary errors generated by hardware imprecision, and nonunitary errors arising from external environmental interaction. Finally, limitations of the method are discussed.

Key words. quantum computation, error correction

1. Introduction.

Any realistic model of computation must conform to certain requirements imposed not by the mathematical properties of the model but by the laws of physics. Computations which require an exponentially increasing precision or exponential amount of time, space, energy, or any other physical resource are normally regarded as unrealistic and intractable.

Any actual computational process is subject to unavoidable hardware imprecision and spurious interaction with the environment, whose nature is dictated by the laws of physics. These effects introduce errors and destabilize the progress of the desired computation. It is, therefore, essential to have some method of stabilizing the computation against these effects.

For classical computation there is a simple and highly effective method of stabilization. Each computational variable is represented redundantly using many more physical degrees of freedom than are logically required, and a majority vote (or average) of all the copies is taken followed by resetting all the copies to the majority

answer. This process is applied periodically during the course of the computation. If we use R copies and the probability of producing the correct answer is $\frac{1}{2}+\eta$ then it can be shown ([1, p. 258]) that the probability E that the majority vote is wrong, is less than $\exp(-\eta^2 R/6)$. This is an extremely resource-efficient stabilization in that the probability of error decreases *exponentially* with the degree of redundancy R. Indeed, suppose that a polynomial-time algorithm runs for M steps, each of which is correct with probability $\frac{1}{2}+\eta$ and majority voting is used after each step. The probability that the final answer will be correct is greater than $(1-E)^M$. Thus any desired success probability $1-\delta$ may be achieved using a degree of redundancy $R = O(\log(M/\delta))$, which is only logarithmic in the input size.

The majority vote method just described cannot be applied in the case of quantum computation because quantum algorithms depend essentially on the maintenance of coherent superpositions of different computational states at each step. The laws of quantum mechanics forbid the identification of an unknown quantum state [17], [18] and forbid even the cloning of an unknown state [19]. Thus the majority voting method is inapplicable as we can neither determine the majority state nor reset the remaining copies to that state. In this paper we propose an alternative quantum mechanical method of stabilization which utilizes redundancy but which has no classical analogue. We discuss its applicability and limitations. The method was first proposed by Deutsch [2] and a brief outline of its underlying principles was given in [3].

An alternative approach to the stabilization of classical computation involves the use of error correcting codes [20]. A quantum mechanical generalization of this approach was recently introduced by Shor [9] and subsequently developed in [13], [10], [12], [11]. These methods are unrelated to those proposed in this paper and provide an interesting supplementary method of stabilizing quantum computation.

The process of simply repeating a whole computation a sufficient number of times may serve to stabilize it in certain circumstances. Suppose that we have a quantum algorithm which succeeds with probability $1-\epsilon$ (where ϵ may increase with input size) and suppose that we know when the computation has been successful. For example, the computation may produce a candidate factor of an input integer which can then be efficiently checked by trial division. For any input size L the success probability can be amplified to any prescribed level $1-\delta$ by repeating the algorithm a sufficiently large number, R, of times since the probability of at least one success in R repetitions is $1-\epsilon^R \to 1$ as $R \to \infty$. Suppose now that the success probability $1-\epsilon$ decreases with input size L as $1/\mathrm{poly(L)}$. Then we can maintain any prescribed success probability by allowing R to increase as a suitable polynomial function of L. Thus if the original algorithm was efficient (i.e., polynomial time) then its R-fold repetition is still efficient, i.e., the algorithm has been stabilized in an efficient manner. (Note that Shor's quantum factoring algorithm [7], [8] is of this type with success probability decreasing as $1/L$ with input size.) However, if the success probability falls *exponentially* with input size L then we must use $R \sim \exp(\mathrm{L})$ to maintain any constant level of success probability. This implies an exponential increase of physical resources for stabilization and hence this method is inefficient in this case. Unfortunately, just such an exponential decay of success probability appears to be a generic feature of any physical implementation of computation, as described below.

In quantum theory, the issue of preventing information from leaking into the environment from a system ("the computer") is generally known as the decoherence problem [4], [5], [6]. According to the analysis of [6], decoherence generally causes an *exponential* decrease in success probability with input size L. Decoherence is

a universal phenomenon and is expected to affect—to some extent—any physical implementation of quantum computation whatever. Thus without some *efficient* form of stabilization, quantum algorithms which are polynomially efficient in the error-free case (like Shor's factoring algorithm) cannot be considered polynomially efficient in practice.

Consider any efficient computation which gives the correct result at each step with probability $1-\epsilon$ where ϵ is constant. This would typically be the case if each step of a computation consisted of the application of an elementary gate operation having a standard tolerance of error. Then after N steps the probability of success is (at least) $(1-\epsilon)^N \sim \exp(-\epsilon N)$, which again decreases exponentially with N. Suppose that we have a stabilization scheme utilizing redundancy R which reduces the error in each step only by a factor $1/R$, i.e., $\epsilon \to \epsilon/R$ (rather than the *exponential* decrease given by classical majority voting). After N steps the probability of success is now $\exp(-\epsilon N/R)$. This can be kept at any prescribed level $1-\delta$ by taking $R = \epsilon N/(-\log(1-\delta))$ which is *polynomial* in N and hence in the input size L. Thus an exponentially growing error (such as results from decoherence) in a polynomial-time computation can be efficiently stabilized by a method which reduces the error per step only as $1/R$ with the degree of redundancy. Our proposed method below will have this property.

An essential ingredient in our stabilization method is the so-called "quantum watched pot" effect (or quantum Zeno effect) [16]. Our method will require the repeated projection of the quantum state of R computers into the symmetric subspace $\mathcal{SYM}$, a subspace of the total state space of the R computers. This projection has a nonzero failure probability so that (in view of the previous paragraph) the cumulative probability of repeated successful projection may be expected to fall exponentially with the number of projections. The quantum watched pot effect provides a means of maintaining the cumulative probability of successful projection arbitrarily close to unity. The basic principle is illustrated in the following simplified example. Consider a quantum system initially in state $|0\rangle$ which rotates into $|1\rangle$ with angular frequency ω. The state at time t (in the absence of any projections) is $\cos\omega t\,|0\rangle + \sin\omega t\,|1\rangle$. If we project this state into Λ_0, the subspace spanned by $|0\rangle$, then the probability of successful projection is $\cos^2\omega t$. If we project repeatedly n times between $t=0$ and $t=1$, i.e., at time intervals $\delta t = 1/n$, then the probability that all projections will be successful is

$$\left(\cos^2\frac{\omega}{n}\right)^n \approx \left(1-\frac{\omega^2}{n^2}\right)^n \to 1 \qquad \text{as} \qquad n\to\infty.$$

Thus if the projections are performed with sufficient frequency then the state may be confined to the subspace Λ_0 with arbitrarily high probability. This is the quantum watched pot effect. In quantum mechanics projection operations correspond to measurements on the system so the above may be loosely phrased as "a frequently observed state never evolves" or "a watched pot never boils," giving the origin of the terminology. A similar analysis holds for Λ_0 replaced by any subspace such as $\mathcal{SYM}$, and for any unitary evolution of a state initially lying in the subspace as elaborated in section 5.

It will be useful in the following to keep in mind the simplest possible example of the stabilization problem where the computer consists of one qubit (i.e., one two-level system) and is performing no computation. In fact this simple model captures the essential features of the stabilization problem for general quantum computations.

The problem of stabilization concerns the time evolution of an "accuracy" observable which has only two eigenvalues. As we shall see our analysis of error correction depends only on such simple observables and is independent of the substance of the computation. Thus we are addressing the problem of stabilizing the *storage* of an (unknown) quantum state of one qubit against environmental interaction and (suitably random) imprecision in the construction of the storage device.

2. The symmetric subspace. Our proposed stabilization method will exploit redundancy but in contrast to the classical majority voting method, it will be based on essentially quantum mechanical properties through use of the symmetric subspace of the full state space of R copies of a physical system. Consider R copies of a quantum system each with state space $\mathcal{H}$. Denote the full state space $\mathcal{H} \otimes \mathcal{H} \otimes \ldots \mathcal{H}$ by $\mathcal{H}^R$.

Remark 1. Here we require that the R copies be distinguishable, e.g., being located in separate regions of space so that the position coordinate provides an extra "external" degree of freedom for distinguishability. The state space $\mathcal{H}$ can be thought of as representing the "internal" degrees of freedom of each system. In our application these are the computational degrees of freedom of each replica of the computer. In our notation we suppress explicit mention of the distinguishing degree of freedom which is implicitly given by the written order of component states in a tensor product state (cf. *Remark* 2 below).

The symmetric subspace $\mathcal{SYM}$ of $\mathcal{H}^R$ may be characterized by either of the two following equivalent definitions.

DEFINITION 1. *$\mathcal{SYM}$ is the smallest subspace of $\mathcal{H}^R$ containing all states of the form $|\psi\rangle |\psi\rangle \ldots |\psi\rangle$ for all $|\psi\rangle \in \mathcal{H}$.*

DEFINITION 2. *$\mathcal{SYM}$ is the subspace of all states in $\mathcal{H}^R$ which are symmetric (i.e., unchanged) under the interchange of states for any pair of positions in the tensor product. (Here we interchange only the internal degrees of freedom leaving the external degrees fixed.)*

Remark 2. To clarify the notion of symmetrization in Definition 2 note that, for example, $|\phi\rangle |\psi\rangle + |\psi\rangle |\phi\rangle \in \mathcal{H}^2$ is in $\mathcal{SYM}$. If we were to show the external degrees of freedom then this state would be written $|\phi; x_1\rangle |\psi; x_2\rangle + |\psi; x_1\rangle |\phi; x_2\rangle$. Consequently, the notion of symmetrization in Definition 2 is different from bosonic symmetrization which requires symmetrization of *all* degrees of freedom. For a pair of bosons the previous state would be $|\phi; x_1\rangle |\psi; x_2\rangle + |\psi; x_2\rangle |\phi; x_1\rangle$.

Definition 1 has the following interpretation. Suppose that we have R copies of a quantum computer. If there were no errors then at each time the joint state would have the form

$$|\psi\rangle |\psi\rangle \ldots |\psi\rangle \in \mathcal{H}^R. \tag{1}$$

In the presence of errors the states will evolve differently resulting in a joint state of the form $|\psi_1\rangle |\psi_2\rangle \ldots |\psi_R\rangle$ or more generally a mixture of superpositions of such states. In quantum mechanics any test ("yes/no" question) that we can apply to a physical system must correspond to a *subspace* of the total state space. States of the form (1) for all $|\psi\rangle \in \mathcal{H}$ do not, by themselves, form a subspace of $\mathcal{H}^R$. According to Definition 1, $\mathcal{SYM}$ is the smallest subspace containing all possible error-free states. It thus corresponds to the "most probing" test we can legitimately apply, which will be passed by all error-free states. Recall that we cannot generally identify the actual quantum state during the course of the computation or indeed gain any information about it without causing some irreparable disturbance [18]. The characterization

given in Definition 2 is especially useful in treating mathematical properties of $\mathcal{SYM}$ as follows.

The equivalence of the two definitions may be proved by viewing the ith component space in the tensor product $\mathcal{H}^R$ as the space of complex polynomials of degree $\leq n-1$ in the variable x_i (where n is the dimension of $\mathcal{H}$). By the fundamental theorem of algebra any such polynomial may be factored as $(x_i-\alpha_1)(x_i-\alpha_2)\dots(x_i-\alpha_{n-1})$. Then Definition 1 defines the subspace of all polynomials $p(x_1,\dots,x_R)$ of degree $\leq n-1$ in each variable, which arise as sums of products of functions of the form

$$f_\alpha(x_1,x_2,\dots,x_R)=\prod_{i=1}^{R}(x_i-\alpha) \tag{2}$$

for any α. On the other hand, Definition 2 defines the space of all symmetric polynomials (of degree $\leq n-1$ in each variable). The equivalence of these subspaces then follows easily from basic properties of the standard elementary symmetric functions [14], which are defined as the coefficients of the powers of α in the expansion of (2).

The equivalence of the two definitions may also be understood via the following illustrative example which gives further insight into the structure of $\mathcal{SYM}$.

Example 1. Suppose that $\mathcal{H}$ is two-dimensional (i.e., a qubit) with computational basis states $|0\rangle$ and $|1\rangle$. Consider triple redundancy $R=3$ and the symmetric subspace $\mathcal{SYM}\subset\mathcal{H}^3$. Let us tentatively denote the symmetric subspaces of Definitions 1 and 2 by $\mathcal{SYM}_{def1}$ and $\mathcal{SYM}_{def2}$, respectively. We wish to show that these coincide. Note first that $\mathcal{SYM}_{def1}$ is the span of all states of the form $|\psi\rangle|\psi\rangle|\psi\rangle$, which are clearly symmetrical in the sense of Definition 2. Hence, $\mathcal{SYM}_{def1}\subseteq\mathcal{SYM}_{def2}$. For the reverse inclusion consider a general state in $\mathcal{H}^3$:

$$\begin{aligned}|\alpha\rangle = {} & a_0|0\rangle|0\rangle|0\rangle \\ & +a_1|1\rangle|0\rangle|0\rangle+a_2|0\rangle|1\rangle|0\rangle+a_3|0\rangle|0\rangle|1\rangle \\ & +a_4|1\rangle|1\rangle|0\rangle+a_5|1\rangle|0\rangle|1\rangle+a_6|0\rangle|1\rangle|1\rangle \\ & +a_7|1\rangle|1\rangle|1\rangle\,.\end{aligned} \tag{3}$$

Interchange of states for any given pair of positions (in the sense of Definition 2) preserves the number of $|0\rangle$'s and $|1\rangle$'s in each term so that $|\alpha\rangle$ will be in $\mathcal{SYM}_{def2}$ if and only if $a_1=a_2=a_3$ and $a_4=a_5=a_6$. Indeed, we see that $\mathcal{SYM}_{def2}$ is four dimensional with orthonormal basis states (labelled by the number of $|1\rangle$'s):

$$\begin{aligned}|e_0\rangle &= |0\rangle|0\rangle|0\rangle \\ |e_1\rangle &= (|1\rangle|0\rangle|0\rangle+|0\rangle|1\rangle|0\rangle+|0\rangle|0\rangle|1\rangle)/\sqrt{3} \\ |e_2\rangle &= (|1\rangle|1\rangle|0\rangle+|1\rangle|0\rangle|1\rangle+|0\rangle|1\rangle|1\rangle)/\sqrt{3} \\ |e_3\rangle &= |1\rangle|1\rangle|1\rangle\,.\end{aligned} \tag{4}$$

(The four normalizing factors $1,\sqrt{3},\sqrt{3},$ and 1 are square roots of the binomial coefficients ${}^3C_0,{}^3C_1,{}^3C_2,{}^3C_3$.) Now for any $|\psi_1\rangle$ of the form $a|0\rangle+|1\rangle$ we get directly that

$$|\psi_1\rangle|\psi_1\rangle|\psi_1\rangle=a^3|e_0\rangle+a^2\sqrt{3}|e_1\rangle+a\sqrt{3}|e_2\rangle+|e_3\rangle\,.$$

Repeating this for four different values of the parameter a we get the following:

$$\begin{pmatrix} a^3 & a^2 & a & 1 \\ b^3 & b^2 & b & 1 \\ c^3 & c^2 & c & 1 \\ d^3 & d^2 & d & 1 \end{pmatrix} \begin{pmatrix} |e_0\rangle \\ \sqrt{3}\,|e_1\rangle \\ \sqrt{3}\,|e_2\rangle \\ |e_3\rangle \end{pmatrix} = \begin{pmatrix} |\psi_1\rangle\,|\psi_1\rangle\,|\psi_1\rangle \\ |\psi_2\rangle\,|\psi_2\rangle\,|\psi_2\rangle \\ |\psi_3\rangle\,|\psi_3\rangle\,|\psi_3\rangle \\ |\psi_4\rangle\,|\psi_4\rangle\,|\psi_4\rangle \end{pmatrix}.$$

Choosing $a, b, c,$ and d so that the coefficient matrix is invertible, we see that the basis states (4) are all in $\mathcal{SYM}_{def1}$ so that $\mathcal{SYM}_{def2} \subseteq \mathcal{SYM}_{def1}$. Hence, these subspaces coincide.

From the above considerations (cf. especially (4)) we readily see that the dimension of $\mathcal{SYM}$ for R qubits is $R+1$ so that $\mathcal{SYM}$ is an exponentially small subspace of $\mathcal{H}^R$ (of dimension 2^R). This is also true in the general case. Suppose that $\mathcal{H}$ has dimension d with orthonormal basis $|0\rangle, |1\rangle \ldots |d-1\rangle$. Then $\mathcal{SYM}$ has an orthogonal basis labelled by all possible ways of making R choices from the d basis states with repetitions possible and the ordering of choices being irrelevant (c.f. (3) and (4)). The solution of this combinatorial problem gives

$$\text{Dimension of } \mathcal{SYM} = {}^{R+d-1}C_{d-1} = \frac{1}{(d-1)!}R^{d-1} + O(R^{d-2}), \tag{5}$$

which is a polynomial in R (for fixed d). Hence, $\mathcal{SYM}$ is again exponentially small inside $\mathcal{H}^R$ of dimension d^R.

3. Projection into $\mathcal{SYM}$. Our proposed method of stabilization consists of frequently repeated projection of the joint state of R computers into the symmetric subspace $\mathcal{SYM}$. According to the interpretation of $\mathcal{SYM}$ above, the error free component of any state always lies in $\mathcal{SYM}$ so that upon successful projection this component will be unchanged and part of the error will have been removed. Note, however, that the projected state is generally not error-free since, for example, $\mathcal{SYM}$ contains many states which are not of the simple product form $|\psi\rangle\,|\psi\rangle \ldots |\psi\rangle$. Nevertheless, the error probability will be suppressed by a factor of $1/R$ as discussed in subsequent sections. Thus the method is not one of error correction but rather of stabilization. By choosing R sufficiently large and the rate of symmetric projection sufficiently high, the residual error at the end of a computation can, in principle, be controlled to lie within any desired small tolerance.

The operation of projection into $\mathcal{SYM}$ is a computation in itself. For our stabilization method to be efficient it is essential that this operation be executable efficiently, i.e., in a number of steps that increases at most polynomially with L and R where $L = \log_2 d$ is the number of qubits required to hold the state of each computer entering into the symmetrization and R is the degree of redundancy. (Also note that R can clearly be at most a polynomial function of L in any efficient scheme.) Only then will a nominally efficient computation remain efficient after stabilization.

We next describe an algorithm for projecting into $\mathcal{SYM}$ and show that it is efficient in the above sense. Consider first a product state $|\Psi\rangle = |a_1\rangle\,|a_2\rangle \ldots |a_R\rangle \in \mathcal{H}^R$. To project $|\Psi\rangle$ into $\mathcal{SYM}$ we carry out the following steps.

Step 1. Introduce an ancilla in a standard state $|0\rangle$ with a state space $\mathcal{A}$ of at least $R!$ dimensions.

Step 2. Make an equal amplitude superposition of the ancilla

$$\mathcal{U} : |0\rangle \to \frac{1}{\sqrt{R!}} \sum_{i=0}^{R!-1} |i\rangle\,.$$

Step 3. Carry out the following computation: if the ancilla state is $|i\rangle$ then perform the ith permutation σ_i of the component states of $|a_1\rangle\,|a_2\rangle\ldots|a_R\rangle$

$$|a_1\rangle\,|a_2\rangle\ldots|a_R\rangle\,|i\rangle \to \left|a_{\sigma_i(1)}\right\rangle\left|a_{\sigma_i(2)}\right\rangle\ldots\left|a_{\sigma_i(R)}\right\rangle|i\rangle\,.$$

This results in the entangled state

$$\sum_i \left|a_{\sigma_i(1)}\right\rangle\left|a_{\sigma_i(2)}\right\rangle\ldots\left|a_{\sigma_i(R)}\right\rangle|i\rangle \in \mathcal{H}^R\otimes\mathcal{A}.$$

Step 4. Apply the reverse computation $\mathcal{U}^{-1}$ of step 2 to the ancilla. The resulting state may be written

$$|\Upsilon\rangle = \sum_i |\xi_i\rangle\,|i\rangle \in \mathcal{H}^R\otimes\mathcal{A}.$$

Since $\mathcal{U}$ transforms $|0\rangle$ to each $|i\rangle$ with equal amplitude it follows that $\mathcal{U}^{-1}$ transforms each $|i\rangle$ back to $|0\rangle$ with equal amplitude. Hence the coefficient of ancilla state $|0\rangle$ in $|\Upsilon\rangle$ is the required symmetrized state, i.e., an equal amplitude superposition of all permutations of the R factor states of $|a_1\rangle\,|a_2\rangle\ldots|a_R\rangle$.

Step 5. Measure the ancilla in its natural basis. If the outcome is "0" then $|\Psi\rangle$ has been successfully projected into $\mathcal{SYM}$. If the outcome is not "0" then the symmetrization has failed. (The issue of the probability of successful symmetrization is discussed in a later section.)

Finally note that by linearity of the process, it will symmetrize a general state in $\mathcal{H}^R$ (not just the product states considered above). If the input state is already symmetric then we get it back unchanged with certainty at the end.

Now consider the computational effort involved in the above steps. Let $d = \dim\mathcal{H}$ and write $L = \log_2 d$. Step 1 requires no computational effort. The ancilla requires $\log_2(R!) = O(R\log R)$ qubits. Step 2 may be achieved by applying the discrete Fourier transform [7], [8] to the ancilla. This requires $O((R\log R)^2)$ steps. For step 3 we note that a general permutation can be effected with $O(R\log R)$ swaps. Swapping states of L qubits requires $O(L)$ operations so overall step 3 requires $O(LR\log R)$ steps. Restoring the ancilla in step 4 requires the same number of operations as step 2. In step 5 we examine separately each of the $O(R\log R)$ qubits occupied by the ancilla, requiring $O(R\log R)$ steps. Overall we require $O(LR\log R + (R\log R)^2)$ steps which is less than $O(LR^2 + R^4)$. Hence the process is efficient.

4. A quantum network for $\mathcal{SYM}$ projection. We now describe how the operation of $\mathcal{SYM}$ projection can be implemented by a network of simple quantum gates. Consider first the following inductive definition of the general permutation of $k+1$ elements $a_1,\ldots,a_k,a_{k+1}$ [23]. Starting from the general permutation $a_{\sigma(1)},\ldots,a_{\sigma(k)}$ of the k elements $a_1,\ldots,a_k$ we adjoin a_{k+1} giving $a_{\sigma(1)},\ldots,a_{\sigma(k)},a_{k+1}$ and then perform separately the $k+1$ operations: identity, swap $a_{\sigma(1)}$ with a_{k+1}, swap $a_{\sigma(2)}$ with a_{k+1}, ... swap $a_{\sigma(k)}$ with a_{k+1}. This generates all possible permutations of $k+1$ elements. In terms of state symmetrization, if we have already symmetrized $|\psi_1\rangle\otimes\cdots\otimes|\psi_k\rangle$ (i.e., we have an equal superposition of all permutations of the states) then we can symmetrize $k+1$ states $|\psi_1\rangle\otimes\cdots\otimes|\psi_k\rangle\otimes|\psi_{k+1}\rangle$ by applying only the operation of state swapping (in suitable superposition). Thus the operation of symmetrization of R states can be built up from $|\psi_1\rangle$ by first symmetrizing $|\psi_1\rangle$ and $|\psi_2\rangle$, then successively

including $|\psi_3\rangle$ up to $|\psi_R\rangle$ always using only state swappings in suitably controlled superpositions.

The basic ingredient in this process is the "controlled swap gate" or Fredkin gate, acting on three input qubits. If the first ("control") quit is $|0\rangle$ (respectively, $|1\rangle$) then the other two ("target") qubits are unaffected (respectively, swapped). We describe this diagrammatically in Fig. 1. The operation of state swapping itself (i.e., $|\psi_1\rangle \otimes |\psi_2\rangle \mapsto |\psi_2\rangle \otimes |\psi_1\rangle$) can be implemented using three controlled–NOT gates as described in [15].

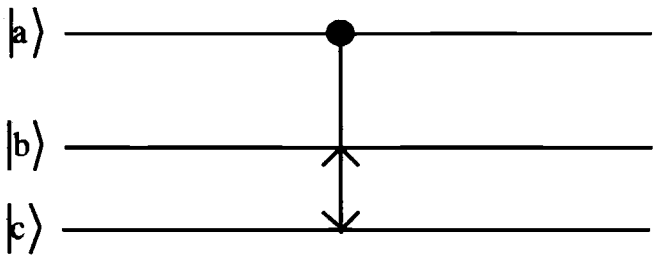

FIG. 1. *Schematic representation of a Fredkin gate. A Fredkin gate exchanges the state of the second and third qubit if and only if the first qubit is in state* $|a\rangle = |1\rangle$.

To symmetrize $k+1$ qubits given that the first k are already symmetrized we introduce k control qubits initially in state $|0\rangle\,|0\rangle \ldots |0\rangle$ and apply a suitable unitary transformation, denoted U_k to generate the superposition

$$\frac{1}{\sqrt{k+1}}\left(|00\ldots0\rangle + |10\ldots0\rangle + |01\ldots0\rangle + \cdots + |00\ldots1\rangle\right). \tag{6}$$

The unitary transformation U_k can be readily obtained by a quantum network consisting of a one bit gate performing the transformation

$$\frac{1}{\sqrt{k+1}}\begin{pmatrix} 1 & -\sqrt{k} \\ \sqrt{k} & 1 \end{pmatrix} \tag{7}$$

on the first quit and a sequence of $k-1$ two bit gates $T_{j,j+1}$ for $j = 1, \ldots, k-1$ acting on the jth and $j+1$th qubits. In the basis $\{|0\rangle, |1\rangle\}$, $T_{j,j+1}$ is given by:

$$T_{j,j+1} = \frac{1}{\sqrt{k-j+1}}\begin{pmatrix} \sqrt{k-j+1} & 0 & 0 & 0 \\ 0 & 1 & \sqrt{k-j} & 0 \\ 0 & -\sqrt{k-j} & 1 & 0 \\ 0 & 0 & 0 & \sqrt{k-j+1} \end{pmatrix}. \tag{8}$$

Having thus initialized the k control qubits, we then apply k Fredkin gates—the jth Fredkin gate (for $j = 1, \ldots k$) uses the jth control quit to control the swapping of the jth and $(k+1)$th target qubits. This leads to an entangled state of the k control qubits and the $k+1$ target qubits but after applying U_k^{-1} to the control qubits, the coefficient of $|0\rangle\,|0\rangle \ldots |0\rangle$ will be the required symmetrization of the $k+1$ qubits (c.f. step 4 of section 3). Finally, a measurement of the control qubits will effect the projection into $\mathcal{SYM}$ (cf. step 5 of section 3).

Thus to symmetrize R qubits we cascade the above construction with $k = 1, 2, \ldots$ up to $k = R-1$ requiring a total number $1+2+\cdots+(R-1) = R(R-1)/2$ of control qubits. The size of the overall network is clearly quadratic in R. For example, for the symmetrization of $R = 4$ qubits we obtain the network shown in Fig. 2.

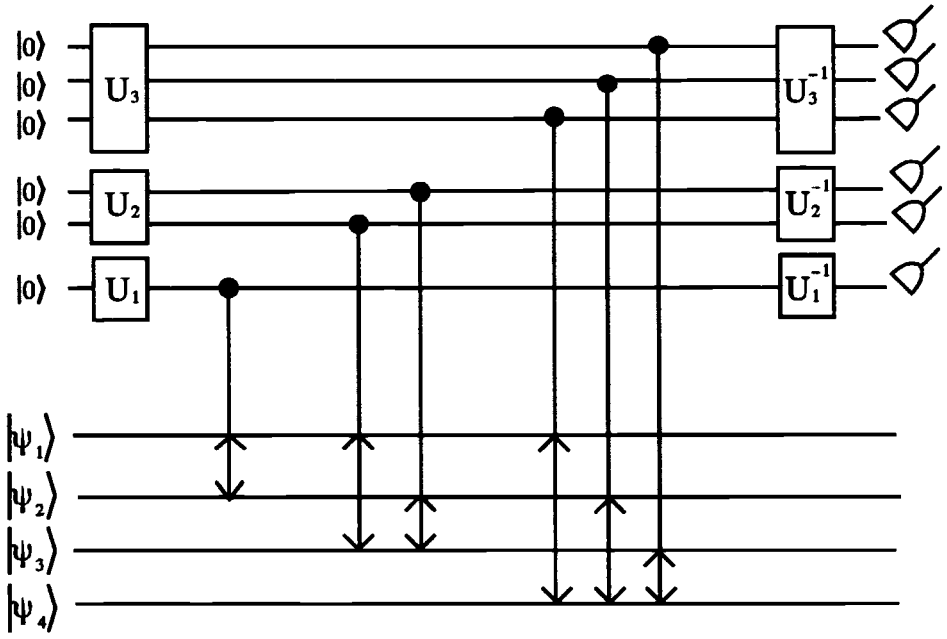

FIG. 2. *Quantum network for symmetrizing $R = 4$ qubits. Six auxiliary qubits initially in state $|0\rangle$ are needed. The auxiliary qubits are put into an entangled state and used to control the state swapping of the four computer qubits. The operations are then undone and the auxiliary qubits measured. If every auxiliary quit is found in state $|0\rangle$ the symmetrization has been successful.*

5. Stabilization against unitary errors. So far we have given an efficient algorithm for projection into the symmetric subspace and provided an intuitive reason why it would be expected to reduce the error while preserving the correct computation. We now turn to a quantitative study of the effect of $\mathcal{SYM}$-projection as a basis for stabilization in the presence of various modes of error production. It is convenient to separate the discussion into two parts considering the case where the joint state of the computers remains in a pure state, in this section, and the case of decoherence due to external environmental interaction in the following section.

Consider the simple model of R qubits initially in state (the "correct" state) $|0\rangle\,|0\rangle\ldots|0\rangle$ with computation being the identity, i.e., we are considering the state storage problem with R–fold redundancy. Suppose that the R storage devices are subject to independent hardware errors which cause the jth state to drift as $e^{iH_j t}\,|0\rangle$. Here the Hamiltonians H_j are random and independent. Since the devices were intended for state storage we assume that the rate of drift is suitably bounded. This is expressed by requiring that all eigenvalues of the H_j's are suitably small

$$|\text{eigenvalues of } H_j| \leq \epsilon, \qquad j = 1, \ldots, R \tag{9}$$

for some (small) constant ϵ. The stabilization process consists of projecting the joint state of the R copies into the symmetric subspace at short time intervals δt. For simplicity we will assume that the projection can be performed essentially instantaneously. Furthermore, we assume that (unlike the computation being stabilized) the projection process itself is error free. These and other assumptions will be discussed in section 7. Under these assumptions we can readily compare the growth of errors with and without the stabilization process.

In the basis $\{|0\rangle, |1\rangle\}$ write

$$H_j = \begin{pmatrix} a_j & c_j^* \\ c_j & b_j \end{pmatrix} \tag{10}$$

so that

$$|c_j| \leq |\lambda_1| + |\lambda_2| \leq 2\epsilon \tag{11}$$

(where λ_1, λ_2 are the eigenvalues of H_j). We will assume that δt is small and we retain only the lowest order terms in δt. After time δt the state will be

$$|\Psi(\delta t)\rangle = \bigotimes_{k=1}^{R} \{(1 + ia_k\delta t)\,|0\rangle + ic_k\delta t\,|1\rangle\}\,. \tag{12}$$

Thus without symmetrization the probability that the ith qubit shows an error is

$$|c_i|^2\delta t^2 \approx 4\epsilon^2\delta t^2. \tag{13}$$

If we expand out the product in (12) we obtain 2^R terms corresponding to the exponentially large dimension of the full space of R qubits. However, the amplitudes of terms involving k errors (i.e., products of $|0\rangle$'s and $|1\rangle$'s involving k $|1\rangle$'s) will have size $O(\delta t^k)$ and only the R terms involving one error will have size $O(\delta t)$. Thus the erroneous state (12) does not occupy these exponentially many dimensions of $\mathcal{H}^R$ equally. We noted previously that $\mathcal{SYM}$ is exponentially small inside $\mathcal{H}^R$ but the preceding observation indicates that $\mathcal{SYM}$–projection will not generally remove *exponentially* much of the error since only R of these exponentially many dimensions are entered (to lowest order) by the erroneous evolution. We now calculate the stabilizing effect of the $\mathcal{SYM}$-projection.

Consider the basis of $\mathcal{SYM}$ given by the $R+1$ orthonormal states (cf. (4) for the case $R = 3$):

$$|e_k\rangle = \frac{1}{\sqrt{{}^RC_k}} \sum_{\text{all } \text{“}k\text{-error”}\ \sigma\text{'s}} |\sigma\rangle\,, \qquad k = 0, \ldots, R. \tag{14}$$

Here the sum is over all ${}^RC_k$ possible strings of 0's and 1's of length R containing exactly k 1's and $R-k$ 0's. Under $\mathcal{SYM}$-projection the lowest order error terms (single-error terms) of (12) will project only onto $|e_1\rangle$. For the term with an error in the kth place we get

$$ic_k\delta t\,|0\rangle \ldots |0\rangle\,|1\rangle\,|0\rangle \ldots |0\rangle \qquad \underset{\longrightarrow}{\mathcal{SYM}\text{ proj}} \qquad \frac{ic_k\delta t}{\sqrt{{}^RC_1}}\,|e_1\rangle\,.$$

Thus the normalized projected state has the form

$$\left\{1 + i\delta t \sum_{j=1}^{R} a_j\right\} |0\rangle \ldots |0\rangle + \alpha_1\,|e_1\rangle + O(\delta t^2)$$

where

$$\alpha_1 = \frac{i\delta t}{\sqrt{R}} \sum_{j=1}^{R} c_j. \tag{15}$$

To estimate the size of α_1, using (11) we write $c_j \approx 2\epsilon e^{i\theta_j}$ where θ_j are random phases. The expectation value of α_1 is then clearly zero but from

$$\text{Expectation value of } \left|\sum_{j=1}^{R} e^{i\theta_j}\right| = \sqrt{R} \tag{16}$$

we get [1]

$$\text{Expectation value of } |\alpha_1|^2 = 4\epsilon^2\delta t^2. \tag{17}$$

Thus, somewhat surprisingly, this probability of a single symmetrized error does not decrease with R. However, it is associated with R copies and to see its residual effect on any *one* copy we use the following fact.

PROPOSITION 1. *Consider the state*

$$|\Xi\rangle = \sum_{k=0}^{R} \alpha_k |e_k\rangle \in \mathcal{SYM} \subseteq \mathcal{H}^R$$

where $|e_k\rangle$ *are as given in* (14). *If one qubit is measured in the basis* $\{|0\rangle, |1\rangle\}$ *the probability of obtaining* $|1\rangle$ *is* $\frac{1}{R}\sum_{k=0}^{R} |\alpha_k|^2 k$.

Proof. Since the state is symmetric the probability of obtaining the result $|1\rangle$ for the ith qubit is the same as this probability for the first qubit. Now $|e_k\rangle$ in (14) consists of ${}^{R}C_k$ orthogonal terms of which ${}^{R-1}C_{k-1}$ have $|1\rangle$ in the first place. Hence, the term $\alpha_k |e_k\rangle$ in $|\Xi\rangle$ contributes probability

$${}^{R-1}C_{k-1} \left|\frac{\alpha_k}{\sqrt{{}^{R}C_k}}\right|^2 = |\alpha_k|^2 k/R$$

of obtaining outcome $|1\rangle$. □

Applying this result to (15) and using (17) we see that after successful symmetrization the probability of error (to lowest order in δt) is $4\epsilon^2\delta t^2/R$, i.e., the error is suppressed by a factor of $1/R$ compared to the case (13) of no symmetrization and in each step the amplitude of correct computation is correspondingly enhanced.

The above result is conditional on the success of the symmetrization, i.e., that the state projects to $\mathcal{SYM}$ rather than $\mathcal{SYM}^{\perp}$. If the projections are done frequently enough then the cumulative probability that they *all* succeed can be made as close as desired to unity. This is a consequence of the so-called "quantum watched pot effect" [16]. Consider a normalized joint state $|\Xi\rangle$ of R copies initially in $\mathcal{SYM}$. Its initial probability of successful projection is 1 which is a *maximum*. Thus as the state evolves by some unitary transformation into the ambient space $\mathcal{H}^R$ the probability of successful projection will begin to change only to second order in time. If we project n times per unit time interval, i.e., $\delta t = 1/n$ then the cumulative probability that all projections in one unit time interval succeed, is

$$(1 - k\delta t^2)^n = \left(1 - \frac{k}{n^2}\right)^n \to 1 \text{ as } n \to \infty.$$

[1] *Remark* [21]. If instead of qubit systems we consider computers with dimensions large compared to the degree of redundancy R, then we would expect the individual random errors to be mutually orthogonal, so when the state is symmetrized their sum does not exhibit the cancelling effects which are present for qubits and lead to (16) and (17). However in that case, (17) and subsequent conclusions still hold because (16) may be replaced by Pythagoras' theorem, i.e., that the sum of R orthonormal vectors has length $\sqrt{R}$.

Here k is a constant depending on the rate of rotation of the state out of $\mathcal{SYM}$. For redundancy degree R and the model of random unitary errors considered above we find that k grows linearly with R (as can be seen by directly calculating the length of the $\mathcal{SYM}$-projection of (12) to $O(\delta t^2)$ terms). Thus to achieve a cumulative probability of successful projection of $1-\zeta$ in a unit time interval we would require a rate of symmetric projection which increases linearly with $-R/\log(1-\zeta)$.

The above conclusions—for a model of random independent unitary errors—will also apply to computations which are not the identity. Formally, we may view the computation in a moving basis relative to which the correct computation is the identity and the previous arguments are unchanged, i.e., none of the arguments depends on the actual identity of the computational basis states.

6. Stabilization against environmental interaction. We now consider the problem of state storage with R-fold redundancy, in the presence of decoherence, i.e., interaction with an external environment. In general each qubit will become entangled with an environment and the state of the qubit alone will no longer be describable by a pure state. It will be represented by a density matrix [16] resulting from forming a partial trace over the environment, of the joint (pure) state of the total qubit-environment system.

Consider R copies of the qubit initially all prepared in pure state $\rho_0 = |0\rangle\langle 0|$. We will assume that they interact with independent environments (this assumption is valid if the coherence length of the reservoir is less than the spatial separation between the copies [6]) so that after some short period of time δt the state of the R copies will have undergone an evolution

$$\rho^{(R)}(0) = \rho_0 \otimes \cdots \otimes \rho_0 \quad \longrightarrow \quad \rho^{(R)}(\delta t) = \rho_1 \otimes \cdots \otimes \rho_R, \tag{18}$$

where $\rho_i = \rho_0 + \sigma_i$ for some Hermitian traceless σ_i and the superscript R denotes the number of states involved. We will retain only terms of first order in the perturbations σ_i so that the overall state at time δt is

$$\begin{aligned} \rho^{(R)} = \rho_0 \otimes \cdots \otimes \rho_0 &+ \sigma_1 \otimes \rho_0 \otimes \cdots \otimes \rho_0 \\ &+ \rho_0 \otimes \sigma_2 \otimes \cdots \otimes \rho_0 \ldots \\ &+ \rho_0 \otimes \rho_0 \otimes \cdots \otimes \sigma_R \\ &+ O(\sigma_i \sigma_j), \end{aligned} \tag{19}$$

and we wish to compute the projection of the state (19) into the symmetric subspace $\mathcal{SYM}$. Then we construct the state of the ith qubit by partial trace over all qubits except the ith and finally compare the resulting state with $\rho_0 + \sigma_i$ and see that its purity has been suitably enhanced, bringing it closer to ρ_0.

The mathematical formalism for symmetrization of mixed states has some curious features which we digress to clarify before treating (19) itself. Consider a state $\rho_1 \otimes \rho_2$ of two qubits. The state $\frac{1}{2}(\rho_1 \otimes \rho_2 + \rho_2 \otimes \rho_1)$ is *not* a symmetric state and in fact $\rho \otimes \rho$ is not symmetric (i.e., it is not a density matrix supported on the subspace $\mathcal{SYM}$) unless ρ is pure! To see this consider ρ written in its diagonalizing basis of orthonormal eigenstates:

$$\rho = \lambda_1 |\lambda_1\rangle\langle\lambda_1| + \lambda_2 |\lambda_2\rangle\langle\lambda_2|. \tag{20}$$

Thus we can represent ρ as a mixture of its two eigenstates, and $\rho \otimes \rho$ as a mixture of the four orthonormal states $|\lambda_i\rangle \otimes |\lambda_j\rangle$ with a priori probabilities $p_{ij} = \lambda_i \lambda_j$. This latter mixture involves *nonsymmetric* states (like $|\lambda_1\rangle \otimes |\lambda_2\rangle$) so $\rho \otimes \rho$ is not symmetric.

One way of constructing the projection of $\rho \otimes \rho$ into $\mathcal{SYM}$ is to project each state of the above mixture into $\mathcal{SYM}$. Let $|\mu_{ij}\rangle$ denote the $\mathcal{SYM}$-projection of $|\lambda_i\rangle \otimes |\lambda_j\rangle$ and $|\hat{\mu_{ij}}\rangle$ denote the corresponding normalized state. The probability of successful projection is $q_{ij} = \langle \mu_{ij} | \mu_{ij} \rangle$. Then the $\mathcal{SYM}$-projection of $\rho \otimes \rho$ is the state corresponding to the mixture $|\hat{\mu_{ij}}\rangle$ with a priori probabilities $p_{ij}q_{ij}/(\sum p_{ij}q_{ij})$, which are the conditional probabilities of occurrence of states $|\hat{\mu_{ij}}\rangle$ given that the $\mathcal{SYM}$-projection was successful.

More formally we may introduce the (Hermitian) permutation operators $P_{12} =$ "identity" and $P_{21} =$ "swap" acting on pure states of two qubits and define the symmetrization operator:

$$S = \frac{1}{2}(P_{12} + P_{21}). \tag{21}$$

The $\mathcal{SYM}$-projection of a pure state $|\Psi_{12}\rangle$ of two qubits is just $S\,|\Psi_{12}\rangle$, which is then renormalized to unity. It follows that the induced map on *mixed* states of two qubits (including renormalization) is

$$\rho_1 \otimes \rho_2 \longrightarrow \frac{S(\rho_1 \otimes \rho_2)S^\dagger}{\operatorname{Tr} S(\rho_1 \otimes \rho_2)S^\dagger}. \tag{22}$$

The state of either qubit is obtained separately by partial trace over the other qubit.

As an example consider the symmetric projection of $\rho \otimes \rho$ followed by renormalization and partial trace (over either qubit) to obtain the final state $\tilde{\rho}$ of one qubit, given that the $\mathcal{SYM}$-projection was successful. A direct calculation based on (22) yields

$$\rho \mapsto \tilde{\rho} = \frac{\rho + \rho^2}{\operatorname{Tr}(\rho + \rho^2)}. \tag{23}$$

For any mixed state ξ of a qubit the expression $\operatorname{Tr} \xi^2$ provides a measure of the purity of the state, ranging from $1/4$ for the completely mixed state $I/2$ (where I is the unit operator) to 1 for any pure state. From (23) we get

$$\operatorname{Tr} \tilde{\rho}^2 > \operatorname{Tr} \rho^2$$

so that $\tilde{\rho}$ is *purer* than ρ. This example illustrates a generic fact (cf. below), that successful projection of a mixed state into $\mathcal{SYM}$ tends to enhance the purity of the individual systems. Indeed, consider further the state $\otimes^R \rho$ consisting of R independent copies of ρ. The symmetrization operator is

$$S = \frac{1}{R!} \sum_{\alpha=1}^{R!} P_\alpha, \tag{24}$$

where the sum ranges over all $R!$ permutations of the R indices. If we project $\otimes^R \rho$ into $\mathcal{SYM}$ and renormalize (as in (22)) and calculate the partial trace over all but one of the qubits, we obtain a reduced state $\tilde{\rho_R}$ which asymptotically tends to a *pure* state as $R \to \infty$. This limiting pure state is the eigenstate of ρ belonging to its largest eigenvalue.

Let us now return to the consideration of (19) and its $\mathcal{SYM}$-projection. The application of the symmetrization operator (24) to each of the R terms of $\rho_0 \otimes \cdots \otimes$

$\sigma_i \otimes \cdots \otimes \rho_0$ of equation (19) generates $R!^2$ terms of the form

$$\frac{1}{R!^2} P_\alpha \rho_0 \otimes \cdots \otimes \sigma_i \otimes \cdots \otimes \rho_0 P_\beta, \tag{25}$$

where P_α and P_β are permutation operators on the state space $\mathcal{H}^R$ of R qubits as above. To calculate the reduced density operator of the first qubit we take the partial trace over the $R-1$ remaining qubits. Note that the reduced states of all qubits individually are equal since the total overall state is symmetric. (To systematize the calculation of the partial traces we have found it very convenient to use the diagrammatic notation for tensor operations introduced by Penrose in [22].) For each σ_i we find that the $R!^2$ terms in (25) then reduce to the following cases:

(i) $(R-1)!^2$ terms each equal to $\sigma_i/R!^2$ corresponding to all permutations P_α and P_β which place σ_i in the first position in (25). In this case the partial trace contracts out all the ρ_0 terms leaving a coefficient of $1/R!^2$ (as the trace of any power of ρ_0 is 1).

(ii) $(R-1)!^2(R-1)R$ terms of the forms $\rho_0\sigma_i\rho_0$, $\rho_0\sigma_i$, $\sigma_i\rho_0$, or $\rho_0\mathrm{Tr}(\sigma_i\rho_0)$, each one divided by $R!^2$. These correspond to all pairs of permutations which result in σ_i contracted onto ρ_0 in all possible ways in the partial traces.

(iii) $(R-1)!^2(R-1)$ terms which result in σ_i being contracted onto itself in the partial traces. These terms are all zero since $\mathrm{Tr}\,\sigma_i = 0$.

Note that each term in (ii) has trace given by $\mathrm{Tr}\,\sigma_i\rho_0/R!^2$ and each term in (i) has zero trace. Thus the resulting density operator, before normalization, has a trace given by

$$1 + (R-1)\mathrm{Tr}(\rho_0\tilde{\sigma}), \tag{26}$$

where we have introduced $\tilde{\sigma} = \frac{1}{R}\sum_{i=1}^{R}\sigma_i$. We normalize the density operator by dividing the sum of all terms in (i) and (ii) for all $i = 1, \ldots, R$ by (26), the resulting symmetrized density operator $\tilde{\rho}$ can be written

$$\begin{aligned}\tilde{\rho} = {} & [1-(R-1)\mathrm{Tr}(\rho_0\tilde{\sigma})]\rho_0 + \frac{1}{R}\tilde{\sigma} \\ & + (R-1)[A\rho_0\tilde{\sigma}\rho_0 + B(\rho_0\tilde{\sigma} + \tilde{\sigma}\rho_0) + C\rho_0\mathrm{Tr}(\tilde{\sigma}\rho_0)] + O(\sigma_i\sigma_j),\end{aligned} \tag{27}$$

where A, B, and C depend on R and $A + 2B + C = 1$.

If a general mixed state ξ of a qubit is measured in the basis $\{|0\rangle, |1\rangle\}$ then the probability that the outcome is 0 is given by $\langle 0|\,\xi\,|0\rangle = \mathrm{Tr}\,\rho_0\xi$. This provides the success probability in our present model. Thus the average success probability *before* symmetrization of the perturbed qubits is

$$\frac{1}{R}\sum_i \mathrm{Tr}\,\rho_0(\rho_0 + \sigma_i) = 1 + \mathrm{Tr}\,\rho_0\tilde{\sigma} \tag{28}$$

(note that consequently $\mathrm{Tr}\,\rho_0\tilde{\sigma}$ is necessarily negative). *After* symmetrization, using (27) we see that

$$\mathrm{Tr}\,\rho_0\tilde{\rho} = 1 + \frac{1}{R}\mathrm{Tr}\,\rho_0\tilde{\sigma}. \tag{29}$$

Hence, the probability of error has again been reduced by a factor of R—exactly as found in the previous section.

We can calculate the average purity of the R copies before symmetrization by calculating the average trace of the squared states:

$$\frac{1}{R}\sum_{i=1}^{R}\mathrm{Tr}((\rho_0+\sigma_i)^2) = 1 + 2\mathrm{Tr}(\rho_0\tilde{\sigma}). \tag{30}$$

After symmetrization each qubit has purity

$$\mathrm{Tr}(\tilde{\rho}^2) = 1 + 2\frac{1}{R}\mathrm{Tr}(\rho_0\tilde{\sigma}). \tag{31}$$

Since $\mathrm{Tr}\,\tilde{\rho}^2$ is closer to 1 than (30), the resulting symmetrized system $\tilde{\rho}$ is left in a purer state. Indeed it follows from (29) that $\tilde{\rho}$ approaches the unperturbed state ρ_0 as R tends to infinity.

7. Limitations. Error correction is itself a quantum computation. The above analysis has ignored the inevitable build up of errors in the computer performing that computation. Indeed for the symmetrization of R qubits the projection algorithm requires an ancilla of at least $R!$ dimensions, i.e., $O(R\log R)$ qubits (in fact $O(R^2)$ in our explicit network). Thus the correcting apparatus is slightly larger than the total system being corrected so the error correction ought to be subject to a similar level of error as is present in the original system. In a situation where the redundancy degree R is small compared to the number L of qubits per computer, the correcting apparatus (still of $O(R^2)$ qubits) will be small compared to the size RL of the system being corrected. However, as seen in section 5, the stabilization of a linear computation on input size L requires redundancy degree $R \sim L$ so that the correcting apparatus and the computer are again of comparable size. This means that each error correcting step introduces errors of a similar, or even greater, probability than those it is correcting. This does not, however, necessarily render it ineffective. Consider the following illustrative example. A certain clock is accurate to one second per day. Each day at noon it is reset using a standard time signal, the resetting operation being accurate only to one minute, i.e., 60 times worse than the error being corrected. Nevertheless, after 10 years the corrected clock will still be in error by at most one minute. If left uncorrected the error could be almost an hour. In our stabilization method the analogue of "resetting noon to within one minute" is projection into $\mathcal{SYM}$ with some error tolerance. Thus although the projection is imperfect, the state never drifts very far from $\mathcal{SYM}$ as it would do in the absence of any stabilization.

The main factor limiting the efficiency of our proposed method will be the frequency with which the error correcting operations can be physically performed. As noted at the end of section 5, to achieve a cumulative probability $1-\delta$ of repeated successful projection in a unit time interval, the rate of symmetric projection must increase linearly with the degree of redundancy R. Also as noted in section 1, the stabilization of a computer with input size L, running for L steps, requires R to increase linearly with L. Hence, we need the overall rate of symmetric projection to increase linearly with L even for a linear time computation. Thus, beyond a certain input size, each symmetrization will have to be performed in a time shorter than that needed to perform the elementary quantum gate operations. Since increasing the rate of computation by a factor k presumably requires resources exponential in k, our method would necessarily require exponential resources for sufficiently large L. This property is shared by all quantum error correction schemes that have been proposed to date. Hence quantum algorithms (such as Shor's factoring algorithm), which are

polynomially efficient in the absence of errors, would not be efficient if physically implemented. We wish to stress that the traditional notion of efficiency (based on the distinction between polynomial and exponential growth) is an asymptotic notion referring to computations on unboundedly large inputs. This may not be appropriate in assessing the feasibility of particular computations in practice. For example, if a quantum computer could factorize a 1000-digit integer in a reasonable time it may still exceed the abilities of any classical computer for the foreseeable future albeit that the factorization of 2000-digit integers might be infeasible on *any* computer.

8. Conclusion. If the technology to implement the scheme we have described were available, it would provide a method of stabilizing general coherent computations though not with exponential efficiency. This is because although only polynomially many steps are required in the stabilization computation, these need to be performed in a fixed time, a characteristic time of error growth per bit.

Acknowledgments. We wish to thank Dorit Aharonov, Ethan Bernstein, Asher Peres, and Umesh Vazirani for developmental discussions, and Rolf Landauer for critical appraisal. We are grateful for the opportunity of collaboration provided by ELSAG-Bailey, Genova, and the Institute for Scientific Interchange, Torino.

THE RANDOM ADVERSARY: A LOWER-BOUND TECHNIQUE FOR RANDOMIZED PARALLEL ALGORITHMS*

PHILIP D. MACKENZIE†

Abstract. The random-adversary technique is a general method for proving lower bounds on randomized parallel algorithms. The bounds apply to the number of communication steps, and they apply regardless of the processors' instruction sets, the lengths of messages, etc. This paper introduces the random-adversary technique and shows how it can be used to obtain lower bounds on randomized parallel algorithms for load balancing, compaction, padded sorting, and finding Hamiltonian cycles in random graphs. Using the random-adversary technique, we obtain the first lower bounds for randomized parallel algorithms which are provably faster than their deterministic counterparts (specifically, for load balancing and related problems).

Key words. parallel algorithms, parallel computation, PRAM model, randomized parallel algorithms, expected time, lower bounds, load balancing

1. Introduction.

Randomization has been a useful tool in developing fast parallel algorithms for a vast spectrum of problems, from computational geometry and graph theory to routing and load balancing. Often these randomized parallel algorithms are significantly faster than the best possible deterministic parallel algorithms. This prompts the question, "To what extent can randomization improve the speed of parallel algorithms?" We have developed the random-adversary technique to help answer this question.

The random-adversary technique can be thought of as an extension or generalization of the random-restriction technique [18]. It is the most general technique to date, and in fact, to date, all known asymptotic lower bounds for the randomized parallel random access machine (PRAM) model (which assume no restrictions on processors' instruction sets nor restrictions on memory) can be proven using the random-adversary technique. In this paper, we will focus on lower bounds for the strongest of the PRAM models, the concurrent-read concurrent-write (CRCW) PRAM. There has been a tremendous amount of work in the area of lower bounds on this model, and tight lower bounds have been shown for many fundamental problems in the deterministic case [4, 5, 8, 9, 11, 14, 16, 25]. The only previous parallel randomized lower bounds known for this model (again, which assume no restrictions on processors' instruction sets nor restrictions on memory), however, were the lower bounds for parity and related problems [1, 4, 31]. Using the random-adversary technique, we have been able to prove lower bounds on the randomized CRCW PRAM model for many other problems, including the fundamental load-balancing problem. Moreover, the random-adversary technique seems to be a very natural way for proving these lower bounds. One key feature of the method is that one abstracts the difficulty of the problem (by

specifying the inputs that are difficult for an algorithm to deal with) before getting into the detailed mechanics of the proof. Hopefully, this idea, and the outline of the technique given later, will make it easier for researchers to prove lower bounds for parallel randomized algorithms solving other problems. We certainly feel that given its natural and fairly easy structure, the random-adversary technique should be the first method one should try in proving any new lower bounds for parallel randomized algorithms.

1.1. Load balancing. One of the most important applications of our technique so far is to the problem of load balancing, which is one of the most fundamental problems in parallel computing. While load balancing is implicit in most deterministic PRAM algorithms, it is often necessary to have an explicit load-balancing procedure in randomized PRAM algorithms. In these algorithms some processors might finish quickly, and to make full use of them, they must be reallocated to help processors which have not finished. Without this reallocation, the time of the algorithm will be dependent on the processor with the most difficult subproblem. Unfortunately, the time for load balancing itself can also increase the running time of an algorithm, and that is what we will analyze in this paper.

We consider the following *load-balancing* problem, as defined by Gil, Matias, and Vishkin [21].

Load balancing. Given h objects distributed among n processors, redistribute the objects so that each processor gets $O(1 + h/n)$ objects.

Note that under any definition of load balancing, at least one processor will end with $\Omega(1+h/n)$ objects. Consequently, by solving the load-balancing problem defined above, the objects will be balanced in an asymptotically optimal manner. Then, assuming the objects are equal length tasks, after this load-balancing operation the tasks can be completed by the processors in asymptotically optimal time. (Note that for $h \geq n$, a more applicable definition for load balancing might be to redistribute objects so that a constant fraction of the processors contain at least one object. However, for $h \leq n$, the definition given above seems to be more appropriate. We are more concerned with the case of $h \leq n$, but for generality, we expand the definition of the problem to deal with all h.)

In general we would like to perform this load balancing in constant time, since then at each step, processors that have finished their tasks could be reassigned to help some other processors right away. We show, however, that load balancing requires $\Omega(\log^* n)$ expected time. We note that there might be a possibility of *batching* or *pipelining* the load balancing, and so an algorithm which would take $\Theta(f(n))$ time with a constant-time load-balancing operation still might be made to take $o(f(n) \log^* n)$ time. That is beyond the scope of the paper.

Load-balancing procedures have been used in Chlebus et al. [12] to perform simulations of strong CRCW PRAM models on weaker CRCW PRAM models, in MacKenzie and Stout [37] for padded sorting, finding nearest neighbors, and constructing the Voronoi diagram, in Gil and Matias [20] to perform parallel hashing, in Hagerup [27] to perform integer chain-sorting, and in Goodrich [24] to construct upper envelopes, answer range queries, and perform hidden surface elimination. Recently, Gil, Matias, and Vishkin [21], Hagerup [27], and Goodrich [24] have all developed $\Theta(\log^* n)$ expected time randomized load-balancing algorithms for worst-case inputs, so the lower bound given in this paper is tight. (The algorithm in Goodrich [24] is for a slightly less general load-balancing problem.)

We will also show $\Omega(\log^* n)$ time lower bounds for the related problems of padded

sorting [37] and compaction [22, 28] on the CRCW PRAM. The definitions for these problems are as follows.

Padded sort. Given n values taken from a uniform distribution over the unit interval $[0, 1]$, arrange them in sorted order in an array of size $n + o(n)$, with the value NULL in all unfilled locations.

Compaction. Given an array of n cells with at most h containing one item each and all others being empty, insert the items into an array of size $O(h)$.

Matias and Vishkin [39] give a $\Theta(\log^* n)$ expected time algorithm for compaction with arbitrary $h \in \{1, \ldots, n\}$, and Hagerup and Raman [29] give a $\Theta(\log^* n)$ expected time algorithm for padded sort. Consequently, our lower bounds are tight.

Recently, Chaudhuri [10] gave an $\Omega(\log \log n)$ deterministic lower bound for compaction, proving that randomization is necessary in obtaining a faster solution. Our lower bound for compaction is the first for a problem that has a provably faster parallel randomized solution than parallel deterministic solution.

We should mention that a further result obtained from the lower bound on compaction is an $\Omega(\log^* n)$ time separation between the standard randomized CRCW PRAM and the randomized CRCW-bit PRAM [6], in which $O(\log^{(k)} n)$ processors are allowed to simultaneously write into different bits of the same word, for some constant $k \geq 1$. This follows from the constant time algorithm for compaction in the randomized CRCW-bit PRAM model given by Goodrich [24].

1.2. Random graph properties. By a *random graph on n vertices*, denoted $G_{n,p}$, we mean that each of the $\binom{n}{2}$ edges is included with probability p, where p is a constant, $0 < p < 1$. Random graphs have been extensively studied and have very interesting properties. For instance, with high probability, in $G_{n,p}$ a Hamiltonian cycle exists; every breadth first spanning tree has height 2; and, for n even, there is a maximal matching which includes all the vertices.

Bollobás, Fenner, and Frieze [7] give an algorithm which constructs a Hamiltonian cycle in $G_{n,p}$ if one exists. This algorithm runs in polynomial expected time for $p \geq 1/2$ [7, Theorem 1.2]. Gurevich and Shelah [26] and Thomason [40] independently improve on this result, giving algorithms which run in linear expected time for any constant p. These algorithms are optimal, since linear time is needed just to write the output. Frieze [17] gives a parallel algorithm which constructs a Hamiltonian cycle from $G_{n,p}$ in $O((\log \log n)^2)$ expected time and uses $n \log^2 n$ processors. MacKenzie and Stout [38] show that one can find a Hamiltonian cycle, a maximal matching, and a breadth first spanning tree in $G_{n,p}$, all in $\Theta(\log^* n)$ expected time using only $n/\log^* n$ processors.

Implicit in each of the problems above is finding an *edge cover*. Using the random-adversary technique we show that finding an edge cover in $G_{n,p}$ from its adjacency matrix requires $\Omega(\log^* n)$ expected time on an n processor CRCW PRAM. MacKenzie and Stout [38] give a simpler proof specific to this problem, but we wish to show how the much more general random-adversary technique can produce the same lower bound.

1.3. Parity on CRCW PRAMs. The random-adversary technique can also prove a lower bound for computing parity using a randomized CRCW PRAM algorithm. The problem of parity is important in that lower bounds for computing parity (using a polynomial number of processors) provide lower bounds for sorting, bit summation, majority, and many other problems (see [4]).

Beame and Håstad [4] gave an $\Omega(\log n/\log \log n)$ lower bound for determinstic

CRCW PRAM algorithms, which matched the known upper bound. Using the results of Ajtai and Ben-Or [1] on converting randomized circuits into deterministic circuits, one could show that this lower bound also holds for randomized CRCW PRAM algorithms. This can also be shown more directly. Beame and Håstad show that given a uniform distribution of inputs, with nonzero probability an algorithm taking fewer than $\Omega(\log n/\log\log n)$ steps will output an incorrect answer, but Håstad [32] shows that in the circuit model, this can be extended to high probability. With minor adjustments, the high probability result also holds in the CRCW PRAM model, and it was known that by using Yao's theorem [41], one could obtain the equivalent lower bound for randomized algorithms over a worst case input. This is actually the first example of the random-adversary technique, though not in its most general form. (It would not be sufficient to prove many of the other lower bounds shown in this paper.)

1.4. Related results. The random-adversary technique has been used in MacKenzie [36] to prove lower bounds for computing some Boolean functions on exclusive-write PRAMs which asymptotically match the previous best lower bounds in Dietzfelbinger, Kutyłowski, and Reischuk [13] (and, in fact, improve the constants on some of those lower bounds) and to prove lower bounds on restricted domain compaction problems on exclusive-write PRAMs.

The random-adversary technique has also been used in Goldberg, Jerrum, and MacKenzie [23] to prove a lower bound for a fundamental routing problem on the optical communication parallel computer (as defined by Anderson and Miller [2] under the name "local memory PRAM"). We refer the reader to that paper for a full overview of the results and a discussion of the model and the specific routing problem.

Finally, the random-adversary technique has been used in MacKenzie [35] to prove a lower bound for compaction on the queue-read queue-write (QRQW) PRAM (see Gibbons, Matias, and Ramachandran [19] for a description of the QRQW PRAM).

2. Definitions. In this paper, we will be concerned only with the PRAM model. See [23] for the definition changes required for the optical communication parallel computer (OCPC) model. Relevant definitions for other models should be relatively easy to develop.

In the PRAM model, processors communicate by reading and writing to a global shared memory. The PRAM model is further subdivided depending on whether concurrent accesses are allowed to memory on reads and/or writes. An exclusive-read (ER) model does not allow concurrent reads to a memory cell, whereas a concurrent-read (CR) model does allow concurrent reads. An exclusive-write (EW) model does not allow concurrent writes to a memory cell, whereas a concurrent-write (CW) model does allow concurrent writes. On concurrent writes, there is also the issue of a contention protocol. In the priority CW model, if two or more processors write to any memory cell, the lowest-numbered processor succeeds in writing its value to that cell. (For more information on PRAM models see, for example, [34].)

Consider an algorithm with multiple inputs. An instantiation of the set of inputs to this algorithm will be called an *input map*. (This will be defined formally in the next section.) We define a *randomized algorithm* as one in which each processor can generate some number of random bits. In our lower bounds, we make no assumption on the number of random bits a processor can generate. The *expected time* of a randomized algorithm will be the average time of the algorithm over the distribution of input maps and the random bits. If we make no assumptions on the distribution of input maps, then the expected time will simply be the worst of the average times (taken over the random bits) for any input map.

We define *high probability* as meaning probability at least $1 - n^{-1}$, and we define *very high probability* as meaning probability at least $1 - e^{-n^{\alpha}}$ for some constant $\alpha > 0$.

For any base $z \geq 2$, we define $\log_z^{(1)} n$ as $\log_z n$ and $\log_z^{(i)} n$ as $\log_z(\log_z^{(i-1)} n)$. We define $\log_z^* n$ as the smallest integer i such that $\log_z^{(i)} n \leq 1$. When z is omitted we assume base 2. It is well known that $\log^* n$ is an extremely slow growing function of n, and, in fact, $\log^* n \leq 5$ for $n \leq 2^{65536}$. Lemma A.1 in the appendix shows a relation between $\log^*$ functions with different bases.

3. Random-adversary technique. The random-adversary technique allows one to prove a lower bound on the time required for a parallel randomized algorithm to solve a given problem. The first step of the technique is to decide on an input distribution for the problem. By Yao's theorem (see below), a lower bound on deterministic algorithms over this distribution provides the same lower bound for randomized algorithms.

The next step is to create a random adversary that proceeds through the given deterministic algorithm step by step, fixing some of the inputs in order to ensure some desired properties. (As shown below, this entails filling in the details of a procedure called REFINE.) Note that the random adversary is similar to a standard deterministic adversary in most parallel lower-bound proofs. However, unlike deterministic adversaries that can fix inputs arbitrarily, the random adversary must fix inputs according to the chosen input distribution, i.e., using the procedure RANDOMSET, as described below. Also, depending on how RANDOMSET fixes the inputs, the desired properties might not hold. Therefore, it is possible that the random adversary might have to make repeated calls to RANDOMSET to ensure the desired properties.

The final step is to show that these desired properties (such as knowledge about the inputs still being widely dispersed among the processors and that the number of inputs left unset is still large) hold with some given probability.

In the rest of this section we formalize this method.

3.1. Definitions. Let P be a problem with multiple inputs and let I be the set of inputs to P. Let Q be the set of possible values to which each input could be set. Define a *partial input map* to be a function f from I to $\{\{*\} \cup Q\}$. Here "$*$" will denote a "blank" or "unset" input. A partial input map is an *input map* if no inputs are mapped to "$*$." Let f_* denote the partial input map which maps every input to "$*$." A partial input map f' is called a *refinement* of a partial input map f if for all $i \in I$, and $q \in Q$, $f(i) = q$ implies $f'(i) = q$. (We denote this by $f' \leq f$.) If we wish to restrict our attention to a subset of the possible input maps, we would call that subset the *relevant input maps.* Likewise, we would say that a partial input map is a *partial relevant input map* if it has a refinement that is a relevant input map. We will often omit the word relevant when it is clear from the context.

3.2. Yao's theorem. The following theorem shows that a lower bound on the average time of a deterministic algorithm over any distribution of input maps implies the same lower bound for the expected time of any randomized algorithm over a worst-case input map or over the same distribution of input maps.

THEOREM 3.1 (see Yao [41]). *Let $\mathcal{D}$ be a distribution of input maps. Let T_1 be the expected running time for a randomized algorithm solving problem P, either over a worst-case input map or over the distribution $\mathcal{D}$. Let T_2 be the average running time over the distribution $\mathcal{D}$, minimized over all possible deterministic algorithms that solve P. Then $T_1 \geq T_2$.*

A nice proof of this theorem is given in Fich et al. [16].

Function RANDOMSET(f, S)
For each $i \in S$ (sequentially)
    Set $f(i)$ according to the conditional distribution of i given that
        the input is drawn from $\mathcal{D}$ and is a refinement of f
Return f
End RANDOMSET

FIG. 3.1. *The RANDOMSET function.*

This theorem greatly simplifies the problem of proving lower bounds for randomized algorithms, as it converts the original problem to one where the only randomness comes from the distribution of input maps, and this can often be set as one wishes. It is of course necessary to choose a distribution that will be difficult for any deterministic algorithm. Note that the distribution cannot place all the probability on one input map (i.e., a worst-case input map), since then a simple deterministic algorithm which checks for this input map and outputs the precomputed answer will succeed with probability 1.

3.3. RANDOMSET procedure. We will assume the distribution chosen is $\mathcal{D}$. Function RANDOMSET in Figure 3.1 can be used to randomly generate an input map one input at a time. It is called with a partial input map f obtained through calls to RANDOMSET and a set S of elements which are mapped to "$*$." The elements in S are then randomly set one by one according to the distribution $\mathcal{D}$, conditional on f.

CLAIM 3.2. *If f is generated solely by calls to RANDOMSET, then f will be generated according to the distribution $\mathcal{D}$.*

Proof. The proof is straightforward. □

3.4. REFINE and GENERATE. Say f is t-good if it satisfies certain properties, which will be defined with respect to the problem P and the input distribution $\mathcal{D}$. For some $T \leq n$, we would like to prove that the problem P cannot be solved in T steps. Let A be an algorithm which allegedly solves problem P over the input distribution $\mathcal{D}$ in T steps.

Given this algorithm A, we create a procedure REFINE, which tells the random adversary how to fix the inputs at each step. Formally, REFINE(t, f) takes a time t and a partial input map f and returns a new partial input map f' that is a refinement of f. We need to prove that the procedure REFINE has two important properties, the first of which is concerned with preservation of "t-goodness."

LEMMA 3.3. *If $t < T$ and* REFINE *is called with parameters (t, f), where f is t-good, then with probability at least $1 - n^{-2}$* REFINE *will return a partial input map f' that is $(t+1)$-good.*

The second property is that REFINE is unbiased. Consider the function GENERATE in Figure 3.2 that starts with the partial input map $f_0 = f_*$ and applies REFINE T times to generate a sequence of partial input maps $f_0 = f_* \geq f_1 \geq \cdots \geq f_T \geq f$ in which each $f_t = \text{REFINE}(t, f_{t-1})$ is a refinement of f_{t-1}, and f is an input map generated according to the conditional distribution over $\mathcal{D}$ from the set of refinements of f_T. Then we need to prove the following lemma.

LEMMA 3.4. *The input map f returned by* GENERATE *is generated according to the distribution $\mathcal{D}$.*

```
Function GENERATE
    Let f_0 = f_*
    Let f = f_0
    Let t = 1
    While t ≤ T Do
        If for some p, f(p) = "*" Then
            Let f_t = REFINE(t, f)
        Else
            Let f_t = f
        Let f = f_t
        Let t = t + 1
    Let P = {p | f(p) = "*"}
    Return RANDOMSET(f, P)
End GENERATE
```

FIG. 3.2. *The GENERATE function.*

In all REFINE procedures we construct in this paper, all inputs are set by calls to RANDOMSET. Consequently, by Claim 3.2, Lemma 3.4 will always hold.

Note that from Lemma 3.3 we also have the following.

LEMMA 3.5. *With probability at least* $1-n^{-1}$*, the partial input map* f_T *is* T*-good.*

Proof. Let Z_t be a binary random variable which is equal to 1 exactly when REFINE returns a t-good function at step t. Then the probability of failing at any step $t \leq T$ is

$$\sum_{t=1}^{T} \Pr(Z_t = 0 \mid Z_{t-1} = 1, \ldots, Z_1 = 1).$$

By Lemma 3.3, this is at most $Tn^{-2} \leq n^{-1}$. □

In summary, to fill in the random-adversary framework for a specific problem P, we must specify

1. an input distribution $\mathcal{D}$,
2. a definition for t-good,
3. a function REFINE,
4. a time T, and
5. a proof for Lemma 3.3.

Once this is done, we can use Lemmas 3.4 and 3.5, along with the specific definition of t-good, to prove the desired lower bound. Since this is highly problem dependent, we do not include it in the description of the general random-adversary technique.

3.5. Comparison to random restriction. In the random-restriction procedure first used in Furst, Saxe, and Sipser [18], a random set of inputs is randomly set according to a uniform distribution over binary inputs. The random adversary extends this idea to carefully chosen sets of inputs, and possibly other input distributions, some in which the inputs are not independent. Also, with random restrictions, there was never a notion of possibly setting more inputs in a single step. In the random adversary, the adversary is allowed to randomly set more inputs if the induction hypothesis does not yet hold.

A recent paper by Impagliazzo, Paturi, and Saks [33] gives a proof of a lower bound for the depth of threshold circuits computing majority using a technique similar to the random adversary, where inputs to be randomly set are chosen carefully. However, the inputs are not set according to any predefined distribution. Thus Yao's theorem would not apply, and this would not translate into a lower-bound proof for randomized threshold circuits.

4. PRAM-specific definitions. Let A be any deterministic algorithm for an n processor PRAM, and let f be any input map. $\text{Trace}(p, 0, f)$ is defined to be the tuple $\langle p \rangle$. $\text{Trace}(p, t, f)$ (for $t > 0$) is defined to be the tuple $\langle p, \lambda_1, \ldots, \lambda_t \rangle$ in which λ_j is the contents of the cell read in step j, if any, and λ_j is the null symbol otherwise. Similarly, $\text{Trace}(c, 0, f)$ is defined to be the tuple $\langle c, \lambda_0 \rangle$, where λ_0 is the initial value in cell c. $\text{Trace}(c, t, f)$ (for $t > 0$) is defined to be the tuple $\langle c, \lambda_0, \ldots, \lambda_t \rangle$ in which λ_j is the contents of the cell after step j.

For the following, assume that v is either a processor or a cell. Let g be any relevant partial input map. We will define $\text{Know}(v, t, g)$ as the smallest set of inputs such that the following property PK is satisfied: for any relevant input maps f_1 and f_2 that refine g and have $f_1(q) = f_2(q)$ for all $q \in \text{Know}(v, t, g)$, $\text{Trace}(v, t, f_1)$ is the same as $\text{Trace}(v, t, f_2)$. (Intuitively, v is not dependent on inputs outside $\text{Know}(v, t, g)$, since these could not affect its trace, and v is dependent on every input inside $\text{Know}(v, t, g)$ by the fact that it is the minimum set of inputs which could affect its trace.)

CLAIM 4.1. *For all v, t, g, Know(v, t, g) exists and is unique.*

Proof. $\text{Know}(v, t, g)$ exists since at least one set (the set of all inputs) satisfies PK, and there are a finite number of sets from which the smallest can be chosen.

$\text{Know}(v, t, g)$ is unique since if two sets satisfy PK, then their intersection satisfies PK (i.e., there cannot be two different smallest sets, since the intersection of them is smaller than either and also satisfies PK). To see this consider two sets A and B which satisfy PK. Consider two input maps f_1 and f_2 that refine g and have $f_1(q) = f_2(q)$ for all $q \in A \cap B$. Define f_3 as follows.

$$f_3(q) = \begin{cases} f_1(q) & \text{for } q \in A, \\ f_2(q) & \text{for } q \notin A. \end{cases}$$

Then by the property PK, $\text{Trace}(v, t, f_1) = \text{Trace}(v, t, f_3)$, and $\text{Trace}(v, t, f_3) = \text{Trace}(v, t, f_2)$. Thus $\text{Trace}(v, t, f_1) = \text{Trace}(v, t, f_2)$. □

Let $\text{AffProc}(i, t, g)$ contain each processor p for which $i \in \text{Know}(p, t, g)$. Let $\text{AffCell}(i, t, g)$ contain each cell c for which $i \in \text{Know}(c, t, g)$.

5. General CRCW PRAM lower bound. Before we prove a lower bound on load balancing, we will prove a general lower bound on the amount of information which can be transferred between processors given a general random input.

Assume the set of possible values for inputs $Q = \{v_1, \ldots, v_{|Q|}\}$. The input distribution we will use is that each input is independently assigned value v_j ($1 \leq j \leq |Q|$) with probability p_j for some $p_1, \ldots, p_{|Q|}$ with $p_1 + \cdots + p_{|Q|} = 1$. Let $p_0 = \min\{p_1, \ldots, p_{|Q|}\}$, and $P = 1/p_0$.

We now define the following constants and functions of n: $k_0 = 1$, for $i > 0$ $k_i = (2400P^3)^{k_{i-1}}$, $r_0 = 0$, and for $i \geq 1$, $r_i = (n/8)\sum_{j=1}^{i} 2^{-j}$. Let $T = \log^* n - \log^*(2400P^3) - 3$. Then the following facts are easily proved (use Lemma A.1 for Fact 5.1).

FACT 5.1. $k_T \leq \log \log n$.

FACT 5.2. *For all $i \geq 1$, $r_i \leq n/8$.*

```
    Function REFINE(t, f)
(1)     Let g = f
(2)     For each c ∈ L
(3)         Let g = RANDOMSET(g, Know(c, t, g))
(4)         Let W = WRITE(c, g)
(5)         For each p ∈ W (in order by proc. number)
(6)             Let g = RANDOMSET(g, Know(p, t, g))
(7)             If p does not write to c
(8)                 Next p
(9)         Next c
(10)    Let f' = g
(11)    Return f'
End REFINE
```

FIG. 5.1. *The REFINE procedure.*

A partial input map f is called *t-good* if the following three conditions are satisfied.

1. For each processor or cell v, $|\text{Know}(v, t, f)| \leq k_t$.
2. For each input i, $|\text{AffProc}(i, t, f)| \leq k_t$ and $|\text{AffCell}(i, t, f)| \leq k_t$.
3. f maps at most r_t inputs to something other than "$*$."

We now describe the algorithm REFINE (shown in Figure 5.1) which is called with a time t and a partial input map f, and which returns a partial input map f' which is a random refinement of f. This random refinement is based on the action of algorithm A at step $t+1$. (A step is assumed to be a write followed by a read.) Let U be the set of inputs that f maps to "$*$." Let U' be the set of inputs that f' maps to "$*$." Say a processor p *write-affects* a cell c with a partial input map g if for some input map g' which refines g, p writes to cell c at step $t+1$. Say a cell c *read-affects* a processor p with a partial input map g if for some input map g' which refines g, p reads from cell c at step $t+1$. Let $\text{WRITE}(c, g)$ be the set of processors that write-affect cell c with a partial input map g, and let $\text{READ}(c, g)$ be the set of processors that c read-affects with a partial input map g. Let L be the set of cells for which $|\text{WRITE}(c, f)| \geq (400P^2)^{k_t}$ or $|\text{READ}(c, f)| \geq (400P^2)^{k_t}$. In algorithm REFINE, we simply go through the processors (in order by processor number) which write-affect (with the current partial input map) each cell in L, and randomly set the inputs in their knowledge sets until one is sure to write or none of them write. Note that at step (4), we use the set $\text{WRITE}(c, g)$ instead of $\text{WRITE}(c, f)$. Since $g \leq f$, $\text{WRITE}(c, g) \subseteq \text{WRITE}(c, f)$, but the sets may not be equal. We must use $\text{WRITE}(c, g)$ so as not to set all the inputs in a set $\text{Know}(p, t, g)$ if p has already been forced not to write to cell c by previous refinements to f.

We say REFINE *fixes* a processor p if REFINE executes step (6) for processor p.

The following claim formally proves the intuitive idea that when the inputs that affect the state of a processor or cell are all fixed, then the state of the processor or cell is fixed.

CLAIM 5.3. *Let f be a partial input map, and let v be a processor or cell. Then if f' refines f and for all $i \in \text{Know}(v, t, f)$, $f'(i)$ does not equal "$*$," then $|\text{Know}(v, t, f')| = 0$.*

Proof. Take any input maps f_1 and f_2 which refine f', Then f_1 and f_2 also refine f and for every input $q \in \text{Know}(v, t, f)$, $f_1(q) = f_2(q)$. By the definition of

Know(v,t,f), this implies that Trace(v,t,f_1) = Trace(v,t,f_2). Thus the minimum set that satisfies the necessary conditions for Know(v,t,f') is the empty set. □

The following claim formally proves that REFINE causes the contents of each cell $c \in L$ to become fixed. It does this by fixing the contents of c previous to the step and then fixing processors that possibly write to c one-by-one until either (1) a processor writes a fixed value to the cell and no lower numbered processor writes to the cell, or (2) no processors write to the cell.

CLAIM 5.4. *If f is t-good, and* REFINE(t,f) *returns f', then for every $c \in L$, $|Know(c,t+1,f')| = 0$.*

Proof. From Step 3 of algorithm REFINE and Claim 5.3, |Know$(c,t,f')| = 0$. Let p be the lowest-numbered processor that REFINE causes to write to c, if any. Otherwise, let $p = \infty$. Let g be the partial input map computed just before the set W is found in Step 4 for cell c. Note that for each processor $p' \in$ WRITE(c,g) with $p' \leq p$, |Know$(p',t,f')| = 0$, and thus the action of p' is fixed at step $t+1$ for any input map which refines f'. If $p = \infty$, then for any input map which refines f', no processor writes to c (i.e., no processor affects Trace$(c,t+1,f')$), and thus Know$(c,t+1,f')$ will contain only those inputs in Know(c,t,f'), which is empty. If $p \neq \infty$, then the contents of c will contain the value written by p (i.e., only the inputs in the Know(p,t,f') could affect the Trace$(c,t+1,f')$), and thus Know$(c,t+1,f')$ will contain only those inputs in Know(p,t,f'), which is empty. □

Recall that $U' = \{i \in I | f'(i) = \text{“}*\text{”}\}$.

LEMMA 5.5. *If f is t-good and* REFINE(t,f) *returns f', then* (1) *for each cell c, $|Know(c,t+1,f')| \leq k_{t+1}$;* (2) *for each processor p, $|Know(p,t+1,f')| \leq k_{t+1}$;* (3) *for each input $i \in U'$, $|AffCell(i,t+1,f')| \leq k_{t+1}$; and* (4) *for each input $i \in U'$, $|AffProc(i,t+1,f')| \leq k_{t+1}$.*

Proof. By Claim 5.4, for each cell $c \in L$, Know$(c,t+1,f')$ contains no inputs. For each cell c not in L, Know$(c,t+1,f')$ contains at most those inputs in Know(c,t,f) and those inputs in Know(p,t,f) for each processor p of the $(400P^2)^{k_t}$ processors in WRITE(c,f), and thus affect Trace$(c,t+1,f')$. Therefore |Know$(c,t+1,f')| \leq k_t + k_t(400P^2)^{k_t}$.

For a processor p, let C be the set of cells c such that $p \in$ READ(c,f). Then $|C| \leq |Q|^{k_t}$, since that is the maximum number of possible settings of inputs in Know(p,t,f). Know$(p,t+1,f')$ contains at most the inputs in Know(p,t,f) plus the inputs in Know$(c,t+1,f')$ for each $c \in C$. Therefore |Know$(p,t+1,f')| \leq k_t + |Q|^{k_t}(k_t + k_t(400P^2)^{k_t})$.

For an input $i \in U'$, let P' be the set of processors p for which $i \in$ Know(p,t,f). Then $|P'| \leq k_t$. For a processor $p \in P'$, let C_p be the set of cells c such that $p \in$ WRITE(c,f). Then $|C_p| \leq |Q|^{k_t}$. Thus i could be contained in Know$(c,t+1,f')$ for at most those cells $c \in \bigcup_{p \in P'} C_p$ and each of the at most k_t cells c for which $i \in$ Know(c,t,f). Then i is contained in Know$(c,t+1,f')$ for at most $k_t + k_t|Q|^{k_t}$ cells c.

For an input $i \in U'$, let C be the set of cells c for which $i \in$ Know$(c,t+1,f')$. Then $|C| \leq k_t + k_t|Q|^{k_t}$. Note that $C \cap L = \emptyset$. For a cell $c \in C$, let P_c be the set of processors p such that $p \in$ READ(c,f). Then $|P_c| \leq (400P^2)^{k_t}$. Then i could be contained in Know$(p,t+1,f')$ for at most those processors $p \in \bigcup_{c \in C} P_c$ and the at most k_t processors p for which $i \in$ Know(p,t,f). Then i is contained in Know$(p,t+1,f')$ for at most $k_t + (k_t + k_t|Q|^{k_t})(400P^2)^{k_t}$ processors p.

The four claims in the lemma then follow from the fact that $1 \leq |Q| \leq P$ and Lemma A.2. □

We say that REFINE(t, f) is *successful* if it calls RANDOMSET with at most $\frac{n}{8(2^{t+1})}$ inputs.

LEMMA 5.6. *If f is t-good and REFINE is successful, then f' is $t+1$-good.*

Proof. This follows from Lemma 5.5 and the fact that

$$r_{t+1} - r_t = \frac{n}{8(2^{t+1})}. \qquad \square$$

Without loss of generality, let the cells $c \in L$ be numbered 1 to $|L|$ in the order in which they are processed by REFINE. Let $f'_0 = f$, and let f'_c be the partial input map obtained after REFINE is finished with cell c.

Let M be the set of partial input maps which could possibly be obtained after REFINE is finished with cell $c-1$. For any $g \in M$, let $W_{c,g}$ be the set of processors in WRITE(c, g) and assume without loss of generality that these processors are numbered from 0 to $|W_{c,g}| - 1$. Construct a set $S_{c,g}$ from $W_{c,g}$ inductively by inserting into $S_{c,g}$ the lowest-numbered processor p from $W_{c,g}$ such that Know(p, t, g) is disjoint from Know(p', t, g) for every processor p' already in $S_{c,g}$. Say the jth processor inserted into $S_{c,g}$ has *rank* j.

CLAIM 5.7. *The number of the jth processor inserted into $S_{c,g}$ is at most $k_t^2(j-1)$.*

Proof. Let p be one of the first $j-1$ processors inserted into $S_{c,g}$. Then $|\text{Know}(p, t, g)| \le k_t$, and since for each $i \in \text{Know}(p, t, g)$, $|\text{AffProc}(i, t, g)| \le k_t$, i is contained in Know(p', t, g) for at most k_t processors p'. In total for processor p, Know$(p, t, g) \cap$ Know$(p', t, g) \neq \emptyset$ for at most k_t^2 processors p'. Then at most $k_t^2(j-1)$ processors p' have Know$(p, t, g) \cap$ Know$(p', t, g) \neq \emptyset$ for some p which is one of the first $j-1$ processors inserted into $S_{c,g}$. $\square$

Let $[g]$ be the event that g is the partial input map obtained after REFINE is finished with cell $c-1$. For a set $G \subseteq M$, let $[G]$ be the event that the partial input map obtained after REFINE is finished with cell $c-1$ is contained in G. Let X_c be the random variable denoting the number of processors in $S_{c,g}$ that REFINE fixes while fixing cell c. (Note that the probability distribution of X_c is taken over the calls to RANDOMSET which define which $g \in M$ is used, and over the calls to RANDOMSET for fixing the processors in $S_{c,g}$.) Let Y be a random variable with a geometric distribution with parameter P^{-k_t}.

CLAIM 5.8. *For any real $a \ge 1$ and any $g \in M$ with* $\Pr([g]) > 0$, *$Pr(X_c > a|[g]) \le Pr(Y > a)$.*

Proof. Let $j = \lfloor a \rfloor$. Given $[g]$, the probability that REFINE has not forced any processors numbered no larger than the jth ranked processor in $S_{c,g}$ to write is less than the probability that it has not forced the first j processors in $S_{c,g}$ to write. The probability of the processor of rank i writing given that the processors of ranks 1 through $i-1$ did not write is at least P^{-k_t}, since they are independent, and RANDOMSET sets the at most k_t inputs in Know(i, t, g) randomly. Then

$$\Pr(X_c > a|[g]) \le \prod_{i=1}^{j}(1 - P^{-k_t}) = (1 - P^{-k_t})^j = \Pr(Y > a). \qquad \square$$

CLAIM 5.9. *For any real $a \ge 1$ and any $G \subseteq M$ with* $\Pr([G]) > 0$, *$Pr(X_c > a|[G]) \le Pr(Y > a)$.*

Proof. Note that for any real a, the event $(X_c > a) \wedge [G]$ can be formulated as

$$\bigvee_{g \in G} ((X_c > a) \wedge [g]).$$

Also note that the terms in this disjunction are disjoint. Then using Claim 5.8,

$$\begin{aligned}\Pr(X_c > a|[G]) &= \frac{\Pr((X_c > a) \wedge [G])}{\Pr([G])} \\ &= \frac{\sum_{g \in G} Pr(X_c > a \wedge [g])}{\Pr([G])} \\ &= \frac{\sum_{g \in G} Pr(X_c > a|[g]) \Pr([g])}{\Pr([G])} \\ &\leq \Pr(Y > a) \frac{\sum_{g \in G} \Pr([g])}{\Pr([G])} \\ &= \Pr(Y > a). \qquad \square\end{aligned}$$

For any natural numbers $b_1, \ldots, b_{c-1}$, let $G_{b_1,\ldots,b_{c-1}}$ be the set of partial input maps for which $X_1 = b_1, \ldots, X_{c-1} = b_{c-1}$.

LEMMA 5.10. *Given independent random variables $Y_1, \ldots, Y_{|L|}$ with geometric distributions with parameter P^{-k_t},*

$$Pr(X_1 + \cdots + X_{|L|} > a) \leq Pr(Y_1 + \cdots + Y_{|L|} > a).$$

Proof. Using Claim 5.9, for any natural numbers $b_1, \ldots, b_{c-1}$, if $\Pr([G_{b_1,\ldots,b_{c-1}}]) > 0$,

$$\begin{aligned}Pr(X_c > a|X_1 = b_1, \ldots, X_{c-1} = b_{c-1}) &= Pr(X_c > a|[G_{b_1,\ldots,b_{c-1}}]) \\ &\leq Pr(Y > a).\end{aligned}$$

Then the lemma follows from Theorem B.1. $\square$

LEMMA 5.11. *If f is t-good then* REFINE(t, f) *is successful with probability at least $1 - n^{-2}$.*

Proof. From Claim 5.7, given that REFINE fixes $X_1 + \cdots + X_{|L|}$ processors in the sets $S_{c,g}$, $(1 \leq c \leq |L|)$, it calls RANDOMSET with at most $k_t^3(X_1 + \cdots + X_{|L|})$ inputs (at most k_t inputs from Know(p, t, g) for each processor $p \in W_{c,g}$ is fixed).

Let $m = |L|$ and let $m^* = 2nP^{k_t}/(400P^2)^{k_t}$. Note that by the definition of the set L, $m \leq m^*$.

From Lemma 5.10 and using the Chernoff bound for sums of geometric distributions given in the appendix to bound $Y_1 + \cdots + Y_L$ (with $\beta = \frac{3m^*}{L} - 1 \geq 2$, $p = 1 - q = P^{-k_t}$, and the fact that $\frac{1}{2} \leq q < 1$), we see that

$$\begin{aligned}Pr(X_1 + \cdots + X_L > 3m^*(1 - P^{-k_t})P^{k_t}) &\leq Pr(Y_1 + \cdots + Y_L > 3m^*(1 - P^{-k_t})P^{k_t}) \\ &\leq e^{-m^*/4},\end{aligned}$$

for $k_t \geq 1$. Note that for sufficiently large n, when $k_t \leq \log\log n$ and $P \leq \log n$, $e^{-m^*/4} \leq e^{-\sqrt{n}}$. With very high probability then, the number of inputs set by RANDOMSET in this step is bounded by

$$\begin{aligned}k_t^3(3m^*P^{k_t}) &\leq \frac{3k_t^3 nP^{2k_t}}{(400P^2)^{k_t}} \\ &\leq \frac{n}{8(2^{k_t})}\end{aligned}$$

for $k_t \geq 1$. Since $k_0 = 1$, and k_t grows much faster than t, it is easy to see that $k_t \geq t+1$ for all $t \geq 0$. Thus we have shown that with very high probability, at most $n/8(2^{t+1})$ processors are set by RANDOMSET at step t. □

LEMMA 5.12. *If $t < T$ and* REFINE *is called with parameters (t, f), where f is t-good, then with probability at least $1 - n^{-2}$* REFINE *will return a partial input map f' that is $(t+1)$-good.*

Proof. This follows from Lemma 5.11 and Lemma 5.6. □

From Lemma 5.12, Fact 5.1, and Fact 5.2 we obtain the following corollary.

COROLLARY 5.13. *For any processor or cell p, $|Know(p, T, f_T)| \leq k_T \leq \log\log n$, and the number of inputs set by RANDOMSET is at most $r_T \leq n/8$ with probability at least $1 - n^{-1}$.*

6. Load-balancing lower bound. Instead of directly proving a lower bound on the general load-balancing problem, it will be convenient to prove a lower bound on the following variation of the load-balancing problem.

Chromatic load balancing (CLB). Let $m \geq 1$, and let Q be a set of $8m$ colors. Assume that there is a set of n groups of $4m$ objects each, and each group of objects is randomly assigned a color from Q. Then the *chromatic load-balancing* problem is to choose any color and distribute the objects of that color into n groups of at most m objects.

Without loss of generality, we will assume the objects are tagged with their original group number and their original rank (1 to $4m$) within that group.

Enhanced chromatic load balancing (ECLB). The *enhanced chromatic load-balancing* problem is the same as the CLB problem with the added requirement that one must produce an $n \times 4m$ array of pointers such that in each row corresponding to a group of the chosen color, and each column corresponding to the rank of a given object, there must be a pointer to the destination group of the object.

CLAIM 6.1. *Given a solution to the CLB problem, one can construct a solution to the ECLB problem on a priority CRCW PRAM in m additional steps.*

Proof. Assign one processor per destination group (of the CLB solution) to step through the at most m objects assigned to that group. For each object with tag (group, rank), have the processor write that destination in the array at location (group, rank). □

LEMMA 6.2. *For $m = o(\log^* n)$, a deterministic algorithm which solves the ECLB problem on a priority CRCW PRAM requires $\Omega(\log^* n)$ expected time.*

Proof. Assume we have finished step T of a deterministic algorithm that solves the ECLB problem. Then $k_T \leq \log\log n$ and $r_T \leq n/8$. Consider a color $q \in Q$. Consider a group g that has not been assigned a color by f_T (i.e., for such a group i, $f_T(i) =$ "$*$") and an object o in group g. Let c be the cell holding the array location (g, o) in the pointer array. Consider the contents of c (the pointer in (g, o)) assuming that the input map which was refined from f_T assigned the color q to all inputs (groups) in Know(c, T, f_T). Do this for all objects in all such groups that have not been assigned a color by f_T. This defines a *potential object map* F. Then F is a function with a domain of size at least $(7n/8)(4m) = 28nm/8$ and a range of size at most n. By a simple counting argument, we can find n disjoint sets of $m+1$ cells, all of which point to the same destination group. (To see this, consider iteratively removing sets of $m+1$ cells that point to the same destination group. One can do this until there are at most m cells pointing to any destination group, or at most nm leftover cells. Then the number of sets removed is at least $(28nm/8 - nm)/(m+1) \geq n$.)

Let S be one of the disjoint sets of cells that we have just found. Each of the $m+1$

cells $c \in S$ have $\text{Know}(c, T, f_T) \leq k_T \leq \log\log n$, and thus at most $(m+1)\log\log n$ inputs affect the contents of these cells. Each of these inputs is in $\text{Know}(c', T, f_T)$ for at most $\log\log n$ other cells c', so at most $(m+1)(\log\log n)^2$ cells are affected by the same inputs that affect the cells in set S. Thus from the n disjoint sets of $m+1$ cells which are mapped by F to the same processor, we can find a subset of $B = \lfloor n/(m+1)(\log\log n)^2 \rfloor$ sets whose cell contents are completely independent. Number these sets from 1 to B.

CLAIM 6.3. *With very high probability, at least one of these B sets uses the same pointers as F.*

Proof. We can see that the probability of all cells c in one of these sets using the pointers from F is at least the probability that f maps all inputs in $\text{Know}(c, T, f_T)$ for each c in the set to the color q, which is at least $1/(8m)^{(m+1)\log\log n}$.

Now for all sets i, let X_i be a random variable which is one if this event occurs, and zero otherwise. Let $X_i' = 1 - X_i$. Let Y_i be a random variable which is one with probability $1/(8m)^{(m+1)\log\log n}$, and zero otherwise. Let $Y_i' = 1 - Y_i$. Then for all sets i and any real number a, $Pr(X_i' > a) \leq Pr(Y_i' > a)$. Since the X_i''s are independent, they obviously satisfy the conditions of Theorem B.1, and thus

$$Pr(X_1' + \cdots + X_B' > a) \leq Pr(Y_1' + \cdots + Y_B' > a).$$

The number of sets in which this event occurs can then be bounded from below using the Chernoff bound for binomial random variables given in the appendix, as follows.

$$\begin{aligned}
&Pr(X_1 + \cdots + X_B < B/2(8m)^{(m+1)\log\log n}) \\
&\leq Pr(X_1' + \cdots + X_B' > B - B/2(8m)^{(m+1)\log\log n}) \\
&\leq Pr(Y_1' + \cdots + Y_B' > B - B/2(8m)^{(m+1)\log\log n}) \\
&\leq Pr(Y_1 + \cdots + Y_B < B/2(8m)^{(m+1)\log\log n}) \\
&\leq e^{-B/8(8m)^{(m+1)\log\log n}} \\
&= \exp\left\{ - \left\lfloor \frac{n}{(m+1)(\log\log n)^2} \right\rfloor \frac{1}{8(8m)^{(m+1)\log\log n}} \right\}.
\end{aligned}$$

For sufficiently large n, this implies a very high probability bound. Also for sufficiently large n, $B/2(8m)^{(m+1)\log\log n} \geq 1$, and thus with very high probability, at least one set of $m+1$ objects will be mapped to the same processor. □

By Claim 6.3, with very high probability the mapping provided by the algorithm for the color q at this point will not be a valid solution to the ECLB problem. (Remember we required that at most m objects map to any one destination group.)

Since with very high probability the mapping will be invalid for any color we choose, and since there are only $8m$ colors, with very high probability there will be no valid solution to the ECLB problem. The lemma follows since $T = \Omega(\log^* n)$. □

COROLLARY 6.4. *For $m = o(\log^* n)$, a deterministic algorithm which solves the CLB problem on a priority CRCW PRAM requires $\Omega(\log^* n)$ expected time.*

Proof. This follows from Claim 6.1 and Lemma 6.2. □

THEOREM 6.5. *Solving the* load-balancing *problem on a randomized priority CRCW PRAM requires $\Omega(\log^* n)$ expected time.*

Proof. Assume there is an algorithm that solves load balancing in expected time t. Then by Yao's theorem, for any input distribution, there is a deterministic algorithm which solves load balancing over that distribution in expected time t. Consider the

chromatic load-balancing problem (with $m = \log\log^* n$) and choose one of the $8m$ colors. (We choose $\log\log^* n$ because it increases with n and is $o(\log^* n)$, as required in Corollary 6.4.) Let $\mathcal{D}$ be the input distribution of the objects of that color, and let A be the algorithm given by Yao's theorem for distribution $\mathcal{D}$. We can then solve the chromatic load-balancing problem using the following procedure. First run A for the objects of the chosen color. Without loss of generality, for some constant C assume A assigns at most $C(1 + h/n)$ objects to each processor, when h objects are given as input. Also assume n is large enough so that $2C < m$. If at most m objects are assigned to each processor then one can easily assign each processor's objects to a destination group. If not, then run a $\Theta(\log n)$ time algorithm to solve chromatic load balancing (for example, using prefix operations).

We now analyze the expected time of this procedure. On average, there will be $4nm/8m$ objects of the chosen color, and with very high probability, there will be at most n objects of that color. If there are at most n objects of that color, at most $2C$ of them will be assigned to any one processor by A. Because of the very high probability of this occurring, the $\Theta(\log n)$ time algorithm (that is run when more than m objects are assigned to any processor) will not asymptotically increase the expected time of the procedure. Thus the chromatic load-balancing problem can be solved in the same asymptotic expected time as A, and by Corollary 6.4, $t = \Omega(\log^* n)$. □

7. Related lower bounds. In this section, we show further applications of the lower-bound technique.

THEOREM 7.1. *Solving* compaction *on a randomized priority CRCW PRAM requires* $\Omega(\log^* n)$ *expected time.*

Proof. Assume there is an algorithm that solves compaction in expected time t. Then by Yao's theorem, for any input distribution, there is a deterministic algorithm which solves compaction over that distribution in expected time t. Consider the chromatic load-balancing problem (with $m = \log\log^* n$) and choose one of the $8m$ colors. Consider an item to be a group of objects of that color, and let $\mathcal{D}$ be the input distribution of the items. Let A be the algorithm given by Yao's theorem for distribution $\mathcal{D}$. We can then solve the chromatic load-balancing problem using the following procedure. First run A with $h = n/4m$. Without loss of generality, for some constant C assume A inserts the items into an array of size Ch, when h is the parameter given in the definition of compaction and the input consists of at most h items. Also assume n is large enough so that $C < m$. If A succeeds, then one can easily assign each item to four destination groups (i.e., m objects to each destination group), and this solves the chromatic load-balancing problem. If A does not succeed, then run a $\Theta(\log n)$ time algorithm to solve chromatic load balancing (for example, using prefix operations).

We now analyze the expected time of this procedure. On average, there will be $n/8m$ items, and with very high probability, there will be at most $n/4m$ items. If there are at most $n/4m$ items, then A will succeed. Because of the very high probability of this occurring, the $\Theta(\log n)$ time algorithm (that is run when A fails) will not asymptotically increase the expected time of the procedure. Thus the chromatic load-balancing problem can be solved in the same asymptotic expected time as A, and by Corollary 6.4, $t = \Omega(\log^* n)$. □

THEOREM 7.2. *Solving the* padded-sort *problem on a randomized priority CRCW PRAM requires* $\Omega(\log^* n)$ *expected time.*

Proof. (We actually prove that this lower bound holds for sorting into any array of size linear in n, not just $n + o(n)$.) We can reduce the chromatic load-balancing

problem (with $m = \log\log^* n$) to the padded-sort problem with no asymptotic increase in running time as follows. Assign the colors individual integers from 0 to $8m-1$. For each group with color i, uniformly choose a random real number from the range $(i/8m, (i+1)/8m]$. Thus each group will be assigned a number from $(0,1]$ and these will be uniformly distributed. Now assume we have a padded-sort algorithm which will place these numbers in sorted order into an array A of size kn for some constant k. Run this padded-sort algorithm. Next we find a color which is mapped to $\leq 3kn/8m$ consecutive positions in constant time as follows.

Assign one processor to each group. Say a processor is of color i if it is assigned to a group of color i. For each $i \in \{0,\ldots,8m-1\}$ perform the following steps. Each processor of color i writes its group's position in A to position i in a new array $P[0\,..\,8m-1]$. (It can easily be detected if a color i has no representative processors, and in that case, color i can be used as a trivial solution to the chromatic load-balancing problem.) Then each processor of color i subtracts $P[i-1]$ from $P[i+1]$ and checks if the result is $\leq 3kn/8m$. Assuming all the colors are present, then one color will find its result is $\leq 3kn/8m$. (Otherwise, every set of three consecutively numbered colors is mapped into $> 3kn/8m$ consecutive positions, and thus $|A| > (3kn/8m)(8m/3) = kn$.) Each processor of color i whose check succeeds writes i to a variable V. We choose the color corresponding to the contents of V.

Assume this color is j. Since $3kn/8m \leq n/4$ for large enough n, we know that the groups of color j are mapped into $A[P[j-1], P[j-1]+n/4]$, so we can easily assign four destination groups to each group of color j (i.e., m objects to each destination group). This solves the chromatic load-balancing problem. ∎

8. Random graphs. The input will consist of an adjacency matrix with a 1 entry if an edge exists, and a 0 entry otherwise. Thus $Q = \{0,1\}$. For a random graph $G_{n,p}$ there will be will be $\binom{n}{2}$ inputs, and the input distribution will be that each input is 1 with probability p and 0 with probability $1-p$.

Let T, the function REFINE, and the notion of t-good be defined as in the general CRCW PRAM lower bound. Then Lemma 5.12 holds.

THEOREM 8.1. *For any constant $0 < p < 1$, any problem which requires the construction of an edge cover (with high probability) in a random graph $G_{n,p}$ represented as an adjacency matrix requires $\Omega(\log^* n)$ expected time on an n processor CRCW PRAM.*

Proof. Assume there is an algorithm that finds an edge cover in a random graph $G_{n,p}$ in expected time t. Then by Yao's theorem, there is a deterministic algorithm that finds an edge cover in a random graph $G_{n,p}$ in the same expected time t. Thus a lower bound for deterministic algorithms will provide the same lower bound for any (randomized) algorithm.

Assume we have finished step T of a deterministic algorithm that finds an edge cover in a random graph $G_{n,p}$. Assume the edge cover is given in an output array $EC[1..n]$ of size n such that $EC[i] = j$ if (i,j) is the alleged edge covering vertex i. (For the rest of the proof, we will also use the index i to denote the memory cell corresponding to the array element $EC[i]$.) By Lemma 5.12, $k_T \leq \log\log n$ and $r_T < n/8$. Consider all the vertices which are only covered by edges which f maps to "$*$." There will be at least $3n/4$ of these. We will find a subset of the array indices corresponding to these vertices for which the sets $\mathrm{Know}(i, T, f_T)$ are disjoint. To do this, we will use a greedy algorithm and obtain a set S of size

$$\frac{3n}{4k_T^2} \geq \frac{3n}{4(\log\log n)^2}.$$

Now consider for each index $i \in S$ the value $EC[i]$, if $\text{Know}(i, T, f_T)$ contains only inputs set to 0 by the final input map f. Then the existence of edge $(i, EC[i])$ does not affect $EC[i]$ (assuming the algorithm doesn't choose an edge that is known not to exist).

The probability of this occurring for any index in S is $\geq (1-p)^{\log\log n}$ and is independent of any other cells in S. Thus the average number of indices j in which the existence of $(j, EC[j])$ does not affect $EC[j]$ will be at least

$$\frac{3n}{4(\log\log n)^2}(1-p)^{\log\log n} = \Omega(\sqrt{n}).$$

Assuming n is large, and using a Chernoff bound, we can show that this occurs for at least half of these indices with high probability. Thus $\Omega(\sqrt{n})$ vertices will have a $1-p$ chance of not being covered. Since an edge can only possibly cover two vertices, at most two vertices will point to the same alleged edge. Thus $\Omega(\sqrt{n})$ vertices point to different alleged edges. Then using another Chernoff bound, it is easy to show that with high probability, many of these will point to nonexistent edges. Thus with high probability the edge cover is invalid. Since $T = \Omega(\log^* n)$, the expected time of this deterministic algorithm must be $\Omega(\log^* n)$. □

COROLLARY 8.2. *For any constant $0 < p < 1$, in a random graph $G_{n,p}$ represented as an adjacency matrix, constructing a Hamiltonian cycle, spanning tree, or maximal matching requires $\Omega(\log^* n)$ expected time on an n processor CRCW PRAM.*

Proof. With high probability a Hamiltonian cycle, a spanning tree, and a maximal matching exist in $G_{n,p}$, and constructing any of these implies construction of an edge cover. Thus by Theorem 8.1, the stated lower bound holds. □

9. Conclusion. We have developed a technique which provides lower bounds on randomized PRAM algorithms. Using this technique, we have been able to prove tight lower bounds for many problems, including the fundamental problem of load balancing, even on the most powerful CRCW PRAM model. In view of the increasing amount of attention being paid to the area of fast randomized algorithms on the PRAM, we believe this lower-bound technique is very important. We hope that this general technique can be used to prove lower bounds on other problems for which very fast randomized algorithms have been developed, including integer chain-sorting [27] and parallel hashing [21].

Appendix A. Technical lemmas.

LEMMA A.1. *For $z \geq 4$, $\log^* n \leq \log_z^* n + \log^* z$.*

Proof. First we claim that for $z \geq 4$, $2\log z \leq z$. This is true as long as $z - 2\log z \geq 0$. Let $f(z) = z - 2\log z$. Then $f'(z) = 1 - (2\log e)/z$. We can check that $f(4) = 0$ and $f'(z) > 0$, for $z \geq 4$, which proves the claim.

Now we claim that $\log^*(z \log_z^{(\log_z^* n - k)} n) \leq k + \log^* z$, for $1 \leq k \leq \log_z^* n - 1$ and $z \geq 4$. We show this by induction. For $k = 1$,

$$\log^*(z \log_z^{(\log_z^* n - 1)} n) \leq \log^* z^2 \leq \log^* 2^z = 1 + \log^* z.$$

For $k > 1$,

$$\begin{aligned}\log^*(z \log_z^{(\log_z^* n - k)} n) &= \log^* z^{1+\log_z^{(\log_z^* n - k+1)} n} \\ &= \log^* 2^{\log z(1+\log_z^{(\log_z^* n - k+1)} n)} \\ &\leq \log^* 2^{2\log z \log_z^{(\log_z^* n - k+1)} n}\end{aligned}$$

$$\begin{aligned}
&= 1 + \log^* \left(2 \log z \log_z^{(\log_z^* n - k + 1)} n\right) \\
&\leq 1 + \log^* \left(z \log_z^{(\log_z^* n - k + 1)} n\right) \\
&\leq 1 + k - 1 + \log^* z \\
&= k + \log^* z,
\end{aligned}$$

where the first inequality uses the fact that $\log_z^{(\log_z^* n - k + 1)} n \geq 1$, the third uses the fact that $z \geq 4$ implies $2 \log z \leq z$, and the fourth uses the induction property.

Now we prove the lemma. For $n \leq z$, the lemma is obvious, since $\log^* n \leq \log^* z$. For $n > z$, using our previous claims we can see that

$$\begin{aligned}
\log^* n &= \log^* 2^{\log n} = \log^* 2^{\log z \log_z n} = 1 + \log^*(\log z \log_z n) \\
&\leq 1 + \log^*(z \log_z^{(\log_z^* n - (\log_z^* n - 1))} n) \\
&\leq 1 + \log_z^* n - 1 + \log^* z \\
&= \log_z^* n + \log^* z. \qquad \square
\end{aligned}$$

LEMMA A.2. *For $k, q \geq 1$, $k + (400q^2)^k(k + kq^k) \leq (2400q^3)^k$.*

Proof. For $k, q \geq 1$,

$$k + (400q^2)^k(k + kq^k) \leq k + (400q^2)^k(2kq^k) \leq k + 2k(800q^3)^k \leq 3k(800q^3)^k.$$

Now we must show that that

$$(2400q^3)^k - (3k(800q^3)^k) \geq 0,$$

or more simply that

$$800^k(3^k - 3k) \geq 0.$$

Since $800^k \geq 0$, we must show that $3^k - 3k \geq 0$. Let $f(k) = 3^k - 3k$. Then $f'(k) = 3^k \ln 3 - 3$. Since $f(1) = 0$ and $f'(k) > 0$ for $k \geq 1$, we know that $f(k) \geq 0$ for $k \geq 1$. $\square$

Appendix B. Probabilistic bounds. First we prove a theorem which allows us to bound the sum of discrete dependent random variables by discrete independent random variables. We note that a similar result for continuous random variables can be proved analogously, using the more advanced probabilistic techniques involved in conditional expectations of continuous random variables. For our purposes, however, we will need to use only discrete random variables.

THEOREM B.1. *Take n discrete random variables $X_1, \ldots, X_n$, all with the same range, which might be dependent, and n discrete random variables $Y_1, \ldots, Y_n$, all with the same range as the X_i's, which are independent of each other and the X_i's, such that for any $i \in \{1, \ldots, n\}$, for any real number a, and for any $b_1, \ldots, b_{i-1} \in \text{range}(X_1)$ such that $\Pr(X_1 = b_1, \ldots, X_{i-1} = b_{i-1}) \geq 0$,*

$$\Pr(X_i > a | X_1 = b_1, \ldots, X_{i-1} = b_{i-1}) \leq Pr(Y_i > a).$$

Then for any real number a

$$\Pr(X_1 + \cdots + X_n > a) \leq \Pr(Y_1 + \cdots + Y_n > a).$$

Proof. Let $Q_{b_1,\ldots,b_{n-1}}$ be the event $(X_1 = b_1, \ldots, X_{i-1} = b_{i-1}, Y_{i+1} = b_i, \ldots, Y_n = b_{n-1})$. We can see that

$$\begin{aligned}
&\Pr(X_1 + \cdots + X_i + Y_{i+1} + \cdots + Y_n > a) \\
&= \sum_{\substack{b_1,\ldots,b_{n-1} \in \text{range}(X_1) \\ \Pr(Q_{b_1,\ldots,b_{n-1}})>0}} \Pr(X_i > a - b_1 - \cdots - b_{n-1} | Q_{b_1,\ldots,b_{n-1}}) \Pr(Q_{b_1,\ldots,b_{n-1}}) \\
&\leq \sum_{\substack{b_1,\ldots,b_{n-1} \in \text{range}(X_1) \\ \Pr(Q_{b_1,\ldots,b_{n-1}})>0}} \Pr(Y_i > a - b_1 - \cdots - b_{n-1} | Q_{b_1,\ldots,b_{n-1}}) \Pr(Q_{b_1,\ldots,b_{n-1}}) \\
&= \Pr(X_1 + \cdots + X_{i-1} + Y_i + \cdots + Y_n > a),
\end{aligned}$$

in which the inequality holds because X_i is independent of all Y_j's, and by the condition placed on X_i in the theorem.

Using this fact, we can see that

$$\begin{aligned}
\Pr(X_1 + \cdots + X_n > a) &\leq \Pr(X_1 + \cdots + X_{n-1} + Y_n > a) \\
&\vdots \\
&\leq \Pr(X_1 + Y_2 + \cdots + Y_n > a) \\
&\leq \Pr(Y_1 + \cdots + Y_n > a). \qquad \square
\end{aligned}$$

We use the Chernoff bound to bound the distribution of a random variable Z which is the sum of n independent random variables. For a binomial random variable $Z \sim B(n, p)$, where Z is the sum of n independent Bernoulli trials with probability of success p, Angluin and Valiant [3] show that for $0 < \beta < 1$, one can obtain the bounds

$$\Pr(Z \geq (1 + \beta)np) \leq e^{-\beta^2 np/3},$$

and

$$\Pr(Z \leq (1 - \beta)np) \leq e^{-\beta^2 np/2}.$$

For a random variable Z, which is the sum of n independent random variables with geometric distributions with parameter p, we obtain the bound (where $q = 1 - p$ and $\beta > 0$)

$$\Pr(Z \geq (1 + \beta)nq/p) \leq \begin{cases} e^{-(q\beta)^2 n/2e^{q\beta}} & \text{if } q\beta < 1, \\ e^{-q\beta n/4} & \text{if } q\beta \geq 1. \end{cases}$$

We prove this here. First we prove that for $x \geq 0$,

$$\frac{1 + x}{e^x} \leq e^{-x^2/2e^x}.$$

This can be shown by using the facts that for all real y, $1 + y \leq e^y$ and

$$e^y = \sum_{i \geq 0} \frac{y^i}{i!},$$

as follows.

$$\begin{aligned}\frac{1+x}{e^x} &= \frac{\sum_{i\geq 0}\frac{x^i}{i!} - \sum_{i\geq 2}\frac{x^i}{i!}}{e^x} \\ &= 1 - \frac{\sum_{i\geq 2}\frac{x^i}{i!}}{e^x} \\ &\leq 1 - \frac{\frac{x^2}{2}}{e^x} \\ &\leq e^{-x^2/2e^x}.\end{aligned}$$

Next we prove that for $x \geq 1$,

$$\frac{1+x}{e^x} \leq e^{-x/4}.$$

This follows from the fact that $e^{3x/4} - x - 1 \geq 0$ for $x \geq 1$, which can be derived from the facts that $e^{3/4} - 2 \geq 0$, and that the derivative of $e^{3x/4} - x - 1$ ($\frac{3}{4}e^{3x/4} - 1$) is positive for $x \geq 1$.

Now let $X_1, \ldots, X_n$ be independent random variables with geometric distributions with parameter p, and let $Z = X_1 + \cdots + X_n$. Let $\beta > 0$ and $t > 0$. Then following along the lines of Hagerup and Rüb [30],

$$\begin{aligned}\Pr(Z \geq (1+\beta)nq/p) &= e^{-t(1+\beta)nq/p}e^{t(1+\beta)nq/p}P(e^{tZ} \geq e^{t(1+\beta)nq/p}) \\ &\leq e^{-t(1+\beta)nq/p}E(e^{tZ}).\end{aligned}$$

Then since $X_1, \ldots, X_n$ are independent and identically distributed, we get

$$\begin{aligned}E(e^{tZ}) = E(e^{t(X_1+\cdots+X_n)}) &= E(e^{tX_1}\cdots e^{tX_n}) = \prod_{i=1}^{n} E(e^{tX_i}) \\ &= \left(E(e^{tX_1})\right)^n = \left(\frac{p}{1-qe^t}\right)^n,\end{aligned}$$

where the last equation holds for $t < \ln(1/q)$ [15, p. 269]. Putting $t = \ln((1+\beta)/(1+q\beta))$ yields

$$\begin{aligned}\Pr(Z \geq (1+\beta)nq/p) &\leq \left(\frac{1+q\beta}{1+\beta}\right)^{(1+\beta)nq/p}(1+q\beta)^n \\ &= \left(1 - \frac{p\beta}{1+\beta}\right)^{(1+\beta)nq/p}(1+q\beta)^n \\ &\leq e^{-q\beta n}(1+q\beta)^n,\end{aligned}$$

which can be bounded using the bounds on $\frac{1+x}{e^x}$ derived above. Note that for $0 < q < 1$ and $\beta > 0$, $\ln((1+\beta)/(1+q\beta)) < \ln(1/q)$.

Acknowledgments. Many thanks to Eric Hao, Doug Van Wieren, and the anonymous referees for careful readings of earlier versions of this paper and many helpful comments and suggestions. Also thanks to Leslie Goldberg for the improved (and easier to understand) description of the random-adversary technique that appears in this version.

RECONFIGURING ARRAYS WITH FAULTS PART I: WORST-CASE FAULTS*

RICHARD J. COLE†, BRUCE M. MAGGS‡, AND RAMESH K. SITARAMAN§

Abstract. In this paper we study the ability of array-based networks to tolerate worst-case faults. We show that an $N \times N$ two-dimensional array can sustain $N^{1-\epsilon}$ worst-case faults, for any fixed $\epsilon > 0$, and still emulate T steps of a fully functioning $N \times N$ array in $O(T + N)$ steps, i.e., with only constant slowdown. Previously, it was known only that an array could tolerate a constant number of faults with constant slowdown. We also show that if faulty nodes are allowed to communicate, but not compute, then an N-node one-dimensional array can tolerate $\log^k N$ worst-case faults, for any constant $k > 0$, and still emulate a fault-free array with constant slowdown, and this bound is tight.

Key words. fault tolerance, array-based network, mesh network, network emulation

1. Introduction.

In a truly large parallel computer, some components are bound to fail. Knowing this, a programmer can write software that explicitly copes with faults in the computer. But building fault tolerance into every piece of software is cumbersome. The programmer would prefer to program a fault-free virtual computer and leave the job of coping with faults to the hardware. Ideally, the emulation of the fault-free computer should entail little slowdown, even if there are many faults in the actual hardware.

The emulation of the fault-free computer consists of two tasks. The faulty computer must emulate the computations performed by the processors of the fault-free computer, and it must emulate the communications between those processors. Emulating the computations does not incur much slowdown. The computation performed by each faulty processor is simply mapped to a fault-free processor. But once the computations are moved around, processors that are neighbors in the fault-free computer may no longer be neighbors in the faulty computer. Thus, there is a risk that the communications will be slowed down. The solution to this problem depends on the communication topology of the computer.

One of the most popular ways to construct a parallel computer is to arrange the processors as a two-dimensional or three-dimensional array. Commercial machines including the Cray T3D [10] and MasPar MP-1 [3] have this topology, as do experimental machines such as iWarp [4] and the J-Machine [18]. In this paper we study the ability of machines like these to tolerate faults. We show, for example, that an

$N \times N$ two-dimensional array can sustain $N^{1-\epsilon}$ worst-case faults, for any fixed $\epsilon > 0$, and still emulate a fault-free $N \times N$ array with constant slowdown.

1.1. Arrays and the fault model. A d-dimensional *array* with side length N consists of N^d nodes, each labeled with a distinct d-tuple $(r_1, r_2, \ldots, r_d)$, where $1 \leq r_i \leq N$ for $1 \leq i \leq d$. Two nodes are connected by a pair of oppositely directed edges if their labels differ by 1 in precisely one coordinate. For example, in a four-dimensional array with side length 8, nodes $(3, 2, 4, 8)$ and $(3, 2, 3, 8)$ are neighbors, but $(3, 2, 4, 8)$ and $(3, 2, 3, 7)$ are not. A two-dimensional array is also called a *mesh*. A 4×4 mesh is shown in Figure 1. For each i, the mesh nodes labeled (i, j), where $1 \leq j \leq N$, are said to belong to the ith row. For each j, the mesh nodes labeled (i, j), where $1 \leq i \leq N$, are said to belong to the jth column. Sometimes two nodes are considered to be neighbors if they differ in precisely one coordinate and their values in that coordinate are 1 and N. In this case we say that the array has *wraparound* edges. A two-dimensional array with wraparound edges is also called a *torus*. All of the results in this paper hold whether or not the array has wraparound edges.

The nodes in an array represent processors and the edges represent communication links. We assume that the array operates in a synchronous fashion. At each time step, each node can receive a message from each of its neighbors, perform a simple local computation, and then send a message to each of its neighbors.

In this paper we assume that only nodes fail, that these failures are static, and that their locations are known. We also assume that the faults appear in a worst-case pattern, i.e., that an adversary decides where to put the faults in the network. We allow information about the locations of the faults to be used in reconfiguring the network. We assume that a faulty node can neither compute nor communicate. All of our results can be extended to handle edge failures by viewing an edge failure as the failure of one of the nodes incident on the edge. In section 4, we use a weaker fault model for one-dimensional arrays by allowing faulty nodes to communicate but not compute. We observe that even in this weaker fault model linear arrays cannot tolerate as many worst-case faults as two-dimensional arrays. In another paper, we

consider random fault patterns. In the case of random faults, we assume that each node fails independently with some fixed probability p.

1.2. Embeddings. The simplest way to show that a network with faults, H, can emulate a fault-free network, G, is to find an embedding of G into H. We call H the *host* network and G the *guest* network. An embedding maps nodes of G to nonfaulty nodes of H, and edges of G to nonfaulty paths in H. The three important measures of an embedding are its load, congestion, and dilation. The *load* of an embedding is the maximum number of nodes of G that are mapped to any node of H. The *congestion* of an embedding is the maximum number of paths that use any edge of H. The *dilation* is the maximum length of any path. Given an embedding of G into H, H can emulate each step of the computation of G by routing a packet for each edge of G along the corresponding path in H. Leighton, Maggs, and Rao [11] showed that if the embedding has load l, congestion c, and dilation d, then the packets can be routed so that the slowdown of the emulation is $O(l + c + d)$.

In order for an embedding-based emulation scheme to have constant slowdown, the load, congestion, and dilation of the embedding must all be constant. Unfortunately, by placing $f(N)$ faults in an N-node two- or three-dimensional array H, where $f(N)$ is any function that is $\omega(1)$, it is possible to force either the load, congestion, or dilation of every embedding of an array G of the same size and dimension to be larger than a constant [7, 8, 12]. Similarly, if $\Theta(N)$ faults are placed in H at random, then with high probability every embedding of G in H will have $\omega(1)$ load, congestion, or dilation. Thus, in order to tolerate more than a constant number of worst-case faults or constant-probability failures, a more sophisticated emulation technique is required.

1.3. Redundant computation. All of the emulations in this paper use a technique called *redundant computation*. The basic idea is to allow H to emulate each node of G in more than one place. This extra freedom makes it possible to tolerate more faults, but it adds the complication of ensuring that different emulations of the same node of G remain consistent over time. The technique of redundant computation was previously used to tolerate faults in hypercubic networks [13], and to construct work-preserving emulations in fault-free networks [6, 9, 15, 16, 17, 21].

1.4. Previous work. A large number of researchers have studied the ability of arrays and other networks to tolerate faults. The most relevant papers are described below.

Raghavan [20] devised a randomized algorithm for solving one-to-one routing problems on $N \times N$ meshes. He showed that even if each node fails with some fixed probability $p \leq .29$, then for almost all random fault patterns, any packet that can reach its destination does so in $O(N \log N)$ steps, with high probability. Mathies [14] improved the $p \leq .29$ bound to $p \approx .4$.

Kaklamanis et al. [8] improved Raghavan's result by devising a deterministic routing algorithm. For almost all random fault patterns, the algorithm guarantees that any packet that can reach its destination does so within $O(N)$ steps. This algorithm can also tolerate worst-case faults. If there are k faults in the network, it runs in time $O(N + k^2)$. Kaklamanis et al. also showed that an $N \times N$ mesh with constant-probability failures or $\Theta(N)$ worst-case faults can sort or route N^2 items, or multiply two $N \times N$ matrices in $O(N)$ time. They also showed that, with high probability, an $N \times N$ mesh with constant-probability failures can emulate a fault-free $N\sqrt{\log N} \times N\sqrt{\log N}$ mesh with $O(\log N)$ slowdown. (Throughout this paper the base of the function log is 2.)

Aumann and Ben-Or [2] used Rabin's information dispersal technique [19] to show that an $N \times N$ mesh H with slack s, $s = \Omega(\log N \log\log N)$, can emulate a fault-free $N \times N$ mesh G with slack s with constant slowdown, even if every node or edge in H fails with some fixed probability $p > 0$ at some point *during* the emulation. (In a slack s computation, each node v in G emulates s virtual nodes. In each *superstep*, v emulates one step of each virtual node, and each virtual node can transmit a message to one of v's four neighbors.) Aumann and Ben-Or assumed that in a single step, an edge in H can transmit a message that is $\log N$ times as large as the largest message that can be transmitted in a single step by G.

Bruck, Cypher, and Ho [5] showed that by adding some spare nodes and edges to a mesh, it is possible for the mesh to sustain many faults and still contain a working fault-free $N \times N$ mesh as a subgraph. In particular, they showed that by adding $O(k^3)$ spare nodes, it is possible to tolerate k worst-case faults, and by adding k spare nodes, for $k = O(N^{2/3})$, it is possible to tolerate k random faults, with high probability. In both cases, the networks have bounded degree. Tamaki [24] showed how to construct an $O(N)$-node network with degree $O(\log\log N)$ with the property that, for any $d \geq 2$, even if every node fails with constant probability, with high probability the network contains a fault-free N-node d-dimensional array as a subgraph. He also showed how to construct a bounded-degree network with the property that even if $N^{(1-2^{-d})/d}$ worst-case faults are placed in the network, the network is guaranteed to contain an N-node d-dimensional array as a subgraph. Ajtai et al. [1] analyzed the technique of adding spare nodes to larger classes of networks that include meshes. In all of these constructions the very large scale integration (VLSI) layout area requirements of the networks with spare nodes and edges are much larger than those of the arrays that they contain as subgraphs.

Leighton, Maggs, and Sitaraman [13] showed that an N-node butterfly can tolerate $N^{1-\epsilon}$ worst-case faults, for any fixed $\epsilon > 0$, and still emulate a fault-free N-node butterfly with constant slowdown. They proved the same result for the shuffle-exchange network. They also showed that, for any constant $k > 0$, an N-node mesh of trees can tolerate $\log^k N$ worst-case faults and still emulate a fault-free mesh of trees with constant slowdown. Finally, they showed that, with high probability, an N-node butterfly (or shuffle-exchange network) can tolerate constant-probability failures with slowdown $2^{O(\log^* N)}$. Tamaki independently showed that, with high probability, an N-node butterfly can be embedded in an N-node butterfly containing constant-probability node failures with load $O(1)$, congestion $O((\log\log N)^{8.2})$, and dilation $O((\log\log N)^{2.6})$ [22]. In [23], he proved a similar result for a class of networks called cube-connected arrays.

1.5. Our results. In section 2 we show that an $N \times N$ array can tolerate $\log^k N$ worst-case faults, for any constant $k > 0$, and still emulate T steps of a fault-free array in $O(T + N)$ steps, i.e., with constant slowdown. Previously it was only known that a constant number of worst-case faults could be tolerated with constant slowdown. Section 2 introduces most of the terminology that is used throughout this paper.

In section 3 we present a method called *multiscale emulation* for tolerating $N^{1-\epsilon}$ worst-case faults on an $N \times N$ mesh with constant slowdown, for any fixed $\epsilon > 0$. This result nearly matches the $O(N)$ upper bound on the number of worst-case faults that can be tolerated with constant slowdown.

In section 4 we show that if faulty nodes are allowed to communicate but not compute, then an N-node one-dimensional array can tolerate $\log^k N$ worst-case faults, for any constant $k > 0$, and still emulate a fault-free N-node linear array only with

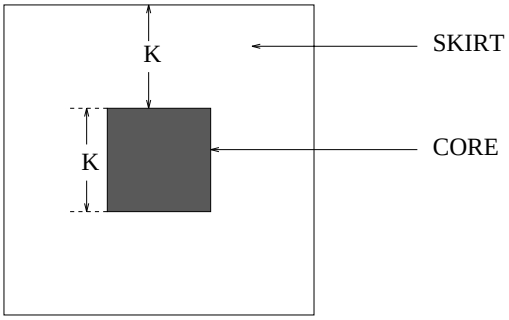

FIG. 2. *A finished box.*

constant slowdown. We also show that an N-node linear array cannot tolerate more than $\log^k N$ worst-case faults without suffering more than constant slowdown, provided that the emulation is static. In a *static* emulation, each host node a emulates a fixed set $\psi(a)$ of guest nodes. Redundant computation is allowed; a guest node u may belong to $\psi(a)$ and $\psi(b)$ for distinct host nodes a and b. In this case we say that there are multiple *instances* of the guest node u. For each guest time step, host node a emulates the computation performed by each node u in $\psi(a)$. Furthermore, for every guest edge $e = (v, u)$ into u, for each instance u' of u in the host, there is a corresponding instance v' of v at some host node such that for each guest time step *the same* instance v' sends a packet for the edge e to u'. (Note that v' may also send packets to other instances of u.) The emulations that use redundant computation in this paper and in [6, 9, 13, 21] are all static.

2. A simple method for tolerating worst-case faults on the mesh. In this section, we show that, for any constant $k > 0$, an $N \times N$ mesh with $\log^k N$ worst-case faults can emulate any computation of an $N \times N$ fault-free mesh with only constant slowdown. The procedure for reconfiguring the computation around faults consists of two steps. The first is a process by which the faults are enclosed within square regions of the mesh called *boxes*. We call this step the *growth process*. We describe this process in section 2.1. The next is an emulation technique that maps the computation of the fault-free mesh (the guest) to nodes in the faulty mesh (the host). The boxes grown in the first step determine how the mapping of the computation is done. This process is described in section 2.2. For simplicity, we assume that the mesh has wraparound edges. This assumption can be easily done away with at the cost of considering some special cases for faults near the border of the mesh.

2.1. The growth process. The growth process grows boxes on the faulty mesh, i.e., the host. There are two types of boxes. The first type is called a *core*. A core has too many faults in it to perform any role in the emulation. The second type is a *finished box*. A finished box can emulate a submesh of the same side length with constant slowdown. (The side length of a box or submesh is the number of nodes on each side, i.e., a box or submesh with side length k has k^2 nodes.) A finished box of side length $3k$ consists of a core of side length k surrounded by a *skirt*, which contains no faults, of width k as shown in Figure 2. (Like side length, width is measured in nodes.)

At every stage of the growth process, the algorithm maintains a set of boxes, some of which are cores while others are finished boxes. At the beginning of the growth

process, every fault is enclosed in a box with unit side length that is a core. In every stage of the growth process, we pick a core—say, of side length k—and grow a skirt of width k around it. If the core or the skirt intersects some other core, we merge the two cores to form a new core whose boundary is the smallest square that contains both cores. If the core or the skirt intersects a finished box, we find the smallest square box that contains both the core and the core of the finished box and turn this bounding box into a core. We also remove the finished box from the list of finished boxes. If the skirt does not intersect any other boxes, the newly created box is labeled a finished box. We continue applying these rules until either some core grows to be too large to grow a skirt around it or no core remains and no two finished boxes intersect. For the former outcome, some core must have side length greater than $N/3$. (Recall that the mesh has wraparound edges.) In Lemma 2.1 we show that this cannot happen if there are fewer than $(\log N)/2$ faults.

Our rules for growing cores assign each fault to a unique core. Initially, every fault is assigned to the unit-sized core enclosing it. Inductively, when two or more cores are merged to form a new core, every fault assigned to the old cores is now assigned to the new core. A core is said to *contain* all the faults assigned to it. Note that if two cores overlap, it is possible for a fault to be geometrically located inside of a core and yet not be contained by that core.

LEMMA 2.1. *If the number of faults is less than* $(\log N)/2$*, then the growth process terminates with nonoverlapping finished boxes.*

Proof. Let $F(k)$ denote the minimum number of faults that a core of side length k must contain. We show by induction that $F(k) \geq (\log k)/2 + 1$. As the base case, $F(1) = 1$, which satisfies the hypothesis. Assume that we have a core of side length $k > 1$. This core must have been created by merging two cores according to one of the two merging rules stated previously. Let x and y denote the side lengths of these two cores. In both cases, $x + y \geq \lfloor k/2 \rfloor + 1$. Using the inductive hypothesis, we have

$$\begin{aligned} F(k) &\geq F(x) + F(y) \\ &\geq (\log x)/2 + 1 + (\log y)/2 + 1. \end{aligned}$$

The values of x and y that minimize the right-hand side of this inequality are $x = \lfloor k/2 \rfloor$ and $y = 1$. Substituting these values, we have

$$\begin{aligned} F(k) &\geq (\log \lfloor k/2 \rfloor)/2 + 2 \\ &\geq (\log k)/2 + 1. \end{aligned} \tag{1}$$

This proves our inductive hypothesis.

Now suppose that there is a core of side length greater than $N/3$. Then it must contain at least $F(\lfloor N/3 \rfloor + 1)$ faults, which is more than $(\log N)/2$, which is a contradiction. Therefore, the growth process must terminate with a set of nonintersecting finished boxes. □

2.2. The emulation. In this section, we show that if the growth process terminates with a set of nonintersecting finished boxes, then the host H can emulate the guest G with constant slowdown.

The emulation of G by H is described as a pebbling process. There are two kinds of pebbles. With every node v of G and every time step t, we associate a state pebble (s-pebble), $\langle v, t \rangle$, which contains the entire state of the computation performed at node v at time t. With each directed edge e in G and every time step t, we associate

a communication pebble (c-pebble), $[e,t]$, which contains the message transmitted along edge e at time step t.

The host H will emulate each step t of G by creating at least one s-pebble $\langle v,t\rangle$ for each node v of G and a c-pebble $[e,t]$ for each edge e of G. A node of H can create an s-pebble $\langle v,t\rangle$ only if it contains s-pebble $\langle v,t-1\rangle$ and all of the c-pebbles $[e,t-1]$, where e is an edge into v. The creation of an s-pebble takes unit time. A node of H can create a c-pebble $[g,t]$ for an edge g out of v only if it contains an s-pebble $\langle v,t\rangle$. The creation of a c-pebble also takes unit time. Finally, a node of H can transmit a c-pebble to a neighboring node in H in unit time. A node of H is not permitted to transmit an s-pebble since an s-pebble may contain a lot of information. All of our emulations are static, i.e., each node of H emulates a fixed set of nodes of G, and for each guest edge $e=(v,u)$ and each instance of u, there is a corresponding instance of v such that for each guest time step, the host node creating s-pebbles for that instance of v sends a c-pebble $[e,t]$ to the host node creating s-pebbles for u. Initially, each node of H contains an s-pebble $\langle v,0\rangle$ for each node v of G that is mapped to it.

Using the growth process of the previous section, we grow a collection of nonintersecting finished boxes on the faulty mesh H. If the faulty mesh H has fewer than $(\log N)/2$ faults, then the growth process will terminate with a set of nonintersecting finished boxes. Every node of H that does not belong to any of the finished boxes will emulate the computation of the corresponding node of G. Every finished box of H will be responsible for emulating the corresponding submesh of G. However, since some of the nodes inside the core of a finished box are faulty, we must make sure that no computation is mapped to them. In fact, there will be no computation mapped to any node inside a core. All the computations will be mapped to the skirt of the finished box, which is completely fault free. Since we would like each finished box to do its share of the emulation with constant slowdown, we need to avoid long communication delays caused by the fact that the core is unusable. As we shall see, we can hide the latency involved in sending c-pebbles long distances across the mesh using a technique called *redundant computation*. In an emulation that performs redundant computation, some nodes of G are emulated by more than one node in H.

The computation of G corresponding to a finished box is mapped with replication to the skirt of that finished box as follows (see Figure 3). Suppose that the core has side length k and the finished box has side length $3k$. We begin by dividing the submesh of G corresponding to a finished box into two regions, the *patch* and the *outerskirt*. The patch is a square region of side length $2k$ whose center is also the center of the finished box. The outerskirt consists of the entire submesh of G with a square of side length k removed from its center. As shown in Figure 3, the patch and the host overlap in an annular region of width k. The patch and the outerskirt are mapped to the finished box as follows. The outerskirt is the same size and shape as the skirt of the finished box; every node in the outerskirt is mapped to its corresponding node in the skirt. The patch, which is a square of side length $2k$, is mapped to a square of side length $k/2$ called the *patch region* shown in Figure 3; the patch region is contained within the skirt of the finished box. This is done in the simplest manner by mapping squares of side length 4 of the patch to one node of the square in the finished box.

We now observe some properties of the mapping. A *ring* is a set of nodes that form the four sides of a square. The nodes in the finished box to which the border of the patch and the inner border of the outerskirt are mapped form rings in the finished box. We call these rings the *border rings*, or b-rings for short. The nodes on the

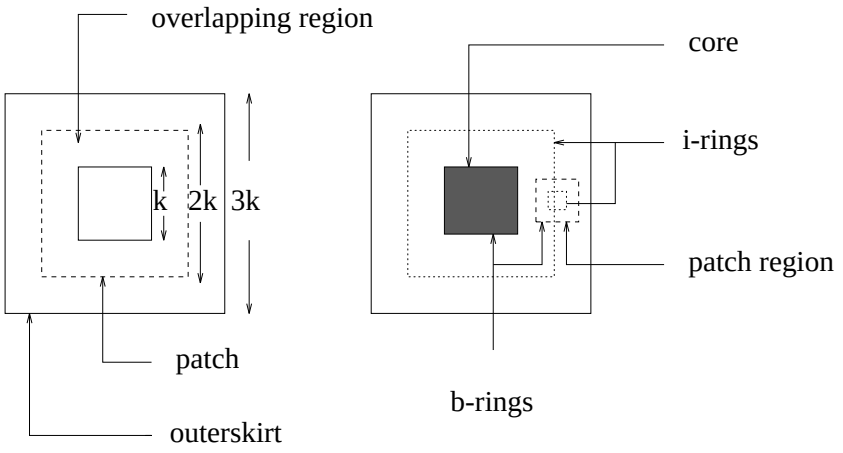

FIG. 3. *Mapping the computation inside a finished box. A finished box in H is shown on the right and the corresponding submesh in G is shown on the left.*

border of the patch have duplicates in the interior of the outerskirt. Similarly, the nodes on the inner border of the outerskirt have duplicates in the interior of the patch. These duplicate nodes in the interior of the patch and the interior of the outerskirt are also mapped to rings in the finished box. We call these rings the *interior rings*, or i-rings for short.

In order for a node m in H to create an s-pebble for a node v in G, it must receive c-pebbles for each of the edges into v in G. If v is in the interior of the patch or the outerskirt, then the s-pebbles for the neighbors of v are created either by m or by the neighbors of m. In this case the required c-pebbles can be obtained in constant time. The s-pebbles for the neighbors of a node v on the border of the patch or outerskirt, however, may not be created near m in H. In our emulation, every node v on the border receives the c-pebbles for *all* of its incoming edges from its duplicate v' that is mapped to a node m' on one of the i-rings in the finished box. These c-pebbles are first created by the four neighbors of v', then sent to m' (in constant time), then forwarded on to m along a path that we call a *communication path*. Thus, for each node m' on an i-ring, we will need to route a communication path to its duplicate m on a b-ring. Note that these paths are determined off-line, before the start of the emulation. The skirt, which is fault free, can be used as a crossbar to route the paths with dilation $O(k)$ and constant congestion. For the sake of brevity, the details are omitted.

We now describe the actual emulation. Each node m of H executes the following algorithm which proceeds as a sequence of macrosteps. Each macrostep consists of the following three substeps.

(1) Computation step: For each node v of G that has been assigned to m, m creates a new s-pebble $\langle v, t\rangle$, provided that m has already created $\langle v, t-1\rangle$ and has received c-pebbles $[e, t-1]$ for every edge e into v.
(2) Communication step: For every node v such that s-pebble $\langle v, t\rangle$ was created by m in the computation step of the current macrostep, and for every edge e out of v, node m creates c-pebble $[e, t]$. If $[e, t]$ is needed by a neighbor m' of m, then m sends $[e, t]$ to m'.
(3) Routing step: If m lies on an i-ring, then m makes copies of any c-pebbles

that were sent to m during the communication step of the current macrostep. Then (whether or not m lies on an i-ring), for every c-pebble $[e, t]$ at m that has not yet reached its destination, m forwards it one step along its communication path.

LEMMA 2.2. *A macrostep takes a constant number of time steps.*

Proof. At each node of H, there are at most 17 s-pebbles to be updated in the computation step and hence this step takes constant time. Each s-pebble update can cause at most 4 c-pebbles (the outdegree of the node in G) to be sent. Thus the communication step takes only constant time. If the s-pebble is on the i-ring, it must send four additional c-pebbles to its duplicate on the b-ring. Since the paths used for routing have constant congestion and since a c-pebble in transit to its destination moves in every macrostep, there are at most a constant number of c-pebbles resident in a node at any time step that have not yet reached their destinations. Therefore, the routing step also takes constant time. □

THEOREM 2.3. *Any computation on a fault-free mesh G that takes time T can be emulated by the faulty mesh H with less than $(\log N)/2$ worst-case faults in $O(T+N)$ time steps.*

Proof. From Lemma 2.1, we know that since the number of worst-case faults in H is less than $(\log N)/2$, the growth process terminates with a set of nonintersecting finished boxes. The computation of G is mapped inside each of these finished boxes as described earlier in this section, and each node m of H performs the emulation algorithm. We will show that only $O(T + N)$ macrosteps are required to emulate a T-step computation of G. The theorem will then follow from Lemma 2.2.

The *dependency tree* of an s-pebble represents the functional dependency of this s-pebble on other s-pebbles and can be defined recursively as follows. As the base case, if $t = 0$, the dependency tree of $\langle v, t\rangle$ is a single node, $\langle v, 0\rangle$. If $t > 0$, the creation of s-pebble $\langle v, t\rangle$ requires an s-pebble $\langle v, t-1\rangle$ and all c-pebbles $[e, t-1]$ such that e is an incoming edge of node v in G. These c-pebbles are sent by some other s-pebbles $\langle u, t-1\rangle$, where u is a neighbor of v in G. The dependency tree of $\langle v, t\rangle$ is defined recursively as follows. The root of the tree is $\langle v, t\rangle$. The subtrees of this tree are the dependency trees of $\langle v, t-1\rangle$ and $\langle u, t-1\rangle$, for all s-pebbles $\langle u, t-1\rangle$ that send c-pebbles to $\langle v, t\rangle$.

We now look at the dependency tree of the s-pebble that was created last. Let the emulation of T steps of G take T' time (in macrosteps) on H. Let $\langle v, T\rangle$ be an s-pebble that was updated in the last macrostep. For every tree node s, we can associate a time (in macrosteps) $\tau(s)$ when that s-pebble was created. We choose a *critical path*, $s_T, s_{T-1}, \ldots, s_0$, of tree nodes from the root to the leaves of the tree as follows. Let $s_T = \langle v, T\rangle$ be the root of the tree. s_T requires the s-pebble $\langle v, T-1\rangle$ and c-pebbles $[e, T-1]$. Let ϕ be the function that maps an s-pebble, $\langle v, t\rangle$ to the node in H that contains it. If the s-pebble $\langle v, T-1\rangle$ was created after all the c-pebbles were received then choose s_{T-1} to be $\langle v, T-1\rangle$. Otherwise, choose the s-pebble that sent the c-pebble that arrived last at node $\phi(\langle v, T\rangle)$ to be s_{T-1}. After choosing s_{T-1}, we choose the rest of the sequence recursively in the subtree with s_{T-1} as the root. We define a quantity l_i as follows. If $\phi(s_i)$ and $\phi(s_{i-1})$ are the same node or neighbors in H, then $l_i = 1$. Otherwise, l_i is the length of the path by which a c-pebble generated by s_{i-1} is sent to s_i. From the definition of our critical path, $\tau(s_i) - \tau(s_{i-1})$ equals l_i. This is because a c-pebble moves once along its communication path in every

macrostep. Therefore

$$T' = \sum_{0<i\leq T} (\tau(s_i) - \tau(s_{i-1})) = \sum_{0<i\leq T} l_i.$$

Now suppose that some l_i is greater than 1. Then $\phi(s_i)$ must lie on the b-ring of a finished box, and some c-pebble must have taken a communication path of length l_i from a node m on an i-ring of the same finished box. In this case either $\phi(s_{i-1}) = m$ or $\phi(s_{i-1})$ is a neighbor of m. The key observation is that since $\phi(s_{i-1})$ is either on or next to an i-ring, in going down the critical path from s_{i-1} to s_0 we can encounter no more communication paths until we reach an s-pebble embedded in the b-ring; i.e., the values of $l_{i-1}, l_{i-2}, \ldots, l_{\max\{i-q,1\}}$ are all equal to 1 for some $q = \Theta(l_i)$. As $l_i = O(N)$, for all i, $T' = \sum_i l_i = O(T + N)$. □

It is possible to apply the construction described in this section recursively to show that, for any constant $k > 0$, an $N \times N$ mesh can sustain $\log^k N$ worst-case faults and still emulate a fault-free mesh with slowdown. Because a stronger result is proven in section 3, the proof is omitted.

THEOREM 2.4. *For any constant $k > 0$, an $N \times N$ mesh with $\log^k N$ worst-case faults can emulate T steps of the computation of a fault-free $N \times N$ mesh in $O(T+N)$ steps with constant slowdown.*

The construction described in this section assumes that large buffers are available at each node in the host to hold c-pebbles that reach their destinations early. Early arrivals can be prevented by slowing down the computation of some nodes and by finding communication paths with the property that all paths within a given finished box have the same length.

3. Multiscale emulation. In this section, we show that an $N \times N$ mesh, H, with any set of $N^{1-\epsilon}$ faults, for any fixed $\epsilon > 0$, can emulate any computation of a fault-free $N \times N$ mesh, G, with constant slowdown.

The major difference between the emulation scheme in this section and that in section 2 is that in this section we allow a finished box to contain smaller finished boxes. In emulating the region of the guest mesh assigned to it, a finished box will in turn assign portions of this computation to each of the smaller boxes that it contains. These smaller boxes might in turn contain even smaller boxes and hence the term *multiscale emulation*.

For simplicity, we assume that the mesh has wraparound edges. This assumption can be easily done away with at the cost of considering some special cases for faults near the border of the mesh.

3.1. The growth process. In this section, we show how to grow boxes on the faulty mesh H. There are two types of boxes: cores and finished boxes. A *core* is not capable of performing any portion of the emulation. A *finished box* consists of a core surrounded by a skirt. An (α-β)-*ensemble* is a collection of possibly intersecting finished boxes. Every finished box B in an (α-β)-ensemble has a distinct round number. The *intersecting region* of a finished box B in the ensemble is defined to be the region formed by nodes that lie both in the skirt of B and in some other finished box with a smaller round number than B. The boxes in an (α-β)-ensemble satisfy the following properties.

(1) Every fault in the mesh H is contained in and assigned to the core of some finished box in the ensemble.
(2) If the core of a finished box has side length k, then the width of the skirt of the finished box is $\lfloor \alpha k \rfloor$.

(3) The sum of the side lengths of the finished boxes in the intersecting region of every finished box B is at most β times the width of the skirt of B.

The growth process produces an (α-β)-ensemble of boxes, where $0 < \alpha, \beta < 1$. It proceeds in rounds until there are no more cores left. Initially, every fault is enclosed in a core with side length $\lceil 1/\alpha \rceil$. Each round produces either a new core or a new finished box. Each new finished box is numbered with the round in which it was created. At the beginning of each round, a core of the smallest side length (say, k) is selected and a skirt of width $\lfloor \alpha k \rfloor$ is grown around it to form a box (call this box B). If $k + 2\lfloor \alpha k \rfloor > N$, then the side length of B will have to be larger than the size of the mesh itself and this is not possible. If this condition arises the growth process halts and is said to have failed. If this condition does not arise then one of the following steps is executed after which the growth process proceeds to the next round.

Expand Step. If the sum of the side lengths of the finished boxes in the intersecting region of B is more than β times the width of the skirt of B (i.e., $\beta\lfloor \alpha k \rfloor$), then we find the smallest bounding box that contains the core of B as well as the cores of all the finished boxes that intersect the skirt or core of B and turn this box into a new core. The finished boxes whose cores were included in this new core cease to exist, and their faults are assigned to the new core.

Create Step. Otherwise, if the sum of the side lengths of the finished boxes in the intersecting region of B is at most $\beta\lfloor \alpha k \rfloor$, then we declare box B to be a finished box.

Note that in the expand step the intersecting region of B is computed using the collection of finished boxes that exist during that round.

LEMMA 3.1. *The growth process produces an (α-β)-ensemble of finished boxes, provided that it does not fail.*

Proof. We must show that all three of the properties of an (α-β)-ensemble are satisfied when the growth process does not fail. The growth process must terminate since at each round either the expand step increases the side length of a core without changing the number of cores, or the create step decreases the total number of cores by one. Property 1 is satisfied initially and since the expand step forms a new core by enclosing a group of old cores, by induction this property will hold after every round. Property 2 is satisfied by construction. Finally, when a finished box B is created in the create step, the sum of the side lengths of the finished boxes in the intersecting region of B is at most β times the width of the skirt of B. New finished boxes created in later rounds do not affect this intersecting region since they all have greater round numbers than B. Some of the finished boxes with round numbers less than B may cease to exist due to the application of the expand step in some later rounds. However, this can only decrease the sum of the side lengths of the finished boxes in the intersecting region of B. Thus, Property 3 will be true for all of the finished boxes when the growth process terminates. □

THEOREM 3.2. *For any fixed constants β and ϵ, where $0 < \beta < 1$ and $0 < \epsilon < 1$, there is a constant α, where $0 < \alpha < 1$, such that for sufficiently large N, for any set of $N^{1-\epsilon}$ faults in H the growth process grows an (α-β)-ensemble of finished boxes.*

Proof. We must show that for any fixed ϵ and β there is a constant α such that the growth process never fails, i.e., no core of side length more than $N/(2\alpha + 1)$ is ever created. Then, by using Lemma 3.1, we can infer the theorem.

The key idea is to prove a lower bound, $F(k)$, on the number of faults that any core of side length k must contain. Let $\delta = \epsilon/2$. We show by induction on k that $F(k) \geq Ak^{1-\delta}$, for some constant A. In order to satisfy the basis of the induction, we will choose A to be small enough that $F(k) \geq Ak^{1-\delta}$ for small values of k. Inductively,

suppose that a new core of side length k is formed in some round. Let x be the side length of the core selected in this round and let $y_1, y_2, \ldots, y_m$ be the side lengths of the other cores that were enclosed to form the new core. Since the new core contains these cores, we have $k > x$ and $k > y_i$, for $1 \le i \le m$. Since the number of faults in the new core is at least as large as the number of faults in the cores used to form it, using the inductive hypothesis we have

$$\begin{aligned} F(k) &\ge F(x) + F(y_1) + \cdots + F(y_m) \\ &\ge Ax^{1-\delta} + Ay_1^{1-\delta} + \cdots + Ay_m^{1-\delta}. \end{aligned} \tag{2}$$

Let y_1 and y_2 be the side lengths of the two largest cores. If a new core was formed, then it must have been formed in the expand step. Thus, the side length k of the new core is at most $(y_1 + y_2)(1 + \alpha) + x(1 + 2\alpha)$. Thus, to prove the inductive hypothesis, it suffices to show that

$$x^{1-\delta} + \sum_{i=1}^{m} y_i^{1-\delta} \ge [(y_1 + y_2)(1 + \alpha) + x(1 + 2\alpha)]^{1-\delta}. \tag{3}$$

Since the cores with side lengths y_i belong to finished boxes created in earlier rounds, $y_i \le x$, for all i. Furthermore, since a new core was created, $\sum_{i=1}^{m} (y_i + 2\lfloor \alpha y_i \rfloor) \ge \beta \lfloor \alpha x \rfloor$, which implies that $\sum_{i=1}^{m} y_i \ge \beta\alpha x/6$ for $0 < \alpha < 1$. Since $\beta < 1$, there must be a largest index $j \ge 2$ such that $\beta\alpha x/6 \le \sum_{i=1}^{j} y_i \le 2x$. Let $y = \sum_{i=1}^{j} y_i$. Then $y \ge y_1 + y_2$. Also, because of the convexity of the function $f(z) = z^{1-\delta}$, $y^{1-\delta} \le \sum_{i=1}^{j} y_i^{1-\delta} \le \sum_{i=1}^{m} y_i^{1-\delta}$. Thus, inequality (3) must hold if

$$[y(1 + \alpha) + x(1 + 2\alpha)]^{1-\delta} \le x^{1-\delta} + y^{1-\delta} \tag{4}$$

holds for all y such that $\beta\alpha x/6 \le y \le 2x$.

Proving that inequality (4) holds for sufficiently small α requires some elementary (but painstaking) calculations. Let $\lambda = y/x$. In terms of λ, we need to show that for sufficiently small α, the inequality

$$[(1 + \alpha)\lambda + (1 + 2\alpha)]^{1-\delta} - 1 - \lambda^{1-\delta} \le 0 \tag{5}$$

holds for all λ such that $\beta\alpha/6 \le \lambda \le 2$. (As we shall see, $\alpha \le \min\{(\beta/24)^{1/\delta}, \delta/16\}$ suffices.) There are three cases to consider.

First, suppose that $\lambda \le \alpha$. In this case, we have

$$[(1 + \alpha)\lambda + (1 + 2\alpha)]^{1-\delta} - 1 - \lambda^{1-\delta} \le (1 + 4\alpha)^{1-\delta} - 1 - (\beta\alpha/6)^{1-\delta} \tag{6}$$

$$\le 4\alpha - \left(\frac{(\beta/6)^{1-\delta}}{\alpha^{\delta}} \right) \alpha \tag{7}$$

$$\le \left(4 - \frac{\beta}{6\alpha^{\delta}} \right) \alpha. \tag{8}$$

Equation (6) is derived using the inequalities $(1 + \alpha) \le 2$, $\lambda \le \alpha$, and $\beta\alpha/6 \le \lambda$. Equation (7) is derived from (6) using the inequality $(1 + 4\alpha)^{1-\delta} \le (1 + 4\alpha)$. Equation (8) is derived from (7) using the inequality $\beta/6 \le (\beta/6)^{1-\delta}$. For $\alpha \le (\beta/24)^{1/\delta}$, the right-hand side of (8) is at most 0.

Second, suppose that $\alpha \le \lambda \le 1$. In this case we have

$$[(1 + \alpha)\lambda + (1 + 2\alpha)]^{1-\delta} - 1 - \lambda^{1-\delta} \le [1 + \lambda + 3\alpha]^{1-\delta} - 1 - \lambda^{1-\delta} \tag{9}$$

$$\le (1 - \delta)(\lambda + 3\alpha) - \lambda^{1-\delta} \tag{10}$$

$$\le 3\alpha + \lambda - \delta\lambda - \lambda^{1-\delta}. \tag{11}$$

Equation (9) is derived using the inequality $\lambda \leq 1$. Equation (10) is derived from (9) using the fact that $(1+a)^b \leq 1+ab$ for any $a \geq 0$ and $0 \leq b \leq 1$. Equation (11) is derived from (10) using the inequality $3\alpha\delta > 0$. Now let $h(\lambda) = 3\alpha + \lambda - \delta\lambda - \lambda^{1-\delta}$. Differentiating with respect to λ, we have $h'(\lambda) = 1 - \delta - (1-\delta)\lambda^{-\delta}$. For $0 < \lambda < 1$, $h'(\lambda) < 0$, and for $\lambda = 1$, $h'(\lambda) = 0$. Thus for $\alpha \leq \lambda \leq 1$, $h(\lambda)$ takes on its maximum value when $\lambda = \alpha$. Returning to (9)–(11), we have

$$[(1+\alpha)\lambda + (1+2\alpha)]^{1-\delta} - 1 - \lambda^{1-\delta} \leq 4\alpha - \delta\alpha - \alpha^{1-\delta} \tag{12}$$

$$\leq (4 - \alpha^{-\delta})\alpha. \tag{13}$$

Equation (13) is derived from (12) using the inequality $\delta > 0$. The right-hand side of (13) is at most 0, provided that $\alpha \leq (\beta/24)^{1/\delta}$, as in the first case.

Finally, suppose that $1 < \lambda \leq 2$. In this case, we have

$$[(1+\alpha)\lambda + (1+2\alpha)]^{1-\delta} - 1 - \lambda^{1-\delta} \tag{14}$$

$$\leq [(1+\lambda) + 4\alpha]^{1-\delta} - 1 - \lambda^{1-\delta}$$

$$\leq (1+\lambda)^{1-\delta}(1+4\alpha)^{1-\delta} - 1 - \lambda^{1-\delta} \tag{15}$$

$$\leq \lambda^{1-\delta}\left(1 + \frac{1-\delta}{\lambda}\right)(1 + 4\alpha(1-\delta)) - 1 - \lambda^{1-\delta} \tag{16}$$

$$= \frac{1-\delta}{\lambda^{\delta}} + \lambda^{1-\delta}\left(1 + \frac{1-\delta}{\lambda}\right)(4\alpha(1-\delta)) - 1 \tag{17}$$

$$\leq 16\alpha - \delta. \tag{18}$$

Equation (14) is derived using the inequality $\lambda \leq 2$. Equation (15) is derived from (14) using the inequality $1/(1+\lambda) \leq 1$. Equation (16) is derived from (15) using the fact that $(1+a)^b \leq 1+ab$ for any $a \geq 0$ and $0 \leq b \leq 1$ (in two places). Equation (18) is derived from (17) using the inequalities $1/\lambda^{\delta} < 1$, $\lambda^{1-\delta} < 2$, $(1-\delta)/\lambda < 1$, and $1 - \delta < 1$. For $\alpha \leq \delta/16$ the right-hand side of (18) is at most 0.

The growth process fails only if a core of side length k is created where $k + 2\lceil \alpha k \rceil > N$. In this case $k > (N-2)/(2\alpha+1) > N/(2\alpha+3)$, for $N > 2\alpha+3$. Such a core must contain at least $F(k) \geq Ak^{1-\delta} \geq A(N/(2\alpha+3))^{1-\delta}$ faults. Recall that $\delta = \epsilon/2$. Thus, for sufficiently large N, $A(N/(2\alpha+3))^{1-\delta} > N^{1-\epsilon}$. So, if there are fewer than $N^{1-\epsilon}$ faults in the mesh, then no such core is created, and the growth process produces an (α-β)-ensemble of finished boxes. □

3.2. Mapping the computation. In this section, we show how to map the computation of the fault free $N \times N$ mesh G onto an $N \times N$ mesh H with $N^{1-\epsilon}$ faults. The mapping requires that an (α-β)-ensemble of finished boxes be grown in H, for some constants α and β, where $0 < \alpha < 1$ and $0 < \beta < 1$. As it turns out, β can be chosen independently of α and ϵ. So we choose β first. Next, we choose α such that for fixed β and ϵ and any set of $N^{1-\epsilon}$ faults an (α-β)-ensemble of boxes can be grown using the growth process outlined in section 3.1.

We will use the pebbling terminology introduced in section 2 to describe the mapping. The mapping is produced by a *mapping process* that progresses iteratively in rounds. Initially, an s-pebble for each node of G is mapped to the corresponding node of H. Like a regular mesh computation, each s-pebble gets c-pebbles from the s-pebbles mapped to the neighboring nodes in H. The mapping process selects a finished box in the ensemble at the beginning of each round in the decreasing order of their round numbers. In each round, the mapping process changes the mapping inside the selected finished box so that no s-pebbles are mapped to the core of that

finished box. This is done by removing s-pebbles from the core, duplicating some s-pebbles, and setting up constant-congestion communication paths between duplicated s-pebbles that avoid routing through any finished boxes with smaller round numbers. The mapping process terminates when all finished boxes in the ensemble have been selected.

A mapping of the computation of G to H is said to be *valid* if no s-pebble of G is mapped to a faulty node in H and no communication path between two s-pebbles passes through a faulty node in H. The initial mapping is *not* valid since it maps s-pebbles to faulty nodes of H. After all the rounds are completed, no s-pebble will be mapped to a faulty node and no communication will pass though a faulty node. Thus, the final mapping will be valid.

The computation mapped onto a finished box B is said to be *meshlike* if each node in B has exactly one s-pebble mapped to it and each s-pebble that is mapped to a node m in B receives a c-pebble from each of the s-pebbles mapped to neighboring nodes of m in B. Our mapping process will ensure that the following invariant will hold true at the beginning of every round.

INVARIANT 3.3. *Suppose that B is a finished box with round number l that is selected at some round. At the beginning of the round, for every finished box B' with round number k, $k \leq l$, either no computation is mapped to B', or a meshlike computation is mapped to B'. Furthermore, no communication path passes through any node in B'.*

The invariant is true at the beginning of the first round since every finished box has a meshlike computation mapped to it and there are no communication paths. At the end of each round, this invariant will hold true inductively. Later in this section, we will outline the steps involved in a specific round of the mapping process in which the computation within the chosen finished box is remapped. We now show that the invariant guarantees that upon termination the mapping process produces a mapping that does not map computation or communication to faulty processors.

THEOREM 3.4. *The mapping process produces a valid mapping of the computation of G into H.*

Proof. We must show that every faulty node of H has neither an s-pebble mapped to it nor a communication path passing through it in the final mapping produced by the iterative mapping process. A node v of H is said to be *active* at a particular round of the mapping process if it either has an s-pebble mapped to it or has a communication path passing through it in the beginning of this round. A node is said to be *inactive* if it is not active. In the first round, every node in H is active.

A key property of the iterative mapping process is that if in some round a node v becomes inactive it remains inactive through the remaining rounds. For a contradiction, suppose that an inactive node v becomes active. Let B be the finished box selected in the last round in which v was inactive. Since only nodes inside B are affected by the remapping, v must be in B. From Invariant 3.3 and the fact that v is inactive, it must be the case that no computation was mapped to B. This means that no computation was remapped in this round, which is a contradiction.

We now show that no faulty node remains active at the end of the mapping process. From Property 1 of an (α-β)-ensemble of finished boxes, every fault in H is contained in some core of some finished box. Let v be a faulty node in H and let B be the finished box whose core contains this fault. If v is already inactive in some round before B is selected, it will remain inactive through the rest of the rounds. Otherwise, if v is active in the round that B is selected, it follows from Invariant 3.3 that there

must be an s-pebble mapped to v but no communication paths passing through v at the beginning of this round. The remapping of computation inside B will remove the computation from v and no new communication path will pass through v. Therefore, v becomes inactive and remains that way through the rest of the mapping process. Thus, no faulty node remains active at the end of the mapping process. □

3.2.1. Remapping the computation within a finished box. In this section, we show how to remap the computation within a finished box chosen in some round of the iterative mapping process. Let B be a box with round number l and side length $(2\alpha + 1)k$ that is selected at some round of the mapping process. (In the remainder of this paper we ignore the issue of whether quantities such as $2\alpha k$ are integral.) We assume that Invariant 3.3 is true at the beginning of this round. Later we show that this invariant is true at the end of the round after the remapping. If there is no computation mapped to B at the beginning of the round, no remapping needs to be done and the invariant holds at the end of the round.

The other possibility is that a meshlike computation is mapped to the nodes of B at the beginning of this round. In this case, the computation is partitioned into two overlapping pieces, the patch and the outerskirt. The precise sizes of the patch and the outerskirt will be specified later. The set of nodes in the finished box to which the border of the patch is mapped forms a ring in the finished box, as does the set of nodes to which the inner border of the outerskirt is mapped. We call these rings the border rings, or b-rings for short. Because the patch and the outerskirt overlap, the nodes on the border of the patch have duplicates in the interior of the outerskirt that perform the same computation. Similarly, the nodes in the inner border of the outerskirt have duplicates in the interior of the patch. These duplicate nodes in the interior of the outskirt and the interior of the patch are also mapped to rings in the finished box. We call these rings the interior rings, or i-rings for short.

The region consisting of nodes in B not more than distance $\alpha k/5$ from the outer border of B is called the *outer region*. The outerskirt will be embedded in this region. Similarly, a square box of side length $3\alpha k/5$ is called the *patch region*. As shown in Figure 4, the patch region is located below and to the left of the core, and does not intersect the outer region. The patch will be embedded in this region.

The first step in remapping the computation within B is to place a b-ring and an i-ring in each of the two regions (see Figure 4). A *free ring* in the patch region or outer region is defined to be a ring that does not pass through any finished boxes B' with smaller round numbers than B. The b- and i-rings satisfy the following *ring properties*.

(1) The i-ring and the b-ring of the outer region must be free rings. Furthermore, between the i-ring and the b-ring of the outer region there must be $\Theta(k)$ free rings. The same condition must hold for the i-ring and the b-ring of the patch region. Further, the i-ring of the patch region must have side length $\Theta(k)$.
(2) For *any* constant-load embedding of s-pebbles into a side of the i-ring of one region and *any* constant-load embedding of the duplicates of these s-pebbles into the corresponding side of the b-ring of the other region, there must be paths of length $\Theta(k)$ from every s-pebble to its duplicate. These paths must have constant congestion, must be completely contained in B, and must not pass through any finished boxes B' with smaller round numbers than B.

The procedure for finding rings with these properties is outlined in section 3.4.

Having determined the i-rings and the b-rings, the next step is to determine the size and layout of the patch and the outerskirt. Recall that a meshlike computation

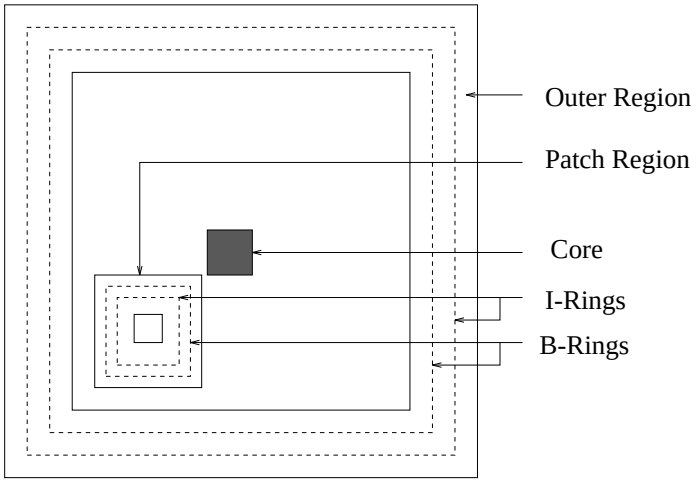

FIG. 4. *Layout of finished box B in the host.*

was mapped into box B at the beginning of this round. The size of the outerskirt and patch will depend on the choice of the i- and b-rings. The computation mapped between the b-ring of the outer region and the border of B at the beginning of this round forms the outerskirt. The computation mapped within the i-ring of the outer region at the beginning of this round forms the patch. Remapping the outerskirt and the patch to nodes within B must be done with care so that Invariant 3.3 is true at the end of this round.

The outerskirt is embedded in the region of B between the b-ring in the outer region and the border of B. Since the size and shape of the outerskirt are the same as the region in which it is embedded, we simply map each s-pebble in the outerskirt to the corresponding node in that region of B.

The patch must be embedded into the square region enclosed by the b-ring in the patch region. This is trickier since the patch is a constant factor larger in size than the square region in which it is embedded. In particular, we must ensure that each finished box B' with a smaller round number than B that intersects this square region receives a meshlike computation or receives no computation at all. A column or row in this square region that intersects such a finished box B' will be called a *bad column* or a *bad row*. The remaining rows and columns are said to be *good rows* and *good columns* respectively. Since the sum of the side lengths of such boxes B' is at most $\beta\alpha k$, if we choose $\beta < 1/10$, then a majority of the $\alpha k/5$ columns and rows will be good. Our embedding is described by two functions ρ and κ such that a node in the ith row and the jth column of the patch is mapped to the $\rho(i)$th row and the $\kappa(j)$th column of the square region. The function ρ is selected so that for all i, $\rho(i) \leq \rho(i+1) \leq \rho(i)+1$. Further, for any value of j there are at most a constant number of values of i with $\rho(i) = j$ and if the jth row is bad there is exactly one value of i with $\rho(i) = j$. The function κ is chosen with similar properties for the columns. That such functions ρ and κ exist follows from the fact that the patch is at most a constant factor larger than the square region and that a majority of the rows and columns of the square region are good. This completes the embedding of the s-pebbles to nodes within B.

Finally, the constant-congestion paths between the s-pebbles in the i-ring and

their duplicates in the b-ring are set up. These paths must not pass through any finished boxes with round numbers smaller than that of B. These paths can be set up since the i-ring and b-ring satisfy the second ring property. Using these paths, each s-pebble on the b-ring receives c-pebbles from its duplicate on the i-ring. The procedure for finding these paths is given in section 3.4.

Now we show inductively that Invariant 3.3 holds at the end of the round in which B was selected.

THEOREM 3.5. *Invariant* 3.3 *is true after the computation within* B *has been remapped.*

Proof. We must show that each finished box B' with a smaller round number than B has a meshlike computation mapped to it or no computation mapped to it at all. All such boxes B' that do not intersect B are not affected by the remapping at all. From ring property 1, we know that no box B' with a smaller round number than B can intersect the b-ring in the outer region. Therefore, any intersecting box B' not entirely contained in B must intersect the region only where the outerskirt is embedded. Since the embedding of this region does not change in the course of the remapping, all such boxes B' still have a meshlike computation mapped to them.

We will now look at boxes B' contained entirely within B. Since the b-rings and i-rings do not pass through B', either B' is contained entirely in the region where the outerskirt is embedded or entirely in the region between the b-ring of the outer region and the core of the box or entirely inside the square region where the patch is embedded. In the first case, the embedding inside B' does not change by the remapping and it continues to have a meshlike computation mapped to it. In the second case, no computation is mapped to B' and no communication path passes through the nodes in it. In the third case, observe that every row or column of B' is in a bad row or bad column of the square region. Thus ρ and κ map exactly one row and one column respectively of the patch to these rows and columns. Thus a meshlike computation is mapped to B'. Finally, none of the newly formed communication paths pass through any of the finished boxes B'. □

3.3. The emulation. In this section, we show that if the growth process terminates with a set of nonintersecting finished boxes, then the host H can emulate the guest G with constant slowdown.

In order for a node in H to create an s-pebble for a node v of G, it must receive c-pebbles for each of the edges into v in G. If this s-pebble is in the interior of a patch or an outerskirt, the s-pebbles for the neighbors of v are created either by the same node in H or by the neighbors of that node in H. Thus, the required c-pebbles can be obtained in constant time. However, the s-pebbles for the neighbors of an s-pebble on the border of the patch or on the inner border of the outerskirt may not be created nearby in H. But, since the patch and the outerskirt overlap, for every s-pebble on the border of the patch or the inner border of the outerskirt there is a duplicate in the interior of the outerskirt or the patch, respectively. In our emulation, every s-pebble on the border will receive the c-pebbles for all of its incoming edges from its duplicate that is mapped to one of the i-rings in the finished box.

The emulation consists of a series of macrosteps as in section 2.2.

LEMMA 3.6. *Each macrostep takes only a constant number of time steps to execute.*

Proof. We will prove that the maximum number of s-pebbles mapped to any node of H and the maximum number of communication paths passing through any node of H is a constant when the mapping process terminates. We prove this by

induction on the rounds of the mapping process. At the beginning of the first round of the mapping process there is exactly one s-pebble mapped to every node of H and no communication paths pass through any node, so the hypothesis is true at the beginning of the first round. Suppose that the hypothesis is true at the beginning of some round. Let the finished box selected at this round be B. There are two possibilities. If there is no computation mapped to B and no communication passing through it, no remapping is done and the hypothesis remains true at the beginning of the next round. Otherwise, from Invariant 3.3, there is a meshlike computation mapped to B and no communication path passes through any of its nodes. Remapping the computation within each finished box B causes at most a constant number of s-pebbles to be mapped to any node within it. Furthermore, the maximum number of paths created in this round that pass through a node in B is a constant. Since no communication path created before this round uses a node in B, the inductive hypothesis is true at the beginning of the next round.

Since there are only a constant number of s-pebbles mapped to any node of H, the computation step takes only constant time. Since each s-pebble can produce at most four c-pebbles in the communication step, there are at most a constant number of c-pebbles created at each step by each node. Thus, the communication step takes only constant time. Since there are only a constant number of paths passing through every node and since every c-pebble moves in every macrostep and only a constant number of c-pebbles enter a particular path at any macrostep, there can be only a constant number of c-pebbles on a particular path resident at a particular node at a particular time. Thus the routing step also takes only a constant number of time steps. □

THEOREM 3.7. *For sufficiently large N, any computation on an $N \times N$ fault-free mesh G that takes time T can be emulated by an $N \times N$ faulty mesh H with $N^{1-\epsilon}$ worst-case faults (for any constant $\epsilon > 0$) in time $O(T + N)$.*

Proof. We show that only $O(T + N)$ macrosteps are required to emulate any T-step computation of G. The final result then follows from Lemma 3.6.

Let $B_1, B_2, \ldots, B_m$ be the finished boxes in the *descending* order of their round numbers and let their side lengths be $k_1, k_2, \ldots, k_m$. The iterative mapping process produces a series of mappings, $\phi_0, \phi_1, \ldots, \phi_m$, where ϕ_i is the mapping of s-pebbles to H at the end of the ith round. The mapping ϕ_i is obtained from the mapping ϕ_{i-1} by remapping the computation within box B_i. The final mapping generated by the mapping process is ϕ_m. Note that because the guest network can be redundant, it is possible for two distinct s-pebbles s and s' to have the same label $\langle v, t\rangle$; i.e., v is the node of G whose state after t steps of computation is represented by both s-pebbles s and s'. Furthermore, it is possible for different mappings ϕ_i and ϕ_j, $i \neq j$, to map different numbers of s-pebbles to H. For example, for each node v in G and each time step t, ϕ_0 maps only one s-pebble to H. For $i > 0$, however, unless there are no faults in H, ϕ_i maps at least two s-pebbles s and s' with the same label to different nodes in H.

The dependency tree and critical path for the final mapping ϕ_m are defined as in section 2.2. In general, a sequence of s-pebbles $s_{i,T}, s_{i,T-1}, \ldots, s_{i,0}$ is called a *T-sequence* with respect to a mapping ϕ_i if, for $0 \leq j < T-1$, $t_{i,j+1} = t_{i,j}+1$, and either $v_{i,j}$ and $v_{i,j+1}$ are the same node of G and $\phi_i(s_{i,j}) = \phi_i(s_{i,j+1})$, or $v_{i,j}$ and $v_{i,j+1}$ are neighbors in G and under ϕ_i, $s_{i,j}$ sends a c-pebble to $s_{i,j+1}$. For a given mapping ϕ_i and a T-sequence $s_{i,T}, s_{i,T-1}, \ldots, s_{i,0}$, $l_{i,j}$ is 1 if nodes $\phi_i(s_{i,j})$ and $\phi_i(s_{i,j-1})$ are the same node or neighbors in H. Otherwise, $l_{i,j}$ is the length of the communication path

by which a c-pebble generated by $s_{i,j-1}$ is sent to $s_{i,j}$. With each mapping ϕ_i we associate one T-sequence. The T-sequence for ϕ_m is the critical path. For $i < m$, the T-sequence for ϕ_i is derived from the T-sequence for ϕ_{i+1}. Let $\langle v_{i+1,j}, t_{i+1,j}\rangle$ be the label of $s_{i+1,j}$. If ϕ_{i+1} does not map $s_{i+1,j}$ to the border of the patch or the outerskirt of box B_{i+1}, then both ϕ_{i+1} and ϕ_i map a single pebble labeled $\langle v_{i+1,j}, t_{i+1,j}\rangle$ to H. In this case, $s_{i,j}$ is the pebble with label $\langle v_{i+1,j}, t_{i+1,j}\rangle$ that ϕ_i maps to H. Otherwise, ϕ_{i+1} maps two duplicate s-pebbles, both labeled $\langle v_{i+1,j}, t_{i+1,j}\rangle$, to box B_{i+1}, but ϕ_i maps only one pebble with that label to B_{i+1}. In this case, $s_{i,j}$ is the one s-pebble with label $\langle v_{i+1,j}, t_{i+1,j}\rangle$ that ϕ_i maps to B_{i+1}.

We now show that for any T-sequence $s_{m,T}, s_{m,T-1}, \ldots, s_{m,0}$ with respect to ϕ_m, $\sum_{0<j\le T} l_{m,j}$ is $O(T+N)$. For each mapping ϕ_i, we define a series of weights c_i, d_i, and $w_{i,j}$, where $0 \le i \le m$ and $0 < j \le T$. The weights are chosen such that for any value i the following two properties are satisfied:

(1) $\sum_j l_{i,j} \le \sum_j w_{i,j} + \sum_{r\le i}(c_r + d_r)$,
(2) For all j, $w_{i,j}$ is less than some fixed constant.

We will find an upper bound on $\sum_j l_{m,j}$, and hence on T', by finding upper bounds on the $w_{m,j}$ (they will be constant) and on $\sum_{r\le m}(c_r + d_r)$ (which will be $O(N)$).

Initially, we define $c_0 = d_0 = 0$ and $w_{0,j} = l_{0,j}$ for all values of j. Since ϕ_0 simply maps the s-pebbles of G to the corresponding nodes of H, every $l_{0,j}$ and hence every $w_{0,j}$ is 1. Thus $\sum_j l_{0,j} = \sum_j w_{0,j} + c_0 + d_0$. Furthermore, for all values of j, $w_{0,j}$ can be bounded from above by a fixed constant.

We choose c_i, d_i, and $w_{i,j}$, $0 < j \le T$ as follows. Inductively assume that we have determined the weights c_r, d_r, $0 \le r \le i-1$, and $w_{i-1,j}$, $0 < j \le T$, such that the two properties listed above are satisfied. Suppose that ϕ_{i-1} maps no computation onto box B_i. Then no remapping is necessary and so $l_{i,j} = l_{i-1,j}$ for all values of j. In this case we set $w_{i,j} = w_{i-1,j}$ for all j and set $c_i = d_i = 0$. Otherwise, from Invariant 3.3, ϕ_{i-1} maps a meshlike computation onto box B_i. The mapping ϕ_i differs from ϕ_{i-1} in that s-pebbles inside box B_i are remapped. Since s-pebbles outside B_i are not affected, $l_{i,j} = l_{i-1,j}$ for all j such that $\phi_{i-1}(s_{i-1,j})$ is not in B_i. We define $w_{i,j} = w_{i-1,j}$ for all such values of j. (Note that if ϕ_{i-1} maps an s-pebble $s_{i-1,j}$ outside B_i but adjacent to its border and maps $s_{i-1,j-1}$ to the border of B_i, then $l_{i,j} = l_{i-1,j}$. This is because the remapping inside B_i will not the change the location of the pebble with the same label as $s_{i-1,j-1}$.)

We now look at s-pebbles mapped inside B_i by ϕ_{i-1}. The new mapping ϕ_i introduces communication paths for s-pebbles $s_{i,j}$ such that $\phi_{i-1}(s_{i-1,j})$ lies on a b-ring of B_i. For all such s-pebbles $s_{i,j}$, $l_{i,j}$ equals the length of the communication path in B_i which is $\Theta(k_i)$, where k_i is the side length of B_i. For all other s-pebbles $s_{i,j}$, $l_{i,j} = l_{i-1,j}$. We determine the weights $w_{i,j}$ for each s-pebble $s_{i,j}$ such that $\phi_{i-1}(s_{i-1,j})$ is in B_i as follows. We will consider every maximal subsequence, $s_{i-1,h+p}, s_{i-1,h+p-1}, \ldots, s_{i-1,h}$, of the T-sequence such that $\phi_{i-1}(s_{i-1,h+q})$ is in B_i for $0 \le q \le p$. Let I be a set of integers q such that $l_{i,h+q} > 1$. There are three cases depending on the value of $|I|$.

If $|I| = 0$, there are no communication paths and for every q such that $0 \le q \le p$, $l_{i,h+q} = l_{i-1,h+q} = 1$. Therefore, we will define $w_{i,h+q} = w_{i-1,h+q}$ for every $0 \le q \le p$ and set $c_i = d_i = 0$.

If $|I| \ne 0$, let $L = \sum_{q\in I}(l_{i,h+q} - l_{i-1,h+q})$, which equals the net increase in the values of $l_{i,h+q}$ in the subsequence.

If $|I| = 1$, there is exactly one communication path. Note that this can happen only if either $\phi_{i-1}(s_{i-1,0})$ or $\phi_{i-1}(s_{i-1,T})$ is in box B_i. This is so because a maximal

subsequence of s-pebbles mapped to B_i that contains neither $s_{i-1,0}$ nor $s_{i-1,T}$ must necessarily begin and terminate with s-pebbles mapped to the border of B_i. Therefore such a subsequence must necessarily use communication paths an even number of times. If $\phi_{i-1}(s_{i-1,0})$ is in B_i, make $c_i = L$, where $L = \Theta(k_i)$ (since there is only one path). Otherwise set $c_i = 0$. Similarly, if $\phi_{i-1}(s_{i-1,T})$ is in B_i, make $d_i = L$. Otherwise set $d_i = 0$. For every $0 \le q \le p$, set $w_{i,h+q} = w_{i-1,h+q}$.

If $|I| > 1$, let J be the set of integers q such that $\phi_i(s_{i-1,h+q})$ is in some free ring either in the patch region or in the outer region. Recall that nodes in the free rings are not contained in any finished box B_l, $l > i$. The value of L is $|I|\Theta(k_i)$ since each communication path in B_i is $\Theta(k_i)$ in length. This increase must be distributed evenly among the weights of the s-pebbles $s_{i,h+q}, q \in J$. Thus for all $q \in J$, $w_{i,h+q} = w_{i-1,h+q} + L/|J|$. For any two s-pebbles $s_{i-1,h+q_1}$ and $s_{i-1,h+q_2}$ such that $q_1 < q_2$ and $q_1, q_2 \in I$, the subsequence $s_{i-1,h+q_1}, \ldots, s_{i-1,h+q_2}$ contains at least $\Theta(k_i)$ s-pebbles $s_{i-1,h+q'}$, such that $q' \in J$. This is so because the i-ring and the b-ring of the patch region or the outer region were chosen such that there are $\Theta(k_i)$ free rings between them. This implies that $|J| = \Theta(k_i|I|)$ and thus $L/|J|$ is a constant. For all other $q \notin |J|$, $l_{i,h+q} = l_{i-1,h+q}$ and $w_{i,h+q} = w_{i-1,h+q}$. We also set $c_i = d_i = 0$. After all such subsequences have been dealt with we go to the next iteration.

The weight assignments in all three cases maintain the condition that $\sum_j l_{i,j} \le \sum_j w_{i,j} + \sum_{r \le i}(c_r + d_r)$. Further, for all i and j, $w_{i,j}$ is at most a constant. This is so because if the weight of some $s_{i-1,j}$ increases at the ith iteration, i.e., $w_{i,j} > w_{i-1,j}$, then it will never increase again since $\phi_{i-1}(s_{i-1,j})$ is in a free ring of the finished box selected in the ith iteration and hence is not contained in any of the finished boxes with smaller round numbers that will be considered in future rounds. Thus its weight will never change after this iteration. Further, as we saw earlier, the increment $w_{i,j} - w_{i-1,j}$ is also a constant.

We bound $\sum_j l_{m,j}$ by bounding $\sum_j w_{m,j}$ and $\sum_{i \le m}(c_i + d_i)$. The fact that $w_{m,j}$ is a constant for all j implies that $\sum_j w_{m,j}$ is $O(T)$. We bound the summation $\sum_i (c_i + d_i)$ as follows. The value of c_i or d_i is either zero or $\Theta(k_i)$. Thus $\sum_i c_i$ can be no more than the sum of the side lengths of all the boxes in the (α-β)-ensemble, i.e., $\sum_i k_i$. We show that this quantity is $O(N)$. By the proof of Theorem 3.2 we know that the core of each B_i has at least $Ak_i^{1-\epsilon/2} > Ak_i^{1-\epsilon}$ faults, where A is a constant. Since each fault is contained in a unique core and there are at most $N^{1-\epsilon}$ faults in the mesh,

$$\sum_i Ak_i^{1-\epsilon} \le N^{1-\epsilon}.$$

The maximum value of $\sum_i k_i$ that satisfies the above constraint occurs when all but one of the values of k_i equal zero, i.e., when one value of k_i is $\Theta(N)$ and the rest are zero. Thus $\sum_i k_i$ and hence $\sum_i c_i$ is $O(N)$. Similarly, $\sum_i d_i$ can be shown to be $O(N)$. Therefore,

$$\sum_j l_{m,j} \le \sum_j w_{m,j} + \sum_{i \le m}(c_i + d_i) = O(T + N). \qquad \square$$

3.4. Finding the i- and b-rings. In this section, we show how to find i- and b-rings in a finished box B in H with side length $(2\alpha + 1)k$ satisfying the two ring properties listed in section 3.2.1.

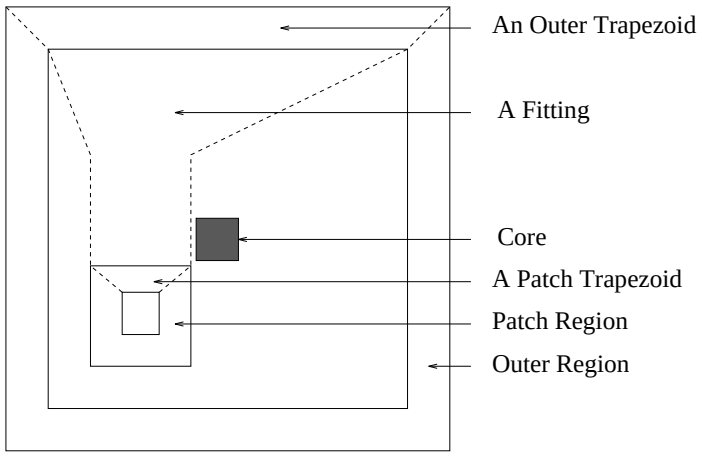

FIG. 5. *Finding i- and b-rings in H.*

Recall that the patch region is a square region in B of side length $3\alpha k/5$ and the outer region is an annular region of width $\alpha k/5$. In the center of the patch region, we place a square of size $\alpha k/5$ (see Figure 5). The i-ring of the patch is required to enclose this square. This guarantees that the i-ring of the patch has size $\Theta(k)$. A *trapezoid* is a four-sided figure consisting of two parallel sides and two nonparallel sides. We define the ith column of a trapezoid to be the set of nodes in the trapezoid at a distance i from the longer parallel side of the trapezoid. By joining the corners of the square in the patch region to the respective corners of the patch region, we partition the patch region, excluding the area enclosed by the square, into four trapezoidal regions (one of these regions is shown in Figure 5). Similarly, the outer region is also partitioned into four trapezoidal regions by joining each corner of the box B to the corresponding corner of the square forming the inner boundary of the outer region. Each ring in the outer or patch region consists of four sides, and each side is a column of one of the trapezoids.

We will define four distinct *zones*, each of which is made up of three parts. (A zone is marked with dotted lines in Figure 5.) The first part of a zone consists of one of the four trapezoids in the outer region (called the *outer trapezoid*) and the last part consists of the corresponding trapezoid in the patch region (called the *patch trapezoid*). The middle part is called the *fitting* and joins the outer trapezoid to the patch trapezoid (see Figure 5). The fitting is either a trapezoidal region or a rectangular region adjoining a trapezoidal region. (The patch region is positioned below and to the left of the core so that this is true.) Each of the four sides of a ring in the patch region or the outer region is a trapezoidal column in one of the four zones. Choosing b- and i-rings is equivalent to finding two trapezoidal columns in the patch trapezoid and two trapezoidal columns in the outer trapezoid of each of the four zones. Further, the four trapezoidal columns, one in each zone, that correspond to a particular ring must be chosen so as to have the same column number.

Since it is easier to work with rectangular grids than trapezoids, we will embed each of the four zones into a single rectangular grid R with $\alpha k/5$ rows and $3\alpha k/5$ columns. Note that R is not part of the guest or the host. It is a tool of the construction only. The grid formed by the first $\alpha k/5$ columns of R is called the *outer grid*, the next $\alpha k/5$ columns the *fitting grid*, and the last $\alpha k/5$ columns the *patch grid*.

The outer trapezoid, the fitting, and the patch trapezoid of each zone are embedded into the outer grid, fitting grid, and patch grid, respectively.

Since the outer trapezoid and the patch trapezoid each have $\alpha k/5$ columns, embedding them into their respective grids can be done by embedding the nodes in the ith trapezoidal column of the outer or the patch trapezoid to nodes in the ith column of the respective grid. Any constant-load and constant-dilation embedding will do for our purposes. We describe such an embedding below. The nodes in each trapezoidal column are grouped into $\alpha k/5$ groups such that each group contains some constant number of consecutive nodes of the column. Further, the cardinality of any two groups in a column differ by at most one and for all $i < j$ the cardinality of the ith group is at most the cardinality of the jth group of the same column. For every trapezoidal column, the ith such group is mapped to the ith node of the corresponding column of the grid. The dilation of this embedding is at most two and the load is constant.

Note that the four sides that form a ring either in the outer region or in the patch region are embedded into the same column in the outer grid or the patch grid, respectively. Therefore, a column in the outer or patch grid corresponds to the ring in the outer or patch region that gets mapped to it.

We can use the above technique to embed the fitting as well. The only difference is that since the fitting may have more than $\alpha k/5$ columns, we may have to embed a constant number of columns of the fitting in each column of the fitting grid.

We define regions in R called *obstacles* as follows. The region of R to which a finished box B' (or a portion of it) with a smaller round number than B is embedded is defined to be an obstacle. Note that the total perimeter of the obstacles in R is at most some constant times the total perimeter of the intersecting region of B.

A *free column* of R is defined to be one that does not pass through any obstacles. From the correspondences between columns in R and rings in the finished box B, in order to find i- and b-rings in B with the required ring properties, it is sufficient to choose i- and b-columns in R with the following *column properties*.

(1) The i-column and the b-column of the outer grid must be free columns. Further, between the i-column and the b-column of the outer grid there must be $\Theta(k)$ free columns. A similar condition must hold for the i-column and the b-column of the patch grid.
(2) The nodes of the i-column in one grid can be connected to the b-column of the other grid in any permutation using constant-congestion paths of length $\Theta(k)$ that do not pass through any of the obstacles.

Note that from the definition of the obstacles, if path p in R avoids all obstacles, then the paths in the four zones that are mapped to p also avoid all the finished boxes with smaller round numbers than B.

For technical reasons, we would like the placement of the obstacles in the outer grid, the patch grid, and the entire rectangular grid R itself to be symmetric about the columns in the centers of these respective grids, i.e., the obstacles in the first half of the columns of the grid are a mirror image of the obstacles in the second half of the columns of each of these three grids. To satisfy this condition we first copy every obstacle in one half of the outer grid to the other half by reflecting this obstacle about its center column. We do the same for the patch grid and then finally for the entire rectangular grid R. This copying can increase the perimeter of the obstacles by at most a constant factor.

We define a square box in R to be *flowless* as follows.

DEFINITION 3.8. *A square box F of side length q is said to be flowless if and*

only if either more than $q/4$ rows or more than $q/4$ columns pass through obstacles.

A column of R that does not intersect any of the flowless boxes is called a *live column*. Note that a live column is also a free column, since a box of size 1 that is not flowless can contain no obstacles.

THEOREM 3.9. *For a small enough value of β, a majority of the columns in the outer grid, fitting grid, and patch grid are live columns.*

Proof. Let f denote the number of columns in R that are not live. We can bound f in terms of the total perimeter of the obstacles in the grid by the following counting argument. Initially, let each nonlive column have one unit of credit associated with it. The total amount of credit in the system is f. For each nonlive column h let the largest flowless box that intersects h be box H. This nonlive column distributes its unit of credit evenly to nodes on the perimeters of the obstacles contained entirely in H. After every nonlive column has redistributed its unit of credit, the total number of credits in the nodes on the perimeters of the obstacles is still f.

Now we will determine the maximum credit received by any node s on the perimeter of an obstacle. Node s may receive credits from many different nonlive columns. First we look at nonlive columns with smaller column numbers than the column of s. Let the farthest such column from s that contributes to s be at a distance q from s. The flowless box F that intersects this nonlive column and contains s must have side length at least q. The total perimeter of the obstacles of a flowless box of size at least q must be at least $q/4$, since such a flowless box has at least $q/4$ rows or $q/4$ columns that pass through obstacles. Therefore the contribution of this nonlive column is at most $4/q$. Further, note that every nonlive column between this nonlive column and the column of s can contribute at most $4/q$. This is because box F intersects all these columns and hence the size of the largest flowless box intersecting these columns is at least q. Thus the total contribution to s from nonlive columns with smaller column numbers than its own column is at most $q \cdot 4/q$, which equals 4. Similarly the total contribution to s from nonlive columns with greater column numbers than its own column can also be bounded by 4. Therefore s receives at most eight credits.

We will now bound f, the number of columns that are not live. The perimeter of the obstacles is at most some constant c (independent of α and β) times the sum of the side lengths of the finished boxes in the intersecting region of B, i.e., at most $c\beta\alpha k$. Thus the total number of credits in the nodes on the perimeters of the obstacles is at most $8c\beta\alpha k$, so $f \leq 8c\beta\alpha k$. For $\beta < 1/80c$, the majority of the $\alpha k/5$ columns in each of the outer, fitting, and patch grids are live columns. □

3.4.1. Permuting grids. We define a *permuting grid* as follows. An $l \times m$ rectangular grid (i.e., a grid with l rows and m columns) is said to be a permuting grid if

(1) Each node on the left side of the grid is connected by a path to a distinct node on the right side of the grid. The paths have constant congestion, do not pass through any obstacles, and each path has length $\Theta(m)$. These paths are called the *horizontal paths*.
(2) There are at least $m/4$ paths from nodes on the top side of the grid to nodes on the bottom side of the grid such that the congestion of these paths is also a constant. These paths do not pass through any of the obstacles and each path has length $\Theta(l)$. These paths are called the *vertical paths*.

Note that the horizontal and vertical paths in a permuting grid are required to satisfy different properties.

LEMMA 3.10. *The l nodes on the left side of an $l \times m$ permuting grid can be connected in any permutation to the nodes on the right side of the grid using constant-congestion paths of length $\Theta(m)$ that do not pass through any obstacles, provided that $l = O(m)$.*

Proof. The idea is to use the horizontal and vertical paths in the grid as a crossbar. Each node on the left side of the permuting grid is assigned a vertical path such that no vertical path is assigned more than $4l/m$ nodes. Let π denote the permutation to be routed. A path from node v in the left side to $\pi(v)$ in the right side is routed in three stages. In the first stage, a path is routed from v along the horizontal path originating at v to the node where this horizontal path first meets the vertical path assigned to v. In the next stage, the path goes along this vertical path to the node where this vertical path first meets the horizontal path ending at $\pi(v)$. In the last stage, the path goes along this horizontal path to the destination node $\pi(v)$. It is easy to see that this path has length $\Theta(l + m) = \Theta(m)$.

The total congestion on any node in the grid can be split into a sum of three parts. The congestion of a node due to paths in the first (last) stage is at most the congestion of the horizontal paths and hence is constant. The congestion due to paths in the middle stage is constant since it is at most $4l/m$ times the congestion of the vertical paths. Hence for $l = O(m)$ the net congestion is a constant. □

We choose the i- and b-columns from the live columns in the outer and patch grids. Recall that live columns do not pass through flowless boxes. We choose β as small as is required by Theorem 3.9 so that the majority of the columns in the outer, fitting, and patch grids are live columns. Note that since the obstacles are symmetric about the middle column of the outer grid, the live columns of the outer grid are symmetric about the middle column as well. Similarly, the live columns in the patch grid and the entire rectangular grid R are symmetric about their middle columns. The live columns with the smallest column number in the outer grid and the patch grid are chosen to be the i-column of the outer grid and the b-column of the patch grid, respectively. The live columns with the largest column number in the outer grid and the patch grid are chosen to be the b-column of the outer grid and the i-column of the patch grid, respectively. The i- and b-rings in the finished box B are the rings that correspond to the chosen i- and b-columns. Let the grid between the i-column and b-column in the outer grid be O, the grid between the b-column of the outer grid and b-column of the patch grid be F, and the grid between the b-column and i-column of the patch be P.

THEOREM 3.11. *The grids* O, F, *and* P *are permuting grids.*

Proof. First we show that O is a permuting grid. O is an $\alpha k/5 \times m$ grid, for some $m \leq \alpha k/5$. Since i- and b-rings in the outergrid are the leftmost and rightmost live columns, respectively, O contains at least $\alpha k/10 \geq m/2 \geq m/4$ live columns. These live columns can serve as the vertical paths in the grid. Now we grow constant congestion paths that do not hit obstacles from every node in the i-column that forms the left side of O to the corresponding node in the b-column that forms the right side of O. These will serve as the horizontal paths of the permuting grid.

The first step is to grow constant-congestion paths that do not hit obstacles from every node in the i-column to nodes in the middle column of O. Every node in the middle column need not have a path ending in it but every node in the i-column must have a path originating in it. We define a series of square boxes of side length $2^i, 0 \leq i \leq \log_2(\alpha k/5)$. (For simplicity, we assume that $\alpha k/5$ is a power of 2.) The left side of every box consists of a set of consecutive nodes in the i-column. All the boxes

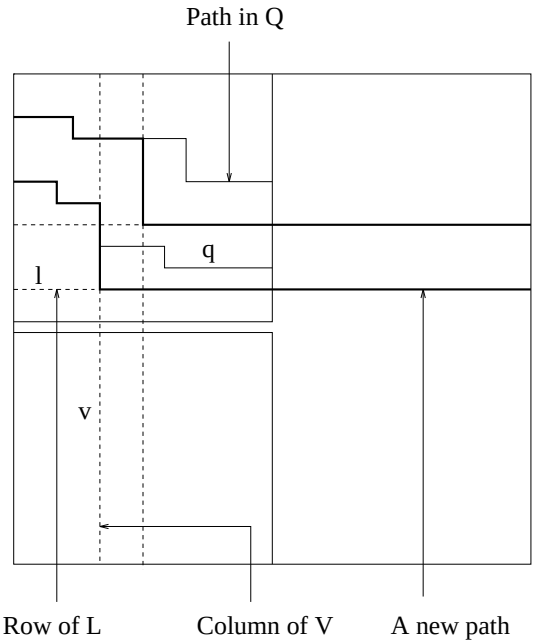

FIG. 6. *A new path constructed from path q, column v, and row l.*

of a particular size are numbered consecutively starting from the top and ending at the bottom of the i-column. Boxes of size 1 are the individual nodes in the i-column itself. Given boxes of size 2^i, we obtain boxes of size 2^{i+1} by enclosing every odd numbered box of size 2^i and the succeeding even numbered box with a box of size 2^{i+1}. There will be exactly one box of the largest size and this box encloses O. It is important to note that none of these boxes are flowless since the i-column is a live column.

We grow paths iteratively from smaller sized boxes to larger sized boxes. At the beginning of the ith iteration, we assume that each box of size 2^{i-1} has paths with maximum length $4 \cdot 2^{i-1}$ originating from every node on its left side and ending at some node on its right side. The paths are grouped into sets of 8, such that two paths share an edge only if they belong to the same group. Hence, the congestion of the paths is at most 8. We show how to construct the groups of 8 paths with maximum length $4 \cdot 2^i$ for every box of size 2^i.

For $i = 0$, it suffices to observe that each box of size 1 has no obstacles in it, since these boxes are not flowless. For $i > 0$, each box of size 2^i encloses two smaller boxes of size 2^{i-1} (see Figure 6). Let D denote the rectangular box formed by the first half of the columns of the big box. D encloses both of the smaller boxes of size 2^{i-1}. Since the big box is not flowless, there are at least $(3/4)2^i$ rows that do not hit obstacles (call this set of rows L) and at least $(3/4)2^i$ columns that do not hit obstacles. Of these $(3/4)2^i$ columns, at least $(1/4)2^i$ columns lie within D (call this set of columns V). Let Q denote the set of paths that are inductively assumed to exist inside both the smaller boxes. We use L and V to extend the paths in Q to nodes on the right side of the big box (see Figure 6). The paths in Q can be ordered sequentially from top to bottom. Likewise, the columns in V are ordered sequentially from left to right and the rows in L are ordered sequentially from top to bottom.

First we group the nodes on the left side of the big box into consecutive groups of size 8 each. To the nodes in the ith such group we assign the ith row in L. The paths from the left side of the big box to the right side of the big box are grown sequentially starting from the first group of nodes.

The first group of nodes uses paths in Q until they hit the centermost column in V. Then each of these eight nodes uses this column in V to reach its assigned row in L. Then it takes this assigned row to reach the right side of the big box (see Figure 6). When routing the next group we must make sure that we do not overlap these paths with the paths already routed since this would increase the congestion. Let w be the column in V that was used by the previous group of nodes. Further suppose that the last node in this group turned upward into column w to reach its row in L. In this case, we use the column in V that succeeds w for the current group of nodes. Similarly, if the last node of the previous group turned downward into column w, we use the column in V that precedes w for the current group. As before, the paths in the current group follow paths in Q until they hit the chosen column in V and then use this column until their assigned row in L. These paths do not share edges with any of the previous paths. We use this procedure to route paths from all the groups of nodes. Since we have $2^i/8$ columns to the right and to the left of the centermost column in V and since there are at most $2^i/8$ groups of nodes, we will never run out of columns in V. Since the paths outside of a group do not overlap, the congestion is at most 8. The maximum length of any path is at most the maximum length of any path in Q ($4 \cdot 2^{i-1}$ by the inductive hypothesis) added to the maximum length of the newly added portion (at most $2 \cdot 2^i$) which is $4 \cdot 2^i$.

After constructing paths in progressively larger boxes, we will have constructed a path from every node of the i-column to the right side of a square box of size $\alpha k/5$. These paths can be truncated at the middle column of O. Note that the obstacles in O are symmetric about its middle column. From this symmetry, exactly the same paths reflected about the middle column connect every node in the b-column to the same set of nodes in the middle column. Concatenating these two sets of paths, we obtain paths from every node in the b-column to a corresponding node in the i-column of congestion at most 8 and length at most $8\alpha k/5 = \Theta(m)$. Thus O is a permuting grid.

The proof that F and P are permuting grids is similar. □

THEOREM 3.12. *The b- and i-columns satisfy both of the column properties.*

Proof. The first property is true since the i- and b-column of the outer grid or the patch grid are chosen so that there are $\Theta(k)$ live columns between them. The second property follows from Lemma 3.10 and Theorem 3.11. To connect the nodes of the i-column of the patch grid to the b-column of the outer grid in some arbitrary permutation, we use the permuting grid P followed by the permuting grid F. One of the grids will be used to route the required permutation and the other will route the identity permutation. From Lemma 3.10, the paths obtained have constant congestion and do not pass through obstacles. Furthermore, each path is $\Theta(k)$ in length. To connect the nodes from the b-column of the patch grid to the i-column of the outer grid in an arbitrary permutation, we use grid F followed by grid O. □

4. A limit on the fault-tolerance of linear arrays. Unlike two-dimensional arrays, one-dimensional arrays are not very fault tolerant. For example, placing $f(N)$ evenly spaced faults in an N-node linear array splits the array into disjoint pieces of size $N/f(N)$, for any function $f(N)$. Emulating the entire linear array on one of these pieces entails a slowdown of at least $f(N)$. Thus if $f(N)$ grows as a function of N, the slowdown is not constant. However, if we assume a weaker model of faults

in which a faulty node cannot perform any computation but can communicate with its neighbors, then the linear array becomes more fault tolerant. In particular, the following theorem shows that an N-node linear array can tolerate $\log^k N$ worst-case faults, for any constant $k > 0$, and still emulate a fault-free N-node linear array with constant slowdown.

THEOREM 4.1. *For any constant $k > 0$, an N-node linear array with $\log^k N$ worst-case faults can emulate T steps of any computation of a fault-free N-node linear array in $O(T + N)$ steps, provided that faulty nodes can communicate with their neighbors.*

Proof. It is straightforward to apply the emulation scheme from section 2 to the linear array. □

In the remainder of this section we show that an N-node linear array with more than $\log^{O(1)} N$ worst-case faults cannot perform a static emulation of a fault-free N-node array with constant slowdown.

4.1. Bounding the load, congestion, and dilation. For the sake of convenience, we repeat the definition of a static emulation here. In a *static* emulation, a *redundant* guest network $G' = (V', E')$ is embedded in the host H. The redundant network is defined as follows. For every node v in the guest network $G = (V, E)$, there is a set of nodes $\pi(v)$ in V'. Each set $\pi(v)$ contains at least one node, and for $u \neq v$, $\pi(v)$ and $\pi(u)$ are disjoint. We call the nodes in $\pi(v)$ the *instances* of v in G'. The network G' is called redundant because it may contain several instances of each guest node. For every node $v' \in \pi(v)$ and every edge (u, v) in E, the redundant network contains a directed edge (u', v') for some $u' \in \pi(u)$. The embedding maps nodes of G' to nonfaulty nodes in the host, and edges of G' to paths in the host. In this section we allow the paths to pass through faulty host nodes.

The host emulates T steps of the guest network's computation as follows. The embedding of G' into H maps a set $\psi(a)$ of nodes of G' to each host node a. Node a emulates each node $v' \in \psi(a)$ by creating an s-pebble $\langle v', t\rangle$ for $1 \leq t \leq T$. An s-pebble $\langle v', t\rangle$ represents the state of node v' at time t. Initially, each node a of H contains s-pebbles $\langle v', 0\rangle$ for $v' \in \psi(a)$. Node a can create an s-pebble $\langle v', t\rangle$ only if it is not faulty, has already created an s-pebble $\langle v', t-1\rangle$, and has received all of the c-pebbles of the form $[e, t-1]$, where e is an edge (u', v') into v'. A c-pebble $[e, t-1]$ represents the communication that v' receives from its neighbor u' in step $t-1$. After creating an s-pebble $\langle v', t\rangle$, a nonfaulty node a can create all of the c-pebbles of the form $[g, t]$ for each edge g out of v'. At each host time step a nonfaulty host node a can create a single s-pebble (and the corresponding c-pebbles). In this section, and this section only, we assume that any node, faulty or nonfaulty, can send and receive one c-pebble on each of its edges at each step. A c-pebble for an edge (u', v') is sent along the path from u' to v' that is specified by the embedding. Note that a node u' may send c-pebbles to a neighbor v' but receive c-pebbles from a different instance v'' of guest node v.

The following three lemmas show that if a static emulation has slowdown s, then the load and congestion of the embedding of G' into H cannot exceed s, and the average dilation of the edges on any cycle in G' cannot exceed s.

LEMMA 4.2. *Suppose that there is a value $T_0 > 0$ such that for all $T > T_0$, the host can perform a static emulation of a T-step guest computation in Ts steps. Then the maximum load on any host node is at most s.*

Proof. Let l be the load of the embedding. Then some node a in H must emulate l nodes of G'. For each of these nodes, a must create T s-pebbles. Since a can create

at most one s-pebble at each step, the total time is at least lT. Thus, if the slowdown is s, the load can be at most s. □

LEMMA 4.3. *Suppose that there is a value $T_0 > 0$ such that for all $T > T_0$, the host can perform a static emulation of a T-step guest computation in Ts steps. Then the maximum congestion on any host edge is at most s.*

Proof. Let c be the congestion of the embedding. Then there is some host edge e through which c paths pass. For each of these paths, T c-pebbles must pass through e. Since e can transmit at most one c-pebble at each step, the total time is at least cT. Thus, if the slowdown is s, the congestion can be at most s. □

LEMMA 4.4. *Suppose that there is a value $T_0 > 0$ such that for all $T > T_0$, the host can perform a static emulation of a T-step guest computation in at most Ts steps. Then the average dilation of the edges on any cycle in G' is at most s.*

Proof. Suppose that there is a cycle of length L in G' with dilation D (the dilation of a cycle is the sum of the dilations of its edges). Let $v'_{L-1}, v'_{L-2}, \ldots, v'_0$ denote the nodes on the cycle. For any t, the s-pebble $\langle v'_0, t\rangle$ cannot be created until a c-pebble $[(v'_1, v'_0), t-1]$ arrives at the host node that emulates v'_0. Since a c-pebble can traverse at most one host edge at each time step, the time for the c-pebble to travel from the node that emulates v'_1 to the node that emulates v'_0 is at least the dilation of the edge (v'_1, v'_0). The dilation is also a lower bound on the time between the creation of s-pebbles $\langle v'_1, t-1\rangle$ and $\langle v'_0, t\rangle$. Working our way around the cycle, we see that the time between the creation of s-pebbles $\langle v'_0, t-L\rangle$ and $\langle v'_0, t\rangle$ is at least the dilation of the cycle, D. Thus, for any T that is a multiple of L, the time between the start of the emulation and the creation of s-pebble $\langle v'_0, T\rangle$ is at least TD/L. For $D/L > s$, this pebble is not created until after step Ts, a contradiction. □

4.2. Bounding the number of faults.

THEOREM 4.5. *For any s, there is a pattern of $h(s)(\log N)^{2s}$ worst-case faults, for any $h(s) > 2^{6s+4}s^{6s+5}$, such that it is not possible for an N-node host linear array with these faults to perform a static emulation of an N-node guest linear array with slowdown s.*

Proof. We begin by placing a layer of $g(s)$ blocks of $f(s)$ consecutive faults in an N-node array so that the number of nonfaulty nodes in the gap between each pair of blocks is at most $N/g(s)$. Formulas for $g(s)$ and $f(s)$ will be determined later.

Next we find a block of faults B that some edges of the redundant network must cross. Because the slowdown is s, and at most $N/g(s)$ host nodes lie between any pair of blocks for $g(s) > s$, it is not possible for the entire emulation to take place in one gap. (If it did, then the load in the gap would be greater than s, which is forbidden by Lemma 4.2.) Since the emulation uses host nodes in at least two gaps, there must be some block B such that some, but not all, of the the guest nodes are emulated on its left, and some, but not all, of the guest nodes are emulated on its right.

Now we find a cycle C in the redundant network G' that crosses B. Let u be a node in the guest network G such that every instance of u in G' on the right side of B receives its left input from the left of B. If there is no such u, then let u be a node in the guest network such that every instance of u on the right side of B receives its right input from the left of B; in the latter case interchange the role of left and right inputs in what follows. Note that since we have chosen B so that the host does not emulate the entire guest on the right side of B, there must be such a node u. Select one of the instances, u', of u and follow the left input edge into u' (i.e., the input edge coming from the node in G' that corresponds to the left neighbor of u in the guest) back to where it came from. It must lead across B to some node v' in G' on the left side of B.

Now follow the left input edge into v' to some other node w' in G' (node w' may be on either side of B). Continue to follow left input edges until reaching a node x' that corresponds to the left endpoint of G. Then follow right input edges until reaching the right endpoint of G, and reverse direction again. Repeat this process until some edge of G' is used twice. When this happens, a cycle C is formed. Furthermore, the cycle C must cross B because it visits every node of G and we know that H does not emulate all of G on one side of B.

The next thing to show is that on one side of B or the other, cycle C visits at least l consecutive nodes of the guest network, where $l > f(s)/2s$, and these nodes are emulated within distance $2sl$ of B in the host. If the slowdown of the emulation is s, then by Lemma 4.4 the dilation of any cycle is at most s times the number of redundant network nodes on the cycle. (The dilation of a cycle or path is equal to the sum of the dilations of the edges on the cycle or path.) Let us define a *segment* to be a maximal subpath of C that begins with an edge that crosses block B, but does not cross B again. Note that every segment either consists of a sequence of right input edges followed by a (possibly empty) sequence of left input edges, or vice versa. Suppose that cycle C crosses block B a total of $2h$ times. Then there are $2h$ segments. Associate with each segment the dilation of the edges on the segment. Note that the average ratio of the dilation of a segment to the number of nodes on the segment must be at most s (since the ratio for the entire cycle C is at most s). Now classify segments into two types: long and short. A short segment is one containing fewer than $f(s)/s$ edges. Since every segment has dilation at least $f(s)$ (due to the first edge on the segment), the ratio of a short segment's dilation to length (number of nodes) is more than s. Since the average ratio over all of the segments is at most s, there must be some long segment whose ratio of dilation to length is at most s. If this segment has more left input edges than right input edges, then discard the right input edges and the nodes that they visit. Otherwise, discard the left input edges. We are left with some set of $l \geq f(s)/2s$ nodes emulated within distance $2sl$ of B. Suppose that there are more left input edges, and let $v'_1, v'_2, \ldots, v'_l$ denote the nodes that were visited on (say) the right side of B, where v_1 is the leftmost node in the guest network. We will call the $2sl$ host nodes on the right of B the *emulation region*. (Note that in the construction of the cycle, we visited v'_l first and v'_1 last.)

Now we show that some communication must pass over the emulation region. Although nodes $v_1, v_2, \ldots, v_l$ are consecutive in the guest network, their instances are not necessarily embedded in the host in consecutive order. Suppose that v'_i is the node embedded the farthest to the right. If $i > l/2$, then the path in the cycle from the left side of B to v'_l to v'_{l-1} and on to v'_i overlaps all of nodes v'_1, $v'_2, \ldots, v'_{l/2}$. On the other hand, if $i \leq l/2$, then the path from v'_i to v'_{i-1} to v'_1 and back across to the left side of B overlaps all of nodes $v'_{l/2+1}, v'_{l/2+2}, \ldots, v'_l$. In either case, we have a set of $l/2$ consecutive nodes in the guest network that the host emulates, and some other edges of G' overlap their emulation with congestion 1.

We now proceed recursively within the emulation region. One last issue that must be dealt with is that some of the $l/2$ nodes that the host is emulating within the emulation region may receive some of their right inputs from outside the emulation region. However, since the embedding has congestion at most s (by Lemma 4.3), at most $2s$ right inputs can enter the emulation region from outside. Thus, there must be a set of at least $(l/2)/2s = l/4s$ redundant network nodes that the host emulates within the emulation region that are consecutive in the guest and receive all of their inputs from within the emulation region. At this point we have placed $g(s)$ blocks of

$f(s)$ faults in the network and we have proved that on one side of one of the blocks, there is an emulation region of size $2sl$ in which at least $l/4s$ consecutive nodes of the guest are emulated, for some $l \geq f(s)/2s$, and some other edges of G' cause congestion 1 in the emulation region. For recursion on sets of $l/4s$ guest nodes, where $l \geq f(s)/2s$, we need $f(s) > 8s^2$.

We are now going to place an additional layer of faults in the network. Because we do not know where the emulation region is, we will place faults immediately adjacent to both sides of each of the $g(s)$ blocks of faults in the first layer. Also, because we do not know how large the emulation region is, we will place the faults in patterns of size $2, 4, 8, \ldots, N$ on top of each other. (Note that N is the size of the entire array.) In a pattern of size 2^k, we will place $g(s)$ blocks of $f(s)$ consecutive faults at spacings of $2^k/g(s)$. Thus, in each pattern there are at most $g(s)f(s)$ faults, and there are at most $\log N$ patterns on each side of the blocks in the first layer. The total number of faults in the second layer is $2g^2(s)f(s)\log N$.

The entire emulation region must lie under some pattern P of faults of size 2^k, where $2^k \leq 4sl$. The blocks of faults in this pattern are spaced at a distance of $2^k/g(s)$, which is at most $4sl/g(s)$. In this region, at least $l/4s$ guest nodes are emulated. If the slowdown is at most s, and $(l/4s)/(2sl/g(s)) > s$, then by Lemma 4.2 it is not possible for the entire emulation to be performed entirely between two blocks of faults in this pattern. (Thus, we need $g(s) > 8s^3$.) Arguing as we did for the first layer, we can show that, for some l', on one side of one of the blocks of P, there is an emulation region of size $2sl'$ and a set of least $l'/4s$ nodes that are consecutive in the guest network that receive their inputs from within the emulation region. But now two units of congestion pass over the new emulation region (possibly in opposite directions).

A third layer of faults is now placed in the network. As before, a set of patterns of faults is placed around each block in the second layer. There are $2g(s)^2 \log N$ blocks in the second layer. Thus, there are $4g(s)^3(\log N)^2 f(s)$ faults in the third layer.

By applying $2s+1$ layers of faults, we find an emulation region over which at least $s+1$ units of congestion (in one direction) pass, which is a contradiction by Lemma 4.3. The $(2s+1)$st layer contains $2^{2s}g(s)^{2s+1}(\log N)^{2s}f(s)$ faults. The total number of faults contained in all the $2s+1$ layers is at most twice the number of faults contained in the $(2s+1)$st layer alone, since the number of faults in the ith layer is at least double the number of faults in the $(i-1)$st layer. Thus the total number of faults is at most $2^{2s+1}g(s)^{2s+1}(\log N)^{2s}f(s) = h(s)\log^{2s} N$, where $h(s) = 2^{2s+1}g(s)^{2s+1}f(s)$, $g(s) > 8s^3$, and $f(s) > 8s^2$. □

5. Remarks. The scheme described in section 2 for tolerating $\log^k N$ faults in an $N \times N$ mesh can be easily generalized to tolerate $\log^k N$ faults in a d-dimensional array with side length N for any fixed $d > 2$. It seems plausible that the techniques described in section 3 can also be generalized to arrays of higher dimension.

MATRIX SEARCHING WITH THE SHORTEST-PATH METRIC*

JOHN HERSHBERGER† AND SUBHASH SURI‡

Abstract. We present an $O(n)$ time algorithm for computing row-wise maxima or minima of an implicit, totally monotone $n \times n$ matrix whose entries represent shortest-path distances between pairs of vertices in a simple polygon. We apply this result to derive improved algorithms for several well-known problems in computational geometry. Most prominently, we obtain linear-time algorithms for computing the geodesic diameter, all farthest neighbors, and external farthest neighbors of a simple polygon, improving the previous best result by a factor of $O(\log n)$ in each case.

Key words. shortest paths, matrix searching, geodesic diameter, farthest neighbors, geometric matching

1. Introduction.

Matrix-searching is the popular term for a technique introduced by Aggarwal et al. [2] for computing row-wise maxima in a totally monotone matrix. A matrix M is called *totally monotone* if

$$M(i,k) < M(i,l) \implies M(j,k) < M(j,l)$$

for any $i < j$ and $k < l$. Aggarwal et al. [2] discovered the importance of totally monotone matrices and showed that many problems in computational geometry can be formulated as finding maxima in a totally monotone matrix. The problem of finding farthest neighbors in a convex polygon is a prototypical application of this technique; we repeat it here for the benefit of the uninitiated.

Consider a convex polygon P and partition its boundary into two disjoint chains $U = \{u_1, u_2, \ldots, u_p\}$ and $V = \{v_1, v_2, \ldots, v_m\}$. The vertices in each chain are ordered counterclockwise, as shown in Figure 2.1. Define a $p \times m$ matrix M that encodes pairwise distances between the vertices of U and V: $M(i,j) = d(u_i, v_j)$ for $1 \le i \le p$ and $1 \le j \le m$. One may easily check that M is totally monotone; the proof follows from the triangle inequality. We observe that a maximum entry in row i of M corresponds to the maximum distance between u_i and any vertex in V. Thus, we can find for all vertices of U a corresponding farthest neighbor in V by computing the row-wise maxima in M.

The main result of Aggarwal et al. [2] says that the row-wise maxima of a totally monotone $n \times n$ matrix can be found with only $O(n)$ comparisons and evaluations of the matrix entries. The matrix is defined implicitly—an entry is evaluated only when needed by the algorithm. If evaluating a matrix entry takes $f(n)$ time, then the row-wise maxima can be computed in time $O(nf(n))$. This result leads to linear-time algorithms for several computational geometry problems set in convex polygons, where the matrix entries correspond to Euclidean distances.

In this paper, we propose a powerful extension of the basic matrix-searching algorithm. We give a linear-time algorithm for computing row-wise maxima in a totally monotone matrix whose entries represent *shortest path* distances between pairs of vertices in a simple polygon. The shortest path distance, also called the *geodesic distance*, is the natural distance measure in a simple nonconvex polygon. Observe, however, that unlike the Euclidean distance, the geodesic distance in general cannot be computed in constant time. Unless one precomputes all the distances, which requires too much preprocessing, the best data structure for computing shortest-path distances is one due to Guibas and Hershberger [6, 10], which achieves $f(n) = O(\log n)$. (After an $O(n)$ time and space preprocessing step, this data structure computes the geodesic distance between two arbitrary points of a simple polygon in $O(\log n)$ time; n denotes the number of vertices in the polygon.) A straightforward combination of the shortest-path query data structure and the basic matrix-searching gives an $O(n \log n)$ time algorithm for computing row-wise maxima of a totally monotone matrix with shortest path distances. Our result in this paper improves the time complexity to optimal $O(n)$.

Our result has applications in computational geometry: we achieve linear-time algorithms for several outstanding open problems. The most straightforward application concerns geodesic diameter and all-farthest neighbors. We obtain $O(n)$ time algorithms for them, improving the previous $O(n \log n)$ bound. A similar improvement also follows for the problem of computing the external farthest neighbors in a simple polygon.

A somewhat less obvious application concerns finding a closest visible vertex pair between two simple polygons. Although this problem does not involve the shortest path metric in its formulation, we apply matrix-searching with shortest paths to get a conceptually simple algorithm for the problem that runs in optimal linear time. Previous linear-time algorithms were quite complicated [3, 4]. In a separate paper [12] we apply this result, along with some additional techniques, to obtain a linear-time algorithm for computing a shortest diagonal of a simple polygon, improving the previous $O(n \log n)$ algorithm.

We can also compute weighted-nearest neighbors between two disjoint chains of a simple polygon in linear time; the weighted distance is defined as $d(u_i, v_j) - w(u_i) - w(v_j)$, where $d(u_i, v_j)$ is the shortest path distance, and w is a real-valued weight function. This improves the complexity of computing an optimal matching on the vertices of a polygon from $O(n \log^2 n)$ to $O(n \log n)$ [13], matching the best bound for a convex polygon.

Our paper is organized in seven main sections. In section 2, we formulate the key problem of our paper and provide a brief summary of the matrix-searching technique. In section 3, we introduce the basic geometric infrastructure required by our algorithm. The algorithm itself is described in section 4, and its analysis is presented in section 5. The applications of our main result are presented in section 6, and we conclude with some remarks in section 7.

2. Matrix-searching and the shortest-path metric. The centerpiece of our paper is an algorithm for computing farthest neighbors between two chains of a simple polygon under the shortest-path metric. In this section, we introduce the problem, define terminology, and provide a brief review of the matrix-searching framework of Aggarwal et al. [2]. Throughout, we assume that P is a simple polygon with n vertices; $\pi(x, y)$ is the shortest path between the points x and y in P; $d(x, y)$ is the length of the path $\pi(x, y)$; and y is a (geodesic) *farthest neighbor* of x if $d(x, y) =$

$\max\{d(x, x') \mid x' \in P\}$.

2.1. Farthest neighbors and the totally monotone matrix. Let $U = (u_1, u_2, \ldots, u_p)$ and $V = (v_1, v_2, \ldots, v_m)$ be two polygonal chains that together partition the vertices of P; the vertices are ordered counterclockwise in each chain, and the total number of vertices is $n = p+m$. We want to compute a farthest neighbor for each vertex of U in the chain V. This problem can be reformulated as a maxima-finding problem in the associated distance matrix.

Let M denote the $p \times m$ matrix that encodes the pairwise distances between the vertices of U and V:

$$M(i, j) \;=\; d(u_i, v_j). \tag{2.1}$$

See Figure 2.1. Our problem is to compute a maximum entry in each row of M. (The equivalence is clear: $M(i, j)$ is a maximum entry in row i if and only if v_j is a geodesic farthest neighbor of u_i.) We break ties by choosing the leftmost maximum in each row.

We use the matrix-searching framework of Aggarwal et al. [2], which depends crucially on a matrix property called *total monotonicity*. The matrix M is *totally monotone* if

$$M(i, k) \;<\; M(i, l) \quad\Longrightarrow\quad M(j, k) \;<\; M(j, l) \tag{2.2}$$

for any $1 \le i < j \le p$ and $1 \le k < l \le m$. The total monotonicity of M follows from the triangle inequality of the geodesic distance function. Total monotonicity also implies that the leftmost maxima form a "staircase" in the matrix: as we move down the rows, the maximum can move only right, but never left.

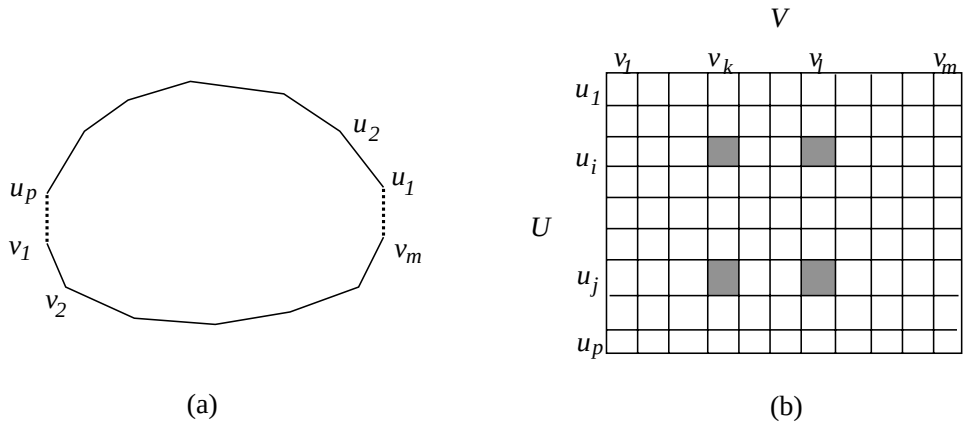

FIG. 2.1. *A polygon, two chains, and the corresponding matrix. The triangle inequality implies that* $M(i, k) + M(j, l) \ge M(i, l) + M(j, k)$, *which in turn shows that* M *is totally monotone.*

The matrix M is defined implicitly: an entry is computed only when needed. The matrix-searching algorithm performs two kinds of operations: evaluation of a matrix entry $M(i, j)$ and comparison between two matrix entries. We use the term *matrix operation* to describe either of these two steps. In general, the comparison step can always be performed in constant time, but the evaluation step can be more complicated. The main result of Aggarwal et al. [2] is the following lemma.

LEMMA 2.1 (see [2]). *The leftmost maximum in each row of a totally monotone $n \times n$ matrix can be determined using $O(n)$ matrix operations. If each matrix operation takes $f(n)$ time, then the row-maxima problem can be solved in time $O(nf(n))$.*

If we use shortest path queries [6, 10] to compute the entries of M, then $f(n) = O(\log n)$, and we get an $O(n \log n)$ time algorithm. Our contribution in this paper is an algorithm that reduces $f(n)$ to amortized $O(1)$, giving an optimal linear-time algorithm.

2.2. The matrix-searching algorithm. Our algorithm assumes some familiarity with the matrix-searching algorithm of [2]. This section gives a brief overview of the matrix-searching technique; however, the reader is encouraged to refer to the original paper for details.

The matrix-searching algorithm of [2] finds the leftmost maximum in each row of a totally monotone matrix using a linear number of matrix operations. The algorithm is recursive; it proceeds in $O(\log n)$ phases. Each phase cuts down each dimension of the matrix by half, after evaluating a linear number of matrix entries. The following pseudocode gives a top-level view of the algorithm.

MSEARCH(M)

(∗ *Compute the position and value of the leftmost maximum in each row of* M ∗)

1. $A \leftarrow$ *REDUCE*(M)
2. **if** $|A| = 1$ **then return** the value of $A[1, 1]$ and its position in M
3. $B \leftarrow$ the matrix consisting of *even* rows of A
4. *MSEARCH*(B)
5. *MFILL*(A, B) (∗ Finds maxima in the odd rows of A ∗)
6. Compute the positions and values of the maxima in M from their positions in A.

REDUCE takes a $p \times m$ matrix M, where $m \geq p$, and returns a $p \times p$ submatrix A. (If $m < p$, *REDUCE* returns just M.) The leftmost maxima in the rows of A and M are identical. *REDUCE* achieves this size reduction using only $O(m)$ matrix operations. In the pseudocode below, A^k refers to the kth column of A.

REDUCE (M)
  $A \leftarrow M$; $k \leftarrow 1$;
  while A has more than p columns **do**
    case
    $A(k,k) \geq A(k,k+1)$ and $k < p$: $k \leftarrow k + 1$.
    $A(k,k) \geq A(k,k+1)$ and $k = p$: Delete column A^{k+1}.
    $A(k,k) < A(k,k+1)$: Delete column A^k; **if** $k > 1$ **then** $k \leftarrow k - 1$.
    endcase
return A.

Figure 2.2 illustrates the pattern of comparisons performed by *REDUCE*. No entry in the shaded portion of the matrix can be a candidate for the leftmost maxima.

The code above, which is essentially in the form given by Aggarwal et al. [2], operates on a dynamic matrix: when a column is deleted, all columns to its right are renumbered. This property makes it somewhat difficult to identify which entries of the original matrix are examined. Because our algorithm depends crucially on the order in which matrix entries are computed, we rewrite the code for *REDUCE* to

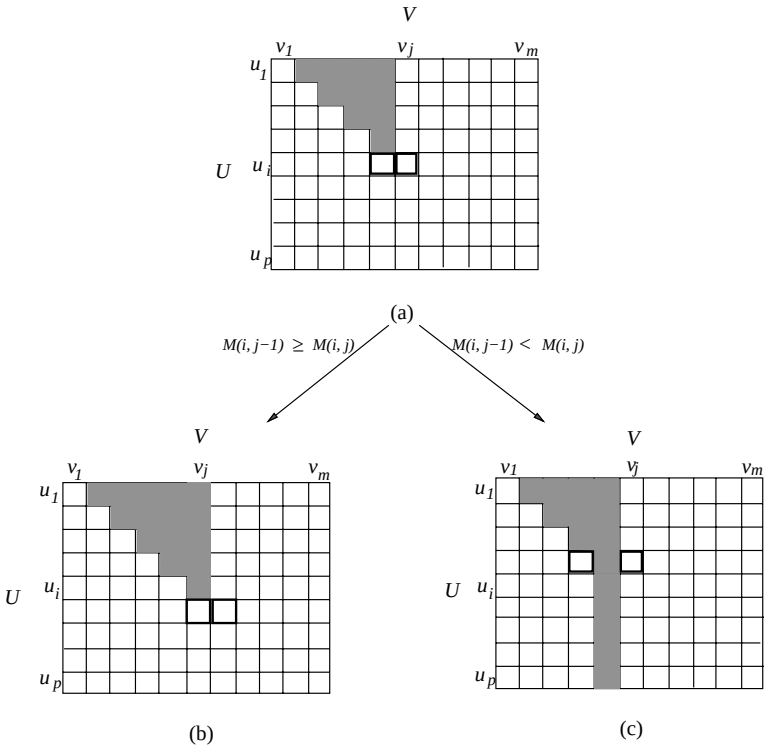

FIG. 2.2. *Illustrating REDUCE. The current comparison is between* $M(i, j-1)$ *and* $M(i, j)$*, shown by the highlighted cells in* (a)*. If* $M(i, j-1) \geq M(i, j)$*, then we arrive at Figure* 2.2(b)*: the first* i *rows of the* j*th column are eliminated, and the next comparison is between* $M(i+1, j)$ *and* $M(i+1, j+1)$*. Otherwise* $M(i, j-1) < M(i, j)$ *and we arrive at Figure* 2.2(c)*: column* $j-1$ *is eliminated entirely. In this case, the search backs up and next compares* $M(i-1, j-2)$ *and* $M(i-1, j)$*.*

clarify the matrix access pattern. The revised version below uses a *predecessor* array (essentially a linked list) to delete columns. Initially $pred[i]$ is set to $i-1$ for all i. To delete a column j such that $pred[k] = j$, the algorithm resets $pred[k] \leftarrow pred[j]$, thereby splicing j out of the list. The following code avoids some of the matrix probes in the version of *REDUCE* above by reusing previously computed values.

```
NEW-REDUCE (M)
    for j ← 1 to m do pred[j] ← j − 1;
    ncols ← m;    j ← 2;    k ← 1;
    value[1] ← M(1, 1);
    while ncols > p do
        (* Note that value[pred[j]] = M(k, pred[j]) *)
        if value[pred[j]] ≥ M(k, j) then
            if k < p then
                k ← k + 1;    value[j] ← M(k, j);
            else
                pred[j + 1] ← pred[j];    ncols ← ncols − 1;
```

```
            endif
            j ← j + 1;
        else
            pred[j] ← pred[pred[j]];    ncols ← ncols − 1;
            if k ≠ 1 then k ← k − 1 else j ← j + 1 endif;
        endif
    endwhile
return the pred[∗] linked list.
```

LEMMA 2.2. *The two algorithms REDUCE and NEW-REDUCE are equivalent.*

Proof. We need to prove the correspondence between the chain of $pred[*]$ pointers in *NEW-REDUCE* and the dynamic matrix in *REDUCE*. To this end, define the function $length(j)$ to be the length of the chain of $pred[*]$ pointers starting at j. That is, $length(j) = h$ iff $pred^h[j] = 0$, but $pred^{h-1}[j] \neq 0$.

We maintain the invariant that at the top of each loop, if column k in *REDUCE* is actually column j of the original matrix M, then $length(j) = k$ in *NEW-REDUCE*. This is established by the **for** loop of *NEW-REDUCE*. The main loop of *REDUCE* corresponds to that of *NEW-REDUCE*. At the top of each **while** loop, column j of *NEW-REDUCE* corresponds to column $k + 1$ in *REDUCE*, and column $pred[j]$ corresponds to column k.

We must prove that the matrix comparisons in *REDUCE* and *NEW-REDUCE* are equivalent. The main loop of *NEW-REDUCE* explicitly computes the value needed on the right-hand side of the comparison in that loop. The value needed on the left-hand side of the comparison is referred to as $A(k, k)$ in *REDUCE*; that is, it is the matrix element $M(k, l)$ such that $length(l) = k$ in *NEW-REDUCE* and $l = pred[j]$. So, we must show that $value[l] = M(k, l)$. If *NEW-REDUCE* does not delete column j, it sets $value[j] \leftarrow M(length(j), j)$ just before it advances to column $j + 1$. Because *NEW-REDUCE* does not change $length(l)$ for any $l < j$, it follows that $value[l] = M(k, l) = A(k, k)$. We leave it as an exercise to the reader to prove the exact correspondence between the statements of *REDUCE* and *NEW-REDUCE*. □

In a high-level view of the algorithm, *REDUCE* and *NEW-REDUCE* are completely equivalent; the latter only fleshes out more details. The $pred[*]$ list that *NEW-REDUCE* returns encodes the reduced matrix A returned by *REDUCE*. In an implementation, *MSEARCH* and *MFILL* would also use *pred* pointers; however, in order to preserve a close parallel with the basic algorithm of [2], we will use *NEW-REDUCE* only in the next subsection, and use *REDUCE* in the remainder of the paper.

Finally, the procedure $MFILL(A, B)$ computes the leftmost maxima for the odd rows of A, given the locations of the maxima for its even rows; recall that the matrix B consists of precisely the even rows of A. This phase also requires $O(m)$ matrix operations. Let C_{2j} denote the column index of the leftmost maximum in the even rows of A, for $j = 1, 2, \ldots, \lfloor p/2 \rfloor$. Then total monotonicity implies that C_{2j+1} lies between C_{2j} and C_{2j+2}. The following pseudocode implements *MFILL*. For convenience we set $C_0 = 1$ and $C_{2\lfloor p/2 \rfloor + 2} = m$.

```
MFILL (A, B)
    for i ← 1 to ⌈p/2⌉ do
        max ← A(2i − 1, C_{2i−2});
        C_{2i−1} ← C_{2i−2};
```

```
        for j ← C_{2i-2} + 1 to C_{2i} do
            if A(2i − 1, j) > max then
                max ← A(2i − 1, j);
                C_{2i-1} ← j;
            endif
        Evaluate A(2i, C_{2i});   (* Extra work, for accounting purposes *)
    endfor;
```

Our algorithm has exactly the same form as that of Aggarwal et al. [2]; only the details of evaluating a matrix entry are different. In [2], each matrix evaluation takes constant time. In our case, the evaluations are trickier and require a careful implementation of a shortest-path algorithm. To this end, we need to understand better the path followed by the matrix evaluations in the subroutine *REDUCE*.

2.3. Summary of matrix searching. Each phase of the recursive algorithm *MSEARCH* halves the matrix dimensions. The core of the algorithm is *REDUCE*, which eliminates columns of the matrix. In the kth phase of the algorithm, *REDUCE* operates on a submatrix A_k of size at most $n_k \times 2n_k$, where $n_k = \lfloor p2^{-k} \rfloor$. From here on we will assume that A_k is exactly $n_k \times 2n_k$. Matrix-searching theory tells us that *REDUCE* performs at most $3n_k$ matrix operations and returns an $n_k \times n_k$ submatrix.

We call the vertices corresponding to rows and columns of A_k *active* vertices; the remaining vertices of U and V are called *dead*. Thus, there are n_k active vertices in the U-chain and $2n_k$ active vertices in the V-chain. Because *MSEARCH* deletes even rows, the active vertices of U are uniformly spaced in U; more precisely, two adjacent active vertices are separated by $2^k - 1$ dead vertices. However, no such regularity necessarily exists among the active vertices of V.

Our algorithm makes critical use of the order in which the matrix-searching algorithm evaluates entries. This order is easier to analyze in *NEW-REDUCE* than in the equivalent routine *REDUCE*. The first matrix entry evaluated by *REDUCE* (or *NEW-REDUCE*) in the kth phase is $A_k[1, 1]$. In each new evaluation, either the row or the column index is changed by one. In particular, the movement in the matrix consists of steps that belong to $\{up,\ down,\ right\}$, where *up* and *down* decrement and increment the row-index and *right* increments the column-index. The column-index is never decremented, so there is no *left* movement in the matrix. We can break the sequence of moves into blocks that start with a *right* move. Each *right* move is followed by zero or more *up* moves and at most one *down* move. Thus the sequence of moves satisfies the following regular expression:

$$(\ right\ \ up^*\ \ (down \mid \epsilon)\ )^*, \tag{2.3}$$

where ϵ is the null move. The sequence of evaluations in *MFILL* also satisfies the same regular expression.

3. Geometric structures. In this section, we introduce the geometric infrastructure necessary for computing the shortest-path distances. We describe both the geometric properties of these structures and their implementations. We start with some notation. The shortest path between two points x and y in P is denoted $\pi(x, y)$. The two extreme vertices of the chain V play a distinguished role in our algorithm. We refer to them with the shorthand notation $a = v_1$ and $b = v_m$.

3.1. The shortest-path tree. Let T_a and T_b denote the shortest-path trees of the polygon P rooted at the vertices $a = v_1$ and $b = v_m$, respectively. (A shortest-path

tree T_p is the union of shortest paths from p to all the vertices of P.) We precompute an array that stores, for every vertex x of P, the parents of x in T_a and T_b, along with the distances from x to a and b. We first triangulate the polygon in linear time using Chazelle's algorithm [5] and then build the shortest-path trees T_a and T_b also in linear time using an algorithm of Guibas et al. [7] or Hershberger and Snoeyink [11].

LEMMA 3.1 (see [7, 11]). *After linear-time preprocessing, the distances $d(x,a)$ and $d(x,b)$, for any vertex $x \in P$, can be computed in $O(1)$ time.*

Given two arbitrary vertices $x, y \in P$, we let $\alpha(x,y)$ denote the *lowest common ancestor* of x and y in T_a. Similarly, $\beta(x,y)$ denotes the lowest common ancestor of x and y in the tree T_b. In our discussion, we so frequently use lowest common ancestors where one of the vertices is a or b that we also introduce the following abbreviated notation:

$$\alpha(x) = \alpha(x,b),$$
$$\beta(x) = \beta(x,a).$$

In Figure 3.1, $\alpha(u_{19}, v_{10}) = v_4$, $\beta(u_{19}, v_{10}) = u_{12}$, $\alpha(v_{10}) = v_4$, and $\beta(v_{10}) = v_{17}$.

We use the linear-time algorithm of Harel and Tarjan [9] or that of Schieber and Vishkin [15] to preprocess our trees for lowest common ancestor queries.

LEMMA 3.2 (see [9, 15]). *After linear-time preprocessing of T_a and T_b, we can compute $\alpha(x,y)$ and $\beta(x,y)$ in constant time for any two vertices $x, y \in P$.*

3.2. The funnel and the funnel-difference. Consider a vertex $v \in V$ and the two shortest paths $\pi(v,a)$ and $\pi(v,b)$. These two paths may coincide for some distance before they diverge at a vertex z, never to meet again. The *funnel* of v, denoted $F(v)$, is the set of edges in the shortest paths from z, called the *apex* of the funnel, to the lowest common ancestor vertices $\alpha(v)$ and $\beta(v)$:

$$F(v) \;=\; \pi(z, \alpha(v)) \;\cup\; \pi(z, \beta(v)). \tag{3.1}$$

Both $\pi(z,\alpha(v))$ and $\pi(z,\beta(v))$ are concave. See Figure 3.1 for an example of funnels.

In our analysis, the difference of two funnels turns out to be important. The idea is applicable to both U and V chains, but we define it here just for the V-chain. Given two vertices $v_i, v_j \in V$, where $i > j$, their funnel-difference is defined as

$$\Delta F(v_i, v_j) \;=\; F(v_i) \setminus F(v_j). \tag{3.2}$$

That is, $\Delta F(v_i, v_j)$ is the set of edges that are in $F(v_i)$ but not in $F(v_j)$. The edges of $\Delta F(v_i, v_j)$ form a contiguous portion of $F(v_i)$ surrounding v_i. The following property of the funnel-difference will be most important to us.

LEMMA 3.3. *$\Delta F(v_i, v_j)$ is edge-disjoint from $F(v_k)$, for any $k < j < i$.*

Proof. The proof uses the following elementary properties of the lowest common ancestor in an ordered tree: (i) the lowest common ancestor relation is commutative and associative, and (ii) the lowest common ancestor of two nodes x and y is above or equal to the lowest common ancestor of any nodes lying between x and y (in symmetric order). These properties imply that $\alpha(v_i, v_k)$ is above or equal to $\alpha(v_i, v_j)$ in T_a and $\beta(v_i, v_k)$ is above or equal to $\beta(v_i, v_j)$, for any $k < j < i$. Thus, no edge of $F(v_k)$ lies in $\Delta F(v_i, v_j)$. This completes the proof. □

3.3. Data structures for computing tangents on funnels. Our main operation on funnels is finding a common tangent between two funnels. Consider a

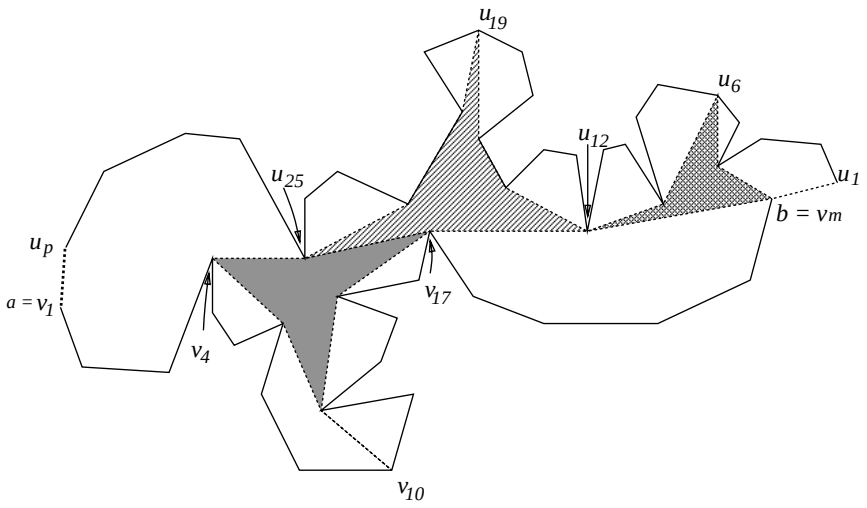

FIG. 3.1. *The example shows funnels for three vertices: v_{10}, u_6, and u_{19}. Lowest common ancestors bounding $F(v_{10})$ are v_4 and v_{17}. The apex of $F(v_{10})$ is v_{12}. Similarly, $F(u_6)$ is bounded by u_6, u_{12}, and $b = v_m$; in this case, u_6 itself is the apex.*

vertex-pair $u \in U$ and $v \in V$. The funnel-pair $(F(u), F(v))$ is *closed* if $\pi(\alpha(u), \beta(u))$ and $\pi(\alpha(v), \beta(v))$ are disjoint except perhaps at endpoints, and *open* otherwise.

An open funnel-pair always admits a unique common tangent. If $(F(u), F(v))$ is an open funnel-pair, then the shortest path $\pi(u, v)$ necessarily uses the tangent between their funnels. We denote the tangent for the funnel-pair $(F(u), F(v))$ by $\ell(u, v)$. The endpoints of $\ell(u, v)$ are denoted u_ℓ and v_ℓ, where $u_\ell \in U$ and $v_\ell \in V$. (Throughout, we adopt the convention that the subscript ℓ will denote the endpoint of a tangent.)

In Figure 3.1, funnels $F(v_{10})$ and $F(u_6)$ form a closed pair, while $F(v_{10})$ and $F(u_{19})$ form an open pair. The tangent between $F(v_{10})$ and $F(u_{19})$ is (u_{22}, v_{15}).

During each execution of *REDUCE*, we maintain funnels $F(u)$ and $F(v)$ for the current vertices u and v. As observed in section 2.3, u moves backward and forward among the active vertices of U, while v moves only forward through the active vertices of V. After each movement of u or v, we compute the tangent for $(F(u), F(v))$, if it is an open funnel-pair.

Let us focus on one of the shortest paths in $F(u)$, say, $\pi(z(u), a)$. We assume that the apex $z(u)$ of $F(u)$ is precomputed; precomputation of all funnel-apexes takes $O(n)$ time altogether using the two shortest-path trees T_a and T_b.

A natural representation of $\pi(z(u), a)$ is a doubly linked list of vertices, but unfortunately this data structure is too inefficient for searching in our application. We speed up the search by breaking the path into subpaths, each represented by a *supernode* that supports fast searches. In this representation, a shortest path is a list of supernodes, linked by *superedges*. In phase k of the algorithm, the subpath within a single supernode has at most 2^k vertices. It is represented by a binary tree of height at most k. The leaves store the subpath vertices. Each internal node represents the subpath of its leaf descendants; it stores the edge linking its left and right subtrees'

paths.

Our tangent-finding algorithm starts its search from two start vertices $u_s \in F(u)$ and $v_s \in F(v)$. The algorithm is a standard binary search [8, 14], with a modified search sequence. Instead of starting from the middle edge of the funnel and then recursively cutting the funnel in half, the search on $F(u)$ walks up from u_s to the root of the supernode binary tree containing u_s, follows the superedges between supernodes, and descends into the supernode binary tree containing the tangent endpoint u_ℓ. The search uses funnel edges in its comparisons, namely, the superedges it follows between supernodes and the edges above u_s and u_ℓ in the supernode binary trees containing those vertices. See Figure 3.2. The following lemma bounds the time of the search.

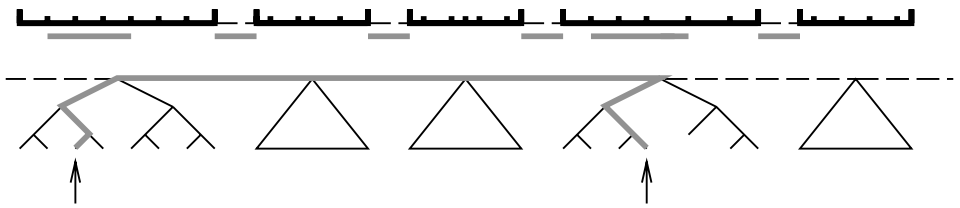

FIG. 3.2. *The supernode representation. The funnel path is shown schematically on top, and its supernode representation on the bottom. The positions of u_s and u_ℓ are shown by arrows, u_s on the left. The search path through the supernode representation is shaded gray, as are the funnel edges examined by the search.*

LEMMA 3.4. *Let $(F(u), F(v))$ be an open funnel-pair with a common tangent $\ell(u, v) = (u_\ell, v_\ell)$, with each funnel represented by two paths of supernodes. Let n_u be the number of supernodes on $F(u)$ between the start vertex u_s and u_ℓ for a particular tangent search; define n_v analogously. If the search occurs during the kth phase of MSEARCH, then computing the tangent $\ell(u, v)$ takes $O(n_u + n_v + k)$ time.*

We need to show how to maintain this representation of $F(u)$ (actually of the path $\pi(z(u), a)$) as u moves among the active vertices of U, and how to initialize the data structure at the start of each phase. To accomplish both tasks, we consider the shortest path tree T_a. In the kth phase we will retain only the vertices of T_a that are ancestors of at least one apex $z(u)$ for some active $u \in U$. This gives a tree with at most n_k leaves, and hence with at most $n_k - 1$ nodes of degree more than two. If we cut T_a below each node of degree greater than two and below each active apex, we get a decomposition of T_a into at most $2n_k - 1$ paths. We partition each of these paths into supernodes, each with at most 2^k vertices. Linking the paths back together gives a shortest path tree of supernodes. We will ensure that the total number of supernodes in the tree is $O(kn_k) = O(kn2^{-k})$.

Given this tree of supernodes and the path of supernodes representing $\pi(z(u), a)$, it is relatively easy to produce the path representing $\pi(z(u'), a)$ for u' an active neighbor of u in U. We compute $\alpha(u, u')$ and map it to the supernode X containing it. The descendant of X is Y, a supernode ancestor of u but not of u'. One of the (at most two) immediate siblings of Y in the shortest path tree is Z, a supernode ancestor of u' but not of u. We unlink X from Y, and link X to Z instead. (If u' is an ancestor or descendant of u, the work required is different but still easy.) All this takes only constant time.

In phase 0 the shortest-path tree of supernodes is just the original tree T_a: all

vertices of U are active and all supernodes contain exactly one vertex. To produce the tree of supernodes for phase $k+1$, given the tree for phase k, we delete dead vertices and combine neighboring supernodes. More precisely, we identify the supernodes that contain active apexes in phase $k+1$ and delete all supernodes that are not (improper) ancestors of at least one such supernode. We cut the tree below every supernode of degree greater than two and every supernode containing an active apex. This gives a decomposition into at most $2n_{k+1} - 1$ paths. On each path with at least two supernodes, we merge adjacent pairs of supernodes. "Merging" two supernodes means that we build a new binary tree whose left and right subtrees are the old supernode trees and whose root contains the superedge linking the old supernodes. It is not hard to show by induction on k that the number of supernodes is at most $(\frac{k+1}{2})n_k$ for $k > 0$. We summarize our data structure's properties in the following lemma.

LEMMA 3.5. *During phase k, the shortest-path tree of supernodes contains $O(kn_k)$ supernodes. The overhead to prepare the data structure for phase k is $O(kn_k)$. Given the supernode representation of $F(u)$, we can modify it to obtain the representation of $F(u')$ for a neighboring active vertex u' in constant time.*

Remark. The bound on the number of supernodes during the kth phase can be improved to $O(n_k)$, at the expense of increasing the tree height to $2k$. The $O(kn_k)$ bound results from merging each supernode tree with at most one other at each phase; this allows the tree height to remain at most k in phase k. By performing two rounds of merging per phase, we can ensure that the number of supernodes is $O(n_k)$, but the two rounds of merging may increase the tree height to $2k$. We use one round of merging because the inferior supernode bound of $O(kn_k)$ is sufficient for our purpose.

3.4. Distance computation. In this section, we show how the primitives of the previous two subsections are used to perform a matrix evaluation. Suppose we want to compute the distance $d(u, v)$, where $u \in U$ and $v \in V$. We start by computing the four lowest common ancestors $\alpha(u), \beta(u), \alpha(v), \beta(v)$. By performing three ancestor queries, we can determine the exact order of these four vertices along the path $\pi(a, b)$. The funnel-pair $(F(u), F(v))$ is closed if and only if the order is either $(\alpha(u), \beta(u), \alpha(v), \beta(v))$ or $(\alpha(v), \beta(v), \alpha(u), \beta(u))$. Otherwise, the pair is an open funnel-pair. Since each ancestor query takes $O(1)$ time, the time to determine whether the funnel-pair is open or not is only a constant. The following two lemmas detail how to compute the distance $d(u, v)$, depending upon whether the funnel-pair is open or closed.

LEMMA 3.6. *If the funnel-pair $(F(u), F(v))$ is closed, $d(u, v)$ can be computed in $O(1)$ time.*

Proof. Without loss of generality, assume that the lowest common ancestor vertices $\alpha(v), \beta(v)$ precede $\alpha(u), \beta(u)$ on $\pi(a, b)$. See Figure 3.1 for an illustration; the funnel-pair $(F(u_6), F(v_{10}))$ is closed. Then it is easy to see that

$$d(u, v) = d(u, \alpha(u)) + d(\alpha(u), \beta(v)) + d(v, \beta(v)). \tag{3.3}$$

These distances can be deduced from shortest-path trees T_a and T_b in constant time each. For instance, $d(u, \alpha(u)) = d(a, u) - d(a, \alpha(u))$, and both the distances on the right-hand side are precomputed in T_a. This completes the proof. □

LEMMA 3.7. *If the funnel-pair $(F(u), F(v))$ is open, $d(u, v)$ can be computed in $O(\tau(u, v))$ time, where $\tau(u, v)$ is the time to compute the tangent $\ell(u, v)$.*

Proof. We compute the tangent $\ell(u, v)$ for the funnel-pair $(F(u), F(v))$. Refer to Figure 3.1, where the funnel-pair $(F(u_{19}), F(v_{10}))$ is open. Then it is easy to see that

$$d(u, v) = d(u, u_\ell) + d(u_\ell, v_\ell) + d(v_\ell, v). \tag{3.4}$$

The distance $d(u_\ell, v_\ell)$ is the Euclidean distance between u_ℓ and v_ℓ. The remaining two terms are deduced from the shortest path trees T_a and T_b in constant time. For example, consider the distance $d(u, u_\ell)$. If u_ℓ is an ancestor of u in T_a, then $d(u, u_\ell) = d(a, u) - d(a, u_\ell)$; otherwise u_ℓ is an ancestor of u in T_b, and $d(u, u_\ell) = d(b, u) - d(b, u_\ell)$. In either case, the distances to a and b are precomputed and accessible in constant time apiece. □

The preceding two lemmas have established that the dominant term in matrix operations is the cost of finding tangents between open funnel-pairs.The next two sections contain the main result of our paper. Section 4 presents our algorithm for computing tangents, and section 5 analyzes the algorithm, showing that it takes $O(k)$ amortized time to compute a tangent in the kth phase of the matrix-searching.

4. The algorithm. We describe how to perform the matrix operations during one phase of the subroutine *REDUCE*. Suppose that we are in the kth phase of the algorithm: the submatrix A_k has size $n_k \times 2n_k$, where $n_k \leq n2^{-k}$. Matrix-searching theory tells us that *REDUCE* performs at most $3n_k$ matrix evaluations. We label the matrix evaluations in time-order, where time runs in integer steps from 1 to $3n_k$. By convention, the matrix entry being evaluated at time t is $d(u(t), v(t))$, where $1 \leq t \leq 3n_k$ and $u(t) \in U$ and $v(t) \in V$ are active vertices. The preceding section shows that the dominant cost in computing $d(u(t), v(t))$ is finding the tangent $\ell(u(t), v(t))$. Therefore, in the remainder of this section, we focus on the tangent-finding component of the matrix operations.

We use the shorthand notation $\ell(t)$ to denote the tangent computed at time t:

$$\ell(t) \;=\; \ell(u(t), v(t)).$$

The vertices $u_\ell(t)$ and $v_\ell(t)$, as before, denote the endpoints of $\ell(t)$. Our main subroutine for implementing *REDUCE* is called *ADVANCE*; it computes the tangent $\ell(t+1) = \ell(u(t+1), v(t+1))$ and advances the current time from t to $t+1$. We maintain the following two auxiliary data fields to support the operations in the subroutine at the current time t:

1. $\ell(t)$: This is the tangent computed at time t; that is, $\ell(t) = \ell(u(t), v(t))$. We store $u_\ell(t)$ and $v_\ell(t)$, the two endpoints of $\ell(t)$, at vertex $v(t)$.
2. $\tilde{\ell}(u)$: This is the most recent tangent computed at the vertex u prior to the current time t; the time t is implicit in this definition. Each vertex $u \in U$ maintains its $\tilde{\ell}(u)$, which is initially set to *NIL*.

The pseudocode for *ADVANCE* finds the tangent $\ell(t+1)$ between the funnels $F(u(t+1))$ and $F(v(t+1))$. The algorithm has two nearly identical parts, one executed when the V-vertex advances, and the other when the U-vertex advances. The two parts differ in one important detail: the choice of the vertex where the search for new tangent begins. When the V-vertex advances (Step 1), the search starts at the lowest common ancestor $\alpha(v(t), v(t+1))$ in V, and at the previous tangent endpoint $u_\ell(t)$ in U. However, when the U-vertex advances (Step 2), a more involved choice of the start vertex is needed. We introduce these vertices, $u^*(t+1)$ and $v^*(t+1)$, in the following; see Figure 4.1.

Let t' denote the time when $\tilde{\ell}(u(t+1))$ was computed; it is undefined if $\tilde{\ell}(u(t+1))$ is *NIL*. Thus $\ell(t') = \tilde{\ell}(u(t+1))$. The two endpoints of $\ell(t')$ are denoted $u_\ell(t')$ and $v_\ell(t')$. Let $u_\alpha = \alpha(u(t), u(t+1))$. Then the start vertex $u^*(t+1)$ is defined as follows.

$$u^*(t+1) \;=\; \begin{cases} u_\alpha & \text{if } t' \text{ is undefined or if } u_\alpha \text{ is a descendant of } u_\ell(t') \text{ in } T_a, \\ u_\ell(t') & \text{otherwise.} \end{cases}$$

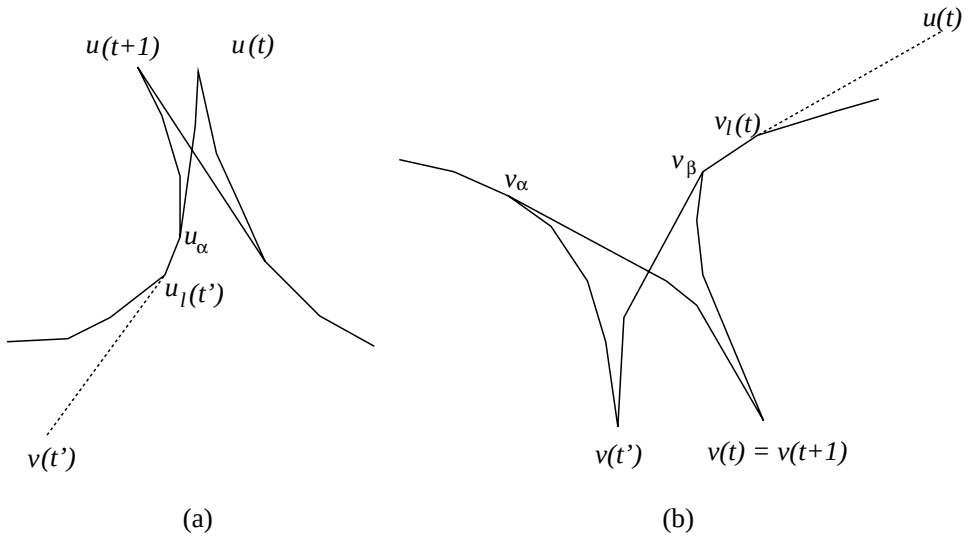

FIG. 4.1. *The definition of the start vertices* $u^*(t+1)$ *and* $v^*(t+1)$. *In* (a), $u^*(t+1) = u_\alpha$, *and in* (b), $v^*(t+1) = v_\beta$.

We observe that $u^*(t+1)$ is a vertex in the funnel-difference $\Delta F(u(t+1), u(t))$.

Next, we define $v^*(t+1)$, which is a vertex in the funnel-difference $\Delta F(v(t), v(t'))$; recall that $v(t')$ is the vertex on the V-chain that was current at time t'. We define v_α and v_β as the vertices bounding the funnel-difference $\Delta F(v(t), v(t'))$:

$$v_\alpha \;=\; \alpha(v(t), v(t')), \qquad v_\beta \;=\; \beta(v(t), v(t')).$$

Finally, recall that $v_\ell(t)$ is the V-chain endpoint of the tangent $\ell(t)$. The start vertex $v^*(t+1)$ is defined as follows.

$$v^*(t+1) \;=\; \begin{cases} v_\alpha & \text{if } t' \text{ is defined and } v_\alpha \text{ is a descendant of } v_\ell(t) \text{ in } T_a, \\ v_\beta & \text{if } t' \text{ is defined and } v_\beta \text{ is a descendant of } v_\ell(t) \text{ in } T_b, \\ v_\ell(t) & \text{otherwise.} \end{cases}$$

With these definitions, we are ready to present the pseudocode for *ADVANCE*. The pseudocode talks about "painting" edges, which is merely a device used by our analysis to prove the linearity of the algorithm. To perform the pseudocode test whether $\ell(t+1)$ is the same as a previously computed tangent ℓ', the algorithm checks whether ℓ' is still tangent to $F(u(t+1))$ and $F(v(t+1))$ at its endpoints. This takes constant time using lowest common ancestor queries.

ADVANCE(t)

(∗ *By matrix-searching theory, either* $v(t+1) \neq v(t)$ *or* $u(t+1) \neq u(t)$, *but not both.* ∗)

1. **if** $v(t+1) \neq v(t)$ **then**
   (a) **if** $\ell(t+1) = \ell(t)$ **then**
   Set $\ell(t+1) = \ell(t)$;
   (b) **else**
   Simultaneously search for $v_\ell(t+1)$ on $F(v(t+1))$ starting from

$\alpha(v(t), v(t+1))$, and for $u_\ell(t+1)$ on $F(u(t+1))$ starting from $u_\ell(t)$.
Paint the edges of $F(u(t+1))$ between $u_\ell(t)$ and $u_\ell(t+1)$;

2. **else** ($* u(t+1) \neq u(t) *$)
   (a) **if** $\ell(t+1) \in \{\ell(t), \tilde{\ell}(u(t+1))\}$ **then**
   Set $\ell(t+1)$ accordingly;
   (b) **else**
   Simultaneously search for $v_\ell(t+1)$ on $F(v(t+1))$ starting from $v^*(t+1)$, and for $u_\ell(t+1)$ on $F(u(t+1))$ starting from $u^*(t+1)$.
   Paint the edges of $F(v(t+1))$ between $v^*(t+1)$ and $v_\ell(t+1)$, and paint the edges of $F(u(t+1))$ between $u^*(t+1)$ and $u_\ell(t+1)$;

end *ADVANCE*

ADVANCE correctly computes the new tangent $\ell(t+1)$: Steps 1a and 2a set $\ell(t+1)$ to a previously computed tangent if that tangent is still valid at time $t+1$. The remaining steps search for the tangent endpoints on funnels $F(u(t+1))$ and $F(v(t+1))$. Since $u_\ell(t+1) \in F(u(t+1))$ and $v_\ell(t+1) \in F(v(t+1))$, these searches are also correct. (The choice of the vertices where the search starts is relevant only for analyzing the running time.)

5. The analysis. This section establishes the linearity of our matrix-searching algorithm. In the kth phase of *MSEARCH*, the submatrix input to *REDUCE* has size $n_k \times 2n_k$, where $n_k \leq n2^{-k}$, and the total number of matrix evaluations performed by *REDUCE* is $O(n_k)$. The discussion in subsection 3.4 shows that the only part of a matrix operation requiring nonconstant work is the tangent computation. Thus, the running time of *ADVANCE* dominates the running time of *REDUCE* in a phase.

5.1. The analysis of *ADVANCE*. The running time of *ADVANCE* is dominated by the searches performed in the tangent-finding steps. The remaining steps take only constant time apiece per step: the tests of tangent equivalence in Steps 1a and 2a can be made in constant time, and the start vertices $u^*(t+1)$ and $v^*(t+1)$ can also be computed in constant time.

We bound the cost of computing tangents in *ADVANCE* during the kth phase by arguing that each funnel edge is searched over at most twice. Using the terminology of section 3.3, if u_s, v_s are the start vertices for the tangent search, then the edges of $F(u)$ between u_s and u_ℓ and the edges of $F(v)$ between v_s and v_ℓ are considered to be *searched over* when $\ell(u, v)$ is computed. (The key point is that the actual cost of computing the tangent is $O(n_u + n_v + k)$, where $n_u + n_v - 2$ is the number of superedges searched over during this tangent-finding operation; see Lemma 3.4.)

Except for the search on the V-chain in Step 1b, all other searches in *ADVANCE* are accounted for by a "painting" paradigm: we paint the edges that are searched over during a tangent computation, and each edge is painted at most once (Lemmas 5.3 and 5.4). We use a separate accounting scheme (Lemma 5.1) to count the edges of V searched over in Step 1b. Together, these lemmas prove that no edge of either U or V is searched over more than twice during a complete phase of *REDUCE*.

LEMMA 5.1. *During a phase of REDUCE, each edge in the V-chain is searched over in Step* 1b *of ADVANCE at most once.*

Proof. Step 1 is executed when $u(t+1) = u(t)$, and $v(t+1) \neq v(t)$. The search in Step 1b is carried out if and only if $\ell(t+1) \neq \ell(t)$. These two facts together

imply that $v_\ell(t+1)$ necessarily lies in the funnel-difference $\Delta F(v(t+1), v(t))$. Only edges of the funnel-difference $\Delta F(v(t+1), v(t))$ are searched over. By Lemma 3.3 the funnel-differences are disjoint at any two distinct times: $\Delta F(v(t'+1), v(t')) \cap \Delta F(v(t''+1), v(t'')) = \emptyset$ for any $0 < t' < t'' < 3n_k$. This completes the proof. □

The proofs of the two remaining lemmas (Lemmas 5.3 and 5.4) are more complicated, and they rely on the following technical lemma.

LEMMA 5.2. *Whenever edges of the V-chain are painted at time $t+1$, their extensions hit the U-chain between $u(t)$ and $u(t+1)$. Similarly, whenever edges of the U-chain are painted at time $t+1$, their extensions hit the V-chain before $v(t+1)$. If the edges of the U-chain are painted because $v(t+1) \neq v(t)$, then their extensions hit the V-chain between $v(t)$ and $v(t+1)$.*

Proof. The proof of the lemma depends on the fact that the painted edges lie on a funnel, and the edges of a funnel have either monotonically decreasing or monotonically increasing slopes from one end to the other. The edges of V painted at time $t+1$ are in $F(v(t+1))$, and they lie between $v^*(t+1)$ and $v_\ell(t+1)$. Because $v_\ell(t+1)$ belongs to $\Delta F(v(t+1), v(t'))$, $v^*(t+1)$ lies on $F(v(t+1))$ between $v_\ell(t)$ and $v_\ell(t+1)$. By the slope property, the slopes of all the painted edges are between the slopes of $\ell(t)$ and $\ell(t+1)$. By the regular expression of section 2.3, $u(t)$ and $u(t+1)$ are two adjacent active vertices in U; notice that $u(t+1)$ can be either the successor or the predecessor of $u(t)$, but the two vertices must be adjacent. Because the extensions of all the painted edges lie between $\pi(v(t), u(t))$ and $\pi(v(t), u(t+1))$, they must hit the U-chain between $u(t)$ and $u(t+1)$. Figure 5.1(a) illustrates this case: the edges painted are shown with heavy lines.

The edges of U can be painted either in Step 1b or in Step 2b. If the edges are painted in Step 1b, then $v(t+1) \neq v(t)$, but $u(t) = u(t+1)$. In this case, the painted edges lie between $u_\ell(t)$ and $u_\ell(t+1)$, the U-endpoints of the tangents at times t and $t+1$. Again, by the slope property, all painted edges have slopes in the range determined by the slopes of $\ell(t)$ and $\ell(t+1)$. Since $v(t)$ and $v(t+1)$ are adjacent active vertices of V, the extensions of all painted edges hit the V-chain between $v(t)$ and $v(t+1)$.

Finally, if the U-edges are painted in Step 2b, then $v(t) = v(t+1)$, but $u(t) \neq u(t+1)$. In this case, the painted edges lie between $u^*(t+1)$ and $u_\ell(t+1)$. Since the matrix-searching algorithm never backs up on the V-chain, the tangent endpoint on $F(u(t+1))$ moves monotonically clockwise with time. In particular, if the old tangent $\tilde{\ell}(u(t+1))$ is not *NIL*, it lies on the shortest path to some vertex $v(t')$ that is before $v(t+1)$ in the V-chain order. Because $u_\ell(t+1)$ belongs to $\Delta F(u(t+1), u(t))$, $u^*(t+1)$ lies on $F(u(t+1))$ between $u_\ell(t')$ and $u_\ell(t+1)$. If $\tilde{\ell}(u(t+1))$ is *NIL*, then $u^*(t+1) = \alpha(u(t), u(t+1))$ is counterclockwise of $u_\ell(t+1)$. In either case, the slope property ensures that the extensions of the U-edges painted in Step 2b hit the V-chain before $v(t+1)$. Figure 5.1(b) illustrates this case: the edges painted are shown with heavy lines. This completes the proof. □

The next two lemmas show that no edge of U or V is painted more than once in a phase. Both lemmas rely on the following observations about Step 2b of *ADVANCE*, in which $v(t+1) = v(t)$ and $u(t+1) \neq u(t)$, and the tangent $\ell(t+1)$ equals neither $\ell(t)$ nor $\tilde{\ell}(u(t+1))$. Let t' denote the time when $\tilde{\ell}(u(t+1))$ is computed, assuming it is not *NIL*; that is, t' is the most recent time before t when a tangent is computed for $F(u(t+1))$. We observe the following vertex-relations:

$$u(t') = u(t+1), \qquad u(t'+1) = u(t), \qquad v(t') = v(t'+1). \tag{5.1}$$

The first relation follows from the definition of t'. The third follows from the first: at

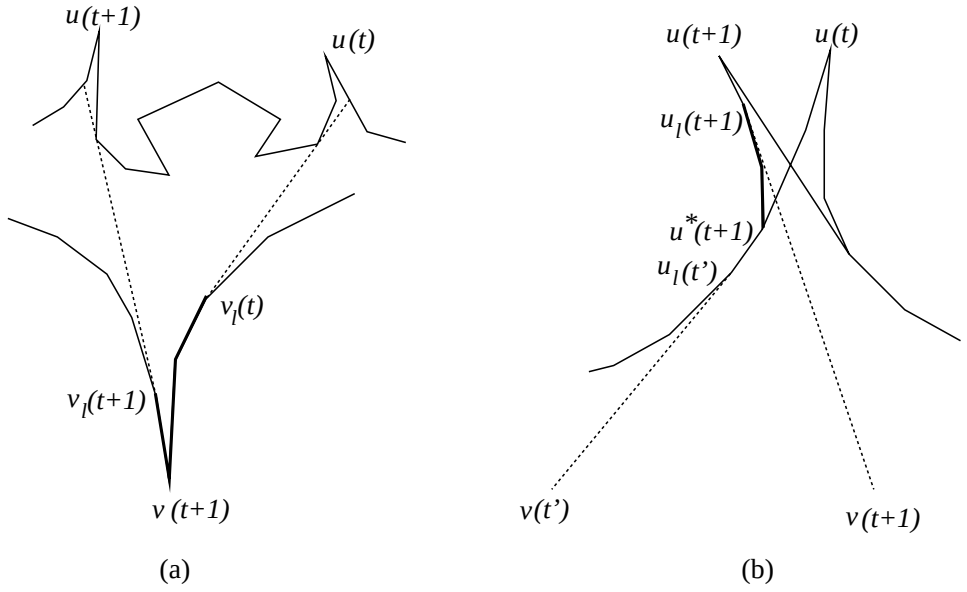

FIG. 5.1. *Illustration for the proof of Lemma* 5.2. *Part* (a) *shows the painting of* V*-edges; a symmetric case arises when* $u(t)$ *is after* $u(t+1)$. *Part* (b) *shows the painting of* U*-edges (in Step* 2b*); in this example, the start vertex is* $u^*(t+1) = \alpha(u(t), u(t+1))$, *and* t' *is the time when the old tangent* $\tilde{\ell}(u(t+1))$ *was computed.*

time $t'+1$, the algorithm must have advanced the U-vertex from $u(t')$ to $u(t'+1)$, keeping the V-vertex the same, since assuming otherwise contradicts the choice of time t'. Finally, the second relation follows from the important fact that *ADVANCE* visits the vertices of U in chain order (either forward or backward), never skipping an active vertex. The direction of movement in the U-chain at time t is opposite to the direction at time t'. A key consequence of the vertex relations in Eq. (5.1) is that between times t' and t, the algorithm visits vertices that are all separated from $u(t+1)$ by $u(t)$. That is, $u(t)$ separates $u(t+1)$ from $u(t'')$, for $t'+1 < t'' < t$.

LEMMA 5.3. *An edge of the* V*-chain is painted at most once per phase.*

Proof. The edges of V are painted only in Step 2b. Our analysis makes crucial use of the funnel difference $\Delta F(v(t), v(t'))$. Since $\ell(t+1) \neq \ell(t')$, it follows that $v_\ell(t+1) \in \Delta F(v(t), v(t'))$. We break up our analysis in two cases, depending upon whether or not $v_\ell(t) \in \Delta F(v(t), v(t'))$.

Case 1. $v_\ell(t) \in \Delta F(v(t), v(t'))$, or t' is undefined. See Figure 5.2.

In this case, we observe that $v^*(t+1) = v_\ell(t)$. Since $v_\ell(t+1)$ lies in the funnel-difference $\Delta F(v(t), v(t'))$, all edges of V painted at time $t+1$ belong to $\Delta F(v(t), v(t'))$. By Lemma 5.2, the extensions of the newly painted edges hit the U-chain between $u(t)$ and $u(t+1)$. If t' is undefined, no painted edge's extension has hit here before, so the newly painted edges have never been painted before. If t' is defined, the most recent time *ADVANCE* traversed this portion of U was at time $t'+1$, when the U-vertex moved from $u(t')$ to $u(t'+1)$. Since the V-funnel at time $t'+1$, namely, $F(v(t'))$, is edge-disjoint from $\Delta F(v(t), v(t'))$, the newly painted edges were not painted at time step $t'+1$. Because $u(t)$ separates $u(t+1)$ from $u(t'')$ for any $t'+1 < t'' < t$, it follows

from Lemma 5.2 that the edges were not painted between time $t'+1$ and time t. By Lemma 3.3, these edges were not painted at any time $t'' \leq t'$, since $\Delta F(v(t), v(t'))$ is disjoint from $F(v(t''))$. Thus, the edges of V painted at time $t+1$ have never been painted before.

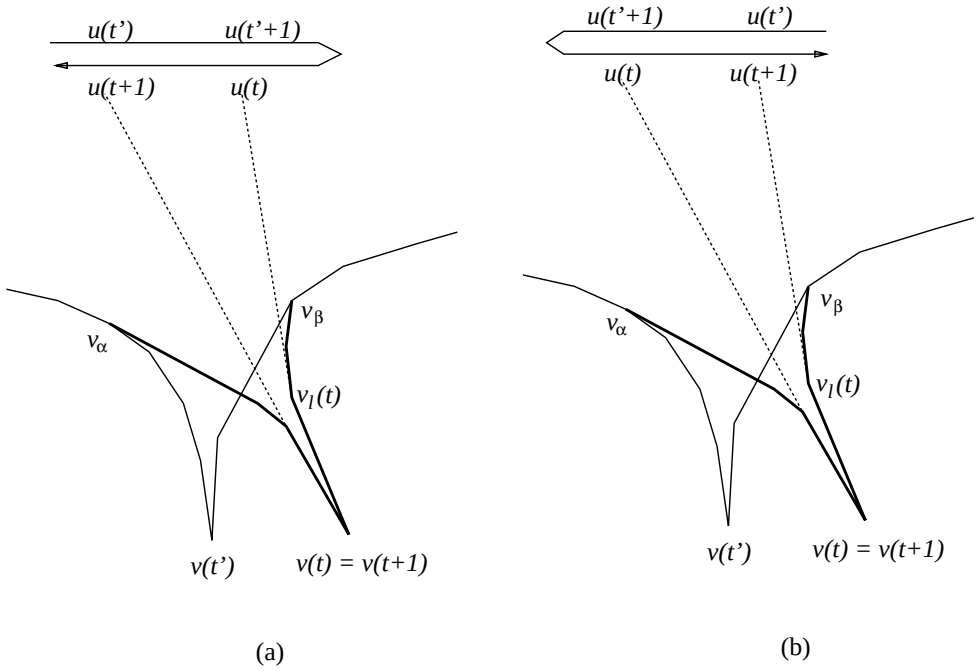

FIG. 5.2. *Illustration for Case* 1 *of Lemma* 5.3. *Parts* (a) *and* (b) *show the two symmetric cases: in* (a)*, the algorithm is moving forward on the U-chain at time t, and in* (b)*, it is moving backward at time t. The motion is suggested by the arrow on top. The funnel-difference* $\Delta F(v(t), v(t'))$ *is shown in heavy lines.*

Case 2. $v_\ell(t) \notin \Delta F(v(t), v(t'))$. See Figure 5.3.

Because $v_\ell(t) \in F(v(t'))$, we have $v_\ell(t) = v_\ell(t'+1)$. Furthermore, $v^*(t+1)$ equals either v_α or v_β, where $v_\alpha = \alpha(v(t), v(t'))$ and $v_\beta = \beta(v(t), v(t'))$. As noted above, $u(t)$ separates $u(t+1)$ from $u(t'')$, for $t' < t'' < t$. Since the V-vertex is confined between $v(t')$ and $v(t)$ during this time interval, we can be sure that tangent endpoints on V lie outside the funnel-difference $\Delta F(v(t), v(t'))$ between times t' and t. In particular, if $v^*(t+1) = v_\beta$, then $v_\ell(t'')$ lies at or above $v_\ell(t)$ in T_b, and if $v^*(t+1) = v_\alpha$, then $v_\ell(t'')$ lies at or above $v_\ell(t)$ in T_a, for any $t' < t'' < t$. Thus, any edges painted on V between times $t'+1$ and t are disjoint from $\Delta F(v(t), v(t'))$. Finally, no edge of $\Delta F(v(t), v(t'))$ is painted at or before t', since Lemma 3.3 ensures that $\Delta F(v(t), v(t'))$ is disjoint from $F(v(t''))$, for any $t'' \leq t'$. This completes the proof. □

LEMMA 5.4. *An edge of the U-chain is painted at most once per phase.*

Proof. The edges of U are painted either in Step 1b or in Step 2b. If the edges are painted in Step 1b, then $v(t+1) \neq v(t)$ and the painted edges lie between $u_\ell(t)$ and $u_\ell(t+1)$. By Lemma 5.2, the extensions of the newly painted edges hit the V chain between $v(t)$ and $v(t+1)$. Because $v(t)$ separates $v(t+1)$ from $v(t')$, for any $t' < t$, the newly painted edges cannot have been painted at an earlier time.

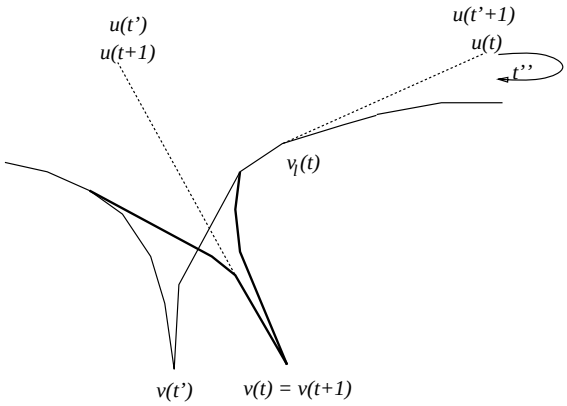

FIG. 5.3. *Illustration for Case* 2 *of Lemma* 5.3. *The symmetric case, in which the algorithm is moving backward on the* U*-chain at time* t*, is not shown.*

If the edges are painted in Step 2b, then $u(t+1) \neq u(t)$, and the painted edges lie between the start vertex $u^*(t+1)$ and $u_\ell(t+1)$. Let t' denote the time when $\tilde{\ell}(u(t+1))$ is computed (possibly undefined). Since $u_\ell(t+1)$ equals neither $u_\ell(t)$ nor $u_\ell(t')$, we know that $u_\ell(t+1)$ lies in the funnel-difference $\Delta F(u(t+1), u(t))$. Since the start vertex $u^*(t+1)$ is guaranteed to be in $\Delta F(u(t+1), u(t))$, all the newly painted edges belong to $\Delta F(u(t+1), u(t))$. If t' is undefined, then by Lemma 3.3 no edge of $\Delta F(u(t+1), u(t))$ has appeared in $F(u(t''))$, for $t'' \leq t$, so none has been painted before. If t' is defined, the edges lying between $u_\ell(t')$ and $u_\ell(t+1)$ have not been painted at or before time t', since their extensions hit the V-chain after $v(t')$ (cf. Lemma 5.2). No edge of the funnel-difference $\Delta F(u(t+1), u(t))$ is painted between times $t'+1$ and t, since the lowest common ancestor property implies that $\Delta F(u(t+1), u(t))$ is disjoint from $F(u(t''))$, for any $t' < t'' \leq t$. Thus, none of the newly painted edges has been painted at an earlier time. This completes the proof. □

5.2. The analysis of *REDUCE* and *MFILL*. We show that the kth phase of *MSEARCH* takes $O(kn_k)$ time, where $n_k \leq n2^{-k}$. The analysis of the preceding section has shown that no edge of U or V is searched over more than twice. There are at most $3n_k$ matrix evaluations during *REDUCE* in the kth phase, and by Lemma 3.4 the time for one evaluation is $O(k + n_u + n_v)$, where $n_u + n_v - 2$ is the number of superedges searched over during the evaluation. The total number of superedges and the total overhead cost of maintaining the funnel data structure during the kth phase is $O((k+1)n_k)$. Thus, the total time spent on matrix evaluations in the kth phase of *REDUCE* is $O((k+1)n_k)$.

The running time of *MFILL* has the same bound. Section 2.3 shows that the matrix evaluations in *MFILL* satisfy the same regular expression as those in *REDUCE*. The same analysis applies, therefore, proving that the running time of *MFILL* at the kth phase is also $O((k+1)n_k)$.

5.3. The time complexity of *MSEARCH*. Finally, we are ready to show that our matrix-searching algorithm runs in $O(n)$ time overall. The algorithm consists of $O(\log n)$ phases, and the matrix in the kth phase has size at most $n_k \times 2n_k$,

where $n_k \leq n2^{-k}$. In each phase, the running time is dominated by the subroutines *REDUCE* and *MFILL*; other steps take $O(n_k)$ time. The cost of executing *REDUCE* and *MFILL* in the kth phase is $O((k+1)n_k)$. Thus, the total cost of the matrix-searching algorithm *MSEARCH* is

$$T(n) = O\left(\sum_{k=0}^{\lceil \log n \rceil} (k+1)n_k\right) = O\left(\sum_{k=0}^{\infty} k\frac{n}{2^k}\right) = O(n).$$

We have established our main theorem.

THEOREM 5.5. *Let P be a simple polygon with n vertices, and let U and V be subchains of its boundary that together partition the vertices of P. Let M denote a $p \times m$ matrix with $M(i,j)$ equal to the shortest path distance between the vertices $u_i \in U$ and $v_j \in V$, where $p = |U|$ and $m = |V|$. Then we can compute the maximum entry in each row of M in $O(n)$ total time.*

5.4. Computing row-wise minima. The algorithm of section 4 also works for computing row-wise minima of M. In fact, by changing the ordering of columns and negating all distances, we can directly apply our maxima-finding algorithm to compute the minima. Let us define an auxiliary $p \times m$ matrix M', where

$$M'(i,j) \;=\; -M(i, m-j+1). \tag{5.2}$$

Notice that the column-ordering of M' is reverse of the column-ordering of M. The triangle inequality again implies that M' is totally monotone.

LEMMA 5.6. *The matrix M' defined in Eq.* (5.2) *is totally monotone.*

We can find the row-wise maxima of M' (which correspond to the row-wise minima in M) using the matrix-searching algorithm of section 4. The direction of travel in the V-chain is now reversed, due to the reversal of columns. To account for this change, we set $a = v_m$ and $b = v_1$. The algorithm and its analysis remain the same. We have the following theorem.

THEOREM 5.7. *Let P be a simple polygon with n vertices, and let U and V be subchains of its boundary that together partition the vertices of P. Let M denote a $p \times m$ matrix with $M(i,j)$ equal to the shortest path distance between the vertices $u_i \in U$ and $v_j \in V$, where $p = |U|$ and $m = |V|$. Then we can compute the minimum entry in each row of M in $O(n)$ total time.*

6. Applications. In this section, we give several applications of Theorems 5.5 and 5.7. Our applications concern problems in simple polygons, where the shortest-path metric is the most natural distance function. In addition, in several problems, we can use the shortest-path metric to mask visibility constraints. Throughout this section, P denotes a simple polygon, whose vertices are labeled $p_1, p_2, \ldots, p_n$ in counterclockwise order around the boundary.

6.1. The geodesic diameter and farthest neighbors. This section describes a linear-time algorithm for computing a farthest neighbor for each vertex of P under the shortest-path metric; the previous best time bound for this problem was $O(n \log n)$ [6, 16]. The *geodesic diameter* of P, denoted $D(P)$, is the maximum length of a shortest path in P:

$$D(P) \;=\; \max\{d(x,y) \mid x, y \in P\}.$$

The diameter is always realized by two vertices of P [16], and so finding it is a special case of the problem of computing farthest neighbors for all vertices of P. By

computing a farthest neighbor of a vertex $p \in P$, we mean two things: identifying a vertex $q \in P$ such that $d(p,q) = \max\{d(p,p') \mid p' \in P\}$, and computing the distance $d(p,q)$. We use a lemma from [16] to decompose the all-farthest neighbor problem into at most three instances of maxima-finding in totally monotone matrices.

Let p_i, p_j and p_k be three vertices of P such that p_j is a farthest neighbor of p_i, and p_k is a farthest neighbor of p_j: $d(p_i,p_j) = \max\{d(p_i,p_l) \mid p_l \in P\}$, and $d(p_j,p_k) = \max\{d(p_j,p_l) \mid p_l \in P\}$. Without loss of generality, assume that p_i, p_j, p_k are in counterclockwise order. The triple p_i, p_j, p_k divides the polygon into three disjoint chains: $P_1 = (p_{i+1}, p_{i+2}, \ldots, p_{j-1})$, $P_2 = (p_{j+1}, p_{j+2}, \ldots, p_{k-1})$, and $P_3 = (p_{k+1}, p_{k+2}, \ldots, p_{i-1})$. Corresponding to these chains are the three complementary chains: $Q_1 = (p_j, p_{j+1}, \ldots, p_i)$, $Q_2 = (p_k, p_{k+1}, \ldots, p_j)$, and $Q_3 = (p_i, p_{i+1}, \ldots, p_k)$. Figure 6.1 shows a schematic diagram of this construction. The following lemma is established in [16].

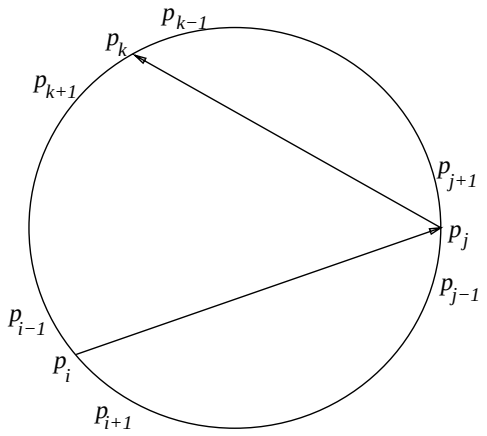

FIG. 6.1. *A schematic diagram showing chains P_i, for $i = 1, 2, 3$, in Lemma 6.1.*

LEMMA 6.1 (see [16]). *Every vertex of the chain P_i has a farthest neighbor in chain Q_i, for $i = 1, 2, 3$.*

Since the farthest neighbors p_j and p_k can be computed in linear time, using shortest path trees [7, 11], Lemma 6.1 gives a linear-time reduction from the farthest-neighbors problem of P to three instances of the farthest-neighbors problem between disjoint chains. The chains P_i, for $i = 1, 2, 3$, cover all vertices of P except p_i, p_j and p_k. Since the farthest neighbors of p_i and p_j are already computed, only p_k remains, and we can compute its farthest neighbor in linear additional time. The farthest-neighbors problem for the chains P_i and Q_i falls within the framework of section 4 and is therefore equivalent to the problem of computing row-wise maxima in a totally monotone matrix. By Theorem 5.5, this can be done in $O(n)$ time, and we have the following theorem.

THEOREM 6.2. *Given a simple polygon P on n vertices, we can compute a geodesic farthest neighbor for each of its vertices in $O(n)$ total time. Consequently, the geodesic diameter of P can also be computed in linear time.*

6.2. The external farthest neighbors. Agarwal et al. [1] gave an $O(n \log n)$ time algorithm for computing an external farthest neighbor for all vertices of a simple polygon. (The external farthest neighbors are computed using the *external* shortest

path metric: the distance between two points is the length of a shortest path in the plane minus the interior of the polygon.) The bottleneck in their algorithm is the computation of *internal* farthest neighbors; the (internal) farthest neighbors algorithm is needed to compute the external farthest neighbors within a "pocket" of the polygon. The remaining steps of the external farthest neighbors algorithm take only $O(n)$ time. Thus, the following result is a direct corollary of Theorem 6.2.

THEOREM 6.3. *Given a simple polygon P on n vertices, we can compute a geodesic external farthest neighbor for each of its vertices in $O(n)$ time. Consequently, the geodesic external diameter of P can also be computed in linear time.*

6.3. Weighted nearest neighbors and Euclidean matching. An internal diagonal of P divides the polygon into two chains. Let U and V be two polygonal chains obtained in this way, where $p = |U|$ and $m = |V|$. Let $w : P \to \Re$ be a real-valued weight function on the vertices of P, and define a $p \times m$ matrix M of weighted distances:

$$M(i,j) \;=\; d(u_i, v_j) - w(u_i) - w(v_j); \tag{6.1}$$

It is easily seen that M is totally monotone, by the triangle inequality. The problem of computing a *weighted nearest neighbor* for each vertex of U in V is equivalent to computing row-wise minima of M. This problem arises in an algorithm of Marcotte and Suri [13] for solving the Euclidean matching problem for points on a polygon. That algorithm finds an optimal matching for the vertices of a simple polygon, under the constraint that each matching edge lies inside the polygon. The algorithm is based on divide-and-conquer, and the dominating term in the conquer step is the complexity of solving the weighted nearest-neighbors problem as defined above. Our algorithm of section 4 solves the row-minima problem for M in linear time, thus improving the result in [13] from $O(n \log^2 n)$ to $O(n \log n)$.

THEOREM 6.4. *The algorithm of Marcotte and Suri* [13] *for computing an optimal matching of the vertices of a simple polygon can be implemented in $O(n \log n)$ time, where n denotes the number of vertices of the polygon.*

6.4. Closest visible vertex pair between two chains. Given two disjoint polygonal chains U and V, the closest visible vertex problem for U and V is to find a closest pair of vertices $u \in U$ and $v \in V$ that are visible to each other. The visibility constraint implies that some vertex-pairs are not legal candidates, and thus the associated distance matrix is not fully defined. Aggarwal et al. [3] gave a complicated linear-time algorithm for this problem that exploits the special structure of the legal entries in the matrix. A linear-time algorithm due to Amato [4] corrects minor problems with the algorithm of Aggarwal et al. Amato's algorithm can also be implemented on a Concurrent Read Concurrent Write Parallel Random Access Machine (CREW PRAM) in time $O(\log n)$ using $O(n)$ processors. However, like the algorithm of Aggarwal et al., Amato's algorithm is quite complicated. In this section, we show that a simpler and considerably more direct linear-time algorithm follows from our paradigm of matrix-searching using the shortest path metric.

Let M denote the $p \times m$ matrix whose (i, j) entry denotes the shortest path distance between u_i and v_j:

$$M(i,j) = d(u_i, v_j).$$

The triangle inequality implies that M is totally monotone, and so by Theorem 5.7, we can compute its row-minima in $O(n)$ time. Suppose that $M(i^*, j^*)$ is the overall

TABLE 7.1

Problem	Previous result	New result
Geodesic diameter	$O(n \log n)$	$O(n)$
All farthest neighbors	$O(n \log n)$	$O(n)$
External farthest neighbors	$O(n \log n)$	$O(n)$
Euclidean matching	$O(n \log^2 n)$	$O(n \log n)$
2-chain closest visible pair	$O(n)$	$O(n)$

minimum entry of M; clearly, this entry is also minimum in row i^*. We claim that the pair (u_{i^*}, v_{j^*}) is a closest visible pair in $U \times V$. By assumption, the distance between u_{i^*} and v_{j^*} is minimum over all u, v pairs, where $u \in U$ and $v \in V$; we need to show only that u_{i^*} and v_{j^*} are mutually visible. We assume otherwise and arrive at a contradiction. If u_{i^*} and v_{j^*} are not visible, then the shortest path $\pi(u_{i^*}, v_{j^*})$ has at least one intermediate vertex, say, z. If $z \in U$, then $d(z, v_{j^*}) < d(u_{i^*}, v_{j^*})$, and if $z \in V$, then $d(u_{i^*}, z) < d(u_{i^*}, v_{j^*})$. In either case, the minimality of $M(i^*, j^*) = d(u_{i^*}, v_{j^*})$ is contradicted. Thus we have the following theorem.

THEOREM 6.5. *Let U and V be two vertex-disjoint chains that partition the vertices of a simple polygon P. Then a closest visible vertex pair of U and V can be found in linear time.*

Theorem 6.5 applies equally well to computing the closest visible pair of vertices in two polygons. In linear time, we can easily transform the problem to two chains U and V that satisfy the conditions of the theorem.

7. Closing remarks. We have presented a linear-time algorithm for computing the row-wise maxima or minima of a totally monotone matrix whose entries correspond to shortest path distances between two chains of a simple polygon. The result appears to be quite powerful and has several applications in computational geometry. The most direct applications concern distance-related problems in simple polygons, since the shortest path metric is the natural metric for nonconvex simple polygons. However, as Theorem 6.5 demonstrates, the result also has applications when the distances are Euclidean but there is an additional visibility constraint. The generalization to the shortest path metric helps mask the visibility constraint. Table 7.1 summarizes the main applications of our result.

Using some additional techniques in combination with the matrix-searching result of this paper, we have also obtained a linear-time algorithm for computing a shortest diagonal of a simple polygon [12].

RANDOMIZED $\widetilde{O}(M(|V|))$ ALGORITHMS FOR PROBLEMS IN MATCHING THEORY*

JOSEPH CHERIYAN†

Abstract. A randomized (Las Vegas) algorithm is given for finding the Gallai–Edmonds decomposition of a graph. Let n denote the number of vertices, and let $M(n)$ denote the number of arithmetic operations for multiplying two $n \times n$ matrices. The sequential running time (i.e., number of bit operations) is within a poly-logarithmic factor of $M(n)$. The parallel complexity is $O((\log n)^2)$ parallel time using a number of processors within a poly-logarithmic factor of $M(n)$. The same complexity bounds suffice for solving several other problems:

(i) finding a minimum vertex cover in a bipartite graph,
(ii) finding a minimum $X \rightarrow Y$ vertex separator in a directed graph, where X and Y are specified sets of vertices,
(iii) finding the allowed edges (i.e., edges that occur in some maximum matching) of a graph, and
(iv) finding the canonical partition of the vertex set of an elementary graph.

The sequential algorithms for problems (i), (ii), and (iv) are Las Vegas, and the algorithm for problem (iii) is Monte Carlo. The new complexity bounds are significantly better than the best previous ones, e.g., using the best value of $M(n)$ currently known, the new sequential running time is $O(n^{2.38})$ versus the previous best $O(n^{2.5}/(\log n))$ or more.

Key words. randomized algorithms, matching theory, Gallai–Edmonds decomposition, allowed edges, canonical partition, bipartite minimum vertex covers, digraph minimum vertex separators

1. Introduction.

A *matching* of an undirected, possibly nonbipartite, graph $G = (V, E)$ is a subset E' of the edges such that no two of the edges in E' have a vertex in common. A *perfect matching* is one with cardinality $|V|/2$. Tutte [T 47] gave a good characterization of graphs that have perfect matchings, i.e., he showed that the perfect matching decision problem (deciding whether or not a given graph has a perfect matching) is in NP ∩ co-NP. One of Tutte's innovations was introducing the skew symmetric adjacency matrix $\widetilde{B}$ of the graph G, defined as follows: Associate each edge ij of G with a distinct variable x_{ij}. Then $\widetilde{B} = \widetilde{B}(x_{ij})$ is a $|V| \times |V|$ matrix whose entries are given by

$$\widetilde{B}_{ij} = \begin{cases} x_{ij} & \text{if } i > j \text{ and } ij \in E, \\ -x_{ij} & \text{if } i < j \text{ and } ij \in E, \\ 0 & \text{otherwise.} \end{cases}$$

Tutte observed that G has a perfect matching iff the determinant of $\widetilde{B}(x_{ij})$, $\det(\widetilde{B}(x_{ij}))$, is not identically zero; here, $\det(\widetilde{B}(x_{ij}))$ is a polynomial in the variables x_{ij}. Lovász [Lo 79] used this observation to give an efficient randomized algorithm for the perfect matching decision problem: Choose a prime number $q = |V|^{O(1)}$, and substitute each

variable x_{ij} in $\widetilde{B}$ by an independent random number drawn from $\{1, 2, \ldots, q-1\}$. Compute the determinant of the resulting random matrix B over the field of integers modulo q. With high probability (i.e., probability $\geq 1 - 1/\Omega(|V|)$; see Lemma 2.1), $\det(B) \neq 0 \mod q$ iff $\det(\widetilde{B}(x_{ij}))$ is not identically zero iff G has a perfect matching. This algorithm has two especially attractive features: it is simple, solving the decision problem by executing one "matrix operation," and it is efficient, running in sequential time $\widetilde{O}(M(|V|)) = O(|V|^{2.38})$ and in parallel time $O((\log |V|)^2)$ using $\widetilde{O}(M(|V|))$ processors. Here, $M(n)$ denotes the number of arithmetic operations for multiplying two $n \times n$ matrices and is currently known to be $O(n^{2.376})$; see Coppersmith and Winograd [CW 90]. Throughout, the bounds on the sequential running time or on the number of parallel processors are stated for the arithmetic complexity model (uniform-cost RAM or PRAM), but they apply also to the bit complexity model because, for each arithmetic operation, comparison, or data transfer, each operand has $O(\log |V|)$ bits, hence the number of bit operations is at most $O((\log |V|)^2)$ times the number of arithmetic operations; see the last paragraph of section 2.

The problem of *finding* a perfect matching of a graph G in time polynomial in $|V(G)|$ remained open until Edmonds [E 65] gave the first algorithm. Edmonds' algorithm solves the following more general problem: For every graph G, the algorithm finds a matching of maximum cardinality in time $|V(G)|^{O(1)}$. One consequence of the algorithm is a theorem that was discovered independently by Gallai [Ga 64], which is the so-called Gallai–Edmonds theorem. According to this theorem, for every graph G the vertex set can be partitioned into three sets $A(G), C(G), D(G)$ in a unique way such that certain properties hold (see Theorem 3.1). The partition gives much useful information, e.g., the cardinality of a maximum matching, the vertices that are incident to every maximum matching, etc. Several algorithms for constructing the partition are known. Edmonds' matching algorithm implicitly constructs the partition. Lovász (see [Kf 86, section 2]) developed a randomized algorithm for finding the Gallai–Edmonds decomposition that runs in time $\widetilde{O}(|V|\, M(|V|))$; though there are faster algorithms for finding the decomposition, the algorithm of [Kf 86] is interesting for its simplicity.

This paper (see Figure 1) presents a simple and efficient randomized algorithm for finding the Gallai–Edmonds decomposition. Lemma 3.3 shows that, with high probability, the partition $A(G) \cup C(G), D(G)$ for a given graph G can be found by computing a basis for the null space of a random skew symmetric adjacency matrix B, i.e., executing one "matrix operation" on B yields this partition. Obtaining the partition $A(G), C(G), D(G)$ from $A(G) \cup C(G), D(G)$ is trivial. The sequential running time is $\widetilde{O}(M(|V|))$ and the parallel time is $O((\log |V|)^2)$ using $\widetilde{O}(M(|V|))$ processors. Our algorithm is closely related to Lovász's algorithm (in [Kf 86]) for the Gallai–Edmonds decomposition; also, the algorithm uses a technique due to Eberly [E 91]. The algorithm, its proof, and running time analysis are all quite simple. Due to the information provided by the Gallai–Edmonds decomposition, our algorithm can be used to find a minimum cardinality vertex cover of a bipartite graph within the same complexity bounds. The minimum cardinality bipartite vertex cover problem is equivalent to the problem of finding a minimum vertex separator for two given vertex sets X and Y in a directed graph (see Proposition 2.4); hence the directed graph problem can be solved within the same complexity bounds.

An edge of a graph G is called *allowed* if it occurs in at least one maximum cardinality matching. Consider the problem of finding the allowed edges. If G has a perfect matching, then the Gallai–Edmonds decomposition gives *no* information about the al-

lowed edges because the partition $A(G), C(G), D(G)$ is trivial with $A(G) = \emptyset = D(G)$. Rabin and Vazirani [RV 89], in an elegant study of the random skew symmetric adjacency matrix B, observed that, if $\det(B) \neq 0$ and the (i, j) minor of B (i.e., the determinant of the submatrix obtained from B by removing row i and column j) is nonzero, then the edge ij (if present) must be allowed. Moreover, all of the (i, j) minors of B can be computed simultaneously by computing the inverse B^{-1}; the (j, i) entry of B^{-1} equals $(-1)^{i+j}/\det(B)$ times the (i, j) minor of B. Combining Rabin and Vazirani's method with our algorithm for the Gallai–Edmonds decomposition gives a randomized algorithm for finding the allowed edges of arbitrary graphs (see section 3.3); the sequential running time is $\widetilde{O}(M(|V|))$ and the parallel time is $O((\log |V|)^2)$ using $\widetilde{O}(M(|V|))$ processors. We also give a randomized algorithm, with the same complexity bounds for finding the canonical partition of an elementary graph, where a

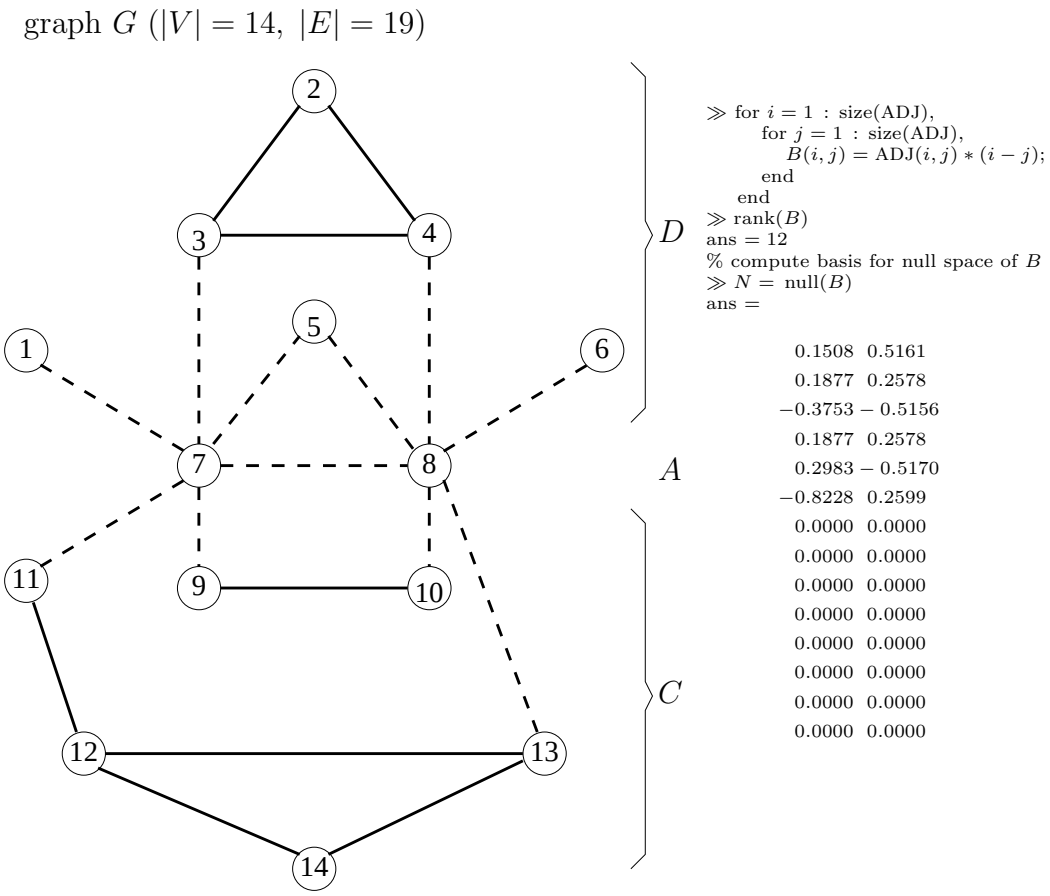

FIG. 1. *Finding the Gallai–Edmonds decomposition of an example graph G, using Lemma* 3.3. *The* MATLAB *code forms a pseudorandom skew symmetric adjacency matrix B from the adjacency matrix* ADJ *of G by substituting $(i - j)$ for each nonzero* ADJ_{ij}. *With high probability, a vertex j is noncritical iff row j of the basis N of the null space of B is nonzero. The resulting partition, $A = \{v_7, v_8\}$, $C = \{v_9, \ldots, v_{14}\}$, $D = \{v_1, \ldots, v_6\}$, is shown. Note that each connected component of D has odd cardinality and each connected component of C has even cardinality. Since* $\text{rank}(B) = 12 = |V| - (\sharp\text{components}(D) - |A|)$, *we have $\nu(G) = 6$. It follows that this partition gives the Gallai–Edmonds decomposition.*

graph is called *elementary* if it has a perfect matching and its allowed edges form a connected spanning subgraph (see section 3.4).

Both Lovász's algorithm for the perfect matching decision problem and our algorithm for the Gallai–Edmonds decomposition are Monte Carlo; however, using results from matching theory, we show how to make both algorithms Las Vegas while achieving the same sequential and parallel complexity bounds. While analyzing our randomized algorithms, we assume that the random bits drawn by the execution have no effect on the sequential or parallel complexity; this assumption may not be appropriate in other contexts. More precisely, for the execution of a randomized algorithm on a *fixed input*, let us take the sequential running time (or parallel running time, or number of parallel processors) to be the maximum sequential running time (or maximum parallel running time, or maximum number of parallel processors) over all possible choices of the random bits. A randomized algorithm is said to be *Monte Carlo* if, for a fixed input, an execution may give incorrect results with small probability. For a randomized algorithm and a problem instance of size n, an event is said to occur with *small* probability if the probability is $\leq 1/\Omega(n)$. A randomized algorithm is said to be *Las Vegas* if, for a fixed input, an execution either returns an output guaranteed to be correct or reports failure, the latter with small probability. A Las Vegas algorithm may be trivially converted into a Monte Carlo algorithm without changing the complexity. To convert a Monte Carlo algorithm into a Las Vegas algorithm, we need a subroutine for verifying whether the output of the Monte Carlo algorithm is correct. If the complexity of the verifying subroutine is bounded by that of the Monte Carlo algorithm, then the Las Vegas and Monte Carlo algorithms have the same order of complexity. This raises a difficulty for our randomized algorithms: We need to verify the correctness of results for problems in matching theory within a complexity bound that is significantly less than that of the best algorithms known for finding a maximum cardinality matching (see the next paragraph). Fortunately, the partition of $V(G)$ computed by our randomized algorithm for the Gallai–Edmonds decomposition can be verified in sequential time $\widetilde{O}(|E| + |V|)$ (or in parallel time $O((\log |V|)^2)$ using $\widetilde{O}(|E| + |V|)$ parallel processors). Consequently, our algorithms for the Gallai–Edmonds decomposition, a minimum vertex cover of a bipartite graph, and a minimum vertex separator of a directed graph all can be made Las Vegas without affecting the complexity. If the graph is bipartite, then our algorithm for finding the allowed edges can be made Las Vegas without affecting the complexity, but for nonbipartite graphs, we do not have a sufficiently efficient subroutine for verifying the allowed edges. Given an elementary graph, there is a sequential $\widetilde{O}(|E| + |V|)$-time algorithm for verifying whether the partition computed by our Monte Carlo algorithm is a canonical partition (see [L 95]), so our sequential algorithm for the canonical partition can be made Las Vegas without affecting the complexity.

We briefly discuss the best sequential and parallel complexities known for computing a maximum cardinality (or a perfect) matching. The fastest known sequential algorithms for finding a maximum matching are due to Micali and Vazirani [MV 80], Blum [B 90], and Gabow and Tarjan [GT 91] (also see [V 94]) and run in time $O(|E|\sqrt{|V|})$ (for dense graphs this is $O(|V|^{2.5})$ time). These algorithms are deterministic, however, and are significantly slower than Lovász's randomized algorithm for the perfect matching decision problem. At present, all efficient (i.e., poly-logarithmic time and polynomial number of processors) parallel algorithms for matching problems use randomization. The best parallel algorithms for finding a maximum matching are the Monte Carlo algorithms of Mulmuley, Vazirani, and Vazirani [MVV 87], Galil and

Pan [GP 88], and Karp, Upfal, and Wigderson [KUW 86]; the parallel complexities are $O((\log|V|)^2)$ time using $\widetilde{O}(|V|\,|E|\,M(|V|))$ processors and $O((\log|V|)^3)$ time using $\widetilde{O}(|V|\,M(|V|))$ processors, respectively. Our parallel complexity bounds are stated for the Exclusive Read Exclusive Write (EREW) PRAM model. Efficient parallel Las Vegas algorithms for matching problems have been designed by Karloff [Kf 86] and Wein [W 91].

It turns out that our algorithm for finding a minimum vertex separator for two given vertex sets X and Y in a directed graph can be developed independently of matching theory; this is done in section 4, building on the work of Linial, Lovász, and Wigderson [LLW 88] and Cheriyan and Reif [CR 94]. Preliminary versions of the results of computing the Gallai–Edmonds decomposition and directed graph $X{\rightarrow}Y$ separators have appeared in [C 94] and [C 93], respectively.

Section 2 contains notation, definitions, and preliminary results. Section 3 develops the algorithms for problems in matching theory. Section 4 is independent of section 3 and develops an algorithm for a minimum $X{\rightarrow}Y$ separator in a directed graph. Finally, Section 5 contains conclusions, and the appendix contains some proofs.

2. Preliminaries. For the given graph $G = (V, E)$, we use n and m to denote the number of vertices and edges, i.e., $n = |V|$ and $m = |E|$. For a subset X of V, $\overline{X}$ denotes $V - X$. For a matrix A with row and column indices from V and two subsets X, Y of V, $A(X, Y)$ denotes the submatrix of A formed by the X-rows and the Y-columns. The vector with a 1 in position j and zeros elsewhere is denoted by e_j, and $\left[\begin{smallmatrix} A \\ e_j \end{smallmatrix}\right]$ denotes the $(n+1) \times n$ matrix formed by adding the $(n+1)$th row e_j to an $n \times n$ matrix A.

A few standard definitions from matching theory are needed; see [LP 86]. An *odd (even) component* of a graph is a connected component whose vertex set has odd (even) cardinality. A *vertex cover* of a graph $G = (V, E)$ is a vertex set $C \subseteq V$ such that each edge is incident with some vertex of C. Given a graph $G = (V, E)$ and a matching E', a vertex is called *matched* if it is incident to an edge of E' and is called *exposed* otherwise. A *near perfect matching* is one with exactly one exposed vertex. For a graph G, $\nu(G)$ denotes the number of edges of a maximum matching. The *deficiency* of G is the number of vertices exposed in a maximum matching $n - 2\nu(G)$. A vertex x is called *noncritical* if it is exposed in at least one maximum matching, otherwise x is called *critical*. Equivalently, x is noncritical if $\nu(G - x) = \nu(G)$ and is critical if $\nu(G - x) < \nu(G)$. A graph H is called *factor critical* if for each of its vertices x, $H - x$ has a perfect matching.

The following lemma due to Zippel [Z 79] and Schwartz [Sc 80] (also see [Ko 91, Corollary 40.2]) is useful for estimating the failure probability of a whole class of randomized algorithms.

LEMMA 2.1 (Zippel–Schwartz). *If $p(x_1, x_2, \ldots, x_m)$ is a nonzero polynomial of degree d with coefficients in a field and S is a subset of the field, then the probability that p evaluates to zero on a random element $(s_1, s_2, \ldots, s_m) \in S^m$ is at most $d/|S|$.*

Recall from section 1 the definition of the skew symmetric adjacency matrix $\widetilde{B} = \widetilde{B}(x_{ij})$ of a graph G and Tutte's observation that $\det(\widetilde{B})$ is not identically zero iff G has a perfect matching. Lovász generalized this observation; for a proof, see [RV 89].

PROPOSITION 2.2 (Lovász). *Let $\widetilde{B} = \widetilde{B}(x_{ij})$ be the skew symmetric adjacency matrix of a graph G. Then* $\operatorname{rank}(\widetilde{B}) = 2\nu(G)$.

A random skew symmetric adjacency matrix B is obtained by substituting the variables x_{ij} in $\widetilde{B}(x_{ij})$ by independent random numbers w_{ij} from a subset $\{1, \ldots, W\}$

of a field. The next result is due to Lovász [Lo 79] and follows from the previous one by applying the Zippel–Schwartz lemma.

PROPOSITION 2.3 (Lovász). *Let* $B = \widetilde{B}(w_{ij})$ *be a random skew symmetric adjacency matrix of a graph* G*, where the* w_{ij} *are independent random numbers from* $\{1, \ldots, W\}$*. Then* $\text{rank}(B) \leq 2\nu(G)$*, and with probability at least* $1 - (n/W)$*,* $\text{rank}(B) = 2\nu(G)$*.*

Given a digraph (directed graph) $G = (V, E)$ and a pair of subsets X and Y of the vertices, an $X \rightarrow Y$ *(vertex) separator* is a set of vertices S such that $G - S$ has no path from a vertex in $X - S$ to a vertex in $Y - S$. For a pair of subsets X and Y of the vertices, $p(X, Y)$ denotes the maximum number of vertex disjoint paths from X to Y (any two of these paths have no vertices in common, not even the terminal vertices). Clearly, every $X \rightarrow Y$ separator has cardinality at least $p(X, Y)$. Menger's theorem states that for every pair of subsets X and Y of the vertices, there exists an $X \rightarrow Y$ separator with cardinality $p(X, Y)$. We call an $X \rightarrow Y$ separator *minimum* if its cardinality is minimum, namely, $p(X, Y)$.

Let us call two problems *linear-time equivalent* if there is a linear-time algorithm to transform an instance of the first problem to an instance of the second such that a solution to the second instance can be transformed in linear time to a solution of the first instance, and vice versa. Part (i) of the next proposition is well known. The novel point of part (ii) is that a digraph minimum vertex separator can be obtained in linear time from an arbitrary minimum vertex cover of an appropriately constructed bipartite graph. See the appendix for a proof of the proposition.

PROPOSITION 2.4.

(i) *The problem of finding a maximum cardinality matching in a bipartite graph is linear-time equivalent to the problem of finding a maximum cardinality set of vertex-disjoint* $X \rightarrow Y$ *paths in a digraph.*

(ii) *The problem of finding a minimum vertex cover in a bipartite graph is linear-time equivalent to the problem of finding a minimum* $X \rightarrow Y$ *separator in a digraph.*

We use the soft-Oh notation to denote the complexity of algorithms. The soft-Oh notation drops poly-logarithmic factors: For functions f and g, f is $\widetilde{O}(g)$ iff there are constants n_0, $k \geq 0$ such that $f(n) \leq g(n)(\log n)^k$, for all $n \geq n_0$. Note that $\widetilde{O}(M(n)) = O(n^{2.38})$, since $M(n)$ is known to be $O(n^{2.376})$ (see section 1). All computations of the algorithms presented below are over the field $\mathbb{Z}_q$ of integers modulo a prime number q. When choosing random numbers w, we assume that they are drawn from the uniform distribution over $\{1, \ldots, W\}$, where W is an integer and $W < q$. Throughout, we take $q = |V(G)|^{O(1)}$; i.e., q is polynomially bounded in the number of vertices of the graph G. Consider the number of bit operations for multiplying two $|V| \times |V|$ matrices over the field of integers modulo q. Since an integer modulo q can be represented using $O(\log q) = O(\log |V|)$ bits and the multiplication of two q-bit numbers takes $O(q^2)$ bit operations, it follows that the number of bit operations is $\widetilde{O}(M(|V|))$.

3. Randomized algorithms for problems in matching theory. This section develops randomized $\widetilde{O}(M(|V|))$-time algorithms for the following problems in matching theory: finding a Gallai–Edmonds decomposition; finding a minimum vertex cover in a bipartite graph; finding the allowed edges of a graph; and finding the canonical partition of an elementary graph.

3.1. A randomized algorithm for the Gallai–Edmonds decomposition. Recall that a vertex x is called *noncritical* if it is exposed in at least one maximum matching, otherwise x is called *critical*. We use $D(G)$ to denote the set of noncritical vertices and $A(G)$ to denote the set of vertices in $V(G) - D(G)$ adjacent to vertices of $D(G)$. The set of remaining vertices, $V(G) - (D(G) \cup A(G))$, is denoted by $C(G)$. For ease of notation, $D(G)$ and $C(G)$ are also used to denote the subgraphs of G induced by the respective vertex sets. See [LP 86, Theorem 3.2.1] for a proof of the next theorem.

THEOREM 3.1 (Gallai–Edmonds). *Let G be a graph, and let $D(G)$, $A(G)$, and $C(G)$ be as defined above. Then*

(i) *each component of the subgraph induced by $C(G)$ has a perfect matching;*
(ii) *each component of the subgraph induced by $D(G)$ is factor critical;*
(iii) *the deficiency of G equals*

$$\sharp\text{components}(D(G)) - |A(G)|,$$

where $\sharp$components$(D(G))$ denotes the number of connected components in the subgraph induced by $D(G)$;
(iv) *every maximum matching of G contains a perfect matching of each component of $C(G)$, a near perfect matching of each component of $D(G)$, and matches all the vertices of $A(G)$ with vertices in distinct components of $D(G)$.*

The key result for our algorithm follows. Recall the notation $\left[\begin{smallmatrix} B \\ e_j \end{smallmatrix}\right]$ from section 2.

LEMMA 3.2. *Let $B = \widetilde{B}(w_{ij})$ be a random skew symmetric adjacency matrix of a graph G, where the w_{ij} are independent random numbers from $\{1, \ldots, W\}$. Consider any vertex x, and let j be its index in B.*

(i) *If x is noncritical, then with probability at least $1 - (2n/W)$ the rank of the matrix $\left[\begin{smallmatrix} B \\ e_j \end{smallmatrix}\right]$ is greater than that of B.*
(ii) *If x is critical, then with probability at least $1 - (n/W)$ the rank of the matrix $\left[\begin{smallmatrix} B \\ e_j \end{smallmatrix}\right]$ equals that of B.*

Proof. Consider the augmented graph G' and its random skew symmetric adjacency matrix B', where G' is obtained from G by adding a new vertex z (with index $n+1$) and the edge xz, and B' is obtained from B by adding a row $r \cdot e_j$ and a corresponding column, where r is a random number independent of the entries of B, i.e.,

$$B' = \begin{bmatrix} B & & & & 0 \\ & & & & \vdots \\ & & & & -r \\ & & & & \vdots \\ 0 & \ldots & r & \ldots & 0 \end{bmatrix}.$$

Consider the cardinality of a maximum matching of G'. If there exists a maximum matching of G with x exposed, then $\nu(G')$ is greater than $\nu(G)$ because the new edge xz of G' may be added to the maximum matching of G. However, if x is matched in every maximum matching of G, then $\nu(G')$ equals $\nu(G)$. In other words, x is noncritical in G iff $\nu(G')$ is greater than $\nu(G)$. Applying Proposition 2.3 to G' and B', we see that if x is noncritical in G, then with probability at least $1 - (2n/W)$,

$$\text{rank}(B') = 2\nu(G') = 2\nu(G) + 2 = \text{rank}(B) + 2.$$

Consider the matrix $\left[\begin{smallmatrix} B \\ e_j \end{smallmatrix}\right]$ obtained from B' by removing the last column and then dividing the last row by r. Since $\text{rank}(\left[\begin{smallmatrix} B \\ e_j \end{smallmatrix}\right]) \geq \text{rank}(B') - 1$, part (i) of the lemma follows.

For part (ii) we have seen that $\nu(G')$ equals $\nu(G)$ if x is critical. Hence, with probability at least $1-(n/W)$, $\text{rank}(B) = 2\nu(G) = 2\nu(G') \geq \text{rank}(B') \geq \text{rank}(\left[\begin{smallmatrix} B \\ e_j \end{smallmatrix}\right]) \geq \text{rank}(B)$. □

ALGORITHM 1. *Monte Carlo Gallai–Edmonds Decomposition*
INPUT: Graph $G = (V, E)$.
OUTPUT: With high probability, the Gallai–Edmonds decomposition of G.
Step 0:
Order the vertices, and number them $1, 2, \ldots, n$.
Fix the number $W = n^{O(1)}$, and choose a prime q, $W < q = n^{O(1)}$.
For each edge ij, choose a random weight $w(ij) \in \{1, 2, \ldots, W\}$.
Construct a random skew symmetric adjacency matrix B of G,
where for each edge ij, $i > j$,
$B_{ij} = w(ij)$ and $B_{ji} = -w(ij)$ ($B_{ij} = 0$ if ij is not an edge).
Step 1:
Compute the rank r of B over the field $\mathbb{Z}_q$.
Step 2:
For each of the vectors e_j, $j = 1, \ldots, n$,
compute the rank r_j of the matrix $\left[\begin{smallmatrix} B \\ e_j \end{smallmatrix}\right]$ over the field $\mathbb{Z}_q$.
Let D be the set of vertices j with $r_j > r$.
Step 3:
Let A be the subset of $V - D$ adjacent to D, and let C be the set
of vertices neither in D nor in A.
With high probability, the Gallai–Edmonds decomposition of G
is given by A, C, D.

FIG. 2.

The algorithm for finding the Gallai–Edmonds decomposition follows immediately from both the previous lemma and Theorem 3.1. Find the set $D(G)$ of noncritical vertices with high probability by comparing the rank of each $\left[\begin{smallmatrix} B \\ e_j \end{smallmatrix}\right]$, $j = 1, \ldots, n$, with the rank of B. The probability that the set $D(G)$ is correctly computed is at least $1-(2n^2/W)$. Knowing $D(G)$, the sets $A(G)$ and $C(G)$ can be found in $\widetilde{O}(n+m)$ time. See Algorithm 1 in Figure 2 for a full description. The working of the algorithm on an example is illustrated in Figure 1. The following straightforward implementation of Algorithm 1 runs in $\widetilde{O}(n \cdot M(n)) = O(n \cdot n^{2.38})$ time: For each $j = 1, \ldots, n$, use the algorithm of [IMH 82] to find the rank of $\left[\begin{smallmatrix} B \\ e_j \end{smallmatrix}\right]$ in $\widetilde{O}(M(n))$ time. We now improve the running time from $\widetilde{O}(n \cdot M(n))$ to $\widetilde{O}(M(n))$. The $\widetilde{O}(M(n))$ bound holds even for the number of bit operations; to see this, recall the remarks at the end of section 2. To obtain a faster implementation, observe that $\text{rank}(\left[\begin{smallmatrix} B \\ e_j \end{smallmatrix}\right])$ is greater than $\text{rank}(B)$ iff e_j is *not* in the row space of B, i.e., iff e_j is not a linear combination of the row vectors of B. We can "simultaneously" compute the ranks of all the $\left[\begin{smallmatrix} B \\ e_j \end{smallmatrix}\right]$'s by computing a matrix N such that for any row vector v, $v \cdot N = 0$ iff v is a linear combination of the row vectors of B. Once N is computed, we simply find the product of the $n \times n$ identity matrix I_n with N. The nonzero rows of N correspond exactly to the vectors e_j having $\text{rank}(\left[\begin{smallmatrix} B \\ e_j \end{smallmatrix}\right])$ greater than $\text{rank}(B)$. Coming to the computation of N, we take N to be a basis for the null space (i.e., kernel) of B. Note that for any

subspace U (e.g., the row space of B) of a finite-dimensional vector space W over a finite field (e.g., the n-dimensional vector space over $\mathbb{Z}_q$), $\dim U + \dim U^{\perp} = \dim W$, and so $(U^{\perp})^{\perp} = U$ [Lo 93, Exercise 5.31]. Hence, even for the n-dimensional vector space over $\mathbb{Z}_q$ we can check whether a vector v is in the row space of B by checking whether $v \cdot N$ is zero. It is well known that for any $n \times n$ matrix B, a basis for the null space can be computed in sequential time $\widetilde{O}(M(n))$ (see [IMH 82, pp. 53–54]) and in randomized parallel time $O((\log n)^2)$ using $\widetilde{O}(M(n))$ processors (see [KP 91, p. 190]).

LEMMA 3.3. *Let $B = \widetilde{B}(w_{ij})$, $w_{ij} \in \{1, \ldots, W\}$, be a random skew symmetric adjacency matrix of a graph, and let the $n \times (n - \mathrm{rank}(B))$ matrix N be a basis for the null space of B. Let v be an arbitrary vertex, and let j be its index in B. If v is critical (noncritical), then with probability at least $1 - (2n/W)$ the jth row of N is zero (nonzero).*

Let A, C, D denote the partition of V computed by an execution of the Monte Carlo algorithm. To make the algorithm Las Vegas, we need to verify whether A, C, D is the Gallai–Edmonds decomposition. We first verify whether $\nu(G)$ is computed correctly and then verify whether the set D equals the set of noncritical vertices $D(G)$. By Proposition 2.3, $\nu(G)$ is at least $\mathrm{rank}(B)/2$, where B is the random skew symmetric adjacency matrix. Suppose that each component of D is odd and each component of C is even. Then $\nu(G)$ is at most $(|V| - (\sharp\mathrm{components}(D) - |A|))/2$, because every matching E' of G leaves at least $\sharp\mathrm{components}(D) - |A|$ exposed vertices; to see this, observe that for each odd component of $G - A$, either the odd component contains an exposed vertex or an edge of E' matches a vertex of the odd component to a vertex of A. Our verification subroutine (in the Las Vegas algorithm) determines the odd and even components of $G - A$ and compares $\mathrm{rank}(B)$ with $|V| - (\sharp\mathrm{components}(D) - |A|)$. If equality fails to hold in the comparison, or one of the components of D is even, or one of the components of C is odd, then the Las Vegas algorithm reports failure. Otherwise, $\nu(G)$ is guaranteed to equal $\mathrm{rank}(B)/2$, and moreover, the set A is guaranteed to be a barrier. A set $X \subseteq V(G)$ is called a *barrier* if $|V| - 2\nu(G)$ (i.e., the deficiency of G) equals the difference of the number of odd components of $G - X$ and $|X|$. We claim that if A is a barrier and $\nu(G) = \mathrm{rank}(B)/2$, then the computed partition A, C, D is the Gallai–Edmonds decomposition. To see this, note that if a vertex with index j has $\mathrm{rank}(\left[\begin{smallmatrix} B \\ e_j \end{smallmatrix}\right])$ greater than $\mathrm{rank}(B) = 2\nu(G)$, then the vertex is noncritical; hence, every vertex in the computed set D is noncritical. Also, every noncritical vertex is contained in D by the following result (see [LP 86, Theorem 3.3.17]): If $X \subseteq V(G)$ is a barrier, then every noncritical vertex is contained in the union of the odd components of $G - X$. Consequently, $D = D(G)$, and so, by construction, $A = A(G)$ and $C = C(G)$.

THEOREM 3.4. *There is a Las Vegas algorithm with a sequential running time of $\widetilde{O}(M(n))$ for finding the Gallai–Edmonds decomposition and the cardinality of a maximum matching of a graph. A parallel version of the algorithm uses $\widetilde{O}(M(n))$ processors and takes parallel time $O((\log n)^2)$.*

3.2. Finding a minimum vertex cover in a bipartite graph. Due to the information provided by the Gallai–Edmonds decomposition, the above Las Vegas algorithm may be applied to solve other problems in matching theory within the same complexity bounds. In this subsection, we show how the algorithm may be used to find a minimum vertex cover of a bipartite graph. Moreover, by the equivalence of the bipartite minimum vertex cover problem and the digraph minimum $X \rightarrow Y$ separator problem (see Proposition 2.4), we can also find a minimum $X \rightarrow Y$ separator in a digraph. We need a theorem from matching theory; see [LP 86, Theorem 3.2.4].

THEOREM 3.5 (Dulmage and Mendelsohn). *Let $G = (V_1, V_2, E)$ be a bipartite graph, where V_1 and V_2 are the sets of the vertex bipartition. For $i = 1, 2$ let $A_i = A(G) \cap V_i$, $C_i = C(G) \cap V_i$, and $D_i = D(G) \cap V_i$, where $A(G)$, $C(G)$, and $D(G)$ are the three sets of the Gallai–Edmonds decomposition of G. Then $C_1 \cup A_1 \cup A_2$ and $C_2 \cup A_1 \cup A_2$ are minimum vertex covers.*

The above theorem, combined with the Las Vegas algorithm for the Gallai–Edmonds decomposition, immediately yields an efficient Las Vegas algorithm for a minimum vertex cover of a bipartite graph $G = (V_1, V_2, E)$. The algorithm may be simplified by focusing on just one of the sets V_i, $i = 1, 2$, of the vertex bipartition and for each vertex in that set computing whether or not it is critical. Also, instead of using the skew symmetric adjacency matrix we use the bipartite adjacency matrix H, which has a row for each vertex in V_1 and a column for each vertex in V_2; an entry H_{ij} is nonzero iff G has the edge ij, $i \in V_1, j \in V_2$. See Algorithm 2 in Figure 3.

ALGORITHM 2. *Monte Carlo Bipartite Minimum Vertex Cover*
INPUT: Bipartite graph $G = (V_1, V_2, E)$.
OUTPUT: With high probability, a minimum vertex cover of G.
Step 0:
Order the vertices of V_1 and V_2, and number them $1, 2, \ldots$.
Fix the number $W = n^{O(1)}$, and choose a prime q, $W < q = n^{O(1)}$.
For each edge ij, $i \in V_1, j \in V_2$, choose a random weight $w(ij) \in \{1, 2, \ldots, W\}$.
Construct a random bipartite adjacency matrix H of G,
where for each edge ij, $i \in V_1, j \in V_2$, $H_{ij} = w(ij)$ ($H_{ij} = 0$ if ij is not an edge).
Step 1:
Compute the rank r of H over the field $\mathbb{Z}_q$.
Step 2:
For each of the vectors e_j, $j = 1, \ldots, |V_2|$,
compute the rank r_j of the matrix $\left[\begin{smallmatrix} H \\ e_j \end{smallmatrix}\right]$ over the field $\mathbb{Z}_q$.
Let $D_2 \subseteq V_2$ be the set of vertices $j \in V_2$ with $r_j > r$.
Step 3:
Let A_1 be the subset of V_1 adjacent to D_2, i.e.,
$A_1 = \{i \in V_1 : ij \in E \text{ and } j \in D_2\}$.
With high probability, a minimum vertex cover of G is given by
$A_1 \cup (V_2 - D_2)$.

FIG. 3.

THEOREM 3.6. *There is a Las Vegas algorithm with a sequential running time of $\widetilde{O}(M(n))$ for finding a minimum cardinality vertex cover of a bipartite graph. A parallel version of the algorithm uses $\widetilde{O}(M(n))$ processors and takes parallel time $O((\log n)^2)$. The same complexity bounds apply for finding a minimum cardinality $X \rightarrow Y$ separator of a digraph.*

In section 4, an algorithm for finding minimum $X \rightarrow Y$ separators in digraphs (and for finding bipartite minimum vertex covers) is designed using different methods than those used in this section. Yet it turns out that the two algorithms for bipartite minimum vertex covers are identical.

3.3. Finding the allowed edges. Recall from section 1 that an edge of a graph $G = (V, E)$ is called *allowed* if it is contained in at least one maximum matching. The notion of an allowed edge is important in matching theory; see [LP 86, Chapter 5]. We develop a Monte Carlo algorithm for finding the set of allowed edges of an arbitrary

graph; the sequential and parallel complexities are the same as those of our algorithm in Theorem 3.4. The best previous sequential or parallel algorithms for finding the set of allowed edges of a graph take at least as much sequential time (or, parallel time and parallel processors) as needed for computing a maximum matching.

Our method for finding the set of allowed edges first constructs the Gallai–Edmonds decomposition $A(G), C(G), D(G)$ using the algorithm of Theorem 3.4. Now observe that every edge incident to a noncritical vertex v is allowed: First, consider a maximum matching such that v is exposed, and switch the matching by adding any edge vw and removing the matched edge incident to w. Second, every edge with one end vertex in $A(G)$ and the other end vertex in either $A(G)$ or $C(G)$ is *not* allowed, by Theorem 3.1. Finally, we are left with the edges with both end vertices in $C(G)$. Since every component of $C(G)$ has a perfect matching, we apply the following result of Rabin and Vazirani (see [RV 89, Lemma 4]) to find (with high probability) the allowed edges of components of $C(G)$.

LEMMA 3.7 (Rabin and Vazirani). *Let G be a graph with a perfect matching, and let B be a random skew symmetric adjacency matrix of G. If $\det(B) \neq 0$, then for each index i, $1 \leq i \leq n$, there is an index j, $1 \leq j \leq n$, such that $B_{ij} \neq 0$ and $(B^{-1})_{ji} \neq 0$; moreover, for each pair i, j satisfying this condition, the corresponding edge $v_i v_j$ is in some perfect matching of G.*

THEOREM 3.8. *With probability at least $1 - (1/n^{\Theta(1)})$, the set of allowed edges of a graph can be computed in sequential time $\widetilde{O}(M(n))$ and in parallel time $O((\log n)^2)$ using $\widetilde{O}(M(n))$ processors.*

The above algorithm is Monte Carlo but not Las Vegas; if the algorithm reports that an edge with both end vertices in $C(G)$ is not allowed, then there is a small probability that the edge is actually allowed. In all other cases, the algorithm's output is correct. For the special case of bipartite graphs, we give a Las Vegas algorithm that achieves the same complexity bounds. Focus on a component $H = (V_1, V_2, E)$ of $C(G)$, where V_1 and V_2 are the sets of the vertex bipartition. We construct the connected subgraphs $H_1, \ldots, H_k$ of H formed by the computed set of allowed edges. For each connected subgraph H_i, $1 \leq i \leq k$, $|V(H_i) \cap V_1|$ must equal $|V(H_i) \cap V_2|$ and each edge with both end vertices in H_i must be allowed (see [LP 86, Theorem 4.1.1]); otherwise, the algorithm reports failure. Next we construct a bipartite graph H' by contracting to a distinct single vertex each of the two sets in the vertex bipartition of each of the connected subgraphs $H_1, \ldots, H_k$; i.e., each $V(H_i) \cap V_j$, $1 \leq i \leq k$, $j = 1, 2$, is contracted to a distinct vertex. We also replace any parallel edges with single edges. Thus each H_i, $1 \leq i \leq k$ is contracted to a distinct edge; observe that these "contracted edges" form a perfect matching of the contracted graph H'. If the contracted graph H' has a unique perfect matching, then the computed set of allowed edges of H is correct; otherwise, the algorithm reports failure; see [LP 86, Lemma 4.3.1]. To test for a unique perfect matching in H', we start with the perfect matching consisting of the edges formed by contracting $H_1, \ldots, H_k$, and check whether there exists an alternating cycle with respect to this matching. The claimed complexity bounds suffice for testing for an alternating cycle.

THEOREM 3.9. *There is a Las Vegas algorithm with a sequential running time of $\widetilde{O}(M(n))$ for finding the set of allowed edges of a bipartite graph. A parallel version of the algorithm uses $\widetilde{O}(M(n))$ processors and takes parallel time $O((\log n)^2)$.*

3.4. Finding the canonical partition of an elementary graph. Recall from section 1 that a graph $G = (V, E)$ is called elementary if it has a perfect matching and its allowed edges form a connected spanning subgraph. Also recall that a set X

of vertices is called a barrier if the deficiency of G, $|V| - 2\nu(G)$, equals the difference of the number of odd components of $G - X$ and $|X|$. For an elementary graph the deficiency is zero, so $X \subseteq V$ is a barrier iff $|X|$ equals the number of odd components of $G - X$. If G is elementary, then the (inclusionwise) maximal barriers of G form a partition $S_1, S_2, \ldots, S_k$ of the vertex set $V(G)$; this partition is called the *canonical partition* [LP 86, section 5.2]. Here we develop an efficient randomized algorithm for finding the canonical partition of an elementary graph. The Monte Carlo algorithm for the canonical partition was discovered jointly with Padayachee. The sequential $\widetilde{O}(m+n)$-time algorithm for verifying the canonical partition is due to La Poutré [L 95].

The following key result underlies our algorithm (see [LP 86, Theorem 5.2.2]): Two (distinct) vertices x and y are in the same set S_i of the canonical partition iff $G - \{x, y\}$ has *no* perfect matching. Based on this result and [RV 89, Lemma 3], we find the canonical partition as follows: Assume that the given graph G is elementary. We construct a random skew symmetric adjacency matrix B of G. If $\det(B) = 0$, then we stop and report failure. Otherwise we compute the inverse of B, B^{-1}. To compute the canonical partition of $V(G)$, we attempt to construct an equivalence relation Ψ on the vertex pairs such that vertices x and y are related iff the (x, y) entry of B^{-1}, $(B^{-1})_{xy}$, is zero. If Ψ is indeed an equivalence relation, then the algorithm outputs the equivalence classes of Ψ as the computed partition (with high probability, this is the canonical partition); otherwise, if Ψ is not an equivalence relation, then we stop and report failure. Verifying that Ψ is an equivalence relation and computing its equivalence classes takes sequential time $\widetilde{O}(n^2)$ and parallel time $O((\log n)^2)$ using $\widetilde{O}(n^2)$ processors; first, observe that Ψ is reflexive ($(x, x) \in \Psi, \forall x \in V$) and symmetric ($(x, y) \in \Psi$ iff $(y, x) \in \Psi$) since B is skew symmetric and n is even; Ψ is transitive iff each connected component of the graph (V, Ψ) is a clique.

THEOREM 3.10 (with Padayachee). *With probability at least* $1 - (1/n^{\Theta(1)})$, *the canonical partition of an elementary graph can be computed in sequential time* $\widetilde{O}(M(n))$ *and in parallel time* $O((\log n)^2)$ *using* $\widetilde{O}(M(n))$ *processors.*

The above algorithm is Monte Carlo but not Las Vegas. For this paragraph, let $S_1, \ldots, S_k$ denote the partition computed by the Monte Carlo algorithm; the canonical partition may differ from $S_1, \ldots, S_k$. If each set S_i, $1 \leq i \leq k$, is a barrier, then the computed partition is the canonical partition. To see this, observe that for any two vertices x and y in two different sets of the computed partition, the (x, y) entry of B^{-1} is nonzero; hence, by [RV 89, Lemma 3] the graph $G - \{x, y\}$ has a perfect matching. Consequently, by the key result on canonical partitions quoted above x and y must be in different sets of the canonical partition. Hence, the canonical partition is a refinement of the partition $S_1, \ldots, S_k$, and if the two partitions differ, then one of the sets S_i is the union of two or more maximal barriers. To obtain a Las Vegas algorithm we do the following: For each set S_i in the computed partition, we determine whether it is a barrier by comparing the number of odd components of $G - S_i$ with $|S_i|$. If every set S_i is a barrier, then we output $S_1, \ldots, S_k$ as the canonical partition; otherwise we report failure. There is a sufficiently efficient sequential algorithm due to La Poutré [L 95] for the key computation in verifying the partition computed by our Monte Carlo algorithm; this algorithm uses Sleator and Tarjan's [ST 83] dynamic trees data structure to maintain the connected components of the current subgraph and works by appropriately deleting and inserting all edges incident to vertices in the set S_i, $1 \leq i \leq k$; also see La Poutré and Westbrook [LW 94].

THEOREM 3.11 (La Poutré). *Given a graph* $G = (V, E)$ *and a collection of*

pairwise disjoint vertex sets $S_1, \ldots, S_k$, the number of odd components in $G - S_i$ for all i, $1 \le i \le k$, can be determined in (deterministic) sequential time $\widetilde{O}(m+n)$.

Alternatively, the sequential $\widetilde{O}(m+n)$ time bound can be achieved by a randomized Las Vegas algorithm using dynamic data structures recently developed by Henzinger and King [HK 95].

THEOREM 3.12. *Given an elementary graph as input, there is a sequential Las Vegas algorithm with a running time of $\widetilde{O}(M(n))$ for finding the canonical partition.*

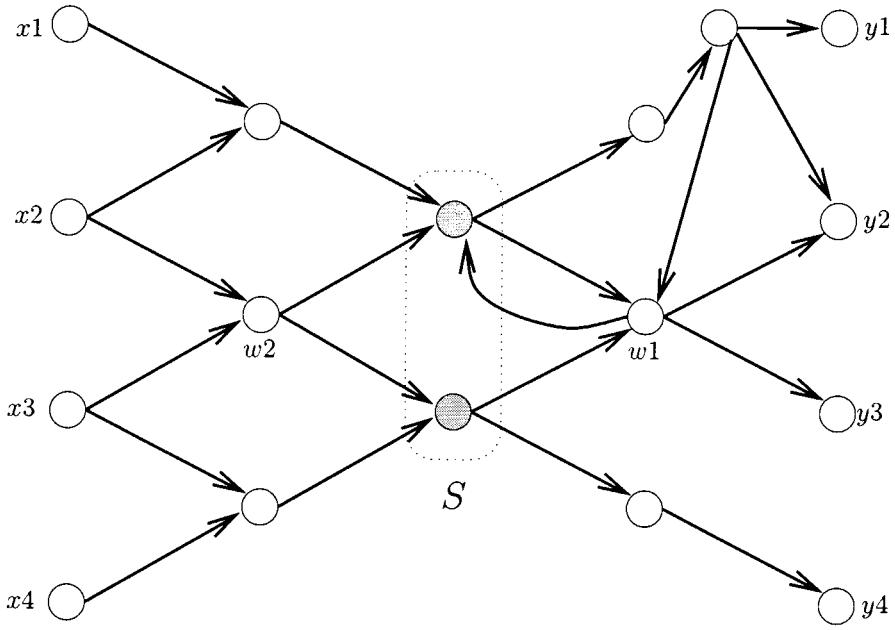

FIG. 4. *A digraph with a unique minimum $X \to Y$ separator S, where $X = \{x_1, x_2, x_3, x_4\}$ and $Y = \{y_1, y_2, y_3, y_4\}$. Vertex w_1 is in $T(S)$ since $p(\{w_1\} \cup X, Y) = 3 > |S|$, but vertex w_2 is not in $T(S)$ since $p(\{w_2\} \cup X, Y) = 2 = |S|$.*

4. An algorithm for digraph minimum $X \to Y$ separators. Using methods different from those employed in the previous section, this section develops a randomized Monte Carlo algorithm for finding a minimum $X \to Y$ separator of a given digraph $G = (V, E)$, where X and Y are specified sets of vertices. In every instance the algorithm outputs a correct solution with high probability, but it may output an incorrect result with small probability. The complexity bounds of this Monte Carlo algorithm suffice for verifying that the computed solution is indeed a minimum $X \to Y$ separator, thus giving a Las Vegas algorithm with the same complexity bounds.

For an $X \to Y$ separator S with $|S| = p(X, Y)$, let $T(S)$ denote the set of vertices such that $G - S$ has a path from each vertex in $T(S)$ to at least one vertex in $Y - S$ (note that $T(S)$ is empty iff $S = Y$). Informally, $T(S)$ forms the "Y-side" of the separator S.

First, consider the simple case when the digraph has a *unique* minimum $X \to Y$ separator S, i.e., any other set of vertices whose removal from G leaves no $X \to Y$ paths has cardinality at least $|S| + 1$. See Figure 4. Then the set $T = T(S)$ has the key property that a vertex v is in T if and only if $p(\{v\} \cup X, Y)$ is greater than $p(X, Y)$. To see this, deduce from Menger's theorem that G must have a separator

S' of cardinality $p(\{v\} \cup X, Y)$ whose removal from G leaves no path from $(\{v\} \cup X)$ to Y. Clearly, S' is also an $X \rightarrow Y$ separator, so $p(\{v\} \cup X, Y) \geq p(X, Y)$. If $v \notin T$, take the separator S' to be S, since $G - S$ has no path from a vertex in $\{v\} \cup X$ to a vertex in Y. Otherwise, if the vertex v is in T, then v is a witness to the fact that $S \neq S'$ and hence, by the uniqueness of S, $|S'| > |S|$. Suppose that there is an efficient method of computing $p(X, Y)$ for any specified pair of sets X and Y of the vertices, i.e., suppose that a fast "black box" subroutine for computing $p(X, Y)$ is available. (Such a method is described below.) Then the separator S may be found as follows. For each vertex $v \in V$, check whether $p(\{v\} \cup X, Y)$ is greater than $p(X, Y)$. Then construct the set T of vertices v that satisfy the inequality. The required separator S consists of the predecessors of T together with the Y-vertices not in T, i.e.,

$$S = \{s \in V - T \mid (s, v) \in E \text{ and } v \in T\} \cup (Y - T).$$

In general, a digraph may have many minimum $X \rightarrow Y$ separators. Fortunately, one of these separators satisfies the key property of the separator S and the vertex set $T(S)$ used above. This is proved in the next lemma. Although a full proof is given, the first part of the lemma is well known.

LEMMA 4.1. *Let $S^\star$ be an $X \rightarrow Y$ separator with cardinality $p(X, Y) = k$ such that $T(S^\star)$ is (inclusionwise) minimal over all $X \rightarrow Y$ separators with cardinality k. Then*

(i) *$S^\star$ is unique, and*

(ii) *for each vertex v of G,*

$$v \in T(S^\star) \qquad \textit{iff} \qquad p(\{v\} \cup X, Y) > k.$$

Proof. For a subset A of G's vertices, define $\Delta(A)$ to be the set of vertices

$$\{u \in V - A \mid (u, v) \in E \text{ and } v \in A\} \cup (Y - A),$$

i.e., $\Delta(A)$ consists of the predecessors of A as well as the Y-vertices not in A. Note that if A is the empty set, then $\Delta(A) = Y$. For every $A \subseteq V$, Y is a subset of $A \cup \Delta(A)$, and moreover, if A is a subset of $V - X$, then note that $\Delta(A)$ is an $X \rightarrow Y$ separator (since every path from a vertex in X to a vertex in $A \cup \Delta(A)$ must contain a vertex in $\Delta(A)$). Let $\delta(A)$ denote the cardinality of $\Delta(A)$. The proof hinges on the fact that the function $\delta : 2^V \longrightarrow \mathbb{Z}$ is submodular, i.e., for any two subsets A and B of G's vertices,

$$\delta(A \cap B) + \delta(A \cup B) \leq \delta(A) + \delta(B). \tag{1}$$

To see this, observe that if a vertex u contributes two to the left-hand side (i.e., $u \in \Delta(A \cap B) \cap \Delta(A \cup B)$), then either $u \in Y - (A \cup B)$ or $u \in V - (A \cup B \cup Y)$ and there is an edge uv, $v \in A \cap B$, so u contributes two to the right-hand side; otherwise, if u contributes one to the left-hand side, then u contributes at least one to the right-hand side.

To prove the first part of the lemma, by way of contradiction, assume that there are two minimum $X \rightarrow Y$ separators S_1 and S_2 such that $T_1 = T(S_1)$ is minimal and $T_2 = T(S_2)$ is minimal. Then note that $T_1 \cap T_2$ is both a proper subset of T_1 and a proper subset of T_2 (possibly, $T_1 \cap T_2$ is the empty set). Consider the vertex sets $T_1 \cap T_2$ and $T_1 \cup T_2$. Neither $T_1 \cap T_2$ nor $T_1 \cup T_2$ has any X-vertices since T_1 has no X-vertices and T_2 has no X-vertices. Hence, $\Delta(T_1 \cap T_2)$ is an $X \rightarrow Y$ separator

and $\Delta(T_1 \cup T_2)$ is an $X \to Y$ separator. Since the minimum cardinality of an $X \to Y$ separator is $p(X,Y) = k$, it is clear that $\delta(T_1 \cap T_2) \geq k$ and $\delta(T_1 \cup T_2) \geq k$. Now, using the submodularity of δ (equation (1)), it follows that $\delta(T_1 \cap T_2) = k$ and $\delta(T_1 \cup T_2) = k$. Let S' denote $\Delta(T_1 \cap T_2)$. Observe that $T(S')$ is a subset of $T_1 \cap T_2$ because, for each vertex $v \notin (T_1 \cap T_2)$, every path from v to a vertex in Y contains a vertex of $\Delta(T_1 \cap T_2)$. This gives the desired contradiction and completes the first part of the lemma, since neither $T_1 = T(S_1)$ nor $T_2 = T(S_2)$ is minimal.

For the second part of the lemma consider any vertex $v \in T(S^\star)$. The maximum number of vertex disjoint paths from $(\{v\} \cup X)$ to Y is either exactly $k = p(X,Y)$ or greater than k. Suppose that the number is k. Then, by Menger's theorem, there exists a separator S' of cardinality k whose removal from G leaves no path from $(\{v\} \cup X)$ to Y. Clearly S' is also a minimum $X \to Y$ separator. Now consider a minimum $X \to Y$ separator S such that $T(S)$ is a subset of $T(S')$ and $T(S)$ is (inclusionwise) minimal over all such separators; since S' exists, S must exist. By the first part of the lemma the separators S and $S^\star$ are the same. This gives the desired contradiction, since $v \in T(S^\star) - T(S)$. We conclude that the maximum number of vertex disjoint paths from $(\{v\} \cup X)$ to Y is greater than k. □

Two results are needed to develop a fast, probabilistic method for computing $p(X,Y)$. The first result is attributed to Ingleton and Piff [IP 73]; for completeness, a proof that follows [LLW 88, Theorem 3.1] is included in the appendix. Associate a variable $x(i,i)$ with each vertex i and a variable $x(i,j)$ with each edge (i,j) (all variables are distinct). The *free adjacency matrix* $\widetilde{F} = \widetilde{F}(x(i,j))$ of G is an $n \times n$ matrix whose entries are given by

$$\widetilde{F}_{ij} = \begin{cases} x(i,i) & \text{if } i = j, \\ x(i,j) & \text{if } i \neq j \text{ and } (i,j) \in E, \\ 0 & \text{otherwise.} \end{cases}$$

THEOREM 4.2 (Ingleton and Piff). *Let G be a digraph, and let $\widetilde{F}$ be its free adjacency matrix. Then for any k-vertex set X and any k-vertex set Y,*

$$p(X,Y) = k \quad \textit{iff} \quad \det \widetilde{F}(\overline{Y}, \overline{X}) \textit{ is not identically zero.}$$

We also need a matrix identity of Jacobi (see [BR 91, Lemma 9.2.10]).

FACT (Jacobi). *If a matrix F is nonsingular, then a square submatrix $F(\overline{Y}, \overline{X})$ is nonsingular iff the complementary submatrix $F^{-1}(X,Y)$ is nonsingular. More precisely,*

$$\det(F^{-1}(X,Y)) = \det(F(\overline{Y}, \overline{X}))/\det(F).$$

To apply the above theorem to the algorithm, the variables are substituted by random values. This is motivated by the Zippel–Schwartz lemma (Lemma 2.1).

THEOREM 4.3. *Let $G = (V,E)$ be a digraph, and let $F = \widetilde{F}(w(i,j))$ be obtained from G's free adjacency matrix by randomly and independently assigning each variable $x(i,j)$ a random number $w(i,j)$ from $\{1, \ldots, W\}$. Then with probability at least $1 - (n/W)$, F is nonsingular. If F is nonsingular, then for every pair of sets X and Y of the vertices,*

$$p(X,Y) \geq \operatorname{rank}(F^{-1}(X,Y)),$$

and with probability at least $1 - (n^2/W)$, $p(X,Y)$ equals $\operatorname{rank}(F^{-1}(X,Y))$.

Proof. View the determinant of the free adjacency matrix $\widetilde{F}$ as a polynomial of degree n in the variables $x(i,j)$, $1 \le i,j \le n$, and notice that it is not identically zero because the diagonal term $\Pi_{i=1}^{n} x(i,i)$ is nonzero and no two nonzero terms cancel out. Hence by Lemma 2.1, F is nonsingular with probability at least $1-(n/W)$.

Consider a maximum-cardinality set of vertex disjoint paths from X to Y. Let A be the set of start vertices of these $X \rightarrow Y$ paths, and let B be the set of end vertices. Obviously, $A \subseteq X$, $B \subseteq Y$, and $|A| = |B| = p(X,Y) = p(A,B)$. Let $\widetilde{H} = \widetilde{H}(x(i,j))$ denote $(\det \widetilde{F})\widetilde{F}^{-1}$, i.e., $\widetilde{H}$ is the $n \times n$ matrix whose (k,ℓ) entry is $(-1)^{k+\ell}$ times the (ℓ,k) minor of $\widetilde{F}(x(i,j))$; every entry of $\widetilde{H}$ is a polynomial of degree $n-1$ in the variables $x(i,j)$. By Jacobi's identity and Theorem 4.2, $\det \widetilde{H}(A,B)$ is not identically zero, while for every integer $q > p(X,Y)$ the determinant of every $q \times q$ submatrix of $\widetilde{H}(X,Y)$ is identically zero. The second part of the theorem follows by observing that if F is nonsingular, then $F^{-1} = \widetilde{F}(w(i,j))^{-1} = \widetilde{H}(w(i,j))/\det \widetilde{F}(w(i,j))$; now apply Lemma 2.1 to $\det \widetilde{H}(A,B)$. □

The algorithm can now be sketched. See Algorithm 3 in Figure 5. Fix a number $W = n^{O(1)}$, and let q be a prime such that $W < q = n^{O(1)}$. All computations are over the field $\mathbb{Z}_q$ of integers modulo q. The matrix F is constructed, and with high probability it is nonsingular. Inverting F gives the matrix F^{-1}. If $r = \text{rank}(F^{-1}(X,Y))$ equals $|Y|$, then by Theorem 4.3 $p(X,Y)$ equals $|Y|$; therefore Y is a minimum $X \rightarrow Y$ separator. Otherwise consider the unique minimum $X \rightarrow Y$ separator $S^\star$ with $T(S^\star)$ minimal. The algorithm attempts to compute the vertex set $T(S^\star)$ by finding the set T of vertices v such that $\text{rank}(F^{-1}(\{v\} \cup X, Y))$ is greater than r. With probability at least $1 - \Theta(n^3)/W$, T equals $T(S^\star)$. Hence, with high probability, the set $S = \Delta(T)$ (i.e., the set of the predecessors of T and the Y-vertices not in T) is the minimum $X \rightarrow Y$ separator $S^\star$.

To efficiently compute for each vertex v whether $\text{rank}(F^{-1}(\{v\} \cup X, Y)) > r$, the algorithm needs to check that v's row vector $F^{-1}(\{v\}, Y)$ is not a linear combination of the row vectors of $F^{-1}(X,Y)$. As in section 3, we "simultaneously" compute the ranks of all the matrices $F^{-1}(\{v\} \cup X, Y)$, $v \in V$, by computing a matrix N such that for any row vector w, $w \cdot N = 0$ iff w is a linear combination of the row vectors of $F^{-1}(X,Y)$. The matrix N is easily obtained by computing a basis for the null space of $F^{-1}(X,Y)$. Once N is computed, we simply find the product of the matrix $F^{-1}(V,Y)$ with N.

To check that the computed set S is indeed a minimum $X \rightarrow Y$ separator, observe that the cardinality of every $X \rightarrow Y$ separator is at least $p(X,Y) \ge r$. Consequently, if the removal of S from G leaves no path from $X - S$ to $Y - S$, and $|S| = r$, then $|S| = p(X,Y) = r$ and hence S is a minimum $X \rightarrow Y$ separator. Also, by using Proposition 2.4 this algorithm may be applied to find a minimum vertex cover in a bipartite graph.

Consider the sequential complexity of the above algorithm. Inverting F takes $\widetilde{O}(M(n))$ bit operations [AHU 74, Theorem 6.5]. Finding a basis for the null space of $F^{-1}(X,Y)$ takes $\widetilde{O}(M(n))$ bit operations [IMH 82, pp. 53–54]. The remaining computations are easy to execute within this bound. Consider the randomized parallel complexity of the algorithm. Inverting F takes parallel time $O((\log n)^2)$ using $\widetilde{O}(M(n))$ processors ([KP 91, Theorem 6]), and these complexity bounds suffice for finding a basis for the null space of $F^{-1}(X,Y)$ ([KP 91, p. 190]) (both computations are randomized, and on a given matrix the computed results may be incorrect with small probability). The remaining steps are easy to implement within these complexity bounds.

ALGORITHM 3. *Monte Carlo Minimum $X \to Y$ Separator*
INPUT: Graph $G = (V, E)$.
OUTPUT: With high probability, a minimum $X \to Y$ separator of G.

Order the vertices, and number them $1, 2, \ldots, n$.
Fix the number $W = n^{O(1)}$, and choose a prime q, $W < q = n^{O(1)}$.
Construct the matrix F by replacing each nonzero entry in the free adjacency matrix of G by an independent random number from $\{1, 2, \ldots, W\}$.

Invert F over the field $\mathbb{Z}_q$ to obtain the matrix F^{-1}.
(If F is singular, the algorithm stops and reports failure.)

Compute the rank r of the submatrix $F^{-1}(X, Y)$ over $\mathbb{Z}_q$.
If $r = |Y|$, then the required separator is $S = Y$. Stop.

Otherwise, compute a basis $\{N_1, \ldots, N_{|Y|-r}\}$ for the null space of the submatrix $F^{-1}(X, Y)$ over $\mathbb{Z}_q$ (each N_i is a vector of dimension $|Y|$).
Compute the matrix $Z = F^{-1}(V, Y) \cdot N$ over $\mathbb{Z}_q$,
where N is the matrix whose ith column is N_i.
Let Z_v denote the row of Z given by $F^{-1}(\{v\}, Y) \cdot N$.
Construct the set of vertices $T = \{v \mid Z_v \text{ is a nonzero vector}\}$.

With high probability, the required separator S consists of the predecessors of T together with the Y-vertices not in T, i.e.,

$$S = \Delta(T) = \{s \in V - T \mid (s, v) \in E \text{ and } v \in T\} \cup (Y - T).$$

Making the algorithm Las Vegas:
If $G - S$ has no path from $X - S$ to $Y - S$, and $|S| = r$,
then guarantee that S is a minimum $X \to Y$ separator; otherwise, report failure.

FIG. 5.

THEOREM 4.4. *Given a digraph G and a pair of sets X, Y of G's vertices, a minimum $X \to Y$ separator can be computed by a Las Vegas algorithm. The sequential running time is $\widetilde{O}(M(n))$. The parallel complexity is $O((\log n)^2)$ time using $\widetilde{O}(M(n))$ processors. The same complexity bounds apply for finding a minimum vertex cover of a bipartite graph.*

5. Conclusions. The most important problem left open is whether a maximum matching can be computed in deterministic or randomized time $O(n^{2.5-\epsilon})$, $\epsilon > 0$. The same problem specialized to bipartite graphs, or equivalently (by Proposition 2.4) the problem of finding a maximum-cardinality set of vertex disjoint $X \to Y$ paths in a digraph in (randomized) time $O(n^{2.5-\epsilon})$, is also open. Another interesting open problem pertains to graphs with 0–1 weights on the edges: Can the maximum weight of a perfect matching, but not necessarily the edge-set of the matching, be computed in (randomized) time $O(n^{2.5-\epsilon})$? Can the algorithm of Theorem 3.8 for finding the allowed edges be made Las Vegas without affecting the complexity bounds? The algorithm for finding a minimum bipartite vertex cover may be derived starting either

from the Gallai–Edmonds theorem (Theorem 3.1) or from the theorem on the free adjacency matrix (Theorem 4.2). Do these two theorems have other connections?

6. Appendix. Proofs of Proposition 2.4 and Theorem 4.2.

Proof of Proposition 2.4. First, we show how to transform instances and recover solutions of the two bipartite graph problems using the corresponding digraph problems. Let $H = (V_1, V_2, E)$ be a bipartite graph, where V_1 and V_2 are the sets of the vertex bipartition. Construct a digraph $G = (V_1 \cup V_2, F)$ from H by orienting all edges from V_1 to V_2. Every matching of H corresponds to a set of vertex disjoint $V_1 \rightarrow V_2$ paths in G. Hence, a maximum matching of H can be found by computing a maximum cardinality set of vertex disjoint $V_1 \rightarrow V_2$ paths in G. Consider the bipartite graph minimum vertex cover problem. A subset of $V_1 \cup V_2$ is a vertex cover of H iff it is a $V_1 \rightarrow V_2$ separator of the digraph G. Therefore, a minimum vertex cover of H can be found by computing a minimum $V_1 \rightarrow V_2$ separator of G.

Next consider the transformation of the two digraph problems to the corresponding bipartite graph problems, and the transformation of the solutions. Let $G = (V, F)$ be the given digraph, and let X and Y be specified subsets of V. Without loss of generality assume that $X \cap Y = \emptyset$; the method here easily extends to the case when $X \cap Y \neq \emptyset$. Let $\overline{n}$ denote $|V(G) - X - Y|$. We construct a bipartite graph $H = (V_1, V_2, E)$ starting from G, X, Y. For each vertex $v \in V(G) - X - Y$, H has a pair of vertices v_1, v_2 with $v_1 \in V_1$ and $v_2 \in V_2$; H also has the edge $v_1 v_2$; for each vertex $x \in X$, H has a vertex $x_1 \in V_1$; and for each vertex $y \in Y$, H has a vertex $y_2 \in V_2$. For every vertex v of G let v_1 and v_2 denote the corresponding vertices in V_1 and V_2 (if they exist); let X_1 denote the set of vertices of H that corresponds to X. For each edge (v, w) of G, $v \notin Y$ and $w \notin X$, there is an edge $v_1 w_2$ in H.

A set of vertex disjoint $X \rightarrow Y$ paths of G of maximum cardinality (namely, $p(X, Y)$) gives a matching E' of H with $|E'| = p(X, Y) + \overline{n}$: start with $E' = \{v_1 v_2 : v \in V(G) - X - Y\}$ and then, sequentially for each of the $X \rightarrow Y$ paths of G in the set mentioned above, augment E' using the corresponding alternating path of H. Moreover, we claim that a matching E' of H gives a set of at least $|E'| - \overline{n}$ vertex disjoint $X \rightarrow Y$ paths of G: starting from the vertices in X_1 in H, use the matching E' and the edges $v_1 v_2$, $v \in V(G) - X - Y$, to construct a set of vertex disjoint paths in G; each of these paths ends either at a vertex in Y or at a vertex $v \notin Y$ such that in H the corresponding vertex v_1 is exposed; hence, at most $|V_1| - |E'| = |X_1| + \overline{n} - |E'|$ of these paths in G have their end vertices in $V - Y$; our claim follows since the number of these paths in G is $|X_1|$. Consequently, $\nu(H) = p(X, Y) + \overline{n}$, and every maximum matching of H yields a set of $p(X, Y)$ vertex disjoint $X \rightarrow Y$ paths of G.

Now consider the problem of finding a minimum $X \rightarrow Y$ separator S of G. We find a minimum vertex cover C of H and then construct S as follows: S contains a vertex $x \in X$ iff C contains the vertex x_1; S contains a vertex $y \in Y$ iff C contains the vertex y_2; and S contains a vertex $v \in V(G) - X - Y$ iff C contains both the vertices v_1 and v_2. Since $|C| = \nu(H) = p(X, Y) + \overline{n}$, and since either $v_1 \in C$ or $v_2 \in C$ for each vertex $v \in V(G) - X - Y$, we see that $|S| = p(X, Y)$. We claim that S is an $X \rightarrow Y$ separator of G. By way of contradiction, suppose that there is a path P in $G - S$ with start vertex $x \in X$ and end vertex $y \in Y$. Focus on the subgraph $H(P)$ of H formed by the edges that correspond to the edges of P, together with the edges $v_1 v_2$ of H that correspond to the internal vertices v of P (i.e., $v \in V(P) - \{x, y\}$). Since C is a vertex cover of H, every edge of $H(P)$ must be incident with some vertex of C. Consequently, either $x \in C$ or $y \in C$ or there is an internal vertex v of P such that $v_1 \in C$ and $v_2 \in C$. We have the desired contradiction since S intersects

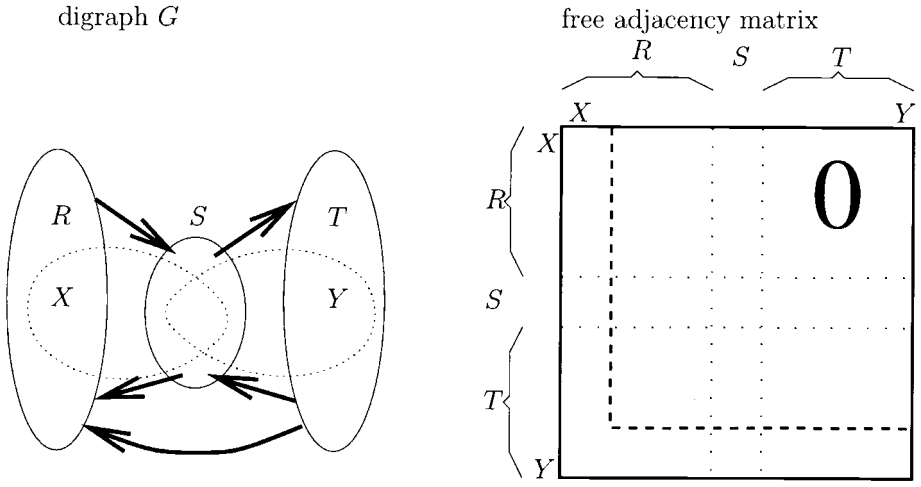

FIG. 6. *An illustration of the proof of Theorem* 4.2. *The submatrix* $\widetilde{F}(\overline{Y}, \overline{X})$ *is indicated by dashed lines.*

P. □

Proof of Theorem 4.2. First, consider the case when $p(X, Y)$ is less than $k = |Y|$. Let S be an $X \rightarrow Y$ separator of cardinality $p(X, Y)$ and let T denote the set of vertices that have paths to $Y - S$ in $G - S$. Let R denote $V - (S \cup T)$. Note that X is a subset of $R \cup S$ and Y is a subset of $S \cup T$. Since G has no edges of the form (r, t), $r \in R$, $t \in T$, each entry of the submatrix $\widetilde{F}(R, T)$ is zero. (See Figure 6.) A line denotes either a row or a column of a matrix. Focus on the number of lines needed to cover all the nonzero entries of $\widetilde{F}(\overline{Y}, \overline{X})$, and consider the columns corresponding to the vertex set $(R \cup S) - X$ and the rows corresponding to the vertex set $(S \cup T) - Y$. Each entry of $\widetilde{F}(\overline{Y}, \overline{X})$ that is not covered by these lines is in an R-row and a T-column; hence the entry is zero. Thus the number of lines needed is at most

$$((n - |T|) - k) + ((n - |R|) - k) \leq (n - k - 1),$$

since $n = |R| + |S| + |T| \leq (k - 1) + |R| + |T|$. Now use the fact that for a bipartite graph, the cardinality of every matching is less than or equal to the cardinality of every vertex cover. It follows that there are at most $(n - k - 1)$ nonzero entries in $\widetilde{F}(\overline{Y}, \overline{X})$ with no two of these entries on a line. Hence, $\det \widetilde{F}(\overline{Y}, \overline{X})$ is identically zero since each term in the standard expansion of the determinant is zero.

Next suppose that $p(X, Y)$ equals $k = |Y|$. Let $P_1, \ldots, P_k$ be a maximum set of vertex disjoint $X \rightarrow Y$ paths. Denote the start vertex of path P_i $(1 \leq i \leq k)$ by x_i and denote the end vertex by y_i. Let A denote the set of vertices not in these paths. For each vertex $v \in A$ define $\sigma(v)$ to be v, and for each vertex $v \in (V - A - Y)$, define $\sigma(v)$ to be the successor of v in the path P_i containing v. Note that σ is well defined even if trivial paths P_i (having $x_i = y_i$) are present. For each $v \in \overline{Y}$, note that $\sigma(v)$ belongs to $\overline{X}$ and that $\widetilde{F}_{v,\sigma(v)}$ is a nonzero entry of the submatrix $\widetilde{F}(\overline{Y}, \overline{X})$. Moreover, observe that σ is one-one, i.e., $\sigma(v) = \sigma(w)$ iff $v = w$, and therefore no two entries from the set $\{\widetilde{F}_{v,\sigma(v)} \mid v \in \overline{Y}\}$ are on a line. It follows that the product $(\pm 1) \cdot \Pi_{v \in \overline{Y}} \widetilde{F}_{v,\sigma(v)}$ is one of the terms in the standard expansion of $\det \widetilde{F}(\overline{Y}, \overline{X})$. Clearly the product is

nonzero. Hence, the determinant evaluates to ± 1 when the value 1 is assigned to each entry $\widetilde{F}_{v,\sigma(v)}$, $v \in \overline{Y}$, and the value 0 is assigned to the remaining entries of $\widetilde{F}(\overline{Y}, \overline{X})$. Therefore, the determinant is not identically zero. □

Acknowledgments. Section 4 has benefited from discussions with Éva Tardos. The Monte Carlo algorithm for the canonical partition in section 3.4 was discovered jointly with K. Padayachee and is included with his consent. J. A. La Poutré communicated an almost linear-time algorithm for verifying the canonical partition. The careful comments by the referees are appreciated.

MAXIMUM AGREEMENT SUBTREE IN A SET OF EVOLUTIONARY TREES: METRICS AND EFFICIENT ALGORITHMS*

AMIHOOD AMIR† AND DMITRY KESELMAN†

Abstract. The *maximum agreement subtree* approach is one method of reconciling different evolutionary trees for the same set of species. An agreement subtree enables choosing a subset of the species for whom the restricted subtree is *equivalent* (under a suitable definition) in all given evolutionary trees.

Recently, dynamic programming ideas were used to provide polynomial time algorithms for finding a maximum homeomorphic agreement subtree of *two* trees. Generalizing these methods to sets of more than two trees yields algorithms that are exponential in the number of trees. Unfortunately, it turns out that in reality one is usually presented with more than two trees, sometimes as many as thousands of trees.

In this paper we prove that the maximum homeomorphic agreement subtree problem is $\mathcal{NP}$-complete for three trees with unbounded degrees. We then show an approximation algorithm of time $O(kn^5)$ for choosing the species that are *not* in a maximum agreement subtree of a set of k trees. Our approximation is guaranteed to provide a set that is no more than 4 times the optimum solution.

While the set of evolutionary trees may be large in practice, the trees usually have very small degrees, typically no larger than three. We develop a new method for finding a maximum agreement subtree of k trees, of which one has degree bounded by d. This new method enables us to find a maximum agreement subtree in time $O(kn^{d+1} + n^{2d})$.

1. Introduction.

One of the methods for classifying hierarchical relations between different objects is by representing them in a tree [12]. In particular, trees have been used to represent evolutionary splits among species (cf. [11, 18, 3]). Different methods of classification may lead to different trees. It is natural to try to resolve differing evolutionary trees in a manner that will increase our confidence in the results.

There are two ways one can go about handling different evolutionary trees for the same species. One may try to construct a *consensus tree* that is "close" to all given trees. This direction was taken by several researchers (e.g., [15]). Another direction, the one that concerns us in this paper, is extracting a maximum set of species about whom we are confident. This method, introduced by Gordon [10], involves obtaining a *maximum agreement subtree*.

There are several alternate ways to define a maximum agreement subtree. One approach was taken by Finden and Gordon [7].

DEFINITION. *Let $S = \{s_1, \ldots, s_n\}$ be a set of* labels. *An S-*labeled *tree T is a tree with n leaves, each labeled with a distinct element of S; i.e., no two leaves have the same label. Let T be an S-labeled tree and let $S' \subseteq S$. $H(T, S')$ is the minimal*

homeomorphic subtree of T (all degree 2 nodes are contracted) containing exactly the leaves labeled by S'.

Let $T_1, \ldots, T_k$ be S-labeled trees. A maximum homeomorphic agreement subtree *of $T_1, \ldots, T_k$ ($MHT(T_1, \ldots, T_k)$) is a maximum cardinality set $S' \subseteq S$ such that $H(T_1, S') = H(T_2, S') = \cdots = H(T_k, S')$. We will also refer to the problem of finding a maximum homeomorphic agreement subtree as* the MHT problem.

We will interchangeably refer to an MHT as a *tree* or *set of labels*. There is no ambiguity since a set of labels uniquely defines the contracted subtree whose leaves are exactly the given set, if that set of labels is in a homeomorphic agreement subtree.

The most general possible way to view agreement subtree is by assigning each edge an *interval weight*, i.e., the conjectured *range* of time it took to evolve along this edge. This idea is very similar to the "graph-sandwich" of Farach, Kannan, and Warnow [4]. Informally, the maximum interval weight agreement subtree (MIWT) of k S-labeled trees $T_1, \ldots, T_k$ is a maximum set $S' \subseteq S$ such that $\forall s, t \in S'$ the distance between s and t is within the allowable range in all trees $T_1, \ldots, T_k$. A precise definition is provided in section 7.

Finden and Gordon [7] gave a heuristic algorithm for the MHT problem for *two trees* T_1, T_2. Their result is not guaranteed to be an $MHT(T_1, T_2)$. An algorithm of complexity $O(n^{1/2+\epsilon \log_2 n})$ was presented by E. Kubicka, G. Kubicki, and McMorris [14]. This algorithm is also for the MHT problem of two trees. This result was improved by Warnow and Steel [17] to finding $MHT(T_1, T_2)$ in time $O(n^2)$ for bounded degree trees and $O(n^{4.5} \log n)$ for unbounded degree trees. A similar method was independently found by Goddard et al. [9] for finding $MHT(T_1, T_2)$ of binary trees in time $O(n^2)$. Farach and Thorup [6] further improved these results to $O(n^2 c^{\sqrt{\log n}})$ for unbounded degree trees.

The algorithms of [17, 6, 9] handle only the restricted case of two trees. They can be generalized, but then they become exponential in the number of trees. In reality, sometimes *thousands* of trees need to be considered [9]. As for the maximum interval weight agreement subtree, there are currently no solutions to this problem.

In this paper we present the first known solution to the realistic versions of the maximum agreement subtree problem. In addition, we use novel methods for tackling this problem. The main idea behind our algorithms is to use divide and conquer rather than dynamic programming. A naive top-down algorithm would quickly reach exponential time, but we exploit some subtle internal properties of tree partitions in a manner that assures an efficient algorithm. Surprisingly, the algorithm is simple and easily programmable.

The main contributions of this paper are the following:

- We show that for unbounded degree trees, $MHT(T_1, T_2, T_3)$ and $MIWT(T_1, T_2, T_3)$ are $\mathcal{NP}$-complete.
- We present an approximation algorithm for finding a set of leaves that are *not* in an MHT of k unbounded degree evolutionary trees. Our algorithm runs in time $O(kn^5)$. The approximation factor of our algorithm is 4.
- For trees $T_1, \ldots, T_k$, where at least one of which has degree bounded by d, we present algorithms for finding $MHT(T_1, \ldots, T_k)$ and $MIWT(T_1, \ldots, T_k)$ in time $O(kn^{d+1} + n^{2d})$.

This paper is organized as follows. In section 2, we prove the $\mathcal{NP}$-completeness of the $MHT(T_1, T_2, T_3)$ and $MIWT(T_1, T_2, T_3)$ problem for unbounded degree trees. In section 3 we give the approximation algorithm for the MHT problem of k unbounded degree trees. In section 4, we define a very simple version of the MIWT problem (the

maximum isomorphic agreement subtree or MIT problem) and give an efficient algorithm for trees of bounded degree. In section 5 we show the algorithm for computing an MHT of k trees, one of which has degree bounded by d. In section 6 we consider the special case of the MIWT problem where all weight ranges are a single weight (the MWT problem). We give an efficient algorithm for finding $MWT(T_1, \ldots, T_k)$, where at least one of the trees has a small bounded degree. In section 7 we provide an efficient algorithm for the maximum interval agreement subtree of a set of trees. We conclude with open problems and future research.

2. Multiple unbounded degree trees. We show that finding the $MHT(T_1, T_2, T_3)$ is an $\mathcal{NP}$-complete problem (the same proof applies to $MIWT(T_1, T_2, T_3)$). First define the decision problem:

Homeomorphic agreement subtree of 3 *unbounded degree trees (*3*-HUT).*

INSTANCE: Three S-labeled trees T_1, T_2, T_3 of unbounded degree, where $S = \{s_1, \ldots, s_n\}$;
integer $i \leq n$.

QUESTION: Is there a subset $S' \subseteq S$ of size i such that $H(T_1, S') = H(T_2, S') = H(T_3, S')$?

THEOREM 1. *The* 3-HUT *problem is $\mathcal{NP}$-complete.*

Proof. It is clearly in $\mathcal{NP}$. We will reduce the 3-dimensional matching problem (3DM) [8] to 3-HUT. In 3DM the input is a set $M \subseteq W \times X \times Y$, where W, X, Y are disjoint q-element sets. We need to answer if there is a set $M' \subseteq M$ of size q, where no two elements of M' agree in any coordinate.

Construct three trees T_1, T_2, T_3 as follows. Each tree T_i has a root r_i and each root has q children. The children of r_1 correspond to the elements of W, the children of r_2 correspond to the elements of X, and the children of r_3 correspond to the elements of Y. Take $S = M$. For every element $e = \langle w, x, y \rangle \in M$ attach a child labeled e to the node that corresponds to w in T_1, to the node that corresponds to x in T_2, and to the node that corresponds to y in T_3.

Assuming that the roots r_1, r_2, r_3 appear in a maximum homeomorphic subtree, then any two elements of M that agree on one or two coordinates will not be on a homeomorphic subtree of all three trees. We force the roots to be in a maximum homeomorphic subtree, by adding to each root $q + 1$ children labeled $x_1, \ldots, x_{q+1}$, where the x_i are new and distinct symbols. Thus it is easy to see that there is an M' of size q iff there is a homeomorphic subtree of all three trees of size $2q + 1$. □

3. An approximation algorithm. We have seen that constructing the set of leaves whose restricted subtree is homeomorphic to their restricted subtree in all trees is an $\mathcal{NP}$-hard problem. We now provide an approximation algorithm for constructing the set of leaves that are not in an MHT. The approximation algorithm is based on the following property, which was first proved by Bandelt and Dress [2]. We present the theorem and a new proof.

THEOREM 2. *Two evolutionary trees are homeomorphic iff all* 4*-leaf subtrees generate homeomorphic subtrees.*

Proof. One direction is immediate. We will prove that if all 4-leaf subtrees generate homeomorphic subtrees then the trees are homeomorphic.

Call a vertex of degree greater than 2 a *non-*2*-vertex.* Call two leaves *twins* if the path connecting them has at most one intermediate non-2-vertex. Every tree contains at least one pair of twins. This can be seen by the following argument. Consider a path with the largest number of non-2-vertices. Let the leaf ends of this path be a and b. Let v be the closest non-2-vertex to a (a similar argument works for b). There

is a path from v to a, to b, and to at least some other leaf c. In the path from v to a and from v to c there are no non-2-vertices otherwise, the path from a to b would not be maximal. Therefore, a and c are twins.

Proceed with proving theorem by induction on the number of leaves n. If $n \leq 4$ theorem is trivially true. For $n > 4$ let x and y be a pair of twins in tree T_1 whose intermediate non-2-vertex is z. We claim that x and y are twins in tree T_2 as well. Otherwise, let z_1 and z_2 be two non-2-vertices on the path from x to y in T_2. Since both are non-2-vertices, there exist leaves p and q such that p branches off z_1 and q branches off z_2. Thus, in the subtree generated by x, y, p, q in T_2, x and y are separated by 2 non-2-vertices; whereas in the subtree generated by x, y, p, q in T_1 they are separated by only one non-2-vertex. Hence, these two subtrees cannot be homeomorphic. See Figure 1.

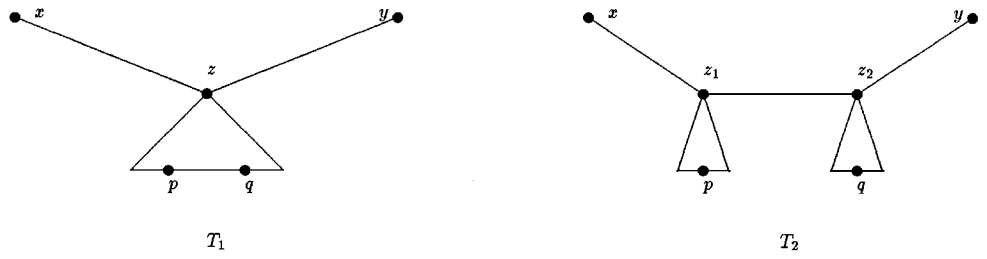

FIG. 1.

Now remove the path from z to y in both trees. Inductively, the resulting two trees are homeomorphic. Clearly then, adding the path from z to y in both T_1 and T_2 will still yield two homeomorphic trees. □

Let $S4$ be the set of all 4-element subsets of S that do not generate a homeomorphic subtree in all trees. $S4$ can be constructed in time $O(kn^5)$. A set $S' \subset S$ is a *cover* of $S4$ if $\forall\{a, b, c, d\} \in S4\ \exists e \in S'$ such that $e \in \{a, b, c, d\}$. S' is a *minimum cover* if S' is a cover of $S4$ and every other cover is at least as large as S'.

Theorem 2 implies that if S' is a minimum cover of $S4$ then the homeomorphic restriction of $S - S'$ in all trees is an MHT.

The following algorithm is similar to the approximation algorithm for vertex cover [8].

Approximation Algorithm

1. $S_a \leftarrow \emptyset$
2. While $S4 \neq \emptyset$ do
   - 2.1 Choose an element $\alpha \in S4$
   - 2.2 $S_a \leftarrow S_a \cup \alpha$
   - 2.3 Delete from $S4$ all elements β such that $\alpha \cap \beta \neq \emptyset$

end Algorithm

Algorithm time $O(|S4|) = O(n^4)$. (The construction of $S4$ requires an additional $O(kn^5)$ time.)

THEOREM 3. *The set S_a produced by the approximation algorithm is a cover of $S4$ and is at most four times the size of a minimum cover of $S4$.*

Proof. S_a is clearly a cover. Let A be the set of all elements of $S4$ chosen by step 2.1. For any $\alpha_1, \alpha_2 \in A$, $\alpha_1 \cap \alpha_2 = \emptyset$. Thus any cover of $S4$ has at least $|A|$ elements. S_a has $4|A|$ elements. □

4. Maximum isomorphic agreement subtree. For simplicity's sake, we start by presenting an algorithm for the MIWT problem for k trees, where the edge weights are uniformly 1. We call this the maximum isomorphic agreement subtree problem (MIT), formally defined below. The general MIWT problem is handled in section 7.

DEFINITION. *Let $T_1, \ldots, T_k$ be S-labeled trees. A* maximum isomorphic agreement subtree *of $T_1, \ldots, T_k$ ($MIT(T_1, \ldots, T_k)$) is a maximum set $S' \subseteq S$ such that $\forall s, t \in S'$ the distance between s and t is the same in all trees $T_1, \ldots, T_k$.*

The following tree property, due to Smolenskii [16], establishes that the subtrees induced by $MIT(T_1, \ldots, T_k)$ in $T_1, \ldots, T_k$ are indeed isomorphic.

THEOREM 4. *Two labeled trees are isomorphic iff the distance between any two leaves with corresponding labels is the same in both trees.*

To further elucidate our idea, let us restrict ourselves to the case of binary trees $T_1, \ldots, T_k$. We also introduce the following notation. Assume we fix a node labeled r as the root. Since r appears in all our trees, we may now consider $T_1, \ldots, T_k$ as directed trees rooted at r. Since all edges are now directed, there is a unique subtree rooted at every node. Let x be a node in T_i. Denote the subtree rooted at x by $T_i(x)$. We denote the distance of node x from the root as a superscript, i.e., if $d(x, r) = p$ then we write x^p.

The main idea behind our algorithm is to use a top-down approach. We will show that the structure of our problem prevents an exponential time blow-up.

The first crucial observation we make is that there is at least one label in $MIT(T_1, \ldots, T_k)$. If we had a priori knowledge of such a label, say r, we could root all the trees at r. This fixes the direction of the edges, so for the next levels in the recursion there is only one possible root for every subtree.

The following lemma is also an important factor in understanding our algorithm.

LEMMA 5. *Let s and t be leaves of $MIT(T_1, \ldots, T_k)$. Suppose there is a tree T_i and $x_i^p \in T_i$ such that $s, t \in T_i(x_i^p)$. Then for every $j = 1, \ldots, k$ there exists a node $x_j^p \in T_j$ for which $s, t \in T_j(x_j^p)$.*

Proof. Consider the meeting point of the three pairwise paths of the leaves s, t, and r. Since s, t, r are leaves of $MIT(T_1, \ldots, T_k)$, then Theorem 4 says their distances from each other are the same in all the trees $T_1, \ldots, T_k$. These distances $d(s, t), d(s, r)$, and $d(t, r)$ determine that the distance from r to the meeting point is $(d(r, s) + d(r, t) - d(s, t))/2 = p$ in all trees. ∎

Algorithm Outline

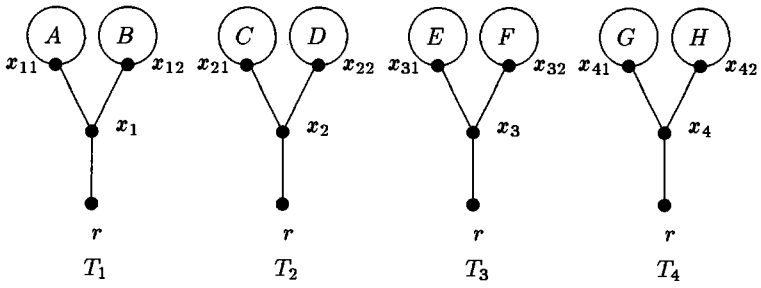
for $r = s_1$ to s_n do
    root all trees at r.
    find $MIT(T_1, \ldots, T_k)$ (A recursive algorithm for rooted MIT follows).
choose the largest of all n rooted MIT's.

end Algorithm

Before we proceed to the algorithm for rooted MIT, we define the concept of *thread intersection*. This is a key concept that appears in many of our algorithms. It is properties of these intersections that prevent an exponential time blow-up of the algorithms.

We first intuitively describe the concept. Suppose a set of k nodes $x_i \in T_i,\ i = 1, ..., k$ is given. Each of these nodes may have several children. A thread is a choice of one son of each of the x_i's.

DEFINITION. *Let $\{x_1, \ldots, x_k\}$ be a fixed set of nodes where $x_i \in T_i,\ i = 1, \ldots, k$, and let $L(x_i) \subseteq S$ be the set of labels in $T(x_i)$ (the subtree rooted at x_i). Let $\{x_{i1}, \ldots, x_{ip_i}\}$ be the set of children of x_i.*



The thread $\sigma = \langle 1, 1, 2, 1\rangle$ for nodes x_1, x_2, x_3, x_4 defines thread intersection $A \cap C \cap F \cap G$.
The thread $\overline{\sigma} = \langle 2, 2, 1, 2\rangle$ for nodes x_1, x_2, x_3, x_4 defines thread intersection $B \cap D \cap E \cap H$.

FIG. 2. *Examples of threads.*

A k-tuple $\sigma_{\langle x_1,\ldots,x_k\rangle} = \sigma[1], \ldots, \sigma[k]$ where $\sigma[i] \in \{1, \ldots, p_i\}$ is called a thread *for nodes $x_1, \ldots, x_k$. (In other words, a thread for a set of k nodes is a pointer from each of the k nodes to a specific one of its children.) Wherever the set of nodes $\{x_1, \ldots, x_k\}$ is clear from the text we will drop the index $\langle x_1, \ldots, x_k\rangle$ and denote the thread simply by σ. A nonempty intersection $\cap_{i=1}^{k} L(x_{i\sigma[i]})$ is a* thread intersection.

For an example see Figure 2.

Let A be the union of all thread intersections for a fixed set of nodes. The following simple observation guarantees that the nonempty thread intersections form a partition of A.

LEMMA 6. *Let σ_1, σ_2 be threads for nodes $x_1, \ldots, x_k$. If $\sigma_1 \neq \sigma_2$ then*

$$\left(\bigcap_{i=1}^{k} L(x_{i\sigma_1[i]})\right) \cap \left(\bigcap_{i=1}^{k} L(x_{i\sigma_2[i]})\right) = \emptyset.$$

Proof. If $\sigma_1 \neq \sigma_2$ then there is a j such that $\sigma_1[j] \neq \sigma_2[j]$.
$\cap_{i=1}^{k} L(x_{i\sigma_1[i]}) \subseteq L(x_{j\sigma_1[j]})$.
$\cap_{i=1}^{k} L(x_{i\sigma_2[i]}) \subseteq L(x_{j\sigma_2[j]})$.
But $\sigma_1[j] \neq \sigma_2[j]$; therefore $L(x_{j\sigma_1[j]}) \cap L(x_{j\sigma_2[j]}) = \emptyset$, and thus

$$\left(\bigcap_{i=1}^{k} L(x_{i\sigma_1[i]})\right) \cap \left(\bigcap_{i=1}^{k} L(x_{i\sigma_2[i]})\right) = \emptyset. \qquad \square$$

The idea behind our algorithm is the straightforward one. Assume we are guaranteed that node r is in a MIT. We now root all the trees at r. Theorem 4 and Lemma 5 now assure us that if other nodes appear in the MIT then the child x_i of r in each tree T_i, $i = 1, \ldots, k$, has to be in the MIT also.

Thus a naive way of constructing the MIT is by considering all possible combinations of children of the x_i's, $i = 1, \ldots, k$. In particular, if all the trees are binary trees, assume the children of x_i are x_{i1} and x_{i2}. For each thread σ of the nodes $x_1, \ldots, x_k$ recursively find an MIT T_1 of $\cap_{i=1}^{k} L(x_{i\sigma[i]})$ and an MIT T_2 of $\cap_{i=1}^{k} L(x_{i\overline{\sigma}[i]})$. Construct a tree whose root is r, its child is x_1 and make the roots of T_1 and T_2 the children of x_1 . Each such tree is an isomorphic agreement subtree. The largest of them is a maximal isomorphic agreement subtree.

The naive algorithm described above has exponential running time since there are 2^k combinations to check at each level of the recursion. The algorithm below is

essentially the same as the naive algorithm but avoids the need to check an exponential number of thread combinations by exploiting the fact that the threads form a partition; hence there are only very few nonempty thread intersections. We check only the nonempty ones.

Recursive Algorithm for Finding Rooted MIT of Binary Trees

1. prune all trees to include only the labels that are equidistant to r in all trees.
   The trees are now of the following form: Tree T_i has root r. r has one child x_i^1. x_i^1 has two children x_{i1}^2 and x_{i2}^2. The rest of the tree is rooted at x_{i1}^2 and x_{i2}^2. We would like to have recursion and choose a maximal isomorphic agreement subtrees of all combinations of children. However, there are 2^k combinations, which we cannot afford. The partition property of thread intersections means there are at most $n-1$ nonempty candidate intersections.
2. construct the i disjoint thread intersections $\{S_1, \ldots, S_i\}$ of $S - \{r\}$ $(i \leq n-1)$.
   Details of the construction appear in the implementation of step 2 below.
   Let the thread intersections be of sizes $n_1, \ldots, n_i$, respectively. ($\sum_{j=1}^{i} n_j \leq n-1$.) Let T_{jl} be the minimal subtree of T_j rooted at x_j and containing exactly the leaves in $T_j \cap S_l$. In the next level of the recursion, x_j has only the single child appearing in the chosen thread. The role of r will be played by x_j. We continue using only the nonroot leaves of the tree as our counting basis, with the root never contributing.
   construct i tuples $\langle T_{11}, \ldots, T_{k1}\rangle, \ldots, \langle T_{1i}, \ldots, T_{ki}\rangle$.
   recursively find the MIT of each of the i tuples.
3. The MIT will be composed of putting together the MITs of different thread intersections. Since our trees are binary trees, a choice of thread σ forces at most one possibility for its counterpart, the thread $\bar{\sigma}$ such that $\bar{\sigma}[i] = 3 - \sigma[i]$. Note that $\bar{\sigma}$ may be empty either because of an empty intersection or even because some x_i has only a single child.
   Let $MIT(\sigma) = MIT(T_{1t}, T_{2t}, \ldots, T_{kt})$ where $S_t = \cap_{l=1}^{k} L(x_{l\sigma[l]})$.
   Pair all threads into $\{\langle \sigma_1, \bar{\sigma_1}\rangle, \ldots, \langle \sigma_{i'}, \bar{\sigma_{i'}}\rangle\}$ where each pair has at least one thread with a nonempty intersection. It is clear that $i' \leq i$. (Recall that i is the number of nonempty disjoint thread intersections found in step 2.)
   Each $MIT(\sigma)$ is a binary tree whose root has a single child. Let $MIT(\langle \sigma, \bar{\sigma}\rangle)$ be the tree resulting from merging the roots of $MIT(\sigma)$ and $MIT(\bar{\sigma})$ into a single node that has two children. This node is the single child of r.
   choose $MIT(T_1, \ldots, T_k)$ as the largest of $\{MIT(\langle \sigma_1, \bar{\sigma_1}\rangle), \ldots, MIT(\langle \sigma_{i'}, \bar{\sigma_{i'}}\rangle)\}$.

end Algorithm

Correctness. The algorithm's main action takes place in step 2. The fact that the MIT is an isomorphic subtree of all trees means that each of $x_1^1, x_2^1, \ldots, x_k^1$ is the child of r in the MIT restricted to $T_1, \ldots, T_k$, respectively. The MIT is then the best combination of children of the x_i's. The partition property of the thread intersections limits the number of recursive cases that need to be considered to $i < n$ rather than 2^k since all other thread intersections are necessarily empty.

Step 3 is correct because in a binary tree every choice of right or left forces a single remaining option. □

Implementation of step 2. Our goal is to decide in polynomial time which of the 2^k possible threads gives a nonempty thread intersection. When constructing a thread, at each of the k trees we make one choice. Either we choose a 1 (if x_{i1} is in the thread) or a 2 (x_{i2} in the thread). Constructing all these choices is equivalent to a breadth-first-search of the complete depth-k binary tree where each node has a

left son labeled 1 and a right son labeled 2. Visiting child e, $e \in \{1,2\}$ at level d means adding x_{de} to the thread. We will in fact be intersecting with $L(x_{de})$. We are guaranteed that the nonempty sets are disjoint at every node at every fixed level. We do not continue the search at any branch where the empty set is reached. The sum of all elements in the sets for each level is at most $n-1$, thus the total time to construct step 2 is $O(kn)$.

Algorithm time. The time for computing the MIT of k rooted trees is given by the following recurrence:

$$f(1) = 1,$$
$$f(n) = f(n_1) + f(n_2) + \cdots + f(n_i) + kn, \quad \text{where } \sum_{l=1}^{i} n_l = n.$$

The closed form is $f(n) = O(kn^2)$.

Total algorithm time. Since the rooted MIT algorithm has to be run n times, the total time is $O(kn^3)$.

It is easy to see that the above algorithm will also work for trees where T_1 has degree bounded by $d > 2$. The only use we made of the fact that the trees are binary was in step 3. In the binary tree case, choosing a σ fixes $\overline{\sigma}$ for purposes of recursively constructing an MIT. Now, however, we need to make sure that we pick the maximum of the choice of all nonconflicting threads, where a thread σ_1 conflicts with a thread σ_2 of the same nodes if $\exists i$ such that $\sigma_1[i] = \sigma_2[i]$. Obviously, two conflicting threads cannot be joined together in the same agreement subtree. There are going to be $\binom{n}{d-1}$ possibilities. The nonconflicting threads may be put together in a brute-force fashion. Each of the $\binom{n}{d-1}$ possibilities requires $O(kd)$ time for verification of nonconflict (since there are at most $d-1$ threads in a combination, and each thread is of length k). Thus all nonconflicting threads can be generated in time $O(k(d-1)n^{d-1}/(d-1)!) = O(kn^{d-1})$. We now choose the best MIT over all nonconflicting thread combinations.

The recurrence is now

$$f(1) = 1,$$
$$f(n) = f(n_1) + f(n_2) + \cdots + f(n_i) + kn^{d-1}, \quad \text{where } \sum_{l=1}^{i} n_l = n.$$

Thus the total algorithm time for degree bounded by d trees is $O(kn^{d+1})$. It should be noted that the algorithm does not require all trees to have bounded degree. It will work even for the case where only *one* tree has bounded degree d. However, if all trees have degree bounded by d, then each set of $d-2$ threads forces a unique $(d-1)$th thread (as in the binary tree case above) and the total algorithm time is then $O(kn^d)$.

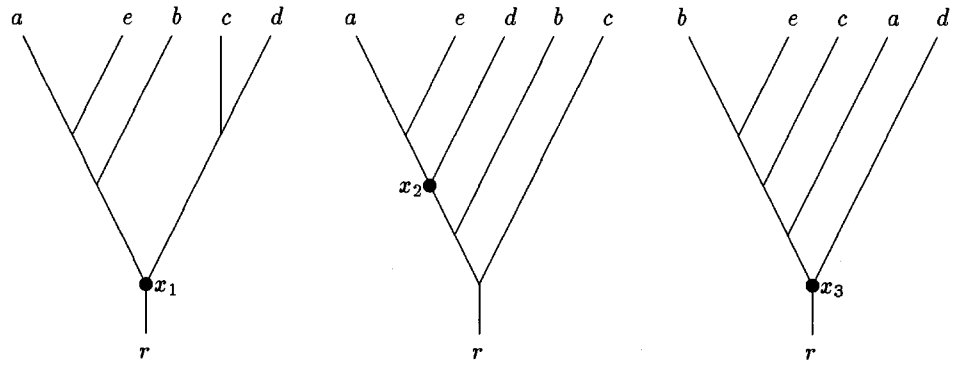
5. Maximum homeomorphic agreement subtree. We now consider the task of finding an MHT subtree of k trees, where the degree of at least one of the trees is bounded.

We follow the same ideas as before. We basically use a naive brute-force algorithm that normally produces an exponential time solution. However, we will define special sets of labels—*maximal decomposable sets*—and show that considering these sets alone is sufficient for finding an MHT. Since there is only a polynomial number of such sets, our algorithm's time is therefore polynomial.

Before presenting the algorithm, we need some more definitions and observations.

Notation. Let $A \subseteq S$. We denote the tree $MHT(H(T_1, A), \ldots, H(T_k, A))$ by $MHT(A)$. To avoid unnecessary notation, we will also use the notation $MHT(A)$ to denote the set of labels of $MHT(A)$.

DEFINITION. *A set $A \subseteq S$ is* decomposable *if there exist $x_1 \in T_1, \ldots, x_k \in T_k$ such that each x_i, $i = 1, \ldots, k$, has at least p children which can be labeled*



$\{a, e, d\}$ is a maximal decomposable set that decomposes to $\{a, e\} \cup \{d\}$.
The roots of the decomposition are x_1, x_2, x_3.

FIG. 3. *Example of a decomposable set.*

$x_{i1}, \ldots, x_{ip}$, $p \geq 2$, *and such that* $A = A_1 \cup \cdots \cup A_p$, *where* A_j *are mutually disjoint nonempty sets and* $A_j \subseteq L(x_{ij})$, $j = 1, \ldots, p$; $i = 1, \ldots, k$. *We say that* A decomposes to $A_1 \cup \cdots \cup A_p$, *and that* $x_1, \ldots, x_k$ *are the* roots of the decomposition.

In other words, there is a node in each one of the trees, where the label set is split among p children in the same fashion. See Figure 3.

Note that the number of decomposable sets may still be exponential. Consider as an example two identical complete binary trees. Every label subset with more than two leaves is a decomposable set. We would like to limit the number of label sets that need to be considered.

DEFINITION. *Let* A *be a decomposable set which decomposes to* $A_1 \cup \cdots \cup A_p$. A *is a* maximal decomposable *set if there does not exist a decomposable set* B *such that* A *is a proper subset of* B *and such that* B *decomposes to* $B_1 \cup \cdots \cup B_q$, $q \geq p$ *where every* A_i, $i = 1, \ldots, p$, *is a subset of a distinct* B_j.

An alternate way of viewing maximal decomposable sets is by considering the roots of the decomposition. A set of nodes $x_1 \in T_1, \ldots, x_k \in T_k$ defines a set of maximal decomposable sets. Each of these maximal decomposable sets is defined by a maximum p ($p \geq 2$) and an ordered list of p children of each x_i, which we will label $x_{i1}, \ldots, x_{ip}$ (although note that the order of these nodes is not necessarily their left-to-right order in the trees). If $\cap_{i=1}^{k} L(x_{ij}) \neq \emptyset$, $j = 1, \ldots, p$, then $\cup_{j=1}^{p} \cap_{i=1}^{k} L(x_{ij})$ is a maximal decomposable set.

The maximality, then, is the fact that this set is the largest decomposable set defined by the given set of nodes. This limitation reduces the number of sets from exponential to polynomial, as can be seen from the following theorem.

THEOREM 7. *Let* $T_1, \ldots, T_k$ *be a set of trees where* T_1 *has degree bounded by* d. *Assume the trees are rooted at a common label* r. *Then there are* $O(n^{d-1})$ *maximal decomposable sets.*

Proof. We know that T_1 is a degree d tree, so in our case, no set can decompose to more than $d-1$ subsets. Observe that if A decomposes to $A_1 \cup \cdots \cup A_{d-1}$, then for every $(d-1)$-tuple $\langle a_1, a_2, \ldots, a_{d-1} \rangle$, where $a_i \in A_i$, $i = 1, \ldots, d-1$, the lowest common ancestor of the $d-1$ elements in each of the k tree is the node defined as the root of the decomposition in that tree. If, however, we are considering a maximal decomposable set, then each such tuple uniquely defines the set. The reason is

that the LCA of the tuple finds the root of the decomposition, and the maximum subset in each of the $d-1$ children that appears in all k trees is the maximal decomposition. □

The following observation guarantees the polynomial time of our algorithm.

Observation 8. If $A \subseteq S$ is a maximal decomposable set decomposable to $A = A_1 \cup \cdots \cup A_p$, then $MHT(A) = MHT(A_1) \cup \cdots \cup MHT(A_p)$. If A is not decomposable, then $MHT(A) = \max\{MHT(B) | B \subseteq A$ and B is maximal decomposable$\}$.

Proof. Let A be maximal decomposable, and let H be the homeomorphic restriction of T_i to $A \cup \{r\}$. The root of H is r. Each x_i, the root of the decomposition in T_i, is the restriction of the only child of r in H. It is clear that the only chance of getting a nonempty MHT is by matching equal subsets to each other. The maximum number we can get is by matching *all* equal subsets to each other.

If A is not maximal decomposable then for each $i,\ i = 1, \ldots, k$, let x_i be the node in T_i that is the restriction of r's child in the MHT. Because $x_1, \ldots, x_k$ appear in the MHT then they are either leaves or each has children $x_{i1}, \ldots, x_{ip},\ p > 1$, where $L(x_{ij}) \cap L(x_{lj}) \neq \emptyset$. Thus if B is the maximal decomposable set of A for nodes $x_1, \ldots, x_k$, then $MHT(A) = MHT(B)$ and $B \subseteq A$. □

The above observation means that it is sufficient to compute the MHT of maximal decomposable sets.

We now present an algorithm for finding the MHT of a set of trees where tree T_1 (which we may assume has the smallest degree) has degree bounded by d. As in the previous sections we present the part that assumes root r. The general algorithm chooses as the MHT the largest tree produced by each of the rooted cases.

For simplicity of the presentation, we will separate the algorithm into two parts. One part that constructs all maximal decomposable subsets of $S - \{r\}$, and a second part that constructs the MHT of all maximal decomposable subsets.

Algorithm for Constructing all Maximal Decomposable Subsets (degree bounded by *d* tree)

For each $(d-1)$-tuple $\langle a_1, \ldots, a_{d-1} \rangle$ of elements from $S - \{r\}$ do:

1. For every tree $T_i,\ i = 1, \ldots, k$ find if there is $x_i \in T_i$ that has $d-1$ distinct children $x_{i1}, \ldots, x_{i(d-1)}$ where $a_j \in L(x_{ij}),\ i = 1, \ldots, d-1$.
2. If such an x_i is found for every $T_i,\ i = 1, \ldots, k$ then construct the maximal sets $A_1, \ldots, A_{d-1}$ such that $a_j \in A_j \subseteq L(x_{ij}),\ i = 1, \ldots, k;\ j = 1, \ldots, d-1$. Take $A = A_1 \cup \cdots \cup A_{d-1}$ as a maximal decomposable set.

end

end Algorithm

Time. The algorithm loops n^{d-1} times. It takes time $O(kn)$ to find the x_i's (step 1) and to construct the A_i's (step 2). The total time is $O(kn^d)$.

Correctness. We have correctness by Theorem 7.

We are now ready to present the algorithm for finding the MHT of k trees one of which has degree bounded by d.

Algorithm for Rooted MHT (degree bounded by *d* tree)

1. Construct all n^{d-1} maximal decomposable sets.
2. Order the maximal decomposable sets by the subset relation.
3. The base subsets (those that have no maximal decomposable subsets) are sets $A = A_1 \cup \cdots \cup A_{d-1}$ where each of the A_i's, $i = 1, \ldots, d-1$, is a singleton set $\{a_i\}$. $MHT(A)$ is A.
   For subsequent maximal decomposable subsets, construct the MHT by the relation $MHT(A) = MHT(A_1) \cup MHT(A_2) \cup \cdots \cup MHT(A_{d-1})$. For any maximal

decomposable A_i, we have already computed the MHT. If any of the A_i is not maximal, its MHT is that of its largest maximal decomposable subset.
$MHT(S)$ is $MHT(A)$, where A is the largest maximal decomposable subset of S.

end Algorithm

Time. Step 1 was already seen to take time $O(n^d)$. For steps 2 and 3, there are $O(n^{d-1})$ maximal decomposable sets. Comparing every two sets takes time $O(n)$. A straightforward implementation of steps 2 and 3 is by a pairwise comparison of all maximal decomposable sets. This can be done in time $O(n^{2d-1})$. The total algorithm time for rooted trees is then $O(kn^d + n^{2d-1})$. For unrooted trees the time is $O(kn^{d+1} + n^{2d})$.

Correctness. The correctness is clear by Observation 8.

6. Maximum weighted agreement subtree (MWT). An MHT of a set of trees produces a tree whose *shape* is common to all trees. However, this does not take into account the conjectured *time* each evolutionary split took. Our final goal is a tree where the distances between nodes are conjectured, i.e., given as a *range* of numbers. However, we start with the case where the distances between nodes in each of the evolutionary trees are given exactly. This case is a special case of the maximum interval subtree discussed in the next section. However, we treat it separately for two reasons: 1) it introduces some concepts that are used later in the interval case 2) it has a faster algorithm than the general case.

DEFINITION. *Let $T_1, \ldots, T_k$ be S-labeled trees with integer weights on the edges. A* maximum weighted agreement subtree *of $T_1, \ldots, T_k$ ($MWT(T_1, \ldots, T_k)$) is a maximum set $S' \subseteq S$ such that $\forall s, t \in S'$ the distance between s and t (the sum of the weights on the edges of the path between them) is the same in all trees $T_1, \ldots, T_k$. We will also refer to the problem of finding a maximum weighted agreement subtree as* the MWT problem.

This is a generalization of the MIT problem (there every edge had weight 1). However, we cannot immediately reduce the MWT problem to the MIT problem by replacing every weight-i edge by i weight-1 edges, since then the problem size may grow exponentially.

Let T_1 and T_2 be two S-labeled trees with integer weights on the edges. T_1 and T_2 are *w-isomorphic* if the distance between every two labeled edges is the same in both trees.

THEOREM 9. *Two labeled trees with no* 2-vertices *(vertices of degree* 2*) are w-isomorphic iff they are isomorphic as leaf-labeled trees and corresponding edges have the same weight.*

Proof. For rational weights, this is an immediate corollary of Theorem 4. □

Theorem 9 asserts that in different trees of the given set, subtrees corresponding to the MWT may differ only in edges incident to 2-vertices. In addition, the sum of the weights of a maximal chain of 2-vertices (whose end points are not 2-vertices) must be the same for all corresponding pairs of non-2-vertices in all the trees.

For the sake of exposition we again assume that all our trees are binary trees. The algorithm outline is generally unchanged from the MIT case. The only exceptions are the following necessary changes.

- As in the MIT case, the recursion always treats rooted trees where the root has a single child x and that child has two children x_1 and x_2. Unlike the MIT case, our root is *always* taken to be r and the weight of the edge from r to x is the sum of the weights from r to x in the original tree.

- If the children of r in all the trees have the same distance to r the case is handled exactly like the MIT algorithm.
- If there are at least two children of r with different distances to r, let i be the tree with the smallest distance $d(x_i, r)$. Because of Theorem 9, it is impossible for x_i to be in an MWT as a 3-vertex. Therefore, we split the tree $T_i(x_i)$ into two trees $T_i(x_{i1})$ and $T_i(x_{i2})$, where x_{i1} and x_{i2} are x_i's children. We now have two MWT problems of smaller size.

Termination. The algorithm terminates since a tree split always reduces the size of the remaining trees. Since there are kn nodes initially, and every split reduces the size of the trees by at least one node, there can be no more than kn splits.

Time. The time complexity of the algorithm does not change. Although we may split the problem several times during the course of the algorithm, the sizes of the problems are reduced with each split. Because of convexity of the time function, the complexity is worst when there is no split. This is exactly the MIT case.

Total algorithm time. $O(kn^3)$.

Total algorithm time for degree bounded by d trees. $O(n^d + kn^3)$.

7. Maximum interval agreement subtree. An MHT of k trees provides, in a sense, the greatest number of leaves whose underlying tree structure has a similar shape. An MWT provides a maximum set of leaves where the exact distances between them are preserved. The big problem is that the exact distances are not usually known. We would like a metric that gives us the advantage of both structure and "approximate" distance. We approximate the distance between two nodes by a pair of numbers $[a, b]$, where $a \leq b$. This pair represents the interval between a and b and its meaning is that the distance between the edge's head and tail is within that interval. We are interested in the largest set of leaves that has an underlying tree with edge weights in the intersection of all appropriate intervals. Formally we have the following definition.

DEFINITION. *Let $T_1, \ldots, T_k$ be S-labeled trees. Assume that every edge is labeled by a pair of numbers $[a, b]$, where $a \leq b$. We call such trees* S-labeled interval labeled trees. *An* instantiation *T' of an S-labeled interval labeled tree T is an S-labeled weighted tree (as defined in section 6) where all nodes and edges of T' are equal to the nodes and edges of T and where every edge of T' is labeled by a number in the interval label of that edge in T.*

A maximum interval agreement subtree *of $T_1, \ldots, T_k$ ($MIWT(T_1, \ldots, T_k)$) is a maximum set $S' \subseteq S$ such that $MIWT(T_1, \ldots, T_k)$ is $MWT(T'_1, \ldots, T'_k)$, where T'_i is an instantiation of T_i for $i = 1, \ldots, k$. We refer to the problem of finding a maximum interval agreement subtree as* the MIWT problem.

Note that all previous agreement metrics are special cases of MIWT. In MIT, we assume all intervals are $[1, 1]$. In MWT, any edge weight a is interval $[a, a]$. In MHT, we assume all intervals are $[1, n-1]$. We presented the case separately for historical and methodological reasons.

The key observation for the MIWT problem is that Theorem 9 guarantees that a MIWT of k trees is also a homeomorphic agreement subtree of those trees (because it is an MWT of some instantiation of them). Once this observation is made the following algorithm follows naturally. Before presenting the algorithm, we need one more definition.

DEFINITION. *The* distance interval *between node x and y in an interval labeled tree is the interval $[z, w]$ where z is the sum of the smaller elements of each of the pairs on the path from x to y, and w is the sum of the larger elements.*

Algorithm for MIWT

We modify the MHT algorithm to return MIWT. The only necessary modification is the following:

1. For each homeomorphic agreement subtree T' handled by the algorithm do
   (a) for each tree T_i, $i = 1, \ldots, k$ do
   for every path in T_i corresponding to an edge in T' compute the distance interval of that path
   (b) { Every edge in T' now has k distance intervals associated with it. }
   for every edge in T' where the k distance intervals have a nonempty intersection, discard the edge and the entire subtree rooted to its head

end Algorithm.

THEOREM 10. *The above algorithm computes a MIWT of k trees in time $O(kn^{d+1} + n^{2d})$, where there is at least one tree of degree bounded by d.*

Proof. Correctness follows immediately from the observation that every MIWT is also a homeomorphic agreement subtree.

We need to prove the time bounds. The added modification can be implemented in time $O(kn)$ and needs to be added for every maximal decomposable set. Since there are $O(n^d)$ such sets, the asymptotic time complexity of the algorithm does not change, and is $O(kn^{d+1} + n^{2d})$. □

8. Future work. Although the $\mathcal{NP}$-completeness proof of the unbounded degree case prepares us for having the degree d as an exponent in our time complexity, it would be nice to reduce the time for finding the MWT to $O(c^d p(n, k))$, where p is a polynomial, rather than $O(n^d)$.

We presented here an approximation for the problem of finding the complement of the MHT. In [13] it was proven that the MHT problem for three trees with unbounded degree cannot be approximated within ratio n^ϵ for any constant $\epsilon \leq 1$.

For the case of bounded degree trees, the time was improved by [5].

From a graph theoretic aspect, it would be interesting to find a maximum agreement subtree in the sense of maximizing the number of edges, while using true contraction. The number is no less than n because every tree can be contracted to a star. However, again in [13] it was shown that this prolem is $\mathcal{NP}$-hard even for two trees.

An ambitious problem is to define "tree closeness" metrics and efficiently find the closest tree to a set of trees keeping all the leaves.

Acknowledgments. We wish to thank Mike Steel for his great help in refining this paper, Bob Robinson for kindly sending us reference material on the subject, and two anonymous referees who were very fast and insightful.

THE UNION OF CONVEX POLYHEDRA IN THREE DIMENSIONS*

BORIS ARONOV†, MICHA SHARIR‡, AND BOAZ TAGANSKY§

Abstract. We show that the number of vertices, edges, and faces of the union of k convex polyhedra in 3-space, having a total of n faces, is $O(k^3 + kn \log k)$. This bound is almost tight in the worst case, as there exist collections of polyhedra with $\Omega(k^3 + kn\alpha(k))$ union complexity. We also describe a rather simple randomized incremental algorithm for computing the boundary of the union in $O(k^3 + kn \log k \log n)$ expected time.

1. Combinatorial bounds.

Let $\mathcal{P} = \{P_1, \ldots, P_k\}$ be a family of k convex polyhedra in 3-space, let n_i be the number of faces of P_i, and let $n = \sum_{i=1}^{k} n_i$. Put $U = \bigcup \mathcal{P}$. By the *combinatorial complexity* of a polyhedral set we mean the total number of its vertices, edges, and faces. Our main result is the following.

THEOREM 1.1. *The combinatorial complexity of the union U is $O(k^3 + kn \log k)$. This bound is almost tight in the worst case, since there are examples where the complexity of such a union is $\Omega(k^3 + kn\alpha(k))$.*

1.1. Background.

This result extends the known sharp bound of $\Theta(k^2 + n\alpha(k))$ on the complexity of the union of k convex polygons in the plane with a total of n edges [7]. It is interesting to note that in both cases the bounds depend only linearly on n.

Our result has several applications, mentioned below, to robot motion planning and to problems in geometric optimization. It is a natural special case of the problem of analyzing the complexity of the union of geometric objects, which is formulated for arrangements of more general curves and surfaces in two and three dimensions, respectively. This problem has received considerable attention recently and has been studied mostly in the plane. Several special cases have been identified where sharp complexity bounds can be established, such as the cases of "pseudodisks" [27] or of "fat" triangles [28]. In three dimensions, however, very few sharp bounds for the complexity of the union of objects are known. One such bound is for the union of n

balls, where a $\Theta(n^2)$ worst-case bound is easy to establish. Another recent bound is for the union of n axis-parallel cubes in any dimension $d \geq 2$. The worst-case bound is $\Theta(n^{\lceil d/2 \rceil})$, and it improves to $\Theta(n^{\lfloor d/2 \rfloor})$ when the cubes have all the same size [11].

The union of geometric objects (or, rather, its complement) is among several important substructures in the arrangement of the objects, such as their lower (or upper) envelope, a single cell of the complement (a "hole" in the union), a subset of cells in the complement, and the collection of all nonconvex or otherwise "interesting" cells of the complement. Considerable progress has recently been made in the analysis of these substructures; see [5, 7, 22, 21, 23, 24, 33, 36].

We also obtain an efficient randomized incremental algorithm for computing the union of k convex polyhedra with a total of n faces, whose expected running time is $O(k^3 + kn \log k \log n)$, and is thus close to optimal in the worst case. Our algorithm computes the portion of the boundary of the union contained in each of the faces of the polyhedra, using a separate randomized incremental procedure for each face. The algorithm and its analysis are adapted from previously known techniques ([13, 16, 20, 30] and others), but it introduces a significant observation, namely that, even without a global randomized insertion mechanism (which is not applicable in our case), sharp expected complexity bounds can still be obtained. This may be of independent interest and may have further applications for efficient construction of other three- (or higher-)dimensional structures. Another complication arises since the objects that we add incrementally do not necessarily have constant complexity, so handling them requires a more complex version of the algorithm and of its analysis.

1.2. Analysis. We first simplify the analysis by assuming that the given polyhedra are in *general position*, meaning that no point is common to the boundaries of any four distinct polyhedra, no vertex of one polyhedron lies on the boundary of another, no two edges of distinct polyhedra meet, and no edge of a polyhedron meets the polygonal curve of intersection of the surfaces of any two other polyhedra. We claim that this assumption involves no loss of generality. Indeed, Lemmas 1.2 and 1.3 below, which are easily seen to hold also when the given polyhedra are not in general position, imply that it suffices to prove the asserted bound for the number of vertices of the union that are formed as the intersection of faces of three (or more) distinct polyhedra. However, it can be easily verified that, if we perturb the vertices of the given polyhedra by sufficiently small displacements, so as to move them into general position, the number of such union vertices does not decrease. Moreover, if the perturbation is sufficiently small, the number of edges and faces of the union also cannot decrease. We can then charge each edge or face of the union to an incident vertex in the perturbed collection and argue that no such vertex is charged more than a constant number of times. These considerations imply that it suffices to establish the bound of Theorem 1.1 for the number of *vertices* of the union of collections $\mathcal{P}$ in general position.

We begin with a derivation of a few simple auxiliary results.

LEMMA 1.2. *The sum of the numbers of vertices, edges, and faces of the pairwise intersections $P_i \cap P_j$, over all $1 \leq i < j \leq k$, is $O(kn)$.*

Proof. $P_i \cap P_j$ is a convex polyhedron bounded by at most $n_i + n_j$ faces, and thus has $O(n_i + n_j)$ vertices and edges. Summing this bound over all (i, j) with $1 \leq i < j \leq k$, we obtain $O(kn)$. □

Define the *arrangement* $\mathcal{A}(\mathcal{P})$ of the collection $\mathcal{P}$ as the decomposition of space into vertices, edges, faces, and three-dimensional cells induced by the faces of the polyhedra of $\mathcal{P}$; for more details on arrangements, see [4, 17, 34].

LEMMA 1.3. *The number of vertices of $\mathcal{A}(\mathcal{P})$, other than those formed as the intersection of faces of three or more distinct polyhedra, is $O(kn)$.*

Proof. Each such vertex is either a vertex of a polygon in $\mathcal{P}$, or a vertex of $P_i \cap P_j$, for some $i \neq j$. The claim now follows from Lemma 1.2. □

LEMMA 1.4 (Aronov, Bern, and Eppstein [1]). *The overall complexity of $\mathcal{A}(\mathcal{P})$ is $O(k^2 n)$, which is tight in the worst case.*

Proof. Each vertex of $\mathcal{A}(\mathcal{P})$ not counted in Lemma 1.3 is the intersection of an edge of some intersection $P_i \cap P_j$ with a face of another polyhedron P_ℓ. Since Lemma 1.2 implies that the total number of such edges is $O(kn)$, and each of them crosses the surface of another polyhedron at most twice, the upper bound follows. For an easy lower bound construction, see [1]. □

Proof of Theorem 1.1. We prove the theorem by induction on k. For $k \leq 3$ the claim follows trivially from Lemma 1.4. Recall that $\mathcal{A}(\mathcal{P})$ is the arrangement in $\mathbb{R}^3$ of the collection of the n facets of the polyhedra in $\mathcal{P}$. An m-face $f \in \mathcal{A}(\mathcal{P})$, for $m = 0, 1, 2$, is a *level-z* face if exactly z polyhedra in $\mathcal{P}$ contain f in their interior. Thus the faces of the union are precisely the level-0 faces.

A vertex $v \in \mathcal{A}(\mathcal{P})$ is said to be an *outer vertex* if it is incident to an edge of a polyhedron in $\mathcal{P}$. Otherwise v is called an *inner vertex*. By Lemma 1.3 the number of outer vertices is $O(kn)$. Thus our main goal is to bound the number of level-0 inner vertices. Denote by $C_z(\mathcal{P})$ the number of level-z inner vertices of $\mathcal{A}(\mathcal{P})$, and by $C_z(k, n)$ the maximum of $C_z(\mathcal{P})$ over all sets $\mathcal{P}$ of k convex polyhedra in general position, with a total of n facets.

The triple (f, e, e') is said to be a *special triple* if f is a level-1 2-face of $\mathcal{A}(\mathcal{P})$, e and e' are edges of f that are level-0 edges of $\mathcal{A}(\mathcal{P})$, and we can trace the boundary of f from e to e' without passing through any other level-0 edge. (Note that e and e' must both lie on the boundary of the unique polyhedron containing f in its interior and thus on the outer boundary component of f.) In this notation, the order of e and e' is immaterial, and we identify (f, e, e') with (f, e', e). Lemma 1.5 below, a main technical step of the proof, shows that the number of such special triples is $O(k^3 + kn \log k)$. We also define a *special triangle* to be any level-1 triangular face of $\mathcal{A}(\mathcal{P})$, with one level-0 edge and two level-1 edges.

Let v_0 be a level-0 inner vertex. Then v_0 is the intersection of three facets F_1, F_2, F_3 of three respective distinct polyhedra P_1, P_2, P_3. The vertex v_0 is incident to three level-0, six level-1, and three level-2 2-faces of $\mathcal{A}(\mathcal{P})$. Let f be one of the incident level-1 faces, say the one contained in $F_1 \cap P_3$ and lying outside P_2. There are two edges of f incident to v_0: a level-0 edge e_0 within $F_1 \cap F_3 \setminus P_2$, and a level-1 edge e_1 within $F_1 \cap F_2 \cap P_3$ (see Figure 1). Let $e_0, v_0, e_1, v_1, e_2, v_2, e_3$ denote the edges and vertices of the (outer) boundary of f in the order of their appearance along the boundary, starting from e_0 (see Figure 1). Note that we may have $e_3 = e_0$.

We now introduce a charging scheme, in which v_0 can be charged to a "nearby" vertex or other feature of the arrangement $\mathcal{A}(\mathcal{P})$. One of the following five cases must arise:

(i) v_1 is an outer vertex of $\mathcal{A}(\mathcal{P})$. In this case we charge one unit to v_1.

(ii) v_1 is a level-0 inner vertex, and thus (f, e_0, e_2) is a special triple. We charge one unit to (f, e_0, e_2).

(iii) v_1 is a level-1 inner vertex, and v_2 is not a level-0 inner vertex. We charge $1/3$ of a unit to v_1.

(iv) v_1 is a level-1 inner vertex, v_2 is a level-0 inner vertex, and $e_0 \neq e_3$. We charge one unit to the special triple (f, e_0, e_3).

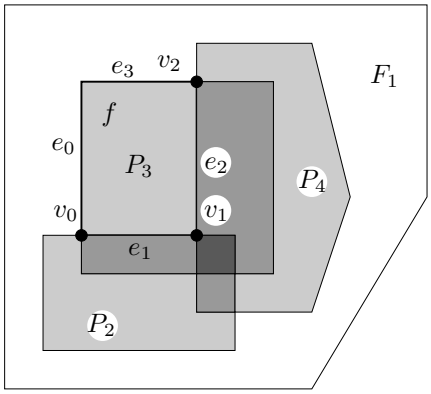

FIG. 1. *The level-*1 *face* f *used for the charging scheme*; *here case* (iv) *is illustrated.*

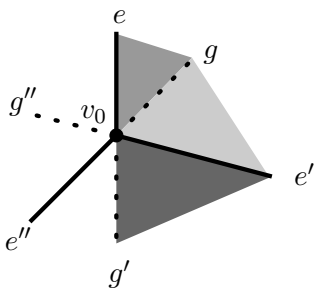

FIG. 2. *Many special triangles incident to* v_0.

(v) v_1 is a level-1 inner vertex, v_2 is a level-0 inner vertex, and $e_0 = e_3$. We charge $1/6$ of a unit to the vertex v_1 and $1/6$ of a unit to the special triangle $\triangle e_0 e_1 e_2$.

If we repeat the above procedure for each of the six level-1 2-faces incident to v_0, the vertex v_0 will receive at least 2 units of charge, at least $1/3$ for each 2-face. Moreover, we claim that v_0 can be incident to at most four special triangles (as in case (v)): Note that v_0 is incident to three level-0 edges e, e', e'', and to three level-1 edges g, g', g'', and each special triangle incident to v_0 is incident to one of these level-0 edges and to one of these level-1 edges. So suppose to the contrary that v_0 is incident to five or more special triangles. It follows that there are three consecutive special triangles incident to v_0, i.e., up to symmetric configurations, one special triangle is incident to e and g, one is incident to g and e', one is incident to e' and g', and e and g' must be collinear; see Figure 2. By definition, the other endpoints of e and g must lie in some original polyhedron facet F_4 not incident to v_0. Similarly, because of the general position assumption, the other endpoints of g and e' must both lie in F_4, and the same holds for the other endpoint of g'. This, however, is impossible, since the line segment $e \cup g'$ has both endpoints on F_4 and contains v_0 which is not on F_4. Hence, v_0 can be incident to at most four special triangles.

It follows that v_0 will receive at least $2 - 4 \times 1/6 = 4/3$ units of charge even if we do not charge the special triangles.

We repeat the charging scheme for all the level-0 inner vertices of $\mathcal{A}(\mathcal{P})$. Each outer vertex w that is charged in this scheme (in type (i) cases) has exactly two incident edges which lie in the intersection of two polyhedra facets. Then w may be

charged up to four times: it can be charged along those two intersection edges, at most twice along each edge, from the two incident level-1 faces, for the total of at most 4 units. Each special triple (f, e, e') may be charged up to four times, once for each vertex of e and e', for the total amount of at most 4 units of charge. Each level-1 inner vertex v is incident to three level-1 2-faces. Within each face it is charged at most $1/3$ of a unit (either in just one charging of type (iii) or in at most two chargings of type (v)). Thus the total charge to v is at most 1 unit. To summarize, in the overall charging scheme, every level-0 inner vertex receives at least $4/3$ units, every level-1 inner vertex pays at most 1 unit, and every outer vertex or special triple pays at most 4 units. This yields:

$$\frac{4}{3}C_0(\mathcal{P}) \le C_1(\mathcal{P}) + O(kn) + O(k^3 + kn\log k) = C_1(\mathcal{P}) + O(k^3 + kn\log k)\,. \tag{1}$$

Let $\mathcal{R} \subset \mathcal{P}$ be a random sample of $k-1$ polyhedra (that is, $\mathcal{R}$ is obtained by deleting at random one polyhedron from $\mathcal{P}$). Arguing as in several recent related works [11, 14, 36], we have

$$\begin{aligned}\frac{k-3+4/3}{k}C_0(\mathcal{P}) &\le \frac{k-3}{k}C_0(\mathcal{P}) + \frac{1}{k}C_1(\mathcal{P}) + \frac{1}{k}O(k^3 + kn\log k)\\ &= \mathbf{E}(C_0(\mathcal{R})) + O(k^2 + n\log k)\,,\end{aligned} \tag{2}$$

where $\mathbf{E}$ denotes expectation with respect to the random sample $\mathcal{R}$. Here we have used (1) and the fact that a level-0 inner vertex of $\mathcal{A}(\mathcal{P})$ remains a level-0 inner vertex of $\mathcal{A}(\mathcal{R})$ with probability $\frac{k-3}{k}$ (this happens if and only if none of the three incident polyhedra is deleted), a level-1 inner vertex of $\mathcal{A}(\mathcal{P})$ turns into a level-0 inner vertex of $\mathcal{A}(\mathcal{R})$ with probability $1/k$ (this happens if and only if the deleted polyhedron is the unique one containing the vertex), and no other vertex of $\mathcal{A}(\mathcal{P})$ can become a level-0 inner vertex in $\mathcal{A}(\mathcal{R})$. Using the induction hypothesis $C_0(k,n) \le ck^3 + ckn\log k$, for some absolute constant c, we obtain

$$\mathbf{E}(C_0(\mathcal{R})) \le \frac{1}{k}\sum_j C_0(k-1, n-n_j) \le c(k-1)^3 + \frac{c(k-1)^2}{k}n\log(k-1)\,.$$

Thus (2) becomes

$$\frac{k-5/3}{k}C_0(\mathcal{P}) \le c(k-1)^3 + \frac{c(k-1)^2}{k}n\log(k-1) + b(k^2 + n\log k)\,,$$

for an appropriate constant b. It is now easy to show that

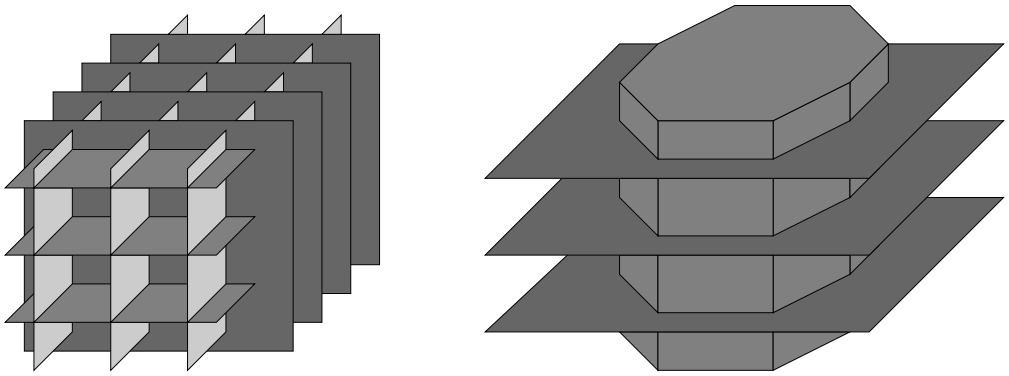
$$c(k-1)^3 + bk^2 \le \frac{k-5/3}{k}\cdot ck^3\,,$$

and that

$$\frac{c(k-1)^2}{k}n\log(k-1) + bn\log k \le \frac{k-5/3}{k}\cdot cnk\log k\,,$$

provided c is chosen sufficiently large. Indeed, the first inequality is trivial to enforce. The second one is implied by the inequality

$$c\left(k-2+\frac{1}{k}\right) + b \le c\left(k-\frac{5}{3}\right)\,,$$



(a) (b)

FIG. 3. *Lower bound construction.*

which is also trivial to enforce for $k > 3$. This completes the induction step and thus establishes the asserted upper bound.

As to the lower bound, $\Omega(k^3)$ is achieved by a gridlike arrangement of almost flat polyhedra (cf. Figure 3(a)). To obtain the second term, take a collection of $k/2$ convex polygons in the xy-plane, with a total of $n - ck/2 - k$ edges, for an appropriate constant c, such that the complexity of their union is $\Omega(n\alpha(k))$. Such a construction is described in [7]. Turn each planar polygon in this construction into a vertical prism, and cut the resulting collection of prisms by $k/2$ parallel horizontal flat polyhedra with c faces each. The union of the resulting collection of k convex polyhedra with a total of n faces has complexity $\Omega(kn\alpha(k))$. General position, if desired, can be achieved by a small perturbation of the planes containing the faces of the polyhedra, without reducing the complexity of the union. Figure 3(b) illustrates a simpler $\Omega(kn)$ construction with a single prism. Combining the two constructions, we obtain a lower bound of $\Omega(k^3 + kn\alpha(k))$, as claimed. □

To finish the proof, next we show the following.

LEMMA 1.5. *The number of special triples in an arrangement $\mathcal{A}(\mathcal{P})$ of k polyhedra with a total of n faces is $O(k^3 + kn \log k)$.*

Proof. Let f be a level-1 face of the arrangement $\mathcal{A}(\mathcal{P})$. Let e_f denote the number of edges of f that lie at level 0. (Note that all these edges must lie on the outer component of ∂f.) Clearly, the number of (unordered) special triples of the form (f, e', e'') is exactly e_f. However, to facilitate our inductive proof, we assign weight $w(f) = \max\{4e_f - 6, 0\}$ to f and proceed to estimate a new quantity, namely $\sum_f w(f)$, where the sum is taken over all level-1 faces f of $\mathcal{A}(\mathcal{P})$. (The reason for replacing e_f by $w(f)$ is, essentially, "induction loading," i.e., strengthening the statement in order to strengthen the induction hypothesis, thereby making the proof simpler.) We denote the maximum value of this quantity, over all collections $\mathcal{P}$ of k polyhedra in general position, with a total of n faces, by $C^{(1)}(k, n)$.

Before proceeding to bound $C^{(1)}$, we observe that it is an upper bound on the number of special triples (f, e, e'). Indeed, we need only consider level-1 faces f that have at least two level-0 edges on their boundary. For such faces f, we have $e_f \geq 2$, and $w(f) = 4e_f - 6 \geq e_f$, so indeed $\sum w(f)$, with the sum taken over all level-1 faces f, bounds the number of special triples in $\mathcal{A}(\mathcal{P})$.

We now estimate $C^{(1)}(k,n)$ by employing a slightly different induction scheme, as used in [2, 3, 5, 19]. That is, we remove a polyhedron P_i, add it back, and estimate the increase in the sum $\sum_f w(f)$, over all level-1 faces f of $\mathcal{A}(\mathcal{P})$, which neither lie on the boundary of P_i nor are contained in its interior. The argument is repeated for all $P_i \in \mathcal{P}$ and the resulting bounds on the increase in $\sum_f w(f)$ are added, to obtain a recurrence for $C^{(1)}$. We note that if f' is such a face in the full arrangement $\mathcal{A}(\mathcal{P})$, then, when P_i is removed, f' may expand, possibly merging with other faces, to form a bigger face f, which is a level-1 face in the reduced arrangement $\mathcal{A}_i = \mathcal{A}(\mathcal{P} \setminus \{P_i\})$.

Thus let f be such a face in $\mathcal{A}_i$. We assume that f is contained in a face F_j of some polyhedron P_j and in the interior of only one other polyhedron P_ℓ, where P_j and P_ℓ are distinct from P_i, and consider what may happen to f when P_i is reinserted. The portion $f \setminus P_i$ of f remains at the first level of the full arrangement, whereas $f \cap P_i$ lies at the second level and so should be ignored. $f \setminus P_i$ may be disconnected and consist of several subfaces $f_1, \ldots, f_u$. We are interested only in situations where $\sum_{q=1}^{u} w(f_q) > w(f)$, for only then does our count go up. Recall that e_f counts the number of level-0 edges of f, i.e., of edges of f on ∂P_ℓ, rather than all edges of f; in particular, we can assume that $e_f \geq 1$, for otherwise neither f nor $f \setminus P_i$ contribute anything to $C^{(1)}$.

Clearly, the cases where P_i contains f in its interior or avoids it altogether are uninteresting. If P_i avoids the outer boundary of f, there is no increase in weight (since all e_f level-0 edges of f lie on that boundary). Thus, from this point on, we assume that ∂P_i does meet the outer boundary of f.

We disregard subfaces f_q for which $w(f_q) = 0$; we are thus interested only in situations where

$$\sum_{w(f_q)>0} (4e_{f_q} - 6) > 4e_f - 6 \,. \tag{3}$$

Each of the at most e_f level-0 edges of f may be split by P_i into at most two subedges that may contribute to the left-hand side of (3), which is thus at most $4e_f + 4e^* - 6u^*$, where e^* is the number of level-0 edges that have been split, with both subedges appearing in positive-weight subfaces, and where u^* denotes the number of subfaces with positive weight. Thus the increase that f contributes to the overall sum of weights is at most $(4e_f + 4e^* - 6u^*) - (4e_f - 6) = 4e^* - 6u^* + 6$ (it can be smaller if $e_f = 1$ or if some of the e_f level-0 edges of f appear only in 0-weight subfaces). Let s be one of the e^* split edges, and let s_1 and s_2 be the two subedges into which s is split. If s_1 and s_2 lie in the same subface f_q of f, then the portion of ∂f_q between s_1 and s_2 must either contain a concave vertex of f_q that is also a vertex of $F_j \cap P_i$ or meet one of the islands (i.e., interior components of the boundary) of f that have become connected to the outer boundary by P_i (cf. the proofs of the Consistency Lemma and the Combination Lemma of [18], and Figure 4). In the former case we charge the splitting to any such concave (i.e., outer) vertex, and in the latter case we charge the splitting to such an island. It is easily seen that any such vertex or island is charged at most once, over all choices of P_i. Notice that the number of these islands, over all choices of a level-1 face $f \subset F_j$ and of P_i, for a fixed face F_j, is k, as it is at most the number of intersections $P_\ell \cap F_j$, for $1 \leq \ell \leq k$. Hence the total number of such charges is $O(kn)$. Similarly, by Lemma 1.3, the total number of concave vertices is also $O(kn)$. Thus the overall number of such edge splittings is $O(kn)$. Note that if an edge splitting of this kind occurs, then only one level-0 edge of ∂f is split by P_i, there is only one subface f_q with positive weight, and the weight increase is at most

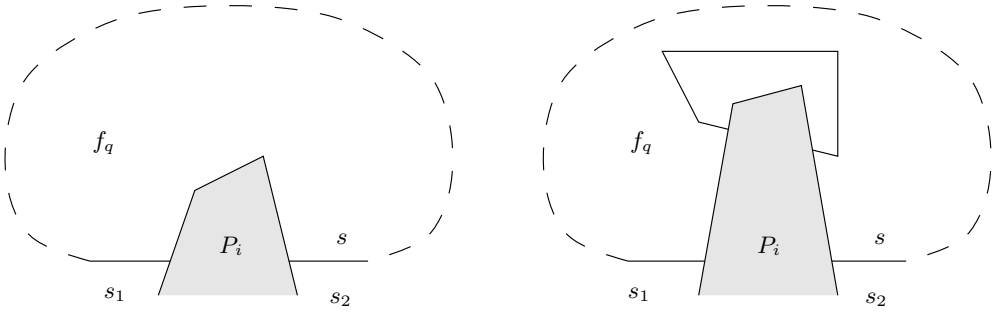


FIG. 4. *Two cases where the subedges of a split edge occur on the boundary of the same subface f_q.*

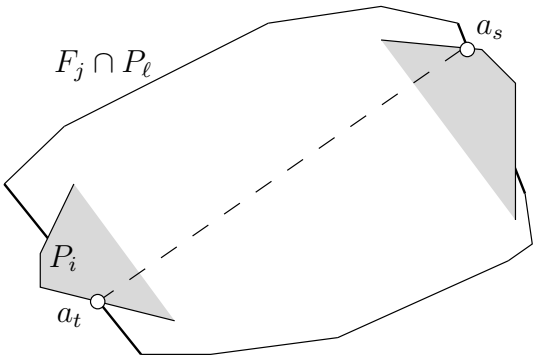

FIG. 5. *Analysis of edges split into different subfaces.*

4 (this follows from the convexity of P_i, F_j, and P_ℓ; see also Figure 4), so the total increase in all the faces in which splittings of this type occur, over all P_i, is $O(kn)$.

It therefore remains to consider the case where s_1 and s_2 lie in different subfaces of f, both having positive weight. Orient s so that f lies on its left, and suppose that s_1 precedes s_2 along s in this direction. Let a_s be the endpoint of s_2 closest to s_1. Label a_s by the subface of f incident to a_s and to s_2. If we trace the outer boundary of f in this direction, we obtain a cyclic sequence of points a_s; their labels form a corresponding cyclic sequence of positive-weight subfaces of f.

We claim that no subface can appear twice in this sequence. Indeed, consider $a_s, a_t \in \partial f$. By construction, $a_s, a_t \in P_i$, so the segment $a_s a_t$ lies in P_i and thus avoids the relative interior of any subface of f. On the other hand, a_s and a_t lie on the boundary of the convex polygon $F_j \cap P_\ell$ that contains f and thus also contains its subfaces. As $a_s a_t$ cuts this polygon in two and the subfaces of f incident to a_s and a_t lie locally on different sides of this segment, they must indeed be distinct subfaces. (Note that for both a_s and a_t the boundary of the incident subface lies locally in counterclockwise direction from the point along ∂f and thus along $\partial(F_j \cap P_\ell)$; see Figure 5.) This proves our claim.

Therefore the number e^* of level-0 edges s of f which are split into two subedges that end up in different positive-weight subfaces of f is at most u^*, the number of such subfaces.

To summarize, the increase that f contributes to our count (ignoring the increase caused by edges split into two subedges of the same subface) is at most $4u^* - 6u^* + 6 =$

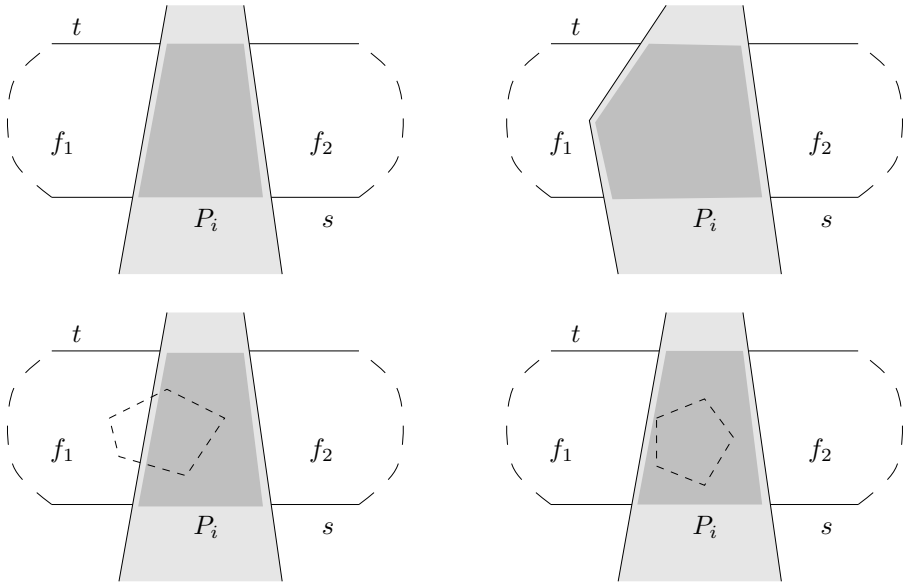

FIG. 6. *Possible configurations of the last kind of splitting. Only the top-left configuration cannot be charged to an outer vertex or to an island.*

$6-2u^*$. This is an increase only if $e^* = u^* \leq 2$; in fact, only the case $u^* = 2$ is relevant, because the preceding arguments give alternative ways of charging for the splittings when $u^* = 1$ (i.e., when there is only one subface with positive weight), and an increase can then occur only when $e^* = u^*$. Thus, reflecting over the preceding discussion, we conclude that it only remains to consider the case when $e^* = u^* = 2$, i.e., where there are two split edges s, t, and where each of the two subfaces in question, f_1, f_2, is bordered by a portion of s and by a portion of t. See Figure 6 for an illustration. Moreover, we can assume that the portions of $f \cap \partial P_i$ which appear along ∂f_1 and along ∂f_2 between s and t do not contain any vertex of $F_j \cap P_i$, and that they do not meet any island of f, because in such cases there are alternative ways of charging for the splitting, similar to those given above. By the same reasoning, we may assume that the shaded quadrilateral confined between s, t, f_1, and f_2, as shown in the bottom-right portion of Figure 6, does not fully contain an island of f, either.

In conclusion, we still need to account for the situations depicted in the top-left portion of Figure 6. That is, we want to count the number of *special quadrilaterals*, that are defined as follows. First, for any $1 \leq i \leq k$, put $U_i = \bigcup_{j \neq i} P_j$. Similarly, for any $1 \leq i < j \leq k$, let $U_{i,j} = \bigcup_{\ell \neq i,j} P_\ell$.

DEFINITION 1. *A quadrilateral Q is* special *if there exist distinct indices $i, j, \ell \in \{1, \ldots, k\}$ (note that the indices are permuted here, with respect to their usage in the above analysis) such that*

1. $Q \subset \partial P_\ell$,
2. $\mathrm{Int}(Q) \subset \mathrm{Int}(P_i \cap P_j)$,
3. *the vertices a, b, c, d of Q are vertices of ∂U,*
4. $Q \subset \partial U_{i,j}$,
5. $ab, cd \subset \partial P_i \cap \partial U_j$, *and*
6. $bc, ad \subset \partial P_j \cap \partial U_i$.

Figure 7 depicts the situation schematically.

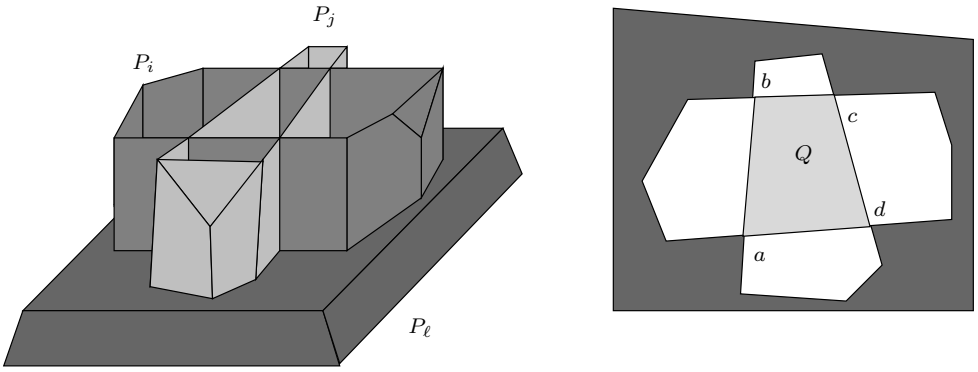

FIG. 7. *A special quadrilateral.*

If we denote the maximum number of such special quadrilaterals, over all collections $\mathcal{P}$ of k convex polyhedra with a total of n faces, by $C^{(2)}(k,n)$, apply the above analysis to each P_i in turn, and sum up the resulting inequalities, we obtain the recurrence

$$(k-2)C^{(1)}(k,n) = \sum_{i=1}^{k} C^{(1)}(k-1, n-n_i) + O(kn + C^{(2)}(k,n)) \,, \tag{4}$$

where the factor $k-2$ appears because, for each level-1 face f, $w(f)$ is counted every time a polyhedron $P \in \mathcal{P}$ is removed and reinserted, except when P is the polyhedron containing f on its boundary or the only polyhedron containing f in its interior.

Lemma 1.6 below provides an $O(k^3+kn)$ bound on $C^{(2)}(k,n)$. Hence, (4) becomes

$$(k-2)C^{(1)}(k,n) \le \sum_{i=1}^{k} C^{(1)}(k-1, n-n_i) + a(k^3+kn) \,,$$

for an appropriate constant a. We claim that the solution of this recurrence is $C^{(1)}(k,n) \le Ak^3 + Bkn\ln k$, where A and B are constants, which we proceed to prove by induction on k. Lemma 1.4 implies that $C^{(1)}(k,n) = O(k^2 n)$, as is easily checked, so choosing B sufficiently large will clearly make our solution valid for $k \le 10$, say. For $k > 10$, the induction hypothesis implies that

$$\begin{aligned}(k-2)C^{(1)}(k,n) &\le \sum_{i=1}^{k} (A(k-1)^3 + B(k-1)(n-n_i)\ln(k-1)) + a(k^3+kn) \\ &\le Ak(k-1)^3 + ak^3 + B(k-1)^2 n\ln(k-1) + akn \,.\end{aligned}$$

Hence it suffices to choose A and B so that

$$Ak(k-1)^3 + ak^3 \le A(k-2)k^3$$

and

$$B(k-1)^2 n\ln(k-1) + akn \le B(k-2)kn\ln k$$

for $k > 10$. The first inequality is equivalent to $ak^2 \le A(k^2-3k+1)$, which will hold if we choose, say, $A > 2a$. The second inequality is equivalent to

$$B\left(1-\frac{1}{k}\right)^2 \ln(k-1) + \frac{a}{k} < B\left(1-\frac{2}{k}\right)\ln k \,,$$

or to

$$\frac{B\ln(k-1)}{k^2}+\frac{a}{k}<B\left(1-\frac{2}{k}\right)\ln\frac{k}{k-1}\ .$$

Since $\ln\frac{k}{k-1}>\frac{1}{k}$ for $k>1$, this inequality is implied by

$$\frac{B\ln(k-1)}{k^2}+\frac{a}{k}<\frac{B}{k}\left(1-\frac{2}{k}\right)$$

or by

$$B\left(1-\frac{2+\ln(k-1)}{k}\right)>a\ ,$$

which holds for $k>10$ if we choose $B>2a$. This completes the proof of our assertion that $C^{(1)}(k,n)<Ak^3+Bkn\ln k$, for appropriate constants A and B. □

It remains to establish the promised upper bound on $C^{(2)}(k,n)$, which is the subject of the following lemma.

LEMMA 1.6. *The number of special quadrilaterals is* $O(k^3+kn)$.

Proof. Consider a special quadrilateral Q. Let $i=i(Q)$, $j=j(Q)$, $\ell=\ell(Q)$ be as in Definition 1. We restrict our attention to special quadrilaterals associated with a particular choice of P_i and P_j, without fixing P_ℓ. Let U' be the set obtained by forming the union of $K=P_i\cap P_j$ with $U_{i,j}$. In other words, we remove these two polyhedra from U and replace them by their intersection. Notice that $\partial Q\subset\partial U'$ and in fact $\partial Q=Q\cap\partial U'$.

A special quadrilateral Q is *trivial* if its boundary is contractible to a point in the closure of $\partial K\setminus U_{i,j}$. Such a contraction defines a "cap" (a topological disk) contained in ∂K and necessarily containing a vertex of K, to which we charge Q. It is easily checked that the caps corresponding to different trivial quadrilaterals form distinct connected components of $\partial K\setminus U_{i,j}$. From Lemma 1.2 we deduce that the number of the corresponding charges, over all choices of i,j, and ℓ, is only $O(kn)$.

We will count the number of those homotopy classes of closed curves in the closure of $\partial K\setminus U_{i,j}$ that contain boundaries of nontrivial quadrilaterals. (See, e.g., [35] for basic material concerning homotopy and related concepts.) By counting classes rather than quadrilaterals we err by a factor of at most 2, because a component of $\partial K\setminus U_{i,j}$, two of whose boundary curves can be continuously transformed into each other without leaving the component, has only two boundary components (since a topological disk with two or more holes has no homotopy-equivalent boundary components).

To carry out the proof, we need a slightly more general formulation of the problem, as follows. Consider a collection $\mathcal{B}=\{B_1,\ldots,B_p\}$ of p convex polyhedra and a collection $\mathcal{K}=\{K_1,\ldots,K_q\}$ of q pairwise-disjoint convex polyhedra. Assume further that no $\mathcal{B}$-polyhedron meets more than one of the $\mathcal{K}$-polyhedra. Let $K=\bigcup\mathcal{K}$ and $B=\bigcup\mathcal{B}$. Two closed curves in the closure $C=C(\mathcal{K},\mathcal{B})$ of $\partial K\setminus B$ are *equivalent* (relative to $(\mathcal{B},\mathcal{K})$) if they are homotopy-equivalent in C. (Here we assume that the components of $\partial K\setminus B$ are sufficiently separated so that a component of the closure is equal to the closure of a component. It is easily checked that in our case this condition holds originally, and that it is maintained inductively.) A closed curve is *trivial* (relative to $(\mathcal{B},\mathcal{K})$) if it is contractible in C to a point, i.e., equivalent to the trivial curve in C. A quadrilateral Q is *nontrivial* if ∂Q is a boundary component of C, ∂Q is not trivial, and Q is contained in the boundary of a $\mathcal{B}$-polyhedron and

avoids the interiors of all $\mathcal{B}$-polyhedra. Notice that this definition of nontriviality is a generalization of the one given above, with $\mathcal{B} = \mathcal{P} \setminus \{P_i, P_j\}$ and $\mathcal{K} = \{P_i \cap P_j\}$. Consider the intersection graph $G = G(\mathcal{B}, \mathcal{K})$ of the polyhedra in $\mathcal{B} \cup \mathcal{K}$, namely, the graph whose vertices are the given polyhedra and whose arcs connect pairs of polyhedra with nonempty intersection. Let $\delta = \delta_G$ be the vertex degree function in G. Let $\bar{\delta}(P) = \max\{\delta(P) - 1, 0\}$. We will prove that the number of homotopy classes of closed paths in C containing the boundary of a nontrivial quadrilateral is at most 2ν, where $\nu = \nu(\mathcal{B}, \mathcal{K}) = \sum_{t=1}^{q} \bar{\delta}(K_t)$. Notice that this claim implies the lemma, because one has, for the original choice of $\mathcal{B}$ and $\mathcal{K}$, $\nu(\mathcal{B}, \mathcal{K}) \leq \delta(P_i \cap P_j) \leq |\mathcal{B}| = k-2$. The argument is repeated for all $1 \leq i < j \leq k$ to yield an $O(k^3)$ bound on the number of nontrivial quadrilaterals.

We proceed by induction on the number of such homotopy classes. The base case, when no nontrivial quadrilaterals exist, is easy, as $\nu \geq 0$ by definition. We now proceed with the general induction step. Let Q be a nontrivial quadrilateral. Without loss of generality, assume that $Q \subset \partial B_1 \cap K_1$. Cut K_1 along Q into two convex portions, and shrink the portion (call it K_1'), that lies in the half-space H bounded by the plane spanned by Q and not containing B_1, slightly away from Q. Extend the other portion (call it K_1'') slightly towards K_1', so that it "pops up" above ∂B_1 but still avoids K_1' and meets only the polyhedra it met before the displacement. See Figure 8 for an illustration. Let $\mathcal{K}' = \mathcal{K} \setminus \{K_1\} \cup \{K_1', K_1''\}$ and $K' = \bigcup \mathcal{K}'$. We have constructed a new instance of the problem, namely $(\mathcal{B}, \mathcal{K}')$. We note that no polyhedron of $\mathcal{B}$ can intersect both portions of K_1 without meeting Q (or, rather, a slight displacement of Q away from B_1), and no polyhedron of $\mathcal{B}$ meets the displaced Q, by assumption. This implies that no $\mathcal{B}$-polyhedron intersects more than one $\mathcal{K}'$-polyhedron, so the new problem satisfies the same assumptions as the old one. We claim that the new problem is "smaller": By definition of a nontrivial quadrilateral, ∂Q cannot be homotopically shrunk to a point in C. On the other hand, Q is clearly trivial in $(\mathcal{B}, \mathcal{K}')$. Moreover, a nontrivial quadrilateral Q' not equivalent to Q in $(\mathcal{B}, \mathcal{K})$ remains nontrivial in $(\mathcal{B}, \mathcal{K}')$—this can be easily deduced by examining the shape of the components of $\partial K \setminus B$ and of $\partial K' \setminus B$ containing $\partial Q'$. However, it is possible for two distinct homotopy classes containing nontrivial quadrilaterals with respect to $(\mathcal{B}, \mathcal{K})$ to merge in $(\mathcal{B}, \mathcal{K}')$. This can happen if the connected component E of C containing Q was topologically equivalent to a disk with two holes, whose three boundary components (one of which is Q) are all nontrivial quadrilaterals; after the splitting at Q, E is transformed into two components, E' and E''. E'' is equivalent to a disk (in fact, $\partial E'' = \partial Q$) and thus does not give rise to a nontrivial quadrilateral, while E' is equivalent to a disk with a single hole and its two bounding quadrilaterals now become homotopic to each other, thus merging two previously distinct classes. This is the only possible merging of homotopy classes, as is easily checked; see Figure 9 for an illustration. Hence the number of classes containing nontrivial quadrilaterals increases by either one or two when we pass from $(\mathcal{B}, \mathcal{K}')$ back to $(\mathcal{B}, \mathcal{K})$.

On the other hand, since Q is nontrivial with respect to $(\mathcal{B}, \mathcal{K})$, ∂Q cannot be shrunk in C by moving along ∂K_1 into the half-space H defined above. Thus K_1' must meet at least one $\mathcal{B}$-polyhedron. Clearly, K_1'' meets B_1 itself. Hence, the degrees of K_1' and of K_1'' in $G' = G(\mathcal{B}, \mathcal{K}')$ are both positive. Thus

$$\bar{\delta}_{G'}(K_1') + \bar{\delta}_{G'}(K_1'') = \delta_{G'}(K_1') - 1 + \delta_{G'}(K_1'') - 1 = \delta_G(K_1) - 2 = \bar{\delta}_G(K_1) - 1.$$

We have used the fact that $\delta_{G'}(K_1') + \delta_{G'}(K_1'') = \delta_G(K_1)$, which follows by observing that the polyhedra of $\mathcal{B}$ that intersect K_1 are exactly those that intersect either K_1'

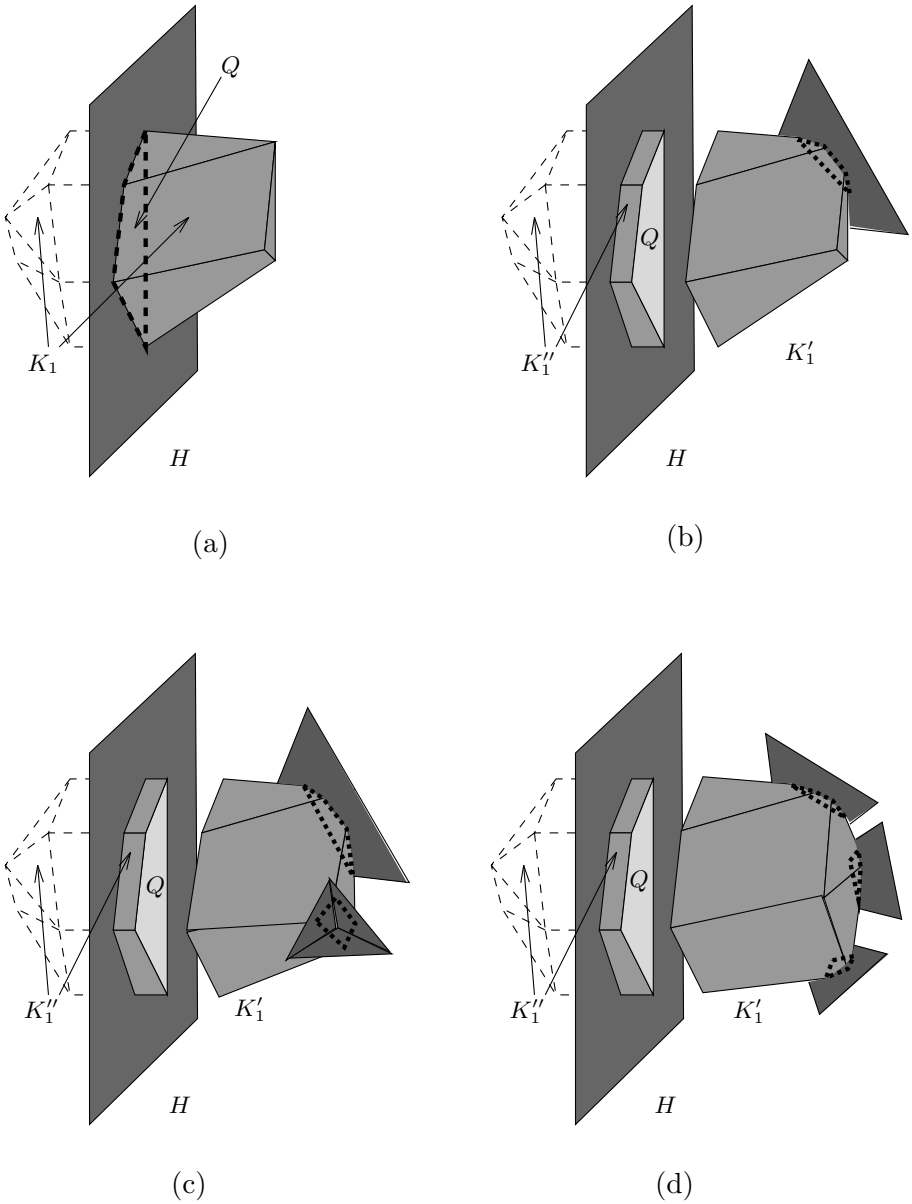

FIG. 8. *Cutting K_1 at a special quadrilateral Q, and the subsequent changes in the homotopy structure. In* (a)*, Q is trivial, so no cut needs to be made. In* (b)*, both Q and the quadrilateral "opposite" to Q become trivial after the cut. In* (c)*, Q becomes trivial, and the homotopy classes of the two adjacent quadrilaterals merge after the cut (this case is also illustrated in Figure* 9*). In* (d)*, Q becomes trivial, and no merges of the homotopy classes of the adjacent quadrilaterals occur.*

or K_1'', and that no polyhedron of $\mathcal{B}$ can intersect both these portions, as argued above. Therefore, $\nu(\mathcal{B},\mathcal{K}) = \nu(\mathcal{B},\mathcal{K}') + 1$, and the increase in 2ν bounds the increase in the number of homotopy classes containing nontrivial quadrilaterals, leading to the desired inequality. This completes the proof of the claim and of the lemma. □

Remarks. (1) The bound given by the last lemma is tight in the worst case. A family $\mathcal{P}$ of polyhedra with $\Omega(k^3)$ special quadrilaterals is given by the gridlike con-

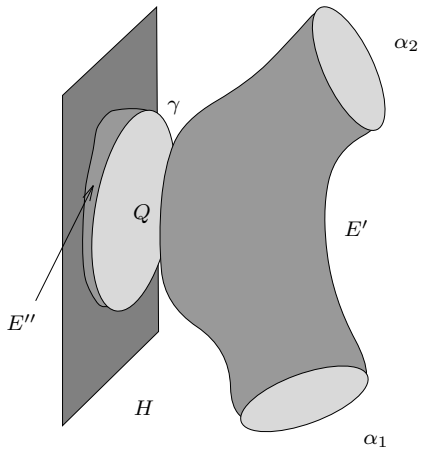

FIG. 9. *A situation where the number of classes decreases by* 2 *as we change* $(\mathcal{B}, \mathcal{K})$ *to* $(\mathcal{B}, \mathcal{K}')$*: The class* γ *containing* ∂Q *becomes trivial and classes* α_1 *and* α_2 *merge after* K_1 *is cut into* K_1' *and* K_1''.

struction in Figure 3(a). A family with $\Omega(kn)$ special quadrilaterals can be obtained as follows: First consider a set consisting of the following three polyhedra. Take P_1 to be any convex polyhedron with n faces. Draw an "X" on each face of P_1 (i.e., a pair of crossing segments) and then lift them slightly away from P_1. Pick one segment out of each pair and form their convex hull; this is polyhedron P_2. The third polyhedron P_3 is the convex hull of the remaining segments. It is easily checked that there is one special quadrilateral associated with each "X," so that this family of three polyhedra with $\Theta(n)$ faces has n special quadrilaterals. Now we repeat the construction but start with a polyhedron P with $\Theta(n/k)$ faces, draw a sufficiently small $k/2 \times k/2$ grid in each face away from the edges of P, lift it outward, and form k new polyhedra by taking convex hulls of collections of segments, one from each grid, thereby exhausting all segments and placing each segment in just one collection. It is easily checked that on each face of P we obtain $k^2/4$ special quadrilaterals, for a total of $\Omega(n/k) \times k^2/4 = \Omega(nk)$. The family consists of $k+1$ polyhedra with $\Theta(n/k) + k \times \Theta(n/k) = \Theta(n)$ faces. The claimed lower bound is attained by combining the two constructions.

(2) It is interesting to note that Lemma 1.6 is the only "source" of the term $O(k^3)$ in the bound for the complexity of the union. See section 3 which mentions an improved bound for an important special case.

We next describe an easy corollary of our main result. Let $\mathcal{P}$ be a collection of k convex polyhedra in general position with a total of n faces. A simple application of the probabilistic technique of [15, 32] yields the following.

THEOREM 1.7. *For any* $1 \le \lambda \le k-2$*, the total number of level-*j *vertices of* $\mathcal{A}(\mathcal{P})$*, for all* $j < \lambda$*, is* $O(k^3 + \lambda kn \log(k/\lambda))$.

Proof. Let $\mathcal{R}$ be a random sample of $r = \lfloor k/\lambda \rfloor$ polyhedra of $\mathcal{P}$. The analysis of [15, 32] implies that the number of inner vertices of $\mathcal{A}(\mathcal{P})$ at level $< \lambda$ is $O(\lambda^3 \mathbf{E}[C_0(\mathcal{R})])$, where $C_0(\mathcal{R})$ is, as above, the number of inner vertices of the union of the polyhedra of $\mathcal{R}$, and where $\mathbf{E}$ denotes expectation with respect to the choice of $\mathcal{R}$. By Theorem 1.1, $C_0(\mathcal{R}) = O(r^3 + rn_{\mathcal{R}} \log r)$, where $n_{\mathcal{R}}$ is the total number of faces of the polyhedra in $\mathcal{R}$. It thus follows that $\mathbf{E}[C_0(\mathcal{R})] = O(r^3 + r \log r \cdot \mathbf{E}[n_{\mathcal{R}}])$. Now $\mathbf{E}[n_{\mathcal{R}}] = O(n/\lambda)$, as any of the n faces of the polyhedra of $\mathcal{P}$ has probability $r/k \le 1/\lambda$ to appear as a face of a polyhedron of $\mathcal{R}$. Hence, the number of vertices

of the above kind that lie at level $< \lambda$ is

$$O\left(\lambda^3 r^3 + \lambda^3 r \log r \cdot \frac{n}{\lambda}\right) = O\left(k^3 + \lambda k n \log \frac{k}{\lambda}\right) .$$

Adding to this estimate the $O(kn)$ bound given in Lemma 1.3 for the number of outer vertices, the theorem follows. □

Remark. When $\lambda = k - 2$, all the vertices of $\mathcal{A}(\mathcal{P})$ are counted in the preceding theorem, and the above bound becomes $O(k^2 n)$, in agreement with Lemma 1.4.

A number of applications of the last result are described in [1]. It is applied there to a geometric pattern matching problem, seeking to determine the rigid translation of one set of points relative to another, which optimizes a certain distance function between the two sets. The paper also describes how the above bound can be used to bound the number of combinatorially distinct Euclidean minimum spanning trees that can be obtained by adding an extra point to a given point set.

2. Efficient construction of the union. We next describe an efficient randomized algorithm for constructing the union U of a collection $\mathcal{P}$ of polyhedra as above. The main idea of the algorithm is quite simple. In principle, we want to insert the given polyhedra one by one in random order and to maintain the union of the polyhedra that have been inserted so far. However, we actually apply the following somewhat modified strategy. First, we compute all pairwise intersections $P_i \cap P_j$, for $1 \le i < j \le k$, by repeated applications of the linear-time algorithm of Chazelle [12] for intersecting two convex polyhedra in 3-space. (A slower algorithm, such as that described in [29, 31], would also suffice for our purposes.) By Lemma 1.3, this takes $O(kn)$ time, and yields, for each face F of any polyhedron P_i, the collection $\mathcal{Q}_F$ of the convex polygons $Q_j = F \cap P_j$, for $j \ne i$. Clearly, the set $U_F = F \setminus \bigcup_{j \ne i} Q_j$ is the portion of F that appears on ∂U, so our goal is to compute the sets U_F, over all faces F. Reconstructing the boundary of U from this information is relatively straightforward, by gluing the portions U_F to each other in an appropriate manner.

Let F be a fixed face of some $P_i \in \mathcal{P}$. We choose a random order of the polyhedra in $\mathcal{P} \setminus \{P_i\}$ and insert the polygons Q_j, one by one, in the corresponding order, maintaining the complement of their union as we go. For this, we use the same technique as in [13, 16, 20, 30], which maintains a vertical decomposition of the complement into trapezoids and a "history dag" of all trapezoids that were ever created by the algorithm. Whenever a new polygon Q_j is inserted, we search through the dag for trapezoids intersected by ∂Q_j and then update the complement of the union by refining the trapezoidal decomposition to reflect the presence of Q_j and by discarding those trapezoids that end up inside Q_j. We refer the reader to the papers cited above for more details. We apply this procedure to every face F of each polyhedron of $\mathcal{P}$, and, as already mentioned, the union of the resulting regions U_F yields the boundary of the desired union U.

The cost of the algorithm is proportional to the number of trapezoids that are created during the execution of the algorithm, plus the initial cost of $O(kn)$ of computing all the collections $\mathcal{Q}_F$, plus the cost of tracing polygons through the history dag. This is more complicated than the standard technique because the number of children of a trapezoid in the dag need not be constant: when a trapezoid τ is "killed" by adding a polygon Q_j, it may be split into many overlapping trapezoids that become its children in the dag. However, when this happens, all but $O(1)$ of these subtrapezoids have a vertex of Q_j as one of their vertices. By Lemma 1.3, the total number of these vertices is only $O(kn)$. Using standard arguments, one can show that the expected

overall number of trapezoids τ that are ever created by the algorithm and contain such a vertex in their interior is $O(kn \log k)$. This allows us to trace the vertices of the inserted polygons Q_j, using a simple binary search mechanism, at a total expected cost of $O(kn \log k \log n)$. With this information available, if the polygon Q_j being inserted intersects an inner trapezoid τ of the dag, it is not difficult to find all the children of τ that it crosses in time proportional to their number. Hence the overall expected cost of tracing polygons through the dag is $O(kn \log k \log n)$ plus the sum of the weights of the trapezoids. Here the *weight* of a trapezoid $\tau \subseteq F$ is the number of polygons $Q_j \in \mathcal{Q}_F$ that intersect the relative interior of τ; each of them either fully contains τ, or is fully contained in τ, or its boundary crosses τ. A "canonical" trapezoid $\tau \subseteq F$ is one that occurs in the trapezoidal decomposition of the complement (within F) of the union of some subset of Q_F. Such a trapezoid is defined by between one and five polyhedra—P_i plus the at most four polyhedra that define its sides and corners in F. The following argument applies only to canonical trapezoids defined by exactly five polyhedra. It has to be repeated, with straightforward modifications, for trapezoids defined by one, two, three, or four polyhedra. Adapting the approach of the papers cited above, and using the Clarkson–Shor analysis technique [15], one easily shows the following.

Claim 1. The probability that a canonical trapezoid $\tau \subseteq F$ with weight w is created during the incremental construction is $1/\binom{w+4}{4}$.

Proof. When the algorithm processes F, the four other polyhedra defining τ have to be inserted before any of the w polyhedra intersecting $\mathrm{Int}(\tau)$ are inserted. □

Claim 2. The overall number T_w of canonical trapezoids with weight less than w, over all faces F of the given polyhedra, is $O(w^2k^3 + w^3kn \log \frac{k}{w})$.

Proof. We use the Clarkson–Shor analysis technique [15]. Since a canonical trapezoid τ is defined by five polyhedra (one of which contains the face F in which τ lies, and the other four define the four sides of τ, as in the papers cited above), it follows that $T_w = O(w^5 \mathbf{E}[T_1(\lceil k/w \rceil)])$, where $\mathbf{E}[T_1(\lceil k/w \rceil)]$ is the expected number of 0-weight trapezoids that arise for a random sample $\mathcal{R}$ of $\lceil k/w \rceil$ polyhedra from $\mathcal{P}$. Clearly, each such trapezoid lies on the boundary of the union $\bigcup \mathcal{R}$, and the expected number of such trapezoids is proportional to the expected complexity of $\bigcup \mathcal{R}$, namely to $O((k/w)^3 + (k/w) \cdot (n/w) \log(k/w))$ (see the proof of Theorem 1.7). The claim is now immediate. □

The expected running time of the algorithm, over all faces F, is thus

$$O\left(kn + \sum_{w=0}^{k-5} \frac{(w+1)t_w}{\binom{w+4}{4}}\right),$$

where t_w is the total number of trapezoids whose weight is exactly w. Since $t_w = T_{w+1} - T_w$ (with $T_0 = 0$), we can rewrite the above sum as

$$\begin{aligned}
&\sum_{w=0}^{k-5} \frac{T_{w+1} - T_w}{(w+4)(w+3)(w+2)} \\
&\quad = \sum_{w=1}^{k-5} T_w \left[\frac{1}{(w+3)(w+2)(w+1)} - \frac{1}{(w+4)(w+3)(w+2)}\right] \\
&\qquad + \frac{T_{k-4}}{(k-1)(k-2)(k-3)}
\end{aligned}$$

$$= O\left(kn + \sum_{w=1}^{k-5} \frac{w^2k^3 + w^3kn\log\frac{k}{w}}{(w+4)(w+3)(w+2)(w+1)}\right)$$

$$= O\left(kn + \sum_{w=1}^{k-5} \frac{k^3}{w^2} + \sum_{w=1}^{k-5} \frac{kn}{w}\log\frac{k}{w}\right)$$

$$= O(k^3 + kn\log^2 k)\ .$$

Hence we have the following.

THEOREM 2.1. *The union of a collection of k convex polyhedra in 3-space with a total of n faces can be computed in randomized expected time $O(k^3 + kn\log k\log n)$.*

Remark. It is worth noting that the algorithm fixes one polyhedron P_i (the one containing the face F), inserts the other polyhedra in random order, and repeats this over all P_i's. Thus the algorithm does not apply a single global insertion order, but this does not affect adversely its analysis.

The following theorem can be proved by an essentially identical argument.

THEOREM 2.2. *Consider a collection $\mathcal{P}$ of k 3-polyhedra with a total of n facets with the property that the union of any subset of k' polyhedra with a total of n' facets has complexity $O(k'n'\log k')$. Then the union of the whole collection can be computed in randomized expected time $O(kn\log k\log n)$.*

3. A motion planning application. A major application where the union of a collection of convex polyhedra in 3-space needs to be computed is that of planning translational motion for a convex polyhedron B in a polyhedral environment. Assume that B has p faces and that the obstacles (the complement of free space) can be represented as k convex polyhedra with pairwise-disjoint interiors, having a total of q faces. For each obstacle polyhedron A_i, for $i = 1, \ldots, k$, we form the *Minkowski sum* $P_i = A_i \oplus (-B)$, and the union U of the k resulting convex polyhedra P_i represents the portion of the *configuration space* of B where it collides with some obstacle; the complement of U is the *free configuration space* of B, which is what we want to compute. See [4, 5] for more details.

If A_i has q_i faces, then P_i has $O(pq_i)$ faces, so the total number of faces of the P_i's is $O(pq)$, where $q = \sum_{i=1}^{k} q_i$. Hence Theorem 1.1 implies that the combinatorial complexity of the free configuration space of B is $O(k^3 + kpq\log k)$. However, in this special case, Lemma 1.6 can be strengthened, using a different topological analysis, to show that there are only $O(kn)$ special quadrilaterals, which in turn implies that the complexity of the free configuration space is only $O(kpq\log k)$. This is proved in a companion paper [8]. Hence, by Theorem 2.2, this space can be constructed in $O(kpq\log k\log\,(pq))$ randomized expected time.

4. Conclusion. In this paper we have obtained almost tight bounds on the maximum complexity of the union of k convex polyhedra with a total of n faces in three dimensions, presented an efficient randomized algorithm for computing the boundary of the union, and mentioned several applications of these results.

The paper raises several open problems. First, we would like to tighten the small remaining gap between the upper and lower bounds for the complexity of the union. We suspect that the logarithmic factor appearing in the upper bound is just an artifact of our proof technique, and conjecture that the lower bound is tight.

Another open problem is to obtain sharp bounds for the complexity of a single component of the complement of the union of k convex polyhedra with a total of n

faces. The result of [5] implies that this complexity is $O(n^2 \log n)$, but we conjecture that the bound is close to $O(kn)$. The lower bound construction in the proof of Theorem 1.1 implies that the complexity of such a component can be $\Omega(nk\alpha(k))$ in the worst case.

It would also be interesting to extend our bounds to higher dimensions. Here is an easy lower bound construction, for any fixed dimension $d > 2$. Let d be even. Consider a planar collection of $k/(d/2)$ polygons with a total of $n/(d/2)$ edges, so that their union has $\Omega(k^2 + n\alpha(k))$ vertices on its boundary [7]. Consider a family of $d/2$ mutually orthogonal 2-flats in d-space. Place one copy of this configuration into each 2-flat and extend each polygon P into a prism in the remaining $d-2$ coordinates (namely, this prism is the Cartesian product of P and the $(d-2)$-space orthogonal to the 2-flat containing P). It is easily verified that the number of vertices of the union of the resulting k prisms, having a total of n facets, is at least $(\Omega(k^2 + n\alpha(k)))^{d/2} = \Omega(k^d + n^{d/2}\alpha^{d/2}(k))$. The construction for odd $d > 3$ is similar, with one of the two-dimensional constructions replaced by the three-dimensional lower bound construction described in section 1, for a total union complexity of $\Omega(k^d + kn^{\lfloor d/2 \rfloor}\alpha^{\lfloor d/2 \rfloor}(k))$. Notice that both bounds are tight at the extremes of the range of k, i.e., when $k = \Theta(1)$ or $k = \Theta(n)$.

Concerning an upper bound, under the assumptions of general position there is an easy argument (see Katona [25] and Kovalev [26] for a more general statement) that shows that the complement of the union of k convex polyhedra in d-space has at most $O(k^d)$ connected components. An upper bound of $O(n^d)$ on the total complexity, where n is the total number of polyhedra facets, is immediate by considering the arrangement induced by the hyperplanes spanned by the polyhedra facets, but this is likely to be a gross overestimate of the true complexity. Indeed, it is pointed out in [1] that the total complexity of the arrangement induced by the facets is $\Theta(k^{\lceil d/2 \rceil} n^{\lfloor d/2 \rfloor})$ in the worst case. How close these bounds are to the true worst-case complexity of the union is not known. Is the preceding lower bound tight or close to being tight?

There are also several algorithmic open problems. One is to obtain an efficient *deterministic* algorithm for constructing the union. Another one is to obtain an efficient technique for point location in the complement of the union of k polyhedra in 3-space with a total of n faces.

STAR UNFOLDING OF A POLYTOPE WITH APPLICATIONS*

PANKAJ K. AGARWAL†, BORIS ARONOV‡, JOSEPH O'ROURKE§, AND CATHERINE A. SCHEVON¶

Abstract. We introduce the notion of a *star unfolding* of the surface $\mathcal{P}$ of a three-dimensional convex polytope with n vertices, and use it to solve several problems related to shortest paths on $\mathcal{P}$.

The first algorithm computes the edge sequences traversed by shortest paths on $\mathcal{P}$ in time $O(n^6\beta(n)\log n)$, where $\beta(n)$ is an extremely slowly growing function. A much simpler $O(n^6)$ time algorithm that finds a small superset of all such edge sequences is also sketched.

The second algorithm is an $O(n^8 \log n)$ time procedure for computing the *geodesic diameter* of $\mathcal{P}$: the maximum possible separation of two points on $\mathcal{P}$ with the distance measured along $\mathcal{P}$.

Finally, we describe an algorithm that preprocesses $\mathcal{P}$ into a data structure that can efficiently answer the queries of the following form: "Given two points, what is the length of the shortest path connecting them?" Given a parameter $1 \le m \le n^2$, it can preprocess $\mathcal{P}$ in time $O(n^6 m^{1+\delta})$, for any $\delta > 0$, into a data structure of size $O(n^6 m^{1+\delta})$, so that a query can be answered in time $O((\sqrt{n}/m^{1/4})\log n)$. If one query point always lies on an edge of $\mathcal{P}$, the algorithm can be improved to use $O(n^5 m^{1+\delta})$ preprocessing time and storage and guarantee $O((n/m)^{1/3}\log n)$ query time for any choice of m between 1 and n.

Key words. convex polytopes, geodesics, shortest paths, star unfolding

1. Introduction.

The widely studied problem of computing shortest paths in Euclidean space amidst polyhedral obstacles arises in planning optimal collision-free paths for a given robot. In two dimensions, the problem has been thoroughly explored and a number of efficient algorithms have been developed; see, e.g., [SS86, Wel85, Mit93, HS93]. However, the problem becomes significantly harder in three dimensions. Canny and Reif [CR87] have shown it to be NP-hard, and the fastest available algorithm runs in singly exponential time [RS89, Sha87]. This has motivated researchers to develop efficient approximation algorithms [Pap85, Cla87, CSY94, HS95] and to study interesting special cases [MMP87, Sha87]. One of the most widely studied special cases is computing shortest paths on the surface of a convex polytope [SS86, MMP87, Mou90]; this problem was originally formulated by H. Dudeney in 1903; see [Gar61, p. 36]. Sharir and Schorr presented an $O(n^3 \log n)$ algorithm

* Received by the editors August 6, 1993; accepted for publication (in revised form) November 27, 1995. for this problem; this algorithm was subsequently improved by Mitchell, Mount, and Papadimitriou [MMP87] to $O(n^2 \log n)$ and then by Chen and Han to $O(n^2)$ [CH90].

In this paper we consider three problems involving shortest paths on the surface $\mathcal{P}$ of a convex polytope in $\mathbb{R}^3$. A shortest path on $\mathcal{P}$ is uniquely identified by its endpoints and by the sequence of edges it encounters. Sharir [Sha87] proved that no more than $O(n^7)$ distinct sequences of edges are actually traversed by the shortest paths on $\mathcal{P}$. This bound was subsequently improved to $\Theta(n^4)$ [Mou85, SO88]. Sharir also gave an $O(n^8 \log n)$ time algorithm to compute an $O(n^7)$ size superset of shortest-path edge sequences. However, computing the exact set of shortest-path edge sequences seems to be very difficult. Schevon and O'Rourke [SO89] presented an algorithm that computes the exact set of all shortest-path edge sequences and also identifies, in logarithmic time, the edge sequences traversed by all shortest paths connecting a given pair of query points lying on edges of $\mathcal{P}$. The sequences can be explicitly generated, if necessary, in time proportional to their length. Their algorithm, however, requires $O(n^9 \log n)$ time and $O(n^8)$ space.[1]

In this paper we propose two edge-sequence algorithms. The first is a simple $O(n^6)$ algorithm to compute a superset of shortest-path edge sequences, thus improving the result of [Sha87]; it is described in section 5. The second computes the exact set of shortest-path edge sequences in $O(n^6 \beta(n) \log n)$ time, where $\beta(\cdot)$ is an extremely slowly growing function. This second algorithm significantly improves the previously mentioned $O(n^9 \log n)$ algorithm. The computation of the collection of all shortest-path edge sequences on a polytope is an intermediate step of several algorithms [Sha87, OS89] and is of interest in its own right.

The second problem studied in this paper is that of computing the *geodesic diameter* of $\mathcal{P}$, i.e., the maximum distance along $\mathcal{P}$ between any two points on $\mathcal{P}$. O'Rourke and Schevon [OS89] gave an $O(n^{14} \log n)$ time procedure for determining the geodesic diameter of $\mathcal{P}$. In [AAOS90], we presented a simpler and faster algorithm whose running time is $O(n^{10})$. Here we improve this to $O(n^8 \log n)$.

The third problem involves answering queries of the following form: "Given $x, y \in \mathcal{P}$, determine the distance between x and y along $\mathcal{P}$." Given a parameter $1 \leq m \leq n^2$, we present a method for preprocessing $\mathcal{P}$, in $O(n^6 m^{1+\delta})$ time, into a data structure of size $O(n^6 m^{1+\delta})$ for any $\delta > 0$, so that a query can be answered in time $O((\sqrt{n}/m^{1/4}) \log n)$. If x is known to lie on an edge of the polytope, the preprocessing and storage requirements are reduced to $O(n^5 m^{1+\delta})$ and the query time becomes $O((n/m)^{1/3} \log n)$ for $1 \leq m \leq n$. Constants of proportionality in the above bounds depend on the choice of δ.

Our algorithms are based on a common geometric concept, the *star unfolding*. Let $x \in \mathcal{P}$ be a point such that the shortest path from x to every vertex of $\mathcal{P}$ is unique. Intuitively, the star unfolding of $\mathcal{P}$ with respect to this point is obtained by removing these n shortest paths from $\mathcal{P}$ and embedding the remaining surface isometrically in the plane. Remarkably, the star unfolding is isometric to a simple planar polygon and the structure of shortest paths emanating from x on $\mathcal{P}$ corresponds to a certain Voronoi diagram in the plane [AO92]. Together with relative stability of the combinatorial structure of the unfolding as x moves within a small neighborhood on $\mathcal{P}$, these properties facilitate the construction of efficient algorithms for the above

[1] A preliminary version of this algorithm [SO88] erroneously claimed a time complexity of $O(n^7 2^{\alpha(n)} \log n)$; this claim was corrected in [SO89]. Hwang, Chang, and Tu [HCT89] suggested a more efficient procedure for solving the same problem, but the key claim (their second Lemma 6) has yet to be convincingly established [Sch89, Chapter 5].

three problems. Although all of the algorithms have high polynomial time complexity as a function of n, they are not so inefficient in relation to the worst-case number of edge sequences, $\Theta(n^4)$.

Chen and Han [CH90] independently discovered the star unfolding and used it for computing the shortest-path information from a single fixed point on the surface of a polytope. The nonoverlap of the unfolding [AO92], however, was not known at the time of their work.

This paper is organized as follows. In section 2, we formalize our terminology and list some basic properties of shortest paths. Section 3 defines the star unfolding and establishes some of its properties. Section 4 sketches an efficient algorithm to compute a superset of all possible shortest-path edge sequences, and in section 5 we present an algorithm for computing the exact set of these sequences; both algorithms are based on the star unfolding. In section 6 we again use the notion of star unfolding to obtain a faster algorithm for determining the geodesic diameter of a convex polytope. Section 7 deals with shortest-path queries. Section 8 contains some concluding remarks and open problems.

2. Geometric preliminaries. We begin by reviewing the geometry of shortest paths on convex polytopes.

Let $\mathcal{P}$ be the surface of a polytope with n vertices. We refer to vertices of $\mathcal{P}$ as *corners*; the unqualified terms *face* and *edge* are reserved for faces and edges of $\mathcal{P}$. We assume that $\mathcal{P}$ is triangulated. This does not change the number of faces and edges of $\mathcal{P}$ by more than a multiplicative constant but does simplify the description of our algorithms.

2.1. Geodesics and shortest paths. A path π on $\mathcal{P}$ that cannot be shortened by a local change at any point in its relative interior is referred to as a *geodesic*. Equivalently, a geodesic on the surface of a convex polytope is either a subsegment of an edge, or a path that (1) does not pass through corners, though it may possibly terminate at them, (2) is straight near any point in the interior of a face, and (3) is transverse to every edge it meets in such a fashion that it would appear straight if one were to "unfold" the two faces incident on this edge until they lie in a common plane; see, for example, Sharir and Schorr [SS86]. The behavior of a geodesic is thus fully determined by its starting point and initial direction. In the following discussion we disregard the geodesics lying completely within a single edge of $\mathcal{P}$. Given the sequence of edges a geodesic crosses and its starting and ending points, the geodesic itself can be obtained by laying out, in order, the faces that it visits in the plane so that adjacent faces share an edge and lie on opposite sides of it, and then by connecting the (images of) the two endpoints with a straight-line segment. In particular, the sequence of traversed edges together with the endpoints completely determine the geodesic.

Trivially, every shortest path along $\mathcal{P}$ is a geodesic and no shortest path meets a face or an edge more than once. We call the length of a shortest path between two points $p, q \in \mathcal{P}$ the *geodesic distance* between p and q, and we denote it by $d(p, q)$. The following additional properties of shortest paths are crucial for our analysis.

LEMMA 2.1 (see Sharir and Schorr [SS86]). *Let π_1 and π_2 be distinct shortest paths emanating from x. Let $y \in \pi_1 \cap \pi_2$ be a point distinct from x. Then either one of the paths is a subpath of the other, or neither π_1 nor π_2 can be extended past y while remaining a shortest path.*

COROLLARY 2.2. *Two shortest paths cross at most once.*

LEMMA 2.3. *If π_1, π_2 are two distinct shortest paths connecting $x, y \in \mathcal{P}$, each of the two connected components of $\mathcal{P} \setminus (\pi_1 \cup \pi_2)$ contains a corner.*

Proof. First, Lemma 2.1 implies that removal of $\pi_1 \cup \pi_2$ splits $\mathcal{P}$ into exactly two components. If one of the two components of $\mathcal{P} \setminus (\pi_1 \cup \pi_2)$ contained no corners, π_1 and π_2 would have to traverse the same sequence of edges and faces. However, there exists at most one geodesic connecting a given pair of points and traversing a given sequence of edges and faces. □

2.2. Edge sequences and sequence trees. A *shortest-path edge sequence* is the sequence of edges intersected by some shortest path π connecting two points on $\mathcal{P}$, in the order met by π. Such a sequence is *maximal* if it cannot be extended in either direction while remaining a shortest-path edge sequence; it is *half-maximal* if no extension is possible at one of the two ends. It has been shown by Schevon and O'Rourke [SO88] that the maximum total number of half-maximal sequences is $\Theta(n^3)$.

Observe that every shortest-path edge sequence σ is a prefix of some half-maximal sequence, namely, the one obtained by extending σ maximally at one end. Thus an exhaustive list of $O(n^3)$ half-maximal sequences contains, in a sense, all the shortest-path edge-sequence information of $\mathcal{P}$. More formally, given an arbitrary collection of edge sequences emanating from a fixed edge e, let the *sequence tree* Σ of this set be the tree with all distinct nonempty prefixes of the given sequences as nodes, with the trivial sequence consisting solely of e as the root, and such that σ is an ancestor of σ' in the tree if and only if σ is a prefix of σ' [HCT89]. The $\Theta(n^3)$ bound on the number of half-maximal sequences implies that the collection of $O(n)$ sequence trees obtained by considering all shortest-path edge sequences from each edge of $\mathcal{P}$ has, in turn, a total of $\Theta(n^3)$ leaves and $\Theta(n^4)$ nodes in the worst case.

2.3. Ridge trees and the source unfolding. The shortest paths emanating from a fixed source $x \in \mathcal{P}$ cover the surface of $\mathcal{P}$ in a way that can be naturally represented by "unfolding" the paths to a planar layout with respect to x. This unfolding, the "source unfolding," has been studied since the turn of the century. We will define it precisely in a moment. A second way to organize the paths in the plane is the "star unfolding," to be defined in section 3. This is not quite as natural and is of more recent lineage. Our algorithms will be built around the star unfolding, but some of the arguments do refer to the source unfolding as well.

Given two points x, y on $\mathcal{P}$, $y \in \mathcal{P}$ is a *ridge point* with respect to x if there is more than one shortest path between x and y. Ridge points with respect to x form a *ridge tree* T_x embedded on $\mathcal{P}$,[2] whose leaves are corners of $\mathcal{P}$, and whose internal vertices have degree at least three and correspond to points of $\mathcal{P}$ with three or more distinct shortest paths to x. In a degenerate situation where x lies on the ridge tree for some corner p, then p will not be a leaf of T_x, but rather will become a degree-2 vertex in T_x; so in general not all corners will appear as leaves of T_x. We define a *ridge* as a maximal subset of T_x consisting of points with exactly two distinct shortest paths to x and containing no corners of $\mathcal{P}$. These are the "edges" of T_x. Ridges are open geodesics [SS86]; a stronger characterization of ridges is given in Lemma 2.4. Fig. 1 shows two views of a ridge tree on a pyramid.

We will refer to a point $y \in \mathcal{P}$ as a *generic* point if it is not a ridge point with respect to any corner of $\mathcal{P}$. The maximal connected portion of a face (resp., an edge) of $\mathcal{P}$ consisting entirely of generic points will be called a *ridge-free region* (resp., an *edgelet*); see Fig. 2.

If we cut $\mathcal{P}$ along the ridge tree T_x and isometrically embed the resulting set in

[2] For smooth surfaces (Riemannian manifolds), the ridge tree is known as the "cut locus" [Kob67].

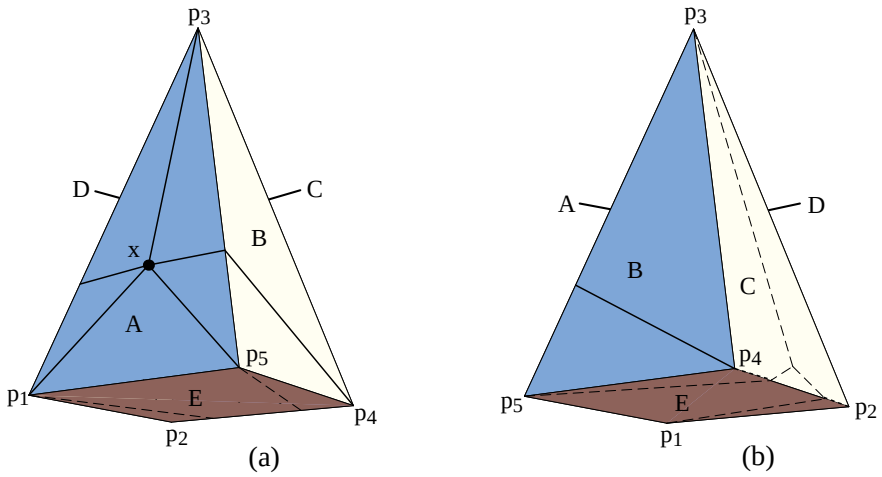

FIG. 1. *Pyramid, front* (a) *and side* (b) *views. Shortest paths to five vertices from source* x *are shown solid; the ridge tree is dashed. Coordinates of vertices are* $(\pm 1, \pm 1, 0)$ *for* p_1, p_2, p_4, p_5*, and* $p_3 = (0, 0, 4)$*;* $x = (0, 3/4, 1)$*. The ridges incident to* p_2 *and* p_4 *lie nearly on the edge* p_2p_4*.*

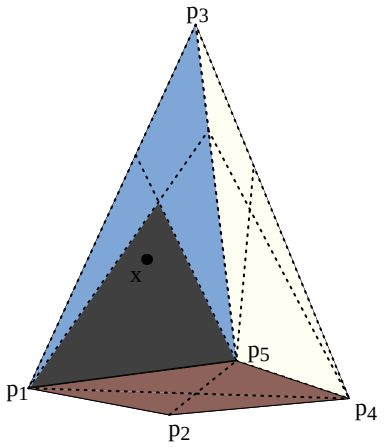

FIG. 2. *Ridge-free regions for Fig.* 1. $T_{p_1} \cup \cdots \cup T_{p_5}$ *are shown dashed (e.g.,* T_{p_3} *is the "X" on the bottom face). The ridge-free region containing* x *is shaded darker.*

$\mathbb{R}^2$, we obtain the *source unfolding* of [OS89].[3] In the source unfolding, the ridges lie on the boundary of the unfolding, while x lies at its "center," which results in a star-shaped polygon [SS86]; see Fig. 3. Let a *peel* be the closure of a connected component of the set obtained by removing from $\mathcal{P}$ both the ridge tree T_x and the shortest paths from x to all corners. A peel is isometric to a convex polygon [SS86]. Each peel's boundary consists of x, the shortest paths to two "consecutive" corners of $\mathcal{P}$, p and p', and the unique path in T_x connecting p to p'. A peel can be thought of as the collection of all the shortest paths emanating from x between xp and xp'. (The peel between xp_1 and xp_5 is shaded in Fig. 3.)

[3] The same object is called $U(\mathcal{P})$ in [SS86], "planar layout" in [Mou85], and "outward layout" in [CH90]. For Riemannian manifolds, it is the "exponential map" [Kob67].

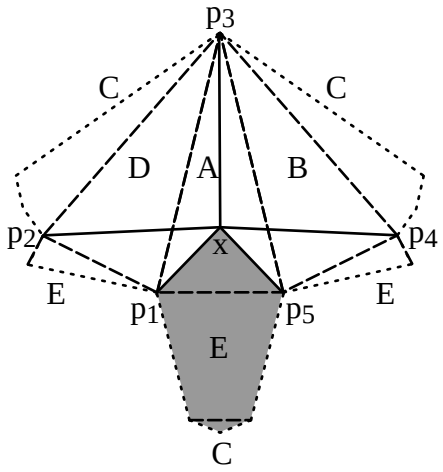

FIG. 3. *Source unfolding for the example in Fig.* 1. *Shortest paths to vertices are solid, polytope edges are dashed, and ridges are dotted. One peel is shaded.*

We need to strengthen the characterization of ridges from geodesics to shortest paths, in order to exploit Corollary 2.2. This characterization seems to be new.

LEMMA 2.4. *Every ridge of the ridge tree T_x, for any point $x \in \mathcal{P}$, is a shortest path.*

Proof. An edge π of the ridge tree is an (open) geodesic consisting of points that have two different shortest paths to x [SS86]. Suppose π is not a shortest path. Then, since it is composed of segments, it contains shortest paths, and in particular, a shortest path π' delimited by two points $a, b \in \pi$ such that there is another shortest path π'' connecting them. Refer to Fig. 4. By Lemma 2.1, $\pi' \cap \pi'' = \{a, b\}$. Let α_1 and α_2 be the two shortest paths from x to a, and let β_1 and β_2 be the two shortest paths from x to b. Notice that, by Lemma 2.1, π', α_1, α_2, β_1, β_2 do not meet except at the endpoints. In particular, we can relabel these paths so that α_2 and β_2 lie in the same connected component of $\mathcal{P} - (\alpha_1 \cup \beta_1 \cup \pi')$. There are two cases to consider.

Case 1. $x \notin \pi''$. Thus, by Lemma 2.1, π'' does not meet α_1 or α_2 except at a. Similarly, π'' does not meet β_1 or β_2 except at b. Thus, without loss of generality, we can assume that π'' lies in the portion Δ of $\mathcal{P}$ bounded by π', α_1, and β_1, and not containing α_2 or β_2. Since α_1, β_1 are shortest paths from x to a and b, respectively, their relative interiors do not intersect T_x. Moreover, π' does not contain a vertex of T_x, so Δ does not contain any corner of $\mathcal{P}$, as each corner is a vertex of T_x. On the other hand, paths $\pi', \pi'' \subset \Delta$ are distinct shortest paths connecting a to b, so by Lemma 2.3 each of the two connected components of $\mathcal{P} \setminus (\pi' \cup \pi'')$ has to contain a corner of $\mathcal{P}$. However, one of these components is entirely contained in Δ—a contradiction.

Case 2. $x \in \pi''$. As π'' and α_1 can be viewed as emanating from a and having x in common, and π'' extends past x, Lemma 2.1 implies that α_1 is a prefix of π''. Similarly, α_2 is a prefix of π'', contradicting distinctness of α_1 and α_2. □

Remark. Case 2 in the above proof is vacuous if x is a corner, which is the case in our applications of this lemma.

As defined, T_x is a tree with n vertices of degree less than 3 and thus has $\Theta(n)$ vertices and edges. However, the worst-case combinatorial size of T_x jumps from $\Theta(n)$

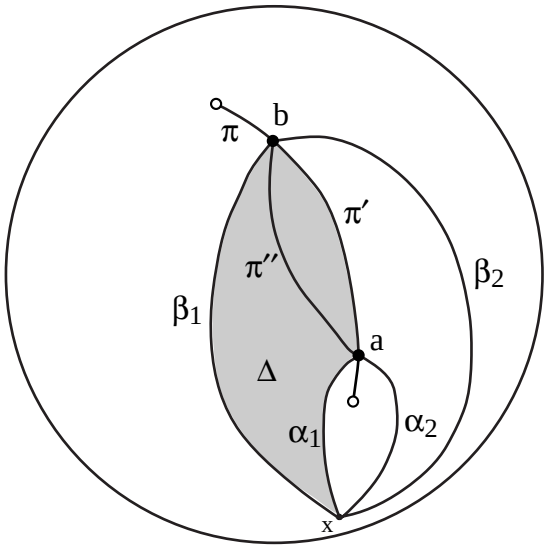

FIG. 4. *Illustration of the proof of Lemma* 2.4. *Here x is the source, and π a geodesic ridge, with $\pi' \subseteq \pi$ a shortest path. The region Δ cannot contain any vertices of $\mathcal{P}$.*

to $\Theta(n^2)$ if one takes into account the fact that a ridge is a shortest path comprised of as many as $\Theta(n)$ line segments on $\mathcal{P}$ in the worst case—and it is possible to exhibit a ridge tree for which the number of ridge-edge incidences is indeed $\Omega(n^2)$ [Mou85]. For simplicity we assume that ridges intersect each edge of $\mathcal{P}$ transversely.

3. Star unfolding. In this section we introduce the notion of the *star unfolding* of $\mathcal{P}$ and describe its geometric and combinatorial properties. Working independently, both Chen and Han [CH90, CH91] and Rasch [Ras90] have used the same notion, and in fact the idea can be found in Aleksandrov's work [Ale58, p. 226], [AZ67, p. 171].

3.1. Geometry of the star unfolding. Let $x \in \mathcal{P}$ be a generic point so that there is a unique shortest path connecting x to each corner of $\mathcal{P}$. These paths are called *cuts* and are comprised of *cut points* (see Fig. 1). If $\mathcal{P}$ is cut open along these cuts the result is a two-dimensional complex that we call the *star unfolding* S_x. If isometrically embedded in the plane, the star unfolding corresponds to a simple polygon. That the star unfolding can be embedded in the plane without overlap is by no means a straightforward claim; it was first established in [AO92] as the following lemma.

LEMMA 3.1 (see Aronov and O'Rourke [AO92]). *If viewed as a metric space with the natural definition of interior metric, S_x is isometric to a simple polygon in the plane (with the internal geodesic metric).*

The polygonal boundary ∂S_x consists entirely of edges originating from cuts. The vertices of S_x derive from the corners of $\mathcal{P}$ and from the source x. An example is shown in Fig. 5. More complex examples will be shown in Fig. 7.

The cuts partition the faces of $\mathcal{P}$ into subfaces, which map to what we call the *plates* of S_x. Since we assume the faces of $\mathcal{P}$ to be triangles, each plate is a compact convex polygon with at most six edges; see Fig. 6(b). We consider these plates to be the faces of the two-dimensional complex S_x. We assume that the complex carries with it labeling information consistent with $\mathcal{P}$.

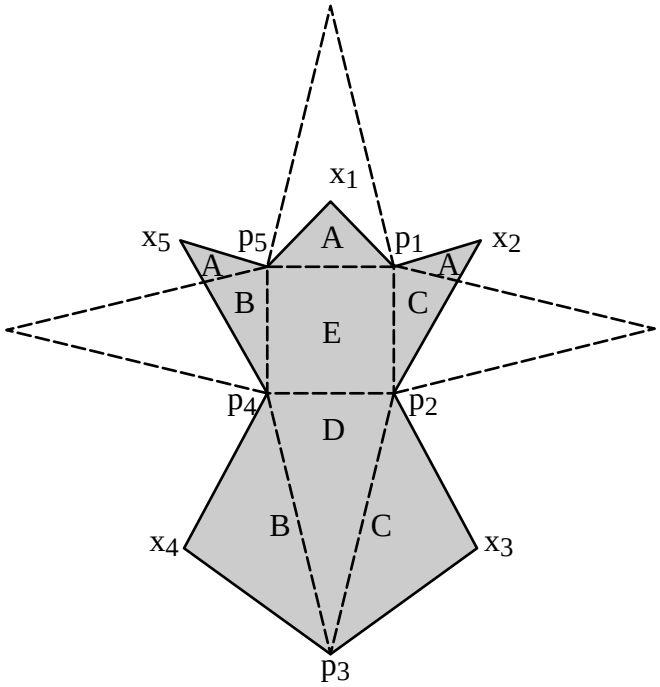

FIG. 5. *Construction of the star unfolding corresponding to Fig.* 1. *S_x is shaded. The superimposed dashed edges show the "natural" unfolding obtained by cutting along the four edges incident to p_3. The A, B, C, D, and E labels indicate portions of S_x derived from those faces.*

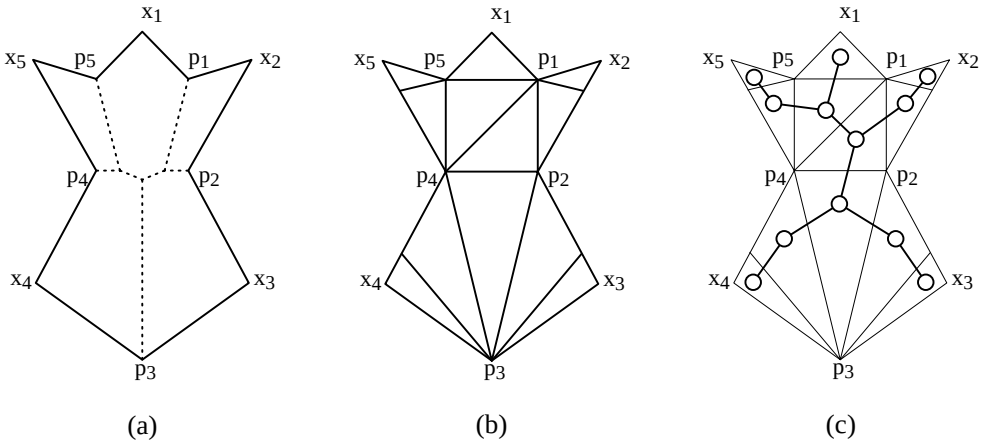

FIG. 6. (a) *Ridge tree,* (b) *plates, and* (c) *pasting tree corresponding to Fig.* 5.

Somewhat abusing the notation, we will freely switch between viewing S_x as a complex and as a simple polygon embedded in the plane. In particular, a path $\pi \subset S_x$ will be referred to as a *segment* if it corresponds to a straight-line segment in this embedding. Note that every segment in S_x is a shortest path in the intrinsic metric of the complex, but not every shortest path in S_x is a segment, as some shortest paths in S_x might bend at corners.

For $p \in \mathcal{P}$, let $U(p)$ be the set of points in S_x to which p maps; U is the "unfolding" map (with respect to x). $U(p)$ is a single point whenever p is not a cut point. A non-corner point $y \in \mathcal{P}$ distinct from x and lying on a cut has exactly two unfolded images in S_x. The corners of $\mathcal{P}$ map to single points. $X = U(x) = \{x_1, \ldots, x_n\}$ is a set of n distinct points in S_x. If $|U(p)| = 1$, then, with a slight abuse of notation, we use $U(p)$ to denote the unique image of p as well. We can extend the definition of the map U to sets in a natural way by putting $U(Q) = \bigcup_{q \in Q} U(q)$. In particular, we have the following lemma.

LEMMA 3.2 (see Sharir and Schorr [SS86]). *For a point $y \in \mathcal{P}$, any shortest path π from x to y maps to a segment $\pi^* \subset S_x$ connecting an element of $U(y)$ to an element of $U(x)$.*

There is also a view of S_x that relates it to the source unfolding: the star unfolding is just an "inside-out" version of the source unfolding, in the following sense. The star unfolding can be obtained by stitching peels together along ridges; see Fig. 6(a). The source unfolding is obtained by gluing them along the cuts; compare this with Fig. 3. (A "peel" was defined in section 2.3 as a subset of $\mathcal{P}$, but by slightly abusing the terminology we also use this term to refer to the corresponding set of points in the source or star unfolding.)

We next define the *pasting tree* Π_x as the graph whose nodes are the plates of S_x, with two nodes connected by an arc if the corresponding plates share an edge in S_x; see Fig. 6(c). For a generic point x, Π_x is a tree with $O(n^2)$ nodes, as it is the dual of a convex partition of a simple polygon without Steiner points. (If x were a ridge point of some corner, S_x would not be connected and Π_x would be a forest.) Π_x has only n leaves corresponding to the triangular plates incident to the n images of x in S_x. By Lemma 3.2, any shortest path from x to $y \in \mathcal{P}$ corresponds to a simple path in Π_x, originating at one of the leaves. Thus, the $O(n^3)$ edge sequences corresponding to the simple paths that originate from leaves of Π_x include all shortest-path edge sequences emanating from x. In fact, there are $O(n^2)$ maximal edge sequences in this set, one for each pair of leaves. This relation between Π_x and the shortest-path sequences is crucial in our sequence algorithms described in sections 4 and 5.

In the following sections we will need the concept of the "kernel" of a star unfolding. Number the corners $p_1, \ldots, p_n$ in the order in which cuts emanate from x. Number the n source images (elements of $X = U(x)$) so that ∂S_x is the cycle $x_1 p_1 x_2 \ldots p_n x_1$ comprised of $2n$ segments (see Fig. 5). The kernel is a subset of S_x; here it is more convenient to view S_x as a simple polygon. Consider the polygonal cycle $p_1 p_2 \ldots p_n p_1$. We claim that it is the boundary of a simple polygon fully contained in S_x. Indeed, each line segment $p_i p_{i+1}$[4] is fully contained in the peel sandwiched between $x_{i+1} p_i$ and $x_{i+1} p_{i+1}$. Thus, the line segments $p_i p_{i+1}$ are segments in S_x, in the sense defined above, and indeed form a simple cycle. The simple n-gon bounded by this cycle is referred to as the *kernel* K_x of the star unfolding S_x. An equivalent way of defining K_x is by removing from S_x all triangles $\triangle p_{i-1} x_i p_i$ for $i = 1, \ldots, n$. As with S_x, we will alternate between viewing K_x as a complex and as a simple polygon in the plane. Fig. 7 illustrates the star unfolding and its kernel for several randomly generated polytopes.[5] Note that neither set is necessarily star-shaped.

The main property of the kernel that we will later need is described in the following lemma.

[4] Here and thereafter $p_{n+1} = p_1$, $p_0 = p_n$, $x_{n+1} = x_1$, $x_0 = x_n$.

[5] The unfoldings were produced with code written by Julie DiBiase and Stacia Wyman of Smith College.

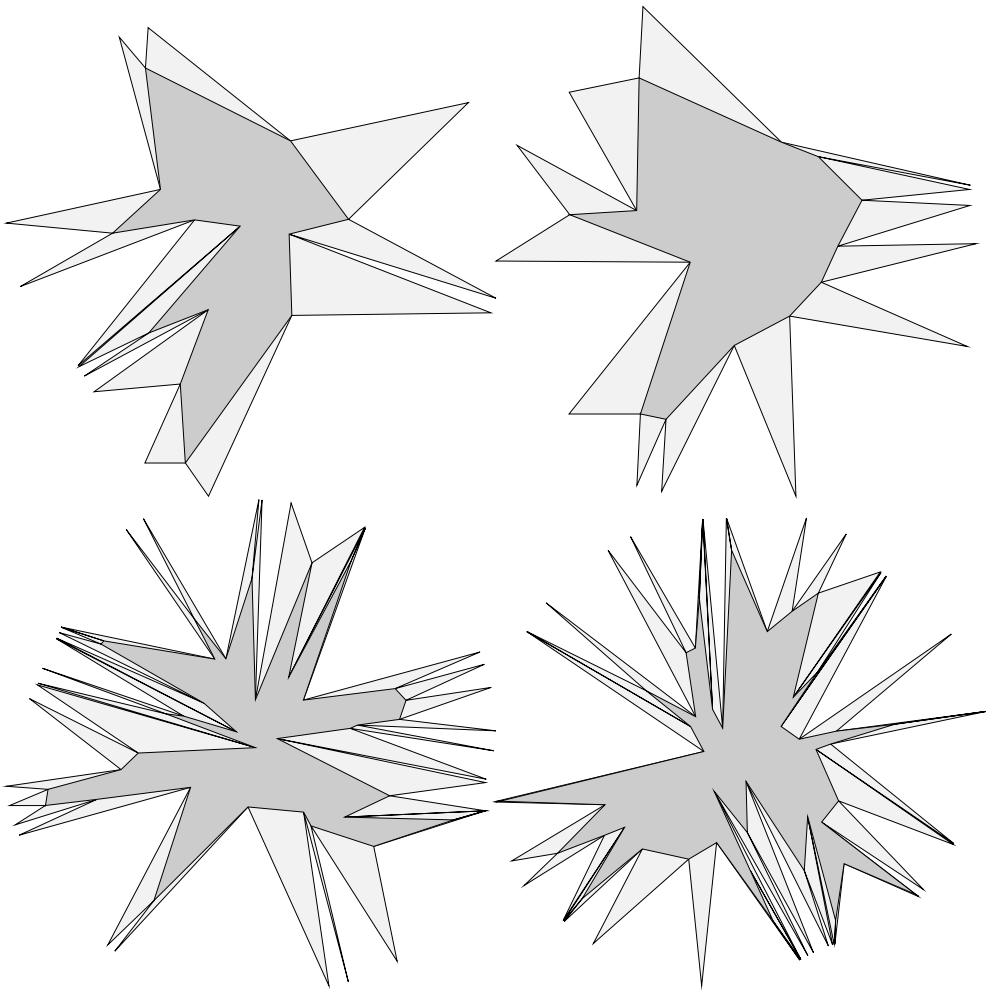

FIG. 7. *Four star unfoldings:* $n = 13, 13, 36, 42$ *vertices, left to right, top to bottom. The kernel is shaded darker in each figure.*

LEMMA 3.3. *The image of the ridge tree is completely contained within the kernel, which is itself a subset of the star unfolding:* $U(T_x) \subset K_x \subset S_x$.

Proof. Since K_x can be defined by subtraction from S_x, $K_x \subset S_x$ is immediate. The ridge tree T_x can be thought of as the union of the peel boundaries that do not come from cuts. As peels are convex, these boundaries remained when we removed triangles $\triangle p_{i-1}x_ip_i$ from S_x to form K_x. □

Aronov and O'Rourke [AO92] proved the following theorem.

THEOREM 3.4. $U(T_x)$ *is exactly the restriction of the planar Voronoi diagram of the set* $X = U(x)$ *of source images to within* K_x *or, equivalently, to within* S_x.

3.2. Structure of the star unfolding. We now describe the combinatorial structure of S_x. A *vertex* of S_x is an image of x, of a corner of $\mathcal{P}$, or of an intersection of an edge of $\mathcal{P}$ with a cut. An *edge* of S_x is a maximal portion of an image of a cut or an edge of $\mathcal{P}$ delimited by vertices of S_x. It is easy to see that S_x consists of $\Theta(n^2)$ plates in the worst case, even though its boundary is formed by only $2n$ segments, i.e.,

the images of the cuts. We define the *combinatorial structure* of S_x as the 1-skeleton of S_x, i.e., the graph whose nodes and arcs are the vertices and edges of S_x, labeled in correspondence with the labels of S_x, which are in turn derived from labels on $\mathcal{P}$. The combinatorial structure of a star unfolding has the following crucial property.

LEMMA 3.5. *Let x and y be two noncorner points lying in the same ridge-free region or on the same edgelet. Then S_x and S_y have the same combinatorial structure.*

Proof. Let f be the face containing the segment xy in its interior. The case when xy is part of an edge is similar.

As the shortest paths from any point $z \in xy$ to the corners are pairwise disjoint except at z (cf. Lemma 2.1) and z is confined to f, the combinatorial structure of S_z is uniquely determined by

(1) the circular order of the cuts around z, and
(2) the sequence of edges and faces of $\mathcal{P}$ met by each of the cuts.

We will show that (1) and (2) are invariants of S_z as long as $z \in xy$ does not cross a ridge or an edge of $\mathcal{P}$. First, the set of points of f, for which some shortest path to a fixed corner p traverses a fixed edge sequence, is convex—it is simply the intersection of f with the appropriate peel with respect to p—implying invariance of (2).

Now suppose the circular order of the cuts around z is not the same for all $z \in xy$. The initial portions of the cuts, as they emanate from any z, cannot coincide, as distinct cuts are disjoint except at z. Hence there can be a change in this circular order only if one of the vectors pointing along the initial portion of the cuts changes discontinuously at some intermediate point $z' \in xy$. However, this can happen only if z' is a ridge point with respect to a corner, and is therefore a contradiction. □

This lemma holds under more general conditions. Namely, instead of requiring that xy be free of ridge points, it is sufficient to assume that the number of distinct shortest paths connecting z to any corner does not change as z varies along xy (this number is larger than 1 if xy is a portion of a ridge).

LEMMA 3.6. *Under the assumptions of Lemma* 3.5*, K_x is isometric to K_y; i.e., they are congruent simple polygons.*

Proof. K_x is determined by the order of corners on $\partial K_x = p_1p_2, \ldots, p_np_1$ and, for each i, by the choice of the shortest path p_ip_{i+1}, if there are two or more such paths. The ordering is fixed once combinatorial structure of S_x is determined. The choice of the shortest path connecting p_i to p_{i+1} is determined by the constraint that $\triangle p_{i-1}x_ip_i$ is free of corners. □

Let R be a ridge-free region. By the above lemma, S_x can be embedded in the plane in such a way that the images of the corners of $\mathcal{P}$ are fixed for all $x \in R$, while the images of x in S_x move as x varies in $R \subseteq \mathcal{P}$. This guarantees that $K_y = K_x$ for all $x, y \in R$. This is illustrated in Fig. 8. In what follows, we will assume such an embedding of S_x and use K_R to denote K_x for all points $x \in R$. Similarly, define K_ε for an edgelet ε.

3.3. The number of different unfoldings. For the algorithms described in this paper, it will be important to bound the number of different possible combinatorial structures of star unfoldings, as we vary the position of source point x, and to compute these unfoldings efficiently (more precisely, compute their combinatorial structure plus some metric description, parameterized by the exact position of the source), as the source moves on the surface of the polytope. Two variants of this problem will be needed. In the first, we assume that the source is placed on an edge of $\mathcal{P}$, and in the second the source is placed anywhere on $\mathcal{P}$. In view of Lemma 3.5,

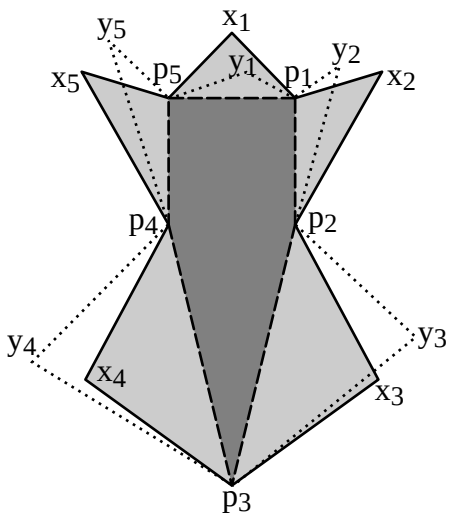

FIG. 8. *The star unfolding when the source x moves to y inside a ridge-free region. The unfolding S_x (Fig. 5) is shown lightly shaded; S_y is shown dotted. Their common kernel $K_x = K_y$ is the central dark region.*

it suffices to bound the number of edgelets and ridge-free regions, respectively.

LEMMA 3.7. *In the worst case, there are $\Theta(n^3)$ edgelets and they can be computed in $O(n^3 \log n)$ time.*

Proof. Each edge can meet a ridge of the ridge tree of a corner at most once, since ridges are shortest paths (recall that we assume that no ridge overlaps an edge—removal of this assumption does not invalidate our argument but only adds a number of technical complications). This gives an upper bound of $n \times O(n) \times O(n)$ on the number of edge-ridge intersections and therefore on the number of edgelets. An example of a convex polytope with $\Omega(n^3)$ edgelets is relatively easy to construct by modifying the lower bound construction of Mount [Mou90].

To compute the edgelets, we construct ridge trees from every corner in $n \times O(n^2)$ time by n applications of the algorithm of Chen and Han [CH90]. The edgelets are now computed by sorting the intersections with ridges along each edge. □

LEMMA 3.8. *In the worst case, there are $\Theta(n^4)$ ridge-free regions on $\mathcal{P}$. They can be computed in $\Theta(n^4)$ time.*

Proof. The overlay of n ridge trees, one from each corner of $\mathcal{P}$, produces a subdivision of $\mathcal{P}$ in which every region is bounded by at least three edges (cf. Fig. 2). Thus, by Euler's formula, the number of regions in this subdivision is proportional to the number of its vertices, which we proceed to estimate.

By Lemma 2.4 ridges are shortest paths and therefore two of them intersect in at most two points (cf. Corollary 2.2) or overlap. In the latter case no new vertex of the subdivision is created, so we restrict our attention to the former. In particular, as there are $n \times O(n) = O(n^2)$ ridges, the total number of their intersection points is $O(n^4)$. Refining this partition further by adding the edges of $\mathcal{P}$ does not affect the asymptotic complexity of the partition, as ridges intersect edges in a total of $O(n^3)$ points (cf. Lemma 3.3). This establishes the upper bound.

It is easily checked that there are $\Omega(n^4)$ ridge-free regions in Mount's example of a polytope with $\Omega(n^4)$ shortest-path edge sequences [Mou90]. Hence there are $\Theta(n^4)$

ridge-free regions on $\mathcal{P}$ in the worst case.

The ridge-free regions can be computed by calculating the ridge tree for every corner and overlaying the trees in each face of $\mathcal{P}$. The first step takes $O(n^3)$ time, while the second step can be accomplished in time $O((r+n^3)\log n) = O(n^4 \log n)$, where r is the number of ridge-free regions in $\mathcal{P}$, using the line-sweep algorithm of Bentley and Ottmann [BO79]. If computing the ridge-free regions is a bottleneck, the last step can be improved to $O(n^4)$ by using a significantly more complicated algorithm of Chazelle and Edelsbrunner [CE92]. (See also [CS89, Ba95].) □

3.4. Encoding ridge trees. In section 3.1, we proved that the combinatorial structure of S_x is the same for all points x in a ridge-free region. As x moves in a ridge-free region, the ridge tree T_x changes continuously (in the Hausdorff metric) as a subset of $\mathcal{P}$. In this subsection, we prove an upper bound on the number of different combinatorial structures of T_x as the source point x varies over a ridge-free region or an edgelet. In fact, we are interested not so much in counting the number of distinct ridge trees as we are in representing all possible ridge trees compactly to, for example, extract all vertices that ever occur in the ridge trees. Apart from being interesting in their own right, these results are needed in the algorithms described in sections 5–7.

Let R be a ridge-free region, and let x be a point in R. By Theorem 3.4, T_x is the Voronoi diagram $\mathcal{V}_x$ of the set $X = U(x)$ of images of x clipped to lie within K_R. Since ridge vertices do not lie on ∂S_x, all changes in T_x, as x varies in R, can be attributed to changes in $\mathcal{V}_x$. Thus it suffices to distinguish distinct combinatorial structures of Voronoi diagrams $\mathcal{V}_x$, $x \in R$. Here, by "combinatorial complexity" we mean an enumeration of vertices, edges, and regions of the Voronoi diagram, together with incidence relations between them.

Let $X = U(x) = \{x_1, \ldots x_n\}$. For each $x_i = (x_{i1}, x_{i2})$, let

$$f_i(y) = d(x_i, y) = \sqrt{(x_{i1} - y_1)^2 + (x_{i2} - y_2)^2}\,,$$

where (y_1, y_2) are the coordinates of a generic point y in the plane. Let

$$f(y) = \min_{1 \le i \le n} f_i(y)$$

be the *lower envelope* of the f_i's. Then $\mathcal{V}_x$ is the same as (the 1-skeleton of) the orthogonal projection of the graph of $f(y)$ onto the y_1y_2-plane, labeled with the name(s) of the function(s) attaining the minimum at each point.

We introduce an orthogonal coordinate system in R and let x have coordinates (s,t) in this system. Then positions of x_i are linear functions of s, t of the form

$$\begin{pmatrix} x_{i1} \\ x_{i2} \end{pmatrix} = \begin{pmatrix} a_i \\ b_i \end{pmatrix} + \begin{pmatrix} \cos\theta_i & \sin\theta_i \\ -\sin\theta_i & \cos\theta_i \end{pmatrix} \begin{pmatrix} s \\ t \end{pmatrix}, \tag{1}$$

where (a_i, b_i) are coordinates of x_i when x is at the origin of the (s,t) coordinate system in R, and θ_i defines the orientation of the ith image of R in the plane.

We now regard f and f_i's as 4-variate functions of s, t, y_1, y_2, and denote by M_R the (labeled) projection of the graph of f onto the (s, t, y_1, y_2)-plane. All possible combinatorial structures of $\mathcal{V}_x$, as x varies over the entire plane, are obviously encoded in M_R, as the diagram for $x = (\alpha, \beta)$ is simply the (1-skeleton) of the cross section of M_R by the 2-flat $s = \alpha$, $t = \beta$. Let

$$g_i(s, t, y_1, y_2) = (f_i(y_1, y_2))^2 - (s^2 + t^2 + y_1^2 + y_2^2)\,. \tag{2}$$

Using (1) we obtain

$$g_i(s,t,y_1,y_2) = C_i^{(0)} + C_i^{(1)}y_1 + C_i^{(2)}y_2 + C_i^{(3)}s + C_i^{(4)}t + C_i^{(5)}sy_1 + C_i^{(6)}sy_2 + C_i^{(7)}ty_1 + C_i^{(8)}ty_2, \tag{3}$$

where, for each i, the C_i's are constants that depend solely on a_i, b_i, and θ_i. Let $g(s,t,y_1,y_2)$ denote the lower envelope of the g_i's. Since $g(s,t,y_1,y_2) = (f(s,t,y_1,y_2))^2 - (s^2+t^2+y_1^2+y_2^2)$, the projection of the graph of g is the same as M_R. Let

$$v_1 = sy_1,\ v_2 = sy_2,\ v_3 = ty_1,\ v_4 = ty_2 \tag{4}$$

and set

$$\bar{g}_i(s,t,y_1,y_2,v_1,v_2,v_3,v_4) = C_i^{(0)} + C_i^{(1)}y_1 + C_i^{(2)}y_2 + C_i^{(3)}s + C_i^{(4)}t + C_i^{(5)}v_1 + C_i^{(6)}v_2 + C_i^{(7)}v_3 + C_i^{(8)}v_4. \tag{5}$$

Then every face of the graph of g is the intersection of the lower envelope of $\bar{g}_i$'s with the surface defined by equation (4). Since each $\bar{g}_i$ is an 8-variate linear function, by the upper bound theorem for convex polyhedra, the graph of their lower envelope has $O(n^4)$ faces of all dimensions (and in fact can be triangulated by using $O(n^4)$ simplices). Hence the number of faces in M_R is also $O(n^4)$. Using the algorithm of Brönnimann, Chazelle, and Matoušek [BCM94], all the faces of this lower envelope, and thus all the edges and vertices of M_R, can be computed in $O(n^4)$ time. (Using the triangulation mentioned above, one could compute a representation of all faces of M_R at the same time by intersecting each simplex of the triangulation with the surface (4). Our algorithms will need only the edges and vertices of M_R, however.) Putting everything together, we conclude with the following lemma.

LEMMA 3.9. *All the ridge trees for source points lying in a ridge-free region R can be encoded in a single lower envelope M_R whose combinatorial complexity is $O(n^4)$. Moreover, the edges and vertices of M_R can be computed in time $O(n^4)$.*

Remark. The only reason for assuming in the above analysis that x stays away from the boundary of R was to ensure that the vertices of the Voronoi diagram avoid the boundary of K_R. However, it is easy to verify that when x is allowed to vary over the closure of R, Voronoi vertices never cross the boundary of K_R but may touch it in limiting configurations. Thus the same analysis applies in that case as well.

If the source point moves along an edgelet ε rather than in a ridge-free region, we can obtain a bound on the number of different combinatorial structures of ridge trees by setting $t = 0$ in (1). Proceeding in the same way as above, each g_i now becomes

$$g_i(s,y_1,y_2) = C_i^{(0)} + C_i^{(1)}y_1 + C_i^{(2)}y_2 + C_i^{(3)}s + C_i^{(5)}sy_1 + C_i^{(6)}sy_2\,.$$

Again, we define g as the lower envelope of g_i's, and the subdivision M_ε as the labeled projection of the graph of the lower envelope g. Let $v_1 = sy_1, v_2 = sy_2$, and set

$$\bar{g}_i(s,y_1,y_2,v_1,v_2) = C_i^{(0)} + C_i^{(1)}y_1 + C_i^{(2)}y_2 + C_i^{(3)}s + C_i^{(5)}v_1 + C_i^{(6)}v_2\,. \tag{6}$$

Since $\bar{g}_i$ is now a 5-variate linear function, by the upper bound theorem, the number of faces in M_ε is $O(n^3)$. A similar bound was proved earlier in [GMR91]. Since the lower envelope of $\bar{g}_i$'s can be computed in $O(n^3)$ time [BCM94], the vertices and edges of M_ε can also be computed in time $O(n^3)$. Hence we obtain the following.

LEMMA 3.10. *All the ridge trees that occur as the source point moves on an edgelet ε can be represented as an envelope M_ε of n trivariate functions; its complexity is $O(n^3)$, and its edges and vertices can be computed in $O(n^3)$ time.*

Remark. Only a portion of M_R (resp., M_ε) is relevant to our analysis of ridge trees. Recall that it encodes the diagrams $\mathcal{V}_x$ for all x. However, we are interested only in $x \in R$ (resp., $x \in \varepsilon$) and not all of $\mathcal{V}_x$ but just the portion contained in K_R (resp., K_ε). Hence only those points $(s, t, y_1, y_2) \in M_R$ (resp., $(s, y_1, y_2) \in M_\varepsilon$) are relevant for which $(s, t) \in R$ (resp., $s \in \varepsilon$) and $(y_1, y_2) \in K_R$ (resp., $(y_1, y_2) \in K_\varepsilon$). When we make use of the information stored in M_R and M_ε at a later point in the computation, we will have to "filter out" irrelevant features. This issue is addressed later in section 5.

4. Edge sequences superset. In this section we describe an $O(n^6)$ algorithm for constructing a superset of the shortest-path edge sequences, which is both more efficient and conceptually simpler than previously suggested procedures, and which produces a smaller set of sequences.

Observe that all shortest-path edge sequences are realized by pairs of points lying on edges of $\mathcal{P}$—any other shortest path can be contracted without affecting its edge sequence so that its endpoints lie on edges of $\mathcal{P}$. Let x be a generic point lying on an edgelet ε. As mentioned in section 3.1, the pasting tree Π_x contains all shortest-path edge sequences that emanate from x. Moreover, by Lemma 3.5 Π_x is independent of choice of x in ε; therefore we will use Π_ε to denote Π_x for any point $x \in \varepsilon$. The set of $O(n^3)$ pasting trees $\{\Pi_\varepsilon \mid \varepsilon \text{ is an edgelet}\}$, each of size $O(n^2)$, contains an implicit representation of a set of $O(n^6)$ sequences ($O(n^5)$ of which are maximal in this set), which includes all shortest-path edge sequences that emanate from generic points.

ALGORITHM 1. *Sequence trees.*

```
for each edge e of P do
    Σ_e = ∅.
    for each edgelet endpoint v ∈ e do
        Compute shortest-path edge sequences Σ_v emanating from v.
        Σ_e = Σ_e ∪ Σ_v.

    for each edgelet ε ⊂ e do
        Compute Π_ε.
        for each maximal sequence σ ∈ Π_ε do
            Σ_e = Σ_e ∪ {σ}.

    T_e = the trivial sequence tree consisting of just e.
    for each sequence σ ∈ Σ_e do
        Traverse σ, augmenting T_e.
        Stop if σ visits the same edge twice.

    T_e is the sequence tree containing shortest-path edge sequences
        emanating from e.
```

Hence we can compute a superset of shortest path edge sequences in three steps: First, partition the points on the edges of $\mathcal{P}$ into $O(n^3)$ edgelets in time $O(n^3)$ as described in Lemma 3.7. Second, compute shortest-path edge sequences from the endpoints of each edgelet, using Chen and Han's shortest-path algorithm. Next, compute the star unfolding from a point in each edgelet, again using the shortest-

path algorithm. The total time spent in the last two steps is $O(n^5)$. Finally, this representation of edge sequences is transformed into $O(n)$ sequence trees, one for each edge (cf. section 2.2); see Algorithm 1 for pseudocode. For each pasting tree Π_ε, we separately traverse Π_ε from each of its leaves, so we spend $O(n^3)$ time per pasting tree. Hence the total time spent is $O(n^6)$. We thus obtain Theorem 4.1.

THEOREM 4.1. *Given a convex polytope in $\mathbb{R}^3$ with n vertices, one can construct, in time $O(n^6)$, $O(n)$ sequence trees that store a set of $O(n^6)$ edge sequences, which include all shortest-path edge sequences of $\mathcal{P}$.*

Remarks. (i) Note that our algorithm uses nothing more complex than the algorithm of Chen and Han for computing shortest paths from a fixed point, plus some sorting and tree traversals. It achieves an improvement over previous algorithms mainly by reorganizing the computation around the star unfolding.

(ii) The sequence-tree representation for just the shortest-path edge sequences is smaller by a factor of n^2 than our estimate on the size of the set produced by Algorithm 1 (cf., section 2.2), but computing it efficiently seems difficult. In addition, it is not clear how far the actual output of our algorithm is from the set of all shortest-path edge sequences. We have a sketch of a construction for a class of polytopes that force our algorithm to produce $\Omega(n^5)$ *non*–shortest-path edge sequences.

5. Exact set of shortest-path edge sequences. In this section, we present an $O(n^3\beta(n)\log n)$ algorithm for computing the exact set of maximal shortest-path edge sequences emanating from an edgelet. Here $\beta(\cdot)$ is an extremely slowly growing function asymptotically smaller than $\log^* n$. Running this algorithm for all edgelets of $\mathcal{P}$, the exact set of maximal shortest-path edge sequences can be computed in time $O(n^6\beta(n)\log n)$, which is a significant improvement over Schevon and O'Rourke's $O(n^9\log n)$ algorithm [SO89].

Let ε be an edgelet. For the purposes of this section we consider S_x embedded in the plane so that $K_x = K_\varepsilon$ does not move as x varies along ε. So on the one hand, K_ε is a fixed simple n-gon in the plane and on the other hand it is a complex constructed of $O(n^2)$ convex pieces of faces of $\mathcal{P}$. By analogy with S_x, we call these pieces *plates of* K_ε. A plate of K_ε is fully contained in a plate of S_x for any $x \in \varepsilon$. This latter plate may change its shape as x moves in ε but always corresponds to the same node of the pasting tree $\Pi_x = \Pi_\varepsilon$. Moreover, there is at most one plate of K_x in a plate of S_x, as a plate of K_x is obtained from a convex set (a plate of S_x) contained in a simple polygon (S_x) by cutting off n triangles ($\triangle x_i p_{i-1} p_i$, for $i = 1, \ldots, n$), each by a chord ($p_{i-1}p_i$).

We are interested in computing the set Σ_ε of those shortest-path edge sequences (corresponding to paths emanating from points on ε) which are maximal over all points in ε. In other words, given a sequence $\sigma \in \Sigma_\varepsilon$, there is a point $x \in \varepsilon$ and a shortest path starting from x that traverses σ, and there is no point on ε from which there is a shortest path that traverses an edge sequence that is an extension of σ. Recall that each sequence in Σ_ε corresponds to a path in the pasting tree Π_ε, originating from one of its leaves. Each leaf of Π_ε corresponds to a triangular plate incident to one of the n images of x. Let $\Sigma_{\varepsilon,i} \subseteq \Sigma_\varepsilon$ denote the set of edge sequences that originate from the ith leaf of Π_ε. If a sequence $\sigma \in \Sigma_{\varepsilon,i}$ is realized by a shortest path π emanating from $x \in \varepsilon$, then π leaves x between xp_{i-1} and xp_i, and it corresponds to a segment in S_x emanating from x_i, the ith image of x. The area swept by all of these segments (for a fixed x) is exactly the ith peel $P_{x,i}$. $P_{x,i}$ consists of the triangle $\triangle x_i p_{i-1} p_i$ and the "remainder" $\hat{P}_{x,i}$, which is the portion of the ith peel that lies in $K_x = K_\varepsilon$. If we concentrate on *maximal* shortest paths contained in $P_{x,i}$, it is sufficient to consider

those paths that end in $\hat{P}_{x,i}$, as any path that ends in $\triangle x_i p_{i-1} p_i$ can be extended to a point in $\hat{P}_{x,i}$ while remaining a shortest path. Put $C_i = \bigcup_{x \in \varepsilon} \hat{P}_{x,i}$; see Fig. 9a.

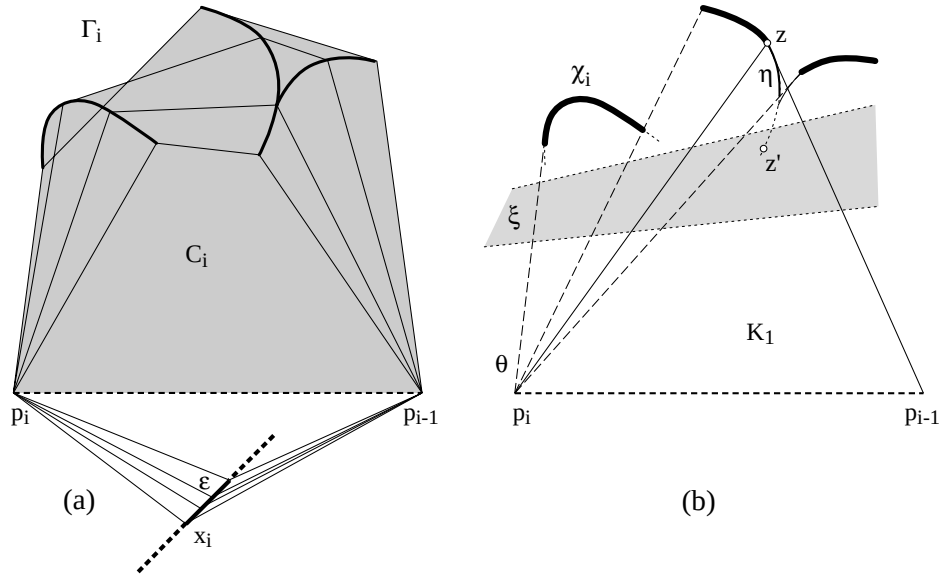

FIG. 9. (a) *C_i is the union of the peel remainders $\hat{P}_{x,i}$. Γ_i comprise the arcs traced by the ridge vertices (shown dark).* (b) *γ_i is the θ-monotone upper envelope (solid) of Γ_i with respect to p_i; several key radial lines from p_i are shown (dashed). γ_i is a superset of the "outer" envelope χ_i (dark); here the arc $\eta \in \gamma_i \setminus \chi_i$. A covering triangle $\triangle z p_{i-1} p_i$ whose apex z covers $z' \in (\cup \Gamma_i) \cap \xi$ is shown (solid).*

LEMMA 5.1. *Let $p, p' \in C_i$ be two points lying in the same plate of K_ε. Suppose $p \in \hat{P}_{x,i}$ and $p' \in \hat{P}_{x',i}$ for some $x, x' \in \varepsilon$. Then the edge sequences corresponding to the segments $x_i p$ and $x_i' p'$ are the same. The edge sequences are different if $p, p' \in C_i$ are contained in different plates of K_ε.*

Proof. Let v be the node of Π_ε corresponding to the plate of K_ε that contains p and p'. Since there is a unique path from the ith leaf to v in Π_ε, the lemma follows. Different plates of K_ε, as observed above, correspond to different nodes of Π_ε, and thus to different sequences of edges, essentially by definition of Π_ε. □

By the above lemma, each point of C_i *determines* a unique shortest-path edge sequence of $\Sigma_{\varepsilon,i}$, and all points of C_i lying in the same plate of K_ε determine the same shortest-path edge sequence of $\Sigma_{\varepsilon,i}$. We mark a node of Π_ε if the corresponding plate of K_ε intersects C_i. Let $\Pi_{\varepsilon,i}$ be the minimal subtree of Π_ε rooted at the ith leaf and containing all marked nodes. Then there is a one-to-one correspondence between the sequences of $\Sigma_{\varepsilon,i}$ and the paths in $\Pi_{\varepsilon,i}$ from its root to its leaves.

LEMMA 5.2. *Let σ be an edge sequence in $\Sigma_{\varepsilon,i}$ realized by a shortest path originating from point $x \in \varepsilon$. Then there is vertex p of $\hat{P}_{x,i}$ such that the segment $x_i p$ realizes the sequence σ.*

Proof. By Lemma 5.1, σ is realized by all points in the intersection of a unique plate ξ of K_ε with C_i. Choose a point $p \in \hat{P}_{x,i} \cap \xi$ such that $|x_i p|$ is maximum among all such points, where $|\ldots|$ denotes the Euclidean length of a segment. (Notice that the maximum must be achieved, for otherwise there is a shortest path from x_i whose sequence extends that of σ.) If p is not a vertex of $\hat{P}_{x,i}$, then we can choose a point

$p' \in \hat{P}_{x,i} \cap \xi$ in a sufficiently small neighborhood of p such that $|x_i p'| > |x_i p|$, which is a contradiction. Hence we can assume that p is a vertex of $\hat{P}_{x,i}$, as desired. □

In view of this lemma, we can restrict our attention to the points of C_i that correspond to the vertices of $\hat{P}_{x,i}$, for any $x \in \varepsilon$. Recall that each vertex of $\hat{P}_{x,i}$ is the image of a ridge vertex. A typical ridge vertex v is incident to three open peels c_j, c_k, c_ℓ; if v has degree more than three and exists at more than just a discrete set of positions of $x \in \varepsilon$, replace the triple of incident peels with a larger tuple in the following discussion. As x moves along ε, the vertex traces an algebraic curve $v = v(x)$ in K_ε. Let a *lifetime* of a ridge vertex v be a maximal connected interval $\varepsilon' \subseteq \varepsilon$ for which $x \in \varepsilon'$ implies that v is a vertex of T_x. Let Γ_i be the set of arcs traced out by ridge vertices that appear on the boundary of $\hat{P}_{x,i}$ during their lifetimes (Fig. 9a); set $n_i = |\Gamma_i|$. It can be verified that the arcs in Γ_i corresponding to a ridge vertex, defined by the triple c_j, c_k, c_ℓ, are the projections onto the xy-plane of those edges of the subdivision M_ε, defined in section 3.4, along which g_j, g_k, g_ℓ simultaneously appear on the lower envelope g. (As we mentioned in section 3.4, M_ε may contain "irrelevant" features. In particular, we must first truncate each aforementioned arc so that it corresponds to positions of the source on ε. Second, we must verify that the Voronoi diagram vertex corresponding to the arc indeed yields a ridge vertex. It is sufficient to check, for a single point of the curve traced out by the vertex as x ranges over ε, that it lies inside K_ε, as a ridge vertex cannot leave K_ε. This is easily accomplished by one point-location query per arc.)

We have previously observed that the maximal sequences of $\Pi_{\varepsilon,i}$ are necessarily realized by points on $\partial C_i \setminus p_{i-1}p_i$. In particular, points that lie in the interior of C_i can be safely disregarded. We will now apply a similar procedure to points of $\cup\Gamma_i$. If we introduce polar coordinates with p_i as the origin, each arc $\eta_j \in \Gamma_i$ can be regarded as a univariate (partial) function $r = \eta_j(\theta)$ (split η_j into a constant number of θ-monotone arcs if it is not θ-monotone; this is possible since η_i is a portion of an algebraic curve of small degree). Consider the graph of the upper envelope γ_i of the functions $\eta_j(\theta)$ (Fig. 9b). Since each arc in Γ_i is algebraic of constant degree, the upper envelope γ_i has $O(n_i\beta(n_i))$ breakpoints [ASS89]; here $\beta(k) = 2^{\alpha^s(k)}$, s is a constant depending on the maximum degree of arcs in Γ_i, and $\alpha(\cdot)$ is the inverse Ackermann function. Using a divide-and-conquer approach, the upper envelope can be computed in time $O(n_i\beta(n_i)\log n_i)$; see [SA95].

We will now show that tracing γ_i through K_ε is sufficient for computing $\Pi_{\varepsilon,i}$—there is no need to examine the entire $\cup\Gamma_i$.

LEMMA 5.3. *Each sequence in $\Sigma_{\varepsilon,i}$ is determined by a point on γ_i.*

Proof. We will show in fact that points on a subset χ_i of γ_i suffice to determine all sequences. Say a point z "covers" a point $z' \neq z$ if the triangle $\triangle z p_{i-1} p_i$ contains z'. Call the set of points of $\cup\Gamma_i$ not covered by any point of $\cup\Gamma_i$ its *outer envelope* χ_i. It is evident that $\chi_i \subseteq \gamma_i$; see Fig. 9b.

Suppose there is a sequence $\sigma \in \Sigma_{\varepsilon,i}$ not realized by any point on χ_i. Let ξ be the plate of K_ε corresponding to σ. Thus some arc of Γ_i meets ξ, but χ_i does not. Hence every point of $(\cup\Gamma_i) \cap \xi$ is covered by a point of χ_i. Pick a point $z \in \chi_i$ that covers some point $z' \in (\cup\Gamma_i) \cap \xi$; see Fig. 9b. By the choice of z', there is an $x \in \varepsilon$ such that the segment xz' corresponds to a shortest path on $\mathcal{P}$. Consider $K_\varepsilon \setminus \xi$. It consists of two or three simple polygons, one of which, say K_1, is incident to $p_{i-1}p_i$ (the case when ξ touches $p_{i-1}p_i$ is slightly different and can be handled by an easier argument). We claim that z does not lie in K_1. Indeed, $\triangle z' p_{i-1} p_i$ is such that both $p_{i-1}z'$ and $p_i z'$ enter ξ and remain there. As $\triangle z p_{i-1} p_i$ contains $\triangle z' p_{i-1} p_i$, removal

of ξ separates K_ε, and $z \notin \xi$ and both $p_{i-1}z$ and p_iz must cross ξ and exit it. As $z \in \chi_i$, there is an $x' \in \varepsilon$ so that the segment $x'z$ is (the image of) a shortest path. However, since $z \notin K_1$, this path crosses ξ, so the edge sequence it traverses is an extension of σ, contradicting maximality of σ.

We have shown that each sequence is realized by a point of χ_i and, therefore, of γ_i. □

If a plate of K_ε is intersected by an edge of γ_i, we call the corresponding node of Π_ε *visited* by γ_i. The above lemma implies that the minimal subtree containing the node corresponding to x_i and all nodes visited by γ_i is the same as $\Pi_{\varepsilon,i}$. It is thus sufficient to determine the nodes of Π_ε visited by γ_i.

ALGORITHM 2. *Exact edge sequences.*

```
Form edgelets.
for each edgelet ε do
    Compute M_ε.
    Γ := Set of projections of edges in M_ε.
    Eliminate irrelevant features from Γ.
    for each image x_i do
        Γ_i := Arcs of Γ at which g_i appears on the lower envelope.
        Compute upper envelope γ_i of Γ_i.
        Compute and triangulate K_ε[p_i].
        Compute the connected arcs ξ_1, ..., ξ_u.
        for each △ in the triangulation do
            Compute Π_△ := Π_ε ∩ △.
            Compute Π^1_△, Π^2_△.
            for each arc ξ_j ⊂ △ do
                Find nodes of Π^1_△, Π^2_△ visited by ξ_j.
```

Note that γ_i is θ-monotone with respect to p_i, and therefore γ_i lies in the portion $K_\varepsilon[p_i]$ of K_ε visible from p_i. Compute $K_\varepsilon[p_i]$, in linear time [EA81], and triangulate $K_\varepsilon[p_i]$ into a linear number of triangles all incident to p_i. Now partition γ_i into connected portions $\xi_1, \ldots, \xi_u$, each fully contained in one of these triangles. This can be done in time proportional to the number of breakpoints in γ_i and the number of triangles involved and produces at most $O(n)$ extra arcs, as γ_i is θ-monotone (with respect to p_i) and thus crosses each segment separating consecutive triangles in at most one point. Since each triangle $\triangle$ is fully contained in K_ε and thus encloses no images of a vertex of $\mathcal{P}$, the set of plates of Π_ε met by $\triangle$ corresponds to a subtree $\Pi_\triangle$ of Π_ε of linear size, with at most one vertex of degree 3 and all remaining vertices of degree at most 2. Hence $\Pi_\triangle$ can be covered by two simple paths $\Pi^1_\triangle, \Pi^2_\triangle \subseteq \Pi_\triangle$, and they can be computed in linear time. For each $\xi_j \subset \triangle$, we determine the furthest node that ξ_j reaches in $\Pi^1_\triangle, \Pi^2_\triangle$ by binary search. Recall that ξ_j consists of a number of algebraic arcs of constant degree. An intersection between ξ_j and a plate of K_ε can be detected in $O(1)$ time per such arc, so the binary search requires only $O(\log n)$ time per arc. The total time spent is thus $O(n_i\beta(n)\log n + n^2)$ over all triangles of $K_\varepsilon[p_i]$. Repeating this procedure over all n leaves of Π_ε, the total time spent in computing Σ_ε is $O(n^3\beta(n)\log n)$, as $\sum_i n_i = O(n^3)$ by Lemma 3.10. The above processing is repeated for each of the $O(n^3)$ edgelets ε. This completes the description of the algorithm. It is summarized in Algorithm 2.

THEOREM 5.4. *The exact set of all shortest-path edge sequences on the surface*

of a 3-polytope on n vertices can be computed in $O(n^6\beta(n)\log n)$ time, where $\beta(n) = o(\log^* n)$ is an extremely slowly growing function.

6. Geodesic diameter. In this section we present an $O(n^8 \log n)$ time algorithm for computing the geodesic diameter of $\mathcal{P}$. As mentioned in the introduction, this question was first investigated by O'Rourke and Schevon [OS89] who presented an $O(n^{14} \log n)$ time algorithm for computing it. Their algorithm relies on the following proposition.

LEMMA 6.1 (see O'Rourke and Schevon [OS89]). *If a pair of points $x, y \in \mathcal{P}$ realizes the diameter of $\mathcal{P}$, then either x or y is a corner of $\mathcal{P}$, or there are at least five distinct shortest paths between x and y.*

Lemma 6.1 suggests the following strategy for locating all diametral pairs. We first dispose of the possibility that either x or y is a corner in $n \times O(n^2) = O(n^3)$ time just as in [OS89]. Next, we fix a ridge-free region R and let M_R be the subdivision defined in section 3.4. We need to compute all pairs of points $x \in \mathrm{cl}\,(R)$ and $y^* \in K_x$ such that there are at least five distinct shortest paths between x and y, with $U(y) = y^*$. By a result of Schevon [Sch89], such a pair x, y can be a diametral pair only if it is the only pair, in a sufficiently small neighborhood of x and y, with at least five distinct shortest paths between them. Such a pair of points corresponds to a vertex of M_R. Hence we use the following approach.

We first compute, in $O(n^4)$ time, all ridge-free regions of $\mathcal{P}$ (cf. Lemma 3.8). Next, for each ridge-free region R, we compute K_R, vertices of M_R, and $f(v)$ for all vertices of M_R (recall that $f(v)$ is the shortest distance from v to any source image; cf. section 3.3). Next, for each vertex $v = (s, t, y_1, y_2)$ of M_R, we determine whether (s, t) lies in the closure of R and $(y_1, y_2) \in K_R$. If the answer to both of these questions is "yes," we add v to the list of candidates for diametral pairs. (This step is exactly the elimination of "irrelevant features" mentioned at the end of section 3.4. Once the two conditions are verified, we know that (s, t) and (y_1, y_2) correspond to actual points x, y on $\mathcal{P}$ and $f(v)$ is exactly $d(x, y)$.)

Finally, among all diametral candidate pairs, we choose a pair that has the largest geodesic distance. See Algorithm 3 for the pseudocode.

For each ridge-free region R, K_R can be computed in time $O(n^2)$ and preprocessed for planar point location in additional $O(n \log n)$ time using the algorithm of Sarnak and Tarjan [ST86]. (Once again, recall that we treat K_R as a simple polygon and use (y_1, y_2)-coordinate system there.) By Lemma 3.9, vertices of M_R and $f(v)$, for all vertices of M_R, can be computed in time $O(n^4)$. We spend $O(\log n)$ time for point location at each vertex of M_R, so the total time spent is $O(n^8 \log n)$.

THEOREM 6.2. *The geodesic diameter of a convex polytope in $\mathbb{R}^3$ with n vertices can be computed in time $O(n^8 \log n)$.*

7. Shortest-path queries. In this section we discuss the preprocessing needed to support queries of the following form: "Given $x, y \in \mathcal{P}$, determine $d(x, y)$." We assume that each face ϕ of $\mathcal{P}$ has its own coordinate system (e.g., a vertex of ϕ is regarded as the origin and the two edges of ϕ incident to it are regarded as the two axes), and that a point $p \in \mathcal{P}$ is specified by the face ϕ containing p and by the ϕ-coordinates of p. Two variants of the query problem are considered: (1) no assumption is made about x and y, and (2) x is assumed to lie on an edge of $\mathcal{P}$.

Our data structure is based on the following observations. Let $x, y \in \mathcal{P}$ be two query points. Suppose $x = (s, t)$ is a generic point lying in a ridge-free region R and

ALGORITHM 3. *Geodesic diameter.*

```
for each corner c of P do
    Construct the ridge tree T_c with respect to c.
    for each vertex v of T_c do
        Add d(c, v) to the list of diameter candidates.
Compute the ridge-free regions.
for each ridge-free region R do
    Compute M_R and f(v) for all vertices v ∈ M_R.
    Compute S_x for some x ∈ R.
    Construct K_R = K_x.
    Preprocess K_R for point location queries.
    Preprocess cl(R) for point location queries.
    for each vertex v = (s, t, y_1, y_2) of M_R do
        if (s, t) ∈ cl(R) and (y_1, y_2) ∈ K_x then
            Add f(v) = d((s, t), (y_1, y_2)) to the list of diameter candidates.
Find a diametral candidate pair with the maximum geodesic distance.
```

$y^* = (y_1, y_2)$ is an image of y in S_x. If y^* lies in the kernel K_R, then

$$d(x,y) = f(s,t,y_1,y_2) = \left(g(s,t,y_1,y_2) + (s^2+t^2+y_1^2+y_2^2)\right)^{1/2},$$

where

$$g(s,t,y_1,y_2) = \min_{1\le i\le n} \bar{g}_i(s,t,y_1,y_2,v_1,v_2,v_3,v_4),$$

as defined in equations (2), (4), and (5). Let H_R be the set of hyperplanes in $\mathbb{R}^9$ corresponding to the graphs of $\bar{g}_i$'s (cf. equation (5))

(7)
$$h_i : v_5 = C_i^{(0)} + C_i^{(1)} y_1 + C_i^{(2)} y_2 + C_i^{(3)} s + C_i^{(4)} t + C_i^{(5)} v_1 + C_i^{(6)} v_2 + C_i^{(7)} v_3 + C_i^{(8)} v_4.$$

Then, computing the value of $g(s,t,y_1,y_2)$ is the same as determining the first hyperplane of H_R intersected by the vertical ray emanating from the point

$$(s,t,y_1,y_2,sy_1,sy_2,ty_1,ty_2,-\infty)$$

in the positive v_5-direction. The desired value is $(v_5 + s^2 + t^2 + y_1^2 + y_2^2)^{1/2}$, where v_5 is the v_5-coordinate of the intersection point.

On the other hand, if $y^* \notin K_x$, then it lies in one of the triangles $\triangle p_{i-1}x_ip_i$ and $d(x,y) = |x_iy^*|$. For a ridge-free region R, let κ_R denote the preimage of ∂K_R on $\mathcal{P}$, i.e., $U(\kappa_R) = \partial K_R$. The following lemma is crucial in answering queries when $y \notin U^{-1}(K_R)$.

LEMMA 7.1. *Let R be a ridge-free region or an edgelet, let ϕ be a face of $\mathcal{P}$, and let Δ be a connected component of $\phi \setminus \kappa_R$ whose image is not contained in K_R. Then the sequence of edges traversed by the shortest-path $\pi(x,y)$ is independent of the choice of $x \in R$ and $y \in \Delta$.*

Proof. For the sake of contradiction, suppose there are two points $y, y' \in \Delta$ such that the sequences of edges traversed by $\pi(x,y')$ and $\pi(x,y'')$ are distinct. Then there

must exist a point $y \in y'y''$ with two shortest paths to x—to obtain such a point, move y from one end of $y'y''$ to the other and observe that the shortest path from x to y changes continuously and maintains the set of edges of $\mathcal{P}$ that it meets, *except* at points y with more than one shortest path to x. Thus $y \in T_x$, so $U(y) \subset U(T_x) \subset K_R$. However, the segment $y'y'' \subset \Delta$ as Δ is convex, implying $U(y) \subset U(\Delta) \subset S_x \setminus K_R$, which is a contradiction.

Similarly, if $x', x'' \in R$ are such that the paths connecting these two points to $y \in \Delta$ traverse different edge sequences, there must exist $x \in x'x''$, which is connected to y by two shortest paths, again forcing y onto T_x and yielding a contradiction. The lemma follows easily. □

Data structure Based on the above observations, we can preprocess $\mathcal{P}$ as follows. We partition every face ϕ of $\mathcal{P}$ into ridge-free regions in time $O(n^4)$ (see Lemma 3.8), and preprocess the resulting subdivision of ϕ for planar point-location queries using any standard algorithm [ST86]. The queries would use ϕ-coordinates. The total time spent in this step is $O(n^4 \log n)$.

Let R be a fixed ridge-free region. We construct the following data structures for R. Choose an arbitrary point $x \in R$. Compute $K_x = K_R$ and the connected components of $\phi \setminus \kappa_R$ for each face ϕ of $\mathcal{P}$. Again, we preprocess the resulting subdivision of each face for planar point-location queries in ϕ-coordinates. We label each component Δ of $\phi \setminus \kappa_R$ as to whether it lies in $U^{-1}(K_R)$. If it does not, we choose a point $y \in \Delta$ and compute the edge sequence σ for the shortest path from x to y. By Lemma 7.1, σ is the same for all pairs $x \in R$ and $y \in \Delta$. We also compute the transformation, corresponding to the edge sequence σ, which maps the ϕ-based coordinates of points in Δ to ϕ'-coordinates of the face of $\mathcal{P}$ containing R. This corresponds to laying out in the plane the faces prescribed by σ from ϕ' to ϕ so that $d(x, y)$ becomes the length of the straight-line segment connecting x and y. All transformations for regions $\Delta \not\subset U^{-1}(K_R)$ can be computed in $O(n^2)$ time by a single depth-first traversal of the shortest-path sequence tree from x, computed by the algorithm of Chen and Han. If, on the other hand, Δ lies in $U^{-1}(K_R)$, the exact sequence of edges traversed by a shortest path from $x \in R$ to $y \in \Delta$ depends on the choice of x and y; the structure for determining it is described below. (Note that such sets Δ correspond exactly to "plates of K_R" as in section 5.) However, in this case any $y \in U^{-1}(K_R)$ has a unique image $y^* \in K_R$, so for each $\Delta \subset U^{-1}(K_R)$ we compute the coordinate transformation U from the ϕ-coordinates, where ϕ is the face of $\mathcal{P}$ containing Δ, to the coordinates in the planar embedding of K_R (they were referred to as (y_1, y_2)-coordinates in section 3.4). The sequences σ and the coordinate transformations U, for all $\Delta \subset U^{-1}(K_R)$, can be computed in $O(n^2)$ time, by performing a depth-first search on Π_x (each node of Π_x corresponds to a connected component Δ).

Next, let H_R be the set of hyperplanes defined in (7). We preprocess H_R into a data structure, so that the first hyperplane of H intersected by a vertical ray emanating from a point with $v_5 = -\infty$ can be computed efficiently. Matoušek and Schwarzkopf [MS93] (also see [AM92]) have proposed such a data structure, which, given a parameter $n \le u \le n^4$, can preprocess H_R, in time $O(u^{1+\delta})$, into a data structure of size $O(u^{1+\delta})$, so that a ray-shooting query can be answered in time $O(\frac{n}{u^{1/4}} \log n)$. This completes the description of the data structures for R. We construct these data structures for each ridge-free region R.

Since there are $O(n^4)$ ridge-free regions, the total time spent in constructing the data structures is $O(n^4(n^2 + u^{1+\delta}))$.

Answering a query. Let $x, y \in \mathcal{P}$ be a query pair. Let ϕ_x, ϕ_y be the faces of $\mathcal{P}$ containing x and y, respectively. Assume first that x is a generic point. By locating x in the point location data structure for ϕ_x, we identify in $O(\log n)$ time the ridge-free region R that contains x. Next, we determine the connected component Δ of $\phi_y \setminus \kappa_R$ that contains y by point location in ϕ_y. If $\Delta \cap U^{-1}(K_R) = \emptyset$, we can use the transformation stored at Δ to compute $d(x, y)$ in $O(1)$ time. If $\Delta \subset U^{-1}(K_R)$, using the second data structure we compute the first hyperplane h of H hit by the ray emanating from $(a_x, b_x, a_y, b_y, a_x a_y, a_x b_y, b_x a_y, b_x b_y, -\infty)$ in the $+v_5$-direction, where (a_x, b_x) and (a_y, b_y) are the coordinates of x and y, respectively. The coordinates of x are in the ϕ_x-coordinate system and the coordinates of y are in the coordinates system associated with the unfolding of K_R—the coordinate transformation from ϕ_y to (y_1, y_2) is stored at Δ. Once we know h, $d(x, y) = (g(a_x, b_x, a_y, b_y) + a_x^2 + a_y^2 + b_x^2 + b_y^2)^2$ can be computed in $O(1)$ time. The total time required is $O((n/u^{1/4}) \log n)$.

Finally, if x is not a generic point then, as mentioned in the remark following Lemma 3.9, we can use the data structures of any of the ridge-free regions whose boundaries contain x. It is easy to see by a continuity argument that all shortest paths from such a point are encoded equally well in the data structures of all of the ridge-tree regions touching x.

Hence setting $u = n^2 m$, we can conclude with the following theorem.

THEOREM 7.2. *Given a polytope $\mathcal{P}$ in $\mathbb{R}^3$ with n vertices and a parameter $1 \leq m \leq n^2$, one can construct, in time $O(n^6 m^{1+\delta})$ for any $\delta > 0$, a data structure of size $O(n^6 m^{1+\delta})$, so that $d(x, y)$ for any two points $x, y \in \mathcal{P}$ can be computed in time $O((\sqrt{n}/m^{1/4}) \log n)$. Constants of proportionality depend on δ.*

If x always lies on an edge, then H is a set of hyperplanes in $\mathbb{R}^6$, so the query time of the analogous vertical ray-shooting data structure in six dimensions is $O(n/u^{1/3} \log n)$ for $n \leq u \leq n^2$. Moreover, we have to construct only $O(n^3)$ different data structures, one for each edgelet, so we can conclude with the following theorem.

THEOREM 7.3. *Given a polytope $\mathcal{P}$ in $\mathbb{R}^3$ with n vertices and a parameter $1 \leq m \leq n$, one can construct, in time $O(n^5 m^{1+\delta})$ for any $\delta > 0$, a data structure of size $O(n^5 m^{1+\delta})$, so that for any two points $x, y \in \mathcal{P}$ such that x lies on an edge of $\mathcal{P}$ one can compute $d(x, y)$ in time $O((n/m)^{1/3} \log^2 n)$.*

8. Discussion and open problems. We have shown that use of the star unfolding of a polytope leads to substantial improvements in the time complexity of three problems related to shortest paths on the surface of a convex polytope: finding edge sequences, computing the geodesic diameter, and distance queries. Moreover, the algorithms are not only theoretical improvements, but also, we believe, conceptual simplifications. This demonstrates the utility of the star unfolding.

We conclude by mentioning some open problems:

1. Can one obtain an upper bound on the number of different combinatorial structures of ridge trees better than $O(n^4)$? Such an improvement would yield a similar improvement in the time complexities of diameter and exact shortest-path edge sequences algorithms.
2. Can one answer a shortest-path query faster if *both* x and y lie on some edge of $\mathcal{P}$? This special case is important for planning paths among convex polyhedra (see Sharir [Sha87]).

Acknowledgment. We thank the referees for comments that led to significant improvements in the presentation of this paper.

COMPUTING ENVELOPES IN FOUR DIMENSIONS WITH APPLICATIONS*

PANKAJ K. AGARWAL†, BORIS ARONOV‡, AND MICHA SHARIR§

Abstract. Let $\mathcal{F}$ be a collection of n d-variate, possibly partially defined, functions, all algebraic of some constant maximum degree. We present a randomized algorithm that computes the vertices, edges, and 2-faces of the lower envelope (i.e., pointwise minimum) of $\mathcal{F}$ in expected time $O(n^{d+\varepsilon})$ for any $\varepsilon > 0$. For $d = 3$, by combining this algorithm with the point-location technique of Preparata and Tamassia, we can compute, in randomized expected time $O(n^{3+\varepsilon})$, for any $\varepsilon > 0$, a data structure of size $O(n^{3+\varepsilon})$ that, for any query point q, can determine in $O(\log^2 n)$ time the function(s) of $\mathcal{F}$ that attain the lower envelope at q. As a consequence, we obtain improved algorithmic solutions to several problems in computational geometry, including (a) computing the width of a point set in 3-space, (b) computing the "biggest stick" in a simple polygon in the plane, and (c) computing the smallest-width annulus covering a planar point set. The solutions to these problems run in randomized expected time $O(n^{17/11+\varepsilon})$, for any $\varepsilon > 0$, improving previous solutions that run in time $O(n^{8/5+\varepsilon})$. We also present data structures for (i) performing nearest-neighbor and related queries for fairly general collections of objects in 3-space and for collections of moving objects in the plane and (ii) performing ray-shooting and related queries among n spheres or more general objects in 3-space. Both of these data structures require $O(n^{3+\varepsilon})$ storage and preprocessing time, for any $\varepsilon > 0$, and support polylogarithmic-time queries. These structures improve previous solutions to these problems.

1. Introduction.

Let $\mathcal{F} = \{f_1, \ldots, f_n\}$ be a collection of n d-variate, possibly partially defined, functions, all algebraic of some constant maximum degree b (and if they are partially defined, their domains of definition are also described each by a constant number of polynomial equalities and inequalities of maximum degree b). Abusing the notation slightly, we will not distinguish between a function and its graph. The *lower envelope* $E_{\mathcal{F}}$ of $\mathcal{F}$ is defined as

$$E_{\mathcal{F}}(\mathbf{x}) = \min_i f_i(\mathbf{x}),$$

where the minimum is taken over all functions of $\mathcal{F}$ that are defined at $\mathbf{x}$. The *minimization diagram* $M_{\mathcal{F}}$ of $\mathcal{F}$ is the decomposition of $\mathbb{R}^d$ into maximal connected regions (of any dimension), called *cells* (or *faces*), so that within each cell the same subset of functions appears on the envelope $E_{\mathcal{F}}$. There is a natural subdivision of

$E_{\mathcal{F}}$ into cells, as well, where a cell of the lower envelope is defined as the portion $E_{\mathcal{F}}$ that projects onto cell of $M_{\mathcal{F}}$. As the correspondence is 1-1, we will abuse the terminology and not make a distinction between the two kinds of cells. (A more detailed definition, treating also the case of partially defined functions, is given in [Sha].) The *combinatorial complexity* of $M_{\mathcal{F}}$ and of $E_{\mathcal{F}}$ is the number of faces of all dimensions in $M_{\mathcal{F}}$ and $E_{\mathcal{F}}$.

Recently, there has been a significant progress in the analysis of the combinatorial complexity of lower envelopes of multivariate functions [HS, Sha]. In particular, it was shown in [Sha] that the maximum complexity of $M_{\mathcal{F}}$ is $O(n^{d+\varepsilon})$, for any $\varepsilon > 0$, where the constant of proportionality depends on ε, d, and b. This result almost settles a major open problem and has already led to many applications [ASa, HS, Sha]. However, less progress has been made on the corresponding algorithmic problem, which calls for the efficient construction of the lower envelope of such a collection $\mathcal{F}$, in time $O(n^{d+\varepsilon})$, for any $\varepsilon > 0$. The ideal output of an algorithm that computes the envelope is a data structure of size $O(n^{d+\varepsilon})$, which can return, for a given point $\mathbf{x} \in \mathbb{R}^d$, the identity of the function(s) attaining the envelope at $\mathbf{x}$ in logarithmic (or polylogarithmic) time. Weaker solutions might provide just an enumeration of the cells of $M_{\mathcal{F}}$ and adjacency structure representing all pairs of cells that touch each other.

Sharir [Sha] presented an algorithm for computing the lower envelope of bivariate functions having the properties listed above, which runs in time $O(n^{2+\varepsilon})$, for any $\varepsilon > 0$. Other algorithms with a similar performance are given in [BD, dBDS]. The simplest solution to this problem, involving a deterministic divide-and-conquer algorithm, was recently presented in [ASS]. All these algorithms facilitate point-location queries of the sort described above. Unfortunately, these methods fail in higher dimensions. For example, the technique of [Sha] relies on the existence of a *vertical decomposition* of the minimization diagram M_R of a sample R of r functions of $\mathcal{F}$, into a small number (that is, $O(r^{d+\varepsilon})$) of cells of *constant description complexity*. Such decompositions exist (and are easy to compute) for $d = 2$, but their existence in higher dimensions is still an open problem.

In this paper we present a randomized algorithm with $O(n^{d+\varepsilon})$ expected time, for any $\varepsilon > 0$, for computing the vertices, edges, and 2-dimensional faces of the lower envelope of n d-variate functions having the properties assumed above. We can use this algorithm to compute the entire lower envelope of a collection $\mathcal{F}$ of n trivariate functions, which has all the desired characteristics; in particular, it preprocesses $\mathcal{F}$, in expected time $O(n^{3+\varepsilon})$, into a data structure of size $O(n^{3+\varepsilon})$ that, for a query point q, can compute $E_{\mathcal{F}}(q)$, and also the function(s) attaining the envelope at q, in $O(\log^2 n)$ time. The algorithm bypasses the problem of having to construct small-size vertical decomposition by applying the technique of Preparata and Tamassia [PT] for point location in certain types of 3-dimensional subdivisions. This allows us to use a coarser decomposition of the minimization diagram, whose size is close to cubic.

Several recent papers [AST, CEGSb, MS] have studied a variety of geometric problems whose solution calls for the construction of, and searching in, lower or upper envelopes in 4-space. These applications fall into two main categories: *preprocess-for-queries* problems, which call for the construction of such an envelope, to be queried repeatedly later; and *batched* problems, where all the queries are known in advance and the goal is to produce the answers to all of them efficiently. We will present some of these applications, as listed in the abstract, where our new algorithm for computing lower envelopes in four dimensions leads to improved solutions.

The paper is organized as follows. In section 2 we present a general efficient randomized technique, which we believe to be of independent interest, for computing all the 0, 1, and 2-dimensional features of lower envelopes in any dimension. Then, in section 3, we apply this algorithm to the case of trivariate functions. This gives us an initial representation of the lower envelope of such a collection, which we then augment by additional features, resulting in a representation suitable for the application of the Preparata–Tamassia technique. In sections 4 and 5 we present applications of our result to a variety of problems in computational geometry, as listed in the abstract.

After the original submission of this paper, Agarwal and Sharir [ASb] observed that, for some of the problems that are solved here, the size of the vertical decomposition of the relevant minimization diagrams is small. This leads to slightly improved solutions to these problems. See also the remark at the end of section 5.1.

2. Lower envelopes in arbitrary dimension. In this section, we present a randomized technique for computing a partial description of lower envelopes of d-variate functions, for $d \geq 2$, whose expected running time is $O(n^{d+\varepsilon})$, for any $\varepsilon > 0$. This technique only computes the vertices, edges, and 2-faces of the envelope, which is sufficient for the full construction of envelopes in 4-space, as will be explained in section 3.

Let $\mathcal{F} = \{f_1, \ldots, f_n\}$ be a collection of (partial) d-variate functions in $\mathbb{R}^{d+1}$, satisfying the conditions described in the introduction. We assume that the functions of $\mathcal{F}$ are in general position; see [Sha] for more details and for a discussion of this assumption. To compute the lower envelope $E_{\mathcal{F}}$ of $\mathcal{F}$, in the above partial sense, we proceed as follows. Let Σ be the family of all $(d-1)$-subsets of $\mathcal{F}$. We fix a subset $\sigma = \{f_1, \ldots, f_{d-1}\} \in \Sigma$, and let

$$\Pi^\sigma = \{\mathbf{x} \in \mathbb{R}^d \mid f_1(\mathbf{x}) = \cdots = f_{d-1}(\mathbf{x})\}.$$

Since the f_i's are assumed to be in general position, Π^σ is a 2-dimensional surface (or a surface patch). For the sake of simplicity, we assume that Π^σ is connected and x_1x_2-monotone (i.e., any $(d-2)$-flat orthogonal to the x_1x_2-plane meets Π^σ in at most one point); otherwise, we decompose it into a constant number of connected portions so that each portion is an x_1x_2-monotone surface patch, and work with each patch separately. For each $i \geq d$, let

$$\gamma_i = \{\mathbf{x} \in \Pi^\sigma \mid f_i(\mathbf{x}) = f_1(\mathbf{x}) = \cdots = f_{d-1}(\mathbf{x})\};$$

γ_i is a 1-dimensional curve, which partitions Π^σ into two (not necessarily connected) regions, K_i^+ and K_i^-, where

$$K_i^+ = \{\mathbf{x} \in \Pi^\sigma \mid f_i(\mathbf{x}) > f_1(\mathbf{x}) = \cdots = f_{d-1}(\mathbf{x})\},$$
$$K_i^- = \{\mathbf{x} \in \Pi^\sigma \mid f_i(\mathbf{x}) < f_1(\mathbf{x}) = \cdots = f_{d-1}(\mathbf{x})\}.$$

Then the intersection $Q^\sigma = \bigcap_{i \geq d} K_i^+$ is the portion of Π^σ over which the envelope $E_{\mathcal{F}}$ is attained by the functions of σ. The algorithm will compute the regions Q^σ, over all choices of $(d-1)$-tuples σ of functions, thereby yielding the vertices, edges, and 2-faces of $M_{\mathcal{F}}$ (because of the general position assumption, any such feature must show up as a feature of at least one of the regions Q^σ). The algorithm actually computes the vertices, edges, and 2-faces of a refinement of $M_{\mathcal{F}}$, but the faces of $M_{\mathcal{F}}$ of dimension at most 2 can be retrieved from them in a straightforward manner. We omit the easy details.

We compute Q^σ using a randomized incremental approach, similar to the ones described in [CEGSS, dBDS, Mua, Mub, SA]. Since the basic idea is by now fairly standard, we give only a brief overview of the algorithm and refer the reader to [CEGSS, SA] for details. We first compute the set $\Gamma^\sigma = \{\gamma_i \mid d \le i \le n\}$.[1] Next, we add the curves γ_i one by one in a random order and maintain the intersection of the regions K_i^+ for the curves added so far. Let $(\gamma_d, \gamma_{d+1}, \ldots, \gamma_n)$ be the (random) insertion sequence, and let Q_i^σ denote the intersection of $K_d^+, \ldots, K_i^+$. We construct and maintain the "vertical decomposition" $\tilde{Q}_i^\sigma$ of Q_i^σ. This is defined as the partitioning of each 2-face ϕ of Q_i^σ into "pseudotrapezoids," obtained by drawing, from each vertex of ϕ and from each locally x_1-extreme point on $\partial\phi$, a curve within ϕ obtained by intersecting ϕ with the hyperplane $x_1 = const$, and by extending it (in both directions if necessary) until it meets $\partial\phi$ again. Each pseudotrapezoid is *defined* by at most four curves of Γ^σ; conversely, any four or fewer curves of Γ^σ define a constant number of pseudotrapezoidal cells, namely, those formed along Π^σ when only these curves are inserted. (Note that this construction is well defined since Π^σ is an x_1x_2-monotone surface.) In the $(i+1)$st step we add K_{i+1}^+ and compute $\tilde{Q}_{i+1}^\sigma$ from $\tilde{Q}_i^\sigma$, using the technique described in [CEGSS].

The analysis of the expected running time of the algorithm proceeds along the same lines as described in [CEGSS, SA]. We define the *weight*, $w(\tau)$, of a pseudotrapezoid τ, defined by the arcs of Γ^σ, to be the number of functions f_i, for $i = d, d+1, \ldots, n$, excluding the up to four functions whose intersections with Π^σ *define* τ, such that $f_i(\mathbf{x}) < f_1(\mathbf{x}) = \cdots = f_{d-1}(\mathbf{x})$ for some point $\mathbf{x} \in \tau$.

As shown in [CEGSS], the cost of the above procedure is proportional to the number of pseudotrapezoids that are created during the execution of the algorithm, plus the sum of their weights, plus an overhead term of $O(n^d)$ needed to prepare the collections of curves γ_i over all 2-dimensional intersection manifolds Π^σ. The analysis given below deals only with pseudotrapezoids that are defined by exactly four such functions (plus the $d-1$ functions defining Π^σ), and easy and obvious modifications are necessary to handle all other pseudotrapezoids.

Let T^σ denote the set of pseudotrapezoids (or "cells" for brevity) defined by four arcs of Γ^σ, and let $T = \bigcup_{\sigma\in\Sigma} T^\sigma$. Each cell in T is defined by $d-1+4 = d+3$ functions of $\mathcal{F}$. In what follows we implicitly assume that the specification of a cell $\tau \in T$ includes the $d+3$ functions defining τ, where there is a clear distinction between the first $d-1$ functions (constituting the set σ) and the last four functions (defining the four curves that generate τ along Π^σ). For an integer $k \ge 0$ and a subset $R \subseteq \mathcal{F}$, let $T_k(R) \subseteq T$ (resp., $T_{\le k}(R) \subseteq T$) denote the set of cells, defined by $d+3$ functions of R, as above, with weight k (resp., at most k). Let $N_k(R) = |T_k(R)|$ and

$$N_k(r) = \max_R N_k(R)\,,$$

where the maximum is taken over all subsets R of $\mathcal{F}$ of size r. Similarly, we define $N_{\le k}(R)$ and $N_{\le k}(r)$. Since each cell of $T_0(R)$ lies on the lower envelope of R, it follows that $N_0(r) = O(r^{d+\varepsilon})$. Adapting the analysis technique of Clarkson and Shor [ClS], we have the following lemma.

[1] We need to assume an appropriate model of computation, in which any of the various primitive operations required by the algorithm can be performed in constant time. For example, we can assume the model used in real computational algebraic geometry [HRR], where each algebraic operation involving a constant number of polynomials of constant maximum degree can be performed exactly, using rational arithmetic in constant time.

LEMMA 2.1. *The probability that a pseudotrapezoidal cell $\tau \in T_k(\mathcal{F})$ is created during the incremental construction of Q^σ, where $\sigma \in \Sigma$ is the tuple for which Π^σ contains τ, is $1/\binom{k+4}{4}$.*

Proof. For τ to be created, it is necessary and sufficient that the four curves of Γ^σ defining τ appear in the random insertion order before any of the curves corresponding to the k functions that contribute to the weight of τ, and this probability is easily seen to be $1/\binom{k+4}{4}$. □

LEMMA 2.2. *For any $0 \le k \le n-d-3$ and for any $\varepsilon > 0$,*

$$N_{\le k}(n) = O((k+1)^{3-\varepsilon} n^{d+\varepsilon}).$$

Proof. We use a variant of the probabilistic analysis technique of Clarkson and Shor [ClS]. If we choose a random sample $R \subseteq \Gamma$ of $r = \lfloor n/(k+1) \rfloor$ functions of $\mathcal{F}$, then a cell $\tau \in T_k(\Gamma)$ is in $T_0(R)$ if all $d+3$ functions, $f_1, \ldots, f_{d+3}$, defining τ are chosen in R, and none of the remaining k functions f_i, such that $f_i(\mathbf{x}) \le f_1(\mathbf{x})$ for some $\mathbf{x} \in \tau$, are chosen in R. The Clarkson–Shor technique implies that

$$\begin{aligned} N_{\le k}(n) &= O((k+1)^{d+3} N_0(\lfloor n/(k+1) \rfloor)) \\ &= O((k+1)^{d+3} (n/(k+1))^{d+\varepsilon}) \\ &= O((k+1)^{3-\varepsilon} n^{d+\varepsilon}), \end{aligned}$$

for any $\varepsilon > 0$. □

For a cell $\tau \in T$, let A_τ be the event that $\tau \in \tilde{Q}_i^\sigma$, for the tuple $\sigma \in \Sigma$ for which T^σ contains τ, and for some $d \le i \le n$. The expected running time of the algorithm, over all choices of $(d-1)$-tuples of functions, is thus proportional to

$$\begin{aligned} \sum_{\tau \in T} \Big[(w(\tau)+1) \cdot \Pr[A_\tau] \Big] + O(n^d) &= \sum_{k \ge 0} \sum_{\tau \in T_k(\mathcal{F})} \Big[(k+1) \cdot \Pr[A_\tau] \Big] + O(n^d) \\ &= \sum_{k=0}^{n-d-3} \frac{(k+1) N_k(\mathcal{F})}{\binom{k+4}{4}} + O(n^d), \end{aligned}$$

where the last inequality follows from Lemma 2.1. Since

$$N_k(\mathcal{F}) = N_{\le k}(\mathcal{F}) - N_{\le (k-1)}(\mathcal{F}),$$

we obtain, using Lemma 2.2,

$$\begin{aligned} &\sum_{k=0}^{n-d-3} \frac{(k+1) N_k(\mathcal{F})}{\binom{k+4}{4}} \\ &= N_0(\mathcal{F}) + 24 \sum_{k=1}^{n-d-3} \frac{N_{\le k}(\mathcal{F}) - N_{\le (k-1)}(\mathcal{F})}{(k+4)(k+3)(k+2)} \\ &= O(n^{d+\varepsilon}) + 24 \sum_{k=1}^{n-d-4} N_{\le k}(n) \left[\frac{1}{(k+4)(k+3)(k+2)} - \frac{1}{(k+5)(k+4)(k+3)} \right] \\ &\qquad + \frac{24 N_{\le n-d-3}(n)}{(n-d+1)(n-d)(n-d-1)} \\ &= O\left(n^{d+\varepsilon} + \sum_{k=1}^{n-d-4} \frac{k^{3-\varepsilon} n^{d+\varepsilon}}{(k+5)(k+4)(k+3)(k+2)} \right) \qquad \text{(using Lemma 2.2)} \end{aligned}$$

$$= O\left(n^{d+\varepsilon} \cdot \sum_{k=1}^{n-d-4} \frac{1}{k^{1+\varepsilon}}\right) = O(n^{d+\varepsilon}) .$$

We thus obtain the following result.

THEOREM 2.3. *The vertices, edges, and 2-faces of the lower envelope of n (partial) d-variate functions, satisfying the conditions stated in the introduction, can be computed in randomized expected time $O(n^{d+\varepsilon})$, for any $\varepsilon > 0$.*

Remark. The preceding analysis shows that, for $d \geq 2$, the expected running time of our algorithm is in fact $O(n^d + \sum_{k=1}^{n} k^{d-1}\varphi(\lfloor n/k \rfloor))$, where $\varphi(r)$ is an upper bound on the complexity of the lower envelope of any subset of S of size at most r. For example, the vertices, edges, and 2-faces of the lower envelope of n simplices in $\mathbb{R}^{d+1}$ can be computed in $O(n^d \alpha(n) \log n)$ expected time, because the complexity of the lower envelope of n d-simplices is $O(n^d \alpha(n))$ [PS].

3. Envelopes in four dimensions. We next apply the results of the preceding section to obtain an efficient algorithm for constructing the lower envelope of a collection $\mathcal{F}$ of n trivariate functions, satisfying the assumptions made above in the following strong sense: One can preprocess $\mathcal{F}$ in randomized expected time $O(n^{3+\varepsilon})$, for any $\varepsilon > 0$, into a data structure of size $O(n^{3+\varepsilon})$ that supports queries of the form: given a point $w \in \mathbb{R}^3$, compute the function(s) attaining $E_{\mathcal{F}}$ at w; each query can be answered in $O(\log^2 n)$ time.

To achieve this we first apply the algorithm summarized in Theorem 2.3 to compute the vertices, edges, and 2-faces of the minimization diagram $M_{\mathcal{F}}$ of $\mathcal{F}$. We next partition each cell of $M_{\mathcal{F}}$ into "monotone" subcells, in the sense of Lemma 3.1, to obtain a refinement $M'_{\mathcal{F}}$ of $M_{\mathcal{F}}$. This refinement satisfies the requirements of the point-location method due to Preparata and Tamassia [PT], which we use to produce the data structure representing the lower envelope in the above manner.

We define and construct $M'_{\mathcal{F}}$ as follows. We mark, along each 2-face F of $M_{\mathcal{F}}$, the locus γ_F of all points of F which are either singular or have a vertical tangency (in the z-direction). The arcs γ_F, for all 2-faces F, lie along $O(n^2)$ curves in $\mathbb{R}^3$, each being the xyz-projection of (i) the locus of all singular points or points with z-vertical tangency along some 2-manifold $f_i = f_j$, for a pair of indices $i \neq j$, or (ii) of points along the boundary of some f_i. We consider below only the former case; the latter case can be handled in almost the same (and, actually, simpler) manner. Let δ be one of these curves. We consider the 2-dimensional surface V_δ, within the xyz-space, obtained as the union of all lines passing through points of δ and parallel to the z-axis; let V_δ^+, V_δ^- denote the portions of V_δ that lie, respectively, above and below δ. (Since δ is not necessarily an xy-monotone arc, V_δ may have self-intersections along some vertical lines, along which V_δ^+ and V_δ^- are not well defined; we omit here details of the (rather easy) handling of such cases.)

Let δ_0 be the portion of δ over which the functions f_i and f_j attain the envelope $E_{\mathcal{F}}$. Clearly, δ_0 is the union of all arcs γ_F that are contained in δ, and the number of connected components in δ_0, summed over all intersection curves δ, is $O(n^{3+\varepsilon})$. Let w be a point in δ_0. Then the cell c of $M_{\mathcal{F}}$ lying immediately above w in the z-direction is such that within c the envelope $E_{\mathcal{F}}$ is attained by either f_i or f_j. Thus the upward-directed z-vertical ray emanating from w leaves c (if at all) at a point above w that lies on the xyz-projection of a 2-manifold of the form $f_i = f_k$ or $f_j = f_k$. (In addition, it is also possible that the ray will encounter a point on the projection of the boundary of the domain of f_i or f_j—this can be handled by similar, but easier, means.) For fixed i and j, there are only $O(n)$ possible 2-manifolds of this kind (i.e., xyz-projections

of surfaces of the form $f_i = f_k$ or $f_j = f_k$). We compute the lower envelope $E^{(\delta)}$ of these $O(n)$ 2-manifolds, restricted to V_δ^+. It is easily seen that the complexity of $E^{(\delta)}$ is $O(\lambda_q(n))$, for some constant q depending on the maximum degree of these 2-manifolds; $\lambda_q(n)$ is the maximum length of Davenport–Schinzel sequences of order q that are composed of n symbols and is close to linear in n for any fixed q [ASS, SA]. We next take the portions of the graph of $E^{(\delta)}$ that lie over δ_0 and "etch" them along the corresponding 2-faces of $M_\mathcal{F}$. We apply a fully symmetric procedure within V_δ^- and repeat these steps for all curves δ. The overall combinatorial complexity of all the added curves is thus $O(n^2\lambda_q(n) + n^{3+\varepsilon}) = O(n^{3+\varepsilon})$, for any $\varepsilon > 0$, and they can be computed in $O(n^{3+\varepsilon})$ time, as is easily verified.

Let $M'_\mathcal{F}$ denote the refined cell decomposition of $\mathbb{R}^3$, obtained by adding to $M_\mathcal{F}$, for each of the curves δ, the arcs γ_F, the etched arcs of the upper and lower envelopes in the vertical manifolds V_δ, and the z-vertical walls (i.e., union of all z-vertical segments) contained in V_δ and connecting the arcs γ_F to the etched arcs. If an edge of $M'_\mathcal{F}$ is not monotone in the y-direction, we split it into $O(1)$ edges by adding a vertex at every local y-extremal point on this edge. As just argued, the combinatorial complexity of $M'_\mathcal{F}$ is still $O(n^{3+\varepsilon})$, and $M'_\mathcal{F}$ has the following crucial property.

LEMMA 3.1. *For each 3-cell c of $M'_\mathcal{F}$, every connected component of a cross section of c by a plane parallel to the xz-plane is x-monotone.*

Proof. Suppose the contrary, and let π be a plane parallel to the xz-plane, for which there exists a connected component c' of $c \cap \pi$ that is not x-monotone. Then there is a point $w \in \partial c'$ so that the z-vertical line passing through w meets c' both slightly above and slightly below w. But then w is either a singular point or a point with z-vertical tangency lying on one of the curves γ_F. By construction, $M'_\mathcal{F}$ must contain the vertical segment passing through w and contained in c, as part of some vertical wall, a contradiction. This completes the proof of the lemma. □

Let $M'_\mathcal{F}(y_0)$ denote the cross section of $M'_\mathcal{F}$ by the plane $y = y_0$. Lemma 3.1 implies that $M'_\mathcal{F}(y_0)$ is an x-monotone planar subdivision, for each y_0. Hence, if we orient the edges of $M'_\mathcal{F}$ in the positive x-direction, add a pair of nominal points s, t at $x = -\infty$ and $x = +\infty$, respectively, and connect them to the appropriate unbounded edges of $M'_\mathcal{F}(y_0)$, this map becomes a planar st-graph, in the notation of Preparata and Tamassia [PT]. (Note that the vertical decomposition that generates $M'_\mathcal{F}$ from $M_\mathcal{F}$ may create z-vertical edges; if these edges are oriented consistently, say in the upward z-direction, then $M'_\mathcal{F}$ remains an st-graph.) We denote this st-graph also by $M'_\mathcal{F}(y_0)$.

LEMMA 3.2. *Let I be an open interval of the y-axis that does not contain the y-coordinate of any vertex of $M'_\mathcal{F}$. Then, for each $y_1, y_2 \in I$, $M'_\mathcal{F}(y_1)$, $M'_\mathcal{F}(y_2)$ are isomorphic, as labeled embedded planar st-graphs.*

Proof. We call a y-coordinate *critical* if it is the y-coordinate of a vertex of $M'_\mathcal{F}$. Since each vertex of $M'_\mathcal{F}(\cdot)$ is an intersection of the sweep plane with an edge of $M'_\mathcal{F}$ and since each edge of $M'_\mathcal{F}$ is y-monotone, the set of vertices of $M'_\mathcal{F}(y)$ can change only at critical values of y. In other words, the set of vertices of the cross section $M'_\mathcal{F}(\cdot)$ does not change combinatorially between any two consecutive critical values. Let (u_1, v_1) be a nonvertical directed edge of $M'_\mathcal{F}(y_1)$, and let u_2, v_2 be the vertices of $M'_\mathcal{F}(y_2)$ corresponding, respectively, to u_1 and v_1 (i.e., the intersections of the sweep plane with the same edges of $M'_\mathcal{F}$). Suppose to the contrary that (u_2, v_2) is not an edge of $M'_\mathcal{F}(y_2)$. There are several ways in which the edge (u_1, v_1) can disappear during the sweep:

(i) it might cease to be x-monotone (with a vertical inflection point, or another

singular point, appearing in its middle),
(ii) some vertical edge might appear and split it in two,
(iii) its two vertices might approach each other and merge into a common vertex, or
(iv) either of the vertices might split into two vertices.

However, as is easily verified, the y-coordinate of any of these events must be one of the critical values of y, contrary to assumption that the interval I does not contain the y-coordinate of any vertex of $M'_{\mathcal{F}}$. A similar argument handles the case where (u_1, v_1) is a vertical edge of $M'_{\mathcal{F}}(y_1)$: such an edge is erected if one of these vertices, say u_1, has a z-vertical tangency, or is otherwise singular along one of the surfaces of $M_{\mathcal{F}}$. As we sweep from y_1 to y_2, this vertical edge might disappear if any of the following events occurs:

(i) the point corresponding to u_1 changes its singular status (for simplicity of exposition, the term "singular" refers here both to singular points and to points with z-vertical tangency);
(ii) the point corresponding to u_1 splits into two vertices or merges with another vertex of the cross section;
(iii) the point corresponding to v_1 splits into two vertices or merges with another vertex;
(iv) the point corresponding to v_1 becomes singular on its surface; or
(v) another singular point appears on the vertical segment u_1v_1.

Again, for any of these events, its y-coordinate must be critical, contrary to assumption. This completes the proof of the lemma. □

We are now in a position to apply the point-location technique of Preparata and Tamassia [PT]. They show that a 3-dimensional subdivision of combinatorial complexity N can be preprocessed in time $O(N \log^2 N)$ into a data structure of size $O(N \log^2 N)$, which supports $O(\log^2 N)$-time point-location queries in the given subdivision. However, for this to hold, the subdivision must have the following two properties:

(a) the 1-skeleton of each cross section of the subdivision by a plane parallel to the xz-plane is a planar st-graph, whose faces are all monotone in the x-direction and whose edges are all oriented in the positive x-direction (or, for vertical edges, in the positive z-direction).
(b) At each point where the cross section, as an st-graph, changes, the graph can be updated by a constant number of operations from the following collection:
  (b.1) insertion of a vertex in the middle of an edge, or the complementary operation of deleting a vertex of in-degree and out-degree 1 and replacing the two incident edges by one, while maintaining x-monotonicity of the incident faces;
  (b.2) insertion of an edge partitioning an x-monotone face into two x-monotone subfaces, or, conversely, deletion of an edge and merging its two adjacent faces, provided their union is x-monotone;
  (b.3) merging two adjacent vertices into one vertex (collapsing the edge connecting them) or splitting a vertex into two vertices (forming a new edge between these vertices), again maintaining x-monotonicity.

It is easily verified that, indeed, each change occurring in the structure of the cross section $M'_{\mathcal{F}}(\cdot)$, at any of the critical y values in Lemma 3.2, can be expressed as a constant number of operations of the types mentioned above. In summary, we thus obtain the following main result of the paper.

THEOREM 3.3. *Let $\mathcal{F}$ be a given collection of n trivariate, possibly partially defined, functions, all algebraic of constant maximum degree, and whose domains of definition (if they are partially defined) are each defined by a constant number of algebraic equalities and inequalities of constant maximum degree. Then, for any $\varepsilon > 0$, the lower envelope $E_{\mathcal{F}}$ of $\mathcal{F}$ can be computed in randomized expected time $O(n^{3+\varepsilon})$, and stored in a data structure of size $O(n^{3+\varepsilon})$, so that, given any query point $w \in \mathbb{R}^3$, we can compute $E_{\mathcal{F}}(w)$, as well as the function(s) attaining $E_{\mathcal{F}}$ at w, in $O(\log^2 n)$ time.*

4. Applications: Query problems. In this section we apply Theorem 3.3 to two problems involving preprocessing and querying certain collections of objects in 3-space.

4.1. Ray shooting amidst spheres. Given a collection $\mathcal{S}$ of n spheres in 3-space, we wish to preprocess $\mathcal{S}$ into a data structure that supports *ray-shooting* queries, each seeking the first sphere, if any, met by a query ray. This problem has recently been studied in [AMb, AGPS, MS]. The first two papers present a data structure that requires $O(n^{4+\varepsilon})$ storage and preprocessing, for any $\varepsilon > 0$, and answers a query in time $O(\log^2 n)$. The third paper [MS] gives a rather elaborate and improved solution that requires $O(n^{3+\varepsilon})$ preprocessing and storage, for any $\varepsilon > 0$, and answers a query in $O(n^{\varepsilon})$ time.

These algorithms use the technique described in [AMa] and reduce the problem to that of determining whether a query segment e intersects any sphere of $\mathcal{S}$. Then, using a multilevel data structure, they reduce the problem to that of detecting whether the line λ containing the segment e intersects any sphere of $\mathcal{S}$. As observed in [AGPS, MS], this problem can be further reduced to point location in the upper envelope of a set of certain trivariate functions, as follows. Let π be the plane passing through λ and orthogonal to the vertical plane V passing through λ. Let π^+ (resp., π^-) be the half-space lying above (resp., below) π. Let S be a sphere whose center lies in π^+ and that intersects V in a disc D. Then the center of D lies above λ, so either λ intersects S or passes below S, in the sense that λ and S are disjoint and there is a point on λ that lies vertically below a point in S (see Figure 1). A similar property holds if S intersects V and its center lies in π^-. We preprocess the centers of spheres of $\mathcal{S}$ into a half-space range-searching data structure of size $O(n^{3+\varepsilon})$. Then, for a query λ, we can decompose $\mathcal{S}$ into $O(1)$ canonical subsets, so that, within each subset, either the centers of all spheres lie in π^+ or they all lie in π^-. Let us consider the case when the centers of all spheres lie in π^+.

Hence, we need to solve the following subproblem: Given a set $\mathcal{S}$ of n spheres in 3-space, and given a query line λ with the property that for each sphere $S \in \mathcal{S}$, either λ intersects S or there is no point of S lying vertically below λ, determine whether λ intersects any sphere of $\mathcal{S}$. We reduce this problem to point location in the lower envelope of certain trivariate functions as follows. We can parametrize a line λ in 3-space by four parameters $(\xi_1, \xi_2, \xi_3, \xi_4)$, so that the equations defining λ are $y = x\xi_1 + \xi_2$, $z = x\xi_3 + \xi_4$. (We assume here that λ is not parallel to the yz-plane; such lines can be handled in a different, and much simpler manner.) For each sphere $S \in \mathcal{S}$, define a function $\xi_4 = F_S(\xi_1, \xi_2, \xi_3)$, so that the line $\lambda(\xi_1, \xi_2, \xi_3, \xi_4)$ is tangent to S from below (F_S is only partially defined, and we put $F_S = +\infty$ when it is undefined; it is easily checked that F_S is algebraic of bounded degree and that its boundary is also algebraic of bounded degree). Let Φ be the lower envelope of the functions F_S, for $S \in \mathcal{S}$. Then a query line $\lambda(\xi_1, \xi_2, \xi_3, \xi_4)$ having the above properties misses all spheres of $\mathcal{S}$ if and only if $\xi_4 < \Phi(\xi_1, \xi_2, \xi_3)$. Thus, by Theorem 3.3,

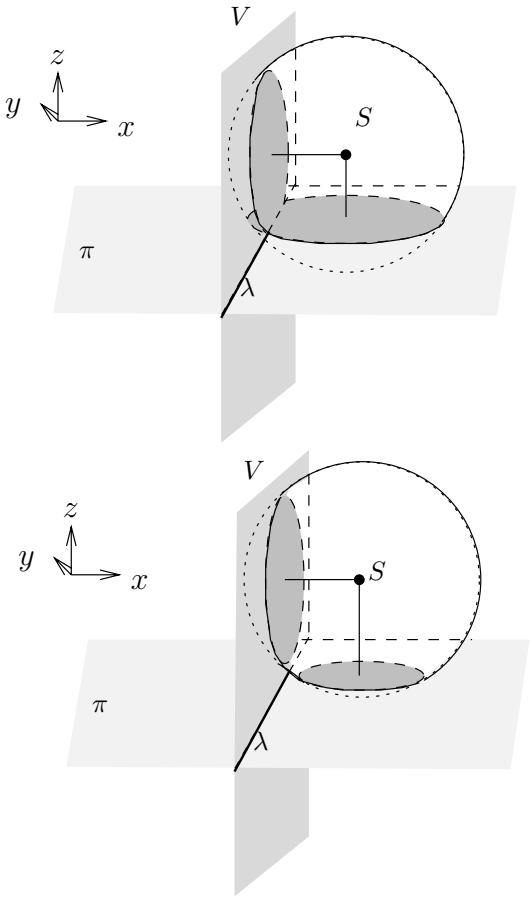

FIG. 1. *In the reduced subproblem, λ either intersects S or passes below it.*

one can answer such queries in time $O(\log^2 n)$, using $O(n^{3+\varepsilon})$ preprocessing time and storage, for any $\varepsilon > 0$. Plugging the half-space range-searching data structure and the point-location data structure into the multilevel data structure described in [AGPS, MS], we obtain a data structure for the segment-emptiness problem. A closer analysis of this data structure shows that the preprocessing time and storage of the overall data structure is still $O(n^{3+\varepsilon})$, for any $\varepsilon > 0$, and that the query time is $O(\log^2 n)$. Finally, plugging this data structure for segment-emptiness queries into the general ray-shooting technique of Agarwal and Matoušek [AMa], we obtain a final data structure, still requiring near-cubic storage and preprocessing, using which one can answer a ray-shooting query in time $O(\log^4 n)$. That is, we have shown the following.

THEOREM 4.1. *A set $\mathcal{S}$ of n spheres in $\mathbb{R}^3$ can be preprocessed in randomized expected time $O(n^{3+\varepsilon})$ into a data structure of size $O(n^{3+\varepsilon})$, for any $\varepsilon > 0$, so that a ray-shooting query can be answered in time $O(\log^4 n)$.*

4.2. Nearest-neighbor queries. Let $\mathcal{S} = \{s_1, \ldots, s_n\}$ be a collection of n objects ("sites") in 3-space, each having *constant description complexity*, namely, each defined by a constant number of algebraic equalities and inequalities of constant max-

imum degree. We wish to compute the *Voronoi diagram* $Vor(\mathcal{S})$ of $\mathcal{S}$ and preprocess it for efficient point-location queries. That is, each query specifies a point w in 3-space and seeks the site of $\mathcal{S}$ nearest to w (say, under the Euclidean distance). This is a generalization to 3-space of the classical *post-office problem*.

As observed in [ES], the problem is equivalent to the computation of the following lower envelope in 4-space. For each $s \in \mathcal{S}$, define $F_s(x, y, z)$ to be the Euclidean distance from (x, y, z) to s, and let Φ be the lower envelope of these functions. Then, given a query point (x, y, z), the site(s) $s \in \mathcal{S}$ nearest to w are those for which F_s attains Φ at (x, y, z). Thus, by Theorem 3.3, S can be preprocessed in $O(n^{3+\varepsilon})$ time, for any $\varepsilon > 0$, into a data structure of size $O(n^{3+\varepsilon})$, so that each query can be answered in $O(\log^2 n)$ time. (Note that Theorem 3.3 is indeed applicable here, because the functions F_s are all (piecewise) algebraic of constant maximum degree, as is easy to verify from the conditions assumed above.) Hence, we can conclude the following.

THEOREM 4.2. *A set $\mathcal{S}$ of n objects in $\mathbb{R}^3$, as described above, can be preprocessed in randomized expected time $O(n^{3+\varepsilon})$ into a data structure of size $O(n^{3+\varepsilon})$, for any $\varepsilon > 0$, so that a nearest-neighbor query can be answered in time $O(\log^2 n)$.*

This is a fairly general framework and admits numerous generalizations, e.g., we may replace the Euclidean distance by other distances, perform queries with objects other than points (as long as the location of a query object can be specified by only three real parameters; this is the case, e.g., if the query objects are translates of some rigid convex object), etc. Of course, any such generalization requires that the metric or the query objects also have constant description complexity, in the above sense. An interesting generalization is to *dynamic* nearest-neighbor queries in the plane, where each object of $\mathcal{S}$ moves along some given trajectory and each query (x, y, t) asks for the object of $\mathcal{S}$ nearest to the point (x, y) at time t. Using the same approach as above, this can be done, under appropriate assumptions on the shape and motion of the objects of $\mathcal{S}$, with $O(n^{3+\varepsilon})$ preprocessing time and storage, for any $\varepsilon > 0$ and $O(\log^2 n)$ query time.

Remarks. (i) In Theorem 4.2 we do not assume that the objects are pairwise disjoint. In this case one cannot hope to do much better, because the complexity of the Voronoi diagram of a set of intersecting objects in $\mathbb{R}^3$ is easily seen to be cubic in the worst case. For example, consider the Voronoi diagram of a set of planes in $\mathbb{R}^3$.

(ii) There is a prevailing conjecture that the complexity of generalized Voronoi diagrams of a set of *pairwise disjoint convex* objects in $\mathbb{R}^3$, and of dynamic Voronoi diagrams in the plane, is only near-quadratic, under reasonable assumptions concerning the distance function and the shape of the sites (and of their motions in the dynamic sense). This was indeed proved recently in [CKSW] for the case where the sites are lines in $\mathbb{R}^3$ and the distance function is induced by a convex polyhedron, and in [BSTY] for point sets under the L_1 or L_∞ metric. If this conjecture is established, then the above algorithm, of near-cubic cost, is far from being optimal for pairwise disjoint objects and will need to be improved considerably.

5. Applications: Batched problems. We next consider *batched* applications. These applications solve a variety of rather unrelated problems, but they all involve an almost identical subproblem, in which lower (or upper) envelopes in 4-space play a role. To avoid repetition, we describe in detail only one application and then state the improved bounds for the other applications without proof, referring the reader to the relevant literature.

The following applications are based on the *parametric-search* technique of Megiddo

[Me], which, in our case, requires a parallel algorithm for computing the lower envelope of a set of surfaces. However, the algorithm presented above is highly unparallelizable, because it uses an incremental insertion procedure of regions into 2-dimensional arrangements and later uses a plane-sweep in 3-space. To finesse this difficulty, we apply the parametric-search technique with an additional twist that avoids the need for a parallel algorithm.

5.1. Width in 3-space. Let S be a set of n points in 3-space. The *width* of S is the smallest distance between a pair of parallel planes so that the closed slab between the planes contains S. In two dimensions, the problem can be easily solved in $O(n \log n)$ time. An $O(n^2)$-time algorithm for three dimensions was presented in [HT]. Recently, Chazelle et al. [CEGSb] presented an $O(n^{8/5+\varepsilon})$-time algorithm for any $\varepsilon > 0$. In this subsection, we present an improved randomized algorithm, whose expected running time is $O(n^{17/11+\varepsilon}) = O(n^{1.546})$.

Clearly, it suffices to compute the width of the convex hull of S, so assume that the points of S are in convex position and that the convex hull $\mathcal{P}$ of S is given. It is known that any two planes defining the width of S are such that either one touches a face of $\mathcal{P}$ and one touches a vertex of $\mathcal{P}$, or each of them touches an edge of $\mathcal{P}$; see [CEGSb, HT]. The first case can be handled in $O(n \log n)$ time [CEGSb, HT]. The difficult case is to compute the smallest distance between a pair of parallel planes supporting $\mathcal{P}$ at two "antipodal" edges because, in the worst case, there can be $\Theta(n^2)$ such pairs of edges. Chazelle et al. [CEGSb] presented an $O(n^{8/5+\varepsilon})$-time algorithm to find the smallest distance, using the parametric-search technique. We will present a randomized algorithm, whose expected running time is $O(n^{17/11+\varepsilon})$, for any $\varepsilon > 0$, using a somewhat different approach.

Let $\mathcal{M}$ denote the *Gaussian diagram* (or *normal diagram*) of $\mathcal{P}$. $\mathcal{M}$ is a spherical map on the unit sphere $\mathbb{S}^2 \subset \mathbb{R}^3$. The vertices of $\mathcal{M}$ are points on $\mathbb{S}^2$, each being the outward normal of a face of $\mathcal{P}$, the edges of $\mathcal{M}$ are great circular arcs, each being the locus of the outward normal directions of all planes supporting $\mathcal{P}$ at some fixed edge, and the faces of $\mathcal{M}$ are regions, each being the locus of the outward normal directions of all planes supporting $\mathcal{P}$ at a vertex. $\mathcal{M}$ can be computed in linear time from $\mathcal{P}$. Let $\mathcal{M}'$ denote the spherical map $\mathcal{M}$ reflected through the origin, and consider the superposition of $\mathcal{M}$ and $\mathcal{M}'$. It suffices to consider the top parts of $\mathcal{M}$ and $\mathcal{M}'$, i.e., their portions within the hemisphere $z \geq 0$. Each intersection point between an edge of $\mathcal{M}$ and an edge of $\mathcal{M}'$ gives us a direction $\mathbf{u}$ for which there exist two parallel planes orthogonal to $\mathbf{u}$ and supporting $\mathcal{P}$ at two so-called "antipodal" edges. Thus the problem reduces to that of finding an intersection point for which the distance between the corresponding parallel supporting planes is minimized.

We centrally project the edges of (the top portions of) $\mathcal{M}$ and $\mathcal{M}'$ onto the plane $z = 1$. Each edge projects to a line segment or a ray. Let $\mathcal{E}$ and $\mathcal{E}'$ be the resulting sets of segments and rays in the plane. Using the algorithm described in [CEGSa], we can decompose $\mathcal{E} \times \mathcal{E}'$, in time $O(n \log^2 n)$, into a family of "canonical subsets"

$$\mathcal{F} = \{(\mathcal{E}_1, \mathcal{E}'_1), (\mathcal{E}_2, \mathcal{E}'_2), \ldots, (\mathcal{E}_t, \mathcal{E}'_t)\}\,, \tag{1}$$

such that

(i) $\mathcal{E}_i \subseteq \mathcal{E}$ and $\mathcal{E}'_i \subseteq \mathcal{E}'$;
(ii) $\sum_{i=1}^{t} (|\mathcal{E}_i| + |\mathcal{E}'_i|) = O(n \log^2 n)$;
(iii) each segment in $\mathcal{E}_i$ intersects every segment of $\mathcal{E}'_i$; and
(iv) for every pair (e, e') of intersecting segments in $\mathcal{E} \times \mathcal{E}'$, there is an i such that $e \in \mathcal{E}_i$ and $e' \in \mathcal{E}'_i$.

By property (iv), it suffices to consider each pair $(\mathcal{E}_i, \mathcal{E}'_i)$ separately. Let $\mathcal{L}_i$ (resp., $\mathcal{L}'_i$) denote the set of lines containing the edges of $\mathcal{P}$ corresponding to the edges of $\mathcal{E}_i$ (resp., $\mathcal{E}'_i$). By construction, all lines of $\mathcal{L}_i$ lie above all lines of $\mathcal{L}'_i$. Property (iii) implies that every pair of parallel planes π, π', where π contains a line λ of $\mathcal{L}_i$ and π' contains a line λ' of $\mathcal{L}'_i$, are supporting planes of $\mathcal{P}$. Hence, we want to compute the smallest distance between two such planes. Since the distance between π and π', as above, is equal to the distance between λ and λ', it follows that this problem is equivalent to that of computing the closest pair of lines in $\mathcal{L}_i \times \mathcal{L}'_i$. Hence, we need to solve the following problem: Given a set $\mathcal{L}$ of m "red" lines and another set $\mathcal{L}'$ of n "blue" lines in $\mathbb{R}^3$, such that all red lines lie above all blue lines, compute the closest pair of lines in $\mathcal{L} \times \mathcal{L}'$. For any pair of lines $\ell, \ell' \in \mathbb{R}^3$, let $d(\ell, \ell')$ be the Euclidean distance between them, and let

$$d(\mathcal{L}, \mathcal{L}') = \min_{\ell \in \mathcal{L},\, \ell' \in \mathcal{L}'} d(\ell, \ell')\,.$$

We first describe a simple randomized divide-and-conquer algorithm for computing $\delta^* = d(\mathcal{L}, \mathcal{L}')$, whose expected running time is $O(n^{3+\varepsilon} + m \log^2 n)$. If $m = O(1)$, we compute $d(\ell, \ell')$ for all pairs $\ell \in \mathcal{L}$, $\ell' \in \mathcal{L}'$ and choose the minimum distance. Otherwise, the algorithm performs the following steps:

(i) Choose a random subset $R_1 \subseteq \mathcal{L}$ of $m/2$ red lines; each subset of size $m/2$ is chosen with equal probability.
(ii) Solve the problem recursively for $(R_1, \mathcal{L}')$. Let $\delta_1 = d(R_1, \mathcal{L}')$.
(iii) Compute the set $R_2 = \{\ell \in \mathcal{L} \setminus R_1 \mid d(\ell, \mathcal{L}') < \delta_1\}$.
(iv) Compute $d(\ell, \ell')$ for all pairs $\ell \in R_2$, $\ell' \in \mathcal{L}'$, and output the minimum distance (or output δ_1 if R_2 is empty).

For a line $\ell' \in \mathcal{L}'$, let $R^{(\ell')} = \{\ell \in \mathcal{L} \mid d(\ell, \ell') < \delta_1\}$, so that $R_2 = \bigcup_{\ell' \in \mathcal{L}'} R^{(\ell')}$. Using a standard probabilistic argument, we can show that the expected size of $R^{(\ell')}$ is $O(1)$, for each $\ell' \in \mathcal{L}'$. Therefore the expected size of R_2 is $O(n)$. Consequently, the expected running time of step (iv) is $O(n^2)$. The only nontrivial step in the above algorithm is step (iii). We compute R_2 as follows. We map each line $\ell \in \mathcal{L}$ to a point $\psi(\ell) = (a_1, a_2, a_3, a_4)$ in $\mathbb{R}^4$, where $y = a_1 x + a_2$ is the equation of the xy-projection of ℓ, and $z = a_3 u + a_4$ is the equation of ℓ in the vertical plane $y = a_1 x + a_2$ (here u denotes the axis orthogonal to the z-axis). We can also map a line ℓ' to a surface $\gamma = \gamma(\ell')$ in this parameter space, which is the locus of all points $\psi(\ell)$ such that $d(\ell, \ell') = \delta_1$ and ℓ lies above ℓ'. Our choice of parameters ensures that $\gamma(\ell')$ is $x_1x_2x_3$-monotone; i.e., any line parallel to the x_4-axis intersects $\gamma(\ell')$ in at most one point. For any point lying below $\gamma(\ell')$ the corresponding line ℓ either lies below ℓ' or lies above ℓ' and $d(\ell, \ell') < \delta_1$. For a point lying above $\gamma(\ell')$, the corresponding line ℓ lies above ℓ' and $d(\ell, \ell') > \delta_1$. In view of the above discussion, $\gamma(\ell')$ is the graph of a partial function $x_4 = f_{\ell'}(x_1, x_2, x_3)$. (The function $f_{\ell'}$ is undefined only at points (x_1, x_2, x_3) that represent lines whose xy-projection is parallel to that of ℓ'; the locus of these points is a plane.) Let

$$F(x_1, x_2, x_3) = \max_{\ell' \in \mathcal{L}'} f_{\ell'}(x_1, x_2, x_3)$$

be the upper envelope of the set $\{f_{\ell'} \mid \ell' \in \mathcal{L}'\}$. For a line $\ell \in \mathcal{L}$ with $\psi(\ell) = (a_1, a_2, a_3, a_4)$, we have $a_4 \geq F(a_1, a_2, a_3)$ if and only if $d(\{\ell\}, \mathcal{L}') \geq \delta_1$. The problem of computing R_2 thus reduces to that of computing the set of points $\psi(\ell)$, for $\ell \in \mathcal{L} \setminus R_1$, that lie below the upper envelope F. By Theorem 3.3, this can be accomplished in

time $O(n^{3+\varepsilon} + m\log^2 n)$, for any $\varepsilon > 0$. The total time spent in steps (iii) and (iv) is thus $O(n^{3+\varepsilon} + m\log^2 n)$. Let $T(m,n)$ denote the maximum expected running time of the algorithm. Then

$$T(m,n) = \begin{cases} O(n) & \text{if } m \le m_0\,, \\ T\left(\frac{m}{2}, n\right) + O(n^{3+\varepsilon} + m\log^2 n) & \text{if } m > m_0\,, \end{cases}$$

where m_0 is a constant. The solution to this recurrence is easily seen to be

$$T(m,n) = O(n^{3+\varepsilon}\log m + m\log^2 n).$$

Hence, we can conclude the following.

LEMMA 5.1. *Given a set $\mathcal{L}$ of m lines and another set $\mathcal{L}'$ of n lines in $\mathbb{R}^3$, such that all lines in $\mathcal{L}$ lie above all lines of $\mathcal{L}'$, the closest pair of lines in $\mathcal{L}\times\mathcal{L}'$ can be computed in time $O(n^{3+\varepsilon}\log m + m\log^2 n)$ for any $\varepsilon > 0$.*

Next, we describe another algorithm for computing $\delta^* = d(\mathcal{L},\mathcal{L}')$, which uses the above procedure as a subroutine. We first describe an algorithm for the "fixed-size" problem that, given a parameter δ, determines whether $\delta^* < \delta$, $\delta^* = \delta$, or $\delta^* > \delta$. Next, we apply the parametric-search technique to this algorithm, with an additional twist, to compute $d(\mathcal{L},\mathcal{L}')$.

Consider the fixed-size problem. If $m > n^{3+\varepsilon}$, the problem can be solved in $O(m\log^2 n)$ time by computing δ^* using Lemma 5.1 and then comparing δ^* with δ. So assume that $m \le n^{3+\varepsilon}$.

We now map each line $\ell' \in \mathcal{L}'$ to the point $\psi(\ell')$, as defined above, and each line $\ell \in \mathcal{L}$ to a surface $\phi(\ell)$, which is the locus of all points $\psi(\ell')$ such that $d(\ell,\ell') = \delta$ and ℓ' lies below ℓ. (This is a dual representation of the problem, where the roles of $\mathcal{L}$ and of $\mathcal{L}'$ are interchanged.) The open region ϕ^- lying below $\phi(\ell)$ consists of points corresponding to lines ℓ' that lie below ℓ and satisfy $d(\ell,\ell') > \delta$. Again, each surface $\phi(\ell)$ is $x_1x_2x_3$-monotone; i.e., $\phi(\ell)$ is the graph of a partial function $x_4 = g_\ell(x_1,x_2,x_3)$. Let

$$G(x_1,x_2,x_3) = \min_{\ell\in\mathcal{L}} g_\ell(x_1,x_2,x_3)$$

be the lower envelope of these functions. By the same argument as above, $d(\mathcal{L},\mathcal{L}') < \delta$ if and only if there is a point $\psi(\ell')$, for some $\ell' \in \mathcal{L}'$, that lies above the lower envelope G, and $d(\mathcal{L},\mathcal{L}') = \delta$ if and only if no point corresponding to the lines of $\mathcal{L}'$ lies above G and at least one such point lies on G. To detect these two conditions, we proceed as follows.

(i) Fix a sufficiently large constant r. Choose a random subset $R \subset \mathcal{L}$ of size $t = cr\log r$, where c is some appropriate constant independent of r.

(ii) Let $\Gamma_R = \{g_\ell \mid \ell \in R\}$ be the set of t trivariate functions corresponding to the lines of R, and let G_R be the lower envelope of Γ_R. Decompose the region of $\mathbb{R}^4$ lying below G_R into a collection $\Xi = \{\tau_1, \ldots, \tau_k\}$ of $k = O(t^4\beta(t)) = O(r^4\beta(r)\log^4 r)$ semialgebraic cells of constant description complexity each; here $\beta(r)$ is a slowly growing function whose exact form is determined by the algebraic degree of the surfaces in Γ. Such a decomposition can be obtained using the algorithms described in [AST, CEGSb]. It is based on a decomposition of $\mathbb{R}^3$ into a family Ξ' of $O(r^4\beta(r)\log^4 r)$ cells of constant description complexity, so that, within each cell, the same set of

function graphs appear on the lower envelope G_R. The decomposition Ξ is then defined as the following collection of semiunbounded "prisms":

$$\Xi = \Big\{ \{(\mathbf{x}, z) \mid \mathbf{x} \in \Delta, z \le G_R(\mathbf{x})\} \mid \Delta \in \Xi' \Big\}.$$

(iii) For each prism $\tau \in \Xi$, let $\mathcal{L}_\tau = \{\ell \in \mathcal{L} \mid \phi(\ell) \cap \tau \neq \emptyset\}$ and $\mathcal{L}'_\tau = \{\ell' \in \mathcal{L}' \mid \psi(\ell') \in \tau\}$.

(iv) If $\bigcup_{\tau \in \Xi} \mathcal{L}'_\tau \neq \mathcal{L}'$ (i.e., there is a line $\ell' \in \mathcal{L}'$ such that the point $\psi(\ell')$ lies above G_R), then return $\delta > \delta^*$. If there is a $\tau \in \Xi$ such that $|\mathcal{L}_\tau| > m/r + 1$, then go back to Step (i).

(v) For each prism $\tau \in \Xi$, if both $\mathcal{L}_\tau, \mathcal{L}'_\tau$ are nonempty, then solve the problem recursively for $\mathcal{L}_\tau$ and $\mathcal{L}'_\tau$. If there is a subproblem for which $\delta > d(\mathcal{L}_\tau, \mathcal{L}'_\tau)$, then return $\delta > \delta^*$. If there is no such subproblem, but there is one subproblem for which $\delta = \delta^*$, then return $\delta = \delta^*$. Finally, if none of these two cases occur, then return $\delta < \delta^*$.

The correctness of the algorithm follows from the above observations. As for the running time, the well-known results on random sampling [ClS, HW] imply that if c is chosen sufficiently large then, with high probability, $|\mathcal{L}_\tau| \le m/r + 1$ for every $\tau \in \Xi$. Hence, the expected number of times we have to go back to step (i) from step (iv) is only a constant. Let $T(m, n)$ denote the expected running time of the algorithm. Then

$$T(m,n) = \begin{cases} O(m \log^2 n) & \text{if } m \ge n^{3+\varepsilon}, \\ \displaystyle\sum_{i=1}^{k} T\Big(\frac{m}{r} + 1, n_i\Big) + O(m+n) & \text{if } m < n^{3+\varepsilon}, \end{cases}$$

where $\sum_i n_i = n$ and $k = O(r^4 \beta(r) \log^4 r)$. The solution of the above recurrence is easily seen to be

$$T(m,n) = O(m^{8/11+\varepsilon'} n^{9/11+\varepsilon'} + m^{1+\varepsilon'} + n^{1+\varepsilon'})$$

for any $\varepsilon' > \varepsilon$.

Next, we describe how to apply the parametric-search technique to this algorithm. As mentioned earlier, we cannot use this algorithm directly in the parametric-search paradigm, because we do not know how to parallelize the first algorithm. We therefore simulate the above sequential algorithm at $\delta = \delta^*$ with the additional twist that, instead of just simulating the solution of the fixed-size problem at δ^*, the algorithm will attempt to compute δ^* explicitly. Since r is chosen to be constant, the set Ξ can be computed by making only $r^{O(1)}$ implicit "sign tests" involving δ^*, thus only a constant number, $r^{O(1)}$, of solutions of the fixed-size problem are needed; see [AST, CEGSb] for details. It can be checked that the problem of determining whether a surface $\phi(\ell)$ intersects a prism $\tau \in \Xi$ or whether a point $\psi(\ell')$ lies in τ can be reduced to computing the signs of a constant number of univariate polynomials, each of constant degree, at δ^* (this follows since τ has constant description complexity). Let $\Pi = \{p_1(\delta), \ldots, p_s(\delta)\}$, where $s = O(m+n)$, be the set of these polynomials, over all lines of $\mathcal{L}, \mathcal{L}'$ and over all prisms of Ξ. Let $\delta_1 < \cdots < \delta_u$ be the real roots of these polynomials, where u is also $O(m+n)$. By a binary search over these roots we compute the largest root δ_α such that $\delta_\alpha \le d(\mathcal{L}, \mathcal{L}')$. Each step of the binary search involves comparing δ^* with some δ_i, which in turn involves solving an instance of the fixed-size problem for some δ_i. If $\delta_\alpha = \delta^*$, we have found the value of δ^* so we stop right away. Thus,

assume that $\delta_\alpha < \delta^*$. We can now easily resolve the signs of all polynomials of Π by evaluating them at $(\delta_\alpha + \delta_{\alpha+1})/2$. Once we have computed $\mathcal{L}_\tau, \mathcal{L}'_\tau$ for all $\tau \in \Xi$, we compute $d(\mathcal{L}_\tau, \mathcal{L}'_\tau)$ recursively and return $\min_{\tau\in\Xi} d(\mathcal{L}_\tau, \mathcal{L}'_\tau)$ as $d(\mathcal{L}, \mathcal{L}')$. (Note that $\bigcup_{\tau\in\Xi} \mathcal{L}'_\tau = \mathcal{L}'$, since we are simulating the algorithm at δ^*.) The correctness of the algorithm is established by the following lemma.

LEMMA 5.2. *If none of the calls to the fixed-size problem in steps* (i)–(iv) *returns the value of* $d(\mathcal{L}, \mathcal{L}')$, *then* $d(\mathcal{L}, \mathcal{L}') = \min_{\tau\in\Xi} d(\mathcal{L}_\tau, \mathcal{L}'_\tau)$.

Proof. Let $\delta^* = d(\mathcal{L}, \mathcal{L}')$, and let $\ell \in \mathcal{L}$, $\ell' \in \mathcal{L}'$ be a pair of lines such that $d(\ell, \ell') = \delta^*$. Since we are simulating the fixed-size problem at $\delta = \delta^*$, no point corresponding to the lines of $\mathcal{L}'$ lies above the lower envelope of the surfaces defined by $\mathcal{L}$ (for $\delta = \delta^*$), that is, there exists a prism $\tau \in \Xi$ such that $\ell' \in \mathcal{L}'_\tau$ (i.e., $\psi(\ell')$ lies in τ). If ℓ does not belong to $\mathcal{L}_\tau$, then $\psi(\ell')$ lies below $\phi(\ell)$, which implies that $d(\ell, \ell') > \delta^*$, a contradiction. Hence the pair (ℓ, ℓ') appears in the subproblem involving $\mathcal{L}_\tau$ and $\mathcal{L}'_\tau$. □

Let $T'(m, n)$ denote the maximum expected running time of the algorithm. Then we obtain the following recurrence

$$T'(m,n) = \begin{cases} O(m \log^2 n) & \text{if } m \geq n^{3+\varepsilon}, \\ \displaystyle\sum_{i=1}^{O(r^4\beta(r)\log^4 r)} T'\Big(\frac{m}{r} + 1, n_i\Big) + r^{O(1)} O(m^{8/11+\varepsilon} n^{9/11+\varepsilon} + m^{1+\varepsilon} + n^{1+\varepsilon}) & \\ & \text{if } m < n^{3+\varepsilon}. \end{cases}$$

The solution of the above recurrence is also

$$T'(m,n) = O(m^{8/11+\varepsilon'} n^{9/11+\varepsilon'} + m^{1+\varepsilon'} + n^{1+\varepsilon'})$$

for a different but still arbitrarily small constant $\varepsilon' > \varepsilon$.

Hence, we obtain the following result.

LEMMA 5.3. *Given a set* $\mathcal{L}$ *of* m *lines and another set* $\mathcal{L}'$ *of* n *lines such that all lines in* $\mathcal{L}$ *lie above all lines of* $\mathcal{L}'$, *the closest pair of lines in* $\mathcal{L} \times \mathcal{L}'$ *can be computed in randomized expected time* $O(m^{8/11+\varepsilon} n^{9/11+\varepsilon} + m^{1+\varepsilon} + n^{1+\varepsilon})$ *for any* $\varepsilon > 0$.

Finally, we apply Lemma 5.3 to all subsets $(\mathcal{E}_i, \mathcal{E}'_i)$ of $\mathcal{F}$ (see (1)) and output the minimum of the distances obtained for each subproblem. This is equal to the minimum distance between any pair of parallel planes, each supporting an edge of $\mathcal{P}$. The total expected running time is

$$\sum_{i=1}^{t} O\left(|\mathcal{E}_i|^{8/11+\varepsilon} |\mathcal{E}'_i|^{9/11+\varepsilon} + |\mathcal{E}_i|^{1+\varepsilon} + |\mathcal{E}'_i|^{1+\varepsilon}\right) = O(n^{17/11+\varepsilon'}),$$

where ε' is yet another but still arbitrarily small positive constant.

Putting everything together, we can conclude the following.

THEOREM 5.4. *The width of a set of* n *points in* $\mathbb{R}^3$ *can be computed in randomized expected time* $O(n^{17/11+\varepsilon})$, *for any* $\varepsilon > 0$.

Remark. Informally speaking, the "ugly" exponent 17/11 is the result of an interaction between the exponent 3, appearing in the bound of Theorem 3.3, and the exponent 4, appearing in the bound for the size of the vertical decomposition Ξ used above. After the original submission of this paper, Agarwal and Sharir [ASb] observed that, for the width problem and for the two problems studied below, one can show that the size of this vertical decomposition is only near cubic in the number of

surfaces. This in turn leads to an improved analysis of the above algorithm and implies that its running time is only $O(n^{3/2+\varepsilon})$ for any $\varepsilon > 0$ (and a similar improvement applies to the two subsequent algorithms given below). Agarwal and Sharir [ASb] gave a different randomized algorithm for these problems, without using parametric searching.

5.2. Biggest stick in a simple polygon. Let P be a simple polygon in the plane having n edges. We wish to find the longest line segment e that is contained in (the closed set) P. Chazelle and Sharir presented in [CS] an $O(n^{1.99})$-time algorithm for this problem, which was later improved by Agarwal, Sharir, and Toledo [AST] to $O(n^{8/5+\varepsilon})$ for any $\varepsilon > 0$. The latter paper reduces this problem, just as in the computation of the width of a point set in 3-space, to that of finding the extreme value of a certain function of two parameters, optimized over all intersection points between the edges of two straight-edge planar maps. This problem, in turn, can be reduced to the problem of optimizing the function over all intersection points of pairs of lines in $\mathcal{L}_1 \times \mathcal{L}_2$, where $\mathcal{L}_1, \mathcal{L}_2$ are two appropriate families of lines in the plane. By regarding the lines of $\mathcal{L}_1$ as data points, and each line of $\mathcal{L}_2$ as inducing a certain function over the lines of $\mathcal{L}_1$, and by using an appropriate parametrization of these points and functions, the problem can be reduced to that of testing whether any point in a certain set of points in 4-space lies above the lower envelope of a certain collection of trivariate functions. Combining the approach of [AST] with the one described in the previous subsection, we can compute the longest segment e in expected time $O(n^{17/11+\varepsilon})$ for any $\varepsilon > 0$. Omitting all the details, which can be found in [AST], we conclude the following.

THEOREM 5.5. *One can compute the biggest stick that fits inside a simple polygon with n edges, in randomized expected time $O(n^{17/11+\varepsilon})$, for any $\varepsilon > 0$.*

5.3. Minimum-width annulus. Let S be a set of n points in the plane. We wish to find the (closed) annulus of smallest width that contains S, i.e., we want to compute two concentric disks D_1 and D_2 of radii r_1 and r_2, such that all points of S lie in the closure of $D_2 \setminus D_1$ and $r_2 - r_1$ is minimized. This problem has been studied in [AST]. It is known [AST, EFNN] that the center of such an annulus is a vertex of the closest-point Voronoi diagram, $\mathrm{Vor}_c(S)$, of S, a vertex of the farthest-point Voronoi diagram, $\mathrm{Vor}_f(S)$, of S, or the intersection point of an edge of $\mathrm{Vor}_c(S)$ and an edge of $\mathrm{Vor}_f(S)$. The difficult part is testing the intersection points of edges of the two diagrams, because there can be $\Theta(n^2)$ such points in the worst case. Following the same idea as in [AST], which reduces the problem to that of batched searching of points relative to an envelope of functions in four dimensions, but using the technique described above for computing the width in 3-space, we obtain the following result (see [AST] for details).

THEOREM 5.6. *The smallest-width annulus containing a set of n points in the plane can be computed in randomized expected time $O(n^{17/11+\varepsilon})$, for any $\varepsilon > 0$.*

A SPECTRAL TECHNIQUE FOR COLORING RANDOM 3-COLORABLE GRAPHS*

NOGA ALON† AND NABIL KAHALE‡

Abstract. Let $G_{3n,p,3}$ be a random 3-colorable graph on a set of $3n$ vertices generated as follows. First, split the vertices arbitrarily into three equal color classes, and then choose every pair of vertices of distinct color classes, randomly and independently, to be edges with probability p. We describe a polynomial-time algorithm that finds a proper 3-coloring of $G_{3n,p,3}$ with high probability, whenever $p \geq c/n$, where c is a sufficiently large absolute constant. This settles a problem of Blum and Spencer, who asked if an algorithm can be designed that works almost surely for $p \geq \text{polylog}(n)/n$ [*J. Algorithms*, 19 (1995), pp. 204–234]. The algorithm can be extended to produce optimal k-colorings of random k-colorable graphs in a similar model as well as in various related models. Implementation results show that the algorithm performs very well in practice even for moderate values of c.

1. Introduction.

A vertex coloring of a graph G is *proper* if no adjacent vertices receive the same color. The *chromatic number* $\chi(G)$ of G is the minimum number of colors in a proper vertex coloring of G. The problem of determining or estimating this parameter has received a considerable amount of attention in combinatorics and in theoretical computer science, as several scheduling problems are naturally formulated as graph coloring problems. It is well known (see [13, 12]) that the problem of properly coloring a graph of chromatic number k with k colors is NP-hard, even for any fixed $k \geq 3$, and it is therefore unlikely that there are efficient algorithms for optimally coloring an arbitrary 3-chromatic input graph.

On the other hand, various researchers noticed that *random* k-colorable graphs are usually easy to color optimally. Polynomial-time algorithms that optimally color random k-colorable graphs, for every fixed k with high probability, have been developed by Kucera [15], Turner [18], and Dyer and Frieze [8]; the latter paper provides an algorithm whose average running time over all k-colorable graphs on n vertices is polynomial. Note, however, that most k-colorable graphs are quite dense and, hence, easy to color. In fact, in a typical k-colorable graph, the number of common neighbors of any pair of vertices with the same color exceeds considerably that of any pair of vertices of distinct colors, and hence a simple coloring algorithm based on this fact already works with high probability. It is more difficult to color sparser random k-colorable graphs. A precise model for generating sparse random k-colorable graphs is described in the next subsection, where the sparsity is governed by a parameter p that specifies the edge probability. Petford and Welsh [16] suggested a randomized

heuristic for 3-coloring random 3-colorable graphs and supplied experimental evidence that it works for most edge probabilities. Blum and Spencer [6] (also see [3] for some related results) designed a polynomial algorithm and proved that it optimally colors, with high probability, random 3-colorable graphs on n vertices with edge probability p provided $p \geq n^{\epsilon}/n$ for some arbitrarily small but fixed $\epsilon > 0$. Their algorithm is based on a path-counting technique and can be viewed as a natural generalization of the simple algorithm based on counting common neighbors (that counts paths of length 2) mentioned above.

Our main result here is a polynomial-time algorithm that works for sparser random 3-colorable graphs. If the edge probability p satisfies $p \geq c/n$, where c is a sufficiently large absolute constant, the algorithm optimally colors the corresponding random 3-colorable graph with high probability. This settles a problem of Blum and Spencer [6] who asked if an algorithm can be designed that works almost surely for $p \geq \text{polylog}(n)/n$. (Here and in what follows, *almost surely* always means "with probability that approaches 1 as n tends to infinity.") The algorithm uses the spectral properties of the graph and is based on the fact that, almost surely, a rather accurate approximation of the color classes can be read from the eigenvectors corresponding to the smallest two eigenvalues of the adjacency matrix of a large subgraph. This approximation can then be improved to yield a proper coloring.

The algorithm can be easily extended to the case of k-colorable graphs, for any fixed k, and to various models of random *regular* 3-colorable graphs.

We implemented our algorithm and tested it for hundreds of graphs drawn at random from the distribution of $G_{3n,p,3}$. Experiments show that our algorithm performs very well in practice. The running time is a few minutes on graphs with up to 100,000 nodes, and the range of edge probabilities on which the algorithm is successful is in fact even larger than what our analysis predicts.

1.1. The model. There are several possible models for random k-colorable graphs. See [8] for some of these models and for the relation between them. Our results hold for most of these models, but it is convenient to focus on one, which will simplify the presentation. Let V be a fixed set of kn labeled vertices. For a real $p = p(n)$, let $G_{kn,p,k}$ be the random graph on the set of vertices V obtained as follows: first, split the vertices of V arbitrarily into k color classes $W_1, \ldots, W_k$, each of cardinality n. Next, for each u and v that lie in distinct color classes, choose uv to be an edge, randomly and independently, with probability p. The input to our algorithm is a graph $G_{kn,p,k}$ obtained as above, and the algorithm succeeds to color it if it finds a proper k coloring. Here we are interested in fixed $k \geq 3$ and large n. We say that an algorithm colors $G_{kn,p,k}$ *almost surely* if the probability that a randomly chosen graph, as above, is properly colored by the algorithm tends to one as n tends to infinity. Note that we consider here deterministic algorithms, and the above statement means that the algorithm succeeds in coloring almost all random graphs generated.

A closely related model to the one given above is the model in which we do not insist that the color classes have equal sizes. In this model one first splits the set of vertices into k disjoint color classes by letting each vertex choose its color randomly, independently, and uniformly, among the k possibilities. Next, one chooses every pair of vertices of distinct color classes to be edges with probability p. All of our results hold for both models, and we focus on the first one as it is more convenient. To simplify the presentation, we restrict our attention to the case $k = 3$ of 3-colorable graphs, since the results for this case easily extend to every *fixed* k. In addition, we

make no attempt to optimize the constants and assume, whenever this is needed, that c is a sufficiently large constant, and the number of vertices $3n$ is sufficiently large.

1.2. The algorithm. Here is a description of the algorithm, which consists of three phases. Given a graph $G = G_{3n,p,3} = (V, E)$, define $d = pn$. Let $G' = (V, E')$ be the graph obtained from G by deleting all edges incident to a vertex of degree greater than $5d$. Denote by A the adjacency matrix of G', i.e., the $3n$ by $3n$ matrix $(a_{uv})_{u,v \in V}$ defined by $a_{uv} = 1$ if $uv \in E'$ and $a_{uv} = 0$ otherwise. It is well known that, since A is symmetric, it has real eigenvalues $\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_{3n}$ and an orthonormal basis of eigenvectors $e_1, e_2, \ldots, e_{3n}$, where $Ae_i = \lambda_i e_i$. The crucial point is that, almost surely, one can deduce a good approximation of the coloring of G from e_{3n-1} and e_{3n}. Note that there are several efficient algorithms to compute the eigenvalues and the eigenvectors of symmetric matrices (cf. [17]) and hence e_{3n-1} and e_{3n} can certainly be calculated in polynomial time. For the remainder of the algorithm, we will deal with G rather than G'.

Let t be a nonzero linear combination of e_{3n-1} and e_{3n} whose median is zero; that is, the number of positive components of t as well as the number of its negative components are both at most $3n/2$. (It is easy to see that such a combination always exists and can be found efficiently.) Suppose also that t is normalized so that its l_2-norm is $\sqrt{2n}$. Define $V_1^0 = \{u \in V : t_u > 1/2\}$, $V_1^0 = \{u \in V : t_u < -1/2\}$, and $V_3^0 = \{u \in V : |t_u| \leq 1/2\}$. This is an approximation for the coloring, which will be improved in the second phase by iterations, and then in the third phase to obtain a proper 3-coloring.

In iteration i of the second phase, $0 < i \leq q = \lceil \log n \rceil$, construct the color classes V_1^i, V_2^i, and V_3^i as follows. For every vertex v of G, let $N(v)$ denote the set of all its neighbors in G. In the ith iteration, color v by the least popular color of its neighbors in the previous iteration. That is, put v in V_j^i if $|N(v) \cap V_j^{i-1}|$ is the minimum among the three quantities $|N(v) \cap V_l^{i-1}|$, $l = 1, 2, 3$, where equalities are broken arbitrarily. We will show that the three sets V_i^q correctly color all but $n2^{-\Omega(d)}$ vertices.

The third phase consists of two stages. First, repeatedly uncolor every vertex colored j that has less than $d/2$ neighbors (in G) colored l for some $l \in \{1, 2, 3\} - \{j\}$. Then, if the graph induced on the set of uncolored vertices has a connected component of size larger than $\log_3 n$, the algorithm fails. Otherwise, find a coloring of every component consistent with the rest of the graph using brute-force exhaustive search. If the algorithm cannot find such a coloring, it fails.

Our main result is the following.

THEOREM 1.1. *If $p > c/n$, where c is a sufficiently large constant, the algorithm produces a proper 3-coloring of G with probability $1 - o(1)$.*

The intuition behind the algorithm is as follows. Suppose that every vertex in G had exactly d neighbors in every color class other than its own. Then $G' = G$. Let F be the two-dimensional subspace of all vectors $x = (x_v : v \in V)$ which are constant on every color class, and whose sum is 0. A simple calculation (as observed in [1]) shows that any nonzero element of F is an eigenvector of A with eigenvalue $-d$. Moreover, if E is the union of random matchings, one can show that $-d$ is almost surely the smallest eigenvalue of A and that F is precisely the eigenspace corresponding to $-d$. Thus, any linear combination t of e_{3n-1} and e_{3n} is constant on every color class. If the median of t is 0 and its l_2-norm is $\sqrt{2n}$, then t takes the values 0, 1, or -1 depending on the color class, and the coloring obtained after phase 1 of the algorithm is a proper coloring. In the model specified in subsection 1.1 these regularity assumptions do not hold, but every vertex has the same *expected* number of neighbors in every color class

other than its own. This is why phase 1 gives only an approximation of the coloring and phases 2 and 3 are needed to obtain a proper coloring.

We prove Theorem 1.1 in the next two sections. We use the fact that, almost surely, the largest eigenvalue of G' is at least $(1-2^{-\Omega(d)})2d$, and that its two smallest eigenvalues are at most $-(1-2^{-\Omega(d)})d$ and all other eigenvalues are in absolute value $O(\sqrt{d})$. The proof of this result is based on a proper modification of techniques developed by Friedman, Kahn, and Szemerédi in [11] and is deferred to section 3. We show in section 2 that our modification implies that each of the two eigenvectors corresponding to the two smallest eigenvalues is close to a vector, which is a constant on every color class, where the sum of these three constants is zero. This suffices to show that the sets V_j^0 form a reasonably good approximation to the coloring of G with high probability.

Theorem 1.1 can then be proved by applying the expansion properties of the graph G (that hold almost surely) to show that the iteration process above converges quickly to a proper coloring of a predefined large subgraph H of G. The uncoloring procedure will uncolor all vertices which are wrongly colored, but will not affect the subgraph H. We then conclude by showing that the largest connected component of the induced subgraph of G on $V-H$ is of logarithmic size almost surely, thereby showing that the brute-force search on the set of uncolored vertices terminates in polynomial time. We present our implementation results in section 4. Section 5 contains some concluding remarks together with possible extensions and results for related models of random graphs.

2. The proof of the main result. Let $G = G_{3n,p,3} = (V, E)$ be a random 3-colorable graph generated according to the model described above. Denote by W_1, W_2, and W_3 the three color classes of vertices of G. Let G' be the graph obtained from G by deleting all edges adjacent to vertices of degree greater than $5d$, and let A be the adjacency matrix of G'. Denote by $\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_{3n}$ the eigenvalues of A and by $e_1, e_2, \ldots, e_{3n}$ the corresponding eigenvectors, chosen so that they form an orthonormal basis of R^{3n}.

In this section we first show that the approximate coloring produced by the algorithm using the eigenvectors e_{3n-1} and e_{3n} is rather accurate almost surely. Then we exhibit a large subgraph H and show that, almost surely, the iterative procedure for improving the coloring colors H correctly. We then show that the third phase finds a proper coloring of G in polynomial time, almost surely. We use the following statement, whose proof is relegated to section 3.

PROPOSITION 2.1. *In the above notation, almost surely,*

(i) $\lambda_1 \geq (1-2^{-\Omega(d)})2d$,

(ii) $\lambda_{3n} \leq \lambda_{3n-1} \leq -(1-2^{-\Omega(d)})d$, *and*

(iii) $|\lambda_1| \leq O(\sqrt{d})$ *for all* $2 \leq i \leq 3n-2$.

Remark. One can show that, when $p = o(\log n/n)$, Proposition 2.1 would not hold if we were dealing with the spectrum of G rather than that of G', since the graph G is likely to contain many vertices of degree $\gg d$, and in this case the assertion of (iii) does not hold for the eigenvalues of G.

2.1. The properties of the last two eigenvectors. In this subsection we show that the eigenvectors e_{3n-1} and e_{3n} are almost constant on every color class. For this, we exhibit two orthogonal vectors constant on every color class which, roughly speaking, are close to being eigenvectors corresponding to $-d$. Let $x = (x_v : v \in V)$ be the vector defined by $x_v = 2$ for $v \in W_1$, and $x_v = -1$ otherwise. Let $y = (y_v : v \in V)$

be the vector defined by $y_v = 0$ if $v \in W_1$, $y_v = 1$ if $v \in W_2$, and $y_v = -1$ if $v \in W_3$. We denote by $\|f\|$ the l_2-norm of a vector f.

LEMMA 2.2. *Almost surely there are two vectors $\epsilon = (\epsilon_v : v \in V)$ and $\delta = (\delta_v : v \in V)$, satisfying $\|\epsilon\|^2 = O(n/d)$ and $\|\delta\|^2 = O(n/d)$ so that $x - \epsilon$ and $y - \delta$ are both linear combinations of e_{3n-1} and e_{3n}.*

Proof. We use the following lemma, whose proof is given below.

LEMMA 2.3. *Almost surely, $\|(A + dI)y\|^2 = O(nd)$ and $\|(A + dI)x\|^2 = O(nd)$.*

We prove the existence of δ as above. The proof of the existence of ϵ is analogous. Let $y = \sum_{i=1}^{3n} c_i e_i$. We show that the coefficients $c_1, c_2, \ldots, c_{3n-2}$ are small compared to $\|y\|$. Indeed, $(A + dI)y = \sum_{i=1}^{3n} c_i(\lambda_i + d)e_i$, and so

$$\|(A + dI)y\|^2 = \sum_{i=1}^{3n} c_i^2(\lambda_i + d)^2 \geq \Omega(d^2) \sum_{i=1}^{3n-2} c_i^2, \tag{2.1}$$

where the last inequality follows from parts (i) and (iii) of Proposition 2.1. Define $\delta = \sum_{i=1}^{3n-2} c_i e_i$. By equation (1) and Lemma 2.3, it follows that $\|\delta\|^2 = \sum_{i=1}^{3n-2} c_i^2 = O(n/d)$. On the other hand, $y - \delta$ is a linear combination of e_{3n-1} and e_{3n}. □

Note that it was crucial to the proof of Lemma 2.2 that, almost surely, $\|(A+dI)y\|^2$ is $O(nd)$ rather than $\Omega(nd)^2$ as is the case for some vectors in $\{-1, 0, 1\}^{3n}$.

Proof of Lemma 2.3. To prove the first bound, observe that it suffices to show that the sum of squares of the coordinates of $(A+dI)y$ on W_1 is $O(nd)$ almost surely, as the sums on W_2 and W_3 can be bounded similarly. The expectation of the vector $(A+dI)y$ is the null vector, and the expectation of the square of each coordinate of $(A + dI)y$ is $O(d)$ by a standard calculation. This is because each coordinate of $(A + dI)y$ is the sum of n independent random variables, each with mean 0 and variance $O(d/n)$. This implies that the *expected* value of the sum of squares of the coordinates of $(A + dI)y$ on W_1 is $O(nd)$. Similarly, the expectation of the fourth power of each coordinate of $(A + dI)y$ is $O(d^2)$. Hence the variance of the square of each coordinate is $O(d^2)$. However, the coordinates of $(A + dI)y$ on W_1 are independent random variables, and hence the variance of the sum of the squares of the W_1 coordinates is equal to the sum of the variances, which is $O(nd^2)$. The first bound can now be deduced from Chebyshev's inequality. The second bound can be shown in a similar manner. We omit the details. □

The vectors $x - \epsilon$ and $y - \delta$ are independent since they are nearly orthogonal. Indeed, if $\alpha(x - \epsilon) + \beta(y - \delta) = 0$, then $\alpha x + \beta y = \alpha\epsilon + \beta\delta$, and so $6n\alpha^2 + 2n\beta^2 = \|\alpha\epsilon + \beta\delta\|^2$. However,

$$\begin{aligned}\|\alpha\epsilon + \beta\delta\| &\leq |\alpha|\ \|\epsilon\| + |\beta|\ \|\delta\| \\ &= O\left((|\alpha| + |\beta|)\sqrt{n/d}\right).\end{aligned}$$

Thus, $6\alpha^2 + 2\beta^2 = O((\alpha^2 + \beta^2)/d)$ and hence $\alpha = \beta = 0$.

Therefore, by the above lemma the two vectors $\sqrt{3n}e_{3n-1}$ and $\sqrt{3n}e_{3n}$ can be written as linear combinations of $x - \epsilon$ and $y - \delta$. Moreover, the coefficients in these linear combinations are all $O(1)$ in absolute value. That is because $x - \epsilon$ and $y - \delta$ are nearly orthogonal, and the l_2-norm of each of the four vectors $x - \epsilon$, $y - \delta$, $\sqrt{3n}e_{3n-1}$, and $\sqrt{3n}e_{3n}$ is $\Theta(\sqrt{n})$. More precisely, if one of the vectors $\sqrt{3n}e_{3n-1}$,

$\sqrt{3n}e_{3n}$ is written as $\alpha(x-\epsilon)+\beta(y-\delta)$, then by the triangle inequality, $\|\alpha x+\beta y\| \leq \Theta(\sqrt{n}) + |\alpha|\,\|\epsilon\| + |\beta|\,\|\delta\|$, which, by a calculation similar to the one above, implies that $6\alpha^2 + 2\beta^2 \leq O(1) + O((\alpha^2+\beta^2)/d)$, and thus α and β are $O(1)$. On the other hand, the coefficients of the vector t defined in subsection 1.2 along the vectors e_{3n-1} and e_{3n} are at most $\|t\| = \sqrt{2n}$. It follows that the vector t defined in the algorithm is also a linear combination of the vectors $x-\epsilon$ and $y-\delta$ with coefficients whose absolute values are both $O(1)$. Since both x and y belong to the vector space F defined in the proof of Proposition 2.1, this implies that $t = f+\eta$, where $f \in F$ and $\|\eta\|^2 = O(n/d)$. Let α_i be the value of f on W_i for $1 \leq i \leq 3$. Assume without loss of generality that $\alpha_1 \geq \alpha_2 \geq \alpha_3$. Since $\|\eta\|^2 = O(n/d)$, at most $O(n/d)$ of the coordinates of η are greater than 0.01 in absolute value. This implies that $|\alpha_2| \leq 1/4$, because otherwise at least $2n - O(n/d)$ coordinates of t would have the same sign, contradicting the fact that 0 is a median of t. As $\alpha_1+\alpha_2+\alpha_3 = 0$ and $\alpha_1^2+\alpha_2^2+a_3^2 = \|f\|^2/n = 2+O(d^{-1})$, this implies that $\alpha_1 > 3/4$ and $\alpha_3 < -3/4$. Therefore, the coloring defined by the sets V_j^0 agrees with the original coloring of G on all but at most $O(n/d) < 0.001n$ coordinates.

2.2. The iterative procedure. Denote by H the subset of V obtained as follows. First, set H to be the set of vertices having at most $1.01d$ neighbors in G in each color class. Then, repeatedly delete any vertex in H having less than $0.99d$ neighbors in H in some color class (other than its own). Thus, each vertex in H has roughly d neighbors in H in each color class other than its own.

PROPOSITION 2.4. *Almost surely, by the end of the second phase of the algorithm, all vertices in H are properly colored.*

To prove Proposition 2.4, we need the following lemma.

LEMMA 2.5. *Almost surely, there are no two subsets of vertices U and W of V such that $|U| \leq 0.001n$, $|W| = |U|/2$, and every vertex v of W has at least $d/4$ neighbors in U.*

Proof. Note that if there are two such (not necessarily disjoint) subsets U and W, then the number of edges joining vertices of U and W is at least $d|W|/8$. Therefore, by a standard calculation the probability that there exist two such subsets is at most

$$\begin{aligned}
\sum_{i=1}^{0.0005n} \binom{3n}{i}\binom{3n}{2i}\binom{2i^2}{di/8}\left(\frac{d}{n}\right)^{di/8} &\leq \sum_{i=1}^{0.0005n} \left(\frac{3en}{i}\right)^{3i}\left(\frac{16ei}{n}\right)^{di/8} \\
&\leq \sum_{i=1}^{0.0005n} \left(\frac{3en}{i}\right)^{di/40}\left(\frac{16ei}{n}\right)^{di/8} \\
&= \sum_{i=1}^{0.0005n} (48e^2)^{di/40}\left(\frac{16ei}{n}\right)^{di/10} \\
&\leq \sum_{i=1}^{0.0005n} (48e^2(16e/2000)^2)^{di/40}\left(\frac{16ei}{n}\right)^{di/20} \\
&\leq \sum_{i=1}^{0.0005n} \left(\frac{16ei}{n}\right)^{di/20} \\
&= O(1/n^{\Omega(d)}). \qquad \square
\end{aligned}$$

If a vertex in H is colored incorrectly at the end of iteration i of the algorithm in phase 2 (i.e., if it is colored j and does not belong to W_j), it must have more than $d/4$ neighbors in H colored incorrectly at the end of iteration $i-1$. To see this, observe that any vertex of H has at most $2(1.01d - 0.99d) = 0.04d$ neighbors outside H, and hence if it has at most $d/4$ wrongly colored neighbors in H, it must have at least $0.99d - d/4 > d/2$ neighbors of each color other than its correct color and at most $d/4 + 0.04d$ neighbors of its correct color. By repeatedly applying the property asserted by the above lemma, with U being the set of vertices of H whose colors in the end of the iteration $i-1$ are incorrect, we deduce that the number of incorrectly colored vertices decreases by a factor of at least two in each iteration, implying that all vertices of H will be correctly colored after $\lceil \log_2 n \rceil$ iterations. This completes the proof of Proposition 2.4. We note that by being more careful one can show that $O(\log_d n)$ iterations suffice here, but since this only slightly decreases the running time, we do not prove the stronger statement here.

A standard probabilistic argument based on the Chernoff bound (see, for example [2, Appendix A]) shows that $H = V$ almost surely if $p \geq \beta \log n/n$, where β is a suitably large constant. Thus, it follows from Proposition 2.4 that the algorithm almost surely properly colors the graph by the end of phase 2 if $p \geq \beta \log n/n$.

For two sets of vertices X and Z, let $e(X, Z)$ denote the number of edges $(u, v) \in E$, with $u \in X$ and $v \in Z$.

LEMMA 2.6. *There exists a constant $\gamma > 0$ such that almost surely the following hold.*

(i) *For any two distinct color classes V_1 and V_2, and any subset X of V_1 and any subset Y of V_2, if $|X| = 2^{-\gamma d}n$ and $|Y| \leq 3|X|$, then $|e(X, V_2 - Y) - d|X|| \leq 0.001d|X|$.*

(ii) *If J is the set of vertices having more than $1.01d$ neighbors in G in some color class, then $|J| \leq 2^{-\gamma d}n$.*

Proof. For any subset X of V_1, $e(X, V_2 - Y)$ is the sum of independent Bernoulli variables. By standard Chernoff bounds, the probability that there exist two color classes V_1 and V_2, a subset X of V_1, and a subset Y of V_2 such that $|X| = \epsilon n$ and $|Y| \leq 3|X|$ and $|e(X, V_2 - Y) - d|X|| > 0.001d|X|$ is at most

$$6\binom{n}{\epsilon n}\sum_{i=0}^{3\epsilon n}\binom{n}{i}2^{-\Omega(\epsilon n d)} = 2^{O(H(\epsilon))n}2^{-\Omega(\epsilon n d)}.$$

Therefore, (i) holds almost surely if γ is a sufficiently small constant. A similar reasoning applies to (ii). Therefore, both (i) and (ii) hold if γ is a sufficiently small constant. □

LEMMA 2.7. *Almost surely, H has at least $(1 - 2^{-\Omega(d)})n$ vertices in every color class.*

Proof. It suffices to show that there are at most $7 \cdot 2^{-\gamma d}n$ vertices outside H. Assume for contradiction that this is not true. Recall that H is obtained first by deleting all the vertices in J and then by a deletion process in which vertices with less than $0.99d$ neighbors in the other color classes of H are deleted repeatedly. By Lemma 2.6 $|J| \leq 2^{-\gamma d}n$ almost surely, and so at least $6 \cdot 2^{-\gamma d}n$ vertices have been deleted because they had less than $0.99d$ neighbors in H in some color class (other than their own). Consider the first time during the deletion process where there exists a subset X of a color class V_i of cardinality $2^{-\gamma d}n$, and a $j \in \{1, 2, 3\} - \{i\}$ such that every vertex of X has been deleted because it had less than $0.99d$ neighbors in the remaining subset of V_j. Let Y be the set of vertices of V_j deleted so far. Then

$|Y| \leq |J| + 2|X| \leq 3|X|$. Note that every vertex in X has less than $0.99d$ neighbors in $V_j - Y$. We therefore obtain a contradiction by applying Lemma 2.6 to (X, Y). □

2.3. The third phase. We need the following lemma, which is an immediate consequence of Lemma 2.5.

LEMMA 2.8. *Almost surely, there exists no subset U of V of size at most $0.001n$ such that the graph induced on U has minimum degree at least $d/2$.*

LEMMA 2.9. *Almost surely, by the end of the uncoloring procedure in phase 3 of the algorithm, all vertices of H remain colored, and all colored vertices are properly colored; i.e., any vertex colored i belongs to W_i. (We assume, of course, that the numbering of the colors is chosen appropriately.)*

Proof. By Proposition 2.4, almost surely all vertices of H are properly colored by the end of phase 2. Since every vertex of H has at least $0.99d$ neighbors (in H) in each color class other than its own, all vertices of H remain colored. Moreover, if a vertex is wrongly colored at the end of the uncoloring procedure, then it has at least $d/2$ wrongly colored neighbors. Assume for contradiction that there exists a wrongly colored vertex at the end of the uncoloring procedure. Then the subgraph induced on the set of wrongly colored vertices has minimum degree at least $d/2$, and hence it must have at least $0.001n$ vertices by Lemma 2.8. However, since it does not intersect H, it has at most $2^{-\Omega(d)}n$ vertices by Lemma 2.7, leading to a contradiction. □

In order to complete the proof of correctness of the algorithm, it remains to show that almost surely every connected component of the graph induced on the set of uncolored vertices is of size at most $\log_3 n$. We prove this fact in the remainder of this section. We note that it is easy to replace the term $\log_3 n$ by $O(\frac{\log_3 n}{d})$, but for our purposes the above estimate suffices. Also note that if $p = o(\log n/n)$ some of these components are actually components of the original graph G, as for such value of p the graph G is almost surely disconnected (and has many isolated vertices).

LEMMA 2.10. *Let K be a graph, (V_1, V_2, V_3) a partition of the vertices of K into three disjoint subsets, i an integer, and L the set of vertices of K that remain after repeatedly deleting the vertices having less than i neighbors in V_1, V_2, or V_3. Then the set L does not depend on the order in which vertices are deleted.*

Proof. Let L be the set of vertices that remain after a deletion process according to a given order. Consider a deletion process according to a different order. Since every vertex in L has at least i neighbors in $L \cap V_1$, $L \cap V_2$, and $L \cap V_3$, no vertex in L will be deleted in the second deletion process (otherwise, we obtain a contradiction by considering the first vertex in L deleted). Therefore, the set of vertices that remain after the second deletion process contains L and thus equals L by symmetry. □

Lemma 2.10 implies that H does not depend on the order in which vertices are deleted.

PROPOSITION 2.11. *Almost surely the largest connected component of the graph induced on $V - H$ has at most $\log_3 n$ vertices.*

Proof. Let T be a fixed tree on $\log_3 n$ vertices of V all of whose edges have their two endpoints in distinct color classes W_i, W_j, $1 \leq i < j \leq 3$. Our objectives are to estimate the probability that G contains T as a subgraph that does not intersect H and to show that this probability is sufficiently small to ensure that, almost surely, the above will not occur for any T. This property would certainly hold if $V - H$ were a random subset of V of cardinality $2^{-\Omega(d)}n$. Indeed, if this were the case, the probability that G contains T as a subgraph that does not intersect H would be upper bounded by the probability $2^{-\Omega(d|T|)}$ that T is a subset of $V - H$ times the probability $(d/n)^{|T|-1}$ that T is a subgraph of G. This bound is sufficiently small for our needs.

Although $V-H$ is *not* a random subset of V, we will be able to show a similar bound on the probability that G contains T as a subgraph that does not intersect H. To simplify the notation, we let T denote the set of edges of the tree. Let $V(T)$ be the set of vertices of T, and let I be the subset of all vertices $v \in V(T)$ whose degree in T is at most 4. Since T contains $|V(T)|-1$ edges, $|I| \geq |V(T)|/2$. Let H' be the subset of V obtained by the following procedure, which resembles that of producing H (but depends on $V(T)-I$). First, set H' to be the set of vertices having at most $1.01d-4$ neighbors in G in each color class V_i. Then delete from H' all vertices of $V(T)-I$. Then, repeatedly delete any vertex in H' having less than $0.99d$ neighbors in H' in some color class (other than its own).

LEMMA 2.12. *Let F be a set of edges, each having endpoints in distinct color classes W_i, W_j. Let $H(F \cup T)$ be the set obtained by replacing E by $F \cup T$ in our definition of H, and $H'(F)$ be the set obtained by replacing E by F in our definition of H'. Then $H'(F) \subseteq H(F \cup T)$.*

Proof. First, we show that the initial value of $H'(F)$, i.e., the value obtained after deleting the vertices with more than $1.01d-4$ neighbors in a color class of G and after deleting the vertices in $V(T)-I$, is a subset of the initial value of $H(F \cup T)$. Indeed, let v be any vertex that does not belong to the initial value of $H(F \cup T)$, i.e., v has more than $1.01d$ neighbors in some color class of $(V, F \cup T)$. We distinguish two cases:

1. $v \in V(T)-I$. In this case, v does not belong to the initial value of $H'(F)$.
2. $v \notin V(T)-I$. Then v is incident with at most 4 edges of T, and so it has more than $1.01d-4$ neighbors in some color class in (V, F).

In both cases, v does not belong to the initial value of $H'(F)$. This implies the assertion of the lemma, since the initial value of $H'(F)$ is a subgraph of the initial value of $H(F \cup T)$ and hence, by Lemma 2.10, any vertex which will be deleted in the deletion process for constructing H will be deleted in the corresponding deletion process for producing H' as well. □

LEMMA 2.13.

$$\begin{aligned} &Pr[T \text{ is a subgraph of } G \text{ and } V(T) \cap H = \emptyset] \\ &\quad \leq Pr[T \text{ is a subgraph of } G]\ Pr[I \cap H' = \emptyset]. \end{aligned}$$

Proof. It suffices to show that

$$\Pr[I \cap H = \emptyset | T \text{ is a subgraph of } G] \leq \Pr\,[I \cap H' = \emptyset].$$

However, by Lemma 2.12

$$\begin{aligned} \Pr[I \cap H' = \emptyset] &= \sum_{F: I \cap H'(F) = \emptyset} \Pr[E(G) = F] \\ &\geq \sum_{F: I \cap H(F \cup T) = \emptyset} \Pr[E(G) = F] \\ &= \sum_{F': F' \cap T = \emptyset, I \cap H(F' \cup T) = \emptyset} \Pr[E(G) - T = F'] \\ &= \sum_{F': F' \cap T = \emptyset, I \cap H(F' \cup T) = \emptyset} \Pr[E(G) - T = F' \mid T \text{ is a subgraph of } G] \\ &= \Pr[I \cap H = \emptyset | T \text{ is a subgraph of } G], \end{aligned}$$

where F ranges over the sets of edges with endpoints in different color classes, and F' ranges over those sets that do not intersect T. The third equation follows by regrouping the edge-sets F according to $F' = F - T$ and noting (the obvious fact) that, for a given set F' that does not intersect T, the probability that $E(G) = F$ for some F such that $F - T = F'$ is equal to $\Pr[E(G) - T = F']$. The fourth equation follows from the independence of the events $E(G) - T = F'$ and T is a subgraph of G. □

Returning to the proof of Proposition 2.11, we first note that we can assume, without loss of generality, that $d \leq \beta \log n$, for some constant $\beta > 0$ (otherwise $H = V$). If this inequality holds then, by modifying the arguments in the proof of Lemma 2.7, one can show that each of the graphs H' (corresponding to the various choices of $V(T)-I$) misses at most $2^{-\Omega(d)}n$ vertices in each color class, with probability at least $1 - 2^{-n^{\Theta(1)}}$. Since the distribution of H' depends only on $V(T) - I$ (assuming the W_i's are fixed), it is not difficult to show that this implies that $\Pr[I \cap H' = \emptyset]$ is at most $2^{-\Omega(d|I|)}$. Since $|I| \geq |V(T)|/2$ and since the probability that T is a subgraph of G is precisely $(d/n)^{|V(T)|-1}$ we conclude, by Lemma 2.13, that the probability of there existing some T of size $\log_3 n$ which is a connected component of the induced subgraph of G on $V - H$ is at most $2^{-\Omega(d \log_3 n)}(d/n)^{\log_3 n - 1}$ multiplied by the number of possible trees of this size, which is

$$\binom{3n}{\log_3 n}(\log_3 n)^{\log_3 n - 2}.$$

Therefore, the required probability is bounded by

$$\binom{3n}{\log_3 n}(\log_3 n)^{\log_3 n - 2}2^{-\Omega(d \log_3 n)}\left(\frac{d}{n}\right)^{\log_3 n - 1} = O(1/n^{\Omega(d)}),$$

completing the proof. □

3. Bounding the eigenvalues. In this section, we prove Proposition 2.1. Let $G = (V, E), A, p, d, \lambda_i, e_i, W_1, W_2, W_3$ be as in section 2. We begin with the following lemma.

LEMMA 3.1. *There exists a constant $\beta > 0$ such that, almost surely, for any subset X of $2^{-\beta d}n$ vertices, $e(X, V) \leq 5d|X|$.*

Proof. As in the proof of Lemma 2.6, the probability that there exists a subset X of cardinality ϵn such that $e(X, V) > 5d|X|$ is at most

$$\binom{3n}{\epsilon n}2^{-\Omega(d\epsilon n)} \leq 2^{3H(\epsilon/3)n}2^{-\Omega(d\epsilon n)} = 2^{-\Omega(d\epsilon n)}$$

if $\log(1/\epsilon) < d/b$, where b is a sufficiently large constant. Therefore, if β is a sufficiently small constant, this probability goes to 0 as n goes to infinity. □

Proof of Proposition 2.1. Parts (i) and (ii) are simple. By the variational definition of eigenvalues (see [19, p. 99]), λ_1 is simply the maximum of $x^t Ax/(x^t x)$ where the maximum is taken over all nonzero vectors x. Therefore, by taking x to be the all-1 vector we obtain the well-known result that λ_1 is at least the average degree of G'. By the known estimates for binomial distributions, the average degree of G is $(1+o(1))2d$. On the other hand, Lemma 3.1 can be used to show that $|E - E'| \leq 2^{-\Omega(d)}n$, as it easily implies that the number of vertices of degree greater than $5d$ in each color class of G is almost surely less than $2^{-\beta d}n$. Hence the average degree of G' is at least $(1 - 2^{-\Omega(d)})2d$. This proves (i).

The proof of (ii) is similar. It is known [19, p. 101] that

$$\lambda_{3n-1} = \min_{F} \max_{x \in F, x \neq 0} \frac{x^t A x}{x^t x},$$

where the minimum is taken over all two-dimensional subspaces F of R^{3n}. Let F denote the two-dimensional subspace of all vectors $x = (x_v : v \in V)$ satisfying $x_v = \alpha_i$ for all $v \in W_i$, where $\alpha_1 + \alpha_2 + \alpha_3 = 0$. For x as above,

$$x^t A x = 2\alpha_1\alpha_2 e'(W_1, W_2) + 2\alpha_2\alpha_3 e'(W_2, W_3) + 2\alpha_1\alpha_3 e'(W_1, W_3),$$

where $e'(W_i, W_j)$ denotes the number of edges of G' between W_i and W_j. Almost surely $e'(W_i, W_j) \geq (1 - 2^{-\Omega(d)})nd$ for all $1 \leq i < j \leq 3$, and since $x^t x = n(\alpha_1^2 + \alpha_2^2 + \alpha_3^2) = -2n(\alpha_1\alpha_2 + \alpha_2\alpha_3 + \alpha_1\alpha_3)$ it follows that $x^t Ax/(x^t x) \leq -(1 - 2^{-\Omega(d)})d$ almost surely for all $x \in F$, implying that $\lambda_{3n} \leq \lambda_{3n-1} \leq -(1 - 2^{-\Omega(d)})d$ and establishing (ii).

The proof of (iii) is more complicated. Its assertion for somewhat bigger p (for example, for $p \geq \log^6 n/n$) can be deduced from the arguments of [10]. To prove it for the graph G' and $p \geq c/n$ we use the basic approach of Friedman, Kahn, and Szemerédi in [11], where they show that the second largest eigenvalue in absolute value of a random d-regular graph is almost surely $O(\sqrt{d})$. (Also see [9] for a different proof.) Since in our case the graph is not regular, a few modifications are needed. Our starting point is again the variational definition of the eigenvalues, from which we will deduce that it suffices to show that, almost surely, the following holds.

LEMMA 3.2. *Let S be the set of all unit vectors $x = (x_v : v \in V)$ for which $\sum_{v \in W_j} x_v = 0$ for $j = 1, 2, 3$, then $|x^t A x| \leq O(\sqrt{d})$ for all $x \in S$.*

The matrix A consists of nine blocks arising from the partition of its rows and columns according to the classes W_j. It is clearly sufficient to show that the contribution of each block to the sum $x^t Ax$ is bounded, in absolute value, by $O(\sqrt{d})$. This, together with a simple argument based on ϵ-nets (see [11, Proposition 2.1]) can be used to show that Lemma 3.2 follows from the following statement.

Fix $\epsilon > 0$, say $\epsilon = 1/2$, and let T denote the set of all vectors x of length n, every coordinate of which is an integral multiple of $\epsilon/\sqrt{n}$, where the sum of coordinates is zero and the l_2-norm is at most 1. Let B be a random n by n matrix with 0, 1 entries, where each entry of B, randomly and independently, is 1 with probability d/n.

LEMMA 3.3. *If d exceeds a sufficiently large absolute constant, then almost surely, $|x^t B y| \leq O(\sqrt{d})$ for every x, $y \in T$ for which $x_u = 0$ if the corresponding row of B has more than $5d$ nonzero entries and for which $y_v = 0$ if the corresponding column of B has more than $5d$ nonzero entries.*

The last lemma is proved, as in [11], by separately bounding the contribution of terms $x_u y_v$ with small absolute values and the contribution of similar terms with large absolute values. Here is a description of the details that differ from those that appear in [11]. Let C denote the set of all pairs (u, v) with $|x_u y_v| \leq \sqrt{d}/n$ and let $X = \sum_{(u,v) \in C} x_u B(u, v) y_v$. As in [11], one can show that the absolute value of the expectation of X is at most $\sqrt{d}$. Next, one has to show that with high probability X does not deviate from its expectation by more than $c\sqrt{d}$. This is different from (and in fact, somewhat easier than) the corresponding result in [11], since here we are dealing with independent random choices. It is convenient to use the following variant of the Chernoff bound.

LEMMA 3.4. *Let $a_1, \ldots, a_m$ be (not necessarily positive) reals, and let Z be the random variable $Z = \sum_{i=1}^{m} \epsilon_i a_i$, where each ϵ_i is chosen, randomly and independently,*

to be 1 *with probability* p *and* 0 *with probability* $1-p$. *Suppose* $\sum_{i=1}^{m} a_i^2 \le D$ *and suppose* $|Sa_i| \le ce^c pD$ *for some positive constants* c, S. *Then* $Pr[|Z - E(Z)| > S] \le 2e^{-S^2/(2pe^c D)}$.

For the proof, one first proves the following.

LEMMA 3.5. *Let* c *be a positive real. Then, for every* $x \le c$,

$$e^x \le 1 + x + \frac{e^c}{2}x^2.$$

Proof. Define $f(x) = 1 + x + \frac{e^c}{2}x^2 - e^x$. Then $f(0) = 0$, $f'(x) = 1 + e^c x - e^x$, and $f''(x) = e^c - e^x$. Therefore, $f''(x) \ge 0$ for all $x \le c$, and as $f'(0) = 0$, this shows that $f'(x) \le 0$ for $x < 0$ and $f'(x) \ge 0$ for $c \ge x > 0$, implying that $f(x)$ is nonincreasing for $x \le 0$ and nondecreasing for $c \ge x \ge 0$. Thus $f(x) \ge 0$ for all $x \le c$, as needed. □

Proof of Lemma 3.4. Define $\lambda = \frac{S}{e^c pD}$; then, by assumption, $\lambda a_i \le c$ for all i. Therefore, by the above lemma,

$$\begin{aligned}
E(e^{\lambda Z}) &= \prod_{i=1}^{m} [pe^{\lambda a_i} + (1-p)] \\
&= \prod_{i=1}^{m} [1 + p(e^{\lambda a_i} - 1)] \\
&\le \prod_{i=1}^{m} \left[1 + p\left(\lambda a_i + \frac{e^c}{2}\lambda^2 a_i^2\right)\right] \\
&\le \exp\left(p\lambda \sum_{i=1}^{m} a_i + p\frac{e^c}{2}\lambda^2 \sum_{i=1}^{m} a_i^2\right) \\
&\le e^{\lambda E(Z) + \frac{pe^c}{2}\lambda^2 D}.
\end{aligned}$$

Therefore,

$$\begin{aligned}
\Pr[(Z - E(Z)) > S] &= \Pr[e^{\lambda(Z - E(Z))} > e^{\lambda S}] \\
&\le e^{-\lambda S} E(e^{\lambda(Z - E(Z))}) \\
&\le e^{-\lambda S + \frac{pe^c}{2}\lambda^2 D} \\
&= e^{-\frac{S^2}{2pe^c D}}.
\end{aligned}$$

Applying the same argument to the random variable defined with respect to the reals $-a_i$, the assertion of the lemma follows. □

Using Lemma 3.4, it is not difficult to deduce that almost surely the contribution of the pairs in C to $|x^t By|$ is $O(\sqrt{d})$. This is because we can simply apply the lemma with $m = |C|$, with the a_i's being all the terms $x_u y_v$ where $(u, v) \in C$, with $p = d/n$, $D = 1$, and $S = ce^c\sqrt{d}$ for some $c > 0$. Since here $|Sa_i| \le ce^c\sqrt{d}\sqrt{d}/n = ce^c pD$, we conclude that for all fixed vectors x and y in T, the probability that X deviates from its expectation (which is $O(\sqrt{d})$) by more than $ce^c\sqrt{d}$ is smaller than $2e^{-c^2 e^c n/2}$, and since the cardinality of T is only b^n for some absolute constant $b = b(\epsilon)$, one can

choose c so that X would almost surely not deviate from its expectation by more than $ce^c\sqrt{d}$.

The contribution of the terms $x_u y_v$, whose absolute values exceed $\sqrt{d}/n$, can be bounded by following the arguments of [11] with a minor modification arising from the fact that the maximum number of ones in a row (or column) of B can exceed d (but can never exceed $5d$ in a row or a column in which the corresponding coordinates x_u or y_v are nonzero). We sketch the argument below, beginning with the following lemma.

LEMMA 3.6. *There exists a constant C such that, with high probability, for any distinct color classes V_1, V_2, and any subset U of V_1 and any subset W of V_2 such that $|U| \le |W|$, at least one of the following two conditions holds:*

1. $e'(U,W) \le 10\mu(U,W)$,
2. $e'(U,W)\log(e'(U,W)/\mu(U,W)) \le C|W|\log(n/|W|)$,

where $e'(U,W)$ is the number of edges in G' between U and W, and $\mu(U,W) = |U|\,|W|d/n$ is the expected number of edges in G between U and W.

Proof. Condition 1 is clearly satisfied if $|W| \ge n/2$, since the maximum degree in G' is at most $5d$. So we can assume without loss of generality that $0 < |W| \le n/2$. Given two subsets U and W satisfying the requirements of the lemma, define $\beta = \beta(|U|,|W|)$ to be the unique positive real number such that $\beta\mu(U,W)\log\beta = C|W|\log(n/|W|)$ (the constant C will be determined later). Condition 2 is equivalent to $e'(U,W) \le \beta\mu(U,W)$. Thus U, W violate condition 1 as well as condition 2 only if $e'(U,W) > \beta'\mu(U,W)$, where $\beta' = \max(10,\beta)$. Hence, by standard Chernoff bounds, the probability of this event is at most $e^{-\gamma\beta'\mu(U,W)\log\beta'} \le (|W|/n)^{\gamma C|W|}$ for some absolute constant $\gamma > 0$. Denoting $|W|/n$ by b, the probability that there exist two subsets U and W that do not satisfy either condition is at most

$$6 \sum_{b:\ bn \text{ integer } \le n/2} \binom{n}{bn}^2 b^{\gamma Cbn} = 6 \sum_{b:\ bn \text{ integer } \le n/2} 2^{O(b\log(1/b)n)} b^{\gamma Cbn}$$

$$= n^{-\Omega(1)}$$

if C is a sufficiently large constant. □

Friedman, Kahn, and Szemerédi [11] show that for any d-regular graph satisfying the conditions of Lemma 3.6 (without restriction on the ranges of U and W), the contribution of the terms $x_u y_v$ whose absolute values exceed $\sqrt{d}/n$ is $O(\sqrt{d})$. Up to replacing some occurrences of d by $5d$, the same proof shows that, for any 3-colorable graph of maximum degree $5d$ satisfying the conditions of Lemma 3.6, the contribution of the terms $x_u y_v$ whose absolute values exceed $\sqrt{d}/n$ is $O(\sqrt{d})$. This implies the assertion of Lemma 3.3, which implies Lemma 3.2.

To deduce part (iii) of Proposition 2.1, we need the following lemma.

LEMMA 3.7. *Let F denote, as before, the two-dimensional subspace of all vectors $x = (x_v : v \in V)$ satisfying $x_v = \alpha_i$ for all $v \in W_i$, where $\alpha_1 + \alpha_2 + \alpha_3 = 0$. Then, almost surely, for all $f \in F$ we have $\|(A + dI)f\|^2 = O(d\|f\|^2)$.*

Proof. Let x, y be as in the proof of Lemma 2.3. Note that $x^t y = 0$ and that both $\|x\|^2$ and $\|y\|^2$ are $\Theta(n)$. Thus, every vector $f \in F$ can be expressed as the sum of two orthogonal vectors x' and y' proportional to x and y, respectively. Lemma 2.3 shows that $\|(A + dI)y'\|^2 = O(d\|y'\|^2)$, which implies that $\|(A + dI)y'\|^2 = O(d\|f\|^2)$, since $\|f\|^2 = \|x'\|^2 + \|y'\|^2$. Similarly, it can be shown that $\|(A + dI)x'\|^2 = O(d\|f\|^2)$. We conclude the proof of the lemma using the triangle inequality $\|(A + dI)f\| \le \|(A + dI)x'\| + \|(A + dI)y'\|$. □

TABLE 1
Implementation results.

Number of vertices	d
1000	12
10000	10
100000	8

We now show that $\lambda_2 \leq O(\sqrt{d})$ by using the formula $\lambda_2 = \min_H \max_{x \in H, x \neq 0} x^t Ax/(x^t x)$, where H ranges over the linear subspaces of R^{3n} of codimension 1. Indeed, let H be the set of vectors whose sum of coordinates is 0. Any $x \in H$ is of the form $f + s$, where $f \in F$ and s is a multiple of a vector in S, and so

$$\begin{aligned} x^t Ax &= f^t Af + 2s^t Af + s^t As \\ &= f^t Af + 2s^t (A + dI)f + s^t As \\ &\leq -(1 - 2^{-\Omega(d)})d\|f\|^2 + 2\|s\| \, \|(A + dI)f\| + O(\sqrt{d})\|s\|^2 \\ &\leq O(\sqrt{d}\|s\| \, \|f\|) + O(\sqrt{d})\|s\|^2 \\ &\leq O(\sqrt{d}(\|s\|^2 + \|f\|^2)) \\ &= O(\sqrt{d}\|x\|^2). \end{aligned}$$

This implies the desired upper bound on λ_2.

The bound $|\lambda_{3n-2}| \leq O(\sqrt{d})$ can be deduced from similar arguments, namely by showing that $x^t Ax/(x^t x) \geq -\Theta(\sqrt{d})$ for any $x \in F^{\perp}$. This completes the proof of Proposition 2.1. □

4. Implementation and experimental results. We have implemented the following tuned version of our algorithm. The first two phases are as described in section 1. In the third phase, we find the minimum i such that, after repeatedly uncoloring every vertex colored j that has less than i neighbors colored l, for some $l \in \{1, 2, 3\} - \{j\}$, the algorithm can find a proper coloring using brute-force exhaustive search on every component of uncolored vertices. If the brute-force search takes more steps than the first phase (up to a multiplicative constant), the algorithm fails. Otherwise, it outputs a legal coloring. The eigenvectors e_{3n} and e_{3n-1} are calculated approximately using an iterative procedure. The coordinates of the initial vectors are independent random variables uniformly chosen in $[0, 1]$.

The range of values of p where the algorithm succeeded was in fact considerably larger than what our analysis predicts. Table 1 shows some values of the parameters for which we tested our algorithm. For each of these parameters, the algorithm was run on more than one hundred graphs drawn from the corresponding distribution and successfully found a proper coloring for all these tests. The running time was less than six minutes on a Sun SPARCstation 2 for the largest graphs. The algorithm failed for some graphs drawn from distributions with smaller integral values of d than the ones in the corresponding row. Note that the number of vertices is not a multiple of 3; the size of one color class exceeds the others by 1.

5. Concluding remarks.

1. There are many heuristic graph algorithms based on spectral techniques but very few rigorous proofs of correctness for any of those in a reasonable model of random graphs. Our main result here provides such an example. Another example is

the algorithm of Boppana [7], who designed an algorithm for graph bisection based on eigenvalues, and showed that it finds the best bisection almost surely in an appropriately defined model of random graphs with a relatively small bisection width. Aspvall and Gilbert [1] gave a heuristic for graph coloring based on eigenvectors of the adjacency matrix, and showed that their heuristic optimally colors complete 3-partite graphs as well as certain other classes of graphs with regular structure.

2. By modifying some of the arguments of section 2, we can show that if p is somewhat bigger ($p \geq \log^3 n/n$ suffices) then almost surely the initial coloring V_i^0 that is computed from the eigenvectors e_{3n-1} and e_{3n} in the first phase of our algorithm is completely correct. In this case the last two phases of the algorithm are not needed. By refining the argument in subsection 2.2, it can also be shown that if $p > 10 \log n/n$, the third phase of the algorithm is not needed, and the coloring obtained by the end of the second phase will almost surely be correct.

3. We can show that a variant of our algorithm finds, almost surely, a proper coloring in the model of random *regular* 3-colorable graphs in which one randomly chooses d perfect matchings between each pair of distinct color classes, when d is a sufficiently large absolute constant. Here, in fact, the proof is simpler, as the smallest two eigenvalues (and their corresponding eigenspaces) are known precisely, as noted in subsection 1.2.

4. The results easily extend to the model in which each vertex first picks a color randomly, independently, and uniformly from among the three possibilities and, next, every pair of vertices of distinct colors becomes an edge with probability $p(> c/n)$.

5. If $G = G_{3n,p,3}$ and $p \leq c/n$ for some small positive constant c, it is not difficult to show that almost surely G does not have any subgraph with minimum degree at least 3, and hence it is easy to 3-color it by a greedy-type (linear-time) algorithm. For values of p that are bigger than this c/n but satisfy $p = o(\log n/n)$, the graph G is almost surely disconnected, and has a unique component of $\Omega(n)$ vertices, which is called the *giant component* in the study of random graphs (see, e.g., [2], [4]). All other components are almost surely sparse, i.e., they contain no subgraph with minimum degree at least 3 and can thus be easily colored in total linear time. Our approach here suffices to find, almost surely, a proper 3-coloring of the giant component (and hence of the whole graph) for all $p \geq c/n$, where c is a sufficiently large absolute constant, and there are possible modifications of it that may even work for all values of p. At the moment, however, we are unable to obtain an algorithm that provably works for all values of p almost surely. Note that, for any constant c, if $p < c/n$ then the greedy algorithm will almost surely color $G_{3n,p,3}$ with a constant number of colors. Thus, our result implies that $G_{3n,p,3}$ can be almost surely colored in polynomial time with a constant number of colors for *all* values of p.

6. Our basic approach easily extends to k-colorable graphs, for every fixed k, as follows. Phases 2 and 3 of the algorithm are essentially the same as in the case $k = 3$. Phase 1 needs to be modified to extract an approximation of the coloring. Let e_i, $i \geq 1$, be an eigenvector of G' corresponding to its ith largest eigenvalue (replace $5d$ by $5kd$ in the definition of G'). Find vectors $x_1, x_2, \ldots, x_{k+1}$ of norm $\sqrt{kn}$ in $\mathrm{Span}(e_1, e_n, e_{n-1}, \ldots, e_{n-k+2})$ such that $x_i = \sqrt{kn} e_i$ and $(x_i, x_j) = -n$ for $1 \leq i < j \leq k+1$. For $2 \leq i \leq n$, and any z, let W_ϵ be the set of vertices whose coordinates in x_i are in $(z - \epsilon, z + \epsilon)$. If, for some i and z, both $|W_{\epsilon_k}|$ and $|W_{\epsilon_k/2}|$ deviate from n by at most $\beta_k n/d$, where ϵ_k and β_k are constants depending on k, color the elements in W_{ϵ_k} with a new color and delete them from the graph. Repeat this

process until the number of vertices left is $O(n/d)$, and color the remaining vertices arbitrarily.

7. The existence of an approximation algorithm based on the spectral method for coloring *arbitrary* graphs is a question that deserves further investigation (and which we do *not* address here). Recently, improved approximation algorithms for graph coloring have been obtained using semidefinite programming [14], [5].

Acknowledgment. We thank two anonymous referees for several suggestions which improved the presentation of the paper.

A FAST ALGORITHM FOR THE COMPUTATION AND ENUMERATION OF PERFECT PHYLOGENIES*

SAMPATH KANNAN† AND TANDY WARNOW†

Abstract. The perfect phylogeny problem is a classical problem in computational evolutionary biology, in which a set of species/taxa is described by a set of qualitative characters. In recent years, the problem has been shown to be *NP-complete* in general, while the different fixed parameter versions can each be solved in polynomial time. In particular, Agarwala and Fernández-Baca have developed an $O(2^{3r}(nk^3+k^4))$ algorithm for the perfect phylogeny problem for n species defined by k r-state characters [*SIAM J. Comput.*, 23 (1994), pp. 1216–1224]. Since, commonly, the character data are drawn from alignments of molecular sequences, k is the length of the sequences and can thus be very large (in the hundreds or thousands). Thus, it is imperative to develop algorithms which run efficiently for large values of k. In this paper we make additional observations about the structure of the problem and produce an algorithm for the problem that runs in time $O(2^{2r}k^2n)$. We also show how it is possible to efficiently build a structure that implicitly represents the set of all perfect phylogenies and to randomly sample from that set.

1. Introduction.

A fundamental problem in biology is that of inferring the evolutionary history of a set S of species, each of which is specified by the set of *traits* or *characters* that it exhibits. Information about evolutionary history can be conveniently represented by an evolutionary or *phylogenetic* tree, often referred to simply as a *phylogeny*. In one of the standard models, the problem can be expressed mathematically as follows. Let $\mathcal{C}$ denote the characters defining the species set $\mathcal{S}$, and $\mathcal{A}_c$ the set of states of character c. Let $|\mathcal{C}| = k$ and $\max_c|\mathcal{A}_c| = r$. For ease of discussion we will assume that $\mathcal{A}_c \in \{1, 2, \ldots, r\}$, so that each species is identified with a vector in Z^k (where Z denotes the integers) and $c(\boldsymbol{s})$ is referred to as the *state of character c for $\boldsymbol{s}$* or the *state of $\boldsymbol{s}$ on character c*.

The input to the perfect phylogeny problem is therefore an $n \times k$ matrix M, where $M_{i,j}$ is the state of the ith species on the jth character. The *perfect phylogeny problem* is to determine whether a given set of n distinct species $\mathcal{S}$ has a tree T with the following properties:

(C1) $\mathcal{S} \subseteq V(T) \subseteq Z^k$;
(C2) every leaf in T is in $\mathcal{S}$; and
(C3) for every $c \in \mathcal{C}$ and every $j \in \mathcal{A}_c$, the set of all $\boldsymbol{u} \in V(T)$ such that $c(u) = j$ induces a subtree of T.

The tree T, if it exists, is called a *perfect phylogeny* for $\mathcal{S}$, and the set of characters $\mathcal{C}$ is said to be *compatible*. In the biology literature, the perfect phylogeny problem is more commonly known as the *character compatibility problem* [8, 9, 14, 15], where it was introduced in the 1950s.

The perfect phylogeny problem was shown to be NP-complete by Bodlaender, Fellows, and Warnow [3] and, independently, by Steel [18]. This fact suggests at least two lines of attack: one is to restrict k, the number of characters; the other is to restrict r.

The perfect phylogeny problem was shown to reduce to a graph-theoretic problem in [5] called the *triangulating colored graphs problem*. The number of characters in an instance I equals the number of colors in the corresponding graph G_I. Algorithms for the perfect phylogeny problem based upon the graph-theoretic formulation were given in [4, 12, 16]. These algorithms are thus useful when the number of characters in the input can be bounded.

In this paper, we pursue the second approach, in which the number of states is bounded (as is the case for molecular data). Gusfield [11] gave an $O(nk)$ algorithm for $r = 2$, the *binary* character case. Dress and Steel [7] devised an $O(nk^2)$ algorithm for $r \leq 3$. Kannan and Warnow [13] gave an $O(n^2k)$ algorithm for $r \leq 4$ (*quaternary* characters). Agarwala and Fernández-Baca [1] give an $O(2^{3r}(nk^3 + k^4))$ algorithm for the perfect phylogeny problem when the characters are restricted to having at most r states.

We present an $O(2^{2r}nk^2)$ time algorithm for this problem. The algorithm we present uses some of the same structure as that of [1] but uses additional lemmas about the problem structure and different data structures to achieve the faster running time.

Biomolecular data (such as DNA, RNA, or amino-acid sequences) define characters for which the maximum number of states is bounded by a small constant ($r = 4$ for DNA or RNA, and $r = 20$ for amino-acid sequences). As a consequence, efficient algorithms for the perfect phylogeny problem for fixed numbers of states are of particular importance in molecular phylogenies.

In most applications of computation in biology, it is not sufficient to know a single optimal solution. Instead it is important to know the entire space of optimal solutions (such information could be used, for example, to settle the *African Eve hypothesis*). In the second half of this paper, we present algorithms that allow us to construct a representation of this space. This representation can be used to count the number of optimal solutions, enumerate all minimal optimal solutions, generate random optimal solutions, and gather aggregate statistics about the set of optimal solutions.

2. Preliminaries. We state some definitions and briefly summarize the algorithm of Agarwala and Fernández-Baca since our algorithm is a modification of theirs. Several of these definitions appear in [1], and equivalent definitions to some of these definitions can also be found in [13].

In the remainder of this section, we will let α denote an arbitrary character in C, and we will refer to the states of α by α-states. We will use $*$ to denote a dummy state for a character.

DEFINITION 2.1. *Suppose T is a perfect phylogeny and let p be some vertex in T. We shall say that the α-state of p is* forced *if p lies on the path between leaves u and v of T with $\alpha(u) = \alpha(v)$.*

DEFINITION 2.2. *A subset $S' \subset S$ is called a* cluster *if for every character α, if $\exists\{x, y\} \subseteq S', \{x', y'\} \subseteq S - S'$ such that $\alpha(x) = \alpha(x')$ and $\alpha(y) = \alpha(y')$, then $\alpha(x) = \alpha(x')$ (i.e., at most one α-state is "shared" by S' and $S - S'$).*

DEFINITION 2.3. *A cluster S' is called a* proper cluster *if there is some character α for which S' does not share any α-state with $S - S'$.*

In the subsequent definitions, we will be interested in defining the character states

of internal nodes according to a canonical labeling; for this purpose, we will use $*$ to indicate the dummy state of a character.

DEFINITION 2.4. *Let G be a cluster. We will denote by $Sv(G)$ the unique vector $v \in (Z \cup \{*\})^k$ such that $\forall \alpha \in C$, if $\exists a \in G, b \in S - G, \alpha(a) = \alpha(b)$, then $\alpha(v) = \alpha(a)$, and otherwise $\alpha(v) = *$. $Sv(G)$ is called the* splitting vector of G.

DEFINITION 2.5. *If $G_1 \subset G$ and both G and G_1 are clusters, then G_1 is said to be* compatible *with G if for all characters for which both $Sv(G)$ and $Sv(G_1)$ are set to nondummy states, they are set to the same state. We will also say that G_1 is compatible with the vector $Sv(G)$ in this case.*

The definitions of splitting vectors and compatibility can be extended as follows.

DEFINITION 2.6. *If G, G_1 are proper clusters and $G_1 \subset G$ is compatible with G, then the splitting vector $Sv(G, G_1)$ is defined as follows: for any character α having a shared state i between G and $S - G$ or between G_1 and $S - G_1$, $\alpha(Sv(G, G_1)) = i$.*

Since G_1 is compatible with G, there will be no conflict in setting the states of $Sv(G, G_1)$.

$Sv(G, G_1)$ is obtained very simply from $Sv(G)$ and $Sv(G_1)$. For any character on which either of the latter two vectors has a nondummy state, $Sv(G, G_1)$ is also set to that state. Otherwise $Sv(G, G_1)$ has the dummy state. We denote this by saying that $Sv(G, G_1) = Sv(G) \oplus Sv(G_1)$.

This extension is motivated by the following scenario. If v is an internal node of degree at least three in a perfect phylogeny T, then the removal of v splits T into three or more components. The definition of $Sv(G, G_1)$ gives a labeling for a node v in a perfect phylogeny (if such a node exists) whose removal will split T into components, some of which union to G_1 and others of which union to $G - G_1$. Note that, in fact, in an *actual* partition into components some of the dummy states of v might be forced. To see this, consider the case where $G - G_1$ partitions into $G_{11}, G_{12}, \ldots, G_{1t}$, where G_{1i} and G_{1j} share an α-state i although no α-state is shared between any two of $S - G, G - G_1$, and G_1; in this situation, the α-state for the splitting vector $Sv(G, G_1)$ is the dummy state, but the actual setting for the node v rooting the subtree defined by G is i for this particular partition.

DEFINITION 2.7. *A perfect phylogeny P for S is* minimal *if for all edges $e \in E(P)$, the topology which results by contracting the edge e in P cannot be vertex-labeled to make a perfect phylogeny.*

Clearly, a set S has a perfect phylogeny if and only if it has a minimal perfect phylogeny.

The relevance of proper clusters to the perfect phylogeny problem and to the algorithm of [1] is shown in the following lemma.

LEMMA 2.8 (see [1, Lemma 1]). *Let T be a minimal perfect phylogeny for S and let T' be an arbitrary subtree of T obtained as a component by the removal of an edge $e = (u, v)$ of T. Let S' be the subset of species from S labeling nodes of T'. Then S' is a proper cluster.*

Proof. S' must be a cluster, since at most one state of each character can be shared across the edge e. Furthermore, if S' is not a proper cluster, then both u and v must be identically labeled (since on each character their state is forced to be the shared state between S' and $S - S'$). Thus an equivalent "reduced" perfect phylogeny could be obtained by collapsing edge e and identifying nodes u and v. Since T is presumed to be a minimal perfect phylogeny, it follows that for any subtree T' as above, the subset S' of S labeling internal nodes of T' forms a proper cluster. □

We need one more definition.

DEFINITION 2.9. *A proper cluster G is* good *if the set $G \cup \{Sv(G)\}$ has a perfect phylogeny. A pair of proper clusters (G, G_1) for which $G_1 \subset G$ and G_1 is compatible with G is* good *if there exists a perfect phylogeny for G with an internal node v labeled by $Sv(G, G_1)$ such that the removal of v partitions G into subsets (defined by the species from S labeling nodes of each component tree) some of which union to G_1.*

Using this idea, the algorithm of [1] works, in a bottom-up dynamic programming fashion, to determine which proper clusters are good.

In [1] it is shown that if G_1 is a good proper cluster and G is another proper cluster containing G_1 and compatible with G_1, then we can determine (in polynomial time) if (G, G_1) is good.

3. The algorithm of Agarwala and Fernández-Baca. Before applying any of the dynamic programming techniques they develop, Agarwala and Fernández-Baca first determine if any of the species in S can occupy an internal node in the perfect phylogeny they construct. This can be determined in polynomial time (in fact, in $O(nk)$ time, as we will show later). If any node can be an internal node, they reduce to subproblems. The more difficult case is where no species in S can be an internal node in any perfect phylogeny for S.

The algorithm in [1] determines, for all proper clusters G' of smaller cardinality than G, whether G' is good. Now, in considering the pair of proper clusters (G, G_1), there are two cases. If $G_2 = G - G_1$ is also a proper cluster, then (G, G_1) is good if and only if G_2 is also good, and this can be determined by a simple table look-up. If on the other hand, G_2 is not a proper cluster, then $Sv(G, G_1)$ is forced for all characters. The algorithm then loops over all possible good proper clusters $G' \subset G_2$ that are compatible with $Sv(G, G_1)$. Then (G, G_1) is good if and only if G_2 is the disjoint union of a set of good proper clusters $G' \subseteq G_2$.

The determination of whether a proper cluster G is good requires finding a proper cluster G_1 which is contained in and compatible with G, such that (G, G_1) is good. In [1], this determination is accomplished by checking all potential proper clusters G_1. For each pair of proper clusters (G, G_1), the algorithm may spend $2^r k$ time going over all possible proper clusters G_2 and for each of these clusters spends $O(n + k)$ time determining whether G_2 is compatible with $Sv(G, G_1)$. Thus the overall running time of the algorithm in [1] is $O(2^{3r} k^3 (k + n))$.

4. Our improvements to the algorithm. While most of the innovation in our algorithm occurs by exploiting structural properties of the solution so as to reduce the number of loops as well as to speed up the inner loop, in order to achieve an overall cost of $O(2^{2r} nk^2)$ time, we will also do some preprocessing of the data.

4.1. Preprocessing. Given a vector $s \in \mathcal{A}_1 \times \cdots \times \mathcal{A}_m$, we can define an equivalence relation E_s on S as the transitive closure of the following relation R: for $a, b \in S$, $(a, b) \in R$ if $\exists c \in C$ s.t. $c(a) = c(b) \neq c(s) \neq *$. It is clear from this definition that two species in S which are in the same equivalence class must be in the same component of $T - \{s\}$ for any perfect phylogeny on $S \cup \{s\}$. We denote the operation of computing the equivalence classes by S/s.

We assume that the species are given in some fixed order $s_1, s_2, \ldots, s_n$. As in the Agarwala and Fernández-Baca algorithm, we first determine whether any $s \in S$ can be internal nodes, and if so reduce to subproblems. The additional preprocessing of the data we perform involves the following steps:

1. Compute all proper clusters.
2. Sort the proper clusters lexicographically and store them in a table.

3. Viewing each proper cluster as a lexicographically ordered sequence of species, build a *trie* for the proper clusters which is pruned so that each internal node has at least one proper cluster that lies below it. Also, any node of the trie that represents a proper cluster will have a pointer to that proper cluster in the table.
4. For every proper cluster G compute $Sv(G)$.
5. For each vector $Sv(G)$ compute $S/Sv(G)$.

Running time.

Step 1. Each proper cluster partitions the species set S by partitioning the states of some character. Let L be the number of proper clusters. There are $O(2^r)$ proper clusters for each character, and hence only $O(2^r k)$ proper clusters in all; thus L is $O(2^r k)$. Generating the set of clusters involves generating all possible subsets of character states and determining which ones are clusters. Generating the subsets takes $O(n)$ time per subset. To check whether a subset A is a cluster we list each state of each character which appears in A. This takes $O(nk)$ time. We then compare the list for A and $S - A$ to check that for each character, at most one state is shared between A and $S - A$. This takes $O(kr)$ time, which is $O(nk)$ since $r \leq n$. Hence the total cost for generating all the clusters is $O(nk)$ per cluster, and so this step uses $O(2^r k^2 n)$ time.

Step 2. Sorting the proper clusters lexicographically (using radix sort) costs $O(2^r kn)$.

Step 3. Note that since each leaf of the trie is a proper cluster and since the depth of the trie is at most n, there are at most $O(2^r kn)$ nodes in the trie. Also, a simple traversal of the sorted list of proper clusters builds the trie in $O(2^r kn)$ steps.

Step 4. The computation of $Sv(G)$ can be done in $O(nk)$ steps. To do this, for each character α build a table of size r, and go through the species in S noting (in the table) which α-states are present in species in G and which α-states are present in the species in $S - G$. (For instance, table entries could be initialized to 0, set to 1 if a species in G has the corresponding state, set to 2 if a species in $S - G$ has that state, and set to 3 if there are species in both sets having that state.) Now, we simply check if there is any table entry which is a "3" and simply set $Sv(G)$ to that state. Otherwise $Sv(G)$ is set to "$*$." Since we do $O(nk)$ work per proper cluster, this costs us $O(2^r nk^2)$ time for Step 4.

Step 5. We need to compute $S/Sv(G)$ in this step. We will show that for any vector x we can compute S/x in $O(nk)$ time.

LEMMA 4.1. *For any vector x, S/x can be computed in $O(nk)$ time.*

Proof. A straightforward implementation using UNION-FIND appears to take $O(nk\alpha(nk, n))$ time. We give a constructive proof of the $O(nk)$ bound. For each character, α such that $\alpha(x)$ is not the dummy state, we maintain information about the equivalence class to which each state of α other than $\alpha(x)$ "belongs." (A state of α belongs to a class if there is some species in that class having the specified α-state.) Note that, since two species which share an α-state other than $\alpha(x)$ must be in the same equivalence class, this is well defined.

Now we process each species in turn taking $O(k)$ time per species. When we look at species s, for each character α we look to see if $\alpha(s)$ belongs to some equivalence class. If so, we include s in that class and, for every character β on which $\beta(x)$ is not the dummy state, if $\beta(s) \neq \beta(x)$, we include $\beta(s)$ as a β-state of that class. If none of the states of s belong to existing classes, we create a new class with s as the only species in that class and we initialize the states of this class appropriately. Also, if s belongs to more than one class, we union these classes and associate with the new

class the union of the set of states associated with each of the old classes. Since there can be at most n unions and each union takes only $O(k)$ time, the total cost for all unions is at most $O(nk)$. The other costs are at most $O(k)$ per species and these also result in a total cost of $O(nk)$. □

The computation of Step 5 costs us a total of $O(2^r nk^2)$. We will represent the equivalence classes of $S/Sv(G)$ by a spanning forest $T_{Sv(G)}$ on S, so that the components of $T_{Sv(G)}$ are the distinct equivalence classes of $S/Sv(G)$.

Overall cost. Thus the total cost of the preprocessing is $O(2^r nk^2)$.

4.2. Reducing to two nested loops. The algorithm of [1] has three nested loops, each of which steps through all possible proper clusters in the worst case. Thus the number of executions of the innermost loop becomes $O(2^{3r}k^3)$. The three loops arise because for all possible proper clusters G, and for all possible proper clusters G_1 that are subsets of G, and for all possible proper clusters which are subsets of $G_2 = G - G_1$ we execute the innermost loop. Since the cost of the innermost loop is bounded by $O(n+k)$, the overall cost of the [1] algorithm is therefore $O(2^{3r}(nk^3+k^4))$.

In this section we will show that we can reduce to only two nested loops, and bring the cost of the innermost loop to $O(n)$ through extensive preprocessing, thus bringing the entire cost of the algorithm to $O(2^{2r}nk^2)$.

We begin with some lemmas.

LEMMA 4.2. *Let s be a vector such that none of its states are equal to the dummy state. If s occurs as the label of an internal node in a minimal perfect phylogeny for S and Q is an equivalence class of S/s, then Q is a proper cluster.*

Proof. Let T be a minimal perfect phylogeny for S where s occurs as the label of an internal node v. By a result in [2], Q is entirely contained in one of the subtrees of $T - \{v\}$. Let T_Q be this subtree. Without loss of generality, we may assume that the leaf-set of T_Q is exactly Q since if T_Q contains leaves outside Q, these leaves can be moved to a different component of $T - \{v\}$. Now, v is adjacent to a single node y in T_Q. Since T is minimal, we cannot contract the edge (v, y), so that for some character α, $\alpha(v)$ and $\alpha(y)$ are both forced and different. However, then Q is a proper cluster, since no state of α crosses the boundary of Q. □

THEOREM 4.3. *Suppose G is a proper cluster, $G_1 \subset G$ a good proper cluster, and $G - G_1 = G_2$ not a proper cluster. Let $x = Sv(G, G_1)$. Then (G, G_1) is good if and only if each $Q \in G_2/x$ is a good proper cluster.*

Proof. Note that for each $Q \in G_2/x$, the splitting vector, $Sv(Q)$ is compatible with x. Thus if each $Q \in G_2/x$ is good, then the perfect phylogenies for each of these components, as well as the perfect phylogeny for G_1, may be made to hang off the node labeled x.

Conversely, suppose that (G, G_1) is good, and let T be a minimal perfect phylogeny for S in which the species in G define an edge-removal-induced subtree T_G and G_1 is the union of the leaves in a collection of subtrees off the root of T_G (such a tree exists by the fact that (G, G_1) is good). The canonical labeling for the root of T_G is x. Since $G - G_1$ is not a proper cluster, x is fully defined (by a lemma proved in [1]) i.e., none of its states are dummy states. By Lemma 4.2, each equivalence class Q of S/x is a proper cluster. It is easy to verify that each $Q \in S/x$ is also good and that $G_2/x \subset S/x$. □

As a consequence of these lemmas, we can reduce the number of loops from three to two.

Reducing the number of loops: Suppose G is a proper cluster, $G_1 \subset G$ is a good proper cluster, and $G_2 = G - G_1$ is not a proper cluster.

Let $x = Sv(G, G_1)$, and compute the equivalence classes Q of G_2/x.

Report *YES* for G, G_1 if and only if each of these equivalence classes is a good proper cluster.

Else return *NO*.

4.3. Speeding up the inner loop. In the process of going from three nested loops to two, we have increased the time of execution of the inner loop from $O(n+k)$ in the algorithm of [1] to $O(nk)$. We can avoid this blow-up using the information computed during preprocessing. In fact, we will reduce the time for the inner loop to $O(n)$. Since k can be $O(n^{r-1})$, this is significant. To see this, let T be a tree with n leaves and $2n-3$ edges; each choice of $r-1$ edges separates the tree into r components, and thus defines a unique r-state character. Thus, we can define $\Omega(n^{r-1})$ distinct characters that are consistent with a perfect phylogeny. Furthermore, most data sets these days use characters derived from biomolecular sequences in which the number of characters equals the length of the sequences in a multiple alignment, and this number can be quite large (and significantly larger than the number of species). Reducing the dependence on k here is important.

Consider how we execute the inner loop. We are given a pair of proper clusters G, G_1, and $G_1 \subset G$. We need to see if (G, G_1) is good (that is, if G has a perfect phylogeny rooted at $Sv(G, G_1)$ in which G_1 is the union of some of the subtrees).

Condition 1. A necessary condition for (G, G_1) to be good is that $Sv(G_1)$ and $Sv(G)$ are compatible. If that condition holds, we then compute $G_2 = G - G_1$. Note that this ensures that G_2 is a cluster.

Condition 2. If G_2 is a proper cluster, then (G, G_1) is good if and only if G_2 is good.

Condition 3. If G_2 is not a proper cluster, then (G, G_1) is good if and only if we can write G_2 as a union of proper clusters $G_{11}, G_{12}, \ldots, G_{1q}$, such that for each G_{1i}, $Sv(G_{1i})$ is compatible with $Sv(G)$ and G_{1i} is good.

LEMMA 4.4. *Let G and $G_1 \subset G$ be clusters. Let $x_1 = Sv(G_1)$ and $x = Sv(G)$. Then x_1 and x are compatible iff there is no edge in T_x between a node in G_1 and a node not in G_1.*

Proof. Suppose that x and x_1 are compatible but that in T_x there is an edge from vertex $u \in G_1$ to vertex $v \notin G_1$. Then there exist $u' \in G_1$ and $v' \notin G_1$ and a character c such that $c(u') = c(v') \neq c(x)$. Since x_1 is defined as the splitting vector of G_1 it follows that $c(x_1) = c(u') \neq c(x)$, contradicting the assumption that x_1 and x are compatible.

Conversely, suppose that x and x_1 are not compatible. Then there is a character c for which $c(x)$ and $c(x_1)$ are set to different states. Since $c(x_1)$ is set, there must be a $u \in G_1$ and a $v \notin G_1$ such that $c(u) = c(x_1) = c(v)$. Since $c(x) \neq c(x_1)$, u and v must be in the same component of T_x. □

Thus the check of Condition 1 takes $O(n)$ time. If Condition 1 holds, we can determine in $O(n)$ time whether G_2 is a proper cluster. If so, we perform a table look-up to see if G_2 is good. Thus, Condition 2 takes only $O(n)$ time to check. Condition 3, surprisingly, also takes only $O(n)$ time (instead of the $O(2^r k(n+k))$ time used in [1]).

LEMMA 4.5. *We can determine whether Condition* 3 *holds in $O(n)$ time.*

Proof. If $G - G_1 = G_2$ is not a proper cluster, then by Theorem 4.3, (G, G_1) is good if and only if each of the equivalence classes of G_2/y is a good proper cluster, where $y = Sv(G, G_1)$.

Let $Sv(G) = x$ and $Sv(G_1) = x_1$. Recall that $y = x \oplus x_1$. Since G_2/x and G_2/x_1 are already known, G_2/y can be computed as follows.

We start with the graphs T_x and T_{x_1}, and we add an edge between each pair of corresponding vertices. We then need to compute the connected components. This takes $O(n)$ time, since the number of edges in each graph is linear. These connected components are the equivalence classes of S/y. Each component is a proper cluster by Lemma 4.2.

To see if each of the components is a good proper cluster, all we need to do is a set of table look-ups. However, there is a subtle point here. We have only $O(n)$ time to perform perhaps as many as $O(n)$ look-ups. To accomplish this we will exploit the fact that there is a trie representing the proper clusters.

When we determine the partition of G_2 into equivalence classes, we will number these classes and determine for each $s \in G_2$ the number of the class to which it belongs.

After this, we go through the species contained in G_2 in lexicographic order. If species s is contained in a class l, we can use this information to narrow down the range of possible indices at which class l may occur in the table of all proper clusters. Thus, only a constant amount of work is performed per species in G_2. At the end it is determined whether each of the classes is a proper cluster, in which case an index is found in the table to each of these proper clusters. It is then easy to perform table look-up to determine which of these proper clusters are good. We can therefore determine whether G has a phylogeny with a subtree T_1 for G_1 hanging off the root x of G. Clearly all of this is accomplished in $O(n)$ time. □

4.4. Analysis of running time. The preprocessing takes $O(2^r nk^2)$. Then we process each proper cluster in turn. For each of the possible pairs (G, G_1) of proper clusters where $G_1 \subset G$ and G_1 is good, we use only $O(n)$ time, for a total cost of $O(2^{2r} nk^2)$ time. The algorithm therefore runs in $O(2^{2r} nk^2)$.

5. Enumerating all minimal perfect phylogenies. In this section we consider the problem of enumerating all minimal perfect phylogenies. We are interested only in minimal perfect phylogenies for two reasons. The first rather banal reason is that there can be many more perfect phylogenies than minimal ones (each minimal perfect phylogeny which has nodes of degree greater than three can yield many different perfect phylogenies by refinement) and since enumeration is costly, it's better if we can just enumerate the minimal ones. The second reason is more significant. Since we wish to determine the evolutionary relationships that are supported by the data, it is in fact the minimal trees which are significant. Since evolutionary hypotheses are usually expressed by saying that speciation events occurred in a specific order, if we resolve a node of degree greater than three, we are (falsely) indicating support for a hypothesis that the minimal tree does not provide. Thus, it behooves us to consider only the minimal perfect phylogenies.

The key issues for efficient enumeration are to avoid following "dead ends" in the dynamic programming algorithm, to ensure that we never enumerate anything twice and that the enumeration is exhaustive.

To simplify our presentation, we will describe only the enumeration of minimal perfect phylogenies where all the species in S are forced to occur as leaves. Slight modifications of the method allow it to be extended to enumerating other minimal perfect phylogenies as well.

We will say that a proper cluster H has a *subphylogeny* if there is a perfect phylogeny P for S with an edge e such that the removal of e partitions the leaves of

P into H and $S - H$. The *root* of the subphylogeny for H is that endpoint of e on whose side the leaf set is H. Note that H being good does not ensure that H has a subphylogeny because there is also a constraint on $S - H$. We will call a proper cluster H *very good* if it has a subphylogeny. This definition easily extends to pairs. A pair of proper clusters (H, G) is very good if and only if (H, G) is good and H has a subphylogeny. It is clear that, after running the algorithm described in the previous section, one more pass through the data structures built up by the algorithm suffices to determine all very good pairs.

Throughout this section let H, G, and G_1 be proper clusters with $G_1 \subset G \subset H$ and such that (H, G) and (G, G_1) are each *very* good pairs.

Since a subphylogeny is, in particular, a perfect phylogeny for a subset of S, we can talk about minimal subphylogenies. We are interested in identifying very good pairs (H, G) such that H has a *minimal* subphylogeny P rooted at r_H and one of the children of r_H is in turn the root, r_G, of a (minimal) subphylogeny for G. We will refer to such minimal subphylogenies by $\mathrm{Min}(H, G)$, while the set of subphylogenies (i.e., not necessarily minimal) of H with this form is indicated by $\mathrm{Sub}(H, G)$.

We now introduce two definitions which are minor variants of previously defined terms. Given a topology T for a perfect phylogeny, we define a canonical labeling of the internal nodes as follows.

DEFINITION 5.1. *Let v be an internal node. Without loss of generality, the degree of v is greater than or equal to 3. Let $T_1(v), T_2(v), \ldots, T_k(v)$ be the subtrees of T obtained by the removal of v. For any character α we define $\alpha(v)$ to be the unique α-state shared by two or more of these subtrees, if such a state exists. Otherwise $\alpha(v)$ is set to equal a dummy state "$*$." The vector so defined is called the* canonical labeling of *v, and we denote this by $cl(v)$.*

We also need to define the notion of *compatibility* in more general terms.

DEFINITION 5.2. *Two vectors x and y in Z^k are* compatible *if for every character α, if $\alpha(x)$ and $\alpha(y)$ are both fixed to nondummy states, then $\alpha(x) = \alpha(y)$.*

With the above definitions, a minimal topology can be thought of as follows.

A topology T (which is perfect) is minimal if the canonical labeling of T does not produce two adjacent nodes whose labels are compatible.

We make the following additional definitions.

DEFINITION 5.3. *The set $Ext(H, G)$ consists of all vectors x such that*

- *$\exists P \in Sub(H, G)$ such that $x = cl(r_H)$;*
- *the leaf set of each subtree of the root r_H is a proper cluster.*

Note that the vector x must have the same state as $Sv(H, G)$ on all characters on which $Sv(H, G)$ has a nondummy state (i.e., x is an extension of $Sv(H, G)$).

LEMMA 5.4. *For H and G as defined, $|Ext(H, G)| \leq 2^{r^2} k^r$.*

Proof. If the root of H has r or more children and each of these children roots a subtree whose leaf set is a proper cluster, then for every character α, a state of α must be shared either between two children of the root or between H and $S - H$. In either case the α-state of the root would be determined. Thus, any vector in the extension must arise from the choice of a set of no more than $r - 1$ proper clusters, and the bound follows. □

DEFINITION 5.5. *Let H be a proper cluster. The set $Conn(H)$ consists of those vectors x such that*

- *$\exists G$ such that (H, G) is very good, and*
- *$\exists P \in \mathrm{Min}(H, G)$ such that $x = cl(r_H)$.*

Note that $Conn(H) \subseteq \cup_{G:(H,G)\mathrm{verygood}} Ext(H, G)$. The reason that $Conn(H)$

may not be identically equal to this union is that $Conn(H)$ consists of canonical labelings of roots in *minimal* perfect phylogenies for H, while $\cup_G Ext(H,G)$ is the set of canonical labelings for roots of perfect phylogenies which may or may not be minimal.

Since we are concerned with enumerating minimal phylogenies we want to avoid listing phylogenies containing edges whose endpoints are labeled compatibly. Consequently, given a very good pair (H,G), we need to ensure that the edge $e = (r_H, r_G)$ cannot be contracted. This will be true if $cl(r_H)$ and $cl(r_G)$ are incompatible.

DEFINITION 5.6. *$Vp(G)$ consists of those vectors x such that*

- *$\exists H(H,G)$ is a very good pair,*
- *$\exists P \in \text{Min}(H,G)$, $x = cl(r_H)$,*
- *$cl(r_H)$ and $cl(r_G)$ are incompatible.*

The set $Vp(G)$ is called the set of valid parents *of G.*

5.1. Algorithms for counting, enumerating, and sampling. The algorithm has three phases. In the first phase, we compute the sets $Ext(H,G)$, $Conn(G)$, and $Vp(G)$ using dynamic programming. In the second phase, a directed acyclic graph (DAG) T is constructed. This DAG is a compact representation of the set of minimal perfect phylogenies and can be used to enumerate, count, or obtain statistical information about the set of minimal perfect phylogenies. The third phase, therefore, can be used for any of these purposes.

5.1.1. Phase I. Computing the sets of vectors. Computing $Ext(H,G)$. Given a very good pair (H,G), we consider all partitions of $H - G$ into at most $r-1$ proper clusters $G_1, G_2, \ldots, G_t$ and consider the (possible) perfect phylogeny for H which has root x with subtrees perfect phylogenies for $G, G_1, G_2, \ldots, G_t$. The canonical labeling for x is then an element of $Ext(H,G)$.

Computing $Conn(H)$. Recall that $Conn(H)$ is the set of all canonical labelings of the roots of *minimal perfect subphylogenies* for H.

The candidates for membership in $Conn(H)$ are the elements of $Ext(H,G)$ where (H,G) is a very good pair. Thus we have only a "small" number of x's to run through. To determine whether a particular x is in $Conn(H)$ we will need the following two lemmas.

LEMMA 5.7. *Suppose x is a vector without dummy states. Then $x \in Conn(H)$ if and only if $x \in Vp(G)$ for every $G \in H/x$.*

Proof. Suppose $x \in Conn(H)$. There is a minimal perfect phylogeny P for H in which the canonical labeling for the root is x. P is also a perfect subphylogeny on G_i for each $G_i \in H/x$ and thus induces a minimal subphylogeny for G_i. In the minimal induced subphylogeny, if the root of G_i has a canonical labeling which is compatible with x, it can be identified with x. This is a contradiction to the definition of H/x. Therefore $x \in Vp(G_i)$ for all $G_i \in H/x$. In fact, this shows that *any* perfect phylogeny for G_i must have a root labeling that is incompatible with x.

Conversely, if $x \in Vp(G)$ for all $G \in H/x$, then we can define a perfect subphylogeny for H by making x the parent of the roots of the perfect phylogenies for each P_G, where P_G is a minimal perfect subphylogeny for G. Thus, $x \in Conn(H)$. ∎

LEMMA 5.8. *Suppose x is a vector with at least one dummy state. Then $x \in Conn(H)$ if and only if there exists a G such that*

- *(H,G) is very good,*
- *$x \in Vp(G)$, and*
- *either $x \in Vp(H-G)$ or $x = Sv(H,G) \oplus y$ for some $y \in Conn(H-G)$.*

Proof. Suppose $x \in Conn(H)$. Then there is a minimal perfect subphylogeny for H for which x is the canonical labeling of the root r_H. If r_H has two children, then H is formed by taking a minimal perfect phylogeny for two proper clusters G and $H-G$, and $x \in Vp(G) \cap Vp(H-G)$. If r_H has more than two children, then first of all, x is an extension of $Sv(H,G)$. In addition, since x is part of a canonical labeling, the reason that any dummy state in $Sv(H,G)$ is set to a nondummy state in x is because the vector $y \in Conn(H-G)$ forces this change. Thus $x = Sv(H,G) \oplus y$.

Conversely, if $x \in Vp(G) \cap Vp(H-G)$ for some very good (H,G), then we can get a minimal perfect phylogeny for H by combining the minimal perfect phylogenies for G and $H-G$ whose roots are incompatible with x. Similarly, if $x \in Vp(G)$ and $x = Sv(H,G) \oplus y$ for some $y \in Conn(H-G)$, then let T be the minimal perfect subphylogeny for $H-G$ whose root has a canonical labeling y, and let T' be the minimal perfect subphylogeny for G whose canonical labeling is $Sv(H,G)$. Then the combination of these two subphylogenies is a subphylogeny for H which is minimal, since the edges from its root (given this canonical labeling x) cannot be contracted. □

Computing $Vp(G)$. To compute $Vp(G)$, we simply look at each very good pair (H,G), examine each $x \in Ext(H,G)$, and include those x such that for some $y \in Conn(G)$, x and y are incompatible.

Analysis of Phase I. To compute these sets, we first compute all very good pairs (H,G). We then compute $Ext(H,G)$ for each such very good pair. Afterwards, we order the proper clusters G which are members of very good pairs, by cardinality, and start with the smallest.

For each such proper cluster G, we compute $Conn(G)$ and $Vp(G)$ by the above method. The most expensive operation is computing $Ext(H,G)$ for all very good pairs (H,G). For $O(2^{2r}k^2)$ pairs (H,G) we need to look at $O(2^{r^2}k^r)$ possible vectors, each of which takes $O(k)$ to examine. Thus the total time is $O(2^{2r+r^2}k^{r+3})$.

5.1.2. Phase II. Constructing the DAG. At this stage, for every proper cluster H that occurs as the set of leaves of a subtree of a minimal phylogeny induced by the removal of an edge, we have determined the sets $Conn(H)$ and $Vp(H)$. We now proceed as follows.

Let H be a proper cluster and let y be a vector in $Vp(H)$. The subroutine we describe determines what minimal perfect phylogenies of H are possible that have y as the parent of the root of H.

Let $x \in Conn(H)$ such that x is not compatible with y. There are two cases. Suppose x is fully set. We create a graph $\Gamma(H,x)$ in which the nodes are the proper clusters G such that (H,G) is very good and $x \in Vp(G)$. There is an edge between two nodes G and G' if they represent two clusters having a nonempty intersection. Then a consequence of Lemma 5.7 is that *every maximal independent set* in this graph represents a partition of H into proper clusters which must be realized in some perfect phylogeny.

Now suppose that x is not fully set. For each G such that (H,G) is very good and $x \in Vp(G)$, we check to see if $x \in Vp(H-G)$ or if there is a vector $z \in Conn(H-G)$ such that $x = z \oplus Sv(H,G)$. Each of these possibilities gives rise to possible structural decompositions of the perfect phylogeny for H, and we recurse on components.

This phase of the algorithm produces the following output.

It produces a DAG where there are two kinds of nodes—sum nodes and product nodes. A sum node is labeled by a pair (H,y), where H is a proper cluster and $y \in Vp(H)$. The children of this sum node are product nodes. Each product node

represents a partition of H into proper clusters $G_1, G_2, \ldots, G_l$ and a choice of a root label x from $Conn(H)$ such that x is not compatible with y and $x \in Vp(G_i)$ for $i = 1, \ldots, l$. These product node children of (H, y) are obtained in the manner described in the above paragraph, i.e., by considering all vectors $x \in Conn(H)$ which are incompatible with y. If x is fully set, the product nodes are obtained from the enumeration of the maximal independent sets of $\Gamma(H, x)$. If x is not fully set, then a product node, $(G, H - G; x)$, is created for each pair $G, H - G$ such that $x \in Vp(G) \cup Vp(H - G)$. Also, for each $z \in Conn(H - G)$ such that $x = Sv(H, G) \oplus z$, we enumerate all maximal independent sets in $\Gamma(H - G, z)$ and create a product node for each such set, where the product node contains the proper clusters in the independent set as well as G and is also labeled by the vector x. Note that the enumeration of maximal independent sets in graphs of the form $\Gamma(H, x)$ may be repeated many times in the above algorithm. We could modify the algorithm to enumerate these sets exactly once for each such $\Gamma(H, x)$ and then memorize the result. While this may improve the practical performance, it does not change the asymptotic complexity since each re-enumeration of these sets produces new minimal perfect phylogenies.

The product node $(G_1, G_2, \ldots, G_l; x)$ in turn points to l different sum nodes which are labeled by pairs (G_i, x) for $i = 1, \ldots, l$. Note that the DAG has at most one sum node for each possible label pair.

To finish the description of the DAG we need to describe its "boundaries." First of all, note that if all species in S are distinct and a perfect phylogeny exists for S, then there must be some state of some character which is present in exactly one species, say x. (If not, look at any perfect phylogeny P for S and note that it contains a pair of sibling leaves a, b. Since both a and b share states with other species on all characters, a and b are forced to be identical.) Thus the top of the DAG will be a sum node labeled $(S - x, x)$. (Note that $S - x$ is a proper cluster.) The bottom of the DAG consists of pairs (G, y) where G is a proper cluster with cardinality 1. Note also that the assumption that all species in S are forced to be leaves guarantees that each singleton subset of S is a proper cluster. (To remove this assumption, we would have to modify the algorithm as follows. When considering proper cluster H and a particular vector $x \in Conn(H)$ if x is compatible with a species $s \in H$, we also allow the possibility that r_H is labeled with s, thus making s an internal node.)

Starting from the top sum node, if we always follow one of the children from each sum node and all of the children from each product node, we will have implicitly defined a minimal perfect phylogeny. (The topology of this perfect phylogeny can be obtained from the above traversal by homeomorphically eliminating the product nodes.)

The following lemma proves some properties of this DAG representation.

LEMMA 5.9.

1. *Every node in the DAG is useful in the implicit representation of some minimal perfect phylogeny.*
2. *Every minimal perfect phylogeny is implicitly represented by the DAG (in the above sense) exactly once.*

Proof. By construction, for any sum node labeled (H, x) there is a minimal perfect phylogeny for S which contains a subphylogeny for H whose root r_H is labeled incompatibly with x. If $(G_1, \ldots, G_l; y)$ is a product node child of H, then y is incompatible with x and can be used to label r_H without destroying minimality. Also, since y is in $Vp(G_i)$ for all i, there are minimal subphylogenies for the G_i's whose roots can be labeled incompatibly with y. Thus, all sum nodes and product nodes are useful in some minimal perfect phylogeny.

Since each sum node has a distinct label, each minimal perfect phylogeny is represented at most once in the DAG. Lemmas 5.7 and 5.8 exhaustively enumerate all possibilities for the top-level decomposition of a subphylogeny for a very good proper cluster H with a valid parent y. Since the DAG contains all these possibilities, it implicitly represents all minimal perfect phylogenies. □

5.1.3. Phase III. Enumerating, counting, or sampling. Once this DAG is generated, we can count the number of minimal perfect phylogenies by working bottom-up. If the number at all descendants of a node has been determined, the number at the node can be determined by an addition if it is a sum node or by a multiplication if it is a product node. Once such a count can be made it is a very simple matter to use these counts to introduce an implicit numbering of the minimal perfect phylogenies and to enumerate or generate the ith minimal perfect phylogeny given the ordering. Clearly, it is also possible to obtain other statistics efficiently from this structure. The technique used to enumerate is also as easy as the counting.

5.2. Analysis. In section 5.1.1 we showed that phase I requires $O(2^{2r+r^2}k^{r+3})$ time. Phases II and III have running times that depend on the number of nodes and edges in the DAG. The generation of sum nodes can be easily accomplished once their parent product nodes have been found. Thus the complexity of phase II is essentially the complexity of finding all product nodes. The critical step in this process is the enumeration of maximal independent sets in graphs of the form $\Gamma(H, x)$. In general, for a graph G containing v nodes and e edges, the enumeration of all maximal independent sets can be done by a simple backtracking algorithm that takes $O(v+e)$ time to produce the next maximal independent set at each point. Such an algorithm is a polynomial delay algorithm [10] since it takes only polynomial time to produce the next member of the list being enumerated. In our case, v is at most $2^r k$ and hence e is at most $2^{2r}k^2$. Noting that the number of product nodes in the DAG is at most n times the number of minimal perfect phylogenies L, we get a bound on the running time of phase II to be $O(2^{2r}k^2Ln)$.

All of the computations of phase III involve simple traversals of the DAG constructed in phase II. The work done at each product node is upper bounded by the number of its children and the work done at each sum node is upper bounded by the number of top-level decompositions of the subphylogeny for the proper cluster represented at that node. By charging this work to individual minimal perfect phylogenies in a natural manner, it can be seen that no minimal perfect phylogeny is charged more than $O(n)$ cost, and hence phase III can be performed in $O(Ln)$ time.

5.3. Polynomial delay. In this section we show that the above approach can be modified to design an algorithm with polynomial delay for the enumeration of all minimal perfect phylogenies. Note that the algorithm, as described above, constructs the DAG in a breadth-first fashion and hence is not polynomial delay. We simply modify the algorithm to work in a depth-first fashion, fully exploring one child of a sum node before constructing others by simple backtracking. Since each product node can be constructed from its parent sum node with $O(2^{2r}k^2)$ delay, and since there are $O(n)$ product nodes in any minimal perfect phylogeny, this depth-first search version of the algorithm is an $O(2^{2r}k^2n)$-delay algorithm for enumerating minimal perfect phylogenies.

6. Comments. The algorithm we have presented here is a significant theoretical improvement on the algorithm of Agarwala and Fernández-Baca [1]. The running time of this algorithm ($O(f(r)nk^2)$) is close to the running time of the algorithms

for $r = 3, 4$, for which $O(n^2k)$ algorithms were found [13], and matches the $O(nk^2)$ running time of the algorithm for $r = 3$ given by Dress and Steel [7]. Although the enumeration algorithms have bad worst-case running times, the actual running time when the number of minimal perfect phylogenies is small is likely to be much more reasonable.

Although perfect phylogenies rarely arise in molecular phylogenies, the recent application of perfect phylogeny to the reconstruction of evolutionary trees for families of natural languages has shown, surprisingly, that properly encoded linguistic information does yield data sets with perfect phylogenies (or in which very few characters must be removed in order to obtain perfect phylogenies [17]). Furthermore, even though perfect phylogenies are rare in molecular phylogenies, biologists still seek maximal sets of compatible characters. The problem of finding a maximum cardinality compatible subset of characters is, unfortunately, *NP-hard*, even for the case of binary characters [6]. Finding maximal sets, on the other hand, can be done in a greedy fashion, given an algorithm to determine compatibility of characters.

Since, until recently, the only algorithms for perfect phylogeny were for binary characters and two characters at a time, biologists have instead looked for maximal sets of pairwise compatible characters. This practice (of seeking sets of characters which are pairwise compatible) does not ensure set-wise compatibility. The algorithm that we have presented provides a tool which could be used by biologists to efficiently construct maximal subsets of compatible characters in a greedy manner. This greedy heuristic has already been shown to produce extremely reasonable phylogenetic trees [19] for biological data and for trees on natural languages [17]. The greedy heuristic for constructing maximal subsets of compatible characters is thus useful for any domain where it is possible to construct perfect phylogenies using almost all of the characters in the data set (i.e., using $k - O(1)$ characters). Perhaps we will find such data in the biological arena as well.

FAULT-TOLERANT MESHES WITH SMALL DEGREE*

JEHOSHUA BRUCK†, ROBERT CYPHER‡, AND CHING-TIEN HO§

Abstract. This paper presents constructions for fault-tolerant, two-dimensional mesh architectures. The constructions are designed to tolerate k faults while maintaining a healthy n by n mesh as a subgraph. They utilize several novel techniques for obtaining trade-offs between the number of spare nodes and the degree of the fault-tolerant network.

We consider both worst-case and random fault distributions. In terms of worst-case faults, we give a construction that has constant degree and $O(k^3)$ spare nodes. This is the first construction known in which the degree is constant and the number of spare nodes is independent of n. In terms of random faults, we present several new degree-6 and degree-8 constructions and show (both analytically and through simulations) that these constructions can tolerate large numbers of randomly placed faults.

1. Introduction.

As the number of processors in parallel machines increases, physical limitations and cost considerations will tend to favor interconnection networks with constant degree and short wires, such as mesh networks [6]. In fact, the two-dimensional mesh is already one of the most important interconnection networks for parallel computers. Examples of existing two-dimensional mesh computers include the MPP (from Goodyear Aerospace), VICTOR (from IBM), and DELTA and Paragon (from Intel).

Another significant issue in the design of massively parallel computers is fault-tolerance. In order to create parallel computers that have very large numbers of complex processors, it will become necessary to utilize these machines even when several components have failed. In particular, the ability to tolerate even a small number of faults may allow a machine to continue operation between the occurrence of the first fault and the repair of the faults.

A large amount of research has been devoted to creating fault-tolerant parallel architectures. The techniques used in this research can be divided into two main classes. The first class consists of techniques which *do not* add redundancy to the desired architecture. Instead, these techniques attempt to mask the effects of faults by using the healthy part of the architecture to simulate the entire machine [2, 11, 17, 19, 23]. These techniques do not pay any costs for adding fault-tolerance, but they can experience a significant degradation in performance. The second class consists of

techniques which *do* add redundancy to the desired architecture. These techniques attempt to isolate the faults, usually by disabling certain links or disallowing certain switch settings, while maintaining the complete desired architecture [1, 3, 4, 7, 8, 9, 10, 13, 14, 15, 18, 20, 22, 24, 25, 26, 27, 29]. The goal of these techniques is to maintain the full performance of the desired architecture while minimizing the cost of the redundant components.

One of the most powerful techniques for adding redundancy is based on a graph-theoretic model of fault-tolerance [18]. In this model, the desired architecture is viewed as a graph (called the *target graph*), and a fault-tolerant graph is created such that after the removal of k faulty nodes, the target graph is still present as a subgraph. This technique yields fault-tolerant networks that can tolerate both node faults and edge faults (by viewing a node incident with the faulty edge as being faulty) and can implement algorithms designed for the target network without any slowdown (due to the simulation of multiple nodes by a single node or the routing of messages through switches or intermediate nodes). Unfortunately, the degree of the fault-tolerant network created with this model can be prohibitively large. In particular, all previously published techniques for creating fault-tolerant meshes with exactly k spares have a degree that is linear in the number of faults being tolerated.

In this paper, we create fault-tolerant n by n meshes with small degree by trading-off the number of spare nodes with the degree of the fault-tolerant network. We consider both worst-case and random fault distributions. In terms of worst-case faults, we give a construction that tolerates k faults and has constant degree and $O(k^3)$ spares. This is the first construction known in which the degree is constant and the number of spares is independent of n. The only other known constant degree construction for this problem requires $\Theta(n^2)$ spares [27]. In terms of random faults, we present several new degree-6 and degree-8 constructions and show (both analytically and through simulations) that they can tolerate large numbers of randomly placed faults. Our constructions require at most $O(n)$ spares and appear to be of practical interest. The only other known construction that is proven to tolerate large numbers of random faults was created by Tamaki [27]. That construction can tolerate nodes and edges which fail with constant probability, but requires $\Theta(n^2)$ spares and has degree $O(\log \log n)$.

In addition, our construction for worst-case faults is shown to require only wires of length $O(k^3)$ in Thompson's VLSI model [28], while our constructions for random faults are shown to require only constant-length wires. Thus our fault-tolerant constructions maintain much of the scalability of the mesh network. We remark that we use Thompson's VLSI model only because it provides a well-established means for quantifying the locality of an interconnection network; the use of this model does not imply that the constructions presented here are designed for the wafer-scale implementation of a parallel machine. In fact, most existing parallel machines have one, or at most a few, processors per chip. This fact motivates our concern about the degree of the fault-tolerant network (because of the limited number of pins available to connect one chip to another [12]).

The remainder of this paper is organized as follows. Definitions and several previously known results are given in section 2. The results for worst-case fault distributions and random fault distributions are presented in sections 3 and 4, respectively.

2. Preliminaries. definitions. Let k be a nonnegative integer and let $T = (V, E)$ be a graph. The graph $F = (V', E')$ is a *k-fault-tolerant graph with respect to T*, denoted a k-FT T, if the subgraph of F induced by any set of $|V'| - k$ nodes

contains T as a subgraph. The graph T will be called the *target graph*. The graph F will be said to contain $|V'| - |V|$ *spare nodes* (or *spares*).

DEFINITION. *The cycle with n nodes will be denoted C_n.*

DEFINITION. *The two-dimensional mesh with $r \geq 2$ rows and $c \geq 2$ columns will be denoted $M_{r,c}$. Each node in $M^{r,c}$ has a unique label of the form (i, j) where $0 \leq ir$ and $0 \leq j < c$. Each node (i, j) is connected to all nodes of the form $(i \pm 1, j)$ and $(i, j \pm 1)$, provided they exist. The node (i, j) will be said to be in* row i *and* column j.

DEFINITIONS. *Let n be a positive integer and let S be a set of integers in the range 1 through $n - 1$. The graph $C(n, S)$, called the n-*node circulant graph with connection set S [16, 14, 10]*, consists of n nodes numbered $0, 1, \ldots, n - 1$. Each node i is connected to all nodes of the form $(i \pm s) \bmod n$, where $s \in S$. The graph $D(n, S)$, called the n-*node diagonal graph with connection set S [10]*, consists of n nodes numbered $0, 1, \ldots, n-1$. Each node i is connected to all nodes of the form $i \pm s$ where $s \in S$, provided they exist. (The terms "circulant" and "diagonal" refer to the structure of the adjacency matrix.) The values in a connection set S will be referred to as "jumps" or "offsets" and an edge defined through an offset s will be referred to as an s-*offset edge.

DEFINITION. *Let S be a set of integers and let k be a nonnegative integer. The* expansion of S *by k, denoted* expand(S, k)*, is the set T where*

$$T = \bigcup_{s \in S} \{s, s + 1, \ldots, s + k\}.$$

The following theorems give constructions for creating fault-tolerant circulant and diagonal graphs. The basic idea is to add offsets so that faulty nodes can be "jumped over." The construction for diagonal target graphs has lower degree because a cluster of faults can be avoided by placing the cluster in the position where the missing wraparound edges would jump over them.

THEOREM 2.1 (see [14]). *Let n be a positive integer, let S be a set of integers in the range 1 through $n - 1$, let k be a nonnegative integer, and let $T = expand(S, k)$. The circulant graph $C(n + k, T)$ is a k-FT $C(n, S)$.*

THEOREM 2.2 (see [10]). *Let n be a positive integer, let $y = \lceil n/3 \rceil$, let S be a set of integers in the range 1 through y, let k be a positive integer, and let $T = expand(S, \lfloor k/2 \rfloor)$. The circulant graph $C(n + k, T)$ is a k-FT $D(n, S)$.*

The following theorems relate meshes, circulant graphs, and diagonal graphs. Combining these theorems with the two previous theorems yields constructions for fault-tolerant meshes. The first theorem follows immediately from the row-major labeling of the nodes in a mesh. The second theorem follows from a *diagonal-major order* of the nodes in a mesh; see Figure 1 for an example.

THEOREM 2.3. *The mesh $M_{r,c}$ is a subgraph of $C(rc, \{1, c\})$ and of $D(rc, \{1, c\})$.*

THEOREM 2.4. *The mesh $M_{r,c}$ is a subgraph of $C(rc, \{c - 1, c\})$.*

Proof. Let $\phi(i, j) = ((i - j) \bmod r)c + j$. It is straightforward to verify that ϕ defines an embedding of $M_{r,c}$ into $C(rc, \{c - 1, c\})$. □

3. Worst-case faults. In this section we present a graph $\tilde{M}$ that is a k-FT $M_{n,n}$ and has constant degree and $O(k^3)$ spares. Our construction is hierarchical. We first construct a graph M' that is a k-FT $M_{r,c}$ (for some suitably chosen parameters r and c) and has degree which is dependent on k. We then replace each node in M' with a supernode (a graph with certain properties) to obtain a graph $\tilde{M}$ with constant degree.

FIG. 1. *An example of a diagonal-major ordering of a mesh.*

3.1. The basic construction. We first present a construction for a k-FT cycle with degree 4 and k^2 spare nodes. We will then use this construction to create the graph M' which is a k-FT $M_{r,c}$.

THEOREM 3.1. *Let k and N be positive integers where $N \geq k^2 + k + 1$, and let the graph $C' = C(N + k^2, \{1, k + 1\})$. The graph C' is a k-FT C_N.*

Proof. First consider the case where $(N + k^2) \bmod (k + 1) = 0$. For each i, $0 \leq i \leq k$, let X_i be the set consisting of all nodes $\{j | j \bmod (k + 1) = i\}$. Because there are only k faults and there are $k+1$ disjoint sets X_i, at least one of them must be fault-free. Let X be such a fault-free X_i. Note that the nodes in X form a fault-free cycle C'' of length $(N + k^2)/(k + 1)$ using the $(k + 1)$-offset edges. Next, we augment C'' to obtain a healthy cycle of length at least N. For any two adjacent nodes a and b in C'', if all k of the nodes in C' between a and b are healthy, we traverse all k of these nodes by using the 1-offset edges. On the other hand, if there is a fault between a and b, we skip over all k of the nodes between them by traversing the $(k + 1)$-offset edge connecting a and b. It is clear that we will traverse $(k + 1)$-offset edges at most k times, so the resulting augmented cycle will have at least N nodes. If it has more than N nodes, we can choose to traverse additional $(k + 1)$-offset edges, rather than 1-offset edges, until the cycle has length exactly N. An example of a 2-FT cycle is shown in Figure 2.

Now consider the case where $(N + k^2) \bmod (k + 1) = x \neq 0$. Let R be a region of $k + 1 + x$ consecutive healthy nodes in C'. Note that such a region must exist because $N + k^2 \geq 2k^2 + k + 1$, so there must be a region of $2k + 1$ or more consecutive healthy nodes between two faults. Without loss of generality, we will assume that R consists of the $k + 1 + x$ highest numbered nodes in C'. For each i, $0 \leq i \leq k$, create the cycle C_i'' as follows. First, start at node i and traverse the $(k + 1)$-offset edges until a node in R is reached. Then, traverse the 1-offset edges x times. Finally, traverse one additional $(k + 1)$-offset edge to return to i. Note that these $k + 1$ cycles share only nodes within R. Because all of the nodes in R are healthy, there must exist an i such that C_i'' is healthy. We can augment C_i'' as before to obtain a cycle of length N. □

THEOREM 3.2. *Let k, r, and c be positive integers where $r, c \geq 2$ and $rc \geq k^2 + k + 1$, let $N = rc$, and let $M' = C(N + k^2, \{1, k + 1\} \cup \{c + ik | 0 \leq i \leq k\})$. The graph M' is a k-FT $M_{r,c}$.*

Proof. Let $T = C(N, \{1, c\})$. We will prove that M' is a k-FT T. Applying Theorem 2.3 will complete the proof. First, it follows from Theorem 3.1 that in the presence of k faults, M' contains a cycle of N healthy nodes. Let C'' denote a cycle of healthy nodes constructed according to the proof of Theorem 3.1, and number the

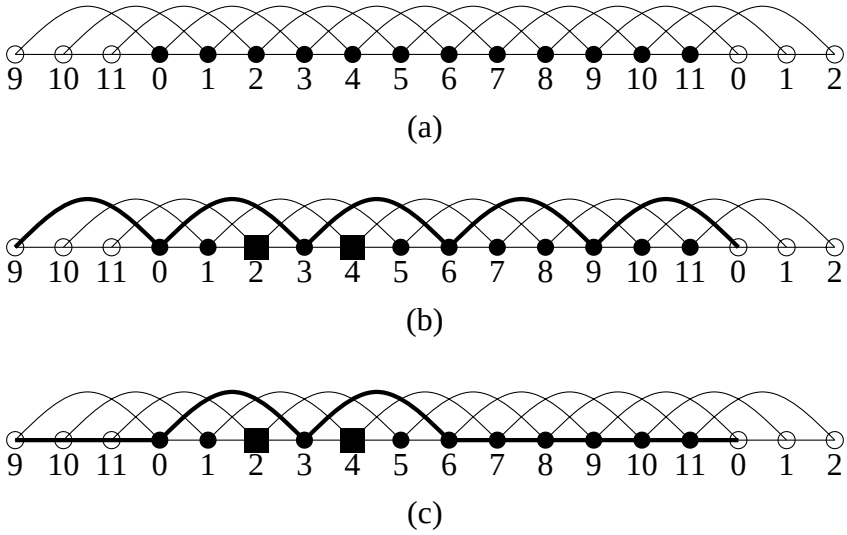

FIG. 2. *A degree-4, 2-fault-tolerant cycle with 4 spare nodes.*

nodes in C'' from 0 through $N-1$. We will now prove that any two nodes numbered a and b in C'', where $(a+c) \bmod N = b$, are connected in M'. Let a' and b' be the labels of a and b in M', and assume without loss of generality that $a' < b'$. We know that it is possible to traverse the cycle C'' from a to b by traversing 1-offset edges and at most k $(k+1)$-offset edges. Therefore, $b' - a' = c + jk$ for some integer j where $0 \leq j \leq k$, which implies that a and b are connected in M'. □

3.2. Hierarchical constructions. In the previous subsection we described a construction of a k-FT cycle with k^2 spare nodes and degree 4 and a construction of a k-FT two-dimensional mesh with k^2 spare nodes and degree $2k+6$. In this subsection we will present techniques for reducing the degree of these FT graphs. The general idea is to replace each node in the original FT graph by a small graph (which we call a supernode). Then, for each edge (a, b) in the original graph, one or more nodes in the supernode corresponding to a is connected to one or more nodes in the supernode corresponding to b. This approach results in a FT graph with lower degree than the original graph, although it does increase the number of spare nodes that are required.

3.2.1. Hierarchical fault-tolerant cycles. We illustrate the concept of a supernode by creating a hierarchical FT cycle.

THEOREM 3.3. *Let k and N be positive integers, where $N \geq k^2+k+1$, and let $\hat{C}$ be the graph with $2N+2k^2$ nodes, numbered 0 through $2N+2k^2-1$, and with edges specified as follows: Each odd numbered node i is connected to nodes $(i+1)$, $(i-1)$, and $i+2k+1$, and each even numbered node i is connected to nodes $(i+1)$, $(i-1)$, and $i-2k-1$, where all of the arithmetic is performed modulo $(2N+2k^2)$. Then $\hat{C}$ is a k-FT C_{2N}.*

Proof. The graph $\hat{C}$ can be obtained from the graph C' of Theorem 3.1 by replacing each node with a supernode consisting of a pair of nodes connected to one another. The edges that correspond to the positive direction connections in C' are connected to odd nodes in $\hat{C}$ while the edges that correspond to negative direction

connections in C' are connected to even nodes in $\hat{C}$. Consider the graph C' in which a node a is faulty iff at least one of the nodes in the supernode corresponding to a in $\hat{C}$ is faulty. It follows from Theorem 3.1 that C' contains a cycle of N healthy nodes. Therefore, $\hat{C}$ must contain a cycle of $2N$ healthy nodes corresponding to the cycle of N healthy nodes in C'. □

Figure 3 shows an example of a 2-FT cycle of degree 3 with $2k^2 = 8$ spares.

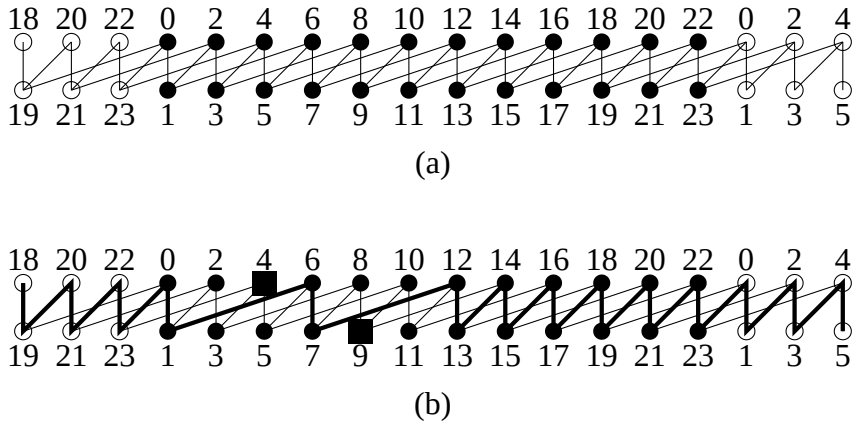

FIG. 3. *A degree-3, 2-fault-tolerant cycle with 8 spare nodes.*

3.2.2. Hierarchical fault-tolerant meshes. We will now show how hierarchical constructions can be used to reduce the degree of the graph M' of Theorem 3.2. We will begin with an approach that reduces the degree to $\Theta(\sqrt{k})$. We will then consider a more powerful technique that reduces the degree to a constant. The first approach uses the following graph as a supernode.

DEFINITION. *Let H_n be a graph with n nodes and degree 3 (if n is even) or degree 4 (if n is odd) such that for every pair of distinct nodes in H_n, there is a Hamiltonian path that has those nodes as endpoints. H_n graphs have been created for all $n \geq 2$* [5]. *See Figure 4 for an example.*

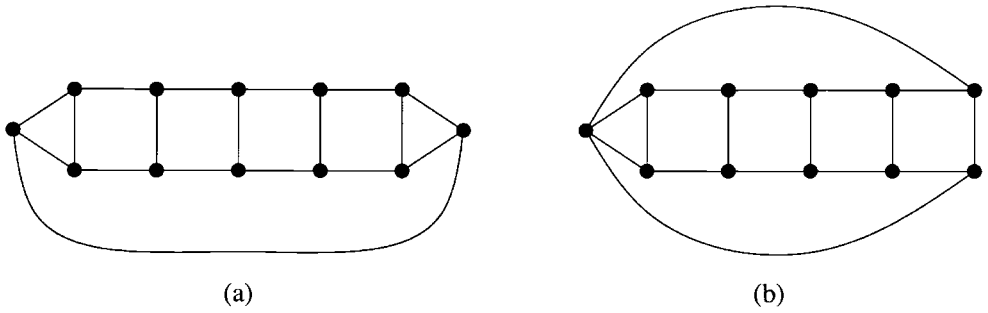

FIG. 4. *Examples of Hamiltonian graphs by Moon* [5] *with minimal degree. The number of nodes is even in* (a) *and is odd in* (b).

CONSTRUCTION 3.1. *Let k, r, c, n, and s be positive integers where $r, c, s \geq 2$, $rc \geq k^2 + k + 1$, and $2rs = c = n$, let $V = \{c + ik | 0 \leq i \leq k\}$, and let the graph $M' = C(rc + k^2, \{1, k+1\} \cup V)$. Let $\hat{M}$ be the hierarchical graph obtained from M' by replacing each node in M' by a supernode H_{2s}. Divide the nodes in each supernode arbitrarily into two halves of s nodes each. Add connections between supernodes as follows:*

1. *Connect each node in each supernode i to every node in supernodes $i-1$, $i+1$, $i-k-1$, and $i+k+1$ (all modulo $rc+k^2$). These edges, called horizontal edges, contribute $8s$ to the degree of each node.*
2. *For each offset $v \in V$ and for every supernode i, connect one of the nodes in the second half of supernode i to one of the nodes in the first half of supernode $(i+v) \bmod (rc+k^2)$. These edges, called vertical edges, should be evenly distributed among the nodes in each half of each supernode so they contribute at most $\lceil (k+1)/s \rceil$ to the degree of each node.*

Note that the degree of $\hat{M}$ is at most $8s + \lceil (k+1)/s \rceil + 3$. Choosing $s = \Theta(\sqrt{k})$ yields a graph $\hat{M}$ with degree $O(\sqrt{k})$ and with $O(k^{5/2})$ spare nodes.

THEOREM 3.4. *The graph $\hat{M}$ defined in Construction* 3.1 *is a k-FT $M_{n,n}$.*

Proof. Consider the graph M' of Theorem 3.2 in which a node a' is faulty iff at least one of the nodes in the supernode corresponding to a' in $\hat{M}$ is faulty. It follows from Theorem 3.2 that M' contains a healthy $M_{r,c}$ subgraph. We will show that this implies that $\hat{M}$ contains a healthy $M_{n,n}$ subgraph.

Let a' be any node in the healthy $M_{r,c}$ subgraph of M', and let $\hat{a}$ be the supernode in $\hat{M}$ corresponding to a'. We will view $\hat{a}$ as a column of $2s$ nodes in $M_{n,n}$. Note that a' has vertical neighbors $a' - v_1 \bmod (rc+k^2)$ and $a' + v_2 \bmod (rc+k^2)$, where v_1 and v_2 are in V. Let t be the node in the first half of $\hat{a}$ that is connected to a node in supernode $\hat{a} - v_1 \bmod (rc+k^2)$, and let b be the node in the second half of $\hat{a}$ that is connected to a node in supernode $\hat{a} + v_2 \bmod (rc+k^2)$. We will view t as being the top node and b as being the bottom node in the column of $2s$ nodes formed by $\hat{a}$. Recall that for every pair of nodes in H_{2s}, there is a Hamiltonian path that has those nodes as endpoints. Therefore, we can use the Hamiltonian path with endpoints t and b as the vertical connections within $\hat{a}$. Furthermore, the connections between the node b in one supernode and the node t in the next supernode provide the vertical connections between supernodes. Finally, note that a' has horizontal neighbors $a' - x_1 \bmod (rc+k^2)$ and $a' + x_2 \bmod (rc+k^2)$ where x_1 and x_2 are in $\{1, k+1\}$. Because each node in $\hat{a}$ is connected to every node in supernodes $\hat{a} - x_1 \bmod (rc+k^2)$ and $\hat{a} + x_2 \bmod (rc+k^2)$, the horizontal connections between supernodes are also present. □

We will now show how the use of a different supernode graph can yield a k-FT mesh with $O(k^3)$ spare nodes and constant degree. The following graph will be used as the supernode graph.

DEFINITION. *The graph P_k consists of $2k+4$ nodes. This graph consists of two parts, denoted S_1 and S_2, each of which is the graph $C(k+2, \{1,2\})$, plus an edge connecting node $k+1$ in S_1 with node $k+1$ in S_2. See Figure* 5 *for an example of P_6.*

Now we describe the construction of a k-FT mesh based on the graph P_k as a supernode.

CONSTRUCTION 3.2. *Let k, r, c, and n be positive integers where $r, c \geq 2$, $rc \geq k^2 + k + 1$, and $(2k+4)r = c = n$, let $V = \{c + ik | 0 \leq i \leq k\}$, and let $M' = C(rc + k^2, \{1, k+1\} \cup V)$.*

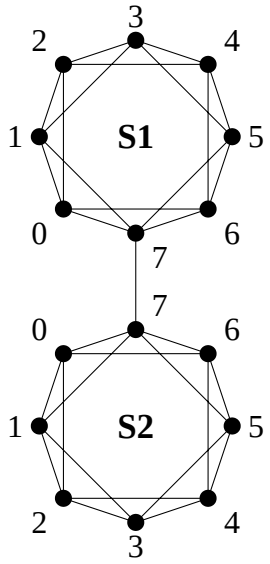

FIG. 5. *An example of the graph* P_6.

Let $\tilde{M}$ *be the hierarchical graph obtained from* M' *by replacing each node in* M' *by the supernode* P_k. *Add connections between supernodes as follows:*

1. *Connect each node* $j \in S_1$ *of supernode* i *to nodes* $\{j-2, j-1, j, j+1, j+2\} \bmod (k+2)$ *in* S_1 *of supernodes* $\{i-1, i+1, i-k-1, i+k+1\} \bmod (rc+k^2)$. *These edges, called horizontal edges, contribute* 20 *to the degree of each node in* S_1.
2. *Connect each node* $j \in S_2$ *of supernode* i *to nodes* $\{j-2, j-1, j, j+1, j+2\} \bmod (k+2)$ *in* S_2 *of supernodes* $\{i-1, i+1, i-k-1, i+k+1\} \bmod (rc+k^2)$. *These edges, also called horizontal edges, contribute* 20 *to the degree of each node in* S_2.
3. *Connect each node* $j \in S_2$ *of supernode* i, *where* $0 \le j \le k$, *to node* $j \in S_1$ *of supernode* $(i + c + jk) \bmod (rc + k^2)$. *These edges, called vertical edges, correspond to the* $k+1$ *offsets in* V *and contribute* 1 *to the degree of each node numbered less than* $k+1$ *in each half of each supernode.*

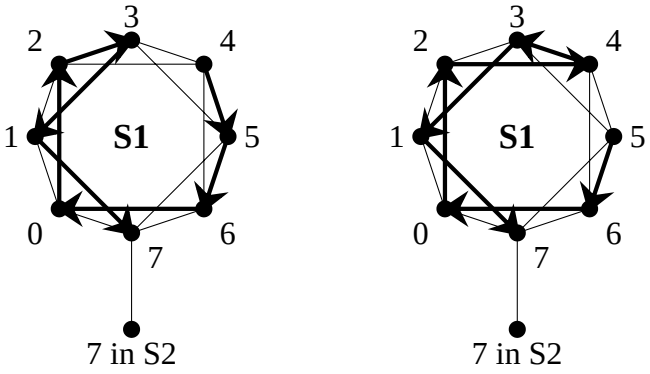
Note that the degree of $\tilde{M}$ is 25. The fact that $\tilde{M}$ is a k-FT mesh relies on the following lemmas.

LEMMA 3.5. *Consider the subgraph* $S = S_1$ (*or equivalently,* $S = S_2$) *of* P_k. *There exists a set of paths* $\{Q_0, Q_1, \ldots, Q_k\}$ *such that for each* i, $0 \le i \le k$, Q_i *is a Hamiltonian path through* S *with endpoints* i *and* $k+1$, *and for each* i, $0 \le i < k$, *and for each* j, $0 \le j \le k+1$, *if* a *is the* j*th node in* Q_i *and* b *is the* j*th node in* Q_{i+1}, *then* $(a-b) \equiv x \pmod{k+2}$ *where* $x \in \{-2, -1, 0, 1, 2\}$.

Proof. For each i, $0 \le i \le k$, define Q_i as follows. Start at i and traverse the 1-offset edges in the positive direction until node k is reached. Then traverse the 2-offset edges in the positive direction until either node $i-1$ or node $i-2$ is reached. If node $i-1$ is reached, traverse the 1-offset edge to node $i-2$ and then traverse the 2-offset edges in the negative direction until node $k+1$ is reached. On the other hand,

if node $i-2$ is reached before node $i-1$, traverse the 1-offset edge to node $i-1$ and then traverse the 2-offset edges in the negative direction until node $k+1$ is reached. See Figure 6 for an example of the paths Q_4 and Q_5 in S_1 of P_6.

If $i \le a \le k-1$, then $b = a+1$. If $a = k$, then $b = 0$. If $a = k+1$, then $b = a$. If $0 \le a \le i-1$, we have the following cases: (i) if a is even and $0 \le a \le i-2$, then $b = a+2$, (ii) if a is even and $a = i-1$, then $b = a+1$, and (iii) if a is odd and $1 \le a \le i-1$, then $b = a$. Therefore, in every case $(a-b) \equiv x \pmod{k+2}$ where $x \in \{-2,-1,0,1,2\}$. □



(a) Path starts from node 4 (b) Path starts from node 5

FIG. 6. *An example of two paths in S_1 of P_6 starting from nodes 4 and 5, respectively.*

LEMMA 3.6. *Let k, r, c, n, V, and M' be as defined in Construction 3.2. Consider any set of k faulty nodes in M' and let M be the healthy mesh $M_{r,c}$ in M' that is obtained by applying Theorem 3.2. Let a, b, a', and b' be any nodes in M' such that a and b are horizontal neighbors in M, a' and b' are horizontal neighbors in M, a and a' are vertical neighbors in M, and b and b' are vertical neighbors in M. If $a' = (a+c+ik) \bmod (rc+k^2)$ and $b' = (b+c+jk) \bmod (rc+k^2)$ where $0 \le i,j \le k$, then $|i-j| \le 1$.*

Proof. Assume without loss of generality that a is to the left of b in M and a' is to the left of b' in M. Note that $(b-a) \equiv x \pmod{rc+k^2}$ where $x \in \{1, k+1\}$ and $(b'-a') \equiv x' \pmod{rc+k^2}$ where $x' \in \{1, k+1\}$. Therefore, $(i-j)k \equiv (c+ik)-(c+jk) \equiv (a'-a)-(b'-b) \equiv x-x' \pmod{rc+k^2}$, which implies that $|i-j| \le 1$. □

THEOREM 3.7. *The graph $\tilde{M}$ defined in Construction 3.2 is a k-FT $M_{n,n}$ and has constant degree and $2k^3+4k^2$ spare nodes.*

Proof. The proof is analogous to that of Theorem 3.4. In particular, as in the proof of Theorem 3.4, we project the faults in $\tilde{M}$ onto M' and use Theorem 3.2 to find a healthy $M_{r,c}$ subgraph of M'.

Let a' be any node in the healthy $M_{r,c}$ subgraph of M' and let $\tilde{a}$ be the corresponding supernode in $\tilde{M}$. We view $\tilde{a}$ as a column of $2k+4$ nodes in $M_{n,n}$. We find top and bottom nodes t and b in $\tilde{a}$ as in the proof of Theorem 3.4, and we use Lemma 3.5 (twice) to create a Hamiltonian path through $\tilde{a}$ with endpoints t and b. Then, let b' be a node that is horizontally adjacent to a' in the healthy $M_{r,c}$ subgraph of M', and let $\tilde{b}$ be the corresponding supernode in $\tilde{M}$. It follows from Lemma 3.6

that the top nodes in $\tilde{a}$ and $\tilde{b}$ have positions within their supernodes that differ by at most one. A similar argument applies to the bottom nodes in $\tilde{a}$ and $\tilde{b}$. Therefore, it follows from Lemma 3.5 that for each i, $0 \leq i < 2k+4$, the ith node in the Hamiltonian path in $\tilde{a}$ has a horizontal connection to the ith node in the Hamiltonian path in $\tilde{b}$, which completes the proof. □

Hence, we have obtained a construction of a k-FT two-dimensional mesh with constant degree and $O(k^3)$ spare nodes. Although the construction given above is for a k-FT $M_{n,n}$ where n is a multiple of $2k+4$, it is straightforward to generalize the construction to arbitrary values of n as follows.

CONSTRUCTION 3.3. *Let k, r, c, and n be positive integers where $r, c \geq 2$, $rc \geq k^2+k+1$, $r = \lfloor n/(2k+4) \rfloor$, and $c = n$, let $V = \{c+ik | 0 \leq i \leq k\}$, and let $M' = C(rc+k^2, \{1, k+1\} \cup V)$.*

Let $n \bmod (2k+4) = \alpha$. If $\alpha = 0$, let $\hat{M}$ be the graph $\tilde{M}$ defined in Construction 3.2. *If $\alpha \neq 0$, first define the graph P'_k from P_k as follows. Add a node, denoted by x, to P_k, connect node x to node $k+1$ of S_1 in P_k, and connect node x to node $k+1$ of S_2 in P_k. Let $\hat{M}$ be the graph obtained by replacing each of the first $\alpha n + k^2$ nodes in M' by the supernode P'_k and replacing each of the remaining nodes in M' by the supernode P_k. Add connections between supernodes as follows:*

1. *Ignore the x nodes in the P'_k supernodes and add connections between supernodes as required by Construction* 3.2.
2. *For each supernode i, where $0 \leq i < \alpha n + k^2$, connect node x in supernode i to node x in supernode j, where $j \in \{i-1, i+1, i-k-1, i+k+1\}$ and $0 \leq j < \alpha n + k^2$.*

The following theorem is immediate from the preceding construction.

THEOREM 3.8. *Let k and n be positive integers, let $r = \lfloor n/(2k+4) \rfloor$, and let $c = n$. If $r, c \geq 2$ and $rc \geq k^2+k+1$, then there exists a k-FT $M_{n,n}$ with constant degree and $2k^3+5k^2$ spare nodes.*

Although the degree of $\hat{M}$ is increased to 26 (as both node $k+1$ of S_1 and node $k+1$ of S_2 have an edge to node x in the same supernode), one can easily reduce the number of horizontal edges of node $k+1$ to 4 (as opposed to 20 in the current definition) so that the degree of $\hat{M}$ remains 25. In fact, we remark that it is possible to reduce the degree still further by using a different graph for each supernode. Specifically, if each supernode is defined to be the product graph of P_k and a 4-node linear array, and if each supernode plays the role of a $(2k+4)$ by 4 submesh, it is possible to obtain a k-FT mesh with degree 12 and $8k^3+16k^2$ spare nodes. The details are omitted.

Finally, we will consider laying out the fault-tolerant graph $\hat{M}$ using Thompson's VLSI model [28]. One of the greatest advantages of two-dimensional mesh networks is that they can be laid out using only short (constant length) wires. The following theorem shows that the fault-tolerant graph $\hat{M}$ may require somewhat longer wires, but the wire lengths are still independent of n.

THEOREM 3.9. *It is possible to lay out the graph $\hat{M}$ defined in Construction* 3.3 *using only wires with length $O(k^3)$.*

Proof. We begin by presenting a mapping from the nodes in M' to the nodes in a torus network which maintains locality. We will then use standard techniques for laying out torus networks to obtain the final layout of $\hat{M}$. First, consider the case where k^2 is a multiple of c. In this case, lay out the nodes in M' in row-major order on an $(rc+k^2)/c$ by c torus. It is straightforward to verify that any pair of nodes that are connected in M' map to nodes that are in columns of the torus that differ by at most $O(k^2)$ and in rows of the torus that differ by at most $O(1)$. This torus can then be

mapped to an $(rc+k^2)/c$ by c grid by using the standard technique of placing the first half of the torus columns (rows) in increasing order in the even numbered columns (rows) of the grid and the remaining torus columns (rows) in decreasing order in the odd numbered columns (rows) of the grid (see, for example, [21, p. 246]). Finally, each node in M' can be laid out using an $O(k)$ by $O(k)$ square. The vertical tracks between grid columns are $O(k)$ wide and the horizontal tracks between grid rows are $O(k^3)$ wide (to accommodate wires that traverse $O(k^2)$ nodes, each of which is $O(k)$ wide). Thus each wire is of length $O(k^3)$.

Now consider the case where c does not evenly divide k^2. In this case, let $\alpha = k^2 \bmod c$ and use a $(rc+k^2)/c$ by $c+1$ torus. The nodes of M' are placed in the torus in row-major order, with the first α rows receiving $c+1$ nodes and all remaining rows receiving only c nodes. Again, it is straightforward to verify that any pair of nodes that are connected in M' map to nodes that are in columns of the torus that differ by at most $O(k^2)$ and in rows of the torus that differ by at most $O(1)$. This torus can then be laid out as described in the case where k^2 is a multiple of c. □

4. Random faults. In this section we consider random fault distributions. More specifically, we will assume that the fault-tolerant graph contains k faults, and that every configuration of k faulty nodes is equally likely. We will focus on the problem of creating fault-tolerant graphs for the mesh $M_{n,n}$. We will present six constructions for fault-tolerant meshes, analyze their asymptotic fault-tolerance, and study their fault-tolerance for realistic values of n.

The first three constructions are simple generalizations of previously known constructions [10] designed to tolerate worst-case fault distributions, while the remaining three constructions are new. In particular, the fourth construction introduces the concept of adding "dummy faults" in order to provide a fairly regular fault pattern. The fifth construction introduces the use of 2 by 2 "submeshes," and the sixth construction combines the use of dummy faults with the use of submeshes.

DEFINITION. *The graph* $T_1(n) = C(n^2, \{n-1, n\})$. *Recall from Theorem* 2.4 *that* $T_1(n)$ *contains* $M_{n,n}$ *as a subgraph.*

DEFINITION. *The graph* $T_2(n) = D(n^2, \{1, n\})$. *Recall from Theorem* 2.3 *that* $T_2(n)$ *contains* $M_{n,n}$ *as a subgraph.*

DEFINITION. *A graph* tolerates $\Theta(f(n))$ random faults *iff* $o(f(n))$ *random faults can be tolerated with a probability that is* $1 - o(1)$ *and* $\omega(f(n))$ *random faults can be tolerated with a probability that is* $o(1)$.

DEFINITION. *Given a circulant graph with* x *nodes, and given integers* y *and* z *where* $0 \le y, z < x$, *the* y*-node window starting at* z, *denoted* $W(y, z)$, *consists of the* y *nodes in the graph numbered* $z, z+1 \bmod x, \ldots, z+y-1 \bmod x$.

DEFINITION. *Given a circulant graph with* x *nodes, and given integers* y *and* z *where* $0 \le y, z < x$, *the distance between* y *and* z, *denoted* $dist(y, z)$, *is the minimum of* $z - y \bmod x$ *and* $y - z \bmod x$, *and nodes* x *and* y *are* consecutive *iff* $dist(y, z) = 1$.

DEFINITION. *Given a circulant graph with* x *nodes, and given integers* y *and* z *where* $1 \le y < x$ *and* $0 \le z < x$, *the* yth healthy node following (respectively, preceding) z *is the healthy node* a *such that there are exactly* y *healthy nodes in the set* $\{z+1 \bmod x, z+2 \bmod x, \ldots, a\}$ (*respectively,* $\{z-1 \bmod x, z-2 \bmod x, \ldots, a\}$).

It will be assumed throughout that $k \le n/2$ and $k = o(n)$. For constructions 1 through 4, we will consider only embeddings of the target graph in which node 0 of the target graph maps to some healthy node h in the fault-tolerant graph, and for each i, node i in the target graph maps to the ith healthy node following node h. For constructions 5 and 6, we will consider only embeddings obtained by viewing 2 by

2 "submeshes" that contain faults as representing faulty nodes in the corresponding fault-tolerant graph.

4.1. Construction 1. The first construction is based on the target graph $T_1(n)$.

DEFINITION. *The graph* $M_1(n,k) = C(n^2+k, \{n-1, n, n+1\})$.

Note that $M_1(n,k)$ has degree 6. The idea behind this construction is that it can tolerate faults by using the $(n+1)$-offset edges to jump over the faults.

LEMMA 4.1. *Assume that* $M_1(n,k)$ *contains* k *faulty nodes.* $M_1(n,k)$ *tolerates the faults iff for each* i, $0 \le i < n^2+k$, $W(n+1,i)$ *contains at most one fault.*

Proof. First, assume that for each i, $0 \le i < n^2+k$, $W(n+1,i)$ contains at most one fault. In this case, given any healthy node i, $W(n+2,i)$ contains at most one fault. Therefore, there is an edge between each healthy node and both the $(n-1)$st healthy node following it and the nth healthy node following it. As a result, $M_1(n,k)$ contains a healthy copy of $T_1(n)$.

Next, assume that there exists an i, $0 \le i < n^2+k$, such that $W(n+1,i)$ contains two or more faults. Let a be the first healthy node preceding i. Let a' be the node in $T_1(n)$ that maps to a, let b' be node $a'+n \bmod n^2$ in $T_1(n)$, and let b be the node to which b' maps. Note that b is the nth healthy node following a, so $b \notin W(n+1,i)$ and a and b are not connected to one another. □

LEMMA 4.2. *Let* M' *be a circulant graph with* $\Theta(n^2)$ *nodes and let* $y = \Theta(n)$. *Assume that* M' *contains* k *randomly located faulty nodes. If* k *is* $o(n^{1/2})$, *the probability that there exists a node* i *such that* $W(y,i)$ *contains two or more faults is* $o(1)$.

Proof. Given any two faults a and b, the probability that there exists a node i such that both a and b lie in $W(y,i)$ is $\Theta(n^{-1})$. There are $o(n)$ distinct pairs of faults, so the probability that there exists a node i such that $W(y,i)$ contains two or more faults is $o(n^{-1}n) = o(1)$. □

LEMMA 4.3. *Let* M' *be a circulant graph with* $\Theta(n^2)$ *nodes and let* $W = W(y,z_1)$, $W(y,z_2)$, $\ldots, W(y,z_q)$ *be a collection of* q *mutually disjoint* y*-node windows in* M', *where* $y = \Theta(n)$ *and* $q = \Theta(n)$. *Assume that* M' *contains* k *randomly located faulty nodes. If* k *is* $\omega(n^{1/2})$, *the probability that there exists a window in* W *that contains two or more faults is* $1 - o(1)$.

Proof. Divide the faults into halves. After the first half of the faults have been placed, if no window in W contains two or more faults then there must be $\omega(n^{3/2})$ healthy locations, each of which lies within a window in W that contains a fault. Therefore, the probability that any given fault in the second half will lie in a window in W that contains another fault is $\omega(n^{-1/2})$. As a result, the probability that no window in W contains two or more faults after all of the faults have been placed is at most $(1-n^{-1/2})^{\omega(n^{1/2})} = (1-n^{-1/2})^{n^{1/2}\omega(1)} = (1/e)^{\omega(1)} = o(1)$. □

THEOREM 4.4. *The graph* $M_1(n,k)$ *tolerates* $\Theta(n^{1/2})$ *random faults.*

Proof. The proof is immediate from Lemmas 4.2, 4.3, and 4.1. □

4.2. Construction 2. The second construction is also based on the target graph $T_1(n)$.

DEFINITION. *The graph* $M_2(n,k) = C(n^2+k, \{n-1, n, n+1, n+2\})$.

Note that $M_2(n,k)$ has degree 8. It is similar to $M_1(n,k)$, except the $(n+2)$-offset edges allows it to jump over more faults. The proof of the following lemma is analogous to that of Lemma 4.1 and is omitted.

LEMMA 4.5. *Assume that* $M_2(n,k)$ *contains* k *faulty nodes.* $M_2(n,k)$ *tolerates the faults iff for each* i, $0 \le i < n^2+k$, $W(n+2,i)$ *contains at most two faults.*

LEMMA 4.6. *Let M' be a circulant graph with $\Theta(n^2)$ nodes and let $y = \Theta(n)$. Assume that M' contains k randomly located faulty nodes. If k is $o(n^{2/3})$, the probability that there exists a node i such that $W(y, i)$ contains three or more faults is $o(1)$.*

Proof. Given any three faults, the probability that there exists a node i such that all three faults lie in $W(y, i)$ is $\Theta(n^{-2})$. There are $o(n^2)$ distinct sets of three faults, so the probability that there exists a node i such that $W(y, i)$ contains three or more faults is $o(n^{-2}n^2) = o(1)$. □

LEMMA 4.7. *Let $f(n)$ be any function such that $1 \leq f(n) \leq n$. Given $\omega(n)$ independent Bernoulli trials, each of which has a probability of success of at least $1/f(n)$, the probability of at least $n/f(n)$ successes is $1 - o(1)$.*

Proof. Divide the trials into $\omega(n/f(n))$ groups, each of which contains at least $\lceil f(n) \rceil$ trials. Given any one group of trials, the probability of at least one success in that group is at least $1/2$. Therefore, given any $2\lceil n/f(n) \rceil$ groups, the probability of at least $n/f(n)$ successes is at least $1/2$. This implies that the probability that the entire set of $\omega(n)$ trials contains at least $n/f(n)$ successes is at least $1-(1/2)^{\omega(1)} = 1-o(1)$. □

LEMMA 4.8. *Let M' be a circulant graph with $\Theta(n^2)$ nodes and let $W = W(y, z_1)$, $W(y, z_2)$, $\ldots, W(y, z_q)$ be a collection of q mutually disjoint y-node windows in M', where $y = \Theta(n)$ and $q = \Theta(n)$. Assume that M' contains k randomly located faulty nodes. If k is $\omega(n^{2/3})$, the probability that there exists a window in W that contains three or more faults is $1 - o(1)$.*

Proof. Divide the faults into three groups, each of which contains $\omega(n^{2/3})$ faults. Consider the three following statements:

Statement 1. At least $n^{2/3}$ windows in W contain at least one fault each.

Statement 2. At least $n^{1/3}$ windows in W contain at least two faults each.

Statement 3. There exists a window in W that contains three or more faults.

For all sufficiently large n, after the first group of faults has been placed, at least one of the three statements above must be true.

First, consider the situation in which Statement 1 is true after the first group of faults has been placed. For each fault in the second group, consider that fault to be a success iff it lies in a window in W that contains a fault from the first group. Given any fault in the second group, the probability that it is a success is $\Omega(n^{-1/3})$. It follows from Lemma 4.7 that, with probability $1 - o(1)$, at least $n^{1/3}$ faults in the second group are successes.

Therefore, regardless of which statement is true after the first group of faults is placed, there is a probability of at least $1 - o(1)$ that, after the second group of faults is placed, either Statement 2 or Statement 3 (or both) is true. Now consider the situation in which, after the second group of faults is placed, Statement 2 is true and Statement 3 is false. For each fault in the third group, consider that fault to be a success iff it lies in a window in W that contains at least two faults from the union of the first and second groups. Given any fault in the third group, the probability that it is a success is $\Omega(n^{-2/3})$. It follows from Lemma 4.7 that with probability $1 - o(1)$ at least one fault in the third group is a success.

As a result, in any case there is a probability of at least $1 - o(1)$ that, after all of the faults have been placed, Statement 3 holds. □

THEOREM 4.9. *The graph $M_2(n, k)$ tolerates $\Theta(n^{2/3})$ random faults.*

Proof. The proof is immediate from Lemmas 4.6, 4.8, and 4.5. □

4.3. Construction 3. All of the remaining constructions are based on the target graph $T_2(n)$.

DEFINITION. *The graph* $M_3(n,k) = C(n^2+k, \{1,2,n,n+1\})$.

Note that $M_3(n,k)$ has degree 8. The 1-offset and 2-offset edges of the fault-tolerant graph implement the 1-offset edges of the target graph, and the n-offset and $(n+1)$-offset edges of the fault-tolerant graph implement the n-offset edges of the target graph.

LEMMA 4.10. *Assume that* $M_3(n,k)$ *contains* k *faulty nodes.* $M_3(n,k)$ *tolerates the faults if for each* i, $0 \le i < n^2+k$, $W(n+1,i)$ *contains at most one fault.*

Proof. Given any healthy node i, $W(n+2,i)$ contains at most one fault. Therefore, there is an edge between each healthy node and both the first healthy node following it and the nth healthy node following it. As a result, $M_3(n,k)$ contains a healthy copy of $T_2(n)$. □

LEMMA 4.11. *Assume that* $M_3(n,k)$ *contains* k *faulty nodes.* $M_3(n,k)$ *does not tolerate the faults if there exist* x *and* y, *where* $0 \le x, y < n^2+k$, $dist(x,y) \ge 2n$, $W(n+1,x)$ *contains at least two faults, and* $W(n+1,y)$ *contains at least two faults.*

Proof. Assume for the sake of contradiction that the faults can be tolerated. Let a be the first healthy node preceding x and let a' be the node in $T_2(n)$ that maps to a. If there exists a node b' in $T_2(n)$ where $b' = a' + n$, let b be the node to which b' maps. Note that b is the nth healthy node following a, so $b \notin W(n+1,x)$ and a and b are not connected to one another. Therefore, no such node b exists, which implies that $a' \ge n^2 - n$.

Let c be the first healthy node preceding y and let c' be the node in $T_2(n)$ that maps to c. A similar argument shows that $c' \ge n^2 - n$. As a result, $|a' - c'| \le n-1$, so $dist(a,c) \le n-1+k$ and $dist(x,y) \le n-1+2k < 2n$, which is a contradiction. □

THEOREM 4.12. *The graph* $M_3(n,k)$ *tolerates* $\Theta(n^{1/2})$ *random faults.*

Proof. If the number of faults is $o(n^{1/2})$, it follows from Lemmas 4.2 and 4.10 that the probability of tolerating the faults is $1 - o(1)$. If the number of faults is $\omega(n^{1/2})$, divide the faults into halves. Let $W_1 = W(y,0), W(y,y), W(y,2y), \ldots, W(y,qy)$ and let $W_2 = W(y,(q+2)y), W(y,(q+3)y), W(y,(q+4)y) \ldots, W(y,2qy)$, where $y = n+1$ and $q = \lfloor n/4 \rfloor$. Apply Lemma 4.3 to the first half of the faults with $W = W_1$, apply Lemma 4.3 to the second half of the faults with $W = W_2$, and apply Lemma 4.11 to complete the proof. □

4.4. Construction 4.

DEFINITION. *The graph* $M_4(n,k) = C(n^2+n+k, \{1,2,n+1,n+2\})$.

Note that $M_4(n,k)$ has degree 8. The 1-offset and 2-offset edges of the fault-tolerant graph implement the 1-offset edges of the target graph, and the $(n+1)$-offset and $(n+2)$-offset edges of the fault-tolerant graph implement the n-offset edges of the target graph. In particular, the $(n+1)$-offset and $(n+2)$-offset edges of $M_4(n,k)$ can implement the n-offset edges of the target graph provided that each window of $n+1$ consecutive nodes contains at least one fault and each window of $n+2$ consecutive nodes contains at most two faults. Although it is very unlikely (or impossible) that each window of $n+1$ consecutive nodes contains at least one fault, we can view up to n healthy nodes as being "dummy faults" (because there are $n+k$ spares) in order to satisfy this requirement.

DEFINITION. *Given a circulant graph with* x *nodes, a* block of healthy nodes *is a window* $W(y,i)$, *where* $1 \le y < x$ *and* $0 \le i < x$, *consisting solely of healthy nodes such that both node* $i-1 \bmod x$ *and node* $i+y \bmod x$ *are faulty.*

Consider the following algorithm for adding dummy faults to $M_4(n,k)$.

ALGORITHM A. Consider separately each block of healthy nodes. Assume a block consists of y healthy nodes. There are three cases based on the value of y.

Case 1. $y \leq n$. In this case, do not add any dummy faults to the block.

Case 2. $n+1 \leq y \leq 2n$. In this case, add one dummy fault to the block. Place the dummy fault in the middle of the block so that it divides the block into two subblocks of healthy nodes, the first of which has $\lceil (y-1)/2 \rceil$ nodes and the second of which has $\lfloor (y-1)/2 \rfloor$ nodes.

Case 3. $2n+1 \leq y$. In this case, add two dummy faults that divide the block into three subblocks of healthy nodes, the first of which has $n-1$ nodes, the second of which has $z = y - 2n$ nodes, and the third of which has $n-1$ nodes. Let a and b denote these two dummy nodes. Then add an additional $x = \lfloor z/(n+1) \rfloor$ dummy faults between a and b. This leaves $w = z - x$ healthy nodes in the block, which are divided into $x+1$ subblocks of healthy nodes by the x dummy faults. Distribute the dummy faults so that each subblock has length $\lfloor w/(x+1) \rfloor$ or $\lceil w/(x+1) \rceil$.

The following lemmas establish properties of Algorithm A.

LEMMA 4.13. *Given w, x, and z in Case* 3 *above, $xn \leq w \leq (x+1)n$.*

Proof. Because $x = \lfloor z/(n+1) \rfloor$, $z \geq x(n+1)$, and $w = z - x \geq xn$. Because $x = \lfloor z/(n+1) \rfloor$, $z \leq xn + n + x$ and $w = z - x \leq xn + n = (x+1)n$. □

LEMMA 4.14. *After applying Algorithm* A*, no block of $n+1$ or more healthy nodes exists.*

Proof. If there is a block of $n+1 \leq y \leq 2n$ healthy nodes prior to applying Algorithm A, the algorithm adds a dummy node that divides the block into subblocks of at most $\lceil (y-1)/2 \rceil \leq n$ healthy nodes each. If there is a block of $2n+1 \leq y$ healthy nodes prior to applying Algorithm A, the algorithm adds dummy nodes a and b that divide the block into subblocks of $n-1$, $z = y - 2n$, and $n-1$ healthy nodes each. Then $x = \lfloor z/(n+1) \rfloor$ dummy faults are added to the subblock of z healthy nodes, leaving $w = z - x$ healthy nodes. These w healthy nodes occur in subblocks of length at most $\lceil w/(x+1) \rceil \leq \lceil (x+1)n/(x+1) \rceil \leq n$. □

LEMMA 4.15. *After applying Algorithm* A*, no dummy fault is consecutive with another (actual or dummy) fault, provided that $n \geq 2$.*

Proof. If there is a block of $n+1 \leq y \leq 2n$ healthy nodes prior to applying Algorithm A, the algorithm adds a dummy node that divides the block into subblocks of at least $\lfloor (y-1)/2 \rfloor \geq \lfloor n/2 \rfloor \geq 1$ healthy nodes each. If there is a block of $2n+1 \leq y$ healthy nodes prior to applying Algorithm A, the algorithm adds dummy nodes a and b that divide the block into subblocks of $n-1$, $z = y - 2n$, and $n-1$ healthy nodes each. Then $x = \lfloor z/(n+1) \rfloor$ dummy faults are added to the subblock of z healthy nodes, leaving $w = z - x$ healthy nodes. If $x = 0$, there are $w = z - 0 = y - 2n \geq 1$ healthy nodes between dummy faults a and b. If $x \geq 1$, the w healthy nodes occur in subblocks of at least $\lfloor w/(x+1) \rfloor \geq \lfloor xn/(x+1) \rfloor \geq \lfloor n/2 \rfloor \geq 1$ nodes each. □

LEMMA 4.16. *Consider any configuration of actual faults such that no two faults are consecutive and there does not exist a node i such that $W(2n+3, i)$ contains three or more faults, where $n \geq 2$. After applying Algorithm* A *to this configuration of faults, no two (actual or dummy) faults will be consecutive and there will not exist a node j such that $W(n+2, j)$ contains three or more (actual or dummy) faults.*

Proof. The fact that no two faults will be consecutive follows immediately from the preceding lemma. Now assume for the sake of contradiction that after applying Algorithm A, there exists a node j such that $W(n+2, j)$ contains three or more faults. Clearly, $W(n+2, j)$ must contain at least one dummy fault. Select one such dummy

fault and denote it as d, and let C denote the block of y originally healthy nodes containing d. Clearly, $y \geq n+1$.

If $n+1 \leq y \leq 2n$, then d is the only dummy fault in C, so either $W(n+2,j)$ contains two actual faults or $W(n+2,j)$ contains some other dummy fault located in some other block of originally healthy nodes. First, consider the case where $W(n+2,j)$ contains two actual faults. Let e and f denote these actual faults. Either y lies between e and f or it does not. If y lies between e and f, $W(n+2,j)$ must contain at least $y+2 \geq n+3$ nodes, which is a contradiction. Thus y does not lie between e and f. Now let y' denote the number of nodes between e and f. Because $W(n+2,j)$ contains only $n+2$ nodes and because there are at least $\lfloor (y-1)/2 \rfloor \geq y/2-1$ nodes between d and every actual fault, it follows that $y'+y/2+2 \leq n+2$, which implies that $y' \leq n-y/2$ and that there were three actual faults within a window of $y+y'+3 \leq n+y/2+3 \leq 2n+3$ nodes, which is a contradiction.

Now, consider the case where $W(n+2,j)$ contains a dummy fault located in another block of originally healthy nodes. Let d' denote such a dummy fault and let C' denote the block of y' originally healthy nodes containing d'. Clearly, $y' \leq 2n$, because otherwise there would be at least $n-1$ healthy nodes between d' and the nearest actual fault. However, note that if C' follows C, then there are at least $\lfloor (y-1)/2 \rfloor \geq \lfloor n/2 \rfloor$ consecutive healthy nodes following d and at least $\lceil (y'-1)/2 \rceil \geq \lceil n/2 \rceil$ consecutive healthy nodes preceding d', which implies that $W(n+2,j)$ contains at least $n+3$ nodes, which is a contradiction. The case in which C' precedes C is analogous.

If $2n+1 \leq y$, then either $W(n+2,j)$ contains at least one actual fault and at least one dummy fault or $W(n+2,j)$ contains three dummy faults and no actual faults. If $W(n+2,j)$ contains at least one actual fault and at least one dummy fault, then it must contain the $n-1$ healthy nodes which separate the dummy faults in C from the actual faults. Furthermore, because no two (actual or dummy) faults are consecutive, $W(n+2,j)$ must contain at least $n+3$ nodes, which is a contradiction. On the other hand, if $W(n+2,j)$ contains three dummy faults and no actual faults, let a, b, w, x, and z be as defined in Case 3 of Algorithm A. It follows that $x \geq 1$ and that $W(n+2,j)$ contains at least two blocks of $\lfloor w/(x+1) \rfloor$ or more healthy nodes in addition to the three dummy faults. However, the fact that $x \geq 1$ implies that $z \geq n+1$. Therefore, the dummy faults designated a and b cannot both be in $W(n+2,j)$, so it follows that $x \geq 2$. Therefore, $\lfloor w/(x+1) \rfloor \geq \lfloor xn/(x+1) \rfloor \geq \lfloor 2n/3 \rfloor \geq n/2$, so $W(n+2,j)$ contains at least n healthy nodes and three dummy faults, which is a contradiction. □

LEMMA 4.17. *After applying Algorithm* A*, at least* n^2 *healthy nodes remain.*

Proof. First, we will show that Algorithm A adds at most one dummy fault per $n+1/3$ originally healthy nodes. In Case 2 of Algorithm A, one dummy fault is added to a block of at least $n+1$ originally healthy nodes. In Case 3 of Algorithm A, if two dummy faults are added, there are at least $2n+1$ originally healthy nodes in the block, so at most one dummy fault is added per $n+1/2$ originally healthy nodes. In Case 3 of Algorithm A, if $i \geq 3$ dummy faults are added, there are at least $in+i-2$ originally healthy nodes in the block, so at most one dummy fault is added per $n+(i-2)/i$ originally healthy nodes. This quantity is minimized when $i=3$, at which point one dummy fault is added per $n+1/3$ originally healthy nodes.

Now consider the case in which exactly k actual faults exist. In this case there must be n^2+n originally healthy nodes, so at most $\lfloor (n^2+n)/(n+1/3) \rfloor \leq n$ dummy faults are added, and at least n^2 healthy nodes remain. Now consider the case in which $k-x$ actual faults exist, where $x \geq 1$. At most $\lfloor (n^2+n+x)/(n+1/3) \rfloor \leq$

$\lfloor (n^2+n)/(n+1/3) \rfloor + \lceil x/(n+1/3) \rceil \leq n+x$ dummy faults are added, and at least n^2 healthy nodes remain. □

The proofs of the following two lemmas are analogous to those of Lemmas 4.10 and 4.11, and are omitted.

LEMMA 4.18. *Assume that $M_4(n,k)$ contains $f \leq n+k$ (actual or dummy) faults. $M_4(n,k)$ tolerates the faults if no two faults are consecutive and for each i, $0 \leq i < n^2+n+k$, $W(n+1,i)$ contains at least one fault and $W(n+2,i)$ contains at most two faults.*

LEMMA 4.19. *Assume that $M_4(n,k)$ contains f faulty nodes. $M_4(n,k)$ does not tolerate the faults if there exist x and y, where $0 \leq x,y < n^2+n+k$, $dist(x,y) \geq 4n$, $W(n+2,x)$ contains at least three faults, and $W(n+2,y)$ contains at least three faults.*

THEOREM 4.20. *The graph $M_4(n,k)$ tolerates $\Theta(n^{2/3})$ random faults.*

Proof. First, consider the case where the number of faults is $o(n^{2/3})$. It follows from Lemma 4.6 that with probability $1-o(1)$ there does not exist a node i such that $W(2n+3,i)$ contains three or more faults. Also, given any two faults, the probability that they are consecutive is $\Theta(n^{-2})$. There are $o(n^2)$ distinct pairs of faults, so the probability that there exists a pair of faults that are consecutive is $o(n^{-2}n^2) = o(1)$. Therefore, it follows from Lemmas 4.17, 4.16, and 4.18 that after applying Algorithm A, the faults can be tolerated with probability $1-o(1)$.

Next, consider the case where the number of faults is $\omega(n^{2/3})$. In this case, divide the faults into halves. Let $W_1 = W(y,0), W(y,y), W(y,2y), \ldots, W(y,qy)$ and let $W_2 = W(y,(q+4)y), W(y,(q+5)y), W(y,(q+6)y), \ldots, W(y,2qy)$, where $y = n+2$ and $q = \lfloor n/4 \rfloor$. Apply Lemma 4.8 to the first half of the faults with $W = W_1$, apply Lemma 4.8 to the second half of the faults with $W = W_2$, and apply Lemma 4.19 to complete the proof. □

4.5. Construction 5. Construction $M_5(n,k)$ is a hierarchical construction based on $M_3(n/2,k)$. It is defined only for even values of n.

DEFINITION. *The graph $M_5(n,k)$ is created from $M_3(n/2,k)$ as follows:*

1. *Create $n' = (n/2)(n/2)+k = n^2/4+k$ squares (that is, cycles of length 4) numbered 0 through $n'-1$.*
2. *For each square i, connect the upper right corner of i to the upper left corners of $(i+1) \bmod n'$ and $(i+2) \bmod n'$, and connect the lower right corner of i to the lower left corners of $(i+1) \bmod n'$ and $(i+2) \bmod n'$.*
3. *For each square i, connect the lower left corner of i to the upper left corners of $(i+n) \bmod n'$ and $(i+n+1) \bmod n'$, and connect the lower right corner of i to the upper right corners of $(i+n) \bmod n'$ and $(i+n+1) \bmod n'$.*

Note that $M_5(n,k)$ has degree 6. The idea behind this construction is that the squares act as 2 by 2 submeshes and the graph can be reconfigured if the corresponding fault-tolerant graph (namely $M_3(n/2,k)$) can tolerate faults located in the positions corresponding to the faulty squares (see the proof of Theorem 3.4 for a description of hierarchical fault-tolerant graphs). The following theorem follows immediately from Theorem 4.12.

THEOREM 4.21. *The graph $M_5(n,k)$ tolerates $\Theta(n^{1/2})$ random faults.*

4.6. Construction 6. Construction $M_6(n,k)$ is a hierarchical construction based on $M_4(n/2,k)$. It is defined only for even values of n.

DEFINITION. *The graph $M_6(n,k)$ is created from $M_4(n/2,k)$ as follows:*

1. *Create $n' = (n/2)(n/2)+(n/2)+k = n^2/4+n/2+k$ squares (that is, cycles of length 4) numbered 0 through $n'-1$.*

2. *For each square i, connect the upper right corner of i to the upper left corners of $(i+1) \bmod n'$ and $(i+2) \bmod n'$, and connect the lower right corner of i to the lower left corners of $(i+1) \bmod n'$ and $(i+2) \bmod n'$.*
3. *For each square i, connect the lower left corner of i to the upper left corners of $(i+n+1) \bmod n'$ and $(i+n+2) \bmod n'$, and connect the lower right corner of i to the upper right corners of $(i+n+1) \bmod n'$ and $(i+n+2) \bmod n'$.*

Note that $M_6(n,k)$ has degree 6. The following theorem follows immediately from Theorem 4.20.

THEOREM 4.22. *The graph $M_6(n,k)$ tolerates $\Theta(n^{2/3})$ random faults.*

4.7. Summary. Table 1 summarizes various characteristics, including the asymptotic fault-tolerance, of the six fault-tolerant constructions.

TABLE 1
Comparison of characteristics of the 6 FT meshes.

Construction	Symbol	Deg.	No. spares	Offsets	Asymp. FT
M_1	circ6	6	k	$\{n-1, n, n+1\}$	$\Theta(n^{1/2})$
M_2	circ8	8	k	$\{n-1, n, n+1, n+2\}$	$\Theta(n^{2/3})$
M_3	diag8	8	k	$\{1, 2, n, n+1\}$	$\Theta(n^{1/2})$
M_4	diag8r	8	$k+n$	$\{1, 2, n+1, n+2\}$	$\Theta(n^{2/3})$
M_5	diag6	6	$4k$	M_3 + submesh	$\Theta(n^{1/2})$
M_6	diag6r	6	$4k+2n$	M_4 + submesh	$\Theta(n^{2/3})$

Notice that both $M_2(n,k)$ and $M_4(n,k)$ have degree 8 and tolerate $\Theta(n^{2/3})$ faults, but $M_4(n,k)$ requires more spares than does $M_2(n,k)$. Thus, the technique of adding dummy faults does not in itself provide a more practical fault-tolerant network. Similarly, notice that both $M_1(n,k)$ and $M_5(n,k)$ have degree 6 and tolerate $\Theta(n^{1/2})$ faults, but $M_5(n,k)$ requires more spares than does $M_1(n,k)$. Thus, the technique of using 2 by 2 submeshes does not in itself provide a more practical fault-tolerant network. However, by combining these two techniques, $M_6(n,k)$ is the only degree 6 network that is capable of tolerating $\Theta(n^{2/3})$ faults.

Finally, we will consider laying out the fault-tolerant graphs presented in this section using Thompson's VLSI model [28]. The following theorem shows that, just like the mesh itself, all of the fault-tolerant constructions can be laid out with constant length wires.

THEOREM 4.23. *It is possible to lay out each of the graphs $M_i(n,k)$ where $1 \leq i \leq 6$ using only wires with length $O(1)$.*

Proof. The layouts for graphs $M_1(n,k)$, $M_2(n,k)$, $M_3(n,k)$, and $M_4(n,k)$ follow immediately from the techniques presented in the proof of Theorem 3.9. The layouts for graphs $M_5(n,k)$ and $M_6(n,k)$ follow from the layouts for $M_3(n/2,k)$ and $M_4(n/2,k)$, respectively, by replacing each node by a square of four nodes. □

4.8. Simulation results. Figures 7 to 9 show the simulation results for the fault tolerance of an $n \times n$ target mesh for $n = 16$, 64, and 256, respectively. The probability given for each construction and each value of k is the result of 10,000 simulation trials.

For each figure, the probability of reconfiguration for each construction of the FT meshes, $M_i(n,k)$ where $1 \leq i \leq 6$, is plotted as a functions of k. Each curve has a name of the form "xyz," where "x" is either "circ" for circulant graph or "diag" for diagonal graph (as the basic target graph), "y" denotes the degree (6 or 8), and "z" is either "r" (designating an extra row of spare nodes or supernodes) or an empty

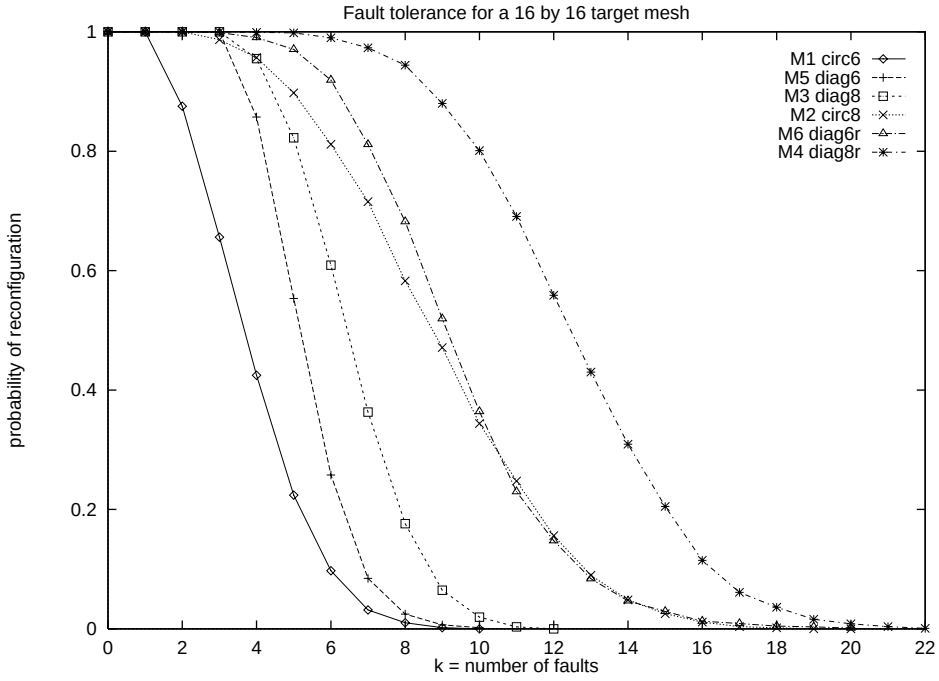


FIG. 7. *Simulation results of fault tolerance for a* 16 *by* 16 *target mesh.*

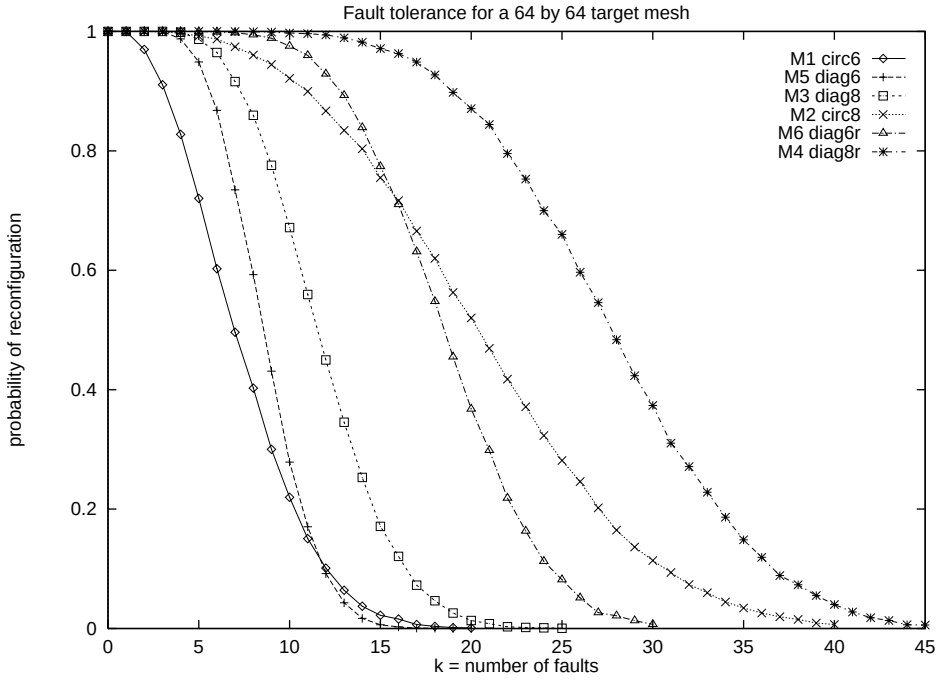

FIG. 8. *Simulation results of fault tolerance for a* 64 *by* 64 *target mesh.*

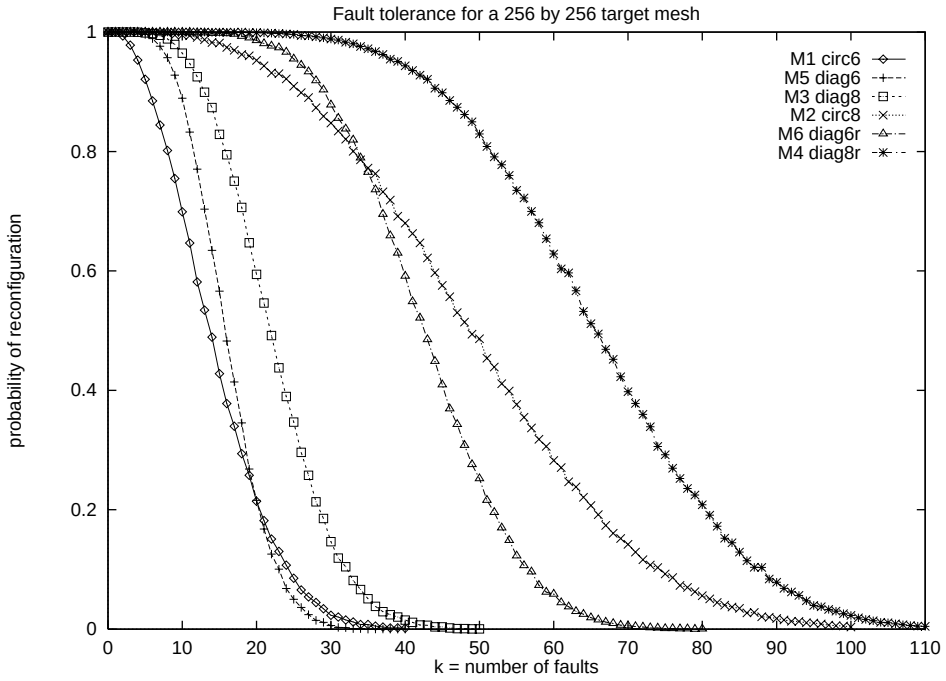

FIG. 9. *Simulation results of fault tolerance for a* 256 *by* 256 *target mesh.*

string. The solid lines denote the degree-6 FT meshes while the dotted lines denote the degree-8 FT meshes.

Note that the FT meshes for the three curves from the left tolerate $\Theta(n^{1/2})$ random faults, while the remaining three curves on the right can tolerate $\Theta(n^{2/3})$ random faults. Thus the asymptotic bounds proven above do appear to describe the behavior of these networks for realistic values of n. Also, note that the graph $M_6(n,k)$ (designated "diag6r" in the figures) performs the best out of the degree-6 networks studied, and that it has over a 90% chance of tolerating 12 faults when $n = 64$.

ON TRANSLATIONAL MOTION PLANNING OF A CONVEX POLYHEDRON IN 3-SPACE*

BORIS ARONOV† AND MICHA SHARIR‡

Abstract. Let B be a convex polyhedron translating in 3-space amidst k convex polyhedral obstacles $A_1, \ldots, A_k$ with pairwise disjoint interiors. The *free configuration space* (space of all collision-free placements) of B can be represented as the complement of the union of the Minkowski sums $P_i = A_i \oplus (-B)$, for $i = 1, \ldots, k$. We show that the combinatorial complexity of the free configuration space of B is $O(nk \log k)$, and that it can be $\Omega(nk\alpha(k))$ in the worst case, where n is the total complexity of the individual Minkowski sums $P_1, \ldots, P_k$. We also derive an efficient randomized algorithm that constructs this configuration space in expected time $O(nk \log k \log n)$.

1. Introduction.

Let $A_1, \ldots, A_k$ be k closed convex polyhedra in three dimensions with pairwise disjoint interiors, and let B be another closed convex polyhedron which, without loss of generality, is assumed to contain the origin o. In the context of motion planning, B is a "robot" that can only translate in 3-space, and the A_i's are obstacles which B must avoid. Suppose A_i has q_i faces and B has p faces, and put $q = \sum_{i=1}^{k} q_i$. Let

$$P_i = A_i \oplus (-B) = \{a - b \mid a \in A_i,\, b \in B\}$$

be the *Minkowski sum* of A_i and $-B$, for $i = 1, \ldots, k$. Let $\mathcal{P} = \{P_i\}_{i=1}^{k}$ be the resulting collection of these so-called *expanded obstacles* and let $U = \bigcup_{i=1}^{k} P_i$ be their union. As is well known, the complement $\mathcal{C}$ of U (also called the *common exterior* of $\mathcal{P}$) represents the *free configuration space* FP of B, in the sense that, for each point $z \in \mathcal{C}$, the placement of B, for which the reference point O lies at z, does not intersect any of the obstacles A_i, and all such free placements are represented in this manner.

As is well known, the combinatorial complexity (i.e., the number of vertices, edges, and faces on the boundary) of each P_i is at most $\Theta(pq_i)$, so the sum n of the complexities of the expanded obstacles is $O(pq)$. In typical situations, n is usually much smaller than pq. The bounds derived in this paper depend only on n and k and not on p and q.

Our main result is that the combinatorial complexity of the union U, and thus also of FP, is $O(nk \log k)$ and $\Omega(nk\alpha(k))$ in the worst case. This should be compared

The research of this author was supported by NSF grant CCR-91-22103, by a Max Planck Research Award, by grants from the U.S.–Israeli Binational Science Foundation, the German–Israeli Foundation for Scientific Research and Development, and the Fund for Basic Research administered by the Israeli Academy of Sciences.

to the recent bound obtained by the authors [4, 5] on the combinatorial complexity of the union of any k convex polyhedra in 3-space with a total of n faces; it is shown [5] that the maximum complexity of such a union is $O(k^3+nk\log k)$ and $\Omega(k^3+nk\alpha(k))$. Thus, the convex polyhedra P_i arising in the context of translational motion planning have special properties that yield the above improved bound, without the cubic term of the general bound.

The problem of obtaining sharp bounds for the combinatorial complexity of the union of Minkowski sums, as above, has been open for the past eight years, and has been studied in several papers during this period. It was raised by Kedem et al. [22] (see also [27]), where the two-dimensional version of the problem was successfully tackled. Related work on the three-dimensional case is described in [2, 3, 4, 5, 15, 20, 26]. Except for [4, 5, 20] (and parts of [2]), these papers studied different (though related) problems involving the complexity of the lower envelope or of a single cell in an arrangement of triangles in 3-space. A recent paper of Halperin and Yap [20] analyzes the complexity of the union of Minkowski expansions, as above, for the case where B is a box, and obtains a bound of $O(n^2\alpha(n))$. Our result is general, and thus almost settles this open problem, except for the sublogarithmic gap between our upper and lower bounds; we conjecture that the correct bound is $\Theta(nk\alpha(k))$.

We also consider the algorithmic problem of efficient construction of FP. We obtain an efficient and rather simple randomized algorithm that computes FP in expected time $O(nk\log k\log n)$. The algorithm and its analysis are adapted from a very similar algorithm given in [4, 5] for constructing the union of arbitrary convex polyhedra in 3-space.

The paper is organized as follows. In section 2 we bound the number of components and local minima of $\mathcal{C}$. The analysis of the topology of U, and of several related structures constructed from a family of convex polyhedra, continues in section 3. Section 4 establishes the main result of the paper, namely, the bounds on the combinatorial complexity of the union of the polyhedra, as stated above. Section 5 describes the randomized algorithm for computing the boundary of the union, and its application in the context of translational motion planning, and section 6 concludes with some remarks and open problems.

2. The number of holes of U and local extrema of $\mathcal{C}$. We first simplify the analysis by assuming that the given polyhedra A_i and B are in *general position*, meaning that the coordinates of the vertices of the A_i's and of B are all transcendentals that are algebraically independent over the rationals. In particular, this implies that (a) no point is common to the boundaries of any four distinct expanded polyhedra P_i; (b) no vertex of one expanded polyhedron lies on the boundary of another expanded polyhedron; (c) no two edges of distinct expanded polyhedra meet; and (d) no edge of an expanded polyhedron meets the polygonal curve of intersection of two other expanded polyhedra. Several other implications of the general position assumption will be needed to simplify the proof of Theorem 2.4. As argued in [4, 5], the general position assumption involves no real loss of generality. This is because one can always slightly perturb the given polyhedra, putting them in general position such that the number of vertices of the union that are incident to three distinct polyhedra does not decrease. The number of all other vertices of the union is only $O(nk)$, as follows from Proposition 2.1 below (which also holds when the polyhedra are not in general position). Also see a remark following Theorem 4.2 that discusses this issue.

To simplify some of the subsequent arguments, we modify the family $\mathcal{P}$ so as to make U bounded. To be more precise, we assume that B is bounded, which will

clearly be the case in our motion planning application. (If B is unbounded, then the resulting set $\mathcal{P}$ of unbounded expanded obstacles has the property that the boundary of its union can be regarded as the upper envelope of k concave polyhedral surfaces with a total of n faces. This problem is much simpler and has already been addressed by Huttenlocher, Kedem, and Sharir [21], where a tight $\Theta(nk\alpha(k))$ bound is obtained.) We then truncate all the unbounded obstacles A_i, by intersecting all obstacles with a sufficiently large tetrahedron, and by slightly perturbing the resulting intersections, so as not to violate the general position assumptions. The tetrahedron is chosen sufficiently large so that the union U of the resulting expanded obstacles P_i does not lose any of the bounded boundary features (vertices, edges, and faces) that it had before the truncation. Thus, the process does not reduce the complexity of the union U. In what follows we will therefore assume that U is bounded, so that $\mathcal{C}$ has a single unbounded component.

To establish our upper bound on the complexity of the union U, it clearly suffices to bound the number of vertices of U. Moreover, it suffices to bound the number of vertices of U that are formed by the intersection of the relative interiors of three faces of three distinct polyhedra P_i, because the number of all other vertices, namely, vertices of the original P_i's and intersections of edges of the original P_i's with faces of other expanded obstacles, is only $O(nk)$. This is a consequence of the following easy proposition (see [4, 5]).

PROPOSITION 2.1. *The number of vertices of $P_i \cap P_j$, summed over all $P_i, P_j \in \mathcal{P}$, is $O(nk)$.*

We first bound the number of connected components of the complement $\mathcal{C}$ of U (the common exterior of $\mathcal{P}$). Under the assumptions made above, $\mathcal{C}$ has a unique unbounded component, so it suffices to estimate the number of bounded components of $\mathcal{C}$, which correspond to "holes" in U.

Let an *intersection edge* be an edge of the intersection of the boundaries of two distinct expanded obstacles. Each such edge e meets the boundary of the union U in at most $k-1$ intervals, as it intersects each of the remaining $k-2$ polyhedra in at most one interval, and the complement (within e) of the union of these $k-2$ intervals consists of at most $k-1$ intervals.

We introduce a real parameter $t \in [0,1]$ (we refer to it as "time"), define $P_i(t) = A_i \oplus (-tB)$, for $i = 1, \ldots, k$, and $U(t) = \bigcup_{i=1}^{k} P_i(t)$, and let $\mathcal{C}(t)$ denote the complement of $U(t)$. Note that the general position assumption does not imply that conditions (a)–(d) hold for $\{P_i(t)\}$ for all values of t. It does imply, however, that, at any given t, we can have at most one degenerate contact between the $P_i(t)$'s. Such a contact can be expressed as a polynomial equality in t and in the coordinates of the vertices of the A_i's and of B. Moreover, there is only a finite number of values of t at which such a degeneracy can occur. For example, if $t_0 > 0$ is the first instant of time at which $P_i(t)$ and $P_j(t)$ meet, then $P_i(t) \cap P_j(t)$ must consist of a single point, for otherwise we would have at least two algebraically independent polynomial equalities holding simultaneously, which is forbidden by the general position assumptions. Moreover, such an initial single-point contact of $P_i(t)$ and $P_j(t)$ must occur either between a vertex of one of these polyhedra and a face of the other, or between two edges, one from each polyhedron. Similarly, it is easy to verify that the first contact between three growing obstacles must occur at a single point.

Before continuing, we recall a well-known fact. Let P and Q be two convex polyhedra. Denote by $\mathcal{N}_P$ the *normal diagram* (also known as the *Gaussian diagram*) of P. This is the decomposition of the Gaussian sphere $\mathcal{S}^2$ of orientations into regions,

each consisting of the outward normals of all planes supporting P at some vertex. Each edge of $\mathcal{N}_P$ is an arc of a great circle consisting of the outward normals of all planes supporting P at some edge. Each vertex of $\mathcal{N}_P$ is the outward normal of some face of P. The normal diagram $\mathcal{N}_Q$ of Q is analogously defined. Then the overlay of $\mathcal{N}_P$ and $\mathcal{N}_Q$ is the normal diagram of the Minkowski sum $P \oplus Q$. This implies that the combinatorial structure (i.e., the number of, and incidence relations between, faces of all dimensions) of $P \oplus Q$ is completely determined by the orientations of the faces of P and Q and by their incidence structures. In particular, the combinatorial structure of $P_i(t) = A_i \oplus (-tB)$ is the same for all $t > 0$. This implies the following property. For $t \in [0, 1]$, let $s(t)$ denote the Minkowski sum of either a fixed edge of A_i and $(-t)$ times a fixed vertex of B, or of a fixed vertex of A_i and $(-t)$ times a fixed edge of B. If $s(t_0)$ is an edge of $P_i(t_0)$, for some $t_0 \in (0, 1]$, then $s(t)$ is an edge of $P_i(t)$ for all $t \in (0, 1]$.

We want to keep track of the number of holes of $U(t)$ as t increases from 0 to 1. At $t = 0$, the number of holes of $U(t)$ is 0. As t increases, $\mathcal{C}(t)$ shrinks, so the number of holes can *increase* only when a component of $\mathcal{C}(t)$ is split into two components.

LEMMA 2.2. *A component of $\mathcal{C}(t)$ can split into two components only at times t when an edge $s(t)$ of some $P_\ell(t)$ meets an intersection edge $e(t)$ of two other polyhedra, $P_i(t)$, $P_j(t)$, at some point v, so that the intersection of $\mathcal{C}(t)$ with a small neighborhood of v is disconnected.*

Proof. We use the observation of de Berg, Matoušek, and Schwarzkopf [6], which states that the number of connected components of $\mathcal{C}(t)$ can increase only at times t, at which the elements of some new triple growing polyhedra intersect for the first time. As noted above, the general position assumptions guarantee that such a triple, $P_i(t)$, $P_j(t)$, $P_\ell(t)$, intersects in a single point. Moreover, the intersection must occur on the boundary of $\mathcal{C}(t)$ and cause a local disconnection of $\mathcal{C}(t)$, or else no change in the topological structure of $\mathcal{C}(t)$ would take place. (Note that the above conditions are only necessary, but not sufficient, for the number of components of $\mathcal{C}(t)$ to increase.) The intersection in question cannot occur at a point in the relative interior of three faces, one on each of these three polyhedra, for then $P_i(t') \cap P_j(t') \cap P_\ell(t')$ would also be nonempty for t' slightly smaller than t. This and the general position assumption are easily seen to imply the lemma. ∎

Suppose that such a configuration does indeed arise at some time t, and suppose that $e(t)$ is formed by the intersection of a face of $P_i(t)$ and a face of $P_j(t)$. The edge $s(t)$ intersects both $P_i(t)$ and $P_j(t)$ at two respective intervals $s(t) \cap P_i(t)$ and $s(t) \cap P_j(t)$, which have a common endpoint and which, by Lemma 2.2, have disjoint relative interiors.

LEMMA 2.3. *If at time t the intervals $s(t) \cap P_i(t)$ and $s(t) \cap P_j(t)$ intersect, then $s(t') \cap P_i(t')$ and $s(t') \cap P_j(t')$ intersect for all $t' > t$.*

Proof. Let $v(t)$ denote some common point of the intervals $s(t) \cap P_i(t)$, $s(t) \cap P_j(t)$. Recall that $s(t)$ is an edge of $A_\ell \oplus (-tB)$. Assume first that $s(t)$ is the Minkowski sum of a vertex a of A_ℓ and $(-t)$ times an edge of B, whose endpoints are b, b'. Since $v(t) \in s(t)$, there exists $\lambda \in [0, 1]$ such that $v(t) = a - t(\lambda b + (1 - \lambda)b')$. We are given that $v(t) \in P_i(t)$, which means that $v(t) = c - tb''$, for some $c \in A_i$ and $b'' \in B$. We claim that the point $v(t') = a - t'(\lambda b + (1 - \lambda)b')$, with the same λ as above, lies in $P_i(t')$, for all $t' > t$ (and, by definition, $v(t') \in s(t')$; see the discussion preceding Lemma 2.2). Indeed, if we put $b_\lambda = \lambda b + (1 - \lambda)b'$, then

$$v(t') = a - tb_\lambda - (t' - t)b_\lambda = c - tb'' - (t' - t)b_\lambda = c - t' \left[\frac{t}{t'} b'' + \frac{t' - t}{t'} b_\lambda \right],$$

which clearly belongs to $A_i \oplus (-t'B)$, whenever $t' \geq t$. An analogous argument shows that $v(t') \in A_j \oplus (-t'B)$, whenever $t' \geq t$. This implies the asserted claim. The case where $s(t)$ is the Minkowski sum of an edge of A_ℓ and $(-t)$ times a vertex of B is handled in a similar manner, as the reader can easily verify. This completes the proof of the lemma. □

Lemmas 2.2 and 2.3 imply that, for each t at which a connected component of $\mathcal{C}$ is split into two components, there exist two polyhedra, $P_i(t)$, $P_j(t)$, and an edge $s(t)$ of another polyhedron $P_\ell(t)$, such that the two intervals $s(t) \cap P_i(t)$ and $s(t) \cap P_j(t)$ meet at a common endpoint that lies on $\partial\mathcal{C}(t)$ and continue to overlap for all $t' > t$. Thus, the number of such "hole-splitting" events, involving the same edge $s(t)$ of any of the expanded polyhedra, is at most $k-2$, so the total number of holes that the union can have is at most $O(nk)$. That is, we have shown the following theorem.

THEOREM 2.4. *The number of connected components of the common exterior $\mathcal{C}$ of Minkowski sums of k polyhedra, as above, is $O(nk)$.*

Remark. We do not know if this bound is tight, as the best lower bound we can construct is $\Omega(k^2)$. Assume for simplicity that $k > 2$ is even. A configuration yielding such a bound consists of $k/2-1$ line obstacles of the form $z = 0$, $x = i$, for $i = 1, \ldots, k/2-1$, of $k/2-1$ line obstacles of the form $z = 0.1$, $y = i$, for $i = 1, \ldots, k/2-1$, and of two plane obstacles $z = \pm 1/2$. The robot is an axis-parallel cube with side length $2/3$.

Let S be any closed polyhedral set in 3-space in general position. (In this paper we consider only polyhedral sets bounded by a finite number of edges, vertices, and faces.) For a point p, let a *neighborhood* of p in S be the intersection of S with a ball centered at p, whose radius is smaller than the distance from p to any edge, face, or vertex of S not incident to p. A point p of S is a *local minimum* if it is a point of smallest z-coordinate in some neighborhood of p in S. (Under the general position assumptions, no face or edge can be parallel to the xy-plane, so p will be the only point in its neighborhood with this z-coordinate.) A *local maximum* is similarly defined. The following theorem is a consequence of Theorem 2.4.

THEOREM 2.5. *The number of local maxima and minima of the closure $\bar{\mathcal{C}}$ of $\mathcal{C}$ is $O(nk)$.*

Proof. We prove the claim only for the number of local minima of $\bar{\mathcal{C}}$, since the treatment of local maxima is fully symmetric. Any bounded convex component K of $\bar{\mathcal{C}}$ has exactly one local minimum (which is also the global minimum of K), because K does not have a lowest horizontal edge, as implied by our general position assumption. Hence, the number of such minima is $O(nk)$ by Theorem 2.4. This also applies to components of $\bar{\mathcal{C}}$, all of whose horizontal cross sections are connected, because such a component has at most one local (and global) minimum as well. So we will proceed to bound the number of local minima of those components that have at least one disconnected horizontal cross section; we refer to these components as *interesting components*. We will in fact prove that the number of such minima is only $O(k^2)$.

Let $\mathcal{C}^*$ denote the union of all interesting components of $\bar{\mathcal{C}}$. Sweep $\mathcal{C}^*$ with a plane π which is parallel to the xy-plane, move upwards, i.e., in the positive z-direction, and keep track of the number I of connected components of $\mathcal{C}^* \cap \pi$. This number is initially 1 (when π is below all vertices of $\mathcal{C}^*$). (Actually, it is possible for the outer component to be uninteresting, in which case the number starts off at 0.) I increases by 1 when π sweeps through a local minimum of $\mathcal{C}^*$ or when a connected component of $\mathcal{C}^* \cap \pi$ splits into two subcomponents; I decreases by 1 when π sweeps through a local maximum of $\mathcal{C}^*$ or when two components of $\mathcal{C}^* \cap \pi$ merge into a single component.

(The general position assumption implies that, at any given z, only two components can merge into a component of $\mathcal{C}^* \cap \pi$, and similarly a component cannot split into more than two subcomponents.) The events at which components may merge or split occur only when π sweeps, repsectively, through the topmost or bottommost vertex of the intersection of some pair P_i, P_j of expanded obstacles, for some $i \neq j$. Indeed, it is easily checked that, under the assumption of general position, splitting always occurs when a vertex of some polygon $\pi \cap P_i$ meets an edge of another polygon $\pi \cap P_j$ in such a way that the two polygons are disjoint before the event and meet in a small triangle after the event. Thus P_i and P_j are disjoint immediately below the critical value of z and meet immediately afterwards, implying our claim that the critical position of π passes through the lowest point of $P_i \cap P_j$. Merges are analyzed in an entirely symmetric fashion. To summarize, the number of splits and merges of cross-sectional components is bounded by $2\binom{k}{2} = O(k^2)$. It remains to prove that this implies that the number of local minima is also $O(k^2)$.

Consider the following dynamic scheme for assigning weights to each component of $\mathcal{C}^* \cap \pi$. When π sweeps through a local minimum point of $\mathcal{C}^*$, a new component of $\mathcal{C}^* \cap \pi$ is created and is assigned weight -1. When two components of $\mathcal{C}^* \cap \pi$ merge, the weight assigned to the new component is 2 plus the sum of the weights of the merged components. When a component shrinks and disappears, its final weight is added to a global count. When a component is split into two subcomponents, each of them is assigned weight $1 + \frac{w}{2}$, where w is the weight of the split component.

We claim that, at any given time during the sweep, the weight of any component of $\mathcal{C}^* \cap \pi$ is always at least -1, and the weight of a component that was formed by a splitting or merging operation is nonnegative. Both claims are easy to prove by induction on the sweep events. Now suppose that, at some point during the sweep, there are s local minima of $\mathcal{C}^*$ below π, and that the number of component splittings and mergings below π is N (which is at most $O(k^2)$). Then the total weight of the components of $\mathcal{C}^* \cap \pi$, plus the value of the current global count (i.e., the sum of the final weights of all cross sections of interesting components of $\mathcal{C}^*$ that have terminated below π), is easily seen, by induction on the sweep events, to be $2N - s$. As argued above, the value of the global count is always nonnegative. When the sweep plane passes the topmost vertex of $\mathcal{C}^*$, the cross section $\mathcal{C}^* \cap \pi$ has just one component, necessarily of nonnegative weight, which thus implies that, at this final stage, $s \leq 2N = O(k^2)$. It follows that the number of local minima of $\mathcal{C}^*$ contained in interesting components is $O(k^2)$. Adding the number of local minima in non-interesting components of $\bar{\mathcal{C}}$, we obtain the bound asserted in the theorem. □

3. On the structure of levels in $\mathcal{A}(\mathcal{P})$. Define the *arrangement* $\mathcal{A}(\mathcal{P})$ of the collection $\mathcal{P}$ of the expanded obstacles to be the decomposition of space into vertices, edges, faces, and three-dimensional cells, induced by the faces of the polyhedra of $\mathcal{P}$; for more details on arrangements, see [2, 14, 29]. For each $s = 1, \ldots, k$, let

$$U^{(s)} = \bigcup \{P_{j_1} \cap \cdots \cap P_{j_s} \,|\, 1 \leq j_1 < j_2 < \cdots < j_s \leq k\}.$$

Furthermore, put $\mathcal{C}^{(s)} = \mathbb{R}^3 \setminus U^{(s)}$. We refer to $\partial\mathcal{C}^{(s+1)} = \partial U^{(s+1)}$ as the *sth level* of the arrangement $\mathcal{A}(\mathcal{P})$. We also denote by $\bar{\mathcal{C}}^{(s)}$ the closure of $\mathcal{C}^{(s)}$. Note that $U^{(1)} = U$ is just the union of the polyhedra of $\mathcal{P}$ and that $\mathcal{C}^{(1)} = \mathcal{C}$ is their common exterior. These definitions are illustrated in the planar case in Figure 1.

In this section we prove some geometric and topological properties of $U^{(2)}$ and $U^{(3)}$ that will be used in the proof of our main theorem (Theorem 4.2 in section 4).

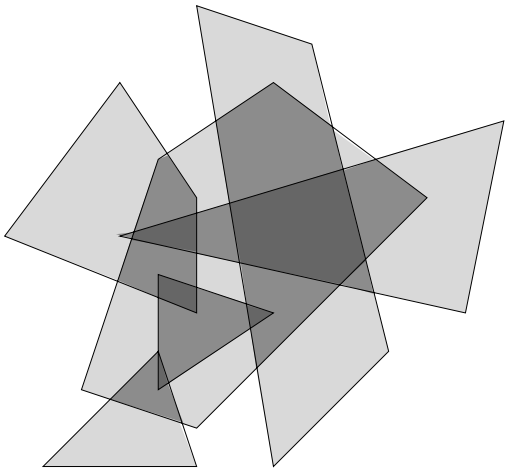

FIG. 1. *A family of convex polygons*; $U^{(1)} \setminus U^{(2)}$, $U^{(2)} \setminus U^{(3)}$, *and* $U^{(3)}$ *are shaded successively darker.*

LEMMA 3.1. *The number of local minima and the number of connected components of* $U^{(3)}$, *for any collection of* k *polyhedra with a total of* n *faces in general position in* 3*-space, are bounded by the number of local maxima of* $\bar{\mathcal{C}}^{(1)}$ *plus* $O(k^2)$.

Proof. $U^{(3)}$ is the union of triple intersections of polyhedra in $\mathcal{P}$. Thus a local minimum of $U^{(3)}$ is necessarily a local minimum of one of these triple intersections. (This immediately bounds the number of local minima by $\binom{k}{3}$.) Since the number of all pairwise intersections of polyhedra in $\mathcal{P}$ is only $\binom{k}{2}$, it suffices to consider only those minima that are formed as intersections of three distinct polyhedron boundaries. By the general position assumption, such an intersection must be the unique common point v of the relative interiors of three faces of three distinct polyhedra in $\mathcal{P}$. Thus, if v is a local minimum in $U^{(3)}$ of this kind, then $U^{(3)}$ near v has the form of an octant O, formed by the three planes containing the faces incident to v, with v at its minimum. Thus, near v, $\bar{\mathcal{C}}^{(1)}$ coincides with the octant opposite to O, which has v as a local maximum. Hence, any local minimum of $U^{(3)}$ that is formed as the triple intersection of three distinct polyhedron boundaries corresponds to a local maximum of $\bar{\mathcal{C}}^{(1)}$. Since any bounded connected component of $U^{(3)}$ has a local minimum, and since we have assumed U and thus also $U^{(s)}$, for any s, to be bounded, it follows that the number of components of $U^{(3)}$ also satisfies the bound asserted in the lemma. □

Applying Theorem 2.5, we obtain the following corollary.

COROLLARY 3.2. *If* $\mathcal{P}$ *is a collection of polyhedra with a total of* n *faces, which arise as Minkowski expansions of a collection of* k *convex polyhedra with pairwise-disjoint interiors by another convex polyhedron, then the number of local minima and the number of connected components of* $U^{(3)}$ *is* $O(nk)$.

Proof. Lemma 3.1 is applicable here even though the expanded polyhedra are not in fully general position. Nevertheless, if we assume that the original A_i's and B are in general position, then the assumptions made in the proof of Lemma 3.1 do hold, as is easily checked, and the corollary thus follows. □

Next we study the topological structure of $U^{(2)}$. We begin by deriving a topological property of general polyhedral sets. Let S be a closed polyhedral set in $\mathbb{R}^3$

in general position; in particular, no two vertices of S have the same z-coordinate. Note that a neighborhood of a point p in S, as defined in the previous section, is star-shaped with respect to p, so its intersection with a horizontal plane through p is also star-shaped and thus connected.

A *merge point* of S is a point $p \in S$ such that, for any neighborhood of p, any horizontal plane lying below p and sufficiently close to it intersects the neighborhood in a disconnected set. (It is easily checked that p must be a vertex of S.) The number of components of such an intersection approaches some limit as the horizontal plane approaches p. We define the *merge number* $m(p)$ of p to be the limit number of connected components in this intersection, less 1. Since every neighborhood of p is a scaled copy of any other neighborhood of p, $m(p)$ is independent of the choice of the neighborhood. We can naturally extend this definition to any nonmerge point p' by putting $m(p') = 0$. We will apply our analysis to $S = U^{(2)}$, so in this case $m(p) \leq 2$ for any point in the set, as is easily implied by the general position assumption on $\mathcal{P}$.

The *first Betti number* of S, denoted $\beta_1(S)$, is the rank of the first singular homology group of S [17]. Informally, it is the number of "linearly independent" homotopy classes of closed cycles in S, where each class consists of all cycles homotopic within S to some given cycle and not contractible to a single point within S.

PROPOSITION 3.3. *The first Betti number $\beta_1(S)$ of any compact polyhedral set S in $\mathbb{R}^3$ in general position does not exceed the sum of the merge numbers of its vertices.*

The proof of this proposition is somewhat technical, and we give it in the appendix.

LEMMA 3.4. *For a collection of k arbitrary convex polyhedra in $\mathbb{R}^3$ in general position, with a total of n faces, $\beta_1(U^{(2)})$ is at most proportional to k^2 plus the number of local minima of $U^{(3)}$. Hence, for collections of Minkowski expansions, as above, this number is $O(nk)$.*[1]

Proof. Applying Proposition 3.3 to $S = U^{(2)}$, we conclude that it suffices to bound the number of merge points of $U^{(2)}$. This is because the merge number of any point of $U^{(2)}$ is at most 2, as follows from the general position assumption (and as already noted above). Let $v \in \partial U^{(2)}$ be a merge point; then v must be a vertex of $\mathcal{A}(\mathcal{P})$. We may assume that v is a vertex formed by the transversal intersection of some three faces F_i, F_j, F_ℓ belonging to three respective distinct polyhedra P_i, P_j, P_ℓ. Indeed, any other vertex is either a vertex of some P_i or of some $P_i \cap P_j$, for $i, j = 1, \ldots, k$. No vertex of the former type can be a merge point of any $U^{(s)}$, as is easily seen. A vertex of the latter type, on the other hand, can be a merge point only if it is the bottommost point of $P_i \cap P_j$, as is readily verified using the general position assumption. Thus, the number of these merge points is at most $\binom{k}{2}$; in fact, the total number of merge points of this form, over all sets $U^{(s)}$, is at most $\binom{k}{2}$.

The planes π_i, π_j, π_ℓ, containing, respectively, the faces F_i, F_j, F_ℓ, partition 3-space into eight octants; in a neighborhood of v, exactly one of these octants, O^+, is contained in all three polyhedra P_i, P_j, P_ℓ, three octants are contained in exactly two of these polyhedra, three other octants are contained in exactly one of these polyhedra, and one octant, O^-, is disjoint from all three polyhedra; the octants O^+ and O^- lie opposite each other. Note that v is not contained in the interior of any polyhedron of $\mathcal{P}$, for otherwise $U^{(2)}$, in a neighborhood of v, contains all octants around v except possibly for O^-, in which case v cannot be a merge point of $U^{(2)}$. We conclude that, near v, $U^{(2)}$ consists of O^+ and of its three adjacent octants.

[1] Again, in the case of Minkowski expansions, the polyhedra are not in fully general position, but they satisfy the assumptions made in the relevant proofs, so the corollary does apply.

We claim that v is the bottommost point of O^+. Indeed, otherwise, by the general position assumption, a horizontal plane π passing just below v would meet O^+. Let O', O'', O''' be the octants adjacent to O^+, each covered, locally near v, by two of the polyhedra P_i, P_j, P_ℓ. Then, near v the cross section $U^{(2)} \cap \pi$ coincides with

$$((O^+ \cup O') \cap \pi) \cup ((O^+ \cup O'') \cap \pi) \cup ((O^+ \cup O''') \cap \pi).$$

Each of $O^+ \cup O'$, $O^+ \cup O''$, $O^+ \cup O'''$ is a convex set, namely, a dihedral wedge. In particular, $U^{(2)} \cap \pi$ near v is the union of three convex sets, all containing the non-empty set $O^+ \cap \pi$, and thus is connected, contradicting the assumption that v is a merge point, and thus establishing the claim. In other words, we have shown that if v is a merge point of $U^{(2)}$ then π must avoid O^+, i.e., O^+ must lie fully above the horizontal plane passing through v, or, equivalently, v must be a local minimum of $U^{(3)}$. This completes the proof of the lemma. □

4. The complexity of the union. Having all this machinery available, we now turn to the analysis of the complexity of U. We apply the analysis technique of [5] (an earlier and somewhat weaker version of that analysis is given in [4]). Here we go quickly through its main steps; we refer the reader to [5] for full details. Let $C(k, n)$ denote the total number of vertices of U incident to three distinct polyhedra of $\mathcal{P}$, maximized over all collections $\mathcal{P}$ of k Minkowski sums, as above, with a total of n faces, in general position. As argued in [4, 5], this number is equal to the total number of vertices, edges, and faces, up to a constant multiplicative factor and an additive term of $O(kn)$. The analysis scheme of [5] yields the following recurrence for $C(k, n)$:

$$(k - 5/3)C(k, n) \leq \sum_{i=1}^{k} C(k - 1, n - n_i) + O(D(k, n)), \tag{1}$$

where n_i is the number of faces of P_i, for $i = 1, \ldots, k$, and where $D(k, n)$ is the maximum, taken over all collections $\mathcal{P}$ as above, of the quantity $\sum_f w(f)$, with the sum ranging over all faces f of $\partial U^{(2)}$; here $w(f) = \max(2e_f - 3, 0)$ and e_f is the number of edges on ∂f that lie on the boundary of the only polyhedron containing f in its interior.

We next estimate $D(k, n)$ exactly as in [4, 5]. The inductive analysis technique used in these papers leads to the recurrence

$$(k - 2)D(k, n) = \sum_{i=1}^{k} D(k - 1, n - n_i) + O(nk + \mathcal{Q}(k, n)), \tag{2}$$

where $\mathcal{Q}(k, n)$ is the number of "special quadrilaterals" of the following form, maximized over all collections $\mathcal{P}$ as above. Such a quadrilateral Q is schematically depicted in Figure 2; it is defined by a triple $(F(Q), P'(Q), P''(Q))$, where $P' = P'(Q)$, $P'' = P''(Q)$ are distinct polyhedra of $\mathcal{P}$, and $F = F(Q)$ is a face of another polyhedron, $P(Q)$, of $\mathcal{P}$; the intersection $P' \cap P'' \cap F$ is the quadrilateral Q, which is assumed to be disjoint from all other polyhedra; the four vertices of Q are vertices of the union U, two opposite edges of Q are contained in $\partial P' \cap F$ and in the interior of only P'', and the other two edges of Q are contained in $\partial P'' \cap F$ and in the interior of only P'. In other words, if we remove P' and P'' from $\mathcal{P}$ and replace them by $P' \cap P''$, then ∂Q appears on the boundary of the union of the modified collection, and the union of all polyhedra in $\mathcal{P}$, except for P' and P'', contains Q on its boundary. In the notation

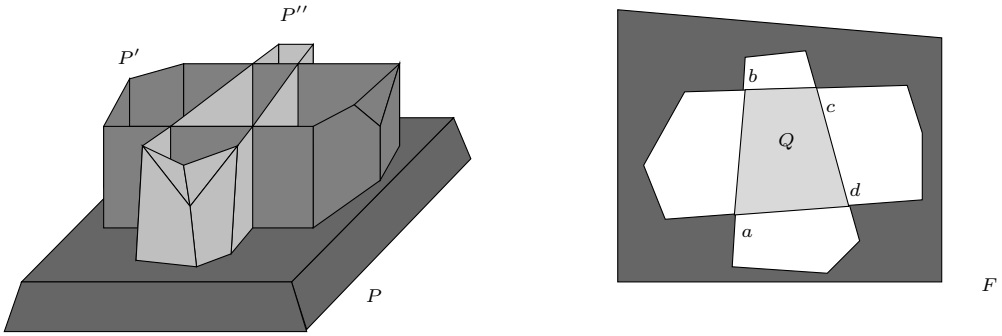

FIG. 2. *A special quadrilateral Q.*

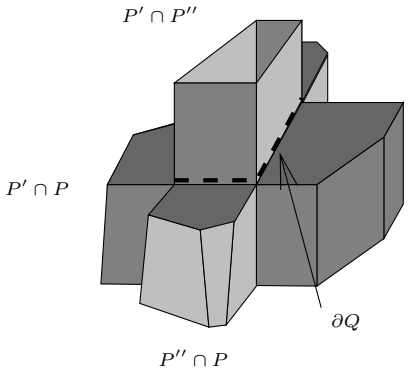

FIG. 3. *$U^{(2)}$ near a special quadrilateral Q.*

of section 3, Q is a special type of face of $\partial U^{(3)}$. The structure of $U^{(2)}$ locally near Q is schematically depicted in Figure 3.

In the case of general convex polyhedra, the authors give in [4, 5] a bound of $O(k^3 + nk)$ for $\mathcal{Q}(k, n)$ and show that it is tight in the worst case. However, we show here that the special properties of $\mathcal{A}(\mathcal{P})$ in the case of Minkowski sums, as established in section 3, lead to an improved bound of only $O(nk)$. Plugging this bound into the recurrences (1) and (2), we obtain, following the analysis of [5], $D(k, n) = O(nk \log k)$ and $C(k, n) = O(nk \log k)$, which thus completes the proof of the upper bound of our main result.

We actually prove the following stronger result.

LEMMA 4.1. *For collections $\mathcal{P}$ of arbitrary convex polyhedra in general position, the number of special quadrilaterals is at most proportional to nk plus the number of local minima of $U^{(3)}$. Hence, for Minkowski expansions this number is $O(nk)$.*

Proof. Let Q be a special quadrilateral defined by $(F(Q), P'(Q), P''(Q))$, as above. The boundary ∂Q of Q is necessarily a bounding cycle of a connected component of $\Sigma(Q) \equiv \partial(P'(Q) \cap P''(Q)) \cap \partial U^{(2)}$. Following an argument similar to that of [4, 5], we observe that the overall number of special quadrilaterals Q whose boundaries are contractible to a point in the corresponding sets $\Sigma(Q)$ is just $O(nk)$, since in the process of contracting ∂Q one has to encounter a vertex of $P'(Q) \cap P''(Q)$, and it is easily checked that no vertex of this form is charged by more than one contractible quadrilateral for fixed P' and P''. The claim now follows from Proposition 2.1. We

thus need to consider only *nontrivial* quadrilaterals, namely, those whose boundaries are not contractible in the above fashion.

Let Q be such a nontrivial special quadrilateral. By definition, Q does not meet the interior of $U^{(3)}$ but is fully contained in $U^{(2)}$. Moreover, $\partial Q \subset \partial U^{(2)}$ (see Figure 3). "Cut" $U^{(2)}$ along Q (or, rather, shift Q slightly away from $P(Q)$ and then cut $U^{(2)}$ along the shifted quadrilateral). We apply this cutting procedure to every nontrivial special quadrilateral, in some arbitrary order. Since, by definition, the relative interiors of any pair of distinct special quadrilaterals are disjoint, it follows that the cuts do not interfere with each other.

Each cut of $U^{(2)}$, performed along some nontrivial special quadrilateral Q, has one of two possible effects: either the first Betti number of $U^{(2)}$ decreases by 1, or the number of connected components of $U^{(2)}$ increases by 1, according to, respectively, whether points of $U^{(2)}$ lying on the two sides of Q sufficiently near Q can or cannot be connected by a path that avoids Q in the current version of $U^{(2)}$. The number of cuts is thus proportional to the increase in the number of connected components of $U^{(2)}$ plus the decrease in the first Betti number of $U^{(2)}$, as effected by the cuts. Since none of the cuts can *increase* the first Betti number of $U^{(2)}$, it follows by Lemma 3.4 that the latter quantity (the decrease in $\beta_1(U^{(2)})$) is bounded by $O(k^2)$ plus the number of local minima of $U^{(3)}$.

To estimate the former quantity, consider a cut performed along a special quadrilateral Q, defined by the triple $(F(Q), P'(Q), P''(Q))$, which increases the number of components of the current version of $U^{(2)}$. Since Q is nontrivial, "dragging" Q along $\partial(P'(Q) \cap P''(Q))$ in either direction encounters a third polyhedron, and thus also a distinct component of $U^{(3)}$. To be more precise, let $U_1^{(2)}$ and $U_2^{(2)}$ be the components obtained by cutting the current version of $U^{(2)}$ along Q. One of the new components of $U^{(2)}$, say $U_1^{(2)}$, contains, near Q, points belonging to $P(Q) \cap P'(Q) \cap P''(Q)$, so $U_1^{(2)}$ contains a component of $U^{(3)}$. The other component of $U^{(2)}$, $U_2^{(2)}$, is bounded near Q by the connected portion K of $\Sigma(Q)$ incident to Q. It is clear that K must also have been incident (before any cuts were made) to some third polyhedron, for otherwise K would have been homeomorphic to a disk whose boundary corresponds to ∂Q, and Q would then have been a trivial quadrilateral, contractible to a point in $K \subset \Sigma(Q)$. There are now two subcases to consider.

(i) The component $U_2^{(2)}$ also contains a component of $U^{(3)}$. (Note that no component of $U^{(3)}$ is ever split by the cuts, because all special quadrilaterals are disjoint from the interior of $U^{(3)}$, so the cuts, performed along slightly shifted copies of the quadrilaterals, are thus disjoint from $U^{(3)}$.) The total increase in the number of components of $U^{(2)}$ formed by cuts of this kind cannot exceed the number of components of $U^{(3)}$. This is because each such cut disconnects in $U^{(2)}$ two components of $U^{(3)}$ that were connected in $U^{(2)}$ before the cut was made. Hence the number of these cuts is bounded by the number of local minima of $U^{(3)}$.

(ii) The component $U_2^{(2)}$ does not contain a component of $U^{(3)}$. The corresponding boundary K, as defined above, was incident, before any cuts were made, to another component of $U^{(3)}$. It follows that this subcase occurs because previous cuts, along other special quadrilaterals incident to K, have separated K from all other adjacent components of $U^{(3)}$. In this case, we charge the current cut to one of these preceding cuts. It is easily checked that no cut is charged in this manner more than once. This implies that the number of special quadrilaterals in this subcase is at most equal to the number of nontrivial special quadrilaterals of the preceding types (those decreasing $\beta_1(U^{(2)})$ and those appearing in case (i) above).

This completes the proof for collections of general convex polyhedra. In the case of Minkowski expansions, as above, Corollary 3.2 implies that the number of special quadrilaterals is $O(nk)$. □

We have thus shown that, in the case of Minkowski expansions, $\mathcal{Q}(k,n) = O(nk)$, which in turn completes the analysis of $C(k,n)$ and yields the upper bound in the following main result of the paper.

THEOREM 4.2. *Let $A_1, \ldots, A_k$ be k convex polyhedra in 3-space with pairwise disjoint interiors, and let B be another convex polyhedron. The combinatorial complexity of the union of the Minkowski sums $A_i \oplus (-B)$, for $i = 1, \ldots, k$, is $O(nk \log k)$, where n is the overall complexity of the individual Minkowski sums. In the worst case, this complexity can be $\Omega(nk\alpha(k))$.*

Remark. The preceding argument assumes general position of the polyhedra A_i and B. Nevertheless, the theorem also holds for collections of polyhedra not in general position, as can be argued using a perturbation scheme [4, 5]. The only delicate part of this reasoning is in the handling of pairs of obstacles whose boundaries overlap. This is done as follows. Shrink each A_i homothetically by a sufficiently small amount. This may cause some features of the union U to disappear. However, each vertex of U that is formed by the transversal intersection of three faces of three distinct P_i's appears as a (slightly perturbed) vertex of the new union. Since the number of all other vertices of U is only $O(nk)$ (see the paragraph preceding Proposition 2.1), it follows that the upper bound of Theorem 4.2 also applies in degenerate configurations of this form.

Proof of the lower bound. We make use of a planar construction, given in [1], of k convex polygons with a total of n edges, such that their union has $\Omega(n\alpha(k))$ edges and vertices. Additionally, the polygons can be arranged so that their union is star-shaped, say with respect to the origin, and at least some fixed fraction of its vertices are visible from the point $(0, +\infty)$, in the strong sense that there exists some fixed angle $\beta > 0$ (independent of k and n), so that, for any such visible vertex v, the wedge whose apex is v, whose bisecting ray is parallel to the positive y-axis, and whose angle is β, does not meet any of the polygon interiors.

Without loss of generality, assume that k is even and $n \geq 4.5k$. We start our three-dimensional construction with a set of $k/2$ convex polygons in xy-plane with $n - 3k$ edges altogether, so that their union U' has $\Omega(n\alpha(k))$ vertices visible from $(0, +\infty, 0)$ in the above strong sense. By scaling, we may assume that the entire construction is contained in the unit disk about the origin in the xy-plane. Now slightly shift and expand the polygons in the z-direction, each by a different amount, to produce pairwise-disjoint flat and thin convex prisms, all contained in, say, the slab $|z| \leq 0.1$; see Figure 4. The second set of $k/2$ polyhedra consists of points $(0, M, i)$, for $i = 1, \ldots, k/2$ (or, rather, tiny tetrahedra centered around these points), where $M \gg k$ is an appropriate parameter. This gives us a collection $\{A_i\}_{i=1}^{k}$ of k pairwise-disjoint convex polyhedra with a total of n faces. The polyhedron B is a tetrahedron with vertices $(0, 0, \pm M')$ and $(\pm M', M, 0)$, where $k \ll M' < M/4$ is another parameter, chosen so that the dihedral angles of B at its horizontal and vertical edges are both equal to some $\beta' < \beta$; note that, by the choice of M', we have $\tan \frac{\beta'}{2} < 1/4$, an inequality that will be needed below. See Figure 4 for an illustration.

Let v be a vertex of U' visible from $(0, +\infty, 0)$ in the above sense. By construction, we can place B so that its vertical edge e_v touches the two prisms corresponding to the two polygons whose boundaries intersect at v; moreover, we can slide B vertically upwards and downwards, by a total distance of close to $2M'$, so that e_v maintains

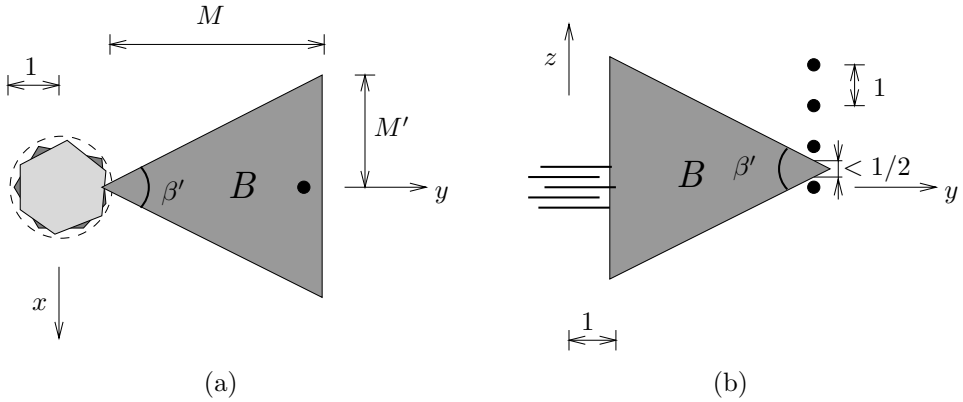

FIG. 4. *The lower bound construction, not to scale:* (a) *a view from above*; (b) *a side view.*

these two contacts, while the interior of B remains disjoint from any of the shifted prisms. It is easily seen that, for an appropriate choice of M, independently of the choice of v, the boundary of B will meet each of the tiny tetrahedra A_i around the points $(0, M, i)$ during the vertical motion. Moreover, our choice of parameters also implies that the intersection of B with the vertical line $x = 0, y = M$ has length less than $2\tan\frac{\beta}{2} < 1/2$, so when B touches one of these A_i's, its interior remains disjoint from all the other polyhedra A_i; see Figure 4(b) for an illustration. In other words, each of the $\Omega(n\alpha(k))$ vertices of U' that is visible from $(0, +\infty, 0)$ gives rise to $\Omega(k)$ placements of B where it makes three contacts with the A_i's, while its interior remains disjoint from all these polyhedra. Since each of the resulting $\Omega(nk\alpha(k))$ placements of B corresponds to a vertex of the union of the expanded polyhedra $\bigcup_{i=1}^{k} A_i \oplus (-B)$, the lower bound of the theorem follows. □

COROLLARY 4.3. *The combinatorial complexity of the free configuration space of a convex polyhedron B, translating in 3-space amidst a collection of k convex obstacles $A_1, \ldots, A_k$ having pairwise disjoint interiors, is $O(nk \log k)$ and can be $\Omega(nk\alpha(k))$ in the worst case, where n is the overall complexity of the Minkowski sums $A_i \oplus (-B)$ for $i = 1, \ldots, k$.*

Remarks. (1) Returning to the parameters p and q that count, respectively, the number of faces of B and of all the A_i's together, we can state the upper bound of Theorem 4.2 and Corollary 4.3 as $O(pqk \log k)$ and the lower bound as $\Omega(qk\alpha(k))$. Another trivial lower bound is $\Omega(pq)$. It remains an open problem to obtain a sharper calibration of the lower bound in terms of the parameters p, q, and k.

(2) Our proof of Theorem 4.2 makes use of the fact that the P_i's are Minkowski sums only in the proof of Theorem 2.4. Hence, our analysis also applies to any collection of k general convex polyhedra with a total of n faces, with the property that, for any subset of r of these polyhedra, the number of components of the complement of their union is $O(rm)$, where m is the total number of faces of those r polyhedra. We pose the open problem of finding other natural examples of collections of convex polyhedra with this property.

5. Efficient construction of the union and its motion planning application. Next we derive an efficient randomized algorithm for constructing the union U of a collection $\mathcal{P}$ of expanded polyhedra, as above. The input to the algorithm consists of the original polyhedra A_i and B, so we first compute the individual Minkowski

sums $P_i = A_i \oplus (-B)$ for $i = 1, \ldots, k$. This computation can be done in several ways, the most efficient of which is by using the technique of Guibas and Seidel [19]. Each P_i can be constructed in time $O(p + q_i + n_i)$, where n_i is the complexity of P_i. Thus the cost of this stage is $O(pk + q + n)$.

The main algorithm is essentially identical to the one given in [4, 5] for the case of general polyhedra; for the sake of completeness, here is a very brief review of the algorithm.

We first compute all the pairwise intersections $P_i \cap P_j$, for $1 \le i < j \le k$, in time $O(nk)$ [9]. In additional $O(nk)$ time, we also extract, for each face F of a polyhedron $P_i \in \mathcal{P}$, the collection $\mathcal{Q}_F$ of the convex polygons $Q_j = F \cap P_j$, for $j \ne i$. The set $U_F = F \setminus \bigcup_{j \ne i} Q_j$ is the portion of F that appears on ∂U, so the algorithm computes the sets U_F, over all faces F, and then glues the sets U_F to each other in an appropriate manner. To construct U_F, for a face F of some $P_i \in \mathcal{P}$, we choose a random order of the polyhedra in $\mathcal{P} \setminus \{P_i\}$ and insert the polygons $Q_j \in \mathcal{Q}_F$, one by one, in the corresponding order, maintaining the complement of their union (within the plane containing F) as we go. For this we use the same technique as in [10, 18, 24], which maintains a vertical decomposition (relative to some direction within F) of the complement into trapezoids. When the incremental procedure ends, we truncate the resulting complement to within F. See [4, 5] for more details.

The analysis of the expected running time of the algorithm is essentially identical to that given in [4, 5]. One only has to plug the improved bound $O(nk \log k)$ on the complexity of the union into the appropriate expressions given in [4, 5]. Omitting these routine calculations, we obtain the following theorem.

THEOREM 5.1. *The union of a collection of k expanded convex polyhedra in 3-space, as above, with a total of n faces, can be computed in randomized expected time $O(nk \log k \log n)$. (In terms of the original parameters p and q, the expected running time is $O(pqk \log k \log (pq))$.)*

Next we apply Theorem 5.1 to the problem of planning a purely translational collision-free motion of the "robot" B amidst the obstacles $A_1, \ldots, A_k$. As observed previously, the complement $\mathcal{C}$ of the union of the expanded obstacles is an adequate representation of the free configuration space of B. However, the representation of $\mathcal{C}$, as computed by the preceding algorithm, needs a few enhancements to facilitate processing of motion planning queries. Here we describe one such method, but alternative (and, hopefully, more efficient and/or simpler) techniques should also be explored.

The first step is to link together all the connected components of the boundary of each connected component of $\mathcal{C}$. This can be done in several ways. For example, we can take the highest point w on each (bounded) boundary component σ and consider the upward-directed ray ρ_w emanating from w. If ρ_w leaves $\mathcal{C}$ near w, then σ is the *outer* boundary of this component of $\mathcal{C}$, and nothing needs to be done. Otherwise, trace ρ_w and find the first polyhedron P_i (if any) met by that ray. The hitting point w' necessarily lies on $\partial\mathcal{C}$ (but not on σ), and the connections between w and w', over all inner boundary components σ, yield the desired links, as is easily verified. (The case when ρ_w meets no polyhedron, which can happen when σ is an unbounded boundary component, requires different, though equally simple, treatment.) To find the point w', we simply find the intersections (if any) of ρ_w with each of the P_i's, by explicit enumeration of all the n faces of the P_i's, and choose the point nearest to w. If w' is found to lie in a face F of some P_i, we use the point location structure for U_F, which is obtained as a byproduct of the incremental construction of the vertical

decomposition of U_F (see [4, 5]), to determine which face of $F \cap \partial U$ contains w'. Since the highest point w on an inner component σ of $\partial\mathcal{C}$ must be the top vertex of one of the P_i's, the whole step takes time $O(nk)$.

We next scan all the faces of $\partial\mathcal{C}$ and assign to each of them the connected component of $\mathcal{C}$ that it bounds. This is easily done by a depth-first search through the adjacency graph of the trapezoids forming $\partial\mathcal{C}$, augmented by the additional adjacencies induced by the new vertical links computed above. This can be done in time linear in the size of $\partial\mathcal{C}$, that is, in time $O(nk \log k)$.

Now, suppose we are given two placements ζ_1, ζ_2 of B and wish to determine whether B can be moved from ζ_1 to ζ_2 without colliding with any A_i. To this end, let ρ_1, ρ_2 be the upward-directed rays emanating from ζ_1, ζ_2, respectively. Apply the procedure described above to these rays, and let ξ_1, ξ_2 be the first points where the respective rays ρ_1, ρ_2 meet $\partial\mathcal{C}$. We then simply check whether the trapezoids on the faces of $\partial\mathcal{C}$ containing ξ_1, ξ_2 bound the same component of $\mathcal{C}$, using the information computed in the preliminary stage. If this is the case, then collision-free translational motion of B from ζ_1 to ζ_2 is possible; otherwise no such motion is possible. This "decision procedure" takes time $O(n)$, if we test explicitly all n faces of the P_i's, as above; this can be improved to $O(k \log n)$ time by preprocessing each polyhedron P_i for efficient line-intersection queries (as in [13]) and then by computing the intersection points of the rays ρ_1, ρ_2 with each polyhedron separately, in logarithmic time per polyhedron. Computing the trapezoids of $\partial\mathcal{C}$ containing ξ_1 and ξ_2, respectively, can be done by point-location queries for ξ_1 and ξ_2 in the respective point-location structures of U_{F_1} and U_{F_2}, computed by the preceding algorithm, where F_i is the face containing ξ_i, for $i = 1, 2$.

It is also rather straightforward to produce a "semifree" motion of B (i.e., a motion during which B does not penetrate, but may touch the obstacles) from ζ_1 to ζ_2, when one exists, as the concatenation of the segments $\zeta_1\xi_1$ and $\zeta_2\xi_2$ with a path that proceeds along the boundary of $\mathcal{C}$, and, if necessary, also along vertical links produced in the preliminary stage. We omit here the rather easy details.

COROLLARY 5.2. *Given a convex polyhedron B, free to translate among k convex polyhedral obstacles with pairwise-disjoint interiors, the entire free configuration space of B can be computed and preprocessed in randomized expected time $O(nk \log k \log n)$, where n is the total number of faces of the Minkowski sums of the obstacles and $-B$. Then, given two placements, ζ_1, ζ_2, of B, we can decide, in $O(k \log n)$ time, whether B can translate in a collision-free manner from ζ_1 to ζ_2.*

Remark. An interesting challenge is to revise the algorithm so that the above reachability queries can be performed in time faster than $O(k \log n)$, perhaps at only polylogarithmic cost.

6. Conclusions. In this paper we have shown that the combinatorial complexity of the union of the Minkowski sums of k convex polyhedra in three dimensions, having pairwise-disjoint interiors, with another convex polyhedron, is $O(nk \log k)$ (and $\Omega(nk\alpha(k))$ in the worst case), where n is the overall complexity of the individual Minkowski sums. We have also presented an efficient and rather simple randomized algorithm for computing the union in expected time $O(nk \log k \log n)$. Both the combinatorial bound and the algorithm have applications to translational motion planning of a convex polyhedral object in a three-dimensional environment amidst polyhedral obstacles, and we have also discussed these applications.

These results almost settle a long-standing open problem but raise a whole collection of new open problems; some of these problems have already been mentioned in

earlier sections. One open problem is to tighten the remaining gap between the lower and upper bounds on the complexity of the union. We conjecture that the correct worst-case bound is $\Theta(nk\alpha(k))$. There are also the problems of designing an efficient deterministic algorithm for computing the union and of improving the performance of the motion planning algorithm described above.

The more challenging and interesting open problems, however, involve generalizations and extensions of our results and techniques. First, what is the combinatorial complexity of the union of Minkowski sums $A_i \oplus B$, where the A_i's are k convex polyhedra with pairwise disjoint interiors, and B is a ball? Even the special case where the A_i's are lines seems to be open; in this case we want to bound the combinatorial complexity of the union of k congruent infinite cylinders, where the conjecture is that this complexity is near-quadratic in k. This problem arises in motion planning, when applying a standard heuristic of enclosing the moving (rigid) object by a ball, and planning the motion of the enclosing ball.

Another open problem involves *generalized Voronoi diagrams* in 3-space. Given $A_1, \ldots, A_k$ and B as above, the B-Voronoi diagram of the A_i's is the partition of 3-space into cells, $V(A_1), \ldots, V(A_k)$, where

$$V(A_i) = \{\xi \mid d_B(\xi, A_i) \le d_B(\xi, A_j) \text{ for all } j \ne i\},$$

where d_B is the *convex distance function* induced by B, namely, $d_B(x, y)$ is the smallest positive λ such that $y \in \{x\} \oplus \lambda B$, and $d_B(x, A) = \min\{d_B(x, y) \mid y \in A\}$. (Here, for the function d_B to be well defined, B must contain the origin in its interior. Also note that if B is a ball, this is the standard Euclidean Voronoi diagram of the "sites" A_i.) See [23] for a study of planar B-Voronoi diagrams. The problem is to bound the combinatorial complexity of the B-Voronoi diagram of the A_i's. If we view the diagram as the lower envelope of graphs of an appropriate collection of trivariate distance functions $w = d_B((x, y, z), A_i)$ in four dimensions, following the standard observation of [16], the results of this paper can be interpreted, as is easily verified, as bounding the complexity of any "horizontal" cross section $w = \text{const}$ of the envelope. The results of [28] imply that the complexity of the B-Voronoi diagram is $O(n^{3+\varepsilon})$, for any $\varepsilon > 0$, where n is the overall complexity of the corresponding Minkowski sums. Considerable progress was made very recently in [11]; it is shown there that the complexity of the Voronoi diagram of n lines in 3-space, under a polyhedral convex distance function, where the underlying polyhedron B has a constant number of edges, is $O(n^2\alpha(n)\log n)$. However, it is still an open problem to extend this result and obtain near-quadratic bounds for the general case where the A_i's and B are arbitrary polyhedra, as above (see [8] for some recent progress on this problem). The main challenge lying ahead is to obtain near-quadratic bounds for the complexity of Euclidean Voronoi diagrams for a set of polyhedral objects. No subcubic bounds are known as yet for this problem, except for the special case where the sites are points (and then the bound is actually quadratic).

Appendix. Proof of Proposition 3.3. In this appendix we give the proof of Proposition 3.3. Recall that this proposition asserts that the first Betti number $\beta_1(S)$ of any compact polyhedral set S in $\mathbb{R}^3$ in general position does not exceed the sum of the merge numbers of its vertices.

Let $z : S \to \mathbb{R}$ be the z-coordinate function. For $a, b \in \mathbb{R}$, let $S[a] = z^{-1}(\{a\})$, $S[a, b] = z^{-1}([a, b])$, and $S^a = z^{-1}((-\infty, a])$.

We begin the proof by stating and sketching a proof of a polyhedral analogue of a basic fact of Morse theory (cf. [25, Theorem 3.1]).

FACT 6.1. *Let $S \subseteq \mathbb{R}^3$ be a triangulated polyhedral set in general position. If $S[a,b]$ contains either no vertex of S, or exactly one vertex v and the z-coordinate of v is a, then $S[a]$ is a strong deformation retract*[2] *of $S[a,b]$.*

Sketch of proof. The proof is an easy and standard exercise in topology, but we include a brief sketch of it here for the sake of completeness. We consider only the case in which there exists a vertex $v \in S[a,b]$ with $z(v) = a$. For each $c \in (a,b]$, the intersection of the triangulation of S with the plane $z = c$ is a convex subdivision of $S[c]$ into triangles and quadrilaterals. It is easy to construct a triangulation, T_c, of this subdivision, in such a way that the combinatorial structure of T_c, for each $c \in (a,b]$, is the same. More formally, if we label each vertex of T_c with the edge of the triangulation of S on which it lies, T_c and $T_{c'}$ are isomorphic labeled planar maps, for any two values $c, c' \in (a,b]$.

For any $c \in (a,b]$ and any $p \in S[c]$, there is a triangle $\triangle(p)$ of T_c containing p, so we can write $p = \alpha_1 u_1 + \alpha_2 u_2 + \alpha_3 u_3$, where u_1, u_2, u_3 are the vertices of $\triangle(p)$, and $\alpha_1, \alpha_2, \alpha_3 \geq 0$, $\sum_i \alpha_i = 1$. For each $\xi \in (a,b]$, define $p(\xi) = \alpha_1 u_1(\xi) + \alpha_2 u_2(\xi) + \alpha_3 u_3(\xi)$, where, for $i = 1,2,3$, $u_i(\xi)$ is the vertex of T_ξ corresponding to u_i (i.e., they both lie on the same edge of the triangulation of S). We have $p(c) = p$, and $p(\xi)$ is a linear function of ξ over $(a,b]$ (for any fixed p), so it is continuous and converges to a limit $p(a)$ as $\xi \to a$. Now define the map $\rho : S[a,b] \times [0,1] \to S[a,b]$, so that, for $p \in S[a,b]$ and $t \in [0,1]$, we have $\rho(p,t) = p\big(z(p)(1-t) + at\big)$ if $z(p) > a$, and $\rho(p,t) = p$ if $z(p) = a$. It is easy to verify that ρ is continuous and satisfies $\rho(p,0) = p$, $\rho(p,1) \in S[a]$, for all $p \in S[a,b]$, and $\rho(p,t) = p$ for all $p \in S[a]$, $t \in [0,1]$. Hence, by definition, $S[a]$ is a strong deformation retract of $S[a,b]$. □

We now return to the proof of Proposition 3.3. We first triangulate S. This may add new vertices to S, but their presence does not affect the statement of the proposition, since they all have merge number 0. Let $z = c$ be a plane below all the vertices of S. Since S is assumed to be bounded, we have $S^c = \emptyset$, so $\beta_1(S^c) = 0$. It suffices to prove that, as t increases from c to $+\infty$, the Betti number $\beta_1(S^t)$ increases at (the z-coordinate of) each vertex of S by at most the merge number of the vertex, and never changes otherwise.

Fact 6.1 implies that $\beta_1(S^t)$ changes only when the plane $z = t$ sweeps through a vertex of S. Indeed, if $t' > t$ is such that no vertex of S has z coordinate in $(t,t']$, then $S[t]$ is a strong deformation retract of $S[t,t']$. However, $S^{t'}$ is the union of S^t and $S[t,t']$, attached along $S[t]$, so S^t is a strong deformation retract of $S^{t'}$ (extending the map provided in Fact 6.1 by the identity map over S^t). Thus S^t and $S^{t'}$ have the same homologies [30, Corollary 1.12], which implies that $\beta_1(S^{t'}) = \beta_1(S^t)$.

Let v be a vertex of S. We want to bound the difference $\beta_1(S^t) - \beta_1(S^{t'})$, where $t = z(v)$ and $t' < t$ is appropriately close to t. One can easily verify that the transformation from $S^{t'}$ to S^t is equivalent, topologically, to gluing a ball D centered at v to $S^{t'}$, choosing the size of D to be such that it intersects all triangles of $T_{t'}$ with at least one vertex approaching v as $t' \to t$, and no other triangles. An easy topological

[2] For a topological space X, a subspace $Y \subseteq X$ is called a *strong deformation retract* of X if there exists a continuous map $\rho : X \times [0,1] \to X$ such that $\rho(x,0) = x$ for all $x \in X$, $\rho(X,1) = Y$, and $\rho(y,t) = y$ for all $y \in Y, t \in [0,1]$; see, for example, [30, p. 56]. Intuitively, it means that X can be deformed into its subspace Y in a continuous fashion while staying in X and not moving a single point of Y.

calculation[3] yields

$$\beta_1(S^t) = \beta_1(S^{t'} \cup D) \leq \beta_1(S^{t'}) + \beta_1(D) + \beta_0(S^{t'} \cap D) - 1.$$

Here $\beta_0(X)$, the 0th Betti number of a topological space X, is the number of connected components of X. Now $\beta_1(D) = 0$ and $\beta_0(S^{t'} \cap D)$ is exactly equal to the number of components of the intersection of a neighborhood of v in S with the plane $z = t'$, lying just below v, namely, it is equal to $m(v) + 1$. Hence $\beta_1(S^t) - \beta_1(S^{t'}) \leq m(v)$, as claimed. This concludes the proof of Proposition 3.3. □

Acknowledgments. We wish to thank Dan Halperin for useful discussions on the problem, and Jiří Matoušek and Igor Rivin for helpful suggestions on matters of topology.

[3] It is easy to show that, for two intersecting path-connected topological spaces X and Y, $\beta_1(X \cup Y) \leq \beta_1(X) + \beta_1(Y) + \beta_0(X \cap Y) - 1$. If X is not path-connected, but Y is, the statement follows by repeated applications of the path-connected version. Note that in our case D is path-connected but $S^{t'}$ need not be. The statement easily follows from arguments based on the Mayer-Vietoris sequence; see, for example, Vick [30, p. 22].
