Each vertex of S^* has at least one neighbor in C'_a by definition of a good pair, and each vertex of $S^* \setminus \Delta$ has at least one neighbor in C'_b since it has at least one neighbor in C_b. The only thing left to show is that each vertex of Δ has a neighbor in C'_b. Let $\delta \in \Delta$. By definition, either δ has a neighbor in N (and hence in C'_b) or there is a vertex $x \in N$ and a connected component D of $G[C_a - \Delta]$ such that both δ and x have a neighbor in D. D is also connected in $G[V - S^*]$ and, since x has a neighbor in D, $D \subset C'_b$. □

THEOREM 9. *Assume S is close to b. Let $S^* \neq S$ be a minimal a, b-separator. There exists a good pair (Δ, N) such that $S^* = (S \cup \Delta) \setminus N$.*

Proof. Let C^*_a and C^*_b be the connected components of $G[V - S^*]$ containing a and b, respectively.

First notice that $S^* \subset C_a \cup C_b \cup S$, since S^* is minimal. Since S is close to b, by Lemma 5, $S^* \subset S \cup C_a$. Let $\Delta = S^* \cap C_a$ and $N = S \setminus S^*$. We show that (Δ, N) is a good pair.

Since $S^* \neq S$ and both are minimal a, b-separators then $N \neq \emptyset$.

Let C'_a be the connected component of $G[C_a - \Delta]$ containing a. We show that N is exactly the set of vertices in S which do not have a neighbor in C'_a. In order to do this we claim that $C'_a = C^*_a$. Since C'_a is a connected component of $G[V - (\Delta \cup S)]$ and since $S^* \subset \Delta \cup S$, $C'_a \subseteq C^*_a$. Now assume there is a vertex $x \in N$ which has a neighbor $y \in C'_a$. Since S is close to b, x is a neighbor of b. This is a contradiction since there would be a path between a and b which does not use any vertex of S^*.

This shows that $C'_a = C^*_a$. Since S^* is minimal, N is exactly the set of vertices in S that do not have a neighbor in C'_a, and every vertex of $\Delta \cup (S \setminus N)$ has at least one neighbor in C'_a.

To prove the last item, first notice that $N \subset C^*_b$ and that C^*_b contains exactly those connected components D of $G[C_a - \Delta]$ for which there is a vertex $y \in N$ which has a neighbor in D. Now let $\delta \in \Delta$. Since S^*_a is minimal, δ has a neighbor x in C^*_b. Since δ only has neighbors in $C_a \cup S$, x must be an element of N or of some component D of $G[C_a - \Delta]$. In this second case, there must also be a vertex $y \in N$ which has a neighbor in D. □

4. Minimal pairs. Again let $G = (V, E)$ be a graph and let a and b be nonadjacent vertices in G. Let S be a minimal a, b-separator and let C_a and C_b be the connected components of $G[V - S]$ containing a and b, respectively. In this section we show how to find some good pairs.

DEFINITION 10. *Let $x \in S$ be nonadjacent to a. Let $C_a(x)$ be the subgraph induced by $C_a \cup \{x\}$. Let Δ be the minimal x, a-separator in $C_a(x)$ close to x, and let C'_a be the connected component containing a. Now let N be the set of vertices of S which do not have a neighbor in C'_a. The pair (Δ, N) is called the* minimal pair *for S and x.*

LEMMA 11. *A minimal pair is good.*

Proof. Notice that $x \in N$; hence $N \neq \emptyset$.

Now, Δ is a minimal x, a-separator in $C_a(x)$ and hence every vertex of Δ has a neighbor in C'_a.

Finally, if $\delta \in \Delta$, then δ is adjacent to x since Δ is close to x. Hence each vertex of Δ has a neighbor in N. □

We want to prove that we can find every minimal a, b-separator by starting with the minimal a, b-separator that is close to b and by recursively using minimal pairs. The following technical lemma proves this.

LEMMA 12. *Let (Δ, N) be a good pair for S. Let $x \in N$ and let (Δ^*, N^*) be the minimal pair for S and x. Let $S^* = (S \cup \Delta^*) \setminus N^*$. Define $\overline{\Delta} = \Delta \setminus \Delta^*$ and $\overline{N} = (N \setminus N^*) \cup (\Delta^* \setminus \Delta)$. Then*

1. *if $\overline{N} = \emptyset$, then $(S \cup \Delta) \setminus N = S^*$, and*
2. *if $\overline{N} \neq \emptyset$, then $(\overline{\Delta}, \overline{N})$ is a good pair for S^* and $(S \cup \Delta) \setminus N = (S^* \cup \overline{\Delta}) \setminus \overline{N}$.*

Proof. We start with some easy observations. Let C'_a be the connected component of $G[C_a - \Delta]$ that contains a and let C^*_a be the connected component of $G[C_a - \Delta^*]$ that contains a. Let $\Delta' = N(x) \cap \Delta$.

- $C'_a \subseteq C^*_a$ since Δ^* contains no vertices of C'_a.
- $\Delta' \subseteq \Delta^*$ since every vertex of Δ' has a neighbor in C'_a.
- $\Delta \setminus \Delta' \subseteq C^*_a$ since every vertex of Δ has a neighbor in C'_a.
- $N^* \subseteq N$ since $C'_a \subseteq C^*_a$.
- C'_a is exactly the connected component of $G[C^*_a - (\Delta \setminus \Delta')]$ containing a since $C^*_a - (\Delta \setminus \Delta')$ contains all vertices of C'_a but no vertex of Δ.
- The set of vertices in S^* without a neighbor in C'_a is exactly $\overline{N}$, which is easy to check.

Assume $\overline{N} = \emptyset$. Then $\Delta^* \subseteq \Delta$ and $N = N^*$ (since $N^* \subseteq N$). Now it is also clear that $\Delta^* = \Delta$; otherwise S^* and $(S \cup \Delta) \setminus N$ are two minimal a, b-separators of which one is properly contained in the other—which is impossible. Hence $S^* = (S \cup \Delta) \setminus N$.

Now assume $\overline{N} \neq \emptyset$. We show that $(\overline{\Delta}, \overline{N})$ is good for S^*. Notice that every vertex of $\overline{\Delta}$ has a neighbor in C'_a, since this holds for every vertex of Δ.

Let $\delta \in \overline{\Delta}$ and assume that δ has no neighbors in $\overline{N}$. Since $\delta \in C_a^*$, δ has no neighbor in N^*. Hence δ has no neighbor in N. Now (Δ, N) is a good pair; hence there is a vertex $z \in N$ and a connected component D of $G[C_a - \Delta]$ such that δ and z have a neighbor in D. Assume by way of contradiction that for no vertex of $\overline{N}$ there is a connected component in $G[C_a^* - \overline{\Delta}]$ such that both this vertex and δ have a neighbor in this component. The following observations lead to a contradiction.

- $N(\delta) \cap D \subseteq C_a^*$. Otherwise, since $\Delta^* \setminus \Delta' \subset \overline{N}$, δ has a neighbor in $\overline{N}$.
- $G[D - \Delta^*]$ is connected. Since otherwise every connected component has a vertex with a neighbor in $\Delta^* \setminus \Delta$, and hence there is a connected component and some vertex in $\overline{N}$ such that both this vertex and δ have a neighbor in this component.
- D contains no vertices of Δ^* by the same argument.

This shows that $D \subset C_a^*$. If $z \in N^*$ then z can have no neighbors in D, since z has no neighbors in C_a^*. Hence $z \in N \setminus N^*$. This is a contradiction, since now there is a connected component D in $G[C_a^* - \overline{\Delta}]$ and a vertex $z \in \overline{N}$ such that both z and δ have a neighbor in D.

The fact that $(S \cup \Delta) \setminus N = (S^* \cup \overline{\Delta}) \setminus \overline{N}$ is obvious. □

Starting with the minimal separator close to b, Theorem 9 ensures that a good pair (Δ, N) exists for every minimal separator. If, at one point, we arrived at a minimal separator S, Lemma 12 shows that we can find the minimal separator $(S \cup \Delta) \setminus N$ by successively choosing minimal pairs (Δ^*, N^*). Notice that the component of S^* containing a is smaller than the component of S containing a. Hence, after a finite number of steps we reach $(S \cup \Delta) \setminus N$. Consequently we obtain the following result.

COROLLARY 13. *Let S be a minimal a,b-separator and let S_1 be the minimal a,b-separator close to b. There exists a sequence $(\Delta_1, N_1), \ldots, (\Delta_t, N_t)$ such that*

1. *(Δ_1, N_1) is a minimal pair for S_1 and some vertex $x_1 \in N_1$.*
2. *for $i = 2, \ldots, t$, (Δ_i, N_i) is a minimal pair for $S_i = (S_{i-1} \cup \Delta_{i-1}) \setminus N_{i-1}$ and some vertex $x_i \in N_i$.*
3. *for $i = 1, \ldots, t$, Δ_i and a are in the same connected component of $G[V - S_i]$.*
4. *$S = (S_t \cup \Delta_t) \setminus N_t$.*

5. An algorithm listing minimal separators. In this section we give an algorithm that, given a graph G and two nonadjacent vertices a and b, finds all minimal a,b-separators. This algorithm is displayed in Figure 1.

THEOREM 14. *Let S be the minimal a,b-separator that is close to b and let $\mathcal{T} = \{S\}$ and $\mathcal{Q} = \{S\}$. Then a call separators$(G, a, b, \mathcal{T}, \mathcal{Q})$ determines a set $\mathcal{Q}$ containing all minimal a,b-separators.*

Proof. By Corollary 13 the set $\mathcal{Q}$ contains all minimal a,b-separators. By Lemma 11 and Theorem 8 all sets in $\mathcal{Q}$ are minimal separators. □

Remark. If we let $\mathcal{T} = \{\{b\}\}$ and $\mathcal{Q} = \emptyset$, then a call separators$(G, a, b, \mathcal{T}, \mathcal{Q})$ has the same result.

THEOREM 15. *Let $R(a,b)$ be the number of minimal a,b-separators (for nonadjacent vertices a and b). The algorithm to determine all minimal a,b-separators can be implemented to run in time $O(n^3 R(a,b))$.*

Proof. Assume that the graph is given with an adjacency matrix. The minimal separator S that is close to b can easily be found in $O(n^2)$ time as follows. Initialize $S = N(b)$. Determine the connected component C_a of $G[V - S]$. Remove vertices from S that do not have a neighbor in C_a.

Consider the time it takes to compute $\mathcal{T}'$. For each $S \in \mathcal{T}$ and for each $x \in S$ not adjacent to a we have to do the following computations. Determining Δ takes at

```
procedure separators(G, a, b, 𝒯, 𝒬)

    𝒯' := ∅;
    for each S ∈ 𝒯 do
    begin
        Determine C_a;
        { C_a is the connected component of G[V − S] that contains a.}
        for each x ∈ S which is not adjacent to a do
        begin
            Determine Δ;
            {Δ is the minimal x,a-separator in C_a(x) that is close to x.}
            Determine C'_a;
            { C'_a is the connected component of G[C_a − Δ] that contains a.}
            Determine N;
            {N is the set of vertices in S that do not have a neighbor in C'_a,}
            S* := (S ∪ Δ) \ N;
            T' := T' ∪ {S*}
            {Add S* to T' only if not yet present!}
        end for
    end for;
    𝒬 := 𝒬 ∪ 𝒯';
    separators(G, a, b, 𝒯', 𝒬)
end.
```

FIG. 1. *Algorithm listing minimal separators.*

most $O(n^2)$ time. Computing C'_a and N can clearly be done in $O(n^2)$ time. Hence the time to compute $\mathcal{T}'$ (which may contain elements that are already in $\mathcal{Q}$) can be performed in $O(n^3|\mathcal{T}|)$ time.

We have to remove minimal separators that have been found before from the new set $\mathcal{T}'$. We can do this by keeping $\mathcal{Q}$ in a suitable data structure, allowing an update in $O(n|\mathcal{T}'|\log R(a,b)) = O(n^2|\mathcal{T}'|) = O(n^3|\mathcal{T}|)$ time. It follows that the computation of $\mathcal{T}'$, containing only new minimal separators, can be performed in $O(n^3|\mathcal{T}|)$ time. Since each newly computed set $\mathcal{T}'$ contains only minimal separators that have not been found before, it follows that the total time needed by the algorithm is $O(n^3R(a,b))$. □

COROLLARY 16. *The set of all minimal separators of a graph can be found in $O(n^5R)$ time, where n is the number of vertices in the graph and R is the total number of minimal separators.*

A somewhat different result is the following.

THEOREM 17. *Assume G has at least R minimal separators. There exists an algorithm that finds R different minimal separators in $O(n^5R)$ time.*

Proof. The claimed algorithm is simply the following. The algorithm listing minimal separators described above is stopped when R different ones have been found. It may take time at most $O(n^5R)$, trying different pairs of nonadjacent vertices for which the total number of different minimal separators is smaller than R. Assume a pair of vertices has been found with enough new minimal separators. Now the analysis in the proof of Theorem 15 shows the claimed result. □

6. Conclusions. In this paper we have presented an algorithm to determine a list of all minimal vertex separators of a graph. The algorithm needs only polynomial time per separator that is found. We would like to mention some open problems.

First of all, we feel that it should be possible to improve the running time of the algorithm presented here.

A related concept is that of an *inclusion minimal separator*. This is a minimal separator with the additional constraint that no proper subset is also a minimal separator. The following lemma shows that our algorithm can be used to find all inclusion minimal separators. However, the example given in the introduction illustrates that this may not be an efficient way to do this.

LEMMA 18. *A separator S of a graph $G = (V, E)$ is inclusion minimal if and only if every vertex of S has a neighbor in every connected component of $G[V - S]$.*

It follows that a list of all inclusion minimal separators can easily be obtained from the list of all minimal separators. Until now, we have not been able to find an efficient algorithm which finds all inclusion minimal separators.

Acknowledgments. We thank B. Monien (University of Paderborn, Germany) for drawing our attention to this important problem. We are grateful to an anonymous referee for helpful comments.

EFFICIENT SELF-EMBEDDING OF BUTTERFLY NETWORKS WITH RANDOM FAULTS*

HISAO TAMAKI†

Abstract. We study the embedding of the butterfly network in its faulty version, where each node is independently faulty with some constant probability p. We give a method of such self-embedding of the N-node butterfly with $O(1)$ load, $O((\log\log N)^{2.6})$ dilation, and $O((\log\log N)^c)$ congestion, which succeeds with probability at least $1 - N^{-1}$ if $p < 1 - \sqrt{2/3} \simeq 0.1835$, where c is a constant that depends on p; c is about 8.84 for $p = 0.1$ and approaches $\log_2 40 \simeq 5.32$ as $p \to 0$. The method is constructive and in fact yields an $N \log^{O(1)} N$ time deterministic algorithm to construct the claimed embedding with the claimed success probability when given the random faulty butterfly. We also show that we can make the dilation as low as $O(\log\log N)$, although at the cost of $\log^{O(1)} N$ congestion. These embeddings are level-preserving in the sense that each node is mapped to a node in the same level of the butterfly as the original node. We also derive a lower bound of $\log\log N - o(\log\log N)$ on the dilation of a level-preserving embedding with N^α load, for any constant $\alpha < 1/3$ and any constant node-failure probability $p > 0$. Thus, the bounds on dilation are tight up to a constant factor, as far as level-preserving embeddings are concerned.

1. Introduction.

In this paper, we study the robustness of interconnection networks against random static faults. We assume that each node of the network is faulty with some constant probability, independently of other nodes. Faulty nodes are conceptually removed from the network together with all of its incident edges. The question we address is if the remaining subnetwork can efficiently embed the fault-free version of the network in the following sense. In general, an *embedding* of a network G in a network H maps each node of G to a node of H and each edge of G to a path of H so that, if an edge (u, v) of G is mapped to a path P of H, then nodes u and v are mapped to the endpoints of P. In our context of self-embedding, G is the fault-free network and H is the network after the removal of faulty nodes. The *load* of the embedding is the maximum number of nodes of G mapped to a single node of H, the *dilation* is the maximum length of a path of H to which some edge is mapped, and the *congestion* is the maximum number of edges of G whose image paths share a common edge of H. A self-embedding with small load, dilation, and congestion implies an efficient simulation of the fault-free network by the faulty network and thus can be considered as evidence of the robustness of the network structure. (In fact, the slowdown factor of the simulation is $O(load + dilation + congestion)$ due to the result of Leighton, Maggs, and Rao [12] on off-line routing.)

Under this model, Håstad, Leighton, and Newman [6] show that the hypercube is highly robust, supporting a self-embedding with $O(1)$ load, $O(1)$ dilation, and $O(1)$ congestion, with high probability. Aiello and Leighton [1] give another proof of this result as an application of their more general embedding technique. This result heavily

†IBM Tokyo Research Laboratory, 1623-14 Shimotsuruma, Yamato, 242 Japan (htamaki@trl.ibm.co.jp). This work was done while the author was at the University of Toronto.

depends on the logarithmic degree of the hypercube, and one naturally asks if a similar robustness can be achieved by bounded-degree networks. For the two-dimensional array, this question is resolved by Kaklamanis et al. [7], who show the upper bound of $O(1)$ load, $O(\log N)$ dilation, and $O(1)$ congestion (with high probability), together with a matching lower bound that any $O(1)$-load embedding requires $\Omega(\log N)$ dilation with high probability. Here, and throughout this paper, we use N to denote the number of nodes in the network. Kaklamanis et al. also give almost tight bounds for the three-dimensional array. Tamaki [16] introduces a new bounded-degree network called cube-connected arrays which admits $O(1)$ load self-embedding with dilation and congestion both $(\log\log N)^{1+o(1)}$. However, the problem has remained open for the so-called hypercubic networks, such as the butterfly, the cube-connected-cycles (CCC), the shuffle-exchange, and the de Bruijn networks. Annexstein [3] gives self-embeddings with $O(\log\log N)$ dilation and $O(1)$ congestion for these networks, but under a weaker model in which an edge is allowed to be mapped to a path containing faulty nodes. Karlin and Nelson [8] show that a faulty butterfly contains a linear-sized connected component with high probability. This means that $O(1)$-load embedding is possible, but their proof technique does not seem to lead to good bounds for dilation and congestion.

Recently, Leighton, Maggs, and Sitaraman [11] extensively studied worst-case faults in bounded-degree networks, and as one of the consequences, interestingly, derived a result on the butterfly with *random faults*: a faulty butterfly can simulate the complete butterfly with slowdown factor $2^{O(\log^* N)}$, which is very close to a constant. This simulation is not based on embedding but uses the more involved scheme of replication [10].

In this paper, we give an efficient self-embedding of the butterfly network with random faults.

THEOREM 1.1. *For node-failure probability $p < 1 - \sqrt{2/3} \simeq 0.1835$, a faulty N-node butterfly can embed a fault-free N-node butterfly with $O(1)$ load, $O((\log\log N)^{2.6})$ dilation, and $O((\log\log N)^c)$ congestion, with probability at least $1 - N^{-1}$, where c is a constant that depends on p; c is about 8.84 for $p = 0.1$ and approaches $\log 40 \simeq 5.32$[1] as $p \to 0$.*

The proof is constructive in the sense that we can extract an efficient deterministic algorithm (that runs in $N \log^{O(1)} N$ steps) for constructing the embedding.

We also show that if we allow congestion of $\log^{O(1)} N$, then we can make the dilation of the embedding as small as $O(\log\log N)$.

Following [11], we call a self-embedding of the butterfly *level-preserving* if it maps each node of the butterfly to a node in the same level as the original. Both of our embeddings in the above results are level-preserving. We also prove the following matching lower bound on the dilation of level-preserving self-embeddings.

THEOREM 1.2. *For any positive constants p and $\alpha < 1/3$, the probability is $1 - 2^{-N^{\Omega(1)}}$ that any level-preserving self-embedding with load N^α in a faulty N-node butterfly with node failure probability p requires dilation at least $\log\log N - o(\log\log N)$.*

The work of Leighton, Maggs, and Sitaraman [11] includes a negative result for worst-case faults: to ensure a self-embedding with $O(1)$ load and dilation, only poly-logarithmic number of worst case faults can be allowed in a butterfly. Their technique does not seem to apply to random faults, nor does ours to worst-case faults.

[1] Throughout the paper, all logarithms are base 2.

This paper improves on its preliminary version [15] in three major points: (1) we give an explicit allowable value of the node-failure probability p for our embedding; (2) we include a dilation upper bound of $O(\log\log N)$; and (3) we have a matching lower bound on the dilation of level-preserving embeddings, improving on the weaker lower bound of $\log\log\log N$ in the preliminary version.

The rest of the paper is organized as follows. In section 2, we define some necessary notions and introduce notations. In section 3, we show that a faulty butterfly maintains a large connected component and a reasonably good routing capability with very high probability. In section 4, we improve the congestion of the routing of section 3 at a slight expense of dilation. In section 5, this result of section 4 is applied to small subbutterflies of a faulty butterfly and yields our main embedding result. On the other hand, the result of section 3, similarly applied, yields the embedding with better dilation and exponentially worse congestion. In section 6, we prove the dilation lower bound. Finally, in section 7 we discuss some open problems.

2. Preliminaries. In this section, we define the butterfly network and review some of its structural properties. We review some probabilistic tools we use and also introduce some terminology for routing.

For two integers m and n, we denote by $[m,\ldots,n]$ the set of integers i satisfying $m \le i \le n$. We also write $[n]$ for $[1,\ldots,n]$. Let m be a positive integer. The m-stage butterfly, denoted by $\mathcal{B}_m$, is an undirected graph on node set $[0,\ldots,m]\times\{0,1\}^m$. If v is a node of the form $\langle i,x\rangle$, $i\in[0,\ldots,m]$ and $x\in\{0,1\}^m$, we call i the *level index* and x the *row index* of v. Two nodes $\langle i,x\rangle$ and $\langle j,y\rangle$ are adjacent if and only if (1) $|i-j|=1$, and (2) x and y are equal at all bit positions except possibly the kth, where k is the larger of i and j. For a fixed i, we refer to the set of all nodes with level index i as *level* i and to the set of all edges between level $i-1$ and level i as *stage* i. We call an edge $(\langle i-1,x\rangle,\langle i,y\rangle)$ a *straight edge* if $x=y$; a *cross edge* if x and y do differ at the ith bit position. We also refer to the set of all nodes with row index x, for a fixed x, as *row* x. Note that if we collapse each row x into a single node, $\mathcal{B}_m$ degenerates into an m-dimensional hypercube, with a cross edge in stage i becoming an edge in dimension i. As in Figure 1, our convention is to draw, and regard, the lower levels to be on the left-hand side.

The following notions and facts about the butterfly will be frequently used. We call a path in $\mathcal{B}_m$ *monotone* if it visits each level at most once. If the leftmost node of a monotone path is u and the rightmost node is v, then we say that the monotone path *starts at* u and *ends at* v. It is sometimes convenient to see a monotone path as being specified by the starting node and a binary string. Let us label each edge $(\langle i-1,x\rangle,\langle i,y\rangle)$ of $\mathcal{B}_m$ with the ith bit of y. When the butterfly is drawn as in Figure 1, of those two edges that go out to the right from each node, the upper one is labeled with 0 and the lower one is labeled with 1. The *label* of a monotone path $(v_0,v_1,\ldots,v_k)$, where the vertices are listed from left to right, is defined to be a bit string $b_1,\ldots,b_k$, where each b_i, $i\in[k]$ is the label of the edge (v_{i-1},v_i). The following facts about $\mathcal{B}_m$ can be easily verified. For $x\in\{0,1\}^*$, $|x|$ denotes the length of x.

1. A node v on level i and a binary string w, $|w|\le m-i$, uniquely specify a monotone path that starts at v and has w as its label.
2. If a monotone path starts at node $\langle i,x\rangle$ and has label w, then it ends at node $\langle i+|w|,ywz\rangle$, where y is the prefix of x with length i and z is the suffix of x with length $m-|w|-i$.
3. For each pair of nodes u on level 0 and v on level m, there is a unique monotone path in $\mathcal{B}_m$ that starts at u and ends at v. The label of this unique monotone path is the row index of v.

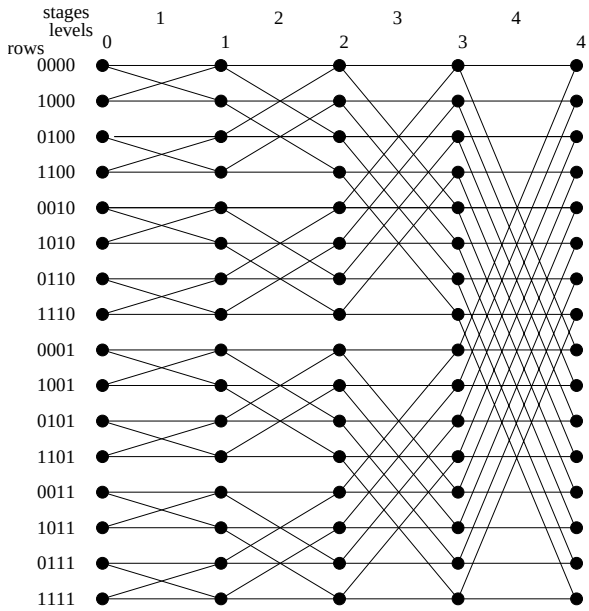

FIG. 1. *The 4-stage butterfly.*

4. For each node u on level 0, the graph formed by all the monotone paths of length m starting at u is a complete binary tree rooted at u.
5. For any monotone path $(v_0, v_1, \ldots, v_m)$ from level 0 to level m, there is an automorphism of $\mathcal{B}_m$ that maps each v_i to node $\langle i, 0^m \rangle$.

Let k and d be integers such that $0 \le k \le k + d \le m$. For $x \in \{0,1\}^k$ and $y \in \{0,1\}^{m-k-d}$, the subgraph of $\mathcal{B}_m$ induced by the set of nodes $\{\langle k + l, xwy \rangle \mid 0 \le l \le d, w \in \{0,1\}^d\}$ is isomorphic to $\mathcal{B}_d$; the standard isomorphism maps node $\langle k + l, xwy \rangle$ of $\mathcal{B}_m$ to node $\langle l, w \rangle$ of $\mathcal{B}_d$. We call this subgraph a *d-stage subbutterfly of $\mathcal{B}_m$ starting at level k (and ending at level $k + d$)*. When we refer to a subbutterfly, we usually view the graph through the standard isomorphism above. If B is a subbutterfly of $\mathcal{B}_m$, *Left*(B) will denote the set of nodes of B on its leftmost (lowest) level and *Right*(B) will denote the set of nodes on its rightmost (highest) level. In particular, *Left*$(\mathcal{B}_m)$ and *Right*$(\mathcal{B}_m)$ are, respectively, the set of nodes on levels 0 and m.

Let F be a subset of $V(\mathcal{B}_m)$. We write $\mathcal{B}_m\langle F \rangle$ to denote the subgraph of $\mathcal{B}_m$ induced by the node set $V(\mathcal{B}_m) \setminus F$. Informally, we will view $\mathcal{B}_m\langle F \rangle$ as the *faulty butterfly with fault set F*. For a subgraph B of $\mathcal{B}_m$, we extend this notation by defining $B\langle F \rangle$ to be the intersection of B and $\mathcal{B}_m\langle F \rangle$. We are primarily interested in the case where F is a random subset of $V(\mathcal{B}_m)$. Let S be a finite set and let X be a random subset of S such that each element of S is independently included in X with probability p. In other words, each fixed X is assigned probability $p^{|X|}(1-p)^{|S|-|X|}$. We denote this probability distribution by $\mathbf{randsub}(S, p)$ and write $X \in \mathbf{randsub}(S, p)$ to mean that X is chosen at random according to this distribution. Then $\mathcal{B}_m\langle F \rangle$, where $F \in \mathbf{randsub}(V(\mathcal{B}_m), p)$, induces a probability distribution over the subgraphs of $\mathcal{B}_m$. We denote this probability distribution by $\mathcal{B}_m\langle p \rangle$ and call it *the randomly faulty m-stage butterfly with node-failure probability p*.

We will use the following forms of the bound on the probability of a large deviation of a sum of independent random variables, usually called the *Chernoff bound*. The proofs can be found in the standard textbooks such as Alon and Spencer [2] or

Motwani and Raghavan [13]. Let X be a sum of independent random variables, each of which takes either 0 or 1 as its value. Let $\mu = \mathbf{E}(X)$ be the expected value of X.

PROPOSITION 2.1. *Let $\epsilon > 0$. Then, $P(|X - \mu| > \epsilon\mu) < e^{-c_\epsilon \mu}$, where c_ϵ is a positive constant depending only on ϵ.*

In one occasion, where we want to bound the probability that X deviates from its mean by more than a constant fraction, we will use the following.

PROPOSITION 2.2. *For any $T > \mu$, $P(X > T) < (\frac{e\mu}{T})^T$.*

There will be a few occasions where we need to deal with a sum of random variables which are not totally independent. If those random variables can be grouped so that the random variables in a single group are mutually independent, then we can apply the Chernoff bound to each subset. This reasoning gives the following proposition which we will refer to as the *partition Chernoff bound*.

PROPOSITION 2.3. *Let $\epsilon > 0$ be a constant and let $0 < p < 1$ be a value that possibly depends on n. Let X_i, for each $i \in [n]$, be a random variable which assumes value 1 with probability p and 0 with probability $1 - p$. Let $X = \sum_{i\in[n]} X_i$. Let $f(n)$ and $g(n)$ be functions such that $\log f(n) = o(pg(n))$, and suppose the set $[n]$ can be partitioned into $f(n)$ subsets with at least $g(n)$ elements each so that, for each part S of the partition, random variables X_i, $i \in S$ are mutually independent. Then, $P(|X - pn| > \epsilon pn) = 2^{-\Omega(pg(n))}$.*

Proof. For $|X - pn| > \epsilon pn$ to happen, there must be some part S of the partition such that $|\sum_{i\in S} X_i - p|S|| > \epsilon p|S|$. The probability of this event for a fixed S is at most $2^{-\Omega(pg(n))}$ by Proposition 2.1. Therefore, the probability that this happens for any S in the partition is at most $f(n)2^{-\Omega(pg(n))} = 2^{-\Omega(pg(n))}$. □

Now we turn to some terminology for routing. A *routing request* on a graph G is a multiset of ordered pairs of nodes of G. A routing request is *one-to-one* if each node appears at most once as the first component of a pair and at most once as the second component of a pair in the request. Otherwise it is *many-to-many*. A routing request on a butterfly is *end-to-end* if each pair consists of a node at level 0 and a node at the last level. A multiset Π of paths of G *realizes* a routing request R if it provides each pair in the request with a path connecting the pair; more formally, if there is a one-to-one mapping f from R to Π such that $f(u, v)$ for every $(u, v) \in R$ is a path with endpoints u and v. The *congestion* of a multiset of paths Π is the maximum number of times a single edge of G appears in the paths of Π. Let U and V be some sets of nodes of G. We say the pair (U, V) is (λ, γ)-*routable* in G if every one-to-one routing request $R \subseteq U \times V$ can be realized by a multiset of paths with maximum length λ and congestion γ. We say U is (λ, γ)-routable in G if (U, U) is (λ, γ)-routable in G.

Let $Q_m = \{0, 1\}^m$ denote the set of nodes of the m-cube and let $Q_m(i, b)$, $i \in [m]$ and $b \in \{0, 1\}$ denote the set of nodes of the subcube of the m-cube where the ith coordinate is fixed to b. For $0 < \delta < 1$, we say that a subset U of Q_m is δ-*dense* if at least a $(1 - \delta)$-fraction of each $Q_m(i, b)$ is contained in U, i.e., $|U \cap Q_m(i, b)| \geq (1 - \delta)2^{m-1}$ for every $i \in [m]$ and $b \in \{0, 1\}$. We will apply this notion to a subset U of a single level of $\mathcal{B}_m$, viewing this level as the set of nodes of the m-cube in the obvious manner.

3. $(O(m), O(2^m))$-routing in the faulty butterfly. The goal of this section is to show that, for appropriate values of δ and p, $\mathcal{B}_m\langle p\rangle$ almost surely contains a δ-dense subset of level 0 that is $(O(m), O(2^m))$-routable. This fact will later be applied to small subbutterflies of $\mathcal{B}_n$ with $m = O(\log n)$ to provide small dilation paths in the embedding of $\mathcal{B}_n$ into $\mathcal{B}_n\langle p\rangle$.

Let $\theta_p = (1-p)^2(1-\frac{p^2(2-p)^2}{(1-p)^4})$.

THEOREM 3.1. *Let δ, $0 < \delta < 1$ be given and fix p so that $\theta_p > 1-\delta$. Then, with probability at least $1 - 2^{-2^{\Omega(m)}}$, $\mathcal{B}_m\langle p\rangle$ has a δ-dense subset of level 0 that is $(4m, 2^{m+2})$-routable.*

In our later application, we need to take $\delta < 1/2$ and hence $\theta_p > 1/2$. To achieve this, it suffices to choose $p < 1 - \sqrt{2/3} \simeq 0.1835$.

The remainder of this section is devoted to the proof of Theorem 3.1. Let $\delta > 0$ be fixed. We first define a mapping Φ_m which is intended to map a faulty butterfly $\mathcal{B}_m\langle F\rangle$ to a set of nodes $U \subseteq \mathit{Left}(\mathcal{B}_m\langle F\rangle)$ such that U is δ-dense and $(O(m), O(2^m))$-routable. We will later prove that Φ_m succeeds with high probability in satisfying these conditions when applied to $\mathcal{B}_m\langle p\rangle$, provided $\theta_p > 1-\delta$.

We need some auxiliary definitions first. Let u and v be nodes on level 0 of $\mathcal{B}_m$ and let $\mathit{meet}(u,v)$ denote the smallest integer k such that u and v belong to the same k-stage subbutterfly starting at level 0. Let $F \subseteq V(\mathcal{B}_n)$ be a fault set. We say u and v are *confluent in* $\mathcal{B}_m\langle F\rangle$ if $\mathcal{B}_m\langle F\rangle$ contains two monotone paths of length $\mathit{meet}(u,v)$ that start at u and v and end at a common node. By convention, a node in $\mathit{Left}(\mathcal{B}_m\langle F\rangle)$ is confluent with itself. For each $v \in \mathit{Left}(\mathcal{B}_m\langle F\rangle)$, let $\mathit{Conf}_F(v)$ denote the set of all nodes that are confluent in $\mathcal{B}_m\langle F\rangle$ with v.

Now we define Φ_m. If there exists a node v such that $\mathit{Conf}_F(v)$ is δ-dense, then we set $\Phi_m(\mathcal{B}_m\langle F\rangle) = \mathit{Conf}_F(v_0)$, where v_0 is the first node in the natural ordering of rows such that $\mathit{Conf}_F(v_0)$ is δ-dense; otherwise we set $\Phi_m(\mathcal{B}_m\langle F\rangle) = \emptyset$.

It is clear that $\Phi_m(\mathcal{B}_m\langle F\rangle)$ is either δ-dense or empty; we say that Φ_m *succeeds* on $\mathcal{B}_m\langle F\rangle$ in the first case and that it *fails* in the second case. The following lemma shows that Φ_m provides what is required, whenever it succeeds.

LEMMA 3.2. *$\Phi_m(\mathcal{B}_m\langle F\rangle)$ is $(4m, 2^{m+2})$-routable in $\mathcal{B}_m\langle F\rangle$, when nonempty.*

Proof. Suppose a one-to-one routing request $Q \subseteq U \times U$ is given where $U = \mathit{Conf}_F(v_0) \neq \emptyset$. Given a pair $(u,v) \in Q$, we arbitrarily choose two monotone paths that witness the confluence of u with v_0 and two monotone paths that witness the confluence of v with v_0. Then, to the pair (u,v), we assign the path consisting of these four paths concatenated together. The total length of the path is at most $4m$. The congestion is at most 2^{m+2} because the number of monotone paths involved is $4|Q|$. □

To estimate the probability that Φ_m succeeds on $\mathcal{B}_m\langle p\rangle$, the following result from the theory of branching processes is needed. We define a *binary branching process with birth probability q* as the following special case of the Galton–Watson process. We start from a single organism in generation 0, which gives birth to some organisms in generation 1, which in turn have some children in generation 2, and so on. Each organism has exactly two potential children, each of which is actually born independently of each other and of any other organisms in the process (except for the obvious dependence to the birth of its ancestors), with probability q. Thus the number of children of each organism obeys a simple binomial distribution with generating function $f(z) = (qz + 1 - q)^2$. Let $Z_0, Z_1, \ldots$, denote the number of organisms in generation 0, 1, ..., respectively. It is well known that if $E(Z_1) = 2q > 1$, there is a positive probability that the process will continue forever ($Z_k > 0$ for every $k \geq 0$); the probability of extinction $\xi_q = P(\exists k Z_k = 0)$ is given as the unique root of $f(z) = z$ in the range $0 < z < 1$. Thus $\xi_q = ((1-q)/q)^2$ in our binary branching process. (See [4].) The following lemma due to Pippenger [14] states that the probability of Z_k being much smaller than its expected value $(2q)^k$ is almost as small as the extinction probability. More informally, a branching process is likely to thrive when it survives.

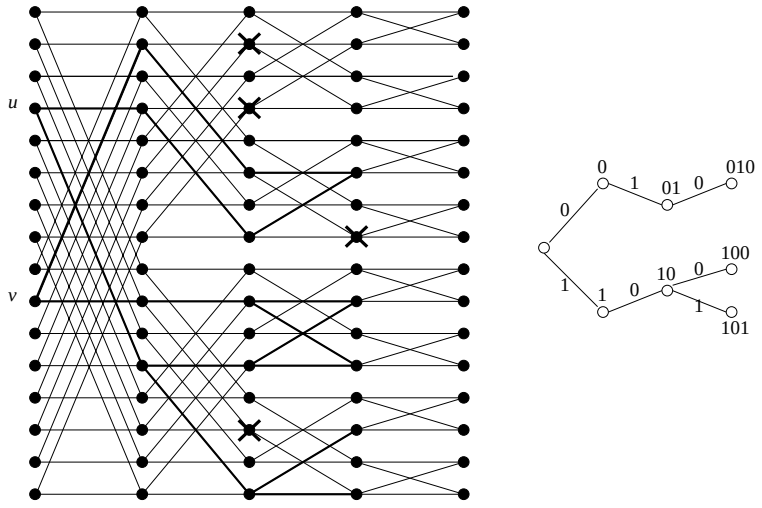

FIG. 2. *A confluence tree (rows are permuted from the standard drawing).*

LEMMA 3.3. *Suppose* $2q > 1$ *and let* τ *be an arbitrary constant* $0 < \tau < 1$. *Then* $P(Z_k < (2q)^{\tau k}) = \xi_q + o(1)$, *as* $k \to \infty$.

We use this lemma to estimate the probability that two nodes are confluent in $\mathcal{B}_m\langle p\rangle$. Let $F \subseteq V(\mathcal{B}_m)$ be a fault set. For each pair of nodes $u, v \in \mathit{Left}(\mathcal{B}_m)$, we define the *confluence tree of* u *and* v *with respect to* F, denoted by $T_{uv}(F)$, as follows. $T_{uv}(F)$ is a rooted binary tree in which each node is a binary string of length at most $\mathit{meet}(u, v)$. Each such string w is a node of $T_{uv}(F)$ if and only if both monotone paths of $\mathcal{B}_m$ with label w that starts at u and v are contained in $\mathcal{B}_m\langle F\rangle$. It is clear that the node set of $T_{uv}(F)$ is closed under the prefix operation; if ww' is a node of $T_{uv}(F)$, then so is w. The edge set of $T_{uv}(F)$ is defined so that there is an edge from w_1 to w_2 if and only if $w_2 = w_1 0$ or $w_2 = w_1 1$. Thus, the empty string is the root of $T_{uv}(F)$ and, in general, each string with length i, $i \in [0, \ldots, \mathit{meet}(u, v)]$ is at depth i of the tree if it is a node of $T_{uv}(F)$. Note that u and v are confluent in $\mathcal{B}_m\langle F\rangle$ if and only if their confluence tree has a node at depth $\mathit{meet}(u, v)$. See Figure 2.

When F is randomly chosen, $T_{uv}(F)$ gives rise to a binary branching process, to which we can apply the tools described above.

PROPOSITION 3.4. *For any two fixed nodes* $u, v \in \mathit{Left}(\mathcal{B}_m)$, *the probability that* u *and* v *are confluent in* $\mathcal{B}_m\langle p\rangle$ *is at least* $\theta_p = (1-p)^2(1 - \frac{p^2(2-p)^2}{(1-p)^4})$.

Proof. Fix $u, v \in \mathit{Left}(\mathcal{B}_m)$ and let $F \in \mathbf{randsub}(V(\mathcal{B}_m), p)$. We first observe that $T_{uv}(F)$ is essentially a binary branching process with birth probability $(1-p)^2$. To see this, consider a potential node w of $T_{uv}(F)$ with $|w| < \mathit{meet}(u, v)$ and its two potential children $w0$ and $w1$. Let u_0 be the node at which the monotone path with label $w0$ starting at u ends and define v_0 similarly with u replaced by v. If w is indeed a node of $T_{uv}(F)$, then $w0$ is a node of $T_{uv}(F)$ if and only if $u_0 \notin F$ and $v_0 \notin F$. Note that $u_0 = v_0$ if and only if $|w0| = \mathit{meet}(u, v)$. Therefore,

$$P(w0 \in T_{uv}(F) \mid w \in T_{uv}(F)) = \begin{cases} (1-p)^2 & \text{if } |w0| < \mathit{meet}(u, v) \\ 1-p & \text{if } |w0| = \mathit{meet}(u, v). \end{cases}$$

The same equality holds for the probability $P(w1 \in T_{uv}(F) \mid w \in T_{uv}(F))$ for the other potential child. Moreover, for any set W of potential nodes of $T_{uv}(F)$, events for

$w \in W$ and $b \in \{0,1\}$ that $wb \in T_{uv}(F)$ are mutually independent when conditioned that $w \in T_{uv}(F)$ for all $w \in W$. Thus, we can view $T_{uv}(F)$ up to depth $meet(u,v)-1$ as an initial part of a binary branching process with birth probability $(1-p)^2$. Though our process deviates at the last depth from the binary branching process, the change is the increased birth probability. Therefore, the probability that there is a descendant in generation $meet(u,v)$ only increases. It follows that the probability of $T_{uv}(F)$ having a node at depth $meet(u,v)$ is at least the survival probability $(1-\xi_{(1-p)^2})$ of the branching process, provided that neither u nor v is in F. The probability that neither u nor v is in F is $(1-p)^2$. Therefore the probability that u and v are confluent in $\mathcal{B}_m\langle F\rangle$ is at least $(1-p)^2(1-\xi_{(1-p)^2}) = \theta_p$. □

If the confluence of pairs were mutually independent, then we would be done; we would take p small enough so that θ_p is greater than $1-\delta$ and then apply the Chernoff bound to conclude that $Conf_F(v)$ is δ-dense with high probability for any $v \in Left(\mathcal{B}_m)$. We cope with the dependency in the following way.

Fix a positive constant $\tau < 1$ and let α be a constant that satisfies

$$0 < \alpha/(1-\alpha) < \tau(1+2\log(1-p))/(1-2\log(1-p)).$$

We assume $\log(1-p) > -1/2$, or equivalently $p < 1-\sqrt{2}/2$, so that the above range for $\alpha/(1-\alpha)$ is nonempty. Set $s = \lceil (1-\alpha)m \rceil$. In the following reasoning, we view $\mathcal{B}_m$ as split at level s and work with s-stage subbutterflies L_y, $y \in \{0,1\}^{m-s}$, starting at level 0 and $m-s$-stage subbutterflies R_x, $x \in \{0,1\}^s$, starting at level s. More precisely, L_y consists of the nodes $\{\langle i, xy\rangle \mid x \in \{0,1\}^s, i \in [0,\ldots,s]\}$ and R_x consists of the nodes $\{\langle i, xy\rangle \mid y \in \{0,1\}^{m-s}, i \in [s,\ldots,m]\}$. We call each L_y a *left subbutterfly* and R_x a *right subbutterfly*. Observe that, for each pair of left and right subbutterflies L_y and R_x, there is a unique row of $\mathcal{B}_m$ that intersects both L_y and R_x, namely row xy. For each node $v \in Left(\mathcal{B}_m)$, let $y(v)$ denote the length $m-s$ suffix of the row index of v. Note that $y(u) = y(v)$ if and only if $meet(u,v) \le s$.

Let $F \in \mathbf{randsub}(V(\mathcal{B}_m), p)$. For each pair of nodes $u, v \in Left(\mathcal{B}_m)$ such that $meet(u,v) > s$, let E_{uv} denote the event that the confluence tree $T_{uv}(F)$ has at least $(2(1-p)^2)^{\tau s}$ nodes at depth s. Note that $(2(1-p)^2)^s$ is the expected number of generation s descendants in a binary branching process with birth probability $(1-p)^2$. Thus, informally, E_{uv} is the event that the branching process associated to the confluence tree of u and v thrives up to generation s.

LEMMA 3.5. *$P(E_{uv}) \ge \theta_p - o(1)$ as $m \to \infty$.*

Proof. Since $meet(u,v) > s$, assuming that $u, v \notin F$, we can view the confluence tree $T_{uv}(F)$ up to depth s as a binary branching process with birth probability $(1-p)^2$. Apply Lemma 3.3 to this branching process. □

We next show that event E_{uv} implies the confluence of u and v with high probability.

LEMMA 3.6. *For every $u, v \in Left(\mathcal{B}_m)$ such that $meet(u,v) > s$, the probability that u and v are confluent in $\mathcal{B}_m\langle F\rangle$ conditional on the event E_{uv} is at least $1-2^{-2^{\alpha m}}$.*

Proof. Fix $u, v \in Left(\mathcal{B}_m)$ such that $meet(u,v) > s$. Note that $meet(u,v) > s$ implies $L_{y(u)} \ne L_{y(v)}$. Let W be the set of nodes at depth s of $T_{uv}(F)$ and suppose that event E_{uv} occurs, i.e., $|W| \ge (2(1-p)^2)^{\tau s}$. Let $w \in W$; w is a binary string of length s such that the two monotone paths with label w starting at u and v both avoid F. Let u_w and v_w be the nodes at which these monotone paths end, respectively. Since the row indices of u_w and v_w both have the same prefix w, they are in the same right subbutterfly R_w. (See Figure 3.) The probability that u_w and v_w are confluent in $R_w\langle F\rangle$ is at least $(1-p)^{2(m-s)}$, considering only one pair of monotone paths

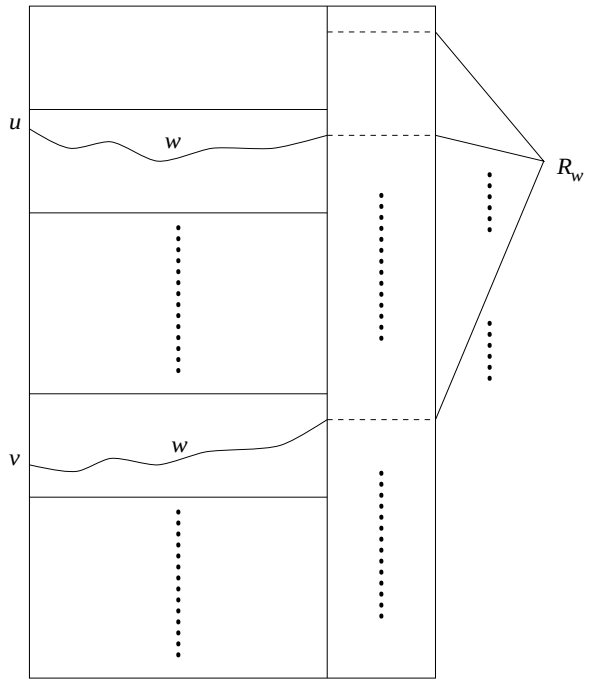

FIG. 3. *Confluent paths lead to a common right subbutterfly.*

that potentially connect these two nodes. Note here that conditioning on event E_{uv} does not affect the selection of faulty nodes at levels higher than s. Because this event that u_w and v_w are confluent in $R_w\langle F\rangle$ is independent for each w, and because $|W| \geq (2(1-p)^2)^{\tau s}$, the probability that none of these subbutterflies completes the confluence between u and v is at most

$$\begin{aligned}(1-(1-p)^{2(m-s)})^{(2(1-p)^2)^{\tau s}} &\leq e^{-(1-p)^{2(m-s)}(2(1-p)^2)^{\tau s}} \\ &\leq e^{-(1-p)^{2\alpha m}(2(1-p)^2)^{\tau(1-\alpha)m}} \\ &\leq e^{-2^{\alpha m}},\end{aligned}$$

where the last inequality follows from $(2(1-p)^2)^{\tau(1-\alpha)m} > (2/(1-p)^2)^{\alpha m}$ which is immediate from our choice of α. □

Let u be a node in $\mathit{Left}(\mathcal{B}_m)$ and let H be a fixed subgraph of $L_{y(u)}$. For each $v \in \mathit{Left}(\mathcal{B}_m)$ such that $y(v) \neq y(u)$, consider the conditional probability $P(E_{uv} \mid L_{y(u)}\langle F\rangle = H)$. Since this conditional event depends only on $L_{y(v)}\langle F\rangle$, this probability does not depend on the location of $L_{y(v)}$ in the entire butterfly. It does not depend on the location of v in $L_{y(v)}$ either, because for any node v' in $\mathit{Left}(L_{y(v)})$, there exists an automorphism of $L_{y(v)}$ that maps v to v' and maps each node in $\mathit{Right}(L_{y(v)})$ to itself; the above conditional probability is invariant under this automorphism. Therefore, this conditional probability does not depend on the choice of v as long as $y(v) \neq y(u)$. We say that a subgraph H of $L_{y(u)}$ is *η-good for u*, if this conditional probability $P(E_{uv} \mid L_{y(u)}\langle F\rangle = H)$ is at least η.

LEMMA 3.7. *For any positive constant $\eta < \theta_p$, the probability that $L_{y(u)}\langle F\rangle$ is η-good for u is at least $\zeta - o(1)$, where $\zeta = (\theta_p - \eta)/(1-\eta) > 0$.*

Proof. By Lemma 3.5, we have

$$P(E_{uv}) \geq \theta_p - o(1)$$

for every pair u, v such that $y(u) \neq y(v)$. On the other hand,

$$\begin{aligned} P(E_{uv}) &= \sum_{H \subseteq L_{y(u)}} P(E_{uv} \mid L_{y(u)}\langle F\rangle = H) P(L_{y(u)}\langle F\rangle = H) \\ &< \sum_{H\colon \eta\text{-good}} 1 \cdot P(L_{y(u)}\langle F\rangle = H) + \sum_{H\colon \text{not } \eta\text{-good}} \eta P(L_{y(u)}\langle F\rangle = H) \\ &= 1 \cdot P(L_{y(u)}\langle F\rangle \text{ is } \eta\text{-good}) + \eta P(L_{y(u)}\langle F\rangle \text{ is not } \eta\text{-good}) \\ &= (1-\eta) P(L_{y(u)}\langle F\rangle \text{ is } \eta\text{-good}) + \eta. \end{aligned}$$

Combining these two inequalities, we get $(1-\eta)P(L_{y(u)}\langle F\rangle \text{ is } \eta\text{-good}) + \eta > \theta_p - o(1)$, from which the required bound follows. □

LEMMA 3.8. *Let δ, $0 < \delta < 1$ be given and suppose $\theta_p > 1-\delta$. Then the probability is at least $1 - 2^{-\Omega(2^{\alpha m})}$ that there exists some $v_0 \in \mathit{Left}(\mathcal{B}_m)$ such that $\mathit{Conf}_F(v_0)$ is δ-dense.*

Proof. Choose η and ϵ so that $1 - \delta < \eta(1-2\epsilon) < \eta < \theta_p$. Consider the following experiment in which we expose nodes (more precisely, expose their membership to the fault set F) in three stages. Let $t = \lfloor \epsilon 2^{\alpha m} \rfloor$ and let Y be an arbitrary subset of $\{0,1\}^{m-s}$ with $|Y| = t$. In the first stage we look at the left subbutterflies L_y, $y \in Y$ and expose faulty nodes in those subbutterflies. For each $y \in Y$, designate $v_y \in \mathit{Left}(L_y)$ arbitrarily and let A_y denote the event that $L_y\langle F\rangle$ is η-good for v_y. Events A_y are mutually independent and $P(A_y) = \zeta - o(1)$, $\zeta > 0$ for each $y \in Y$ by Lemma 3.7. Therefore, with probability at least $1 - 2^{-\Omega(t)} = 1 - 2^{-\Omega(2^{\alpha m})}$, at least one of the events A_y occurs.

Suppose now that at least one of the events A_y does occur. Thus, we have some node v_0 such that $L_{y(v_0)}\langle F\rangle$ is η-good for v_0. We now enter the second stage of the experiment and expose nodes in the remaining $2^{m-s} - t$ subbutterflies L_y, $y \notin Y$. Let $V = \bigcup_{y \notin Y} \mathit{Left}(L_y)$ and let $U = \{u \in V \mid E_{uv_0}\}$.

Having fixed this set U, we enter the third stage and now expose nodes on levels higher than s. By Lemma 3.6, for each $u \in U$, the probability that u is confluent with v_0 is at least $1 - 2^{-2^{\alpha m}}$ and therefore, the probability that every $u \in U$ is confluent with v_0 is at least $1 - 2^m 2^{-2^{\alpha m}} = 1 - 2^{-\Omega(2^{\alpha m})}$. Thus, with at least this probability, $U \subseteq \mathit{Conf}_F(v_0)$.

Now we return to the second stage and show that U is δ-dense with high probability. Fix $i \in [m]$ and $b \in \{0,1\}$ and let $V' = \{\langle 0, z\rangle \in V \mid \text{the } i\text{th bit of } z \text{ is } b\}$. Note $|V'| \geq 2^{m-1} - \epsilon 2^m = (1-2\epsilon)2^{m-1}$ and therefore, the expected number of nodes $u \in V'$ such that E_{uv_0} occurs is at least $\eta(1-2\epsilon)2^{m-1}$ because $L_{y(v_0)}$ is η-good for v_0. Noting that $\eta(1-2\epsilon) > 1-\delta$, we estimate the tail probability that the number of such nodes is less than $(1-\delta)2^{m-1}$ in the following way. Partition V' into 2^s subsets V'_x, $x \in \{0,1\}^s$, where $\langle 0, z\rangle$ is in V'_x if and only if x is the length s prefix of z. Thus, each subset contains at most one node from each of the subbutterflies L_y, $y \in Y$, and the size of each subset is at least $(1-\epsilon)2^{m-t-1} = \Omega(2^{\alpha m})$. Since the events E_{uv_0} are mutually independent for nodes u belonging to a single subset, we can apply the partition Chernoff bound (Proposition 2.3): the probability is $1 - 2^{-\Omega(2^{\alpha m})}$ that we have at least $(1-\delta)2^{m-1}$ nodes $u \in V'$ for which E_{uv_0} occurs. The probability that this is true for all choices of i and b, hence implying that U is δ-dense, is at least $1 - 2m2^{-\Omega(2^{\alpha m})} = 1 - 2^{-\Omega(2^{\alpha m})}$. □

We have shown that Φ_m succeeds on $\mathcal{B}_m\langle p\rangle$ with probability at least $1-2^{-2^{\Omega(m)}}$ which together with Lemma 3.2 establishes Theorem 3.1.

COROLLARY 3.9. *For any positive constant $\delta < 1/2$ and a positive constant p such that $\theta_p > 1-\delta$, the probability is $1-2^{-2^{\Omega(m)}}$ that $\mathcal{B}_m\langle p\rangle$ contains a δ-dense set U_j on each level $j \in [0,\dots,m]$ such that $\bigcup_j U_j$ is connected.*

Proof. Let F be randomly chosen from $\mathbf{randsub}(V(\mathcal{B}_m), p)$. For each $j \in [0,\dots,\lceil m/2\rceil]$, apply the theorem to each subbutterfly starting at level j and ending at level m. Because there are only $O(2^m)$ subbutterflies to consider and each subbutterfly has at least $m/2$ stages, each of those subbutterflies will yield a δ-dense subset of its left end, which is connected in $\mathcal{B}_m\langle F\rangle$ with probability $1-2^{-2^{\Omega(m)}}$. Collect these δ-dense subsets from all subbutterflies starting at level j and call their union U_j. Then U_j is δ-dense by definition. We claim that $U = \bigcup_j U_j$ is connected in $\mathcal{B}_m\langle F\rangle$. To see this, focus on a particular subbutterfly starting at level j, $j \le \lceil m/2\rceil - 1$ and on one of its two subbutterflies starting at level $j+1$. The δ-dense sets of these subbutterflies we have obtained share at least one row, since $\delta < 1/2$ by the assumption; hence, these sets are connected through a straight edge. Applying this argument to every interface of two subbutterflies starting at consecutive levels, we conclude that U is connected. Applying the argument symmetrically to the right half of $\mathcal{B}_m\langle F\rangle$, we obtain a set U' that is connected in $\mathcal{B}_m\langle F\rangle$ and includes a δ-dense set on each level j, $\lfloor m/2\rfloor \le j \le m$. Now, U and U' share at least one node and thus are connected. □

4. $(O(m^{\log 6}), m^{O(1)})$-routing. In this section, we prove the following theorem which improves the congestion of routing from $O(2^m)$ of the previous section to $m^{O(1)}$, at the expense of the path length of routing. Due to the inductive structure of the proof, we need to consider end-to-end routings instead of routings among nodes at one end of the butterfly.

THEOREM 4.1. *Let δ and p be positive constants satisfying $\delta < 1/2$ and $\theta_p > 1-\delta$. Then, with probability $1-2^{-2^{\Omega(m)}}$, $\mathcal{B}_m\langle p\rangle$ contains a δ-dense set U of nodes on level 0 and a δ-dense set V of nodes on level m such that (U,V) is $(O(m^{\log 6}), m^{O(1)})$-routable.*

Fix $\delta < 1/2$. In the following, we define a mapping Ψ_m that takes a faulty butterfly $\mathcal{B}_m\langle F\rangle$ and is supposed to give a pair (U,V) such that U and V are δ-dense subsets of $\mathit{Left}(\mathcal{B}_m)$ and $\mathit{Right}(\mathcal{B}_m)$, respectively, and such that (U,V) is $(O(m^{\log 6}), m^{O(1)})$-routable in $\mathcal{B}_m\langle F\rangle$. We will later show that Ψ_m succeeds in giving such a pair with high probability when applied to $\mathcal{B}_m\langle p\rangle$, where p is sufficiently small.

The definition of Ψ_m is by induction on m. The induction is based on the following structure of the butterfly.

First consider the $2m$-stage butterfly $\mathcal{B}_{2m}$. Split this butterfly at level m, let L_y, $y \in \{0,1\}^m$ be the left m-stage subbutterflies, and let R_x, $x \in \{0,1\}^m$ be the right m-stage subbutterflies. As before, the node set of L_y is $\{\langle i, xy\rangle \mid x \in \{0,1\}^m, i \in [0,\dots,m]\}$ and the node set of R_x is $\{\langle i, xy\rangle \mid y \in \{0,1\}^m, i \in [m,\dots,2m]\}$. Observe as before that each pair (L_y, R_x) intersects at exactly one node $\langle m, xy\rangle$. To depict this global structure of $\mathcal{B}_{2m}$, we define a complete bipartite graph $\mathcal{S}_{2m}$ on node sets $\{l_y \mid y \in \{0,1\}^m\}$ and $\{r_x \mid x \in \{0,1\}^m\}$. The intention here is to associate left subbutterfly L_y with node l_y, right subbutterfly R_x with node r_x, and the intersection node of L_y and R_x with edge (l_y, r_x) of $\mathcal{S}_{2m}$. We call $\mathcal{S}_{2m}$ the *skeleton graph* of $\mathcal{B}_{2m}$.

We have similar definitions for the odd-stage butterfly $\mathcal{B}_{2m+1}$. The left subbutterfly L_y, $y \in \{0,1\}^{m+1}$ is an m-stage subbutterfly consisting of the nodes $\{\langle i, x'y\rangle \mid x' \in$

$\{0,1\}^m, i \in [0,\ldots,m]\}$ and the right subbutterfly R_x, $x \in \{0,1\}^{m+1}$ is an m-stage subbutterfly consisting of the nodes $\{\langle i, xy'\rangle \mid y' \in \{0,1\}^m, i \in [m+1,\ldots,2m]\}$. Observe that each pair (L_y, R_x) is connected by exactly one edge, $(\langle m, x'y\rangle, \langle m+1, xy'\rangle)$, where x' is the length m prefix of x and y' is the length m suffix of y. The skeleton graph $\mathcal{S}_{2m+1}$ is defined similarly, with edge (l_y, r_x) of $\mathcal{S}_{2m+1}$ now corresponding to the edge of $\mathcal{B}_{2m+1}$ that connects L_y and R_x.

As we remove faulty nodes from the butterfly $\mathcal{B}_{2m}$ or $\mathcal{B}_{2m+1}$, we will remove nodes and edges of its skeleton graph, in a manner to be made precise later. Roughly speaking, if the shared node of L_y and R_x of $\mathcal{B}_{2m}$ is removed or disconnected from the major connected component of L_y or R_x, then we remove edge (l_y, r_x) of the skeleton graph. If the resulting subgraph of the skeleton graph is dense, we can expect that the faulty butterfly is still capable of efficient routing. This motivates the following definition of a measure of the density of a bipartite graph.

Let u and v be nodes on the same side of a bipartite graph. The *codegree* of u and v is the number of common neighbors of u and v. The *minimum codegree* of a bipartite graph is the minimum of codegrees of all pairs (u, v) where u and v are nodes on the same side of the bipartite graph.

Now we are ready to define the mapping Ψ_m. The definition depends on positive constants δ, g, p, α, m_0, and β, chosen as follows. We have already fixed $\delta < 1/2$. Fix $g \le 1/2$ and, according to Corollary 3.9, choose positive constants p, $\alpha < 1/2$, and m_0' so that $\mathcal{B}_m\langle p\rangle$ contains a connected set that includes a $\delta(1-g)$-dense set at each level with probability at least $1 - 2^{-2^{\alpha m}}$ for every $m \ge m_0'$. Choose $\beta < (1-2\delta)^2$. Let $m_0 \ge m_0'$ be a constant that satisfies the following conditions. Let $\mu_m = 2^{-2^{\alpha m}} 2^{m-1}$ and $T_m = \delta g (2g^{1/m_0})^m/2$. We require that for every $m \ge m_0$,

M1 $T_m \ge 2^{2\alpha m} + \log m + 3$,
M2 $e\mu_m/T_m < 1/2$,
M3 $2^{-2^{\alpha m}} \le \delta g^m$, and
M4 $e^{-c_\epsilon (1-2\delta)^2 2^m} \le 2^{-(2^{\alpha m}+2m+2)}$, where $\epsilon = (1-2\delta)^2/\beta - 1$ and c_ϵ is the constant in Proposition 2.1.

The meaning of these conditions will become clear when they are used later. We note here that all of these conditions can be satisfied by choosing m_0 sufficiently large.

Define $\delta_m = \delta(1 - g^{\frac{m}{m_0}})$ for every $m \ge m_0$. Note that δ_m is increasing in m and less than δ.

As the base case, we first define Ψ_m for $m_0 \le m < 2m_0$. Consider $\mathcal{B}_m$, $m_0 \le m < 2m_0$, and fix a fault set $F \subseteq V(\mathcal{B}_m)$. Suppose $\mathcal{B}_m\langle F\rangle$ contains a connected component C such that $C \cap \mathit{Left}(\mathcal{B}_m)$ and $C \cap \mathit{Right}(\mathcal{B}_m)$ are both δ_m-dense. Then, set $\Psi_m(\mathcal{B}_m\langle F\rangle) = (C \cap \mathit{Left}(\mathcal{B}_m), C \cap \mathit{Right}(\mathcal{B}_m))$, choosing one such C with an arbitrary criterion. Otherwise set $\Psi_m(\mathcal{B}_m\langle F\rangle) = (\emptyset, \emptyset)$, indicating the failure of the mapping.

Suppose Ψ_m is already defined. Now we define Ψ_{2m} and Ψ_{2m+1}. We first deal with Ψ_{2m}. Fix a fault set $F \subseteq V(\mathcal{B}_{2m})$. We apply Ψ_m to each left subbutterfly $L_y\langle F\rangle$ and each right subbutterfly $R_x\langle F\rangle$ of $\mathcal{B}_{2m}\langle F\rangle$ through the standard isomorphisms. More precisely, for each $y \in \{0,1\}^m$, let ψ_y denote the standard isomorphism mapping L_y to $\mathcal{B}_m$ and set $(U_y, V_y) = \psi_y^{-1}(\Psi_m(\psi_y(L_y\langle F\rangle)))$. Similarly for each $x \in \{0,1\}^m$, let ψ_x' denote the standard isomorphism mapping R_x to $\mathcal{B}_m$ and set $(W_x, Z_x) = \psi_x'^{-1}(\Psi_m(\psi_x'(R_x\langle F\rangle)))$. The *skeleton graph* $\mathcal{S}_{2m}(F)$ *of the faulty butterfly* $\mathcal{B}_{2m}\langle F\rangle$ is a subgraph of $\mathcal{S}_{2m}$, where (1) node l_y is included if and only if $V_y \ne \emptyset$; (2) node r_x is included if and only if $W_x \ne \emptyset$; and (3) edge (l_y, r_x) is included if and only if $V_y \cap W_x \ne \emptyset$. We set

$$\Psi_{2m}(\mathcal{B}_{2m}\langle F\rangle) = \left(\bigcup_{y\in\{0,1\}^m} U_y, \bigcup_{x\in\{0,1\}^m} Z_x\right),$$

if the minimum codegree of $\mathcal{S}_{2m}(F)$ is at least $\beta 2^m$ and, moreover, $\bigcup_y U_y$ and $\bigcup_x Z_x$ are both δ_{2m}-dense; otherwise set

$$\Psi_{2m}(\mathcal{B}_{2m}\langle F\rangle) = (\emptyset, \emptyset).$$

Ψ_{2m+1} is defined similarly. We apply Ψ_m to subbutterflies $L_y\langle F\rangle$ and $R_x\langle F\rangle$ of $\mathcal{B}_{2m+1}\langle F\rangle$ to obtain pairs (U_y, V_y) and (W_x, Z_x). The skeleton graph $\mathcal{S}_{2m+1}(F)$ is also defined similarly as above, with item (3) replaced by: (3′) edge (l_y, r_x) is included if and only if there is some $v \in V_y$ and some $w \in W_x$ such that (v, w) is an edge of $\mathcal{B}_{2m+1}$. Then, set $\Psi_{2m+1}(\mathcal{B}_{2m+1}\langle F\rangle) = (\bigcup_y U_y, \bigcup_x Z_x)$ if the minimum codegree of $\mathcal{S}_{2m+1}(F)$ is at least $\beta 2^{m+1}$ and, moreover, $\bigcup_y U_y$ and $\bigcup_x Z_x$ are both δ_{2m+1}-dense; otherwise set $\Psi_{2m+1}(\mathcal{B}_{2m+1}\langle F\rangle) = (\emptyset, \emptyset)$.

It is easy to see that we can compute $\Psi_m(\mathcal{B}_m\langle F\rangle)$ for given $\mathcal{B}_m\langle F\rangle$ in time polynomial in the number of nodes of $\mathcal{B}_m$.

We say that Ψ_m *succeeds on* $\mathcal{B}_m\langle F\rangle$ if $\Psi_m(\mathcal{B}_m\langle F\rangle) \neq (\emptyset, \emptyset)$; otherwise it *fails*. By definition, Ψ_m gives δ-dense sets when it succeeds. To show that it also gives an $(O(m^{\log 6}), m^{O(1)})$-routable pair, we first need the following lemma, which is intended to be applied to the skeleton bipartite graph of a faulty butterfly.

LEMMA 4.2. *Let G be a bipartite graph on node sets A and B such that $|A|, |B| \leq n$ and the minimum codegree of G is at least βn, where β is some positive constant. Let Q be an arbitrary multiset of pairs from $A \times B$ in which each node appears at most n times. Then we can route all pairs of Q in G with a multiset of paths of length 3 so that each edge is used at most Γ_β times, where Γ_β is some constant depending only on β.*

Proof. Assume, without loss of generality, that $2/\beta$ is an integer (otherwise reason with the largest $\beta' < \beta$ for which this is true) and set $\Gamma_\beta = \frac{4}{\beta}(\frac{4}{\beta} + 1)$. We prove a stronger claim by induction on the size of Q: the multiset of paths described above can be chosen to have an additional property that each node appears as an internal node of at most $2n/\beta$ paths from the multiset.

The base case $Q = \emptyset$ is trivial. Suppose Q is nonempty and the claim holds for all Q' with $|Q'| = |Q| - 1$. Removing one pair (a, b) of Q, we can route the remaining pairs of Q in G with paths Π, as in the claim, by the induction hypothesis. We show that we can add a path for (a, b) to Π without violating the constraints in the claim. We say that an edge of G is *saturated* (with respect to Π) if the edge appears Γ_β times in Π. Similarly, a node of G is *saturated* if it appears as an internal node in $2n/\beta$ paths of Π. Because each node appears at most n times in Q, Q contains at most n^2 pairs. Therefore, the number of paths in Π which equals the number of pairs in $Q \setminus \{(a, b)\}$ is strictly less than n^2. Because each path has exactly one internal node in A, these paths in Π can saturate strictly fewer than $\beta n/2$ nodes of A; the same holds for B. Next consider the set of edges incident to an arbitrary node c. Because at most n paths of Π end at c and at most $2n/\beta$ paths go through c, these edges are used at most $(\frac{4}{\beta} + 1)n$ times in total. Therefore, at most $(\frac{4}{\beta} + 1)n/\Gamma_\beta = \beta n/4$ edges incident to c are saturated.

Now we can choose the path for (a, b). Since a has at least βn edges, of which at least $\beta n - \beta n/4 > \beta n/2$ are unsaturated, there is at least one unsaturated neighbor, say b', such that the edge (a, b') is unsaturated. We take this b' as the first intermediate

node in the path. Nodes b and b' have at least βn common neighbors, of which at least $\beta n - \beta n/4 - \beta n/4 = \beta n/2$ are reachable from both b' and b through unsaturated edges. One of these $\beta n/2$ neighbors must be unsaturated, completing a path for (a, b) free of saturated edges or nodes. Adding this path to Π preserves the conditions in the claim. □

LEMMA 4.3. *If Ψ_m succeeds on $\mathcal{B}_m\langle F\rangle$ and $\Psi_m(\mathcal{B}_m\langle F\rangle) = (U, V)$, then (U, V) is $(c_1 m^{\log 6}, c_2 m^{\log \Gamma_\beta})$-routable in $\mathcal{B}_m\langle F\rangle$ where c_1 and c_2 are some constants independent of m, β is the constant fixed in the definition of Ψ_m, and Γ_β is the constant given in Lemma 4.2.*

Proof. The proof is by induction on m. Since m_0 is a constant, we can choose c_1 and c_2 so that the statement holds for all Ψ_m in the base cases $m_0 \le m < 2m_0$. Suppose the statement holds for Ψ_m. We first show that it also holds for Ψ_{2m}. Fix a faulty butterfly $\mathcal{B}_{2m}\langle F\rangle$, let $\Psi_{2m}(\mathcal{B}_{2m}\langle F\rangle) = (U, V)$, and assume U and V are nonempty. Recall the definition of $\Psi_{2m}(\mathcal{B}_{2m}\langle F\rangle)$ and notation used there. In particular, (U_y, V_y), $y \in \{0,1\}^m$ is the pair produced by Ψ_m applied to the left subbutterfly $L_y\langle F\rangle$ of $\mathcal{B}_{2m}\langle F\rangle$, and (W_x, Z_x), $x \in \{0,1\}^m$ is the pair for the right subbutterfly $R_x\langle F\rangle$. Let $A = \{l_y \mid V_y \neq \emptyset\}$ and $B = \{r_x \mid W_x \neq \emptyset\}$. Recall that A and B are the node sets of the skeleton graph $\mathcal{S}_{2m}(F)$.

Now, let $Q \subseteq U \times V$ be an arbitrary one-to-one routing request. We define a many-to-many routing request $\hat{Q}$ on (A, B) induced by Q as follows. For each node $u \in U$, let $l(u)$ denote $l_y \in A$ such that u belongs to L_y and, for each node $v \in V$, let $r(v)$ denote $r_x \in B$ such that v belongs to R_x. Now, we construct multiset $\hat{Q}$ by putting an occurrence of $(l(u), r(v))$ for each pair (u, v) of Q. Then, each l_y or r_x appears at most 2^m times in $\hat{Q}$. On the other hand, by the definition of Ψ_m, the minimum codegree of $\mathcal{S}_{2m}(F)$ is at least $\beta 2^m$. Therefore, we can apply Lemma 4.2 to $\hat{Q}$ and $\mathcal{S}_{2m}(F)$, with $n = 2^m$, obtaining a realization of $\hat{Q}$ with paths of length exactly 3 and with congestion at most Γ_β.

We now translate this realization of $\hat{Q}$ on $\mathcal{S}_{2m}(F)$ back to the realization of Q on $\mathcal{B}_{2m}\langle F\rangle$. Suppose $(l_y, r_{x'}, l_{y'}, r_x)$ is the path in $\mathcal{S}_{2m}(F)$ assigned to pair $(l(u), r(v)) \in \hat{Q}$. The path from u to v in our realization of Q consists of four parts: a path in L_y from u to the intersection node of L_y and $R_{x'}$; a path in $R_{x'}$ from this node to the intersection node of $R_{x'}$ and $L_{y'}$ via some node in $Z_{x'}$; a path from this intersection node to the intersection node of $L_{y'}$ and R_x via some node in $U_{y'}$; and finally a path in R_x from this intersection node to v. (See Figure 4.) When we provide such paths for all pairs in Q, the number of times the intersection node of a particular pair L_y and R_x appears in the above path construction is exactly the congestion of the edge (l_y, r_x) in our realization of $\hat{Q}$ in $\mathcal{S}_{2m}(F)$, which is at most Γ_β. Thus, within each subbutterfly L_y (or R_x), the total routing request can be decomposed into at most Γ_β one-to-one routing requests for the pair (U_y, V_y) (or (W_x, Z_x), respectively). Because all pairs (U_y, V_y) and (W_x, Z_x) involved are $(c_1 m^{\log 6}, c_2 m^{\log \Gamma_\beta})$-routable by the induction hypothesis, each subbutterfly can realize all the routing requirements with path length at most $c_1 m^{\log 6}$ and congestion at most $\Gamma_\beta c_2 m^{\log \Gamma_\beta} = c_2 (2m)^{\log \Gamma_\beta}$. Since the path assigned to a pair $(l(u), r(v))$ is a concatenation of six end-to-end routing paths in the subbutterflies, its length is at most $6 \cdot c_1 m^{\log 6} = c_1 (2m)^{\log 6}$. This completes the proof that Ψ_{2m} produces a $(c_1 (2m)^{\log 6}, c_2 (2m)^{\log \Gamma_\beta})$-routable pair when it succeeds.

The proof for Ψ_{2m+1} is similar and therefore omitted. We note that we need a variation of Lemma 4.2 which assumes each node to appear in the routing request at most $n/2$ times and gives the congestion bound of $\Gamma_\beta/2$. □

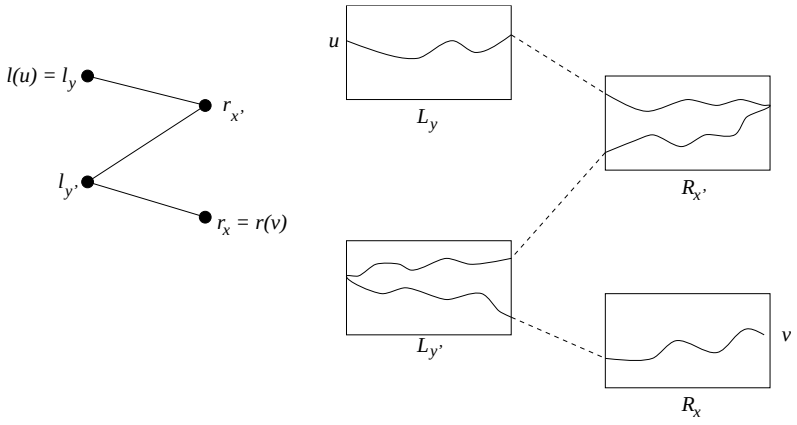

FIG. 4. *Bipartite routing to butterfly routing.*

It remains to show that the probability of Ψ_m failing is small.

LEMMA 4.4. *Let p and α be constants as fixed in the definition of Ψ_m. Then, the probability that $\Psi_m(\mathcal{B}_m\langle p\rangle) = (\emptyset, \emptyset)$ is at most $2^{-2^{\alpha m}}$.*

Proof. The proof is by induction on m. The base cases, $m_0 \le m < 2m_0$, are immediate from the definition of Ψ_m.

For the induction step, we assume that the claim holds for Ψ_m, $m \ge m_0$ and show that it also holds for Ψ_{2m} and Ψ_{2m+1}. We first consider Ψ_{2m}. Let $F \in$ **randsub**$(V(\mathcal{B}_{2m}), p)$, let $\Psi_{2m}(\mathcal{B}_{2m}\langle F\rangle) = (U, V)$, and recall the notation in the definition of Ψ_{2m}. More specifically, Ψ_m applied to the left subbutterfly $L_y\langle F\rangle$ yields (U_y, V_y) and, similarly, Ψ_m applied to the right subbutterfly $R_x\langle F\rangle$ yields (W_x, Z_x). There are two ways in which $\Psi_{2m}(\mathcal{B}_{2m}\langle F\rangle)$ fails: (1) Ψ_m applied to left and right subbutterflies fails on too many subbutterflies and thus $\bigcup_y U_y$ or $\bigcup_x V_x$ fails to be δ_{2m}-dense; (2) the minimum codegree of the skeleton graph of $\mathcal{B}_{2m}\langle F\rangle$ is less than $\beta 2^m$.

We bound the probability of each of these cases in turn.

We first bound the probability that $\bigcup_y U_y$ is not δ_{2m}-dense. Recall that δ_m is defined to be $\delta(1 - g^{\frac{m}{m_0}})$ for every $m \ge m_0$. Now define $\epsilon_m = \delta g^{(\frac{m}{m_0}+1)}$ so that $\delta_m + \epsilon_m \le \delta_{2m}$. Let Y_i^b, $i \in [m]$, $b \in \{0,1\}$, denote the set of bit strings $y \in \{0,1\}^m$ such that the ith bit of y is b and $U_y = \emptyset$.

CLAIM 4.5. *If $\bigcup_y U_y$ is not δ_{2m}-dense, then $|Y_i^b| \ge \epsilon_m 2^{m-1}$ must hold for some i and b.*

Proof. Suppose $\bigcup_y U_y$ is not δ_{2m}-dense. Then, for some $h \in [2m]$ and $b' \in \{0,1\}$, the number of nodes of $\bigcup_y U_y$ whose row indices have b' as their hth bit must be less than $(1-\delta_{2m})2^{2m-1}$. Fix h and b' such that this holds and call this set of nodes U. We have two cases.

Case $h \le m$. Because each nonempty U_y, $y \in \{0,1\}^m$ is δ_m-dense, each such U_y contributes at least $(1-\delta_m)2^{m-1}$ nodes to U. Therefore, U_y must be empty for at least $\epsilon_m 2^m$ values of y because otherwise, $|U| \ge (1-\epsilon_m)2^m(1-\delta_m)2^{m-1} \ge (1-\delta_{2m})2^{2m-1}$, contradicting our assumption. Therefore, for any $i \in [m]$, we have $|Y_i^0 \cup Y_i^1| \ge \epsilon_m 2^m$. Choose any i and choose an appropriate b so that $|Y_i^b| \ge \epsilon_m 2^{m-1}$.

Case $h > m$. Set $i = h - m$ and $b = b'$. Note that each U_y is entirely included in U if the ith bit of y is b and is entirely excluded from U otherwise. Because each

nonempty U_y has at least $(1-\delta_m)2^m$ nodes, U_y must be empty for at least $\epsilon_m 2^{m-1}$ values of y such that the ith bit of y is b. □

Fix i and b. We bound the probability of event $|Y_i^b| \geq \epsilon_m 2^{m-1}$. Note the probability of $U_y = \emptyset$ for a fixed y is at most $2^{-2^{\alpha m}}$ by the induction hypothesis and, since this event is independent among $y \in Y_i^b$, we can use the Chernoff bound.

Applying Proposition 2.2, we have

$$P(|Y_i^b| \geq T_m) < \left(\frac{e\mu_m}{T_m}\right)^{T_m},$$

where $\mu_m = 2^{-2^{\alpha m}} 2^{m-1}$ and $T_m = \epsilon_m 2^{m-1}$. By condition M1 on the choice of m_0, we have $T_m \geq 2^{2\alpha m} + \log m + 3$. Moreover, we have $e\mu_m/T_m \leq 1/2$ by condition M2. Combining these inequalities, we get

$$P(|Y_i^b| \geq \epsilon_m 2^{m-1}) < \frac{1}{8m} 2^{-2^{2\alpha m}},$$

and because we have only $2m$ pairs (i,b) to consider,

$$P(\textstyle\bigcup_y U_y \text{ is not } \delta_{2m}\text{-dense}) < 2^{-2^{2\alpha m}-2}.$$

The bound for the probability that $\bigcup_x Z_x$ is not δ_{2m}-dense is the same.

We now bound the probability that the minimum codegree of $\mathcal{B}_{2m}\langle F\rangle$ is less than $\beta 2^m$. Let $v_{xy} = \langle m, xy\rangle$ denote the intersection node of L_y and R_x for each pair $x, y \in \{0,1\}^m$. We first claim that $P(v_{xy} \in W_x) \geq 1-\delta$. To show this, first note that Ψ_m gives δ_m-dense sets with probability at least $1 - 2^{-2^{\alpha m}}$ when applied to $R_x\langle F\rangle$. Each node of $\mathit{Left}(R_x)$ is equally likely to be in W_x due to the symmetry of Ψ_m with respect to automorphisms of $\mathcal{B}_m$. Thus, conditional on the event that W_x is δ_m-dense, which implies that $|W_x|/|\mathit{Left}(R_x)| \geq 1-\delta_m$, the probability that $v_{xy} \in W_x$ is at least $1-\delta_m$. It follows that the probability that $v_{xy} \in W_x$ is at least $1 - 2^{-2^{\alpha m}} - \delta_m$. By condition M3 on the choice of m, we have $2^{-2^{\alpha m}} + \delta_m \leq \delta(g^m + 1 - g^{\frac{m}{m_0}}) \leq \delta$, establishing the claim.

Fix distinct bit strings $y, y' \in \{0,1\}^m$. We bound the probability that nodes l_y and $l_{y'}$ are both in the skeleton graph $\mathcal{S}_{2m}(F)$ and the codegree of l_y and $l_{y'}$ is smaller than $\beta 2^m$. This probability is at most the conditional probability that the codegree of l_y and $l_{y'}$ is smaller than $\beta 2^m$ under the condition that l_y and $l_{y'}$ are nodes of $\mathcal{S}_{2m}(F)$. To bound this conditional probability, consider an experiment in which we expose the membership of nodes to F in two stages: in the first stage we expose the nodes in the left subbutterflies L_y and $L_{y'}$ and in the second stage we expose the remaining nodes. The first stage determines whether or not l_y and $l_{y'}$ are nodes of $\mathcal{S}_{2m}(F)$. Suppose that l_y and $l_{y'}$ are nodes of $\mathcal{S}_{2m}(F)$. Let $X_{yy'} = \{x \mid v_{xy} \in V_y, v_{xy'} \in V_{y'}\}$. Because both V_y and $V_{y'}$ are nonempty, and hence δ_m-dense, by the definitions of the skeleton graph and the mapping Ψ_m, we have $|V_y|, |V_{y'}| \geq (1-\delta)2^m$ and therefore $|X_{yy'}| \geq (1-2\delta)2^m$. Now consider R_x where $x \in X_{yy'}$. The only nodes of R_x that are exposed in the first stage of the experiment are v_{xy} and $v_{xy'}$. The condition $x \in X_{yy'}$ implies that these two nodes are revealed to be *not* in F. Thus, since the event that a fixed node is in W_x is increasing, the inequalities $P(v_{xy} \in W_x) \geq 1-\delta$ and $P(v_{xy'} \in W_x) \geq 1-\delta$ that we observed earlier are valid even when conditioned on the result of the first stage of the experiment. Therefore, we have

$$P(v_{xy}, v_{xy'} \in W_x) \geq 1 - 2\delta$$

in the second stage. Thus, the expected number of values of x such that $x \in X_{yy'}$ and $v_{xy}, v_{xy'} \in W_x$ is at least $(1-2\delta)^2 2^m$. Since the event in the second stage that both v_{xy} and $v_{xy'}$ are in W_x is mutually independent for different values of $x \in X_{yy'}$ and since $(1-2\delta)^2 > \beta$ by our choice of β, we can apply the Chernoff bound: the probability is at most $2^{-\Omega(2^m)}$ that the number of values of $x \in X_{yy'}$ such that $v_{xy}, v_{xy'} \in W_x$, or equivalently the codegree of l_y and $l_{y'}$, is less than $\beta 2^m$. By condition M4 on the choice of m_0, this probability bound is at most $2^{-(2^{\alpha m}+2m+2)}$.

Summing up this probability for all pairs of distinct $y, y' \in \{0,1\}^m$ and also considering the codegree of the pairs $r_x, r_{x'}$, the overall probability that the codegree condition is violated anywhere is at most $2^{-2^{\alpha m}-1}$.

Summing up the above two cases, we conclude that the probability that Ψ_{2m} fails is at most $2^{-2^{\alpha m}}$.

The analysis for Ψ_{2m+1} is similar and is omitted. □

Finally, Theorem 4.1 follows immediately from Lemmas 4.3 and 4.4.

5. Embedding. In this section we prove our main embedding results using the routing results in the previous sections.

The overall structure of our embedding is as follows. We look at the n-stage butterfly $\mathcal{B}_n$ as a collection of overlapping m-stage subbutterflies, where $m = \Theta(\log n)$. We partition each level of $\mathcal{B}_n$ into *blocks* based on these subbutterflies. A set of nodes is a *left-block* if it is *Left*(B) for some m-stage subbutterfly B; it is a *right-block* if it is *Right*(B) for some m-stage butterfly B. In our embedding, a node on level $i \in [0, \ldots, n-m]$ is mapped to a node within the left-block it belongs to; an edge in level $i \in [1, \ldots, n-m]$ joining two left-blocks *Left*(B) and *Left*(B') is mapped to a path that goes through B and B'. We call this part of the embedding the *left-embedding*. The mapping of nodes and edges in the last m stages are similar, with right-blocks replacing the role of left-blocks in the left-embedding. We call this part of the embedding the *right-embedding*. However, in the above scheme, the left- and right-embeddings give two possibly inconsistent mappings of nodes at level $n-m$. We resolve this problem by providing a path between the two images of each node on level $n-m$.

Let us formalize the above embedding strategy. A *range assignment* ρ for $\mathcal{B}_n$ is a pair of mappings (ρ_l, ρ_r), where ρ_l assigns to each m-stage subbutterfly B a subset of *Left*(B), and ρ_r assigns to each m-stage subbutterfly B ending at level $i \in [n-m, \ldots, n]$ a subset of *Right*(B). The intention of a range assignment ρ is to specify the range of the node mapping in our embedding; we map a node in each *Left*(B) to a node in $\rho_l(B)$ and map a node in each *Right*(B), where B is ending at level $i \in [n-m, \ldots, n]$, to a node in $\rho_r(B)$.

We say that a range assignment ρ is $(\lambda, \gamma, \delta, \beta)$-*good* for $\mathcal{B}_n\langle F\rangle$ if it satisfies the following three conditions C1, C2, and C3; we first describe the first two conditions.

- **C1** For every m-stage subbutterfly B of $\mathcal{B}_n$, $\rho_l(B)$ is disjoint from F, δ-dense, and (λ, γ)-routable in $B\langle F\rangle$.
- **C2** For every m-stage subbutterfly B of $\mathcal{B}_n$ that ends at level $i \in [n-m, \ldots, n]$, $\rho_r(B)$ is disjoint from F, δ-dense, and (λ, γ)-routable in $B\langle F\rangle$.

Condition C1 will ensure the existence of an efficient left-embedding and condition C2 an efficient right-embedding. To describe the third condition which would allow us to efficiently resolve the inconsistency of the left- and right-embeddings, we need some definitions. Let D be a $2m$-stage subbutterfly that ends at level n, let L_y, $y \in \{0,1\}^m$ be the left m-stage subbutterflies of D, and let R_x, $x \in \{0,1\}^m$ be the right m-stage subbutterflies of D. Define a bipartite graph $\mathcal{S}_D(\rho)$ to be a subgraph of the skeleton

graph $\mathcal{S}_{2m}$ in which all nodes are included and edge (l_y, r_x) is included if and only if $\rho_r(L_y) \cap \rho_l(R_x) \neq \emptyset$.

C3 For each $2m$-stage subbutterfly D that ends at level n, the bipartite graph $\mathcal{S}_D(\rho)$ has co-degree at least $\beta 2^m$.

LEMMA 5.1. *Let ρ be a range assignment that is $(\lambda, \gamma, \delta, \beta)$-good for $\mathcal{B}_n\langle F\rangle$. Let D be a $2m$-stage subbutterfly that ends at level n, let L_y, $y \in \{0,1\}^m$ be the left m-stage subbutterflies of D, and let R_x, $x \in \{0,1\}^m$ be the right m-stage subbutterflies of D. Then the set of nodes $\bigcup_y \rho_r(L_y) \cup \bigcup_x \rho_l(R_x)$ on level $n-m$ is $(8\lambda, (\Gamma_\beta+1)\gamma)$-routable in $D\langle F\rangle$, where Γ_β is the constant that depends on β as given in Lemma 4.2.*

Proof. The proof uses Lemma 4.2 and is similar to the proof of Lemma 4.3. The details are omitted. □

LEMMA 5.2. *If there exists a $(\lambda, \gamma, \delta, \beta)$-good range assignment for $\mathcal{B}_n\langle F\rangle$, where $\delta < 1/2$ and β are positive constants, then $\mathcal{B}_n$ can be embedded in $\mathcal{B}_n\langle F\rangle$ with $O(1)$ load, $O(\lambda)$ dilation, and $O(m\gamma)$ congestion.*

Proof. Let ρ be a $(\lambda, \gamma, \delta, \beta)$-good range assignment for $\mathcal{B}_n\langle F\rangle$. We first provide a left-embedding. Since $\rho_l(B)$ is δ-dense ($\delta < 1/2$) for each m-stage subbutterfly B, for each B we can map nodes of the left-block *Left*(B) to nodes of $\rho_l(B)$ with load at most 2; choose and fix such a mapping for each B. To provide the mapping of edges, consider an m-stage subbutterfly B that starts with level i, $i < n-m$. The left-block *Left*(B) is adjacent to two left-blocks on level $(i+1)$, one of which we call *Left*(B'). There are 2^m edges between *Left*(B) and *Left*(B') of which 2^{m-1} are straight edges and the rest are cross edges. We call a straight edge a *bridge* between these two blocks if it spans $\rho_l(B)$ and $\rho_l(B')$. Because $\rho_l(B)$ and $\rho_l(B')$ are both δ-dense, there are at least $(1-2\delta)2^{m-1}$ bridges between *Left*(B) and *Left*(B'). We map each edge between *Left*(B) and *Left*(B') to a path consisting of three parts: a path in B, a bridge, and a path in B'. To choose such a path for each edge, we first choose a bridge (x, y) for each edge (u, v) so that each bridge is chosen for at most $2/(1-2\delta)$ edges. Let $u' \in \rho_l(B)$ and $v' \in \rho_l(B')$, respectively, denote the nodes to which u and v are mapped. Then we connect u' with x by a path of $B\langle F\rangle$ and connect y with v' by a path of $B'\langle F\rangle$. The routing requirements in $B\langle F\rangle$ generated by all edges between *Left*(B) and *Left*(B') can be decomposed into at most $2/(1-2\delta)$ one-to-one routing requests on $\rho_l(B)$, because each node of $\rho_l(B)$ appears at most that many times as the endpoint x of a bridge. Therefore, they can be realized by a set of paths with length at most $O(\lambda)$ and congestion at most $O(\gamma)$. The routing in $B'\langle F\rangle$ is done similarly. To provide paths for every adjacent pairs of blocks, we have to multiply the congestion by $4m$, because each block is adjacent to four blocks (to the right and to the left) and each edge belongs to m overlapping subbutterflies. We also have to add the congestion of an edge as a bridge, but this is at most a constant because an edge can be a bridge of at most one pair of blocks. Therefore, the overall congestion for the left-embedding is $O(m\gamma)$. The dilation is clearly $O(\lambda)$.

The right-embedding is provided similarly using condition C2 on the range assignment. Let ψ_1 denote the left-embedding and ψ_2 denote the right-embedding. Our final task is to provide a path between $\psi_1(v)$ and $\psi_2(v)$ for each node v on level $n-m$. Let D_v denote the $2m$-stage subbutterfly of $\mathcal{B}_n$ ending at level n and containing node v. Then, D_v also contains both $\psi_1(v)$ and $\psi_2(v)$. Now, for each such subbutterfly D, consider the routing request $Q = \{(\psi_1(v), \psi_2(v)) \mid D_v = D\}$. Since the loads of ψ_1 and ψ_2 are both 2, we can decompose Q into at most two one-to-one routing requests. Therefore, by Lemma 5.1 Q can be realized by paths of length $O(\lambda)$ and congestion $O(\gamma)$. Our final embedding maps a node v to $\psi_1(v)$ if v is on levels 0 up to $n-m$

and to $\psi_2(v)$ if v is on levels $n-m+1$ up to n; it maps an edge (u,v), where u is on level $n-m$ and v is on level $n-m+1$, to a path consisting of the path connecting $\psi_1(u)$ and $\psi_2(u)$ as given above, followed by the path $\psi_2(u,v)$. □

Now we are ready to prove our main theorem.

THEOREM 5.3. *For $p < 1-\sqrt{2/3}$, $\mathcal{B}_n\langle p\rangle$ admits a level-preserving self-embedding with $O(1)$ load, $O(\log^{\log 6} n)$ dilation, and $\log^{O(1)} n$ congestion, with probability at least $1-2^{-n}$.*

Proof. In view of Lemma 5.2, it suffices to show that we can find a good range assignment with high probability.

Fix $p < 1-\sqrt{2/3}$. Then, since $\theta_p \geq 1/2$, we can choose $\delta < 1/2$ so that $\theta_p > 1-\delta$. Choose positive constants α and $\beta < (1-2\delta)^2$ so that mapping Ψ_m applied to $\mathcal{B}_m\langle p\rangle$ gives a δ-dense $(O(m^{\log 6}), O(m^{\log \Gamma_\beta}))$-routable set on its leftmost level with probability at least $1-2^{-2^{\alpha m}}$ for large enough m.

Set $m = (1/\alpha)(\log n + 2)$ so that the probability of Ψ_m failing on a single m-stage subbutterfly of $\mathcal{B}_n\langle p\rangle$ is at most 2^{-4n}. We apply Ψ_m to these subbutterflies to obtain a range assignment. If Ψ_m yields a pair (U,V) for subbutterfly B, then we set $\rho_l(B) = U$ and, if B ends at one of the last $m+1$ levels, set $\rho_r(B) = V$. The probability that Φ_m fails at any of the subbutterflies is at most 2^{-3n} in total because there are fewer than 2^n such subbutterflies. If none fail, then we have a range assignment that satisfies conditions C1 and C2. Moreover, by an analysis similar to the one in the proof of Lemma 4.4, we can bound the probability to be at most 2^{-2n} that condition C3 is violated by the resulting range assignment ρ. Therefore, overall, with probability at least $1-2^{-n}$, the range assignment is $(O(m^{\log 6}), O(m^{\log \Gamma_\beta}), \delta, \beta)$-good for $\mathcal{B}_n\langle p\rangle$. Therefore by Lemma 5.2, with that probability we have an embedding with $O(1)$ load, $O(\log^{\log 6} n)$ dilation, and $O(\log^{\Gamma_\beta+1} n)$ congestion. □

Note that the embedding can be constructed by a deterministic algorithm with running time $N\log^{O(1)} N$, where N is the number of nodes of $\mathcal{B}_n$. This is because the mapping of each node or edge can be determined locally by looking at one or two subbutterflies consisting of $\log^{O(1)} N$ nodes. The time of such local computation, the main task of which is to compute the mapping Ψ_m, is polynomial in the size of the subbutterflies involved.

Using Theorem 3.1 instead of Theorem 4.1, we get the following theorem with better dilation although with exponentially worse congestion.

THEOREM 5.4. *For $p \leq 1-\sqrt{2/3}$, $\mathcal{B}_n\langle p\rangle$ admits a level-preserving self-embedding with $O(1)$ load, $O(\log n)$ dilation, and $n^{O(1)}$ congestion, with probability at least $1-2^{-n}$.*

6. A tight dilation lower bound for level-preserving embeddings. In this section, we prove a lower bound on the dilation of a level-preserving embedding in the faulty butterfly. The lower bound for $\mathcal{B}_n$ is $\log n - o(\log n)$, matching the upper bound of Theorem 5.4 up to a constant factor.

In fact, our lower bound is on a quantity called *drift* which in turn gives a lower bound for the dilation. We first define the drift of a path and then define the drift of a level-preserving embedding. Consider a path in $\mathcal{B}_n$ with an endpoint v at level i. The *drift* of the path from endpoint v is the maximum integer d such that the path contains a node on level $i-d$ or $i+d$. The *drift* of a path is the greater of the drifts of the path from its two endpoints. Finally, let Π denote the multiset of paths used in a level-preserving embedding, i.e., each single edge of the butterfly is mapped to a path of Π under the embedding. Then, the *drift* of the embedding is the maximum

of the drifts of the paths in Π. Note that the two endpoints of a path used in a level-preserving embedding always lie on consecutive levels. If such a path has drift d, then its length must be at least $2d-1$. Therefore, the dilation of a level-preserving embedding with drift d is at least $2d-1$.

Our strategy in proving the lower bound is to reduce the problem to the problem of *simple* embedding. We call a self-embedding of the butterfly *simple* if it is level-preserving and its dilation is one. We first show that, if a level-preserving self-embedding in $\mathcal{B}_n\langle p\rangle$ with drift d exists, then there must be a simple self-embedding in a smaller butterfly in which the distribution of faults depends on d as well as p. Then, we show that such a simple self-embedding is highly unlikely for small d.

Let i be in the range $d \le i \le n-d$, $x \in \{0,1\}^{i-d}$, and $y \in \{0,1\}^{n-i-d}$. The *d-disc on level i specified by x and y*, denoted by $D_d(x,y)$, is the set of nodes $\{\langle i, xwy\rangle \mid w \in \{0,1\}^{2d}\}$. Note that a d-disc on level i is the center level of a $2d$-stage subbutterfly. Also note that there is a path of drift at most d between every pair of vertices in a d-disc. The size of a d-disc is 2^{2d}.

We say two d-discs D and D' are *adjacent* if there exist $u \in D$ and $v \in D'$ such that u and v are adjacent in $\mathcal{B}_n$. Let $\mathcal{D}_{n,d}$ denote the graph where the nodes are d-discs of $\mathcal{B}_n$ and the adjacency is defined as above.

PROPOSITION 6.1. *$\mathcal{D}_{n,d}$ is isomorphic to $\mathcal{B}_{n-2d}$. More specifically, $\psi_{n,d} : \mathcal{B}_{n-2d} \to \mathcal{D}_{n,d}$ is an isomorphism if we set $\psi_{n,d}(\langle i, xy\rangle) = D_d(x,y)$ for each $i \in [0,\ldots,n-2d]$, $x \in \{0,1\}^i$, and $y \in \{0,1\}^{n-2d-i}$.*

Proof. Because x and y with $xy \in \{0,1\}^{n-2d}$ uniquely determines a d-disc $D_d(x,y)$, $\psi_{n,d}$ is clearly one-to-one. It is also onto because the numbers of nodes of the two graphs are the same. Now consider two adjacent nodes $u = \langle i, x_1 b x_2\rangle$ and $v = \langle i+1, x_1 b' x_2\rangle$ of $\mathcal{B}_{n-d}$, where $|x_1| = i$ and $b, b' \in \{0,1\}$. The d-disc $\psi_{n,d}(u) = D_d(x_1, bx_2)$ contains node $\langle i+d, x_1 b' 0^{2d-1} b x_2\rangle$ and the d-disc $\psi_{n,d}(v) = D_d(x_1 b', x_2)$ contains node $\langle i+d+1, x_1 b' 0^{2d-1} b x_2\rangle$; these nodes are adjacent and so are these discs. On the other hand, suppose d-discs $D_d(x_1,x_2)$ and $D_d(y_1,y_2)$, where $|x_1| = i$ and $|y_1| = i+1$, are adjacent in $\mathcal{D}_{n,d}$. Then, there is a node of the form $\langle i+d, x_1 x x_2\rangle \in D_d(x_1,x_2)$ and a node of the form $\langle i+d+1, y_1 y y_2\rangle \in D_d(y_1,y_2)$, which are adjacent in $\mathcal{B}_n$. This means that $x_1 x x_2$ and $y_1 y y_2$ may possibly disagree only at the $(i+d+1)$th bit. Therefore, x_1 is a prefix of y_1 and y_2 is a suffix of x_2; hence nodes $\langle i, x_1 x_2\rangle$ and $\langle i+1, y_1 y_2\rangle$ are adjacent in $\mathcal{B}_{n-2d}$. ∎

PROPOSITION 6.2. *If node u on level i, $d \le i < n-d$, and node v on level $i+1$ have a path of drift at most d connecting them, then the d-discs of u and v are adjacent.*

Proof. Simply note that any path from u with drift at most d keeps us in the rows that intersect with the d-disc of u. ∎

Now we can relate a level-preserving embedding of $\mathcal{B}_n$ with drift d to a simple embedding of $\mathcal{B}_{n-2d}$. For a fault set $F \in V(\mathcal{B}_n)$, let $\hat{F} \in V(\mathcal{B}_{n-2d})$ be defined by $\hat{F} = \{v \mid \psi_{n,d}(v) \subseteq F\}$, where $\psi_{n,d}$ is the isomorphism defined in Proposition 6.1. Intuitively, we regard a node in $\mathcal{B}_{n-2d}$ faulty if its corresponding d-disc is completely knocked out.

LEMMA 6.3. *Suppose there is a level-preserving embedding of $\mathcal{B}_n$ in $\mathcal{B}_n\langle F\rangle$ with load l and drift d. Then there is a simple embedding of $\mathcal{B}_{n-2d}$ in $\mathcal{B}_{n-2d}\langle \hat{F}\rangle$ with load at most $l2^{2d}$.*

Proof. Let ϕ be a level-preserving embedding of $\mathcal{B}_n$ in $\mathcal{B}_n\langle F\rangle$ with load l and drift d. Let ψ denote the standard isomorphism that maps $\mathcal{B}_{n-2d}$ to some fixed $(n-2d)$-stage subbutterfly of $\mathcal{B}_n$ starting at level d. We define a mapping ϕ' of nodes of $\mathcal{B}_{n-2d}$

to those of $\mathcal{B}_{n-2d}\langle\hat{F}\rangle$ by $\phi'(v) = \psi_{n,d}^{-1}(D)$, where $\psi_{n,d}$ is the isomorphism from $\mathcal{B}_{n-2d}$ to $\mathcal{D}_{n,d}$ and D is the d-disc that contains node $\phi(\psi(v))$. In other words, ϕ' maps v to a node that corresponds to the d-disc into which ϕ maps $\psi(v)$. Since ϕ avoids a d-disc completely contained in F, ϕ' avoids $\hat{F}$. Since each d-disc has 2^{2d} nodes, ϕ' maps at most $l2^{2d}$ nodes to a single node. Finally, by Propositions 6.1 and 6.2 it maps adjacent nodes to adjacent nodes. □

To prove our lower bound on the dilation of a level-preserving embedding, we use the unlikelihood of a simple embedding with small load. A simple embedding maps a monotone path to a monotone path preserving the levels of the endpoints. Therefore, the mapping of nodes on the outermost levels completely determines the embedding. We exploit this lack of flexibility of simple embeddings. In particular, we use the fact that the image of a simple embedding must contain a large number of binary trees rooted at level 0 which have an identical "shape" in the following sense.

Let h be an integer in $[n]$ and let P be a nonempty subset of $\{0,1\}^h$. A *P-tree of* $\mathcal{B}_n$ is a binary tree of height h contained in $\mathcal{B}_n$ such that

1. its root is on level 0; and
2. if the root is $\langle 0, xy\rangle$, where $|x| = h$, then the set of its leaves is $\{\langle h, zy\rangle \mid z \in P\}$.

Note that for each P there are exactly 2^n P-trees of $\mathcal{B}_n$, one for each node on level 0. These roots can be partitioned into 2^{n-h} subsets, the 2^h elements of each subset sharing a single set of leaves.

LEMMA 6.4. *Suppose there is a simple embedding of $\mathcal{B}_n$ in $\mathcal{B}_n\langle F\rangle$ with load l. Then, for every $h \in [n]$, there must be some $P \subseteq \{0,1\}^h$ with $|P| \geq 2^h/l$ such that the number of P-trees of $\mathcal{B}_n$ contained in $\mathcal{B}_n\langle F\rangle$ is at least $2^n/l$.*

Proof. Let ψ be a simple embedding of $\mathcal{B}_n$ in $\mathcal{B}_n\langle F\rangle$ with load l. Since ψ maps a monotone path to a monotone path, if u is a node on level 0 and v is a node on level n, then the monotone path from $\psi(u)$ to $\psi(v)$ does not intersect F. Let $U = \psi(Left(\mathcal{B}_n))$ and $V = \psi(Right(\mathcal{B}_n))$. Because the load of ψ is l, we have $|U| \geq 2^n/l$ and $|V| \geq 2^n/l$. Fix h and define $P = \{z \in \{0,1\}^h \mid \exists w \in \{0,1\}^{n-h} : \langle n, zw\rangle \in V\}$. Since $|V| \leq 2^{n-h}|P|$, we have $|P| \geq 2^h/l$ from the bound on V above. Let $u \in U$ and consider the P-tree T of $\mathcal{B}_n$ rooted at u. Since the monotone path from u to any leaf of T is the initial segment of some path from u to V, it must avoid F. Therefore T is contained in $\mathcal{B}_n\langle F\rangle$. Because this is true for any $u \in U$, the number of P-trees contained in $\mathcal{B}_n\langle F\rangle$ is at least $|U|$. □

Now we are ready to prove our lower bound.

THEOREM 6.5. *For any positive constants $p < 1$ and $\alpha < 1/3$, the probability is $1 - 2^{-\Omega(2^{n/3})}$ that any level-preserving embedding of $\mathcal{B}_n$ in $\mathcal{B}_n\langle p\rangle$ with load at most $2^{\alpha n}$ requires drift at least $(1/2 - o(1))\log n$.*

Proof. Let β be an arbitrary constant such that $0 < \beta < 1$. Suppose we have an embedding of $\mathcal{B}_n$ in $\mathcal{B}_n\langle F\rangle$ with load $2^{\alpha n}$ and drift at most $d = (\beta/2)\log n$. Then by Lemma 6.3, there is a simple embedding of $\mathcal{B}_m$ in $\mathcal{B}_m\langle\hat{F}\rangle$ with load at most $l = 2^{\alpha n}n^{\beta}$, where $m = n - 2d = n - \beta\log n$. This in turn implies, by Lemma 6.4, that for any $h \in [m]$, there exists a subset P of $\{0,1\}^h$ with $|P| \geq 2^h/l$ such that the number of P-trees contained in $\mathcal{B}_m\langle\hat{F}\rangle$ is at least $2^m/l$.

Set $h = n/3$. Let $F \in \mathbf{randsub}(V(\mathcal{B}_n), p)$. Then $\hat{F}$ is distributed according to $\mathbf{randsub}(V(\mathcal{B}_m), p^{n^\beta})$ because the size of a d-disc is n^β and d-discs are mutually disjoint. Call a P-tree *good* if it is contained in $\mathcal{B}_m\langle\hat{F}\rangle$. Our goal is to bound the probability that there exists $P \subseteq \{0,1\}^h$ with $|P| \geq 2^h/l$ such that the number of good P-trees is at least $2^m/l$. We start by estimating the probability of this event for a fixed $P \subseteq \{0,1\}^h$. We first claim that, for a fixed node u on level 0, the probability

that the P-tree rooted at u is good is at most $1/2l$ for sufficiently large n. This probability is simple to calculate:

$$\begin{aligned}(1-p^{n^\beta})^{2^h/l} &\le \exp[-p^{n^\beta}2^h/l] \\ &= \exp[-2^{h-\alpha n-o(n)}],\end{aligned}$$

but the negative exponent of this expression is exponential in $\Omega(n)$, while the exponent in $l = 2^{\alpha n}n^\beta$ is linear in n. Therefore this probability is definitely smaller than $1/(2l)$ for sufficiently large n. It follows that the expected number of P-trees contained in $\mathcal{B}_m\langle F\rangle$ is at most $2^m/(2l)$. To obtain a tail estimate, we partition the set of 2^m nodes on level 0 of $\mathcal{B}_m$ into 2^h subsets $U_x = \{\langle 0, xy\rangle \mid y \in \{0,1\}^{m-h}\}$, $x \in \{0,1\}^h$. Then, for each fixed $x \in \{0,1\}^h$, the P-trees rooted at nodes in U_x do not intersect each other and hence the events that they are contained in $\mathcal{B}_m\langle \hat{F}\rangle$ are independent of each other. Therefore, we can apply the partition Chernoff bound (Proposition 2.3): the probability that at least $2^m/l$ nodes on level 0 are roots of good P-trees is

$$\begin{aligned}2^{-\Omega(2^{m-h}/l)} &= 2^{-\Omega(2^{(2/3-\alpha)n-o(n)})} \\ &= 2^{-\Omega(2^{\gamma n})},\end{aligned}$$

where γ is a constant $1/3 < \gamma < 2/3 - \alpha$.

Now consider all possible subsets $P \subseteq \{0,1\}^h$. There are at most 2^{2^h} such subsets to consider so that the probability that there exist any P with the required property is at most $2^{2^h-\Omega(2^{\gamma n})} = 2^{-\Omega(2^{\gamma n})}$. □

7. Open questions. Although our upper bound easily transfers to the CCC, it is not clear if the result can be extended to the shuffle-exchange or the de Bruijn network, which belong to the other type of hypercubic bounded-degree networks. For the butterfly itself, although we have a tight bound for the dilation of level-preserving embeddings, no nontrivial lower bound is known for general embeddings. We might also ask for the best possible load/dilation/congestion ever achievable by any bounded-degree network.

Recently, Karlin, Nelson, and Tamaki [9] have shown the existence of a critical probability for the presence of a linear-sized connected component in the random subgraph of the butterfly. In their edge fault model, where each edge fails independently with probability p, the critical probability p_c is shown to be between 0.564 and 0.663; for $p < p_c$ the faulty butterfly contains a component with $\Omega(N)$ nodes with high probability, whereas for $p > p_c$ it lacks such a component with high probability. A similar critical probability can be obtained for our node fault mode. It is an interesting question whether the embedding results of this paper can be extended to every node-failure probability smaller than the critical probability.

Even more recently, Cole, Maggs, and Sitaraman [5] have provided yet more evidence that the butterfly network is highly fault tolerant: in a faulty butterfly with some constant node-failure probability, it is possible to identify a set of $\Theta(N)$ nodes among which any permutation routing is performed in $O(n)$ steps with high probability. Constant-factor slowdown simulation of the butterfly by such a faulty butterfly, however, is still open.

Acknowledgments. I would like to thank Allan Borodin for valuable comments on this work, Nick Pippenger for his suggestion of the use of branching processes in tackling the problem, and Tino Tamon for reading an earlier manuscript and making useful comments.

SPLITTINGS, ROBUSTNESS, AND STRUCTURE OF COMPLETE SETS*

HARRY BUHRMAN†, ALBRECHT HOENE‡, AND LEEN TORENVLIET§

Abstract. We investigate the structure of *EXP*-complete and hard sets under various kinds of reductions. In particular, we are interested in the way in which information that makes the set complete is stored in the set. We study for various types of reductions the question of whether the set difference $A - S$ for a hard set A and a sparse set S is still hard. We also address the question of which complete sets A can be split into sets A_1 and A_2 such that $A \equiv_r^P A_1 \equiv_r^P A_2$ for reduction type r, i.e., which complete sets are *mitotic*. We obtain both positive and negative answers to these questions depending on the reduction type and the structure of the sparse set.

1. Introduction.

The structure of complete sets under various types of reductions is a well-studied subject in complexity theory. The question "Which sets can be complete under which type of reductions?" has been posed many times and answered for many complexity classes. (See [9] for an overview.)

A complete set represents, through the reduction under which it is complete, an entire complexity class. A membership algorithm for the complete set combined with a reduction (of the appropriate type) gives a membership algorithm for a set in the class. Viewed as such, the complete set contains the information of any particular set in the class.

In this paper we investigate the structure of the information that makes the set complete for deterministic exponential time and for various types of reductions. We take an approach pioneered by Schöning [21]. To investigate the structure of a complete set we compare this set with another set. Schöning in particular showed that for a $\leq_m^P$-complete set A in *EXP* and a polynomial time computable set D, the set $A\Delta D$ is of exponential density. Tang, Fu, and Liu took in [23] the approach of taking the difference of sets complete in exponential time with a sparse subexponential time computable (sub)set and asked the question of whether the resulting set is complete. In section 3, we extend their work by studying analogous questions for other types of completeness. We obtain similar results and show that for several types of reductions and arbitrary sparseness conditions there exists a *single* subexponential time computable set S that meets this sparseness condition and, furthermore, has the property that for any set A, complete under the reduction for which this S is constructed, the set $A - S$ is no longer complete. In addition, it seems possible to make S "almost

polynomial time computable." It follows from the constructions that, by taking a sufficiently slow enumeration of reductions, we can lower the time complexity of S to any reasonably behaved superpolynomial function. We also address the flip question in this section: "For which reductions and which sparse sets is it the case that the set $A - S$ is complete?" We study sparse sets S of simple *structure* rather than computationally simple sets. Selman [22] introduced p-selective sets as a resource bounded analog of semirecursive sets introduced by Jockusch [13]. For any tally set, a polynomial time Turing equivalent p-selective set can be found. Therefore p-selective sets can be computationally very complex. Nonetheless, p-selective sets are intuitively easy to compute since, for any two strings x and y, it can be decided in polynomial time which of the two is more likely (or actually no less likely) to be in the set. It turns out that for most of the reductions studied in subsection 3.1 the set $A - S$ remains complete if S is a p-selective set. We prove this theorem for disjunctive, conjunctive, and 2-truth-table (2-*tt*) reductions. One might expect that, as is the case with many results on reductions, our 2-truth-table theorem can be extended to at least bounded truth-table reductions. From a recent result of Buhrman, Fortnow, and Torenvliet [6] it follows, however, that the 2-*tt* result cannot be extended even to 3-*tt*.

In section 4 we study sets that remain complete even when another *complete* set is removed, i.e., we study sets that can be "split" into two or more sets that are again complete. Such sets have been studied in recursion theory and are called *mitotic* sets. We follow the line of Ambos-Spies [1] and prove that $\leq_m^P$-complete sets for *EXP* indeed are (weakly p-m) mitotic. In contrast, we show that there exists a $\leq_{3\text{-}tt}^P$-complete set that is not weakly p-m mitotic. Finally, we show a counterpart to Ladner's splitting theorems [16], i.e., we construct a set that can be split into two parts that are strictly below the degree of complete sets and that are $\equiv_m^P$ instead of incomparable.

2. Definitions and notation. We assume that the reader is familiar with standard notions in structural complexity theory as they are defined, e.g., in [2]. All kinds of *polynomial-time bounded* reductions—many-one, (disjunctive and conjunctive) truth-table and Turing—are frequently used without explanation. We use the following notation for the (polynomial-time computable versions) of the different types of reductions: $\leq_m^P$ for many-one reductions, $\leq_1^P$ for one-one reductions, $\leq_{k\text{-}tt}^P$ for k-truth-table reductions, $\leq_{btt}^P$ for bounded truth-table reductions, $\leq_{tt}^P$ for truth-table reductions, $\leq_c^P$ for conjunctive truth-table reductions, $\leq_d^P$ for disjunctive truth-table reductions, $\leq_{k-d}^P$ for k-disjunctive truth-table reductions, and $\leq_T^P$ for Turing reductions. The symbols $\leq_m$ and $\leq_T$ also appear in the paper, without the superscript P, to indicate the version of these reductions without time bound.

Various definitions for these types of reductions can be found in the literature, e.g., in [17, 7, 5, 8]. We think of polynomial-time bounded reductions as being modeled by adaptive and nonadaptive oracle machines. We use various enumerations $\{M_i\}_i$ of (oracle) Turing machine programs with varying properties. If the type of machine is not clear from the context, we explicitly mention the machine type. An enumeration $\{M_i\}_i$ can thus stand for an enumeration of all polynomial-time bounded machines in one theorem and an enumeration of all bounded truth-table reductions in the next. In the case of enumeration of many-one reductions, i.e., where the machines are transducers, we also use $\{f_i\}_i$ to emphasize this fact. For polynomial-time bounded machines we always assume machine M_i in such an enumeration to be time bounded by $n^i + i$, where n is the length of the input. Usually, we denote the set of strings queried on input x by machine i with oracle A by $Q_i^A(x)$, or by $Q_i(x)$ if M_i is non-adaptive.

The result of the computation (accept/reject or the value computed) of machine M_i on input x (relative to oracle A) is sometimes denoted as $M_i(x)$ ($M_i^A(x)$), where $M_i(x) = 0$ or 1 means that the computation rejects or accepts, respectively.

Sets of strings are denoted by capital letters and are subsets of Σ^*, where $\Sigma = \{0, 1\}$. Strings are denoted as small letters $x, y, u, v, \ldots$. The length of a string x is denoted by $|x|$.

We assume *pairing and projection functions* that are easy to compute. For strings, the pairing of $x_1, \ldots, x_n$ is denoted by $<x_1, \ldots, x_n>$, and $\pi_i(y)$ is the projection of y onto its ith coordinate. We assume all kinds of convenient properties of these pairing functions, e.g., pairing functions can be designed such that $<x, y> < <x, z>$ whenever $y < z$ or such that $|<x, z>| = |<x, z'>|$ for a large (exponential in this length) number of pairs z and z'. In fact, the specific properties of different pairing functions may depend on the context of the proof in which they are used. Integer numbers can also appear as arguments to pairing functions. If so, the integer is identified with its binary representation.

An ordering on Σ^* is assumed where $x < y$ if $|x| < |y|$ and that coincides with the lexicographical ordering if $|x| = |y|$. The cardinality of a set A is denoted as $\|A\|$. The value of the *characteristic function* of a set A on a string x is denoted by $\chi_A(x)$, i.e., $\chi_A(x) = 1$ if $x \in A$ and 0 otherwise. Following Kelly [14], we let the notation $\bigcup\{S : S \text{ meets condition }\}$ stand for the union of all sets S that meet the given condition. For sets A and B the notation $A \oplus B$ stands for the disjoint union of A and B, i.e., $\{0x : x \in A\} \cup \{1x : x \in B\}$.

For a set A

- for $n \in \omega$, we let the notation $A^{\leq n}$ stand for the set consisting of all strings in A of length $\leq n$; and
- for a string x, we let $A^{[x]}$ stand for the x *section of* A, i.e., the set $\{<y, z> : y = x \text{ and } <y, z> \in A\}$.
- in order to measure the density of A, we say that A is $g(n)$ sparse for some nondecreasing total function $g : \omega \to \omega$, if for all n, $\|A^{\leq n}\| < g(n)$.

The main complexity classes considered in this paper are P (polynomial time), EXP (exponential time), and $NEXP$ (nondeterministic exponential time). For the latter classes, we allow polynomials to act as exponents in the time bounds, e.g., $EXP = \bigcup\{DTIME(2^{n^i}) : i \in \omega\}$. For EXP, the set K is the universal complete set. $K = \{<i, x, l> : M_i \text{ accepts } x \text{ in} \leq l \text{ steps }\}$.

3. The robustness of completeness notions for exponential time. In this section we study the question of which sparse sets can be removed from exponential-time complete sets of different types without disturbing the completeness of these sets. The question originates from work of Schöning [21], who showed that for every $\leq_m^P$-hard set A for EXP and every set D in P, the set $A \Delta D$ is of exponential density. In [23], Tang, Fu, and Liu showed, as a corollary to an analogous result on parity reductions, that even for subexponential time computable D, the difference $A \Delta D$ remains $\leq_m^P$-hard for exponential time.

They further show that for an arbitrary sparseness condition, there exists a single subexponential time computable set S, such that for *any* exponential time complete set A, the set $A - S$ is no longer exponential time hard. Their proof hinges on the fact that for any exponential time computable set B and any exponential time complete set A, there exists a *length increasing* reduction from B to A. Subsequently, the subexponential time computable set is constructed by choosing a sufficiently sparse polynomial-time computable subset of $\{0\}^*$ and defining S as the image of this set

varying over all polynomial-time computable functions, i.e., $S = \{0^{b_i} : |f_i(0^{b_i})| > b_i\}$, where b_i are chosen sufficiently far apart.

A closer look at the proof shows although the theorem just states that S is subexponential time computable, that there are various ways of making S come arbitrarily close to polynomial time. It therefore seems reasonable to ask whether we can also choose S to be polynomial-time computable. The answer to this question is negative, as observed in [23]. From the $\leq_1^P$-reduction of $K' = K \times \Sigma^*$ to the *EXP* complete set A, we can easily construct a $\leq_m^P$-reduction to $A - S$ for any polynomial-time computable sparse set S. In this section we will investigate, for different types of reductions, which sparse sets can destroy the completeness of a given set, and for which sparse sets completeness is preserved.

3.1. Sparse sets that destroy completeness. The set K' defined above is, of course, $\leq_m^P$-complete for *EXP*. In fact it is $\leq_d^P$-complete for *EXP* in a special way. For a given string x either all strings $<x, y>$ are in this set, or all are out depending on $x \in K$. Therefore, as long as S is $p(n)$ sparse, the set $K' - S$ remains $\leq_d^P$-complete for *EXP*. The reduction from K to K' on input x queries just the set $\{<x, y> | 0 \leq y \leq p(2n) + 1\}$. Since all of these strings have length $\leq 2|x|$, at least one of them is not in S and it is in K' iff $x \in K$. This explains why the theorem "*there exists a sparse set S, such that for any* $\leq_d^P$*-complete set A for EXP, the set* $A - S$ *is not* $\leq_d^P$*-complete for EXP*" cannot exist.

The best we can hope for is a theorem for reductions that can query at most $\|S^{\leq n}\|$ strings for each length n. Since we want the construction of S to meet any given sparseness condition, this implies that the number of queries cannot be a function of n that grows to infinity with n. In other words, the number of queries must be some fixed constant. Such reductions are called *bounded truth-table reductions*, and for these reductions we can obtain the theorem. In fact, since the proof method of our theorem is not dependent on the reductions being nonadaptive, we can obtain the theorem for bounded Turing reductions ($\leq_{bT}$).

THEOREM 3.1. *Let g be a recursively computable nondecreasing function with $\lim_{n\mapsto\infty} g(n) = \infty$, and let f be a function that is superpolynomial, subexponential, and time constructible. There exists a $g(n)$-sparse $O(f(n))$-time computable set S such that for any $\leq_{btt}^P$-complete set A for EXP, the set $A - S$ is no longer $\leq_{btt}^P$-complete.*

Proof. For a given set A, we demonstrate the existence of a set L_A such that $L_A \leq_{btt}^P A$ iff there exists a reduction M_i that queries at least one string $y \in A$ with $|y| > b(i)$ on input $0^{b(i)}$. Next, we let all such strings be elements of S, thereby preventing the existence of such a reduction from L_{A-S} to $A - S$ and hence completeness of $A - S$. This technique was borrowed from Watanabe [25].

Let $\{M_i\}_i$ be an enumeration of all $\leq_{btt}^P$-reductions. Without loss of generality, we may assume that machine M_i generates $\leq i$ queries on any input. First we define a set of numbers $\{b(i)\}$ sufficiently far apart and sufficiently easy to recognize, i.e., we want that, for each n, the question "$\exists i : n = b(i)$?" can be answered in time $O(n)$, and furthermore we want for each i that $g(b(i)) > i^2$. This means that we can define at least i^2 strings in $S^{\leq b(i)}$ without disturbing the sparseness condition on S. In fact, we will put just $\leq i$ strings in each interval $S^{\leq b(i+1)} - S^{\leq b(i)}$. Finally, we wish to compute $Q_i(0^{b(i)})$ to define strings in S. To be able to do this in time $f(b(i))$, we need that $2^{b(i)} > f(b(i)) > (b(i))^i + i$, for all i.

We let $S = \{y : \exists i[y \in Q_i(0^{b(i)}) \wedge |y| > b(i)]\}$ and claim that S is the set searched for. First, $\|S^{\leq n}\| \leq g(n)$ for each n, since for each n the only strings that are in $S^{\leq n}$ are in $\bigcup\{Q_j(0^{b(j)}) : j \leq i\}$ for i maximal such that $b(i) \leq n$. Hence, there are at

most i^2 strings in $S^{\leq n}$, and $b(i)$ was chosen such that $g(n) \geq g(b(i)) > i^2$ as required. Next, S is $O(f(n))$-time computable by the choice of $b(i)$. Finally, the set $A - S$ is not $\leq^P_{btt}$-complete. To see this, assume that $A - S$ is $\leq^P_{btt}$-complete and define the set $L_{A-S} = \{0^{b(i)} : M_i^{(A-S)^{\leq b(i)}}(0^{b(i)}) = 0\}$. L_{A-S} is exponential time computable since $2^{b(i)} > b(i)^i + i$ and since both A and S are exponential time computable and are only queried on inputs of length $\leq b(i)$ on input $0^{b(i)}$. It follows that $L_{A-S} \leq^P_{btt} A - S$. Let M_j be the reduction from L_{A-S} to $A - S$. Then $Q_j(0^{b(j)}) \cap (A - S) \subseteq \Sigma^{\leq b(j)}$ and therefore $0^{b(j)} \in L_{A-S}$ iff $M_j^{A-S}(0^{b(j)})$ rejects, which is a contradiction. □

If we change S in the construction above to $\{\min\{y : y \in Q_i(0^{b_i}) \wedge |y| > b_i\} : i \in \omega\}$, we get the following corollary from the same construction.

COROLLARY 3.2. *Given a recursively computable nondecreasing function $g(n)$ with $\lim_{n\mapsto\infty} g(n) = \infty$, there exists a $g(n)$-sparse subexponential time computable set S such that for any $\leq^P_c$-complete set A for EXP the set $A - S$ is no longer $\leq^P_c$ complete.*

Conjunctive truth-table (c-*tt*) reducibilities form an exception in yet another way. For these reductions we can even let the set A be *EXP* hard instead of *EXP* complete. We use the fact that for conjunctive truth-table reductions we can get a kind of 1-1 behavior for the query sets. A similar result for $\leq^P_m$-hard sets that uses the fact that these sets are also hard under $\leq^P_1$-reductions appears in [23]. We isolate and prove this property in the following lemma.

LEMMA 3.3. *If A is $\leq^P_c$-hard for EXP, then for any set B in EXP there exists a $\leq^P_c$-reduction M_j from B to A such that $Q_j(x) \not\subset \bigcup\{Q_j(y) : y \in B \wedge y < x\}$.*

Proof. Let $\{M_i\}_i$ be an enumeration of $\leq^P_c$-reductions We construct a set W as follows. On input $<i, x>$ compute $Q_i(<i, x>)$. If $Q_i(<i, x>) \subseteq \bigcup\{Q_i(<i, y>) : <i, y> < <i, x> \wedge <i, y> \in W\}$, then we let $<i, x> \notin W$; otherwise $<i, x> \in W$ iff $x \in B$.

It is easy to see that W is in *EXP*, so there exists a $\leq^P_c$-reduction from W to A, say, M_j. For this reduction it follows that $Q_j(<j, x>) \not\subset \bigcup\{Q_j(<j, y>) : <j, y> \in W \wedge <j, y> < <j, x>\}$. By assumption on the pairing function that $<i, x> < <i, y> \leftrightarrow x < y$ the function $M'(x) = M_j(<j, x>)$ computes a $\leq^P_c$-reduction with the required property. □

From this lemma we get the following theorem.

THEOREM 3.4. *Let $g(n)$ be a recursively computable nondecreasing function with $\lim_{n\mapsto\infty} g(n) = \infty$. There exists a $g(n)$-sparse set S in EXP such that for any $\leq^P_c$-hard set A for EXP the set $A - S$ is no longer $\leq^P_c$-hard.*

Proof. Again, we let the numbers $b(i)$ be sufficiently far apart to guarantee $g(n)$ sparseness of S if we put one string in S for each $b(i)$ and such that $0^{b(i)}$ is again easy to recognize. Furthermore, we let $2 \times (b(i-1))^{(i-1)} < b(i)$ to avoid confusion later on. Then we put the least string in $\bigcup\{Q_i(<0^{b(i)}, y>) : |y| \leq b(i)\}$ of length $\geq b(i)/2 - 1$ in S. (If no such string exists we do nothing.)

S is exponential time computable since, to decide membership of a string x in S, we search for a $0^{b(i)}$ such that $b(i) \leq 2 \times |x|$ and $|x| < (b(i))^i$. (There can be only one candidate.) Now compute the query sets on the, at most, $2^{2|x|}$ different y in time $\leq 2^{2|x|} \times (2|x|)^i + i$, and see if x is the least string of the right length in the union of these sets.

$A - S$ is not $\leq^P_c$-hard. If it were, then one of the $\leq^P_c$-reductions from $D = \{<x, y> : x \in \{0\}^*, y \in \Sigma^*\}$ to A would behave as predicted by Lemma 3.3.

Let M_j be such a reduction. It follows that $\|\bigcup\{Q_j(<0^{b(j)}, y>) : |y| \leq b(j)\}\| \geq 2^{b(j)}$ from Lemma 3.3. Hence there is one string in this set of length $\geq b(j)/2 - 1$.

The least of these strings z_0 is not in $A - S$ by construction, and M_j must reject any input $<0^{b(j)}, y>$ for which z_0 is in $Q_j(<0^{b(j)}, y>)$. Yet $<0^{b(j)}, y> \in D$, so M_j cannot be a reduction from D to $A - S$. □

Conjunctive and disjunctive truth-table reducibilities are kind of each other's complement. If a set is conjunctive truth-table reducible to a set A, then its complement is disjunctive truth-table reducible to $\overline{A}$. So we find the following.

COROLLARY 3.5. *Let $g(n)$ be a recursively computable nondecreasing function with $\lim_{n\mapsto\infty} g(n) = \infty$. There exists a $g(n)$-sparse subexponential time computable set S such that for any $\leq_d^P$-complete set A for EXP the set $A \cup S$ is no longer $\leq_d^P$-complete.*

In addition we have the following.

COROLLARY 3.6. *Let $g(n)$ be a recursively computable nondecreasing function with $\lim_{n\mapsto\infty} g(n) = \infty$. There exists a $g(n)$-sparse set S in EXP such that for any $\leq_d^P$-hard set A for EXP the set $A \cup S$ is no longer $\leq_d^P$-hard.*

Proof. If $K \leq_c^P A$ via M_i, then

$$\begin{array}{rrcl} & x \in K & \Leftrightarrow & Q_i(x) \subset A, \\ \text{or} & x \notin K & \Leftrightarrow & Q_i(x) \cap \overline{A} \neq \emptyset. \end{array}$$

Now $\overline{K} \in EXP$ so $\overline{K} \leq_m^P K$, say, via f.

$$\begin{array}{rrcccl} \text{So} & x \in \overline{K} & \Leftrightarrow & f(x) \in K & \Leftrightarrow & Q_i(f(x)) \subset A, \\ \text{or} & x \notin \overline{K} & \Leftrightarrow & f(x) \notin K & \Leftrightarrow & Q_i(f(x)) \cap \overline{A} \neq \emptyset, \\ \text{or} & x \in K & \Leftrightarrow & f(x) \notin K & \Leftrightarrow & Q_i(f(x)) \cap \overline{A} \neq \emptyset, \end{array}$$

so $\overline{A}$ is $\leq_d^P$-hard via $M_i(f(x))$. Along the same lines, if A is $\leq_d^P$-hard then $\overline{A}$ is $\leq_c^P$-hard. So A is $\leq_d^P$-complete (hard) iff $\overline{A}$ is $\leq_c^P$-complete (hard) for EXP. But if $\overline{A}$ is $\leq_c^P$-complete (hard), then there exists a $g(n)$-sparse subexponential (exponential) time computable set S such that $\overline{A} - S$ is no longer $\leq_c^P$-complete (hard), and then $A \cup S$ is no longer $\leq_d^P$-complete (hard). □

3.2. Easy sparse sets. As in the case of $\leq_m^P$-complete sets, we can let the time complexity of the set S in the previous subsection come arbitrarily close to polynomial time. For some—but surprisingly not all—reductions, a polynomial-time computable sparse set that destroys completeness does not exist. To show this we take a slightly more general view of the complexity of the set S. Instead of taking S polynomial-time computable, we let S be p-selective. p-selective sets were introduced by Selman [22] as a resource bounded analogue of semirecursive sets, which were introduced by Jockusch [13].

DEFINITION 3.7. *A set A is called* p-selective *iff there exists a polynomial-time computable function $f : \Sigma^* \times \Sigma^* \mapsto \Sigma^*$, called a* p-selector, *such that for any $x, y \in \Sigma^*$*

1. *$f(x, y) \in \{x, y\}$, and*
2. *$\chi_A(f(x, y)) = \max\{\chi_A(x), \chi_A(y)\}$.*

The following "ordering lemma" is used in the proofs of the theorems in this section and can be found (in various forms) in, e.g., [24, 10, 11].

LEMMA 3.8. *Let $V = \{v_1, \ldots, v_n\}$ be a finite set of strings, and let A be a p-selective set with p-selector f. The strings in V can be ordered "according to f" as $v_{i_1}, \ldots, v_{i_n}$ such that $v_{i_j} \in A \to v_{i_{j+1}} \in A$ in time polynomial in $|v_1| + \cdots + |v_n|$.*

As only polynomial time is involved, we sometimes assume a finite set "ordered according to a p-selector," without loss of generality.

For any (nonfinite) sparseness condition a p-selective set (which may be infinite) that meets this condition can be constructed. For polynomially sparse p-selective

sets we can show counterparts to the theorems of subsection 3.1. For conjunctive, disjunctive, and 2-*tt* reductions, for a set A that is complete under this reduction, and for a set S that is polynomially sparse and p-selective, the set $A - S$ remains complete under the same reduction. Since all sets in P are p-selective, the same results follow for sparse polynomial-time computable sets.

It might be instructive here to compare our results to those of Tang, Fu, and Liu [23, Theorems 3.6 and 3.7]. They show that sets complete under conjunctive and disjunctive reductions stay complete when a sparse subexponential-time computable *subset* is removed. Our sparse set may be *any* set.

THEOREM 3.9. *For any set A that is $\leq_c^P$-hard for EXP and any $p(n)$-sparse p-selective set S, the set $A - S$ remains $\leq_c^P$-hard for EXP.*

Proof. Let f be a p-selector for S. We construct an exponential time-computable set W such that, for some index w of a conjunctive truth-table reduction M_w from W to A, it holds that the universal set K is many-one reducible to $W^{[w]}$ and $W^{[w]}$ is in turn conjunctive truth-table reducible to $A - S$. This then establishes completeness of $A - S$.

The set W consists of strings $<i, x, z>$ for $i \in \omega$, $x \in \Sigma^*$, and z ranging from $0^{|x|}$ through $1^{|x|}$. Fix i and x and let $n = |<i, x, x>|$. By appropriate assumptions on the pairing function, all of the pairs $<i, x, z>$ are of the same length. So, since S is $p(n)$ sparse, there exists some polynomial q such that at most $q(n)$ of the different strings queried on such an input can be in S. Let Z be the set of the lexicographically first $q(n)+1$ strings in the interval $0^{|x|}$ through $1^{|x|}$. We describe membership of $<i, x, z>$ in W. If $z \notin Z$, then $<i, x, z> \notin W$. Let $U = \bigcup\{Q_i(<i, x, z>) : z \in Z\}$. Assume that $U = \{u_1, u_2, \ldots, u_m\}$ such that $u_i \in S \rightarrow u_{i+1} \in S$ and let $U' = \{u_{m-q(n)+1}, \ldots, u_m\}$. If $U = \emptyset$ or time 2^n is insufficient to compute U and sort U according to the p-selector, then no string $<i, x, z>$ is in W. It will follow from the construction that the first case cannot occur if i is a program that computes a c-*tt* reduction from W to A. The latter case can only occur for finitely many different x.

Now there are two cases.

Case 1. There is a $z \in Z$ such that $Q_i(<i, x, z>) \subseteq \bigcup\{Q_i(<i, x, z'>) : z' \in Z \wedge z' \neq z\}$. Let z_0 be the least such z. We let $<i, x, z> \in W \iff z \neq z_0$.

Case 2. There is no such z. Then $\|Q_i(<i, x, z>) - \bigcup\{Q_i(<i, x, z'>) : z' \in Z \wedge z' < z\}\| \geq 1$ for all $z \in Z$ and hence, there is a z such that $Q_i(<i, x, z>) - U' \neq \emptyset$ *and* $Q_i(<i, x, z>) \cap U' \subseteq \bigcup\{Q_i(<i, x, z'>) : z' \in Z \wedge z' < z\}$. Let z_0 be the least such z. We let $<i, x, z_0> \in W \leftrightarrow x \in K$. We let $<i, x, z> \in W$ for all $z < z_0$ in Z and let $<i, x, z> \notin W$ for all $z > z_0$ in Z.

This ends the construction of W.

Since W is computable in exponential time, there is a conjunctive truth-table reduction from W to A. Let M_w be such a reduction. We show a reduction from $W^{[w]}$ to $A - S$. Let $<w, x, z>$ be some input.

1. As mentioned above, there is a finite number of cases for which the string $<w, x, z>$ is not in W because of insufficient computation time. In these cases, or in the case where z is not among the first $q(|<w, x, x>|)+1$ strings, our reduction rejects. (Or, equivalently, produces some fixed string not in $A - S$.)
2. Otherwise, compute the set $U = \{u_1, \ldots, u_m\}$ as described above. (Since w is a fixed constant, this can be done in polynomial time in $|<w, x, z>|$.) Since M_w is a reduction from W to A it follows that the construction falls in Case 2. If z is the least string in Z satisfying Case 2, then produce $Q_w(<w, x, z>) - U'$. Otherwise accept or reject according to Case 2.

This reduction accepts $<w, x, z>$ iff $<w, x, z> \in W^{[w]}$ and queries only strings in $A - S$.

The reduction from K to $W^{[w]}$ is the following. If x belongs to the finite number of exceptional cases, then we find out by table-lookup if $x \in K$ and accept or reject accordingly. Otherwise, we compute U for this w and x and the least z satisfying Case 2 and let $f(x) = <w, x, z>$. □

In the proof of this theorem we defined a set W such that the reduction of W to A must query strings that are in A on certain inputs. We did this by defining certain strings in W (hence a conjunctive reduction must get the answer yes on queries produced on this input). On the other hand, the reduction of W to A must query some strings outside S on some inputs. We did this by diagonalizing against reductions for which the cardinality of the union of the query sets on the inputs $<i, x, z>$ was small enough to "fit" inside S. Then a reduction from any exponential time-computable set to $A - S$ can be constructed, using W, by assuming that queries that may be in S are answered yes, and querying the remaining ones.

For $\leq_d^P$-hard sets, we can change the strategy of the proof to construct a set W such that we know that queries that may be in S are answered *negatively* (by leaving enough strings *out* of W). A completely analogous proof then yields the following.

THEOREM 3.10. *For any set A that is $\leq_d^P$-hard for EXP and any $p(n)$-sparse p-selective set S, the set $A - S$ remains $\leq_d^P$-hard for EXP.*

By complementation Theorems 3.9 and 3.10 yield the following corollaries, respectively.

COROLLARY 3.11. *For any set A that is $\leq_d^P$-hard for EXP and any $p(n)$-sparse p-selective set S, the set $A \cup S$ remains $\leq_d^P$-hard for EXP.*

COROLLARY 3.12. *For any set A that is $\leq_c^P$-hard for EXP and any $p(n)$-sparse p-selective set S, the set $A \cup S$ remains $\leq_c^P$-hard for EXP.*

We can also prove the same theorem for $\leq_{2\text{-}tt}^P$-hard sets.

THEOREM 3.13. *Let A be $\leq_{2\text{-}tt}^P$-hard for EXP and let S a p-selective $p(n)$-sparse set. The set $A - S$ is still $\leq_{2\text{-}tt}^P$-hard for EXP.*

Proof. We will construct an exponential time-computable set W that is used in defining a $\leq_{2\text{-}tt}^P$-reduction from K to $A - S$. Let f be the p-selector for S. W consists of strings $<i, x, z>$, where $|z| = |x|$.

Fix some i and x. Let $n = |<i, x, x>|$. We will define membership of $<i, x, z>$ in W for all z. For this proof we will assume that $\|Q_i(x)\| = 2$ for all i and all x.

There exists some polynomial q' such that S can contain at most $q'(n)$ of the strings in $\bigcup\{Q_i(<i, x, z>) : |z| = |x|\}$. There exists some polynomial q'' such that S can contain at most $q''(n)$ different *pairs* of strings in $\bigcup\{Q_i(<i, x, z>) : |z| = |x|\}$. We let $q(n) = q'(n) + q''(n) + 1$. It holds for all but finitely many x that $\|\{z{:}|z| = |x|\}\| > q(n)$ and $q''(|x|) > 2q'(|x|) + 1$. (Note that q'' is quadratic in q'.)

In the remainder of this proof we will consider only strings for which both inequalities hold. (We will use tabular lookup in the reduction for other strings.) Let Z consist of the lexicographically first $3 \times q(n)$ strings of length $|x|$. Only strings $<i, x, z>$ with $z \in Z$ may enter W. Let $U = \bigcup\{Q_i(<i, x, z>) : z \in Z\}$. Assume $U = \{u_1, \ldots, u_m\}$, where $u_i \in S \rightarrow u_{i+1} \in S$, and let $U' = \{u_{m-q'(n)+1}, \ldots, u_m\}$. Note that $U \cap S \subseteq U'$.

There are two cases.

Case 1. $\|U\| < q''(n)$.

As there are more than $3 \times q''(n)$ strings in Z it must hold that there are $z_1 \neq z_2 \neq z_3$ in Z such that $Q_i(<i, x, z_1>) = Q_i(<i, x, z_2>) = Q_i(<i, x, z_3>)$. Consider the truth table(s) produced on this input. By setting $<i, x, z>$ in

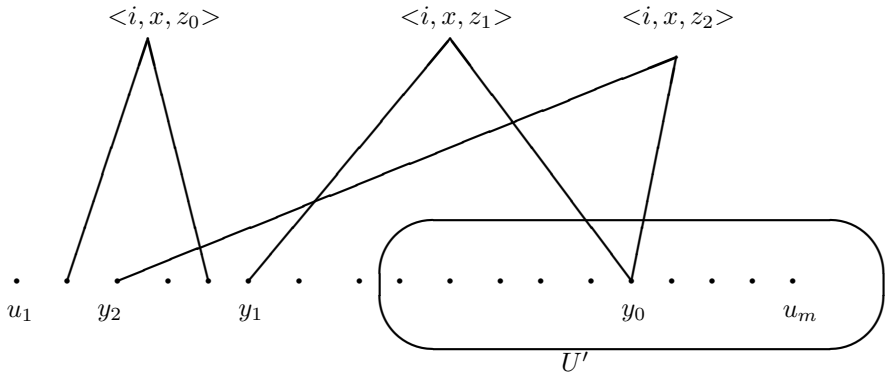

FIG. 3.1. *Possible query sets.*

or out of W we can eliminate at least half of the possible settings (element of A or not) of the two queries in $Q_i(<i, x, z_1>)$. As there are only four possible settings for these two strings, repeating this procedure for z_2 and z_3, we eliminate all possible settings, thereby forcing the fact that M_i is not a reduction from W to A.

Case 2. $\|U\| \geq q''(n)$. (It then follows that $\|U\| \geq 2 \times q'(n) + 1$.)

Either of the following holds (see also Figure 3.1):

Case 2a. There is a z in Z such that $Q_i(<i, x, z>) \cap U' = \emptyset$. Let the least such z be z_0. We let $<i, x, z_0>$ be in W iff $x \in K$ and let $<i, x, z> \notin W$ for all other z.

Case 2b: There is no such z. Then for each of the $\geq q'(n) + 1$ strings u_j in $U - U'$ there is a $z(u_j)$ in Z such that $\|Q_i(<i, x, z(u_j)>) \cap U'\| = \|Q_i(<i, x, z(u_j)>) \cap U - U'\| = 1$. It follows that there is a pair z_j, z'_j such that $\|Q_i(<i, x, z_j>) \cap Q_i(<i, x, z'_j>) \cap U'\| = 1$. Without loss of generality, we assume that z_1 and z_2 are minimal with this property and $z_1 < z_2$. Let

$$\{y_0\} = Q_i(<i, x, z_1>) \cap Q_i(<i, x, z_2>) \cap U',$$
$$\{y_1\} = Q_i(<i, x, z_1>) \cap U - U',$$
$$\{y_2\} = Q_i(<i, x, z_2>) \cap U - U'.$$

Then we know that $\{y_1, y_2\} \cap S = \emptyset$. In the following we will set, depending on the truth table computed by M_i on input $<i, x, z_1>$, the string $<i, x, z_1>$ in W such that $<i, x, z_2> \in W$ can be computed from the queries y_1 and y_2 and hence from queries to $A - S$.

We let $<i, x, z_2> \in W \leftrightarrow x \in K$. In the case we are considering here, only the strings $<i, x, z_1>$ and $<i, x, z_2>$ may enter W. So $<i, x, z> \notin W$ for all $z \in Z - \{z_1, z_2\}$.

Let α be the truth table computed by M_i on input $<i, x, z_1>$. There are sixteen possible truth tables that fall into four cases.

i. If $\alpha \equiv 1$, we let $<i, x, z_1> \notin W$ and if $\alpha \equiv 0$, we let $<i, x, z_1> \in W$. This prohibits M_i from being a 2-truth-table reduction of W to A. This covers two of the sixteen cases.

ii. If there is only *one* combination of $a, b \in \{0, 1\}$ for which $\alpha(a, b) = 1$, then $<i, x, z_1> \in W$, and if there is only *one* such combination where $\alpha(a, b) = 0$, then $<i, x, z_1> \notin W$. If this M_i is a 2-truth-

table reduction from W to A, then for this particular input we can compute $\chi_A(y_0)$ and $\chi_A(y_1)$ in polynomial time. This covers eight of the sixteen cases.

iii. If α is in fact a 1 truth table then the value of α depends on either y_0 or y_1. In the first case we put $<i, x, z_1>$ in W if and only if α takes on *true* if the entry for y_0 is fixed to *false*. Otherwise we let $<i, x, z_1> \in W$ iff $x \in K$.

iv. In the remaining two cases, α is either $\chi_A(y_0) = \chi_A(y_1)$ (equality) or $\chi_A(y_0) \oplus \chi_A(y_1)$ (parity). In the first case we let $<i, x, z_1> \in W$ and in the second case we let $<i, x, z_1> \notin W$ (then in both cases $y_0 \in A \Leftrightarrow y_1 \in A$.)

This completes the construction of W.

We will now show that we can use W to compute a $\leq^P_{2\text{-}tt}$-reduction for any set in *EXP* to $A - S$. Since W is exponential-time computable there is some $\leq^P_{2\text{-}tt}$-reduction of W to A. Let M_w be the machine that computes this reduction. For any set B in *EXP* let f_B be the many-one reduction of B to K. The $\leq^P_{2\text{-}tt}$-reduction from B to $A - S$ works as follows.

On input y, first compute $f_B(y)$. Let $x = f_B(y)$. Now use w and x to compute the set Z as above. Compute U, sort it according to the p-selector, find U', and find out which of the two cases (Case 2a or Case 2b) holds. (We have already argued that Case 1 cannot occur if w is the reduction from W to A.) In Case 2a, find the least z such that $Q_w(w, x, z) \cap U' = \emptyset$ and produce $Q_w(w, x, z)$ as a query set. In Case 2b find z_1 and z_2. We are in one of the subcases ii–iv. In subcases ii and iii we have either fixed the value of $\chi_A(y_0)$ or this value doesn't influence the value of the truth table, so we need only query y_1. Then we can compute membership of $x \in K$ from either the truth table produced by M_w on input $<i, x, z_1>$ or $<i, x, z_2>$, respectively. In subcase iv we fixed things such that $\chi_A(y_0) = \chi_A(y_1)$. We can query y_1 and y_2 and use these values as $\chi_A(y_0)$ and $\chi_A(y_2)$ in the truth table computed by M_w on input $<w, x, z_2>$. □

As every set in P is p-selective, we note the following corollary.

COROLLARY 3.14. *Theorems* 3.9, 3.10, *and* 3.13 *also hold when "p-selective" is replaced by "polynomial-time computable."*

We notice an interesting phenomenon here. In a recent paper, Buhrman, Fortnow, and Torenvliet [6] proved the existence of a 3-tt complete set in *EXP* that is not b-tt autoreducible. (Recall that a set A is r autoreducible if $A \leq^P_r A$ via a reduction that does not query its input.) Inspection of the proof shows that the set is constructed by diagonalizing against autoreductions on inputs in the set $\{0^{b(n)} : n \in \omega\}$, where $b(n)$ is some suitably chosen gap function. They prove that a 3-tt complete set A can be constructed such that every b-tt reduction (from A to A) that does not query its input must, for some n, incorrectly compute membership of $0^{b(n)}$ in A. Without essentially changing the proof, $b(n)$ can be chosen such that $\{0^{b(n)} : n \in \omega\}$ is a polynomial-time computable sparse set. The following corollary follows immediately from their proof.

COROLLARY 3.15 (see [6]). *There exists a* 3*-tt complete set* A *in EXP and a sparse set* S *in* P *such that* $A - S$ *is not b-tt hard for EXP.*

So Theorem 3.13 states an optimal result. A set that is not b-tt hard may of course still be Turing hard. Hence the corollary above hence does not rule out that every Turing-complete set may remain Turing complete when a sparse set is removed. However, we can show that such a result can only be obtained by nonrelativizing methods. We show that there exists an oracle set A relative to which *EXP* has a

$\leq_{tt}^{P}$-complete tally set T. Then $T - \{0\}^* = \emptyset$, which cannot be complete. We suspect the following to be a folk theorem. We prove it here just for completeness.

LEMMA 3.16. *If EXP $\subseteq$ P/poly, then there exists a tally set T that is $\leq_{tt}^{P}$-complete for EXP.*

Proof. It is well known that A is in $P/poly$ iff $A \leq_{tt}^{P} T$ for some tally set T. So from our hypothesis this gives us a tally set T, that is, truth-table *hard* for EXP. We will show how to construct a tally set T' (from T) that is complete for EXP.

The fact that there exists a tally set T that is hard for EXP gives us a truth-table reduction, say, by machine M_i from K to T. Now fix n and consider all strings of length n. Without loss of generality, we may assume that M_i queries on input x of length n, always the same strings to T, namely, $y_1, \ldots, y_{n^i}$, where $y_i = 0^i$. The idea is to find the minimal (in some way) setting of the y_j's in T such that $x \in K$ iff $M_i(x)$ accepts with this setting. Let x_j indicate the jth string of length n in lexicographic order. Let $P_j = \{<a_1, \ldots, a_{n^i}> : \text{when } a_i \text{ used as answer to query } y_i \text{ then } M_i(x_j) \text{ accepts iff } x_j \in K\}$.

P_j codes exactly those tally sets T' that, when used as an oracle for $M_i(x_j)$, let M_i compute the correct answer for $x_j \in K$. Note here that $\|P_j\| \leq 2^{n^i}$ for $0 \leq j < 2^n$. Set $P' = \bigcap_{i=1}^{2^n} P_i$ and let p_i be the ith projection of the tuple y, where y is the minimal $y \in P'$. Put $0^{<n,i>}$ in T' iff $p_i = 1$. Obviously, T' is tally and from the construction it is clear that T' is computable in exponential time. From the fact that T exists we get that T' exists and that $K \leq_{tt}^{P} T'$. □

THEOREM 3.17. *There exists an oracle A, such that there exists a $\leq_{tt}^{P^A}$-complete set B for EXP^A and a polynomial-time computable, sparse set S, such that $B - S$ is not $\leq_{tt}^{P^A}$-hard for EXP^A.*

Proof. Wilson [26] showed the existence of an oracle A where $EXP^A \subseteq P^A/poly$. Using this oracle, together with Lemma 3.16, we get that there exists a tally set T that is complete for EXP^A. Setting $B = T$ and $S = \{0\}^*$, we get that $B - S = \emptyset$ and $\emptyset$ is not $\leq_{tt}^{P^A}$-complete for EXP^A. □

4. Splittings of *EXP* complete sets. In this section we want to investigate to what extent one can *split* EXP-complete sets. A splitting of an r.e. (EXP) set is the construction of two r.e. (EXP) sets $A_0, A_1 \subseteq A$, such that $A_0 \bigcap A_1 = \emptyset$ and $A_0 \bigcup A_1 = A$. One of the questions to look at is: "Can this splitting be done so that both subsets have the same information as A?" For complete sets this would mean that the complete set can be split into subsets that are themselves again complete. This type of question has been studied in a recursion theoretical setting by Ladner [15]. He observed that there exist sets that are nonsplittable, or non-*mitotic*, as he called them. The recursion theoretical definition is as follows.

DEFINITION 4.1. *An r.e. set A is called mitotic iff there exist r.e. sets A_1 and A_0 such that*

1. $A_1 \subseteq A,\ A_0 \subseteq A,\ A_1 \bigcap A_0 = \emptyset,\ A_1 \bigcup A_0 = A.$
2. $A \equiv_T A_1 \equiv_T A_0.$

If additionally $A \equiv_m A_1 \equiv_m A_0$, then A is called m-mitotic.

Note here that point 2 in the definition can be weakened, in the case of $\leq_T$ reductions, to $A_1 \equiv_T A_0$. To see this note that $A \leq_T A_1 \oplus A_0$ and $A_1 \oplus A_0 \leq_T A_1$. To reduce A_1 to A, the reduction queries on input x whether or not x is in A. If this is not the case, it rejects straight out. Otherwise, it starts enumerating A_1 and A_0, since x must be in one of them.

Ambos-Spies [1] studied the complexity theoretical variant of mitotic sets and introduced the term *p-mitotic* sets. It is not clear how to define mitoticity in the complexity theoretical setting. Ambos-Spies introduced four definitions; two for the Turing reductions and two for the many-one reductions. One option is to change point 2 in Definition 4.1 into demanding $A \equiv_T^P A_1 \equiv_T^P A_0$. Since we are interested in complete sets for complexity classes, we could demand that A_0 and A_1 should be in the complexity class under consideration. A problem is that this definition cannot be weakened to $A_1 \equiv_T^P A_0$. (Take, for example, $\Sigma^* = A \bigcup \overline{A}$ for some *EXP* Turing-complete set A. Now both A and $\overline{A}$ are in *EXP*, split Σ^*, and are Turing equivalent but obviously do not Turing reduce to Σ^*.)

Ambos-Spies chose a Breidbart–Owings [4, 19] type of splitting (*by* another set).

DEFINITION 4.2 (see [1]). *A recursive set A is p-m(T) mitotic if there is a set $B \in P$ such that $A \equiv_{m(T)}^P A \bigcap B \equiv_{m(T)}^P A \bigcap \overline{B}$.*

When using this definition, the problem of reducing A_1 to A is settled for the Turing case. Namely, x is in A_1 iff x is in B and x is in A. A disadvantage of this definition, however, is that the requirement that the splitting has to be polynomial-time computable seems too strong. In order to capture this feeling, we also want to look at the definition discussed above. Note here also that since our main interest is in complete sets, we will not have the trouble that A_0 (or A_1) does not reduce to A. (This is because A is complete.)

DEFINITION 4.3. *An r.e. set A is called weakly p-T mitotic iff there exist r.e. sets A_1 and A_0, such that*

1. $A_1 \subseteq A,\ A_0 \subseteq A,\ \ A_1 \bigcap A_0 = \emptyset,\ \ A_1 \bigcup A_0 = A.$
2. $A \equiv_T^P A_1 \equiv_T^P A_0.$

If additionally $A \equiv_m^P A_1 \equiv_m^P A_0$, then A is called weakly p-m mitotic.

One of the questions that arise is: "Are $\leq_m^P$-complete sets for *EXP* (weakly) *p-m* mitotic?" In order to answer this question, we first take a look at the r.e.-complete sets. There it is known, due to Myhill [18], that all of the $\leq_m$-complete sets are isomorphic. Now, using the fact that K, the standard r.e. $\leq_m$-complete set, is m mitotic and that this property is preserved under isomorphisms, it follows that all $\leq_m$-complete sets are m mitotic. Unfortunately it is not known whether the $\leq_m^P$-complete sets for *EXP* are p isomorphic, but it is known that they are all 1-1 length increasing equivalent [3, 12, 25]. This is sufficient to prove that they are weakly *p-m* mitotic.

THEOREM 4.4. *All $\leq_m^P$-complete sets for EXP are weakly p-m mitotic.*

Proof. Let A be a $\leq_m^P$-complete set for *EXP*. Let $A \oplus A \leq_m^P A$ via f that is 1-1 and length increasing. Set $A_0 = \{y : \exists 0x[x \in A \wedge y = f(0x)]\}$. Since f is 1-1 and length increasing, A_0 is in *EXP*. It is also $\leq_m^P$-complete, because $x \in A$ iff $f(0x) \in A_0$. Now set $A_1 = A - A_0$. Then $A_0 \bigcup A_1 = A$ and $A_0 \bigcap A_1 = \emptyset$. It remains to show that A_1 is also $\leq_m^P$-complete. Let $A^1 = \{1x : x \in A\}$. Note that $A^1 \subseteq A \oplus A$ and is $\leq_m^P$-complete. Because f is 1-1, $1x \in A^1 \Rightarrow f(1x) \in A - A_0$, and $1x \notin A^1 \Rightarrow 1x \notin A \oplus A \Rightarrow f(1x) \notin A \Rightarrow f(1x) \notin A - A_0$. □

For *EXP*, the 1-1 length increasing property is enough to get weak *p-m* mitoticity. For *NEXP* the situation is somewhat different, because we do not know whether we have the length increasing property for complete sets. We do however have the 1-1 property and the fact that the reductions are not more than exponential length decreasing, i.e., $2^{|f(x)|} > |x|$. (The precise term here is "exponentially honest" [12].) The main problem, however, is that when applying the same proof as above, the set difference used to define $A_1 = A - A_0$ is not known to be in *NEXP*, because it is not known whether *NEXP* is closed under complementation (and thus under set difference). We *can* prove something that at first glance looks hopeful in order to prove weakly *p-m* mitoticity for *NEXP*-complete sets.

THEOREM 4.5. *Every $\leq_m^P$-complete set A for NEXP can be split into infinitely many disjoint subsets $A_1, A_2, \ldots$ such that $\bigcup_{i=0}^{\infty} A_i = A$, such that for all i, $A_i \subseteq A$ and A_i is complete for NEXP.*

Proof. We start the same way as in the *EXP* case. Let $A \oplus A \leq_m^P A$ via f that is 1-1 and exponentially honest. Set $A_0 = \{y : \exists\ 0x[y = f(0x) \wedge y \in A]\}$. Note that it is equivalent, in the definition of A_0, to say that $x \in A$ or $y \in A$, because f is a many-one reduction. Now A_0 is in *NEXP* : on input y guess $0x$ such that $f(0x) = y$. This can be done in nondeterministic exponential time because $|x| < 2^{|y|}$, by the exponential honesty of f. Now accept y iff $y \in A$. We define A_1 in a similar way. $A_1 = \{y : \exists\ 1x[y = f(1x) \wedge y \in A]\}$. We now have two complete sets A_0 and A_1 and some leftover of A, namely, $T_0 = A - (A_0 \bigcup A_1)$. At this point we repeat this procedure with A_0 resulting in A_{00} and A_{01} and again have some leftover T_1. The process of repeatedly splitting the set A_{0^ℓ} thus results in an infinite sequence of sets $(A_{0^\ell 1})_{\ell \in \omega}$ and a set $T = \bigcup_{i=0}^{\infty} T_i$ so that $(\bigcup_{\ell=0}^{\infty} A_{0^\ell 1}) \bigcup T = A$. Since T is countable (it is a subset of ω), we can add the ith element of T to $A_{0^i 1}$ resulting in a sequence $A'_{0^i 1}$ satisfying the properties of the theorem. □

Although this looks hopeful, the following example shows that the infinite version of mitoticity can be independent of mitoticity. Ladner [15] showed the existence of *nonmitotic* sets. Together with the following observation this yields the somewhat bizarre existence of a set that cannot be split into two parts but can be split into infinitely many parts of the same complexity.

OBSERVATION 4.6. *Every infinite r.e. set A can be split into infinitely many disjoint r.e. subsets $A_1, A_2, \ldots$ of A such that they remain in the same Turing degree as A.*

Proof. It is well known that every infinite r.e. set A has an infinite subset B that is recursive. Let B be such an infinite recursive subset of A. Since B is recursive and infinite, it is (recursively) isomorphic to Σ^*. So we can code A into B, i.e., let f be the isomorphism between Σ^* and B and define $A' = \{f(x) \mid x \in A\}$. Obviously A' is an infinite r.e. set and $A' \equiv_T (A - B)$. Furthermore there exists a T_1 such that $A = (A - B) \bigcup A' \bigcup T_1$. Now using the same "divide and split" trick as in the previous theorem, we get the desired sequence of subsets. □

We follow the same line as Ladner [15] and try to prove that there exist non-(weakly *p-m*) mitotic sets in *EXP*. We succeed in this and can also prove that those sets can be $\leq_3^P$-*tt*-complete. (Note that this also proves that the same result is true for *p-m* mitoticity.)

THEOREM 4.7. *There exists a set A in EXP that is not weakly p-m mitotic and $\leq_{3-tt}^P$-complete.*

Proof. In order to prove this, we prove the following: there exists a set A so that for all sets $A_0, A_1 \in EXP$ that split A, $A_0 \not\equiv_m^P A_1$. First note that if $A_i \notin EXP$, then $A_i \not\equiv_m^P A$ so, in the construction, we may assume that both A_0 and A_1 are recognized by exponential-time bounded machines. Or, equivalently, only pairs of exponential-time bounded machines represent candidate splittings of A against which we have to diagonalize.

Let $\{M_i\}_i$ be an enumeration of exponential-time machines that run in time 2^{n^i}, and let $\{f_k\}_k$ be an enumeration of polynomial-time many-one reductions computable in time n^k.

To construct A, we have requirements for all $n = \langle i, j, k, \ell \rangle$: if $L(M_i)$ and $L(M_j)$ split A, then either $L(M_j) \not\leq_m^P L(M_i)$ via f_ℓ or $L(M_i) \not\leq_m^P L(M_j)$ via f_k.

We introduce a function b having a set of strings to diagonalize on. Let $b(0) = 1$ and $b(i) = b(i-1)^{i-1} + 1$. At each stage n we will also define a number d_{n+1} such that if $n + 1 = \langle i', j', k', \ell' \rangle$, i.e., the *next* stage will diagonalize against ma-

chines $M_{i'}$ and $M_{j'}$ and functions $f_{k'}$ and $f_{\ell'}$, then d_{n+1} is some number satisfying $b(n+1)^{1/\max\{i',j'\}} > d_{n+1} > \max\{k',l'\} \times \log b(n+1)$. We will assume appropriate properties on the pairing function such that the interval from d_n to d_{n+1} is suitable for the construction. All strings in A with length between d_n and d_{n+1} will be defined at stage n.

The idea is to put three copies of K into A and make sure that at least one of the pairs $<i,x>$ $(i = 1,2,3)$ is in A. A is then $\leq^P_{3\text{-}tt}$(in fact $\leq^P_{3\text{-}d}$)-complete by the following reduction from K to A: $x \in K$ iff $<i,x>(i = 1,2,3)$ in A. On the other hand we can leave out at most two of the pairs $<i,x>$ to prevent A from becoming a mitotic set.

Construction:

stage 0: $A = \{<i,x> \mid i = 1,2,3 \text{ and } x \in K\}$. This is the "base set A." At any subsequent stage n of the construction, at most two strings y_0 and y_1, respectively, with $d_n \leq |y_0|, |y_1| < d_{n+1}$ and the string $0^{b(n)}$ will be added to or removed from A. A will be decided for all strings of length $\leq d_{n+1}$ after stage n.

Without loss of generality, we assume for this proof that the pairing function does not output strings that start with a 0. Then, we can define strings of the form $0^{b(i)}$ in or outside A without disturbing the completeness.

stage n:

Let $n = <i,j,k,\ell>$. This stage will diagonalize against the possibility that $A = L(M_i) \cup L(M_j)$ and/or that $L(M_i) \equiv^P_m L(M_j)$ via the functions f_k and f_ℓ Consider $f_k(0^{b(n)}) = y_0$ and $f_\ell(0^{b(n)}) = y_1$.

We have several cases to consider.

1. $y_0 = 0^{b(n)}$ or $y_1 = 0^{b(n)}$ in this case we put $0^{b(n)}$ into A.
2. $y_0 = y_1$, and not case 1. We have two subcases:
   (a) $|y_0| > d_n$. Leave y_0 out of A and put $0^{b(n)}$ in A.
   (b) $|y_0| \leq d_n$. Put $0^{b(n)}$ in A iff $y_0 \notin A$
3. $y_0 \neq y_1$, and not case 1. We have three subcases:
   (a) $|y_0| > d_n$ and $|y_1| > d_n$. Leave both y_0 and y_1 out of A and put $0^{b(n)}$ in A.
   (b) $|y_0| > d_n$ and $|y_1| \leq d_n$. ($|y_0| \leq d_n$ and $|y_1| > d_n$ is treated analogously.) We leave y_0 out of A and have two subcases:
      i. $y_1 \notin A$. Put $0^{b(n)}$ in A.
      ii. $y_1 \in A$. $0^{b(n)} \in A$ iff $M_j(y_1)$ accepts.
   (c) $|y_0| \leq d_n$ and $|y_1| \leq d_n$. We have three subcases:
      i. $y_1 \notin A$ and $y_0 \notin A$. Put $0^{b(n)}$ in A.
      ii. $y_1 \in A$ and $y_0 \notin A$. (The other way around is symmetric) $0^{b(n)} \in A$ iff $M_j(y_1)$ accepts.
      iii. $y_1 \in A$ and $y_0 \in A$. $0^{b(n)} \in A$ iff $M_i(y_0)$ accepts *and* $M_j(y_1)$ accepts.

end of stage n

End of Construction

This ends the construction of A. The proof of correctness of the construction is an analysis of the cases in the construction. First, A is exponential-time computable. A consists of strings $<i,x>$ where $x \in K$. Possible membership of these strings in A can be decided because K is exponential-time computable. To decide membership of other strings y in A, we need to compute $f_\ell(0^{b(n)})$ where $d_n \leq |y|$. This can be done in (linear) exponential time since $|y| \geq \max\{\ell,k\} \times \log b(n)$. Finally, to decide membership of $0^{b(n)}$ in A we sometimes need to compute $M_j(y)$ and/or $M_k(y)$ on some input y of length $\leq d_n$. This can be done in linear exponential time since $b(n) \geq d_n^{\max\{i,j\}}$.

Next, if A were m mitotic, then there exists a pair k, ℓ such that A is split into A_0 and A_1 and $A_0 \leq_m^P A_1$ via f_k and $A_1 \leq_m^P A_0$ via f_ℓ. Moreover, $A_0 \in EXP$ as is witnessed by machine M_i and $A_1 \in EXP$ as is witnessed by machine M_j.

The cases of the construction can be split into two types, namely, the type where both y_0 and y_1 are free, i.e., $> d_n$, and the type where either y_0 or y_1 is forced ($\leq d_n$). In the "free" cases we diagonalize by putting $0^{b(n)}$ in A and leaving both y_1 and y_0 out of A. Since $0^{b(n)} \in A$, it has to be in either A_0 or A_1, but if it is in either one then the corresponding reduction fails since its image is not in A (and therefore certainly not in the other part of A). In these cases we diagonalize directly against the many-one reductions. In the other cases we are forced to leave y_1 and y_0 in A in order not to destroy the work done at previous stages. But in these cases we are able to compute in exponential time the splittings we want to diagonalize against. We will show the correctness of case 3c(iii) in the construction. The other cases have a similar proof. In this case, both y_0 and y_1 are fixed and in A. By putting $0^{b(n)}$ in A, we force y_0 and y_1 for any *possible correct* splitting both to be in either A_0 or A_1. Yet, the machines M_i and M_j witness that y_0 and y_1 are in A_0 and A_1, respectively. On the other hand, by leaving $0^{b(n)}$ out of A, y_1 has to be in A_p and and y_0 in A_{1-p} ($p = 0, 1$). Since one of the machines rejects in this case, the other machine has to witness that y_0 and y_1 are both in A_0 or A_1. If, for instance, M_i witnesses that both strings are in A_0, then, since $0^{b(n)} \notin A_1$, reduction f_ℓ fails to be a reduction from A_1 to A_0. □

The next logical step would be to prove this result for Turing-complete sets and T mitoticity. This question remains open for further research.

Another line of splittings in recursion theory is the existence of a splitting of an r.e. set A in A_0 and A_1 that are incomparable. Examples of this are the splitting theorem of Sacks [20] and the time bounded versions by Ladner [16]. The next theorem is in a way a counterpart to this.

In the original splittings one gets the following structure: A_0 and A_1 are Turing (or many one) incomparable but do reduce to A, thus achieving that A does not reduce to A_0 or A_1, i.e., A_0 and A_1 are strictly below A. In the next theorem the sets A_0 and A_1 are strictly below A, but are in the same many-one degree. Seen in another light, this theorem can be seen as a generalization of the fact that there exists $\leq_{2-d}^P$-complete sets for EXP that are not $\leq_m^P$-complete [25, 12].

THEOREM 4.8. *If A is $\leq_m^P$-complete for EXP, then A can be split into A_0 and A_1, such that*

- $A_0 \equiv_m^P A_1$.
- *A_0 and A_1 are $\leq_{2\text{-}d}^P$-complete for EXP but not $\leq_m^P$-complete.*

Proof. Let A be $\leq_m^P$-complete and K be the standard $\leq_m^P$-complete set. Since the $\leq_m^P$-complete sets for EXP are 1-1 length increasing equivalent, we can construct the following length increasing 1-1 function h from A to A. Let f be the 1-1, length increasing reduction from A to K, and let g be the one from K to A. Let $h(x) = f(g(x))$. We say that x is a *root* if $h^{-1}(x)$ is undefined and x is *on a chain* if $h^{-1}(x)$ is defined.

One possible way to construct A_0 and A_1 is as follows (the real construction follows later): $A_0 = \{x \mid x \in A \text{ and } x \text{ is a root } \} \bigcup \{x \mid x \in A \text{ and } x \text{ is on a chain and } h^i(x_r) = x \text{ and } x_r \text{ is a root and } i \text{ is even}\}$ and $A_1 = \{x \mid x \in A \text{ and } x \text{ is on a chain and } h^i(x_r) = x \text{ and } x_r \text{ is a root and } i \text{ is odd}\}$.

Clearly A_0 and A_1 split A, are in EXP, and $A_0 \equiv_m^P A_1$ via h. A_0 and A_1 are $\leq_{2\text{-}d}^P$-complete: $x \in A \iff (x \in A_0 \text{ or } x \in A_1) \iff (x \in A_0 \text{ or } h(x) \in A_0)$. The only thing to do now is to show that A_0 and A_1 are not $\leq_m^P$-complete. Note here that in order to get the above properties (i.e., splitting of A, the $\equiv_m^P$, and the $\leq_{2\text{-}d}^P$-completeness)

it doesn't matter if the roots are in A_0 or A_1 as long as it holds that $x \in A_i$, then $h(x) \in A_{1-i}$. This gives enough freedom to diagonalize against $\leq_m^P$-reductions. We are going to construct a set $W \in EXP$ so that $W \not\leq_m^P A_0$. Note that then A_1 cannot be $\leq_m^P$-complete either. Again let $\{f_i\}_i$ be an enumeration of $\leq_m^P$-reductions such that f_i runs in time $n^i + i$. We also need a function $b(n)$ to denote the set of strings to diagonalize on. Let $b(0) = 1$ and $b(i+1) = b(i)^i + 1$. W is going to be a subset of 0^*.

We construct W, A_0, and A_1 in stages such that elements of A_0 and A_1 are either roots or successive elements on a chain and W is exponential-time computable, but reducible to neither A_0 nor A_1.

At stage 0, $W = A_0 = A_1 = \emptyset$.

stage n:

We have constructed W, A_0, and A_1 up to strings of length $\leq b(n-1)^{n-1}$. We simulate $f_n(0^{b(n)}) = y$. We now have three cases for the construction of W:

1. $|y| \leq b(n-1)^{n-1}$. Put $0^{b(n)}$ in W iff $y \notin A_0$.
2. $\exists\, y' \leq b(n-1)^{n-1}$ such that $h^i(y') = y$. Put $0^{b(n)}$ in W iff $y' \notin A_{i \bmod 2}$.
3. Otherwise put $0^{b(n)}$ in W.

This ends the construction of W.

Construction of A_0 and A_1.

Let $b(n-1)^{n-1} < |x| < b(n)^n + 1$ and $x \in A$.

1. $x \neq y$.
   (a) x is a root.
   - $\exists\, i$ such that $h^i(x) = y$
     - put x in A_0 iff i is odd.
     - put x in A_1 iff i is even.
   - put x in A_0.

   (b) x is on a chain, x_r is the root of x, $x_r \in A_j$, and $h^i(x_r) = x$. Put x in $A_{(i+j) \bmod 2}$.
2. $x = y$. Put x in A_0 iff $0^{b(n)} \notin W$.

end of stage n

It is not hard to see that W, A_0, and A_1 are all in EXP. Furthermore A_0 and A_1 split A and $A_0 \equiv_m^P A_1$. It remains to be shown that $W \not\leq_m^P A_0$. Suppose it is via reduction f_j; then $f_j(0^{b(j)}) = y$. For cases 1 and 2 in the above construction, $0^{b(j)} \in W$ iff $y \notin A_0$, and from the construction of A_0 and case 3, $0^{b(j)} \in W$ and $y \notin A_0$. □

Acknowledgments. We thank Peter van Emde Boas for discussions about the results. We thank Steven Homer, Dick de Jongh, and Jan van Neerven for discussions and ideas. We thank Stephen Wilcox for pointing out an error that we thought was grammatical but that turned out to be mathematical.

CONSTRUCTING LEVELS IN ARRANGEMENTS AND HIGHER ORDER VORONOI DIAGRAMS *

PANKAJ K. AGARWAL†, MARK DE BERG‡, JIŘÍ MATOUŠEK§, AND OTFRIED SCHWARZKOPF¶

Abstract. We give simple randomized incremental algorithms for computing the $\leq k$-level in an arrangement of n lines in the plane or in an arrangement of n planes in $\mathbb{R}^3$. The expected running time of our algorithms is $O(nk + n\alpha(n)\log n)$ for the planar case and $O(nk^2 + n\log^3 n)$ for the three-dimensional case. Both bounds are optimal unless k is very small. The algorithm generalizes to computing the $\leq k$-level in an arrangement of discs or x-monotone Jordan curves in the plane. Our approach can also compute the k-level; this yields a randomized algorithm for computing the order-k Voronoi diagram of n points in the plane in expected time $O(k(n-k)\log n + n\log^3 n)$.

1. Introduction.

Arrangements of hyperplanes have been studied for a long time in combinatorial and computational geometry and yet they have kept some of their secrets. Some of the intriguing open questions are related to the concept of *levels*. We say that a point p is at level k with respect to a set H of nonvertical hyperplanes in $\mathbb{R}^d$ if there are exactly k hyperplanes in H that lie strictly above p. The k-level of an arrangement $\mathcal{A}(H)$ of hyperplanes is the closure of all $(d-1)$-cells of $\mathcal{A}(H)$ whose interior points have level k with respect to H. It is a monotone piecewise-linear surface; see Figure 1. The $\leq k$-level of $\mathcal{A}(H)$ is the complex induced by all cells of $\mathcal{A}(H)$ lying on or above the k-level. The k-level and the $\leq k$-level of arrangements of monotone surfaces are defined analogously. In fact, one can give a more general definition of levels, which is useful in certain applications. Given a family Γ of subsets (also called *ranges*) of $\mathbb{R}^d$, define the level of a point p with respect to Γ to be the number of ranges that contain p in their interior; k-level and $\leq k$-level are defined as above. For a set H of hyperplanes, if we choose ranges to be the halfspaces lying below the hyperplanes of H, then the level of p is the same under the two definitions.

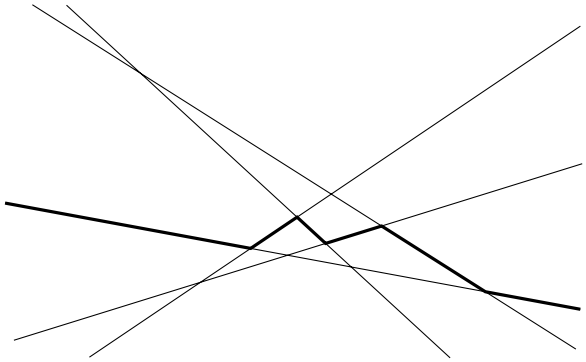

FIG. 1. *The* 2*-level in an arrangement of lines.*

We will not distinguish between the two definitions of levels, as it will be clear from the context to which of them we are referring.

The maximum combinatorial complexity of the $\leq k$-level in an arrangement of hyperplanes in $\mathbb{R}^d$ is known precisely. Using a probabilistic argument, Clarkson and Shor [CS89] proved that it is $\Theta(n^{\lfloor d/2 \rfloor} k^{\lceil d/2 \rceil})$. By a similar technique, Sharir [Sha91] proved that the maximum complexity of the $\leq k$-level for a set of n discs is $\Theta(nk)$. He also proved that the complexity of the $\leq k$-level for n x-monotone Jordan curves, each pair of which intersects in at most s points, is $O(k^2 \lambda_s(n/k))$. Here $\lambda_s(m)$ is the maximum length of an (m, s) Davenport–Schinzel sequence; $\lambda_s(m)$ is roughly linear in m for any constant s [ASS89].

The problem of efficiently computing the $\leq k$-level has not been resolved completely. Mulmuley [Mul91b] gave a randomized incremental algorithm for computing the $\leq k$-level in hyperplane arrangements in any dimension. For $d \geq 4$, the expected running time of his algorithm is $O(n^{\lfloor d/2 \rfloor} k^{\lceil d/2 \rceil})$, which is optimal. For $d = 2, 3$ the expected running time of his algorithm is $O(nk^{\lceil d/2 \rceil} \log(n/k))$, which exceeds the output size by a logarithmic factor. Recently, Everett, Robert, and van Kreveld [ERvK96] gave an optimal $O(n \log n + nk)$ expected time randomized algorithm for computing the $\leq k$-level in an arrangement of lines in the plane. Their algorithm does not easily extend to more general ranges.

Mulmuley's algorithm can be applied to compute the $\leq k$-level of arrangements of x-monotone Jordan curves in the plane, but it is not clear how to generalize it for computing the $\leq k$-level for more general ranges like discs. Sharir [Sha91] presented a divide-and-conquer algorithm for computing the $\leq k$-level of rather general ranges in the plane. Its worst-case running time is roughly $\log^2 n$ times the maximum size of the $\leq k$-level.

In this paper we give a somewhat different randomized incremental algorithm for computing the $\leq k$-level whose expected running time is $O(nk + n \log n\, \alpha(n))$ in the plane and $O(nk^2 + n \log^3 n)$ in 3-space, which is worst-case optimal unless k is very small. The main difference of this algorithm compared with Mulmuley's algorithm [Mul91b, Mul93] is as follows. Mulmuley's algorithm inserts the hyperplanes one by one in a random order and maintains the $\leq k$-level of $\mathcal{A}(R)$, the arrangement of the hyperplanes that have already been inserted. When adding a new hyperplane h, the algorithm first updates the arrangement locally at cells that are intersected by h. Then it removes cells that have "fallen off" because they are now on level $k+1$; Mulmuley calls this the *peeling step*. Our algorithm maintains a part of $\mathcal{A}(R)$ that is in general

smaller than the $\leq k$-level. Namely, when inserting a new hyperplane, the algorithm estimates the level of each of the newly created cells of the current cell complex with respect to H, the full set of hyperplanes. Mulmuley's algorithm, in contrast, looks at the level with respect to R, the set of hyperplanes already inserted. As soon as our estimate shows that a cell lies completely outside the $\leq k$-level, it is discarded. This strategy can also be used in situations where Mulmuley's algorithm has difficulty accessing the cells of the current complex that must be peeled off. This is, for instance, the case where one wants to compute the $\leq k$-level in an arrangement of discs.

Our approach can also be used to compute the k-level in an arrangement. This time a cell of the current cell complex is discarded as soon as it becomes clear that it does not intersect the k-level of $\mathcal{A}(H)$. The complexity of this algorithm depends on combinatorial bounds on the complexity of a k-level, and here the knowledge is less satisfactory than for the $\leq k$-level. Lovász proved that a k-level in an arrangement of n lines in the plane has $O(n\sqrt{k})$ vertices [Lov71], and Erdős et al. [ELSS73] proved a lower bound of $\Omega(n \log(k+1))$. There was no progress on this problem for the last twenty-five years except for a slightly improved upper bound by Pach, Steiger, and Szemerédi [PSS92]. Recently, Dey [Dey97] improved the upper bound to $O(nk^{1/3})$. See [AAS97, DE93, ZV92] for known results on k-levels in higher dimensions. Edelsbrunner and Welzl [EW86] gave an algorithm for computing the k-level in the plane, which was later slightly improved by Cole, Sharir, and Yap [CSY87] to $O(n \log n + m \log^2 k)$ running time, where m stands for the actual complexity of the k-level. Our algorithm yields $O(nk^{1/3} \log^{2/3} n + n \log^2 n)$ expected time complexity. (If one could prove better worst-case bounds for the k-level maximum complexity, we would get an improvement in the algorithm's complexity as well; see section 4 for exact bounds.) This compares favorably to the worst-case running times of previous algorithms; however, our algorithm is not fully output sensitive (its running time depends on the complexity of levels in arrangements of various random subsets of the given lines). In principle, our algorithm for computing the k-level also works in higher dimensions, and its running time can be obtained by plugging the known bounds on the complexity of the k-level in higher dimensions [ABFK92, DE93, ZV92] into the analysis of our algorithm. We, however, do not discuss it in this paper, because our main interest lies in the special three-dimensional case discussed next.

If all the hyperplanes are tangent to the unit paraboloid, the maximum complexity of the k-level of a three-dimensional arrangement is known to be $\Theta(k(n-k))$. This situation arises when the planes are the images of a set of points in the plane under the transformation that maps the order-k Voronoi diagram of these points to the k-level of the planes (see, e.g., [Ede87]). Most known algorithms for computing the k-level in three-dimensional space actually compute the $\leq k$-level [Mul91b, CE87, BDT93]. Since the complexity of the $\leq k$-level is $\Theta(nk^2)$ in the situation sketched above, the running time of these algorithms is at least $\Omega(nk^2 + n \log n)$. The randomized incremental algorithm by Aurenhammer and Schwarzkopf [AS92] maintains only the k-level, but it can be shown that any randomized incremental algorithm that maintains the k-level of the intermediate arrangements must take time $\Omega(nk^2)$ as well, since the expected number of structural changes in the k-level is $\Omega(nk^2)$ [AS92]. The only algorithm that approaches the desired $O(k(n-k))$ time bound was presented by Clarkson [Cla87], and it runs in time $O(n^{1+\varepsilon}k)$, where $\varepsilon > 0$ is an arbitrarily small constant. His algorithm can probably be improved somewhat by using more recent results on geometric cuttings.

We show that our algorithm for computing the k-level for n planes tangent to the unit paraboloid runs in $O(k(n-k)\log n + n\log^3 n)$ expected time in this case. We conjecture that the running time is in fact $O(k(n-k)+n\log n)$, which is asymptotically optimal, but currently we cannot prove it.

2. Preliminaries.

Arrangements. Let H be a set of n hyperplanes in d-dimensional space. We denote the arrangement of H by $\mathcal{A}(H)$. We regard it as a cell complex with cells (also called faces) of dimensions 0 to d that are relatively open. We define the *level* of a cell of $\mathcal{A}(H)$ as the level of any point of its relative interior.

For simplicity of exposition, we assume that the hyperplanes are in general position. This assumption can be removed by a more careful (and technically a little more complicated) treatment or by standard perturbation arguments [Ede87].

Canonical triangulations. Let $\mathcal{C}$ be a subcomplex of $\mathcal{A}(H)$, that is, a collection of cells of $\mathcal{A}(H)$ such that whenever $C \in \mathcal{C}$ and C' is a face of C, then also $C' \in \mathcal{C}$. The *canonical triangulation*[1] of $\mathcal{C}$ ([Cla88]), which we denote by $\mathcal{C}^\nabla$, is defined as follows. Let C be a j-dimensional cell of $\mathcal{C}$ (thus, a convex polytope), and let v be the bottom vertex of C, that is, the lexicographically smallest vertex of C. If $j = 1$, then C is a segment and it is already a (one-dimensional) simplex. If $j > 1$, then we recursively triangulate the $(j-1)$-dimensional faces of C and extend each $(j-1)$-simplex to a j-simplex using the vertex v. (Unbounded cells require some care in this definition [Cla88].) The canonical triangulation of a cell with m vertices has $O(m)$ simplices. The canonical triangulation $\mathcal{C}^\nabla$ of the subcomplex $\mathcal{C}$ is the simplicial complex obtained by triangulating each cell of $\mathcal{C}$ in this manner.

Let R be a subset of H. For a (relatively open) simplex $\Delta \in \mathcal{A}(R)^\nabla$, let $K(\Delta)$ denote the set of hyperplanes of H intersecting Δ, and put $w(\Delta) = |K(\Delta)| + 1$. The hyperplanes from $K(\Delta)$ are said to be *in conflict with* Δ, and $w(\Delta)$ is called the *weight* of Δ.

For each simplex Δ of the canonical triangulation, let $D(\Delta) \subseteq H$ be a set of hyperplanes such that Δ appears in the canonical triangulation of the arrangement of $D(\Delta)$, but does not appear in the canonical triangulation of $\mathcal{A}(D')$ for any proper subset $D' \subset D(\Delta)$. It can be shown that if H is in general position, $D(\Delta)$ is unique and its size is bounded by a constant $b = b(d)$. This $D(\Delta)$ is called the *defining set* of Δ. For instance, for $d = 2$ a typical triangle Δ is defined by five lines—the two lines whose intersection is the bottom vertex, the line containing the side opposite to the bottom vertex, and the two lines intersecting this side at the other two vertices of Δ, so $b(2) = 5$. The following fact is often used in the analysis of randomized geometric algorithms; among others, it captures the above-mentioned uniqueness of the defining set. For a proof and detailed discussion, see Chazelle and Friedman [CF90, sec. 5].

FACT 2.1. *Let $S \subseteq H$, and let Δ be a simplex of $\mathcal{A}(S)^\nabla$. Then the following condition holds: for any $R \subseteq H$, $\Delta \in \mathcal{A}(R)^\nabla$ if and only if $D(\Delta) \subseteq R$ and $R \cap K(\Delta) = \emptyset$.*

When generalizing the algorithm below to computing the $\le k$-level in more general arrangements (for example, in an arrangement of discs), we need to define an appropriate analog of the canonical triangulation having the above property.

A tool for analyzing randomized incremental algorithms. We now discuss a random-sampling result that we need for the analysis of our algorithms. We do not state it in a full generality but only in the specific setting in which we need it.

[1] Sometimes the name *bottom vertex triangulation* is used in the literature.

LEMMA 2.2. *For each $R \subseteq H$, let $\mathcal{C}(R)$ be a subcomplex of the arrangement $\mathcal{A}(R)$. Assume that the subcomplexes have the following "monotonicity" property:*

(∗) *Let $R' \subseteq R \subseteq H$, let C be a cell of $\mathcal{C}(R)$, and let C' be the cell of $\mathcal{A}(R')$ containing C. Then $C' \in \mathcal{C}(R')$.*

(For instance, $\mathcal{C}(R)$ may be the collection of all cells in $\mathcal{A}(R)$ intersecting some fixed set $X \subseteq \mathbb{R}^d$, plus their lower-dimensional faces. Then (∗) clearly holds. In our applications, the definition of $\mathcal{C}(R)$ will be a bit more technical, but it will have a similar flavor.)

Let $f : \mathbb{N} \to \mathbb{R}^+$ be a nondecreasing function so that $f(r)$ is an upper bound for the expected total number of vertices of $\mathcal{C}(R)$, where R is a randomly chosen r-element subset of H. Then we have the following:

(i) *Let R be a randomly chosen r-element subset of H, and let c be a constant. Then*

$$\mathbf{E}\left[\sum_{\Delta\in\mathcal{C}(R)^\nabla} w(\Delta)^c\right] = O\left(\left(\frac{n}{r}\right)^c f(r)\right).$$

(ii) *Consider a randomized incremental algorithm that inserts the hyperplanes of H one by one in a random order and maintains $\mathcal{C}(R)^\nabla$, where $R = \{h_1, h_2, \ldots, h_r\}$ is the set of hyperplanes already inserted. Let $\mathcal{N}_r$ denote the set of simplices newly created at step r, that is, $\mathcal{N}_r = \mathcal{C}(\{h_1, h_2, \ldots, h_r\})^\nabla \setminus \mathcal{C}(\{h_1, h_2, \ldots, h_{r-1}\})^\nabla$. Then for any constant $c \geq 0$ we have*

$$\mathbf{E}\left[\sum_{\Delta\in\mathcal{N}_r} w(\Delta)^c\right] = O\left(\frac{n^c}{r^{c+1}} f(r)\right).$$

Part (i) says that, under condition (∗), the expected average weight $w(\Delta)$ of a simplex in $\mathcal{C}(R)^\nabla$ is about n/r even if we take the cth degree averages. Often the amount of work that a randomized algorithm performs at step r is directly related to the weight of the newly created simplices; part (ii) can then be used to analyze the running time.

Sketch of proof. Results of this type were first obtained by Chazelle et al. [CEG+93], who essentially proved (ii) with $c = 1$ (in a more general setting) by analyzing a randomized incremental algorithm. The general case, where $c > 1$, can be obtained by an extension of their analysis, as is shown by de Berg, Dobrindt, and Schwarzkopf [dBDS94]. A somewhat different approach, going via the "static" part (i) and generalizing an approach of Chazelle and Friedman [CF90], is presented by Agarwal, Matoušek, and Schwarzkopf [AMS97]. In order to apply the general framework of [AMS97] to our situation, we need the following properties of the canonical triangulation of $\mathcal{C}(R)$:

(a) If a simplex Δ is present in $\mathcal{C}(R)^\nabla$, then $D(\Delta) \subseteq R$ and $K(\Delta) \cap R = \emptyset$.

(b) For any $\Delta \in \mathcal{C}(R)^\nabla$, we have $\Delta \in \mathcal{C}(R')^\nabla$ whenever $R' \subseteq R$ and $D(\Delta) \subseteq R'$.

Condition (a) is immediate from Fact 2.1, and condition (b) follows from Fact 2.1 together with property (∗). Under these conditions, (i) is proved by Agarwal, Matoušek, and Schwarzkopf [AMS97]. Part (ii) can now be derived from (i) by *backward analysis*: the simplices of $\mathcal{N}_r$ are those destroyed by deleting the hyperplane h_r from $R = \{h_1, h_2, \ldots, h_r\}$. Since the order of hyperplanes is random, h_r is a random hyperplane of R. Each simplex of $\mathcal{C}(R)^\nabla$ is only destroyed by deleting h_r if $h_r \in D(\Delta)$.

Therefore, the expected sum $\sum_\Delta w(\Delta)^c$ over the simplices destroyed by deleting a random hyperplane of R is at most b/r times the expectation of $\sum_{\Delta\in\mathcal{C}(R)^\nabla} w(\Delta)^c$, and since R is a random r-element subset of H, we can use (i). □

3. Computing the $\leq k$-level and k-level for hyperplanes.

Outline of the algorithm. We describe the algorithm for an arbitrary dimension $d \geq 2$ because it may be a useful alternative to Mulmuley's algorithm even for $d \geq 4$ (although the asymptotic running time for $d \geq 4$ is the same as that of his algorithm).

We first generate a random permutation $h_1, h_2, \ldots, h_n$ of H and then insert the hyperplanes one by one in this order. Let R denote the set $\{h_1, \ldots, h_r\}$ of hyperplanes inserted in the first r steps. As the hyperplanes are inserted, the algorithm maintains the following structures:

- The canonical triangulation $\mathcal{K}_r^\nabla$ of a subcomplex $\mathcal{K}_r$ of $\mathcal{A}(R)$ (more precisely, we store the simplices as well as their adjacency relations).
- The conflict lists: for every simplex $\Delta \in \mathcal{K}_r^\nabla$, the list $K(\Delta)$ of hyperplanes of $H \setminus R$ intersecting its relative interior, and for every hyperplane $h \in H \setminus R$, the list of all simplices with $h \in K(\Delta)$.
- For every simplex $\Delta \in \mathcal{K}_r^\nabla$, the level ℓ_Δ of one of its (arbitrarily chosen) interior points with respect to $\mathcal{A}(H)$.

At a high level, the insertion of a new hyperplane h_r can be described as follows.

1. Find all cells of $\mathcal{K}_{r-1}$ intersected by h_r using the conflict lists. Split such cells, retriangulate them as necessary, update the conflict lists, and compute the level information for the new simplices.
2. Test each of the newly created cells to see whether it is *active* (the meaning of this will be described below). If a new cell is not active, its simplices and their conflict lists are discarded. The resulting complex is $\mathcal{K}_r$.

We now discuss these steps in more detail.

Updating the information. In the first step, we identify all the simplices in $\mathcal{K}_{r-1}^\nabla$ intersected by h_r using the conflict lists. Since we know the adjacency relations among the simplices, we can compute the intersected simplices as a collection of groups, one for each cell that h_r intersects. Consider such a group, and let C be the corresponding cell. All the simplices in the group have to be deleted and replaced by a number of new simplices. We first consider the situation for $d = 2$, which is illustrated in Figure 2. To deal with the part of C that lies on the same side of h_r as the bottom vertex v of C, we draw new diagonals from v to the two intersection points of h_r with the boundary of C; this creates three new simplices. The part of C lying on the opposite side of h_r is simply triangulated from scratch. This way the canonical triangulations of the two cells that result from the splitting of C are constructed in time that is linear in the number of new simplices that are created. The adjacency relations among the simplices can easily be determined during the process.

Things are not very different in higher dimensions. Consider a three-dimensional cell C. We first retriangulate the two-dimensional facets that are intersected, in the way we just described. We also triangulate the facet $C \cap h_r$. It remains to connect the triangles of the boundary triangulation to the correct bottom vertex (this is necessary only if they were not already connected to this vertex in the triangulation of C, of course); this is analogous to the two-dimensional case. In general, in dimension d we first treat the parts of the $(d-1)$-facets incident to intersected simplices recursively, and then we connect the $(d-1)$-simplices that still need to be extended to d-simplices to the correct bottom vertex.

Our second task is to compute the conflict lists of the new simplices. Let C be a cell that has been split by h_r into two new cells C' and C'', where C' is the cell that

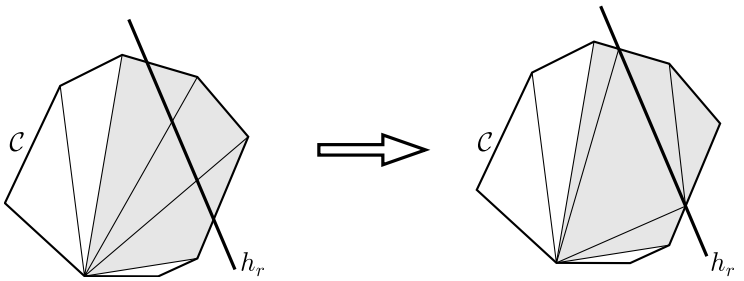

FIG. 2. *Retriangulation of a cell that is split.*

contains the bottom vertex of C. Let S be the set of new simplices in C' and C''. Some of the simplices of C' may already have existed in C; these simplices already have the correct conflict list and are not present in S. The union of the conflict lists for the simplices in S is the same as the union of the conflict lists of the simplices of C that were destroyed by h_r (minus h_r itself). We denote this set of hyperplanes by $K(S)$. To find the conflict lists for the simplices in S, we first determine for each hyperplane $h \in K(S)$ one simplex of S that it intersects — its *initial simplex* — as follows.

Consider a hyperplane $h \in K(S)$. If h intersects some simplex of S in an edge that is also an edge of the old cell C, then this simplex can serve as initial simplex for h. We can find it through the conflict list of a destroyed simplex of C that contained that edge. If h intersects none of the simplices of S in an edge of C, then h must separate the bottom vertex of C' from $C \cap h_r$. Hence, any simplex of C' that has a facet on $C \cap h_r$ can serve as an initial simplex for h. We conclude that we can find initial simplices for all hyperplanes in $K(S)$ in time linear in the total size of the old conflict lists. (We may find more than one initial simplex for a hyperplane, but this is no problem.)

Once we have an initial simplex for each hyperplane $h \in K(S)$, we traverse the adjacency graph of the simplices to find the other simplices in S that are intersected by h. Since the subgraph of the adjacency graph induced by these simplices is connected, the total time spent in traversals, over all hyperplanes of $K(S)$, is linear in the total size of the new conflict lists.

The last thing we have to do in step 1 is to determine for each new simplex the level of one of its interior points with respect to $\mathcal{A}(H)$. To this end, we consider a simplex of C that was destroyed by h_r. Let p be the point interior to the destroyed simplex that defined its level. Let Δ_p be the new simplex that contains p. Trivially, we now know the level of a point interior to Δ_p. To compute the level of an interior point for each of the other new simplices, we again traverse the adjacency graph. The traversal starts at Δ_p. When we step from one simplex to the next, we can update the level of an interior point in time proportional to the size of the conflict lists of the two simplices. Hence, the total time we need is linear in the total size of the conflict lists of the new simplices.

Testing active cells. Recall that ℓ_Δ denotes the level of an interior point of the simplex Δ. The level of any other point in Δ must lie in the range

$$I_\Delta = \ell_\Delta - w(\Delta), \ldots, \ell_\Delta + w(\Delta).$$

We call Δ *active* if I_Δ contains a level that we wish to compute. So if we are comput-

ing the $\leq k$-level, then Δ is active if $I_\Delta \cap \{0, 1, 2, \ldots, k\} \neq \emptyset$, and if we are computing the k-level, then Δ is active if $k \in I_\Delta$. Since we are maintaining a subcomplex of $\mathcal{A}(R)$, we cannot discard individual simplices: a cell either has to be kept as a whole, or it has to be discarded as a whole. Of course, we should not discard cells that contain active simplices. Therefore we define a cell to be active if at least one of the simplices of its canonical triangulation is active. Note that after inserting the last hyperplane all conflict lists are empty, and so the remaining cell complex is exactly what we wish to compute. (If we are computing the k-level, the remaining complex consists of the cells of level k, from which the k-level can be reconstructed easily.)

Step 2 of our algorithm tests whether the new cells created by the insertion of h_r are active. To this end, we store with each cell a counter indicating the number of active simplices in its canonical triangulation. Let C be a cell that was split, and let C' be one of the two new cells. To compute the counter for C' we should only spend time on its new simplices and on the simplices from C that were destroyed; we should not spend time on simplices in C' that were already present in C. But this is easy given the counter for C and the levels of the new and old simplices. We conclude that we can test whether C' is active in time proportional to the number of new simplices in C' plus the number of destroyed simplices from C.

4. The analysis. We have seen that the total work for inserting h_r is proportional to the total size of the conflict lists of the simplices destroyed by h_r and of the newly created simplices. Since the simplices being destroyed must have been created before, the total work is proportional to $\sum_\Delta w(\Delta)$, where the summation is over all simplices created by the algorithm. Observe that it could happen that we create a new cell, spend time to triangulate it and to compute the conflict lists and the levels of all its simplices, and then immediately discard it. In other words, we may spend time on (simplices of) cells that are never active. Our analysis must take this into consideration, of course.

We are going to apply Lemma 2.2 to estimate the sum $\sum_\Delta w(\Delta)$ over all created simplices. The complex $\mathcal{K}_r$ maintained by the algorithm does not seem to be directly suitable for the analysis. We thus define for every $R \subseteq H$ an auxiliary complex $\bar{\mathcal{K}}(R)$, which can be used in the role of $\mathcal{C}(R)$ in Lemma 2.2.

For a cell C of $\mathcal{A}(R)$, its diameter $\operatorname{diam}(C)$ is defined as the maximum number of hyperplanes of H intersecting a segment fully contained in C. We define an auxiliary set $\bar{\mathcal{K}}_0(R)$ of d-cells of $\mathcal{A}(R)$. The algorithm for computing the $(\leq k)$-level includes a d-cell $C \in \mathcal{A}(R)$ into $\bar{\mathcal{K}}_0(R)$ if and only if it intersects $(\leq k')$-level in $\mathcal{A}(H)$, where $k' = k'(C) = k + 2(d+1)\operatorname{diam}(C) + d + 1$ (note that we take cells of the arrangement of R, but we consider levels in the arrangement of H). Similarly, the algorithm for computing the k-level includes a d-cell $C \in \mathcal{A}(R)$ in $\bar{\mathcal{K}}_0(R)$ if it intersects the region between the levels $k - 2(d+1)\operatorname{diam}(C) + d + 1$ and $k + 2(d+1)\operatorname{diam}(C) + d + 1$ of $\mathcal{A}(H)$. The complex $\bar{\mathcal{K}}(R)$ consists of the cells that belong to $\bar{\mathcal{K}}_0(R)$ or that share a facet with a cell of $\bar{\mathcal{K}}_0(R)$, plus their lower-dimensional faces.

LEMMA 4.1. *All simplices Δ created by the actual algorithm in the rth step are contained in $\bar{\mathcal{K}}(\{h_1, \ldots, h_r\})^\nabla \setminus \bar{\mathcal{K}}(\{h_1, \ldots, h_{r-1}\})^\nabla$; thus, a fictitious algorithm that maintains $\bar{\mathcal{K}}(R)^\nabla$ will create all simplices created by the actual algorithm.*

Proof. We prove the lemma for the algorithm that computes the k-level; the proof for the computation of the $\leq k$-level is analogous.

All cells created by the actual algorithm arise by splitting an active cell C. Let C' and C'' denote the two cells into which C is split. One of these two cells, say C', has diameter at least $(\operatorname{diam}(C) - 1)/2$. We shall prove that C' is in $\bar{\mathcal{K}}_0(\{h_1, \ldots, h_r\})$.

Since C' and C'' share a facet, we get that both C' and C'' lie in $\bar{\mathcal{K}}(\{h_1, \ldots, h_r\})$, from which the lemma follows.

Let Δ be an active simplex of C, and let p be the point in the interior of Δ defining its level ℓ_Δ. Since $w(\Delta) \le d \cdot \operatorname{diam}(C)$ and Δ is active, we know that

$$\ell_\Delta - d \cdot \operatorname{diam}(C) \le k \le \ell_\Delta + d \cdot \operatorname{diam}(C).$$

Let q be an arbitrary point in C'. The level of q differs from the level of p by at most $\operatorname{diam}(C)$. Hence,

$$\text{level of } q - (d+1)\operatorname{diam}(C) \le k \le \text{level of } q + (d+1)\operatorname{diam}(C),$$

and since $\operatorname{diam}(C') \ge (\operatorname{diam}(C) - 1)/2$, this proves the lemma. □

It is easy to check that the complex $\bar{\mathcal{K}}(R)$ satisfies the monotonicity condition $(*)$ in Lemma 2.2, so we may apply Lemma 2.2(ii) for $c = 1$ to $\bar{\mathcal{K}}(R)$. By Lemma 4.1 we can now bound the expected running time of our algorithm as follows.

COROLLARY 4.2. *Let f be a nondecreasing function such that $\mathbf{E}\left[|\bar{\mathcal{K}}(R)^\nabla|\right] \le f(r)$ for any $r = 1, 2, \ldots, n$, where the expectation is over a random choice of an r-element set $R \subseteq H$. Then the expected running time of the algorithm is*

$$O\left(\sum_{r=1}^{n} \frac{n}{r^2} f(r)\right).$$

An ε-net argument. We are going to estimate the function $f(r) = \mathbf{E}\left[|\bar{\mathcal{K}}(R)^\nabla|\right]$. General results of Haussler and Welzl [HW87] imply that, for a suitable constant $c = c(d)$, a random r-element sample $R \subseteq H$ has the following property with probability at least $1 - 1/r^d$: any line segment s that does not intersect any hyperplane of R intersects at most $c\frac{n}{r}\log r$ hyperplanes of H. (This is usually expressed by saying that R is an ε-net with respect to segments, with $\varepsilon = c\log r/r$ [HW87].) Let ε-NET(R) be a predicate expressing this property, that is, ε-NET(R) is true if and only if R has this property. We can write, using conditional expectations

$$\begin{aligned}\mathbf{E}\left[|\bar{\mathcal{K}}(R)^\nabla|\right] = {} & \mathbf{E}\left[|\bar{\mathcal{K}}(R)^\nabla| \;\middle|\; \varepsilon\text{-NET}(R)\right] \cdot \Pr[\varepsilon\text{-NET}(R)] \\ & + \mathbf{E}\left[|\bar{\mathcal{K}}(R)^\nabla| \;\middle|\; NOT\ \varepsilon\text{-NET}(R)\right] \cdot \Pr[NOT\ \varepsilon\text{-NET}(R)].\end{aligned}$$

Since $\bar{\mathcal{K}}(R)^\nabla$ has never more than $O(r^d)$ simplices, this is at most

$$(1 - 1/r^d) \cdot \mathbf{E}\left[|\bar{\mathcal{K}}(R)^\nabla| \;\middle|\; \varepsilon\text{-NET}(R)\right] + O(1). \tag{1}$$

Let us consider the case when ε-NET(R) is true. Let M be the maximum diameter of a cell in $\mathcal{A}(R)$; we thus have $M = O((n/r)\log r)$. Consider a cell C of $\bar{\mathcal{K}}(R)$. By definition of $\bar{\mathcal{K}}(R)$, C is adjacent to a cell C' that intersects the $\le(k+2(d+1)M+d+1)$-level of $\mathcal{A}(H)$ (this concerns the algorithm for $(\le k)$-level computation). Hence, C is completely contained in the $\le(k + 2(d+2)M + 2d + 1)$-level of $\mathcal{A}(H)$ (the constants could be improved by a more careful argument). Now set $\delta = 2(d+2)M + 2d + 1$. so all cells of $\bar{\mathcal{K}}(R)$ are contained in the $\le(k+\delta)$-level of $\mathcal{A}(H)$. Similarly, in the case of computing the k-level, all cells of $\bar{\mathcal{K}}(R)$ are contained in the region between levels $k - \delta$ and $k + \delta$. We denote the region that contains the cells of $\bar{\mathcal{K}}(R)$ in either algorithm by $T = T(r)$. Thus the quantity $|\bar{\mathcal{K}}(R)^\nabla|$ that we want to bound is at most proportional to the number of vertices of $\mathcal{A}(R)$ lying in the region T.

If R is a random r-element subset of H, then for any fixed vertex v of $\mathcal{A}(H)$ the probability of it being a vertex of $\mathcal{A}(R)$ is at most $(r/n)^d$. If R is conditioned to satisfy ε-NET(R), this probability can increase at most by the factor of $(1-r^{-d})^{-1}$. Hence, the expected number of vertices of $\mathcal{A}(R)$ in T is at most $(1-r^{-d})^{-1}(r/n)^d N_T$, where N_T stands for the number of vertices of $\mathcal{A}(H)$ in T. From equation (1) we get $f(r) = O(1 + N_T r^d/n^d)$. By Corollary 4.2, we can now bound the expected running time of the algorithm by

$$O(n) + \frac{O(1)}{n^{d-1}} \sum_{r=1}^{n} r^{d-2} N_T \,. \tag{2}$$

(This holds provided that f comes out as a nondecreasing function, which is the case in all our applications.)

Specific results. We can now bound the expected running time of our algorithm in various situations by substituting appropriate bounds on N_T.

First we look at the computation of the $\leq k$-level in three-dimensional space. Here N_T is bounded by the number of vertices of the $\leq(k+\delta)$-level, so $N_T = O(n(k+\delta)^2)$.

For the computation of the k-level, N_T is the total complexity of the levels $k-\delta$ to $k+\delta$. In the three-dimensional case we are mainly interested in sets of planes that are the image of a set of points in the plane under the transformation that maps the order-k Voronoi diagram of the points to the k-level of the planes. In this case all planes are tangent to the unit paraboloid and $N_T = O(n(k+\delta)\delta)$. For the k-level of a set of lines in the plane, we can use the following result by Dey [Dey97]: for any arrangement of n lines in the plane and for any integer $s < n-k$, the complexity of all j levels for $k \leq j \leq k+s$ is $O\left(n(k+s)^{1/3}s^{2/3}\right)$. In our situation $s = \delta$, so we obtain $N_T = O\left(n(k+\delta)^{1/3}\delta^{2/3}\right)$.

We summarize the results of these calculations in the following theorem.

THEOREM 4.3.

(i) *The $\leq k$-level in an arrangement of n planes in $\mathbb{R}^3$ can be computed in $O(nk^2 + n\log^3 n)$ expected time.*

(ii) *The kth order Voronoi diagram for n points in the plane can be computed in $O((n-k)k\log n + n\log^3 n)$ expected time by computing the k-level in the corresponding arrangement of n planes in $\mathbb{R}^3$.*

(iii) *The k-level in an arrangement of n lines in the plane can be computed in $O(nk^{1/3}\log^{2/3} n + n\log^2 n)$ expected time.*

Our algorithm also works in other situations, such as the computation of the $\leq k$-level of a set of lines, discs, or monotone curves in the plane. In these situations, however, there is an algorithm that obtains slightly better bounds. The details of this are described in the next section.

5. Improvements and extensions. The algorithm of the previous section is suboptimal when k is very small (polylogarithmic in n); in this case Mulmuley's algorithm is better. We can illustrate this on the algorithm for computing the $\leq k$-level in the plane, when k is a constant. The analysis of our algorithm accounts for the maintenance of the portion of $\mathcal{A}(R)$ roughly within the $\leq\delta$-level, where $\delta = O((n/r)\log r)$. According to this analysis we maintain a region of complexity $O(r\log r)$. Mulmuley's algorithm maintains the $\leq k$-level in the arrangement of the lines already inserted, which has only $O(r)$ complexity.

One simple improvement is, of course, to run Mulmuley's algorithm in parallel with ours and see which one finishes first. This eliminates the potential advantage of our algorithm—namely, that no peeling step is necessary—so it cannot be directly

applied to discs, say. We indicate another route to an improvement; currently, however, it only works for the planar case (which is not so interesting for lines, since an optimal algorithm has been known there). We first explain the approach for the construction of the $\leq k$-level in an arrangement of lines in the plane. We then show that the improved algorithm also works for discs and curves.

Lazy clean-up and refined activity test. To improve the running time of the algorithm we should maintain fewer cells. In other words, the cells we maintain should be closer to the $\leq k$-level. To achieve this we will insist that each cell in the current complex $\mathcal{K}_r$ intersects the $\leq(k+2n/r)$-level (while the previous analysis used the fact that with high enough probability, each cell intersects the $\leq(k+O((n/r)\log r))$-level). There are two issues to be addressed. First, the new requirement is time dependent: a cell that was acceptable at some step r may have to be eliminated at some later step r', though it has not been split. Second, we have to refine the test of activity for a simplex: there can be simplices intersected by many more than n/r lines at step r, so we cannot use just one interior point to estimate the level of all points in such a simplex accurately enough.

To deal with the first issue, we use the so-called *lazy* strategy [dBDS94]. That is, we do not worry about cells that are not split but should be deactivated because r has increased. Thus, when we insert a new line we only perform an activity test for the newly created cells. Of course, cells that should be eliminated cannot be kept around for too long. We discard these cells at periodic clean-up steps. In particular, we do a clean-up after steps $1, 2, 4, 8$, and so on. Since we do only a logarithmic number of clean-ups, we can afford to do them in a brute-force manner: we traverse the entire current complex and eliminate all cells that do not contain a point of the $\leq(k+n/r)$-level, performing an activity test described below for each cell and discarding those which do not pass the test. In this way, we make sure that at any step r each cell intersects the $\leq(k+2n/r)$-level.

Now we describe the activity test for a cell C at step r. Again, we test each simplex $\Delta \in C^{\nabla}$ separately. We subdivide the simplex into smaller simplices, each intersected by at most n/r lines of $H \setminus R$, and we determine the level of an interior point for each of these small simplices. Now Δ is active if and only if at least one of these points is at level less than or equal to $k + n/r$. This test is again conservative: cells that contain a part of the $\leq k$-level are always active. Subdividing Δ into smaller simplices plus determining their levels can be performed in $O(w(\Delta)^2 r/n)$ expected time using a randomized algorithm of Chazelle and Friedman [CF90] (see also [Mat91]). At a regular insertion step, this refined activity test is performed only for the newly created cells. At the clean-up steps the test is performed for all the cells. This implies that a cell that is present at step r must have been tested (and found active) at some step r' with $r/2 \leq r' \leq r$. Hence, a cell that is present at time r (that is, after the insertion of the rth line has been completed) contains a point of level at most $k + 2n/r$. This finishes the description of the modifications to the algorithm.

More general ranges. The modified algorithm (and also the basic algorithm) can be applied to arrangements of ranges other than halfspaces. We only need to supply a suitable notion of a canonical triangulation (a subdivision of the arrangement into constant complexity cells) and implement the steps of the algorithm suitably. As an illustration, we mention two planar cases, namely discs and x-monotone Jordan curves with a bounded number of intersections for every pair of curves.

As a canonical triangulation, we use the *vertical decomposition* of the cells: we extend a vertical segment upward from every intersection point of two curves until it hits another curve and extend a vertical segment downward until it hits another

curve; if a vertical segment does not intersect any curve, it is extended to infinity. We call the constant complexity cells arising in this decomposition the *trapezoids*. The vertical decomposition can be updated is the same way as in randomized incremental algorithms for computing full planar arrangements of curves [Mul91a]. For the refined activity test we need one more ingredient: we must be able to decompose a trapezoid into smaller trapezoids, each intersected by at most n/r curves. An obvious modification of the Chazelle and Friedman algorithm [CF90] can compute such a subdivision in $O(w(\Delta)^2 r/n)$ expected time. Now we have all the tools available to implement the algorithm described above (or the basic one of the previous section).

The analysis. To analyze the modified algorithm we again define an auxiliary, possibly larger complex $\widetilde{\mathcal{K}}(R)$: a cell $C \in \mathcal{A}(R)$ belongs to $\widetilde{\mathcal{K}}(R)$ if it has a point of level $\leq(k+2n/r)$ or is adjacent to a cell with such a point, where $r = |R|$. The complex $\widetilde{\mathcal{K}}(R)$ has the monotonicity property $(*)$ needed in Lemma 2.2. There is also an analog of Lemma 4.1, namely, that all cells created in the rth step of the algorithm are in $\widetilde{\mathcal{K}}(\{h_1, \ldots, h_r\}) \setminus \widetilde{\mathcal{K}}(\{h_1, \ldots, h_{r-1}\})$, and all cells present in the actually maintained collection in the rth step are in $\widetilde{\mathcal{K}}(\{h_1, \ldots, h_r\})$.

The time needed for the insertion steps (not counting the clean-up phases) is bounded by $\sum_\Delta w(\Delta)^2 r(\Delta)/n$, where we sum over all simplices created by the algorithm, and where $r(\Delta)$ is the moment of creation of Δ. Using Lemma 2.2(ii) for $c = 2$ we get the bound of

$$O\left(\sum_{r=1}^{n} \frac{n}{r^2} f(r)\right), \tag{3}$$

where $f(r)$ is a nondecreasing upper bound for $\mathbf{E}\left[|\widetilde{\mathcal{K}}(R)^\nabla|\right]$.

The clean-up phases can be accounted for as follows. The simplices that are discarded in a clean-up phase after inserting the rth line passed an activity test at some time $r' \geq r/2$, so the time for the activity test that discards them can be charged to that previous test. Every test gets charged at most once this way. The simplices that pass the activity test at the clean-up phase after step r belong to $\widetilde{\mathcal{K}}(R)^\nabla$, $R = \{h_1, \ldots, h_r\}$, and hence the time for these tests at the considered clean-up phase is at most $\sum_{\Delta \in \widetilde{\mathcal{K}}(R)^\nabla} (w(\Delta)^2 r/n)$. Applying Lemma 2.2(i) with $c = 2$ and summing up over all clean-up phases, we get a contribution of $\sum_{i=1}^{\lfloor \log_2 n \rfloor} (n/2^i) f(2^i)$, which will be of the same order as equation (3).

It remains to provide a good bound on the expected size of $\widetilde{\mathcal{K}}(R)^\nabla$. This is at most proportional to the expected number of vertices of $\widetilde{\mathcal{K}}(R)$. We could use an ε-net argument again, arguing that, with high probability, all such vertices are at level at most $k + O((n/r)\log r)$ in the arrangement of H. This, however, gives nothing better than the analysis of the basic algorithm. In the planar case, a refined argument can be given (although the resulting bound is probably still not tight). We start with the case of lines.

First, we pick a number k' in the range $[k + 2n/r, 2(k + 2n/r)]$ such that the k'-level in $\mathcal{A}(H)$ has $O(n)$ complexity (this is possible since the total complexity of all levels in this range is $O(n(k + n/r))$). Then we divide the vertices of $\widetilde{\mathcal{K}}(R)$ into two types: those within the $\leq k'$-level of H and those outside. The expected number of vertices of the first type is $O((r/n)^2 nk')$. As for the vertices of the second type, they all belong to cells of $\mathcal{A}(R)$ intersecting L, the k'-level of $\mathcal{A}(H)$, or the adjacent cells. The collection of such cells can naturally be called the 1-*zone* of L. It follows from the probabilistic argument of Clarkson and Shor [CS89] that the complexity of

the 1-zone is of the same order as the complexity of the *zone* of L, that is, of the cells intersecting L, and it remains to bound the expected complexity of this zone. Let m denote the number of intersections of the lines of R with L (a contiguous segment is counted as one intersection). The number of intersections of the lines of H with L is $O(n)$ (each line meeting L does so at a vertex), and hence the expectation of m is $O(r)$. We may now use a standard trick to convert the zone of L to a single cell in an arrangement of $O(m+r)$ (possibly unbounded) segments, namely, we remove from each line of R a small portion around its intersections with L. By [GSS89], the complexity of a single cell in an arrangement of n segments is $O(n\alpha(n))$, and so the expected zone complexity in our case is $O(r\alpha(n))$. We may thus conclude that $f(r) = O(r^2k/n + r\alpha(n))$, and the expected running time of the algorithm is $O(nk + n\log n\,\alpha(n))$.

The same analysis can be applied for other ranges as long as we can bound the expected complexity of the zone of the k'-level. For the case of discs or x-monotone Jordan curves, the zone complexity can be bounded using the same argument, since one has a good bound on the complexity of a single cell in an arrangement of the corresponding (curvilinear) segments: a single cell defined by n segments of curves with at most s intersections per pair has complexity $O(\lambda_{s+2}(n))$ [GSS89]. We obtain the following result.

THEOREM 5.1. *The $\le k$-level in an arrangement of n discs in the plane can be computed in expected $O(nk + \lambda_4(n)\log n)$ time. The $\le k$-level in an arrangement of n x-monotone Jordan curves with each pair having most s intersections can be computed in expected $O(k^2\lambda_s(n/k) + \lambda_{s+2}(n)\log n)$ time.*

6. Concluding remarks. We presented randomized incremental algorithms for computing $\le k$-levels or k-levels in arrangements. The main difference from previous algorithms is that we use estimates of the level in the final arrangement to decide which part of the current arrangement to keep, whereas previous algorithms used the level in the current arrangement. Consequently, our algorithm maintains less information (unless k is very small) and therefore it is faster. For most values of k we have shown that our algorithm is optimal. We think that it is also optimal for small k, but we have not been able to prove this.

This is one of the questions we leave open: is it possible to tighten the analysis of the basic algorithm and show that it is optimal for any k (both for computing the $\le k$-level and for computing the kth order Voronoi diagram in the plane)? If one cannot do this for the basic algorithm, then maybe it is possible for the modified algorithm. Here one has a purely combinatorial question: what is the expected complexity of the zone of $L_{k'}$ in the arrangement of a random sample of size r, where $L_{k'}$ is the k'-level in the full arrangement? (Here k' can be chosen suitably so that the k'-level has no more than the average complexity.) It seems quite likely that this expectation should be $O(r)$ in the plane and $O(r^2k'/n)$ in 3-space.

A CONSTANT TIME OPTIMAL PARALLEL ALGORITHM FOR TWO-DIMENSIONAL PATTERN MATCHING*

MAXIME CROCHEMORE†, LESZEK GĄSIENIEC‡, RAMESH HARIHARAN§, S. MUTHUKRISHNAN¶, AND WOJCIECH RYTTER‖

Abstract. We give an alphabet-independent deterministic parallel algorithm for finding all occurrences of a pattern array of size $m_h \times m_w$ in a text array of size $n_h \times n_w$ in the concurrent-read-concurrent-write–parallel-random-access-machine (CRCW–PRAM) model. Our algorithm runs in $O(1)$ time performing optimal, that is, $O(n_h \times n_w)$ work, following preprocessing of the pattern. This improves the previous best bound of $O(\log\log m)$ time with optimal work [A. Amir, G. Benson, and M. Farach, *Proceedings 5th Annual ACM Symposium on Parallel Algorithms and Architectures*, ACM, New York, 1993, pp. 79–85], following preprocessing of the pattern, where $m = \max\{m_h, m_w\}$.

The preprocessing required by our algorithm (and that due to Amir, Benson, and Farach) can be accomplished in $O(\log\log m)$ time and $O(m_h \times m_w)$ work [M. Crochemore et al., manuscript, 1993], [R. Cole et al., manuscript, 1993].

1. Introduction.

The problem of *two-dimensional matching* (henceforth called 2D-matching) is to find all occurrences of a pattern array p of size $m_h \times m_w$ in a text array t of size $n_h \times n_w$. Without loss of generality, we assume that $m_w \geq m_h$. The text and the pattern are drawn from an alphabet set Σ. Our interest lies in designing an alphabet-independent parallel algorithm for this problem, that is, one with complexity not dependent on the alphabet size $|\Sigma|$. The one-dimensional matching problem, or the *string matching problem* as it is known, is that of finding all occurrences of a pattern string of length m in a text string of length n.

The early algorithms for sequential 2D-matching were based on multiple-pattern matching [Bi77, Ba78] or suffix trees [AL88] and were therefore alphabet-dependent. More precisely, these algorithms took time $O((n_h \times n_w + m_h \times m_w)\log|\Sigma|)$. The first alphabet-independent sequential algorithm for 2D-matching was obtained by Amir, Benson, and Farach [ABF92]. Their algorithm takes linear, i.e., $O(n_h \times n_w)$, time

following preprocessing of the pattern. They also showed how this preprocessing could be accomplished in an alphabet-dependent manner in $O((m_h \times m_w) \log |\Sigma|)$ time. Recently, Galil and Park [GP92] showed how this preprocessing can be accomplished in $O(m_h \times m_w)$ time, independent of the alphabet size. Thus the sequential complexity of 2D-matching is $O(n_h \times n_h + n_w \times n_w)$ time, independent of the alphabet size. Crochemore and Rytter [CR95] give an easier exposition of this preprocessing.

Mathies [M88] gave a parallel deterministic algorithm for 2D-matching which took $O(\log^2 m_w)$ time using linear number of processors in the CRCW–PRAM model. Amir and Landau [AL88] gave an $O(\log m_w)$ time algorithm using $O(n_h \times n_w)$ processors in the CRCW–PRAM model. Both these algorithms are suboptimal. Karp and Rabin [KR87] obtained the first optimal $O(\log m_w)$ time algorithm for parallel 2D-matching on the exclusive-read-exclusive-write–parallel-random-access-machine (EREW–PRAM) model; however, their algorithm was a Monte Carlo type randomized algorithm. The first optimal deterministic algorithm was obtained by Kedem, Landau, and Palem [KLP89]. They used the technique of *naming* due to Karp, Miller, and Rosenberg [KMR72] to obtain an $O(\log m_w)$ time optimal algorithm for 2D-matching in the CRCW–PRAM model using quadratic space. (Also, see [CR91] for algorithms for 2D-matching based on naming.) Both these optimal algorithms for 2D-matching are alphabet-dependent. The first alphabet-independent optimal parallel 2D-matching algorithm was recently obtained by Amir, Benson, and Farach [ABF93]. They present two optimal algorithms, one that takes $O(\log \log m_w)$ time on the CRCW–PRAM, and another that takes $O(\log m_w)$ time on the concurrent-read-exclusive-write–parallel-random-access-machine (CREW–PRAM), both following preprocessing of the pattern. Their algorithms use linear space.

Our main result is a deterministic parallel CRCW–PRAM algorithm for 2D-matching which takes $O(1)$ time using $O(n_h \times n_w)$ processors, following preprocessing of the pattern. Our algorithm is alphabet-independent and uses linear space. This result is analogous to the recent result of Galil [Ga92] stating that string matching can be performed in $O(1)$ time and optimal work following preprocessing of the pattern. Indeed, our result is obtained by providing a simple constant time Turing-reduction from 2D-matching to string matching and utilizing the result in [Ga92]. Our result also yields a new linear time sequential algorithm for 2D-matching and a new parallel $O(\log m_w)$ time optimal algorithm for 2D-matching in the CREW–PRAM model.

Fast parallel algorithms for string matching rely on the concept of periodicity [Ga85] and witnesses [Vi85]. Similarly, the notions of two-dimensional periodicity developed by [AB92] have played a significant role in developing both sequential [ABF92, GP92] and parallel [ABF93] algorithms for 2D-matching. It is particularly interesting that in contrast to these algorithms, our algorithm was obtained without using any ideas regarding two-dimensional periodicity. Only a version of one-dimensional periodicity suitably generalized to two dimensions, which we term *h-periodicity* (or horizontal periodicity), is used. However, we use ideas from two recent parallel algorithms for string matching, namely, those in [Vi90] and [Ga92]. Our algorithm uses the notion of *deterministic samples*, introduced by Vishkin [Vi90] for string matching, suitably generalized to two dimensions. The constant time optimal string matching algorithm in [Ga92] is used as a black box. Our overall algorithm is surprisingly simple.

The crucial preprocessing in all alphabet-independent 2D-matching algorithms (including ours) is that of computing witnesses for the two-dimensional pattern. Recently it has been shown that witnesses can be computed in $O(\log \log m_w)$ time and

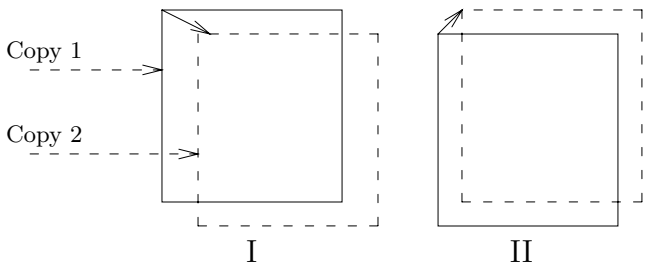

FIG. 1. *Quad* I *and* II *vectors.*

$O(m_h \times m_w)$ work [CG+93b]; this algorithm is both time and work optimal. Additionally, our algorithm (as the string matching algorithms of [Vi90, Ga92]) requires the computation of deterministic samples suitably generalized to two dimensions. This can be performed in $O(1)$ time optimally using the ideas in [CC+93], [CG+93a]. Thus the preprocessing required by our algorithm (and that in [ABF93]) takes $O(\log \log m_w)$ time and $O(m_h \times m_w)$ work.

Our algorithm is designed for the Common CRCW–PRAM model, i.e, simultaneous writes to the same location by several processors are guaranteed to be of the same value [Ja91]. Throughout this paper, the complexity bounds are stated in terms of time and work. Processor scheduling to attain these time and work bounds is always possible and hence omitted except where it is not obvious.

The paper is organized as follows. Section 2 gives some preliminary definitions. We describe important ideas underlying our algorithm in section 3. Section 4 describes the text processing algorithm.

2. Definition and preliminaries. Let p be the pattern array of size $m_h \times m_w$. Let t be the text array of size $n_h \times n_w$. Let $m' = \lfloor \frac{m_w}{3} \rfloor$ and $m'' = \lfloor \frac{m_h}{3} \rfloor$. Let $m = \max\{m_h, m_w\}$. Without loss of generality, assume that $m = m_w$. Let the column coordinates of p and t increase horizontally to the right and the row coordinates increase downwards, both starting from 1. The horizontal side of an array is called the *width* and its vertical side is called the *height*.

A pattern instance *associated* with text position l is a copy of p with top left corner at l; let p_l denote this pattern instance. We say that p *occurs* at l if p_l completely matches the text, i.e., if $l = (i, j)$, then $t(i+r-1, j+c-1) = p_l(r, c)$ for all $1 \leq r \leq m_h$ and $1 \leq c \leq m_w$. In this case, l is said to be an *occurrence* of p. The problem of *2D-matching* is to determine all occurrences of a given pattern p in a given text t.

Consider two copies of p. Place the second copy so that its left margin is either on or to the right of the left margin of the first copy. In addition, either the top left corner or the bottom left corner of the second copy must be within the first copy. The vector v joining the top left corner of the first copy to the top left corner of the second copy is called a Quad I vector in the former case and a Quad II vector in the latter case (see Figure 1). A *witness* for the two copies (or a witness for vector v) is a position in the first copy, if any, where the two copies mismatch. If a witness exists, then at least one of the two copies cannot match the text completely (if the two copies are visualized to lie on the text). One of these two copies can thus be eliminated by simply comparing the character at the witness in the first copy with the overlapping text character. This process of eliminating one of two overlapping copies of p possessing a witness is called a *duel* [Vi85] between the two copies.

If the two overlapping copies considered above are consistent, i.e., lack a witness, the vector joining the top left corners of these two consistent pattern copies is called a *period vector* of p. A period vector that is horizontal is called a *horizontal period vector* or *hpv* of p.

The *length* of a vector is either the difference between the row coordinates of its endpoints or the difference between the column coordinates of its endpoints, whichever is bigger. A vector is said to be *valid* if its row length is less than $\lfloor \frac{m_w}{3} \rfloor$ and its column length is less than $\lfloor \frac{m_h}{3} \rfloor$. If p has a valid *hpv*, we call p *h-periodic*. Otherwise, we call p *h-aperiodic*.

The *period* of a string s is defined to be $|s| - k$, where k is the length of the longest prefix of s which is also a suffix of s. s is said to be *periodic* if its smallest period is at most $\lfloor \frac{m}{3} \rfloor$ and *aperiodic* otherwise. Witnesses and duels are defined for strings in a manner analogous to the two-dimensional case.

The *distance* between two locations in a string is one more than the number of locations between them. This definition is extended to locations in the same row or column of a two-dimensional pattern in the natural way.

Recall that in the common CRCW–PRAM, given a boolean vector of i bits, their boolean AND and OR can be computed in $O(1)$ time using i processors. This fact, as well as the following lemma, are used repeatedly in our algorithm.

LEMMA 2.1 (see [FRW88]). *Given a binary vector V of size i, the leftmost or rightmost* 1 *in V can be found in $O(1)$ time using i processors on the common CRCW–PRAM.*

3. Horizontal periodicity. The following fact will be utilized repeatedly. It follows immediately from the definition of the shortest *hpv* of p.

FACT 3.1. *Any two occurrences of p with top left corners in some row of t must be at least distance l apart, where l is the length of the shortest hpv of p.*

Next, we state a crucial property of the h-aperiodic patterns.

LEMMA 3.2. *Suppose p is h-aperiodic. Then there exists a row r of p that, considered as a string, has period at least $\frac{\log m'}{2}$.*

Proof. The length of the smallest *hpv* of p is clearly the least common multiple (LCM) of the periods of the various rows of p considered as strings. By a weak form of the prime number theorem [RS62], the number of primes less than any number j is at most $2\frac{j}{\log j}$. Note that the LCM of the numbers $1, \ldots, j$ is the product of the highest powers at most j of all such primes. Therefore, the LCM of the numbers $1, \ldots, j$ is at most $j^{\frac{2j}{\log j}} \leq 4^j$. If all rows of p have period less than $\frac{\log m'}{2}$, then the length of the smallest *hpv* of p must be less than $4^{\frac{\log m'}{2}} \leq m'$. Since p has no such *hpv*, this is a contradiction. □

Next, we present the following two-dimensional variant of Vishkin's deterministic sampling lemma [Vi90] for strings.

LEMMA 3.3 (the two-dimensional deterministic sampling lemma). *Suppose p is h-aperiodic. For any $e \leq m'$, there exists a number f, $0 \leq f \leq e-1$, and a set of at most* $\log e$ *positions in p, called the (e, f)* h-sample*, with the following property. Let s be a text location and suppose all characters at locations in the h-sample of p_s match their aligned text characters. Then p cannot occur at any text location in the same row as s which is at most $e - f - 1$ locations to the left of s or at most f locations to the right of s.*

The proof of existence and the construction of an (e, f) *h-sample* for some suitable value of e are described in section 5.

4. Text processing. In what follows, we assume that witnesses in p, if any, for all valid vectors have been precomputed. We also assume that an (e, f) h-sample has been precomputed for $e = \lfloor (m')^{\frac{1}{4}} \rfloor$. In addition, we assume that the periods of all rows of p have been precomputed and the row r defined in Lemma 3.2 has been determined and preprocessed for matching it against any given text string using the algorithm in [Ga92]. In section 5, we consider the complexity of this precomputation.

4.1. *h*-aperiodic pattern. Assume that p is h-aperiodic. The case when p is h-periodic is a standard modification of this case and is described in section 4.2.

Definitions. Recall that p_l is the copy of p with top left corner at text position l. If p_l potentially matches the text, then l is a *source*. If p_l matches the text, then l is a *complete match*. A source l is *eliminated* if p_l is determined not to match the text. A source is said to *survive* at a given instant if it has not yet been eliminated. Sources k and l are *compatible* if p_k and p_l match wherever they overlap.

Initially, all text locations are sources. The algorithm eliminates sources until only complete matches survive. Consider the subarray t' of t of size $(n_h - m_h + 1) \times (n_w - m_w + 1)$ with the same top left corner as t. Clearly, pattern does not occur at any location outside t'. The subarray t' is divided into disjoint blocks of size $m'' \times m'$ (at the bottom and right boundaries of t', these blocks could be smaller than $m'' \times m'$). These blocks are called *text blocks*. There are $O(\frac{n_h \times n_w}{m_h \times m_w})$ text blocks. Each row in a text block is called a *text block row*.

Each text block T is processed identically in parallel in two phases. Phase I is survived only by a set of mutually compatible sources in T. In Phase II, each of these sources is either confirmed to be a complete match or is eliminated. Each phase takes $O(1)$ time and $O(m_h \times m_w)$ work per text block. The total work over all text blocks is $O(n_h \times n_w)$.

4.1.1. Phase I. Text block T is processed in two steps in this phase.

1. All but at most one of the sources in each text block row in T are eliminated.
2. Of the surviving sources, all but a set of mutually compatible sources are eliminated.

Each phase takes $O(1)$ time and $O(m_h \times m_w)$ work per text block.

We describe each step in detail.

Step 1. In each text block row in T, there cannot be more than one complete match since the pattern has no *hpv* of length less than m' (by Fact 3.1). In this step, all but at most one of the sources in each text block row in T are eliminated. This is achieved in the following two steps. All text block rows in T are considered in parallel in these steps. Consider one text block row $R[1, \ldots, m']$ in T.

Step 1.1. Following this step, at most $\frac{2m'}{\log m'}$ sources survive in R.

Let r be the row of p given by Lemma 3.2 and suppose that r is the ith row in p. Consider the text block row $R'[1, \ldots, m']$ that is $i - 1$ rows below R. Galil's algorithm [Ga92] is used to find all occurrences of r (considered as a string) beginning at positions in R'. This takes $O(1)$ time and $O(m' + m_w) = O(m')$ work. Since r has period at least $\frac{\log m'}{2}$ by Lemma 3.2, r occurs in R' beginning at, at most, $\frac{2m'}{\log m'}$ locations. Clearly, p occurs in R with its top left corner at $R[j]$ only if r occurs beginning at $R'[j]$, where $1 \leq j \leq m'$. Therefore, at most $\frac{2m'}{\log m'}$ sources in R survive this step.

Step 1.2. All but at most one of the sources in R are eliminated in this step.

This is done in several steps as follows. The (e, f) h-sample of p is used in the process, where $e = \lfloor (m')^{\frac{1}{4}} \rfloor$.

Step 1.2a. The text block row R is divided into disjoint subblocks of length $e = \lfloor (m')^{\frac{1}{4}} \rfloor$ (the rightmost subblock could be smaller). Following this step, at most two sources survive in each subblock.

Each surviving source in R is processed in parallel. Consider one source i and the pattern instance p_i associated with it. The set of locations in p_i which correspond to the (e, f) h-sample of p are considered. The characters at these locations are compared with their aligned text characters in parallel. This takes $O(1)$ time and $O(\frac{2m'}{\log m'} \times \log e) = O(m')$ work for R. We say that source i's sample *matches* if all the above comparisons are successful. Lemma 4.1 shows that the only sources in R which survive this step are the rightmost and leftmost sources in R whose sample matches in the above step. These sources are easily found in $O(1)$ time and $O(m')$ work using Lemma 2.1.

To perform the above step, $\lfloor \log e \rfloor$ processors have to be allocated to each surviving source in R from a pool of m' processors. This is done as follows. The text block row R is divided into disjoint subblocks of length $\lfloor \frac{\log m'}{2} \rfloor$. In each of these subblocks at most one source survives from Step 1.1. One processor is assigned to each of the m' locations in the text block row R, and the surviving source, if any, in each subblock, is determined. The surviving source in the kth subblock from the left in R is stored at location k in an auxiliary array A of size $\frac{m'}{\lfloor \log m'/2 \rfloor} = O(\frac{2m'}{\log m'})$. To each location in A, $\lfloor \log e \rfloor$ processors are assigned. The $\lfloor \log e \rfloor$ processors assigned to the location k in A are assigned to the surviving source in the kth subblock of R. That completes the assignment of $O(\frac{2m'}{\log m'} \times \log e) = O(m')$ processors in constant time.

LEMMA 4.1. *Source i in R survives Step* 1.2a *only if it is the rightmost or leftmost source in R whose sample matches.*

Proof. Clearly, if the sample of i does not match then p_i cannot be a complete match. Let j and k be the leftmost and rightmost sources in R whose samples match. Suppose the sample of i matches and i is between j and k. By Lemma 3.3, p cannot occur at any text location in R which is at most $e - f - 1$ locations to the left of k or at most f locations to the right of j. Since $(e - f - 1) + f > e - 2$, and i is in the middle $e - 2$ characters of R, p_i cannot be a complete match. □

Step 1.2b. The text block row R is divided into disjoint segments of length $\lfloor (m')^{\frac{1}{2}} \rfloor$ (the rightmost segment could be smaller). Following this step, at most one source survives in each segment.

All segments are processed in parallel. Consider a particular segment S. It comprises of $O(e)$ disjoint subblocks of length e from Step 1.2a. Each of these subblocks contains at most two surviving sources. In all, there are at most $O(2e)$ surviving sources in S. All pairs of surviving sources in S are duelled in parallel in $O(1)$ time and $O((2e)^2) = O(\sqrt{m'})$ work. Over all segments, the work done is $O(m')$. A source in S survives this step if and only if it survives each of these duels. Clearly, only one source in S survives all duels since p is h-aperiodic (by Fact 3.1).

Step 1.2c. At most one source survives in each block row R following this step.

Following Step 1.2b, there are $O(\sqrt{m'})$ disjoint segments of length $\lfloor \sqrt{m'} \rfloor$ in R, each of which contains at most one surviving source. In all there are at most $O(\sqrt{m'})$ surviving sources in R. Each pair of surviving sources in R is duelled; this takes $O(1)$ time and $O(m')$ work. A source survives this phase if and only if it survives each of these duels. Clearly, only one source in R survives all duels since p is h-aperiodic (by Fact 3.1).

Step 2. All text blocks are processed in parallel. Consider a particular text block T. Only sources in T that are mutually compatible survive this step.

Following Step 1, at most one source per text block row in T survives. In all there are at most m'' sources in T. Each pair of surviving sources is duelled in parallel; this takes $O(1)$ time and $O(m'' \times m'')$ work. Recall that $m_w \geq m_h$ and $m'' = \lfloor \frac{m_h}{3} \rfloor$. Therefore, the work done in this step is $O(m_h \times m_w)$. A source in T survives this phase if and only if it survives each of these duels. Clearly, all sources in T that survive this phase are mutually compatible.

That completes the description of Phase I. There are $O(\frac{n_h \times n_w}{m_h \times m_w})$ blocks in all and each step for each text block takes $O(1)$ time and $O(m_h \times m_w)$ work. Therefore Phase I takes $O(1)$ time and $O(n_h \times n_w)$ work over the entire text.

4.1.2. Phase II. In Phase II, each surviving source in each text block is either eliminated or confirmed to be a complete match. Each text block is considered in parallel. We describe Phase II for a particular text block T.

Consider the set of text locations overlapped by at least one of the p_i's, where i is a surviving source in T. There are at most $O(m_h \times m_w)$ such text locations, all of which lie in a text block T' of size $(m'' + m_h - 1) \times (m' + m_w - 1)$ whose top left corner coincides with the top left corner of T. From Phase I, all surviving sources in T are mutually compatible. Therefore, each text location in T' is overlapped by the same character, if any, in all p_i's. Hence, it suffices to compare each text location x in T' with the overlapping character in any of the p_i's which overlap x.

We say that a text location x in T' *belongs to* source y in T if x is overlapped by p_y. Phase II proceeds in three steps.

1. Each text location x in T' is marked with a source y in T, if any, to which x belongs.
2. Each text location x in T' which is marked with a source y is compared with the character in p_y which overlaps x.
3. For each surviving source y in T, if a mismatch occurs in Step 2 at a text location x overlapped by p_y, then y is eliminated.

We describe the three steps in Phase II in detail.

Step 1. This step marks each text location x in T' with a source y in T to which it belongs. Initially, none of the text locations in T' is marked. There are two substeps.

Step 1a. Each of the m' leftmost columns of B' are processed in parallel. Consider a particular column c. The uppermost and lowermost surviving sources, u and l, in c are determined. This is done in $O(1)$ time and $O(m_h)$ work using Lemma 2.1. Each text location x in c which is above l but below u (including u) is marked with source u. Each text location x in c which is at most distance $m_h - 1$ below l (including l) is marked with source l.

Step 1b. All rows of T' are processed in parallel. Consider row R. Let R' denote the leftmost m' locations of R. The leftmost and rightmost text locations in R' which were marked in Step 1a are determined in $O(1)$ time and $O(m_w)$ work. Let them be denoted by a and b, respectively. The text locations in R are marked as follows. Each unmarked text location in R which is to the left of b but to the right of a is marked with the same source as a. Each unmarked text location in R which is at most distance $m_w - 1$ to the right of b is marked with the same source as b.

LEMMA 4.2. *A text location x in T' is marked with exactly one of the sources, if any, to which it belongs.*

Proof. It can be easily seen that if x is marked with source y in Steps 1a or 1b, then x belongs to y. We show that if x belongs to some source in T, then it is marked with one such source. We consider two cases.

First, suppose x belongs to some source in the same column as x. Let u and l denote the uppermost and lowermost surviving sources in this column. If x is above l, then it must be coincident with or below u; it is then marked with source u in Step 1a. Otherwise, if x is coincident with or below l then it is at most distance $m_h - 1$ below l; it is then marked with source l.

Second, suppose x does not belong to any source in the same column c as x but belongs to some source in a column to the left of c. In Step 1a, x will not be marked as all sources in the same column, as x must be the distance of at least m_h above x. Let a and b be the leftmost and rightmost locations in the same row as x which were marked in Step 1a. Since x belongs to some source in T to the left of c, a and b are defined by the first argument above, although they are not necessarily distinct.

Let $s(a)$ and $s(b)$ denote the sources with which a and b are marked, respectively. Note that $s(a)$ is in the same column as a and likewise for $s(b)$. None of the locations to the right of b in the same row as x is marked in Step 1a. By the first case, none of these locations belongs to any of the sources in their respective columns. It follows that x does not belong to any of the sources in these columns. Since x does belong to some source in T, either x is to the left of b and coincident with or to the right of a, or x is within distance $m_w - 1$ to the right of b. In the former case, x belongs to $s(a)$, and in the latter case, x belongs to $s(b)$. In Step 1b, x is marked with $s(a)$ in the former case and with $s(b)$ in the latter case. □

Step 2. Consider each text location x in T' marked with a source y. Then the character at x is compared with the overlapping character in p_y.

A text location that mismatches in Step 2 is called a *bad* position.

Step 3. Note that a mismatch at text location x in Step 2 eliminates all sources in a $m_h \times m_w$ block whose bottom right corner is x. A second kind of marking is done in this step. Initially none of the locations in T' is marked. Finally, for each bad text location x, all text locations in T' which are in a $m_h \times m_w$ block with bottom right corner at x are marked. This is done in two steps.

Step 3a. All rows of T' are considered in parallel. Consider row R of T'. We divide R into two parts; the first part R_1 consists of the leftmost m_w text locations and the second part R_2 consists of the remaining locations. The rightmost and leftmost bad text locations a and b, respectively, in R_1, and the rightmost and leftmost bad text locations c and d, respectively, in R_2 are determined. This is done in constant time and $O(m_w)$ work using Lemma 2.1.

Every text location that is in R and at most distance $m_w - 1$ to the left of either a or c is marked, as are those text locations between a and b and between c and d.

Step 3b. All columns of T' are considered in parallel. Consider a particular column C of T'. We divide C into two parts; the first part C_1 consists of the top m_h text locations and the second part C_2 consists of the remaining locations. The lowermost and uppermost marked text locations a and b, respectively, in C_1, as well as the lowermost and uppermost marked text locations c and d, respectively, in C_2 are determined in constant time and $O(m_h)$ work using Lemma 2.1. Every text location which is in C and which is at most distance $m_h - 1$ above either a or c is marked. All text locations between a and b and between c and d are also marked.

LEMMA 4.3. *A surviving source y in T is marked if and only if there exists a bad location x which belongs to y.*

Proof. The argument proceeds as in the proof of Lemma 4.2. In Step 3a, a mark is placed on a text location in T' if and only if it is at most distance $m_w - 1$ to the left of some bad text location in the same row. In Step 3b, a mark is placed on each text location in T which is at most distance $m_h - 1$ above some text location in the

same column that was marked in Step 3a. From these two claims, the lemma follows as in the proof of Lemma 4.2. □

Finally, all surviving sources in T which are not marked are declared to be complete matches in Step 3. It follows from Lemma 4.3 that these are the only complete matches. Each step in Phase II takes $O(1)$ time and $O(n_h \times n_w)$ work. That completes the description of the algorithm for h-aperiodic patterns.

4.2. *h*-periodic patterns. Our approach for this case is essentially an adaptation of the approaches in [BG90, Vi90] to two-dimensional patterns and is described here for the sake of completeness.

Say the smallest *hpv* of p has length l, $l < \frac{m_w}{3}$. Then $p = u^k v$ where u comprises the leftmost l columns in p, v comprises the ($m_w \bmod l$) rightmost columns of p, and $k = \lfloor \frac{m_w}{l} \rfloor \geq 3$. In addition, the ($m_w \bmod l$) leftmost columns of u and p are identical to v. Define p' to be uuv.

LEMMA 4.4. *p' is h-aperiodic and l is the length of its shortest hpv.*

Proof. Clearly, p' has an *hpv* of length l. Suppose for a contradiction that p' also has an *hpv* of length $l' < l$. Then, by a straightforward generalization of the GCD lemma [LS62], p' has an *hpv* of length $\gcd(l', l) = l'' < l$. Clearly, l'' divides l and therefore $u = u'^{k'}$, where u' comprises the first l'' columns of u. It follows that p has an *hpv* of length $l'' < l$, which is a contradiction. □

In order to find all occurrences of p in t, all occurrences of p' in t are found as described in section 4.1. Given all occurrences of p', all occurrences of p are determined in $O(1)$ time and $O(n_h \times n_w)$ work as described below.

The rows of the text are divided into disjoint blocks of length $\lfloor \frac{m_w}{4} \rfloor$ (the rightmost block in each row could be smaller). All such blocks are processed in parallel. Occurrences of p with top left corner in each such block are found in $O(1)$ time and $O(m_w)$ work per block. We describe the procedure for one such block B.

For a location x in B, $x + l$ is defined to be the location which is distance $l - 1$ to the right of x in its row. Given two locations a and b in the same row of the text, b to the right of a, let $b - a$ denote the distance between a and b. The following steps are performed.

Step 1. The rightmost location x in B such that p' matches the top left corner at x is determined in $O(1)$ time and $O(m_w)$ work using Lemma 2.1.

Step 2. The leftmost location y in B such that $x - y$ is a multiple of l and p' matches the top left corner at $y, y + l, y + 2l, \ldots, x$ is determined in $O(1)$ time and $O(m_w)$ work using Lemma 2.1. Similarly, the rightmost location z at most distance $m_w - 1$ to the right of x such that $z - x$ is a multiple of l and p' matches the top left corner at $x, x + l, x + 2l, \ldots, z$ is determined in $O(1)$ time and $O(m_w)$ work using Lemma 2.1. Note that z need not be in B.

Step 3. All occurrences of p with top left corner in B are found using Lemma 4.5 in $O(1)$ time and $O(m_w)$ work.

LEMMA 4.5. *Suppose p' matches the text with top left corner at location a in B. p_a matches the text if and only if $z - a \geq (k - 2)l$ and a is either coincident with or to the right of y.*

Proof. First, suppose a is either coincident with or to the right of y and $z - a \geq (k - 2)l$. Since p' occurs with top left corner at $y, y + l, \ldots, x$ and since l is the length of the shortest *hpv* of p', $a - y$ is a multiple of l. Further, the right boundary of p_a is aligned with or to the left of the right boundary of the copy of p' with top left corner at z. It follows that there is an occurrence of u with top left corner at $a + l, a + 2l, \ldots, a + (k - 1)l$ and an occurrence of v at $a + kl$. Therefore, p_a matches the text.

Second, suppose either a is to the left of y or a is coincident with or to the right of y and $z - a < (k-2)l$. We consider the two cases separately.

Suppose a is coincident with or to the right of y and $z - a < (k-2)l$. As shown in the previous paragraph, $a - y$ is a multiple of l. For p_a to match the text, p' should occur at $a+il$, for all i, $1 \le i \le k-2$. Since $z-a < (k-2)l$, there exists $i \le k-2$ such that $a+il = z+l$. So p_a matches the text only if p' occurs with top left corner at $z+l$. By the definition of x, $z - x < (k-2)l$ and therefore $z + l - x \le (k-2)l \le m_w - 1$. By the definition of z, p' cannot occur with its top left corner at $z + l$ and therefore p_a does not match the text.

Next, suppose a is to the left of y in B. Let h be the smallest number such that $a+hl \ge y$. If $a+hl > y$ and p' occurs with top left corner at $a+(h-1)l$ then, since p' also occurs with top left corner at y, p' has an *hpv* of length smaller than l, which is a contradiction to Lemma 4.4. Therefore, either $a + hl = y$ or p' does not occur with top left corner at $a+(h-1)l$. This, along with the definition of y, implies that p' does not occur with top left corner at $a+(h-1)l$ in either case and $a+(h-1)l$ is to the left of y. Recall that y, a are in B and $k \ge 3$. Therefore, $(k-2)l \ge \frac{m_w}{4} \ge y - a \ge (h-1)l$ and $h - 1 \le k - 2$. For p_a to match the text, p' should occur at $a + il$, for all i, $1 \le i \le k-2$. Since p' does not occur with its top left corner at $a + (h-1)l$, p_a does not match the text. □

That completes the description of the entire algorithm and gives the following theorem.

THEOREM 4.6. *There is a deterministic CRCW–PRAM algorithm for 2D-matching which runs in $O(1)$ time performing $O(n_h \times n_w)$ work, following preprocessing of the pattern.*

Consider the complexity of 2D-matching on the CREW–PRAM model, that is, the PRAM model in which simultaneous writes are forbidden [Ja91]. Our 2D-matching algorithm uses the string matching algorithm due to Galil which utilizes concurrent writes. This can be replaced by the text processing of Vishkin's algorithm [Vi85] which takes $O(\log m)$ time and optimal work on a CREW–PRAM. In addition, in our 2D-matching algorithm, concurrent writes are used only to find either the boolean AND of the values in a boolean vector or the leftmost and rightmost 1's of a binary vector. These computations can easily be performed optimally on a CREW–PRAM with logarithmic time by computing along a balanced binary tree [Ja91]. That leads to the following theorem.

THEOREM 4.7. *There is a deterministic CREW–PRAM algorithm for 2D-matching which runs in $O(\log m_w)$ time performing $O(n_h \times n_w)$ operations, following preprocessing of the pattern.*

5. Preprocessing. We assume that p is h-aperiodic. If p is h-periodic then, as shown in section 4.2, only an h-aperiodic portion of p needs to be preprocessed; this h-aperiodic portion can be preprocessed similarly. Whether or not p is h-periodic can be determined in $O(1)$ time and $O(m_h \times m_w)$ work using the string witness computation algorithm of [BG90].

The following preprocessing is required by the text processing algorithm.

1. Witnesses, if any, for all valid Quad I and Quad II vectors of p.

The witnesses, if any, for valid Quad I and Quad II vectors of p are computed in $O(\log \log m)$ time and $O(m_h \times m_w)$ work [CG+93b].

2. The periods of each row of p considered as a string as well as the row r in Lemma 3.2.

Periods of each row are computed optimally in $O(\log \log m)$ [BG90, ABG92] time. Following this the row r can be identified in $O(1)$ time using m_h processors.

3. The precomputation required for Galil's string matching algorithm [Ga92] applied to row r (as defined in Lemma 3.2) of p.

This is accomplished in $O(\log\log m)$ time and $O(m_w)$ work [CG+93a].

4. The $(\lfloor (m')^{1/4} \rfloor, f)$ h-sample of p for some f, $0 \leq f \leq \lfloor (m')^{1/4} \rfloor - 1$.

Let $\alpha = \lfloor (m')^{1/4} \rfloor$. We show how to compute an (α, f) h-sample of p for some f, $0 \leq f \leq \alpha - 1$, in $O(1)$ time and $O(m_h \times m_w)$ work. This is done by a straightforward generalization of the algorithm of [CG+93a] for computing the deterministic sample for a string. We describe it here for the sake of completeness.

Definitions. Define an *α-block* to be a rectangle of width α and height m_h. B_i is defined to be the α-block comprising the columns $i, \ldots, i+\alpha-1$ of p, for $1 \leq i \leq \alpha$.

First, it is determined if B_i and B_j are identical for some i and j, $1 \leq i < j \leq \alpha$. This is done in $O(1)$ time and $O(m_h \times m_w)$ work by comparing all such pairs of α-blocks explicitly in parallel. There are $O((\alpha)^2)$ such pairs, comparing each of which takes $O(1)$ time and $O(m_h \times \alpha)$ work. In all, this step takes $O(1)$ time and $O(m_h \times (\alpha)^3) = O(m_h \times m_w)$ work. There are two cases next.

Case A. B_i and B_j are identical, for some i, j, $1 \leq i < j \leq \alpha$.

Let $j - i = c$.

Since p is h-aperiodic and $c < \alpha \leq m'$, there exists a column in p which differs from the cth column to its right. This column cannot be column i, as B_i and B_j are identical. Therefore, such a column must exist either to the left or right of column i. We consider two subcases next, depending on where this column lies.

Case A.1. There exists a column in p to the right of column i which differs from the cth column to its right. Let k be the leftmost such column.

Let l be the topmost row in which columns k and $k+c$ differ. Recall that B_i and B_j are identical. Note that if column k is in B_i, then column $k+c$ is in B_j and therefore columns k and $k+c$ are identical, which is a contradiction. It follows that column k is to the right of B_i, i.e., $k \geq i + \alpha$.

In this case, we claim that the (α, f) h-sample is $\{(l,k), (l,k+c)\}$, with $f = \alpha - 1$. This is shown as follows. In p, the characters at locations (l,k) and $(l,k+c)$ are different. In addition, by the definition of k, the characters at locations (l,k') and $(l,k'+c)$ are identical for all columns k', $i < k' < k$. Since $k \geq i + \alpha$, any copy p' of p shifted at most $\alpha - 1$ positions horizontally to the right of p has some k'th column aligned with column k in p, where $i < k' < k$. Since the characters at locations (l,k') and $(l,k'+c)$ are identical, p' differs from p at at least one of the positions $\{(l,k), (l,k+c)\}$.

Case A.2. Every column in p to the right of column i is identical to the cth column to its right. In addition, there exists a column in p to the left of column i which differs from the cth column to its right. Let k be the rightmost such column.

Let l be the topmost row in which columns k and $k+c$ differ. In this case, we claim that the (α, f) h-sample is $\{(l,k), (l,k+c)\}$, with $f = 0$. This is shown as follows. In p, the characters at locations (l,k) and $(l,k+c)$ are different. In addition, by the definition of k, the characters at locations (l,k') and $(l,k'+c)$ are identical for all columns k', $k' > k$. Since $k + \alpha < m_w$, any copy p' of p shifted at most $\alpha - 1$ positions horizontally to the left of p has some k'th column aligned with column k in p, where $k' > k$. Since the characters at locations (l,k') and $(l,k'+c)$ are identical, p' differs from p at at least one of the positions $\{(l,k), (l,k+c)\}$.

It remains to show how k and l can be computed in Cases A.1 and A.2. Each column is compared with the cth column to its right in parallel and the smallest row in which they differ, if any, is determined in $O(1)$ time and $O(m_h \times m_w)$ work. Following that, k and l can be computed easily in $O(1)$ time and $O(m_h \times m_w)$ work.

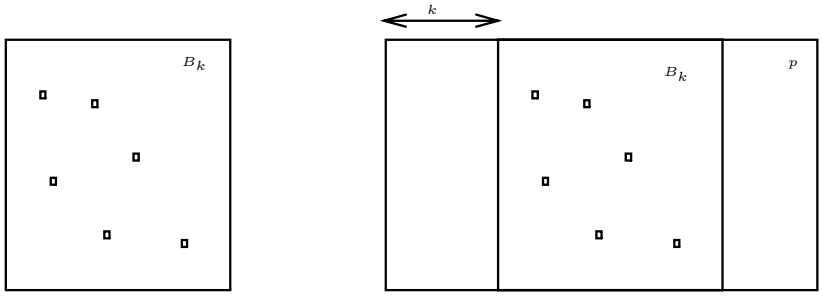

FIG. 2. *The sets $\mathcal{S}$ and $\mathcal{S}'$.*

This completes Case A.

Case B. B_i and B_j are different, for all i, j, $1 \leq i < j \leq \alpha$.

Consider the scenario in which $B_1, \ldots, B_\alpha$ are laid on top of each other with their boundaries aligned. We show how to compute a value k and a set $\mathcal{S}$ of at most $\log \alpha$ locations in B_k satisfying the following property: for each B_i, $i \neq k$, there exists $j \in \mathcal{S}$ such that B_i differs from B_k at location j, i.e., the character in B_i which overlaps location j in B_k differs from the character at location j in B_k. The required (α, f) h-sample of p, $f = k - 1$, is then determined as follows.

We claim that the h-sample of p is the set $\mathcal{S}'$ of locations in p which correspond to the locations in B_k which are in $\mathcal{S}$ (see Figure 2). This is shown as follows. If p' is any copy of p shifted horizontally to the right of p by i, $1 \leq i \leq k-1$, then the portion of p' which overlaps block B_k in p is identical to the block B_{k-i}. If p' is any copy of p shifted horizontally to the left of p by i, $1 \leq i \leq \alpha - k$, then the portion of p' which overlaps block B_k in p is identical to the block B_{k+i}. In each case, since B_k differs from all other α-blocks at some location in $\mathcal{S}$, p' differs from p at some location in $\mathcal{S}'$.

Computing k and $\mathcal{S}$. Let A be a two-dimensional table of size $\alpha \times (m_h \times \alpha)$ initialized to 0. The row i in A stands for B_i. Location (i, j) of A corresponds to the location (a, b) in B_i, where $a \in [1, \ldots, m_h]$, $b \in [1, \ldots, \alpha]$, $(a-1) \times m_h + b = j$; we refer to location (a, b) in B_i as location j in B_i.

The table A is filled in so as to satisfy the following criterion: $A(i, j) = 1$ if and only if for some $l \neq i$, $1 \leq l \leq \alpha$, j is the smallest number such that B_l differs from B_i at location j in B_i (note that the minimality of j signifies that B_l and B_i match at all columns to the left of the column containing location j in B_i and at all locations above location j in the column containing location j in B_i). This is done by exhaustively comparing all pairs of α-blocks in $O(1)$ time and $O((\alpha \times \alpha) \times (m_h \times \alpha)) = O(m_h \times \alpha^3) = O(m_h \times m_w)$ work. Here $\alpha \times \alpha$ is the number of pairs of α-blocks and $m_h \times \alpha$ is the size of each α-block.

Recall that all α-blocks are distinct; therefore, for all i, $1 \leq i \leq \alpha$, each B_l, $l \neq i$, differs from B_i at some location in B_i in the set $\mathcal{S}_i = \{j | A(i, j) = 1\}$. In Lemma 5.1, we show that there exists an f such that $|\mathcal{S}_f| \leq \log \alpha$. We also show that one such f can be found in $O(1)$ time and $O(m_h \times m_w)$ work. k is chosen to be the f so found and $\mathcal{S}$ is chosen to be $\mathcal{S}_f$.

LEMMA 5.1. *There exists an f, $1 \leq f \leq \alpha$ such that $|\mathcal{S}_f| \leq \log \alpha$.*

Proof. Recall that we are considering the scenario in which $B_1, \ldots, B_\alpha$ are laid on top of each other with their borders aligned. Also recall that all the B_i's are distinct.

The proof is constructive. The construction has at most $\log \alpha$ iterations. In each iteration, at least half of the α-blocks currently being considered are removed from further consideration until, finally, only one α-block remains. In iteration l, we also pick a number j_l. The following invariants hold at the end of iteration l.

1. All α-blocks B_i which remain under consideration after iteration l are identical at the locations $1, \ldots, j_l$.
2. For all α-blocks B_i which remain under consideration after iteration l, $A(i, j) = 1$ if and only if $j \in \{j_1, \ldots, j_l\}$, where $1 \leq j \leq j_l$.
3. If B_i is removed from consideration in iteration l, then it differs from all $B_{i'}$'s which are still under consideration at location j_l.

Let B_f be the only α-block which remains finally. We will show that $\mathcal{S}_f = \{j_1, \ldots, j_r\}$, where r is the number of iterations. The lemma follows immediately.

We describe the lth iteration. Let C be the set of α-blocks still under consideration. All α-blocks in C are identical at locations $1, \ldots, j_{l-1}$. j_l is chosen to be the smallest number greater than j_{l-1} with the property that $A(i, j_l) = 1$ for some $B_i \in C$ is chosen. Clearly, all α-blocks in C are identical at locations $1, \ldots, j_l - 1$, and two α-blocks in C differ at location j_l. Consider the multiset of characters which occur at location j_l in the α-blocks in C; there are at least two such characters. Let a be the character which appears the least number of times in this multiset. The set D of α-blocks which remain under consideration is comprised of all those α-blocks which have the character a in location j_l.

Clearly, $|D| \leq \lfloor \frac{|C|}{2} \rfloor$ and all α-blocks in D are identical at locations $1, \ldots, j_l$. Thus invariant 1 holds. In addition, if $B_i \in D$, then $A(i, j_l) = 1$. By the definition of j_l, $A(i, j) = 0$ for all $B_i \in D$ and $j_{l-1} < j < j_l$. Thus invariant 2 holds. For all $B_i \in C - D$ and $B_{i'} \in D$, B_i differs from $B_{i'}$ at location j_l. Thus invariant 3 holds as well.

It remains to show that $\mathcal{S}_f = \{j_1, \ldots, j_r\}$. Suppose for a contradiction that $\mathcal{S}_f \neq \{j_1, \ldots, j_r\}$. From invariant 2, it follows that there exists a $j > j_r$ such $A(f, j) = 1$. Then there exists B_i, $i \neq f$, such that B_i and B_f are identical at locations $1, \ldots, j_r$ but differ at location j. Since B_i was removed from consideration in some iteration l, B_l differs from B_f at location j_l by invariant 3, which is a contradiction. □

Finding a row in A with at most $\log \alpha$ 1's. It remains to determine one row in table A which contains at most $\log \alpha$ 1's. All rows are considered in parallel. For each row it is determined if it has at most $\log \alpha$ 1's, and in case it does, the locations containing 1's are compacted into an array of size $\log \alpha$. Lemma 5.2 shows that this can be done in $O(1)$ time and $O(m_h \times \alpha)$ work per row; this sums to $O(m_h \times \alpha^2) = O(m_h \times m_w)$ work over all rows.

LEMMA 5.2 (see [Ra90]). *Given a binary array X of size i and a parameter j, there is an algorithm which determines whether X has at most j 1's, and if so, compacts the indices containing 1's into an array of size j. This algorithm takes time $O(\log j / \log \log i)$ time and $O(i)$ work.*

This yields the following theorem.

THEOREM 5.3. *A two-dimensional pattern of size $m_h \times m_w$ can be matched against a two-dimensional text of size $n_h \times n_w$ in $O(1)$ time and $O(n_h \times n_w)$ work, after the pattern has been preprocessed in $O(\log \log m_w)$ time and $O(m_h \times m_w)$ work.*

Acknowledgments. We thank Richard Cole for his comments.

IMPROVED RANDOMIZED ON-LINE ALGORITHMS FOR THE LIST UPDATE PROBLEM*

SUSANNE ALBERS†

Abstract. The best randomized on-line algorithms known so far for the list update problem achieve a competitiveness of $\sqrt{3} \approx 1.73$. In this paper we present a new family of randomized on-line algorithms that beat this competitive ratio. Our improved algorithms are called TIMESTAMP algorithms and achieve a competitiveness of $\max\{2-p, 1+p(2-p)\}$, for any real number $p \in [0,1]$. Setting $p = (3-\sqrt{5})/2$, we obtain a ϕ-competitive algorithm, where $\phi = (1+\sqrt{5})/2 \approx 1.62$ is the golden ratio. TIMESTAMP algorithms coordinate the movements of items using some information on past requests. We can reduce the required information at the expense of increasing the competitive ratio. We present a very simple version of the TIMESTAMP algorithms that is 1.68-competitive. The family of TIMESTAMP algorithms also includes a new deterministic 2-competitive on-line algorithm that is different from the MOVE-TO-FRONT rule.

1. Introduction.

The *list update problem* is among the first on-line problems that have been studied with respect to competitiveness. The problem consists in maintaining a set of items as an unsorted linear list. A list of n items is given. A list update algorithm is presented with a sequence of *requests* that must be served in their order of occurrence. Each request specifies an item in the list. In order to serve a request, a list update algorithm must *access* the requested item, i.e., it has to start at the front of the list and search linearly through the items until the desired item is found. Accessing the ith item in the list incurs a cost of i. Immediately after an access, the requested item may be moved at no extra cost to any position closer to the front of the list. These exchanges are called *free exchanges*. All other exchanges of two consecutive items in the list cost 1 and are called *paid exchanges*. The goal is to serve the request sequence so that the total cost is as small as possible. A list update algorithm is *on-line* if it serves every request without knowledge of any future requests.

We analyze the performance of on-line algorithms for the list update problem using *competitive analysis* [6]. In a competitive analysis, an on-line algorithm A is compared to an *optimal off-line* algorithm. An optimal off-line algorithm knows the entire request sequence in advance and can serve it with minimum cost. Given a request sequence σ, let $C_A(\sigma)$ denote the cost incurred by on-line algorithm A in serving σ and let $C_{OPT}(\sigma)$ denote the cost incurred by the optimal off-line algorithm OPT in processing σ. Then the algorithm A is called c-competitive if there is a constant a such that $C_A(\sigma) \leq c \cdot C_{OPT}(\sigma) + a$ for all request sequences σ. The *competitive factor* of A is the infimum of all c such that A is c-competitive.

Sleator and Tarjan [6] have shown that the well-known MOVE-TO-FRONT algorithm is 2-competitive. This deterministic on-line algorithm moves an item to the

front of the list each time it is requested. Karp and Raghavan [4] have observed that no deterministic on-line algorithm for the list update problem can be better than 2-competitive. Thus the MOVE-TO-FRONT algorithm achieves the best possible competitive factor. A natural question is if the competitive factor of 2 can be improved using randomization. It was shown that, against *adaptive adversaries*, no randomized on-line algorithm for the list update problem can be better than 2-competitive [1, 5]. Adaptive adversaries may see the on-line algorithm's random choices on past requests when generating a new request in a request sequence σ. On the other hand, against *oblivious adversaries*, the optimal competitive factor of randomized on-line algorithms has not yet been determined. An oblivious adversary specifies a request sequence in advance and is not allowed to see the random choices made by the on-line algorithm. A randomized on-line algorithm A is called c-competitive against any oblivious adversary if there exists a constant a such that for all request sequences σ generated by oblivious adversaries, $E[C_A(\sigma)] \leq c \cdot C_{OPT}(\sigma) + a$, where the expectation is taken over the random choices made by A. In this paper we always evaluate on-line algorithms with respect to oblivious adversaries. Irani [3] exhibited the first randomized on-line algorithm for the list update problem; the SPLIT algorithm she proposed is $\frac{31}{16}$-competitive. Reingold, Westbrook, and Sleator [5] have given a family of COUNTER and RANDOM RESET algorithms that achieve a competitive ratio of $\sqrt{3} \approx 1.73$. This has been the best upper bound known so far for randomized list update algorithms. The best lower bound known is due to Teia [7]. He shows that no randomized on-line algorithm for the list update problem can be better than 1.5-competitive.

In this paper we present improved randomized on-line algorithms for the list update problem that beat the competitive ratio of $\sqrt{3}$. Our new algorithms are called TIMESTAMP algorithms and achieve a competitiveness of $\max\{2-p, 1+p(2-p)\}$ for any real number $p \in [0,1]$. Choosing $p = (3-\sqrt{5})/2$, we obtain a ϕ-competitive algorithm, where $\phi = (1+\sqrt{5})/2 \approx 1.62$ is the golden ratio. TIMESTAMP algorithms do not always move the requested item x to the front of the list but sometimes to a position that is only a bit closer to the front. This position can be computed easily when the algorithm scans the items preceding x in the list. However, in the implementation of the algorithm, the computation of this position requires a second pass through the list after the item x has been accessed. Moreover, some information on past requests is necessary in order to determine the desired position. We can simplify the TIMESTAMP algorithms so that they need less knowledge of previous requests; this increases the competitive ratio. We present a simplified version of the TIMESTAMP algorithms that is 1.68-competitive. The family of TIMESTAMP algorithms also includes two deterministic 2-competitive on-line algorithms, one of which is the MOVE-TO-FRONT rule. The second, new algorithm is the only other deterministic on-line algorithm found so far that achieves a competitive factor of 2; Sleator and Tarjan [6] have proved that the well-known deterministic algorithms TRANSPOSE and FREQUENCY COUNT are not 2-competitive.

The list update problem as defined above is the *static* version of the problem. Each request is an access to an item. In the *dynamic* variant of the problem, insertions and deletions of items are allowed. A new item is inserted by scanning the entire list and appending the item at the end of the list. A deletion of an item is processed by searching for the item in the list and deleting it. In the following sections, when we develop and analyze randomized list update algorithms, we always consider the static version of the problem. However, the on-line algorithms we will propose can

be extended in the obvious way so that they can handle insertions and deletions, too. All theorems that we will present also hold for the dynamic list update problem.

2. TIMESTAMP algorithms. We present a new family of randomized on-line algorithms for the list update problem. The following algorithm works for any real number $p \in [0,1]$.

Algorithm TIMESTAMP(p). Given a request sequence $\sigma = \sigma(1), \sigma(2), \ldots, \sigma(m)$, each request $\sigma(t)$, $1 \leq t \leq m$ is processed as follows. Suppose that $\sigma(t)$ is a request to item x.

With probability p, execute Step (a).

(a) Move x to the front of the list.

With probability $1-p$, execute Step (b).

(b) If x has not been requested so far during the time interval $[1, t-1]$, then do not change the position of x in the list. Otherwise let $t' \in [1, t-1]$ be the time at which x was requested most recently and serve the request $\sigma(t)$ as follows. Let $v_x(t)$ be the item closest to the front of the list that precedes x in the list and

(i) that was not requested during the interval $[t', t-1]$

or

(ii) that was requested exactly once during $[t', t-1]$ and the corresponding request was served using Step (b) of the algorithm.

If there is no such item, then let $v_x(t) = x$.

Insert x immediately before $v_x(t)$.

THEOREM 1. *For any real number $p \in [0,1]$, TIMESTAMP(p) is c-competitive, where $c = \max\{2-p,\ 1+p(2-p)\}$.*

COROLLARY 1. *TIMESTAMP($\frac{3-\sqrt{5}}{2}$) is ϕ-competitive, where $\phi = \frac{1}{2}(1+\sqrt{5})$ is the golden ratio.*

An interesting feature of the TIMESTAMP(p) algorithm is that at a request to item x, all items y satisfying condition (i) or (ii) in Step (b) are stored consecutively in front of x. In other words, all items stored between x and $v_x(t)$ satisfy condition (i) or (ii); we will prove this later in Lemma 2.

We assume that the algorithm TIMESTAMP(p) maintains a time stamp $ST(y)$ for each item y in the list. While a request sequence in served, $ST(y)$ always stores the time of the most recent request to y. When there is a request to item x, TIMESTAMP(p) can easily determine the first item in the list that satisfies condition (i) in Step (b). The algorithm just has to find the first item y with $ST(y) < ST(x)$. Finding the first item in the list that satisfies condition (ii) in Step (b) requires more information on previous requests. We can simplify the TIMESTAMP(p) algorithm at the expense of increasing the competitive ratio. Suppose that we drop condition (ii) in Step (b). Then $v_x(t)$ is simply the item closest to the front of the list that precedes x and has not been requested during the interval $[t', t-1]$. We can show the following performance.

THEOREM 2. *If condition* (ii) *is dropped in Step* (b) *of TIMESTAMP(p), then the resulting algorithm is c-competitive, where $c = \max\{2-p, 1+p(2-p), 2-\frac{3}{2}p+2p^2-\frac{1}{2}p^3\}$. Setting $p = \frac{1}{2}(5-\sqrt{17})$, we obtain a competitive ratio of $\frac{3}{2}(\sqrt{17}-3) \approx 1.68$.*

We will prove this theorem after we have proven Theorem 1.

Although the item $v_x(t)$ specified in TIMESTAMP(p) can be computed easily, in a real implementation of the algorithm we need a second pass through the list in order to actually locate $v_x(t)$. Note that a number of on-line algorithms that have been proposed in the literature, such as the algorithm FREQUENCY COUNT, also

require such a second pass after each access to an item. There is an alternative formulation of TIMESTAMP(p) that does not need a second pass. In this alternative formulation, we maintain a pointer $ptr(x)$ for each item x in the list; $ptr(x)$ either points to x or to an item preceding x in the list. At a request to item x, x is inserted at the front of the list or immediately before $ptr(x)$. The element specified by $ptr(x)$ always corresponds to $v_x(t)$. The drawback of this alternative formulation is that we need time to update the pointers. Essentially, at a request to item x, the pointers of all elements y with $ptr(y) = x$ must be set to the successor of x in the list, and $ptr(x)$ must be set to the front of the list. We prefer the formulation of the TIMESTAMP(p) algorithm given above because it explicitly describes the properties of the position $v_x(t)$ in front of which an item x is to be inserted.

TIMESTAMP(p) describes two deterministic algorithms. Setting $p = 1$ we obtain the MOVE-TO-FRONT algorithm. Theorems 1 and 2 confirm the well-known fact that the MOVE-TO-FRONT rule is 2-competitive. On the other hand, assume $p = 0$ and consider the simplified version of the TIMESTAMP algorithm in which condition (ii) of Step (b) is dropped. The resulting deterministic algorithm always inserts the requested item x immediately before the first item in the list that has not been requested since the last request to x. Theorem 2 implies that this deterministic strategy is 2-competitive.

We now proceed with the proof of Theorem 1. Consider a fixed $p \in [0, 1]$. Let $\sigma = \sigma(1), \sigma(2), \ldots, \sigma(m)$ be an arbitrary request sequence consisting of m requests and let $\sigma(t)$ denote the request at time t, $1 \leq t \leq m$. We first present two lemmata that describe the relative positions of items in the list while TIMESTAMP(p) serves a request sequence.

LEMMA 1. *Let x and y, $x \neq y$ be two items. Suppose that x is requested at time t' and at time t, $t' < t$, and that y is not requested during the interval $[t', t]$. Then, immediately after the service of $\sigma(t)$, x precedes y in TIMESTAMP(p)'s list and this relation does not change before the next request to y.*

Proof. If TIMESTAMP(p) executes Step (a) when serving $\sigma(t)$, then x is moved to the front of the list and must precede y in the list. If TIMESTAMP(p) executes Step (b) when serving $\sigma(t)$, then condition (i) in Step (b) of the algorithm ensures that x is inserted at some position in front of item y because y is not requested during $[t', t]$. In any case, x precedes y in TIMESTAMP(p)'s list immediately after the service of $\sigma(t)$. Since y is only moved when it is requested, the relative position of x and y cannot change before the next request to y. □

LEMMA 2. *Let t be a time in $[1, m]$. If the item $x = \sigma(t)$ was requested at least once in $[1, t-1]$, then the following two statements hold. Let t', $t' < t$ denote the time at which x was requested most recently.*

(a) *If item y, $y \neq x$ was requested at least twice during $[t', t-1]$, then y precedes item $v_x(t)$ in TIMESTAMP(p)'s list at time t.*
(b) *If item y, $y \neq x$ was requested exactly once during $[t', t-1]$ and the corresponding request was served using Step* (a) *of TIMESTAMP(p), then y precedes item $v_x(t)$ in TIMESTAMP(p)'s list at time t.*

Proof. Suppose that there is a time in $[1, m]$ at which Lemma 2 does not hold. Then let $t_0 \in [1, m]$ be the earliest point of time at which the lemma is violated. Furthermore, let t_0', $t_0' < t_0$ be the time at which item $x = \sigma(t_0)$ was requested most recently, and let $z = v_x(t_0)$.

First we examine the case that statement (a) of the lemma does not hold. Thus, there exists an item y, $y \neq x$ that is requested at least twice in $[t_0', t_0 - 1]$ and that does not precede z at time t_0. Let t_y be the time of the last request to y in $[t_0', t_0 - 1]$. We show that after the service of $\sigma(t_y)$, item y precedes z in TIMESTAMP(p)'s list. If

$\sigma(t_y)$ is served using Step (a) of the algorithm, then there is nothing to show. Suppose that $\sigma(t_y)$ is served using Step (b) of TIMESTAMP(p). By the definition of $v_x(t_0)$, item z is requested at most once in $[t_0', t_0 - 1]$, and such a request is served using Step (b) of the algorithm. This implies that when TIMESTAMP(p) serves $\sigma(t_y)$, z cannot precede $v_y(t_y)$ (due to conditions (i) and (ii) in Step (b) of the algorithm). Hence y is inserted at some position in front of z. We conclude that y must precede z after the service of $\sigma(t_y)$. Since, by assumption, z precedes y at time t_0, item z must be requested at some time $t_z \in [t_y + 1, t_0 - 1]$ and z must be inserted at some position in front of y when $\sigma(t_z)$ is served. This implies that y cannot precede $v_z(t_z)$ at time t_z because $\sigma(t_z)$ is served using Step (b) of the algorithm. Note that at time t_z, y was requested at least twice since the last request to z. Hence statement (a) of the lemma does not hold at time t_z, and we have a contradiction to the minimality of t_0.

Now assume that statement (b) of the lemma is violated. Let y, $y \neq x$ be an item for which statement (b) does not hold, and let $t_y \in [t_0', t_0 - 1]$ be the time at which y is requested. By assumption, y does not precede $z = v_x(t_0)$ at time t_0. Since $\sigma(t_y)$ is served using Step (a) of the algorithm, y precedes z after the service of $\sigma(t_y)$. Using the same arguments as above, we can derive a contradiction to the choice of t_0. □

In the following we will evaluate TIMESTAMP(p)'s and OPT's cost on request sequence σ. Let $C_{TS}(\sigma)$ be the cost incurred by TIMESTAMP(p) in serving σ. We will show that

$$E[C_{TS}(\sigma)] \leq c \cdot C_{OPT}(\sigma), \tag{2.1}$$

where $c = \max\{2 - p, 1 + p(2 - p)\}$. This proves Theorem 1. Here we assume, without loss of generality, that TIMESTAMP(p) and OPT start with the same initial list. In the following, when analyzing on-line and off-line cost, we will always use the $(i-1)$-*cost measure*, i.e., we assume that an access to the ith item in the list incurs a cost of $i - 1$ rather than i. Obviously, an on-line algorithm that is c-competitive in the $(i-1)$-cost measure is also c-competitive in the i-cost measure.

We need some notation. Let L be the set of items in the list. For any $t \in [1, m]$ and any item $x \in L$, let $C_{TS}(t, x)$ be the cost incurred by item x when TIMESTAMP(p) serves $\sigma(t)$. More precisely, $C_{TS}(t, x) = 1$ if at time t, item x precedes the item requested by $\sigma(t)$ in TIMESTAMP(p)'s list; otherwise $C_{TS}(t, x) = 0$. We have

$$\begin{aligned} E[C_{TS}(\sigma)] &= E\left[\sum_{t\in[1,m]} \sum_{x\in L} C_{TS}(t,x)\right] \\ &= E\left[\sum_{x\in L} \sum_{t\in[1,m]} C_{TS}(t,x)\right] \\ &= E\left[\sum_{x\in L} \sum_{y\in L} \sum_{\substack{t\in[1,m] \\ \sigma(t)=y}} C_{TS}(t,x)\right]. \end{aligned}$$

Let $\{x, y\}$ be an unordered pair of items x and y with $x \neq y$. Every pair $\{x, y\}$ contributes two terms in the last line of the above equation, namely,

$$\sum_{\substack{t\in[1,m] \\ \sigma(t)=x}} C_{TS}(t,y) \quad \text{and} \quad \sum_{\substack{t\in[1,m] \\ \sigma(t)=y}} C_{TS}(t,x).$$

Thus,

$$E[C_{TS}(\sigma)] = E\left[\sum_{\substack{\{x,y\}\\ x\neq y}}\left(\sum_{\substack{t\in[1,m]\\ \sigma(t)=x}} C_{TS}(t,y) + \sum_{\substack{t\in[1,m]\\ \sigma(t)=y}} C_{TS}(t,x)\right)\right]. \tag{2.2}$$

The cost incurred by OPT can be written in a similar way, i.e.,

$$C_{OPT}(\sigma) = \sum_{\substack{\{x,y\}\\ x\neq y}}\left(\sum_{\substack{t\in[1,m]\\ \sigma(t)=x}} C_{OPT}(t,y) + \sum_{\substack{t\in[1,m]\\ \sigma(t)=y}} C_{OPT}(t,x) \;+\; p(x,y)\right). \tag{2.3}$$

Here $C_{OPT}(t,y)$ and $C_{OPT}(t,x)$ denote the costs incurred by items y and x when OPT serves $\sigma(t)$. For any unordered pair $\{x,y\}$ of items $x \neq y$, $p(x,y)$ denotes the total number of paid exchanges that OPT incurs in moving x in front of y or y in front of x.

Now, for any pair $\{x,y\}$ of items with $x \neq y$, let σ_{xy} be the request sequence that is obtained from σ if we delete all requests in σ that are neither to x nor to y. Let $E[C_{TS}(\sigma_{xy})]$ be the expected cost incurred by TIMESTAMP(p) if it serves σ_{xy} on a list consisting of x and y only. Lemma 2 implies that if TIMESTAMP(p) serves a request $\sigma(t)$ in σ using Step (b), then the requested item $x = \sigma(t)$ never passes an item that was requested at least twice since the last request to x, or an item that was requested exactly once and the corresponding request was served using Step (a) of the algorithm. Thus, for any pair $\{x,y\}$ of items, the following statement holds. If TIMESTAMP(p) serves σ on the entire list, then the relative position of x and y changes in the same way as if TIMESTAMP(p) is run on the two item list consisting of x and y with request sequence σ_{xy}. Therefore, we have

$$E[C_{TS}(\sigma_{xy})] = E\left[\sum_{\substack{t\in[1,m]\\ \sigma(t)=x}} C_{TS}(t,y) + \sum_{\substack{t\in[1,m]\\ \sigma(t)=y}} C_{TS}(t,x)\right]$$

and, by equation (2.2),

$$E[C_{TS}(\sigma)] = \sum_{\substack{\{x,y\}\\ x\neq y}} E[C_{TS}(\sigma_{xy})].$$

Let $C_{OPT}(\sigma_{xy})$ be the cost incurred by OPT if it serves σ_{xy} on the list consisting of x and y only. In this two item list, OPT can always arrange x and y optimally, which might not be possible when OPT serves σ on the entire list. Hence

$$C_{OPT}(\sigma_{xy}) \leq \sum_{\substack{t\in[1,m]\\ \sigma(t)=x}} C_{OPT}(t,y) + \sum_{\substack{t\in[1,m]\\ \sigma(t)=y}} C_{OPT}(t,x) \;+\; p(x,y),$$

and equation (2.3) implies

$$C_{OPT}(\sigma) \geq \sum_{\substack{\{x,y\}\\ x\neq y}} C_{OPT}(\sigma_{xy}).$$

This method of analyzing cost by considering pairs of items was also used in [2, 3]. In the following we show that for any pair of items $\{x, y\}$ with $x \neq y$,

$$E[C_{TS}(\sigma_{xy})] \leq c \cdot C_{OPT}(\sigma_{xy}), \tag{2.4}$$

where $c = \max\{2 - p, 1 + p(2 - p)\}$. This proves inequality (2.1).

Consider an arbitrary pair $\{x, y\}$ with $x \neq y$. Let $\sigma_{xy} = \sigma(t_1), \sigma(t_2), \ldots, \sigma(t_k)$ for some nonnegative integer k. For $i = 1, 2, \ldots, k$, let u_i be the item requested by $\sigma(t_i)$. Lemma 1 suggests partitioning σ_{xy} into phases $P(1), P(2), \ldots, P(l)$ for some l so that the following condition holds. If phase $P(j)$, $1 \leq j \leq l$ starts at time t_{b_j}, then it ends at time t_{e_j}, where

$$e_j = \min\{i > b_j | u_{i-1} = u_i \text{ and } u_i \neq u_{i+1}\}.$$

In other words, a phase ends when, for the first time, there have been two consecutive requests to the same item and the next request is different. The phases we obtain can be classified as follows.

Type 1:	(a) $P(j) = x^h$	or	(b) $P(j) = y^h$	for some $h \geq 2$.
Type 2:	(a) $P(j) = xy^h$	or	(b) $P(j) = yx^h$	for some $h \geq 2$.
Type 3:	(a) $P(j) = (xy)^{h_1}x^{h_2}$	or	(b) $P(j) = (yx)^{h_1}y^{h_2}$	for some $h_1 \geq 1, h_2 \geq 2$.
Type 4:	(a) $P(j) = (xy)^{h_1}y^{h_2}$	or	(b) $P(j) = (yx)^{h_1}x^{h_2}$	for some $h_1 \geq 2, h_2 \geq 1$.

We may assume, without loss of generality, that the item first requested in a phase $P(j)$, $1 \leq j \leq l$ is behind the other item of the pair $\{x, y\}$ in the two item lists maintained by TIMESTAMP(p) and OPT. This is easy to see for phase $P(1)$. If the first item in $P(1)$, say x, precedes y in the initial list, then we can simply omit the first requests to x in σ_{xy} until we obtain the first request to y. This does not change the cost incurred by TIMESTAMP(p) and OPT in $P(1)$ because we assume that TIMESTAMP(p) and OPT start with the same initial list. Now consider a phase $P(j)$, $2 \leq j \leq l$. The item first requested in $P(j)$ differs from the item requested by the two previous requests. Lemma 1 immediately implies that the first item in $P(j)$ is behind the other item of the pair $\{x, y\}$ in the list maintained by TIMESTAMP(p). Consider OPT's movements when it serves the request sequence σ_{xy} on the two item list. We may assume, without loss of generality, that whenever there are two consecutive requests to the same item, OPT moves that item to the front of the list, provided that it has not been there yet. This implies, without loss of generality, that immediately before the first request in a phase $P(j)$, the item requested first in the phase is also behind the other item of the pair $\{x, y\}$ in OPT's two item list.

In the following we evaluate the expected cost incurred by TIMESTAMP(p) and the cost incurred by OPT in each phase of σ_{xy}. For each $j = 1, 2, \ldots, l$, the expected cost incurred by TIMESTAMP(p) in phase $P(j)$ of σ_{xy} is

$$E[C_{TS}(P(j))] = E\left[\sum_{i=b_j}^{e_j}(C_{TS}(t_i, y) + C_{TS}(t_i, x))\right].$$

Similarly, for $j = 1, 2, \ldots, l$, let $C_{OPT}(P(j))$ be the cost incurred by OPT when it serves phase $P(j)$ of σ_{xy}. We will prove the following lemmata.

LEMMA 3. *If $P(j)$ has type 1, then $E[C_{TS}(P(j))] \leq (2 - p)C_{OPT}(P(j))$.*

LEMMA 4. *If $P(j)$ has type 2, then $E[C_{TS}(P(j))] \leq (1 + p(2 - p))C_{OPT}(P(j))$.*

LEMMA 5. *If $P(j)$ has type 3 or 4, then $E[C_{TS}(P(j))] \leq \max\{2-p, 1+p(2-p)\}C_{OPT}(P(j))$.*

Before we prove the lemmata we finish the proof of inequality (2.4). Lemmata 3–5 imply that

$$\begin{aligned} E[C_{TS}(\sigma_{xy})] &= E\left[\sum_{j=1}^{l} C_{TS}(P(j))\right] \\ &\leq \max\{2-p, 1+p(2-p)\}\sum_{j=1}^{l} C_{OPT}(P(j)) \\ &= \max\{2-p, 1+p(2-p)\}C_{OPT}(\sigma_{xy}), \end{aligned}$$

and inequality (2.4) is proved.

We have classified phases $P(1), P(2), \ldots, P(l)$ into four types. For each type, subtypes (a) and (b) are symmetric to each other. In the following, we will always assume, without loss of generality, that the considered phase has subtype (a). Let $P(j)$ be an arbitrary phase. By the above discussion we know that immediately before the first request in $P(j)$, x is behind y in the two item lists maintained by TIMESTAMP(p) and OPT. Thus $E[C_{TS}(t_{b_j}, y)] = C_{OPT}(t_{b_j}, y) = 1$, for $j = 1, 2, \ldots, l$.

Claim 1 below will be useful when proving Lemmata 3–5. We will present a proof of this claim later.

CLAIM 1. *After the service of the first request $\sigma(t_{b_j})$ in a phase $P(j)$, $1 \leq j \leq l$, item $x = \sigma(t_{b_j})$ precedes item y if and only if TIMESTAMP(p) serves $\sigma(t_{b_j})$ using Step* (a) *of the algorithm.*

Proof of Lemma 3. We have $C_{TS}(P(j)) = \sum_{i=b_j}^{e_j} C_{TS}(t_i, y)$. By Lemma 1, x precedes y in TIMESTAMP(p)'s list after the service of $\sigma(t_{b_j+1})$. Hence, y cannot cause a cost at the third and all remaining requests to x in $P(j)$. We obtain

$$\begin{aligned} E[C_{TS}(P(j))] &= E[C_{TS}(t_{b_j}, y)] + E[C_{TS}(t_{b_j+1}, y)] \\ &= 1 + E[C_{TS}(t_{b_j+1}, y)]. \end{aligned}$$

$E[C_{TS}(t_{b_j+1}, y)]$ is the probability that item $x = u_{b_j+1}$ is behind item y in TIMESTAMP(p)'s list when $\sigma(t_{b_j+1})$ is served. Applying Claim 1 we infer that x is behind y if and only if TIMESTAMP(p) serves $\sigma(t_{b_j})$ using Step (b), which happens with probability $1-p$. We conclude $E[C_{TS}(t_{b_j+1}, y)] = 1-p$ and $E[C_{TS}(P(j))] = 2-p$. Since $C_{OPT}(P(j)) = 1$, the lemma follows. □

Proof of Lemma 4. TIMESTAMP(p)'s cost in phase $P(j)$ is $C_{TS}(P(j)) = C_{TS}(t_{b_j}, y) + \sum_{i=b_j+1}^{e_j} C_{TS}(t_i, x)$. Lemma 1 implies that x cannot cause a cost at the third and all remaining requests to y in $P(j)$. Hence

$$\begin{aligned} E[C_{TS}(P(j))] &= E[C_{TS}(t_{b_j}, y)] + E[C_{TS}(t_{b_j+1}, x)] + E[C_{TS}(t_{b_j+2}, x)] \\ &= 1 + E[C_{TS}(t_{b_j+1}, x)] + E[C_{TS}(t_{b_j+2}, x)]. \end{aligned}$$

We have $C_{TS}(t_{b_j+1}, x) = 1$ if the TIMESTAMP(p) algorithm moves x in front of y when serving $\sigma(t_{b_j})$. By Claim 1, this happens if TIMESTAMP(p) processes $\sigma(t_{b_j})$ using Step (a). Therefore, $E[C_{TS}(t_{b_j+1}, x)] = p$. We analyze $E[C_{TS}(t_{b_j+2}, x)]$. We have $C_{TS}(t_{b_j+2}, x) = 1$ if TIMESTAMP(p) moves x in front of y when serving $\sigma(t_{b_j})$ and does not move y in front of x when serving $\sigma(t_{b_j+1})$. Claim 1 implies that with probability p, TIMESTAMP(p) moves x in front of y when serving $\sigma(t_{b_j})$. Item y

can only stay behind x in TIMESTAMP(p)'s list if $\sigma(t_{b_j+1})$ is served using Step (b), which happens with probability $1-p$. Thus, the expected cost on $\sigma(t_{b_j+2})$ is at most $p(1-p)$. We obtain $E[C_{TS}(P(j))] \leq 1+p+p(1-p) = 1+p(2-p)$, and the lemma follows because $C_{OPT}(P(j)) = 1$. □

Proof of Lemma 5. We know that $C_{TS}(t_{b_j}, y) = 1$ and, using Claim 1, $E[C_{TS}(t_{b_j+1}, x)] = p$. First we assume that $P(j)$ has type 3. Then $P(j)$ consists of a head of $2h_1$ alternating requests to x and y and of a tail of h_2 requests to x. Lemma 1 ensures that in the tail of requests to x, item x must precede y in TIMESTAMP(p)'s list after the service of the second request to x. Hence y cannot cause a cost at any of the remaining requests in $P(j)$, i.e., $C_{TS}(t_i, y) = 0$ for $i = b_j + 2(h_1+1), \ldots, e_j$. Thus

$$C_{TS}(P(j)) = 1 + p + \sum_{i=b_j+2}^{b_j+2h_1} C_{TS}(t_i, u_{i-1}) + C_{TS}(t_{b_j+2h_1+1}, y).$$

For the analysis of the cost incurred at the alternating requests to x and y we need the following claim that we will prove later.

Claim 2. *Let $\sigma(t_{i-3})\sigma(t_{i-2})\sigma(t_{i-1}) = xyx$ or $\sigma(t_{i-3})\sigma(t_{i-2})\sigma(t_{i-1}) = yxy$ be three consecutive requests in σ_{xy} with $4 \leq i \leq k$. Then, after the service of $\sigma(t_{i-1})$, with probability $1-p+p^2$, u_{i-1} precedes u_{i-2} in the list maintained by TIMESTAMP(p).*

If we have a phase $P(j)$ with $j \geq 2$, then Claim 2 implies that, for $i = b_j + 2, \ldots, b_j + 2h_1$, immediately before the request to $\sigma(t_i)$, item u_{i-1} precedes $u_i = u_{i-2}$ with probability $1-p+p^2$. Therefore, $E[C_{TS}(t_i, u_{i-1})] = 1-p+p^2$ for $i = b_j + 2, \ldots, b_j + 2h_1$. We remark that we may apply Claim 2 for $i = b_j + 2$ because $u_{b_j-1} \neq u_{b_j}$. For phase $P(1)$, Claim 2 gives $E[C_{TS}(t_i, u_{i-1})] = 1-p+p^2$ for $i = b_1+3, \ldots, b_1+2h_1$. However, it is easy to show that for request $\sigma(t_{b_1+2})$, $E[C_{TS}(t_{b_1+2}, u_{b_1+1})] = 1-p+p^2$. We now evaluate the cost $C_{TS}(t_{b_j+2h_1+1}, y)$. Claim 2 gives that immediately before the request $\sigma(t_{b_j+2h_1+1})$, item x precedes item y with probability $1-p+p^2$ in TIMESTAMP(p)'s list. Hence $E[C_{TS}(t_{b_j+2h_1+1}, y)] = 1-(1-p+p^2) = p-p^2$. We conclude that

$$\begin{aligned} E[C_{TS}(P(j))] &= 1 + p + (2h_1 - 1)(1-p+p^2) + p - p^2 \\ &= 2(h_1+1)(1-p+p^2) - 2 + 5p - 4p^2 \\ &\leq 2(h_1+1)(1-p+p^2) \end{aligned}$$

for all $p \in [0,1]$. Thus

$$\begin{aligned} E[C_{TS}(P(j))] &\leq 2(h_1+1)(1-p+p^2) \\ &= (h_1+1)(2-p) + (h_1+1)(-p+2p^2) \\ &\leq (h_1+1)(2-p) \end{aligned}$$

for all $p \leq \frac{1}{2}$. Moreover,

$$\begin{aligned} E[C_{TS}(P(j))] &\leq 2(h_1+1)(1-p+p^2) \\ &= (h_1+1)(1+p(2-p)) + (h_1+1)(1-4p+3p^2) \\ &\leq (h_1+1)(1+p(2-p)) \end{aligned}$$

for all $p \geq \frac{1}{3}$. Since $C_{OPT}(P(j)) = h_1 + 1$, we obtain

$$E[C_{TS}(P(j))] \leq \max\{2-p, 1+p(2-p)\} C_{OPT}(P(j)).$$

The analysis for a phase $P(j)$ having type 4 is very similar. By Lemma 1, $C_{TS}(t_i, x) = 0$ for $i = b_j + 2h_1 + 1, \ldots, e_j$. Hence

$$C_{TS}(P(j)) = 1 + p + \sum_{i=b_j+2}^{b_j+2h_1-1} C_{TS}(t_i, u_{i-1}) + C_{TS}(t_{b_j+2h_1}, x).$$

Applying Claim 2 we obtain $E[C_{TS}(t_i, u_{i-1})] = 1-p+p^2$, for $i = b_j+2, \ldots, b_j+2h_1-1$, and $E[C_{TS}(t_{b_j+2h_1}, x)] = p - p^2$. Thus

$$\begin{aligned} E[C_{TS}(P(j))] &= 1 + p + 2(h_1 - 1)(1 - p + p^2) + p - p^2 \\ &= h_1(2 - p) + h_1(-p + 2p^2) - 1 + 4p - 3p^2 \\ &\leq h_1(2 - p) \end{aligned}$$

for all $p \leq \frac{1}{3}$. Furthermore, we can show

$$\begin{aligned} E[C_{TS}(P(j))] &= h_1(1 + p(2 - p)) + (h_1 - 1)(1 - 4p + 3p^2) \\ &\leq h_1(1 + p(2 - p)) \end{aligned}$$

for all $p \geq \frac{1}{3}$. We have $C_{OPT}(P(j)) = h_1$ and therefore,

$$E[C_{TS}(P(j))] \leq \max\{2 - p, 1 + p(2 - p)\} C_{OPT}(P(j)). \qquad \square$$

Proof of Claim 1. We know that item x is behind y in TIMESTAMP(p)'s list before the service of $\sigma(t_{b_j})$. If TIMESTAMP(p) executes Step (a) when serving $\sigma(t_{b_j})$, then x is moved to the front of the list and must precede y. On the other hand, suppose that $\sigma(t_{b_j})$ is served using Step (b). If x was not requested during $[1, t_{b_j} - 1]$, then the position of x remains unchanged and x stays behind y in the list. If x was requested at least once in $[1, t_{b_j} - 1]$, then Lemma 2a implies that y precedes $v_x(t_{b_j})$ at time t_{b_j}. Again, x cannot be moved in front of y during the service of $\sigma(t_{b_j})$. $\square$

Proof of Claim 2. We analyze the sequence $\sigma(t_{i-3})\sigma(t_{i-2})\sigma(t_{i-1}) = xyx$. The case $\sigma(t_{i-3})\sigma(t_{i-2})\sigma(t_{i-1}) = yxy$ is symmetric. We have to compute the probability that x precedes y in TIMESTAMP(p)'s list after the service of $\sigma(t_{i-1})$. If TIMESTAMP(p) serves $\sigma(t_{i-1})$ using Step (a) of the algorithm, then x is moved to the front of the list and precedes y. Now assume that $\sigma(t_{i-1})$ is served using Step (b) of TIMESTAMP(p). If $\sigma(t_{i-2})$ was processed using Step (b) of the algorithm, then condition (ii) in Step (b) ensures that x is inserted at some position in front of y when TIMESTAMP(p) serves $\sigma(t_{i-1})$. On the other hand, if $\sigma(t_{i-2})$ was processed using Step (a) of the algorithm, then Lemma 2b implies that y precedes $v_x(t_{i-1})$ and x is inserted behind y when TIMESTAMP(p) serves $\sigma(t_{i-1})$.

We conclude that item x precedes item y in TIMESTAMP(p)'s list after the service of $\sigma(t_{i-1})$ if and only if one of the following events occurs. (A) TIMESTAMP(p) serves $\sigma(t_{i-1})$ using Step (a); (B) TIMESTAMP(p) serves $\sigma(t_{i-2})$ and $\sigma(t_{i-1})$ using Step (b). Event (A) occurs with probability p whereas event (B) occurs with probability $(1 - p)^2$. Thus, with probability $p + (1 - p)^2 = 1 - p + p^2$, x precedes y in TIMESTAMP(p)'s list after the service of $\sigma(t_{i-1})$. $\square$

In the above analysis we assume that the last phase $P(l)$ is a full phase of one of the phase types 1–4. It is easy to see that Lemmata 3–5 also hold for a phase $P(l)$ that is a prefix of one of the phase types. The proof of Theorem 1 is complete.

Next we analyze the performance of the simplified TIMESTAMP(p) algorithm.

Proof of Theorem 2. The proof has the same structure as the proof of Theorem 1. The statements of Lemmas 1 and 2 can be shown in the same way as before. The proofs of the lemmata become simpler, though, because we do not have to consider items that satisfy condition (ii) in Step (b) of the TIMESTAMP(p) algorithm. We compare the on-line and off-line cost for each pair $\{x, y\}$ of items with $x \neq y$ and prove

$$E\left[\sum_{\substack{t\in[1,m]\\ \sigma(t)=x}} C_{TS}(t,y) + \sum_{\substack{t\in[1,m]\\ \sigma(t)=y}} C_{TS}(t,x)\right] \leq c \cdot C_{OPT}(\sigma_{xy}), \tag{2.5}$$

where $c = \max\{2-p, 1+p(2-p), 2-\frac{3}{2}p+p^2-\frac{1}{2}p^3\}$. We partition the request sequence σ_{xy} in the same way as before. Lemmata 3 and 4 as well as their proofs (including Claim 1) remain the same. In the proof of Claim 2, only a weaker statement can be shown. We know that item u_{i-1} precedes item u_{i-2} after the service of $\sigma(t_{i-1})$ if the simplified TIMESTAMP(p) algorithm serves $\sigma(t_{i-1})$ using Step (a). Also, u_{i-1} cannot precede u_{i-2} if the simplified algorithm serves $\sigma(t_{i-2})$ using Step (a) and $\sigma(t_{i-1})$ using Step (b). Unfortunately, we do not have information about the relative position of u_{i-2} and u_{i-1} if the simplified algorithm processes $\sigma(t_{i-2})$ and $\sigma(t_{i-1})$ using Step (b). Therefore, Claim 2 changes to the following statement.

CLAIM 3. *Let $\sigma(t_{i-3})\sigma(t_{i-2})\sigma(t_{i-1}) = xyx$ or $\sigma(t_{i-3})\sigma(t_{i-2})\sigma(t_{i-1}) = yxy$ be three consecutive requests in σ_{xy} with $4 \leq i \leq k$. Then, after the service of $\sigma(t_{i-1})$, with probability at most $1-p+p^2$, u_{i-1} precedes u_{i-2} in the list maintained by the simplified TIMESTAMP(p) algorithm.*

For a proof of a statement corresponding to Lemma 5, we first consider a phase $P(j)$ having type 3. Again,

$$C_{TS}(P(j)) = 1 + p + \sum_{i=b_j+2}^{b_j+2h_1} C_{TS}(t_i, u_{i-1}) + C_{TS}(t_{b_j+2h_1+1}, y).$$

We examine $C_{TS}(t_{b_j+2h_1+1}, y)$. We have $C_{TS}(t_{b_j+2h_1+1}, y) = 1$ if $C_{TS}(t_{b_j+2h_1}, y) = 1$ and item $x = u_{b_j+2h_1}$ is not moved in front of y at time $t_{b_j+2h_1}$. Item x can only stay behind y if $\sigma(t_{b_j+2h_1})$ is served using Step (b) of the algorithm. The event that the simplified TIMESTAMP algorithm serves $\sigma(t_{b_j+2h_1})$ using Step (b) is independent of the event that $C_{TS}(t_{b_j+2h_1}, y) = 1$. Hence $E[C_{TS}(t_{b_j+2h_1+1}, y)] \leq (1-p+p^2)(1-p)$. This implies

$$E[C_{TS}(P(j))] \leq 1 + p + (2h_1 - 1)(1-p+p^2) + (1-p)(1-p+p^2).$$

Using the same techniques as in the proof of Lemma 5, we can show

$$E[C_{TS}(P(j))] \leq \max\{2-p, 1+p(2-p)\} \cdot C_{OPT}(P(j)).$$

Now consider a phase $P(j)$ having type 4. We have

$$E[C_{TS}(P(j))] \leq 1 + p + 2(h_1 - 1)(1-p+p^2) + (1-p)(1-p+p^2).$$

Hence

$$\begin{aligned} E[C_{TS}(P(j))] &\leq 2h_1(1-p+p^2) - (1+p)(-p+p^2) \\ &= h_1(2-2p+2p^2) + p(1-p^2). \end{aligned}$$

Since $h_1 \geq 2$,

$$E[C_{TS}(P(j))] \leq h_1 \left(2 - 2p + 2p^2 + \frac{p}{2}(1-p^2)\right)$$
$$= h_1 \left(2 - \frac{3}{2}p + 2p^2 - \frac{1}{2}p^3\right).$$

The statement corresponding to Lemma 5 is as follows.

LEMMA 6. *If $P(j)$ has type 3 or 4, then $E[C_{TS}(P(j))] \leq c \cdot C_{OPT}(P(j))$, where $c = \max\{2-p,\ 1+p(2-p), 2 - \frac{3}{2}p + 2p^2 - \frac{1}{2}p^3\}$.*

Lemma 6 and the statements of Lemmata 3 and 4 imply inequality (2.5). The proof of Theorem 2 is complete. □

We conclude with some remarks. TIMESTAMP algorithms use $\Theta(m)$ random bits on a request sequence of length m. We can modify the original version of TIMESTAMP(p) so that it uses only $O(n)$ random bits during an initialization phase and runs completely deterministically thereafter. The competitive ratio is still $c = \max\{2-p, 1+p(2-p)\}$. The idea is to have two different types of items, item type (a) and item type (b). Initially, we decide for each item in the list which type it should have. With probability p an item has type (a), and with probability $1-p$ it has type (b); the initializations are done independently. When a request sequence is served, each request to a type (a) item is served using Step (a) of the algorithm and every request to a type (b) item is served using Step (b). This technique cannot be applied in the simplified TIMESTAMP algorithm in which condition (ii) in Step (b) is dropped. Our analysis of the simplified TIMESTAMP algorithm makes use of the fact that the decision of whether a given request is processed using Step (a) or (b) does not depend on previous requests (see the analysis after Claim 3). In the simplified TIMESTAMP algorithm we can reduce the number of random bits using a technique presented by Reingold, Westbrook, and Sleator [5]. For each item in the list we maintain a mod i counter, where i is a positive integer. These counters are initialized independently and uniformly at random to a value in $\{0, 1, \ldots, i-1\}$. Furthermore, we choose a nonempty subset I of $\{0, 1, \ldots, i-1\}$. At a request to item x, the TIMESTAMP algorithm first decrements x's counter by 1. If the counter is I, the algorithm serves the request using Step (a); otherwise it executes Step (b). Choosing i and I appropriately, we can achieve a competitive ratio of $c + \epsilon$ for any $\epsilon > 0$; here $c = \max\{2-p, 1+p(2-p), 2 - \frac{3}{2}p + 2p^2 - \frac{1}{2}p^3\}$.

Acknowledgment. The author thanks Rudolf Fleischer and Stefan Schirra for reading an earlier version of this paper.

COMPUTING THE ADDITIVE COMPLEXITY OF ALGEBRAIC CIRCUITS WITH ROOT EXTRACTING*

DIMA GRIGORIEV† AND MAREK KARPINSKI‡

Abstract. We design an algorithm for computing the generalized (algebraic circuits with root extracting; cf. Pippenger [*J. Comput. System Sci.*, 22 (1981), pp. 454–470], Ja'Ja' [*Proc. 22nd IEEE FOCS*, 1981, pp. 95–100], Grigoriev, Singer, and Yao [*SIAM J. Comput.*, 24 (1995), pp. 242–246]) *additive complexity* of any rational function. It is the first computability result of this sort on the additive complexity of algebraic circuits.

Key words. additive complexity, algebraic circuits, root extracting, minimal computation

1. Introduction.

Whether the additive complexity of functions is computable is a well-known open problem in the theory of computation. Note that both multiplicative and total complexities of functions are computable. In this paper we prove, somewhat surprisingly, the *computability* of the generalized additive complexity for algebraic circuits with root extraction. These circuits were considered in [J 81] where a lower bound on the number of root extracting operations for computing on algebraic functions has been proven. This was recently generalized in [GSY 93] for the algebraic circuits which also contain exponential and logarithmic functions. Our result is the first computability result of this sort on the *additive* complexity of algebraic circuits.

Let us give the definition of the generalized additive complexity. $\bar{\mathbb{Q}}$ denotes the algebraic closure of $\mathbb{Q}$, the set of algebraic numbers. We say that a rational function $f \in \mathbb{Q}(X_1, \ldots, X_n)$ has a generalized additive complexity at most t if there exists a sequence of algebraic functions:

$$u_{i+1} = \varepsilon^{(i+1)} X_1^{\alpha_1^{(i+1)}} \cdots X_n^{\alpha_n^{(i+1)}} u_1^{\beta_1^{(i+1)}} \cdots u_i^{\beta_i^{(i+1)}} + \kappa^{(i+1)} X_1^{\gamma_1^{(i+1)}} \cdots X_n^{\gamma_n^{(i+1)}} u_1^{\delta_1^{(i+1)}} \cdots u_i^{\delta_i^{(i+1)}}$$

for $0 \le i \le t$, where $\kappa^{(t+1)} = 0$, $f = u_{t+1}$ and all the exponents $\alpha_1^{(i+1)}, \ldots, \delta_i^{(i+1)} \in \mathbb{Q}$, $0 \le i \le t$ are rationals, and coefficients $\varepsilon^{(i+1)}, \kappa^{(i+1)} \in \bar{\mathbb{Q}}$ are algebraic. The rationality of the exponents (rather than being integers) differs the *generalized* additive complexity from the usual *additive* complexity. In other words, we consider algebraic circuits in which (in addition to the usual arithmetic operations) extracting arbitrary roots is allowed.

If t is equal to the generalized additive complexity of f, then we say that computation $u_1, \ldots, u_{t+1}$ of f is generalized additive minimal.

In the section 2 we consider the computations in which the exponents $\alpha_1^{(i+1)}, \ldots, \delta_i^{(i+1)}$, $0 \le i \le t$ are allowed to be algebraic, and we refer to it as *the quasi-additive*

complexity. The computation of the quasi-additive complexity is reduced (see the lemma below) to the problem of quantifier elimination in the theory of differentially closed fields (solved in [Se 56]; for its complexity see [G 89]).

In section 3 we prove (see the proposition below) that any quasi-additive minimal computation of a rational function can be transformed into a generalized additive-minimal computation with the same number of additions which contain only rational exponents; thus quasi-additive and generalized additive complexities coincide. Moreover, the corollary in section 3 gives a possibility of constructing the rational exponents of a generalized additive-minimal computation. In section 4 we describe an algorithm for producing a generalized additive-minimal computation. In the case of one variable ($n = 1$) we give an (elementary) complexity bound of the designed algorithm (see the theorem below) as it uses the quantifier elimination algorithm from [G 89]. In the general case ($n \geq 2$) we do not give complexity bounds because the quantifier elimination method from [Se 56] is used which relies in turn on the efficient bounds in Hilbert's idealbasissatz which are not known to be elementary.

Note that first lower bounds on the additive complexity of f in terms of the variety of real roots of f were obtained in [BC 76] and [G 83] (see also [Ri 85]). One can find in [G 83] also a survey on other lower bounds, in particular on the additive complexity (see also [G 82] and [SW 80]). The lower bound from [G 83] is used (see the end of section 3) to show that there are polynomials with the generalized additive complexity equal to 3 and arbitrary large additive complexity.

Another interesting issue is the dependence of the (standard) additive complexity on the coefficients which are involved in *straight-line programs* (cf. [W 78]). If we allow only real algebraic coefficients (from $\bar{\mathbb{Q}} \cap \mathbb{R}$) instead of $\bar{\mathbb{Q}}$ (see above), then the additive complexity could jump drastically as the following example indicates. The polynomial $(1 + iX)^n + (1 - iX)^n \in \mathbb{Z}[x]$ (cf. [W 78]) *evidently* has the additive complexity at most 3 over $\bar{\mathbb{Q}}$. It also has all its roots in $\bar{\mathbb{Q}} \cap \mathbb{R}$; therefore, its *additive complexity* over $\bar{\mathbb{Q}} \cap \mathbb{R}$ is greater than $\Omega(\log^{\frac{1}{2}} n)$ (cf. [G 83], [Ri 85]).

2. Describing the quasi-additive complexity in terms of the first-order theory of differentially closed fields. We start with designing an algorithm for testing, whether there exist (and if so, also to produce) *algebraic* exponents $\alpha_1^{(i+1)}, \ldots, \delta_i^{(i+1)} \in \bar{\mathbb{Q}}$ (the algebraic closure of $\mathbb{Q}$ in $\mathbb{C}$) in the computation $u_1, \ldots, u_{t+1}$ providing an identity $u_{t+1} = f$ holds. In this case we say that f has the quasi-additive complexity at most t. For this purpose we introduce the (differential) unknowns

$$u_{i+1}, \tilde{\alpha}_1^{(i+1)}, \ldots, \tilde{\delta}_i^{(i+1)}, v_1^{(i+1)}, \ldots, v_n^{(i+1)}, w_1^{(i+1)}, \ldots, w_i^{(i+1)},$$
$$\tilde{v}_1^{(i+1)}, \ldots, \tilde{v}_n^{(i+1)}, \tilde{w}_1^{(i+1)}, \ldots, \tilde{w}_i^{(i+1)}$$

for all $0 \leq i \leq t$ and the system of (partial) differential equations (denote $D_i = \frac{d}{dX_i}$ and by D any of the operators $D_1, \ldots, D_n$; denote the Kronecker symbol by $\delta(l, j)$):

$(1a)_{i+1}$ $\quad D(\tilde{\alpha}_1^{(i+1)}) = \cdots = D(\tilde{\delta}_i^{(i+1)}) = 0,$

$(1b)_{i+1}$ $\quad D_j(v_l^{(i+1)}) = \frac{\tilde{\alpha}_l^{(i+1)}}{X_l} v_l^{(i+1)} \delta(l, j), \qquad D_j(\tilde{v}_l^{(i+1)}) = \frac{\tilde{\gamma}_l^{(i+1)}}{X_l} \tilde{v}_l^{(i+1)} \delta(l, j),$
$1 \leq l, j \leq n,$

$(1c)_{i+1}$ $\quad D(w_l^{(i+1)}) = \tilde{\beta}_l^{(i+1)} w_l^{(i+1)} \frac{Du_l}{u_l}, \qquad D(\tilde{w}_l^{(i+1)}) = \tilde{\delta}_l^{(i+1)} \tilde{w}_l^{(i+1)} \frac{Du_l}{u_l},$
$1 \leq l \leq i,$

$(1d)_{i+1}$ $\quad u_{i+1} = v_1^{(i+1)} \cdots v_n^{(i+1)} w_1^{(i+1)} \cdots w_i^{(i+1)} + \tilde{v}_1^{(i+1)} \ldots \tilde{v}_n^{(i+1)} \tilde{w}_1^{(i+1)} \ldots \tilde{w}_i^{(i+1)}$

for all $0 \le i \le t$ together with the equation $u_{t+1} = f$. The resulting system we denote by (1).

Note that the equations $(1a)_{i+1}$ imply that $\tilde{\alpha}_1^{(i+1)}, \ldots, \tilde{\delta}_i^{(i+1)} \in \bar{\mathbb{Q}}$ are the constants; $(1b)_{i+1}$ imply that $v_l^{(i+1)} = \mu_l^{(i+1)} X_l^{\tilde{\alpha}_l^{(i+1)}}, \tilde{v}_l^{(i+1)} = \tilde{\mu}_l^{(i+1)} X_l^{\tilde{\gamma}_l^{(i+1)}}$ for the appropriate constants $\mu_l^{(i+1)}, \tilde{\mu}_l^{(i+1)} \in \bar{\mathbb{Q}}$; $(1c)_{(i+1)}$ imply that $w_l^{(i+1)} = \nu_l^{(i+1)} u_l^{\tilde{\beta}_l^{(i+1)}}, \tilde{w}_l^{(i+1)} = \tilde{\nu}_l^{(i+1)} u_l^{\tilde{\delta}_l^{(i+1)}}$ for the appropriate constants $\nu_l^{(i+1)}, \tilde{\nu}_l^{(i+1)} \in \bar{\mathbb{Q}}$.

Thus, the following lemma is proved.

LEMMA. *The solvability of system* (1) (*in all its differential unknowns*) *is equivalent to the fact that the quasi-additive complexity of* f *is at most* t.

Now we consider the statement of solvability of the system (1) as an existential formula of the first-order theory of differentially closed fields [Se 56]. Applying to it a quantifier elimination algorithm [Se 56] one can eliminate unknowns

$$u_{i+1}, v_1^{(i+1)}, \ldots, v_n^{(i+1)}, w_1^{(i+1)}, \ldots, w_i^{(i+1)}, \tilde{v}_1^{(i+1)}, \ldots, \tilde{v}_n^{(i+1)}, \tilde{w}_1^{(i+1)}, \ldots, \tilde{w}_i^{(i+1)} \quad \text{for all } 0 \le i \le t.$$

As a result we get an (existential) equivalent formula containing only the unknowns $\tilde{\alpha}_1^{(i+1)}, \ldots, \tilde{\delta}_i^{(i+1)}, 0 \le i \le t$. Because of (1a) the latter formula can be considered as a formula in the language of polynomials (so, without derivatives), thus as a system of polynomial equations and inequalities with integer coefficients.

Thus, given a rational function f the algorithm tries $t = 1, 2, \ldots$, and for each t tests (using [CG 83], [C 86]) whether the above constructed system of polynomial equations and inequalities has a solution (over $\bar{\mathbb{Q}}$). For a minimal such t we take any of these solutions $\alpha_1^{(i+1)}, \ldots, \delta_i^{(i+1)} \in \bar{\mathbb{Q}}, 0 \le i \le t$. In the next section we show that in this case there exists as well a rational solution of this system, and moreover we show how to construct it.

To solve the system (1) of differential equations we applied the algorithm from [Se 56] for which the elementary complexity bound is unknown since it relies on an efficient bound in Hilbert's idealbasissatz. But the complexity of quantifier elimination is elementary in the case of ordinary differential equations for the algorithm designed in [G 89], i.e., when $n = 1$, and in other words when there is only one independent variable X. In this case system (1) contains $O(t^2)$ unknowns, the order of highest occurring derivatives in the equations is at most 1, the degree of the equations is at most $O(t) + \deg f$ and the number of equations is at most $O(t^2)$, and the bit-size of the coefficients of the occurring equations is at most $O(1) + M$, where M is the bit-size of the coefficients of f. Therefore (see the bounds in [G 89]), one can eliminate quantifiers and produce a system of polynomial equations and inequalities with integer coefficients (see above) in the unknowns $\tilde{\alpha}_1^{(i+1)}, \ldots, \tilde{\delta}_i^{(i+1)}, 0 \le i \le t$ in time $\mathcal{N} = M^{O(1)} (\deg f)^{2^{2^{O(t^2)}}}$; the degrees of the polynomials occurring in this system do not exceed $\mathcal{N}_1 = (\deg f)^{2^{2^{O(t^2)}}}$, the number of these polynomials is at most $\mathcal{N}_1$, and the bit-size of (integer) coefficients occurring in this system can be bounded by $\mathcal{N}$.

Therefore, to solve this system of polynomial equations and inequalities we apply the algorithm from [CG 83] (cf. also [C 86]) which requires time $M^{O(1)} (\deg f)^{2^{2^{O(t^2)}}}$. The algorithm from [CG 83] finds (provided that the system is solvable) a solution $\alpha_1^{(i+1)}, \ldots, \delta_i^{(i+1)} \in \bar{\mathbb{Q}}, 0 \le i \le t$ in the following form. The algorithm produces an irreducible over $\mathbb{Q}$ polynomial $\varphi(Z) \in \mathbb{Q}[Z]$ and polynomials $\bar{\alpha}_1^{(i+1)}(Z), \ldots, \bar{\delta}_i^{(i+1)}(Z) \in$

$\mathbb{Q}[Z], 0 \le i \le t$ such that $\alpha_1^{(i+1)} = \bar{\alpha_1}^{(i+1)}(\theta), \dots, \delta_i^{(i+1)} = \bar{\delta}_i^{(i+1)}(\theta)$, where $\theta \in \bar{\mathbb{Q}}$ is a root of $\varphi(\theta) = 0$. From [CG 83] we obtain the following bounds:

$$\deg(\varphi), \deg(\bar{\alpha}_1^{(i+1)}), \dots, \deg(\bar{\delta}_i^{(i+1)}) \le (\deg f)^{2^{2^{O(t^2)}}}, 0 \le i \le t,$$

and the bit-size of every coefficient occurring in the listed polynomials does not exceed $M^{O(1)}\ (\deg f)^{2^{2^{O(t^2)}}}$.

3. Rational exponents in the quasi-additive minimal computation. In this section we prove (see the proposition below) the equivalence of the generalized additive and quasi-additive complexities for rational functions. Moreover, we show (see the corollary below) for given algebraic exponents of a quasi-additive minimal computation how to produce the exponents of a certain generalized additive-minimal computation of the same rational function, thus containing only rational exponents. The similar statements were proved also for the rationality of the exponents in the minimal sparse representations of a rational function [GKS 92a] and of a real algebraic function [GKS 92b]. But the latter statements have a nature different from the one in the present paper; another difference is that we prove here the existence of the rational exponents rather than the rationality as it was the case in [GKS 92a], [GKS 92b].

So, let

$$u_{i+1} = \varepsilon^{(i+1)} X_1^{\alpha_1^{(i+1)}} \cdots X_n^{\alpha_n^{(i+1)}} u_1^{\beta_1^{(i+1)}} \cdots u_i^{\beta_i^{(i+1)}} + \kappa^{(i+1)} X_1^{\gamma_1^{(i+1)}} \cdots X_n^{\gamma_n^{(i+1)}} u_1^{\delta_1^{(i+1)}} \cdots u_i^{\delta_i^{(i+1)}},$$

where $0 \le i \le t, \kappa^{(t+1)} = 0$ and all the exponents and coefficients

$$\alpha_1^{(i+1)}, \dots, \delta_i^{(i+1)}, \varepsilon^{(i+1)}, \kappa^{(i+1)} \in \bar{\mathbb{Q}}\,.$$

PROPOSITION. *Assume that $f = u^{(t+1)} \in \bar{\mathbb{Q}}(X_1, \dots, X_n)$ is a rational function and t is the minimal possible (so t is equal to the quasi-additive complexity of f). Then there exist rational exponents $a_1^{(i+1)}, \dots, d_i^{(i+1)} \in \mathbb{Q}, 0 \le i \le t$, respectively, providing also a computation of f (thus, t is also equal to the generalized additive complexity).*

Proof. For each $1 \le j \le n$ consider a $\mathbb{Q}$-basis $\bar{\theta}_j^{(1)}, \bar{\theta}_j^{(2)}, \dots \in \bar{\mathbb{Q}}$ of the $\mathbb{Q}$-linear hull $\mathbb{Q}\{\alpha_j^{(s)}, \gamma_j^{(s)}\}_{1 \le s \le t+1}$. If 1 (thereby $\mathbb{Q}$) is contained in the latter linear hull, then we set $\bar{\theta}_j^{(1)} = 1$. Denote $\{\theta_j^{(1)}, \theta_j^{(2)}, \dots\} = \{\bar{\theta}_j^{(1)}, \bar{\theta}_j^{(2)}, \dots\} \setminus \{1\}$.

Consider a differential field $F_j, 0 \le j \le n$ generated over $\bar{\mathbb{Q}}(X_1, \dots, X_n)$ by the elements $\log X_1, X_1^{\theta_1^{(1)}}, X_1^{\theta_1^{(2)}}, \dots, \log X_j, X_j^{\theta_j^{(1)}}, X_j^{\theta_j^{(2)}}, \dots$. Then in the terminology of [RC 79] each $F_j, 0 \le j \le n$ is a log-explicit extension of its field of constants $\bar{\mathbb{Q}}$ (one can represent $X^\beta = \exp(\beta \log X)$).

We claim that the elements $X_{j+1}^{\theta_{j+1}^{(1)}}, X_{j+1}^{\theta_{j+1}^{(2)}}, \dots \in F_{j+1}$ are algebraically independent over the field $F_j(\log X_{j+1})$. Assume the contrary. Then Corollary 3.2 of [RC 79] (see also [Ro 76]) implies the existence of a constant $\kappa \in \bar{\mathbb{Q}}$, rational numbers

$$l_1^{(0)}, l_1^{(1)}, \dots, l_j^{(0)}, l_j^{(1)}, \dots, l_{j+1}^{(0)}, l_{j+1}^{(1)}, \dots \in \mathbb{Q}$$

such that not all $l_{j+1}^{(1)}, l_{j+1}^{(2)}, \dots$ are zeros, and

$$X_{j+1}^{l_{j+1}^{(0)} + \Sigma_{k \ge 1} l_{j+1}^{(k)} \theta_{j+1}^{(k)}} = \kappa X_1^{l_1^{(0)} + \Sigma_{k \ge 1} l_1^{(k)} \theta_1^{(k)}} \cdots X_j^{l_j^{(0)} + \Sigma_{k \ge 1} l_j^{(k)} \theta_j^{(k)}},$$

but this leads to a contradiction since the derivative $\frac{d}{dX_{j+1}}$ of the left side is nonzero, but the derivative of the right side is equal to zero.

For each $1 \le i \le t$ consider a $\mathbb{Q}$-basis $\bar\eta_i^{(1)}, \bar\eta_i^{(2)}, \ldots \in \bar{\mathbb{Q}}$ of the $\mathbb{Q}$-linear hull $\mathbb{Q}\{\beta_i^{(s)}, \delta_i^{(s)}\}_{i+1\le s\le t+1}$. If 1 (thereby $\mathbb{Q}$) is contained in the latter linear hull, then we set $\bar\eta_i^{(1)} = 1$. Denote $\{\eta_i^{(1)}, \eta_i^{(2)}, \ldots\} = \{\bar\eta_i^{(1)}, \bar\eta_i^{(2)}, \ldots\} \setminus \{1\}$.

Denote by E_i, $0 \le i \le t$ a field generated over F_n by the elements

$$\log u_1, u_1^{\eta_1^{(1)}}, u_1^{\eta_1^{(2)}}, \ldots, \log u_i, u_i^{\eta_i^{(1)}}, u_i^{\eta_i^{(2)}}, \ldots .$$

It is a log-explicit extension of its field of constants $\bar{\mathbb{Q}}$.

We claim that for $0 \le i \le t-1$ the elements $u_{i+1}^{\eta_{i+1}^{(1)}}, u_{i+1}^{\eta_{i+1}^{(2)}}, \ldots \in E_{i+1}$ are algebraically independent over the field $E_i(\log u_{i+1})$. Assume the contrary. Then again using Corollary 3.2 of [RC 79] we conclude that there exists a constant $\varepsilon \in \bar{\mathbb{Q}}$, rational numbers

$$p_1, p_1^{(1)}, p_1^{(2)}, \ldots, p_n, p_n^{(1)}, p_n^{(2)}, \ldots, z_1, z_1^{(1)}, z_1^{(2)}, \ldots, z_{i+1}, z_{i+1}^{(1)}, z_{i+1}^{(2)}, \ldots \in \mathbb{Q}$$

such that not all $z_{i+1}^{(1)}, z_{i+1}^{(2)}, \ldots$ are zeros and

$$u_{i+1}^{z_{i+1}+\Sigma_{j\ge1} z_{i+1}^{(j)}\eta_{i+1}^{(j)}} = \varepsilon X_1^{p_1+\Sigma_{j\ge1}p_1^{(j)}\theta_1^{(j)}} \cdots X_n^{p_n+\Sigma_{j\ge1}p_n^{(j)}\theta_n^{(j)}} u_1^{z_1+\Sigma_{j\ge1}z_1^{(j)}\eta_1^{(j)}} \cdots u_i^{z_i+\Sigma_{j\ge1}z_i^{(j)}\eta_i^{(j)}}.$$

This provides an expression of u_{i+1} as a product of powers of $X_1, \ldots, X_n, u_1, \ldots, u_i$, and thereby we can diminish t by 1 in the computation of f; this contradiction with the minimality of t proves the algebraic independence of $u_{i+1}^{\eta_{i+1}^{(1)}}, u_{i+1}^{\eta_{i+2}^{(2)}}, \ldots$ over $E_i(\log u_{i+1})$.

Consider the expansions

$$\begin{aligned}
\alpha_j^{(s)} &= a_j^{(s)} + \sum_{k\ge1} a_{j,k}^{(s)}\theta_j^{(k)}, \gamma_j^{(s)} = \quad c_j^{(s)} + \sum_{k\ge1} c_{j,k}^{(s)}\theta_j^{(k)}, \quad 1 \le j \le n, \qquad 1 \le s \le t+1,\\
\beta_i^{(s)} &= b_i^{(s)} + \sum_{k\ge1} b_{i,k}^{(s)}\eta_i^{(k)}, \delta_i^{(s)} = \quad d_i^{(s)} + \sum_{k\ge1} d_{i,k}^{(s)}\theta_i^{(k)}, \quad 1 \le i \le t+1, \quad i < s \le t+1,
\end{aligned} \tag{2}$$

where $a_j^{(s)}, \ldots, d_{i,k}^{(s)} \in \mathbb{Q}$ are suitable rationals. Remark that if $1 \notin \{\bar\theta_j^{(1)}, \bar\theta_j^{(2)}, \ldots\}$, then $a_j^{(s)} = c_j^{(s)} = 0$; also if $1 \notin \{\bar\eta_i^{(1)}, \bar\eta_i^{(2)}, \ldots\}$, then $b_i^{(s)} = d_i^{(s)} = 0$. Then we can rewrite the initial computation $u_1, u_2, \ldots$ as follows:

$$\begin{aligned}
u_{i+1} = \varepsilon^{(i+1)} & X_1^{a_1^{(i+1)}} (X_1^{\theta_1^{(1)}})^{a_{1,1}^{(i+1)}} (X_1^{\theta_1^{(2)}})^{a_{1,2}^{(i+1)}} \cdots X_n^{a_n^{(i+1)}} (X_n^{\theta_n^{(1)}})^{a_{n,1}^{(i+1)}} \cdots \\
& u_1^{b_1^{(i+1)}} (u_1^{\eta_1^{(1)}})^{b_{1,1}^{(i+1)}} (u_1^{\eta_1^{(2)}})^{b_{1,2}^{(i+1)}} \cdots u_i^{b_i^{(i+1)}} (u_i^{\eta_i^{(1)}})^{b_{i,1}^{(i+1)}} (u_i^{\eta_i^{(2)}})^{b_{i,2}^{(i+1)}} \cdots \\
& + \kappa^{(i+1)} X_1^{c_1^{(i+1)}} (X_1^{\theta_1^{(1)}})^{c_{1,1}^{(i+1)}} (X_1^{\theta_1^{(2)}})^{c_{1,2}^{(i+1)}} \cdots X_n^{c_n^{(i+1)}} (X_n^{\theta_n^{(1)}})^{c_{n,1}^{(i+1)}} \cdots \\
& u_1^{d_1^{(i+1)}} (u_1^{\eta_1^{(1)}})^{d_{1,1}^{(i+1)}} (u_1^{\eta_1^{(2)}})^{d_{1,2}^{(i+1)}} \cdots u_i^{d_i^{(i+1)}} (u_i^{\eta_i^{(1)}})^{d_{i,1}^{(i+1)}} (u_i^{\eta_i^{(2)}})^{d_{i,2}^{(i+1)}} \cdots .
\end{aligned} \tag{3}$$

From the latter expression one can show by induction on i that u_{i+1} (and thereby each of the previous elements $u_1, \ldots, u_i$) is algebraic over the field $E_i' \subset E_i$ generated over $\bar{\mathbb{Q}}(X_1, \ldots, X_n)$ by the elements

$$X_1^{\theta_1^{(1)}}, X_1^{\theta_1^{(2)}}, \ldots, X_n^{\theta_n^{(1)}}, X_n^{\theta_n^{(2)}}, \ldots, u_1^{\eta_1^{(1)}}, u_1^{\eta_1^{(2)}}, \ldots, u_i^{\eta_i^{(1)}}, u_i^{\eta_i^{(2)}}, \ldots .$$

Above we have proved that the latter elements are algebraically independent over $\bar{\mathbb{Q}}(X_1,\dots,X_n)$. Because $u_{t+1}=f\in\bar{\mathbb{Q}}(X_1,\dots,X_n)$ we can substitute in the expression (3) instead of the elements

$$X_1^{\theta_1^{(1)}},X_1^{\theta_1^{(2)}},\dots,X_n^{\theta_n^{(1)}},X_n^{\theta_n^{(2)}},\dots,u_1^{\eta_1^{(1)}},u_1^{\eta_1^{(2)}},\dots,u_t^{\eta_t^{(1)}},u_t^{\eta_t^{(2)}},\dots$$

almost (in the sense of Zariski topology) arbitrary constants

$$y_1^{(1)},y_1^{(2)},\dots,y_n^{(1)},y_n^{(2)},\dots,z_1^{(1)},z_1^{(2)},\dots,z_t^{(1)},z_t^{(2)},\dots\in\bar{\mathbb{Q}},$$

respectively, with the mere requirement that in the intermediate computations of $u_1,u_2,\dots,u_{t+1}=f$ no nonpositive powers of zero are taken (each time we choose some branch of a rational power).

As a result we get a computation of $\tilde{u}_1,\tilde{u}_2,\dots,\tilde{u}_{t+1}=f$ in which only rational exponents occur; namely,

$$\tilde{u}_{i+1}=\tilde{\varepsilon}^{(i+1)}X_1^{a_1^{(i+1)}}\cdots X_n^{a_n^{(i+1)}}\tilde{u}_1^{b_1^{(i+1)}}\cdots\tilde{u}_i^{b_i^{(i+1)}}+\tilde{\kappa}^{(i+1)}X_1^{c_1^{(i+1)}}\cdots X_n^{c_n^{(i+1)}}\tilde{u}_1^{d_1^{(i+1)}}\cdots\tilde{u}_i^{d_i^{(i+1)}} \tag{4}$$

for some $\tilde{\varepsilon}^{(i+1)},\ \tilde{\kappa}^{(i+1)}\in\bar{\mathbb{Q}}$. The proposition is proved.

From the proof of the proposition we extract the following corollary.

COROLLARY. *For every* $1\le i\le t,\ 1\in\mathbb{Q}\{\beta_i^{(s)},\delta_i^{(s)}\}_{i+1\le s\le t+1}$. *For any* $\mathbb{Q}$*-basis* $\bar{\theta}_j^{(1)},\bar{\theta}_j^{(2)},\dots$ *of* $\mathbb{Q}\{\alpha_j^{(s)},\gamma_j^{(s)}\}_{1\le s\le t+1}$ *and any* $\mathbb{Q}$*-basis* $\bar{\eta}_i^{(1)},\bar{\eta}_i^{(2)},\dots$ *of* $\mathbb{Q}\{\beta_i^{(s)},\delta_i^{(s)}\}_{i+1\le s\le t+1}$ *we get the rational exponents of the resulting computation of* $\tilde{u}_1,\dots,\tilde{u}_{t+1}$ *(see* (4)*) from the expansions* (2).

In order to show that $1\in\mathbb{Q}\{\beta_i^{(s)},\delta_i^{(s)}\}_s$, observe that otherwise $b_i^{(s)}=d_i^{(s)}=0$ for all $i+1\le s\le t+1$, and we could diminish t by deleting $\tilde{u}_i$ from the computation $\tilde{u}_1,\dots,\tilde{u}_{t+1}$ and get a contradiction with a minimality of t.

Remark that the corollary together with Lemma 12 of [GKS 92a] entail that for any i the constructible set of all the possible exponent vectors $(\beta_i^{(i+1)},\dots,\beta_i^{(t+1)},\delta_i^{(i+1)},\dots,\delta_i^{(t)})\in\bar{\mathbb{Q}}^{2t-2i+1}$ is contained in a finite union of the hyperplanes of the kind

$$\sum_{i+1\le j\le t+1}\hat{b}_i^{(j)}\beta_i^{(j)}+\sum_{i+1\le j\le t}\hat{d}_i^{(j)}\delta_i^{(j)}=\hat{d},$$

where $\hat{b}_i^{(j)},\hat{d}_i^{(j)},\hat{d}\in\mathbb{Z}$. The similar case also holds for the vectors $(\alpha_i^{(1)},\dots,\alpha_i^{(t+1)},\gamma_i^{(1)},\dots,\gamma_i^{(t)})\in\bar{\mathbb{Q}}^{2t+1}$. But we will not use this remark.

Note also that in the resulting computation (4) the rational exponents depend on the choice of the $\mathbb{Q}$-basis (see the corollary). The following simple example demonstrates that the dependency really can happen:

$$u_1=X^\alpha(X+1),u_2=X^{-a\alpha}u_1^a+X^{-b\alpha}u_1^b=(X+1)^a+(X+1)^b,$$

where $\alpha\in\bar{\mathbb{Q}}\setminus\mathbb{Q},a,b\in\mathbb{Q}$. Choosing a basis $\alpha+z,1\in\mathbb{Q}\{1,\alpha\}$ for arbitrary $z\in\mathbb{Q}$, we get

$$\begin{aligned}u_1&=(X^{\alpha+z})X^{1-z}+(X^{\alpha+z})X^{-z},\\ u_2&=(X^{\alpha+z})^{-a}X^{za}u_1^a+(X^{\alpha+z})^{-b}X^{zb}u_1^b,\end{aligned}$$

and by the corollary we get

$$\begin{aligned}u_1&=wX^{1-z}+wX^{-z},\\ u_2&=w^{-a}X^{za}u_1^a+w^{-b}X^{zb}u_1^b\end{aligned}$$

for arbitrary $w\in\bar{\mathbb{Q}}\setminus\{0\}$.

4. Constructing a generalized additive-minimal computation. The previous two sections (see the lemma and corollary) give us a possibility of computing a generalized additive complexity t of a rational function f. Now we complete an algorithm which finds some generalized additive-minimal circuit computing f. Using the corollary from section 3, the algorithm finds rational exponents $\alpha_1^{(i+1)}, \ldots, \delta_i^{(i+1)} \in \mathbb{Q}, 0 \leq i \leq t$; it remains to find the coefficients $\varepsilon^{(i+1)}, \kappa^{(i+1)} \in \bar{\mathbb{Q}}, 0 \leq i \leq t$.

Denote by $\mathcal{M}$ a bound on the bit-sizes of the rational exponents $\alpha_1^{(i+1)}, \ldots, \delta_i^{(i+1)} \in \mathbb{Q}, 0 \leq i \leq t$. Then by induction on i one can easily show that each $u_{i+1}, v_1^{(i+1)}, \ldots, \tilde{w}_i^{(i+1)},\ 0 \leq i \leq t$ is an algebraic function of the degree (i.e., the degree of a minimal polynomial which satisfies the function) at most $N = (\exp(\mathcal{M}))^{t^{O(t)}}$. Hence the coefficients $\varepsilon^{(i+1)}, \kappa^{(i+1)},\ 0 \leq i \leq t$ fit if and only if for every $1 \leq x_1, \ldots, x_n \leq N^2$ for which all the intermediate computations of the circuit are definable, the equality $u_{t+1}(x_1, \ldots, x_n) = f(x_1, \ldots, x_n)$ holds. So, for every fixed $1 \leq x_1, \ldots, x_n \leq N^2$ we introduce the variables

$$u_{t+1}(x_1, \ldots, x_n), v_1^{(i+1)}(x_1, \ldots, x_n), \ldots, \tilde{w}_i^{(i+1)}(x_1, \ldots, x_n),\ 0 \leq i \leq t$$

and write down a system of polynomial equations and inequalities expressing all the operations of the circuit (provided that they are all definable) and finally the relation $u_{t+1}(x_1, \ldots, x_n) = f(x_1, \ldots, x_n)$. Then the algorithm invoking [CG 83] solves this system in $N^{2n} + 2t + 1$ variables and finds in particular $\varepsilon^{(i+1)}, \kappa^{(i+1)} \in \bar{\mathbb{Q}}, 0 \leq i \leq t$. More precisely, for each subset $J \subset \{1, \ldots, N^2\}^n$ we consider a system as above including in it just the points $(x_1, \ldots, x_n) \in J$ (so J plays the role of the set of points in which the computation is defined). The algorithm solves this system and takes J with the maximal cardinality for which the system is solvable. In a more sophisticated way we can partition the cube $\{1, \ldots, N^2\}^n$ into N^n subcubes with sides equal to N and as J take each of these subcubes, but this improvement does not change the complexity bounds below.

In the ordinary case ($n = 1$) we can bound the complexity of the described algorithm. First, observe that in this case $\mathcal{M} \leq M^{O(1)}(\deg f)^{2^{2^{O(t^2)}}}$ (see the end of section 1). Therefore, the system of polynomial equations and inequalities constructed above contains $\exp(M^{O(1)}(\deg f)^{2^{2^{O(t^2)}}})$ polynomials of degrees at most $\exp(M^{O(1)}(\deg f)^{2^{2^{O(t^2)}}})$ in $\exp(M^{O(1)}(\deg f)^{2^{2^{O(t^2)}}})$ variables. Hence one can solve it using the algorithm from [CG 83] in time $\exp(\exp(M^{O(1)}(\deg f)^{2^{2^{O(t^2)}}}))$ and find $\varepsilon^{(i+1)}, \kappa^{(i+1)} \in \bar{\mathbb{Q}}$, $0 \leq i \leq t$, representing them as algebraic numbers as at the end of section 1 with the size also bounded by the latter value.

Summarizing, we formulate the following theorem.

THEOREM. (a) *There is an algorithm calculating the generalized additive complexity of a rational function $f \in \mathbb{Q}(x_1, \ldots, x_n)$ and constructing a generalized additive-minimal circuit computing f.*

(b) *In the case of one-variable rational functions f the running time of the algorithm from* (a) *can be bounded by* $\exp(\exp(M^{O(1)}(\deg f)^{2^{2^{O(t^2)}}}))$, *where M bounds the bit-size of each* (*rational*) *coefficient of f. The absolute values of the numerators and denominators of the found rational exponents in a generalized additive-minimal circuit computing f do not exceed* $\exp(M^{O(1)}(\deg f)^{2^{2^{O(t^2)}}})$.

At the end we demonstrate that there could be a big gap between the additive complexity and generalized additive complexity. Consider a polynomial

$$f_n = (1 + X^{\frac{1}{2}})^n + (1 - X^{\frac{1}{2}})^n \in \mathbb{Z}[X]$$

with the generalized additive complexity at most 3. Because all its $\lfloor \frac{n}{2} \rfloor$ roots are negative reals, the additive complexity of f_n is at least $\Omega((\log n)^{\frac{1}{2}})$ because of the result of [G 83] (see also [Ri 85]) based on the method from [Kh 91].

5. Further research. It remains an interesting open problem on improving the complexity bounds of our algorithm. Also it will be very interesting to shed some more light on the status of the problem of computing the *standard additive* complexity of rational functions. At this point we do not know much about this problem.

Acknowledgments. We are thankful to Richard Cleve for starting us thinking about the additive complexity of polynomials and to Allan Borodin, Joachim von zur Gathen, Thomas Lickteig, Michael Singer, Volker Strassen, and Andy Yao for many interesting discussions.

AN $\Omega(D\log(N/D))$ LOWER BOUND FOR BROADCAST IN RADIO NETWORKS*

EYAL KUSHILEVITZ† AND YISHAY MANSOUR‡

Abstract. We show that for any *randomized* broadcast protocol for radio networks, there exists a network in which the expected time to broadcast a message is $\Omega(D\log(N/D))$, where D is the diameter of the network and N is the number of nodes. This implies a tight lower bound of $\Omega(D\log N)$ for any $D \leq N^{1-\varepsilon}$, where $\varepsilon > 0$ is any constant.

Key words. radio networks, broadcast, lower bounds

AMS subject classifications. 68Q22, 68M10

1. Introduction.

Traditionally, radio networks have received considerable attention due to their military significance. The growing interest in cellular telephones and wireless communication networks has reinforced the interest in radio networks. The basic feature of radio networks, which distinguishes them from other networks, is that a processor can receive a message only from a *single* neighbor at a certain time. If two (or more) neighbors of a processor transmit concurrently, then the processor would not receive either messages.

In many applications, the users of the radio network are mobile, and therefore the topology is unstable. For this reason, it is desirable for radio-networks algorithms to refrain from making assumptions about the network topology, or about the information that processors have concerning the topology. In this work we assume that none of the processors initially have any topological information, except for the size of the network and its diameter.[1] See [Tan81, Gal85, BGI92, BGI91] for a discussion on this model and related models.

We study *broadcast* protocols; those protocols are initiated by a single processor (the *originator*) that has a message M it wishes to propagate to all the other processors in the network. In many of the radio-networks applications (e.g., cellular phones) broadcast is a central primitive which is frequently used, for example, to perform a network-wide search for a user.

Bar-Yehuda, Goldreich, and Itai [BGI92] present a *randomized* broadcast algorithm, that runs in expected $O(D\log N + \log^2 N)$ time slots, where N is the number of processors in the network and D is its diameter. In contrast, they show that for any *deterministic* broadcast algorithm there are networks of constant diameter on which the algorithm needs $\Omega(N)$ time slots.

[1]Usually, when the topology is unstable, the diameter is unknown to the processors and only a bound on the size of the network is available. However, since we are proving a *lower bound*, this assumption only makes the result stronger.

Alon et al. [ABLP91] made the first step towards proving the optimality of the upper bound of [BGI92]. Their result can be viewed as a graph-theoretic result; they show that there exist networks of diameter $D = 3$ on which any schedule needs at least $\Omega(\log^2 N)$ time slots. This lower bound shows that there are networks on which broadcast requires this many time slots, and it matches the known upper bounds [BGI92, CW87], in the case of constant-diameter networks.

In this work we complete the picture by proving an $\Omega(D \log(N/D))$ lower bound. Our result is of a different nature; we show that for any *randomized* broadcast algorithm and parameters N and D, there is an ordering of the N processors in a network of diameter D such that the expected number of time slots, used by the algorithm, is $\Omega(D \log(N/D))$. For $D \leq N^{1-\varepsilon}$ this gives an $\Omega(D \log N)$ lower bound. Hence, it proves the tightness of the upper bound of [BGI92] for all N and $D \leq N^{1-\varepsilon}$. Moreover, the lower bound holds even if each of the N processors is allowed to use a *different* program (e.g., the processors can use their IDs). In a recent work, Gaber and Mansour [GM95] have shown that for every network, there exists a schedule whose time is $O(D + \log^5 N)$. The scheduler there needs to get the topology of the network in advance, in order to build the schedule. The result of [GM95] shows that the lower bound presented here must rely heavily on the lack of topological knowledge at the processors.

Broadcast in radio networks has received considerable attention in previous works. [CW87] present a deterministic sequential algorithm that, given the network, finds in polynomial time a legal schedule that requires at most $O(D \log^2 N)$ time slots. Broadcast that is based on using a spanning tree was suggested in [CK85a, CK87]. In [BII93] it is shown how to reduce the amortized cost per broadcast by using a breadth-first-search (BFS) tree. Simulation of point to point networks on radio networks is found in [CK85b, ABLP92, BGI91].

An important issue in the study of radio networks is whether collisions can be detected; namely, whether a listener can distinguish between the case when none of its neighbors transmit and the case when two or more of them transmit. In our model it is assumed that the listener cannot distinguish between the two cases (say, it hears noise in both cases). There is another common model in which it is assumed that the two cases are distinguishable (say, if no neighbor transmits, the listener hears silence, while if two or more neighbors transmit, the listener hears noise). A discussion justifying both models can be found in [Gal85, BGI92]. Willard [Wil86] studies a broadcast problem in a single multiaccess channel under this second model (i.e., when collision detection is available). He shows matching upper and lower bounds of $\Theta(\log \log n)$ expected time slots[2] in this model. Our main lemma implies an $\Omega(\log n)$ lower bound for the same problem in our model. Again, this lower bound holds even if the processors use different programs. Hence, we demonstrate a provable exponential gap between these two models.

The rest of this paper is organized as follows: section 2 contains some necessary definitions. Section 3 contains the proof of the main lemma in the *uniform* case, where all the processors use the same program. Section 4 contains the proof of the main lemma in the *nonuniform* case, where processors may use different programs. The

[2]Willard shows an $\Omega(\log \log n)$ lower bound in the single multiaccess channel model. Although this bound applies to a different model, it should be noted that his bound is also significantly restricted by the types of algorithms for which it applies. In particular, he requires independence between the decision whether to transmit in a certain time slot and the decisions made in previous time slots. In our case such a restriction is unacceptable, as the upper bound of [BGI92] has such dependencies. Also, he does not handle the case where each processor uses a different program.

proof for this case is based on a probabilistic reduction to the uniform case. Finally, in section 5, we prove the main theorem. The proof involves constructing a "difficult" network in a probabilistic way.

2. Preliminaries. A *radio network* is described by an undirected graph $G(V, E)$,[3] where $N = |V|$ and D is the diameter of the graph. The nodes of the graph represent processors of the network, and an edge between nodes v and u implies that v can send messages to u (and vice-versa). The *neighborhood* of a node u includes all the nodes v such that there is an edge (u, v) in E.

The time is viewed as divided into slots (or *rounds*). In any given slot, a node (processor) can either transmit some message (a string in $\{0,1\}^*$) or not (i.e., remain silent). A radio network has the property that if two or more nodes in the neighborhood of a node u transmit at the same time slot, then none of the messages is received at u. More formally, we can define the set of possible transmissions as $W = \{0,1\}^* \cup \{silent\}$. If exactly one of the node's neighbors transmits at time t and the message that this neighbor transmits is some $m \in \{0,1\}^*$, then m is received by the node. In any other case (i.e., if either none of the neighbors transmits or more than one neighbor transmits) this node hears *silent*. The *history* of length ℓ of a node is a vector in W^ℓ which consists of its view of the first ℓ rounds.

Each processor P_i in the radio network uses a *probabilistic* program. This program defines whether the processor will transmit at the next time slot j or not. As we are not concerned with the computational power of the processors we can simply view this program as a probability distribution, which may depend on the history. More formally, for each processor P_i and step j there is a probabilistic function $\Gamma_i^j : W^{j-1} \to W$ that, based on the history, determines the action of P_i in step j (i.e., whether it remains silent, or else the value of the message it sends). The *program* of P_i is a collection $\Gamma_i = (\Gamma_i^1, \Gamma_i^2, \ldots)$ that defines the actions of P_i in each step. A *protocol* $\mathcal{P}_{N,D}$ is simply a collection of N such programs, one per processor. A protocol is *uniform* if all processors use the same program. Otherwise, if each processor has a different program, the protocol is *nonuniform*. The above definition allows the protocols to use the values of N and D. On the other hand, the protocol "does not know" the topology of the graph, meaning that the same protocol must work for all graphs of N nodes and diameter D.

A *broadcast* protocol is a protocol that is initiated by a single processor, called *originator*, that holds a message M. Any other processor is inactive (i.e., it remains silent) until receiving a message for the first time. The aim of the protocol is that each processor in the network will receive a copy of the message M.

3. Uniform processors. In this section we prove the main lemma for the uniform case, where all processors use the same program. It shows that if there are n processors[4] arranged in a clique, then there exists a t $(2 \le t \le n)$ such that if t processors wish to transmit (we call these t processors the *participants*), then the expected number of rounds (time slots) until a round in which exactly one of them transmits is $\Omega(\log n)$. In fact, we show that this is the case for most of the t's of the form $t = 2^i$. Note that the assumption that the topology is not known to the processors, in the context of this lemma, means that t, the number of processors that

[3] None of the results presented in this work will be changed if the network is a directed one. However, it is common in this area to assume that the network is undirected.

[4] Note that we use here n (and not N) as the number of processors. This will be convenient while using the lemma in the proof of the theorem.

are trying to transmit, is not known to any processor. We can view the scenario as having a family of networks with $n+1$ nodes, composed from a clique of size n and an originator which is connected to t of the nodes in the clique. The (unknown) topology is chosen to be one of these networks.

For a broadcast protocol Π, we call a round *successful* if exactly one processor transmits. Let $E(T_\ell^\Pi)$ denote the expected number of rounds until the *first* successful round, given that the number of participants is 2^ℓ (the expectation is taken over the probabilistic choices of the processors).

LEMMA 1. *Let Π be a broadcast protocol, let the network be as above, and let n be an upper bound on the number of participants. Then,*

$$E_\ell[E(T_\ell^\Pi)] = \Omega(\log n),$$

where E_ℓ denotes the expectation when ℓ is chosen uniformly from the range $1 \le \ell \le \log n$.

Proof. The first observation that we make is that the lemma deals only with the *first* success. This, in a sense, allows us to get rid of the dependency in the history—we can assume that the (probabilistic) decision as to which rounds a processor tries to transmit is made at the beginning of the protocol. This is done by letting each of the 2^ℓ processors choose whether to transmit in round s or not in the same way as it chooses in the original protocol, when all previous rounds were unsuccessful. Clearly, as far as the *first* success is concerned, this modification has no effect on the protocol. Also, as only the first success is considered, it does not matter what the values of the messages that the processors try to transmit are. Hence, the decision of a processor on whether to transmit in round s may depend on the round number, s, and the probabilistic choices of the processor in the first $s-1$ rounds, but it does *not* depend on choices made by other processors.[5] Therefore, we can think about the processors as if they choose *in advance*, for every round $s = 1, 2, \ldots$, whether they will try to transmit.[6]

For simplicity of notation, we assume that n is a power of 2. Define

$$p_{s,\ell} \stackrel{\triangle}{=} Pr(\text{failure in rounds } 1, \ldots, s-1 \ \textbf{and} \ \text{success in round } s | 2^\ell \text{ participants}).$$

As the events described in the definition are disjoint (for *fixed* ℓ and different s's), and assuming that the protocol succeeds with probability 1 (no matter what ℓ is), we have for all ℓ

$$\sum_{s=1}^{\infty} p_{s,\ell} = 1. \tag{1}$$

At some point in the proof below, it will be inconvenient if $p_{s,\ell}$ depends on events that happen in previous rounds. However, we can get rid of this dependency simply by writing

$$p_{s,\ell} \le Pr(\text{ success in round } s | 2^\ell \text{ participants}). \tag{2}$$

[5]The message M that the processors need to broadcast also influences their decisions. However, it can be thought of as part of the program used by the processors.

[6]To avoid measurability concerns, it is convenient to assume that the protocol is such that s is in the range $1, \ldots, F$, for some *finite* F. If this is not the case, we can always choose F such that the probability of choosing only in the range $1, \ldots, F$ is arbitrarily close to 1. This will cause minor changes in our proof.

The next claim gives a bound on the sum of the success probabilities in a given round. Intuitively it says that you cannot have high probability of success in (a fixed) round s for more than a few values of 2^ℓ. This would imply that since the number of participants is unknown, $\Omega(\log n)$ rounds would be required to reach a success for all numbers of participants. Formally, we make the following claim.

CLAIM 2. *For any s,*

$$\sum_{\ell=1}^{\log n} Pr(\textit{success in round } s \mid 2^\ell \textit{ participants}) < 2.$$

Proof. Fix s. As already discussed, we assume that the processors make all their choices in advance. The *history* of choices of a processor is a string in $\{0,1\}^{s-1}$, where the value of the ith bit means trying ("1") or not trying ("0"). Define

$$q(s) \stackrel{\triangle}{=} Pr(\text{trying in round } s) = \sum_{\text{history } h} Pr(h) \cdot Pr(\text{trying in round } s|h).$$

Note that $q(s)$ does *not* depend on ℓ. We assume, without loss of generality, that $q(s) > 0$ (rounds with $q(s) = 0$ can be omitted from the protocol). Recall that a successful round is one in which exactly one processor is trying to transmit. Therefore,

$$Pr(\text{success in round } s \mid 2^\ell \text{ participants}) = 2^\ell \cdot q(s) \cdot (1-q(s))^{2^\ell - 1}.$$

We get

$$\begin{aligned}
\sum_{\ell=1}^{\log n} Pr(\text{success in round } s|2^\ell \text{ participants}) &= \sum_{\ell=1}^{\log n} 2^\ell q(s)(1-q(s))^{2^\ell-1} \\
&= q(s) \sum_{\ell=1}^{\log n} 2^\ell (1-q(s))^{2^\ell-1} \\
&\le 2 \cdot q(s) \sum_{j=1}^{n-1} (1-q(s))^j \\
&= 2 \cdot q(s) \cdot \frac{1-(1-q(s))^n}{q(s)} < 2
\end{aligned}$$

which completes the proof of the claim. □

Let k be a parameter (to be fixed later). We are interested in $\sum_{s=1}^{k} p_{s,\ell}$, which is intuitively the probability that, given that there are 2^ℓ participants, the algorithm succeeds in one of the first k rounds. Using equation (2) and Claim 2, we get

$$\sum_{\ell=1}^{\log n} \sum_{s=1}^{k} p_{s,\ell} \le \sum_{s=1}^{k} \sum_{\ell=1}^{\log n} Pr(\text{success in round } s|2^\ell \text{ participants}) < 2k. \tag{3}$$

By definition,

$$E_\ell[E(T_\ell^\Pi)] = \sum_{\ell=1}^{\log n} \frac{1}{\log n} \sum_{s=1}^{\infty} p_{s,\ell} \cdot s \ge \frac{k}{\log n} \sum_{\ell=1}^{\log n} \sum_{s=k}^{\infty} p_{s,\ell}.$$

By equation (1), this equals

$$\frac{k}{\log n}\sum_{\ell=1}^{\log n}\left(1-\sum_{s=1}^{k-1}p_{s,\ell}\right),$$

which, by equation (3), is greater than

$$\frac{k}{\log n}\cdot(\log n-2(k-1)).$$

By choosing $k=\frac{1}{4}\log n$, we have that

$$E_\ell[E(T_\ell^\Pi)]\geq\frac{1}{8}\log n+\frac{1}{2},$$

which completes the proof of the lemma.[7] □

4. Nonuniform processors. In this section we prove the main lemma for the nonuniform case, where the n processors may use *different* programs. The main idea of the proof is to "reduce" the nonuniform case to the uniform one, and use the result of the previous section (Lemma 1).

LEMMA 3. *Let* Π *be a protocol for* n *distinct processors* $P_1,\ldots,P_n$ *that run (possibly) different programs. Let* $E(T_\ell^\Pi)$ *denote the expected number of rounds until the* first *successful round, given that a* random *set of* 2^ℓ *processors participates (the expectation is taken over the choice of the set and the probabilistic choices made by the processors). Then*

$$E_\ell[E(T_\ell^\Pi)]=\Omega(\log n),$$

where ℓ *is chosen uniformly from the range* $1\leq\ell\leq\log n$.

Proof. As argued in the previous section, as only the first successful round is considered, each program can be thought of as a "schedule"—a choice of a subset of rounds in which the processor will transmit. Processor P_i chooses its schedule from a distribution μ_i.

We now define, based on the (possibly different) programs used by $P_1,\ldots,P_n$, a new program that will be used by each of L *uniform* processors $Q_1,\ldots,Q_L$: processor Q_j chooses (uniformly) at random $1\leq i\leq n$ and simulates the program of processor P_i. Namely, it chooses a schedule s with probability $\frac{1}{n}\sum_{i=1}^n\mu_i(s)$, where $\mu_i(s)$ is the probability that processor P_i chooses the schedule s. We denote by $c(Q_j)$ the processor P_i that Q_j chose to simulate. We emphasize that all the Q_j's run the *same* program (i.e., they are uniform), and that different Q_j's may choose to simulate the same processor P_i (we will choose L "small enough" so that this will happen only with a "small" probability).

The following claim says that, given that all the $c(Q_j)$'s are distinct for $Q_1,\ldots,Q_{2^\ell}$, then the probability distribution of the schedules chosen by the Q_j's is the same as that of a *random* set of 2^ℓ processors P_i.

CLAIM 4. *Let* $Q=\{Q_1,\ldots,Q_{2^\ell}\}$. *For every* $Q_j\in Q$, *let* $c(Q_j)$ *be a random processor* P_i. *If* $\forall j_1\neq j_2\ :\ c(Q_{j_1})\neq c(Q_{j_2})$, *then* $P=\{c(Q_j)|Q_j\in Q\}$ *is a random*

[7] In the original version of this paper [KM93], we proved a slightly better lower bound of $\frac{1}{4}\log n$; however, the proof here is simpler.

set of 2^ℓ processors (in $P_1, \ldots, P_n$), and the following holds: for every choice of 2^ℓ schedules $\vec{s}_{2^\ell} = (s_1, \ldots, s_{2^\ell})$,

$$Pr[\vec{s}_{2^\ell} | \textit{processors } Q \textit{ run }] = Pr[\vec{s}_{2^\ell} | \textit{processors } P \textit{ run }].$$

The following claim is the main tool in the reduction from the nonuniform case to the uniform case.

CLAIM 5. *Let Q be as above and let $Q' = \{Q'_1, \ldots, Q'_{2^\ell}\}$ be a set of 2^ℓ processors. Each processor Q'_j runs the program of Q_j at the odd steps and the* [BGI92] *program at the even steps. (Note that the* [BGI92] *program is also a uniform protocol, and therefore, so is the program run by the processors Q'.) Let β_ℓ be the probability that $\forall j_1 \neq j_2,\ c(Q_{j_1}) \neq c(Q_{j_2})$. Let $T_\ell^{Q'}$ be the random variable indicating the time of first success when the 2^ℓ identical programs in Q' run, and recall that T_ℓ^{Π} is the random variable indicating the time of first success when a random subset of 2^ℓ distinct programs $P_{i_1}, \ldots, P_{i_{2^\ell}}$ run. Then,*

$$E[T_\ell^{Q'}] \leq 2\beta_\ell E[T_\ell^{\Pi}] + 8(1-\beta_\ell)\log n.$$

In the above claim we mixed the given (unknown) protocol with the [BGI92] protocol. This is because we have no guarantee about the running time of the simulation, in the case when some Q_j's choose to simulate the same P_i. For example, a protocol that lets processor P_i transmit at time slot i would not terminate if all the Q_j simulate the same processor P_i.

Proof. Let *unique* be the event that $\forall Q_{j_1}, Q_{j_2} \in Q',\ c(Q_{j_1}) \neq c(Q_{j_2})$. Then,

$$E[T_\ell^{Q'}] = E[T_\ell^{Q'} | \textit{unique}] \cdot Pr[\textit{unique}] + \ E[T_\ell^{Q'} | \textit{not unique}] \cdot Pr[\textit{not unique}].$$

By definition, $Pr[\textit{unique}] = \beta_\ell$. By Claim 4,

$$E[T_\ell^{Q'} | \textit{unique}] \leq 2E[T_\ell^{\Pi}],$$

where the additional factor of 2 is due to the interleaving of the two protocols. In the case when the choices of $c(Q_j)$ are not unique, we cannot use the properties of the original protocol. However, we can use the fact that the [BGI92] protocol has the expected time until the first success of at most $4\log n$. Therefore,

$$E[T_\ell^{Q'} | \textit{not unique}] \leq 8\log n,$$

which completes the proof of the claim. □

The next claim says that with "high probability" the choices $c(Q_j)$ are unique.

CLAIM 6. *Let β_ℓ be the probability that $\forall j_1 \neq j_2,\ c(Q_{j_1}) \neq c(Q_{j_2})$, and assume that $2^\ell \leq n^{1/4}$. Then,*

$$\beta_\ell > 1 - \frac{1}{\sqrt{n}}.$$

Proof. Note that

$$Pr[j_1 \neq j_2 \text{ and } c(Q_{j_1}) = c(Q_{j_2})] = \frac{1}{n}.$$

Therefore,

$$\beta_\ell = Pr[\forall j_1 \neq j_2 \ : \ c(Q_{j_1}) \neq c(Q_{j_2})] \geq 1 - \binom{2^\ell}{2}\frac{1}{n}.$$

Since $2^\ell \leq n^{1/4}$ the lemma follows. □

Let $L = n^{1/4}$. By Claims 5 and 6,

$$E[T_\ell^{Q'}] \leq 2\beta_\ell E[T_\ell^\Pi] + (1-\beta_\ell)8\log n \leq 2E[T_\ell^\Pi] + \frac{8\log n}{\sqrt{n}}$$

or

$$E[T_\ell^\Pi] \geq \frac{1}{2}E[T_\ell^{Q'}] - \frac{4\log n}{\sqrt{n}}.$$

We now take the expectation over all values $1 \leq \ell \leq \log L$ and get

$$E_\ell[E[T_\ell^\Pi]] \geq \frac{1}{2}E_\ell[E[T_\ell^{Q'}]] - \frac{4\log n}{\sqrt{n}}.$$

By Lemma 1,

$$E_\ell[E[T_\ell^{Q'}]] = \Omega(\log L) = \Omega(\log n),$$

which implies that

$$E_\ell[E[T_\ell^\Pi]] = \Omega(\log n),$$

as desired. □

5. Main theorem. In this section we prove the main theorem. We show that for every broadcast algorithm that does not know the topology of the network, for every N and every D, there exist networks of N processors and diameter D such that the expected running time of the algorithm (until all processors receive the message) is $\Omega(D\log(N/D))$. This implies a similar lower bound for the *worst case* running time, when a small probability of error is allowed (which is the scenario in which the upper bound of [BGI92] is described).

Given an algorithm and the values N and D, we construct a network as follows. Let $n = N/D$, and assume for simplicity that n is a power of 2. We construct a complete layered network of $D+2$ layers. The first layer (layer 0) contains one node, s, which will be the originator of the broadcast. Each of the next D layers (layers $1, 2, \ldots, D$) consists of $n_i = 2^{\ell_i} \leq n$ nodes, where ℓ_i is chosen uniformly (and independently for each layer i) in the range $1, \ldots, \log n$. The last layer contains all the other nodes (so that the total number of nodes will be N). Each node in layer i is connected to all nodes in layers $i-1$ and $i+1$. (See Figure 1.)

Recall that the topology of the network is not known to the processors. (If the topology was known, then an efficient uniform protocol would be to let a processor at layer i broadcast with probability $1/n_i$, with expected time $O(D)$. A nonuniform protocol that knows the topology simply lets one node in each layer transmit.) The algorithm can depend, however, on other information that the processors have, in particular, the history, the number of steps, etc. (As mentioned, other information which is independent of the graph, such as the message M to be broadcast, the

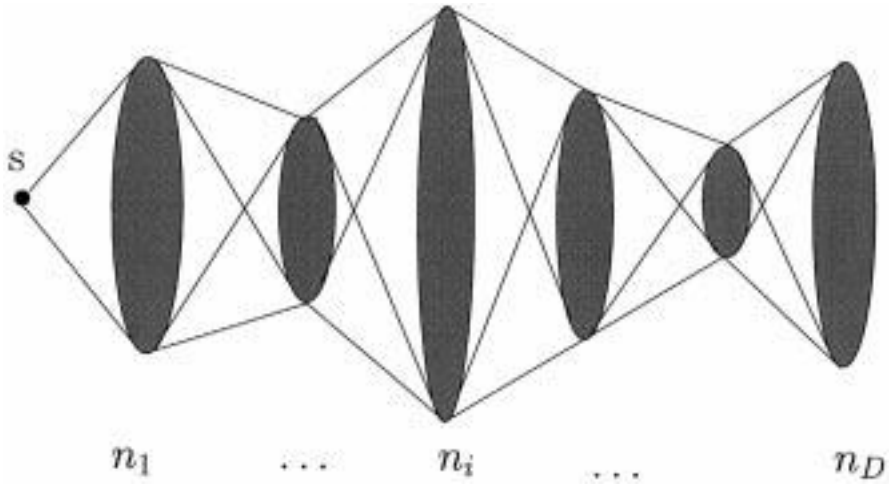

FIG. 1. *Structure of the network.*

processors' IDs, or the value of a clock, can be thought of as encoded into the programs of the processors.)

We discuss the uniform case, in the sense that all the processors at layer i have the same protocol. The extension to the nonuniform case employs the techniques of the previous section, and the proof is the same but the notation becomes cumbersome. (In particular, in the nonuniform case, at each layer i we will choose not only n_i but also a random set of n_i processors.) The main property of this construction is the following. For all i and all runs of the protocol, all the processors in layer i have the same view; every message received at one of these processors is received by all other processors at the same time. Therefore, the broadcast progresses in a layer-by-layer fashion. Moreover, this implies that all the processors in layer i choose schedules according to the same distribution μ (the choice of μ depends on the history, but all the processors of layer i share the same history), which allows us to use Lemma 1.

Finally, before going into the details, we make one more assumption that makes our argument simpler. We give the processors of layer i, at the time they get the first message from a processor in layer $i-1$, all the other messages they will get from layer $i-1$ in the future, as well as the actual values of $\ell_1, \ldots, \ell_{i-1}$. As this extra information can only help the processors to make the broadcast faster, we are allowed to make this assumption.

Let t_i be the random variable indicating the number of rounds from the time the processors of layer i get the message (and become active) until their success (the first time that a single processor in layer i transmits). We need to show that for some choice of $\ell_1, \ldots, \ell_D$ we get $E_\Pi(\sum_{i=1}^{D} t_i) = \Omega(D \log(N/D))$, where the expectation is taken over the random choices of the algorithm Π. Certainly, it is enough to show that $E_{\ell_1,\ldots,\ell_D,\Pi}(\sum_{i=1}^{D} t_i) = \Omega(D \log(N/D))$. By linearity of expectation, we get

$$E_{\ell_1,\ldots,\ell_D,\Pi}\left(\sum_{i=1}^{D} t_i\right) = \sum_{i=1}^{D} E_{\ell_1,\ldots,\ell_D,\Pi}(t_i).$$

So all we have to bound now is $E_{\ell_1,\ldots,\ell_D,\Pi}(t_i)$. Clearly, the choice of $\ell_{i+1}, \ldots, \ell_D$ has

no influence on the expectation of t_i; i.e.,

$$E_{\ell_1,\ldots,\ell_D,\Pi}(t_i) = E_{\ell_1,\ldots,\ell_i,\Pi}(t_i).$$

Also, by the discussion above, with every history (which depends on the random choices made in the first $i-1$ layers, including the choice of $\ell_1,\ldots,\ell_{i-1}$) we can associate a probability distribution μ used by the processors in layer i to choose their schedules. (Note that since we assume that the processors of layer i get all the future information with the first message, they can make all their random choices at this time.) Therefore, we can write

$$E_{\ell_1,\ldots,\ell_i,\Pi}(t_i) = \sum_{b_1,\ldots,b_{i-1}} E_{\ell_i,\Pi}(t_i|\ell_1 = b_1,\ldots,\ell_{i-1} = b_{i-1})\cdot Pr[\ell_1 = b_1,\ldots,\ell_{i-1} = b_{i-1}]. \tag{4}$$

It remains to bound the expression $E_{\ell_i,\Pi}(t_i|\ell_1 = b_1,\ldots,\ell_{i-1} = b_{i-1})$. As mentioned, we allow the processors at layer i to have access to $b_1,\ldots,b_{i-1}$ (the actual values of $\ell_1,\ldots,\ell_{i-1}$). Therefore, we need to evaluate $E_{\ell_i,\Pi_i}(t_i)$, where Π_i is the protocol at layer i, with the additional information about the lower layers. By Lemma 1, for each such Π_i,

$$E_{\ell_i,\Pi_i}(t_i) \geq c\log n$$

for some constant c. Therefore, for every $b_1,\ldots,b_{i-1}$, we have

$$E_{\ell_i,\Pi}(t_i|\ell_1 = b_1,\ldots,\ell_{i-1} = b_{i-1}) \geq c\log n,$$

which by (4), implies

$$E_{\ell_1,\ldots,\ell_i,\Pi}(t_i) \geq c\log n.$$

This implies

$$E_{\ell_1,\ldots,\ell_D,\Pi}\left(\sum_{i=1}^{D} t_i\right) = \Omega(D\log n) = \Omega(D\log(N/D)),$$

which completes the proof of our main theorem.

THEOREM 7. *For any nonuniform broadcast protocol, for every number of processors N and every diameter D, there exists a network in which the expected time to complete a broadcast is $\Omega(D\log(N/D))$.*

When $D \leq N^{1-\varepsilon}$, the above proof shows a lower bound of $\Omega(D\log N)$. Combining our result with the results of Alon et al. [ABLP91] and Bar-Yehuda, Goldreich, and Itai [BGI92], we have the following tight result.

COROLLARY 8. *For any nonuniform broadcast protocol, for every number of processors N and every diameter D, there exists a network in which the time to complete a broadcast is $\Omega(\log^2 N + D\log(N/D))$. Furthermore, there is a (uniform) protocol that requires only $O(\log^2 N + D\log N)$ expected time (which is tight for $D \leq N^{1-\varepsilon}$).*

Note that unlike [ABLP91] we show that for any protocol there exists a network for which the lower bound holds, while they prove that there exists a network on which any protocol requires the lower bound.

Acknowledgments. We wish to thank Oded Goldreich and the anonymous referees for their very useful comments.

OPTIMAL ON-LINE SEARCH AND SUBLINEAR TIME UPDATE IN STRING MATCHING*

PAOLO FERRAGINA† AND ROBERTO GROSSI‡

Abstract. This paper investigates the problem of searching on-line for the occurrences (*occ*) of an arbitrary pattern of length p in a text of length n subjected to some updates after its preprocessing. Each text update consists of inserting or deleting an arbitrary string of length y. We present the first dynamic algorithm that achieves *optimal* query time, i.e., $\Theta(p+occ)$, *sublinear* time per update, i.e., $O(\sqrt{n}+y)$, and *optimal* space, i.e., $\Theta(n)$, in the worst case. As a result, our algorithm obtains the same query time and space usage of suffix trees [McCreight, *J. Assoc. Comput. Mach.*, 23 (1976), pp. 262–272] while improving their $O(n+y)$ update performance.

Key words. string matching, suffix tree, text indexing, dynamic data structures

1. Introduction.

The problem of encoding all the substrings of a given string for string-matching purposes is amply treated in current literature. Given a *text* string $T[1,n]$ made up of n characters taken from an ordered alphabet Σ, we want to *preprocess* T in order to represent all of its substrings compactly (there could be as many as $\Theta(n^2)$) and therefore answer the following two *on-line* search queries efficiently for any *pattern* string $P[1,p]$:

(a) check to see if P is one of T's substrings;

(b) find all of T's substrings equal to P (let *occ* be their number).

There are three main groups of methods used for preprocessing T and solving the above problem. Over the last twenty years, they have been "rediscovered" in scientific literature disguised under different names and studied in various forms (e.g., see [3, 9]). The following is a brief list of them (we assume that Σ has constant size).

(1) The first group is made up of *compacted tries* that include, among other things, the compacted prefix bi-tree [33] (or prefix tree [9]), the PAT tree [19], the position tree [1, 23, 26], the repetition finder [30], the subword tree [3, 9], and the suffix tree [28] (the latter is definitely the best known). The text suffixes are stored in the compacted trie leaves so that every text substring is represented by a (unique) path descending from the root. Two examples of suffix trees are given in Fig. 1. Compacted tries require optimal $O(n)$ space and construction time (e.g., see [28, 33]). A query can be answered in optimal time, namely in $O(p)$ time for query (a) and in $O(p+occ)$ time for query (b). It is also possible to obtain some efficient statistics on T's substrings (e.g., see [3, 33]). Furthermore, compacted tries have successfully been generalized to matrices [4, 17, 18] and parameterized strings [5].

(2) The second group is made up of *automata* or *word graphs*, such as the complete inverted file [7], the directed acyclic word graph (DAWG) [6], and the minimal suffix and factor automata [10, 11]. They are either labeled directed acyclic graphs

or automata whose nodes correspond to the nodes of the compacted trie built on the string T [7] or T's reversal [6, 10, 11]. Two examples of compact DAWGs are given in Fig. 2. Their space usage, construction time, and query time are identical to the ones required by compacted tries. Directed acyclic word graphs and minimal suffix and factor automata allow us to perform queries (a), whereas complete inverted files enable more queries than just (a) and (b).

(3) Finally, the third group is characterized by *lexicographically ordered data structures*, such as the suffix array [27] and the dynamic suffix array [14], the PAT array [19], and the SB-tree [15]. They all maintain T's suffixes in lexicographic order, which can be equivalently obtained by traversing the compacted trie leaves. Two examples of suffix arrays in their simplest form are given in Fig. 3. The space required is still optimal, i.e., $O(n)$, but the construction time is $O(n \log n)$ in the worst case (which becomes $O(n)$ on the average for suffix arrays [27]). Query (a) takes $O(p+\log n)$ time and query (b) takes $O(p + \log n + occ)$ time (see [27] for further details).

In this paper, we only discuss query (b) because query (a) derives from it. As previously mentioned, groups (1)–(3) are very efficient and, when dealing with a *static* text, there is no better asymptotic bound possible than (1) and (2). However, in many common situations—e.g., text editors and text retrieval systems [32, section 5.3]—the preprocessed text T undergoes some changes. Some special cases can be handled by the methods in (1)–(3), namely, strings can be appended to one end of T with suffix trees [2, 21, 33] and compact DAWGs [7], or a subset of T's suffixes can be *logically*

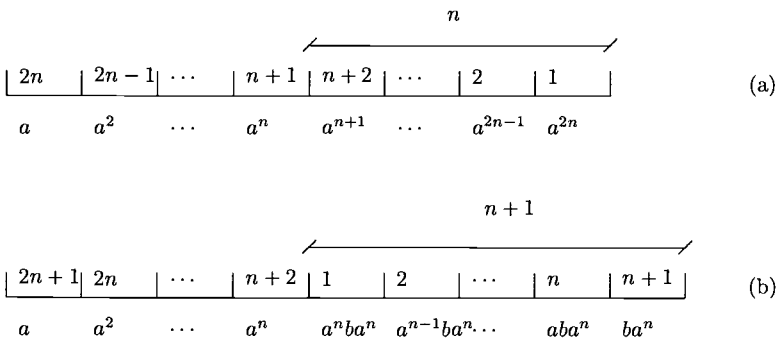

FIG. 3. *The suffix array for* (a) $T = a^{2n}$ *and* (b) $T' = a^n b a^n$.

deleted and undeleted [14]. However, the general problem of *dynamically* modifying T in arbitrary positions by inserting or deleting *strings* after preprocessing, seems a difficult task to solve efficiently. Evidence of this can be found in the following illustrative example: let us assume that $T = a^{2n}$ becomes $T' = a^n b a^n$ after a single character b is inserted into it, with $a \neq b$. Then $\Omega(n)$ locations must be updated in each of the known data structures that implement (1)–(3) (see Figs. 1–3). Consequently, updating the data structures basically costs the same as rebuilding them from scratch! Furthermore, as pointed out in [20], a naive method for avoiding the rebuilding that consists of keeping a "to-do-list" of changes is still very expensive.

Due to the trivial $\Omega(y)$ lower bound to the time needed for inserting or deleting a string $Y[1, y]$, we realized the importance of obtaining a *sublinear* time update, i.e., $o(n) + \Theta(y)$ for *all* y, while maintaining optimal query time, i.e., $O(p + occ)$, and optimal space usage, i.e., $O(n)$. In this paper we illustrate how to solve this problem.

In current literature, an important step has been done with *dynamic text indexing*, introduced in [20] with the aim of attaining an efficient time trade-off between pattern searching and single-character (text) updating. This trade-off was generalized in [13, 14] to text *string* insertions (or deletions) which are seen as atomic changes rather than sequences of single-character changes. It is worth noting that all of these dynamic text indexing results deal with *nonoblivious* queries: while the length of the "history" of insertions and deletions increases, the query's performance degenerates independently of the current text and pattern length. It is therefore reasonable to design *oblivious* dynamic text indexing algorithms whose query time does not explicitly depend on the "history." There are some well-known examples of oblivious dynamic algorithms: dynamic graph algorithms, for example, have a time complexity that only depends on the current graph size (e.g., see [12]).

We start out by proposing a simple technique for obtaining oblivious queries by means of a text partitioning technique. We provide the first dynamic text indexing algorithm that achieves an *optimal* query time, i.e., $O(p + occ)$. Updating the text under the insertion (or deletion) of a string $Y[1, y]$ takes $O((y + \sqrt{n \log n}) \log(n + y))$ time. The space required is $O(n \log n)$ (see Theorem 3.2).

However, our main contribution in this paper is presenting the first dynamic algorithm that achieves in the worst case:

- optimal query time $\Theta(p + pocc)$ (Theorem 4.3);
- sublinear time per update $O(\sqrt{n} + y)$ (Theorem 4.4);
- optimal space $\Theta(n)$.

As far as we know, this is the first dynamic algorithm that provides both a query in optimal $\Theta(p + occ)$ time and an update in sublinear $o(n) + \Theta(y)$ time for *every* y, in optimal space. Our result is significant for the following reasons: "start-over" solutions requiring $O(n + y)$ time per update can be obtained by running the static algorithms from scratch. These start-over solutions show that the known dynamic text indexing algorithms still obtain a trade-off because their fast updates are *not always* $o(n)+\Theta(y)$ *for every* y (e.g., let us take $y = \Omega(\frac{n}{\log n})$ in Theorem 3.2). Moreover, their space usage is $O(n \log n)$ (except for [20]). Therefore, if we consider the start-over solutions from a theoretical point of view, to our surprise, we discover that they are the best-known text updating methods for *almost all* input strings (see footnote[1]). In our results, we do not simply reduce the update cost and the amount of space required by a polylogarithmic factor (still maintaining an optimal query time), but we also show that our oblivious algorithm is *not* a trade-off because it is *always better* than the start-over solutions for every y. Since no better asymptotic bounds can exist for $y = \Omega(\sqrt{n})$, our algorithm is the best one possible in this case. Furthermore, our solution is still *optimal* for a *static* text T. As a result, we obtain the same query time and space usage of suffix trees, automata, etc., while improving their update performance.

Our paper is organized as follows. We discuss some preliminary notions in section 2. In section 3 we introduce the notion of "balanced" text partitioning, while we outline our main result in section 4. In sections 5–7, we describe the implementation details and new techniques.

2. Preliminaries. Our preliminary remarks regard string periodicity [24] and suffix trees [28, 33]. (Readers familiar with them can skip this section.)

Let $X[1, m]$ be a string of m characters taken from the ordered alphabet Σ, and let $X[1, i]$ be the ith prefix and $X[j, m]$ be the jth suffix of X. *A period* of X is any proper prefix π such that X is in the form of $\pi^r\pi'$, where $r \geq 1$ and π' is a (maybe empty) prefix of π. Analogously, $X[i] = X[i + |\pi|]$ for every $1 \leq i \leq m - |\pi| + 1$. *The* period π of X is its *shortest* period. The following lemma is well known.

LEMMA 2.1 (see Knuth, Morris, and Pratt (KMP) [24]). *If p and q are the lengths of any two periods of X, such that $p+q \leq m+gcd(p, q)$, then $gcd(p, q)$ is also the length of a period of X.*

The following simple fact regarding X's periodicity will be useful later.

FACT 2.2. *Any substring $X[i, j]$ longer than $|\pi|$ has a cyclic shift of π's characters as a period.*

We wish to point out that a cyclic shift of π is not necessarily *the* period of $X[i, j]$ (which may be shorter).

For $1 \leq i \leq m$, the decomposition of each prefix $X[1, i]$ in the form of $\pi_i^r\pi_i'$, where π_i is *the* period of $X[1, i]$, can be obtained in $O(m)$ time with KMP's algorithm [24]. The same computation can be performed for each of X's suffixes by using X's reversal, denoted by X^R. We will also use the notion of border. A *border* is a proper prefix of X that is also its suffix. We can compute the *longest* border *Shift*$(X[1, i])$ of each prefix $X[1, i]$ in a total of $O(m)$ time by using the algorithm in [24].

[1] For example, we want to delete a generic string $Y[1, y]$ and let us assume it costs $O(y \log n)+o(n)$ time. This bound is better than $O(n + y)$ when $y = O(n/\log n)$. This happens for $\Theta(|\Sigma|^{cn/\log n})$ input strings Y, for some constant $c > 0$, whereas for other $\Theta(|\Sigma|^n - |\Sigma|^{cn/\log n})$ input strings Y the start-over solutions in (1)–(2) are faster. In this case, the former term is asymptotically smaller than the latter.

The *suffix tree* ST_X [28, 33] for the string X is a compacted trie built on the augmented string $X[1, m+1]$, where $X[m+1] = \$ \notin \Sigma$ is an endmarker. It stores the suffixes $X[i, m+1]$ in its leaves, for $1 \leq i \leq m$, and can be built optimally in $O(m)$ time and space (e.g., see [28]). Each ST_X arc is labeled with a substring $X[i, j]$ represented by a triple (X, i, j), and sibling arcs are ordered according to the first character of their label (see Fig. 1). We adopt the following terminology for suffix trees. Given a node $u \in ST_X$, the concatenation of the labels encountered along the downward path in ST_X from the root to u is denoted by $W(u)$. This node u is called the *locus* of $W(u)$. The *extended locus* of a string Y in ST_X is the unique node v, if it exists, such that Y is a prefix of $W(v)$ and $W(p(v))$ is a proper prefix of Y, where $p(v)$ is v's parent in ST_X. The following property of ST_X is used throughout the paper, and ensures that, given a node $u \in ST_X$, all the leaves descending from u store the suffixes having the same prefix $W(u)$.

PROPERTY 2.3. *Two suffixes have a common prefix, i.e. Y, if and only if they share a path from the root to the extended locus of Y.*

We can preprocess ST_X in $O(m)$ time [22, 31] in order to answer constant-time queries for finding the *lowest common ancestor* of any two nodes (hereafter called *LCA query*). LCA queries can be used for finding the *longest common prefix* of any two substrings of X, in $O(1)$ time, by Property 2.3 (see [25]).

We call the suffix tree generalization to a set Δ of strings [2, 21] a *generalized suffix tree* (GST_Δ for short). It is the compacted trie obtained by "superimposing" suffix trees ST_X for all $X \in \Delta$ incrementally, in $O(|X|)$ time each. Two arcs are superimposed whenever their labels have a common prefix. Multiple equal strings are associated with the same leaf and kept in a doubly linked list. The fundamental point is that, given $\Delta = \{X_1, X_2, \ldots, X_k\}$, the compacted trie GST_Δ is isomorphic to $ST_{X_1\$X_2\$\ldots\$X_k\$}$, where each instance of \$ is assumed to be different from the others. The out-degree of each node can be kept bounded by alphabet size $|\Sigma|$ according to [2]. The insertion of a suffix determines a leaf insertion (and sometimes the insertion of its parent). The symmetrical operation of deleting a string X from Δ can also be obtained in $O(|X|)$ time. In this case, too, Property 2.3 holds. See [2, 21] for further details about GST_Δ building and updating by means of McCreight's algorithm.

3. A simple technique for optimal query: "Balanced" partition. In this section, we introduce a simple technique for maintaining a "balanced" partition of text T; that is, we decompose T into substrings of roughly the same size. We give an example of its application to a known dynamic text indexing solution and obtain the first *oblivious* algorithm having *optimal* query time. We use the following result.

THEOREM 3.1 (see Ferragina and Grossi [14, section 6.4]). *The dynamic text indexing problem on $T[1, n]$ can be solved with the following bounds: finding the occurrences of $P[1, p]$ requires $O(p + occ + |\mathcal{L}| \log p + \log n)$ time, where occ is the number of occurrences; inserting or deleting a string $Y[1, y]$ takes $O(y \log(y + n))$ time. The space required is $O(n \log n)$.*

Our idea for using this result is based on maintaining $T = I_1 \cdots I_k$ as a list $\mathcal{L} = \{I_1, \ldots, I_k\}$ of its substrings (called *intervals*) whose length satisfies $\ell \leq |I_i| < 2\ell$, where ℓ is a parameter specified later on. As a result, $\mathcal{L}$'s size is $k = \Theta(\frac{n}{\ell})$ and this is called a *balanced* partition. Let us maintain an $O(n)$-size generalized suffix tree GST_Δ built on the set $\Delta = \{I_1 I_2, I_2 I_3, \ldots, I_{k-1} I_k\}$ of pairs of consecutive intervals. Any two consecutive strings in Δ overlap for exactly one of $\mathcal{L}$'s intervals.

We can now find P in two main cases according to its length p: (1) If $p \leq \ell$, then each occurrence is entirely contained in a pair of consecutive intervals. Therefore,

all the occurrences are easily found in $O(p + occ)$ time by accessing the leaves that descend from P's extended locus into GST_Δ (by Property 2.3). Multiple occurrences are listed twice at most. (2) If $p > \ell$, then listing all the occurrences takes $O(p+occ+\frac{n}{\ell}\log p + \log n)$ time by Theorem 3.1 (since $|\mathcal{L}| = O(\frac{n}{\ell})$). By fixing $\ell = \sqrt{n \log n}$, the query time becomes optimal, i.e., $O(p + occ)$.

Text partitioning can be maintained consistently under string insertions and deletions by means of some split and merge operations on intervals. Let us assume that we must insert a string $Y[1, y]$ into an interval $I_i = I'I''$ to produce the string $X = I'YI''$. We split X into $h = \lfloor \frac{|X|}{\ell} \rfloor$ intervals $I'_1, \ldots, I'_h$, such that $|I'_1| = \cdots = |I'_{h-1}| = \ell$ and $\ell \leq |I_h| < 2\ell$. Text T must be updated by replacing I_i with the intervals created because of X. We also update GST_Δ consistently by deleting the strings $I_{i-1}I_i$ and I_iI_{i+1} and inserting the strings $I_{i-1}I'_1, I'_1I'_2, \ldots, I'_hI_{i+1}$ of length $O(\ell)$ each. Since there are $O(y/\ell + 1)$ of them, the update requires $O(y + \ell)$ total time by the algorithms in [2]. We then update the data structures in Theorem 3.1 by deleting the whole I_i and inserting the sequence of $O(y/\ell + 1)$ strings $I'_1, \ldots, I'_h$ into $\mathcal{L}$, in $O((y + \ell)\log(n + y + \ell))$ total time. Since we fixed $\ell = \sqrt{n \log n}$, the bound becomes $O((y + \sqrt{n \log n}) \log(y + n))$.

When deleting a string $Y[1, y]$, we remove $\mathcal{L}$'s shortest sublist that denotes T's substring $I'YI''$ entirely containing Y. Then we insert string $I'I''$ into T again, with $|I'I''| < 4\ell$. This requires making a deletion in $O((y + \ell)\log n)$ time and an insertion of no more than two new intervals in $O(\ell \log(n + \ell))$ time (by Theorem 3.1). Since we fixed $\ell = \sqrt{n \log n}$, the bound becomes $O((y + \sqrt{n \log n}) \log n)$. Our first result is therefore proved.

THEOREM 3.2. *Searching for a pattern $P[1, p]$ in the text $T[1, n]$ requires optimal $O(p+occ)$ time, where occ is the total number of occurrences. Updating the text under the insertion or deletion of a string $Y[1, y]$ takes $O((y + \sqrt{n \log n}) \log(y + n))$ time. The space required is $O(n \log n)$.*

4. Optimal query, sublinear time update, and optimal space. We now give a high-level overview of our main result for finding pattern occurrences optimally, i.e., $O(p+occ)$ time, while also obtaining sublinear time update, i.e., $O(\sqrt{n}+y)$, and optimal space, i.e., $O(n)$. We combine the basic idea of balanced partitioning described in section 3 with some new techniques for updating and searching efficiently in the intervals' list $\mathcal{L}$. In the following, we indicate the ideas we base our data structures and algorithmic techniques on.

We recall that the text is maintained as a partition of intervals whose length goes from ℓ to 2ℓ and which are stored into a list $\mathcal{L} = \{I_1, I_2, \ldots, I_k\}$ of size $k = \Theta(\frac{n}{\ell})$. String insertions and deletions are implemented by performing split and merge operations on $\mathcal{L}$'s intervals (to maintain their length between ℓ and 2ℓ). By setting $\ell = \Theta(\sqrt{n})$, we obtain a balanced partition in which an interval's length is proportional to the intervals' number. Due to this partition the pattern can be searched for in two different ways depending on its length. We call a pattern *short* if it is not longer than $c\ell$ (for a proper constant c, to be fixed below) and call it *long* otherwise.

Short patterns can be searched for by maintaining a generalized suffix tree GST_S on a set S of text substrings obtained by concatenating a sequence of consecutive intervals. For each interval I_i, we insert the smallest substring $I_i \ldots I_{i+r}$ whose length is at least $c\ell + 4\ell$ into GST_S (which contains $O(\frac{n}{\ell})$ strings). This makes sure that each short pattern occurrence is entirely contained in a string stored in GST_S because no interval is longer than 2ℓ.

Long patterns can be searched for in a more involved way. Since $p = \Omega(\ell) = \Omega(\frac{n}{\ell})$,

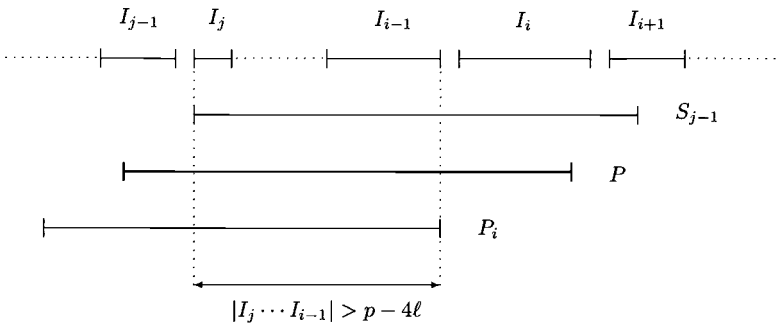

FIG. 4. *A pattern occurrence ending in interval I_i.*

we have enough time for scanning $\mathcal{L}$. Therefore, we process this list and, for each interval I_i, we compute both the pattern's longest prefix P_i that is a suffix of $I_1 \dots I_{i-1}$ and the pattern's longest suffix S_i that is a prefix of $I_{i+1} \dots I_k$. After that, we put P_i's and S_i's together to find the pattern occurrences. Our approach is different from the ones in [13, 14, 20] because it exploits long-pattern periodicity. We now want to state some constants that we will use later on in our algorithms and data structures.

Let us assume that there are some occurrences ending in I_i. Since the pattern is long, we have the property that each such occurrence completely overlaps a sequence of consecutive intervals preceding I_i. Let us choose the minimum integer j, such that the sequence $I_j I_{j+1} \dots I_{i-1}$ is maximal and contains all of the occurrences ending in I_i. In the worst case, an occurrence ends in I_i's last position and occupies $|I_i| < 2\ell$ positions to the right of I_{i-1} and less than 2ℓ positions to the left of I_j. We therefore have (see Fig. 4):

$$|I_j I_{j+1} \dots I_{i-1}| > p - 4\ell. \tag{4.1}$$

It is worth noting that P_i and S_{j-1} actually cover a text's substring containing all the occurrences ending in I_i, and $I_j I_{j+1} \dots I_{i-1}$ is the overlapping part between P_i and S_{j-1}. We use P_i and S_{j-1} to determine these occurrences. Since we shall prove that the sum of P_i's and S_{j-1}'s period lengths is upper bounded by 6ℓ, we want to have $p - 4\ell > 6\ell$ in (1). This makes sure that $|I_j I_{j+1} \dots I_{i-1}| > 6\ell$, and thus both P_i's and S_{j-1}'s periods occur in $I_j I_{j+1} \dots I_{i-1}$. We then apply Lemma 2.1 and find out that these periods are equal; because of this, we are able to determine all the occurrences in optimal time. Therefore, in order to guarantee that $p - 4\ell > 6\ell$ in (1), we define a long pattern to be of length $p > 10\ell$ (and so we set $c = 10$). In brief, a pattern is short if $p \leq 10\ell$, and GST_S stores strings at least $(c+4)\ell = 14\ell$ long. We work with P_i's and S_{j-1}'s periods whose total length is no more than 6ℓ. We use these constants to introduce our main data structures.

4.1. A data structure pool. We let $\mathcal{L} = \{I_1, \dots, I_k\}$, where $k = \Theta(\frac{n}{\ell})$ and $\ell \leq |I_i| < 2\ell$. There are also two dummy intervals $I_0 = I_{k+1}$ of length 14ℓ. Both I_0 and I_{k+1} are entirely made up of \$'s, where \$ does not occur in Σ. We define for each interval $I_i \in \mathcal{L}$:

- $string(I_i) = I_i \cdots I_{i+r}$, where r is the smallest integer such that $|I_i| + \cdots + |I_{i+r}| \geq 14\ell$ (we have $r \leq 14$).
- C_i is a set of two strings, called I_i's *cover*, which is made up of I_i's prefix and suffix of length ℓ. Since $\ell \leq |I_i| < 2\ell$, the two strings are *overlapping*.

- L_i is the suffix of $I_0 I_1 \cdots I_i$ of *length* 6ℓ and R_i is the prefix of $I_i \cdots I_k I_{k+1}$ of *length* 6ℓ.

Our data structure pool is made up of four main data structures $\{GST_S, GST_C, GST_L, GST_R\}$ and is maintained together with list $\mathcal{L}$. Let $P[1,p]$ be an arbitrary pattern to be queried in the pool. We define:

- GST_S is a generalized suffix tree for set $\Delta_S = \{string(I_1), \ldots, string(I_k)\}$. We perform the on-line search of short patterns in the strings of Δ_S by finding the pattern's extended locus in GST_S.
- GST_C is a generalized suffix tree for set $\Delta_C = \cup_{i=1}^{k} C_i$ (where each C_i is a set of two strings of the same length ℓ). We can perform on this set:
  - `Query-C(`P`)`: For all $X \in \Delta_C$, find a pattern substring (if it exists) equal to X, denoted by $SubEq(P, X)$.
- GST_R and GST_L are two *augmented* generalized suffix trees built on the strings in the set $\Delta_R = \{R_1, \ldots, R_k\}$ and on the *reversal* of the strings in the set $\Delta_L = \{L_1, \ldots, L_k\}$, respectively. We can perform on these sets:
  - `Query-R(`P`)`: For all $X \in \Delta_R$, find the pattern's *longest suffix* that is a *prefix* of X, denoted by $SufPref(P, X)$.
  - `Query-L(`P`)`: For all $X \in \Delta_L$, find the pattern's *longest prefix* that is a *suffix* of X, denoted by $PrefSuf(P, X)$.

Each data structure in the pool has $O(n)$ size and $O(\ell)$ depth, and the pool requires a total of optimal $O(n)$ space. It is not straightforward to implement the above queries because of the changes that can be performed on the GSTs in the pool by means of the following operations:

- Given a set $\Delta \in \{\Delta_S, \Delta_C, \Delta_L, \Delta_R\}$ and a string $Z[1,z]$, with $z = O(\ell)$, the operation `Add(`Z, Δ`)` (resp., `Remove(`Z, Δ`)`) adds string Z to (resp., removes it from) Δ and updates GST_Δ.

In section 5, we give a detailed description of the data structure pool along with a complexity analysis of their query and update operations.

4.2. Pattern searching. The algorithm listing all the occurrences (*occ*) of a pattern $P[1,p]$ in the current text T is outlined below, while a technical discussion of it can be found in section 6.

ALGORITHM `Find(`P`)`.

(1) If the pattern is short ($p \leq 10\ell$), then we find its extended locus in GST_S and list the distinct occurrences associated with the leaves descending from the locus. Otherwise the pattern is long ($p > 10\ell$) and we go on to steps (2) and (3).
(2) For all $i = 1, \ldots, k$, we find the pattern's *longest prefix* P_i that is a suffix of $I_1 \cdots I_{i-1}$ and the pattern's *longest suffix* S_i that is a prefix of $I_{i+1} \cdots I_k$. We proceed inductively by scanning list $\mathcal{L}$ from left to right for P_i and from right to left for S_i. We exploit the data structure pool and the fact that the length of each I_i varies from ℓ to 2ℓ (see section 6.1).
(3) For all $i = 1, \ldots, k$, we find the occurrences ending in I_i. We take prefix P_i and suffix S_{j-1} for some suitable $j < i$, such that P_i and S_{j-1} *overlap* for at least $p - 4\ell > 6\ell$ positions (see Fig. 4). More specifically:
   (3.1) We compute $n_i = \sum_{r=1}^{i-1} |I_r|$ for all i (where $n_1 = 0$). For each I_i, we find its *mate* interval I_j, such that j is the minimum integer satisfying $n_i - n_j < p - |I_i|$ (and so $n_i - n_j = |I_j \cdots I_{i-1}| > p - 4\ell$).
   (3.2) We list all the occurrences in $P_i I_i$ by deploying the large overlapping between P_i and S_{j-1}. Namely, we find the occurrences ending in I_i

and contained in the text substring covered by P_i and S_{j-1} when $|P_i|, |S_{j-1}| > n_i - n_j$. We do this by executing a procedure CPS which is described in section 6.2.

Algorithm `Find`'s correctness is illustrated in the following two cases.

If the pattern is short ($p \leq 10\ell$), then every occurrence is a substring of a $string(I_i) \in \Delta_S$, and so the pattern is found by using GST_S in step (1). Even though some occurrences might be listed more than once, each of them can appear no more than 14 times. Thus step (1) can be performed in $O(p + occ)$ time by using an uninitialized boolean vector for discarding all the multiple occurrences. (We do not discuss this case in the rest of the paper.)

If the pattern is long ($p > 10\ell$), then we use the other data structures (i.e., GST_C, GST_R, and GST_L). We scan $\mathcal{L}$ (see [20, 13, 14]) and deploy the bounded length of $\mathcal{L}$'s intervals. Let us now examine an occurrence *ending* in I_i. Its starting position is to the left of I_j because $n_i - n_j < p - |I_i|$ (see Fig. 4). We decompose this occurrence in two overlapping substrings $\hat{P}$ and $\hat{S}$, such that $\hat{P}$ is both a pattern prefix and a suffix of $I_1 \cdots I_{i-1}$, and $\hat{S}$ is both a pattern suffix and a prefix of $I_j \cdots I_k$. By definition, $\hat{P}$ must be a suffix of P_i and $\hat{S}$ must be a prefix of S_{j-1}. Therefore, the occurrence lies entirely within the text substring covered by P_i and S_{j-1} and hence is subsequently listed in step (3.2).

Remark 4.1. Step (2) requires $O(p + n)$ time when the KMP automaton [24] is used. We could obtain better time, i.e., $O(p + \frac{n}{\ell} \log p)$, if the border tree data structure [20] is used. In this paper, we drop the $O(\log p)$ factor by charging $O(1)$ time per character and $\mathcal{L}$'s interval. That is, we achieve $O(p + \ell + \frac{n}{\ell}) = O(p + \frac{n}{\ell})$ time because $p > 10\ell$ (see section 6.1). In this case, the solution is optimal.

Remark 4.2. We can implement step (3.2) in $O(h + p)$ time by simply checking all the candidate positions, where h is the total number of occurrences retrieved. We can obtain an exponential speed-up, i.e., $O(h + \log p)$ time (see [20]), by means of the border tree data structure using the pair (P_i, S_{i-1}). In this paper, we show how to use the pair (P_i, S_{j-1}) in order to drop the $O(\log p)$ factor and yield $\Theta(h+1)$ optimal time (see section 6.2).

In the rest of this paper, we show how to implement steps (2) and (3) *optimally* in $O(p + \frac{n}{\ell})$ and $O(p + \frac{n}{\ell} + occ)$ time in order to achieve our goal of answering `Find`(P) in optimal $O(p + occ)$ time. Indeed, by setting $\ell = \sqrt{n}$, we obtain $O(p + \sqrt{n} + occ)$ query time for a long pattern. Since $p > 10\ell = 10\sqrt{n}$, we achieve the following result.

THEOREM 4.3. *Searching for a pattern $P[1, p]$ in the text $T[1, n]$ requires optimal $O(p + occ)$ worst-case time, where occ is the total number of occurrences.*

4.3. Text updating. In this section, we describe the insertion of a string $Y[1, y]$ into the current text, from a high-level point of view. Our aim is to achieve a *sublinear* update time in the worst case (see section 7 for the technical discussion).

ALGORITHM `Insert`(Y).

(1) We scan $\mathcal{L}$ to find the interval I_i in which the string Y must be inserted to produce $X = I'\, Y\, I''$, where $I_i = I'\, I''$.

(2) We replace I_i with the intervals created from X as follows. We split X into $h = \lfloor \frac{|X|}{\ell} \rfloor = O(y/\ell + 1)$ intervals $I'_1, \ldots, I'_h$, such that $|I'_1| = \cdots = |I'_{h-1}| = \ell$ and $\ell \leq |I_h| < 2\ell$. Then we update $\mathcal{L}$ to obtain the new list $\mathcal{L} = I_1, \ldots, I_{i-1}, I'_1, \ldots, I'_h, I_{i+1}, \ldots, I_k$.

(3) We update the pool $\{GST_S, GST_C, GST_L, GST_R\}$ consistently. In particular, for each set $\Delta \in \{\Delta_S, \Delta_C, \Delta_L, \Delta_R\}$ we have to identify the strings to be deleted and the ones to be inserted because I_i is replaced by $I'_1, \ldots, I'_h$. This process

deletes all the strings in Δ overlapping I_i, and inserts (from scratch) the strings in Δ overlapping at least one of the $h = O(y/\ell + 1)$ new intervals $I'_1, \ldots, I'_h$. Since each interval has a length from ℓ to 2ℓ, the number of strings in Δ overlapping a given interval is a *constant* for all $\Delta \in \{\Delta_S, \Delta_C, \Delta_L, \Delta_R\}$: there are no more than 14 for Δ_S, 2 for Δ_C, 6 for Δ_L, and 6 for Δ_R. This implies that the total number of deleted strings is $O(1)$, while the number of inserted ones is $O(y/\ell+1)$, where each string has $O(\ell)$ length. The data structure pool updating is done by `Add` and `Remove` operations (defined in section 4.1).

We wish to point out that, even if $y < \ell$ and $\ell \leq |X| < 2\ell$, we must insert the whole new interval $I'_1 = X$ from scratch by updating the data structure pool in $O(\ell)$ time.

Deleting a string Y by Algorithm `Delete` is similar to Algorithm `Insert`. We scan $\mathcal{L}$ and remove its shortest sublist $\mathcal{L}'$ that denotes a text substring $I'YI''$. We then delete all the strings in Δ overlapping at least one interval of $\mathcal{L}'$, for each $\Delta \in \{\Delta_S, \Delta_C, \Delta_L, \Delta_R\}$. However, since we do not have to delete I' and I'', we insert them into T again as the string $I'I''$ (if not empty) by Algorithm `Insert` (note that $|I'| + |I''| < 4\ell$). The deletion process therefore removes $O(|\mathcal{L}'|) = O(y/\ell + 1)$ strings and inserts $O(1)$ strings of length $O(\ell)$, for each set $\Delta \in \{\Delta_S, \Delta_C, \Delta_R, \Delta_L\}$.

In the rest of the paper, we provide insertion and deletion procedures that require $O(y + \ell + \frac{n}{\ell})$ time in the worst case (see section 7). By setting $\ell = \sqrt{n}$ (as previously done in the `Find` operation) we obtain the bound we claimed.

THEOREM 4.4. *Inserting a string $Y[1, y]$ in (or deleting it from) $T[1, n]$ requires $O(y + \sqrt{n})$ worst-case time.*

5. Details about the data structure pool. The pool is composed of four main data structures $\{GST_S, GST_C, GST_L, GST_R\}$. In section 4.1, we saw that GST_S and GST_C are generalized suffix trees built on the strings in set $\Delta_S = \{string(I_1), \ldots, string(I_k)\}$ and set $\Delta_C = \cup_{i=1}^{k} C_i$, respectively (we remember that C_i is a set of two strings, namely, I_i's prefix and suffix of length ℓ).

The two other data structures GST_R and GST_L are built on the strings in $\Delta_R = \{R_1, \ldots, R_k\}$ and on the reversal of the strings in $\Delta_L = \{L_1, \ldots, L_k\}$, respectively. Since L_i is the suffix of $I_1 \cdots I_i$ having length 6ℓ, and R_i is the prefix of $I_i \cdots I_k$ having length 6ℓ, the depth of GST_L and GST_R is at most 6ℓ and the number of their nodes is $O(n)$. Although any two equal strings in Δ_L (resp., Δ_R) can share the same leaf in GST_L (resp., GST_R), they cannot be each other's prefix because they have the same length 6ℓ. In what follows, we explain only how to augment GST_R, bearing in mind that the same holds for GST_L.

The leaves of GST_R that only store the strings in Δ_R and not their proper suffixes are *marked*. Two dummy marked leaves (whose parent is the root) are always the leftmost and the rightmost ones in GST_R. A doubly linked list, DLL, maintains the marked leaves in left-to-right order, and its size satisfies $|DLL| \leq |\Delta_R| + 2 = O(\frac{n}{\ell})$. Each leaf f in DLL has an initially empty *push-list*(f) and an initially zero *pop-counter*(f) associated with it. Two pointers LM and RM are associated with all the nodes in GST_R. For a node u, if the leftmost and rightmost marked leaves (i.e., in DLL) descending from u exist, then they can be retrieved by $LM(u)$ and $RM(u)$, respectively. (If those leaves do not exist, then $LM(u) = RM(u) = nil$.) Moreover, the arc linking u to a child v is *marked* whenever v is an ancestor of a marked leaf.

We go on to describe the solution to the operations mentioned in section 4.1 (we recall that the query for GST_S is the ordinary suffix tree search [33]). We also use in our solutions the elegant *matching statistics* that have been presented by Chang and

Lawler [8] and Galil and Giancarlo [16]. They show that, for any given pattern $P[1,p]$, it is possible to build *on-line* two vectors, here called $LONGEST$ and $EXLOCUS$, such that $LONGEST[i]$ contains the *length* of the longest prefix of $P[i,p]$ whose *extended locus* is in GST_Δ, and $EXLOCUS[i]$ contains the pointer to this locus, for $1 \le i \le p$. The on-line computation of these vectors requires a total of $O(p)$ time and space, *provided that* GST_Δ is given.

5.1. Solution to `Query-C`. We now show how to find the pattern substring $SubEq(P,X)$ (if it exists) that is equal to X, for each $X \in \Delta_C$. We use vectors $LONGEST$ and $EXLOCUS$ (described above) computed for the whole pattern and GST_C in $O(p)$ time. The leaves storing the strings in Δ_C, all of length ℓ, can be easily distinguished from the leaves storing their proper suffixes because the latter are always shorter than ℓ. Moreover, no strings longer than ℓ are stored in GST_C. Therefore, if $LONGEST[i] = \ell$, we know that leaf $EXLOCUS[i]$ stores some strings from Δ_C that are equal to $P[i, i+\ell-1]$. Vice versa, if $LONGEST[i] < \ell$, then we can discard $EXLOCUS[i]$ because it points to the extended locus of a *proper* substring of some strings in Δ_C.

We proceed as follows to answer `Query-C`: for $i = 1, \ldots, p$, if $LONGEST[i] = \ell$, then we assign position i to leaf $EXLOCUS[i]$ (unless an integer $j < i$ has already been assigned). Then, for each leaf f having an assigned integer, say i, we retrieve all the strings X whose locus is f (we have $X \in \Delta_C$) and set $SubEq(P,X) := P[i, i+\ell-1]$. At the end, $SubEq(P,X)$ is set equal to the empty string for all the remaining strings $X \in \Delta_C$ that are not involved in the computation above.

LEMMA 5.1. `Query-C(P)` *can be correctly answered in* $O(p + \frac{n}{\ell})$ *time.*

Proof. Let X be a string stored in a leaf, say, f. We know that $X \in \Delta_C$ if and only if $|X| = \ell$. If an integer i is assigned to f, then, by definition of $EXLOCUS$ and $LONGEST$, we have $LONGEST[i] = \ell$. Therefore, $P[i, i+\ell-1]$ can be correctly taken as $SubEq(P,X)$. If an integer is not assigned to f, then either $X \notin \Delta_C$ (because $|X| < \ell$) or $X \in \Delta_C$ and it does not occur in P. The computation of both vectors requires $O(p)$ time [8], and there are $O(\frac{n}{\ell})$ strings in the leaves having an assigned integer (we recall that $|DLL| = O(\frac{n}{\ell})$). □

`Query-C` is particularly useful for performing constant-time comparisons between an interval I_i and a pattern substring, say $P[j, j+|I_i|-1]$. If they are not identical, the computation returns their *longest common prefix* (LCP) in $O(1)$ time. Indeed, let C_i be I_i's cover, given by its prefix I' and its suffix I'' of length ℓ. If either $SubEq(P,I')$ or $SubEq(P,I'')$ is empty, then $I_i \neq P[j, j+|I_i|-1]$. Otherwise, $I_i = P[j, j+|I_i|-1]$ if and only if $SubEq(P,I') = P[j, j+\ell-1]$ and $SubEq(P,I'') = P[j+|I_i|-\ell, j+|I_i|-1]$. These two checks can be performed in constant time through two LCA queries on the suffix tree ST_P (see section 2). If we fail (i.e., $I_i \neq P[j, j+|I_i|-1]$), then we obtain the LCP's length in $O(1)$ time. From now on we refer to that computation as *LCP query*.

5.2. Solution to `Query-R` and `Query-L`. We now show how to find the pattern's *longest suffix* $SufPref(P,X)$ that is a *prefix* of X, for each $X \in \Delta_R$. We take the string $P[p-6\ell+1, p]$ and compute $LONGEST[i]$ and $EXLOCUS[i]$ for all i, such that $p-6\ell+1 \le i \le p$, by Chang and Lawler's algorithm [8] performed on GST_R. (Since $|X| = 6\ell$ for each $X \in \Delta_R$, we only deal with pattern suffixes not longer than 6ℓ.) We then select the set EXN of *distinct* nodes from $EXLOCUS[p-6\ell+1, p]$, such that they are extended loci of *at least one suffix* of $P[p-6\ell+1, p]$. This constraint can be easily verified by checking whether or not $LONGEST[i] = p-i+1$. After that, we associate the position $pos(u) = \min\{i \in [p-6\ell+1, p] : u = EXLOCUS[i]$ and $LONGEST[i] =$

$p-i+1\}$ with each node $u \in EXN$. That is, $pos(u)$ corresponds to the longest suffix of $P[p-6\ell+1, p]$ whose extended locus is u. Finally, the nodes $u \in EXN$ are sorted in *increasing order* according to their $pos(u)$ values. The whole computation is performed in $O(\ell)$ time by scanning $EXLOCUS[p-6\ell+1, p]$ from left to right.

LEMMA 5.2. *Let f be the leaf of GST_R storing a string $X \in \Delta_R$. We have SufPref$(P, X) = P[i, p]$ if and only if $i = pos(u)$ where u is the first of f's ancestors encountered in a left-to-right scan of the sorted set EXN.*

Proof. If $P[i, p]$ is the longest suffix giving SufPref(P, X), then $P[i, p]$'s extended locus is an ancestor of f, say v, which belongs to EXN. Since v is the deepest of f's ancestors having this property, v must be the first node in EXN that is an ancestor of f. We therefore have that $v = u$ and $pos(u) = i$. Conversely, since $i = pos(u)$ and u is an ancestor of f, we infer that $P[i, p]$ is definitely a prefix of X (by the suffix tree's properties). Since u is the first (i.e., deepest) of f's ancestors in EXN, no suffix $P[j, p]$, with $j < i$, can be a prefix of X. Otherwise, $v = EXLOCUS[j]$ would be an ancestor of f with $pos(v) < i$, and so v should occur before u in the sorted EXN, which contradicts our hypothesis. In conclusion, $P[i, p] =$ SufPref(P, X). □

As far as answering `Query-R` is concerned, we only have to apply Lemma 5.2 to the leaves in GST_R that belong to DLL (they store the strings in Δ_R). Since GST_R contains $O(n)$ nodes and has $O(\ell)$ depth, we cannot compute the deepest ancestor in EXN of each leaf in DLL by traversing the tree upwards because it would require $O(|DLL| \cdot \ell)$ time. Instead, we *simulate* this traversal in optimal $O(|DLL|) = O(\frac{n}{\ell})$ time as follows.

We read the *sorted* set EXN from left to right. For each node $u \in EXN$, such that $LM(u), RM(u) \in DLL$, we update the *push-list* in $LM(u)$ and the *pop-counter* in $RM(u)$, as follows: we append $pos(u)$ to the beginning of the *push-list* in $LM(u)$ and increment the *pop-counter* in $RM(u)$. It is worth noting that for any two nodes in EXN, one of which is the other's ancestor, the deepest one is examined first (due to EXN's ordering).

Next, we scan DLL from left to right by means of a stack S. When processing a leaf $f \in DLL$, we push all the elements contained in *push-list*(f) into S (unless *push-list*(f) is empty). We then set SufPref$(P, X) = P[i, p]$ for all $X \in \Delta_R$ stored in f, where i is the integer currently at the top of S (unless S is empty). We execute a pop operation on S for *pop-counter*(f) times, and then go on scanning DLL. At the end, *push-list*(f) and *pop-counter*(f) are reset.

`Query-L` is symmetrical to `Query-R` because PrefSuf$(P, X) =$ SufPref(P^R, X^R). Therefore, we can manage this case by computing $LONGEST$ and $EXLOCUS$ for string $P[1, 6\ell]$'s reversal.

LEMMA 5.3. `Query-L(`P`)` *and* `Query-R(`P`)` *can be correctly answered in $O(\ell + \frac{n}{\ell})$ time.*

Proof. The time complexity readily derives from the preceding considerations. As a matter of fact, we spend $O(\ell)$ time to compute vectors $EXLOCUS$ and $LONGEST$ for $P[p-6\ell+1, p]$, and $O(\frac{n}{\ell})$ time to scan list DLL and vector EXN. We prove the correctness by means of Lemma 5.2 and EXN's ordering. The strategy adopted for setting *push-list*(l) and *pop-counter*(l) (where $l = LM(u)$ or $l = RM(u)$ for $u \in EXN$) allows our simulation to yield the following implicit parenthesis representation of EXN's nodes and DLL's leaves.

We start out with a standard parenthesis representation for trees (e.g., the Euler tour) and apply it to GST_Δ, where $\Delta \in \{\Delta_R, \Delta_L\}$. We cancel all parentheses not corresponding to nodes in EXN or leaves in DLL. The resulting list is still well

balanced. The *nearest pair* of parentheses *enclosing* the pair associated with a leaf $f \in DLL$ corresponds to its deepest ancestor belonging to EXN. We cannot apply this approach directly because its cost would be proportional to GST_Δ's size, i.e., $O(n)$. Consequently, we only deal with the leaves $l \in DLL$ and obtain a construction in $O(\frac{n}{\ell})$ time. Let us assume that $u, v \in EXN$ exist such that $LM(u) = LM(v) = f$, for some $f \in DLL$ (the case of $RM(u) = RM(v) = f$ is simpler). Therefore, u and v must be each other's ancestor, say u ancestor of v. Due to EXN's ordering, v is visited before u in EXN and thus $pos(v)$ is put into the *push-list*(f) before $pos(u)$. Therefore, the *pos*-values associated with each *push-list* maintain the correct nesting of the corresponding parentheses in the Euler tour of GST_Δ. This means that, for every $f \in DLL$, the *pos*-values in *push-list*(f) are in decreasing order (i.e., by their increasing suffix length). Moreover, the counter *pop-counter*(f) is used for balancing the left parentheses with their matching (right) ones.

Let us now assume that $X \in \Delta_R$ is stored in leaf $f \in DLL$. If *push-list*(f) is not empty, the *last* integer i in *push-list*(f) corresponds to the nearest pair of parentheses enclosing f. As a result, this pair of parentheses corresponds, in turn, to the longest suffix $P[i, p]$ that is a prefix of X, as stated by Lemma 5.2. Indeed, integer i is the *pos*-value associated with the first (i.e., deepest) of f's ancestors encountered in EXN. We have that integer i is at the top of S when processing f (because it is the last item in *push-list*(f)). If *push-list*(f) is empty, then none of f's ancestors are in EXN. In brief, since the parentheses are balanced, we always correctly find the integer i associated with the nearest pair of parentheses enclosing the ones for f at the top of S (i.e., the deepest of f's ancestors in EXN). □

5.3. Solution to `Add` and `Remove`. Given a set $\Delta \in \{\Delta_S, \Delta_C, \Delta_L, \Delta_R\}$ and a string $Z[1, z]$, with $z = O(\ell)$, we recall that the operation `Add`(Z, Δ) (resp., `Remove`(Z, Δ)) adds string Z to (resp., removes it from) Δ and updates GST_Δ.

If $\Delta = \Delta_S$ (with $z \leq 14\ell$) or $\Delta = \Delta_C$ (with $z = \ell$), we only have to use the algorithms in [2], which require $O(\ell)$ time. We now discuss only `Add`(Z, Δ_R) without any loss in generality (with $z = 6\ell$). Let Z be a string of length 6ℓ to be added to Δ_R. We insert all of Z's suffixes into GST_R in $O(\ell)$ time by using the algorithm in [2]. Each inserted suffix $Z[i, 6\ell]$ is associated with its locus, namely leaf f_i, for $i = 1, \ldots, 6\ell$. If f_i already exists, then we only have to append $Z[i, 6\ell]$ to the list of (equal) strings associated with f_i. Otherwise, we create f_i and possibly its parent $p(f_i)$. We then update DLL, LM, RM, and the marks in GST_R as follows.

The first suffix (i.e., Z itself) is handled differently from the others. Let Π be the leaf-to-root path from f_1 in GST_R, immediately after the insertion of $Z[1, 6\ell] = Z$. We insert f_1 into the doubly-linked list DLL (because $Z \in \Delta_R$) by finding f_1's predecessor in DLL. We do this by applying a brute-force algorithm that exploits the fact that GST_R cannot be deeper than 6ℓ. Indeed, we go upwards in Π until we reach the deepest node u having an outgoing marked arc to the left of Π. In this case, we follow u's rightmost outgoing marked arc that is to the left of Π and thus we reach a child v. We then insert f_1 into DLL right after $RM(v)$ and update the bi-directional links properly. The insertion of $Z[1, 6\ell]$ into DLL leads to rearranging the pointers LM and RM of some nodes in Π and setting the marks in all of Π's arcs. Finally, we create and initialize *push-list*(f_1) and *pop-counter*(f_1). The overall cost is proportional to GST_R's depth, i.e., $O(\ell)$.

Any other proper suffix $Z[i, 6\ell]$, with $i > 1$, is handled in a simpler way and takes $O(1)$ time each. The pointers LM and RM and the marks associated with the arcs in GST_R do not need to be updated because $Z[i, 6\ell]$ is not inserted into DLL. If

leaf f_i is created, then we set $LM(f_i) = RM(f_i) = nil$. If $p(f_i)$ is also created (by splitting a GST_R's arc), then it can only have two children, namely f_i and another node, say v. The pointers LM and RM in $p(f_i)$ are set equal to v's because $f_i \notin DLL$. If $LM(v), RM(v) \neq nil$, then the arc from $p(f_i)$ to v is marked. (In this case, the arc connecting $p(f_i)$ to its parent has already been marked.) We can now state the following result.

LEMMA 5.4. *Given* $\Delta \in \{\Delta_S, \Delta_C, \Delta_R, \Delta_L\}$ *and a string* Z *of length* $O(\ell)$, `Add(`Z, Δ`)` *and* `Remove(`Z, Δ`)` *can be executed in* $O(\ell)$ *time.*

6. `Find` implementation. We only discuss steps (2) and (3) because step (1) was already described in section 4.2.

6.1. Step (2) of the `Find` algorithm. We remember that we want to compute the pattern's longest prefix P_i that is a suffix of $I_1 \cdots I_{i-1}$ for every $i = 1, \ldots, k$, with $k = \Theta(\frac{n}{\ell})$. (Since finding S_i is symmetrical, we do not discuss it here.) We present a solution requiring $O(p + \ell + \frac{n}{\ell})$ time.

Preprocessing. We execute `Query-L(`P`)` in $O(\ell + \frac{n}{\ell})$ time (Lemma 5.3) in order to compute the pattern's longest prefix *PrefSuf*(P, L_i) that is a suffix of L_i, for all $i = 1, \ldots, k-1$ (see section 4.1 for the definition of L_i). Since $|L_i| = 6\ell$, we have $|\textit{PrefSuf}(P, L_i)| \leq 6\ell$. We also execute `Query-C(`$P$`)` in $O(\ell + \frac{n}{\ell})$ time (Lemma 5.1). We then build the pattern's suffix tree ST_P and preprocess it for handling LCA queries [22, 31] in order to obtain constant-time LCP queries between an interval I_i and a pattern substring (see section 5.1). Finally, we compute the periods of all pattern prefixes in $O(p)$ time by using the algorithm described in [24] (see section 2).

Assuming that P_i has already been found correctly (by induction on $i = 1, \ldots, k-1$, where P_1 is the empty string), we find P_{i+1} in the form of the pattern's longest prefix that is a suffix of $P_i I_i$. We know that P_{i+1} cannot be longer than $P_i I_i$ because otherwise we would have determined a longer P_i. We begin by introducing a simple solution called Algorithm *Naive*.

We check to see if $P_i I_i$ is a pattern prefix by means of an LCP query on I_i and $P[|P_i| + 1, |P_i| + |I_i|]$. If the answer is that the latter two strings are equal, then we set $P_{i+1} := P_i I_i$. Otherwise, we use the *Shift* function in order to examine P_i's borders according to their decreasing lengths (see section 2): we set $P'_i := P_i$ and repeat $P'_i := \textit{Shift}(P'_i)$ until either $P'_i I_i$ is a pattern prefix and $|P'_i| + |I_i| > 6\ell$ or we find $|P'_i| + |I_i| \leq 6\ell$. In the former case, we perform the check in constant time by first making an LCP query that compares I_i to $P[|P'_i| + 1, |P'_i| + |I_i|]$ and then by setting $P_{i+1} := P'_i I_i$ (whenever the LCP query is successful); in the latter case, we set $P_{i+1} := \textit{PrefSuf}(P, L_i)$.

As far as Algorithm *Naive*'s correctness is concerned, we let X denote string concatenation $P'_i I_i$ and assume that X is *not* a pattern prefix. We maintain the invariant that P_{i+1} is a suffix of X by considering two cases. (1) If $|X| > 6\ell$, then P_{i+1}'s prefix (having length $|P_{i+1}| - |I_i| \geq 0$, if it exists) must be a border of P'_i. Thus we can safely take the *longest* border *Shift*(P'_i) to maintain the invariant and continue the computation. (2) If $|X| \leq 6\ell$, then we can correctly set $P_{i+1} := \textit{PrefSuf}(P, L_i)$ because $|P_{i+1}| \leq 6\ell$ (by the invariant). Algorithm *Naive*'s complexity is $O(p + n)$ time because *Shift* is executed for $O(n)$ times in the worst case.

Algorithm *Naive* is inefficient when $|X| > 6\ell$ (and so $|P'_i| \geq 4\ell$) because we can call function *Shift* many times. We let $m = |P'_i| - |\textit{Shift}(P'_i)|$ be the number of characters that are skipped in a *Shift* call. It is worth noting that $m \geq 2\ell$ can occur a total of $O(\frac{n}{m}) = O(\frac{n}{\ell})$ times and so we can pay for its computational cost (this figure appears in the time complexity that we want to obtain in this step). Therefore,

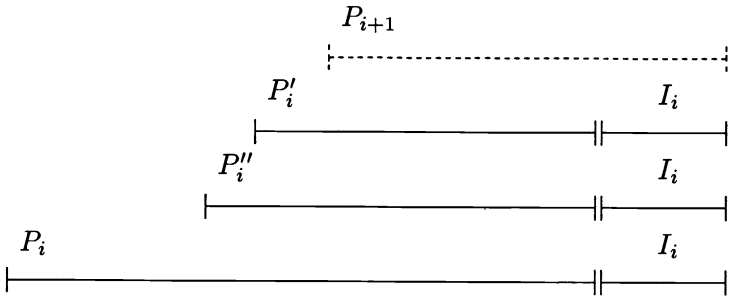

FIG. 5. *The invariant on pattern prefixes P''_i and P'_i.*

$m < 2\ell$ turns out to be Algorithm *Naive*'s most expensive case to deal with. Further on in this paper we prove that, if $|X| > 6\ell$ and $m < 2\ell$, then the period of P'_i is shorter than 2ℓ (i.e., the intervals' maximum length). Hence, we obtain a faster algorithm by exploiting these properties.

We let π denote *the* period of P'_i, such that $|\pi| < 2\ell$, and let P'_i be in the form of $\pi^r\pi'$ for some integer $r \geq 1$. Every border of P'_i has π as *a* period. By examining the borders longer than, or equal to, 4ℓ (by means of some *Shift* calls), we obtain the stronger property that π is actually *the* period of these borders.

LEMMA 6.1. *Every border of P'_i longer than, or equal to, 4ℓ is in the form of $\pi^j\pi'$ for some $j \leq r$ (where $P'_i = \pi^r\pi'$ and $|\pi| < 2\ell$).*

Proof. We take a border $P[1, s]$ of P'_i, with $s \geq 4\ell$, and let $P[1, z]$ be the shortest prefix of P'_i that is in the form $\pi^j\pi'$ (for some $j \leq r$) and contains $P[1, s]$ as prefix (i.e., $z \geq s$ and $z - |\pi| < s$). Our aim is to prove that $z = s$. Let us assume that $z > s$ by way of contradiction. Since both $P[1, z]$ and $P[1, s]$ are borders of P'_i, we deduce that $P[1, s]$ is a suffix of $P[1, z]$. Therefore, $P[1, z - s]$ is a period of $P[1, z]$. Since $z - s < |\pi|$, we have $|\pi| + (z - s) < 2|\pi| < 4\ell \leq z$ and so we can apply Lemma 2.1 to periods π and $P[1, z - s]$ in order to state that $\hat{\pi} = P[1, gcd(|\pi|, z - s)]$ is also a period of $P[1, z]$, where $|\hat{\pi}| < |\pi|$. However, $|\hat{\pi}|$ divides $|\pi|$ and so $\hat{\pi}$ is *shorter* than π, and this contradicts the fact that π is the period of P'_i. Consequently, we must have $s = z$ and the lemma follows because π is thus the period of $P[1, s]$. □

Lemma 6.1 implies that the borders of P'_i longer than, or equal to, 4ℓ are shifted over P'_i by a *multiple* of $|\pi|$ positions. This proves Corollary 6.2, which provides us with a necessary condition for characterizing the candidates for being P_{i+1} (we only deal with the ones longer than 6ℓ).

COROLLARY 6.2. *Let us take a suffix of $X = P'_iI_i$ longer than 6ℓ that is also a pattern prefix, say $P[1, s + |I_i|]$ with $s \geq 4\ell$. We have: $P[1, s]$ is a border of P'_i and its period is π; therefore, $P[1, s + |I_i|]$ is shifted over X by a* multiple *of $|\pi|$ positions.*

By using Lemma 6.1 and Corollary 6.2, and since $\ell \leq |I_i| < 2\ell$, we are able to simulate Algorithm *Naive*'s ith step more efficiently. We maintain two prefixes P''_i, P'_i of P_i under the following invariant (see Fig. 5):

- P''_i, P'_i are P_i's borders, such that $|P''_i| \geq |P'_i|$ and $|P'_i| + |I_i| \geq |P_{i+1}|$ (i.e., P_{i+1} is a suffix of $X = P'_iI_i$).

The invariant initially holds for $P''_1 = P'_1 = P_1 = \epsilon$, where ϵ denotes the empty string. We illustrate the ith inductive step in detail below and use the macro "`Output(`Y`)`" for the following sequence of instructions: "if $|Y| > 6\ell$ then $P_{i+1} := Y$

else $P_{i+1} := \mathit{PrefSuf}(P, L_i)$; $P''_{i+1} := P'_{i+1} := P_{i+1}$; repeat the case analysis for $i := i + 1$."

STEP(i): CASE ANALYSIS.

(1) We let $X = P'_i I_i$. If X is a pattern prefix, then we execute `Output(`X`)`.
(2) If X is *not* a pattern prefix, then we set $P''_i := P'_i$ and $P'_i := \mathit{Shift}(P'_i)$ (and so $|P''_i| > |P'_i|$). We let X denote the new string concatenation $P'_i I_i$. Three cases follow from this:
  (2.1) Case $|X| \leq 6\ell$. Since we have $|P_{i+1}| \leq 6\ell$ by the invariant, we execute `Output(`ϵ`)`.
  (2.2) Case $|X| > 6\ell$ and $|P''_i| - |P'_i| \geq 2\ell$. Since we have a shift of at least 2ℓ positions (i.e., more than the intervals' maximum length), we can repeat the case analysis (1)–(2).
  (2.3) Case $|X| > 6\ell$ and $|P''_i| - |P'_i| < 2\ell$. We let π be the period of P'_i (we show that $|\pi| < 2\ell$ in Lemma 6.3's proof). We write X in the form of $\pi^q\alpha$ and P in the form of $\pi^t\beta$, where π is not a prefix of α and β and so q and t are maximum.
    (2.3.1) If X has period π (i.e., α is a prefix of π) and $q < t$, then we execute `Output(`X`)`.
    (2.3.2) If X has period π and $q \geq t$, then we check to see if α is a prefix of β. If so, then we execute `Output(`$\pi^t\alpha$`)`; otherwise, we execute `Output(`$\pi^{t-1}\alpha$`)`.
    (2.3.3) If X does not have period π and $q < t$, then we execute `Output(`ϵ`)` (we show that $|P_{i+1}| \leq 6\ell$ in Lemma 6.3's proof).
    (2.3.4) If X does not have period π and $q \geq t$, then we check to see if α is a prefix of β. If so, then we execute `Output(`$\pi^t\alpha$`)`; otherwise, we execute `Output(`ϵ`)` (we show that $|P_{i+1}| \leq 6\ell$ in Lemma 6.3's proof).

LEMMA 6.3. *The case analysis in Step(i) correctly finds P_{i+1}.*

Proof. We prove that the preceding case analysis in Step(i) correctly simulates Algorithm *Naive*'s ith step. We assume that we have already found P_i (the basis trivially holds). By the invariant, P_{i+1} is a suffix of $P'_i I_i$. In Case 1, we check to see if $P_{i+1} = P'_i I_i$. If the check fails, then we go to case (2) and examine P'_i and its largest border $\mathit{Shift}(P'_i)$ (as in Algorithm *Naive*). Cases (2.1) and (2.2) closely follow Algorithm *Naive* when we test condition $|P'_i| + |I_i| \leq 6\ell$ and execute one loop step (for $|P''_i| - |P'_i| \geq 2\ell$), respectively, and so we do not go into their details.

Vice versa, we deal with case (2.3) in detail because it occurs when less than 2ℓ characters are skipped by calling $\mathit{Shift}(P'_i)$ (we recall that this was Algorithm *Naive*'s most expensive case). This readily implies that the period of P'_i is shorter than 2ℓ, and hence the period of $\mathit{Shift}(P'_i)$ is also shorter than 2ℓ. Since we previously set $P''_i := P'_i$ and $P'_i := \mathit{Shift}(P'_i)$, we let π be the period of the new P'_i, with $|\pi| < 2\ell$, and X be the new string concatenation $P'_i I_i$. We also have $X = \pi^q\alpha$ and $P = \pi^t\beta$, such that q and t are maximum (i.e., π^{q+1} is not a prefix of X and π^{t+1} is not a prefix of P). It is worth noting that $q, t \geq 2$ because P'_i is a prefix of both X and P and $|P'_i| \geq 4\ell$.

The rationale in case (2.3) is that either P_{i+1} is in the form of $\pi^j\alpha$ for an integer j (when it is longer than 6ℓ) or $P_{i+1} = \mathit{PrefSuf}(P, L_i)$ (when it is not longer than 6ℓ). We therefore show that determining P_{i+1} amounts to executing `Output(`$\hat{P}$`)` for a string $\hat{P}$ defined as follows: let j be the *largest* integer, such that $\pi^j\alpha$ is both a pattern *prefix* and one of X's *suffixes*, with $0 \leq j \leq q$. If such a j exists, then we

take $\hat{P} = \pi^j\alpha$; otherwise, we set $\hat{P} = \epsilon$. We first prove that P_{i+1} is the pattern prefix returned by `Output`$(\hat{P})$, and then we show how to compute $\hat{P}$. Two cases follow.

• If $|P_{i+1}| > 6\ell$, then P_{i+1} must be shifted over X by a multiple of $|\pi|$ positions (Corollary 6.2). Since $\hat{P} = \pi^j\alpha$ is also shifted over X by a multiple of $|\pi|$ positions and is the longest pattern prefix having this property, we deduce that $P_{i+1} = \hat{P}$ (which is the string returned by `Output`$(\hat{P})$ because it is longer than 6ℓ).

• If $|P_{i+1}| \leq 6\ell$, then $\hat{P}$ is a (maybe empty) border of P_{i+1}, and so $|\hat{P}| \leq |P_{i+1}| \leq 6\ell$. Consequently, `Output`$(\hat{P})$ returns $\mathit{PrefSuf}(P, L_i)$, which is P_{i+1} by Lemma 5.3.

The crucial point in the rest of this proof is to show that cases (2.3.1)–(2.3.4) actually find $\hat{P}$. We distinguish two main cases: X has period π (cases (2.3.1)–(2.3.2)) or X does not have period π (cases (2.3.3)–(2.3.4)).

Let us examine X having period π. We deduce that α is a (maybe empty) prefix of π. In case (2.3.1), the whole string X is a pattern prefix and so $\hat{P} = X$ (and we have $j = q$). In case (2.3.2), when α is β's prefix, $\pi^t\alpha$ is a pattern prefix. We choose $\hat{P} = \pi^t\alpha$ (and so $j = t$) because π^{t+1} cannot be a pattern prefix. When α is not β's prefix, we know that α is π's prefix (since X is periodic) and thus $\pi^{t-1}\alpha$ is a prefix of π^t (and so it is a pattern prefix). We choose $\hat{P} = \pi^{t-1}\alpha$ (and so $j = t-1$) because $\pi^t\alpha$ is not a pattern prefix.

Let us now examine X not having period π. We deduce that α and π cannot be each other's prefix. In case (2.3.3), P_{i+1} is not longer than 6ℓ. The proof is obtained by contradiction. If P_{i+1} were longer than 6ℓ, then we could apply Corollary 6.2 to it and find out that P_{i+1} is shifted over X by a multiple of $|\pi|$ positions and is in the form of $\pi^h\alpha$ for some $h \leq q < t$. Since both $P_{i+1} = \pi^h\alpha$ and π^{h+1} would be pattern prefixes (because $h+1 \leq t$), we would have the contradiction that either α is a prefix of π or vice versa. Therefore, P_{i+1} has length 6ℓ at most and cannot be in the form of $\pi^h\alpha$ for any h. In our case analysis, we choose $\hat{P} = \epsilon$; consequently, `Output`$(\hat{P})$ returns $\mathit{PrefSuf}(P, L_i)$, which is P_{i+1}. In case (2.3.4), when α is β's prefix, $\pi^t\alpha$ is a pattern prefix and X's suffix (because $q \geq t$). Since π^{t+1} cannot be a pattern prefix, we choose $\hat{P} = \pi^t\alpha$ (and so $j = t$) and `Output`$(\hat{P})$ returns P_{i+1}. When α is not β's prefix, we can prove $|P_{i+1}| \leq 6\ell$ by following the proof in case (2.3.3). By contradiction, if P_{i+1} were longer than 6ℓ, then we could apply Corollary 6.2 to it and find out that P_{i+1} is shifted over X by a multiple of $|\pi|$ positions and is in the form of $\pi^h\alpha$ for some integer h. We cannot have $h = t$ because $\pi^t\alpha$ would be a pattern prefix and α would be β's prefix. We cannot have $h > t$ because π^{t+1} cannot be a pattern prefix. Finally, we cannot have $h < t$ because both π^{h+1} and $\pi^h\alpha$ would be pattern prefixes and this would imply that either α is a prefix of π or vice versa. As a result, P_{i+1} has length 6ℓ at most and cannot be in the form of $\pi^h\alpha$ for any h. In our case analysis, we choose $\hat{P} = \epsilon$; consequently, `Output`$(\hat{P})$ returns $\mathit{PrefSuf}(P, L_i)$, which is P_{i+1}.

Summarizing our results, we can say that `Output`$(\hat{P})$ always computes P_{i+1} in the case analysis. Since the invariant is maintained for Step$(i+1)$, the correctness proof follows. □

The efficient implementation of Step(i) requires some further comments. In case (1), we can verify that $X = P'_iI_i$ is a pattern prefix in constant time by means of an LCP query on I_i and $P[|P'_i|+1, |P'_i|+|I_i|]$ (see section 5). In cases (2.3.1)–(2.3.4), we do the following. We know that P'_i is in the form of $\pi^r\pi'$ after pattern preprocessing and $r \geq 2$ because $|\pi| < 2\ell$ and $|P'_i| \geq 4\ell$. This allows us to find out if X has period π in constant time: X has period π if and only if I_i occurs in P at position $|\pi'|+1$ (i.e., I_i extends the periodicity of P'_i and this can be checked by an LCP

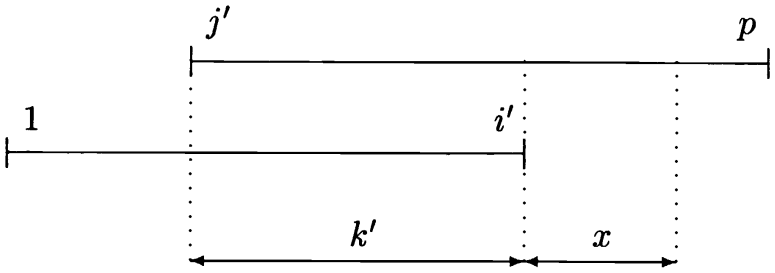

FIG. 6. *The constrained prefix-suffix problem.*

query). We also need to compare q to t in constant time. By an LCP query, we can compute integer q, such that X is in the form of $\pi^q\alpha$. We compute t by performing an LCP query on P and $P[|\pi|+1, p]$.

LEMMA 6.4. *For every $i = 1, \ldots, k$, a total of $O(p + \ell + \frac{n}{\ell})$ time is required for finding the pattern's longest prefix P_i that is a suffix of $I_1 \cdots I_{i-1}$, and the pattern's longest suffix S_i that is a prefix of $I_{i+1} \cdots I_k$.*

Proof. The correctness follows by applying Lemma 6.3 to all the inductive steps. As far as the time complexity is concerned, the preprocessing phase consists of answering `Query-C(`P`)` in $O(p+\frac{n}{\ell})$ time (see Lemma 5.1). Moreover, we execute `Query-L(`P`)` and `Query-R(`P`)` in $O(\ell + \frac{n}{\ell})$ time (see Lemma 5.3). We take $O(p)$ time to build and preprocess ST_P for LCA queries [22, 31]. At a generic step (i), all cases cost $O(1)$ time. Only case (2.2) makes us repeat the case analysis; all other cases give an answer and terminate the computation for the ith step. Therefore, either we perform a shift of at least 2ℓ text positions (case (2.2)) or we find P_{i+1} and increment i in $O(1)$ time (all the other cases). Since $|T| = n$, we perform $O(\frac{n}{\ell})$ shifts at most and increment i for no more than $k = O(\frac{n}{\ell})$ times to visit all of $\mathcal{L}$'s intervals. Therefore, our case analysis takes $O(\frac{n}{\ell})$ time. □

Remark 6.5. It is possible to modify the case analysis of Step(i) to solve the prefix-substring problem [20] in $O(\log p)$ time without using the border tree. The details are left to the reader.

6.2. Step (3) of the `Find` algorithm. As previously mentioned, we want to determine all the occurrences ending at a position inside a given interval I_i. In step (3) (where $p > 10\ell$; see section 4.2), we therefore examined the occurrences in the text substring covered by P_i and S_{j-1}. This computation can be formalized as follows. Given a pattern prefix $P[1, i']$ and a pattern suffix $P[j', p]$, where $1 \le j' \le i' \le p$, the prefix-suffix problem defined in [20] requires us to find all the occurrences in the string concatenation $P[1, i']P[j', p]$. We introduce here a variant of this problem (see Fig. 6) called *constrained prefix-suffix problem* and defined for:

1. two positions i', j', where $1 \le j' \le i' \le p$;
2. an integer $k' > p - 4\ell$, such that $P[i' - k' + 1, i'] = P[j', j' + k' - 1]$ (we have $k' > 6\ell$ because $p > 10\ell$);
3. an interval length x, with $\ell \le x < 2\ell$.

We provide an algorithm $CPS(i', j', k', x)$ to answer the following query: determine all the occurrences in the string $P[1, i']P[j' + k', j' + k' + x - 1]$ obtained by concatenating $P[1, i']$ and one of $P[j', p]$'s substrings of length x. Substep (3.2) in Algorithm `Find` is performed by calling $CPS(i', j', k', x)$ with parameters $i' = |P_i|, j' = p - |S_{j-1}| + 1, k' = n_i - n_j$, and $x = |I_i|$.

We now introduce the following notation regarding $CPS(i', j', k', x)$. We write $P[1, i']$ in the form of $\pi_1^r \pi_1'$ and $P[j', p]$ in the form of $\pi_2^q \pi_2'$ (where π_1 is *the* period of $P[1, i']$, π_2 is *the* period of $P[j', p]$, and π_1', π_2' are prefixes of π_1, π_2, respectively). We indicate the pattern period by π. We go on to prove some properties that are crucial for achieving optimality; they apply to a *long* string $Z = P[1, i']P[j' + k', p]$, with $|Z| > p$.

LEMMA 6.6. *If P occurs in $Z = P[1, i']P[j' + k', p]$ starting at a position in $P[2, i' - k']$ and ending at a position in $P[j' + k', j' + k' + x - 2]$, then $|\pi_1| = |\pi_2| < x < 2\ell$.*

Proof. We let $P' = P[1, i']$ and $S' = P[j', p]$ and assume that there is at least one such occurrence. Since this occurrence starts at $P[2, i' - k']$ and ends in $P[j' + k', j' + k' + x - 2]$, we can consider it a string concatenation $P[1, s]P[s + 1, p]$ (where $s \leq i'$ and $s + x > p$). We deduce that $P'' = P[1, s]$ is a proper suffix of P', and $S'' = P[s - k' + 1, p]$ is a proper prefix of S' (see Fig. 7). Moreover, by letting $K = P[j', j' + k' - 1] = P[i' - k' + 1, i']$ (see point 2), we have $K = P[s - k' + 1, s]$.

We first prove $|\pi_1| < x < 2\ell$ and $|\pi_2| < 4\ell$. By using point 3 and inequality $s + x > p$, we have $i' - s \leq p - s < x < 2\ell$. Since P'' is a border of P', we deduce that $P[1, i' - s]$ is *a period* of P'. By definition, π_1 is the shortest period of P' and so $|\pi_1| \leq i' - s < x < 2\ell$. Furthermore, K is a prefix of both S' and S''. Consequently, the same argument used for π_1 gives us $|\pi_2| < 4\ell$ because $|\pi_2| \leq |S'| - |S''| = s - j' + 1 - k' \leq p - k' < 4\ell$ (by point 2).

We then prove $|\pi_1| = |\pi_2|$. By contradiction, let us assume that $|\pi_1| < |\pi_2|$ (the other case, $|\pi_1| > |\pi_2|$, is similar). K is a suffix of P' and a prefix of S', where $|K| > 6\ell$ by point 2. Let $\hat{\pi}_1$ be K's prefix having length $|\pi_1|$ (i.e., $\hat{\pi}_1 = P[i' - k' + 1, i' - k' + |\pi_1|]$ is a cyclic shift of π_1's characters). According to Fact 2.2, $\hat{\pi}_1$ and π_2 are both K's periods. Moreover, $|\hat{\pi}_1| + |\pi_2| < 6\ell < k' = |K|$. Therefore, by applying Lemma 2.1 to periods $\hat{\pi}_1$ and π_2, we conclude that K has a period of length $G = gcd(|\hat{\pi}_1|, |\pi_2|) = gcd(|\pi_1|, |\pi_2|) < |\pi_2|$. Since G divides $|\pi_2|$, we can infer that S' has a period that is *shorter* than *the* period π_2. This contradicts our hypothesis. □

LEMMA 6.7. *There is an occurrence in $Z = P[1, i']P[j' + k', p]$ starting at $P[2, i' - k']$ and ending in $P[j' + k', j' + k' + x - 2]$ if and only if $|\pi| = |\pi_1| = |\pi_2| < x < 2\ell$ and $i' + x > p + |\pi|$, where π is* the *pattern period.*

Proof. ($\Rightarrow$) Let us assume that such an occurrence exists. By Lemma 6.6, we have $|\pi_1| = |\pi_2| < x < 2\ell$. We show $|\pi| = |\pi_1| = |\pi_2|$ by proving that $|\pi| = |\pi_1|$. Since π_2 is a period of $P[j', p]$ and $|\pi_1| = |\pi_2|$, then π_2 is a cyclic shift of π_1 (i.e., $\pi_2 = P[i' - k' + 1, i' - k' + |\pi_1|]$). Since $P[i' - k' + 1, i'] = P[j', j' + k' - 1]$ with $k' > 6\ell$, we can conclude that π_1 is a period of the whole string Z (π_2 extends π_1's periodicity). Moreover, since $P[1, i']$ is a pattern prefix, we have $|\pi_1| \leq |\pi|$. We cannot have $|\pi_1| < |\pi|$ because P occurs in Z and π_1 is a period of Z, and this would imply that π_1 is a shorter period for P. Therefore, $|\pi| = |\pi_1|$, and $i' + x > p + |\pi|$ because the occurrence in Z starts after the first position and ends before the last one (by our hypothesis).

($\Leftarrow$) Let us assume that $|\pi| = |\pi_1| = |\pi_2| < x < 2\ell$ and $i' + x > p + |\pi|$. Since $Z = P[1, i']P[j' + k', p]$ and $K = P[i' - k' + 1, i'] = P[j', j' + k' - 1]$, with $k' > 6\ell$, we can infer that Z is periodic and its period has length $|\pi| < x < 2\ell$. Therefore, there must be some occurrences that are neither a prefix nor a suffix of $P[1, i']P[j' + k', j' + k' + x - 1]$ because $i' + x > p + |\pi|$. In other words, they start at $P[2, i' - k']$ and end in $P[j' + k', j' + k' + x - 2]$. □

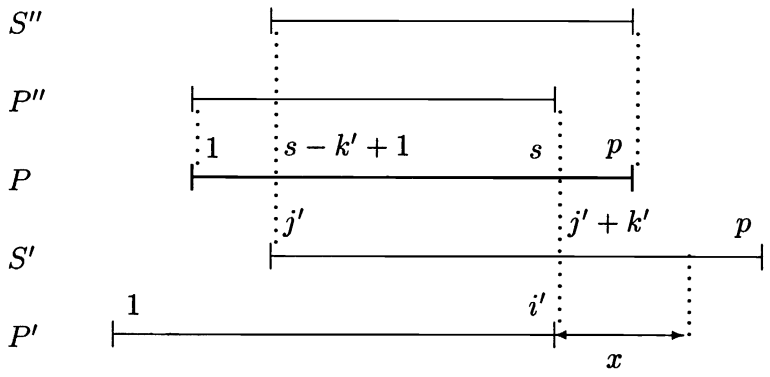

FIG. 7. *A decomposition of a pattern occurrence into its prefix P'' and its suffix S''. Note that P'' (resp., S'') is a border of P' (resp., S').*

COROLLARY 6.8. *If some occurrences in $P[1,i']P[j'+k',p]$ start at $P[2,i'-k']$ and end in $P[j'+k',j'+k'+x-2]$ then they correspond exactly to positions $1+t|\pi|$ in Z, for $t=1,2,\ldots$, such that $t|\pi|+p<i'+x$.*

Proof. From Lemma 6.7, internal occurrences in Z can exist if Z's and P's periods are equal. Therefore, $Z[1+t|\pi|,p+t|\pi|]=P$, for each $t=1,2,\ldots$. Each of these occurrences overlaps both $P[1,i']$ and $P[j'+k',j'+k'+x-2]$ so $t|\pi|+p<i'+x$ makes sure that the occurrences end in $P[j'+k',j'+k'+x-2]$. □

Lemma 6.7 and Corollary 6.8 employ the fact that there is a *large overlapping* $k'>6\ell$ between $P[1,i']$ and $P[j',p]$. We now show how to use them.

Preprocessing. We build and preprocess the suffix tree ST_P in $O(p)$ time in order to answer constant-time LCA queries [22, 28, 31]. Consequently, any two pattern substrings can be compared in constant time by an LCP query (see section 5.1). We also assume that we have previously computed all the pattern prefixes' and suffixes' periods in $O(p)$ time [24]. We let $Pref(P,i')$ (resp., $Suf(P,j')$) denote the length of $P[1,i']$'s (resp., $P[j',p]$'s) period.

ALGORITHM CPS.

Input: Integers i',j',k',x, such that $1\le j'\le i'\le p$, with $p>10\ell$; $k'\ge p-4\ell$ satisfies $P[i'-k'+1,i']=P[j',j'+k'-1]$, and $\ell\le x<2\ell$.

Output: All occurrences in $P[1,i']P[j'+k',j'+k'+x-1]$.

(1) If $i'+x<p$, then we stop because this means that there cannot be any occurrences at all. If $i'+x\ge p$, then we need to find out if P is a prefix or a suffix of $P[1,i']P[j'+k',j'+k'+x-1]$ in constant time. We do it by checking to see if either $P[i'+1,p]$ is a prefix of $P[j'+k',j'+k'+x-1]$ or $P[1,j'+k'-1]$ is a suffix of $P[1,i']$; we use LCP queries for this purpose.

(2) We list the occurrences that are *fully within* $P[1,i']P[j'+k',j'+k'+x-1]$, i.e., that start at $P[2,i'-k']$ and end in $P[j'+k',j'+k'+x-2]$. Specifically, we verify that $|\pi|=Pref(P,i')=Suf(P,j')<x<2\ell$ and $i'+x>p+|\pi|$ in constant time (Lemma 6.7). If so, the occurrences fully within $P[1,i']P[j'+k',j'+k'+x-1]$ are the ones identified by Corollary 6.8 (otherwise, they do not exist).

LEMMA 6.9. *After preprocessing P in $O(p)$ time, each execution of Algorithm CPS correctly finds the h occurrences ending in interval I_i in optimal $\Theta(h+1)$ time.*

Proof. The correctness readily derives from the preceding observations. As far as the time analysis of CPS is concerned, preprocessing takes $O(p)$ time (as previously mentioned). Step (1) requires constant time through LCP queries; step (2) takes $\Theta(h+1)$ time. □

6.3. Analysis of `Find`: Proof of Theorem 4.3. We now prove Theorem 4.3 regarding Algorithm `Find`'s complexity by using the results described in sections 6.1 and 6.2, in which we have two possible cases. If the pattern is short ($p \leq 10\ell$), then GST_S's traversal in step (1) requires $O(p+occ)$ time. If the pattern is long ($p > 10\ell$), then we prove that searching P by means of steps (2) and (3) requires $O(p+\ell+\frac{n}{\ell}+occ)$ time. In step (2), `Query-C(`P`)` requires $O(p+\frac{n}{\ell})$ time (by Lemma 5.1); `Query-R(`P`)` and `Query-L(`P`)` can be answered in $O(\ell+\frac{n}{\ell})$ time (by Lemma 5.3). The case analysis in section 6.1 takes a total of $O(\frac{n}{\ell})$ time plus $O(p)$ preprocessing time (Lemma 6.4). In step (3), we scan $\mathcal{L}$ in $O(\frac{n}{\ell})$ time and list all the occurrences in $O(p+\frac{n}{\ell}+occ)$ time by making $O(\frac{n}{\ell})$ calls to CPS after $O(p)$ preprocessing time (Lemma 6.9). Consequently, searching in steps (2)–(3) takes a total of $O(p+\ell+\frac{n}{\ell}+occ) = O(p+\frac{n}{\ell}+occ)$ time because $p > 10\ell$. By setting $\ell = \sqrt{n}$ (see section 4.2), we prove Theorem 4.3 and the following corollary.

COROLLARY 6.10. *Let Σ be an unbounded ordered alphabet. Searching for a pattern $P[1,p]$ in the text $T[1,n]$ takes $O(p \log|\Sigma| + occ)$ worst-case time, where occ is the total number of occurrences.*

Proof. We store the children list associated with each suffix tree node into a balanced search tree of $O(g)$ size, where $g \leq |\Sigma|$ is the list's size. This implementation introduces a logarithmic slowdown in the data structure pool's traversal and suffix tree construction. The total space required is still $\sum_g O(g) = O(n)$. □

7. `Insert` and `Delete` implementation. Given the interval list $\mathcal{L}$, we want to maintain it consistently under insertion and deletion of new strings. We only deal with insertions here because the same criteria hold for deletions. We refer back to Algorithm `Insert` in section 4.3 and analyze its computational cost. We assume that a string $Y[1,y]$ must be inserted into an interval I_i to produce $X = I'YI''$. In step (1), we scan $\mathcal{L}$ and find the interval I_i in which Y has to be inserted in $O(\frac{n}{\ell})$ time. In step (2), we update $\mathcal{L}$ in $O(y+\ell)$ time by replacing I_i with the intervals $I'_1, \ldots, I'_h$ created from X, where $h = O(y/\ell+1)$. In step (3), $\mathcal{L}$'s change affects sets $\Delta_S, \Delta_C, \Delta_L$, and Δ_R and their generalized suffix trees in the data structure pool (section 4.1). We point out that $O(1)$ strings of length $O(\ell)$ are removed and $O(y/\ell+1)$ strings of length $O(\ell)$ are added to those sets by `Remove` and `Add` operations (see section 5.3). The sets are then updated in a total of $O(y+\ell)$ time (by Lemma 5.4). The cost of `Insert`'s steps amounts to $O(y+\ell+\frac{n}{\ell})$ time.

We wish to add some remarks on insertions and deletions to complete our analysis. Text T can shrink or grow arbitrarily and violate the condition that $\ell = \sqrt{n}$ (we assume that $\sqrt{n}$ is a power of 2 without any loss in generality). Let T_i be the text T after i updates (i.e., string insertions or deletions) and $n_i = |T_i|$, where T_0 is the initial text. We recall that list $\mathcal{L}$ represents T_i's partition into intervals, whose length goes from ℓ to 2ℓ. When $n_i = 4n_0$, parameter ℓ should be *doubled* and list $\mathcal{L}$ recomputed because the intervals are now from 2ℓ to 4ℓ long (so we should set $T_0 := T_i$, $n_0 := n_i$, and $\ell := 2\ell$). The same happens when $n_i = \frac{n_0}{4}$ (i.e., ℓ should be halved). At this point, the reconstruction cost for the data structure pool from scratch could be charged on previous updates' cost but, in this way, the bounds stated in Theorem 4.4 would be *amortized*. Instead, we propose a method based on the "global rebuilding" technique described in [29] in order to obtain worst-case bounds.

Our basic idea consists of maintaining two "partial copies" of the pool and updating them "incrementally." One copy is tuned by parameter 2ℓ and the other by parameter $\frac{\ell}{2}$. For brevity's sake, we only describe how our idea works on $\mathcal{L}$ and GST_S for the copy tuned by parameter 2ℓ.

Given $\mathcal{L} = \{I_1, \ldots, I_k\}$, let us assume that $k/2$ is an integer without any loss in generality, and define $I'_j = I_{2j-1}I_{2j}$ for $j \in [1, k/2]$. It is worth noting that $I'_1 \cdots I'_{k/2}$ represents T_i's partition into intervals of length 2ℓ. We let $string'(I'_j)$ be the prefix of $I'_j \cdots I'_{k/2}$ of length $6 \cdot 2\ell = 12\ell$ (we recall that $string(I_j)$ is the prefix of $I_j \cdots I_k$ of length 6ℓ). Given text T_i, we maintain the following data structures according to a variable $j \in [0, k/2]$:

- a list $\mathcal{L}' = \{I'_1, \ldots, I'_j\}$ (empty for $j = 0$);
- an augmented generalized suffix tree GST'_S on $\Delta'_S = \{string'(I'_1), \ldots, string'(I'_j)\}$ (the set is empty for $j = 0$);
- a garbage area GA containing $O(|I'_{j+1}| + \cdots + |I'_{k/2}|)$ memory cells that we want to dispose of.

At the beginning (for T_0 and $j = 0$), list $\mathcal{L}'$, generalized suffix tree GST'_S, and set Δ'_S are all empty, and GA contains $O(n_0)$ memory cells. When $n_i = 4n_0$, we prove that list $\mathcal{L}'$ is T_i's partition according to the parameter 2ℓ because $j = k/2$. Moreover, at that point, GA is empty and GST'_S stores the whole set $\Delta'_S = \{string'(I'_1), \ldots, string'(I'_{k/2})\}$. As a result, we do not need to reconstruct anything from scratch and we can set $\mathcal{L} := \mathcal{L}'$, $GST_S := GST'_S$, $\Delta_S := \Delta'_S$, and GA to the area containing the "old" pools (i.e., $O(n_i)$ space). We also have to set $T_0 := T_i$, $n_0 := n_i$, $\ell := 2\ell$, $j := 0$, and to reset $\mathcal{L}'$, GST'_S, and Δ'_S to be empty. After that, $|GA| = O(n_0)$ and the invariant is maintained. All this computation requires $O(1)$ worst-case time.

We now show how to maintain the data structures incrementally. Given the insertion or deletion of string $Y[1, y]$, we update $\mathcal{L}$, GST_S, etc., in $O(y + \ell + \frac{n}{\ell})$ time (as shown above). This means adding and removing $O(y/\ell + 1)$ intervals in $\mathcal{L}$. If the intervals in $\mathcal{L}$ have been changed, we must update the corresponding $O(y/\ell + 1)$ intervals in $\mathcal{L}'$. As a consequence, $O(y/\ell + 1)$ strings in Δ'_S and GST'_S are added or removed within the same time bounds. We now introduce the global rebuilding idea. Our updating process also performs some operations that affect the "partial copies" while executing the standard insertion and deletion operations (described above). We append intervals $I'_{j+1}, \ldots, I'_{j+y/\ell+1}$ to $\mathcal{L}'$ by adding $string'(I'_{j+1}), \ldots, string'(I'_{j+y/\ell+1})$ to Δ'_S and by updating GST'_S in $O(y + \ell)$ time by means of Algorithm `Add` (section 5.3). Then we set $j := j + y/\ell + 1$. We also dispose $O(y + \ell)$ memory cells in GA (for some suitable constant factor). This process requires a total of $O(y + \ell + \frac{n}{\ell})$ time that is less than the data structure pool's updating cost.

We now show that everything has been correctly set when $n_i = 4n_0$. Since $|\mathcal{L}| \leq \frac{4n_0}{\ell}$ and some strings (whose total length was $3n_0$) were inserted or deleted (so producing text T_i), at least $2\lceil \frac{3n_0}{\ell} \rceil \geq |\mathcal{L}|$ distinct intervals in $\mathcal{L}$ were used to form list $\mathcal{L}'$ (two intervals in $\mathcal{L}$ form an interval in $\mathcal{L}'$). This allows us to conclude that the final list $\mathcal{L}'$ is the correct partition of T_i according to the parameter 2ℓ because, as soon as $n_i = 4n_0$, we have that $j = k/2$, GA is empty (since we disposed of all the $O(n_0)$ cells), and GST'_S stores $\Delta'_S = \{string'(I'_1), \ldots, string'(I'_{k/2})\}$.

LEMMA 7.1. *Inserting in or deleting a string $Y[1, y]$ from $T[1, n]$ requires $O(y + \ell + \frac{n}{\ell})$ worst-case time.*

Proof. As observed above, we can update the pool and its two "partial copies" and manage the shrinking and growing of the current text incrementally in a total of $O(y + \ell + \frac{n}{\ell})$ time. ∎

By setting $\ell = \sqrt{n}$ (see section 4.3), we obtain Theorem 4.4's proof and the following corollary.

COROLLARY 7.2. *Let Σ be an unbounded ordered alphabet. Inserting in or deleting a string $Y[1, y]$ from $T[1, n]$ requires $O((y + \sqrt{n}) \log |\Sigma|)$ worst-case time.*

8. Conclusions. We studied the problem of searching on-line for the *occ* occurrences of an arbitrary pattern $P[1, p]$ in a text $T[1, n]$ that can change after its preprocessing. We introduced the first dynamic algorithm that achieves optimal query time, i.e., $\Theta(p + occ)$, and sublinear time per update, i.e., $O(\sqrt{n} + y)$ for *every* y, in the worst case. The space required is optimal $\Theta(n)$. This implies that we can achieve the same query time and space usage of suffix trees while improving their update performance.

At present, we do not know if a better $O(t(n)+y)$ update time can be obtained by dynamic text indexing algorithms while maintaining *optimal* query time and *optimal* space usage in the worst case. Our results show that $t(n) = O(\sqrt{n})$. The question is if we can obtain $t(n) = o(\sqrt{n})$ or prove $t(n) = \Omega(\sqrt{n})$ in the worst case. The latter implies that our solution would also be optimal for updates.

Our techniques and data structures may turn out to be useful from a practical point of view. Our search is optimal and we only have to handle some text part of $O(\sqrt{n}+y)$ size for each update operation (e.g., few kilobytes versus several megabytes occupied by the whole text). Moreover, since performance depends on parameter ℓ, we think it might be more convenient in practice to tune ℓ properly by exploiting the fact that p is usually small in real situations. This would allow us to keep optimal query time and faster updating time. Although a long patterns' search would no longer be optimal, we can choose some proper ℓ values to make sure that this actually occurs very rarely.

Acknowledgments. We thank Raffaele Giancarlo and Fabrizio Luccio for their helpful comments and suggestions.

Introduction to Special Section on Probabilistic Proof Systems

The study of *probabilistically verifiable proofs* originated in the mid 1980s with the introduction of Interactive Proof Systems (IPs). The primary focus of research in this area in the '80s has been twofold:

- the role of zero-knowledge interactive proofs within cryptographic protocols, and
- characterizing which languages are efficiently interactively provable.

In the 1990s, the focus of research on the topic shifted. Extensions of the interactive proof model, such as Multiprover Interactive Proofs (MIPs) and Probabilistically Checkable Proofs (PCPs), were considered with the intention of expanding our notion of what should be considered efficiently verifiable. In addition, researchers have taken a closer look at the exact resources (and tradeoffs amongst them) needed to verify a proof using various proof systems. This culminated in the important discovery that it is possible to verify NP statements (with a constant error probability) by only examining a constant number of bits of a PCP and using logarithmic amount of randomness.

Perhaps, however, the most dramatic development has been the connection which was found between probabilistically verifiable proofs and proving hardness of approximation for optimization problems. It has been shown that a large variety of optimization versions of NP-hard problems (e.g., the maximum size of a clique in a graph, the minimum number of colors necessary to color a graph, and the maximum number of clauses satisfiable in a CNF formula) are not only NP-hard to solve exactly but also NP-hard to approximate in a very strong sense. The tools to establish hardness of approximation came directly from results on MIPs and PCPs. Indeed, almost every improvement in the efficiency of these proof systems translates directly into showing larger factors within which these optimization problems are hard to approximate.

In 1994–1995 two exciting workshops were held at the Weizmann Institute in Israel on the new developments in probabilistically verifiable proofs and their applications to approximation problems, cryptography, program checking, and complexity theory at large. Over 60 papers were presented in the workshop series, and we are proud to include three of them in this special section.

"On the Power of Finite Automata with Both Nondeterministic and Probabilistic States" by Anne Condon, Lisa Hellerstein, Samuel Pottle, and Avi Wigderson, considers constant round interactive proof systems where the verifier is restricted to use constant space and public coins. An equivalent characterization is finite automata with both nondeterministic and random states (npfa's), which accept their languages with a small probability of error. The paper shows that npfa's restricted to run in polynomial expected time accept only the regular languages in the case of npfa with 1-way input head, and that if L is a nonregular language, then either L or its complement is not accepted by any npfa with a 2-way input head.

"A Parallel Repetition Theorem" by Ran Raz, addresses and resolves the Parallel Repetition Conjecture which has eluded researchers for some time. The broader topic is what happens to the error probability of proof systems when they are composed. It has been known for awhile that sequential composition of proof systems (both single and multiprover interactive proofs) reduces the error exponentially, but this increases the number of rounds. For interactive proof systems, parallel repetition is known to reduce the error exponentially, and the Parallel Repetition Conjecture asserts that the same holds in a *one-round two-prover* proof system. Raz proves a constructive bound on the probability of error which indeed reduces at an exponential rate. The

constant in the exponent is logarithmic in the total number of possible answers of the two provers, which means one can achieve two-prover one-round MIPs for NP statements with arbitrarily small constant error probability. This, in turn, has played a crucial role in further developments in the area and in particular in those reported in the next paper.

"Free Bits, PCPs, and Nonapproximability—Towards Tight Results" by Mihir Bellare, Oded Goldreich, and Madhu Sudan, continues the investigation of PCPs and nonapproximability with emphasis on trying to get closer to tight results. The work consists of three parts. The first part presents several PCP proof systems for NP, based on a new error-correcting code called the Long Code. The second part shows that the connection between PCPs and hardness of approximation is not accidental. In particular, it shows that the transformation of a PCP for NP into hardness results for MaxClique can be reversed. Finally, the third part initiates a systematic investigation of the properties of PCPs as a function of the various parameters: randomness, query complexity, free-bit complexity, amortized free-bit complexity, proof size, etc.

Two more papers submitted for this special section were not ready at this time for publication. They will appear in future issues of the *SIAM Journal on Computing.*

ON THE POWER OF FINITE AUTOMATA WITH BOTH NONDETERMINISTIC AND PROBABILISTIC STATES*

ANNE CONDON†, LISA HELLERSTEIN‡, SAMUEL POTTLE§, AND AVI WIGDERSON¶

Abstract. We study finite automata with both nondeterministic and random states (npfa's). We restrict our attention to those npfa's that accept their languages with a small probability of error and run in polynomial expected time. Equivalently, we study Arthur–Merlin games where Arthur is limited to polynomial time and constant space.

Dwork and Stockmeyer [*SIAM J. Comput.*, 19 (1990), pp. 1011–1023] asked whether these npfa's accept only the regular languages (this was known if the automaton has only randomness or only nondeterminism). We show that the answer is yes in the case of npfa's with a 1-way input head. We also show that if L is a nonregular language, then either L or $\bar{L}$ is not accepted by any npfa with a 2-way input head.

Toward this end, we define a new measure of the complexity of a language L, called its 1-tiling complexity. For each n, this is the number of tiles needed to cover the 1's in the "characteristic matrix" of L, namely, the binary matrix with a row and column for each string of length $\leq n$, where entry $[x, y] = 1$ if and only if the string $xy \in L$. We show that a language has constant 1-tiling complexity if and only if it is regular, from which the result on 1-way input follows. Our main result regarding the general 2-way input tape follows by contrasting two bounds: an upper bound of polylog(n) on the 1-tiling complexity of every language computed by our model and a lower bound stating that the 1-tiling complexity of a nonregular language or its complement exceeds a function in $2^{\Omega(\sqrt{\log n})}$ infinitely often.

The last lower bound follows by proving that the characteristic matrix of *every* nonregular language has rank n for infinitely many n. This is our main technical result, and its proof extends techniques of Frobenius and Iohvidov developed for Hankel matrices [*Sitzungsber. der Könnigl. Preuss. Akad. der Wiss.*, 1894, pp. 407–431], [*Hankel and Toeplitz Matrices and Forms: Algebraic Theory*, Birkhauser, Boston, 1982].

1. Introduction.

The classical subset construction of Rabin and Scott [25] shows that finite state automata with just nondeterministic states (nfa's) accept exactly the regular languages. Results of Rabin [24], Dwork and Stockmeyer [7], and Kaņeps and Freivalds [17] show that the same is true of probabilistic finite state automata which run in polynomial expected time. Here and throughout the paper, we restrict attention to automata which accept languages with error probability that is some constant ϵ less than 1/2.

However, there has been little previous work on finite state automata which have both probabilistic and nondeterministic states. Such automata are equivalent to the Arthur–Merlin games of Babai and Moran [3], restricted to constant space, with an unbounded number of rounds of communication between Arthur and Merlin. In this paper, we refer to them as npfa's. In the computation of an npfa, each transition from a probabilistic state is chosen randomly according to the transition probabilities from that state, whereas from a nondeterministic state, it is chosen so as to maximize the probability that an accepting state is eventually reached. We let 1NPFA and 2NPFA-polytime denote the classes of languages accepted by npfa's which have a 1-way or 2-way input head, respectively, and which run in polynomial expected time. Dwork and Stockmeyer [8] asked whether 2NPFA-polytime is exactly the set of regular languages, which we denote by *Regular*.

In this paper, we prove the following two results on npfa's.

THEOREM 1.1. *1NPFA = Regular.*

THEOREM 1.2. *If L is nonregular, then either L or $\bar{L}$ is not in 2NPFA-polytime.*

Thus, we resolve the question of Dwork and Stockmeyer for npfa's with 1-way head, and in the case of the 2-way head model, we reduce the question to that of deciding whether 2NPFA-polytime is closed under complement. Theorem 1.1 also holds even if the automaton has universal as well as nondeterministic and probabilistic states. Moreover, Theorem 1.2 holds even for Arthur–Merlin games that use $o(\log \log n)$ space.

In proving the two results, we introduce a new measure of the complexity of a language L called its 1-*tiling complexity*. Tiling complexity arguments have been used previously to prove lower bounds for communication complexity (see, e.g., Yao [29]). With each language $L \subseteq \Sigma^*$, we associate an infinite binary matrix M_L, whose rows and columns are labeled by the strings of Σ^*. Entry $M_L[x, y]$ is 1 if the string $xy \in L$ and is 0 otherwise. Denote by $M_L(n)$ the finite submatrix of M_L, indexed by strings of length $\leq n$. Then, the 1-tiling complexity of L (and of the matrix $M_L(n)$) is the minimum size of a set of 1-*tiles* of $M_L(n)$ such that every 1-valued entry of $M_L(n)$ is in at least one 1-tile of the set. Here, a 1-tile is simply a submatrix (whose rows and columns are not necessarily contiguous) in which all entries have value 1.

In section 3, we prove the following theorems, relating language acceptance of npfa's to tiling complexity. The proofs of these theorems build on previous work of Dwork and Stockmeyer [8] and Rabin [24].

THEOREM 3.1. *A language L is in 1NPFA only if the 1-tiling complexity of L is $O(1)$.*

THEOREM 3.4. *A language L is in 2NPFA-polytime only if the 1-tiling complexity of L is bounded by a polynomial in $\log n$.*

What distinguishes our work on tiling is that we are interested in the problem of tiling the matrices $M_L(n)$, which have distinctive structural properties. If L is a unary language, then $M_L(n)$ is a matrix in which all entries along each diagonal from the top right to the bottom left are equal. Such a matrix is known as a *Hankel matrix*. An elegant theory on properties of such Hankel matrices has been developed [15], from which we obtain strong bounds on the rank of $M_L(n)$ if L is unary. In the case that L is not a unary language, the pattern of 0's and 1's in $M_L(n)$ is not as simple as in the unary case, although the matrix still has much structure. Our main technical contribution, presented in section 4, is to prove new lower bounds on the rank of $M_L(n)$ when L is not unary. Our proof uses techniques of Frobenius and Iohvidov developed for Hankel matrices [11], [15].

THEOREM 4.11. *If L is nonregular, then the rank of $M_L(n)$ is at least $n+1$ infinitely often.*

By applying results from communication complexity relating the rank of a matrix to its tiling complexity, we can obtain a lower bound on the 1-tiling complexity of non-regular languages.

THEOREM 4.12. *If L is nonregular, then the 1-tiling complexity of either L or $\bar{L}$ exceeds a function in $2^{\Omega(\sqrt{\log n})}$ infinitely often.*

However, there are nonregular languages, even over a unary alphabet, with 1-tiling complexity $O(\log n)$ (see section 4). Thus the above lower bound on the 1-tiling complexity of L or $\bar{L}$ does not always hold for L itself. A simpler theorem holds for regular languages.

THEOREM 4.2. *The 1-tiling complexity of L is $O(1)$ if and only if L is regular.*

By combining these theorems on the 1-tiling complexity of regular and nonregular languages with the theorems relating 1-tiling complexity to acceptance by npfa's, our two main results (Theorems 1.1 and 1.2) follow as immediate corollaries.

The rest of the paper is organized as follows. In Section 2, we define our model of the npfa and the tiling complexity of a language. We conclude that section with a discussion of related work on probabilistic finite automata and Arthur–Merlin games. In section 3, we present Theorems 3.1 and 3.4, which relate membership of a language L in the classes 1NPFA and 2NPFA-polytime to the 1-tiling complexity of L. A similar theorem is presented for the class 2NPFA, in which the underlying automata are not restricted to run in polynomial expected time. In section 4, we present our bounds on the tiling complexity of both regular and nonregular languages. Theorems 1.1 and 1.2 are immediate corollaries of the main results of sections 3 and 4. Extensions of these results to alternating automata and to Turing machines with small space are presented in section 5. Conclusions and open problems are discussed in section 6.

2. Preliminaries. We first define our npfa model in section 2.1. This model includes as special cases the standard models of nondeterministic and probabilistic finite state automata. In section 2.2 we define our notion of the tiling complexity of a language. Finally, in section 2.3, we discuss previous work on this and related models.

2.1. Computational models and language classes. A *two-way nondeterministic probabilistic finite automaton* (2npfa) consists of a set of states Q, an input alphabet Σ, and a transition function δ, with the following properties. The states Q are partitioned into three subsets: the *nondeterministic states* N, the *probabilistic* (or *random*) states R, and the *halting states* H. H consists of two states: the *accepting state* q_a and the *rejecting state* q_r. There is a distinguished state q_0, called the *initial state*. There are two special symbols $\text{¢}, \$ \notin \Sigma$, which are used to mark the left and right ends of the input string, respectively.

The transition function δ has the form

$$\delta : Q \times (\Sigma \cup \{\text{¢}, \$\}) \times Q \times \{-1, 0, 1\} \to \{0, 1/2, 1\}.$$

For each fixed q in R, the set of random states, and $\sigma \in (\Sigma \cup \{\text{¢}, \$\})$, the sum of $\delta(q, \sigma, q', d)$ over all q' and d equals 1. The meaning of δ in this case is that if the automaton is in state q reading symbol σ, then with probability $\delta(q, \sigma, q', d)$ the automaton enters state q' and moves its input head one symbol in direction d (left if $d = -1$, right if $d = 1$, stationary if $d = 0$). For each fixed q in N, the set of nondeterministic states, and $\sigma \in (\Sigma \cup \{\text{¢}, \$\})$, $\delta(q, \sigma, q', d) \in \{0, 1\}$ for all q'

and d. The meaning of δ in this case is that if the automaton is in state q reading symbol σ, then the automaton nondeterministically chooses some q' and d such that $\delta(q, \sigma, q', d) = 1$, enters state q' and moves its input head one symbol in direction d. Once the automaton enters state q_a (respectively, q_r), the input head moves repeatedly to the right until the right endmarker \$ is read, at which point the automaton halts. In other words, for $q \in \{q_a, q_r\}$, $\delta(q, \sigma, q, 1) = 1$ for all $\sigma \in \Sigma \cup \{\mathfrak{c}\}$, and $\delta(q, \sigma, q', 1) = 0$ for all $\sigma \in \Sigma \cup \{\mathfrak{c}\}$ and $q' \neq q$. On a given input, the automaton is started in the *initial configuration*, that is, in the initial state with the head at the left end of the input. If the automaton halts in state q_a on the input, we say that it *accepts* the input, and if it halts in state q_r, we say that it *rejects* the input.

Fix some input string $w = w_0 w_1 w_2, \ldots, w_n w_{n+1}$, where $w_0 = \mathfrak{c}$ and $w_{n+1} = \$$. A *nondeterministic strategy* (or just *strategy*) on w is a function

$$S_w : N \times \{0, \ldots, n+1\} \to Q \times \{-1, 0, 1\}$$

such that $\delta(q, \sigma, q', d) = 1$ whenever $S_w(q, j) = (q', d)$ and $w_j = \sigma$. The meaning of S_w is that if the automaton is in state $q \in N$ reading w_j, then if $S_w(q, j) = (q', d)$, the automaton enters state q' and moves its input head one symbol in direction d. The strategy indicates which nondeterministic choice should be made in each configuration.

A language $L \subseteq \Sigma^*$ is accepted with *bounded error probability* if for some constant $\epsilon < 1/2$,

1. for all $w \in L$, there exists a strategy S_w on which the automaton accepts with probability $\geq 1 - \epsilon$, and
2. for all $w \notin L$, on every strategy S_w, the automaton accepts with probability $\leq \epsilon$.

Language acceptance could be defined with respect to a more general type of strategy, in which the nondeterministic choice made from the same configuration at different times may be different. It is known (see [4, Theorem 2.6]) that if L is accepted by an npfa with respect to this more general definition, then it is also accepted with respect to the definition above. Hence, our results also hold for such generalized strategies.

A *one-way nondeterministic probabilistic finite automaton* (1npfa) is a 2npfa which can never move its input head to the left; that is, $\delta(q, \sigma, q', -1) = 0$ for all q, q', and σ. Also, a *probabilistic finite automaton* (pfa) and a *nondeterministic finite automaton* (nfa) are special cases of an npfa in which there are no nondeterministic and no probabilistic states, respectively.

We denote by 1NPFA and 2NPFA the classes of languages accepted with bounded error probability by 1npfa's and 2npfa's, respectively. If, on all inputs w and all nondeterministic strategies, the 2npfa halts in polynomial expected time, we say that L is in the class 2NPFA-polytime. The classes 1PFA, 2PFA, and 2PFA-polytime are defined similarly, with pfa replacing npfa. Finally, Regular denotes the class of regular languages.

Our model of the 2npfa is equivalent to an Arthur–Merlin game in which Arthur is a 2pfa, and our classes 2NPFA and 2NPFA-polytime are identical to the classes AM(2pfa) and AM(ptime-2pfa), respectively, of Dwork and Stockmeyer [8].

2.2. The tiling complexity of a language. We adapt the notion of the tiling complexity of a function, used in communication complexity theory, to obtain a new measure of the complexity of a language. Given a finite, two-dimensional matrix M, a *tile* is a submatrix of M in which all entries have the same value. A tile is specified by a pair (R, C) where R is a nonempty set of rows and C is a nonempty set of columns.

The entries in the tile are said to be *covered* by the tile. A tile is a b-tile if all entries of the submatrix are b. A set of b-tiles is a *b-tiling* of M if every b-valued entry of M is covered by at least one tile in the set. If M is a binary matrix, the union of a 0-tiling and a 1-tiling of M is called a *tiling* of M. Let $T(M)$ be the minimum size of a tiling of M. Let $T^1(M)$ be the minimum size of a 1-tiling of M, and let $T^0(M)$ be the minimum size of a 0-tiling of M. Then, $T(M) = T^1(M) + T^0(M)$. Note that in these definitions it is permitted for tiles of the same type to overlap.

We can now define the tiling complexity of a language. Associated with a language L over alphabet Σ is an infinite binary matrix M_L. The rows and columns of M_L are indexed (say, in lexicographic order) by the strings in Σ^*. Entry $M_L[x, y] = 1$ if and only if $xy \in L$. Let L_n be the strings of L of length $\leq n$. Let $M_L(n)$ be the finite submatrix of M_L whose rows and columns are indexed by the strings of length $\leq n$. The 1-*tiling complexity* of a language L is defined to be the function $T^1_L(n) = T^1(M_L(n))$. Similarly, the 0-*tiling complexity* of L is $T^0_L(n) = T^0(M_L(n))$ and the *tiling complexity* of L is $T_L(n) = T(M_L(n))$.

A tiling of a matrix M is *disjoint* if every entry $[x, y]$ of M is covered by exactly one tile. The disjoint tiling complexity of a matrix M, $\tilde{T}(M)$, is the minimum size of a disjoint tiling of M. Also, the disjoint tiling complexity of a language, $\tilde{T}_L(n)$, is $\tilde{T}(M_L(n))$.

Tilings are often used in proving lower bounds in communication complexity [29], [30]. Let $f : X \times Y \to \{0, 1\}$. The function f is represented by a matrix M_f whose rows are indexed by elements of X and whose columns are indexed by elements of Y, such that $M_f[x, y] = f(x, y)$. Let T_f denote $T(M_f)$. Suppose that two cooperating parties, P_1 and P_2, get inputs $x \in X$ and $y \in Y$, respectively, and want to compute $f(x, y)$. They can do so by exchanging information according to some protocol (precise definitions of legal protocols can be found in [13]). If the protocol is deterministic, then the worst case number of bits that need to be exchanged (that is, the deterministic communication complexity) is bounded below by $\log \tilde{T}_f$ [29]. If the protocol is nondeterministic, then the lower bound is $\log T_f$ [1]. Finally, if the object of the nondeterministic protocol is only to verify that $f(x, y) = 1$ (if that is indeed the case), then the lower bound on the number of bits exchanged is $\log T^1_f$.

2.3. Related work. Our work on npfa's builds upon a rich literature on probabilistic finite state automata. Rabin [24] was the first to consider probabilistic automata with bounded error probability. He showed that 1PFA = Regular. However, with a 2-way input head, pfa's can recognize nonregular languages. This was shown by Freivalds [10], who constructed a 2pfa for the language $\{0^n 1^n \mid n \geq 0\}$. Greenberg and Weiss [12] showed that exponential expected time is required by any 2pfa accepting this language. Dwork and Stockmeyer [7] and, independently, Kaņeps and Freivalds [17] showed that, in fact, any 2pfa which recognizes a nonregular language must run in exponential expected time. It follows that 2PFA-polytime = Regular.

Roughly, Rabin's proof shows that any language L accepted by a 1pfa has only finitely many equivalence classes. Here, two strings x, x' are equivalent if and only if for all y, $xy \in L \Leftrightarrow x'y \in L$. The Myhill-Nerode theorem [14] states that a language has a finite number of equivalence classes if and only if it is regular. This, combined with Rabin's result, implies that 1PFA = Regular. Two decades later, this idea was extended to 2pfa's. A strengthened version of the Myhill-Nerode theorem is needed for this extension. Given a language L, we say that two strings x, x' are *pairwise n-inequivalent* if for some y, $xy \in L \Leftrightarrow x'y \notin L$, and furthermore, $|xy|, |x'y| \leq n$. Let $N_L(n)$ (the *nonregularity* of L) be the size of the largest set of pairwise n-inequivalent

strings. Kaŋeps and Freivalds [16] showed that $N_L(n) \geq \lfloor (n+3)/2 \rfloor$ for infinitely many n. (It is interesting to note that, to prove their bound, Kaŋeps and Freivalds first showed that $N_L(n)$ equals the number of states of the minimal deterministic 1-way finite automaton that accepts all words of length $\leq n$ that are in L and rejects all words of length $\leq n$ that are not in L. Following Karp [19], we denote the latter measure by $\phi_L(n)$. Karp [19] previously proved that $\phi_L(n) > n/2 + 1$ for infinitely many n. Combining this with the fact that $N_L(n)$ and $\phi_L(n)$ are equal, it follows immediately that $N_L(n) > n/2 + 1$ for infinitely many n. This is stronger (by 1) for even n than the lower bound of Kaŋeps and Freivalds. We also note that Dwork and Stockmeyer [7] obtained a weaker bound on $N_L(n)$ without using $\phi_L(n)$. Using tools from Markov chain theory, Dwork and Stockmeyer [7] and Kaŋeps and Freivalds [17] showed that if a language is accepted by a 2pfa in polynomial expected time, then the language has "low" nonregularity. In fact, $N_L(n)$ is bounded by some polynomial in $\log n$. This, combined with the result of Kaŋeps and Freivalds, implies that 2PFA-polytime = Regular.

Models of computation with both nondeterministic and probabilistic states have been studied intensively since the work of Papadimitriou [23] on games against nature. Babai and Moran [3] defined Arthur–Merlin games to be Turing machines with both nondeterministic and probabilistic states, which accept their languages with bounded error probability. Their work on polynomial time bounded Arthur–Merlin games laid the framework for the remarkable progress on interactive proof systems and their applications (see, for example, [2] and the references therein). Space bounded Arthur–Merlin games were first considered by Condon and Ladner [6]. Condon [4] showed that AM(log-space), that is, the class of languages accepted by Arthur–Merlin games with logarithmic space, is equal to the class P. However, it is not known whether the class AM(log-space, polytime)—the subclass of AM(log-space) where the verifier is also restricted to run in polynomial time—is equal to P, or whether it is closed under complement. Fortnow and Lund [9] showed that NC is contained in AM(log-space, polytime).

Dwork and Stockmeyer [8] were the first to consider npfa's, which are Arthur–Merlin games restricted to constant space. They described conditions under which a language is not in either of the classes 2NPFA or 2NPFA-polytime. The statements of our Theorems 3.2 and 3.4 generalize and simplify the statements of their theorems, and our proofs build on theirs. In communication complexity theory terms, their proofs roughly show that languages accepted by npfa's have low "fooling set complexity." This measure is defined in a manner similar to the tiling complexity of a language, based on the following definition. Define a 1-fooling set of a binary matrix A to be a set of entries $\{[x_1, y_1], [x_2, y_2], \ldots, [x_m, y_m]\}$ such that $A[x_i, y_j] = 1$ if and only if $i = j$. The size of a 1-fooling set of a binary matrix is always at most the 1-tiling complexity of the matrix, because no two distinct entries in the 1-fooling set, $[x_i, y_i]$ and $[x_j, y_j]$, can be in the same tile. However, the 1-tiling complexity may be significantly larger than the 1-fooling set complexity; in fact, for a random $n \times n$ binary matrix, the expected size of the largest 1-fooling set is $O(\log n)$, whereas the expected number of tiles needed to tile the 1-entries is $\Omega(n/\log n)$ [1].

3. NPFA's and tiling. Three results are presented in this section. For each of the classes 1NPFA, 2NPFA, and 2NPFA-polytime, we describe upper bounds on the tiling complexity of the languages in these classes. The proof for 1NPFA's is a natural generalization of Rabin's proof that 1PFA = Regular [24]. The other two proofs build on previous results of Dwork and Stockmeyer [8] on 2npfa's.

3.1. 1NPFA and tiling.

THEOREM 3.1. *A language L is in 1NPFA only if the 1-tiling complexity of L is $O(1)$.*

Proof. Suppose L is accepted by some 1npfa M with error probability $\epsilon < 1/2$. Let the states of M be $\{1, \ldots, c\}$.

Consider the matrix M_L. For each 1-entry $[x, y]$ of M_L, fix a nondeterministic strategy that causes the string xy to be accepted with probability at least $1 - \epsilon$. With respect to this strategy, define two vectors of dimension c. Let $\mathbf{p}_{xy}$ be the *state probability vector* at the step when the input head moves off the right end of x. That is, the ith entry of the vector is the probability of being in state i at that moment, assuming that the automaton is started at the left end of the input $\mathfrak{c}\, xy\$$ in the initial state. Let $\mathbf{r}_{xy}$ be the column vector whose ith entry is the probability of accepting the string xy, assuming that the automaton is in state i at the moment that the head moves off the right end of x. Then the probability of accepting the string xy is the inner product $\mathbf{p}_{xy} \cdot \mathbf{r}_{xy}$.

Let $\mu = (1/2 - \epsilon)/c$. Partition the space $[0, 1]^c$ into *cells* of size $\mu \times \mu \times \cdots \times \mu$ (the final entry in the cross product should actually be less than μ if 1 is not a multiple of μ). Associate each 1-entry $[x, y]$ with the cell containing the vector $\mathbf{p}_{xy}$; we say that $[x, y]$ belongs to this cell.

With each cell C, associate the *rectangle* R_C defined as

$$\{x| \text{ there exists } y \text{ such that } [x, y] \text{ belongs to } C\} \times \{y| \text{ there exists } x \text{ such that } [x, y] \text{ belongs to } C\}.$$

This is the minimal submatrix that covers all of the entries associated with cell C.

We claim that R_C is a valid 1-tile; that is, R_C covers only 1-entries. To see this, suppose $[x, y] \in R_C$. If $[x, y]$ belongs to C, then it must be a 1-entry. Otherwise, there exist x' and y' such that $[x, y']$ and $[x', y]$ belong to C; that is, $xy', x'y \in L$, and $\mathbf{p}_{xy'}$ and $\mathbf{p}_{x'y}$ are in the same cell.

We claim that xy is accepted with probability at least $1/2$ on some strategy, namely, the strategy that, while reading x, uses the strategy for xy', and while reading y, uses the strategy for $x'y$. To see this, note that

$$\begin{aligned}(\mathbf{p}_{x'y} - \mathbf{p}_{xy'}) \cdot \mathbf{r}_{x'y} &= \sum_{i=1}^{c} [\mathbf{p}_{x'y} - \mathbf{p}_{xy'}]_i [\mathbf{r}_{x'y}]_i \\ &\leq \mu \sum_{i=1}^{c} [\mathbf{r}_{x'y}]_i \\ &\leq \mu c \\ &= 1/2 - \epsilon, \quad \text{by our choice of } \mu.\end{aligned}$$

Hence, the probability that xy is accepted on the strategy described above is

$$\begin{aligned}\mathbf{p}_{xy'} \mathbf{r}_{x'y} &\geq \mathbf{p}_{x'y} \mathbf{r}_{x'y} - (1/2 - \epsilon) \\ &\geq (1 - \epsilon) - (1/2 - \epsilon) \\ &= 1/2 > \epsilon.\end{aligned}$$

Because xy is accepted with probability greater than ϵ on this strategy, it cannot be that $xy \notin L$. Hence, for all $[x, y] \in R_C$, xy must be in L. Therefore R_C is a 1-tile in M_L.

Every 1-entry $[x, y]$ is associated with some cell C and is covered by the 1-tile R_C that is associated with C. Thus, every 1-entry of M_L is covered by some R_C.

Hence, L can be 1-tiled using one tile per cell, which is a total of $\lceil 1/\mu \rceil^c = O(1)$ tiles. □

3.2. 2NPFA and tiling. We next show that if $L \in$ 2NPFA, then $T_L^1(n)$ is bounded by a polynomial.

THEOREM 3.2. *A language L is in 2NPFA only if the 1-tiling complexity of L is bounded by a polynomial in n.*

Proof. Suppose L is accepted by some 2npfa M with error probability $\epsilon < 1/2$. Let c be the number of states of M. As in Theorem 3.1, for each 1-entry $[x, y]$ of $M_L(n)$, fix a nondeterministic strategy that causes M to accept the string xy with probability at least $1 - \epsilon$.

We construct a stationary Markov chain H_{xy} that models the computation of M on xy using this strategy.

This Markov chain has $d = 2c + 4$ states. $2c$ of the states are labeled (q, l), where q is a state of M and $l \in \{0, 1\}$. The other states are labeled Initial, Accept, Reject, and Loop. The state $(q, 0)$ of H_{xy} corresponds to M being in state q while reading the rightmost symbol of $\mathfrak{c}\, x$. The state $(q, 1)$ of H_{xy} corresponds to M being in state q while reading the leftmost symbol of $y\$$. The state Initial corresponds to the initial configuration of M. The states Accept, Reject, and Loop are sink states of H_{xy}.

A single step of the Markov chain H_{xy} corresponds to running M on input xy (using the fixed nondeterministic strategy) from the appropriate configuration for one or more steps until M enters a configuration corresponding to one of the chain states (q, l). If M halts in the accepting (respectively, rejecting) state before entering one of these configurations, H_{xy} enters the Accept (respectively, Reject) state. If M does not halt and never again reads the rightmost symbol of $\mathfrak{c}\, x$ or the leftmost symbol of $y\$$, then H_{xy} enters the Loop state. The transition probabilities are defined accordingly.

Consider the transition matrix of H_{xy}. Collect the rows corresponding to the chain states Initial and $(q, 0)$ (for all q) and call this submatrix P_{xy}. Collect the rows corresponding to the chain states $(q, 1)$ and call this submatrix R_{xy}. Then the transition matrix looks like this:

$$H_{xy} = \begin{array}{r|c|c} \text{Initial} & \multicolumn{2}{c}{\multirow{2}{*}{P_{xy}}} \\ (q,0) & \multicolumn{2}{c}{} \\ \hline (q,1) & \multicolumn{2}{c}{R_{xy}} \\ \hline \begin{array}{r}\text{Accept}\\ \text{Reject}\\ \text{Loop}\end{array} & 0 & I_3 \end{array},$$

where I_3 denotes the identity matrix of size 3. (We shall engage in a slight abuse of notation by using H_{xy} to refer to both the transition matrix and the Markov chain itself.) Note that the entries of P_{xy} depend only on x and the nondeterministic strategy used; these transition probabilities do not depend on y. This assertion appears to be contradicted by the fact that our choice of nondeterministic strategy may depend on y; however, the idea here is that if we replace y with y' while maintaining the same nondeterministic strategy we used for xy, then $P_{xy'}$ will be identical to P_{xy}, because

the transitions involved simulate computation of M on the left part of its input only. Similarly, R_{xy} depends only on y and the strategy, and not on x.

We now show that if $|x| \leq n$ and if p is a nonzero element of P_{xy}, then $p \geq 2^{-cn-1}$. Form a second Markov chain $K(\mathfrak{c}\, x)$ with states of the form (q, l), where q is a state of M and $1 \leq l \leq |\mathfrak{c}\, x| + 1$. The chain state (q, l) with $l \leq |\mathfrak{c}\, x|$ corresponds to M being in state q scanning the lth symbol of $\mathfrak{c}\, x$. Transition probabilities from these states are obtained from the transition probabilities of M in the obvious way. Chain states of the form $(q, |\mathfrak{c}\, x| + 1)$ are sink states of $K(\mathfrak{c}\, x)$ and correspond to the head of M falling off the right end of $\mathfrak{c}\, x$ with M in state q. Now consider a transition probability p in P_{xy}. Suppose that, in the Markov chain H_{xy}, p is the transition probability from $(q, 0)$ to $(q', 1)$. Then $p \in \{0, 1/2, 1\}$, since if H_{xy} makes this transition, it must be simulating a single computation step of M. Suppose p is the transition probability from $(q, 0)$ to $(q', 0)$. If $p > 0$, then there must be some path of nonzero probability in $K(\mathfrak{c}\, x)$ from state $(q, |\mathfrak{c}\, x|)$ to $(q', |\mathfrak{c}\, x|)$ that visits no state $(q'', |\mathfrak{c}\, x|)$, and since $K(\mathfrak{c}\, x)$ has at most cn states that can be on this path, there must be such a path of length at most $cn + 1$. Since $1/2$ is the smallest nonzero transition probability of M, it follows that $p \geq 2^{-cn-1}$. The cases where p is a transition probability from the Initial state are similar.

Similarly, if $|y| \leq n$ and if r is a nonzero element of R_{xy}, then $r \geq 2^{-cn-1}$.

Next we present a lemma that bounds the effect of small changes in the transition probabilities of a Markov chain. This lemma is a slight restatement of a lemma of Greenberg and Weiss [12]. This version is due to Dwork and Stockmeyer [8].

If k is a sink state of a Markov chain R, let $a(k, R)$ denote the probability that R is (eventually) trapped in state k when started in state 1. Let $\beta \geq 1$. Say that two numbers r and r' are *β-close* if either: (i) $r = r' = 0$, or (ii) $r > 0, r' > 0$, and $\beta^{-1} \leq r/r' \leq \beta$. Two Markov chains $R = \{r_{ij}\}_{i,j=1}^{s}$ and $R' = \{r'_{ij}\}_{i,j=1}^{s}$ are *β-close* if r_{ij} and r'_{ij} are β-close for all pairs i, j.

LEMMA 3.3. *Let R and R' be two s-state Markov chains which are β-close, and let k be a sink state of both R and R'. Then $a(k, R)$ and $a(k, R')$ are β^{2s}-close.*

The proof of this lemma is based on the Markov chain tree theorem of Leighton and Rivest [20] and can be found in [8].

Our approach is to partition the 1-entries of $M_L(n)$ into equivalence classes, as in the proof of Theorem 3.1, but this time we will make entries $[x, y]$ and $[x', y']$ equivalent only if the corresponding Markov chains H_{xy} and $H_{x'y'}$ are β-close, where β will be chosen small enough that we can use Lemma 3.3 to show that xy' and $x'y$ are accepted with high probability by combining the strategies for xy and $x'y'$.

If $[x, y]$ is a 1-entry such that $|x| \leq n$ and $|y| \leq n$, then for any nonzero p of P_{xy} (or r of R_{xy}), $p \in [2^{-cn-1}, 1]$, so $\log_2 p \in [-cn - 1, 0]$ (and similarly $\log_2 r \in [-cn - 1, 0]$).

By partitioning each coordinate interval $[-cn - 1, 0]$ into subintervals of length μ, we divide the space $[-cn - 1, 0]^{d^2}$ into at most $\lceil (cn + 1)/\mu \rceil^{d^2}$ cells, each of size at most $\mu \times \mu \times \cdots \mu$.

Partition the 1-entries in $M_L(n)$ into equivalence classes by making xy and $x'y'$ equivalent if H_{xy} and $H_{x'y'}$ have the property that for each state transition, if p and p' are the respective transition probabilities, either $p = p' = 0$, or $\log p$ and $\log p'$ are in the same (size μ) subinterval of $[-cn - 1, 0]$.

Note that the number of equivalence classes is at most $(\lceil (cn + 1)/\mu \rceil + 1)^{d^2}$.

We claim that if μ is chosen small enough, these equivalence classes induce a 1-tiling of $M_L(n)$ of size at most the number of equivalence classes. As in Theorem

3.1, we associate with each equivalence class C the rectangle R_C defined by

$$\{x|\text{there exists } y \text{ such that } [x,y] \in C\} \times \{y|\text{there exists } x \text{ such that } [x,y] \in C\}.$$

We claim that for each $[x,y]$ in R_C, $xy \in L$. That is, all entries in the rectangle are 1, so the rectangle forms a 1-tile. Let $[x,y]$ be in R_C. There must be some y' such that $[x,y'] \in C$ and some x' such that $[x',y] \in C$. Consider the associated Markov chains $H_{xy'}$ and $H_{x'y}$, and in particular, consider the transition submatrices $P_{xy'}$ and $R_{x'y}$. The first is associated with a particular nondeterministic strategy on x, namely, one which assumes the input is xy' and tries to cause xy' to be accepted with high probability. The second is associated with a particular nondeterministic strategy on y, namely, one which assumes the input is $x'y$ and tries to cause $x'y$ to be accepted with high probability. The two matrices $P_{xy'}$ and $R_{x'y}$ taken together correspond to a hybrid strategy on xy: while reading x, use the strategy for xy', and while reading y, use the strategy for $x'y$. We will argue that this hybrid strategy causes xy to be accepted with probability $\geq 1/2$.

We construct a hybrid Markov chain H_{xy} using $P_{xy'}$ and $R_{x'y}$. This chain models the computation of M on xy using the hybrid strategy.

Since the 1-entries $[x,y']$ and $[x',y]$ are in the same equivalence class C, it follows that if p and p' are corresponding transition probabilities in the Markov chains $H_{xy'}$ and $H_{x'y}$, then either $p = p' = 0$ or $|\log p - \log p'| \leq \mu$. Therefore, $H_{xy'}$ and $H_{x'y}$ are 2^μ-close, and it immediately follows that H_{xy} is 2^μ-close to $H_{xy'}$ (and to $H_{x'y}$). Let $a_{xy'}$ be the probability that M accepts input xy' on the strategy for xy', and let a_{xy} be the probability that M accepts input xy using the hybrid strategy. Then $a_{xy'}$ (respectively, a_{xy}) is exactly the probability that the Markov chain $H_{xy'}$ (respectively, H_{xy}) is eventually trapped in the Accept state when started in the Initial state. Now $xy' \in L$ implies $a_{xy'} \geq 1 - \epsilon$. Since H_{xy} and $H_{xy'}$ are 2^μ-close, Lemma 3.3 implies that

$$\frac{a_{xy}}{a_{xy'}} \geq 2^{-2d\mu},$$

which implies

$$a_{xy} \geq (1-\epsilon)2^{-2d\mu}.$$

Since ϵ and d are constants, and since $\epsilon < 1/2$, we can choose μ to be a constant so small that $a_{xy} \geq 1/2$. Therefore xy must be in L.

Since each 1-entry $[x,y]$ is in some equivalence class, the matrix $M_L(n)$ can be 1-tiled using at most $(\lceil (cn+1)/\mu \rceil + 1)^{d^2}$ tiles. Therefore,

$$T_L^1(n) \leq (\lceil (cn+1)/\mu \rceil + 1)^{d^2}.$$

Since c, d, and μ are constants independent of n, this shows that $T_L^1(n)$ is bounded by a polynomial in n. □

3.3. 2NPFA-polytime and tiling. We now show that if $L \in$ 2NPFA-polytime, then $T_L^1(n)$ is bounded by a polylog function.

THEOREM 3.4. *A language L is in 2NPFA-polytime only if the 1-tiling complexity of L is bounded by a polynomial in $\log n$.*

Proof. Suppose L is accepted by some 2npfa M with error probability $\epsilon < 1/2$ in expected time at most $t(n)$. Let c be the number of states of M. For each 1-entry $[x,y]$ of $M_L(n)$, fix a nondeterministic strategy that causes M to accept the string xy with probability at least $1 - \epsilon$.

We construct the Markov chain H_{xy} just as in Theorem 3.2.

Say that a probability p is *small* if $p < t(n)^{-2}$; otherwise, p is *large*. Note that if p is a large transition probability, then $p \in [t(n)^{-2}, 1]$, so $\log_2 p \in [-2\log_2 t(n), 0]$. When dividing the 1-entries of $M_L(n)$ into equivalence classes, make xy and $x'y'$ equivalent if H_{xy} and $H_{x'y'}$ have the property that for each state transition, if p and p' are the respective transition probabilities, either p and p' are both small, or $\log p$ and $\log p'$ are in the same (size μ) subinterval of $[-2\log_2 t(n), 0]$.

This time the number of equivalence classes is at most $(\lceil 2\log_2 t(n)/\mu \rceil + 1)^{d^2}$.

Model the computation of M on inputs $x'y$, xy', and xy by Markov chains $H_{x'y}$, $H_{xy'}$, and H_{xy}, respectively, as before.

If p and p' are corresponding transition probabilities in any two of these Markov chains, then either p and p' are 2^{μ}-close or p and p' are both small. Let $\mathcal{E}_{x'y}$ be the event that, when $H_{x'y}$ is started in state Initial, it is trapped in state Accept or Reject before any transition labeled with a small probability is taken; define $\mathcal{E}_{xy'}$ and $\mathcal{E}_{xy}$ similarly. Since M halts in expected time at most $t(n)$ on the inputs $x'y$, xy', and xy, the probabilities of these events go to 1 as n increases. Therefore, by changing all small probabilities to zero, we do not significantly change the probabilities that $H_{x'y}$, $H_{xy'}$, and H_{xy} enter the Accept state, provided that n is sufficiently large. A formal justification of this argument can be found in Dwork and Stockmeyer [8].

After these changes, we can argue that

$$a_{xy} \geq (1-\epsilon)2^{-2d\mu}$$

and choose μ so that $a_{xy} \geq 1/2$, as before. It then follows that

$$T_L^1(n) \leq (\lceil 2\log_2 t(n)/\mu \rceil + 1)^{d^2} \tag{1}$$

for all sufficiently large n, establishing the result. □

4. Bounds on the tiling complexity of languages. In this section, we obtain several bounds on the tiling complexity of regular and nonregular languages. In section 4.1, we prove several elementary results. First, all regular languages have constant tiling complexity. Second, the 1-tiling complexity of all nonregular languages is at least $\log n - O(1)$ infinitely often. We also present an example of a (unary) nonregular language which has 1-tiling complexity $O(\log n)$. In section 4.2, we use a rank argument to show that for all nonregular languages L, either L or its complement has "high" 1-tiling complexity infinitely often.

4.1. Simple bounds on the tiling complexity of languages. The following lemma is useful in proving some of the theorems in this section. Its proof is implicit in work of Melhorn and Schmidt [21]; we include it for completeness.

LEMMA 4.1. *Any binary matrix A that can be 1-tiled with m tiles has at most 2^m distinct rows.*

Proof. Let A be a binary matrix that can be 1-tiled by m tiles $\{T_1, \ldots, T_m\}$, where $T_j = (R_j, C_j)$. For each row r of A, let $I(r) = \{T_j \mid j \in \{1, \ldots, m\}$ such that $r \in R_j\}$. Suppose r_1 and r_2 are rows such that $I(r_1) = I(r_2)$. We show that in this case, rows r_1 and r_2 are identical. To see this, consider any column c of A. Suppose that entry $[r_1, c]$ has value 1 and is covered by some tile $T_j \in I(r_1)$. Therefore, $c \in C_j$. Since $I(r_1) = I(r_2)$, $T_j \in I(r_2)$ and therefore, $r_2 \in R_j$ and $[r_2, c]$ is covered by tile T_j. Hence, entry $[r_2, c]$ must have value 1, since T_j is a 1-tile. Hence, if $[r_1, c]$ has value 1, so does $[r_2, c]$. Similarly, if $[r_2, c]$ has value 1, then so does entry $[r_1, c]$. Therefore r_1 and r_2 are identical rows. Since there are only 2^m possible values for $I(r)$, A can have at most 2^m distinct rows. □

THEOREM 4.2. *The* 1*-tiling complexity of* L *is* $O(1)$ *if and only if* L *is regular.*

Proof. By the Myhill-Nerode theorem [14, Theorem 3.6], L is regular if and only if M_L has a finite number of distinct rows.

Suppose L is regular. Then by the above fact there exists a constant k such that M_L has at most k distinct rows. Consider any (possibly infinite) set R of identical rows in M_L. Let C_b be the set of columns which have bit b in the rows of R, for $b = 0, 1$. Then the subset specified by (R, C_b) is a b-tile and covers all the b-valued entries in the rows of R. It follows that the 1-valued entries of R can be covered by a single tile, and hence there is a 1-tiling of $M_L(n)$ of size k. (Similarly, there is a 0-tiling of $M_L(n)$ of size k.)

Suppose L is not regular. Since L is not regular, M_L has an infinite number of distinct rows. It follows immediately from Lemma 4.1 that M cannot be tiled with any constant number of tiles. □

The above theorem uses the simple fact that the 1-tiling complexity $T_L^1(n)$ of a language L is a lower bound on the number of distinct rows of $M_L(n)$. In fact, the number of distinct rows of $M_L(n)$, for a language L, is closely related to a measure that has been previously studied by many researchers. Dwork and Stockmeyer called this measure *nonregularity*, and denoted the nonregularity of L by $N_L(n)$ [7]. $N_L(n)$ is the maximum size of a set of n*-dissimilar* strings of L. Two strings, w and w', are considered n-dissimilar if $|w| \leq n$ and $|w'| \leq n$, and there exists a string v such that $|wv| \leq n$, $|w'v| \leq n$, and $wv \in L$ if and only if $w'v \notin L$. It is easy to show that the number of distinct rows of $M_L(n)$ is between $N_L(n)$ and $N_L(2n)$. Previously, Kaŋeps and Freivalds [16] showed that $N_L(n)$ is equal to the number of states of the minimal 1-way deterministic finite state automaton which accepts a language L' for which $L'_n = L_n$, where L_n is the set of strings of L of length $\leq n$.

Shallit [28] introduced a similar measure: the *nondeterministic nonregularity* of L, denoted by $NN_L(n)$, is the minimal number of states of a 1-way nondeterministic finite automaton which accepts a language L' for which $L'_n = L_n$. In fact, it is not hard to show that

$$T_L^1(n) \leq NN_L(2n).$$

To see this, suppose that M is an automaton with $NN_L(2n)$ states, which accepts a language L' for which $L'_{2n} = L_{2n}$. We construct a 1-tiling of $M_L(n)$ with one tile T_q per state q of M, where entry $[x, y]$ is covered by T_q if and only if there is an accepting path of M on xy which enters state q as the head falls off the rightmost symbol of x. It is straightforward to verify that the set of tiles defined in this way is indeed a valid 1-tiling of $M_L(n)$. A similar argument was used by Schmidt [27] to prove lower bounds on the number of states in an unambiguous nfa.

We next turn to simple lower bounds on the 1-tiling complexity of nonregular languages. From Theorem 4.2, it is clear that if L is nonregular, then $T_L^1(n)$ is unbounded. We now use a known lower bound on the nonregularity of nonregular languages to prove a lower bound for $T_L^1(n)$.

THEOREM 4.3. *If* L *is not regular, then* $T_L^1(n) \geq \log_2 n - 1$ *for infinitely many* n*.*

Proof. Kaŋeps and Freivalds [16] proved that if L is not regular, then $N_L(n) \geq \lfloor (n+3)/2 \rfloor$ for infinitely many n. By the definition of $N_L(n)$, the matrix $M_L(n)$ must have at least $N_L(n)$ distinct rows. Therefore, by Lemma 4.1, $T_L^1(n) \geq \log_2 N_L(n)$. The lemma follows immediately. □

We next present an example of a unary nonregular language, with 1-tiling complexity $O(\log n)$. Thus, the lower bound of Theorem 4.3 is optimal to within a constant factor.

THEOREM 4.4. *Let L be the complement of the language $\{a^{2^k-1} \mid k > 0\}$. Then, L has 1-tiling complexity $O(\log n)$.*

Proof. We show that the 1-valued entries of $M_L(n)$ can be covered with $O(\log n)$ 1-tiles. Let $\lg n$ denote $\lfloor \log_2 n \rfloor + 1$, and let $\lg 0 = 0$. Let x and y be binary numbers of length at most $\lg n$. Number the bits of these numbers from right to left, starting with 1, so that, for example, $y = y_{\lg n} \dots y_2 y_1$. For any binary number q, $\lg q$ is the maximum index i such that $q_i = 1$ ($\lg q = 0$ if $q = 0$).

Clearly, if q is equal to $2^k - 1$ for some integer $k > 0$, then for all indices $i, 1 \leq i \leq \lg q$, $q_i = 1$. The next fact follows easily.

FACT. *$x + y = 2^k - 1$ for some integer $k > 0$ if and only if for all j such that $j \leq \max\{\lg x, \lg y\}$, $x_j \neq y_j$.*

Roughly, we construct a 1-tiling of $M_L(n)$, corresponding to the following nondeterministic communication protocol. The party P_1 guesses an index j and sends j and x_j to P_2. Also, P_1 sends P_2 one bit indicating whether or not $j \leq \lg x$. If $j \leq \lg x$, then P_2 checks that $y_j = x_j$. If $j > \lg x$, P_2 checks that $j \leq \lg y$ and that $y_j = x_j$, or equivalently, that $y_j = 0$. In either case, P_2 can conclude that $y_j = x_j$, and so entry $[a^x, a^y]$ of $M_L(n)$ is 1. The number of bits sent from P_1 to P_2 is $\lg \lg n + 2$.

We now describe the 1-tiling corresponding to this protocol. It is the union of two sets of tiles. The first set has one tile $T_{j,b}$ for each j, b such that $\lg n \geq j \geq 0$ and $b \in \{0, 1\}$, where

$$T_{j,b} = \{a^x \mid 0 \leq x \leq n, \lg x \geq j, x_j = b\} \times \{a^y \mid 0 \leq y \leq n, y_j = b\}.$$

The second set of tiles has one tile $S_{j,0}$, for all j such that $\lceil \log n \rceil \geq j \geq 1$.

$$S_{j,0} = \{a^x \mid 0 \leq x \leq n, \lg x < j, x_j = 0\} \times \{a^y \mid 0 \leq y \leq n, \lg y \geq j, y_j = 0\}.$$

To see that all the 1's in the matrix are covered by one of these tiles, note that if entry $[a^x, a^y]$ of the matrix is 1, then by the above fact, there exists an index j such that $j \leq \max\{\lg x, \lg y\}$, and either $x_j = y_j = 1$, or $x_j = y_j = 0$. So, for example, if $\lg x \geq \lg y$, and j is such that $j \leq \lg x$ and $x_j = y_j = 0$, then entry $[a^x, a^y]$ is covered by tile $T_{j,0}$. □

The nondeterministic communication protocol in the above proof is a slight variation of a simple (and previously known) protocol for the complement of the set distinctness problem. In the set distinctness problem, each of the two parties holds a subset of $\{1, \dots, m\}$ and must determine whether the subsets are distinct. In our application, the problem is to determine, for $m = \max\{\lg x, \lg y\}$, whether the subset of $\{1, \dots, m\}$, whose corresponding values in x are 0, is distinct from the subset of $\{1, \dots, m\}$ whose corresponding values in y are 1.

4.2. Lower bounds on the tiling complexity of nonregular languages. In this section we prove that if a language L is nonregular, then the 1-tiling complexity of either L or $\bar{L}$ is "high" infinitely often. To prove this, we first prove lower bounds on the rank of M_L when L is nonregular. We then apply theorems from communication complexity relating rank to tiling complexity.

The proofs of the lower bounds on the rank of M_L are heavily dependent on distinctive structural properties of M_L. Consider first the case where L is a unary language over the alphabet $\Sigma = \{a\}$. In this case, for all i, j where $j > 1$, $a^i a^j = a^{i+1} a^{j-1}$, and therefore $M_L[a^i, a^j] = M_L[a^{i+1}, a^{j-1}]$. It follows that for every n, $M_L(n)$ is such that its auxiliary diagonal (the diagonal from the top right to the bottom left) consists of equal elements, as do all diagonals parallel to that diagonal. An example is shown in Figure 1. Such matrices are classically known as *Hankel matrices* and have been extensively studied [15]. In fact, a direct application of known results on the rank of

Hankel matrices shows that if L is nonregular, then $\text{rank}(M_L(n)) \geq n+1$ infinitely often. This was first proved by Iohvidov (see [15, Theorem 11.3]), based on previous work of Frobenius [11].

If L is a nonunary language, then M_L does not have the simple diagonal structure of a Hankel matrix. Nevertheless, M_L still has structural properties that we are able to exploit. In fact, the term Hankel matrix has been extended from its classical meaning to refer to matrices M_L of nonunary languages (see [26]). In what follows, we generalize the results on the rank of classical Hankel matrices and prove that for any nonregular language L, over an arbitrary alphabet, $\text{rank}(M_L(n)) \geq n+1$ infinitely often.

4.2.1. Notation and basic facts. Let L be a language over an arbitrary alphabet, and let $M = M_L$.

Consider a row of M indexed by a string w. This row corresponds to strings that have the prefix w. For any string s, row ws corresponds to strings with the prefix ws. Thus the entries in row ws can be determined by looking at those entries in row w whose columns are indexed by strings beginning with s (see Figure 2). In what follows, we consider this relationship between the rows of M more formally.

Let $M(n,m)$ denote the set of vectors (finite rows) of M which are indexed by strings x of length $\leq n$ and whose columns are indexed by strings of length $\leq m$. Let $\hat{M}(n,m)$ denote the subset of vectors of $M(n,m)$ which are indexed by strings x of

length exactly n. If v' is row x of $M(n, m+i)$, where $i > 0$ and v is row x of $M(n, m)$, then v' is called an *extension* of v.

Suppose $v \in M(n, m)$. Let s be a string over Σ of length $\leq m$ (possibly the empty string, ϵ). Define $\text{split}^{(s)}(v)$ to be the subvector formed from v by selecting exactly those columns whose labels have s as a prefix. Also, relabel the columns of $\text{split}^{(s)}(v)$ by removing the prefix s. Note that $\text{split}^{(\epsilon)}(v) = v$. Note also that if Σ is unary, say $\{\sigma\}$, then $\text{split}^{(\sigma)}(v)$ is v with the first column removed. Let $|v|$ denote the dimension (number of entries) of vector v. If Σ is binary and $\sigma \in \Sigma$, then

$$|\ \text{split}^{(\sigma)}(v)| = (|v| - 1)/2.$$

More generally, if $|\Sigma| = c > 1$ and $\sigma \in \Sigma$, then

$$|v| = \frac{c^{m+1} - 1}{c - 1}, \text{ and}$$
$$|\ \text{split}^{(\sigma)}(v)| = \frac{|v| - 1}{c} = \frac{c^m - 1}{c - 1}.$$

Also, the vector v consists of the first entry (indexed by the empty string, ϵ), plus an "interleaving" of the entries of $\text{split}^{(\sigma)}(v)$, for each $\sigma \in \Sigma$. More precisely, we have the following fact.

FACT 4.1. *Let $j', s, j \in \Sigma^*$, where $j' = sj$. Then, $v[j'] = \text{split}^{(s)}(v)[j]$.*

We generalize the definition of the split function to sets of vectors. If V is a set of vectors in $M(n, m)$, and $|s| \leq m$, let $\text{split}^{(s)}(V) = \{\ \text{split}^{(s)}(v) \mid v \in V\}$. Then we have the following.

FACT 4.2. $\cup_{|s|=i}\text{split}^{(s)}(\hat{\text{M}}(n, m)) = \hat{\text{M}}(n + i, m - i)$. *Thus,*

(a) $\hat{\text{M}}(n + i, m - i) \subseteq \cup_{|s|=i}\text{split}^{(s)}(M(n, m))$, *and*

(b) $\cup_{|s|=i}\text{split}^{(s)}(M(n, m)) = M(n + i, m - i)$.

In what follows, the vectors we consider are assumed to be elements of vector spaces over an arbitrary field $\mathbf{F}$ (e.g., our proofs will hold if $\mathbf{F}$ is taken to be the field of rationals $\mathbf{F}$). All references to rank, span, and linear independence apply to vector spaces over $\mathbf{F}$.

LEMMA 4.5. *Suppose that $b_1, \ldots, b_p \in M(n, m)$ and that*

$$v = \alpha_1 b_1 + \cdots + \alpha_p b_p,$$

where the α_i are in the field $\mathbf{F}$. Suppose that for $1 \leq k \leq p$, b'_k is an extension in $M(n, m + 1)$ of b_k and that v' is an extension of v to the same length as the b'_k.

Suppose also that for some $i, 0 \leq i \leq m + 1$, it is the case that for all s of length i,

$$\text{split}^{(s)}(v') = \alpha_1\text{split}^{(s)}(b'_1) + \cdots + \alpha_p\text{split}^{(s)}(b'_p).$$

Then $v' = \alpha_1 b'_1 + \cdots + \alpha_p b'_p$.

Proof. Clearly, $v'[j] = \alpha_1 b'_1[j] + \cdots + \alpha_p b'_p[j]$, if j is a string of length $\leq m$. Consider a string j' of length $m + 1$. Let $j' = sj$, where $|s| = i$. By Fact 4.1,

$$v'[j'] = \ \text{split}^{(s)}(v')[j].$$

Also,

$$b'_k[j'] = \ \text{split}^{(s)}(b'_k)[j], \quad \text{for } 1 \leq k \leq p.$$

By the hypothesis of the lemma,

$$\text{split}^{(s)}(v')[j] = \alpha_1 \text{ split}^{(s)}(b'_1)[j] + \cdots + \alpha_p \text{ split}^{(s)}(b'_p)[j].$$

Putting the last three equalities together, $v'[j'] = \alpha_1 b'_1[j'] + \cdots + \alpha_p b'_p[j']$, as required. □

Let $\text{rank}(M(n,m))$ be the rank of the set of vectors $M(n,m)$ and let $\text{span}(M(n,m))$ be the vector space generated by the vectors in $M(n,m)$. The next lemma follows immediately from the definitions.

LEMMA 4.6. *If* $v' \in \text{span}(M(n,m)), m > 0$ *and* $v = \text{split}^{(\sigma)}(v')$, *where* $\sigma \in \Sigma$, *then*

$$v \in \text{span}(\text{split}^{(\sigma)}(M(n,m))).$$

4.2.2. A lower bound on the rank of $M(n)$ when L is nonregular. A trivial lower bound on the rank of $M(n)$ is given by the following fact.

FACT 4.3. *L is nonregular if and only if there is an infinite sequence of integers p_r satisfying* $\text{rank}(M(p_r)) \geq r+1$ *for all integers r.*

This is easily shown using the Myhill-Nerode theorem. Clearly, such a sequence exists if and only if the rank of $M(n)$ (as n increases) is unbounded. Moreover, the rank of $M(n)$ is unbounded if and only if the number of distinct rows in $M(n)$ is unbounded. The Myhill-Nerode theorem states that the number of equivalence classes of L (equivalently, the number of distinct rows of M) is finite if and only if L is regular. It follows that L is nonregular if and only if the rank of $M(n)$ is unbounded. This conclusion has already been noted (see sections II.3 and II.5 of [26], which describes results from the literature on rational power series and regular languages).

The above lower bound is very weak. In what follows, we significantly improve it by using the special structure of $M(n)$. Namely, we show that there is an infinite sequence of values of n such that $\text{rank}(M(n)) \geq n+1$. We define the first value of n in our sequence to be the length of the shortest word in L (clearly $\text{rank}(M(n)) \geq n+1$ in this case). To construct the remainder of the sequence, we show (in Lemma 4.9) that because L is nonregular, for any value of n, there is some $m \geq n$ such that $\text{rank}(M(n+1,m+1)) > \text{rank}(M(n,m+1))$. We then prove (in Lemma 4.10 and the proof of Theorem 4.11) that if n is such that $\text{rank}(M(n)) \geq n+1$, and we choose the smallest $m \geq n$ such that $\text{rank}(M(n+1,m+1)) > \text{rank}(M(n,m+1))$, then in fact $\text{rank}(M(m+1)) \geq m+2$.

We begin with the following useful lemma.

LEMMA 4.7. *Let $n \geq 0, m \geq 1$. Suppose that $M(n+1,m) \subseteq \text{span}(M(n,m))$. Then, for all $i, 1 \leq i \leq m$, $M(n+i, m-i+1) \subseteq \text{span}(M(n, m-i+1))$.*

Proof. The proof is by induction on i. The result is true by hypothesis of the lemma in the case $i = 1$. Suppose $1 < i \leq m$ and that the lemma is true for $i-1$.

It follows from the induction hypothesis that if $v \in M(n+i-1, m-i+2)$, then also $v \in \text{span}(M(n, m-i+2))$. Hence, it must also be the case that if $v \in M(n+i-1, m-i+1)$, then $v \in \text{span}(M(n, m-i+1))$. It remains to consider the vectors in $\hat{M}(n+i, m-i+1)$. By Fact 4.2(a), each such vector v is of the form $\text{split}^{(\sigma)}(v')$, where $v' \in M(n+i-1, m-i+2)$, for some $\sigma, |\sigma| = 1$. By the inductive hypothesis, $v' \in \text{span}(M(n, m-i+2))$. Hence, by Lemma 4.6, $v \in \text{span}(\text{split}^{(\sigma)}(M(n, m-i+2)))$.

Then, by Fact 4.2(b), all of the vectors in $\text{split}^{(\sigma)}(M(n, m-i+2))$ are in $M(n+1, m-i+1)$. Hence, $v \in \text{span}(M(n+1, m-i+1))$. Finally, by the hypothesis of the lemma, $\text{span}(M(n+1, m-i+1)) = \text{span}(M(n, m-i+1))$. Hence, $v \in \text{span}(M(n, m-i+1))$, as required. □

COROLLARY 4.8. *For any* $n \geq 0$, *if* $\operatorname{rank}(M(n+1,2p)) = \operatorname{rank}(M(n,2p)) \leq r$, *then* $\operatorname{rank}(M(p)) \leq r$.

Proof. If $n \geq p$, then $M(p)$ is a submatrix of $M(n,2p)$ so the result follows trivially. Otherwise, choose i so that $n+i=p$. Then $M(p)$ is a submatrix of $M(n+i,2p-i+1)$, and hence by Lemma 4.7, the rows of $M(p)$ are contained in $\operatorname{span}(M(n,p))$. Thus again, $\operatorname{rank}(M(p)) \leq r$. □

The following lemma shows the existence of an $m \geq n$ such that $\operatorname{rank}(M(n+1,m+1)) > \operatorname{rank}(M(n,m+1))$.

LEMMA 4.9. *Let* L *be a nonregular language. Then for any* n, *there exists an* $m \geq n$ *such that* $\operatorname{rank}(M(n+1,m+1)) > \operatorname{rank}(M(n,m+1))$.

Proof. Let r be the number of strings of length $\leq n$. Clearly, $\operatorname{rank}(M(n,m)) \leq r$ for all m, since there are r rows in $M(n,m)$. Let $p = p_r$ as in Fact 4.3, that is, $\operatorname{rank}(M(p)) \geq r+1$. Hence, by Corollary 4.8, it must be the case that $\operatorname{rank}(M(n+1,2p)) > \operatorname{rank}(M(n,2p))$. Thus, $2p$ is one possible value of m that satisfies the lemma. □

It remains to show that if n is such that $\operatorname{rank}(M(n)) \geq n+1$, and m is the smallest number such that $m \geq n$ and $\operatorname{rank}(M(n+1,m+1)) > \operatorname{rank}(M(n,m+1))$, then $\operatorname{rank}(M(m+1)) \geq m+2$. This is clearly true if for all $i \in [0,\ldots,m-n]$, $\operatorname{rank}(M(n,m-i)) < \operatorname{rank}(M(n,m-i+1))$, because in this case $\operatorname{rank}(M(n,m+1)) \geq m+2$. The difficult case is when there exist values of i such that $\operatorname{rank}(M(n,m-i)) = \operatorname{rank}(M(n,m-i+1))$. To help deal with this case, we prove the following lemma.

LEMMA 4.10. *Suppose that the following properties hold:*

1. $M(n+1,n+1) \subseteq \operatorname{span}(M(n,n+1))$.
2. m *is the smallest number* $> n$ *such that* $M(n+1,m+1) \not\subseteq \operatorname{span}(M(n,m+1))$.
3. i *is a number in the range* $[0,\ldots,m-n]$ *such that*

$$\operatorname{rank}(M(n,m-i)) = \operatorname{rank}(M(n,m-i+1)).$$

Then, there is some vector in $M(n+i+1,m-i+1)$ *which is not in* $\operatorname{span}(M(n,m-i+1))$.

Proof. Let $v' \in M(n+1,m+1) - \operatorname{span}(M(n,m+1))$, where v' is the extension of some $v \in M(n+1,m)$.

Then, we claim that for some $s, |s| = i$, $\operatorname{split}^{(s)}(v') \notin \operatorname{span}(M(n,m-i+1))$. Since $\operatorname{split}^{(s)}(v') \in M(n+i+1,m-i+1)$ by Fact 4.2(b), this is sufficient to prove the lemma.

Suppose to the contrary that for all s of length i, $\operatorname{split}^{(s)}(v') \in \operatorname{span}(M(n,m-i+1))$.

Let $\{b_1,\ldots,b_p\}$ be a basis of $M(n,m)$. Let $\{b'_1,\ldots,b'_p\}$ be an extension of this basis in $M(n,m+1)$. By properties 1 and 2 of the lemma, v is in $\operatorname{span}(M(n,m))$. Let $v = \alpha_1 b_1 + \cdots + \alpha_p b_p$. Then, applying Fact 4.1, we see that for all $s, |s| = i$,

$$\operatorname{split}^{(s)}(v) = \alpha_1 \operatorname{split}^{(s)}(b_1) + \cdots + \alpha_p \operatorname{split}^{(s)}(b_p). \tag{2}$$

We want to show that for all s of length i,

$$\operatorname{split}^{(s)}(v') = \alpha_1 \operatorname{split}^{(s)}(b'_1) + \cdots + \alpha_p \operatorname{split}^{(s)}(b'_p).$$

It follows from this and Lemma 4.5 that

$$v' = \alpha_1 b'_1 + \cdots + \alpha_p b'_p,$$

contradicting the fact that $v' \notin \operatorname{span}(M(n,m+1))$.

Consider the vectors $\text{split}^{(s)}(b'_k)$. These are in $M(n+i, m-i+1)$, by Fact 4.2 (b). If $i = 0$, this is clearly in $\text{span}(M(n, m+1))$. If $0 < i \leq m-n$, by Lemma 4.7 and by property 2 of this lemma, these vectors are in $\text{span}(M(n, m-i+1))$. Let $c_1, \ldots, c_l$ be a basis for $\text{span}(M(n, m-i))$, and for $1 \leq k \leq l$, let c'_k be an extension in $M(n, m-i+1)$ of c_k. Clearly the set $\{c'_1, \ldots, c'_l\}$ is also linearly independent, and since $\text{rank}(M(n, m-i)) = \text{rank}(M(n, m-i+1))$, this set is a basis for $\text{span}(M(n, m-i+1))$. Let

$$\text{split}^{(s)}(b'_k) = \gamma^{(s)}_{k,1} c'_1 + \cdots + \gamma^{(s)}_{k,l} c'_l. \tag{3}$$

Then, also

$$\text{split}^{(s)}(b_k) = \gamma^{(s)}_{k,1} c_1 + \cdots + \gamma^{(s)}_{k,l} c_l. \tag{4}$$

Also, since $v \in M(n+1, m)$, from Fact 4.2(b) it must be that the vectors $\text{split}^{(s)}(v)$ are in $M(n+i+1, m-i)$. Hence, again by property 2 of this lemma, and by Lemma 4.7, these vectors are in $\text{span}(M(n, m-i))$.

Since $c_1, \ldots, c_l$ is a basis for $\text{span}(M(n, m-i))$, it follows that there exists a unique sequence of coefficients $\tau_1, \ldots, \tau_l$ such that

$$\text{split}^{(s)}(v) = \tau_1 c_1 + \tau_2 c_2 + \cdots + \tau_l c_l.$$

Also, by combining equation (2) with equation (4), we see that

$$\begin{aligned} \text{split}^{(s)}(v) \quad = \quad & \alpha_1[\gamma^{(s)}_{1,1} c_1 + \cdots + \gamma^{(s)}_{1,l} c_l] \\ + \quad & \alpha_2[\gamma^{(s)}_{2,1} c_1 + \cdots + \gamma^{(s)}_{2,l} c_l] \\ + \quad & \cdots \\ + \quad & \alpha_p[\gamma^{(s)}_{p,1} c_1 + \cdots + \gamma^{(s)}_{p,l} c_l]. \end{aligned}$$

Thus $\tau_k = \alpha_1 \gamma^{(s)}_{1,k} + \cdots + \alpha_p \gamma^{(s)}_{p,k}$ for all $k \in [1, \ldots, l]$.

We claim

$$\begin{aligned} \text{split}^{(s)}(v') \quad = \quad & \alpha_1[\gamma^{(s)}_{1,1} c'_1 + \cdots + \gamma^{(s)}_{1,l} c'_l] \\ + \quad & \alpha_2[\gamma^{(s)}_{2,1} c'_1 + \cdots + \gamma^{(s)}_{2,l} c'_l] \\ + \quad & \cdots \\ + \quad & \alpha_p[\gamma^{(s)}_{p,1} c'_1 + \cdots + \gamma^{(s)}_{p,l} c'_l]. \end{aligned}$$

We now justify the claim. By our initial assumption, $\text{split}^{(s)}(v')$ is in $\text{span}(M(n, m-i+1))$. Thus for some unique coefficients $\tau'_1, \ldots, \tau'_l$,

$$\text{split}^{(s)}(v') = \tau'_1 c'_1 + \tau'_2 c'_2 + \cdots + \tau'_l c'_l.$$

Each c'_k is an extension of c_k, and there is a unique linear combination of $c_1, c_2, \ldots c_l$ that is equal to $\text{split}^{(s)}(v)$. It follows that each $\tau'_k = \tau_k$. This proves the claim.

Combining the claim with equation (3) yields

$$\text{split}^{(s)}(v') = \alpha_1 \text{ split}^{(s)}(b'_1) + \cdots + \alpha_p \text{ split}^{(s)}(b'_p),$$

as desired. □

We now prove the lower bound.

THEOREM 4.11. *If L is nonregular, then* $\text{rank}(M(n)) \geq n+1$ *infinitely often.*

Proof. The base case is n such that the shortest word in the language is of length n.

Suppose that $\text{rank}(M(n)) \geq n+1$ for some fixed n. Let m be the smallest number $\geq n$ such that $\text{rank}(M(n+1,m+1)) > \text{rank}(M(n,m+1))$. By Lemma 4.9 there is such an m. We claim that $\text{rank}(M(m+1)) \geq m+2$.

If $m = n$, then the claim is clearly true. Suppose $m > n$.

Let B_k be a basis for $M(n,k)$, $n \leq k \leq m+1$, where the extensions of all vectors in B_k are in B_{k+1}. Let B'_{k-1} denote the subset of B_k which are extensions of vectors in B_{k-1}.

We construct a set of $m+2$ linearly independent vectors in $M(m+1)$ as follows. For k from n to $m+1$, we define a linearly independent set C_k of vectors in $M(m+1,k)$, of size at least $k+1$. Then, C_{m+1} is the desired set.

Let $C_n = B_n$. This is by definition a linearly independent set, and it has size $\geq n+1$ because (by our initial assumption) $\text{rank}(M(n)) \geq n+1$. Suppose that $n \leq k < m+1$ and that C_k is already constructed and is linearly independent. Construct C_{k+1} as follows.

(i) Let C'_k be the set of extensions in $M(m+1,k+1)$ of the vectors in C_k. Add C'_k to C_{k+1}.

(ii) Add B_{k+1} to C_{k+1}. (Thus, C_{k+1} is expanded to contain those vectors in B_{k+1} which are not in B'_k.)

(iii) Finally, suppose nothing is added to C_{k+1} in step (ii); that is, $\text{rank}(M(n,k)) = \text{rank}(M(n,k+1))$. If i is such that $k = m-i$, then this is equivalent to $\text{rank}(M(n,m-i)) = \text{rank}(M(n,m-i+1))$. Thus, we can apply Lemma 4.10 to obtain a vector $v' \in M(n+i+1, m-i+1)$ which is not in $\text{span}(M(n,m-i+1))$. (Thus, $v' \in M(n+m+1-k, k+1)$ but is not in $\text{span}(B'_k)$.) Add v' to C_{k+1}.

We claim that the vectors in C_{k+1} are linearly independent. Clearly the set C'_k is linearly independent. Consider each vector u' added to C_{k+1}, which is not in C'_k. By the construction, u' is not in $\text{span}(B'_k)$. Let u' be the extension of vector u in $M(m+1,k)$. We claim that the vector u must be linearly dependent on the set B_k. This is true if u' is added in step (ii), since in this case u is in $M(n,k)$ and B_k is a basis for $M(n,k)$. It is also true in the case that $u' = v'$, the vector added in step (iii), since then by Lemma 4.7, $u = v \in \text{span}(B_k)$.

Hence, $u \in \text{span}(C_k)$, since $B_k \subseteq C_k$. Moreover, u can be expressed as a unique linear combination of the vectors of C_k, with nonzero coefficients only on those vectors in B_k.

If u' were in $\text{span}(C'_k)$, then since it is an extension of u, it would also be expressible as a unique linear combination of the vectors of C'_k, with nonzero coefficients only on those vectors in B'_k. But that contradicts the fact that $u' \notin \text{span}(B'_k)$. □

4.2.3. The tiling complexity lower bound.

THEOREM 4.12. *If L is nonregular, then the 1-tiling complexity of either L or $\bar{L}$ is at least $2^{\sqrt{\log n}-2} - 1$ infinitely often.*

Proof. Melhorn and Schmidt, and, independently, Orlin, showed that for any binary matrix A, *rank*$(A) \leq \tilde{T}(A)$ [21, 22]. Their result holds for A over any field. Halstenberg and Reischuk [13], refining a proof of Aho, Ullman, and Yannakakis [1], showed that $\lceil \log \tilde{T}(A) \rceil \leq \lceil \log T^1(A) \rceil (\lceil \log(T^0(A)+1) \rceil + 2) + 1$. Let $T^*(A) = \max(T^1(A), T^0(A))$. Then $\lceil \log \text{rank}(A) \rceil \leq (\lceil \log(T^*(A)+1) \rceil + 1)^2$.

By Theorem 4.11, if L is nonregular, then the rank of $M(n)$ is at least $n+1$ infinitely often. It follows that for infinitely many n, $T^*(M(n)) = \max(T^1_L(n), T^0_L(n)) \geq 2^{\sqrt{\log n}-2} - 1$. □

5. Variations on the model. In this section, we discuss extensions of our main results to other related models.

We first show that Theorem 1.1 also holds for the following "alternating probabilistic" finite state automaton model. In this model, which we call a 2apfa, the nondeterministic states N are partitioned into two subsets N_E and N_U of existential and universal states, respectively. Accordingly, for a fixed input, there are two types of strategy, defined as follows for a fixed input string $w = w_0 w_1 w_2 \dots w_n w_{n+1}$. An *existential (universal) strategy* on w is a function

$$E_w : N_E \times \{0, \dots, n+1\} \to Q \times \{-1, 0, 1\},$$

$$(U_w : N_U \times \{0, \dots, n+1\} \to Q \times \{-1, 0, 1\}),$$

such that $\delta(q, \sigma, q', d) = 1$ whenever $E_w(q, j) = (q', d)$ $(U_w(q, j) = (q', d))$ and $w_j = \sigma$.

A language $L \subseteq \Sigma^*$ is accepted with *bounded error probability* if for some constant $\epsilon < 1/2$,

1. for all $w \in L$, there exists an existential strategy E_w on which the automaton accepts with probability $\geq 1 - \epsilon$ on all universal strategies U_w, and
2. for all $w \notin L$, on every existential strategy E_w, the automaton accepts with probability $\leq \epsilon$ on some universal strategy U_w.

The complexity classes 1APFA, 1APFA-polytime, and so on, are defined in the natural way, following our conventions for the npfa model.

THEOREM 5.1. *1APFA = Regular.*

Proof. As in Theorems 1.1 and 3.1, we show that if L is a language accepted by a 1APFA, then the tiling complexity of L is bounded. We first extend the notation of Theorem 3.1.

If E is an existential strategy on xy and U is a universal strategy on xy, let $\mathbf{p}_{xy}(E, U)$ be the state probability (row) vector at the step when the input head moves off the right end of x, on the strategies E, U. Let $\mathbf{r}_{xy}(E, U)$ be the column vector whose ith entry is the probability of accepting the string xy, assuming that the automaton is in state i at the moment that the head moves off the right end of x, on the strategies E, U. For each 1-entry $[x, y]$ of M_L, fix an existential strategy E_{xy}, that causes xy to be accepted with probability at least $1 - \epsilon$, for all universal strategies.

Partition the space $[0, 1]^c$ into cells of size $\mu \times \mu \times \cdots \times \mu$, as before. Let $\mathcal{C}$ be a nonempty subset of the cells. We say that entry $[x, y]$ of M_L belongs to $\mathcal{C}$ if $xy \in L$, and $\mathcal{C}$ is the smallest set of cells which contain all the vectors $\mathbf{p}_{xy}(E_{xy}, U)$, for all universal strategies U.

With each nonempty subset $\mathcal{C}$ of the cells, associate a rectangle $R_{\mathcal{C}}$ defined as follows.

$$\{x \mid \text{there exists } y \text{ such that } [x, y] \text{ belongs to } \mathcal{C}\}$$
$$\times$$
$$\{y \mid \text{there exists } x \text{ such that } [x, y] \text{ belongs to } \mathcal{C}\}.$$

Then, $R_{\mathcal{C}}$ is a valid 1-tile. To see this, suppose that $[x, y] \in R_{\mathcal{C}}$. If $[x, y]$ belongs to $\mathcal{C}$, then it must be a 1-entry. Otherwise, there exist x' and y' such that $[x, y']$ and $[x', y]$ belong to $\mathcal{C}$.

Consider the strategy E that, while reading x, uses the strategy $E_{xy'}$, and while reading y, uses the strategy $E_{x'y}$. We claim that xy is accepted with probability at least $1/2$ on existential strategy E and any universal strategy U on xy. The probability that xy is accepted on strategies E, U is

$$\mathbf{p}_{xy}(E, U)\mathbf{r}_{xy}(E, U) = \mathbf{p}_{xy'}(E_{xy'}, U)\mathbf{r}_{x'y}(E_{x'y}, U).$$

Since $[x, y']$ and $[x', y]$ belong to the same set of cells $\mathcal{C}$, $\mathbf{p}_{xy'}(E_{xy'}, U)$ and $\mathbf{p}_{x'y}(E_{x'y}, U')$ are in the same cell, for some universal strategy U'. Moreover,

$$\mathbf{p}_{x'y}(E_{x'y}, U')\mathbf{r}_{x'y}(E_{x'y}, U) \geq 1 - \epsilon.$$

This is because this quantity is the probability that $x'y$ is accepted on existential strategy $E_{x'y}$ and a universal strategy which is a hybrid of U and U'; also, by definition of $E_{x'y}$, the probability that $x'y$ is accepted with respect to $E_{x'y}$ and any universal strategy is $\geq 1 - \epsilon$. Hence,

$$\begin{aligned}(\mathbf{p}_{x'y}(E_{x'y}, U') - \mathbf{p}_{xy'}(E_{xy'}, U))\ \mathbf{r}_{x'y}(E_{x'y}, U) & \\ &= \textstyle\sum_{i=1}^{c} [\mathbf{p}_{x'y}(E_{x'y}, U') - \mathbf{p}_{xy'}(E_{xy'}, U)]_i [\mathbf{r}_{x'y}(E_{x'y}, U)]_i \\ &\leq \mu \textstyle\sum_{i=1}^{c} [\mathbf{r}_{x'y}(E_{x'y}, U)]_i \\ &\leq \mu c \\ &= 1/2 - \epsilon, \quad \text{by our choice of } \mu.\end{aligned}$$

Hence, the probability that xy is accepted on the strategies E, U is

$$\begin{aligned}\mathbf{p}_{xy'}(E_{xy'}, U)\mathbf{r}_{x'y}(E_{x'y}, U) &\geq \mathbf{p}_{x'y}(E_{x'y}, U')\mathbf{r}_{x'y}(E_{x'y}, U) - (1/2 - \epsilon) \\ &\geq (1 - \epsilon) - (1/2 - \epsilon) \\ &= 1/2 > \epsilon.\end{aligned}$$

Since U is arbitrary, it follows that there is an existential strategy E such that on all strategies U, the probability that xy is accepted on the strategies E, U is greater than ϵ, and so it cannot be that $xy \notin L$. Hence, for all $[x, y] \in R_{\mathcal{C}}$, xy must be in L. Therefore $R_{\mathcal{C}}$ is a 1-tile in M_L.

The proof is completed as in Theorem 3.1. □

In the same way, Theorem 3.4 can also be extended to obtain the following.

THEOREM 5.2. *A language L is in 2APFA-polytime only if the 1-tiling complexity of L is bounded by $2^{polylog(n)}$.*

Thus, for example, the language *Pal*, consisting of all strings over $\{0, 1\}^*$ which read the same forwards as backwards, is not in the class 2APFA-polytime. To see this, consider the submatrix of $M_L(n)$, consisting of all rows and columns labeled by strings of length exactly n. This matrix contains a fooling set of size 2^n; hence a 1-tiling of $M_L(n)$ requires at least 2^n tiles.

We next extend Theorem 1.2 to automata with $o(\log \log n)$ space. We refer to these as Arthur–Merlin games, since this is the usual notation for such automata which are not restricted to a finite number of states [7]. The definition of an Arthur–Merlin game is similar to that of an npfa, except that the machine has a fixed number of read/write worktapes. The Arthur–Merlin game runs within space $s(n)$ if on any input w with $|w| \leq n$, at most $s(n)$ tape cells are used on any worktape. Thus, the number of different configurations of the Arthur–Merlin game is $2^{O(s(n))}$.

THEOREM 5.3. *Let M and $\bar{M}$ be Arthur–Merlin games which recognize a nonregular language L and its complement $\bar{L}$, respectively, within space $o(\log \log n)$. Suppose that the expected running time of both M and $\bar{M}$ is bounded by $t(n)$. Then, for all $b < 1/2$, $\log \log t(n) \geq (\log n)^b$. In particular, $t(n)$ is not bounded by any polynomial in n.*

Proof. The proof of Theorem 1.2 can be extended to space bounded Arthur–Merlin games to yield the following generalization of equation (1). Let $c(n)$ be an upper bound on the number of different configurations of M on inputs of length n,

and let $d(n) = 2c(n) + 4$. Then, for sufficiently large n, the number of 1-tiles needed to cover $M_L(n)$ is at most

$$T_L^1(n) \leq (\lceil 2 \log_2 t(n)/\mu \rceil + 1)^{d^2(n)} = 2^{\Theta(d^2(n) \log\log t(n))}.$$

Since M uses $o(\log\log n)$ space, for any constant $c > 0$, $d(n) \leq (\log n)^c$, for sufficiently large n.

Now, suppose to the contrary that for some $b < 1/2$, $\log\log t(n) < (\log n)^b$ for sufficiently large n. Then,

$$d^2(n) \log\log t(n) = o(\sqrt{\log n}).$$

Hence, the number of tiles needed to cover the 1-valued entries of $M_L(n)$ is $2^{o(\sqrt{\log n})}$. The same argument for $\bar{M}$ shows that also, for sufficiently large n, the number of tiles needed to cover the 1-valued entries of $M_{\bar{L}}(n)$ is $2^{o(\sqrt{\log n})}$.

Hence, by Theorem 4.12 L must be regular, which is a contradiction. □

Finally, we consider a restriction of the 2npfa model, which, given polynomial time, can only recognize regular languages. A *restricted 2npfa* is a 2npfa for which there is some $\epsilon < 1/2$ such that on all inputs w and strategies S_w, the probability that the automaton accepts is either $\geq 1 - \epsilon$ or $< \epsilon$.

THEOREM 5.4. *Any language accepted by a restricted 2npfa with bounded error probability in polynomial time is regular.*

Proof. Let L be accepted by a 2npfa M with bounded error probability in polynomial expected time. Let Σ be the alphabet, δ the transition function, $Q = \{q_1, q_2, \ldots, q_{|Q|}\}$ the set of states, and $N \subset Q$ the set of nondeterministic states of M. Without loss of generality, let $N = \{q_1, \ldots, q_{|N|}\}$.

We first define a representation of strategies as strings over a finite alphabet. Let $\Sigma' = (N \times Q \times \{-1, 0, 1\})^{|N|}$. Without loss of generality, assume that $\Sigma \cap \Sigma' = 0$. A string $S_0 S_1 \ldots S_{n+1}$ corresponds to a strategy on $\mathfrak{c}\, w\$$, where $\mathfrak{c}\, w\$ = \sigma_0 \sigma_1 \ldots \sigma_{n+1}$, if for $0 \leq j \leq n+1$, S_j is of the form

$$S_j = ((q_1, q_1', d_1), (q_2, q_2', d_2), \ldots, (q_{|N|}, q_{|N|}' d_{|N|})),$$

and $\delta(q_i, \sigma_j, q_i', d_i) = 1$.

Define L' to be the set of strings of the form $\sigma_0 S_0 \sigma_1 S_1 \ldots \sigma_{n+1} S_{n+1}$, where each σ_i is in the alphabet Σ, each S_i is in the alphabet Σ', and furthermore, $S = S_0 S_1 \ldots S_{n+1}$ corresponds to a strategy of M on input $w = \sigma_0 \sigma_1 \ldots \sigma_{n+1}$, which causes w to be accepted.

Then, L' is accepted by a 2pfa with bounded error probability in polynomial time. Thus, L' is regular [7]. Moreover, note that a string of the form $w = \sigma_0 \sigma_1 \ldots \sigma_{n+1}$ is in L if and only if for some choice of $S_0, S_1 \ldots S_{n+1}$, $\sigma_0 S_0 \sigma_1 S_1 \ldots \sigma_{n+1} S_{n+1}$ is in L'. Let M' be a one-way deterministic finite state automaton for L' and assume, without loss of generality, that the set of states in which M' can be when the head is at an even position is disjoint from the set of states in which M' can be when the head is at an odd position. Then, from M' we can construct a one-way nondeterministic finite state automaton for L by replacing the even position states by nondeterministic states. Hence, L is regular. □

6. Conclusions. We have introduced a new measure of the complexity of a language, namely its tiling complexity, and have proved a gap between the tiling complexity of regular and nonregular languages. We have applied these results to prove limits on the power of finite state automata with both probabilistic and nondeterministic states. These results first appeared in [5].

An intriguing question left open by this work is whether the class 2NPFA-polytime is closed under complement. If it is, we can conclude that 2NPFA-polytime = Regular. Recall that the class 2NPFA does contain nonregular languages, since it contains the class 2PFA, and Freivalds [10] showed that $\{0^n1^n \mid n \geq 0\}$ is in this class. However, Kaņeps [18] showed that the class 2PFA does not contain any nonregular unary language. Another open question is whether the class 2NPFA contains any nonregular unary language. It is also open whether there is a nonregular language in 2APFA-polytime.

There are several other interesting open problems. Can one obtain a better lower bound on the tiling complexity of nonregular languages than that given by Theorem 4.12, perhaps by an argument that is not based on rank? We know of no nonregular language with tiling complexity less than $\Omega(n)$ infinitely often, so the current gap is wide.

A PARALLEL REPETITION THEOREM*

RAN RAZ†

Abstract. We show that a parallel repetition of any two-prover one-round proof system (MIP(2, 1)) decreases the probability of error at an exponential rate. No constructive bound was previously known. The constant in the exponent (in our analysis) depends only on the original probability of error and on the total number of possible answers of the two provers. The dependency on the total number of possible answers is logarithmic, which was recently proved to be almost the best possible [U. Feige and O. Verbitsky, *Proc. 11th Annual IEEE Conference on Computational Complexity*, IEEE Computer Society Press, Los Alamitos, CA, 1996, pp. 70–76].

1. Introduction and basic notations.

1.1. History and motivation. We consider two-prover one-round proof systems (MIP(2, 1)), as introduced in [12]. In an MIP(2, 1) proof system, two computationally unbounded provers (that are not allowed to communicate with each other) try to convince a probabilistic polynomial time verifier that a common input I belongs to a prespecified language L. The proof proceeds in one round: The verifier generates a pair of questions (x, y), based on I and on a random string r, and sends x to the first prover and y to the second prover. The first prover responds by sending u, and the second prover responds by sending v. Based on I, r, x, y, u, v, the verifier decides whether to accept or reject the conjecture: $I \in L$. In what follows, the strategy of the verifier (the way to generate the questions and to decide whether $I \in L$) is called "a proof system," and the pair of strategies of the provers is called "a protocol." A language L is in MIP(2, 1) with probability of error ϵ if there exists a proof system (of this type), such that: (1) For $I \in L$, there exists a protocol that causes the verifier to always accept; (2) For $I \notin L$, for any possible protocol, the verifier accepts with probability smaller than ϵ. For the exact definitions of MIP(2, 1) proof systems and the family of languages MIP(2, 1), see [12, 23].

The class of languages MIP(2, 1) turned out to be very powerful. In particular, it follows from [7, 37, 25] that NEXPTIME = MIP(2, 1) with exponentially small probability of error. MIP(2, 1) proof systems have cryptographic applications (see [12, 13, 36, 18]), and have also been used as a starting point to prove that certain optimization problems are hard to approximate (see [22, 4, 5, 25, 6, 10, 38, 8]). For more discussion about the class MIP(2, 1) and its applications, see [23] and the references there.

Sequential repetition of MIP(2, 1) proof systems decreases the probability of error exponentially, but requires multiple rounds. Parallel repetition preserves the number of rounds. At what rate is the probability of error decreased by parallel repetition? At first, it was believed that, as in the sequential case, repeating a proof system k times

*Received by the editors January 17, 1995; accepted for publication (in revised form) July 29, 1996. A preliminary version of the paper appeared in Proceeding of the 27th Annual ACM Symposium on the Theory of Computing, ACM, New York, 1995, pp. 447–556.

in parallel decreases the probability of error to ϵ^k (see [26, 28]). A counter example for this conjecture was given in [21] (see also [36, 19, 25, 27]). For years it was not even known whether parallel repetition can make the probability of error arbitrarily small. This was recently proved in [44]. No constructive bound, however, was given there for the number of repetitions required to decrease the probability of error below a given bound.

In the simpler special case, where the provers' questions, x and y, are chosen independently, it has been known that repeating a proof system k times in parallel decreases the probability of error exponentially. The proof was first given in [15], and the bound was further improved in [36, 39, 19, 1]. Another special case, a tree-like-measure case, was recently settled in [45]. The constant in the exponent in all those proofs, however, is (at least) polynomial in the number of possible questions (x, y). We remark that in most interesting cases, the questions x, y are not chosen independently and the measure is not tree-like.

Researchers were interested in analyzing the probability of error of a parallel repetition, not only as a mathematical problem, but also because an efficient technique to decrease the probability of error was needed. In the literature there are many results that use different techniques to decrease the probability of error [19, 33, 37, 25, 8, 23, 43]. For certain applications, however, these techniques are insufficient. Parallel repetition was suggested as a technique to decrease the probability of error, because it was believed to be very efficient, and because it preserves many canonical properties of the proof system (e.g., zero knowledge).

Since the appearance of a preliminary version of this paper in STOC95 [40], our results were used by [9, 32] to improve many of the hardness results for approximation of optimization problems (see also [2, 3, 24, 11, 30, 31]). In particular, [32] uses our results to prove very impressive optimal inapproximability results for some of the most basic optimization problems (e.g., for Max-3-SAT). Our result was also used by [42] to prove a new direct sum theorem for probabilistic communication complexity.

The reader can find more about the problem of parallel repetition in [19, 25, 23, 20].

1.2. Main result. We will concentrate on the deterministic case, where the verifier decides whether to accept or reject the conjecture: $I \in L$, based on I, x, y, u, v only (and not on the random string r). The probabilistic case, where this decision depends also on r, is shortly discussed in section 7.

Following [15, 19, 25], we model the problem as a problem on games:
A game G consists of four finite sets X, Y, U, V, with a probability measure $\mu : X \times Y \to \mathbf{R}^+$, and a predicate $Q : X \times Y \times U \times V \to \{0, 1\}$. We think of Q also as a set. A protocol for G consists of a function $u : X \to U$, and a function $v : Y \to V$. The value of the protocol is defined as

$$\sum_{X \times Y} \mu(x, y) Q(x, y, u(x), v(y)),$$

i.e., the μ-probability that $Q(x, y, u(x), v(y)) = 1$. The value of the game, $w(G)$, is defined to be the maximal value of all protocols for G. The answer size of the game, $s(G)$, is defined by $s(G) = |U||V|$.

We think of G as a game for two players (provers): Player I receives $x \in X$, and player II receives $y \in Y$, according to the pair distribution $\mu(x, y)$. We think of x, y as the inputs for the game. Each player doesn't know the other player's input. Player I has to give an "answer" $u' \in U$, and player II has to give an "answer" $v' \in V$.

The goal of the players is to maximize the μ-probability that Q is satisfied (i.e., the probability that $Q(x, y, u', v') = 1$). We remark that this probability corresponds to the probability of error.

The game $G \otimes G$ consists of the sets $X \times X$, $Y \times Y$, $U \times U$, $V \times V$, with the measure

$$\mu \otimes \mu((x_1, x_2), (y_1, y_2)) = \mu(x_1, y_1)\mu(x_2, y_2)$$

and the predicate

$$Q \otimes Q((x_1, x_2), (y_1, y_2), (u_1, u_2), (v_1, v_2)) = Q(x_1, y_1, u_1, v_1)Q(x_2, y_2, u_2, v_2).$$

In the same way, the game $G^{\otimes k}$ consists of the sets X^k, Y^k, U^k, V^k, with the measure

$$\mu^{\otimes k}(x, y) = \prod_{i=1}^{k} \mu(x_i, y_i)$$

and the predicate

$$Q^{\otimes k}(x, y, u, v) = \prod_{i=1}^{k} Q(x_i, y_i, u_i, v_i),$$

where $x \in X^k, y \in Y^k, u \in U^k, v \in V^k$. Here and throughout, z_i stands for the ith coordinate of a vector z. We denote $G^{\otimes k}, Q^{\otimes k}, X^k, Y^k, U^k, V^k, \mu^{\otimes k}$ also by $\bar{G}, \bar{Q}, \bar{X}, \bar{Y}, \bar{U}, \bar{V}, \bar{\mu}$.

Assume w.l.o.g. that $s(G) \geq 2$. In this paper we prove the following parallel repetition theorem.

THEOREM 1.1. *There exists a global function $W : [0, 1] \to [0, 1]$, with $z < 1 \Rightarrow W(z) < 1$, such that given a game G, with value $w(G)$, and answer size $s(G) \geq 2$:*

$$w(G^{\otimes k}) \leq W(w(G))^{k/\log_2(s(G))}.$$

The exact behavior of the function $W(z)$ is not the focus of this paper. We will make, however, a few comments about the function $W(z)$ implicit in the paper:

1. When z tends to 0, the function $W(z)$ (implicit in this paper) tends to a constant $const_1 > 0$. In fact, for every $0 < z \leq 1$, $W(z) > const_1$. It is still not clear whether a tendency of $W(z)$ to 0, when z tends to 0, can be achieved.
2. Obviously, if $w(G)$ is a global constant (e.g., $w(G) = 1/2$) then $W(w(G))$ is just a different global constant. For example, there exists a constant $const_2 < 1$, s.t. for every $0.01 \leq z \leq 0.99$, $const_1 < W(z) < const_2$.
3. Obviously, when z tends to 1, $W(z)$ also tends to 1. It will be simpler to denote $t = 1 - z$, and to analyze the behavior of $[1 - W(1 - t)]$ when t tends to 0. It is implicit in this paper that there exists a (small) constant $const_3$, (1/34 seems to be enough), s.t. when t tends to 0, $[1 - W(1 - t)]$ can be bounded by $O(t^{const_3})$. For example, there exists a constant $const_4$, s.t. for every $t \leq 0.01$, $[1 - W(1 - t)] \leq const_4 \cdot t^{const_3}$, i.e.,

$$W(1 - t) \geq 1 - const_4 \cdot (1 - z)^{const_3}.$$

It was recently shown in [27] that in certain examples the number of repetitions, k, required to decrease the probability of error from $w(G) = 1/2$ to $w(G^{\otimes k}) \leq 1/8$ is

$$\Omega\left(\frac{\log_2(s(G))}{\log_2 \log_2(s(G))}\right).$$

This shows that the factor $\log_2(s(G))$ in Theorem 1.1 is almost the best possible.

It was observed by [42] that in Theorem 1.1, the term $\log_2(s(G))$ can be replaced with the (possibly smaller) $CC(G)$, or with the (possibly smaller) $\rho(G)$, defined in the following way.

For every $(x, y) \in X \times Y$, define $Q_{x,y} : U \times V \to \{0, 1\}$, by $Q_{x,y}(u, v) = Q(x, y, u, v)$. Define $CC_{x,y}$ to be the deterministic communication complexity of the function $Q_{x,y}$, and define $\rho_{x,y}$ to be the exact cover number of the same function (for the definitions see [42, 34]). Then define $CC(G)$ to be the maximum, taken over x, y, of $CC_{x,y}$, and define $\rho(G)$ to be the maximum, taken over x, y, of $\rho_{x,y}$. It is well known (and very easy to prove) that

$$\rho(G) \leq CC(G) \leq \log_2(s(G)).$$

Throughout the paper (sections 2, 3, 4, 5, 6), X, Y, U, V, Q, μ refer to the game G, from Theorem 1.1. Similarly, $k, \bar{G}, \bar{X}, \bar{Y}, \bar{U}, \bar{V}, \bar{Q}, \bar{\mu}$ refer to Theorem 1.1 as well. Denote, for the rest of the paper $s = s(G) = |U||V|$.

1.3. Main technical theorem. In what follows, we will sometimes denote the game G by G_μ, and denote its value by $w(\mu)$. We will sometimes say that the protocol is a protocol for μ (as X, Y, U, V, Q will be fixed). We will look at the values $w(\gamma)$, for different probability measures $\gamma : X \times Y \to \mathbf{R}^+$.

For a measure $\alpha : \Omega \to \mathbf{R}^+$, and a set $C \subset \Omega$, we use the usual notation

$$\alpha(C) = \sum_{z \in C} \alpha(z).$$

For a probability measure $\alpha : \Omega \to \mathbf{R}^+$, and a set $C \subset \Omega$, denote by $\alpha_C : \Omega \to \mathbf{R}^+$ the probability measure

$$\alpha_C(z) = \begin{cases} 0 & \text{for } z \notin C, \\ \frac{\alpha(z)}{\alpha(C)} & \text{for } z \in C. \end{cases}$$

We will think of α_C also as $\alpha_C : C \to \mathbf{R}^+$. This definition makes sense only if $\alpha(C) > 0$. For C, with $\alpha(C) = 0$, define $\alpha_C(z)$ to be identically 0.

More generally, the term $\frac{0}{0}$ can appear in some places in this paper. Unless said otherwise, $\frac{0}{0}$ is defined to be 0. The term $0z$ is defined to be 0, even if $z = \infty$, or z is undefined. This can occur when we take the expectancy (or a weighted average) of a variable z, which is undefined with probability 0 (or with a weight of 0).

For a set $C \subset \bar{X} \times \bar{Y}$, define the game $G_C^{\otimes k} = \bar{G}_C$ to consist of $\bar{X}, \bar{Y}, \bar{U}, \bar{V}$, with the measure $\bar{\mu}_C$ and the predicate $\bar{Q}$. We think of $\bar{G}_C$ as the restriction of $\bar{G}$ to the set C.

In the proof we will always work with a product set $A = A_X \times A_Y$, where $A_X \subset \bar{X}$, $A_Y \subset \bar{Y}$. Since in most parts of the paper we work with one specific $A = A_X \times A_Y$, it will be convenient to denote (throughout the paper) the measure

$\bar{\mu}_A$ by $\bar{\pi}$. The game $\bar{G}_A$ will also be denoted by $\bar{G}_{\bar{\pi}}$, and its value will also be denoted by $\bar{w}(\bar{\pi})$.

Define the predicate $\bar{Q}^i : \bar{X} \times \bar{Y} \times U \times V \to \{0,1\}$ by

$$\forall x \in \bar{X}, y \in \bar{Y}, u' \in U, v' \in V \ : \ \bar{Q}^i(x,y,u',v') = Q(x_i, y_i, u', v').$$

Define the game $\bar{G}^i_A$ to consist of $\bar{X}, \bar{Y}, U, V$ with the measure $\bar{\pi}$, and the predicate $\bar{Q}^i$. We also denote $\bar{G}^i_A$ by $\bar{G}^i_{\bar{\pi}}$, and its value by $w_i(\bar{\pi})$. We think of $\bar{G}^i_{\bar{\pi}}$ as the restriction of $\bar{G}_{\bar{\pi}}$ to one coordinate. Notice that for an input $(x,y) \in \bar{X} \times \bar{Y}$, the game $\bar{G}_{\bar{\pi}}$ just means playing simultaneously all the games $\bar{G}^i_{\bar{\pi}}$ (on the same input).

The following is our main technical theorem. The theorem claims that if $A = A_X \times A_Y$ is large, then $w_i(\bar{\pi})$ is small for at least one coordinate i.

THEOREM 1.2. *There exists a global function $W_2 : [0,1] \to [0,1]$, with $z < 1 \Rightarrow W_2(z) < 1$, and a global constant c_0, such that for all games G: for any k, and any product set $A = A_X \times A_Y \subset \bar{X} \times \bar{Y}$ (where $A_X \subset \bar{X}, A_Y \subset \bar{Y}$), and any $0 \le \Delta \le 1$, if $-\log_2 \bar{\mu}(A) \le \Delta k$ (i.e., $\bar{\mu}(A) \ge 2^{-\Delta k}$) then there exists i with*

$$w_i(\bar{\pi}) \le W_2(w(G)) + c_0 \Delta^{1/16}.$$

Again, achieving the best function W_2 and the best constant c_0, and improving the constant $1/16$, are not the focus of this paper.

1.4. More notations and basic facts. For a measure or function $\alpha : \Omega^k \to \mathbf{R}$ define α^i to be the projection of α on the ith coordinate. Thus, for $a \in \Omega$

$$\alpha^i(a) = \sum_{\{z \in \Omega^k \mid z_i = a\}} \alpha(z).$$

In particular for $\alpha : \bar{X} \times \bar{Y} \to \mathbf{R}$, define $\Omega = X \times Y$, and think of α as a measure (or function) $\alpha : \Omega^k \to \mathbf{R}$. The projection α^i is now a measure (or function) $\alpha^i : X \times Y \to \mathbf{R}$.

In particular we will be interested in the projections $\bar{\pi}^i$.

For a probability measure $\gamma : X \times Y \to \mathbf{R}^+$, we will be interested, from time to time, in the γ-probability of an element $x \in X$. We denote this probability by $\gamma(x)$; thus

$$\gamma(x) = \sum_{y \in Y} \gamma(x,y).$$

For simplicity we use the same notation $\gamma(y)$ for the γ-probability of an element $y \in Y$. The difference will be that we use the letters x, x_i, a, a_i, for elements of X, and the letters y, y_i, b, b_i, for elements of Y. It will always be clear if the element is an element of X or an element of Y.

When X, Y, U, V, Q are fixed, we will be interested in the value of the game, $w(\gamma)$, as a function of the measure $\gamma : X \times Y \to \mathbf{R}^+$. First notice that w is a continuous function. Also, if for γ_1, γ_2, the L_1 distance satisfies $\| \gamma_1 - \gamma_2 \|_1 \le \epsilon$ then $|w(\gamma_1) - w(\gamma_2)| \le \epsilon$. This is true since every protocol for one of the measures can be viewed as a protocol for the other one, with value different by at most ϵ. Thus w has a Lipschitz constant of 1.

If $\gamma = p\gamma_1 + (1-p)\gamma_2$, for $0 \le p \le 1$, then

$$w(\gamma) \le pw(\gamma_1) + (1-p)w(\gamma_2).$$

This is true because every protocol for γ can be viewed as a protocol for γ_1 and γ_2. Thus, the function w is concave. If $\gamma = \sum_{i=1}^{m} p_i \gamma_i$, where $\forall i : 0 \leq p_i \leq 1$, and $\sum_{i=1}^{m} p_i = 1$, then

$$w(\gamma) \leq \sum_{i=1}^{m} p_i w(\gamma_i).$$

For a game G, it is sometimes convenient to consider also probabilistic protocols. In a probabilistic protocol, the "answers" of the players can depend also on a random string. Thus the "answers" are $u(x,h), v(y,h)$ (rather than $u(x), v(y)$), where h is a random string. The value of the protocol will be the probability, over the inputs (x,y), and over the random strings that $Q(x,y,u(x,h),v(y,h)) = 1$.

However, since a probabilistic protocol can be viewed as a convex combination of deterministic ones, the value of any probabilistic protocol can be achieved by a deterministic one.

Remark. In this paper the logarithm function log is always taken base 2. The natural logarithm is denoted by ln.

1.5. Organization of the paper. The paper is organized as follows: In section 2, we show how Theorem 1.2 leads to the proof of Theorem 1.1. In section 3, we review the definition, and the basic properties of the informational divergence, a basic tool of information theory. This tool is needed for the proof of Theorem 1.2. Theorem 1.2 is proved in section 4. The proof of the main lemma is deferred to section 5, and the proof of another lemma is deferred to section 6. In section 7 several generalizations of Theorem 1.1 are shortly discussed.

We remark that two "shortcuts" can be done in the paper. First, in the special case where the measure μ is a product measure (i.e., $\mu = \mu_X \times \mu_Y$), the entire argument is much simpler, and the proof follows simply from section 2 and the beginning of section 4 (plus simpler versions of several lemmas in section 3, using entropy instead of informational divergence). Also, section 6 is not really needed for the proof of the parallel repetition conjecture, but it is needed to improve the constant in the exponent to $\log(s(G))$. A simpler proof which does not use section 6 can be given, but the constant in the exponent in that proof is much worse.

2. Proof of the parallel repetition theorem. In this section, we show how Theorem 1.2 leads to the proof of Theorem 1.1.

Theorem 1.1 claims an upper bound for the value $w(\bar{G})$. We will prove even more: we will upper bound the value $w(\bar{G}_A)$, of the game $\bar{G}_A$, for any large product set $A = A_X \times A_Y \subset \bar{X} \times \bar{Y}$.

We will first give some intuition: The proof uses a simple induction on the dimension k. The idea is to assume by Theorem 1.2 w.l.o.g. an upper bound for $w(\bar{G}^1_A)$. Given a protocol for $\bar{G}_A$, we partition A into product subsets, according to the behavior of the protocol on the first coordinate. The size of this partition is not too big, and therefore, the average size of a subset in the partition is not too small. In many of these subsets the protocol fails to satisfy $\bar{Q}$, because it fails to satisfy $\bar{Q}^1$. We can disregard these subsets. In every other subset, the predicate $\bar{Q}$ can be thought of as a $k-1$ dimensional predicate, and we can use induction to upper bound the size of the set of points, which satisfy this predicate. By this argument, we will get a recursive bound for $w(G_A^{\otimes k})$, as a function of the dimension k, and the size $\bar{\mu}(A)$.

For the game G, define $C_G(k,r)$ to be the maximum, taken over A, of the value $w(G_A^{\otimes k})$, of a game $G_A^{\otimes k} = \bar{G}_A = \bar{G}_{\bar{\pi}}$, where $A = A_X \times A_Y$ is a product set (with

$A_X \subset \bar{X}, A_Y \subset \bar{Y}$), with

$$-\log \bar{\mu}(A) \leq r$$

(i.e., $\bar{\mu}(A) \geq 2^{-r}$). Here, k is the dimension and $r \geq 0$ is real. For $k = 0$, it will be convenient to define $C_G(0, r) = 1$. We will prove an upper bound for $C_G(k, r)$ as a function of $w(G)$. The theorem will follow by taking $r = 0$.

Recall that X, Y, U, V, Q, μ refer to the game G from Theorem 1.1 and that $s = s(G)$. Assume for simplicity that $0 < w(G) < 1$ (otherwise the game is trivial). Take $0 < \Delta < 1$, (Δ will be determined later on). For $r \leq \Delta k$, take $A = A_X \times A_Y \subset \bar{X} \times \bar{Y}$, with $-\log \bar{\mu}(A) \leq r$, which achieves $C_G(k, r)$. Thus,

$$w(\bar{G}_{\bar{\pi}}) = C_G(k, r).$$

By Theorem 1.2, there exists i with

$$w(\bar{G}^i_{\bar{\pi}}) = w_i(\bar{\pi}) \leq W_2(w(G)) + c_0 \Delta^{1/16}$$

where W_2, c_0 are taken from Theorem 1.2. Without loss of generality assume that $i = 1$. Denote

$$\hat{w} = W_2(w(G)) + c_0 \Delta^{1/16}.$$

We will later on assume that Δ is such that

$$0 < \hat{w} < 1$$

and

$$2^{-\frac{1}{2}} < \hat{w}^{\frac{1}{2(\log(s)+\Delta)}} < 1$$

(at this point, the reader can ignore these two assumptions).

Let $u : \bar{X} \to \bar{U}$, $v : \bar{Y} \to \bar{V}$ be a protocol for $\bar{G}_{\bar{\pi}}$, achieving the value $w(\bar{G}_{\bar{\pi}})$. The pair $(x_1, u_1(x))$ is a function of $x \in \bar{X}$. Partition A_X according to $(x_1, u_1(x))$. Formally, $\forall x' \in X, u' \in U$ define

$$A_X(x', u') = \{x \in A_X \mid x_1 = x', u_1(x) = u'\}.$$

Then the family $\{A_X(x', u')\}$ is a partition of A_X. In the same way, define

$$A_Y(y', v') = \{y \in A_Y \mid y_1 = y', v_1(y) = v'\}.$$

Then the family $\{A_Y(y', v')\}$ is a partition of A_Y. For simplicity, denote in all the following $Z = X \times Y \times U \times V$ and $z = (x', y', u', v') \in Z$. For all $z = (x', y', u', v') \in Z$ denote

$$A(z) = A_X(x', u') \times A_Y(y', v').$$

Then the family $\{A(z)\}$ is a partition of A, and we have

$$A = \bigcup_{z \in Z} A(z).$$

For all $z \in Z$, define

$$B(z) = \left\{(x, y) \in A(z) \mid \bar{Q}(x, y, u(x), v(y)) = 1\right\},$$

i.e., $B(z)$ is just the set of elements of $A(z)$ satisfying $\bar{Q}$. Notice that for $z \notin Q$ (i.e., z such that $Q(z) = 0$) we have $(x, y) \in A(z) \Rightarrow Q(x_1, y_1, u_1(x), v_1(y)) = Q(z) = 0$. Therefore, $z \notin Q$ implies $B(z) = \emptyset$. On the other hand, for $z \in Q$ we have that $(x, y) \in A(z) \Rightarrow Q(x_1, y_1, u_1(x), v_1(y)) = Q(z) = 1$. Therefore, for $z \in Q$ and $(x, y) \in A(z)$,

$$\bar{Q}(x, y, u(x), v(y)) = \prod_{i=2}^{k} Q(x_i, y_i, u_i(x), v_i(y)).$$

Thus in this case, $B(z)$ is a set of elements satisfying a $k-1$-dimensional predicate. This fact enables us to use induction.

For all z define

$$\alpha(z) = \bar{\pi}(A(z)), \quad \beta(z) = \frac{\bar{\pi}(B(z))}{\bar{\pi}(A(z))}.$$

Then we have the following.

CLAIM 2.1.

$$\sum_{z \in Q} \alpha(z) \leq \hat{w}.$$

Proof. $u_1 : \bar{X} \to U$, $v_1 : \bar{Y} \to V$ can be viewed as a protocol for $\bar{G}^1_{\bar{\pi}}$. The value of this protocol is clearly

$$\sum_{z \in Q} \bar{\pi}(A(z)) = \sum_{z \in Q} \alpha(z),$$

but this value is at most $w(\bar{G}^1_{\bar{\pi}}) \leq \hat{w}$. □

CLAIM 2.2. *For all $z = (x', y', u', v') \in Q$, with $\alpha(z) > 0$,*

$$\beta(z) \leq C_G(k-1, r - \log[\alpha(z)/\mu(x', y')]).$$

Proof. First notice that if $\alpha(z) > 0$ then also $\mu(x', y') > 0$, thus the logarithm is well defined.

For $k = 1$, the claim is immediate. Assume that $k > 1$. Ignoring the first coordinate, which is fixed, $A(z)$ can be viewed as a set of dimension $k-1$. Formally, define $A'(z) \subset X^{k-1} \times Y^{k-1}$ by

$$A'(z) = \left\{ (\tilde{x}, \tilde{y}) \in X^{k-1} \times Y^{k-1} \;\middle|\; ((x', \tilde{x}), (y', \tilde{y})) \in A(z) \right\}$$

where $(x', \tilde{x})$ denotes $x \in X^k$, with $x_1 = x'$, and $(x_2, \ldots, x_k) = \tilde{x}$ (and, similarly, $(y', \tilde{y})$).

Since for $(x, y) \in A(z)$: $x_1 = x'$, and $y_1 = y'$, we have by definition

$$\mu^{\otimes k}(A(z)) = \mu(x', y') \mu^{\otimes k-1}(A'(z)).$$

In the same way, define

$$B'(z) = \left\{ (\tilde{x}, \tilde{y}) \in X^{k-1} \times Y^{k-1} \;\middle|\; ((x', \tilde{x}), (y', \tilde{y})) \in B(z) \right\}.$$

Then we have

$$\mu^{\otimes k}(B(z)) = \mu(x', y') \mu^{\otimes k-1}(B'(z)).$$

The last $k-1$ coordinates of $u\colon \bar{X} \to \bar{U}, v\colon \bar{Y} \to \bar{V}$ can be viewed as a protocol for the game $G_{A'(z)}^{\otimes k-1}$. Since $z \in Q$, this protocol satisfies $Q^{\otimes k-1}$ at the set of elements $B'(z)$. Therefore, the value of this protocol is

$$\frac{\mu^{\otimes k-1}(B'(z))}{\mu^{\otimes k-1}(A'(z))} = \frac{\bar{\mu}(B(z))}{\bar{\mu}(A(z))} = \frac{\bar{\mu}(B(z))/\bar{\mu}(A)}{\bar{\mu}(A(z))/\bar{\mu}(A)} = \frac{\bar{\pi}(B(z))}{\bar{\pi}(A(z))} = \beta(z),$$

so by the definition of C_G we have

$$\begin{aligned}\beta(z) &\le C_G(k-1, -\log \mu^{\otimes k-1}(A'(z)) = C_G(k-1, -\log[\bar{\mu}(A(z)/\mu(x',y')]) \\ &= C_G(k-1, -\log[\bar{\mu}(A)\alpha(z)/\mu(x',y')]) \le C_G(k-1, r - \log\alpha(z) + \log\mu(x',y'))\end{aligned}$$

(recall that by definition $C_G(k',r')$ is monotone in r'). Notice that since $\mu^{\otimes k-1}(A'(z)) \le 1$, $r - \log\alpha(z) + \log\mu(x',y') \ge 0$, thus C_G is defined. ∎

Claim 2.3.

$$C_G(k,r) = \sum_{z\in Q} \alpha(z)\beta(z).$$

Proof. The protocol u, v satisfies $\bar{Q}$ at the set of elements $\bigcup_{z\in Z} B(z)$. Therefore,

$$C_G(k,r) = w(\bar{G}_{\bar{\pi}}) = \bar{\pi}\left(\bigcup_{z\in Z} B(z)\right) = \sum_{z\in Z} \bar{\pi}(B(z)) = \sum_{z\in Z} \bar{\pi}(A(z))\frac{\bar{\pi}(B(z))}{\bar{\pi}(A(z))} = \sum_{z\in Z} \alpha(z)\beta(z)$$

but $z \notin Q$ implies $\beta(z) = 0$. Thus,

$$C_G(k,r) = \sum_{z\in Q} \alpha(z)\beta(z). \qquad ∎$$

Denote

$$T = \{z \in Q \mid \alpha(z) > 0\}.$$

From Claims 2.2 and 2.3 we have the recursive inequality

$$C_G(k,r) \le \sum_{z\in T} \alpha(z) C_G(k-1, r - \log[\alpha(z)/\mu(x',y')]) \tag{1}$$

where, by Claim 2.1,

$$\sum_{z\in T} \alpha(z) \le \hat{w}.$$

We will now assume that Δ is such that

$$0 < \hat{w} < 1$$

and

$$2^{-1/2} < \hat{w}^{1/(2(\log(s)+\Delta))} < 1.$$

We will prove by induction on k the following inequality.

CLAIM 2.4.

$$C_G(k,r) \leq \left(\hat{w}^{1/(2(\log(s)+\Delta))}\right)^{\Delta k - r}.$$

Proof. For $k = 0$, the claim is trivial, (since $0 < \hat{w} < 1$, and $r \geq 0$).
For $k \geq 1$ assume the inequality for $k-1$, and substitute in inequality (1) to get

$$\begin{aligned} C_G(k,r) &\leq \sum_{z \in T} \alpha(z) \left(\hat{w}^{1/(2(\log(s)+\Delta))}\right)^{\Delta(k-1)-r+\log[\alpha(z)/\mu(x',y')]} \\ &= \left(\hat{w}^{1/(2(\log(s)+\Delta))}\right)^{\Delta k - r} \sum_{z \in T} \alpha(z) \left(\hat{w}^{1/(2(\log(s)+\Delta))}\right)^{-\Delta+\log[\alpha(z)/\mu(x',y')]}. \end{aligned}$$

Hence, it will be enough to prove

$$\sum_{z \in T} \alpha(z) \left(\hat{w}^{1/(2(\log(s)+\Delta))}\right)^{-\Delta-\log(s)+\log[s\alpha(z)/\mu(x',y')]} \leq 1.$$

Define

$$t(z) = \begin{cases} 0 & \text{for } z \notin T, \\ \dfrac{s\alpha(z)}{\mu(x',y')} & \text{for } z \in T. \end{cases}$$

Then the inequality is equivalent to

$$\sum_{z \in T} \left(\frac{\mu(x',y')}{s}\right) t(z) \left(\hat{w}^{1/(2(\log(s)+\Delta))}\right)^{\log t(z)} \leq \hat{w}^{1/2}.$$

Define $p(z) = \mu(x',y')/s$, and $f : \mathbf{R}^+ - \{0\} \to \mathbf{R}$ by

$$f(t) = tc^{\log t} = t^{1+\log c}$$

where

$$c = \hat{w}^{1/(2(\log(s)+\Delta))}.$$

In these notations, we have to prove

$$\sum_{z \in T} p(z) f(t(z)) \leq \hat{w}^{1/2}.$$

We assumed $2^{-1/2} < c < 1$. Therefore, $-\frac{1}{2} < \log c < 0$, thus $f(t) = tc^{\log t} = t^{1+\log c}$ is convex. Notice that

$$\sum_{z \in Z} p(z) = \sum_{U \times V} \sum_{X \times Y} \frac{\mu(x',y')}{s} = \frac{1}{s} \sum_{U \times V} \sum_{X \times Y} \mu(x',y') = \frac{1}{s} \sum_{U \times V} 1 = \frac{1}{s} s = 1.$$

Therefore, we can use Jensen's inequality to conclude

$$\sum_{z \in T} p(z) f(t(z)) = \sum_{z \in T} p(z) t(z)^{1+\log c} = \sum_{z \in Z} p(z) t(z)^{1+\log c} \leq \left(\sum_{z \in Z} p(z) t(z)\right)^{1+\log c},$$

but

$$\sum_{z\in Z} p(z)t(z) = \sum_{z\in T} p(z)t(z) = \sum_{z\in T} \frac{\mu(x',y')}{s}\frac{s\alpha(z)}{\mu(x',y')} = \sum_{z\in T}\alpha(z) \le \hat{w}$$

and since the function $t^{1+\log c}$ is monotone in t, we have

$$\sum_{z\in T} p(z)f(t(z)) \le \left(\sum_{z\in Z} p(z)t(z)\right)^{1+\log c} \le \hat{w}^{1+\log c} \le \hat{w}^{1-1/2} = \hat{w}^{1/2}$$

(where the third inequality uses the assumption $\log c > -1/2$). □

By Claim 2.4 and by $\Delta < 2\log_2(s)$ (which follows from the assumptions: $\Delta < 1$, and $s \ge 2$), we can now conclude

$$w(G^{\otimes k}) = C_G(k,0) \le \left(\hat{w}^{1/(2(\log(s)+\Delta))}\right)^{\Delta k} \le \left(\hat{w}^{1/(4\log(s))}\right)^{\Delta k} = \left(\hat{w}^{(1/4)\Delta}\right)^{k/\log(s)}$$

where $\hat{w} = W_2(w(G)) + c_0\Delta^{1/16}$, and $0 < \Delta < 1$ satisfies $0 < \hat{w} < 1$, and

$$2^{-1/2} < \hat{w}^{1/(2(\log(s)+\Delta))} < 1.$$

Since $0 < W_2(w(G)) < 1$, and since $\hat{w}$ is monotone in Δ, the conditions are satisfiable. Just start from $\Delta = 0$ and increase Δ until the conditions hold.

Thus Theorem 1.1 follows. We will take in Theorem 1.1

$$W(w(G)) = \inf\left(\hat{w}^{(1/4)\Delta}\right)$$

where the infimum is taken over all $0 < \Delta < 1$, which satisfy the conditions.

3. Informational divergence. In this section, we define the informational divergence, a basic tool of information theory, and review some of its basic properties that will be used in the paper. The reader can find excellent treatments of the subject in [29, 17].

Given a finite probability space Ω, with two probability measures ϑ, ψ, the divergence of ϑ with respect to ψ is defined by

$$\mathbf{D}(\vartheta \parallel \psi) = \sum_{z\in\Omega} \vartheta(z)\log\frac{\vartheta(z)}{\psi(z)}.$$

In this definition, $0\log\frac{0}{0}$ is defined to be 0, and for $z > 0$, $z\log\frac{z}{0}$ is defined to be ∞. Thus $\mathbf{D}(\vartheta \parallel \psi) < \infty$ if and only if ϑ is absolutely continuous with respect to ψ (i.e., $\psi(z) = 0$ implies $\vartheta(z) = 0$).

In the special case where ψ is the uniform distribution, we have

$$\mathbf{D}(\vartheta \parallel \psi) = \log_2|\Omega| - \mathbf{H}(\vartheta),$$

where $\mathbf{H}(\vartheta)$ is the standard entropy of ϑ. More generally, the divergence $\mathbf{D}(\vartheta \parallel \psi)$ can be thought of as the entropy of the measure ϑ, relative to the measure ψ, as opposed to the standard entropy of ϑ, which is taken relative to the uniform distribution.

$\mathbf{D}(\vartheta \parallel \psi)$ has many names and notations throughout the literature. In [29] it is also called "relative entropy," and denoted by $\mathbf{H}_{\vartheta\parallel\psi}(\mathcal{Q})$, where $\mathcal{Q}$ is the partition of Ω

into single points. This is a special case of the following definition: For a measurement f on Ω, with a finite alphabet A, let $\mathcal{Q}$ be the induced partition $\{f^{-1}(a)\}_{a\in A}$. Let ϑ_f, ψ_f be the corresponding probability mass functions, i.e., for $a \in A$

$$\vartheta_f(a) = \vartheta(\{z \in \Omega \mid f(z) = a\}), \quad \psi_f(a) = \psi(\{z \in \Omega \mid f(z) = a\}).$$

The relative entropy of f, with measure ϑ, with respect to the measure ψ, is defined by

$$\mathbf{H}_{\vartheta\|\psi}(f) = \mathbf{H}_{\vartheta\|\psi}(\mathcal{Q}) = \sum_{a\in A} \vartheta_f(a) \log \frac{\vartheta_f(a)}{\psi_f(a)}.$$

In this paper, we prefer to use the notation $\mathbf{D}\left(\vartheta \parallel \psi\right)$.

The following lemma, known as the divergence inequality, is probably the most basic property of the informational divergence.

LEMMA 3.1. *For all ϑ, ψ, we have*

$$\mathbf{D}\left(\vartheta \parallel \psi\right) \geq 0.$$

Proof. See [29, Chapter 2, Theorem 2.3.1]. □

For measures $\bar{\vartheta}, \bar{\psi}$ on $\otimes_{i=1}^{k}\Omega_i$, recall that $\bar{\vartheta}^i, \bar{\psi}^i$ are the projections of $\bar{\vartheta}, \bar{\psi}$ on the ith coordinate.

LEMMA 3.2. *For measures $\bar{\vartheta}, \bar{\psi}$ on $\Omega_1 \times \Omega_2$, such that $\bar{\psi} = \bar{\psi}^1 \times \bar{\psi}^2$,*

$$\mathbf{D}\left(\bar{\vartheta} \parallel \bar{\psi}\right) \geq \mathbf{D}\left(\bar{\vartheta}^1 \parallel \bar{\psi}^1\right) + \mathbf{D}\left(\bar{\vartheta}^2 \parallel \bar{\psi}^2\right).$$

Proof. See [29, Chapter 2, Lemma 2.5.3]. The lemma is stated there as: $M_{XY} = M_X \times M_Y$ implies

$$\mathbf{H}_{P\|M}(X, Y) \geq \mathbf{H}_{P\|M}(X) + \mathbf{H}_{P\|M}(Y). \qquad \square$$

The next lemma can be viewed as a generalization of the well-known entropy inequality

$$\mathbf{H}(z_1, \ldots, z_k) \leq \mathbf{H}(z_1) + \cdots + \mathbf{H}(z_k)$$

(for any random variable z), and as a generalization of the previous lemma.

LEMMA 3.3. *For measures $\bar{\vartheta}, \bar{\psi}$ on Ω^k, such that $\bar{\psi} = \otimes_{i=1}^{k}\bar{\psi}^i$*

$$\mathbf{D}\left(\bar{\vartheta} \parallel \bar{\psi}\right) \geq \sum_{i=1}^{k} \mathbf{D}\left(\bar{\vartheta}^i \parallel \bar{\psi}^i\right).$$

Proof. The proof is immediate from Lemma 3.2. □

For a function $\alpha : \Omega \to \mathbf{R}$, denote by $\| \alpha \|_1$ the standard L_1 norm of α, i.e.,

$$\| \alpha \|_1 = \| \alpha(z) \|_1 = \sum_{z\in\Omega} |\alpha(z)|.$$

If α is a probability measure then $\| \alpha \|_1 = 1$. In this paper we use $\| \vartheta - \psi \|_1$ as a distance function between measures (or functions). It is not true that the divergence $\mathbf{D}\left(\vartheta \parallel \psi\right)$ is a distance function. However, it is true that if $\mathbf{D}\left(\vartheta \parallel \psi\right)$ is small then the L_1 distance between ϑ and ψ is also small.

LEMMA 3.4. *For all ϑ, ψ, we have*

$$(2\ln 2)\mathbf{D}(\vartheta \parallel \psi) \geq (\parallel \vartheta - \psi \parallel_1)^2.$$

Proof. See [17, Chapter 3, Exercise 17] and the references therein. □

The next lemma computes the value of $\mathbf{D}(\vartheta \parallel \psi)$, in the special case $\vartheta = \psi_A$, where $A \subset \Omega$.

LEMMA 3.5. *For a measure ψ, and a set $A \subset \Omega$, we have*

$$\mathbf{D}(\psi_A \parallel \psi) = -\log \psi(A).$$

Proof.

$$\mathbf{D}(\psi_A \parallel \psi) = \sum_{z\in\Omega} \psi_A(z) \log \frac{\psi_A(z)}{\psi(z)} = \sum_{z\in A} \psi_A(z) \log \frac{\psi_A(z)}{\psi(z)}$$

$$= \sum_{z\in A} \psi_A(z) \log \frac{\psi(z)/\psi(A)}{\psi(z)} = \sum_{z\in A} \psi_A(z)(-\log \psi(A)) = -\log \psi(A). \quad \square$$

For a probability measure $\alpha : \Omega \to \mathbf{R}^+$, where $\Omega = X \times Y$, define $\alpha(a,\cdot) : Y \to \mathbf{R}^+$ to be the probability measure on Y, derived from α by fixing $x = a$. Thus, $\alpha(a,\cdot)$ is the following probability measure: for all $y \in Y$,

$$\alpha(a,\cdot)(y) = \frac{\alpha(a,y)}{\alpha(a)}$$

where $\alpha(a) = \sum_{y\in Y} \alpha(a,y)$. This definition makes sense only if $\alpha(a) > 0$. Otherwise, define $\alpha(a,\cdot)$ to be identically 0.

In the same way, define the measure $\alpha(\cdot,y) : X \to \mathbf{R}^+$.

For the measures $\vartheta, \psi : X \times Y \to \mathbf{R}^+$, we will be interested in the values of $\mathbf{D}(\vartheta(x,\cdot) \parallel \psi(x,\cdot))$, and $\mathbf{D}(\vartheta(\cdot,y) \parallel \psi(\cdot,y))$. Define

$$\mathbf{V_X}(\vartheta \parallel \psi) = \sum_{x\in X} \vartheta(x)\mathbf{D}(\vartheta(x,\cdot) \parallel \psi(x,\cdot)),$$

and

$$\mathbf{V_Y}(\vartheta \parallel \psi) = \sum_{y\in Y} \vartheta(y)\mathbf{D}(\vartheta(\cdot,y) \parallel \psi(\cdot,y)).$$

These are denoted in [29] by $\mathbf{H}_{\vartheta\parallel\psi}(Y|X)$, and $\mathbf{H}_{\vartheta\parallel\psi}(X|Y)$. In addition, define

$$\mathbf{V}(\vartheta \parallel \psi) = \frac{1}{2}[\mathbf{V_X}(\vartheta \parallel \psi) + \mathbf{V_Y}(\vartheta \parallel \psi)].$$

The notion $\mathbf{V}(\vartheta \parallel \psi)$ is central in the rest of the paper. In particular, we will be interested in cases were $\mathbf{V}(\vartheta \parallel \psi)$ is small. We saw before that if $\mathbf{D}(\vartheta \parallel \psi)$ is small then $\parallel \vartheta - \psi \parallel_1$ is also small. Is the same true for $\mathbf{V}(\vartheta \parallel \psi)$? Taking $X = Y = \{0,1\}$ and

$$\psi = \begin{pmatrix} \frac{1}{2} & 0 \\ 0 & \frac{1}{2} \end{pmatrix}, \quad \vartheta = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}$$

we have $\mathbf{V}(\vartheta \parallel \psi) = 0$, but still $\parallel \vartheta - \psi \parallel_1 = \frac{1}{2}$. Hence, in general it is not the case.

A measure $\psi : X \times Y \to \mathbf{R}^+$ is called irreducible, if there are no nontrivial partitions $X = X_1 \cup X_2$, $Y = Y_1 \cup Y_2$ such that $\psi(X_1 \times Y_2) = \psi(X_2 \times Y_1) = 0$. Every measure $\psi : X \times Y \to \mathbf{R}^+$ decomposes into its irreducible components. In general, it is true that if $\mathbf{V}(\vartheta \parallel \psi) = 0$ then ϑ has the same components as ψ and behaves like ψ on each one of them, but the ϑ-probability of each component can be different from the ψ-probability.

For irreducible ψ it can be shown that if $\mathbf{V}(\vartheta \parallel \psi) = 0$ then $\vartheta = \psi$, and that if ψ is fixed $\mathbf{V}(\vartheta \parallel \psi) \to 0$ implies $\vartheta \to \psi$. However, this convergence is not uniform. For example, we can take $X = Y = \{0, 1\}$, and

$$\psi = \begin{pmatrix} \frac{1}{2} & \epsilon \\ 0 & \frac{1}{2} - \epsilon \end{pmatrix}, \quad \vartheta = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}.$$

In this case ψ is irreducible, and $\mathbf{V}(\vartheta \parallel \psi) = O(\epsilon)$, but still $\| \vartheta - \psi \|_1 = \frac{1}{2}$.

Therefore, in this paper we will use a different characterization of measures ϑ, with small $\mathbf{V}(\vartheta \parallel \psi)$. This characterization, proved in Lemma 6.6, will intuitively say that in this case there are measures ϑ', ψ', such that ϑ' is very close to ϑ, and ψ' is very close to ψ, and such that ϑ', ψ' have the same irreducible components, and behave the same on each one of them (but not necessarily give the same mass to each component).

We remark that this characterization is not necessary to prove the parallel repetition conjecture. It is done here only to improve the constants.

4. Proof of the main theorem. In this section we give the proof of Theorem 1.2. The proofs of two important lemmas are deferred to sections 5 and 6. Given X, Y, U, V, Q, k, define for any probability measure $\bar{\alpha} : \bar{X} \times \bar{Y} \to \mathbf{R}^+$, the following games:

1. The game $G_{\bar{\alpha}^i}$, consisting of X, Y, U, V, Q, with the measure $\bar{\alpha}^i$.
   Denote the value of this game by $w(\bar{\alpha}^i)$.
2. The game $\bar{G}_{\bar{\alpha}}$, consisting of $\bar{X}, \bar{Y}, \bar{U}, \bar{V}, \bar{Q}$, with the measure $\bar{\alpha}$.
   Denote the value of this game by $\bar{w}(\bar{\alpha})$.
3. The game $\bar{G}^i_{\bar{\alpha}}$, consisting of $\bar{X}, \bar{Y}, U, V$, with the predicate $\bar{Q}^i$, defined by

$$\forall (x, y, u, v) \in \bar{X} \times \bar{Y} \times U \times V \quad : \quad \bar{Q}^i(x, y, u, v) = Q(x_i, y_i, u, v)$$

   and with the measure $\bar{\alpha}$. Denote the value of this game by $w_i(\bar{\alpha})$.

Recall that for any probability measure $\gamma : X \times Y \to \mathbf{R}^+$, we denote by $w(\gamma)$ the value of the game G_γ , consisting of X, Y, U, V, Q, γ.

Theorem 1.2 claims that if $A = A_X \times A_Y$ is large then $w_i(\bar{\pi})$ cannot be too large for all coordinates i. If A is large it is easy to show that for many coordinates i, $\bar{\pi}^i$ is very close to μ, and, therefore, $w(\bar{\pi}^i)$ is very close to $w(\mu)$ and is not too large. Hence, it could be enough to show that for some coordinates i, $w_i(\bar{\pi})$ is upper bounded by some "well behaved" function of $w(\bar{\pi}^i)$.

For any $\bar{\alpha} : \bar{X} \times \bar{Y} \to \mathbf{R}^+$, any protocol for $G_{\bar{\alpha}^i}$ defines also a corresponding protocol, with the same value, for $\bar{G}^i_{\bar{\alpha}}$. This is true because if the distribution of (x, y) is $\bar{\alpha}$ then the distribution of (x_i, y_i) is $\bar{\alpha}^i$. Thus, given an input (x, y), for the game $\bar{G}^i_{\bar{\alpha}}$, (x_i, y_i) can be used as an input for the protocol for $G_{\bar{\alpha}^i}$. The output of this protocol, can be viewed as an output for the game $\bar{G}^i_{\bar{\alpha}}$. Therefore, we always have

$$w(\bar{\alpha}^i) \leq w_i(\bar{\alpha}).$$

The other direction is false, as the the other coordinates can give a lot of information on (x_i, y_i). There is an important special case, however, in which $w(\bar{\alpha}^i) = w_i(\bar{\alpha})$.

LEMMA 4.1. *If there exist* $\alpha_1 : X \times Y \to \mathbf{R}$, $\alpha_2 : \bar{X} \to \mathbf{R}$, $\alpha_3 : \bar{Y} \to \mathbf{R}$ *such that for all* $(x, y) \in \bar{X} \times \bar{Y}$

$$\bar{\alpha}(x, y) = \alpha_1(x_i, y_i)\alpha_2(x)\alpha_3(y),$$

then

$$w(\bar{\alpha}^i) = w_i(\bar{\alpha}).$$

Proof. We will show that in this case a protocol for $\bar{G}^i_{\bar{\alpha}}$ defines a corresponding protocol, with the same value for $G_{\bar{\alpha}^i}$. This will be true because in this special case a pair (x, y), with distribution $\bar{\alpha}$, can simply be created by the two players from a pair (a_i, b_i), with distribution $\bar{\alpha}^i$.

First notice that $\alpha_1, \alpha_2, \alpha_3$ are not unique, as we can multiply α_1 and divide α_2, by the same function $f(x_i)$, as long as for all $a \in X : f(a) \neq 0$. In the same way, we can multiply α_1 and divide α_3, by the same function $g(y_i)$, as long as for all $b \in Y : g(b) \neq 0$. Therefore, we can assume w.l.o.g. that for all a_i, b_i:

$$\sum_{\{x \in \bar{X} \mid x_i = a_i\}} \alpha_2(x), \quad \text{and} \quad \sum_{\{y \in \bar{Y} \mid y_i = b_i\}} \alpha_3(y)$$

are always 0 or 1. Also, we can assume w.l.o.g. that if one of them is 0 then $\alpha_1(a_i, b_i)$ is also 0. Therefore, in this case

$$\begin{aligned}\bar{\alpha}^i(a_i, b_i) &= \sum_{\{(x,y) \in \bar{X} \times \bar{Y} \mid (x_i, y_i) = (a_i, b_i)\}} \alpha_1(a_i, b_i)\alpha_2(x)\alpha_3(y) \\ &= \alpha_1(a_i, b_i) \left(\sum_{\{x \in \bar{X} \mid x_i = a_i\}} \alpha_2(x) \right) \left(\sum_{\{y \in \bar{Y} \mid y_i = b_i\}} \alpha_3(y) \right) = \alpha_1(a_i, b_i).\end{aligned}$$

Notice that now, given $a_i \in X$, with $\bar{\alpha}^i(a_i) \neq 0$, we have $\sum_{\{x \in \bar{X} \mid x_i = a_i\}} \alpha_2(x) = 1$. Therefore, for all $a_i \in X$, with $\bar{\alpha}^i(a_i) \neq 0$, we can define a probability distribution on $\bar{X}$ by

$$\Pr_{a_i}(x) = \begin{cases} 0 & \text{if } x_i \neq a_i, \\ \alpha_2(x) & \text{if } x_i = a_i. \end{cases}$$

Note that $\Pr_{a_i}(x)$ is exactly the α-probability for x, given that $x_i = a_i$. In the same way define for $b_i \in Y$, with $\bar{\alpha}^i(b_i) \neq 0$,

$$\Pr_{b_i}(y) = \begin{cases} 0 & \text{if } y_i \neq b_i, \\ \alpha_3(y) & \text{if } y_i = b_i. \end{cases}$$

Given (a_i, b_i), with $\bar{\alpha}^i(a_i, b_i) \neq 0$, choose randomly $x \in \bar{X}$ according to $\Pr_{a_i}(x)$ and $y \in \bar{Y}$ according to $\Pr_{b_i}(y)$. If (a_i, b_i) are chosen with probability $\bar{\alpha}^i(a_i, b_i)$ then (x, y) are chosen with probability

$$\bar{\alpha}^i(x_i, y_i)\Pr_{x_i}(x)\Pr_{y_i}(y) = \alpha_1(x_i, y_i)\alpha_2(x)\alpha_3(y) = \bar{\alpha}(x, y).$$

Thus, if (a_i, b_i) is a random variable, with distribution $\bar{\alpha}^i$, then (x, y) is a random variable with distribution $\bar{\alpha}$.

Players I, II can use a protocol for $\bar{G}^i_{\bar{\alpha}}$ to define a probabilistic protocol for $G_{\bar{\alpha}^i}$ in the following way: Given an input pair $(a_i, b_i) \in X \times Y$ for the game $G_{\bar{\alpha}^i}$, player I chooses randomly $x \in \bar{X}$, according to $\Pr_{a_i}(x)$, and player II chooses randomly $y \in \bar{Y}$, according to $\Pr_{b_i}(y)$. Since (a_i, b_i) is a random variable with distribution $\bar{\alpha}^i$, (x, y) is a random variable with distribution $\bar{\alpha}$ and can be used as an input for $\bar{G}^i_{\bar{\alpha}}$.

Players I, II can now use the protocol for $\bar{G}^i_{\bar{\alpha}}$ on the input (x, y), as a protocol for $G_{\bar{\alpha}^i}$ on the input (a_i, b_i). Formally, if $u : \bar{X} \to U$, $v : \bar{Y} \to V$ is the protocol for $\bar{G}^i_{\bar{\alpha}}$, and h is the random string used by the players, the protocol for $G_{\bar{\alpha}^i}$ will be $u'(a_i, h) = u(x)$, $v'(b_i, h) = v(y)$, (where x, y are created from a_i, b_i, h by the previous procedure). Since

$$\bar{Q}^i(x, y, u(x), v(y)) = Q(x_i, y_i, u(x), v(y)) = Q(a_i, b_i, u'(a_i, h), v'(a_i, h)),$$

the probability that $Q(a_i, b_i, u'(a_i, h), v'(a_i, h)) = 1$ equals exactly the probability that $\bar{Q}^i(x, y, u(x), v(y)) = 1$. Since (x, y) is a random variable with distribution $\bar{\alpha}$, this probability is the value of the original protocol for $\bar{G}^i_{\bar{\alpha}}$.

Thus we proved that a protocol for $\bar{G}^i_{\bar{\alpha}}$ defines a probabilistic protocol with the same value for $G_{\bar{\alpha}^i}$. It is well known that since a probabilistic protocol can be viewed as a convex combination of deterministic ones, there must exist a deterministic protocol with the same value. □

Since the conditions of Lemma 4.1 do not hold usually, we cannot expect them to hold for the measure $\bar{\pi}$. The idea will be to represent $\bar{\pi}$ as a convex combination of measures that satisfy the conditions of Lemma 4.1 and then to deduce bounds for the values $w_i(\bar{\pi})$.

We remark that in the simpler case, in which the original measure μ is a product measure, the measure $\bar{\pi}$ does satisfy the conditions of Lemma 4.1. Had we considered only this simpler case, the entire proof would have ended here!

Recall that in all the following $\bar{\pi} = \bar{\mu}_A$, where the set A is taken from Theorem 1.2 and satisfies,

$$-\log \bar{\mu}(A) \leq \Delta k.$$

The following definition is probably the most important notion in this paper. This definition enables the representation of $\bar{\pi}$ as a convex combination of measures with nice properties. A similar idea was used before in [35, 41].

A scheme M of type $\mathcal{M}^l$ consists of:

1. A partition of the set of coordinates $[k] - \{l\}$ into $I \cup J$.
2. Values $a_i \in X$, for all $i \in I$, and $b_j \in Y$, for all $j \in J$.

(Formally, M should be denoted by $M^l_{I,J,a_{i_1},\ldots,a_{i_{|I|}},b_{j_1},\ldots,b_{j_{|J|}}}$; however, for simplicity we will just use the notation M.) We also denote by M the set

$$M = \left\{ (x, y) \in \bar{X} \times \bar{Y} \;\middle|\; \forall i \in I \;:\; x_i = a_i \;,\; \forall j \in J \;:\; y_j = b_j \right\}.$$

We also denote by $\mathcal{M}^l$ the family of all sets M of type $\mathcal{M}^l$ (i.e., for all possible $I, J, a_{i_1}, \ldots, a_{i_{|I|}}, b_{j_1}, \ldots, b_{j_{|J|}}$). Notice that each $\mathcal{M}^l$ is a cover of $\bar{X} \times \bar{Y}$. Each element $(x, y) \in \bar{X} \times \bar{Y}$ is covered 2^{k-1} times by each $\mathcal{M}^l$.

For all l, define the following two probability measures, $\nu_l, \rho_l : \mathcal{M}^l \to \mathbf{R}^+$ by

$$\nu_l(M) = \frac{\bar{\mu}(M)}{2^{k-1}}, \quad \rho_l(M) = \frac{\bar{\pi}(M)}{2^{k-1}} = \frac{\bar{\mu}_A(M)}{2^{k-1}} = \frac{\bar{\mu}(A \cap M)}{\bar{\mu}(A) 2^{k-1}}$$

(ν_l, ρ_l are obviously probability measures, by the above observation that each element (x, y) is covered exactly 2^{k-1} times by $\mathcal{M}^l$).

Recall that for the set M, we have the measures $\bar{\mu}_M : \bar{X} \times \bar{Y} \to \mathbf{R}^+$, $\bar{\pi}_M : \bar{X} \times \bar{Y} \to \mathbf{R}^+$. For M with $\bar{\mu}(M) > 0$ (respectively, $\bar{\pi}(M) > 0$), these measures are probability measures (recall that otherwise they are defined to be identically 0). Recall that $\bar{\mu}_M^i, \bar{\pi}_M^i : X \times Y \to \mathbf{R}^+$ are the projections of these measures on the ith coordinate. For $M \in \mathcal{M}^l$, we will be mainly interested in the projections $\bar{\mu}_M^l, \bar{\pi}_M^l$. Note that since $\bar{\mu} = \mu^{\otimes k}$, the projection $\bar{\mu}_M^l$ is just μ.

The important fact for M is the following.

CLAIM 4.1. *For $M \in \mathcal{M}^l$ (with $\rho_l(M) > 0$),*

$$w_l(\bar{\pi}_M) = w(\bar{\pi}_M^l).$$

Proof. This is a simple application of Lemma 4.1. For $(x, y) \in M$, we have

$$\begin{aligned}\bar{\mu}_M(x,y) = \bar{\mu}(M)^{-1}\bar{\mu}(x,y) \;&=\; \bar{\mu}(M)^{-1}\prod_{i=1}^{k}\mu(x_i,y_i)\\ &= \bar{\mu}(M)^{-1}\mu(x_l,y_l)\prod_{i\in I}\mu(x_i,y_i)\prod_{j\in J}\mu(x_j,y_j)\\ &= \bar{\mu}(M)^{-1}\mu(x_l,y_l)\prod_{i\in I}\mu(a_i,y_i)\prod_{j\in J}\mu(x_j,b_j).\end{aligned}$$

Define $\mu_1 : X \times Y \to \mathbf{R}$, $\mu_2 : \bar{X} \to \mathbf{R}$, $\mu_3 : \bar{Y} \to \mathbf{R}$ by

$$\mu_1(x_l,y_l) = \bar{\mu}(M)^{-1}\mu(x_l,y_l),\;\; \mu_2(x) = \prod_{j\in J}\mu(x_j,b_j),\;\; \mu_3(y) = \prod_{i\in I}\mu(a_i,y_i).$$

Then for $(x, y) \in M$, we have

$$\bar{\mu}_M(x,y) = \mu_1(x_l,y_l)\mu_2(x)\mu_3(y).$$

The event $(x, y) \in M \cap A$ can be written as

$$(x \in A_X \;\cap\; \forall i \in I : x_i = a_i) \bigcap (y \in A_Y \;\cap\; \forall j \in J : y_j = b_j).$$

Therefore, defining $\chi_2 : \bar{X} \to \mathbf{R}$, $\chi_3 : \bar{Y} \to \mathbf{R}$ by

$$\chi_2(x) = \begin{cases} 1 & \text{if } x \in A_X \;\cap\; \forall i \in I \;:\; x_i = a_i,\\ 0 & \text{otherwise,}\end{cases}$$

$$\chi_3(y) = \begin{cases} 1 & \text{if } y \in A_Y \;\cap\; \forall j \in J \;:\; y_j = b_j,\\ 0 & \text{otherwise,}\end{cases}$$

we have $\forall (x, y) \in \bar{X} \times \bar{Y}$

$$\bar{\pi}_M(x,y) = \bar{\mu}_{A\cap M}(x,y) = (\bar{\mu}_M)_A(x,y) = \bar{\mu}_M(A)^{-1}\chi_2(x)\chi_3(y)\bar{\mu}_M(x,y),$$

and since $(x, y) \notin M$ implies $\chi_2(x)\chi_3(y) = 0$, we have

$$\bar{\pi}_M(x,y) = \bar{\mu}_M(A)^{-1}\chi_2(x)\chi_3(y)\mu_1(x_l,y_l)\mu_2(x)\mu_3(y).$$

Define

$$\begin{aligned}\pi_1(x_l,y_l) &= \bar{\mu}_M(A)^{-1}\mu_1(x_l,y_l),\\ \pi_2(x) &= \chi_2(x)\mu_2(x),\\ \pi_3(y) &= \chi_3(y)\mu_3(y).\end{aligned}$$

Then $\bar{\pi}_M(x, y) = \pi_1(x_l, y_l)\pi_2(x)\pi_3(y)$ and the claim follows from Lemma 4.1. ∎

Recall the definitions of the probability measures ν_l, ρ_l. Since every (x,y) is covered the same number of times by $\mathcal{M}^l$, for any l, the measure $\bar{\pi}$ can be written as the convex combination

$$\bar{\pi} = \sum_{M \in \mathcal{M}^l} \rho_l(M) \bar{\pi}_M. \tag{2}$$

We will use the equality (2) in two ways. First note that a protocol for $\bar{G}^l_{\bar{\pi}}$ is also a protocol for each $\bar{G}^l_{\bar{\pi}_M}$. Therefore,

$$w_l(\bar{\pi}) \leq \sum_{M \in \mathcal{M}^l} \rho_l(M) w_l(\bar{\pi}_M) = \mathbf{E}_{\rho_l}\left(w_l(\bar{\pi}_M)\right),$$

(which reflects the concavity of the function w_l–see in the Introduction), and by Claim 4.1 we have

$$w_l(\bar{\pi}) \leq \mathbf{E}_{\rho_l}\left(w\left(\bar{\pi}^l_M\right)\right). \tag{3}$$

Thus, if we can only upper bound the values $w\left(\bar{\pi}^l_M\right)$, of the one-dimensional measures $\bar{\pi}^l_M$, we will have an upper bound for $w_l(\bar{\pi})$.

In order to deduce an upper bound for $\mathbf{E}_{\rho_l}\left(w\left(\bar{\pi}^l_M\right)\right)$, we need some more properties of the family $\left\{\bar{\pi}^l_M\right\}_{M \in \mathcal{M}^l}$: First take the projection of equality (2) to get

$$\bar{\pi}^l = \sum_{M \in \mathcal{M}^l} \rho_l(M) \bar{\pi}^l_M.$$

We also need the following lemma.

LEMMA 4.2 (main). *There exists l_0 such that*

$$\mathbf{E}_{\rho_{l_0}}\left(\mathbf{V}\left(\bar{\pi}^{l_0}_M \,\middle\|\, \mu\right)\right) \leq \frac{2}{k}(-\log \bar{\mu}(A))$$

and

$$\mathbf{D}\left(\bar{\pi}^{l_0} \,\|\, \mu\right) \leq \frac{2}{k}(-\log \bar{\mu}(A)).$$

The proof is given in the next section.

In order to understand the intuition behind Lemma 4.2, one should think of the right-hand side, $\frac{2}{k}(-\log \bar{\mu}(A))$, as a very small ϵ. The lemma just says that there exists l_0 s.t. $\bar{\pi}^{l_0}$ is very close to μ (by Lemma 3.4), and s.t. for an average M, $\mathbf{V}(\bar{\pi}^{l_0}_M \| \mu)$ is very small.

Thus fixing l_0 from the last lemma, and fixing $\epsilon = 2/k(-\log \bar{\mu}(A))$, the family of measures $\{\bar{\pi}^{l_0}_M\}_{M \in \mathcal{M}^{l_0}}$ satisfies

$$\sum_{M \in \mathcal{M}^{l_0}} \rho_{l_0}(M) \mathbf{V}\left(\bar{\pi}^{l_0}_M \,\middle\|\, \mu\right) \leq \epsilon$$

and

$$\mathbf{D}\left(\sum_{M \in \mathcal{M}^{l_0}} \rho_{l_0}(M) \bar{\pi}^{l_0}_M \,\middle\|\, \mu\right) = \mathbf{D}\left(\bar{\pi}^{l_0} \,\|\, \mu\right) \leq \epsilon.$$

In these conditions, the following lemma proves an upper bound for

$$\sum_{M \in \mathcal{M}^{l_0}} \rho_{l_0}(M) w\left(\bar{\pi}_M^{l_0}\right) = \mathbf{E}_{\rho_{l_0}}\left(w\left(\bar{\pi}_M^{l_0}\right)\right),$$

i.e., an upper bound for the value $w\left(\bar{\pi}_M^{l_0}\right)$, for an average M.

LEMMA 4.3. *There exists a global function $W_2 : [0,1] \to [0,1]$, with $z < 1$ implying $W_2(z) < 1$, and a global constant c_1 such that: if $\{\gamma_d\}_{d \in D}$ is a family of probability measures on $X \times Y$, and $\{p_d\}_{d \in D}$ are weights satisfying $\forall d : p_d \geq 0$, and $\sum_{d \in D} p_d = 1$. Assume that for some $0 \leq \epsilon \leq 1$*

$$\sum_D p_d \mathbf{V}(\gamma_d \parallel \mu) \leq \epsilon$$

and

$$\mathbf{D}\left(\sum_D p_d \gamma_d \,\middle\|\, \mu\right) \leq \epsilon.$$

Then,

$$\sum_D p_d w(\gamma_d) \leq W_2(w(\mu)) + c_1 \epsilon^{1/16}.$$

The proof is given in section 6.

Using Lemma 4.3, and inequality (3), and the fact that

$$\epsilon \stackrel{\text{def}}{=} \frac{2}{k}(-\log \bar{\mu}(A)) \leq \frac{2}{k}\Delta k \leq 2\Delta,$$

we can now conclude

$$w_{l_0}(\bar{\pi}) \leq \mathbf{E}_{\rho_{l_0}}\left(w\left(\bar{\pi}_M^{l_0}\right)\right) \leq W_2(w(\mu)) + c_1(2\Delta)^{1/16},$$

which proves Theorem 1.2.

Lemma 4.2, which is the most important lemma in the paper, is proved in the next section. Lemma 4.3 is proved in section 6.

We remark that Lemma 4.3 is not really necessary: for small enough ϵ, and irreducible μ, the fact that $\mathbf{V}(\gamma_d \parallel \mu) \leq \epsilon$ implies that $\parallel \gamma_d - \mu \parallel_1$ is very small. Therefore, it can be proved easily that

$$\mathbf{E}_{\rho_{l_0}}\left(w\left(\bar{\pi}_M^{l_0}\right)\right) \approx w(\mu),$$

which implies the parallel repetitions conjecture for irreducible measures. It turns out that the general case follows easily from the irreducible one.

However, as we mentioned in section 3, only for a very small ϵ it is the case that $\mathbf{V}(\gamma_d \parallel \mu) \leq \epsilon$ implies that $\parallel \gamma_d - \mu \parallel_1$ is small. In fact, such an ϵ needs to be much smaller than the ϵ used here. In particular, since the measure μ is arbitrary, such an ϵ depends on the size of the input set, $|X \times Y|$, as opposed to the ϵ used here, which depends only on $w(\mu)$ and is independent of other parameters of the game. Thus using Lemma 4.3 improves the constants in the exponent (in our analysis) in the parallel repetition theorem.

5. The main lemma. In this section we give the proof of Lemma 4.2. Our proof uses tools, and intuition from [41].

The main idea of the proof is to introduce a new type of scheme. A scheme M of type $\mathcal{M}$ consists of

1. a partition of the set of coordinates $[k]$ into $I \cup J$;
2. values $a_i \in X$, for all $i \in I$, and $b_j \in Y$, for all $j \in J$;

Note that this is the same as before, except that here $I \cup J = [k]$ rather than $[k] - \{l\}$. As before, we also denote by M the set

$$M = \left\{ (x,y) \in \bar{X} \times \bar{Y} \;\middle|\; \forall i \in I \;:\; x_i = a_i \;,\; \forall j \in J \;:\; y_j = b_j \right\}$$

and by $\mathcal{M}$ the family of all the sets M of type $\mathcal{M}$. Notice that each element $(x,y) \in \bar{X} \times \bar{Y}$ is covered 2^k times, by the cover $\mathcal{M}$. As before, define two probability measures $\nu, \rho : \mathcal{M} \to \mathbf{R}^+$ by

$$\nu(M) = \frac{\bar{\mu}(M)}{2^k} \quad , \quad \rho(M) = \frac{\bar{\pi}(M)}{2^k} = \frac{\bar{\mu}_A(M)}{2^k} = \frac{\bar{\mu}(A \cap M)}{\bar{\mu}(A) 2^k}.$$

As before, we have for the set M the measures $\bar{\mu}_M : \bar{X} \times \bar{Y} \to \mathbf{R}^+$, and $\bar{\pi}_M = \bar{\mu}_{M \cap A} : \bar{X} \times \bar{Y} \to \mathbf{R}^+$. Recall that $\bar{\mu}^i_M, \bar{\pi}^i_M$ are the projections of these measures on the ith coordinate.

For $i \in I$, $x_i = a_i$ is fixed. In this case $\bar{\mu}^i_M, \bar{\pi}^i_M$ are concentrated on $\{a_i\} \times Y$ and can also be thought of as measures on Y. In the same way, if $j \in J$ then $\bar{\mu}^j_M, \bar{\pi}^j_M$ can be thought of as measures on X.

Notice also that since $\bar{\mu} = \mu^{\otimes k}$, we have

$$\bar{\mu}_M = \otimes_{i=1}^k \bar{\mu}^i_M.$$

Claim 5.1.

$$\sum_{i=1}^k \mathbf{E}_\rho \left(\mathbf{D} \left(\bar{\pi}^i_M \parallel \bar{\mu}^i_M \right) \right) \leq - \log \bar{\mu}(A).$$

Proof. The proof follows from the basic properties of informational divergence: For any scheme $M \in \mathcal{M}$ with $\rho(M) > 0$, we have by Lemma 3.5,

$$\begin{aligned} \mathbf{D} \left(\bar{\pi}_M \parallel \bar{\mu}_M \right) &= \mathbf{D} \left(\bar{\mu}_{M \cap A} \parallel \bar{\mu}_M \right) = \mathbf{D} \left((\bar{\mu}_M)_A \parallel \bar{\mu}_M \right) \\ &= - \log \bar{\mu}_M(A) = - \log \frac{\bar{\mu}(M \cap A)}{\bar{\mu}(M)} = - \log \frac{\rho(M) \bar{\mu}(A)}{\nu(M)}. \end{aligned}$$

Therefore,

$$\begin{aligned} \mathbf{E}_\rho \left(\mathbf{D} \left(\bar{\pi}_M \parallel \bar{\mu}_M \right) \right) &= - \sum_{M \in \mathcal{M}} \rho(M) \log \frac{\rho(M) \bar{\mu}(A)}{\nu(M)} \\ &= - \sum_{M \in \mathcal{M}} \rho(M) \left[\log \frac{\rho(M)}{\nu(M)} + \log \bar{\mu}(A) \right] \\ &= -\mathbf{D} \left(\rho \parallel \nu \right) - \log \bar{\mu}(A) \;\; \leq \;\; - \log \bar{\mu}(A) \end{aligned}$$

(by Lemma 3.1). But by Lemma 3.3, for all M, with $\rho(M) > 0$,

$$\mathbf{D} \left(\bar{\pi}_M \parallel \bar{\mu}_M \right) \geq \sum_{i=1}^k \mathbf{D} \left(\bar{\pi}^i_M \parallel \bar{\mu}^i_M \right)$$

and we can conclude that

$$\sum_{i=1}^{k} \mathbf{E}_\rho \left(\mathbf{D} \left(\bar{\pi}^i_M \parallel \bar{\mu}^i_M \right) \right) = \mathbf{E}_\rho \left(\sum_{i=1}^{k} \mathbf{D} \left(\bar{\pi}^i_M \parallel \bar{\mu}^i_M \right) \right)$$
$$\leq \mathbf{E}_\rho \left(\mathbf{D} \left(\bar{\pi}_M \parallel \bar{\mu}_M \right) \right) \leq -\log \bar{\mu}(A). \qquad \square$$

Fix l. In what follows we denote by M a scheme of type $\mathcal{M}$, and by M' a scheme of type $\mathcal{M}^l$. Denote by I, J the partition of coordinates, corresponding to the scheme M, and by I', J' the one corresponding to M'. A scheme M agrees with a scheme M' if and only if $I' = I \cap ([k] - \{l\})$, $J' = J \cap ([k] - \{l\})$, and M, M' agree on the values of a_i, b_j, for all $i \in I', j \in J'$. For a scheme M' of type $\mathcal{M}^l$, denote the set of all schemes M of type $\mathcal{M}$, agreeing with M', by $N(M')$. Then the family of sets $\{M\}_{M \in N(M')}$ is a cover of the set M', where each element $(x, y) \in M'$ is covered exactly twice (as we have to choose $l \in I$ or $l \in J$ and then fix the value of a_l or b_l). Therefore, we have

$$\bar{\pi}(M') = \frac{1}{2} \sum_{M \in N(M')} \bar{\pi}(M),$$

and hence,

$$\rho_l(M') = \sum_{M \in N(M')} \rho(M).$$

Assume in all of the following that $\rho_l(M') > 0$. Then $\rho(M)/\rho_l(M')$ is a probability measure on $N(M')$. A scheme M can be randomly chosen, according to the distribution ρ, by first choosing M' according to ρ_l and then choosing $M \in N(M')$ with probability $\rho(M)/\rho_l(M')$.

CLAIM 5.2. *For every l,*

$$\mathbf{V} \left(\bar{\pi}^l_{M'} \parallel \bar{\mu}^l_{M'} \right) = \sum_{M \in N(M')} \frac{\rho(M)}{\rho_l(M')} \mathbf{D} \left(\bar{\pi}^l_M \parallel \bar{\mu}^l_M \right).$$

Proof. The proof follows by looking carefully into the definitions. For $M \in N(M')$

$$\frac{\rho(M)}{\rho_l(M')} = \frac{\bar{\pi}(M)/2^k}{\bar{\pi}(M')/2^{k-1}} = \frac{1}{2} \frac{\bar{\pi}(M)}{\bar{\pi}(M')} = \frac{1}{2} \bar{\pi}_{M'}(M).$$

If for the scheme M, $l \in I$, then $\bar{\pi}_{M'}(M)$ is just the probability to have $x_l = a_l$ in the set M'. By definition this probability is $\bar{\pi}^l_{M'}(a_l)$. Therefore, in this case,

$$\frac{\rho(M)}{\rho_l(M')} = \frac{1}{2} \bar{\pi}^l_{M'}(a_l).$$

Also in this case, $\bar{\pi}_M$ is derived from $\bar{\pi}_{M'}$ by fixing x_l to be a_l. Hence, $\bar{\pi}^l_M = \bar{\pi}^l_{M'}(a_l, \cdot)$. In the same way, we have $\bar{\mu}^l_M = \bar{\mu}^l_{M'}(a_l, \cdot)$. Therefore, for $l \in I$

$$\frac{\rho(M)}{\rho_l(M')} \mathbf{D} \left(\bar{\pi}^l_M \parallel \bar{\mu}^l_M \right) = \frac{1}{2} \bar{\pi}^l_{M'}(a_l) \mathbf{D} \left(\bar{\pi}^l_{M'}(a_l, \cdot) \parallel \bar{\mu}^l_{M'}(a_l, \cdot) \right).$$

In the same way, for $l \in J$

$$\frac{\rho(M)}{\rho_l(M')} \mathbf{D} \left(\bar{\pi}^l_M \parallel \bar{\mu}^l_M \right) = \frac{1}{2} \bar{\pi}^l_{M'}(b_l) \mathbf{D} \left(\bar{\pi}^l_{M'}(\cdot, b_l) \parallel \bar{\mu}^l_{M'}(\cdot, b_l) \right).$$

Partitioning $M \in N(M')$ into schemes with $l \in I$, and schemes with $l \in J$, we have

$$\begin{aligned}
&\sum_{M \in N(M')} \frac{\rho(M)}{\rho_l(M')} \mathbf{D}\left(\bar{\pi}^l_M \parallel \bar{\mu}^l_M\right) \\
&= \sum_{a \in X} \frac{1}{2} \bar{\pi}^l_{M'}(a) \mathbf{D}\left(\bar{\pi}^l_{M'}(a,\cdot) \parallel \bar{\mu}^l_{M'}(a,\cdot)\right) + \sum_{b \in Y} \frac{1}{2} \bar{\pi}^l_{M'}(b) \mathbf{D}\left(\bar{\pi}^l_{M'}(\cdot,b) \parallel \bar{\mu}^l_{M'}(\cdot,b)\right) \\
&= \frac{1}{2} \mathbf{V}_{\mathbf{X}}\left(\bar{\pi}^l_{M'} \parallel \bar{\mu}^l_{M'}\right) + \frac{1}{2} \mathbf{V}_{\mathbf{Y}}\left(\bar{\pi}^l_{M'} \parallel \bar{\mu}^l_{M'}\right) \;=\; \mathbf{V}\left(\bar{\pi}^l_{M'} \parallel \bar{\mu}^l_{M'}\right). \qquad \square
\end{aligned}$$

Claim 5.3.

$$\sum_{l=1}^{k} \mathbf{E}_{\rho_l}\left(\mathbf{V}\left(\bar{\pi}^l_{M'} \parallel \bar{\mu}^l_{M'}\right)\right) \leq -\log \bar{\mu}(A).$$

Proof. By Claim 5.2 we have

$$\begin{aligned}
\mathbf{E}_{\rho}\left(\mathbf{D}\left(\bar{\pi}^l_M \parallel \bar{\mu}^l_M\right)\right) &= \sum_{M \in \mathcal{M}} \rho(M) \mathbf{D}\left(\bar{\pi}^l_M \parallel \bar{\mu}^l_M\right) \\
&= \sum_{M' \in \mathcal{M}^l} \rho_l(M') \sum_{M \in N(M')} \frac{\rho(M)}{\rho_l(M')} \mathbf{D}\left(\bar{\pi}^l_M \parallel \bar{\mu}^l_M\right) \\
&= \sum_{M' \in \mathcal{M}^l} \rho_l(M') \mathbf{V}\left(\bar{\pi}^l_{M'} \parallel \bar{\mu}^l_{M'}\right) \;=\; \mathbf{E}_{\rho_l}\left(\mathbf{V}\left(\bar{\pi}^l_{M'} \parallel \bar{\mu}^l_{M'}\right)\right).
\end{aligned}$$

Since this is true for all l, we can sum up and conclude by Claim 5.1 that

$$\sum_{l=1}^{k} \mathbf{E}_{\rho_l}\left(\mathbf{V}\left(\bar{\pi}^l_{M'} \parallel \bar{\mu}^l_{M'}\right)\right) = \sum_{l=1}^{k} \mathbf{E}_{\rho}\left(\mathbf{D}\left(\bar{\pi}^l_M \parallel \bar{\mu}^l_M\right)\right) \leq -\log \bar{\mu}(A). \qquad \square$$

Since $\mathbf{V}(\vartheta \parallel \psi)$ is always non-negative (see section 3), we can conclude from the last claim that less than $\frac{k}{2}$ coordinates l satisfy

$$\mathbf{E}_{\rho_l}\left(\mathbf{V}\left(\bar{\pi}^l_{M'} \parallel \bar{\mu}^l_{M'}\right)\right) > -\frac{2}{k} \log \bar{\mu}(A).$$

Therefore, more than $\frac{1}{2}k$ coordinates l satisfy

$$\mathbf{E}_{\rho_l}\left(\mathbf{V}\left(\bar{\pi}^l_{M'} \parallel \bar{\mu}^l_{M'}\right)\right) \leq -\frac{2}{k} \log \bar{\mu}(A).$$

By Lemmas 3.3 and 3.5, we also have

$$\sum_{l=1}^{k} \mathbf{D}\left(\bar{\pi}^l \parallel \bar{\mu}^l\right) \leq \mathbf{D}\left(\bar{\pi} \parallel \bar{\mu}\right) = \mathbf{D}\left(\bar{\mu}_A \parallel \bar{\mu}\right) = -\log \bar{\mu}(A)$$

and as before, more than $\frac{1}{2}k$ coordinates l satisfy

$$\mathbf{D}\left(\bar{\pi}^l \parallel \bar{\mu}^l\right) \leq -\frac{2}{k} \log \bar{\mu}(A).$$

Therefore, there exists l with

$$\mathbf{E}_{\rho_l}\left(\mathbf{V}\left(\bar{\pi}^l_{M'} \parallel \bar{\mu}^l_{M'}\right)\right) \le -\frac{2}{k}\log\bar{\mu}(A)$$

and

$$\mathbf{D}\left(\bar{\pi}^l \parallel \bar{\mu}^l\right) \le -\frac{2}{k}\log\bar{\mu}(A).$$

Since $\bar{\mu} = \mu^{\otimes k}$, we have $\bar{\mu}^l_{M'} = \mu$ and $\bar{\mu}^l = \mu$. Thus Lemma 4.2 follows.

6. Families of local protocols. Given X, Y, U, V, Q, every probability measure, $\gamma : X \times Y \to \mathbf{R}^+$, defines a game G_γ. In this section, as before, we denote the value of this game by $w(\gamma)$. The original measure μ is one measure of this type (with value $w(\mu)$). For some finite set D, let $\{\gamma_d\}_{d\in D}$ be a family of measures of this type. Thus, for all $d \in D$, $\gamma_d : X \times Y \to \mathbf{R}^+$ is a probability measure, and has a value $w(\gamma_d)$. Let $p_d \ge 0$ be an arbitrary weight ($\forall d \in D$). We will not always require $\sum_{d\in D} p_d = 1$. However, in the cases that we consider $\sum_{d\in D} p_d$ will be very close to 1. Thus p_d will be "almost" a probability measure on D.

Define

$$w_d = w(\gamma_d), \quad w = \sum_{d\in D} p_d w_d$$

(note that w may be larger than 1, because we didn't require $\sum_{d\in D} p_d = 1$), and the measure $\gamma : X \times Y \to \mathbf{R}^+$ by

$$\gamma = \sum_{d\in D} p_d \gamma_d.$$

In this section we assume that γ is close to μ. We would like to deduce, under some conditions on the measures $\{\gamma_d\}_{d\in D}$, a lower bound for $w(\mu)$ as a function of w, or conversely, an upper bound for w as a function of $w(\mu)$. The conditions on $\{\gamma_d\}_{d\in D}$ will intuitively say that each measure γ_d "locally" describes the behavior of the original measure μ. The goal of the section is to prove Lemma 4.3, which is stated in section 4.

6.1. The basic lemma. First assume that for all $d \in D$, we have sets $X_d \subset X$ and $Y_d \subset Y$, such that

$$\gamma_d = \mu_{X_d \times Y_d}.$$

For all $d \in D$, define

$$a_d = \mu(X_d \times Y_d)$$

and

$$r_d = \frac{\mu\left[(X_d \times (Y - Y_d)) \cup ((X - X_d) \times Y_d)\right]}{\mu(X_d \times Y_d)}.$$

Define

$$r = \sum_{d\in D} p_d r_d.$$

The next lemma gives our basic lower bound for $w(\mu)$ as a function of w.

LEMMA 6.1. *Assume that for some constants $0 \leq \epsilon_0 \leq 1$, $0 \leq \epsilon_1 \leq 1$, we have $\| \gamma - \mu \|_1 \leq \epsilon_0$, and $r \leq \epsilon_1$, and assume (for simplicity) that $w \leq 1$. Let $f : \mathbf{R} \to \mathbf{R}$ be any increasing monotone function such that $f(z) \leq 0$, for $z \leq 0$, and such that for all $0 \leq z \leq 1$, $0 < \delta \leq 1$, we have the inequality*

$$(1-\delta)z + \delta f\left[\frac{1}{\delta}(z-(1-\delta))\right] \geq f(z).$$

Then

$$w(\mu) \geq f(w - 2\sqrt{\epsilon_1} - \epsilon_0).$$

We remark that ϵ_0, ϵ_1 should be thought of as small constants. Some examples for functions f, as above, are given in Corollaries 6.2, 6.3, 6.4. It is always true that for $0 \leq z \leq 1$, $f(z) \leq z$, (to see this, substitute $\delta = 1/2$ to get $f(z) \leq z/2 + f(2z-1)/2$, and by the fact that f is monotone, and $z \leq 1$, we get $f(z) \leq z/2 + f(z)/2$).

Proof. We will first give some intuition. Every measure μ decomposes into its irreducible components. In the simplest case, where $\epsilon_0 = \epsilon_1 = 0$, for all $d : r_d = 0$. Therefore, in this case, $X_d \times Y_d$ is a component of the measure μ (not necessarily irreducible). Since we can further decompose each one of these components, we can assume w.l.o.g. that $X_d \times Y_d$ is irreducible, and therefore that the family $\{\gamma_d\}_{d \in D}$ describes the decomposition of the measure μ into irreducible components. Every protocol for μ defines a protocol for each one of its components. Also, given a protocol for each one of the irreducible components, we can define a protocol for μ (we define the protocol for μ on each irreducible component separately). The value of the protocol for μ is the weighted average of the values of the protocols for the components. Therefore in the special case $\epsilon_0 = \epsilon_1 = 0$, we can simply conclude that $w(\mu) = w$, and the claim follows. In the general case the intuition is basically the same: We will find d_0 such that $X_{d_0} \times Y_{d_0}$ is "almost" a component of μ (i.e., d_0 with small r_{d_0}) and such that w_{d_0} is very close to w. We will concentrate on the set $(X - X_{d_0}) \times (Y - Y_{d_0})$ and continue by induction. Intuitively, we will get a subfamily of $\{\gamma_d\}_{d \in D}$ that will "almost" describe a decomposition of the measure μ into "almost" irreducible components.

First note that

$$\| \gamma \|_1 = \left\| \sum_{d \in D} p_d \gamma_d \right\|_1 = \sum_{d \in D} p_d \| \gamma_d \|_1 = \sum_{d \in D} p_d.$$

Therefore, since $\| \gamma - \mu \|_1 \leq \epsilon_0$ and since $\| \mu \|_1 = 1$, we have by the triangle inequality

$$1 - \epsilon_0 \leq \sum_{d \in D} p_d \leq 1 + \epsilon_0.$$

CLAIM 6.1. *There exists $d_0 \in D$ with*

$$r_{d_0} \leq \sqrt{\epsilon_1}$$

and

$$w_{d_0} \geq w - \sqrt{\epsilon_1} - \epsilon_0.$$

Proof. Denote

$$Z = \{d \in D \mid r_d \geq \sqrt{\epsilon_1}\}.$$

Then,

$$\epsilon_1 \geq r = \sum_{d\in D} p_d r_d \geq \sum_{d\in Z} p_d r_d \geq \sqrt{\epsilon_1} \sum_{d\in Z} p_d.$$

Hence,

$$\sum_{d\in Z} p_d \leq \sqrt{\epsilon_1};$$

thus,

$$w = \sum_{Z} p_d w_d + \sum_{D-Z} p_d w_d \leq \sum_{Z} p_d 1 + \sum_{D-Z} p_d w_d \leq \sqrt{\epsilon_1} + \sum_{D-Z} p_d w_d$$

and therefore,

$$\sum_{D-Z} p_d w_d \geq w - \sqrt{\epsilon_1}.$$

Let $d_0 \in D - Z$ be the element with the maximal w_{d_0}. Then,

$$w_{d_0} \sum_{D-Z} p_d \geq \sum_{D-Z} p_d w_d \geq w - \sqrt{\epsilon_1},$$

and by $\sum_{D-Z} p_d \leq \sum_{d\in D} p_d \leq 1 + \epsilon_0$, we have

$$w_{d_0} \geq (w - \sqrt{\epsilon_1})/(1 + \epsilon_0) \geq (w - \sqrt{\epsilon_1})(1 - \epsilon_0) \geq w - \sqrt{\epsilon_1} - \epsilon_0$$

(since $w \leq 1$).

This completes the proof of Claim 6.1. □

Fix d_0 from the last claim. Define

$$X' = X - X_{d_0}, \quad Y' = Y - Y_{d_0}, \quad \delta = \mu(X' \times Y').$$

Assume that $\delta > 0$. For all $d \in D$ define

$$X'_d = X_d \cap X', \quad Y'_d = Y_d \cap Y', \quad \gamma'_d = \mu_{X'_d \times Y'_d}, \quad w'_d = w(\gamma'_d), \quad a'_d = \mu(X'_d \times Y'_d),$$
$$r'_d = \frac{\mu\left[(X'_d \times (Y' - Y'_d)) \cup ((X' - X'_d) \times Y'_d)\right]}{\mu(X'_d \times Y'_d)}, \quad p'_d = p_d \frac{1}{\delta} \frac{a'_d}{a_d}$$

(recall that $\frac{0}{0}$ is defined to be 0). Notice that r'_d can be ∞, but then $p'_d = 0$. Define

$$r' = \sum_{D} p'_d r'_d, \quad w' = \sum_{D} p'_d w'_d, \quad \gamma' = \sum_{D} p'_d \gamma'_d.$$

Clearly,

$$\gamma'_d(x,y) = \begin{cases} \dfrac{a_d}{a'_d}\gamma_d(x,y) & \text{for } (x,y) \in X' \times Y', \\ 0 & \text{for } (x,y) \notin X' \times Y'. \end{cases}$$

Therefore, by the definitions,

$$\gamma'(x,y) = \begin{cases} \dfrac{1}{\delta}\gamma(x,y) & \text{for } (x,y) \in X' \times Y', \\ 0 & \text{for } (x,y) \notin X' \times Y'. \end{cases}$$

So

$$\gamma' = \left(\frac{1}{\delta}\gamma(X' \times Y')\right)\gamma_{X' \times Y'}.$$

Therefore, we also have

$$\sum_D p'_d \ = \parallel \gamma' \parallel_1 = \ \gamma(X' \times Y')/\delta.$$

We would like to use induction (of the lemma), with the family $\{\gamma'_d\}_{d \in D}$, to deduce a lower bound for $w(\mu_{X' \times Y'})$. In order to use the lemma, we need bounds for r', $\parallel \gamma' - \mu_{X' \times Y'} \parallel_1$, and for w'.
First note that

$$\begin{aligned} r'_d a'_d &= \mu\left[(X'_d \times (Y' - Y'_d)) \cup ((X' - X'_d) \times Y'_d)\right] \\ &\leq \mu\left[(X_d \times (Y - Y_d)) \cup ((X - X_d) \times Y_d)\right] \ = \ r_d a_d. \end{aligned}$$

Therefore, defining

$$\epsilon'_1 = \frac{\epsilon_1}{\delta}$$

we have

$$r' = \sum_D p'_d r'_d = \frac{1}{\delta}\sum_D p_d \frac{a'_d}{a_d} r'_d \leq \frac{1}{\delta}\sum_D p_d r_d = \frac{r}{\delta} \leq \frac{\epsilon_1}{\delta} = \epsilon'_1.$$

Also, define

$$\epsilon'_0 = \parallel \gamma' - \mu_{X' \times Y'} \parallel_1;$$

then clearly,

$$\begin{aligned} \delta\epsilon'_0 = \parallel \delta\gamma' - \delta\mu_{X' \times Y'} \parallel_1 \ &= \ \parallel \gamma(X' \times Y')\gamma_{X' \times Y'} - \mu(X' \times Y')\mu_{X' \times Y'} \parallel_1 \\ = \sum_{X' \times Y'} |\gamma(x,y) - \mu(x,y)| \leq \sum_{X \times Y} |\gamma(x,y) - \mu(x,y)| \ &= \parallel \gamma - \mu \parallel_1 = \epsilon_0. \end{aligned}$$

Thus we have bounds for r',$\parallel \gamma' - \mu_{X' \times Y'} \parallel_1$. The bound for w' will follow from the following two claims.

Claim 6.2.

$$\parallel \gamma \parallel_1 - \delta \parallel \gamma' \parallel_1 \leq \ \epsilon_0 - \delta\epsilon'_0 + (1 - \delta).$$

Proof. Define $Z = (X \times Y) - (X' \times Y')$, and $Z' = X' \times Y'$. Then $\gamma = \gamma(Z)\gamma_Z + \gamma(Z')\gamma_{Z'}$, and $\mu = \mu(Z)\mu_Z + \mu(Z')\mu_{Z'}$. Therefore,

$$\parallel \gamma \parallel_1 = \parallel \gamma(Z)\gamma_Z \parallel_1 + \parallel \gamma(Z')\gamma_{Z'} \parallel_1 = \parallel \gamma(Z)\gamma_Z \parallel_1 + \delta \parallel \gamma' \parallel_1 . \tag{4}$$

In addition,

$$\begin{aligned} \epsilon_0 \geq \parallel \gamma - \mu \parallel_1 &= \parallel \gamma(Z)\gamma_Z - \mu(Z)\mu_Z \parallel_1 + \parallel \gamma(Z')\gamma_{Z'} - \mu(Z')\mu_{Z'} \parallel_1 \\ &= \parallel \gamma(Z)\gamma_Z - \mu(Z)\mu_Z \parallel_1 + \parallel \delta\gamma' - \delta\mu_{Z'} \parallel_1 = \parallel \gamma(Z)\gamma_Z - \mu(Z)\mu_Z \parallel_1 + \delta\epsilon'_0. \end{aligned}$$

Thus, by the triangle inequality,

$$\epsilon_0 - \delta\epsilon_0' \geq \| \gamma(Z)\gamma_Z - \mu(Z)\mu_Z \|_1 \geq \| \gamma(Z)\gamma_Z \|_1 - \| \mu(Z)\mu_Z \|_1 = \| \gamma(Z)\gamma_Z \|_1 - (1-\delta),$$

so,

$$\| \gamma(Z)\gamma_Z \|_1 \leq \epsilon_0 - \delta\epsilon_0' + (1-\delta).$$

The proof follows by substituting this in (4). □

CLAIM 6.3.

$$w' \geq (w - (1-\delta) - \epsilon_0 + \delta\epsilon_0')/\delta.$$

Proof. Any protocol for the game with the measure $\mu_{X_d \times Y_d}$ defines a corresponding protocol for the game with the measure $\mu_{X_d' \times Y_d'}$. Take the best protocol for $\mu_{X_d \times Y_d}$. This protocol for $\mu_{X_d \times Y_d}$ satisfies Q on a set of points of μ-measure $w_d a_d$. At most μ-measure of $a_d - a_d' = \mu(X_d \times Y_d) - \mu(X_d' \times Y_d')$ is outside $X_d' \times Y_d'$. Therefore, at least μ-measure of $w_d a_d - (a_d - a_d')$ is inside. Thus, the corresponding protocol for $\mu_{X_d' \times Y_d'}$ satisfies Q on a set of points of μ-measure $w_d a_d - (a_d - a_d')$ (at least). But this cannot be more than $w_d' a_d'$; thus,

$$w_d' a_d' \geq w_d a_d - a_d + a_d'.$$

Therefore,

$$p_d' w_d' = p_d \frac{1}{\delta} \frac{a_d'}{a_d} w_d' \geq p_d \frac{1}{\delta} \frac{1}{a_d} [w_d a_d - a_d + a_d'] = \frac{1}{\delta} p_d w_d - \frac{1}{\delta} p_d + p_d',$$

and we have

$$\begin{aligned} w' &= \sum_D p_d' w_d' \geq \frac{1}{\delta} \sum_D p_d w_d - \frac{1}{\delta} \sum_D p_d + \sum_D p_d' \\ &= \frac{1}{\delta} w - \frac{1}{\delta} \| \gamma \|_1 + \| \gamma' \|_1 = \frac{1}{\delta} [w - (\| \gamma \|_1 - \delta \| \gamma' \|_1)], \end{aligned}$$

and by Claim 6.2

$$w' \geq (w - (1-\delta) - \epsilon_0 + \delta\epsilon_0')/\delta. \qquad \square$$

By Claim 6.3, we can conclude

$$\begin{aligned} w' - 2\sqrt{\epsilon_1'} - \epsilon_0' &\geq \frac{1}{\delta}(w - (1-\delta) - \epsilon_0 + \delta\epsilon_0') - 2\sqrt{\frac{\epsilon_1}{\delta}} - \epsilon_0' \\ &= \frac{1}{\delta}(w - (1-\delta) - 2\sqrt{\delta}\sqrt{\epsilon_1} - \epsilon_0) \geq \frac{1}{\delta}(w - (1-\delta) - 2\sqrt{\epsilon_1} - \epsilon_0). \end{aligned}$$

Now, we can use induction and apply the lemma for $\mu_{X' \times Y'}$, with the family $\{\gamma_d'\}_{d \in D}$ to get a lower bound

$$w(\mu_{X' \times Y'}) \geq f\left[w' - 2\sqrt{\epsilon_1'} - \epsilon_0'\right] \geq f\left[\frac{1}{\delta}(w - 2\sqrt{\epsilon_1} - \epsilon_0 - (1-\delta))\right]$$

(since f is monotone). Define $z = w - 2\sqrt{\epsilon_1} - \epsilon_0$ to get

$$w(\mu_{X' \times Y'}) \geq f\left[\frac{1}{\delta}(z - (1-\delta))\right].$$

Recall that $w_{d_0} \geq w - \sqrt{\epsilon_1} - \epsilon_0$. Since $a_{d_0} + r_{d_0} a_{d_0} + \delta = \mu(X \times Y) = 1$, we have $a_{d_0} = (1-\delta)/(1+r_{d_0})$. But $r_{d_0} \leq \sqrt{\epsilon_1}$, and therefore

$$a_{d_0} \geq (1-\delta)/(1+\sqrt{\epsilon_1}) \geq (1-\delta)(1-\sqrt{\epsilon_1})$$

and we have

$$a_{d_0} w_{d_0} \geq (1-\delta)(1-\sqrt{\epsilon_1})(w - \sqrt{\epsilon_1} - \epsilon_0) \geq (1-\delta)(w - 2\sqrt{\epsilon_1} - \epsilon_0) = (1-\delta)z.$$

Recall that $X_{d_0} \cap X' = \emptyset$, and $Y_{d_0} \cap Y' = \emptyset$. Given the best protocol for $\mu_{X_{d_0} \times Y_{d_0}}$ and the best protocol for $\mu_{X' \times Y'}$, define a protocol for μ that behaves like the first one on $X_{d_0} \times Y_{d_0}$ and like the other one on $X' \times Y'$. This protocol satisfies Q on a set of points of μ-measure $\mu(X_{d_0} \times Y_{d_0}) w(\mu_{X_{d_0} \times Y_{d_0}}) + \mu(X' \times Y') w(\mu_{X' \times Y'})$ (at least), and therefore proves that

$$\begin{aligned} w(\mu) &\geq a_{d_0} w_{d_0} + \delta w(\mu_{X' \times Y'}) \\ &\geq (1-\delta)z + \delta f\left[\frac{1}{\delta}(z - (1-\delta))\right] \geq f(z) = f(w - 2\sqrt{\epsilon_1} - \epsilon_0), \end{aligned}$$

which proves the lemma. The assumption $z \leq 0 \Rightarrow f(z) \leq 0$ is needed for the base case of the induction. We remark that if $\delta = 0$ the lemma is proved simply from Claim 6.1 or by a continuity argument. □

COROLLARY 6.2. *Under the assumptions of Lemma* 6.1,

$$w(\mu) \geq f(w - 2\sqrt{\epsilon_1} - \epsilon_0),$$

where f is defined by

$$f(z) = \begin{cases} \frac{1}{2}z^2 & \text{for } 0 \leq z \leq 1, \\ 0 & \text{for } z \leq 0. \end{cases}$$

Proof. We just have to prove the inequality (as in Lemma 6.1) for f.

Case a. $z \geq 1 - \delta$.

In this case

$$\begin{aligned} (1-\delta)z + \delta f\left[\frac{1}{\delta}(z-(1-\delta))\right] - f(z) &= (1-\delta)z + \frac{1}{2\delta}(z-(1-\delta))^2 - \frac{1}{2}z^2 \\ &= \frac{1}{2\delta}\left[2\delta(1-\delta)z + z^2 - 2(1-\delta)z + (1-\delta)^2 - \delta z^2\right] \\ &= \frac{1}{2\delta}\left[z^2(1-\delta) - 2z(1-\delta)^2 + (1-\delta)^2\right] \\ &\geq \frac{1-\delta}{2\delta}\left[z^2 - 2z(1-\delta) + (1-\delta)^2\right] \\ &= \frac{1-\delta}{2\delta}\left[z-(1-\delta)\right]^2 \quad \geq \quad 0. \end{aligned}$$

Case b. $z \leq 1 - \delta$.

In this case

$$\begin{aligned} (1-\delta)z + \delta f\left[\frac{1}{\delta}(z-(1-\delta))\right] - f(z) &= (1-\delta)z + 0 - \frac{1}{2}z^2 \\ &\geq z^2 - \frac{1}{2}z^2 = \frac{1}{2}z^2 \geq 0. \end{aligned}$$

□

It is sometimes convenient to denote $v(\mu) = 1 - w(\mu)$, $v = 1 - w$, and $g(t) = 1 - f(1-t)$. In these notations the inequality

$$(1-\delta)z + \delta f\left[\frac{1}{\delta}(z-(1-\delta))\right] - f(z) \geq 0$$

(for $0 \leq z \leq 1$, $0 < \delta \leq 1$), is equivalent (by setting $t = 1 - z$) to

$$(1-\delta)t + \delta g(t/\delta) \leq g(t)$$

(for $0 \leq t \leq 1$, $0 < \delta \leq 1$).

COROLLARY 6.3. *Under the assumptions of Lemma* 6.1, *if* $g : \mathbf{R} \to \mathbf{R}$ *is an increasing monotone function such that* $g(t) \geq 1$, *for* $t \geq 1$, *and such that for all* $0 \leq t \leq 1$, $0 < \delta \leq 1$, *we have*

$$(1-\delta)t + \delta g(t/\delta) - g(t) \leq 0;$$

then,

$$v(\mu) \leq g(v + 2\sqrt{\epsilon_1} + \epsilon_0).$$

COROLLARY 6.4. *Under the assumptions of Lemma* 6.1,

$$v(\mu) \leq 2\sqrt{v + 2\sqrt{\epsilon_1} + \epsilon_0}.$$

Proof. Take $g(t) = 2\sqrt{t}$, then for $0 \leq t \leq 1$, $0 < \delta \leq 1$,

$$\begin{aligned}(1-\delta)t + \delta g(t/\delta) - g(t) &= (1-\delta)t + 2\sqrt{\delta}\sqrt{t} - 2\sqrt{t} \\ &= (1+\sqrt{\delta})(1-\sqrt{\delta})\sqrt{t}\sqrt{t} - 2(1-\sqrt{\delta})\sqrt{t} \\ &= (1-\sqrt{\delta})\sqrt{t}[(1+\sqrt{\delta})\sqrt{t} - 2] \quad \leq \quad 0\end{aligned}$$

(because $(1+\sqrt{\delta})\sqrt{t} - 2 \leq 2 - 2 = 0$). □

It will be convenient to define the function $W_1 : \mathbf{R} \to \mathbf{R}$ in the following way:

$$W_1(z) = \sup_f f(z)$$

where the supremum is taken over all the strictly increasing monotone functions, satisfying the conditions as in Lemma 6.1. Conversely, define $W_2 : \mathbf{R} \to \mathbf{R}$ by

$$W_2(z) = \inf_f f^{-1}(z)$$

where the infimum is taken over the same family of functions.

Take, for convenience, $\epsilon_0 = \epsilon_1 = \epsilon$, and assume for convenience that $w \leq 1$. Lemma 6.1 can now be restated in the following way.

COROLLARY 6.5. *If for a family* $\{\gamma_d\}_{d\in D}$ *we have* $\| \gamma - \mu \|_1 \leq \epsilon$ *and* $r \leq \epsilon$, *then*

$$w(\mu) \geq W_1(w - O(\sqrt{\epsilon}))$$

or, conversely,

$$w \leq W_2(w(\mu)) + O(\sqrt{\epsilon}).$$

By Corollaries 6.2 and 6.4 we have

$$0 < z \Rightarrow 0 < W_1(z), \quad \lim_{z\to 1} W_1(z) = 1, \quad \lim_{z\to 0} W_2(z) = 0, \quad z < 1 \Rightarrow W_2(z) < 1$$

(where the last fact is the important one for us). Also, since f was monotone, $W_1(z), W_2(z)$ are both monotone. Thus, W_1, W_2 are "well behaved." In this manuscript we will not investigate their exact behavior.

6.2. Characterization of measures ϑ, with small $\mathbf{V}(\vartheta \parallel \mu)$. Lemma 4.3 talks about measures γ_d, with small $\mathbf{V_X}(\gamma_d \parallel \mu)$ and small $\mathbf{V_Y}(\gamma_d \parallel \mu)$. We would like to prove this lemma by a reduction to Lemma 6.1. In order to do that, we need one more lemma that gives a characterization of measures ϑ, with small $\mathbf{V_X}(\vartheta \parallel \mu)$ and small $\mathbf{V_Y}(\vartheta \parallel \mu)$. Again, $\mu : X \times Y \to \mathbf{R}^+$ and $\vartheta : X \times Y \to \mathbf{R}^+$ are probability measures.

LEMMA 6.6. *If* $\mathbf{V_X}(\vartheta \parallel \mu), \mathbf{V_Y}(\vartheta \parallel \mu) \leq \epsilon$ *then, for some* m*, there exist partitions* $X = \bigcup_{i=1}^m X_i$, $Y = \bigcup_{i=1}^m Y_i$*, and positive weights* $\{q_i\}_{i=1}^m$ *(i.e., for all* $i : q_i \geq 0$*), such that the function* $h : X \times Y \to \mathbf{R}$*, defined by*

$$h(x,y) = \sum_{i=1}^{m} q_i \mu_{X_i \times Y_i}(x,y)$$

satisfies

$$\parallel \vartheta - h \parallel_1 \leq O(\epsilon^{1/8})$$

and such that

$$\sum_{i=1}^{m} q_i r_i \leq O(\epsilon^{1/8}),$$

where

$$r_i = \frac{\mu\left[(X_i \times (Y - Y_i)) \cup ((X - X_i) \times Y_i)\right]}{\mu(X_i \times Y_i)}.$$

Proof. Assume that $\vartheta(x), \vartheta(y), \mu(x), \mu(y)$ take only strictly positive values (otherwise, just add small constants and normalize). This is done only to simplify the notations. Assume that ϵ is small enough ($\epsilon < 2^{-10}$ is enough), (for $\epsilon \geq 2^{-10}$, $O(\epsilon^{1/8}) = O(1)$, thus $h = \mu$ does the job).

The first claim describes the basic structure of the measure ϑ.

CLAIM 6.4.

$$\left\| \vartheta(x,y) - \frac{\vartheta(x)}{\mu(x)}\mu(x,y) \right\|_1 \leq \sqrt{2\ln 2}\sqrt{\epsilon},$$

$$\left\| \vartheta(x,y) - \frac{\vartheta(y)}{\mu(y)}\mu(x,y) \right\|_1 \leq \sqrt{2\ln 2}\sqrt{\epsilon}.$$

Proof. We will prove the first inequality. The second can be proved in a similar manner.

By Lemma 3.4 we have

$$\begin{aligned}\sum_{x \in X} \vartheta(x) \left(\parallel \vartheta(x,\cdot) - \mu(x,\cdot) \parallel_1\right)^2 &\leq (2\ln 2) \sum_{x \in X} \vartheta(x) \mathbf{D}\left(\vartheta(x,\cdot) \parallel \mu(x,\cdot)\right) \\ &= (2\ln 2)\mathbf{V_X}(\vartheta \parallel \mu) \leq (2\ln 2)\epsilon.\end{aligned}$$

Since for any random variable z: $(\mathbf{E}(z))^2 \leq \mathbf{E}(z^2)$, we have

$$\sum_{x \in X} \vartheta(x) \left(\parallel \vartheta(x,\cdot) - \mu(x,\cdot) \parallel_1\right) \leq \sqrt{2\ln 2}\sqrt{\epsilon},$$

but

$$\sum_{x\in X}\vartheta(x)\left(\parallel \vartheta(x,\cdot)-\mu(x,\cdot)\parallel_1\right) = \sum_{x\in X}\vartheta(x)\sum_{y\in Y}\left|\frac{\vartheta(x,y)}{\vartheta(x)}-\frac{\mu(x,y)}{\mu(x)}\right|$$
$$= \sum_{X\times Y}\left|\vartheta(x,y)-\frac{\vartheta(x)}{\mu(x)}\mu(x,y)\right| = \left\|\,\vartheta(x,y)-\frac{\vartheta(x)}{\mu(x)}\mu(x,y)\,\right\|_1$$

and the claim follows. □

Define

$$R_X(x)=\frac{\vartheta(x)}{\mu(x)},\quad R_Y(y)=\frac{\vartheta(y)}{\mu(y)},\quad R(x,y)=\frac{R_Y(y)}{R_X(x)}$$

(note that $R(x,y)$ is asymmetric). By our assumption, these values are always well defined and strictly positive. Define

$$h_1(x,y)=R_X(x)\mu(x,y),\quad h_2(x,y)=R_Y(y)\mu(x,y).$$

We proved

$$\parallel \vartheta-h_1\parallel_1\le\sqrt{2\ln 2}\sqrt{\epsilon},\quad \parallel \vartheta-h_2\parallel_1\le\sqrt{2\ln 2}\sqrt{\epsilon}.$$

Therefore, by the triangle inequality we also have

$$\parallel h_1\parallel_1\le\parallel\vartheta\parallel_1+\parallel\vartheta-h_1\parallel_1\le\ 1+\sqrt{2\ln 2}\sqrt{\epsilon}.$$

Similarly,

$$\parallel h_2\parallel_1\le\ 1+\sqrt{2\ln 2}\sqrt{\epsilon}$$

and

$$\parallel h_1-h_2\parallel_1\le\parallel\vartheta-h_1\parallel_1+\parallel\vartheta-h_2\parallel_1\le\ 2\sqrt{2\ln 2}\sqrt{\epsilon}.$$

The last inequality shows that most of the measure μ is concentrated on pairs (x,y), with $R_X(x)$ very close to $R_Y(y)$. In the simplest case, where $\epsilon=0$, the entire measure μ is concentrated on pairs, with $R_X(x)=R_Y(y)$. In this case we can partition X according to $R_X(x)$, and Y according to $R_Y(y)$, and define the weight of a subset as $R_X(x)$ (or $R_Y(y)$). The lemma follows then from Claim 6.4 and from the last inequality. In the general case the intuition will be the same, but we will have to partition X and Y into subsets, according to the value of $R_X(x)$ and $R_Y(y)$, where each subset allows small deviations in the value.

Denote

$$\epsilon_1=2\sqrt{2\ln 2}\sqrt{\epsilon}$$

and define

$$Z=\{(x,y)\in X\times Y\ \mid\ |1-R(x,y)|\ge\sqrt{\epsilon_1}\}.$$

Claim 6.5.

$$\sum_Z h_1(x,y)\le\sqrt{\epsilon_1},\quad \sum_Z h_2(x,y)\le\sqrt{\epsilon_1}.$$

Proof. By the definitions

$$\| h_1(x,y)\,(1-R(x,y)) \|_1 = \| h_1 - h_2 \|_1 \leq 2\sqrt{2\ln 2}\sqrt{\epsilon} = \epsilon_1.$$

Therefore,

$$\sum_Z h_1(x,y)\sqrt{\epsilon_1} \leq \sum_Z h_1(x,y)\,|1-R(x,y)| \leq \sum_{X,Y} h_1(x,y)\,|1-R(x,y)| \leq \epsilon_1.$$

Thus,

$$\sum_Z h_1(x,y) \leq \sqrt{\epsilon_1}.$$

The second inequality is proved in the same way. □

Denote

$$\epsilon_2 = \sqrt{-\ln(1-\sqrt{\epsilon_1})}.$$

Then since $\epsilon < 2^{-10}$,

$$\epsilon_2 \leq \sqrt{\ln(1+2\sqrt{\epsilon_1})} \leq \sqrt{2\sqrt{\epsilon_1}} \leq 2\epsilon^{1/8}.$$

For $(x,y) \notin Z$, we have

$$1-\sqrt{\epsilon_1} \leq R(x,y) \leq 1+\sqrt{\epsilon_1}.$$

Hence,

$$\ln(1-\sqrt{\epsilon_1}) \leq \ln R(x,y) \leq \ln(1+\sqrt{\epsilon_1}) \leq -\ln(1-\sqrt{\epsilon_1}).$$

Thus, $(x,y) \notin Z$ implies

$$-\epsilon_2^2 \leq \ln R(x,y) \leq \epsilon_2^2.$$

Let r be a random variable uniformly distributed in the interval $[0,1]$. For every integer i define

$$X_i(r) = \{x \in X \mid (i-1+r)\epsilon_2 \leq \ln R_X(x) < (i+r)\epsilon_2\},$$
$$Y_i(r) = \{y \in Y \mid (i-1+r)\epsilon_2 \leq \ln R_Y(y) < (i+r)\epsilon_2\}.$$

Then, for all r, $\{X_i(r)\}_{i=-\infty}^{\infty}$ is a partition of X, and $\{Y_i(r)\}_{i=-\infty}^{\infty}$ is a partition of Y. Define

$$\hat{Z}(r) = \left\{ (x,y) \in X \times Y \;\middle|\; (x,y) \notin \bigcup_{i=-\infty}^{\infty} X_i \times Y_i \right\}.$$

We will prove that for some r these partitions satisfy the lemma.

Claim 6.6.

$$(x,y) \notin Z \;\Rightarrow\; \Pr_r\left[(x,y) \in \hat{Z}(r)\right] \leq \epsilon_2.$$

Proof. $(x,y) \notin Z$ implies

$$|\ln R_X(x) - \ln R_Y(y)| = |\ln R(x,y)| \le \epsilon_2^2.$$

Assume w.l.o.g. that $\ln R_X(x) \ge \ln R_Y(y)$. For a fixed r, $(x,y) \in X_i(r) \times Y_i(r)$ for some i, unless there exists in the interval $[\ln R_Y(y), \ln R_X(x)]$, a number of the form $(j+r)\epsilon_2$ (for some integer j). The probability for that (over r) is

$$\frac{\ln R_X(x) - \ln R_Y(y)}{\epsilon_2} \le \frac{\epsilon_2^2}{\epsilon_2} = \epsilon_2. \qquad \square$$

CLAIM 6.7.

$$\mathbf{E}_r\left(\sum_{\hat{Z}(r)} h_1(x,y)\right) \le 3\epsilon_2, \quad \mathbf{E}_r\left(\sum_{\hat{Z}(r)} h_2(x,y)\right) \le 3\epsilon_2.$$

Proof. By changing the order of the summations,

$$\begin{aligned}
\mathbf{E}_r\left(\sum_{\hat{Z}(r)} h_1(x,y)\right) &= \sum_{X\times Y} h_1(x,y)\mathrm{Pr}_r\left[(x,y) \in \hat{Z}(r)\right] \\
&= \sum_{X\times Y - Z} h_1(x,y)\mathrm{Pr}_r\left[(x,y) \in \hat{Z}(r)\right] + \sum_{Z} h_1(x,y)\mathrm{Pr}_r\left[(x,y) \in \hat{Z}(r)\right] \\
&\le \sum_{X\times Y - Z} h_1(x,y)\epsilon_2 + \sum_{Z} h_1(x,y)1 \le \epsilon_2 \sum_{X\times Y} h_1(x,y) + \sum_{Z} h_1(x,y) \\
&\le \epsilon_2 \parallel h_1 \parallel_1 + \sqrt{\epsilon_1} \ \le\ \epsilon_2(1 + \sqrt{2\ln 2}\sqrt{\epsilon}) + \sqrt{\epsilon_1} \ \le\ 3\epsilon_2.
\end{aligned}$$

The second inequality is proved in the same way. $\square$

Since $h_1(x,y), h_2(x,y)$ are always positive, we can conclude from the last claim the existence of r_0 with

$$\sum_{\hat{Z}(r)} h_1(x,y) \le 6\epsilon_2, \quad \sum_{\hat{Z}(r)} h_2(x,y) \le 6\epsilon_2.$$

Fix this r_0. Define

$$X_i = X_i(r_0), \quad Y_i = Y_i(r_0), \quad \hat{Z} = \hat{Z}(r_0).$$

We will prove that these partitions satisfy the lemma. Define $h_3 : X \times Y \to \mathbf{R}$ by

$$h_3(x,y) = \begin{cases} h_1(x,y) & \text{for } (x,y) \notin \hat{Z}, \\ 0 & \text{for } (x,y) \in \hat{Z}. \end{cases}$$

Then clearly,

$$\parallel h_1 - h_3 \parallel_1 = \sum_{X,Y} |h_1(x,y) - h_3(x,y)| = \sum_{\hat{Z}} h_1(x,y) \le 6\epsilon_2.$$

By the definitions,

$$h_3(x,y) = \sum_{i=-\infty}^{\infty} R_X(x)\mu(X_i \times Y_i)\mu_{X_i\times Y_i}(x,y).$$

Define

$$q_i = e^{(i-1+r_0)\epsilon_2}\mu(X_i \times Y_i)$$

and

$$h(x,y) = \sum_{i=-\infty}^{\infty} q_i \mu_{X_i \times Y_i}(x,y).$$

CLAIM 6.8.

$$\| h_3 - h \|_1 \leq 2\epsilon_2.$$

Proof. For $x \in X_i$,

$$e^{(i-1+r_0)\epsilon_2} \leq R_X(x) < e^{(i+r_0)\epsilon_2};$$

thus, by the definition of q_i,

$$R_X(x)\mu(X_i \times Y_i) \;\geq\; q_i \;>\; R_X(x)\mu(X_i \times Y_i)e^{-\epsilon_2} \geq R_X(x)\mu(X_i \times Y_i)(1-\epsilon_2).$$

Therefore, for $x \in X_i$

$$0 \;\leq\; R_X(x)\mu(X_i \times Y_i) - q_i \;\leq\; R_X(x)\mu(X_i \times Y_i)\epsilon_2.$$

Since $\mu_{X_i \times Y_i}(x,y) > 0 \Rightarrow x \in X_i$, we have for all x, y,

$$|R_X(x)\mu(X_i \times Y_i) - q_i|\, \mu_{X_i \times Y_i}(x,y) \;\leq\; \epsilon_2 R_X(x)\mu(X_i \times Y_i)\mu_{X_i \times Y_i}(x,y)$$

and therefore,

$$\begin{aligned}
\| h_3 - h \|_1 &= \left\| \sum_{i=-\infty}^{\infty} R_X(x)\mu(X_i \times Y_i)\mu_{X_i \times Y_i}(x,y) - \sum_{i=-\infty}^{\infty} q_i \mu_{X_i \times Y_i}(x,y) \right\|_1 \\
&\leq \left\| \sum_{i=-\infty}^{\infty} |R_X(x)\mu(X_i \times Y_i) - q_i|\, \mu_{X_i \times Y_i}(x,y) \right\|_1 \\
&\leq \left\| \sum_{i=-\infty}^{\infty} \epsilon_2 R_X(x)\mu(X_i \times Y_i)\mu_{X_i \times Y_i}(x,y) \right\|_1 \\
&= \epsilon_2 \| h_3 \|_1 \leq \;\epsilon_2 \| h_1 \|_1 \;\leq\; 2\epsilon_2. \qquad \square
\end{aligned}$$

By the triangle inequality, we can now conclude that

$$\begin{aligned}
\| h - \vartheta \|_1 &\leq \| \vartheta - h_1 \|_1 + \| h_1 - h_3 \|_1 + \| h_3 - h \|_1 \\
&\leq \sqrt{2 \ln 2}\sqrt{\epsilon} + 3\epsilon_2 + 2\epsilon_2 = O(\epsilon^{1/8}).
\end{aligned}$$

Notice that in the definition of h, the sum is actually finite, because X, Y are finite ($\mu(X_i \times Y_i)$ can take a nonzero value only a finite number of times).

CLAIM 6.9.

$$\sum_{i=-\infty}^{\infty} q_i \frac{\mu[X_i \times (Y - Y_i)]}{\mu(X_i \times Y_i)} \leq O(\epsilon^{1/8}),$$

$$\sum_{i=-\infty}^{\infty} q_i \frac{\mu[(X - X_i) \times Y_i]}{\mu(X_i \times Y_i)} \leq O(\epsilon^{1/8}).$$

Proof. Notice that $\mu(X_i \times Y_i)$ can be 0, only if q_i is also 0. As in the previous claim for $x \in X_i$, $q_i \le R_X(x)\mu(X_i \times Y_i)$. Thus,

$$q_i \frac{\mu[X_i \times (Y - Y_i)]}{\mu(X_i \times Y_i)} = \sum_{(x,y)\in X_i\times(Y-Y_i)} \frac{q_i}{\mu(X_i \times Y_i)}\mu(x,y) \le \sum_{(x,y)\in X_i\times(Y-Y_i)} R_X(x)\mu(x,y),$$

and therefore,

$$\sum_{i=-\infty}^{\infty} q_i \frac{\mu[X_i \times (Y - Y_i)]}{\mu(X_i \times Y_i)} \;\le\; \sum_{i=-\infty}^{\infty} \left(\sum_{(x,y)\in X_i\times(Y-Y_i)} R_X(x)\mu(x,y) \right)$$

$$= \sum_{(x,y)\in \hat{Z}} R_X(x)\mu(x,y) \;=\; \sum_{\hat{Z}} h_1(x,y) \;\le\; 6\epsilon_2 \;=\; O(\epsilon^{1/8}).$$

The second inequality is proved in the same way. □

Claim 6.9 and the inequality before give the proof of Lemma 6.6. □

6.3. Proof of Lemma 4.3. Lemma 4.3 will follow as a simple application of Lemmas 6.1 and 6.6. Given ϑ, with

$$\mathbf{V_X}(\vartheta \parallel \mu), \mathbf{V_Y}(\vartheta \parallel \mu) \le \epsilon$$

take m, $\{q_i\}_{i=1}^m$, $\{X_i\}_{i=1}^m$, $\{Y_i\}_{i=1}^m$ from Lemma 6.6. Define

$$\gamma_i = \mu_{X_i \times Y_i}, \quad w_i = w(\gamma_i)$$

and

$$r_i = \frac{\mu[(X_i \times (Y - Y_i)) \cup ((X - X_i) \times Y_i)]}{\mu(X_i \times Y_i)}$$

as in Lemma 6.1. By Lemma 6.6 we have

$$\sum_{i=1}^{m} q_i r_i \;\le\; O(\epsilon^{1/8})$$

and

$$\left\| \vartheta - \sum_{i=1}^{m} q_i \gamma_i \right\|_1 \;\le\; O(\epsilon^{1/8}).$$

Every protocol for ϑ defines also a protocol for each one of the γ_i-s. Therefore, the last inequality also gives

$$w(\vartheta) \;\le\; \sum_{i=1}^{m} q_i w_i + O(\epsilon^{1/8}),$$

which reflects the fact that the function $w(\gamma)$ is concave and has a Lipschitz constant of 1 (see the Introduction).

Lemma 4.3 can be proved now in the following way. Given a family $\{\gamma_d\}_{d\in D}$ of probability measures on $X \times Y$ and weights $\{p_d\}_{d\in D}$, such that $\sum_{d\in D} p_d = 1$, and such that for all $d : p_d \ge 0$, define

$$w_d = w(\gamma_d), \quad w = \sum_{d\in D} p_d w_d, \quad V_d = \mathbf{V}(\gamma_d \parallel \mu).$$

Lemma 4.3 assumes

$$\sum_{d \in D} p_d V_d \ \leq \ \epsilon$$

and

$$\mathbf{D}\left(\sum_{d \in D} p_d \gamma_d \ \middle\| \ \mu \right) \ \leq \ \epsilon,$$

and therefore, by Lemma 3.4

$$\left\| \mu - \sum_{d \in D} p_d \gamma_d \right\|_1 \ \leq \ O(\epsilon^{1/2}).$$

For each measure γ_d, we have by the previous discussion, $\{\gamma_{d,i}\}_{i=1}^{m_d}$, and $\{q_{d,i}\}_{i=1}^{m_d}$, such that

$$\sum_{i=1}^{m_d} q_{d,i} r_{d,i} \ \leq \ O(V_d^{1/8})$$

and

$$\left\| \gamma_d - \sum_{i=1}^{m_d} q_{d,i} \gamma_{d,i} \right\|_1 \ \leq \ O(V_d^{1/8});$$

and as before, we also have

$$w_d \ \leq \ \sum_{i=1}^{m_d} q_{d,i} w_{d,i} + O(V_d^{1/8})$$

(where $r_{d,i}, w_{d,i}$ are defined as before). Define the set $\hat{D}$ by

$$\hat{D} = \{(d,i) \ \mid \ d \in D \ , \ 1 \leq i \leq m_d\}.$$

For each $\hat{d} = (d,i) \in \hat{D}$, define the weight

$$\hat{p}_{(d,i)} = p_d q_{d,i}$$

and the measure

$$\hat{\gamma}_{(d,i)} = \gamma_{d,i}.$$

Look at the family of measures $\{\hat{\gamma}_{(d,i)}\}_{(d,i) \in \hat{D}}$. For this family, define as before

$$\hat{w}_{(d,i)} = w(\hat{\gamma}_{(d,i)}), \quad \hat{w} = \sum_{\hat{d} \in \hat{D}} \hat{p}_{\hat{d}} \hat{w}_{\hat{d}}, \quad \hat{r}_{(d,i)} = r_{d,i}.$$

Then, by the convexity of the function $f(z) = z^{1/8}$, we have

$$\sum_{\hat{d} \in \hat{D}} \hat{p}_{\hat{d}} \hat{r}_{\hat{d}} = \sum_{d \in D} p_d \sum_{i=1}^{m_d} q_{d,i} r_{d,i} \ \leq \ \sum_{d \in D} p_d O(V_d^{1/8}) \ \leq \ O\left(\sum_{d \in D} p_d V_d \right)^{1/8}$$

$$\leq O(\epsilon^{1/8})$$

and

$$\begin{aligned}\left\| \mu - \sum_{\hat{d}\in\hat{D}} \hat{p}_{\hat{d}}\hat{\gamma}_{\hat{d}} \right\|_1 &\le \left\| \mu - \sum_{d\in D} p_d\gamma_d \right\|_1 + \left\| \sum_{d\in D} p_d\gamma_d - \sum_{\hat{d}\in\hat{D}} \hat{p}_{\hat{d}}\hat{\gamma}_{\hat{d}} \right\|_1 \\ &\le O(\epsilon^{1/2}) + \sum_{d\in D} p_d \left\| \gamma_d - \sum_{i=1}^{m_d} q_{d,i}\gamma_{d,i} \right\|_1 \\ &\le O(\epsilon^{1/2}) + \sum_{d\in D} p_d O(V_d^{1/8}) \le O(\epsilon^{1/2}) + O\left(\sum_{d\in D} p_d V_d\right)^{1/8} \\ &\le O(\epsilon^{1/8}),\end{aligned}$$

and also as before,

$$\begin{aligned}\hat{w} = \sum_{\hat{d}\in\hat{D}} \hat{p}_{\hat{d}}\hat{w}_{\hat{d}} &= \sum_{d\in D} p_d \sum_{i=1}^{m_d} q_{d,i}w_{d,i} \ge \sum_{d\in D} p_d \left(w_d - O(V_d^{1/8})\right) \\ &= w - \sum_{d\in D} p_d O(V_d^{1/8}) \\ &\ge w - O(\epsilon^{1/8}).\end{aligned}$$

Now we can apply Corollary 6.5 for the family $\{\hat{\gamma}_{\hat{d}}\}_{\hat{d}\in\hat{D}}$ to get

$$\hat{w} \le W_2(w(\mu)) + O(\epsilon^{1/16})$$

and we can conclude

$$w \le \hat{w} + O(\epsilon^{1/8}) \le W_2(w(\mu)) + O(\epsilon^{1/16}).$$

7. Conclusions. Theorem 1.1 can be generalized using methods introduced herein in many ways. Let us briefly describe two generalizations that seem to follow. The proofs were not verified as carefully as the rest of the paper and should be trusted accordingly. Several other generalizations are described in [42].

7.1. Product of games. Given a game G and a game G', the product game $G \otimes G'$ is defined in the same manner as $G \otimes G$, i.e., if G consists of X, Y, U, V, μ, Q, and G' consists of X', Y', U', V', μ', Q', then the game $G \otimes G'$ consists of the sets $X \times X'$, $Y \times Y'$, $U \times U'$, $V \times V'$ with the measure

$$\mu \otimes \mu'((x,x'),(y,y')) = \mu(x,y)\mu'(x',y')$$

and the predicate

$$Q \otimes Q'((x,x'),(y,y'),(u,u'),(v,v')) = Q(x,y,u,v)Q'(x',y',u',v').$$

In the same way, given k games $G_1, \ldots, G_k$, the product $G_1 \otimes \cdots \otimes G_k$ is defined.

Since in the entire proof of Theorem 1.1 we didn't use the fact that the same game, G, is repeated, and since the function W from Theorem 1.1 is global (and in particular doesn't depend on the game G), the following generalization of Theorem 1.1 follows.

THEOREM 7.1. *Let $W : [0,1] \to [0,1]$ be the function from Theorem* 1.1. *Given k games $G_1, \ldots, G_k$, define*

$$w = MAX[w(G_1), \ldots, w(G_k)],$$

and

$$s = MAX[s(G_1), \ldots, s(G_k), 2].$$

Then

$$w(G_1 \otimes \cdots \otimes G_k) \leq W(w)^{k/\log_2(s)}.$$

As before, $w = \text{MAX}[s(G_1), \ldots, s(G_k), 2]$ can be replaced with

$$w = \text{MAX}[CC(G_1), \ldots, CC(G_k), 2]$$

or with

$$w = \text{MAX}[\rho(G_1), \ldots, \rho(G_k), 2].$$

7.2. Probabilistic predicates. Our second generalization deals with the probabilistic case, where the predicate Q, of a game G, depends also on the random string r (i.e., Q is probabilistic). Without loss of generality we can assume that there exists a second random string, $\tilde{r}$, such that $\tilde{r}$ is independent of r (and, therefore, also of (x, y, u, v)), and such that the predicate Q depends on $x, y, u, v, \tilde{r}$ (and not on the random string r).

As before, the value of a protocol for the game G is defined to be the probability that $Q(x, y, u(x), v(y), \tilde{r}) = 1$, where (x, y) is chosen according to μ. As before, the value of the game, $w(G)$, is defined to be the maximal value of all protocols for G.

THEOREM 7.2. *Let $W : [0,1] \to [0,1]$ be the function from Theorem* 1.1. *Given a probabilistic game G (as above), with value $w(G)$, and answer-size $s(G) \geq 2$:*

$$w(G^{\otimes k}) \leq W(w(G))^{k/\log_2(s(G))}.$$

As before, $\log_2(s(G))$ can be replaced with $CC(G)$, or with $\rho(G)$, defined in the following way: Define $G_{\tilde{r}}$ to be the deterministic game obtained by fixing the second random string to $\tilde{r}$. Then define $CC(G)$ to be the maximum, taken over $\tilde{r}$, of $CC(G_{\tilde{r}})$, and define $\rho(G)$ to be the maximum, taken over $\tilde{r}$, of $\rho(G_{\tilde{r}})$.

Sketch of proof. First we claim that the proof of Theorem 1.2 holds (with minor changes) for probabilistic games as well. In section 4, the fact that the function w_l is concave is used to prove inequality (3) (and the inequality before). The concavity of the value function of a game is proved in the introduction for deterministic games. The same argument, however, holds for probabilistic games. Using this fact, one can verify that the entire argument of section 4 holds for probabilistic games as well. Now, section 4 uses Lemmas 4.2 and 4.3. Lemma 4.2 does not depend on the game G at all. The proof of Lemma 4.3 (in section 6) is based on Lemmas 6.1 and 6.6. Lemma 6.6 does not depend on the game G as well. Therefore, we just have to verify that the proof of Lemma 6.1 holds for probabilistic games. In the proof of Lemma 6.1 we use the fact that the game is deterministic only in the proof of Claim 6.3. It is not hard to see, however, that a probabilistic version of that proof can be given.

Theorem 7.2 is now proved using Theorem 1.2 in the same manner as before (see section 2). The difference is that now, given $z = (x', y', u', v') \in Z$, $\bar{Q}^1$ is still

not determined on the set $A(z)$, because $\bar{Q}^1$ depends also on the second random string corresponding to the first coordinate (denote this random string by $\tilde{r}^1$). In the deterministic case, we disregarded sets $A(z)$ for every z s.t. Q is not satisfied on z. In order to be able to do the same in the probabilistic case, we will have to have a copy of $A(z)$ for every possible $\tilde{r}^1$ (for $\tilde{r}^1 = r'$ denote this copy by $A_{r'}(z)$). We then disregard every copy $A_{r'}(z)$ for every z, r' s.t. Q is not satisfied on z, r'.

A different way to see how Theorem 7.2 is proved using Theorem 1.2 is to define $q(z)$ to be the probability that $Q(z, \tilde{r}) = 1$. (For a deterministic game, $q(z)$ is always 0 or 1). It is not too hard to see that the entire argument of section 2 can be generalized to the case where $0 \leq q(z) \leq 1$.

Alternatively, we can present the proof of Theorem 7.2 in the following way.

We can view a probabilistic game G in the following equivalent way. Player I receives (as an input) the pair $(x, \tilde{r})$ and Player II receives the pair $(y, \tilde{r})$. The protocols of the players are restricted as to depend only on the first input, i.e., x for the first player, and, respectively, y for the second player, (and not on the second input $\tilde{r}$). We call such a protocol a restricted protocol.

The game G is now deterministic because we can think of the predicate as being depended only on the inputs and the answers of the two players. The class of allowed protocols, however, is now a subclass of all possible protocols. We claim that the entire proof of Theorem 1.1 (including the proof of Theorem 1.2) is correct even if we allow only restricted protocols.

In some parts of the proof (e.g., section 4), we start from a protocol, P, for a game, and obtain from this protocol many protocols for many other games. These protocols are obtained either by projection (on one coordinate) or by restriction to a product subset. In other parts (e.g., section 6) a protocol P for a game is composed from other protocols for different games. In order to see that the proof of Theorem 1.1 holds even if we allow only restricted protocols, one should verify that if the original protocols are restricted then every protocol obtained by one of these three methods is also restricted. If the new protocol is obtained by projection of a restricted protocol or by composition of restricted protocols (i.e., by the first or third method), then it is very easy to see that the new protocol is also restricted. If the new protocol is obtained by a restriction of a restricted protocol to a subset, then the new protocol is not necessarily restricted. If that subset does not depend on $\tilde{r}$, however, then the new protocol is restricted. It is not hard to verify that the subsets used (in the proof) never depend on $\tilde{r}$.

Theorem 1.1 is thus correct even if we allow only restricted protocols. Theorem 7.2 follows. □

Acknowledgments. I would like to thank Uri Feige and Moni Naor for presenting the problem to me, and Uri Feige, Peter Hajnal, Joe Kilian, Dieter Van Melkebeek, Mario Szegedy, Endre Szemeredi, Gabor Tardos, Oleg Verbitsky, and Avi Wigderson for helpful and encouraging discussions on the subject and on the content of this paper. I would like to thank the two referees for many helpful comments. This research was carried out while the author was a postdoc at Princeton University and DIMACS.

FREE BITS, PCPS, AND NONAPPROXIMABILITY—TOWARDS TIGHT RESULTS*

MIHIR BELLARE†, ODED GOLDREICH‡, AND MADHU SUDAN§

In honor of Shimon Even's 60th birthday

Abstract. This paper continues the investigation of the connection between probabilistically checkable proofs (PCPs) and the approximability of NP-optimization problems. The emphasis is on proving *tight* nonapproximability results via consideration of measures such as the "free-bit complexity" and the "amortized free-bit complexity" of proof systems.

The first part of the paper presents a collection of new proof systems based on a new error-correcting code called the long code. We provide a proof system that has amortized free-bit complexity of $2 + \epsilon$, implying that approximating MaxClique within $N^{\frac{1}{3}-\epsilon}$, and approximating the Chromatic Number within $N^{\frac{1}{5}-\epsilon}$, are hard, assuming NP $\neq$ coRP, for any $\epsilon > 0$. We also derive the first explicit and reasonable constant hardness factors for Min Vertex Cover, Max2SAT, and Max Cut, and we improve the hardness factor for Max3SAT. We note that our nonapproximability factors for MaxSNP problems are appreciably close to the values known to be achievable by polynomial-time algorithms. Finally, we note a general approach to the derivation of strong nonapproximability results under which the problem reduces to the construction of certain "gadgets."

The increasing strength of nonapproximability results obtained via the PCP connection motivates us to ask how far this can go and whether PCPs are inherent in any way. The second part of the paper addresses this. The main result is a "reversal" of the connection due to Feige et al. (FGLSS connection) [*J. ACM*, 43 (1996), pp. 268–292]: where the latter had shown how to translate proof systems for NP into NP-hardness of approximation results for MaxClique, we show how any NP-hardness of approximation result for MaxClique yields a proof system for NP. Roughly, our result says that for any constant f, if MaxClique is NP-hard to approximate within $N^{1/(1+f)}$, then NP $\subseteq \overline{\text{FPCP}}[\log, f]$, the latter being the class of languages possessing proofs of logarithmic randomness and amortized free-bit complexity f. This suggests that PCPs are inherent to obtaining nonapproximability results. Furthermore, the tight relation suggests that reducing the amortized free-bit complexity is necessary for improving the nonapproximability results for MaxClique.

The third part of our paper initiates a systematic investigation of the properties of PCP and FPCP (free PCP) as a function of the following various parameters: randomness, query complexity, free-bit complexity, amortized free-bit complexity, proof size, etc. We are particularly interested in "triviality" results, which indicate which classes are *not* powerful enough to capture NP. We also distill the role of randomized reductions in this area and provide a variety of useful transformations between proof checking complexity classes.

Key words. intractability, approximation, NP-hardness, probabilistic proof systems

1. Introduction. In the MaxClique problem, we are given a graph G and must find the value of MaxClique$(G) = \max\{\,|S| : S \text{ is a clique in } G\,\}$. This is an example of an NP-optimization problem, of which others are to find the chromatic number of a graph; the size of the smallest vertex cover, etc. These problems arise in many settings and efficient solutions are much desired. Unfortunately, many important NP-optimization problems (those mentioned above in particular) are NP-hard to solve. So algorithm designers seek efficient (polynomial time) approximation algorithms.

An approximation algorithm delivers a number that is supposed to be close to optimal. The quality of the algorithm is measured in terms of how close this number is to optimal. For example, if $\mu(N) \geq 1$ is a function of the number N of vertices in a graph G, then we say an algorithm A approximates MaxClique within μ, or is a factor μ approximation algorithm, if MaxClique$(G)/\mu(N) \leq A(G) \leq$ MaxClique(G) for every graph G. (For a minimization problem such as Chromatic Number, we require instead that ChromNum$(G) \leq A(G) \leq \mu(N) \cdot$ ChromNum(G), where ChromNum(G) is the chromatic number of G.)

The search for efficient approximation algorithms achieving good factors has met with varied success. For some problems, good approximation algorithms were found. For some important problems, including MaxClique and Chromatic Number, the best approximation algorithms found achieved factors only marginally better than the trivial factor of N. For others, like Minimum Vertex Cover, simple algorithms achieving reasonable factors were discovered quite quickly, but it was unclear whether one could do better. Algorithm designers want to know whether this is due to some inherent intractability or only to the lack of cleverness in algorithm design.

Some early nonapproximability results were able to indicate (at least for some problems) that very good approximation (i.e., achieving factors very close to optimal) can be NP-hard. But the real breakthrough came more recently when a strong hardness of approximation result for MaxClique was shown by establishing a connection between MaxClique and the existence of probabilistically checkable proof (PCP) systems for NP. Since then, similar connections have been found to other optimization problems. Meanwhile, with the construction of more efficient proof systems, the factors within which approximation is shown hard continue to increase. Indeed, in some cases, even tight results seem in sight.

This paper continues the development of the connection between PCPs and hardness of approximation with the goal of getting tight results. On the one hand, we continue past work by building new proof systems and obtaining improved nonapproximability results; on the other hand we open some new directions with an exploration of the limits of the PCP connection.

In what follows we provide a little background and then a high level overview of our results. The rich history of the ideas in this area is overviewed in section 1.3, and more detailed histories are provided in the body of the paper.

1.1. Some background and definitions. We will be informal and as brief as possible; formal definitions can be found in section 2.

Proof systems and parameters. A probabilistic proof system is described by a probabilistic, polynomial time *verifier* V. It takes an input x of length n and tosses coins R. It has oracle access to a poly(n) length string σ describing the proof; to access a bit it writes an $O(\log n)$ bit address and the corresponding bit of the proof is returned. Following its computation, it will either accept or reject its input x. The accepting probability, denoted $\mathtt{ACC}[\,V(x)\,]$, is the maximum, over all σ, of the probability (over R) that V accepts x on coins R and proof string σ. While the task is typically language recognition (namely, to recognize whether x is in some fixed

language L) we will, more generally, consider promise problems (A, B) consisting of a set A of "positive" instances and a set B of "negative" instances [36]. A language L is identified with the promise problem $(L, \overline{L})$.

Of interest in our applications are various parameters of the system. The completeness probability $c = c(n)$ and the soundness probability $s = s(n)$ are defined in the usual ways. In case $c = 1$, we say that the system has *perfect completeness*. The gap is $g = c/s$. The query complexity is the maximum (over all coin tosses and proof strings) of the number of bits of the proof that are examined by the verifier. The free-bit complexity, roughly speaking, is the logarithm of number of possible accepting configurations of V on coins R and input x. (For example, a verifier which makes three queries and accepts, iff the parity of the answers is odd, has four accepting configuration and thus free-bit complexity 2.)

Either the query or the free-bit complexity may be considered in amortized form, for example, the amortized free-bit complexity is the free-bit complexity (of a proof system with perfect completeness) divided by the logarithm of the gap (i.e., the number of free bits needed per factor of 2 increases in the gap). Also, either the query or free-bit complexity may be considered on the average, the average being over the random string of the verifier.

Denote by $\mathrm{PCP}_{c,s}[r, q]$ the class of promise problems recognized by verifiers tossing r coins, having query complexity q, and achieving completeness probability c and soundness probability s. The class $\mathrm{FPCP}_{c,s}[r, f]$ is defined analogously with f being the free-bit complexity, $\overline{\mathrm{PCP}}[r, q]$ is defined analogously with q being the amortized query complexity, and $\overline{\mathrm{FPCP}}[r, f]$ is defined analogously with f being the amortized free-bit complexity.

MaxClique approximation. Although we look at many optimization problems there is a particular focus on MaxClique. Recall that the best known polynomial-time approximation algorithm for MaxClique achieves a factor of only $N^{1-o(1)}$ [28], scarcely better than the trivial factor of N. (Throughout the paper, when discussing the MaxClique problem or any other problem about graphs, N denotes the number of vertices in the graph.) Does there exist an $N^{1-\epsilon}$ factor approximation algorithm for MaxClique for some $\epsilon > 0$? An additional motivation for searching for such "weak" approximation algorithms was suggested by Blum [26]. He showed that a polynomial-time $N^{1-\epsilon}$-factor approximation algorithm for MaxClique implies a polynomial-time algorithm to color a three colorable graph with $O(\log N)$ colors [26], which is much better than what is currently known [63]. But perhaps $N^{1-o(1)}$ is the best possible. Resolving the approximation complexity of this basic problem seems, in any case, to be worth some effort.

Gaps in clique size. Hardness of approximation (say of MaxClique) is typically shown via a reduction to a promise problem with gaps in MaxClique size. Specifically, let $\mathsf{Gap}\text{-MaxClique}_{c,s}$ be the promise problem (A, B) defined as follows: A is the set of all graphs G with $\mathrm{MaxClique}(G)/N \geq c(N)$, and B is the set of all graphs G with $\mathrm{MaxClique}(G)/N < s(N)$. The gap is defined as c/s. Now, a hardness result will typically specify a value of the gap $g(N) = c(N)/s(N)$ for which $\mathsf{Gap}\text{-MaxClique}_{c,s}$ is NP-hard under a (randomized) Karp reduction. This means that there is no polynomial-time algorithm to approximate the MaxClique size of an N node graph within $g(N)$, unless NP has randomized polynomial-time algorithms.[1]

[1] Throughout this paper, the latter assumption is formulated by writing NP $\neq$ coRP. We comment that this form is equivalent to NP $\neq$ ZPP, where ZPP denotes the intersection of the classes RP and coRP. Note that if NP is contained in coRP, then coNP $\subseteq$ RP and NP $\subseteq$ coRP $\subseteq$ coNP $\subseteq$ RP follows.

Focus	Error	Queries	Free Bits	Previous Related Result
3 queries	0.85	3	2	error $\frac{72}{73}$ via MaxSAT [23]
2 free bits	0.794	$O(1)$	2	
error 1/2	$\frac{1}{2}$	11	7	32 queries (24 on average) [41]
amortized free bits	$O(2^{-m})$	2^{3m}	$2m$	$3m$ free bits [23]

FIG. 1. *New PCP systems for NP, all with logarithmic randomness.*

Gap problems can be similarly defined for all the other optimization problems we consider. From now on, we discuss approximation in terms of these gap problems.

THE CONNECTION: MAKING GAPS FROM PROOFS. The FGLSS reduction [40] is a reduction of a promise problem (A, B) to Gap-MaxClique$_{c,s}$ for some appropriate c, s defined by the reduction. It works by using a verifier V of a pcp system for (A, B) to map any instance $x \in A \cup B$ to a graph G_x so that MaxClique(G_x) reflects $\mathtt{ACC}[\,V(x)\,]$. For the best results, one typically uses a randomized form of this reduction due to [25, 86] and it is this form that we will assume henceforth.

An NP-hard gap problem is obtained roughly as follows. First, one exhibits an appropriate proof system for NP. Then one applies the FGLSS reduction. The factor indicated hard depends on the proof system parameters. A key element in getting better results has been the distilling of appropriate pcp-parameters. The sequence of works [40, 9, 8, 21, 41, 23] leads us through the following sequence of parameters: query complexity, free-bit complexity and, finally, for the best known results, amortized free-bit complexity. The connection, in terms of amortized free bits, can be stated as follows: if NP reduces to $\overline{\text{FPCP}}[\log, f]$, then NP also reduces to Gap-MaxClique$_{c,s}$, with gap $c(N)/s(N) = N^{1/(1+f)}$. (In both cases, the reduction is via randomized Karp reductions, and terms of $\epsilon > 0$ which can be arbitrarily small are ignored.) In particular if NP $\subseteq \overline{\text{FPCP}}[\log, f]$, then approximating the MaxClique size of an N vertex graph within $N^{1/(1+f)}$ in polynomial time is not possible unless NP has efficient randomized polynomial-time algorithms.

1.2. Overview of our results.

1.2.1. New proof systems and nonapproximability results. This section describes the new proof systems that we construct and the nonapproximability results that we derive from them.

NEW PROOF SYSTEMS. Summarized below and also presented in Figure 1 are several new ways of capturing NP via probabilistic proof systems:

(1) For every $\epsilon > 0$ it is the case that NP $\subseteq \overline{\text{FPCP}}[\,\log,\, 2 + \epsilon\,]$.
(2) NP $\subseteq \text{PCP}_{1,1/2}[\log, 11]$.
(3) NP $\subseteq \text{FPCP}_{1,s}[\log, 2]$ for $s = 0.794$.
(4) NP $\subseteq \text{PCP}_{1,s}[\log, 3]$ for any $s > 0.85$.

As explained below, some of these results are motivated by applications; others are purely interesting items in complexity theory.

The search for proof systems of low amortized free-bit complexity is motivated, of course, by the FGLSS reduction. Bellare and Sudan [23] have shown that NP $\subseteq \overline{\text{FPCP}}[\,\log,\, 3+\epsilon\,]$ for every $\epsilon > 0$. The first result above improves upon this, presenting a new proof system with amortized free-bit complexity $2 + \epsilon$.

The question of how low one can get the (worst-case and average) query complexity required to attain soundness error 1/2 was investigated in earlier works due to their applicability to obtaining MaxClique hardness results. We now know that one can do better with amortized free-bit complexity. Nevertheless, the original question

Problem	Approx		Non-Approx		
	Factor	Due to	Our Factor	Previous Factor	Assumption
Max3SAT	1.258	[85, 51, 84]	1.038	$1+\frac{1}{72}$ [23]	P $\neq$ NP
MaxE3SAT	$1+\frac{1}{7}$	folklore	$1+\frac{1}{26}$	unspecified [8]	P $\neq$ NP
Max2SAT	1.075	[51, 39]	1.013	$1+\frac{1}{504}$ (implied by [23])	P $\neq$ NP
Max$\oplus$SAT	2	folklore	$1+\frac{1}{7}$		P $\neq$ NP
MaxCUT	1.139	[51]	1.014	unspecified [8]	P $\neq$ NP
MinVC	$2-o(1)$	[14, 74]	$1+\frac{1}{15}$	unspecified [8]	P $\neq$ NP
MaxClique	$N^{1-o(1)}$	[28]		$N^{\frac{1}{4}}$ [23]	NP $\not\subseteq$ coR$\tilde{\text{P}}$
			$N^{\frac{1}{3}}$	$N^{\frac{1}{5}}$	coRP $\neq$ NP
			$N^{\frac{1}{4}}$	$N^{\frac{1}{6}}$ [23]	P $\neq$ NP
Chromatic Number	$N^{1-o(1)}$	[28]		$N^{\frac{1}{10}}$ [23]	NP $\not\subseteq$ coR$\tilde{\text{P}}$
			$N^{\frac{1}{5}}$	$N^{\frac{1}{7}}$ [45]	coRP $\neq$ NP
			$N^{\frac{1}{7}}$	$N^{\frac{1}{14}}$ [23]	P $\neq$ NP

FIG. 2. *Approximation factors attainable by polynomial-time algorithms (denoted Approx) versus factors we show are hard to achieve (denoted Non-Approx).* Max$E$3SAT *(resp.,* Max$\oplus$SAT*) denotes the maximization problem for conjunctive normal form (CNF) formulae having exactly three different literals in each clause (resp., a conjunction of parity clauses).*

is still one to which we are curious to know the answer. Our second result above refers to this question.

Minimizing the soundness error obtainable using only two (nonamortized!) free bits is important for a more pragmatic reason. It enables us to get the first explicit and reasonably strong constant nonapproximability result for the Min Vertex Cover problem. This application is discussed below.

Finally, the soundness achievable using only three query bits is natural to consider given the results on the Max3SAT gap problem. Indeed, if there is an NP-hard Max3SAT gap problem with certain gap, then one can easily get a three query proof system with the same gap. However, one can do better as indicated above.

NEW NONAPPROXIMABILITY RESULTS. Our results are summarized in Figure 2. (In the last items, we ignore terms of N^{ϵ} where $\epsilon > 0$ is an arbitrarily small positive constant.) Refer to section 2.4.2 for the definitions of the problems.

The conclusion for MaxClique follows, of course, from the FGLSS reduction and the first proof system listed above. The conclusion for the Chromatic Number follows from a recent reduction of Fürer [45], which in turn builds on reductions in [71, 66, 23]. (Fürer's work and ours are contemporaneous and thus we view the $N^{\frac{1}{5}}$ hardness result as jointly due to both papers.)

The improvements for the MaxSNP problems are perhaps more significant than the improvements for the MaxClique problem; we see hardness results for MaxSNP problems that are comparable to the factors achieved by known polynomial-time approximation algorithms.

We obtain the first explicit and reasonable nonapproximability factors for Max2SAT, MaxCUT, and minimum Vertex Cover. Recall that the latter is approximable within 2-$o(1)$ [14, 74]. Our results for MaxCUT and Max2SAT show that it is infeasible to find a solution with value which is only a factor of 1.01 from optimal. This may be contrasted with the recent results of [51, 39] which show that solutions which are within 1.14 and 1.075, respectively, of the optimum are obtainable in polynomial time. Thus, even though we do not know if the "pcp approach" allows us to

get the best possible nonapproximability results for these problems, we feel that the current results are not ridiculously far from the known upper bounds.

General framework. We emphasize a general framework for the derivation of strong nonapproximability results for MaxSNP problems which results from our tests and proof systems. We use direct reductions from verifiers to the problems of interest. (This follows and extends [21], prior to which results had used "generic" reductions, which did not take advantage of the nature of the tests performed by the verifier.) In particular, in our case it turns out that the verifier performs only two kinds of tests: (1) verify that $a+b+c=\sigma \pmod 2$; and (2) verify that $a+b_c=\sigma_c$, where a, b, b_0, b_1, c are answer bits obtained from the oracle and the σ's are fixed bits. By constructing local gadgets (i.e., one gadget per random coin toss sequence) to verify each of the verifier's tests, we achieve better nonapproximability results than by using more general reductions. In particular, our work seems to suggest that optimizing for gadgets which "check" the two conditions listed above will lead to reasonably good lower bounds for many MaxSNP problems. In this way, obtaining a nonapproximability result for a particular problem is reduced to the construction of appropriate "gadgets" for "representing" two simple functions.

Techniques. Our main technical contribution is a new error-correcting code which we have called the "long code." This code encodes an n-bit string as a 2^{2^n} bit string which consists of the value of every Boolean function on the n-bit string. It is easy to see that such codes have large Hamming distance. We show that this code is also easily "testable" and "correctable" and derive the new proof systems based on this.

As in all recent constructions of efficient pcp's, our construction also relies on the use of recursive construction of verifiers introduced by Arora and Safra [9]. We have the advantage of being able to use, at the outer level, the recent verifier of Raz [79], which was not available to previous authors. The inner level verifier relies on the use of a "good" encoding scheme. Beginning with [8], constructions of this verifier have used the Hadamard code; in this paper we use instead the long code.

1.2.2. Proofs and approximation: Potential and limits. As the above indicates, nonapproximability results are getting steadily stronger, especially for MaxClique. How far can they go? And, in minimizing amortized free bits, are we on the right track? Are there other ways? The next set of results provides answers to these kinds of questions.

Reversing the connection: Making proofs from gaps. The FGLSS reduction lemma indicates that one route to good nonapproximability results for MaxClique is to show NP $\subseteq \overline{\text{FPCP}}[\log, f]$ for values of f which are as small as possible. We present a "reverse connection" which says that, in a sense, this is the *only* way to proceed. Namely, we "invert" the above FGLSS reduction. Roughly, we show that, for any constant f, the following statements are equivalent:

(1) NP reduces to Gap-MaxClique$_{c,s}$ with gap $c(N)/s(N) = N^{1/(1+f)}$.

(2) NP reduces to $\overline{\text{FPCP}}[\log, f]$.

The (2)⇒(1) direction is the FGLSS reduction; the (1)⇒(2) direction is our reversed connection. (The statement ignores terms of $\epsilon > 0$ which can be arbitrarily small. The proof and a more precise statement are in section 8.) In both cases the reduction is randomized. Furthermore, the statement holds for both Karp and Cook reductions. Also, if (1) holds with a deterministic Karp reduction, then NP $\subseteq \overline{\text{FPCP}}'[\log, f]$, where FPCP$'$ is defined as being the amortized free-bit complexity of proof systems with almost-perfect completeness (i.e., $c = 1 - o(1)$).

In other words, *any* method of proving NP-hardness of MaxClique approximation to a factor of $N^{1/(1+f)}$ implies that NP has proof systems of amortized free-bit complexity f.

We stress both the "qualitative" and "quantitative" aspects of this result. Qualitatively, it provides an answer to the following kind of question: "What do proofs have to do with approximating clique size, and can we not prove non-approximability results without using proof checking?" The result indicates that proofs are inherent, and explains, perhaps, why hardness results avoiding the proof connection have not appeared.

However, at this stage it is the quantitative aspect that interests us more. It says that to get tighter results on MaxClique hardness, we must construct proof systems to minimize the amortized free-bit complexity. So our current efforts (recall that we have the amortized free-bit complexity down to 2, yielding a $N^{\frac{1}{3}}$ hardness for MaxClique) are in the right direction. To prove that, say, MaxClique is hard to approximate within $\sqrt{N}$, our reverse connection says we must construct proof systems with amortized free-bit complexity 1.

Yet the reverse connection does more than guide our choice of parameters. It is also a useful conceptual tool since it allows us to go from graphs to proof systems and vice versa, in the process perhaps gaining some property. As an example we show how all known hardness results for chromatic number can be viewed (with almost no loss in efficiency) as reductions from MaxClique, even though these were essentially hardness results based on proof checking. Other examples demonstrating the usefulness of the equivalence may be found in section 8.4. We believe that further exploring and exploiting this duality is a fruitful avenue to pursue.

A LOWER BOUND ON AMORTIZED FREE BITS. Having shown that the minimization of amortized free bits is unavoidable, we asked ourselves how low we can take them. Our approach here was to look at current techniques and assess their limitations. We stress that this approach makes various assumptions about methods and is intended to show that significantly novel techniques are required to go further. But it does not suggest an *inherent* limitation.

We show that, under the framework used within this and previous papers on this subject, amortized free-bit complexity of 2 seems to be a natural barrier: any proof system in this framework must use $2 - \epsilon$ amortized free bits, where $\epsilon > 0$ as usual can be arbitrarily small. The result, including a definition of what we mean by the "framework," is in section 9. Loosely speaking, it considers proof systems which, among other things, probe two oracles in order to check that one oracle is "close" to a codeword (i.e., a codeword test) and the second oracle encodes a projection of the information encoded in the first oracle (i.e., a projection test).

In retrospect, our lower bounds justify Håstad's two deviations from the current framework; specifically, his relaxation of the codeword test [55] and his relaxation of the projection test [56]. Specifically, Håstad [55, 56] constructed a pcp system (for NP) of amortized free-bit complexity ϵ, $\forall \epsilon > 0$. This was done in two stages/papers. In his first paper [55], Håstad builds on the framework presented in the current work but introduces a relaxed codeword test which is conducted within amortized free-bit complexity ϵ. In his second paper [56], he further modifies the current framework and utilizes a relaxed projection test which is conducted within amortized free-bit complexity ϵ. Our lower bounds justify Håstad's deviations from the intuitive but more stringent forms of the codeword and projection tests.

1.2.3. Properties and transforms of PCP and FPCP. Probabilistic proofs involve a vast arena of complexity parameters: query complexity, free-bit complexity, amortized free-bit complexity, randomness, and proof sizes, to name a few. Some might, at first glance, seem less "natural" than others, yet all are important in applications. A better understanding of the basic properties and relations between these parameters would help move us forward.

We initiate, therefore, a systematic investigation of the properties of pcp complexity classes as a function of the parameter values. Besides providing new results, we take the opportunity to state and prove a few folklore results.

A contribution of this work is to distill and formalize the role of randomized reductions. These transforms provide an elegant and concise way to state connections between PCPs and approximability, or just between different kinds of proof systems, and make it easier to manipulate the many connections that exist to derive new results.

We begin with "triviality results," namely, results which say that certain parameter combinations yield classes that are probably not capable of capturing NP. For simplicity we restrict our attention in this part to classes of languages, not classes of promise problems.

Triviality results. Perhaps the first thing to ask is whether, instead of amortized free-bit complexity, we could work with any of the simpler measures. After all, $\overline{\text{FPCP}}[\log, f]$ contains each of the following classes:

$$\text{PCP}_{1,1/2}[\log, f] \ ; \ \overline{\text{PCP}}[\log, f] \ ; \ \text{FPCP}_{1,1/2}[\log, f] \ .$$

Thus it would suffice to minimize the query complexity to get error 1/2; or the amortized query complexity; or the free-bit complexity to get error 1/2. However, it turns out that these complexities will not enable us to reach our target (of reducing the complexity to almost zero and thus proving that clique is hard to approximate to within a $N^{1-\epsilon}$ factor, for every $\epsilon > 0$). This is because the following classes are all contained in P:

(1) $\text{PCP}_{1,1/2}[\log, 2]$,
(2) $\overline{\text{PCP}}[\log, 1]$,
(3) $\text{FPCP}_{1,1/2}[\log, 1]$.

Thus, we cannot expect to construct pcp systems for NP with either query complexity 2 (this is actually folklore predating our work), or amortized query complexity 1, or free-bit complexity 1. However, it is a feature of amortized free-bit complexity that so far it seems entirely possible that NP reduces to $\overline{\text{FPCP}}[\log, f]$, with f an arbitrarily small constant. Indeed, if we believe (conjecture) that MaxClique is hard to approximate with $N^{1-\epsilon}$ for any $\epsilon > 0$, then such proof systems must exist, by virtue of the equivalence stated above. In fact, it turns out that the amortized query bit parameter is too weak to capture the hardness of the clique function: if MaxClique is hard to approximate to within N^{α}, then the best hardness result obtainable from the amortized query bit parameter would be of the form $N^{\frac{\alpha}{2-\alpha}}$. This is shown by invoking Corollary 10.11 which shows that the amortized query complexity parameter is always one unit larger than the amortized free-bit parameter (and we know that the amortized free-bit parameter captures the hardness of MaxClique tightly).

Other results. We have already mentioned above that strict limitations on various query parameters make PCP very weak. Actually, for every $s < 1$, the classes $\text{PCP}_{1,s}[\log, 2]$ and $\text{FPCP}_{1,s}[\log, 1]$ collapse to P. This means that pcp systems with

perfect completeness are very weak when restricted to either *two queries* or to *free-bit complexity* 1. However, pcp systems with completeness error and the very same query (resp., free-bit) bounds are not so weak. In particular, it is well known that $\mathrm{NP} = \mathrm{PCP}_{c,s}[\log, 2]$ for some $0 < s < c < 1$ (e.g., by using the NP-hardness of approximating Max2SAT). We show that $\mathrm{NP} = \mathrm{FPCP}_{c,s}[\log, 1]$ for some $0 < s < c < 1$ (specifically, $c = 1/2$ and $s = 0.8 \cdot c$). Furthermore, for some smaller $0 < s < c < 1$, the following holds:

$$\mathrm{NP} = \mathrm{FPCP}_{c,s}[\log, 0] \tag{1}$$

(specifically, with $c = \frac{1}{4}$ and $s = \frac{1}{5}$). We find the last assertion quite intriguing. It seems to indicate that one needs to be very careful when making conjectures regarding free-bit complexity. Furthermore, one has to be very careful also when making conjectures regarding amortized free-bit complexity; for example, the result $\mathrm{P} = \overline{\mathrm{PCP}}[\log, 1]$ holds also when one allows nonperfect completeness (in the definition of $\overline{\mathrm{PCP}}[\cdot, \cdot]$) as long as the gap is greater than 2^q per q queries, but an analogous result cannot hold for *two-sided error* amortized free-bit complexity (i.e., $\overline{\mathrm{FPCP}}[\cdot, \cdot]$).

Trying to understand the power of pcp systems with low free-bit complexity, we have waived the bound on the randomness complexity. Recall that in this case pcp systems are able to recognize nondeterministic exponential time (i.e., $\mathrm{NEXPT} = \mathrm{PCP}_{1,1/2}[\mathrm{poly}, \mathrm{poly}]$) [11]. Thus, it may be of interest to indicate that for every $s < 1$,

$$\mathrm{FPCP}_{1,s}[\mathrm{poly}, 0] \subseteq \mathrm{coNP}, \tag{2}$$

$$\mathrm{FPCP}_{1,s}[\mathrm{poly}, 1] \subseteq \mathrm{PSPACE}. \tag{3}$$

It seems that $\mathrm{FPCP}_{1,1/2}[\mathrm{poly}, 0]$ is not contained in BPP, since quadratic nonresiduosity and graph nonisomorphism belong to the former class. (Specifically, the interactive proofs of [53] and [52] can be viewed as a pcp system with polynomial randomness, query complexity 1, and free-bit complexity 0.) Thus, it seems that the obvious observation $\mathrm{PCP}_{1,s}[\mathrm{poly}, 1] \subseteq \mathrm{AM}$ (for every $s < 1$, where AM stands for one round Arthur–Merlin games) would also be hard to improve upon.

Transformations between proof systems. We provide various useful transformations of pcp systems. These transformations are analogous to transformations that can be applied to graphs with respect to the MaxClique problem. In view of the relation (mentioned above), between FPCP and the gap-clique promise problem, this analogy is hardly surprising.

One type of transformation amplifies the gap (i.e., the ratio between completeness and soundness bounds) of the proof system while preserving its amortized free-bit complexity and incurring a relatively small additional cost in the randomness complexity. Specifically, using a randomized reduction we can transform $\mathrm{FPCP}_{1,1/2}[\log, f]$ into $\mathrm{FPCP}_{1,2^{-k}}[\log + k, k \cdot f]$ (ignoring multiplicative factors of $1 + \epsilon$ for arbitrarily small $\epsilon > 0$). This transformation is analogous to the well-known transformation of Berman and Schnitger [25]. Alternatively, using a known deterministic amplification method based on [2, 70], one can transform $\mathrm{FPCP}_{1,1/2}[\log, f]$ into $\mathrm{FPCP}_{1,2^{-k}}[\log + 2k, k \cdot f]$. Both alternatives are important ingredients in transforming pcp results into clique inapproximability results via the FGLSS method.

A second type of transformation moves the location of the gap (or, equivalently, the completeness parameter). The gap itself is preserved by the transformation but moving it is related to changing the free-bit complexity (and thus the amortized free-bit complexity is not preserved). Moving the gap "up" requires increasing the

free-bit complexity, whereas moving the gap "down" allows us to decrease the free-bit complexity. For example, we randomly reduce $\mathrm{FPCP}_{c,s}[\log, f]$ to $\mathrm{FPCP}_{1,s\cdot\log}[\log, f + \log(1/c) + \log\log]$. On the other hand, for every $k \leq f$, we (deterministically) reduce $\mathrm{FPCP}_{c,s}[\log, f]$ into $\mathrm{FPCP}_{\frac{c}{2^k},\frac{s}{2^k}}[\log, f-k]$, provided that the original system has at least 2^k accepting configurations per each possible sequence of coin tosses. (This condition is satisfied in many natural pcp systems, even for $k = f$.)

1.3. History. Early work in nonapproximability includes that of Garey and Johnson [47] showing that it is NP-hard to approximate the chromatic factor within a factor less than 2. The indication of higher factors, and results for other problems, had to wait for the PCP connection.

Interactive proofs were introduced by Goldwasser, Micali, and Rackoff [53] and Babai [10]. Ben-Or et al. [24] extended these ideas to define a notion of multiprover interactive proofs. Fortnow, Rompel, and Sipser [44] showed that the class MIP of languages possessing multiprover interactive proofs equals the class of languages which have (using today's terms) probabilistically checkable proofs (of unrestricted, and thus polynomial, randomness, and query complexity).

The first indication of the power of interactive proof systems was given in [52], where it was shown that interactive proofs exist for graph nonisomorphism (whereas this language is not known to be in NP). However, the real breakthrough came with the result of Lund et al. [72] who used algebraic methods to show that all coNP languages (and actually, all languages in $\mathrm{P}^{\#P}$) have interactive proof systems. These techniques were used by Shamir [81] to show that IP = PSPACE.

A central result that enabled the connection to hardness of approximation is that of Babai, Fortnow, and Lund [11]. They showed that the class MIP equals the class NEXP (i.e., languages recognizable in nondeterministic exponential time). The latter result has been "scaled down" to the NP-level by two independent groups of researchers. Babai et al. [12] showed that if the input is encoded using a special error-correcting code (for which encoding and decoding can be performed in polynomial time), then NP has transparent proof systems (i.e., it is possible to verify the correctness of the proof in polylogarithmic time). Feige et al. [40] showed that NP has probabilistically checkable proofs of polylogarithmic randomness and query complexity; namely, $\mathrm{NP} \subseteq \mathrm{PCP}_{1,1/2}[r, q]$, where $r(n) = q(n) = O(\log n \cdot \log\log n)$.

A hardness of approximation result based on interactive proofs was first proved by Condon [31]. The breakthrough *PCP connection (to approximation)* was made by Feige et al. [40]. They showed that $\mathrm{NP} \subseteq \mathrm{PCP}_{1,s}[r, q]$ implies that approximating the maximum clique in a $2^{r(n)+q(n)}$-vertices graph to within a $1/s(n)$ factor is infeasible (i.e., not doable in polynomial-time), provided that NP is not in $\mathrm{Dtime}(2^{O(r+q)})$. (Here n is the length of the input x to the pcp verifier.) Combined with the above-mentioned results, they obtained the first in a sequence of strong nonapproximability results for MaxClique: a nonapproximability factor of $2^{\log^{1-\epsilon} N}$, $\forall \epsilon > 0$, assuming NP does not have quasi-polynomial time algorithms.

After the work of [40] the field took off in two major directions. One was to extend the interactive proof approach to prove the nonapproximability of other optimization problems. Direct reductions from proofs were used to show the hardness of quadratic programming [22, 43], Max3SAT [8], set cover [71], and other problems [16]. The earlier work of Papadimitriou and Yannakakis, introducing the class MaxSNP [76], now came into play; by reduction from Max3SAT it implied hardness of approximation for any MaxSNP-hard problem. Also, reductions from MaxClique lead to hardness results for the Chromatic Number [71] and other problems [86].

The other direction was to increase factors, and reduce assumptions, for existing hardness of approximation results. This involves improving the efficiency of the underlying proof systems and/or the efficiency of the reductions.

The first stage of this enterprise started with the work of Arora and Safra [9]. They showed that NP $\subseteq$ PCP$_{1,1/2}[\log, o(\log)]$. This provided the first strong NP-hardness result for MaxClique (specifically, a hardness factor of $2^{\sqrt{\log N}}$). This work introduced the idea of recursive proof checking, which turned out to play a fundamental role in all subsequent developments. Interestingly, the idea of encoding inputs in an error-correcting form (as suggested in [12]) is essential to make "recursion" work. Arora et al. [8] reduced the query complexity of pcp systems for NP to a constant while preserving the logarithmic randomness complexity; namely, they showed that NP = PCP$_{1,1/2}[\log, O(1)]$. This immediately implied the NP-hardness of approximating MaxClique within N^{ϵ}, for some $\epsilon > 0$. Furthermore, it also implied that Max3SAT is NP-hard to approximate to within some constant factor [8] and so is any MaxSNP-hard problem [76].

The second stage of this enterprise started with the work of Bellare et al. [21]. The goal was to improve (increase) the constant ϵ in the exponent of the hardness of approximation factor for MaxClique and also to improve the constant values of the hardness factors in the MaxSNP hardness results. They presented new proof systems minimizing query complexity and exploited a slightly improved version of the FGLSS reduction due to [25, 86] to get a $N^{1/30}$ hardness of approximation factor for MaxClique. Feige and Kilian [41], however, observed that one should work with free bits, and noted that the free-bit complexity of the system of [21] was 14, yielding a $N^{1/15}$ hardness factor. Bellare and Sudan then suggested the notion of amortized free bits [23]. They constructed proof systems achieving amortized free-bit complexity 3 and thus obtained a $N^{\frac{1}{4}}$ hardness for MaxClique assuming NP $\not\subseteq$ co$\widetilde{\text{RP}}$.

Detailed histories for specific topics are given in sections 2.2.3 and 2.4.3.

1.4. Related work. Following the presentation of our results, Arora has also investigated the limitations of proof checking techniques in proving nonapproximability results [6]. As in our free-bit lower bound result, he tries to assess the limitations of current techniques by making some assumptions about these techniques and then showing a lower bound. His focus is on the reductions, which he assumes are "code like." In this setting he can show that one should not expect to prove nonapproximability of MaxClique within $N^{1/2}$. (The assumptions made by us and by Arora do not seem to be comparable; neither implies the other. In retrospect, both sets of assumptions could be bypassed as done by Håstad [55, 56].)

1.5. Subsequent work. Our prophecy that the PCP approach is leading to tight nonapproximability results is in the process of materializing (see Figure 3). By now, tight results are known for central problems such as Min Set Cover (cf. [71, 21, 38]), MaxClique (cf. [55, 56]), Min Coloring [42], and Max3SAT (cf. [57]). The latter results were obtained subsequent to, and while building on the current work.

Amortized free bits and MaxClique. The most intriguing problem left open by our work has been resolved by Håstad [55, 56]. He proved our conjecture (cf. [20]) by which, for every $\epsilon > 0$, it is the case that NP $\subseteq \overline{\text{FPCP}}[\log, \epsilon]$. The long code, introduced in this work, plays a pivotal role in Håstad's work. He also uses the idea of folding (introduced here). Applying the FGLSS reduction to the new proof system, Håstad obtains a tight result for MaxClique by showing that for every $\epsilon > 0$, assuming

Problem	EASY to Approx. Factor		HARD to Approx. Factor			Tight?
	Factor	Due to	Ours	Subsequent	Assumption	
Max3SAT	$1+\frac{1}{7}+\epsilon$	[64]	$1+\frac{1}{26}$	$1+\frac{1}{7}-\epsilon$ [57]	P $\neq$ NP	Yes
MaxE3SAT	$1+\frac{1}{7}$	folklore	$1+\frac{1}{26}$	$1+\frac{1}{7}-\epsilon$ [57]	P $\neq$ NP	Yes
Max2SAT	1.075	[51, 39]	1.013	1.047 [57]	P $\neq$ NP	No

FIG. 3. *State of the art regarding easy and hard approximation factors* (*updated July* 1997). *Here* $\epsilon > 0$ *is an arbitrarily small constant.*

NP $\neq$ coRP, there is no polynomial-time algorithm to approximate MaxClique within a factor of $N^{1-\epsilon}$.

IMPROVED 3-QUERY PROOFS AND MAXSNP. Another challenge, one we even did not dare state, was achieved as well. Håstad [57] has recently obtained optimal nonapproximability results to MaxSNP problems such as Max3SAT. Furthermore, he has improved over all our nonapproximability results for MaxSNP problems, obtaining nonapproximability factors of 22/21 and 17/16 for Max2SAT and MaxCUT, respectively. Underlying these results is a new proof system for NP which yields NP $\subseteq$ PCP$_{1-\epsilon,0.5}[\log, 3]$, for any $\epsilon > 0$. In addition, Håstad [57] shows that NP is contained in PCP$_{1,0.75+\epsilon}[\log, 3]$ (and it follows that NP $\subseteq$ PCP$_{1,0.5}[\log, 9]$). The long code plays a pivotal role in all of these proof systems.

IMPROVED 2-FREE-BITS PROOFS AND MINVC. The above-mentioned proof system of Håstad [57] uses two (nonamortized) free bits, and so NP $\subseteq$ FPCP$_{1-\epsilon,0.5}[\log, 2]$, for every $\epsilon > 0$. This sets the nonapproximability bound for Min Vertex Cover at $\frac{7}{6}-\epsilon$.

CHROMATIC NUMBER. Feige and Kilian [42] have introduced a new approach to showing hardness of approximability of ChromNum, based on a new measure of proof checking complexity called the covering complexity. By modifying our proof systems so as to preserve the amortized free-bit complexity and achieve low covering complexity, they proved that approximating ChromNum within $N^{\frac{1}{3}}$ is hard unless NP = coRP. They were able to similarly modify Håstad's proof systems [55, 56] and thereby improve the hard factor to $N^{1-\epsilon}$, for any $\epsilon > 0$.

GADGETS. Another research direction, suggested in early versions of this work [20], was taken on by Trevisan et. al. [84] who initiated a systematic study of the construction of gadgets. In particular, they showed that the gadgets we have used in our reductions to the MaxSAT problems were optimal, and constructed better (and actually optimal) gadgets for reduction to MaxCUT.

WEIGHTS. An important issue neglected in our treatment of MaxSNP problems is that of weights. For example, in our MaxSAT problems we have allowed the same clause to appear many times in the formula, which can be considered as allowing "small" weights. Certainly, one may want nonapproximability results for the unweighted case (where one does not allow multiple occurrences of the same clause). This issue is treated in a subsequent paper by Crescenzi, Silvestri, and Trevisan [34]. Essentially, they show that the unweighted cases of all problems considered in our paper are as hard as the weighted cases.

1.6. Directions for further research. Although the most intriguing open problems suggested in previous versions of this work [20] have been resolved, some very interesting problems remain. We mention a few.

2-FREE-BITS PROOFS AND MINVC. As we show, NP $\subseteq$ FPCP$_{c,s}[\log, f]$ implies that approximating Min Vertex Cover up to a $\frac{2^f-s}{2^f-c}$ factor is NP-hard. This motivates us to ask whether the following, increasingly stronger, conjectures hold.

(1) NP $\subseteq$ FPCP$_{1-\epsilon,\epsilon}[\log, 2]$ (or even NP $\subseteq$ FPCP$_{1,\epsilon}[\log, 2]$) for every $\epsilon > 0$. This would imply a hardness factor of $\frac{4}{3} - \epsilon$ for MinVC.

(2) For $f \stackrel{\text{def}}{=} \log_2 3$, NP $\subseteq$ FPCP$_{1-\epsilon,\epsilon}[\log, f]$ (or even NP $\subseteq$ FPCP$_{1,\epsilon}[\log, f]$) for every $\epsilon > 0$. This would imply a hardness factor of $\frac{3}{2} - \epsilon$.

(3) NP $\subseteq$ FPCP$_{1-\epsilon,\epsilon}[\log, 1]$ for every $\epsilon > 0$. This would imply a hardness factor of $2 - \epsilon$.

Recall that FPCP$_{1,s}[\log, 1] \subseteq$ P, for every $s < 1$, whereas NP $\subseteq$ FPCP$_{1-\epsilon,0.5}[\log, 2]$ [57]. It will be even interesting (though of no application for MinVC) to know whether NP $\subseteq$ FPCP$_{1,0.5+\epsilon}[\log, 2]$, for every $\epsilon > 0$.

PERFECT VERSUS IMPERFECT COMPLETENESS. Håstad's work [57] is indeed the trigger for the last question and similarly, we wonder whether NP $\subseteq$ PCP$_{1,0.5+\epsilon}[\log, 3]$. Nonperfect completeness seems to be useful in [57], but it is to be seen if this usage is inherent. Similar issues arise with respect to some results in the current work (e.g., see our transformations for increasing acceptance probability of proof systems).

DERANDOMIZATION. We know that $\overline{\text{FPCP}}[\log, f]$ is *randomly* reducible to

$$\text{FPCP}_{1,2^{-k}}[\log +(1+\epsilon)k, (1+\epsilon)k \cdot f] \,.$$

On the other hand, the former class is contained in (i.e., is *deterministically* reduced to) the class FPCP$_{1,2^{-k}}[\log +(2+\epsilon)k, (1+\epsilon)k \cdot f]$, for arbitrarily small $\epsilon > 0$. Can one obtain the best of both worlds, namely, a deterministic reduction of $\overline{\text{FPCP}}[\log, f]$ to, say, FPCP$_{1,2^{-k}}[\log +(1+\epsilon)k, (1+\epsilon)k \cdot f]$, for arbitrarily small $\epsilon > 0$? An affirmative answer will allow us to infer from NP $\subseteq \overline{\text{FPCP}}[\log, f]$ that approximating Max Clique to within an $N^{\frac{1}{1+f+\epsilon}}$ factor is NP-hard (rather than NP-hard under randomized reductions).

One ingredient of our method for reversing the FGLSS reduction is the randomized reduction of the class FPCP$_{c,s}[\log, f]$ to the class FPCP$_{1,\frac{\log}{c}.s}[\log, f + \log(1/c) + \log\log]$. (This statement is proved using the ideas in section 11. An alternative exposition, making use of a randomized graph-layering process, is given in section 8.) Anyhow, randomness plays an essential role in obtaining a pcp system with perfect completeness.[2] The question is whether the class FPCP$_{c,s}[\log, f]$ is contained in the class FPCP$_{1,\frac{\log}{c}.s}[\log, f + \log(1/c) + \log\log]$ (rather than being randomly reducible to it).

1.7. Organization. This introduction is followed by a section that contains definitions as well as detailed histories. The main content of the paper is divided into three parts:

Part I—*New proof systems and nonapproximability results*—consisting of sections 3 to 7, contains the material discussed in section 1.2.1. See overview in section 3.1.

[2]This makes our results more elegant, but actually, as indicated in section 8, we could have settled for "almost perfect" completeness which suffices for presenting an inverse of the "FGLSS reduction."

Part II—*Proofs and approximation: Potential and limitations*—consisting of sections 8—9, contains the material discussed in section 1.2.2. Specifically, section 8 contain the "reverse reduction" of clique hardness to PCP, and section 9 contains lower bounds on the free-bit complexity of certain tasks.

Part III—*PCP: Properties and transformations*—consisting of sections 10 and 11, contains the material discussed in section 1.2.3. Specifically, section 10 studies the expressive power of PCP systems with certain parameters, and section 11 contains transformations among PCP classes.

2. Definitions and histories.

2.1. General notation and definitions. For a set S, we denote by $e \stackrel{R}{\leftarrow} S$ the operation of selecting e uniformly in S. For integer n let $[n] = \{1, \ldots, n\}$. A graph always means an undirected graph with no self-loops, unless otherwise indicated. We let $\|G\|$ denote the number of vertices in graph $G = (V, E)$.

A probabilistic machine K has one or more inputs, denoted $x_1, x_2, \ldots$. It tosses coins to create a random string R, usually of some length $r(\cdot)$ which is a function of the (lengths of the) inputs. We let $K(x_1, x_2, \ldots; R)$ denote the output of K when it uses the random string, denoted R. Typically we are interested in the probability space associated with a random choice of R.

A function is *admissible* if it is polynomially bounded and polynomial-time computable. We will ask that all functions measuring complexity (e.g., the query complexity $q = q(n)$) be admissible.

In defining complexity classes we will consider promise problems rather than languages. (This convention is adopted since approximation problems are easily cast as promise problems.) Following Even, Selman, and Yacobi [36], a promise problem is a pair of disjoint sets (A, B), the first being the set of "positive" instances and the second the set of "negative" instances. A language L is identified with the promise problem $(L, \overline{L})$.

2.2. Proof systems.

2.2.1. Basic setting. A verifier is a probabilistic machine V taking one or more inputs, and it is also allowed access to one or more oracles. Let x denote the sequence of all inputs to V and let n denote its length. During the course of its computation on coins R and input x, the verifier makes queries of its oracles. Its final decision to accept or reject is a function $\mathsf{DEC}_V(x, a; R)$ of x, R and the sequence a of all the bits obtained from the oracle in the computation. Contrary to standard terminology, acceptance in this paper will correspond to outputting 0 and rejection to outputting 1. This is done since, in most technical discussions, our focus is on the reject event.

Oracles are formally functions, with the context specifying for each the domain and range. Sometimes, however, an algorithm will be given a string s as an oracle. (Giving a verifier s as an oracle models a "written proof" model in which someone has "written" s somewhere and the verifier wants to check it.) This is to be interpreted in the natural way; namely, the oracle takes an index i and returns the ith bit of s. Let π denote the sequence (tuple) of all proof oracles supplied to the verifier V. Now for verifier V, examining the proofs π and having input x, we let

$$\mathtt{ACC}\left[\, V^{\pi}(x) \,\right] \;=\; \Pr_R \left[V^{\pi}(x; R) = 0 \right]$$

denote the probability that V accepts when its random string is R. We then let

$$\mathtt{ACC}\left[\, V(x) \,\right] \;=\; \max_{\pi} \; \mathtt{ACC}\left[\, V^{\pi}(x) \,\right].$$

This is the maximum accepting probability over all possible choices of proof sequences π. (The domain from which the proofs are chosen depends, as mentioned above, on the context.)

Let $\mathsf{pattern}_V(x;R)$ be the set of all sequences a such that $\mathsf{DEC}_V(x,a;R)=0$. (That is, all sequences of oracle answers leading to acceptance). A *generator* for V is a poly(n)-time computable function G such that $G(x,R)=\mathsf{pattern}_V(x;R)$ for all x,R. (That is, it can efficiently generate the set of accepted patterns.)

2.2.2. Parameters. We are interested in a host of parameters that capture various complexity measures of the proof checking process. They are all functions of the length n of the input x given to the verifier V. In the following, σ denotes the concatenation of all the proof strings given to the verifier. Also recall that we are interested in proof systems for promise problems (A,B) rather than just for languages.

$\mathsf{coins}=$ Number of coins tossed by verifier. Typically denoted r.

$\mathsf{pflen}=$ Length of the proof provided to the verifier. Typically denoted l.

$c=$ Completeness probability. Namely,

$$\min\{\,\mathtt{ACC}[\,V(x)\,]\;:\;x\in A \text{ and } |x|=n\,\}\,.$$

$s=$ Soundness probability. Namely,

$$\max\{\,\mathtt{ACC}[\,V(x)\,]\;:\;x\in B \text{ and } |x|=n\,\}\,.$$

$g=$ Gap. Namely c/s.

Now we move to various measures of the "information" conveyed by the oracle to the verifier. For simplicity we consider here only oracles that return a single bit on each query; that is, they correspond to strings, or "written proofs."

$\mathsf{query}=$ The query complexity on input x is the maximum, over all possible random strings R of V, of the number of bits of σ accessed by V on input x. The query complexity of the system $q=q(n)$ is the maximum of this over all inputs $x\in A\cup B$ of length n.

$\mathsf{query}_{\mathrm{av}}=$ The average query bit complexity on input x is the average, over R, of the number of bits of the proof σ accessed by V on input x and coins R. The average query complexity of the system is the maximum of this over all $x\in A\cup B$ of length n. Typically denoted q_{av}.

$\overline{\mathsf{query}}=$ V is said to have amortized query bit complexity $\bar{q}$ if $q/\lg(g)\le\bar{q}$, where q is the query bit complexity and g is the gap, and, furthermore, q is at most logarithmic in n.

$\mathsf{free}=$ The free-bit complexity of V is f if there is a generator G such that $|G(x,R)|\le 2^f$ for all R and all $x\in A\cup B$ of length n.

$\mathsf{free}_{\mathrm{av}}=$ The average free-bit complexity of V is f_{av} if there is a generator G such that $\mathbf{E}_R[|G(x,R)|]\le 2^{f_{\mathrm{av}}}$ for all $x\in A\cup B$ of length n.

$\overline{\mathsf{free}}=$ V is said to have amortized free-bit complexity $\bar{f}$ if $f/\lg(g)\le\bar{f}$, where f is the free-bit complexity and g is the gap.

Notice that amortized query complexity is restricted to be at most logarithmic. We don't need to explicitly make this restriction for the amortized free-bit complexity since it is a consequence of the efficient generation condition.

In case the completeness parameter equals 1 (i.e., $c=1$), we say that the system is of *perfect completeness*. In case the completeness parameter, c, satisfies $c(n)=1-o(1)$, we say that the system is of *almost-perfect completeness*.

The consideration of combinations of all these parameters gives rise to a potentially vast number of different complexity classes. We will use a generic notation in which the parameter values are specified by name, except that, optionally, the completeness and soundness can, if they appear, do so as subscripts. Thus for example we have:

$$\mathrm{PCP}_{c,s}[\,\mathsf{coins} = r\,;\ \mathsf{query} = q\,;\ \mathsf{pflen} = 2^r\,;\ \mathsf{free} = f\ldots]\,.$$

However most often we'll work with the following abbreviations:

$$\begin{aligned}
\mathrm{PCP}_{c,s}[r,q] &\stackrel{\text{def}}{=} \mathrm{PCP}_{c,s}[\,\mathsf{coins} = r\,;\ \mathsf{query} = q\,],\\
\overline{\mathrm{PCP}}_c[\,r,\,q\,] &\stackrel{\text{def}}{=} \mathrm{PCP}_{c,\cdot}[\,\mathsf{coins} = r\,;\ \overline{\mathsf{query}} = q\,],\\
\mathrm{FPCP}_{c,s}[r,f] &\stackrel{\text{def}}{=} \mathrm{PCP}_{c,s}[\,\mathsf{coins} = r\,;\ \mathsf{free} = f\,],\\
\mathrm{FPCP}_{c,s}[r,f,l] &\stackrel{\text{def}}{=} \mathrm{PCP}_{c,s}[\,\mathsf{coins} = r\,;\ \mathsf{free} = f\,;\ \mathsf{pflen} = l\,],\\
\overline{\mathrm{FPCP}}_c[\,r,\,f\,] &\stackrel{\text{def}}{=} \mathrm{PCP}_{c,\cdot}[\,\mathsf{coins} = r\,;\ \overline{\mathsf{free}} = f\,]\,.
\end{aligned}$$

We stress that in the definitions of the amortized classes, $\overline{\mathrm{PCP}}_c[\,r,\,q\,]$ and $\overline{\mathrm{FPCP}}_c[\,r,\,f\,]$, we refer to the completeness parameter c (but not to the soundness parameter). In case $c = 1$, we may omit this parameter and shorthand the amortized classes of perfect completeness by $\overline{\mathrm{PCP}}[\,r,\,q\,]$ and $\overline{\mathrm{FPCP}}[\,r,\,f\,]$, respectively. Namely,

$$\begin{aligned}
\overline{\mathrm{PCP}}[\,r,\,q\,] &\stackrel{\text{def}}{=} \overline{\mathrm{PCP}}_1[\,r,\,q\,],\\
\overline{\mathrm{FPCP}}[\,r,\,f\,] &\stackrel{\text{def}}{=} \overline{\mathrm{FPCP}}_1[\,r,\,f\,].
\end{aligned}$$

2.2.3. History of proof systems.

MODELS AND PARAMETERS. The model underlying what are now known as "probabilistically checkable proofs" is the "oracle model" of Fortnow, Rompel, and Sipser [44], introduced as an equivalent version (with respect to language recognition power) of the multiprover model of Ben-Or et al. [24]. Interestingly, as shown by [12, 40], this framework can be applied in a meaningful manner also to languages in NP. These works provide the verifier V with a "written" proof, modeled as an oracle to which V provides the "address" of a bit position in the proof string and is returned the corresponding bit of the proof. Babai et al. [12] suggested a model in which the inputs are also given as oracles encoded in a special (polynomial-time computable and decodable) error-correcting code and the verifier works in polylogarithmic time. Here we follow the model of Feige et al. [40], where the verifier is probabilistic polynomial time (as usual) and one considers finer complexity measures such as the query and randomness complexity. The FGLSS reduction (cf. [40]), stated in terms of the query complexity (number of binary queries), randomness complexity, and error probability of the proof system, has focused attention on the above model and these parameters. The class $\mathrm{PCP}_{1,1/2}[r,q]$ was made explicit by [9].

The parameterization was expanded by [21] to explicitly consider the answer size (the oracle was allowed to return more than one bit at a time) and query size. Their notation included five parameters: randomness, number of queries, size of each query, size of each answer, and error probability. They also similarly parameterized (single round) multiprover proofs, drawing attention to the analogue with pcp. This served to focus attention on the roles of various parameters, both in reductions and in

FIG. 4. *Worst case* (q) *and average* (q_{av}) *number of queries needed to get soundness error* 1/2 *with logarithmic randomness and perfect completeness; that is, results of the form of Eq.* (4).

constructions. Also, they introduced the consideration of average query complexity, the first in a sequence of parameter changes toward doing better for clique.

Free bits are implicit in [41] and formalized in [23]. Amortized free bits are introduced in [23] but formalized a little better here.

Proof sizes were considered in [12, 78]. We consider them here for a different reason—they play an important role in that the randomized FGLSS reduction [25, 86] depends, actually, on this parameter (rather than on the randomness complexity).

The discussion of previous proof systems is coupled with the discussion of MaxClique in section 2.4.3. We conclude the current section by discussing two somewhat related topics: query minimization and constant-prover proof systems.

QUERY COMPLEXITY MINIMIZATION. One seeks results of the form

$$\text{NP} \;=\; \text{PCP}_{1,1/2}[\,\mathsf{coins} = \log\,;\,\mathsf{query} = q\,;\,\mathsf{query}_{\text{av}} = q_{\text{av}}\,]\,. \tag{4}$$

This was originally done for deriving NP-hardness results for the approximation of MaxClique, but subsequent work has indicated that other parameters actually govern this application. Still, the query complexity of a proof system remains a most natural measure, and it is an intriguing question as to how many bits of a proof you need to look at to detect an error with a given probability. Specifically, we consider the question of determining the smallest values of q, q_{av} for which Eq. (4) holds.

The fundamental result of [8] states that q, q_{av} may be constants (independent of the input length). Reductions in the values of these constants were obtained since then and are depicted in Figure 4. See section 6 for our results.

ROLE OF CONSTANT-PROVER PROOFS IN PCP: PERSPECTIVE. Constant-prover proofs have been instrumental in the derivation of nonapproximability results in several ways. One of these is that they are a good starting point for reductions—examples of such are reductions of two-prover proofs to quadratic programming [22, 43] and set cover [71]. However, it is a different aspect of constant-prover proofs that is of direct concern to us. This aspect is the use of constant-prover proof systems as the penultimate step of the recursion, and begins with [8]. It is instrumental in getting PCP systems with only a constant number of queries. Their construction requires that these proof systems have low complexity: error which is any constant and randomness and answer sizes that are preferably logarithmic. The number of provers and the randomness and query complexity determine the quality of many nonapproximability results (e.g., polylogarithmic rather than logarithmic complexities translate into nonapproximability results using assumptions about quasi-polynomial time classes rather than polynomial-time classes). The available constant-prover proof systems appear in Figure 5 and are discussed below. Throughout this discussion we consider proof systems obtaining an *arbitrary small constant* error probability, denoted ϵ.

The two-prover proofs of Lapidot and Shamir [67] and Feige and Lovász [43] have polylogarithmic randomness and answer sizes. Arora et al. [8] used a modification of

Due to	Provers	Coins	Answer size	Canonical?	Can be made canonical?
[67, 43]	2	polylog	polylog	No	Yes [23]
[8]	poly(ϵ^{-1})	log	polylog	No	?
[21]	4	log	polyloglog	No	?
[82]	3	log	$O(1)$	No	?
[41]	2	log	$O(1)$	No	With 3 provers [23]
[79]	2	log	$O(1)$	Yes	(NA)

FIG. 5. *Constant-prover proof systems achieving error which is a fixed, but arbitrarily small, constant* ϵ.

these proofs, so to reduce randomness complexity, in the process increasing the number of provers to a constant much larger than 2. Later constructions of few-prover proofs of [21, 82, 41] lead to better nonapproximability results.

Bellare and Sudan [23] identified some extra features of constant-prover proofs whose presence they showed could be exploited to further increase the nonapproximability factors. These features are captured in their definition of canonical verifiers (cf. section 3.4). But the proof systems of [41] that had worked above no longer sufficed—they are not canonical. So instead, [23] used (a slight modification of) the proofs of [67, 43], thereby incurring polylogarithmic randomness and answer sizes, and so that the assumptions in their nonapproximability results pertain to quasi-polynomial-time classes. (Alternatively they modify the system of [41] to a canonical three-prover system, but then incur a decrease in the nonapproximability factors due to having more provers).

A breakthrough result in this area is Raz's parallel repetition theorem which implies the existence of a two-provers proof system with logarithmic randomness and constant answer size [79]. Furthermore, this proof system is canonical.

2.3. Reductions between problems and classes. We will consider reductions between promise problems. A deterministic Karp reduction from (A_1, B_1) to (A_2, B_2) is a polynomial-time function T which for all x satisfies the following: if $x \in A_1$, then $T(x) \in A_2$, and if $x \in B_1$, then $T(x) \in B_2$. A randomized Karp reduction from (A_1, B_1) to (A_2, B_2) is a probabilistic, polynomial-time process T which takes two arguments, an input x and a security parameter k; the latter written in unary. The transformation is required to have the property that

$$\begin{aligned} x \in A_1 \quad &\Longrightarrow \quad p_1(x,k) \stackrel{\text{def}}{=} \Pr\left[\, T(x,1^k) \in A_2 \,\right] \geq 1 - 2^{-k}, \\ x \in B_1 \quad &\Longrightarrow \quad p_2(x,k) \stackrel{\text{def}}{=} \Pr\left[\, T(x,1^k) \in B_2 \,\right] \geq 1 - 2^{-k}\,. \end{aligned}$$

The probability is over the coin tosses of T. We say the reduction has perfect completeness if $p_1 = 1$ and perfect soundness if $p_2 = 1$. Notice a deterministic reduction corresponds to a randomized reduction in which $p_1 = p_2 = 1$. We write $(A_1, B_1) \leq_R^K (A_2, B_2)$ if there is a randomized Karp reduction from (A_1, B_1) to (A_2, B_2). If the reduction is deterministic we omit the subscript of "R" or, sometimes for emphasis, replace it by a subscript of "D."

An example is the randomized FGLSS transformation [40, 25, 86]. Here (A_1, B_1) is typically an NP-complete language L, and (A_2, B_2) is $\mathsf{Gap}\text{-MaxClique}_{c,s}$ for some c, s which are determined by the transformation. (See section 2.4 for a definition of the latter.) This transformation has perfect soundness, while, on the other hand, it is possible to get $p_1 = 1 - 2^{-\operatorname{poly}(k)}$.

Similarly, one can define (randomized) Cook reductions. The notation for these reductions is $\leq_R^C$.

Let C be a complexity class (e.g., NP). We say that C reduces to (A_2, B_2) if for every (A_1, B_1) in C it is the case that (A_1, B_1) reduces to (A_2, B_2). An example is to say that NP reduces to Gap-MaxClique$_{c,s}$. We say that C_1 reduces to C_2, where C_1 and C_2 are complexity classes, if for every (A_1, B_1) in C_1 there is an (A_2, B_2) in C_2 such that (A_1, B_1) reduces to (A_2, B_2). An example is to say that NP reduces to $\overline{\mathrm{FPCP}}[\log, f]$. The notation of $\leq_R^K$ or $\leq_R^C$ extends to these cases as well.

Notice that our definition of reducibility ensures that this relation is transitive.

For simplicity we sometimes view a randomized reduction T as a function only of x, and write $T(x)$. In such a case it is to be understood that the security parameter has been set to some convenient value, such as $k = 2$.

HISTORICAL NOTE. We've followed the common tradition regarding the names of polynomial-time reductions: many-to-one reductions are called Karp reductions whereas (polynomial-time) Turing reductions are called Cook reductions. This terminology is somewhat unfair toward Levin whose work on NP-completeness [69] was independent of those of Cook [32] and Karp [65]. Actually, the reductions considered by Levin are more restricted as they also efficiently transform the corresponding NP-witnesses (this is an artifact of Levin's desire to treat search problems rather than decision problems). In fact, such reductions (not surprisingly termed Levin reductions) are essential for results such as Corollary 8.15. (Yet this is the only example in the current paper.)

2.4. Approximation problems and quality. We discuss optimization problems, approximation algorithms for them, and how hardness is shown via the "production of hard gaps." We then list all the problems considered in this paper. A continuously updated compendium of NP-optimization problems is available in [33].

2.4.1. Optimization problems, approximation, and gaps. An *optimization problem* $\Phi = (S, g, \|\cdot\|, \|\cdot\|^*, \mathrm{opt})$ is specified by

- a function S associating to any *instance* w a *solution set* $S(w) \neq \emptyset$.
- an *objective function* g associating to any instance w and solution $y \in S(w)$ a nonnegative real number $g(w, y)$. This number is sometimes called the *value* of solution y.
- two *norm* functions $\|\cdot\|, \|\cdot\|^*$, the first admissible, the second polynomial-time computable, each associating to any instance w a nonnegative real number; their roles will be explained later.
- an indication $\mathrm{opt} \in \{\min, \max\}$ of the *type* of optimization, whether maximization or minimization.

The task, given w, is to either maximize (this if opt = max) or minimize (this if opt = min), the value $g(w, y)$, over all $y \in S(w)$.

DEFINITION 2.1. *Let* $\Phi = (S, g, \|\cdot\|, \|\cdot\|^*, \mathrm{opt})$ *be an optimization problem. The* optimum *value for instance* w *is denoted* $\Phi(w)$ *and defined by*

$$\Phi(w) \;=\; \begin{cases} \max_{y \in S(w)} g(w, y) & \text{if } \Phi \text{ is a maximization problem,} \\ \min_{y \in S(w)} g(w, y) & \text{if } \Phi \text{ is a minimization problem.} \end{cases}$$

The normalized optimum *is defined by* $\overline{\Phi}(w) = \Phi(w)/\|w\|^*$.

The above definition illustrates the role of the second norm, which is to normalize the optimum. Thus $\|\cdot\|^*$ will usually be chosen to make $0 \leq \overline{\Phi}(w) \leq 1$.

APPROXIMATION. An *approximation algorithm* for $\Phi = (S, g, \|\cdot\|, \|\cdot\|^*, \text{opt})$ is an algorithm A which on input w tries to output a number as close as possible to $\Phi(w)$. Unless otherwise indicated, an approximation algorithm runs in time polynomial in the length of w.

While the complexity of the algorithm is measured as a function of the length of the input, the approximation quality is often measured as a function of some other measure associated with the input. This is the first norm of w, denoted $\|w\|$. For example, for graph problems the first norm is typically the number of vertices in the graph.

The notion of an approximation algorithm achieving a certain approximation factor is different depending on whether it is a maximization problem or a minimization problem.

DEFINITION 2.2. *An approximation algorithm A for optimization problem $\Phi = (S, g, \|\cdot\|, \|\cdot\|^*, \text{opt})$ is said to achieve a factor $\mu(\cdot) \geq 1$ if for all instances w its output $A(w)$ satisfies*

- $\dfrac{\Phi(w)}{\mu(\|w\|)} \leq A(w) \leq \Phi(w)$ *if Φ is a maximization problem, or*
- $\Phi(w) \leq A(w) \leq \mu(\|w\|) \cdot \Phi(w)$ *if Φ is a minimization problem.*

Note that as per this definition, our convention is that an approximation factor is always a number at least 1. In some other sources, the approximation factor, at least in the case of minimization problems, is a number less than 1: they set it to the reciprocal of what we set it.

GAP PROBLEMS. We are interested in instances of an optimization problem for which the optimum is promised to be either "very high" or "very low." We capture this by associating to any optimization problem a promise problem, depending on a pair of "thresholds" c, s, both admissible functions of the first norm and satisfying $0 < s(\cdot) < c(\cdot)$. It is convenient to make the definition in terms of the normalized optimum rather than the optimum. In these cases, $c \leq 1$ typically holds. We consider maximization and minimization problems separately.

DEFINITION 2.3. *Let $\Phi = (S, g, \|\cdot\|, \|\cdot\|^*, \max)$ be a maximization problem, and let $0 < s(\cdot) < c(\cdot)$ be admissible functions of the first norm. Define*

$$\begin{aligned} Y &= \{\, w \,:\, \overline{\Phi}(w) \geq c(\|w\|) \,\}, \\ N &= \{\, w \,:\, \overline{\Phi}(w) < s(\|w\|) \,\}, \\ \textsf{Gap-}\Phi_{c,s} &= (Y, N)\,. \end{aligned}$$

The gap *of the promise problem is defined to be c/s.*

It is important that the inequality in the definitions of Y, N is strict in one case and not strict in the other. The same is true below, where we chose to maintain $s < c$ and so reversed the roles of s and c.

DEFINITION 2.4. *Let $\Phi = (S, g, \|\cdot\|, \|\cdot\|^*, \min)$ be a minimization problem, and let $0 < s(\cdot) < c(\cdot)$ be admissible functions of the first norm. Define*

$$\begin{aligned} Y &= \{\, w \,:\, \overline{\Phi}(w) \leq s(\|w\|) \,\}, \\ N &= \{\, w \,:\, \overline{\Phi}(w) > c(\|w\|) \,\}, \\ \textsf{Gap-}\Phi_{c,s} &= (Y, N)\,. \end{aligned}$$

The gap *of the promise problem is defined to be c/s.*

Each of the optimization problems we consider will give rise to a gap problem.

SHOWING NONAPPROXIMABILITY VIA GAPS. Hardness of approximation of some optimization problem is shown by reducing NP to $\mathsf{Gap}\text{-}\Phi_{c,s}$ via a (possibly randomized) Karp reduction. (This is called "producing hard gaps.") The following proposition says that we can show that Φ is hard to approximate within a factor g by showing $\mathrm{NP} \leq^{K} \mathsf{Gap}\text{-}\Phi_{c,s}$, for some s and $c = g \cdot s$, and the assumption under which the nonapproximability result holds depends on the type of reduction. It is this proposition that motivates the consideration of gap problems.

PROPOSITION 2.5. *Optimization problem Φ has no factor c/s approximation algorithm.*

Under the assumption:	*If it holds that:*
$\mathrm{P} \neq \mathrm{NP}$,	$\mathrm{NP} \leq_D^K \mathsf{Gap}\text{-}\Phi_{c,s}$,
$\mathrm{NP} \neq \mathrm{coRP}$,	$\mathrm{NP} \leq_R^K \mathsf{Gap}\text{-}\Phi_{c,s}$ *via a reduction with perfect completeness,*
$\mathrm{NP} \not\subseteq \mathrm{BPP}$,	$\mathrm{NP} \leq_R^K \mathsf{Gap}\text{-}\Phi_{c,s}$.

Proof. Let us illustrate by proving the first of the three claims, for the case that the problem is one of maximization. We proceed by contradiction. Given a (polynomial-time) algorithm A that achieves an approximation factor of $\mu = c/s$ for Φ, we present a polynomial-time algorithm B to decide L, where L is any language in NP. Let T be a (deterministic, Karp) reduction of L to $\mathsf{Gap}\text{-}\Phi_{c,s}$. On input x our algorithm B computes $w = T(x)$. Next it computes $\alpha = s(\|w\|) \cdot \|w\|^*$. Finally, B invokes A on w, outputs 1 (indicating $x \in L$) if $A(w) \geq \alpha$, and 0 otherwise (indicating $x \notin L$).

Since A runs in polynomial-time and the functions T, s, $\|\cdot\|$, $\|\cdot\|^*$ are polynomial-time computable (by hypothesis), the algorithm B runs in polynomial time. We claim that B is always right. To see this, let Y, N be the two parts of the promise problem $\mathsf{Gap}\text{-}\Phi_{c,s}$ as per Definition 2.3. Consider two cases.

First suppose $x \in L$. Then $w = T(x) \in Y$ because T is a correct reduction of L to $\mathsf{Gap}\text{-}\Phi_{c,s}$. So $\overline{\Phi}(w) \geq c(\|w\|)$ by Definition 2.3. However, starting from Definition 2.2 and simplifying, we have

$$\begin{aligned} A(w) \geq \frac{\Phi(w)}{c(\|w\|)/s(\|w\|)} &= \frac{\overline{\Phi}(w) \cdot \|w\|^*}{c(\|w\|)/s(\|w\|)} \\ \geq \frac{c(\|w\|) \cdot \|w\|^*}{c(\|w\|)/s(\|w\|)} &= s(\|w\|) \cdot \|w\|^* = \alpha\,. \end{aligned}$$

Thus B will output 1 as desired.

Now suppose $x \notin L$. Then $w = T(x) \in N$. So $\overline{\Phi}(w) < s(\|w\|)$ by Definition 2.3. Starting from Definition 2.2 and simplifying, we have

$$A(w) \leq \Phi(w) = \overline{\Phi}(w) \cdot \|w\|^* < s(\|w\|) \cdot \|w\|^* = \alpha\,.$$

Thus B will output 0 as desired.

The proofs for the other cases are similar (and thus omitted). □

2.4.2. Some optimization problems we consider. A *formula* is a set (actually a multiset) of clauses (i.e., or-clauses) over some set of literals. We consider various classes of formulae. In particular, 3-SAT formulae (at most three literals in each clause), E3-SAT formulae (exactly three different literals in each clause) and 2-SAT formulae (at most two literals in each clause). We use the generic notation X-SAT to stand for some specified class of formulae; thus the above correspond to $\mathrm{X} \in \{3, \mathrm{E3}, 2\}$. To each value of X we associate the following optimization problem.

Problem: MaxXSAT.
Instance: X-SAT formula φ.
Solutions: An assignment v which associates with any variable x of φ a Boolean value $v(x) \in \{0, 1\}$. (Not necessarily a satisfying assignment!)
Objective Function: The value of an assignment v is the number of clauses in φ that v makes true.
Norms: The norm $\|\varphi\|$ of formula φ is the number of clauses in it, and $\|\varphi\|^*$ is the same.
Type: Maximization.

In particular we have optimization problems Max2SAT, Max3SAT, MaxE3SAT, and their corresponding gap problems. A related optimization problem refers to sets of xor-clauses, or put differently, to a set of linear equations over GF(2).

Problem: MaxLinEq.
Instance: A sequence of linear equations over GF(2).
Solutions: An assignment v which associates with any variable x in the sequence a value $v(x) \in \mathrm{GF}(2)$.
Objective Function: The value of an assignment v is the number of equations that v satisfies.
Norms: Both norms are set to the number of equations in the instance.
Type: Maximization.

Problem: MaxCUT.
Instance: G, w, where $G = (V, E)$ is a graph and w: $E \to \mathcal{R}^+$ is a weight function.
Solutions: A *cut* $S, \overline{S}$ in G, meaning a partition $V = S \cup \overline{S}$ of V into disjoint sets.
Objective Function: The value of a cut is its weight $w(S, \overline{S})$, the sum of the weights of the edges with one endpoint in S and the other in $\overline{S}$.
Norms: $\|G, w\| = |V|$ and $\|G, w\|^* = \sum_{e \in E} w(e)$.
Type: Maximization.

We note that our inapproximability result (see section 4.3) holds also when w is an admissible integral function; that is, $w(e) \in \{1, \ldots, \text{ poly}(|E|)\}$, for every $e \in E$.

Problem: MinVC.
Instance: Graph $G = (V, E)$.
Solutions: A *vertex cover* in G, meaning a set $V' \subseteq V$ such that $V' \cap \{u, v\} \neq \emptyset$ for every $\{u, v\} \in E$.
Objective Function: The value of a vertex cover V' is its size, meaning the number of vertices in it.
Norms: $\|G\| = \|G\|^* = |V|$ is the number of vertices in the graph.
Type: Minimization.

Problem: MaxClique.
Instance: Graph $G = (V, E)$.
Solutions: A *clique* in G, meaning a set $C \subseteq V$ such that $\{u, v\} \in E$ for every pair u, v of distinct vertices in C.
Objective Function: The value of a clique C is its size, meaning the number of vertices in it.
Norms: $\|G\| = \|G\|^* = |V|$ is the number of vertices in the graph.
Type: Maximization.

Problem: ChromNum.
Instance: Graph $G = (V, E)$.
Solutions: A *coloring* of G, meaning a map $c\colon V \to \{1, \ldots, k\}$, for some k, such that $c(u) \neq c(v)$ for any $\{u, v\} \in E$.
Objective Function: The value of a coloring, c, is the number k of colors it uses.
Norms: $\|G\| = \|G\|^* = |V|$ is the number of vertices in the graph.
Type: Minimization.

As per our general notation, $\Phi(w)$ is the optimum for instance w of optimization problem Φ. Given the above, this means, for example, that MaxClique(G) is the maximum clique size in graph G; ChromNum(G) is the chromatic number of G; MinVC(G) is the minimum vertex cover size of G, etc. The corresponding normalized versions get bars overhead. We will use these notations in what follows.

By the above, MaxXSAT(φ) is the maximum number of simultaneously satisfiable clauses in φ. We abuse notation slightly by dropping the "X" and writing just MaxSAT(φ)—similarly for the normalized version.

2.4.3. History of approximability results for these problems.

Satisfiability problems. Max3SAT is the canonical MaxSNP complete problem [76]. A polynomial-time algorithm due to Yannakakis [85] approximates it to within a factor of $4/3 < 1.334$ (see [50] for an alternative algorithm). The best known polynomial-time algorithm for Max3SAT achieves a factor of $8/7$ (and is due to Karloff and Zwick [64], improving upon [51, 84]. For MaxE3SAT, which is also MaxSNP complete, a very simple algorithm achieves an approximation of $8/7 \leq 1.143$ (where $7/8$ is the expected fraction of clauses satisfied by a uniformly chosen assignment).

Max2SAT is also MaxSNP complete [49, 76]. This problem is particularly interesting because it has been the focus of recent improvements in the approximation factor attainable in polynomial time. Specifically, Goemans and Williamson [51] exhibited a polynomial-time algorithm achieving an approximation factor of $\frac{1}{0.878} \approx 1.139$, and subsequently Feige and Goemans [39] exhibited an algorithm achieving $\frac{1}{0.931} \approx 1.074$.

Nonapproximability results for MaxSNP problems begin with Arora et al. [8] who proved that there exists a constant $\epsilon > 0$ such that $\mathsf{Gap\text{-}3SAT}_{1,1-\epsilon}$ is NP-hard. They did this by providing a reduction from a given NP language L to the promise problem in question, constructed by encoding as a 3-SAT instance the computation of a $\mathrm{PCP}_{1,1/2}[\log, O(1)]$ verifier for an NP-complete language, the variables in the instance corresponding to bits in the proof string. The basic paradigm of their reduction has been maintained in later improvements.

Figure 6 depicts the progress. Improvements (in the constant value of the nonapproximability factor) begin with Bellare et al. [21]. They used Hadamard code based inner verifiers following [8]. They also introduced a framework for better analysis and improved some previous analyses; we exploit in particular their better analyses of linearity testing (cf. section 3.5) and of Freivalds's matrix multiplication test (cf. Lemma 3.16). The improvement of Feige and Kilian [41] was obtained via new proof systems; that of [23] by use of the canonicity property of constant-prover proofs and some optimizations. (See section 2.2.3 for a discussion of the role of constant-prover proofs in this context.)

Garey, Johnson, and Stockmeyer [49] had provided, as early as 1976, a reduction of Max3SAT to Max2SAT which showed that if the former is nonapproximable within $(k + 1)/k$, then the latter is nonapproximable within $(7k + 1)/(7k)$. With the best

FIG. 6. *Nonapproximability results for* Max3SAT *indicating the factor shown hard and the assumption under which they were achieved.*

previous nonapproximability factor for Max3SAT (namely 66/65) we would only get a 456/455 factor nonapproximability for Max2SAT. In fact, even using our new Max3SAT result we would get a hardness factor of only 185/184. See section 4.2 for our results.

LINEAR EQUATIONS. The MaxLinEq problem is known to be MaxSNP complete (see [29] or [77]).

We remark that the problem of *maximizing* the number of satisfiable equations should not be confused with the "complementary" problem of *minimizing* the number of violated constraints, investigated by Arora et al. [7]. Also, the case of maximum satisfiable linear constraints over larger fields (of size q) has been considered by Amaldi and Kann [5], who show that this problem is hard to approximate to within a factor of q^ϵ for some universal $\epsilon > 0$. See section 4.2.2 for our results.

MAX CUT. In 1976, Sahni and Gonzales [80] gave a simple 2-approximation algorithm for this problem. Recently, in a breakthrough result, Goemans and Williamson [51] gave a new algorithm which achieves a ratio of $\frac{1}{0.878} = 1.139$ for this problem. On the other hand, [76] give an approximation preserving reduction from Max3SAT to MaxCUT. Combined with [8] this shows that there exists a constant $\alpha > 1$ such that approximating MaxCUT within a factor of α is NP-hard. No explicit bounds were given since and even using the best known hardness results for MAX3SAT, one suspects that the bound for MaxCUT would not be very large, since the reduction uses constructions of constant degree expanders, etc. See section 4.3 for our results.

VERTEX COVER. There is a simple polynomial-time algorithm to approximate MinVC in unweighted graphs within a factor of 2. The algorithm, due to F. Gavril (cf. [48]) consists of taking all vertices which appear in a maximal matching of the graph. For weighted graphs, Bar-Yehuda and Even [13] and Hochbaum [58] gave algorithms achieving the same approximation factor. The best known algorithm today achieves a factor only slightly better, namely, $2 - (\log\log|V|)/(2\log|V|)$ [14, 74].

Evidence to the hardness of approximating MinVC was given by Bar-Yehuda and Moran who showed that, for every $k \geq 2$ and $\epsilon > 0$, a $1 + \frac{1}{k} - \epsilon$ approximator for (finding) a minimum vertex cover would yield an algorithm for coloring $(k+1)$-colorable graphs using only logarithmically many colors [15]. The version of MinVC in which one restricts attention to graphs of bounded degree, is MaxSNP complete [76]. In particular they provide a reduction from Max3SAT. Combined with [8] this implies the existence of a constant $\delta > 0$ such that approximating MinVC within a factor of $1 + \delta$ is hard unless P = NP. No explicit value of δ has been stated

until now. Indeed, the value that could be derived, even using the best existing nonapproximability results for Max3SAT, will be very small because of the cost of the reduction of [76], which first reduces Max3SAT to its bounded version using expanders, and then reduces this to the bounded-degree version of MinVC. See section 5.2 for our results.

MaxClique. The best known polynomial-time approximation algorithm for MaxClique achieves a factor of only $N^{1-o(1)}$ [28], scarcely better than the trivial factor of N. There is not even a heuristic algorithm that is conjectured to do better. (The Lovász theta function had been conjectured to approximate the MaxClique size within $\sqrt{N}$, but this conjecture was disproved by Feige [37].)

Prior to 1991, no nonapproximability results on MaxClique were known. In 1991 the connection to proofs was made by Feige et al. [40]. The FGLSS reduction says that $\mathrm{PCP}_{1,e}[\,\mathsf{coins} = r\,;\,\mathsf{query} = q\,]$ Karp reduces to $\mathsf{Gap}\text{-MaxClique}_{c,s}$ via a reduction running in time $\mathrm{poly}(2^{r+q})$, and with the gap c/s being a function of (r, q, and) the error e. In applying the reduction one works with PCP classes containing NP. One obtains a result stating that MaxClique has no polynomial-time approximation algorithm achieving a certain factor, under an assumption about the deterministic time complexity of NP (the time complexity depends on r, q, and the factor on these, but, most importantly, on the error e). In particular, these authors were able to "scale down" the proof system of [11] to indicate strong nonapproximability factors of $2^{\log^{1-\epsilon} N}$ for all $\epsilon > 0$, assuming NP is not in quasi-polynomial deterministic time. They also initiated work on improving the factors and assumptions via better proof systems. The best result in their paper is indicated in Figure 7.

Arora and Safra [9] reduced the randomness complexity of a PCP verifier for NP to logarithmic; they showed $\mathrm{NP} = \mathrm{PCP}_{1,1/2}[\,\mathsf{coins} = \log\,;\,\mathsf{query} = \sqrt{\log N}\,]$. On the other hand, it is easy to see that random bits can be recycled for error reduction via the standard techniques of [2, 30, 59]. The consequence was the first NP-hardness result for MaxClique approximation. The corresponding factor was $2^{\sqrt{\log N}}$.

Arora et al. [8] showed that $\mathrm{NP} = \mathrm{PCP}_{1,1/2}[\,\mathsf{coins} = \log\,;\,\mathsf{query} = O(1)\,]$, which implied that there exists an $\epsilon > 0$ for which approximating MaxClique within N^ϵ was NP-complete. The number of queries was unspecified but was estimated to be $\approx 10^4$, and so $\epsilon \approx 10^{-4}$. Later work has focused on increasing the constant value of ϵ in the exponent.

In later work a slightly tighter form of the FGLSS reduction due to [25, 86] has been used. It says that $\mathrm{PCP}_{1,1/2}[\,\mathsf{coins} = r\,;\,\mathsf{query}_{\mathrm{av}} = q_{\mathrm{av}}\,]$ reduces, via a randomized Karp reduction, to $\mathsf{Gap}\text{-MaxClique}_{c,s}$ for some c, s satisfying $c(N)/s(N) = N^{1/(1+q_{\mathrm{av}})}$, and with the running time of the reduction being $\mathrm{poly}(2^r)$. (We assume $q_{\mathrm{av}} = O(1)$ for simplicity, and omit factors of $N^{\epsilon'}$ where $\epsilon' > 0$ can be arbitrarily small, here and in the following.) Thus the hardness factor was tied to the (average) number of queries required to get soundness error $1/2$. Meanwhile the assumption involved the probabilistic rather than deterministic time complexity of NP—it would be $\mathrm{NP} \not\subseteq \widetilde{\mathrm{coRP}}$ if $r = \mathrm{polylog}(n)$ and $\mathrm{NP} \neq \mathrm{coRP}$ if $r = \log(n)$.

The improved proof systems of [21] obtain significantly smaller query complexity; they showed $\mathrm{NP} \subseteq \mathrm{PCP}_{1,1/2}[\,\mathsf{coins} = \mathrm{polylog}; \mathsf{query} = 24\,]$ and $\mathrm{NP} \subseteq \mathrm{PCP}_{1,1/2}[\,\mathsf{coins} = \log\,;\,\mathsf{query} = 29\,]$. This leads to their hardness results shown in Figure 7. However, significantly reducing the (average) number of bits queried seemed hard.

As observed by Feige and Kilian, the performance of the FGLSS reduction actually depends on the free-bit complexity, which may be significantly smaller than the query

FIG. 7. *Progress in the project of increasing the nonapproximability factors for MaxClique.*

complexity [41]. Namely, the factor in the above mentioned reduction is $N^{1/(1+f)}$ where f is the free-bit complexity. They observed that the proof system of [21] has free-bit complexity 14, yielding a $N^{1/15}$ hardness of approximation factor.

The notion of amortized free bits was introduced by Bellare and Sudan [23]. They observed that the performance of the reduction depended, in fact, on this quantity and that the factor was $N^{1/(1+\bar{f})}$, where $\bar{f}$ is the amortized free-bit complexity. They then showed that NP $\subseteq \overline{\text{FPCP}}[\text{polylog}, 3]$. This lead to a $N^{1/4}$ hardness factor assuming NP $\neq$ co$\widetilde{\text{RP}}$. See section 7 for our results.

CHROMATIC NUMBER. The first hardness result for the chromatic number is due to Garey and Johnson [47]. They showed that if P $\neq$ NP, then there is no polynomial-time algorithm that can achieve a factor less than 2. This remained the best result until the connection to proof systems, and the above mentioned results, emerged.

Hardness results for the chromatic number were obtained via reduction from MaxClique. An N^{ϵ} factor hardness for MaxClique translates into a N^{δ} factor hardness for the Chromatic number[3], with $\delta = \delta(\epsilon)$ a function of ϵ. In all reductions $\delta(\epsilon) = \min\{h(\epsilon), h(0.5)\}$, for some function h. The bigger h, the better the reduction.

The first reduction, namely that of Lund and Yannakakis [71], obtained $h(\epsilon) = \epsilon/(5-4\epsilon)$. Via the MaxClique hardness results of [9, 8], this implies that the chromatic number is hard to approximate within N^{δ} for some $\delta > 0$. But, again, δ is very small. Improvements to δ were derived by both improvements to ϵ and improvements to the function h used by the reduction.

A subsequent reduction of Khanna, Linial, and Safra [66] is simpler, but in fact slightly less efficient, having $h(\epsilon) = \epsilon/(5+\epsilon)$. A more efficient reduction is given by [23]—they present a reduction obtaining $h(\epsilon) = \epsilon/(3-2\epsilon)$. Our $N^{\frac{1}{3}}$ hardness for Clique would yield, via this, a $N^{1/7}$ hardness for the chromatic number. But more recently an even more efficient reduction has become available, namely that of Fürer [45]. This reduction achieves $h(\epsilon) = \epsilon/(2-\epsilon)$, and thereby we get our $N^{\frac{1}{5}}$ hardness.

Following the appearance of our results, Feige and Kilian [42] have introduced a new approach to showing hardness of approximability of ChromNum. See discussion in section 1.5.

[3]Actually, all the reductions presented here make assumptions regarding the structure of the graph and hence do not directly yield the hardness results stated here. However, as a consequence of some results from this paper, we are able to remove the assumptions made by the earlier papers and hence present those results in a simpler form. See section 8.4 for details.

Randomized and derandomized error reduction. As mentioned above, randomized and derandomized error reduction techniques play an important role in obtaining the best clique hardness results via the FGLSS method. Typically, one first reduces the error so that its logarithm relates to the query (or free-bit) complexity and so that the initial randomness cost can be ignored (as long as it was logarithmic). (Otherwise, one would have needed to construct proof systems which also minimize this parameter, i.e., the constant factor in the logarithmic randomness complexity.)

The randomized error reduction method originates in the work of Berman and Schnitger [25], where it is applied to the Clique-Gap promise problem. An alternative description is given by Zuckerman [86]. Another alternative description, carried out in the proof system, is presented in section 11.

The derandomized error-reduction method consists of applying general, derandomized, error-reduction techniques to the proof system setting.[4] The best method, known as the "expander walk" technique, is due to Ajtai, Komlos, and Szemeredi [2] (see also [30, 59]). It is easy to see that it is applicable to the pcp context. (The usage of these methods in the pcp context begins with [9].) It turns out that the (constant) parameters of the expander, specifically the ratio $\rho \stackrel{\text{def}}{=} \frac{\log_2 d}{\log_2 \lambda}$, where d is the degree of the expander and λ is the second eigenvalue (of its adjacency matrix), play an important role here. In particular, $\rho - 1$ determines how much we lose with respect to the randomized error reduction (e.g., $\text{NP} \in \overline{\text{FPCP}}[\log, f]$ translates to a hardness factor of $N^{\frac{1}{1+f}}$ under $\text{NP} \not\subseteq \text{BPP}$ and to a hardness factor of $N^{\frac{1}{\rho+f}}$ under $\text{NP} \neq \text{P}$). Thus the Ramanujan expander of Lubotzky, Phillips, and Sarnak [70] plays an important role yielding $\rho \approx 2$ (cf. Proposition 11.4), which is the best possible (when using the expander walk technique).

Part I: New proof systems and nonapproximability results.

3. The long code and its machinery.

3.1. New PCPs and hardness results: Overview and guidemap. The starting point for all of our proof systems is a two-prover proof system achieving arbitrarily small but fixed constant error with logarithmic randomness and constant answer size, as provided by Raz [79]. This proof system has the property that the answer of the second prover is supposed to be a predetermined function of the answer of the first prover. Thus, verification in it amounts to checking that the first answer satisfies some predicate and that the second answer equals the value obtained from the first answer. Following the "proof composition" paradigm of Arora and Safra [9], the proof string provided to the PCP verifier will consist of "encodings" of the answers of the two provers under a suitable code. The PCP verifier will then check these encodings. As usual, we will check both that these encodings are valid and that they correspond to answers which would have been accepted by the original verifier.

Our main technical contribution is a new code, called the *long code*, and the means to check it. The long code of an n-bit information word a is the sequence of 2^{2^n} bits consisting of the values of all possible Boolean functions at a. The long code is certainly a disaster in terms of coding efficiency, but it has big advantages in the context of proof verification because it carries enormous amounts of data about a.

[4] An alternative approach, applicable to the Gap-Clique problem and presented in [3], is to "derandomize" the graph product construction of [25].

The difficulty will be to check that a prover claiming to write the long code of some string a is really doing so.

The long code is described in section 3.3. In section 3.5 we provide what we call the "atomic" tests for this code. These tests and their analyses are instrumental to all that follows. Section 3.4 is also instrumental to all that follows. This section sets up the framework for recursive proof checking which is used in all the later proof systems.

The atomic tests are exploited in section 4.1 to construct a verifier that queries the proof at three locations and performs one of two simple checks on the answers obtained. These simple checks are implemented by gadgets of the MaxSNP problem at hand, yielding the nonapproximability results. Section 4.2 presents gadgets which are CNF formulae of the corresponding type and section 4.3 presents MaxCUT gadgets. The nonapproximability results for Max3SAT, MaxE3SAT, Max2SAT, and MaxCUT follow. The verifier of section 4.1 benefits from another novel idea which is referred to as *folding* (see section 3.3). Folding contributes to the improved results for Max3SAT, MaxE3SAT, Max2SAT, and MaxCUT, but not to the results regarding MaxClique (and Chromatic Number).

A reasonable nonapproximability result for MinVC (Minimum Vertex Cover) can be obtained by the above methodology, but a better result is obtained by constructing a different verifier, for NP languages, that uses exactly two free bits. This verifier is then used to create a reduction of NP to MinVC via the FGLSS and standard Karp reductions. This approach is presented in section 5, where we try to minimize the soundness error attainable using exactly two free bits.

In section 6 we minimize the number of bits queried in a PCP to attain soundness error 1/2—the result is not of direct applicability, but it is intriguing to know how low this number can go.

We then turn to MaxClique (and Chromatic Number). In section 7.1 we provide the "iterated" tests. (Here the atomic tests are invoked (sequentially) many times, but these invocations are not independent of each other.) This leads to a proof system in which the number of *amortized free bits* used is two. We then draw the implications for MaxClique (and Chromatic Number). A reader interested only in the (amortized) free-bit and MaxClique results can proceed directly from section 3.5 to section 7.

The improvement in the complexities of the proof systems is the main source of our improved nonapproximability results. In addition we also use (for the MaxSAT, MaxCUT, and MinVC problems) a recent improvement in the analysis of linearity testing [17], and introduce (problem specific) gadgets which represent the various tests of the resulting PCP system.

3.2. Preliminaries to the long code. Here $\Sigma = \{0, 1\}$ will be identified with the finite field of two elements, the field operations being addition and multiplication modulo two. If X and Y are sets, then $\mathsf{Map}(X, Y)$ denotes the set of all maps of X to Y. For any integer m we regard Σ^m as a vector space over Σ so that strings and vectors are identified. If $a \in \Sigma^m$, then $a^{(i)}$ denotes its ith bit. Similarly, if f is any function with range Σ^m, then $f^{(i)}$ denotes the ith bit of its output.

LINEARITY. Let G, H be groups. A map $f\colon G \to H$ is *linear* if $f(x + y) = f(x) + f(y)$ for all $x, y \in G$. Let $\textsc{Lin}(G, H)$ denote the set of all linear maps of G to H. When $G = \Sigma^n$ and $H = \Sigma$, a function $f\colon G \to H$ is linear if and only if there exists $a \in \Sigma^n$ such that $f(x) = \sum_{i=1}^{n} a^{(i)} x^{(i)}$ for all $x \in \Sigma^n$.

DISTANCE. The *distance* between functions f_1, f_2 defined over a common finite domain D is

$$\mathrm{Dist}(f_1, f_2) \;=\; \mathrm{Pr}_{x \stackrel{R}{\leftarrow} D}\left[f_1(x) \neq f_2(x)\right].$$

Functions f_1, f_2 are *ϵ-close* if $\mathrm{Dist}(f_1, f_2) < \epsilon$. If f maps a group G to a group H we denote by $\mathrm{Dist}(f, \textsc{Lin})$ the minimum, over all $g \in \textsc{Lin}(G, H)$, of $\mathrm{Dist}(f, g)$. (Note that the notation does not specify G, H, which will be evident from the context.) We are mostly concerned with the case where G is a vector space V over Σ and H is Σ. Notice that in this case we have $\mathrm{Dist}(f, \textsc{Lin}) \leq 1/2$ for all $f\colon V \to \Sigma$.

Boolean functions. Let l be an integer. We let $\mathcal{F}_l \stackrel{\text{def}}{=} \mathsf{Map}(\Sigma^l, \Sigma)$ be the set of all maps of Σ^l to Σ. We regard $\mathcal{F}_l$ as a vector space (of dimension 2^l) over Σ. Addition and multiplication of functions are defined pointwise.

We let $\mathcal{L}_m \subseteq \mathcal{F}_m$ be the set $\textsc{Lin}(\Sigma^m, \Sigma)$ of linear functions of Σ^m to Σ and let $\mathcal{L}_m^* = \mathcal{L}_m - \{0\}$ be the nonzero linear functions.

Let $g \in \mathcal{F}_m$ and $\vec{f} = (f_1, \ldots, f_m) \in \mathcal{F}_l^m$. Then $g \circ \vec{f}$ denotes the function in $\mathcal{F}_l$ that assigns the value $g(f_1(x), \ldots, f_m(x))$ to $x \in \Sigma^l$.

The monomial basis. For each $S \subseteq [l]$ we let $\chi_S \in \mathcal{F}_l$ be the monomial corresponding to S, defined for $x \in \Sigma^l$ by

$$\chi_S(x) \;=\; \textstyle\prod_{i \in S} x^{(i)} \;.$$

The empty monomial, namely $\chi_\emptyset$, is defined to be the constant-one function (i.e., $\chi_\emptyset(x) \;=\; \bar{1}$, for all $x \in \Sigma^l$). The functions $\{\chi_S\}_{S \subseteq [l]}$ form a basis for the vector space $\mathcal{F}_l$ which we call the *monomial basis.* This means that, for each $f \in \mathcal{F}_l$, there exists a unique vector $\mathcal{C}(f) = (\, C_f(S)\,)_{S \subseteq [l]} \in \Sigma^{2^l}$ such that

$$f \;=\; \textstyle\sum_{S \subseteq [l]} C_f(S) \cdot \chi_S \;. \tag{5}$$

The expression on the right-hand side above is called the *monomial series* for f, and the members of $\mathcal{C}(f)$ are called the *coefficients of f* with respect to the monomial basis. We note that $\mathcal{C}\colon \mathcal{F}_l \to \Sigma^{2^l}$ is a bijection. (The monomial basis is reminiscent of the Fourier basis, but the two are actually different.)

3.3. Evaluation operators, the long code, and folding.

Evaluation operators. Let $a \in \Sigma^l$. We define the map $E_a\colon \mathcal{F}_l \to \Sigma$ by $E_a(f) = f(a)$ for all $f \in \mathcal{F}_l$. We say that a map $A\colon \mathcal{F}_l \to \Sigma$ is an *evaluation operator* if there exists some $a \in \Sigma^l$ such that $A = E_a$. We now provide a useful characterization of evaluation operators. First we need a definition.

Definition 3.1 (respecting the monomial basis). *A map $A\colon \mathcal{F}_l \to \Sigma$ is said to* respect the monomial basis *if*

(1) $A(\chi_\emptyset) = 1$ *and*

(2) $\forall\, S, T \subseteq [l] \;\;:\;\; A(\chi_S) \cdot A(\chi_T) = A(\chi_{S \cup T})$.

Proposition 3.2 (characterization of the evaluation operator). *A map $\tilde{A}\colon \mathcal{F}_l \to \Sigma$ is an evaluation operator if and only if it is linear and respects the monomial basis.*

Proof. Let $a \in \Sigma^l$. It is easy to see that E_a is linear: $E_a(f + g) = (f + g)(a) = f(a) + g(a) = E_a(f) + E_a(g)$. It is also easy to see that E_a respects the monomial basis. Firstly, we have $E_a(\chi_\emptyset) = \chi_\emptyset(a) = 1$. Next, for every $S, T \subseteq [l]$,

$$E_a(\chi_S) \cdot E_a(\chi_T) \;=\; \chi_S(a) \cdot \chi_T(a) \;=\; \textstyle\prod_{i \in S} a^{(i)} \;\cdot\; \prod_{i \in T} a^{(i)} \;.$$

However, $x^2 = x$ for any $x \in \Sigma$, so

$$\textstyle\prod_{i \in S} a^{(i)} \;\cdot\; \prod_{i \in T} a^{(i)} \;=\; \prod_{i \in S \cup T} a^{(i)} \;=\; \chi_{S \cup T}(a) \;=\; E_a(\chi_{S \cup T}).$$

Now we turn to the converse. Let $\tilde{A}\colon \mathcal{F}_l \to \Sigma$ be linear and respect the monomial basis. For $i = 1, \ldots, l$, let $a_i \stackrel{\text{def}}{=} \tilde{A}(\chi_{\{i\}})$, and let $a \stackrel{\text{def}}{=} a_1, \ldots, a_l$. We claim that $\tilde{A} = E_a$. The proof is as follows. We first claim that

$$\forall\, S \subseteq [l] \quad : \quad \tilde{A}(\chi_S) = \chi_S(a)\,. \tag{6}$$

Since $\tilde{A}$ respects the monomial basis we have $\tilde{A}(\chi_\emptyset) = 1$ which in turn equals $\chi_\emptyset(a)$, proving Eq. (6) for $S = \emptyset$. To establish Eq. (6) for $S = \{i_1, \ldots, i_t\} \neq \emptyset$, we write

$$\tilde{A}(\chi_S) \;=\; \tilde{A}\left(\chi_{\{i_1\}\cup\cdots\cup\{i_t\}}\right) \;=\; \textstyle\prod_{j=1}^{t} \tilde{A}(\chi_{\{i_j\}}) \;=\; \prod_{j=1}^{t} a_{i_j} \;=\; \chi_S(a)\,,$$

where the second equality is due to the fact that $\tilde{A}$ respects the monomial basis. This establishes Eq. (6). Now for any $f \in \mathcal{F}_l$ we can use the linearity of $\tilde{A}$ to see that

$$\begin{aligned}\tilde{A}(f) = \tilde{A}\left(\textstyle\sum_S C_f(S)\cdot\chi_S\right) \;&=\; \textstyle\sum_S C_f(S)\cdot\tilde{A}(\chi_S)\\ = \textstyle\sum_S C_f(S)\cdot\chi_S(a) \;&=\; f(a) \;=\; E_a(f)\,.\end{aligned}$$

Thus $\tilde{A} = E_a$. □

THE LONG CODE. Intuitively, the encoding of $a \in \{0,1\}^l$ (via the long code) is the 2^{2^l} bit string which in position $f \in \mathcal{F}_l$ stores the bit $f(a)$. The long code is thus an extremely "redundant" code, encoding an l-bit string by the values, at a, of *all* functions in $\mathcal{F}_l$.

DEFINITION 3.3 (long code). *The* long code $E\colon \Sigma^l \to \mathsf{Map}(\mathcal{F}_l, \Sigma)$ *is defined for any* $a \in \Sigma^l$ *by* $E(a) = E_a$.

In some natural sense E is the longest possible code: E is the longest code which is not repetitive (i.e., does not have two positions which are identical in all codewords).

We let $\mathrm{Dist}(A, \textsc{Eval}) = \min_{a\in\Sigma^l} \mathrm{Dist}(A, E_a)$ be the distance from A to a closest codeword of E. It is convenient to define $E^{-1}(A) \in \Sigma^l$ as the lexicographically least $a \in \Sigma^l$ such that $\mathrm{Dist}(A, E_a) = \mathrm{Dist}(A, \textsc{Eval})$. Notice that if $\mathrm{Dist}(A, \textsc{Eval}) < 1/4$, then there is exactly one $a \in \Sigma^l$ such that $\mathrm{Dist}(A, E_a) = \mathrm{Dist}(A, \textsc{Eval})$, and so $E^{-1}(A)$ is this a.

The long code is certainly a disaster in terms of coding efficiency, but it has a big advantage in the context of proof verification. Consider, for example, the so-called "circuit test" (i.e., testing that the answer of the first prover satisfies some predetermined predicate/circuit). In this context one needs to check that the codeword encodes a string which satisfies a predetermined predicate (i.e., the codeword encodes some $w \in \{0,1\}^n$, which satisfies $h(w) = 0$, for some predetermined predicate h). The point is that the value of this predicate appears explicitly in the codeword itself, and furthermore it can be easily "self-corrected" by probing the codeword for the values of the functions f and $f + h$, for a uniformly selected function $f : \{0,1\}^n \to \{0,1\}$ (as all these values appear explicitly in the codeword). Actually, the process of verifying, via self-correction, that the value under h is zero can be incorporated into the task of checking the validity of the codeword; this is done by the notion of "$(h, 0)$-folding" (see below). The fact that we can avoid testing whether the codeword encodes a string which satisfies a given function (or that this testing does not cost us anything) is the key to the complexity improvements in our proof systems (over previous proof systems in which a "circuit test" was taking place and had a considerable cost).

FOLDING. The intuition behind the notion we will now define is like this. When A is the long code of some string x for which it is known that $h(x) = b$, for some function h and bit b, then half of the bits of A become redundant because they can

be computed from the other half via $A(f) = A(f+h) - b$. This phenomenon enables us to reduce the proof checking complexity. To capture it we now define the notion of folding.

Fix $\prec$ to be some canonical, polynomial-time computable total order (reflexive, antisymmetric, transitive) on the set $\mathcal{F}_l$. Given functions $A\colon \mathcal{F}_l \to \Sigma$ and $h \in \mathcal{F}_l \setminus \{\bar{0}\}$ (i.e., h is not the constant function $\bar{0}$) and bit $b \in \Sigma$, the (h,b)-*folding* of A is the function $A_{(h,b)}\colon \mathcal{F}_l \to \Sigma$ given by

$$A_{(h,b)}(f) = \begin{cases} A(f) & \text{if } f \prec h+f \\ A(f+h) - b & \text{otherwise.} \end{cases}$$

(Notice that the above is well defined for any $h \neq \bar{0}$.) For sake of technical simplicity (see Definition 3.9), we define the $(\bar{0},0)$-folding of A to be A itself; namely, $A_{(\bar{0},0)}(f) = A(f)$, for every $f \in \mathcal{F}_l$. As shown below, the (h,b)-folding of a function A is forced to satisfy $A_{(h,b)}(f+h) = A_{(h,b)}(f) + b$, for every $f \in \mathcal{F}_l$ (whereas A itself may not necessarily satisfy these equalities). Before proving this, let us generalize the notion of folding to folding over several, specifically two, functions $h_1, h_2 \in \mathcal{F}_l$ (and bits $b_1, b_2 \in \Sigma$).

DEFINITION 3.4 (folding). *Let $f, h_1, h_2 \in \mathcal{F}_l$. The* (h_1,h_2)-span *of f, denoted* $\textsc{span}_{h_1,h_2}(f)$*, is defined as the set* $\{f + \sigma_1 h_1 + \sigma_2 h_2 : \sigma_1, \sigma_2 \in \Sigma\}$*. Let* $\textsc{mincoef}_{h_1,h_2}(f)$ *be the pair (σ_1,σ_2) of elements of Σ for which $f+\sigma_1 h_1+\sigma_2 h_2$ is the smallest function (according to $\prec$) in* $\textsc{span}_{h_1,h_2}(f)$*. Let $A\colon \mathcal{F}_l \to \Sigma$. Assume that h_1, h_2 are distinct and nonzero, and let $b_1, b_2 \in \Sigma$. The* folding *of A* over (h_1,b_1) and (h_2,b_2)*, denoted $A_{(h_1,b_1),(h_2,b_2)}$, is defined for every $f \in \mathcal{F}_l$ by*

$$A_{(h_1,b_1),(h_2,b_2)}(f) = A(f + \sigma_1 h_1 + \sigma_2 h_2) - \sigma_1 b_1 - \sigma_2 b_2 \ ,$$

where $(\sigma_1,\sigma_2) = \textsc{mincoef}_{h_1,h_2}(f)$.

The definition extends naturally to the following two cases. In case $(h_1,b_1) = (h_2,b_2)$, folding over the two (identical) pairs is defined as folding over one pair. In case $h_1 \equiv \bar{0}$ and $b_1 = 0$, folding over both (h_1,b_1) and (h_2,b_2) is defined as folding over (h_2,b_2). Note that folding over two pairs is invariant under the order between the pairs; namely, $A_{(h_1,b_1),(h_2,b_2)} \equiv A_{(h_2,b_2),(h_1,b_1)}$. Finally, observe that a function $A\colon \mathcal{F}_l \to \Sigma$ that is folded over two functions (i.e., over both (h_1,b_1) and (h_2,b_2)) is folded over each of them (i.e., over each (h_i,b_i)).

PROPOSITION 3.5 (folding forces equalities). *Let $A\colon \mathcal{F}_l \to \Sigma$, $h_1, h_2 \in \mathcal{F}_l$, and $b_1, b_2 \in \Sigma$ (with $b_i = 0$ in case $h_i \equiv \bar{0}$). Then, for every $f \in \mathcal{F}_l$,*

$$A_{(h_1,b_1),(h_2,b_2)}(f+h_1) = A_{(h_1,b_1),(h_2,b_2)}(f) + b_1.$$

Proof. By definition, $A_{(h_1,b_1),(h_2,b_2)}(f) = A(f + \sigma_1 h_1 + \sigma_2 h_2) - \sigma_1 b_1 - \sigma_2 b_2$, where the function $f + \sigma_1 h_1 + \sigma_2 h_2$ is the smallest function in $\textsc{span}_{h_1,h_2}(f)$. Since $\textsc{span}_{h_1,h_2}(f+h_1) \equiv \textsc{span}_{h_1,h_2}(f)$, we have $A_{(h_1,b_1),(h_2,b_2)}(f+h_1) = A(f + \sigma_1 h_1 + \sigma_2 h_2) - (\sigma_1 - 1)b_1 - \sigma_2 b_2$. The claim follows. □

As a corollary to the above (combined with the self-correcting paradigm [27]), we get the following proposition.

PROPOSITION 3.6 (folding and the evaluation operator). *Let $A\colon \mathcal{F}_l \to \Sigma$, $h \in \mathcal{F}_l$, $b \in \Sigma$, and $a \in \Sigma^l$. Suppose that for any $f \in \mathcal{F}_l$ it is the case that $A(f+h) = A(f)+b$. Then* $\mathrm{Dist}(A, E_a) < 1/2$ *implies $h(a) = b$. Consequently, if* $\mathrm{Dist}(A_{(h,b),(h',b')}, E_a) < 1/2$*, then $h(a) = b$, provided $b = 0$ if $h \equiv \bar{0}$.*

Proof. By the hypothesis, we have $A(h+f) = A(f)+b$, for every $f \in \mathcal{F}_l$. Suppose that $\mathrm{Dist}(A, E_a) < 1/2$. Then, noting that E_a is linear and applying a self-correction process (cf. Corollary 3.14 below), we get $E_a(h) = b$. Using the definition of the evaluator operator (i.e., $E_a(h) = h(a)$), we have $h(a) = b$. The consequence for $A_{(h,b),(h',b')}$ follows since by Proposition 3.5 we have $A_{(h,b),(h',b')}(f + h) = A_{(h,b),(h',b')}(f) + b$ for any $f \in \mathcal{F}_l$. □

The verifiers constructed below make virtual access to "folded" functions rather than to the functions themselves. Virtual access to a folding of A is implemented by actual accessing A itself according to the definition of folding (e.g., say one wants to access $A_{(h,0)}$ at f; then one determines whether or not $f \prec h + f$ and accesses either $A(f)$ or $A(f + h)$, accordingly). One benefit of folding in our context is illustrated by Proposition 3.6; in case a (h, b)-folded function is close to a codeword (in the long code), we infer that the codeword encodes a string a satisfying $h(a) = b$. We will see that folding (the long code) over $(h, 0)$ allows us to get rid of a standard ingredient in proof verification—the so-called "circuit test."

In the following, we will use folding over the pairs $(h, 0)$ and $(\bar{1}, 1)$, where $h \in \mathcal{F}_l$ is an arbitrary function (typically not identically zero) and $\bar{1}$ is the constant-one function. Folding over $(\bar{1}, 1)$ allows us to simplify the "codeword" test (w.r.t. the long code).

3.4. Recursive verification of proofs. This section specifies the basic structure of proof construction and in particular provides the definitions of the notions of inner and outer verifiers which will be used throughout. It is useful to understand these things before proceeding to the tests.

Overview. The constructions of efficient proofs that follow will exploit the notion of recursive verifier construction due to Arora and Safra [9]. We will use just one level of recursion. We first define a notion of a *canonical outer verifier* whose intent is to capture two-prover, one-round proof systems [24] having certain special properties; these verifiers will be our starting point. We then define a canonical inner verifier. Recursion is captured by an appropriate definition of a composed verifier whose attributes we relate to those of the original verifiers in Theorem 3.12.

The specific outer verifier we will use is one obtained by a recent work of Raz [79]. We will construct various inner verifiers based on the long code and the tests in sections 3.5 and 7.1. Theorem 3.12 will be used ubiquitously to combine the two.

Comparison with previous work. For a history and a better understanding of the role of constant-prover proof systems in this context, see section 2.4.3. In comparison, our definition of outer verifiers (below) asks for almost the same canonicity properties as in [23]. (The only difference is that they have required σ to be a projection function, whereas we can deal with an arbitrary function. But we don't take advantage of this fact.) In addition we need answer sizes of $\log \log n$ as opposed to the $O(\log n)$ of previous methods, for reasons explained below. This means that even the (modified) [67, 43] type proofs won't suffice for us. We could use the three-prover modification of [41] but the cost would wipe out our gain. Luckily this discussion is moot since we can use the recent result of Raz [79] to provide us with a canonical two-prover proof having logarithmic randomness, constant answer size, and any constant error. This makes an ideal starting point. To simplify the definitions below we insisted on constant answer size and two provers from the start.

The inner verifiers used in all previous works are based on the use of the Hadamard code constructions of [8]. (The improvements mentioned above are obtained by checking this same code in more efficient ways.) We instead use a new code, namely, the

long code, as the basis of our inner verifiers. Note that the codewords (in the long code) have length double exponential in the message, explaining our need for $\log \log n$ answer sizes in the outer verifier. We also incorporate into the definitions the new idea of folding which we will see means that we don't need a circuit test (a hint toward this fact is already present in the definition of a good inner verifier).

3.4.1. Outer verifiers. As mentioned above, outer verifiers will model special kinds of two-prover, one-round proof systems. We think of the verifier as being provided with a pair of (nonboolean) proof oracles π, π_1, and allowed one query to each. The desired properties concern the complexity of the system and a certain behavior in the checking of the proof, as we now describe.

Let $r_1, s, s_1 \colon \mathcal{Z}^+ \to \mathcal{Z}^+$ and let l and l_1 be positive integers. An (l, l_1)-*canonical outer verifier* V_{outer} takes as input $x \in \Sigma^n$ and has oracle access to a pair of proofs $\bar{\pi} \colon [s(n)] \to \Sigma^l$ and $\bar{\pi}_1 \colon [s_1(n)] \to \Sigma^{l_1}$. It does the following.

(1) Picks a random string R_1 of length $r_1(n)$.
(2) Computes, as a function of x and R_1, queries $q \in [s(n)]$ and $q_1 \in [s_1(n)]$, and a (circuit computing a) function $\sigma \colon \Sigma^l \to \Sigma^{l_1}$ (which is determined by x and R_1); determines, based on x and q, a function $h \colon \Sigma^l \to \Sigma$ (and computes an appropriate representation of it).
(We stress that h does not depend on R_1 but only on q and x).
(3) Lets $a = \bar{\pi}(q)$ and $a_1 = \bar{\pi}_1(q_1)$.
(4) If $h(a) \neq 0$ then rejects.
(5) If $\sigma(a) \neq a_1$ then rejects.
(6) Otherwise accepts.

We call s, s_1 the *proof sizes* for V_{outer} and r_1 the *randomness* of V_{outer}. Both s and s_1 are bounded above by 2^{r_1}.

Recall that by the conventions in section 2, $\mathtt{ACC}[V_{\text{outer}}^{\bar{\pi},\bar{\pi}_1}(x)]$ denotes the probability, over the choice of R_1, that V_{outer} accepts, and $\mathtt{ACC}[V_{\text{outer}}(x)]$ denotes the maximum of $\mathtt{ACC}[V_{\text{outer}}^{\bar{\pi},\bar{\pi}_1}(x)]$ over all possible proofs $\bar{\pi}, \bar{\pi}_1$.

DEFINITION 3.7 (goodness of outer verifier). *Outer verifier* V_{outer} *is* ϵ-good *for language* L *if for all* x *it is the case that*
(1) $x \in L$ *implies* $\mathtt{ACC}[V_{\text{outer}}(x)] = 1$.
(2) $x \notin L$ *implies* $\mathtt{ACC}[V_{\text{outer}}(x)] \leq \epsilon$.

Employing the FRS method [44] to any PCP(log,O(1)) system for NP (e.g., [8]) one gets a canonical verifier which is δ-good for some $\delta < 1$. (Roughly, the method is to take the given pcp system, send all queries to one oracle, and, as a check, send a random query to the other oracle.) Using the parallel repetition theorem of Raz [79], we obtain our starting point.

LEMMA 3.8 (construction of outer verifiers). *Let* $L \in$ NP. *Then for every* $\epsilon > 0$ *there exist positive integers* l, l_1 *and* c *such that there exists an* (l, l_1)-*canonical outer verifier which is* ϵ-*good for* L *and uses randomness* $r(n) = c \log_2 n$.

Actually, Raz's theorem [79] enables one to assert that l, l_1 and c are $O(\log \epsilon^{-1})$; but we will not need this fact. Also, the function σ determined by this verifier is always a projection, but we don't use this fact either.

3.4.2. Inner verifiers. Inner verifiers are designed to efficiently verify that the encoding of answers, which a (canonical) outer verifier expects to see, indeed satisfies the checks which this outer verifier performs. Typically, the inner verifier performs a combination of a codeword test (i.e., tests that each oracle is indeed a proper encoding relative to a fixed code—in our case the long code), a projection test (i.e., that the decoding of the second answer corresponds to the value of σ applied to the decoding

of the first), and a "circuit test" (i.e., that the decoding of the first answer evaluates to 0 under the function h).

Let $r_2, l, l_1 \in \mathcal{Z}^+$. An (l, l_1)-*canonical inner verifier* V_{inner} takes as inputs functions $\sigma\colon \Sigma^l \to \Sigma^{l_1}$ and $h \in \mathcal{F}_l$. (It may also take additional inputs, depending on the context.) It has oracle access to a pair of functions $A\colon \mathcal{F}_l \to \Sigma$ and $A_1\colon \mathcal{F}_{l_1} \to \Sigma$ and uses r_2 random bits. The parameters $\delta_1, \delta_2 > 0$ in the following should be thought of as extremely small: in our constructions, they are essentially 0 (see comment below).

DEFINITION 3.9 (goodness of inner verifier). *An inner verifier* V_{inner} *is* $(\rho, \delta_1, \delta_2)$-good *if, for all* σ, h *as above, the following hold.*

(1) *Suppose* $a \in \Sigma^l$ *is such that* $h(a) = 0$. *Let* $a_1 = \sigma(a) \in \Sigma^{l_1}$. *Then*

$$\mathtt{ACC}\left[\, V_{\text{inner}}^{E_a, E_{a_1}}(\sigma, h)\,\right] = 1\ .$$

(2) *Suppose* A, A_1 *are such that* $\mathtt{ACC}\left[\, V_{\text{inner}}^{A, A_1}(\sigma, h)\,\right] \geq \rho$. *Then there exists* $a \in \Sigma^l$ *such that*

(2.1) $\text{Dist}(A_{(h,0),(\bar{1},1)}, E_a) < 1/2 - \delta_1$.

(2.2) $\text{Dist}(A_1, E_{\sigma(a)}) < 1/2 - \delta_2$.

We stress that, although the inner verifier has access to the oracle A (and the hypothesis in condition (2) of Definition 3.9 refers to its computations with oracle A), the conclusion in condition (2.1) refers to A folded over both $(h, 0)$ and $(\bar{1}, 1)$, where $\bar{1}$ is the constant-one function. (Typically, but not necessarily, the verifier satisfying Definition 3.9 accesses the virtual oracle $A_{(h,0),(\bar{1},1)}$ by actual access to A according to the definition of folding.) Furthermore, by Proposition 3.6, condition (2.1) implies that $h(a) = 0$. (Thus, there is no need to explicitly require that $h(a) = 0$ in order to make Theorem 3.12 work.) We comment that the upper bounds in conditions (2.1) and (2.2) are chosen to be the largest ones which still allow us to prove Theorem 3.12 (below). Clearly, the complexity of the inner verifier decreases as these bounds increase. This is the reason for setting δ_1 and δ_2 to be extremely small. We stress that this optimization is important for the MaxSNP results but not for the MaxClique result. In the latter case, we can use δ_i's greater than $\frac{1}{4}$ which simplifies a little the analysis of the composition of verifiers (below).

Remark 3.10 (a tedious one). The above definition allows h to be identically zero (although this case never occurs in our constructions nor in any other reasonable application). This is the reason that we had to define folding over (0,0) as well. An alternative approach would have been to require $h \not\equiv 0$ and assert that this is the case with respect to the outer verifier of Lemma 3.8.

3.4.3. Composition of verifiers. We now describe the *canonical* composition of a (canonical) outer verifier with a corresponding (canonical) inner verifier. Let V_{outer} be an (l, l_1)-canonical outer verifier with randomness r_1 and proof sizes s, s_1. Let V_{inner} be an (l, l_1)-canonical inner verifier with randomness r_2. Their composed verifier $\langle V_{\text{outer}}, V_{\text{inner}}\rangle$ takes as input $x \in \Sigma^n$ and has oracle access to proofs $\pi\colon [s(n)] \times \mathcal{F}_l \to \Sigma$ and $\pi_1\colon [s_1(n)] \times \mathcal{F}_{l_1} \to \Sigma$. It behaves as follows:

—Picks random strings for both V_{outer} and V_{inner}; namely, picks a random string R_1 of length $r_1(n)$ and a random string R_2 of length $r_2(n)$.

—Computes queries q and q_1 and functions σ and h as V_{outer} would compute them given x, R_1.

—Outputs $V_{\text{inner}}^{A, A_1}(\sigma, h; R_2)$, where $A(\cdot) = \pi(q, \cdot)$ and $A_1(\cdot) = \pi_1(q_1, \cdot)$.

The randomness complexity of the composed verifier is $r_1 + r_2$ whereas its query and free-bit complexities equal those of V_{inner}.

We show how the composed verifier $\langle V_{\text{outer}}, V_{\text{inner}}\rangle$ inherits the goodness of the V_{outer} and V_{inner}. To do so we need the following lemma. It is the counterpart of a claim in [21, Lemma 3.5] and will be used in the same way. The lemma is derived from a coding theory bound which is a slight extension of the bounds in [73, Chap. 7] (see Appendix).

LEMMA 3.11. *Suppose* $0 < \delta \leq 1/2$ *and* $A\colon \mathcal{F}_l \to \Sigma$. *Then there are at most* $1/(4\delta^2)$ *codewords that have distance less than* $1/2 - \delta$ *from* A. *That is,*

$$\left|\{\, a \in \Sigma^l \,:\, \text{Dist}(A, E_a) \leq 1/2 - \delta \,\}\right| \;\leq\; \frac{1}{4\delta^2}\,.$$

Furthermore, for $\delta > 1/4$ *the above set contains at most one string.*

Proof. We know that E_a is linear for any a (cf. Proposition 3.2). So it suffices to upper bound the size of the set

$$\mathcal{A} \;=\; \{\, X \in \mathit{Lin}(\mathcal{F}_l, \Sigma) \,:\, \text{Dist}(A, X) \leq 1/2 - \delta \,\}\,.$$

This set has the same size as

$$\mathcal{B} \;=\; \{\, X - A \,:\, X \in \mathit{Lin}(\mathcal{F}_l, \Sigma) \text{ and } \text{Dist}(A, X) \leq 1/2 - \delta \,\}\,.$$

Let $n = 2^{2^l}$ and identify $\mathsf{Map}(\mathcal{F}_l, \Sigma)$ with Σ^n in the natural way. Let $w(\cdot)$ denote the Hamming weight. Now note that $Z = X - A \in \mathcal{B}$ implies $w(Z)/n = \text{Dist}(X, A) \leq 1/2 - \delta$. Furthermore, if $Z_1 = X_1 - A$ and $Z_2 = X_2 - A$ are in $\mathcal{B}$, then $\text{Dist}(Z_1, Z_2) = \text{Dist}(X_1, X_2)$ and the latter is $1/2$ if $X_1 \neq X_2$, since X_1, X_2 are linear. Thus, $\mathcal{B}$ is a set of binary vectors of length n, each of weight at most $(0.5 - \delta)n$, and any two of distance at least $0.5n$ apart. Invoking Lemma A.1 (with $\alpha = \delta$ and $\beta = 0$), we upper bound the size of $\mathcal{B}$ as desired. Finally, when $\delta > 1/4$, the triangle inequality implies that we cannot have $a_1 \neq a_2$ so that $\text{Dist}(A, E_{a_i}) \leq 1/2 - \delta < 1/4$ for both $i = 1, 2$. □

In some applications of the following theorem, $\delta_1, \delta_2 > 0$ will first be chosen to be so small that they may effectively be thought of as 0. (This is done in order to lower the complexities of the inner verifiers.) Once the δ_i's are fixed, ϵ will be chosen to be so much smaller (than the δ_i's) that $\epsilon/(16\delta_1^2\delta_2^2)$ may be thought of as effectively 0. The latter explains why we are interested in outer verifiers which achieve a constant, but arbitrarily small, error ϵ. For completeness we provide a proof following the ideas of [9, 8, 21].

THEOREM 3.12 (the composition theorem). *Let* V_{outer} *be an* (l, l_1)*-canonical outer verifier. Suppose it is* ϵ*-good for* L. *Let* V_{inner} *be an* (l, l_1)*-canonical inner verifier that is* $(\rho, \delta_1, \delta_2)$*-good. Let* $V = \langle V_{\text{outer}}, V_{\text{inner}}\rangle$ *be the composed verifier, and let* $x \in \Sigma^*$. *Then*

(1) *if* $x \in L$, *then* $\mathtt{ACC}[\,V(x)\,] = 1$.

(2) *if* $x \notin L$, *then* $\mathtt{ACC}[\,V(x)\,] \leq \rho + \epsilon/16\delta_1^2\delta_2^2$.

For $\delta_1, \delta_2 > 1/4$ *the upper bound in* (2) *can be improved to* $\rho + \epsilon$.

The latter case (i.e., $\delta_1, \delta_2 > 1/4$) suffices for the MaxClique results.

Proof. Let $n = |x|$, and let s, s_1 denote the proof sizes of V_{outer}.

Suppose $x \in L$. By Definition 3.7 there exist proofs $\bar{\pi}\colon [s(n)] \to \Sigma^l$ and $\bar{\pi}_1\colon [s_1(n)] \to \Sigma^{l_1}$ such that $\mathtt{ACC}[\,V_{\text{outer}}^{\bar{\pi},\bar{\pi}_1}(x)\,] = 1$. Let $\pi\colon [s(n)] \times \mathcal{F}_l \to \Sigma$ be defined by $\pi(q, f) = E_{\bar{\pi}(q)}(f)$. (In other words, replace the l bit string $\bar{\pi}(q)$ with its 2^{2^l} bit encoding under the long code, and let the new proof provide access to the bits in this encoding). Similarly let $\pi_1\colon [s_1(n)] \times \mathcal{F}_{l_1} \to \Sigma$ be defined by $\pi_1(q_1, f_1) = E_{\bar{\pi}_1(q_1)}(f_1)$.

The reader may easily verify that the item (1) properties in Definitions 3.7 and 3.9 (of the outer and inner verifiers, respectively) imply that $\mathtt{ACC}[\,V^{\pi,\pi_1}(x)\,] = 1$.

Now suppose $x \notin L$. Let $\pi\colon [s(n)] \times \mathcal{F}_l \to \Sigma$ and let $\pi_1\colon [s_1(n)] \times \mathcal{F}_{l_1} \to \Sigma$ be proof strings for V. We will show that $\mathtt{ACC}[\,V^{\pi,\pi_1}(x)\,] \le \rho + \epsilon/(16\delta_1^2\delta_2^2)$. Since π, π_1 are arbitrary, this will complete the proof.

We set $N_1 = \lfloor 1/(4\delta_1^2) \rfloor$ and $N_2 = \lfloor 1/(4\delta_2^2) \rfloor$ (with $N_1 = 1$ if $\delta_1 > 1/4$ and $N_2 = 1$ if $\delta_2 > 1/4$). The idea to show $\mathtt{ACC}[\,V^{\pi,\pi_1}(x)\,] \le \rho + N_1 N_2 \cdot \epsilon$ is as follows. We will first define a collection of N_1 proofs $\bar\pi^1, \ldots, \bar\pi^{N_1}$ and a collection of N_2 proofs $\bar\pi_1^1, \ldots, \bar\pi_1^{N_2}$ so that each pair $(\bar\pi^i, \bar\pi_1^j)$ is a pair of oracles for the *outer* verifier. Next we will partition the random strings R_1 of the *outer* verifier into two categories, depending on the performance of the *inner* verifier on the inputs (i.e., the functions σ, h and the oracles A, A_1) induced by R_1. On the "bad" random strings of the *outer* verifier, the *inner* verifier will accept with probability at most ρ; on the "good" ones, we will use the soundness of the *inner* verifier to infer that the *outer* verifier accepts under some oracle pair $(\bar\pi^i, \bar\pi_1^j)$, for $i \in [N_1]$ and $j \in [N_2]$. The soundness of the *outer* verifier will be used to bound the probability of such acceptances.

We now turn to the actual analysis. We define N_1 proofs $\bar\pi^1, \ldots, \bar\pi^{N_1}\colon [s(n)] \to \Sigma^l$ as follows. Fix $q \in [s(n)]$ and let $A = \pi(q, \cdot)$. Let $B_q = \{a \in \Sigma^l : \mathrm{Dist}(A_{(h,0),(\bar 1,1)}, E_a) \le 1/2 - \delta_1\}$. (Notice that for this set to be well defined we use the fact that h is well defined given q.) Note that $|B_q| \le N_1$ by Lemma 3.11. Order the elements of B_q in some canonical way, adding dummy elements to bring the number to exactly N_1, so that they can be written as $a^1(q), \ldots, a^{N_1}(q)$. Now set $\bar\pi^i(q) = a^i(q)$ for $i = 1, \ldots, N_1$. In a similar fashion we define $\bar\pi_1^j(q_1) = a_1^j(q_1)$ for $j = 1, \ldots, N_2$, where each $a_1^j = a_1^j(q_1)$ satisfies $\mathrm{Dist}(\pi_1(q_1, \cdot), E_{a_1^j}) \le 1/2 - \delta_2$.

Let R_1 be a random string of V_{outer}. We say that R_1 is *good* if

$$\mathtt{ACC}[\,V_{\mathrm{inner}}^{\pi(q,\cdot),\pi_1(q_1,\cdot)}(\sigma, h)\,] \;\ge\; \rho\,,$$

where q, q_1, σ, h are the queries and functions specified by R_1. If R_1 is not good we say it is *bad*. The claim that follows says that if R_1 is good then there is some choice of the above defined proofs which leads the outer verifier to accept on coins R_1.

CLAIM. *Suppose R_1 is good. Then there is an $i \in [N_1]$ and a $j \in [N_2]$ such that $V_{\mathrm{outer}}^{\bar\pi^i, \bar\pi_1^j}(x; R_1) = 0$.*

Proof. Let q, q_1, σ, h be the queries and functions specified by R_1. Let $A = \pi(q, \cdot)$ and $A_1 = \pi_1(q_1, \cdot)$ (be the oracles accessed by the inner verifier). Since R_1 is good we have $\mathtt{ACC}[\,V_{\mathrm{inner}}^{A,A_1}(\sigma, h)\,] \ge \rho$. So by item 2 of Definition 3.9 there exists $a \in \Sigma^l$ such that $\mathrm{Dist}(A_{(h,0),(\bar 1,1)}, E_a) < 1/2 - \delta_1$ and $\mathrm{Dist}(A_1, E_{\sigma(a)}) < 1/2 - \delta_2$. Let $a_1 = \sigma(a)$. Since $\mathrm{Dist}(A_{(h,0),(\bar 1,1)}, E_a) \le 1/2 - \delta_1$ it must be the case that $a \in B_q$, and hence there exists $i \in [N_1]$ such that $a = \bar\pi^i(q)$. Similarly $\mathrm{Dist}(A_1, E_{\sigma(a)}) < 1/2 - \delta$ implies that there is some $j \in [N]$ such that $a_1 = \bar\pi_1^j(q_1)$. By Proposition 3.6 we have $h(a) = 0$, and we have $\sigma(a) = a_1$ by (the above) definition. Now, by definition of the (execution of the) canonical outer verifier, $V_{\mathrm{outer}}^{\bar\pi^i, \bar\pi_1^j}(x; R_1) = 0$ holds. □

By conditioning we have $\mathtt{ACC}[\,V^{\pi,\pi_1}(x)\,] \le \alpha + \beta$, where

$$\alpha = \Pr_{R_1}[R_1 \text{ is good}],$$
$$\beta = \Pr_{R_1,R_2}[\,V^{\pi,\pi_1}(x; R_1 R_2) = 0 \mid R_1 \text{ is bad}\,]\,.$$

The definition of badness of R_1 implies $\beta \le \rho$. On the other hand, we can use the

claim to see that

$$\begin{aligned}\alpha &\le \Pr_{R_1}\left[\exists i \in [N_1]\ ,\ j \in [N_2]\ :\ V_{\text{outer}}^{\bar{\pi}^i,\bar{\pi}_1^j}(x;R_1)=0\right]\\ &\le \textstyle\sum_{i=1}^{N_1}\sum_{j=1}^{N_2}\Pr_{R_1}\left[V_{\text{outer}}^{\bar{\pi}^i,\bar{\pi}_1^j}(x;R_1)=0\right]\\ &\le N_1N_2\cdot\epsilon\ ,\end{aligned}$$

where the last inequality holds by the soundness of V_{outer} (i.e., item 2 of Definition 3.7). Using the bound on N_1 and N_2, the proof is concluded. □

3.5. The atomic tests.

MOTIVATION. Our constructions of proofs systems will use the outer verifier of Lemma 3.8, composed via Theorem 3.12 with inner verifiers to be constructed. The brunt of our constructions is the construction of appropriate inner verifiers. The inner verifier will have oracle access to a function $A\colon \mathcal{F}_l \to \Sigma$ and a function $A_1\colon \mathcal{F}_{l_1} \to \Sigma$. In all of our applications, A is supposed to be a folding of an encoding of the answer a of the first prover (in a two-prover proof system) and A_1 is supposed to be the encoding of the answer a_1 of the second prover. The verifier will perform various tests to determine whether these claims are true. The design of these tests is the subject of this subsection.

The atomic tests we provide here will be used directly in the proof systems for showing nonapproximability of Max3SAT, Max2SAT, and MaxCUT. Furthermore, they are also the basis of iterated tests which will lead to proof systems of amortized free-bit complexity ≈ 2, which in turn are used for the MaxClique and Chromatic Number results. We remark that for the applications to the above-mentioned MaxSNP problems (but not for the application to MaxClique) it is important to have the best possible analysis of our atomic tests, and what follows strives to this end. We stress that the exposition and analysis of these tests, in this subsection, are independent of the usage of the codes in our proof systems.

TESTING FOR A CODEWORD. The first task that concerns us is to design a test which, with high probability, passes if and only if A is close to an evaluation operator (i.e., a valid codeword). The idea is to exploit the characterization of Proposition 3.2. Thus we will perform (on A) a linearity test and then a "respect of monomial basis" (RMB) test. Linearity testing is well understood, and we will use the test of [27] with the analyses of [27, 21, 17]. The main novelty is the respect of monomial basis test.

CIRCUIT AND PROJECTION. Having established that A is close to some evaluation operator E_a, we now want to test two things. The first is that $h(a) = 0$ for some predetermined function h. This test which would normally be implemented by "self-correction" (i.e., evaluating $h(a)$ by uniformly selecting $f \in \mathcal{F}_l$ and computing $A(f + h) - A(f)$) is not needed here since in our applications we will use an $(h, 0)$-folding of A instead of A. Thus, it is left to test that the two oracles are consistent in the sense that A_1 is not too far from an evaluation operator which corresponds to $\sigma(a)$ for some predetermined function σ.

SELF-CORRECTION. The following self-correction lemma is due to [27] and will be used throughout.

LEMMA 3.13 (self-correction lemma [27]). *Let $A, \tilde{A}\colon \mathcal{F}_l \to \Sigma$ with $\tilde{A}$ linear, and let $x = \text{Dist}(A, \tilde{A})$. Then for every $g \in \mathcal{F}_l$,*

$$\Pr_{f \overset{R}{\leftarrow} \mathcal{F}_l}\left[A(f+g) - A(f) = \tilde{A}(g)\right] \ \ge\ 1 - 2x\ .$$

The atomic tests. Here $A\colon \mathcal{F}_l \to \Sigma$ and $A_1\colon \mathcal{F}_{l_1} \to \Sigma$ are the objects being tested. The tests also take additional inputs or parameters: below $f, f_1, f_2, f_3 \in \mathcal{F}_l$; $g \in \mathcal{F}_{l_1}^m$; and $\sigma\colon \Sigma^l \to \Sigma^{l_1}$.

LinTest$(A; f_1, f_2)$ (Linearity Test).
If $A(f_1) + A(f_2) = A(f_1 + f_2)$, then output 0 else output 1.

MBTest$(A; f_1, f_2, f_3)$ (Respecting-Monomial-Basis Test).
If $A(f_1) = 0$, then check if $A(f_1 \cdot f_2 + f_3) = A(f_3)$.
Otherwise (i.e., $A(f_1) = 1$) then check if $A(f_1 \cdot f_2 + f_2 + f_3) = A(f_3)$.
Output 0 if the relevant check succeeded, else output 1.

ProjTest$_\sigma(A, A_1; f, g)$ (Projection Test).
If $A_1(g) = A(g \circ \sigma + f) - A(f)$, then output 0, else output 1.

The passing probabilities. These are the probabilities we are interested in:

$$\begin{aligned}
\textsc{LinPass}(A) &= \Pr_{f_1, f_2 \overset{R}{\leftarrow} \mathcal{F}_l}[\,\mathbf{LinTest}(A; f_1, f_2) = 0\,],\\
\textsc{MBPass}(A) &= \Pr_{f_1, f_2, f_3 \overset{R}{\leftarrow} \mathcal{F}_l}[\,\mathbf{MBTest}(A; f_1, f_2, f_3) = 0\,],\\
\textsc{ProjPass}_\sigma(A, A_1) &= \Pr_{f \overset{R}{\leftarrow} \mathcal{F}_l\,;\, g \overset{R}{\leftarrow} \mathcal{F}_{l_1}}[\,\mathbf{ProjTest}_\sigma(A, A_1; f, g) = 0\,].
\end{aligned}$$

FIG. 8. *The atomic tests and their passing probabilities.*

Proof.

$$\begin{aligned}
&\Pr_{f \overset{R}{\leftarrow} \mathcal{F}_l}\left[A(f+g) - A(f) = \tilde{A}(g)\right]\\
&\geq \Pr_{f \overset{R}{\leftarrow} \mathcal{F}_l}\left[A(f+g) = \tilde{A}(f+g) \ \text{ and } \ A(f) = \tilde{A}(f)\right]\\
&\geq 1 - \left(\Pr_{f \overset{R}{\leftarrow} \mathcal{F}_l}\left[A(f+g) \neq \tilde{A}(f+g)\right] + \Pr_{f \overset{R}{\leftarrow} \mathcal{F}_l}\left[A(f) \neq \tilde{A}(f)\right]\right).
\end{aligned}$$

However, each of the probabilities in the last expression equals x. □

COROLLARY 3.14. *Let $A, \tilde{A}\colon \mathcal{F}_l \to \Sigma$ with $\tilde{A}$ linear, and suppose $x \overset{\text{def}}{=} \text{Dist}(A, \tilde{A}) < 1/2$. Suppose also that $A(f + h) = A(f) + b$, for some fixed $h \in \mathcal{F}_l$, $b \in \Sigma$, and every $f \in \mathcal{F}_l$. Then $\tilde{A}(h) = b$.*

Proof. By the hypothesis, we have $A(f + h) - A(f) = b$ for all functions f. Thus, we can write

$$\Pr_{f \overset{R}{\leftarrow} \mathcal{F}_l}\left[A(f+h) - A(f) = \tilde{A}(h)\right] \;=\; \Pr_{f \overset{R}{\leftarrow} \mathcal{F}_l}\left[b = \tilde{A}(h)\right],$$

but the right-hand side (and hence the left) is either 0 or 1 (as both h and b are fixed). However, by Lemma 3.13 the left-hand side is bounded below by $1 - 2x > 0$ and so the corollary follows. □

CONVENTION. All our tests output a bit with 0 standing for accept and 1 for reject.

3.5.1. Atomic linearity test. The *atomic linearity test* shown in Figure 8 is the one of Blum, Luby, and Rubinfeld [27]. We want to lower bound the probability $1 - \textsc{LinPass}(A)$ that the test rejects, when its inputs f_1, f_2 are chosen at random, as

a function of $x = \mathrm{Dist}(A, \textsc{Lin})$. The following lemma, due to Bellare et. al. [17], gives the best known lower bound.

LEMMA 3.15 (see [17]). *Let $A\colon \mathcal{F}_l \to \Sigma$ and let $x = \mathrm{Dist}(A, \textsc{Lin})$. Then $1 - \textsc{LinPass}(A) \geq \Gamma_{\mathrm{lin}}(x)$, where the function $\Gamma_{\mathrm{lin}}\colon [0, 1/2] \to [0, 1]$ is defined as follows:*

$$\Gamma_{\mathrm{lin}}(x) \stackrel{\mathrm{def}}{=} \begin{cases} 3x - 6x^2 & 0 \leq x \leq 5/16, \\ 45/128 & 5/16 \leq x \leq 45/128, \\ x & 45/128 \leq x \leq 1/2. \end{cases}$$

The above lower bound is composed of three different bounds with "phase transitions" at $x = \frac{5}{16}$ and $x = \frac{45}{128}$. It was shown in [17] (see below) that this combined lower bound is close to the best one possible.

PERSPECTIVE. The general problem of linearity testing as introduced and studied by Blum, Luby, and Rubinfeld [27] is stated as follows. Given a function $A\colon G \to H$, where G, H are groups, obtain a lower bound on r_A as a function of x_A, where

$$r_A = \Pr_{a,b \stackrel{R}{\leftarrow} G}[A(a) + A(b) \neq A(a + b)]$$
$$x_A = \mathrm{Dist}(A, \textsc{Lin}) .$$

Blum, Luby, and Rubinfeld showed that $r_A \geq \frac{2}{9} x_A$, for every A. Their analysis was used in the proof system and Max3SAT nonapproximability result of [8]. Interest in the tightness of the analysis began with Bellare et al. [21], with the motivation of improving the Max3SAT nonapproximability results. They showed that $r_A \geq 3x_A - 6x_A^2$, for every A. This establishes the first segment of the lower bound quoted above (i.e., of the function Γ_{lin}). Also, it is possible to use [27] to show that $r_A \geq \frac{2}{9}$ when $x_A \geq \frac{1}{4}$. Putting these together implies a two-segment lower bound with phase transition at the largest root of the equation $3x - 6x^2 = \frac{2}{9}$ (i.e., at $\frac{1}{4} + \frac{\sqrt{33}}{36}$). This lower bound was used in the Max3SAT analyses of [21] and [23].

However, for our applications (i.e., linearity testing over $\mathcal{F}_l$ as in Lemma 3.15), the case of interest is when the underlying groups are $G = \mathrm{GF}(2)^n$ and $H = \mathrm{GF}(2)$ (since $\mathcal{F}_l$ may be identified with $\mathrm{GF}(2)^n$ for $n = 2^l$). The work of Bellare et al. [17] focused on this case and improved the bound on r_A for the case $x_A \geq \frac{1}{4}$, where $A\colon \mathrm{GF}(2)^n \to \mathrm{GF}(2)$. Specifically, they showed that $r_A \geq 45/128$ for $x_A \geq \frac{1}{4}$ which establishes the second segment of Γ_{lin}. They also showed that $r_A \geq x_A$, for every $A\colon \mathrm{GF}(2)^n \to \mathrm{GF}(2)$. Combining the three lower bounds, they have derived the three-segment lower bound stated in Lemma 3.15.

The optimality of the above analysis has been demonstrated as well in [17]. Essentially,[5] for every $x \leq \frac{5}{16}$ there are functions $A\colon \mathrm{GF}(2)^n \to \mathrm{GF}(2)$ witnessing $r_A = \Gamma_{\mathrm{lin}}(x_A)$ with $x_A = x$. For the interval $(\frac{5}{16}, 1/2]$, no tight results are known. Instead, Bellare et al. [17] reports of computer constructed examples of functions $A\colon \mathrm{GF}(2)^n \to \mathrm{GF}(2)$ with x_A in every interval $[\frac{k}{100}, \frac{k+1}{100}]$, for $k = 32, 33, \ldots, 49$, and $r_A < \Gamma_{\mathrm{lin}}(x_A) + \frac{1}{20}$. Furthermore, they showed that there exist such functions with both x_A and r_A arbitrarily close to $1/2$.

3.5.2. Monomial basis test. Having determined that A is close to linear, the *atomic respect of monomial basis* test makes sure that the linear function close to A respects the monomial basis. Let us denote the latter function (i.e., the linear function closest to A) by $\tilde{A}$. Recalling Definition 3.1 we need to establish two things, namely, that $\tilde{A}(\chi_\emptyset) = 1$ and that $\tilde{A}(\chi_S) \cdot \tilde{A}(\chi_T) = \tilde{A}(\chi_{S \cup T})$, for every $S, T \subseteq [l]$. Recall that we do not have access to $\tilde{A}$ but rather to A; still, the self-correction lemma provides

[5] Actually, the statement holds only for x's which are integral multiples of 2^{-n}.

an obvious avenue to bypass the difficulty provided $\mathrm{Dist}(A, \tilde{A}) < \frac{1}{4}$. This would have yielded a solution, but quite a wasteful one (though sufficient for the MaxClique and Chromatic Number results). Instead, we adopt the following more efficient procedure.

Firstly, by considering only oracles folded over $(\bar{1}, 1)$, we need not check that $\tilde{A}(\chi_\emptyset) = 1$. (This follows by combining Corollary 3.14 and the fact that the $(\bar{1}, 1)$-folded oracle A satisfies $A(f + \bar{1}) = A(f) + 1$, for all $f \in \mathcal{F}_l$.) Secondly, we test that $\tilde{A}(\chi_S) \cdot \tilde{A}(\chi_T) = \tilde{A}(\chi_{S \cup T})$, for every $S, T \subseteq [l]$, by taking random linear combinations of the S's and T's to be tested. Such linear combinations are nothing but uniformly selected functions in $\mathcal{F}_l$. Namely, we wish to test $\tilde{A}(f) \cdot \tilde{A}(g) = \tilde{A}(f \cdot g)$, where f and g are uniformly selected in $\mathcal{F}_l$. Since A is close to $\tilde{A}$, we can inspect $A(f)$ (resp., $A(g)$) rather than $\tilde{A}(f)$ (resp., $\tilde{A}(g)$) with little harm. However, $f \cdot g$ is not uniformly distributed (when f and g are uniformly selected in $\mathcal{F}_l$) and thus self-correction will be applied here. The resulting test is

$$A(f_1) \cdot A(f_2) = A(f_1 \cdot f_2 + f_3) - A(f_3). \tag{7}$$

This test was analyzed in a previous version of this work [20]; specifically, this test was shown to reject a folded oracle A, with $\tilde{A}$ (the linear function closest to A) which does not respect the monomial basis, with probability at least $(1-2x) \cdot (\frac{3}{8} - x + \frac{x^2}{2}) = \frac{3}{8} - \frac{7}{4}x + \frac{5}{2}x^2 - x^3$, where $x = \mathrm{Dist}(A, \tilde{A})$. Here we present an adaptive version of the above test, which performs even better. We observe that if $A(f_1) = 0$, then there is no need to fetch $A(f_2)$ (since the left-hand side of Eq. (7) is zero regardless of $A(f_2)$). Thus, we merely test whether $A(f_1 \cdot f_2 + f_3) - A(f_3) = 0$. But what should be done if $A(f_1) = 1$? In this case we may replace f_1 by $f_1 + \bar{1}$ (yielding $A(f_1 + \bar{1}) = A(f_1) + 1 = 0$) and test whether $A((f_1 + \bar{1}) \cdot f_2 + f_3) - A(f_3) = 0$. The resulting test is depicted in Figure 8.

A TECHNICAL LEMMA. First we recall the following lemma of [21] which provides an improved analysis of Freivalds' matrix multiplication test in the special case when the matrices are symmetric with common diagonal.

LEMMA 3.16 (symmetric matrix multiplication test [21]). *Let M_1, M_2 be N-by-N symmetric matrices over Σ which agree on their diagonals. Suppose that $M_1 \neq M_2$. Then*

$$\Pr_{x,y \stackrel{R}{\leftarrow} \Sigma^N} [xM_1y \neq xM_2y] \geq \frac{3}{8}.$$

Furthermore, $\Pr_{x \stackrel{R}{\leftarrow} \Sigma^N} [xM_1 \neq xM_2] \geq 3/4$.

Proof. Let $M \stackrel{\mathrm{def}}{=} M_1 - M_2$. The probability that a uniformly selected combination of the rows of M yields an all-zero vector is 2^{-r}, where r is the rank of M. Since M is symmetric, not identically zero and has a zero diagonal, it must have rank at least 2. Thus, $\Pr_{x \stackrel{R}{\leftarrow} \Sigma^N} \left[xM \neq 0^N\right] \geq 3/4$ and the lemma follows. □

RMB DETECTORS. Suppose that A is actually linear. In that case, the following lemma provides a condition under which A respects the monomial basis. We start with a definition.

DEFINITION 3.17 (RMB detector). *Let A: $\mathcal{F}_l \to \Sigma$ and $f \in \mathcal{F}_l$. We say that f is a* detector for A *if*

$$\Pr_{g \stackrel{R}{\leftarrow} \mathcal{F}_l} [A(f' \cdot g) \neq 0] \geq 1/2,$$

where $f' = f$ if $A(f) = 0$ and $f' = f + \bar{1}$ otherwise.

The number of detectors is clearly related to the rejection probability of the RMB test. Suppose that A (or rather $\tilde{A}$) is linear. Clearly, if A respects the monomial basis, then it has no detectors. On the other hand, the following lemma asserts that if A does not respect the monomial basis, then it has many detectors.

LEMMA 3.18 (RMB test for linear functions). *Suppose $\tilde{A}\colon \mathcal{F}_l \to \Sigma$ is linear, $\tilde{A}(\chi_\emptyset) = 1$, and $\tilde{A}$ does not respect the monomial basis. Then at least a $3/4$ fraction of the functions in $\mathcal{F}_l$ are detectors for $\tilde{A}$.*

Proof. Let $N = 2^l$. We define a pair of N-by-N matrices whose rows and columns are indexed by the subsets of $[l]$. Specifically, for $S, T \subseteq [l]$, we set

$$M_1[S,T] = \tilde{A}(\chi_S) \cdot \tilde{A}(\chi_T),$$
$$M_2[S,T] = \tilde{A}(\chi_{S \cup T})\ .$$

Clearly, both M_1 and M_2 are symmetric, and they agree on the diagonal. Using $\tilde{A}(\chi_\emptyset) = 1$ we have, for every $T \subseteq [l]$,

$$M_1[\emptyset, T] = \tilde{A}(\chi_\emptyset) \cdot \tilde{A}(\chi_T) = 1 \cdot \tilde{A}(\chi_T) = M_2[\emptyset, T]. \tag{8}$$

By the hypothesis that $\tilde{A}$ does not respects the monomial basis, it follows that $M_1 \neq M_2$. Our aim is to relate the inequality of the above matrices to the existence of detectors for $\tilde{A}$. We first express the condition $\tilde{A}(fg) = \tilde{A}(f) \cdot \tilde{A}(g)$ in terms of these matrices.

Recall that $\mathcal{C}\colon \mathcal{F}_l \to \Sigma^{2^l}$ is the transformation which to any $f \in \mathcal{F}_l$ associates the vector $(\, C_f(S)\,)_{S \subseteq [l]}$ whose entries are the coefficients of f in its monomial series. Using the linearity of $\tilde{A}$ we note that

$$\begin{aligned}
\tilde{A}(f) \cdot \tilde{A}(g) &= \tilde{A}\left(\textstyle\sum_S C_f(S) \cdot \chi_S\right) \cdot \tilde{A}\left(\textstyle\sum_T C_g(T) \cdot \chi_T\right) \\
&= \left[\textstyle\sum_S C_f(S) \cdot \tilde{A}(\chi_S)\right] \cdot \left[\textstyle\sum_T C_g(T) \cdot \tilde{A}(\chi_T)\right] \\
&= \textstyle\sum_{S,T} C_f(S) \cdot \tilde{A}(\chi_S) \cdot \tilde{A}(\chi_T) \cdot C_g(T) \\
&= \mathcal{C}(f) M_1 \mathcal{C}(g)\ .
\end{aligned}$$

For the next step we first need the following.

Fact. Let $f, g \in \mathcal{F}_l$ and $U \subseteq [l]$. Then $C_{fg}(U) = \sum_{S \cup T = U} C_f(S) \cdot C_g(T)$.

Using this fact (and the linearity of $\tilde{A}$) we have

$$\begin{aligned}
\tilde{A}(fg) &= \tilde{A}\left(\textstyle\sum_U C_{fg}(U) \cdot \chi_U\right) \\
&= \textstyle\sum_U C_{fg}(U) \cdot \tilde{A}(\chi_U) \\
&= \textstyle\sum_U \sum_{S \cup T = U} C_f(S) \cdot C_g(T) \cdot \tilde{A}(\chi_U) \\
&= \textstyle\sum_{S,T} C_f(S) \cdot C_g(T) \cdot \tilde{A}(\chi_{S \cup T}) \\
&= \mathcal{C}(f) M_2 \mathcal{C}(g)\ .
\end{aligned}$$

Since $\tilde{A}$ is linear and $\tilde{A}(\bar{1}) = 1$ (as $\bar{1} = \chi_\emptyset$), we can rephrase the condition $A(f' \cdot g) \neq 0$, where $f' = f$ if $\tilde{A}(f) = 0$ and $f' = f + \bar{1}$ otherwise, as $A(f' \cdot g) \neq A(f') \cdot A(g)$. Thus, for every f (setting f' as above), we conclude that

$$A(f' \cdot g) \neq A(f') \cdot A(g) \quad \text{if and only if} \quad \mathcal{C}(f') M_2 \mathcal{C}(g) \neq \mathcal{C}(f') M_1 \mathcal{C}(g)\,.$$

A key observation is that $\mathcal{C}(f)$ and $\mathcal{C}(f')$ are identical in all entries except, possibly, for the entry corresponding to $\emptyset$ (i.e., $C_f(S) = C_{f'}(S)$ for all $S \neq \emptyset$). On the other hand, by Eq. (8), we have $M_1[\emptyset, \cdot] = M_2[\emptyset, \cdot]$. Thus,

$$A(f' \cdot g) \neq A(f') \cdot A(g) \quad \text{if and only if} \quad \mathcal{C}(f) M_2 \mathcal{C}(g) \neq \mathcal{C}(f) M_1 \mathcal{C}(g)\,.$$

Now we note that $\mathcal{C}$ is a bijection, so that if h is uniformly distributed in $\mathcal{F}_l$ then $\mathcal{C}(h)$ is uniformly distributed in Σ^{2^l}. Fixing any $f \in \mathcal{F}_l$ and setting f' as above, we

have, for $x = \mathcal{C}(f)$,

$$\Pr_{g \stackrel{R}{\leftarrow} \mathcal{F}_l}\left[\tilde{A}(f') \cdot \tilde{A}(g) \;=\; \tilde{A}(f'g)\right] = \Pr_{g \stackrel{R}{\leftarrow} \mathcal{F}_l}\left[\mathcal{C}(f)M_1\mathcal{C}(g) \;=\; \mathcal{C}(f)M_2\mathcal{C}(g)\right]$$
$$= \Pr_{y \stackrel{R}{\leftarrow} \Sigma^{2^l}}\left[xM_1y \;=\; xM_2y\right].$$

The latter probability is $1/2$ if $xM_1 \neq xM_2$ and zero otherwise. Invoking Lemma 3.16 we conclude that the first case, which coincides with f being a detector for $\tilde{A}$, holds for at least a $3/4$ fraction of the $f \in \mathcal{F}_l$. The lemma follows. □

Lemma 3.18 suggests that if we knew A was linear we could test that it respects the monomial basis by picking f, g at random and testing whether $A(f'g) = 0$, where $f' = f$ if $A(f) = 0$ and $f' = f + \bar{1}$ otherwise. The lemma asserts that in case A is linear and does not respect the monomial basis, we will have

$$\Pr_{f,g \stackrel{R}{\leftarrow} \mathcal{F}_l}\left[A(f'g) \neq 0\right] \geq \frac{3}{4} \cdot \frac{1}{2},$$

where $3/4$ is a lower bound on the probability that f is a detector for A and

$$\Pr_{g \stackrel{R}{\leftarrow} \mathcal{F}_l}\left[A(f'g) \neq 0\right] \geq \frac{1}{2}$$

for any detector f (by definition). However, we only know that A is close to linear. Still, we can perform an approximation of the above test via self-correction of the value $A(f'g)$. This, indeed, is our test as indicated in Figure 8.

THE RMB TEST. We are interested in lower bounding the probability $1 - \text{MBPASS}(A)$ that the test rejects, when f_1, f_2, f_3 are chosen at random, as a function of the distance of A to a linear function $\tilde{A}$, given that $\tilde{A}$ does not respect the monomial basis. We assume that A satisfies $A(f + \bar{1}) = A(f) + 1$ (for all $f \in \mathcal{F}_l$), as is the case in all our applications (since we use verifiers which access a $(\bar{1}, 1)$-folded function). The first item of the following lemma is in the spirit of previous analyses of analogous tests. The second item is somewhat unusual and will be used only in our construction of verifiers of free-bit complexity 2 (cf. section 5).

LEMMA 3.19 (RMB test—final analysis). *Let $A, \tilde{A}: \mathcal{F}_l \to \Sigma$ be functions such that $\tilde{A}$ linear but does* NOT *respect the monomial basis. Let $x = \text{Dist}(A, \tilde{A})$. Suppose that the function A satisfies $A(f + \bar{1}) = A(f) + 1$, for all $f \in \mathcal{F}_l$. Then*

(1) $1 - \text{MBPASS}(A) \;\geq\; \Gamma_{\text{RMB}}(x) \stackrel{\text{def}}{=} \frac{3}{8} \cdot (1 - 2x)$.

(2) $\Pr_{f_1,f_3 \stackrel{R}{\leftarrow} \mathcal{F}_l}\left[\exists f_2 \in \mathcal{F}_l \;\; s.t. \;\; \mathbf{MBTest}(A; f_1, f_2, f_3) = 1\right] \;\geq\; 2 \cdot \Gamma_{\text{RMB}}(x)$.

In particular, the lemma holds for $A_{(h,0),(\bar{1},1)}$, where $A: \mathcal{F}_l \to \Sigma$ is arbitrary and $h \in \mathcal{F}_l$. We will consider the linear function closest to $A_{(h,0),(\bar{1},1)}$, denoted $\tilde{A}$, and the case in which $\tilde{A}$ DOES NOT respect the monomial basis. (In this case $\text{Dist}(A_{(h,0),(\bar{1},1)}, \tilde{A})) = \text{Dist}(A_{(h,0),(\bar{1},1)}, \text{LIN}) \leq 1/2$.)

Proof. As a preparation for using Lemma 3.18, we first show that $\tilde{A}(\bar{1}) = 1$. For $x < 1/2$ this is justified by Corollary 3.14 (using the hypothesis $A(f + \bar{1}) = A(f) + 1$, $\forall f \in \mathcal{F}_l$). Otherwise (i.e., in case $x \geq 1/2$) the claimed lower bound (i.e., $\frac{3}{8} \cdot (1 - 2x) \leq 0$) holds vacuously.

Using Lemmas 3.18 and 3.13 we lower bound the rejection probability of the test, $1 - \text{MBPASS}(A)$, as follows:

$$\Pr_{f_1 \stackrel{R}{\leftarrow} \mathcal{F}_l}\left[f_1 \text{ is a detector for } \tilde{A}\right]$$
$$\cdot \min_{f \text{ is a } \tilde{A}\text{-detector}} \left\{\Pr_{f_2,f_3 \stackrel{R}{\leftarrow} \mathcal{F}_l}\left[\mathbf{MBTest}(A; f, f_2, f_3) = 1\right]\right\}$$

$$\geq \frac{3}{4} \cdot \min_{f \text{ is a } \tilde{A}\text{-detector}} \left\{ \Pr_{f_2, f_3 \stackrel{R}{\leftarrow} \mathcal{F}_l} [A(f'f_2 + f_3) \neq A(f_3)] \right\}$$

$$\geq \frac{3}{4} \cdot \min_{f \text{ is a } \tilde{A}\text{-detector}} \left\{ \Pr_{f_2, f_3 \stackrel{R}{\leftarrow} \mathcal{F}_l} \left[0 \neq \tilde{A}(f'f_2) \;=\; A(f'f_2 + f_3) - A(f_3) \right] \right\}$$

$$\geq \frac{3}{4} \cdot \frac{1}{2} \cdot \min_{f',\, g \quad \text{s.t.} \quad \tilde{A}(f'g) \neq 0} \left\{ \Pr_{f_3 \stackrel{R}{\leftarrow} \mathcal{F}_l} \left[\tilde{A}(f' \cdot g) \;=\; A(f' \cdot g + f_3) - A(f_3) \right] \right\}$$

$$\geq \frac{3}{8} \cdot (1 - 2x),$$

where the first inequality uses Lemma 3.18, the third inequality follows by the definition of a detector for $\tilde{A}$ (by which $\Pr_{g \stackrel{R}{\leftarrow} \mathcal{F}_l} \left[\tilde{A}(f'g) \neq 0 \right] \geq 1/2$), and the last inequality follows by Lemma 3.13. This concludes the proof of part 1. Part 2 is proven analogously with the exception that we don't lose a factor of two in the third inequality (since here f_2 is not selected at random but rather set existentially). □

Remark 3.20. An RMB test for arbitrary A's (rather than ones satisfying $A(f + \bar{1}) = A(f) + 1$, $\forall f \in \mathcal{F}_l$) can be derived by augmenting the above test with a test of $A(f + \bar{1}) = A(f) + 1$ for uniformly chosen $f \in \mathcal{F}_l$. The analysis of the augmented part is as in the circuit test (below).

3.5.3. Atomic projection test. The final test checks that the second function A_1 is not too far from the evaluation operator E_{a_1}, where $a_1 = \sigma(a)$ is a function of the string a whose evaluation operator is close to A. Here, unlike previous works (for instance, [23]), σ may be an arbitrary mapping from Σ^l to Σ^{l_1} rather than being a projection (i.e., satisfying $\sigma(x) = x^{(i_1)}, \ldots, x^{(i_{l_1})}$ for some sequence $1 \leq i_1 < \cdots < i_{l_1} \leq l$ and all $x \in \Sigma^l$). Thus, the term "projection test" is adopted for merely historical reasons.

LEMMA 3.21. *Let $A\colon \mathcal{F}_l \to \Sigma$ and let $\sigma\colon \Sigma^l \to \Sigma^{l_1}$ be a function. Let $a \in \Sigma^l$ and let $x = \mathrm{Dist}(A, E_a)$. Let $a_1 = \sigma(a) \in \Sigma^{l_1}$. Then $1 - \textsc{ProjPass}_\sigma(A, A_1) \geq \mathrm{Dist}(A_1, E_{a_1}) \cdot (1 - 2x)$.*

Proof. We lower bound the rejection probability as follows:

$$\begin{aligned}
&\Pr_{f \stackrel{R}{\leftarrow} \mathcal{F}_l \,;\, g \stackrel{R}{\leftarrow} \mathcal{F}_{l_1}} [A_1(g) \neq A(g \circ \sigma + f) - A(f)] \\
&\geq \Pr_{f \stackrel{R}{\leftarrow} \mathcal{F}_l \,;\, g \stackrel{R}{\leftarrow} \mathcal{F}_{l_1}} [A_1(g) \neq E_a(g \circ \sigma) \text{ and } A(g \circ \sigma + f) - A(f) = E_a(g \circ \sigma)] \\
&\geq \Pr_{g \stackrel{R}{\leftarrow} \mathcal{F}_{l_1}} [A_1(g) \neq E_a(g \circ \sigma)] \cdot (1 - 2x) \,.
\end{aligned}$$

Here we used Lemma 3.13 in the last step. Now we note that $E_a(g \circ \sigma) = (g \circ \sigma)(a) = g(\sigma(a)) = E_{a_1}(g)$. Hence the first term in the above product is just

$$\Pr_{g \stackrel{R}{\leftarrow} \mathcal{F}_{l_1}} [A_1(g) \neq E_{a_1}(g)] \;=\; \mathrm{Dist}(A_1, E_{a_1}) \,.$$

This concludes the proof. □

3.5.4. Atomic circuit test. For sake of elegance, we also present an atomic circuit test, denoted $\mathbf{CircTest}_h(A; f)$. The test consists of checking whether $A(h + f) = A(f)$, and it outputs 0 if equality holds and 1 otherwise. Assuming that A is close to some evaluation operator E_a, the atomic circuit test uses self-correction [27] to test that a given function h has value 0 at a. As explained above, this test is not needed since all of our proof systems will use a $(h, 0)$-folding (of A) and thus will

The MaxSNP inner verifier. Given functions $h \in \mathcal{F}_l$ and $\sigma\colon \Sigma^l \to \Sigma^{l_1}$, the verifier has access to oracles for $A\colon \mathcal{F}_l \to \Sigma$ and $A_1\colon \mathcal{F}_{l_1} \to \Sigma$. In addition it takes three $[0,1]$ valued parameters p_1, p_2, and p_3 such that $p_1+p_2+p_3 = 1$.

Pick $p \overset{R}{\leftarrow} [0,1]$.

Case: $p \le p_1$:
Pick $f_1, f_2 \overset{R}{\leftarrow} \mathcal{F}_l$.
LinTest$(A_{(h,0),(\bar{1},1)}; f_1, f_2)$.

Case: $p_1 < p \le p_1 + p_2$:
Pick $f_1, f_2, f_3 \overset{R}{\leftarrow} \mathcal{F}_l$.
MBTest$(A_{(h,0),(\bar{1},1)}; f_1, f_2, f_3)$.

Case: $p_1 + p_2 < p$:
Pick $f \overset{R}{\leftarrow} \mathcal{F}_l$ and $g \overset{R}{\leftarrow} \mathcal{F}_{l_1}$.
ProjTest$_\sigma(A_{(h,0),(\bar{1},1)}, A_1; f, g)$.

Remark: access to $A_{(h,0),(\bar{1},1)}(f)$ is implemented by accessing either $A(f)$, $A(f+h)$, $A(f+\bar{1})$, or $A(f+h+\bar{1})$.

FIG. 9. *The MaxSNP inner verifier* V_{SNPinner}.

impose $h(a) = 0$. The analysis lower bounds the rejection probability, as a function of the distance of A from linear, given that $h(a) = 1$.

LEMMA 3.22. *Let* $A\colon \mathcal{F}_l \to \Sigma$ *and let* $a \in \Sigma^l$. *Let* $h \in \mathcal{F}_l$ *and* $x = \text{Dist}(A, E_a)$. *If* $h(a) = 1$, *then* $1 - \textsc{CircPass}_h(A) \ge 1 - 2x$, *where*

$$\textsc{CircPass}_h(A) \overset{\text{def}}{=} \Pr_{f \overset{R}{\leftarrow} \mathcal{F}_l}[\,\textbf{CircTest}_h(A; f) = 0\,].$$

4. A new 3-query PCP and improved MaxSNP hardness results.

4.1. The MAXSNP verifier.

In this section we present a simple verifier which performs one of two simple checks, each depending on only three queries. This verifier will be the basis for the nonapproximability results for several MaxSNP problems, in particular Max3SAT, Max2SAT, and MaxCUT, whence its name.

4.1.1. The inner verifier. Figure 9 describes an inner verifier. Our verifier is adaptive, that is, some of its queries are determined as a function of answers to previous queries. (The adaptivity is not obvious from Figure 9; it is rather "hidden" in the RMB test; see section 3.5.2.) Adaptivity is used to improve the performance of our verifier and to strengthen the nonapproximability results which follow (cf. previous versions of this paper [20]).

The inner verifier, V_{SNPinner}, takes the usual length parameters l, l_1 as well as additional (probability) parameters p_1, p_2, and p_3 such that $p_1 + p_2 + p_3 = 1$. It performs just one test: with probability p_1 the linearity test; with probability p_2 the respect of monomial basis test; and with probability p_3 the projection test. Formally, this is achieved by picking p at random and making cases based on its value.[6] To

[6]For simplicity, p is depicted as being chosen as a random real number between 0 and 1. Of course we cannot quite do this, but we will see later that the values of p_1, p_2, p_3 in our final verifiers are appropriate constants. So in fact an appropriate choice of p can be made using $O(1)$ randomness, which is what we will implicitly assume.

improve the results, we perform the tests on a folding of A over both $(h,0)$ and $(\bar{1},1)$ (i.e., on $A_{(h,0),(\bar{1},1)}$). We stress that $A_{(h,0),(\bar{1},1)}$ is a virtual oracle which is implemented by the verifier which accesses the actual oracle A (on points determined by the definition of folding). We now examine the goodness of V_{SNPinner}. Recall the definitions of $\Gamma_{\text{lin}}(x)$ (specifically, note that $\Gamma_{\text{lin}}(x) \geq x$) and of $\Gamma_{\text{RMB}}(x) = \frac{3}{8}(1-2x)$, for all x.

Informally, the following lemma considers all the possible strategies of a "dishonest" prover and indicates the probability (denoted $1-\rho$) with which the verifier detects an error (when run against such strategies). The three cases correspond to the events that

(1) the function $A_{(h,0),(\bar{1},1)}$ may be very far from being linear;
(2) the function $A_{(h,0),(\bar{1},1)}$ is x-close to linear, for some $x < 1/2 - \delta_1$, but is not x-close to a valid codeword (i.e., to a linear function which respects the monomial basis); and
(3) the function $A_{(h,0),(\bar{1},1)}$ is x-close to a codeword, but the encoding of

$$\sigma(E^{-1}(A_{(h,0),(\bar{1},1)}))$$

is very far from the function A_1.

LEMMA 4.1 (soundness of V_{SNPinner}). *Suppose $\delta_1, \delta_2 > 0$, and $l, l_1 \in \mathcal{Z}^+$. Suppose $p_1, p_2, p_3 \in [0,1]$ satisfy $p_1 + p_2 + p_3 = 1$. Then the (l,l_1)-canonical inner verifier V_{SNPinner} is $(\rho, \delta_1, \delta_2)$-good, where $1-\rho = \min(T_1, T_2, T_3)$ and*

(1) $T_1 \stackrel{\text{def}}{=} p_1 \cdot (1/2 - \delta_1)$,
(2) $T_2 \stackrel{\text{def}}{=} \min_{x \leq 1/2-\delta_1} [\, p_1 \cdot \Gamma_{\text{lin}}(x) + p_2 \cdot \Gamma_{\text{RMB}}(x) \,]$,
(3) $T_3 \stackrel{\text{def}}{=} \min_{x \leq 1/2-\delta_1} [\, p_1 \cdot \Gamma_{\text{lin}}(x) + p_3 \cdot (1/2 - \delta_2)(1-2x) \,]$.

Proof. We consider an arbitrary pair of oracles, (A, A_1), and the behavior of V_{SNPinner} when given access to this pair of oracles. Our analysis is broken up into cases depending on (A, A_1); specifically, the first case-partition depends on the distance of $A_{(h,0),(\bar{1},1)}$ (i.e., the folding of A) from linear functions. We show that, in each case, either the verifier rejects with probability bounded below by one of the three quantities (above), or the oracle pair is such that rejection is not required.

Let $x = \text{Dist}(A_{(h,0),(\bar{1},1)}, \text{LIN})$.

Case 1. $x \geq 1/2 - \delta_1$. Lemma 3.15 implies that $1 - \text{LINPASS}(A_{(h,0),(\bar{1},1)}) \geq \Gamma_{\text{lin}}(x) \geq x \geq 1/2 - \delta_1$. (The second inequality follows from the fact that $\Gamma_{\text{lin}}(x) \geq x$ for all x.) Since V_{SNPinner} performs the atomic linearity test with probability p_1, we have

$$1 - \texttt{ACC}[\, V^{A,A_1}_{\text{SNPinner}}(\sigma, h) \,] \;\geq\; p_1 \cdot \left(\frac{1}{2} - \delta_1\right) \;\geq\; 1 - \rho. \tag{9}$$

Case 2. $x \leq 1/2 - \delta_1$. Lemma 3.15 implies that $1 - \text{LINPASS}(A_{(h,0),(\bar{1},1)}) \geq \Gamma_{\text{lin}}(x)$, and so the probability that V_{SNPinner} performs the linearity test and rejects is at least $p_1 \cdot \Gamma_{\text{lin}}(x)$. Now let $\tilde{A}$ be a linear function such that $\text{Dist}(A_{(h,0),(\bar{1},1)}, \tilde{A}) = x$. We consider the following subcases.

Case 2.1. $\tilde{A}$ does not respect the monomial basis. In this case, part 1 of Lemma 3.19 implies that $1 - \text{MBPASS}(A_{(h,0),(\bar{1},1)}) \geq \Gamma_{\text{RMB}}(x)$. So the probability that V_{SNPinner} performs the atomic respect of monomial basis test and rejects is at least $p_2 \cdot \Gamma_{\text{RMB}}(x)$. Since the event that the verifier performs a linearity test and the event that it performs a respect of monomial basis test are mutually exclusive, we can add the probabilities of rejection and thus get

$$1 - \texttt{ACC}[\, V^{A,A_1}_{\text{SNPinner}}(\sigma, h) \,] \;\geq\; p_1 \cdot \Gamma_{\text{lin}}(x) + p_2 \cdot \Gamma_{\text{RMB}}(x) \;\geq\; 1 - \rho. \tag{10}$$

Case 2.2. $\tilde{A}$ respects the monomial basis. By Proposition 3.2, $\tilde{A}$ is an evaluation operator. So there exists $a \in \Sigma^l$ such that $\tilde{A} = E_a$. So $\mathrm{Dist}(A_{(h,0),(\bar{1},1)}, E_a) = x$. Let $a_1 = \sigma(a)$. The proof splits into two further subcases.

Case 2.2.1. $d \stackrel{\text{def}}{=} \mathrm{Dist}(A_1, E_{a_1}) \geq 1/2 - \delta_2$. By Lemma 3.21 we have

$$1 - \textsc{ProjPass}_\sigma(A_{(h,0),(\bar{1},1)}, A_1) \geq d \cdot (1-2x) \geq \left(\frac{1}{2} - \delta_2\right) \cdot (1-2x) \; .$$

So the probability that V_{SNPinner} performs the projection test and rejects is at least $p_3 \cdot (1/2 - \delta_2)(1-2x)$. Thus, adding probabilities, as in Case 2.1, we get

$$(11) \quad 1 - \mathtt{ACC}\left[\, V^{A,A_1}_{\mathrm{SNPinner}}(\sigma, h)\,\right] \;\geq\; p_1 \cdot \Gamma_{\mathrm{lin}}(x) + p_3 \cdot (1/2 - \delta_2)(1-2x) \;\geq\; 1 - \rho.$$

Case 2.2.2. Else, we have $x = \mathrm{Dist}(A_{(h,0),(\bar{1},1)}, E_a) \leq 1/2 - \delta_1$ and $\mathrm{Dist}(A_1, E_{a_1}) < 1/2 - \delta_2$. Thus the functions $A_{(h,0),(\bar{1},1)}$ and A_1 satisfy conditions (2.1) and (2.2) in Definition 3.9.

Observe that the only case which does not yield $1 - \mathtt{ACC}\left[\, V^{A,A_1}_{\mathrm{PCPinner}}(\sigma, h)\,\right] \geq 1 - \rho$ is Case (2.2.2). However, Case (2.2.2) satisfies conditions (2.1) and (2.2) of Definition 3.9. Thus, V_{PCPinner} satisfies condition (2) of Definition 3.9. Clearly, V_{PCPinner} also satisfies condition (1) of Definition 3.9, and thus the lemma follows. □

The upper bound on the soundness error of V_{SNPinner}, provided by Lemma 4.1, is somewhat complicated to grasp. Fortunately, using $\Gamma_{\mathrm{RMB}}(x) = \frac{3}{8}(1-2x)$ and $\Gamma_{\mathrm{lin}}(x) \geq x$, for all $x \leq 1/2$, we can simplify the expression as follows.

Claim 4.2. *Let T_1, T_2, and T_3 be as in Lemma* 4.1, $\delta = \max(\delta_1, \delta_2) > 0$, *and $p_1, p_2, p_3 \in [0,1]$ satisfy $p_1 + p_2 + p_3 = 1$. Then, $T_2 \geq \min\{\frac{1}{2}p_1, \frac{3}{8}p_2\}$, $T_3 \geq \min\{\frac{1}{2}p_1, \frac{1}{2}p_3\} - \delta$, and*

$$\min\{T_1, T_2, T_3\} \geq \min\left\{\frac{1}{2}p_1, \frac{3}{8}p_2, \frac{1}{2}p_3\right\} - \delta \; .$$

Interestingly, this lower bound is tight.

Proof. Clearly, $T_1 = (\frac{1}{2} - \delta_1)p_1 \geq \frac{1}{2}p_1 - \delta$. To analyze T_2, let $h(x) \stackrel{\text{def}}{=} p_1 \cdot \Gamma_{\mathrm{lin}}(x) + p_2 \cdot \Gamma_{\mathrm{RMB}}(x)$.

Fact 1. $\min_{x \leq 1/2}\{h(x)\} = \min\{\frac{3}{8}p_2, \frac{1}{2}p_1\} = \min\{h(0), h(1/2)\}$.

Proof. By considering two cases and using $\Gamma_{\mathrm{lin}}(x) \geq x$ and $\Gamma_{\mathrm{RMB}}(x) = \frac{3}{8} - \frac{3}{4}x$.

Case 1. $p_1 \geq \frac{3}{4}p_2$;

$$h(x) \geq p_1 x + \frac{3}{8}p_2 - \frac{3}{4}p_2 x = \frac{3}{8}p_2 + \left(p_1 - \frac{3}{4}p_2\right) \cdot x \geq \frac{3}{8}p_2.$$

Case 2. $p_1 \leq \frac{3}{4}p_2$;

$$h(x) \geq p_1 x + \frac{3}{8}p_2 - \frac{3}{4}p_2 x = \frac{1}{2}p_1 + \left(\frac{3}{4}p_2 - p_1\right) \cdot \left(\frac{1}{2} - x\right) \geq \frac{1}{2}p_1.$$

The fact follows by observing that $h(0) = \frac{3}{8}p_2$ and $h(1/2) = \frac{1}{2}p_1$. □

Thus, we have $T_2 = \min_{x \leq 1/2 - \delta_1}[h(x)] \geq \min\{\frac{1}{2}p_1, \frac{3}{8}p_2\}$. The term T_3 is analyzed similarly, by defining $g(x) \stackrel{\text{def}}{=} p_1 \cdot \Gamma_{\mathrm{lin}}(x) + p_3 \cdot (1-2x)/2$, and using the following fact.

Fact 2. $\min_{x \leq 1/2}\{g(x)\} = \min\{\frac{1}{2}p_3, \frac{1}{2}p_1\} = \min\{g(0), g(1/2)\}$.

Proof. The proof is by considering two cases and using $\Gamma_{\mathrm{lin}}(x) \geq x$.

Case 1. $p_1 \geq p_3$;

$$g(x) \geq p_1 x + \frac{1}{2}p_3 - p_3 x = \frac{1}{2}p_3 + (p_1 - p_3) \cdot x \geq \frac{1}{2}p_3.$$

Case 2. $p_1 \leq p_3$;

$$g(x) \geq p_1 x + \frac{1}{2}p_3 - p_3 x = \frac{1}{2}p_1 + (p_3 - p_1) \cdot \left(\frac{1}{2} - x\right) \geq \frac{1}{2}p_1.$$

The fact follows by observing that $g(0) = \frac{1}{2}p_3$ and $g(1/2) = \frac{1}{2}p_1$. □

Thus, we have $T_3 \geq \min_{x \leq 1/2 - \delta_2}[g(x)] - \delta \geq \min\{\frac{1}{2}p_1, \frac{1}{2}p_3\} - \delta$. The claim follows. □

4.1.2. Main application: The MaxSNP verifier. We are now ready to state the main result of this section. It is a simple verifier for NP which achieves soundness error approaching 85% while performing one of two very simple tests.

PROPOSITION 4.3 (the MaxSNP verifier). *For any $\gamma > 0$ and for any language $L \in$ NP, there exists a verifier V_{SNP} for L such that*

- *V_{SNP} uses logarithmic randomness and has perfect completeness;*
- *V_{SNP} has soundness error $\frac{17}{20} + \gamma$; and*
- *on access to an oracle π (and according to the outcome of the verifier's coin tosses), the verifier V_{SNP} performs one of the following actions:*
  (1) Parity check. *V_{SNP} determines a bit b, makes three queries q_1, q_2, and q_3, and rejects if $\pi(q_1) \oplus \pi(q_2) \oplus \pi(q_3) \neq b$.*
  (2) RMB check. *V_{SNP} determines two bits b_0, b_1, makes three out of four predetermined queries q_1, q_2, q_3, and q_4, and rejects if either $(\pi(q_1) = 0) \wedge (\pi(q_2) \oplus \pi(q_4) \neq b_0)$ or $(\pi(q_1) = 1) \wedge (\pi(q_3) \oplus \pi(q_4) \neq b_1)$.*
  That is, the verifier inspects $\pi(q_1)$ and consequently checks either $\pi(q_2) \oplus \pi(q_4) \stackrel{?}{=} b_0$ or $\pi(q_3) \oplus \pi(q_4) \stackrel{?}{=} b_1$.

  Furthermore, the probability (over its coin tosses) that V_{SNP} performs a parity check is $\frac{3}{5}$ (and the probability that V_{SNP} performs an RMB check is $\frac{2}{5}$).

Proof. Set $\delta_1 = \delta_2 = \gamma/2$ and $\epsilon = \frac{\gamma}{2} \cdot (16\delta_1^2\delta_2^2) = \frac{\gamma^5}{2} > 0$. Now, let l and l_1 be integers such that the outer verifier, V_{outer}, guaranteed by Lemma 3.8 is (l, l_1)-canonical and ϵ-good for L. Consider the (l, l_1)-canonical inner verifier V_{SNPinner}, working with the parameters p_1, p_2, and p_3 set to minimize its error. Obviously this calls for setting $1/2p_1 = \frac{3}{8}p_2 = 1/2p_3$, which yields

$$p_1 = \frac{3}{10} \;;\; p_2 = \frac{4}{10} \;;\; p_3 = \frac{3}{10}. \tag{12}$$

Let V_{SNP} be the verifier obtained by composing V_{outer} with V_{SNPinner}.

We start by analyzing the soundness error of V_{SNP}. By Lemma 4.1 and Claim 4.2, we know that the inner verifier V_{SNPinner}, with p_i's as in Eq. (12), is $(\rho, \delta_1, \delta_2)$-good, for

$$\rho \;\leq\; 1 - \frac{1}{2} \cdot p_3 + \delta_1 \;=\; 1 - \frac{3}{20} + \frac{1}{2} \cdot \gamma\,.$$

Invoking Theorem 3.12, we upper bound the soundness error of V_{SNP} by $1 - \frac{3}{20} + \frac{\gamma}{2} + \frac{\epsilon}{16\delta_1^2\delta_2^2}$ which by the setting of ϵ yields the claimed soundness bound (of $0.85 + \gamma$).

Clearly, V_{SNP} uses logarithmic randomness, has perfect completeness, and its computation on the answers of the oracles are determined by V_{SNPinner}. It is left to

observe that each of the three tests (i.e., linearity, monomial basis, and projection), performed by V_{SNPinner}, is either a parity check or an RMB check and that the latter occurs with probability 0.4. First observe that with probability p_1, V_{SNPinner} performs $\mathbf{LinTest}(A_{(h,0),(\bar{1},1)}; f_1, f_2)$, where $f_1, f_2 \in \mathcal{F}_l$. Recall that query f to $A_{(h,0),(\bar{1},1)}$ translates to a query in the set $\{f, f+h, f+\bar{1}, f+h+\bar{1}\}$ answered by A and that the answer is possibly complemented (by adding 1 mod 2). Thus, the above linearity test translates to checking the exclusive-or of three predetermined locations of A against a predetermined bit b (i.e., this bit is determined by the number of times which have shifted a potential query by $\bar{1}$). Similarly, $\mathbf{MBTest}(A_{(h,0),(\bar{1},1)}; f_1, f_2, f_3)$ translates to an RMB check with b_0, b_1, and the four possible queries being determined by the folding over $\bar{1}$. Finally, we observe that the projection test, performed by V_{SNPinner}, also amounts to a parity check, this time on answers taken from two different oracles (which can actually be viewed as one oracle). □

Remark 4.4 (a tedious one). The probability that verifier V_{SNP}, of the above proposition, makes two identical queries is negligible. Specifically, it can be made smaller than γ (mentioned in the proposition). Thus, we can ignore this case[7] in the next two sections and assume, without loss of generality, that all queries are distinct.

Implementing the MaxSNP verifier via gadgets. In the following sections we use the verifier of Proposition 4.3 to obtain hardness results for various variants of MaxSAT as well as for MaxCUT. The hardness results are obtained by constructing an instance of the problem at hand so that the instance represent the verifier's computation on input x. The primary aspect of the reduction is the construction of gadgets which reflect the result of the verifier's computation (i.e., accept/reject) after performing one of the two types of checks, i.e., parity check or RMB check. We define a performance measure of a gadget and relate the hardness result achieved to the performance measure obtained by the gadgets in use.[8]

Sources of our improvements. The explicit statement of a generic verifier for deriving MaxSNP hardness results is a novelty of our paper. Thus, a quantitative comparison to previous works is not readily available. Certainly, we improve over these works thanks to the use of the new long code-based inner verifier, the atomic tests and their analysis in section 3.5, the new idea of folding, and the improved analysis of linearity testing due to [17].

4.1.3. Another application: Minimizing soundness error in 3-query pcp. As a direct corollary to Proposition 4.3, we obtain the following.

Theorem 4.5. *For any* $s > 0.85$, $\text{NP} \subseteq \text{PCP}_{1,s}[\,\mathsf{coins} = \log; \mathsf{query} = 3; \mathsf{free} = 2\,]$.

4.2. Satisfiability problems. In this section we mainly deal with CNF formulae. However, the last subsection deals with formulae consisting of a conjunction of PARITY (rather than OR) clauses. Refer to section 2.4 for definitions, in particular for the problem MaxXSAT and the promise problem Gap-XSAT. Recall that $\text{MaxSAT}(\varphi)$ is the maximum number of simultaneously satisfiable clauses in

[7] Formally, suppose that, when it occurs, the verifier performs some standard check on fixed different queries. This modification increases the soundness error by at most γ which tends to zero anyhow.

[8] Given that the performance of the various gadgets might be different for the different checks, one might suspect that it might have been a better idea to first construct the gadgets and then to optimize the soundness of V_{SNP}, keeping in mind the relative performance measures of the two kinds of gadgets being employed. Surprisingly enough it turns out (cf. [20]) that the optimization is not a function of the performance of the gadgets and indeed the choice of parameters p_1, p_2, and p_3, as in Eq. (12), is optimal for the following reductions.

formula φ, and $\overline{\text{MaxSAT}}(\varphi) = \text{MaxSAT}(\varphi)/\|\varphi\|$ is the normalized version, where $\|\varphi\|$ is the number of clauses in formula φ. See section 2.4.3 for a description of previous work.

A consequence of the following theorem (obtained by applying Proposition 2.5) is that, assuming P $\neq$ NP, there is no polynomial-time algorithm to approximate the following: (1) Max3SAT within a factor of 1.038; (2) MaxE3SAT within a factor of 1.038; (3) Max2SAT within a factor of 1.013.

THEOREM 4.6 (MaxSAT nonapproximability results). *The following problems are* NP*-hard:*

(1) Gap-$3SAT_{c,s}$ *with* $c = 1$ *and* $s = 26/27$.
(2) Gap-$E3SAT_{c,s}$ *with* $c = 1$ *and* $s = 26/27$.
(3) Gap-$2SAT_{c,s}$ *for some* $0 < s < c < 1$ *satisfying* $c > 0.9$ *and* $c/s = 74/73$.

Actually, items 1 and 2 hold for any $s > 1 - \frac{3}{80}$ whereas item 3 holds as long as $\frac{c}{s} < 1 + \frac{3}{217}$. Item 1 is implied by item 2 so we will prove only the latter.

4.2.1. The hardness of MaxE3SAT and Max2SAT.

GADGETS. In the context of MaxSAT problems, we may easily replace a condition of the form $a + b + c = 1$ by $\bar{a} + b + c = 0$, where $\bar{a}$ is the negation of the variable a. Thus, the task of designing gadgets is simplified, and we need to implement two (simplified) types of checks: the parity check (checking that $a + b = c$ for a, b, and c obtained from the oracle) and the RMB check for a, b_0, b_1, and c obtained from the oracle). Accordingly a parity check (PC) gadget, $\text{PC}(a, b, c, x_1, x_2, \ldots, x_n)$, is a set of clauses over three *distinguished* variables a, b, c and n auxiliary variables $x_1, \ldots, x_n$. It is an (α, β)*-PC gadget* if the following is true: if $a + b = c$, then $\text{MaxSAT}(\text{PC}(a, b, c, x_1, x_2, \ldots, x_n)) = \alpha$; else it is at most $\alpha - \beta$. Similarly a respect-monomial-basis check (RMBC) gadget, $\text{RMBC}(a, b_0, b_1, c, x_1, \ldots, x_n)$, is a set of clauses over four *distinguished* variables a, b_0, b_1, c and n auxiliary variables $x_1, \ldots, x_n$. It is an (α, β)*-RMBC gadget* if the following is true: if $b_a = c$, then $\text{MaxSAT}(\text{RMBC}(a, b_0, b_1, c, x_1, x_2, \ldots, x_n)) = \alpha$; else it is at most $\alpha - \beta$. We stress that in both cases the maximum number of clauses which are simultaneously satisfied is at most α. A gadget is said to be an X-SAT gadget if, as a formula, it is an X-SAT formula.

The following lemma describes how gadgets of the above form can be used to obtain the hardness of MaxSAT.

LEMMA 4.7 (MaxSAT implementation of a verifier). *Let V be a verifier for L of logarithmic randomness, with perfect completeness and soundness s, such that V performs either a single parity check (with probability q) or a single RMB check (with probability $1 - q$). Furthermore, suppose that in either case, the verifier never makes two identical queries. If there exists an (α_1, β)-parity-check X-SAT gadget containing m_1 clauses and an (α_2, β)-RMBC X-SAT gadget containing m_2 clauses, then L reduces to* Gap-$XSAT_{c',s'}$ *for*

$$c' = \frac{\alpha_1 q + \alpha_2(1-q)}{m_1 q + m_2(1-q)},$$

$$s' = \frac{\alpha_1 q + \alpha_2(1-q) - (1-s)\beta}{m_1 q + m_2(1-q)}.$$

In particular $\frac{c'}{s'} \geq 1 + \frac{(1-s)\beta}{\alpha_1 q + \alpha_2(1-q) - (1-s)\beta}$.

Remark 4.8. In the above lemma, we have assumed that both the PC and RMBC gadgets have the same second parameter β. This assumption is not really a restriction since we can transform a pair of (α_1, β_1)-PC and (α_2, β_2)-RMBC gadgets into a pair of $(\alpha_1\beta_2, \beta_1\beta_2)$-PC and $(\alpha_2\beta_1, \beta_1\beta_2)$-RMBC gadgets, thereby achieving this feature. (Actually, what really matters are the fractions α_i/β.)

Proof. Let $\mathrm{PC}(a, b, c, x_1, \ldots, x_{n_1})$ be the parity check gadget and let $\mathrm{RMBC}(a, b, c, d, x_1, \ldots, x_{n_2})$ be the RMBC gadget. We encode V's computation on input x by a CNF formula φ_x. Corresponding to every bit $\pi[q]$ of the proof (oracle) accessed by the verifier V, we create a variable $y[q]$. In addition we create some auxiliary variables $y_{\mathrm{Aux}}[R, i]$ for each random string R used by the verifier V and i going from 1 to $\max(n_1, n_2)$. For each such R we will construct a formula φ_R which encodes the computation of the verifier when its coins are R. The union of all these formulae will be our φ_x.

On random string R, if the verifier performs a parity check on bits $\pi[q_1], \pi[q_2]$, and $\pi[q_3]$, then φ_R consists of the clauses $PC(y[q_1], y[q_2], y[q_3], y_{\mathrm{Aux}}[R, 1], \ldots, y_{\mathrm{Aux}}[R, n_1])$. On the other hand if the verifier performs an RMB check on bits $\pi[q_1], \pi[q_2], \pi[q_3]$, $\pi[q_4]$, then φ_R consists of the clauses $RMBC(y[q_1], y[q_2], y[q_3], y[q_4], y_{\mathrm{Aux}}[R, 1], \ldots, y_{\mathrm{Aux}}[R, n_2])$.

Let N denote the number of possible random strings used by V. Observe that the number of clauses in φ_x equals $m_1 \cdot qN + m_2 \cdot (1-q)N$. We now analyze the value of $\mathrm{MaxSAT}(\varphi_x)$.

If $x \in L$, then there exists an oracle π such that $V^\pi(x)$ always accepts. Consider the assignment $y[q] = \pi[q]$ (i.e., $y[q]$ is true iff $\pi[q] = 1$). Then for every R, there exists an assignment to the variables $y_{\mathrm{Aux}}[R, i]$ such that the number of clauses of φ_R that are satisfied by this assignment is α_1 if R corresponds to a parity check and α_2 if R corresponds to an RMB check. Since qN of the gadgets are PC gadgets and $(1-q)N$ of the gadgets are RMBC gadgets, we have $\mathrm{MaxSAT}(\varphi_x) \geq qN\alpha_1 + (1-q)N\alpha_2$, and the expression for c' follows.

Now consider the case when $x \notin L$. We prove below that if there exists an assignment which satisfies $qN\alpha_1 + (1-q)N\alpha_2 - (1-s)N\beta$ clauses of φ_x, then there exists an oracle π such that $V^\pi(x)$ accepts with probability at least s. Since we know this cannot happen, we conclude that $\mathrm{MaxSAT}(\varphi_x) < qN\alpha_1 + (1-q)N\alpha_2 - (1-s)N\beta = s'|\varphi_x|$.

To prove the above claim, we convert any assignment to the variables y into an oracle π in the natural way, i.e., $\pi[q] = 1$ iff $y[q]$ is true. Now, by the property of the gadgets, if a PC gadget $PC(y[q_1], y[q_2], y[q_3], y_{\mathrm{Aux}}[R, 1], \ldots)$ has more than $\alpha_1 - \beta$ clauses satisfied, then $\pi[q_1] \oplus \pi[q_2] = \pi[q_3]$. In turn this implies that the verifier V accepts π on random string R. A similar argument can be made about the random strings R which correspond to RMB checks. We also use the property that a PC (resp., RMB) gadget cannot have more than α_1 (resp., α_2) satisfied clauses, even if the claim it checks does hold. Thus, if an assignment satisfies $qN \cdot (\alpha_1 - \beta) + (1-q)N \cdot (\alpha_2 - \beta) + sN\beta$ clauses, then there must exist sN random strings R on which V accepts. This proves the claim and the lemma follows. □

Figure 10 describes gadgets which will be used for our MaxE3SAT construction; notice that they are *exact*-3-SAT gadgets. We have a $(4, 1)$-PC gadget, PC_3, and a $(4, 1)$-RMB gadget, RMBC_3, each consisting of four clauses in which all the clauses have exactly three variables. Both gadgets have no auxiliary variables. The $\mathrm{PC}_3(a, b, c)$ gadget is merely the canonical 3CNF of the expression $a + b + c = 0$. The first two clauses in the $\mathrm{RMBC}_3(a, b, b', c)$ gadget are the canonical 3CNF of the

The MaxE3SAT gadgets.

$$\mathrm{PC}_3(a,b,c) = \{(a \vee b \vee \overline{c}),\ (a \vee \overline{b} \vee c),\ (\overline{a} \vee b \vee c),\ (\overline{a} \vee \overline{b} \vee \overline{c})\}$$

$$\mathrm{RMBC}_3(a,b,b',c) = \{(a \vee b \vee \overline{c}),\ (a \vee \overline{b} \vee c),\ (\overline{a} \vee b' \vee \overline{c}),\ (\overline{a} \vee \overline{b'} \vee c),\ \}$$

The MAX2SAT gadgets.

$$\begin{aligned}\mathrm{PC}_2(a,b,c,x_{00},x_{01},x_{10},x_{11}) = \\ \{&(\overline{x_{00}} \vee \overline{a}), (\overline{x_{00}} \vee \overline{b}), (x_{00} \vee c),\\ &(\overline{x_{01}} \vee a), (\overline{x_{01}} \vee \overline{b}), (x_{01} \vee \overline{c}),\\ &(\overline{x_{10}} \vee \overline{a}), (\overline{x_{10}} \vee b), (x_{10} \vee \overline{c}),\\ &(\overline{x_{11}} \vee a), (\overline{x_{11}} \vee b), (x_{11} \vee c)\}.\end{aligned}$$

$$\begin{aligned}\mathrm{RMBC}_2(a,b,b',c,x_{00},x_{11},y_{00},y_{11}) = \\ \{&(\overline{x_{00}} \vee \overline{b}), (\overline{x_{00}} \vee \overline{c}), (a \vee x_{00}),\\ &(\overline{x_{11}} \vee b), (\overline{x_{11}} \vee c), (a \vee x_{11}),\\ &(\overline{y_{00}} \vee \overline{b'}), (\overline{y_{00}} \vee \overline{c}), (\overline{a} \vee y_{00}),\\ &(\overline{y_{11}} \vee b'), (\overline{y_{11}} \vee c), (\overline{a} \vee y_{11})\}.\end{aligned}$$

FIG. 11. *The* Max2SAT *gadgets.*

expression $(a = 0) \Rightarrow (b = c)$, whereas the latter two clauses are the canonical 3CNF of the expression $(a = 1) \Rightarrow (b' = c)$. Figure 11 similarly describes 2-SAT gadgets for our Max2SAT construction. We have a $(11, 1)$-PC gadget, PC_2, and a $(11, 1)$-RMB gadget, RMBC_2, each consisting of 12 clauses. Each gadget has four auxiliary variables. The auxiliary variable $x_{\tau\sigma}$ in the PC_2 gadget is supposed to be the indicator of the event $((a = \sigma) \wedge (b = \tau))$. Thus, $a + b = c$ allows us to satisfy 11 clauses by appropriately setting the indicator variables (e.g., if $a = b = c = 0$, then setting $x_{00} = 1$ and the other $x_{\tau\sigma}$'s to 0 satisfies all clauses except the last one). The RMBC_2 gadget is composed of two parts; the first six clauses handle the expression $(a = 0) \Rightarrow (b = c)$, whereas the latter six clauses are for the expression $(a = 1) \Rightarrow (b' = c)$.

LEMMA 4.9 (SAT gadgets). *The following gadgets exist.*

(1) *E*3-SAT *gadgets: a* $(4, 1)$*-PC gadget of four clauses and a* $(4, 1)$*-RMB gadget of four clauses.*

(2) 2-SAT *gadgets: a* $(11, 1)$*-PC gadget of* 12 *clauses and a* $(11, 1)$*-RMB gadget of* 12 *clauses.*

Remark 4.10. In previous versions of this work [20], it was observed that a ratio of 4 between the number of clauses and the second parameter (i.e., β) is minimal for both E 3-SAT gadgets. Several questions regarding the α/β ratios achievable by 3-SAT and 2-SAT gadgets were posed. Answers were subsequently provided in [84], which undertakes a general study of the construction of optimal gadgets.

Proof of Lemma 4.9. We use the gadgets presented in Figures 10 and 11. The claim regarding E3-SAT follows from the motivating discussion above (i.e., by which these gadgets are merely the canonical 3CNF expressions for the corresponding conditions). The analysis of the 2-SAT gadgets in Figure 11 is straightforward but tedious; it is omitted from this version and can be found in previous versions of this work [20]. □

Proof of Theorem 4.6. The theorem follows by applying Lemma 4.7 to the verifier of Proposition 4.3 and the gadgets of Lemma 4.9. Details follow.

Recall that by Remark 4.4, we may assume that the verifier does not make two identical queries. Applying Lemma 4.7 to the verifier of Proposition 4.3 we obtain a reduction of any language in NP to $\mathsf{Gap\text{-}XSAT}_{c',s'}$ for values of c' and s' determined as a function of the gadget parameters, the probability parameter q, and the soundness s of the verifier of Proposition 4.3. Specifically, we observe that for E3-SAT we have $c' = 1$ (since $\alpha_i = m_i = 4$ for $i = 1, 2$), whereas for 2-SAT we have $0.9 < c' < 1$ (since $\frac{\alpha_i}{m_i} = \frac{11}{12} = 4$ for $i = 1, 2$). In both cases, $\beta = 1$ and the expression for c'/s' is given by

$$1 + \frac{1 - s}{q\alpha_1 + (1 - q)\alpha_2 - (1 - s)}, \tag{13}$$

where s and q are determined by Proposition 4.3; that is, (for every $\gamma > 0$),

$$s = 1 - \frac{3}{20} + \gamma, \tag{14}$$

$$q = \frac{3}{5}, \tag{15}$$

Substituting Eqs. (14) and (15) into Eq. (13), and letting $\gamma \to 0$, we get

$$\frac{c'}{s'} \to 1 + \frac{3}{12\alpha_1 + 8\alpha_2 - 3}.$$

The bounds for E3-SAT and 2-SAT now follow by using the α_i's values of Lemma 4.9. In particular, for E3-SAT we get $s' \to 77/80$ and for 2-SAT we get $\frac{c'}{s'} \to 1 + \frac{3}{217}$. □

We conclude this subsection by presenting a variant of Lemma 4.7. This variant refers only to 3-SAT formulae, but makes no restrictions on the verifier in the PCP system.

LEMMA 4.11 (Max3SAT implementation of a generic verifier). *Let L be in* $\mathrm{PCP}_{1,1-\delta}[\log, 3]$, *for some* $0 < \delta < 1$. *Then, L reduces to* $\mathsf{Gap\text{-}3SAT}_{1,1-\frac{\delta}{4}}$.

Proof. Let V be a verifier as guaranteed by the hypothesis. Building on Lemma 4.7, it suffices to show that the computation of V on any possible random tape can be captured by a 3CNF formula with at most four clauses. We consider the depth-3 branching program which describes the acceptance of V on a specific random tape. (The variables in this program correspond to queries that the verifier may make on this fixed random tape. Since the verifier may be adaptive, different variables may appear on different paths.) In case this tree has at most four rejecting leaves (i.e., marked FALSE), writing corresponding 3CNF clauses (which state that these paths are not followed), we are done. Otherwise, we consider the four depth-1 subtrees. For each such subtree we do the following. In case both leaves are marked FALSE, we write a 2CNF clause (which states that this subtree is not reached at all). In case a single leaf is marked FALSE, we write one 3CNF clause (as above), and if no leaf is marked FALSE, we write nothing. □

Remark 4.12. *The above argument can be easily extended to show that, for any* $0 \leq \epsilon, \delta < 1$,

$$\mathrm{PCP}_{1-\epsilon,1-\delta}[\log, 3] \leq_D^K \textsf{Gap-3SAT}_{1-\epsilon,1-\frac{\delta}{4}}.$$

4.2.2. Maximum satisfiable linear constraints (parity clauses). Analogously to the MaxSAT problems considered above, we consider parity clauses rather than disjunctive clauses. In other words, we are given a system of linear equations over GF(2), and need to determine the maximum number of equations which may be simultaneously satisfied. The problem in question is MaxLinEq (cf. section 2.4.2). Here we provide an explicit hardness factor via a direct reduction from the MaxSNP verifier.

THEOREM 4.13. $\textsf{Gap-MaxLinEq}_{c,s}$ *is* NP*-hard for* $c = 6/7$ *and any* $\frac{c}{s} < 8/7$.

Proof. The theorem follows by constructing appropriate gadgets. A $(1,1)$-PC gadget is straightforward here. We present a $(3,2)$-RMB gadget consisting of four equations. Specifically, for $\mathrm{RMB}(a, b_0, b_1, c)$ we present the equations $b_0 + c = 0$, $a + b_0 + c = 0$, $b_1 + c = 0$, and $a + b_1 + c = 1$. Observe that we can think of the RMB gadget as a $(1.5, 1)$ gadget with two clauses (or, equivalently, think of the parity gadget as a $(2,2)$ gadget with two clauses).

We obtain a hardness for $\textsf{Gap-MaxLinEq}_{c',s'}$ by proceeding as in the proof of Theorem 4.6, where

$$\frac{c'}{s'} \to 1 + \frac{3}{12\alpha_1 + 8\alpha_2 - 3} = 1 + \frac{3}{12 + 12 - 3} = \frac{8}{7},$$

and $c' = \frac{3\alpha_1 + 2\alpha_2}{3m_1 + 2m_2} = \frac{6}{7}$. ∎

4.3. MaxCUT. Refer to section 2.4 for the definition of the MaxCUT problem and the associated gap problem $\textsf{Gap-MaxCUT}_{c,s}$. See section 2.4.3 for discussion of status and previous work. The following theorem (combined with Proposition 2.5) shows that MaxCUT is NP-hard to approximate to within a factor of 1.014. We note that the result of the following theorem holds also when the weights of the graph are presented in unary (or, equivalently, when considering unweighted graphs with parallel edges).

THEOREM 4.14 (MaxCUT nonapproximability result). $\textsf{Gap-MaxCUT}_{c,s}$ *is NP-hard for some* c, s *satisfying* $c > 0.6$ *and* $c/s > 1.014$ *(anything below* $72/71$*).*

A weaker result can be obtained for simple graphs without weights or parallel edges. In particular, one may reduce the MaxCUT problem for graphs with parallel edges to MaxCUT for simple graphs by replacing every edge by a path of three edges. This causes a loss of a factor of 3 in the hardness factor, that is, we would get a hardness factor of $214/213$ for the MaxCUT problem restricted to simple graphs. A better reduction which preserves the nonapproximation ratio has been recently suggested by Crescenzi, Silvestri, and Trevisan [34].

GADGETS. Unlike with the MaxSAT problem, here we cannot negate variables at zero cost. Still, we first define simplified gadgets for parity and RMB checking and make the necessary adaptations inside Lemma 4.15.

Gadgets will be used to express the verifier's computation in terms of cuts in graphs. A parity check gadget $\text{PC-CUT}(a, b, c, T; x_1, \ldots, x_n)$ is a weighted graph on $n+4$ vertices. Of these three vertices, a, b, c correspond to oracle queries made by the verifier. The vertex T will be a special vertex mapping cuts to truth values so that a vertex corresponding to an oracle query is considered set to 1 if it resides in the T-side of the cut (i.e., a is considered set to 1 by a cut $(S, \overline{S})$ iff either $a, T \in S$ or $a, T \in \overline{S}$).

The gadget is an (α, β)-PC gadget if MaxCUT(PC-CUT$(a, b, c, T; x_1, \ldots, x_n)$) is exactly α when restricted to cuts which induce $a+b=c$ (i.e., either 0 or 2 of the vertices $\{a, b, c\}$ lie on the same side of the cut as T), and is at most $\alpha - \beta$ when restricted to cuts for which $a+b \neq c$. A cut gadget to check if $a+b \neq c$ can be defined similarly. Similarly, a weighted graph RMBC-CUT$(a, b_0, b_1, c, T; x_1, \ldots, x_n)$ is an (α, β)-RMBC gadget if it satisfies the property that MaxCUT(RMBC-CUT$(a, b_0, b_1, c, T; x_1, \ldots, x_n)$) is exactly α when restricted to cuts satisfying $b_a = c$ and is at most $\alpha - \beta$ otherwise. Cut gadgets for the other generalized RMB checks (checking if $b_a \neq c$, $b_a = c + a$, or $b_a \neq c+a$) can be defined similarly. The following lemma (similar to Lemma 4.7) shows how to use the above forms of gadgets to derive a reduction from NP to Gap-MaxCUT.

LEMMA 4.15 (MaxCUT implementation of a verifier). *Let V be a verifier for L of logarithmic randomness, with perfect completeness and soundness s, such that V performs either a single parity check (with probability q) or a single RMB check (with probability $1-q$). Here, we refer to the generalized checks as defined in Proposition* 4.3. *Furthermore suppose that, in either case, the verifier never makes two identical queries. If there exists an $(\alpha_1 - \beta, \beta)$-PC gadget consisting of edges of total weight $w_1 - \beta$ and an $(\alpha_2 - \beta, \beta)$-RMBC gadget consisting of edges of total weight $w_2 - \beta$, then L reduces to* Gap-MaxCUT$_{c',s'}$ *for $c' = \frac{\alpha_1 q + \alpha_2(1-q)}{w_1 q + w_2(1-q)}$ and $s' = \frac{\alpha_1 q + \alpha_2(1-q) - (1-s)\beta}{w_1 q + w_2(1-q)}$. In particular, $c'/s' \geq 1 + \frac{(1-s)\beta}{\alpha_1 q + \alpha_2(1-q) - (1-s)\beta}$.*

Remark 4.16. Actually, the conclusion of the lemma holds provided all the *generalized* parity check (resp., RMB check) functions have (α_1, β) gadgets (resp., (α_2, β) gadgets).

Proof. Let PC-CUT$(a, b, c, T, x_1, \ldots, x_{n_1})$ denote the parity check gadget and RMBC-CUT$(a, b_0, b_1, c, T, x_1, \ldots, x_{n_2})$ denote the RMBC gadget. These are simplified gadgets as defined above. Increasing the α value by β, we can easily obtain the general gadgets as defined in Proposition 4.3. For example, to check that $a+b+c=1$, we introduce a gadget which, in addition to the variables $a, b, c, T, x_1, \ldots, x_{n_1}$, has an auxiliary vertex denoted $\bar{a}$. The new gadget consists of the edge $(a, \bar{a})$ having weight β together with the weighted graph PC-CUT$(\bar{a}, b, c, T, x_1, \ldots, x_{n_1})$. Clearly, the result is an (α_1, β) gadget of weight w_1 for $a+b+c=1$. Likewise we can check the condition $b_a + c = \tau_a$, where τ_0, τ_1 are any fixed bits as follows. In case $\tau_0 = \tau_1 = 1$, we introduce an auxiliary vertex $\bar{c}$, connect it to c by an edge of weight β, and use the graph RMBC-CUT $(a, b_0, b_1, \bar{c}, T, x_1, \ldots, x_{n_2})$. In case $\tau_0 = 0$ and $\tau_1 = 1$, we introduce an auxiliary vertex $\bar{b}_1$, connect it to b_1 by an edge of weight β, and use the graph RMBC-CUT$(a, b_0, \bar{b}_1, c, T, x_1, \ldots, x_{n_2})$. The case $\tau_0 = 1$ and $\tau_1 = 0$ is analogous, whereas $\tau_0 = \tau_1 = 0$ is obtained by the simplified gadget itself. Thus, we have (α_2, β) gadgets for all cases of the RMB check. Throughout the rest of the proof, PC-CUT and RMBC-CUT denote the generalized gadgets.

We create a graph G_x and weight function w_x which encodes the actions of the verifier V on input x. The vertices of G_x are as follows:

(1) For every bit $\pi[q]$ of the proof queried by the verifier V, the graph G_x has a vertex $v_{\pi[q]}$.

(2) For every random string R tossed by the verifier V, we create vertices $v_{R,i}$, for i going from 1 to $\max\{n_1, n_2\}$.

(3) There will be one special vertex T.

The edges of G_x are defined by the various gadgets. We stress that the same edge may appear in different gadgets (and its weight in these gadgets may be different). The graph G_x is defined by taking all these edges and thus it is a graph (or multigraph) with parallel edges and weights. The natural conversion of G_x into a graph with no parallel edges replaces the parallel edges between two vertices with a single

edge whose weight is the sum of the weights of the original edges. Alternatively, since the weights are constants which do not depend on x, we can transform G_x into a unweighted graph with parallel edges.

Suppose that on random string R the verifier V queries the oracle for bits $\pi[q_1]$, $\pi[q_2]$, and $\pi[q_3]$ and then does a parity check on these three bits. Then, corresponding to this random string, we add the weighted edges of the graph G_R to the graph G_x where $G_R = \text{PC-CUT}(v_{\pi[q_1]}, v_{\pi[q_2]}, v_{\pi[q_3]}, T; v_{R,1}, \ldots, v_{R,n_1})$. Alternatively, if the verifier V performs a respect of monomial basis test on the bits $\pi[q_1]$, $\pi[q_2]$, $\pi[q_3]$, and $\pi[q_4]$, then we add the weighted edges of the graph $G_R = \text{RMBC-CUT}(v_{\pi[q_1]}, v_{\pi[q_2]}, v_{\pi[q_3]}, v_{\pi[q_4]}, T; v_{R,1}, \ldots, v_{R,n_2})$.

Let N denote the number of possible random strings used by V. Observe that the total weight of the edges of G_x is $w_1 qN + w_2(1-q)N$. We now analyze the value of $\text{MaxCUT}(G_x)$.

If $x \in L$, then there exists an oracle π such that $V^\pi(x)$ always accepts. We define a cut $(S, \bar{S})$ in G_x in the following way: we place $T \in S$ and for every query q we place $v_{\pi[q]} \in S$ iff $\pi[q] = 1$. Then for each R, there exists a placement of the vertices $v_{R,i}$ so that the size of the cut induced in G_R is α_1 if R corresponds to V performing a parity check and α_2 if R corresponds to V performing an RMB check. The weight of the so obtained cut is $\alpha_1 qN + \alpha_2(1-q)N$.

Now consider $x \notin L$. We claim that if there exists a cut $(S, \bar{S})$ such that the weight of the cut is greater than $qN\alpha_1 + (1-q)N\alpha_2 - (1-s)N\beta$, then there exists an oracle π, such that $V^\pi(x)$ accepts with probability at least s. Since we know this cannot happen, we conclude that $\text{MaxCUT}(G_x) < qN\alpha_1 + (1-q)N\alpha_2 - (1-s)N\beta$. To prove the claim, we convert any cut in G_x into an oracle π where $\pi[q] = 1$ iff T and $v_{\pi[q]}$ lie on the same side of the cut. Now, by the property of the gadgets, if a graph $G_R = \text{PC-CUT}(y[q_1], y[q_2], y[q_3], T; x_1, \ldots, x_{n_1})$ contributes more than a weight of $\alpha_1 - \beta$ to the cut, then V accepts π on random string R. (Similarly, if the graph G_R is an RMBC gadget and contributes more than $\alpha_2 - \beta$ to the cut, then V accepts π on random string R.) Recall that no gadget can contribute more than the corresponding α to any cut. Thus if the total weight of the cut is more than $(\alpha_1 - \beta)qN + (\alpha_2 - \beta)(1-q)N + sN \cdot \beta$, then V accepts on at least sN random strings. This proves the claim and the lemma follows. □

We now turn to the construction of cut gadgets. Our first gadget, denoted

$$\text{PC-CUT}(a, b, c, T; \textsc{Aux}) ,$$

is a complete graph defined on five vertices $\{a, b, c, T, \textsc{Aux}\}$. The weight function, w, assigns to the edge $\{u, v\}$ weight $w_u \cdot w_v$, where $w_a = w_b = w_c = w_T = 1$ and $w_{\textsc{Aux}} = 2$. The following claim shows how $\text{PC-CUT}(a, b, c, T; \textsc{Aux})$ functions as a parity check gadget.

CLAIM 4.17 (MaxCUT PC gadget). *PC-CUT*$(a, b, c, T; \textsc{Aux})$ *is a* $(9, 1)$*-parity check gadget consisting of edges of total weight* 14.

The straightforward (but tedious) proof is omitted (and can be found in [20]).

The second gadget, denoted $\text{RMBC-CUT}(a, b_0, b_1, c, T; \textsc{Aux}_1, \textsc{Aux}_2, \textsc{Aux}_3, a')$, is composed of two graphs denoted G_1 and G_2, respectively. To motivate the construction we first observe that the condition $b_a = c$ (i.e., $(a = 0) \Rightarrow (b_0 = c)$ and $(a = 1) \Rightarrow (b_1 = c)$) is equivalent to the conjunction of $(b_0 = b_1) \Rightarrow (b_0 = c)$ and $(b_0 \neq b_1) \Rightarrow (a + b_0 + c = 0)$. The graph $G_1(b_0, b_1, c; \textsc{Aux}_1)$ will take care of the first implication. It consists of the vertex set $\{b_0, b_1, c, \textsc{Aux}_1\}$, the unit-weight edges $\{b_0, \textsc{Aux}_1\}$ and $\{b_1, \textsc{Aux}_1\}$, and a weight 2 edge $\{c, \textsc{Aux}_1\}$. The graph

$G_2(a, b_0, b_1, c, T; \text{AUX}_2, \text{AUX}_3, a')$, taking care of the second implication, consists of two subgraphs PC-CUT$(a, b_0, c, T; \text{AUX}_2)$ and $\overline{\text{PC-CUT}}(a, b_1, c, T; \text{AUX}_3, a')$, where the latter is supposed to "check" $a + b_1 + c = 1$. Specifically, $\overline{\text{PC-CUT}}(a, b, c, T; \text{AUX}, a')$ consists of the graph PC-CUT$(a', b, c, T; \text{AUX})$ and a unit-weight edge $\{a, a'\}$. The following claim shows exactly how good this gadget is in "verifying" that $b_a = c$.

CLAIM 4.18 (MaxCUT RMB gadget). *RMBC-CUT*$(a, b_0, b_1, c, T; \text{AUX}_1, \text{AUX}_2, \text{AUX}_3, a')$ *is a* $(22, 2)$*-RMBC gadget consisting of edges of total weight* 33.

Again, the straightforward proof is omitted (and can be found in [20]).

Proof of Theorem 4.14. The theorem follows by combining Proposition 4.3, Lemma 4.15, and Claims 4.17 and 4.18 (when regarding the RMB gadget as a $(11, 1)$ gadget rather than a $(22, 2)$ gadget). Details follows.

As in the proof of Theorem 4.6, when applying Lemma 4.15 to the verifier in Proposition 4.3, we obtain the same expression for the gap, c'/s', for which NP $\leq_D^\kappa$ Gap-MaxCUT$_{c',s'}$; namely,

$$\begin{aligned}\frac{c'}{s'} &\to 1 + \frac{(1-s)\beta}{q \cdot \alpha_1 + (1-q) \cdot \alpha_2 - (1-s)\beta} \\ &= 1 + \frac{3}{12\alpha_1 + 8\alpha_2 - 3}.\end{aligned}$$

Recall that here $\alpha_1 - 1 = 9$ and $\alpha_2 - 1 = 11$ (rather than $\alpha_1 = 9$ and $\alpha_2 = 11$; see Lemma 4.15). The above simplifies to $1 + \frac{3}{213} = 72/71$ and the bound on $\frac{c'}{s'}$ follows. As for c', it equals $\frac{3\alpha_1 + 2\alpha_2}{3w_1 + 2w_2} > 0.6$ (as $w_1 - 1 = 14$ and $w_2 - 1 = 16.5$). □

5. Free bits and vertex cover. It is known that approximating the minimum vertex cover of a graph to within a $1+\epsilon$ factor is hard, for some $\epsilon > 0$ [76, 8]. However, we do not know of any previous attempt to provide a lower bound for ϵ. An initial attempt may use VC gadgets that implement the various tests in V_{SNPinner} analogously to the way it was done in the previous sections for the MaxSAT versions and MaxCUT. This yields a lower bound of $\epsilon > \frac{1}{43} > 0.023$ (see details in previous versions of this work [20]). However, a stronger result is obtained via free-bit complexity:[9] We apply the FGLSS reduction to a proof system (for NP) of low free-bit complexity, specifically to a proof system which uses two free bits and has soundness error below 0.8. Consequently, the clique size, in case the original input is in the language, is at least one-fourth (1/4) of the size of the graph, which means that translating clique-approximation factors to VC-approximation factors yields only a loss of a factor of 3. Since the FGLSS transformation translates the completeness/soundness ratio to the gap factor for approximating clique, our first goal is to construct for NP a proof system which uses two free bits and has soundness error as low as possible. We remark that the proof system of section 6 uses seven free bits and achieves soundness error less than 1/2. The reader may observe that, following the above approach, it is not worthwhile to use the proof system of section 6 or any proof systems which achieves a soundness error of 1/2 at the cost of five free bits or more. On the other hand, in light of the results of section 10, we cannot hope for a proof system of free-bit complexity 1 (and perfect completeness) for NP.

5.1. Minimizing the error achievable with two free bits. The pcp system of Proposition 4.3 had free-bit complexity 2 (and query complexity 3). However, a

[9] Furthermore, there seems to be little hope that the former approach can ever yield an improvement over the better bounds subsequently obtained by Håstad [57].

The enhanced RMB test. Again, $A\colon \mathcal{F}_l \to \Sigma$ is the object being tested, and the test take additional inputs or parameters $f_1, f_2 \in \mathcal{F}_l$.

EMBTest$(A; f_1, f_2)$ (enhanced monomial-basis test).
For every $f \in \mathcal{F}_l$, invoke **MBTest**$(A; f_1, f, f_2)$.
Output 0 if all invocations answered with 0, else output 1.

The passing probability:

$$\textsc{embPass}(A) = \Pr_{f_1, f_2 \stackrel{R}{\leftarrow} \mathcal{F}_l}[\,\mathbf{EMBTest}(A; f_1, f_2) = 0\,].$$

FIG. 12. *The enhanced RMB test and its passing probability.*

The two free-bit inner verifier. Given functions $h \in \mathcal{F}_l$ and $\sigma\colon \Sigma^l \to \Sigma^{l_1}$, the verifier has access to oracles for $A\colon \mathcal{F}_l \to \Sigma$ and $A_1\colon \mathcal{F}_{l_1} \to \Sigma$. In addition it takes a parameter $p \in [0,1]$.

Pick $q \stackrel{R}{\leftarrow} [0,1]$.

Case: $q \le p$:
Pick $f_1, f_2 \stackrel{R}{\leftarrow} \mathcal{F}_l$.
LinTest$(A_{(h,0),(\bar{1},1)}; f_1, f_2)$.
EMBTest$(A_{(h,0),(\bar{1},1)}; f_1, f_2)$.

Case: $q > p$:
Pick $f \stackrel{R}{\leftarrow} \mathcal{F}_l$ and $g \stackrel{R}{\leftarrow} \mathcal{F}_{l_1}$.
ProjTest$_\sigma(A_{(h,0),(\bar{1},1)}, A_1; f, g)$.

Remark: access to $A_{(h,0),(\bar{1},1)}(f)$ is implemented by accessing either $A(f)$ or $A(f+h)$ or $A(f+\bar{1})$ or $A(f+h+\bar{1})$.

FIG. 13. *The two free-bit inner verifier* $V_{2\text{inner}}$.

smaller soundness error can be achieved if we make more queries. Our starting point is part 2 of Lemma 3.19 which suggests an RMB test with a detection probability that is twice as big, still using 2 free bits (alas, $2^l + 2$ rather than three queries). Specifically, we consider an *enhanced* RMB test which, on input $f_1, f_2 \in \mathcal{F}_l$, goes over all $f \in \mathcal{F}_l$ invoking the atomic RMB test with input functions f_1, f, f_2. The enhanced RMB Test, denoted **EMBTest**, is depicted in Figure 12. Further improvement is obtained by "packing" together the linearity test and the enhanced RMB test (in contrast to V_{SNPinner} in which these tests were performed exclusively). Both tests make three queries of which two are common, and the answers to these queries determine the answer to the third query (which is different in the two tests). The resulting inner verifier, denoted $V_{2\text{inner}}$, is depicted in Figure 13. As V_{SNPinner}, the verifier $V_{2\text{inner}}$ works with functions/oracles A that are folded twice—once across $(h,0)$ and once across $(\bar{1},1)$.

The following corollary is immediate from part 2 of Lemma 3.19.

COROLLARY 5.1 (analysis of the enhanced monomial-basis test). *Let* $A, \tilde{A}\colon \mathcal{F}_l \to \Sigma$ *with* A *satisfying* $A(f+\bar{1}) = A(f)+1$ *for all* f *and* $\tilde{A}$ *linear but not respecting the*

monomial basis. Let $x = \mathrm{Dist}(A, \tilde{A})$. *Then*

$$1 - \textsc{embPass}(A) \;\geq\; \frac{3}{4} \cdot (1 - 2x).$$

The following lemma is analogous to Lemma 4.1. Loosely speaking, it considers three possible strategies of a "dishonest" prover and indicates the probability with which the verifier detects an error.

LEMMA 5.2 (soundness of $V_{2\mathrm{inner}}$). *Let* $\delta_1, \delta_2 > 0$, $0 \leq p \leq 1$, *and* $l, l_1 \in \mathcal{Z}^+$. *Then the* (l, l_1)*-canonical inner verifier* $V_{2\mathrm{inner}}$ *(with parameter* p*) is* $(\rho, \delta_1, \delta_2)$*-good, where* $1 - \rho = \min(T_1, T_2, T_3)$ *and*

(1) $T_1 \stackrel{\mathrm{def}}{=} (1/2 - \delta_1) \cdot p$,

(2) $T_2 \stackrel{\mathrm{def}}{=} p \cdot \min_{x \leq 1/2 - \delta_1} [\, \max(\Gamma_{\mathrm{lin}}(x)\,,\, 3/4 \cdot (1 - 2x)) \,]$,

(3) $T_3 \stackrel{\mathrm{def}}{=} \min_{x \leq 1/2 - \delta_1} [\, p \cdot \Gamma_{\mathrm{lin}}(x) + (1 - p) \cdot (1/2 - \delta_2)(1 - 2x) \,]$.

Proof. The analysis is broken up into several cases as in the proof of Lemma 4.1. Let $x = \mathrm{Dist}(A_{(h,0),(\bar{1},1)}, \textsc{Lin})$.

Case 1. $x \geq 1/2 - \delta_1$. Lemma 3.15 implies that $1 - \textsc{LinPass}(A_{(h,0),(\bar{1},1)}) \geq \Gamma_{\mathrm{lin}}(x) \geq x \geq 1/2 - \delta_1$. Since $V_{2\mathrm{inner}}$ performs the atomic linearity test with probability p, we have in this case

$$1 - \mathtt{ACC}\,[\, V_{2\mathrm{inner}}^{A,A_1}(\sigma, h)\,] \geq p \cdot (1/2 - \delta_1).$$

Case 2. $x < 1/2 - \delta_1$. Again, Lemma 3.15 implies that $1 - \textsc{LinPass}(A_{(h,0),(\bar{1},1)}) \geq \Gamma_{\mathrm{lin}}(x)$, and

$$1 - \mathtt{ACC}\,[\, V_{2\mathrm{inner}}^{A,A_1}(\sigma, h)\,] \;\geq\; p \cdot \Gamma_{\mathrm{lin}}(x)$$

follows. Now let $\tilde{A}$ be a linear function such that $\mathrm{Dist}(A_{(h,0),(\bar{1},1)}, \tilde{A}) = x$. We consider the following subcases.

Case 2.1. $\tilde{A}$ does not respect the monomial basis. In this case Corollary 5.1 implies that $1 - \textsc{embPass}(A_{(h,0),(\bar{1},1)}) \geq \frac{3}{4} \cdot (1 - 2x)$. So the probability that $V_{2\mathrm{inner}}$ rejects is at least $p \cdot \frac{3}{4} \cdot (1 - 2x)$. Combining the two lower bounds on $1 - \mathtt{ACC}\,[\, V_{2\mathrm{inner}}^{A,A_1}(\sigma, h)\,]$, we get

$$1 - \mathtt{ACC}\,[\, V_{2\mathrm{inner}}^{A,A_1}(\sigma, h)\,] \;\geq\; p \cdot \max\left(\Gamma_{\mathrm{lin}}(x), \frac{3}{4}(1 - 2x)\right).$$

Case 2.2. $\tilde{A}$ respects the monomial basis. By Proposition 3.2, $\tilde{A}$ is an evaluation operator. So there exists $a \in \Sigma^l$ such that $\tilde{A} = E_a$. So $\mathrm{Dist}(A_{(h,0),(\bar{1},1)}, E_a) = x$. Let $a_1 = \sigma(a)$. The proof splits into two further subcases.

Case 2.2.1. $d \stackrel{\mathrm{def}}{=} \mathrm{Dist}(A_1, E_{a_1}) \geq 1/2 - \delta_2$. By Lemma 3.21 we have $1 - \textsc{ProjPass}_{\sigma}(A_{(h,0),(\bar{1},1)}, A_1) \geq d \cdot (1 - 2x) \geq (1/2 - \delta_2) \cdot (1 - 2x)$. So the probability that $V_{2\mathrm{inner}}$ performs the projection test and rejects is at least $(1 - p) \cdot (1/2 - \delta_2)(1 - 2x)$. To this we add the probability of the exclusively disjoint event in which the verifier performs the linearity test and rejects, obtaining

$$1 - \mathtt{ACC}\,[\, V_{2\mathrm{inner}}^{A,A_1}(\sigma, h)\,] \;\geq\; p \cdot \Gamma_{\mathrm{lin}}(x) + (1 - p) \cdot (1/2 - \delta_2)(1 - 2x).$$

Case 2.2.2. In this case, we have $x = \mathrm{Dist}(A_{(h,0),(\bar{1},1)}, E_a) < 1/2 - \delta_1$ and $\mathrm{Dist}(A_1, E_{a_1}) < 1/2 - \delta_2$. Thus the functions $A_{(h,0),(\bar{1},1)}$ and A_1 satisfy conditions (2.1) and (2.2) in Definition 3.9.

Similarly to the proof of Lemma 4.1, we infer that the lower bound on $1-\rho$ is as claimed and the lemma follows. □

We now simplify the soundness bound of the lemma. The proof of the first item uses the fact that $\Gamma_{\mathrm{lin}}(x) \geq 45/128$ for all $x \geq \frac{1}{4}$. The second item uses the fact that $\Gamma_{\mathrm{lin}}(x) \geq x$ for all $x \leq 1/2$.

CLAIM 5.3.

(1) $\min_{x \leq 1/2-\delta_1} [\max(\Gamma_{\mathrm{lin}}(x)\,,\, \frac{3}{4}(1-2x))] \geq 45/128$.

(2) $\min_{x \leq 1/2-\delta_1} [\, p \cdot \Gamma_{\mathrm{lin}}(x) + (1-p) \cdot (1/2 - x)\,] \geq \frac{1}{2} \cdot \min(p\,,\, 1-p)$.

(3) *Let T_1, T_2 and T_3 be as in Lemma* 5.2. *Then*

$$\min(T_1, T_2, T_3) \;\geq\; \min\left\{ \frac{45}{128} \cdot p\,,\; \frac{1}{2} \cdot (1-p) \right\} - \max(\delta_1, \delta_2).$$

Interestingly, the lower bound provided by item 3 is tight. Optimization calls for setting $\frac{45}{128} \cdot p = \frac{1}{2} \cdot (1-p)$, which yields $p = \frac{64}{109}$ and a soundness bound of $1 - \frac{45}{128}p + \max(\delta_1, \delta_2) = 1 - \frac{45}{218} + \max(\delta_1, \delta_2)$.

Proof. Toward proving part 1 we consider two cases.

Case 1.1. $x \geq 1/4$. In this case, by definition of Γ_{lin}, we have

$$\max(\Gamma_{\mathrm{lin}}(x)\,,\, \frac{3}{4}(1-2x)) \;\geq\; \Gamma_{\mathrm{lin}}(x) \;\geq\; \frac{45}{128}.$$

Case 1.2. $x \leq 1/4$. In this case we have

$$\max\left(\Gamma_{\mathrm{lin}}(x)\,,\, \frac{3}{4}(1-2x)\right) \;\geq\; \frac{3}{4}(1-2x) \;\geq\; \frac{3}{8} \;>\; \frac{45}{128}.$$

This establishes part 1. Towards proving part 2 we consider two different cases.

Case 2.1. $p \leq (1-p)$. In this case,

$$p \cdot \Gamma_{\mathrm{lin}}(x) + (1-p) \cdot \left(\frac{1}{2} - x\right) \;\geq\; p \cdot x + p \cdot \left(\frac{1}{2} - x\right) \;=\; \frac{p}{2}.$$

Case 2.2. $p \geq (1-p)$. In this case,

$$p \cdot \Gamma_{\mathrm{lin}}(x) + (1-p) \cdot \left(\frac{1}{2} - x\right) \;\geq\; (1-p) \cdot x + (1-p) \cdot \left(\frac{1}{2} - x\right) \;=\; \frac{1-p}{2}.$$

This establishes part 2. To prove part 3 use parts 1 and 2 to lower bound T_2 and T_3, respectively, and get

$$\begin{aligned} \min(T_1, T_2, T_3) &\geq \min\left\{ \left(\frac{1}{2} - \delta_1\right) \cdot p\,,\; \frac{45}{128} \cdot p\,,\; \frac{1}{2} \cdot \min(p\,,\, 1-p) - \delta_2 \right\} \\ &\geq \min\left\{ \frac{45}{128} \cdot p\,,\; \frac{1}{2} \cdot (1-p) \right\} - \max(\delta_1, \delta_2). \end{aligned}$$

The claim follows. □

Composing the above inner verifier with an adequate outer verifier, we get the following.

THEOREM 5.4. *For any* $s > \frac{173}{218} \approx 0.79357798$, $\mathrm{NP} \subseteq \mathrm{FPCP}_{1,s}[\log, 2]$, *and furthermore, there is a constant* q *such that* $\mathrm{NP} \subseteq \mathrm{PCP}_{1,s}[\,\mathsf{coins} = \log\,;\,\mathsf{free} = 2\,;\,\mathsf{query} = q\,]$.

Proof. Let $\delta = s - \frac{173}{218}$, $\delta_1 = \delta_2 = \delta/3$, and $\epsilon = \delta/3 \cdot 16\delta_1^2\delta_2^2 = \frac{16\delta^5}{243}$. Now, let l and l_1 be integers such that the outer verifier, V_{outer}, guaranteed by Lemma 3.8, is (l, l_1)-canonical and ϵ-good for $L \in \mathrm{NP}$. Consider the (l, l_1)-canonical inner verifier $V_{2\mathrm{inner}}$ working with parameter $p = \frac{64}{109}$. Using Lemma 5.2 and Claim 5.3, we conclude that $V_{2\mathrm{inner}}$ is (ρ, δ, δ)-good for $\rho = 1 - 45/218 + \max(\delta_1, \delta_2)$.

Composing V_{outer} and $V_{2\mathrm{inner}}$ we obtain a verifier, $V_{2\mathrm{free}}$, which by Theorem 3.12 has soundness error bounded above by $\frac{173}{218} + \max(\delta_1, \delta_2) + \frac{\epsilon}{16\delta_1^2\delta_2^2} = s$, as required. Furthermore, $V_{2\mathrm{free}}$ uses logarithmically many coins. We claim that $V_{2\mathrm{free}}$ has query complexity $2^{2^l} + 2$ and free-bit complexity 2. The claim is obvious in case $V_{2\mathrm{inner}}$ performs the projection test. Otherwise, $V_{2\mathrm{inner}}$ performs a linearity test with parameters f_1 and f_2 and an enhanced RMB test with the same parameters. Clearly, the answers on f_1 and f_2 determine the acceptable (by linearity test) answer on $f_1 + f_2$. The key observation is that the former two answers also determine all 2^{2^l} acceptable answers in the enhanced RMB test (i.e., for every $f \in \mathcal{F}_l$, the answer on $f_1' \cdot f + f_2$ should equal the answer on f_2, where $f_1' = f_1$ if the answer on f_1 is zero and $f_1' = f_1 + \bar{1}$ otherwise). □

By repeating the above proof system three times, we obtain the following.

COROLLARY 5.5. $\mathrm{NP} \subseteq \mathrm{FPCP}_{1,1/2}[\log, 6]$. *Furthermore, there is a constant* q *such that*

$$\mathrm{NP} \subseteq \mathrm{PCP}_{1,1/2}[\,\mathsf{coins} = \log\,;\,\mathsf{free} = 6\,;\,\mathsf{query} = q\,]\,.$$

Proof. There exists $\epsilon > 0$ such that $\left(\frac{173}{218} + \epsilon\right)^3 \leq 1/2$. □

5.2. Hardness of vertex cover. Refer to section 2.4 for the definition of the MinVC problem and the associated gap problem $\mathsf{Gap}\text{-}\mathrm{MinVC}_{c,s}$, and to section 2.4.3 for status and previous work.

GOING FROM FREE BITS TO VC. Instead of reducing from Max3SAT, we first use Theorem 5.4 to get gaps in clique size and then apply the standard reduction.

PROPOSITION 5.6. $\mathrm{FPCP}_{c,s}[\log, f] \leq_D^K \mathsf{Gap}\text{-}\mathrm{MinVC}_{c',s'}$ *for* $s' = 1 - 2^{-f}c$ *and* $\frac{c'}{s'} = 1 + \frac{c-s}{2^f - c}$.

Proof. The FGLSS reduction says that $\mathrm{FPCP}_{c,s}[\log, f] \leq_D^K \mathsf{Gap}\text{-}\mathrm{MaxClique}_{c'',s''}$, where $c'' = 2^{-f} \cdot c$ and $s'' = 2^{-f} \cdot s$. (See section 2.4 for definition of Gap-MaxClique.) Now we apply the standard Karp reduction (of MaxClique to MinVC) which maps a graph G to its complement $\overline{G}$, noting that $\overline{\mathrm{MinVC}}(\overline{G}) = 1 - \overline{\mathrm{MaxClique}}(G)$. Thus $\mathsf{Gap}\text{-}\mathrm{MaxClique}_{c'',s''} \leq_D^K \mathsf{Gap}\text{-}\mathrm{MinVC}_{1-s'',1-c''}$. Now set $c' = 1 - s''$ and $s' = 1 - c''$, and note

$$\frac{c'}{s'} \;=\; \frac{1 - s''}{1 - c''} \;=\; \frac{1 - s2^{-f}}{1 - c2^{-f}} \;=\; 1 + \frac{c - s}{2^f - c}\,.$$

This completes the proof. □

OUR RESULTS. We obtain the first explicit and reasonable constant factor non-approximability result for MinVC. A consequence of the following theorem is that, assuming P ≠ NP, there is no polynomial-time algorithm to approximate MinVC within a factor of 1.0688.

THEOREM 5.7. $\mathsf{Gap}\text{-}\mathrm{MinVC}_{c,s}$ *is* NP*-complete for some* c, s *satisfying* $c/s \geq 1.0688 > 16/15$. *Moreover,* $s = 3/4$.

Proof. The proof follows immediately from Proposition 5.6 and Theorem 5.4. Namely, for any $s' > \frac{173}{218}$, $\mathrm{NP} \subseteq \mathrm{FPCP}_{1,s'}[\log, 2] \leq_D^K \mathsf{Gap}\text{-}\mathrm{MinVC}_{c,s}$ for $s = 1-2^{-2} = 3/4$ and $\frac{c}{s} = 1 + \frac{1-s'}{2^2-1} = 1 + \frac{1-s'}{3}$. Thus, $\frac{c}{s} = 1 + \frac{15}{218} - \frac{\epsilon}{3} > 1.068807 - \frac{\epsilon}{3}$, where $\epsilon \stackrel{\mathrm{def}}{=} s' - \frac{173}{218}$. □

We remark that a special case of Proposition 5.6, in which the statement is restricted to $f = 0$, would have sufficed for proving the above theorem, the reason being that we could have applied Proposition 11.8 to Theorem 5.4 and obtained $\mathrm{NP} \subseteq \mathrm{FPCP}_{1/4,s/4}[\log, 0]$, for $s = 0.7936$, which by the special case of Proposition 5.6 is reducible to $\mathsf{Gap}\text{-}\mathrm{MinVC}_{c',s'}$ with $s' = 1-1/4 = 3/4$ and $\frac{c'}{s'} = 1 + \frac{(1/4)-(s/4)}{1-(1/4)} = 1 + \frac{1-s}{3}$ (as above). Interestingly, the special case of Proposition 5.6 can be "reversed," namely, $\mathsf{Gap}\text{-}\mathrm{MinVC}_{c',s'}$ is reducible to $\mathrm{FPCP}_{c,s}[\log, 0]$ with $s = 1-c'$, $c = 1-s'$, and $\frac{c}{s} = \frac{1-s'}{1-c'}$ (which reverses $\frac{c'}{s'} = \frac{1-s}{1-c} = 1 + \frac{c-s}{1-c}$). The key fact in proving this "reverse reduction" is Corollary 8.5 which asserts that $\mathsf{Gap}\text{-}\mathrm{MaxClique}_{c,s} \leq_D^K \mathrm{FPCP}_{c,s}[\log, 0]$. However, we do not know if it is possible to "reverse" the other step in the alternative proof, namely, whether $\mathrm{FPCP}_{c,s}[\log, 0]$ is reducible to $\mathrm{FPCP}_{4c,4s}[\log, 2]$ (our reverse transformation is weaker; see Proposition 11.6).

6. Minimizing the number of queries for soundness 0.5. The problem we consider here is to minimize the values of q (and q_{av}) for which we can construct PCPs for NP using q queries in the worst case (and q_{av} on the average) to achieve a soundness error of $1/2$. We allow only logarithmic randomness. See section 2.2.3 for description of past records.

Sources of our improvements. The principal part of our improvement comes from the use of the new long code based inner verifier, the atomic tests and their analysis in section 3.5, and the new idea of folding. By repeating the proof system of Theorem 4.5 five times, we obtain that Eq. (4) holds for $q = 15$. (Note that $5 = \min\{i \in \mathsf{N} : 0.85^i < 0.5\}$.) A straightforward implementation of the recycling technique of [21] yields that Eq. (4) holds for $q = 12$ and $q_{\mathrm{av}} = 11.74$. Using a more careful implementation of this technique, we reduce the query complexity by an additional bit.

6.1. The PCP inner verifier. Our result is based on the construction of the (l, l_1)-canonical inner verifier V_{PCPinner} depicted in Figure 14. In addition to its standard inputs h, σ, it takes parameters $p_1, p_2, p_3 \geq 0$ so that $p_1 + p_2 + p_3 = 1$. The inner verifier V_{PCPinner} combines the atomic tests in three different ways.

(1) Some tests are performed independently (i.e., the main steps in Figure 14);
(2) Some tests are performed while reusing some queries (i.e., the tests in Step 2 reuse f_3);
(3) Some tests are performed in a mutually exclusive manner (i.e., the tests in Step 3).

As in previous sections, the tests are executed on the function $A_{(h,0),(\bar{1},1)}$ to which the verifier has an effective oracle access given its access to A. By inspection it is clear that the total number of accesses to the oracles for A and A_1 is $3 + 5 + 3 = 11$ (whereas the free-bit complexity is $2 + 3 + 2 = 7$). We now examine the goodness of V_{PCPinner}. Recall the definitions of the functions $\Gamma_{\mathrm{lin}}(x)$ (from Lemma 3.15) and $\Gamma_{\mathrm{RMB}}(x) = \frac{3}{8}(1-2x)$ (from Lemma 3.19).

Lemma 6.1 (soundness of V_{PCPinner}). *For any $0 < \delta_1, \delta_2 < 0.1$ and any l, l_1, p_1, p_2, and p_3, satisfying $p_1 + p_2 + p_3 = 1$ and $5p_1 = 2p_2$, the (l, l_1)-canonical inner*

The PCP inner verifier. This (l, l_1)-canonical inner verifier is given functions $h \in \mathcal{F}_l$ and $\sigma\colon \Sigma^l \to \Sigma^{l_1}$, and has access to oracles for $A\colon \mathcal{F}_l \to \Sigma$ and $A_1\colon \mathcal{F}_{l_1} \to \Sigma$. In addition it takes three nonnegative parameters p_1, p_2, and p_3 which sum up to 1.

Pick functions $f_1, \ldots, f_8 \overset{R}{\leftarrow} \mathcal{F}_l$ and $g_1, g_2 \overset{R}{\leftarrow} \mathcal{F}_{l_1}$.

Step 1: Linearity test.
LinTest$(A_{(h,0),(\bar{1},1)}; f_1, f_2)$.

Step 2: Combined RMB and projection test.
MBTest$(A_{(h,0),(\bar{1},1)}; f_3, f_4, f_5)$.
ProjTest$_\sigma(A_{(h,0),(\bar{1},1)}, A_1; f_3, g_1)$.

Step 3: Invoking V_{SNPinner} with parameters p_1, p_2, p_3.
Pick $p \overset{R}{\leftarrow} [0,1]$.

Case $p \le p_1$:	**LinTest**$(A_{(h,0),(\bar{1},1)}; f_6, f_7)$.
Case $p_1 < p \le p_1 + p_2$:	**MBTest**$(A_{(h,0),(\bar{1},1)}; f_6, f_7, f_8)$.
Case $p_1 + p_2 < p$:	**ProjTest**$_\sigma(A_{(h,0),(\bar{1},1)}, A_1; f_6, g_2)$.

Accept iff all the above tests accept.

Remark: access to $A_{(h,0),(\bar{1},1)}(f)$ is implemented by accessing either $A(f)$, $A(f+h)$, $A(f+\bar{1})$, or $A(f+h+\bar{1})$.

FIG. 14. *The PCP inner verifier* V_{PCPinner}.

verifier V_{PCPinner} *is* $(\rho, \delta_1, \delta_2)$*-good, where* $1-\rho$ *is the minimum of the following three quantities:*

(1) $1/2 + \frac{p_1}{10} - \delta_1$;
(2) $1 - (11/14)^3 - \frac{p_3}{1-p_3} > 0.51494168 - \frac{p_3}{1-p_3}$;
(3) $\min\{1/2 + \frac{p_3}{20} - \delta_2\,,\, 1 - (0.55218507 + \delta_2) \cdot (1 - 45/128 p_1)\}$.

Furthermore, if $p_1 > 10\delta_1$, $p_3 > 20\delta_2$ *and* $p_3 \le 0.01$, *then* $1 - \rho > 1/2$.

Proof. We split the analysis into several cases based on the value of

$$x \;=\; \text{Dist}(A_{(h,0),(\bar{1},1)}, \textsc{Lin})\,.$$

Case 1. $x \ge 1/2 - \delta_1$. Lemma 3.15 implies that $\textsc{LinPass}(A_{(h,0),(\bar{1},1)}) \le 1 - \Gamma_{\text{lin}}(x) \le 1 - x \le 1/2 + \delta_1$. Thus, in this case

$$\texttt{ACC}\,[\,V^{A,A_1}_{\text{PCPinner}}(\sigma, h)\,] \;\le\; \rho_1 \overset{\text{def}}{=} (1-p_1)\cdot\left(\frac{1}{2}+\delta_1\right) + p_1 \cdot \left(\frac{1}{2}+\delta_1\right)^2 \;<\; \frac{1}{2}+\delta_1 - \frac{p_1}{10}.$$

(The last inequality is due to $\delta_1 < 0.1$.) Using $p_1 > 10\delta_1$ we get $\rho_1 < 1/2$.

Case 2. $x < 1/2 - \delta_1$. Let $\tilde{A}\colon \mathcal{F}_l \to \Sigma$ be a linear function such that $\text{Dist}(A_{(h,0),(\bar{1},1)}, \tilde{A}) = x$. The proof splits into two subcases.

Case 2.1. $\tilde{A}$ does not respect the monomial basis. In this case, by Lemmas 3.15 and 3.19 we have, using $\Gamma_{\text{lin}}(x)$, $\Gamma_{\text{RMB}}(x) < 1$, in the second inequality,

$$\begin{aligned}\mathtt{ACC}\,[\,V^{A,A_1}_{\mathrm{PCPinner}}(\sigma,h)\,] &\le (1-\Gamma_{\mathrm{lin}}(x))\cdot(1-\Gamma_{\mathrm{RMB}}(x))\cdot(1-p_1\Gamma_{\mathrm{lin}}(x)-p_2\Gamma_{\mathrm{RMB}}(x))\\ &< (1-\Gamma_{\mathrm{lin}}(x))\cdot(1-\Gamma_{\mathrm{RMB}}(x))\\ &\quad\cdot\left(1-\frac{p_1}{p_1+p_2}\cdot\Gamma_{\mathrm{lin}}(x)-\frac{p_2}{p_1+p_2}\cdot\Gamma_{\mathrm{RMB}}(x)+\frac{p_3}{1-p_3}\right)\\ &< \alpha\cdot\beta\cdot[q\alpha+(1-q)\beta]+\frac{p_3}{1-p_3},\end{aligned}$$

where $q \stackrel{\mathrm{def}}{=} \frac{p_1}{p_1+p_2}$, $\alpha = 1-\Gamma_{\mathrm{lin}}(x)$, and $\beta = 1-\Gamma_{\mathrm{RMB}}(x)$. Using $p\cdot x+(1-p)\cdot y \ge x^p\cdot y^{1-p}$, we show that $\alpha\cdot\beta\cdot[q\alpha+(1-q)\beta] \le [\frac{1+q}{3}\alpha+\frac{2-q}{3}\beta]^3$. Specifically,

$$\begin{aligned}\left[\frac{1+q}{3}\alpha+\frac{2-q}{3}\beta\right]^3 &= \left[\frac{2}{3}\cdot\left(\frac{1}{2}\alpha+\frac{1}{2}\beta\right)+\frac{1}{3}\cdot(q\alpha+(1-q)\beta)\right]^3\\ &\ge \left(\frac{1}{2}\alpha+\frac{1}{2}\beta\right)^{\frac{2}{3}\cdot 3}\cdot(q\alpha+(1-q)\beta)^{\frac{1}{3}\cdot 3}\\ &= \left[\frac{1}{2}\cdot\alpha+\frac{1}{2}\cdot\beta\right]^2\cdot(q\alpha+(1-q)\beta)\\ &\ge \alpha\cdot\beta\cdot(q\alpha+(1-q)\beta).\end{aligned}$$

Combining the above with Claim 4.2 (i.e., the lower bound on T_2), we obtain (for every $x<1/2$)

$$\begin{aligned}\mathtt{ACC}\,[\,V^{A,A_1}_{\mathrm{PCPinner}}(\sigma,h)\,] &< \left[1-\frac{1+q}{3}\cdot\Gamma_{\mathrm{lin}}(x)-\frac{2-q}{3}\cdot\Gamma_{\mathrm{RMB}}(x)\right]^3+\frac{p_3}{1-p_3}\\ &\le \left[1-\min\left(\frac{1+q}{6},\frac{2-q}{8}\right)\right]^3+\frac{p_3}{1-p_3}.\end{aligned}$$

Observe that $\min(\frac{1+q}{6},\frac{2-q}{8})$ is maximized at $q=2/7$ where its value is $3/14$. Indeed this value of q is consistent with $p_1=\frac{2}{7}\cdot(p_1+p_2)$ and so, in this case, we get

$$\mathtt{ACC}\,[\,V^{A,A_1}_{\mathrm{PCPinner}}(\sigma,h)\,] \;\le\; \rho_2 \stackrel{\mathrm{def}}{=} \left[\frac{11}{14}\right]^3+\frac{p_3}{1-p_3} \;<\; 0.48505832+\frac{p_3}{1-p_3}.$$

Using $p_3 \le 0.01$ we get $\rho_2 < 1/2$.

Case 2.2. $\tilde{A}$ respects the monomial basis. By Proposition 3.2, $\tilde{A}$ is an evaluation operator. So there exists $a\in\Sigma^l$ such that $\tilde{A}=E_a$. So $\mathrm{Dist}(A_{(h,0),(\bar{1},1)},E_a)=x$. Let $a_1=\sigma(a)$. The proof splits into two further subcases.

Case 2.2.1. $d \stackrel{\mathrm{def}}{=} \mathrm{Dist}(A_1,E_{a_1}) \ge 1/2-\delta_2$. By Lemma 3.21 we have

$$\textsc{ProjPass}_\sigma(A_{(h,0),(\bar{1},1)},A_1) \le 1-d\cdot(1-2x) < \frac{1}{2}+x+\delta_2\ .$$

Letting $\Gamma_{\mathrm{PRJ}}(x) \stackrel{\mathrm{def}}{=} 1/2-x-\delta_2$, we get in this case

$$\mathtt{ACC}\,[\,V^{A,A_1}_{\mathrm{PCPinner}}(\sigma,h)\,] \;\le\; \rho_3 \stackrel{\mathrm{def}}{=} (1-\Gamma_{\mathrm{lin}}(x))\cdot(1-\Gamma_{\mathrm{PRJ}}(x))\cdot(1-p_1\Gamma_{\mathrm{lin}}(x)-p_3\Gamma_{\mathrm{PRJ}}(x)).$$

We upper bound ρ_3 by considering three subcases (corresponding to the segments of Γ_{lin}).

Case 2.2.1.1. $x \leq 1/4$. In this case we use $\Gamma_{\text{lin}}(x) \geq 3x(1-2x)$ and obtain

$$\begin{aligned}\rho_3 &< (1-\Gamma_{\text{lin}}(x)) \cdot (1-\Gamma_{\text{PRJ}}(x)) \cdot (1-p_3\Gamma_{\text{PRJ}}(x)) \\ &< (1-3x(1-2x)) \cdot \left(\frac{1}{2}+x+\delta_2\right) \cdot \left(1-\frac{p_3}{10}\right) \\ &< \frac{1}{2} \cdot \left[1-x+12x^3\right] \cdot \left[1-\frac{p_3}{10}\right] + \delta_2 \\ &\leq \frac{1}{2} \cdot \left[1-\frac{p_3}{10}\right] + \delta_2,\end{aligned}$$

where the last inequality uses the fact that the function $x - 12x^3$ is nonnegative in the interval $[0, 1/4]$. Using $p_3 > 20\delta_2$ we obtain $\rho_3 < 1/2$.

Case 2.2.1.2. $x \geq 1/4$ and $x \leq 45/125$. In this case we use $\Gamma_{\text{lin}}(x) \geq 45/128 = \Gamma_{\text{lin}}(45/128)$ and $\Gamma_{\text{PRJ}}(x) \geq \Gamma_{\text{PRJ}}(45/128)$ and obtain

$$\begin{aligned}\rho_3 &< (1-\Gamma_{\text{lin}}(x)) \cdot (1-\Gamma_{\text{PRJ}}(x)) \cdot (1-p_1\Gamma_{\text{lin}}(x)) \\ &\leq \left(1-\Gamma_{\text{lin}}\left(\frac{45}{128}\right)\right) \cdot \left(1-\Gamma_{\text{PRJ}}\left(\frac{45}{128}\right)\right) \cdot \left(1-p_1\Gamma_{\text{lin}}\left(\frac{45}{128}\right)\right) \\ &< \frac{83}{128} \cdot \left(\frac{109}{128}+\delta_2\right) \cdot \left(1-p_1\frac{45}{128}\right) \\ &< (0.55218507+\delta_2) \cdot \left(1-p_1\frac{45}{128}\right).\end{aligned}$$

Using $\delta_2 < \frac{p_3}{10} \leq 0.001$ and $p_1 \geq \frac{2}{7} \cdot 0.99 > 0.28$, we obtain $\rho_3 < 0.5532 \cdot 0.902 < 0.499$.

Case 2.2.1.3. $x \geq 45/128$. In this case we use $\Gamma_{\text{lin}}(x) \geq x \geq 45/128$ and obtain

$$\begin{aligned}\rho_3 &< (1-\Gamma_{\text{lin}}(x)) \cdot (1-\Gamma_{\text{PRJ}}(x)) \cdot (1-p_1\Gamma_{\text{lin}}(x)) \\ &< (1-x) \cdot \left(\frac{1}{2}+x+\delta_2\right) \cdot \left(1-p_1\frac{45}{128}\right).\end{aligned}$$

The latter expression decreases in the interval $[45/128\,,\,1/2]$ and is hence maximized at $x = 45/128$. Thus we obtain the same expression as in Case 2.2.1.2, and the bound on ρ_3 follows identically.

We conclude that in Case 2.2.1 we have

$$\rho_3 \;<\; \max\left[\frac{1}{2}-\frac{p_3}{20}+\delta_2\;,\;(0.55218507+\delta_2) \cdot \left(1-p_1\frac{45}{128}\right)\right],$$

and under the hypothesis regarding p_1, p_3, and δ_2, we always have $\rho_3 < 0.5$.

Case 2.2.2. Else, we have $x = \text{Dist}(A_{(h,0),(\bar{1},1)}, E_a) \leq 1/2-\delta_1$ and $\text{Dist}(A_1, E_{a_1}) < 1/2 - \delta_2$. Thus the functions $A_{(h,0),(\bar{1},1)}$ and A_1 satisfy the properties required in conditions (2.1) and (2.2) of Definition 3.9.

Let $\rho \stackrel{\text{def}}{=} \max\{\rho_1, \rho_2, \rho_3\}$. We conclude that the only case which allows

$$\texttt{ACC}\left[\, V_{\text{PCPinner}}^{A,A_1}(\sigma, h)\,\right] > \rho$$

is Case 2.2.2, which also satisfies conditions (2.1) and (2.2) of Definition 3.9. Thus, V_{PCPinner} satisfies condition (2) of Definition 3.9. Clearly, V_{PCPinner} also satisfies condition (1) of Definition 3.9, and thus the lemma follows. □

6.2. The new proof system. Combining the above inner verifier with an adequate outer verifier, we obtain a pcp system for NP with query complexity 11.

THEOREM 6.2. $\mathrm{NP} = \mathrm{PCP}_{1,1/2}[\mathsf{coins} = \log\,;\ \mathsf{query} = 11\,;\ \mathsf{query}_{\mathrm{av}} = 10.89\,;\ \mathsf{free} = 7]$.

Proof. We consider a canonical (l, l_1)-inner verifier V_{PCPinner} with parameters $p_3 = 0.001$, $p_1 = 2/7 \cdot 0.999$ and $p_2 = \frac{5}{7} \cdot 0.999$. By Lemma 6.1, V_{PCPinner} is $(\rho, \delta_1, \delta_2)$-good for $\delta_1 = \delta_2 = 0.00001$ and $\rho = 0.49999$. We now choose an appropriate outer verifier. Let $\epsilon = 16 \cdot (0.5 - \rho)\delta_1^2\delta_2^2$. Lemma 3.8 provides us with l and l_1 such that an ϵ-good (l, l_1)-canonical outer verifier V_{outer} with randomness $O(\log n)$ exists. Let $V = \langle V_{\mathrm{outer}}, V_{\mathrm{PCPinner}} \rangle$ be the composition of V_{outer} and V_{PCPinner} according to the definitions in section 3.4. This verifier has randomness $O(\log n)$. Apply Theorem 3.12 to see that V has completeness parameter 1 and soundness parameter $\rho + \epsilon/(16\delta_1^2\delta_2^2) = 1/2$. The query (and free-bit) complexity of V is the same as that of V_{PCPinner} above (i.e., 11 and 7, respectively).

To obtain the bound on the average query complexity, we observe that we can afford not to perform the RMB test with some small probability. Specifically, Case 2.1 in the proof of Lemma 6.1, which is the only case where the RMB test is used, yields error of $0.48505832 + \frac{p_3}{1-p_3}$. Thus, if we modify V_{PCPinner} so that, whenever the RMB test is invoked it is performed only with probability 0.973, we get that Case 2.1 detects violation with probability at least $(1 - 0.48505832 - 0.0010011) \cdot 0.973 > 0.50006$. Consequently, the modified inner verifier errs with probability bounded away from $1/2$ and so does the composed verifier. The modification decreases the average query complexity by $(1 - 0.973) \cdot (2 + p_2 \cdot 3) > 0.027 \cdot 4.12 > 0.11$. (The reduction is both from step 2 and the second case in step 3.) The theorem follows. ∎

7. Amortized free bits and MaxClique hardness.

7.1. The iterated tests. The "iterated tests" will be used in the next section to derive a proof system for NP having amortized free-bit complexity ≈ 2. Intuitively, we will be running each of the atomic tests many times, but, to keep the free-bit count low, these will NOT be independent repetitions. Rather, following [23], we will run about $2^{O(m)}$ copies of each test in a way which is pairwise, or "almost" pairwise independent, to lower the error probability to $O(2^{-m})$. This will be done using $2m$ free bits. Specifically, we will select uniformly m functions in $\mathcal{F}_l$ (and m functions in $\mathcal{F}_{l_1}$) and invoke the atomic tests with functions resulting from all possible linear combinations of the selected functions.

7.1.1. Linearity and randomness. We begin with some observations relating stochastic and linear independence. Note that $\mathcal{L}_m$ is a subvector space of $\mathcal{F}_m$, and in particular a vector space over Σ in its own right. So we can discuss the linear independence of functions in $\mathcal{L}_m$. We say that $\vec{L} = (L_1, \ldots, L_k) \in \mathcal{L}_m^k$ is linearly independent if $L_1, \ldots, L_k$ are linearly independent. Furthermore, we say that $\vec{L}_1 = (L_{1,1}, \ldots, L_{1,k})$ and $\vec{L}_2 = (L_{2,1}, \ldots, L_{2,k})$ are *mutually linearly independent* if the $2k$ functions $L_{1,1}, L_{2,1}, \ldots, L_{1,k}, L_{2,k}$ are linearly independent.

LEMMA 7.1. *For $\vec{L} = (L_1, \ldots, L_k) \in \mathcal{L}_m^k$ let $J_{\vec{L}} \colon \mathcal{F}_l^m \to \mathcal{F}_l^k$ be defined by $J_{\vec{L}}(\vec{f}) = (L_1 \circ \vec{f}, \ldots, L_k \circ \vec{f})$, for $\vec{f} = (f_1, \ldots, f_m)$. Fix $\vec{L}$ and consider the probability space defined by having $f_1, \ldots, f_m$ be uniformly and independently distributed over $\mathcal{F}_l$. Regard the $J_{\vec{L}}$'s as random variables over the above probability space. Then*

(1) *if $\vec{L}$ is linearly independent, then $J_{\vec{L}}$ is uniformly distributed in $\mathcal{F}_l^k$.*

(2) *if $\vec{L}_1, \vec{L}_2$ are mutually linearly independent, then $J_{\vec{L}_1}$ and $J_{\vec{L}_2}$ are independently distributed.*

The iterated tests. Here A: $\mathcal{F}_l \to \Sigma$ and A_1: $\mathcal{F}_{l_1} \to \Sigma$ are the objects being tested. The tests also take additional inputs or parameters: below $\vec{f} \in \mathcal{F}_l^m$; $\vec{g} \in \mathcal{F}_{l_1}^m$; $L, L_1, L_2, L_3 \in \mathcal{L}_m$; and σ: $\Sigma^l \to \Sigma^{l_1}$. The tests are specified in terms of the atomic tests of Figure 8.

$$\mathbf{LinTest}^m(A; \vec{f}, L_1, L_2) = \mathbf{LinTest}(A; L_1 \circ \vec{f},\ L_2 \circ \vec{f}).$$

$$\mathbf{MBTest}^m(A; \vec{f}, L_1, L_2, L_3) = \mathbf{MBTest}(A; L_1 \circ \vec{f},\ L_2 \circ \vec{f},\ L_3 \circ \vec{f}).$$

$$\mathbf{ProjTest}_\sigma^m(A, A_1; \vec{f}, \vec{g}, L) = \mathbf{ProjTest}_\sigma(A, A_1; L \circ \vec{f},\ L \circ \vec{g}).$$

The passing probabilities. These are the probabilities we are interested in:

$$\textsc{LinPass}^m(A) = \Pr_{\vec{f} \stackrel{R}{\leftarrow} \mathcal{F}_l^m}\left[\forall\, L_1, L_2 \in \mathcal{L}_m\ :\ \mathbf{LinTest}^m(A; \vec{f}, L_1, L_2) = 0\right].$$

$$\textsc{MBPass}^m(A) = \Pr_{\vec{f} \stackrel{R}{\leftarrow} \mathcal{F}_l^m}\left[\forall\, L_1, L_2, L_3 \in \mathcal{L}_m\ :\ \mathbf{MBTest}^m(A; \vec{f}, L_1, L_2, L_3) = 0\right].$$

$$\textsc{ProjPass}_\sigma^m(A, A_1) = \Pr_{\vec{f} \stackrel{R}{\leftarrow} \mathcal{F}_l^m\ ;\ \vec{g} \stackrel{R}{\leftarrow} \mathcal{F}_{l_1}^m}\left[\forall\, L \in \mathcal{L}_m\ :\ \mathbf{ProjTest}_\sigma^m(A, A_1; \vec{f}, \vec{g}, L) = 0\right].$$

FIG. 15. *The iterated tests and their passing probabilities.*

The proof of this lemma is quite standard and thus omitted; it amounts to saying that linearly independent combinations of stochastically independent random variables result in stochastically independent random variables.

The analysis of the iterated projection test (see Figure 15) can be done in a relatively straightforward way, given the above, because the invoked projection test uses a single linear combination of each sequence of random functions, rather than several such combinations (as in the other iterated tests). Thus we begin with the iterated projection tests. The analysis of the other iterated tests, where the atomic tests are invoked on two/three linear combinations of the same sequence of random function, require slightly more care. The corresponding lemmas could have been proven using the notion of "weak pairwise independence" introduced in [23]. However, we present here an alternative approach.

7.1.2. Iterated projection test. The *iterated projection test* described in Figure 15 takes as input vectors $\vec{f}, \vec{g} \in \mathcal{F}_l^m$, and also a linear function $L \in \mathcal{L}_m$. Note that $f = L \circ \vec{f}$ is in $\mathcal{F}_l$, and $g = L \circ \vec{g}$ is in $\mathcal{F}_{l_1}$. Thus, the test is just the atomic projection test on f and g. The following lemma says that if the passing probability $\textsc{ProjPass}_\sigma^m(A)$, representing 2^m invocations of the atomic projection test, is even slightly significant, and if A is close to E_a, then A_1 is close to the encoding of the projection of a.

LEMMA 7.2. *There is a constant c_3 such that the following is true. Let σ: $\Sigma^l \to \Sigma^{l_1}$ be a function. Let $a \in \Sigma^l$ be such that* $\mathrm{Dist}(E_a, A) \le 1/4$, *and let $a_1 = \sigma(a) \in \Sigma^{l_1}$. If* $\textsc{ProjPass}_\sigma^m(A, A_1) \ge c_3 \cdot 2^{-m}$, *then* $\mathrm{Dist}(E_{a_1}, A_1) \le 0.1$.

Proof. The proof is similar to that of [23, Lemma 3.5]. Let $\epsilon_1 = \mathrm{Dist}(A_1, E_{a_1})$ and assume it is at least 0.1. We show that there is a constant c_3 such that $\textsc{ProjPass}_h^m(A) < c_3 \cdot 2^{-m}$.

Let $N = |\mathcal{L}_m^*| = 2^m - 1$. For $L \in \mathcal{L}_m^*$ let $X_L \colon \mathcal{F}_l^m \times \mathcal{F}_{l_1}^m \to \Sigma$ be defined by

$$X_L(\vec{f}, \vec{g}) \stackrel{\text{def}}{=} \mathbf{ProjTest}_\sigma^m(A, A_1; \vec{f}, \vec{g}, L) \;=\; \mathbf{ProjTest}_\sigma(A, A_1; L \circ \vec{f},\, L \circ \vec{g}) \,.$$

Regard it as a random variable over the uniform distribution on $\mathcal{F}_l^m \times \mathcal{F}_{l_1}^m$. Let $X = \sum_{L \in \mathcal{L}_m^*} X_L$. It suffices to show that $\Pr[\, X = 0 \,] \le O(1/N)$.

Lemma 7.1 (with $k = 1$) implies that $\{X_L\}_{L \in \mathcal{L}_m^*}$ are pairwise independent, identically distributed random variables. Let $L \in \mathcal{L}_m^*$ and let $p = \mathbf{E}[X_L]$. Again using Lemma 7.1 we have

$$\begin{aligned} p &= \Pr_{\vec{f} \stackrel{R}{\leftarrow} \mathcal{F}_l^m \,;\, \vec{g} \stackrel{R}{\leftarrow} \mathcal{F}_{l_1}^m} \left[\mathbf{ProjTest}_\sigma(A, A_1; L \circ \vec{f},\, L \circ \vec{g}) = 1 \right] \\ &= \Pr_{f \stackrel{R}{\leftarrow} \mathcal{F}_l \,;\, g \stackrel{R}{\leftarrow} \mathcal{F}_{l_1}} \left[\mathbf{ProjTest}_\sigma(A, A_1; f, g) = 1 \right] , \end{aligned}$$

but by Lemma 3.21 p is at least $\epsilon_1(1 - 2\epsilon) \ge 0.05$, since $\epsilon \stackrel{\text{def}}{=} \mathrm{Dist}(E_a, A) \le 1/4$. We can conclude by applying Chebyshev's inequality. Namely,

$$\Pr[\, X = 0 \,] \;\le\; \Pr[\, |X - Np| \ge Np \,] \;\le\; \frac{Np}{(Np)^2} \;\le\; \frac{20}{N} \,,$$

as desired. □

7.1.3. Technical claim. For analyzing the other two tests we will use the following simple claim.

CLAIM 7.3. *Let $k \ge 1$ and $N = 2^m$. Then $\mathcal{L}_m^k$ contains a subset S of cardinality $\frac{N}{2^{2k}}$ such that every $\vec{L}_1 \ne \vec{L}_2 \in S$ are mutually linearly independent.*

Proof. Let $\vec{L} \in \mathcal{L}_m^k$ be linearly independent. Then, the probability that L chosen uniformly in $\mathcal{L}_m$ is linearly independent of $\vec{L}$ is $1 - \frac{2^k}{N}$. Thus, the probability that a uniformly chosen $\vec{L}' \in \mathcal{L}_m^k$ is mutually linearly independent of $\vec{L}$ is greater than $1 - \sum_{i=1}^{k} \frac{2^{k+i-1}}{N} > 1 - \frac{2^{2k}}{N}$. Now, consider a graph with vertex set $\mathcal{L}_m^k$ and edges connecting pairs of mutually linearly independent sequences (i.e., $\vec{L}_1$ and $\vec{L}_2$ are connected if and only if they are mutually linearly independent). This graph has N^k vertices and every vertex which is linearly independent has degree greater than $(1 - \frac{2^{2k}}{N}) \cdot N^k$. Clearly this graph has a clique of size $\frac{N}{2^{2k}}$ (e.g., consider a greedy algorithm which picks a vertex of maximal degree among all vertices connected to the previously selected vertices). Noting that a clique corresponds to a set of mutually linear independent sequences, we are done. □

7.1.4. Iterated linearity test. The *iterated linearity test* described in Figure 15 takes as input a vector $\vec{f} \in \mathcal{F}_l^m$ and also linear functions $L_1, L_2 \in \mathcal{L}_m$. Note that $f_1 = L_1 \circ \vec{f}$ and $f_2 = L_2 \circ \vec{f}$ are in $\mathcal{F}_l$. The test is just the atomic linearity test on these inputs. The following lemma says that if the passing probability is even slightly significant, then A is almost linear.

LEMMA 7.4. *There is a constant c_1 such that if $\textsc{LinPass}^m(A) \ge c_1 \cdot 2^{-m}$, then $\mathrm{Dist}(A, \textsc{Lin}) \le 0.1$.*

Proof. Assume that $\epsilon \stackrel{\text{def}}{=} \mathrm{Dist}(A, \textsc{Lin}) \ge 0.1$. We show that there is a constant c_1 such that $\textsc{LinPass}^m(A) < c_1 \cdot 2^{-m}$. For $\vec{L} = (L_1, L_2) \in \mathcal{L}_m^2$ let $X_{\vec{L}} \colon \mathcal{F}_l^m \to \Sigma$ be

defined by

$$X_{\vec{L}}(\vec{f}) \stackrel{\text{def}}{=} \mathbf{LinTest}^m(A; \vec{f}, L_1, L_2) \;=\; \mathbf{LinTest}(A; L_1 \circ \vec{f},\, L_2 \circ \vec{f}) \,.$$

Regard it as a random variable over the uniform distribution on $\mathcal{F}_l^m$. Let $S \subset \mathcal{L}_m^2$ be a set as guaranteed by Claim 7.3 and $X = \sum_{\vec{L} \in S} X_{\vec{L}}$. It suffices to show that $\Pr[\, X = 0 \,] \leq O(2^{-m})$. (Thus our analysis of $\text{LinPass}^m(A)$ is based only on a small fraction of all possible invocations of the iterated linear test; yet, this small fraction corresponds to a sufficiently large number of invocations.)

Using Lemma 7.1 (with $k = 2$), it follows that the random variables $\{X_{\vec{L}}\}_{\vec{L} \in S}$ are pairwise independent and that for every $\vec{L} \in S$,

$$p \stackrel{\text{def}}{=} \Pr_{\vec{f} \stackrel{R}{\leftarrow} \mathcal{F}_l^m} \left[X_{\vec{L}}(\vec{f}) = 1 \right] \;=\; \Pr_{f_1, f_2 \stackrel{R}{\leftarrow} \mathcal{F}_l} [\mathbf{LinTest}(A; f_1, f_2) = 1] \,.$$

By Lemma 3.15, $p \geq \Gamma_{\text{lin}}(\epsilon)$, and so $p \geq 3\epsilon - 6\epsilon^2$ if $\epsilon \leq 1/4$ and $p \geq 45/128$ otherwise. In either case, for $\epsilon \geq 0.1$, we get $p > 0.2$. Now by Chebyshev's inequality we have

$$\Pr[\, X = 0 \,] \leq \Pr[\, |X - N'p| \geq N'p \,] \leq \frac{1}{N'p} < \frac{5}{N'},$$

where $N' \stackrel{\text{def}}{=} |S| = 2^m/2^{2 \cdot 2} = 2^m/16$. The lemma follows. □

7.1.5. Iterated RMB test. The *iterated respect of monomial basis test* in Figure 15 takes an input $\vec{f}$ and also takes three linear functions $L_1, L_2, L_3 \in \mathcal{L}_m$. For simplicity of exposition, we assume that A is folded over $(\bar{1}, 1)$. (This assumption is justified by our usage of the test; see next subsection.) If the probability $\text{MBPass}^m(A)$ is significant, we can conclude that the linear function close to A respects the monomial basis.

LEMMA 7.5. *There is a constant c_2 such that the following is true. Let $A\colon \mathcal{F}_l \to \Sigma$ so that $A(f + \bar{1}) = A(f) + 1$, for every $f \in \mathcal{F}_l$. Let $\epsilon \leq 0.1$ so that A is ϵ-close to a linear function $\tilde{A}$ and suppose that $\text{MBPass}^m(A) \geq c_2 \cdot 2^{-m}$. Then $\tilde{A}$ respects the monomial basis.*

Proof. Assume that $\tilde{A}$ is linear but does not respect the monomial basis. We will show that there is a constant c_2 such that $\text{MBPass}^m(A) < c_2 \cdot 2^{-m}$.

For $\vec{L} = (L_1, L_2, L_3) \in \mathcal{L}_m^3$ let $X_{\vec{L}}\colon \mathcal{F}_l^m \to \Sigma$ be defined by

$$X_{\vec{L}}(\vec{f}) \stackrel{\text{def}}{=} \mathbf{MBTest}^m(A; \vec{f}, L_1, L_2, L_3) \;=\; \mathbf{MBTest}(A; L_1 \circ \vec{f},\, L_2 \circ \vec{f},\, L_3 \circ \vec{f}) \,.$$

Regard it as a random variable over the uniform distribution on $\mathcal{F}_l^m$. Again, let $S \subset \mathcal{L}_m^3$ be a set as guaranteed by Claim 7.3 (in this case $|S| = 2^m/2^{2 \cdot 3}$) and $X = \sum_{\vec{L} \in S} X_{\vec{L}}$. It suffices to show that $\Pr[\, X = 0 \,] \leq O(2^{-m})$.

Using Lemma 7.1 (with $k = 3$), it follows that the random variables $\{X_{\vec{L}}\}_{\vec{L} \in S}$ are pairwise independent and that for every $\vec{L} \in S$

$$p \stackrel{\text{def}}{=} \Pr_{\vec{f} \stackrel{R}{\leftarrow} \mathcal{F}_l^m} \left[X_{\vec{L}}(\vec{f}) = 1 \right] \;=\; \Pr_{f_1, f_2, f_3 \stackrel{R}{\leftarrow} \mathcal{F}_l} [\mathbf{MBTest}(A; f_1, f_2, f_3) = 1] \,.$$

By Lemma 3.19, $p \geq \frac{3}{8} - 7\epsilon/4 + 5\epsilon^2/2 - \epsilon^3$. Using $\epsilon \leq 0.1$, it follows that $p > 0.2$. Using Chebyshev's inequality, as in the previous proof, we are done. □

Remark 7.6. For general A's (which are not folded over $(\bar{1}, 1)$), a similar result can be proven by augmenting the iterated RMB test so that on input A, $\vec{f}$, and $\vec{L} = (L_1, L_2, L_3)$ it also checks if $A((L_1 \circ \vec{f}) + \bar{1}) = A(L_1 \circ \vec{f}) + 1$.

7.1.6. Putting some things together. The last two lemmas above allow us to conclude that if $A_{(h,0),(\bar{1},1)}$ passes the first two tests with any significant probability, then $A_{(h,0),(\bar{1},1)}$ is close to some evaluation operator E_a so that $h(a) = 0$. Thus, again, there is no need for a "circuit test."

COROLLARY 7.7. *There is a constant c such that the following is true. Let $A\colon \mathcal{F}_l \to \Sigma$, and suppose* $\text{LINPASS}^m(A_{(h,0),(\bar{1},1)}) \geq c \cdot 2^{-m}$ *and* $\text{MBPASS}^m(A_{(h,0),(\bar{1},1)}) \geq c \cdot 2^{-m}$. *Then there is a string $a \in \Sigma^l$ such that* $\text{Dist}(E_a, A_{(h,0),(\bar{1},1)}) \leq 0.1$ *and* $h(a) = 0$.

Proof. Let c be the larger of the constants from Lemmas 7.4 and 7.5. By the first lemma there is a linear $\tilde{A}$ such that $\text{Dist}(A_{(h,0),(\bar{1},1)}, \tilde{A}) < 0.1$. Now the second lemma implies that $\tilde{A}$ respects the monomial basis (using the fact that $A_{(h,0),(\bar{1},1)}(f + \bar{1}) = A_{(h,0),(\bar{1},1)}(f) + 1$ for all f's). So Proposition 3.2 says that $\tilde{A}$ is an evaluation function. Finally, by Proposition 3.6, we have $h(a) = 0$. ∎

7.2. NP in amortized free-bit complexity 2.

SOURCES OF OUR IMPROVEMENTS. We adopt the basic framework of the construction of proof systems with low free-bit complexity as presented in [23]. Our improvement comes from the use of the new long code, instead of the Hadamard code, as a basis for the construction of inner verifiers. This allows us to save one bit in the amortized free-bit complexity, the reason being that the long code contains explicitly all functions of the encoded string, whereas the Hadamard code contains only linear combinations of the bits of the string. Typically, we need to check that the verifier accepts a string and this condition is unlikely to be expressed by a linear combination of the bits of the string. Thus, one needs to keep also the linear combinations of all two-bit products and, using these extra combinations (via self-correcting), increases the amortized free bit by one. Instead, as seen above, the long code allows us to directly handle any function. The fact that we take linear combinations of these functions should not confuse the reader; these are linear combinations of random functions rather than linear combinations of random LINEAR functions (as in [23]).

Our construction of a proof system with amortized free-bit complexity of two bits is obtained by composing the (l, l_1)-canonical outer verifier of Lemma 3.8 with a (l, l_1)-canonical inner verifier, denoted $V_{\text{free-in}}$, which is depicted in Figure 16. The inner verifier $V_{\text{free-in}}$ consists of invoking the three iterated tests of Figure 15. In addition, $V_{\text{free-in}}$ also applies the linearity test to the oracle A_1. This is not done to improve the rejection probability of $V_{\text{free-in}}$ (in case the oracles A and A_1 are far from being fine), but rather to decrease the number of accepting configurations (and consequently the free-bit complexity). We also remark that $V_{\text{free-in}}$ invokes the iterated tests while providing them with access to a double folding of A (i.e., $A_{(h,0),(\bar{1},1)}$) rather than to A itself. This eliminates the need for checking that A encodes a string which evaluates to zero under h and simplifies the iterated RMB test (see Remark 7.6 at the end of subsection 7.1.5). However, unlike in previous subsections, these simplifications do not buy us anything significant (here), since the additional testing could have been done without any additional cost in free bits.

LEMMA 7.8. *There exists a constant c such that the following is true. Let l, l_1, m be integers. Then the (l, l_1)-canonical inner verifier $V_{\text{free-in}}$ with parameter m is $(\rho, \delta_1, \delta_2)$-good, where $\rho = c \cdot 2^{-m}$ and $\delta_i = 0.4$, for $i = 1, 2$.*

Proof. Here the analysis can be less careful than in analogous statements such as in Lemmas 4.1 and 5.2. Using Corollary 7.7, with respect to the oracle $A_{(h,0),(\bar{1},1)}$, we conclude that if $A_{(h,0),(\bar{1},1)}$ passed both the iterated linearity and RMB tests with

The free inner verifier. Given functions $h \in \mathcal{F}_l$ and $\sigma\colon \Sigma^l \to \Sigma^{l_1}$, the verifier has access to oracles for $A\colon \mathcal{F}_l \to \Sigma$ and $A_1\colon \mathcal{F}_{l_1} \to \Sigma$. It also takes an integer parameter m.

Random choices: $\vec{f} \stackrel{R}{\leftarrow} \mathcal{F}_l^m$; $\vec{g} \stackrel{R}{\leftarrow} \mathcal{F}_{l_1}^m$

$\forall\, L_1, L_2 \in \mathcal{L}_m$: $\mathbf{LinTest}^m(A_{(h,0),(\bar{1},1)}; \vec{f}, L_1, L_2)$

$\forall\, L_1, L_2, L_3 \in \mathcal{L}_m$: $\mathbf{MBTest}^m(A_{(h,0),(\bar{1},1)}; \vec{f}, L_1, L_2, L_3)$

$\forall L \in \mathcal{L}_m$: $\mathbf{ProjTest}_\sigma^m(A_{(h,0),(\bar{1},1)}, A_1; \vec{f}, \vec{g}, L)$

$\forall\, L_1, L_2 \in \mathcal{L}_m$: $\mathbf{LinTest}^m(A_1; \vec{g}, L_1, L_2)$

Remark: access to $A_{(h,0),(\bar{1},1)}(f)$ is implemented by accessing either $A(f)$, $A(f+h)$, $A(f+\bar{1})$, or $A(f+h+\bar{1})$.

FIG. 16. *The free inner verifier* $V_{\text{free-in}}$.

probability at least $c \cdot 2^{-m}$, then there exists a string $a \in \Sigma^l$ such that

$$\text{Dist}(E_a, A_{(h,0),(\bar{1},1)}) \;\le\; 0.1 \;=\; \frac{1}{2} - \delta_1 < \frac{1}{4}$$

and $h(a) = 0$. Using Lemma 7.2, we conclude that if $(A_{(h,0),(\bar{1},1)}, A_1)$ passed the iterated projection test, with probability at least $c_3 \cdot 2^{-m}$, then

$$\text{Dist}(E_{\sigma(a)}, A_1) \;<\; 0.1 \;=\; \frac{1}{2} - \delta_2\ .$$

Setting $\rho = c' \cdot 2^{-m}$, where $c' = \max\{c, c_3\}$, we conclude that $V_{\text{free-in}}$ satisfies condition (2) of Definition 3.9. Clearly, $V_{\text{free-in}}$ also satisfies condition (1), and the lemma follows. □

PROPOSITION 7.9. *Let l, l_1, m be integers. Then the (l, l_1)-canonical inner verifier $V_{\text{free-in}}$ with parameter m uses $2m$ free bits.*

Proof. We consider only accepting computations of $V_{\text{free-in}}$. We start by observing that all oracle values obtained from A, during the iterated linearity test (on $A_{(h,0),(\bar{1},1)}$), are determined by the values of A in locations $f_1', f_2', \ldots, f_m'$, where each f_i' is one of the four functions $f_i, f_i+h, f_i+\bar{1}$, and $f_i+h+\bar{1}$. Likewise, all oracle values obtained from A, during the iterated RMB test, are determined by the values of A in these locations $f_1', f_2', \ldots, f_m'$. Finally, all oracle values obtained from A, during the iterated projection test, are determined by the values of A_1 in locations $L \circ \vec{g}$ (for all L's) and the values of A in the locations $f_1', f_2', \ldots, f_m'$.

Now we use the fact that $V_{\text{free-in}}$ applies an iterated linearity test to the oracle A_1. It follows that all oracle values obtained from A_1, in accepting computations of $V_{\text{free-in}}$, are determined by the values of A_1 in locations $g_1, g_2, \ldots, g_m$.

We conclude that, in accepting computations of $V_{\text{free-in}}$, all values obtained from the oracles are determined by $2m$ bits (i.e., $A(f_1'), \ldots, A(f_m')$ and $A_1(g_1), \ldots, A_1(g_m)$). □

Composing the canonical outer verifier of Lemma 3.8 and the canonical inner verifier $V_{\text{free-in}}$, we get the following.

THEOREM 7.10. *For any $\epsilon > 0$ it is the case that* $\text{NP} \subseteq \overline{\text{FPCP}}[\log, 2+\epsilon]$.

Proof. Given an NP language L and an integer m (see below), we use Lemma 3.8 to construct a 2^{-m}-good outer verifier, denoted V_{outer}, for L. Recall that this outer verifier uses logarithmic randomness (actually the randomness also depends linearly on m which is a constant). Next, compose V_{outer} with the $(c \cdot 2^{-m}, 0.4, 0.4)$-good inner verifier, $V_{\text{free-in}}$, guaranteed by Lemma 7.8, where $V_{\text{free-in}}$ uses m as its integer parameter. The composed verifier has free-bit complexity $2m$ (as inherited from $V_{\text{free-in}}$ by Proposition 7.9). By Theorem 3.12 the soundness error of the composed verifier is at most $c \cdot 2^{-m} + 2^{-m}$. Selecting m to be sufficiently large (i.e., $m \geq \frac{2+\epsilon}{\epsilon} \cdot \log_2(c+1)$), the theorem follows. ∎

7.3. Hardness of MaxClique. See section 2.4 for definitions of the MaxClique and ChromNum problems and their associated gap problems, and section 2.4.3 for a description of previous work. Using the FGLSS transformation, we get the following.

THEOREM 7.11. *For any $\epsilon > 0$,*

(1) $\text{NP} \leq_R^K \textsf{Gap-MaxClique}_{c,s}$ *for* $s(N) = N^\epsilon/N$ *and* $c(N) = N^{\frac{1}{3}}/N$.

(2) $\text{NP} \leq_D^K \textsf{Gap-MaxClique}_{c,s}$ *for* $s(N) = N^\epsilon/N$ *and* $c(N) = N^{1/4}/N$.

Proof. For part (1) we use Corollary 11.3 (below), with $r = O(\log n)$ and $k = \frac{r}{\epsilon}$. We get that NP is randomly reducible to a pcp system with randomness $r + k + O(1)$, free-bit complexity $(2+\epsilon)k$, and error probability 2^{-k}. The FGLSS graph corresponding to the resulting pcp system has size $N = 2^{(r+k+O(1))+(2+\epsilon)k}$ and a gap in clique size of factor 2^k, which can be rewritten as $N^{1/(1+2+2\epsilon)}$. The clique size, in case the input is not in the language, is 2^r which can be rewritten as N^ϵ. Substituting ϵ for $\epsilon/2$, the claim of part 1 follows. For part 2 we use Corollary 11.5 and get a pcp system for NP with randomness $r + (2+\epsilon)k$, free-bit complexity $(2+\epsilon)k$, and error probability 2^{-k}. Using the FGLSS construction on this system, the claim of part (2) follows. ∎

Combining the above with a recent reduction of Fürer [45], we get the following.

THEOREM 7.12. *For any $\epsilon > 0$,*

(1) $\text{NP} \leq_R^K \textsf{Gap-ChromNum}_{c,s}$ *for* $c(N)/s(N) = N^{\frac{1}{5}-\epsilon}$.

(2) $\text{NP} \leq_D^K \textsf{Gap-ChromNum}_{c,s}$ *for* $c(N)/s(N) = N^{\frac{1}{7}-\epsilon}$.

Part II: Proofs and approximation: Potential and limitations.

8. The reverse connection and its consequences. Feige et al. [40] describe a procedure which takes a verifier V and an input x and constructs a graph, which we denote $\mathcal{G}_V(x)$, whose vertices correspond to possible accepting transcripts in V's computation and edges corresponding to consistent/nonconflicting computations. They then show the following connection between the maximum (over all possible oracles) acceptance probability of the verifier and the clique size in the graph. Recall that $\textsf{ACC}[V(x)] = \max_\pi \Pr_R[V^\pi(x;R) = 0]$ is the maximum accepting probability. Also recall that MaxClique(G) is the maximum clique size.

THEOREM 8.1 ((the FGLSS reduction) [40]). *If, on input x, a verifier V tosses r coins, then the following relationship holds:*

$$\textsf{ACC}[V(x)] = \frac{\text{MaxClique}(\mathcal{G}_V(x))}{2^r}.$$

In this section we essentially show an inverse of their construction.

8.1. The Clique-Gap verifier. We stress that by the term *graph* we mean an undirected simple graph (i.e., no self-loops or parallel edges).

THEOREM 8.2 (clique verifier of ordinary graphs). *There exists a verifier, denoted W, of logarithmic randomness complexity, logarithmic query length, and zero free-bit complexity, that, on input an N-node graph G, satisfies*

$$\mathtt{ACC}[\,W(G)\,] = \frac{\text{MaxClique}(G)}{N}\ .$$

Furthermore, $\mathcal{G}_W(G)$ is isomorphic to G, where the isomorphism is easily computable. Lastly, given a proof/oracle π we can construct in polynomial-time a clique of size pN in G, where p is the probability that W accepts G with oracle access to π.

Proof. On input a graph G on N nodes, the verifier W works with proofs of length $\binom{N}{2} - |E(G)|$. The proof π is indexed by the edges in $\overline{G}$ (i.e., nonedges in G). For clarity we assume that the binary value $\pi(\{u,v\})$ is either u or v. This is merely a matter of encoding (i.e., consider a 1-1 mapping of the standard set of binary values, $\{0,1\}$, to the set $\{u,v\}$). On input G and access to oracle π, the verifier W acts as follows:

—picks uniformly a vertex u in the vertex set of G.

—for every $\{u,v\} \in E(\overline{G})$, the verifier W queries the oracle at $\{u,v\}$ and rejects if $\pi(\{u,v\}) \neq u$.

—if the verifier did not reject by now (i.e., all queries were answered by u), then it accepts.

Properties of W. Clearly, W tosses $\log_2 N$ coins. Also, once W picks a vertex u, the only pattern it may accepts is $(u,u,\ldots,u)$. Thus the free-bit complexity of W is 0. To analyze the probability that W accepts the input G, when given the best oracle access, we first prove the following.

CLAIM. *The graphs $\mathcal{G}_W(G)$ and G are isomorphic.*

Proof. The proof is straightforward. One needs first to choose an encoding of accepting transcripts of the computation of W on input G. We choose to use the "full transcript" in which the random coins as well as the entire sequence of queries and answers is specified. Thus, a generic accepting transcript has the form

$$T_u \stackrel{\text{def}}{=} (u, (\{u,v_1\},u), \ldots, (\{u,v_d\},u)),$$

where u is the random vertex selected by the verifier and $\{v_1,\ldots,v_d\}$ is the set of non-neighbors of u. We stress that T_u is the only accepting transcript in which the verifier has selected the vertex u. Also, for each vertex u, the transcript T_u is accepting. Thus, we may consider the 1-1 mapping, ϕ, that maps T_u to u. We claim that ϕ is an isomorphism between $\mathcal{G}_W(G)$ and G.

Suppose that T_u and T_v are adjacent in $\mathcal{G}_W(G)$. Then, by definition of the FGLSS graph, these transcripts are consistent. It follows that the same query cannot appear in both (accepting) transcripts (otherwise it would have been given conflicting answers). By definition of W, we conclude that (u,v) is NOT a nonedge, namely, $(\phi(T_u),\phi(T_v)) = (u,v) \in E(G)$. Suppose, on the other hand, that $(u,v) \in E(G)$. It follows that the query $\{u,v\}$ does not appear in either T_u or T_v. Since no other query may appear in both transcripts, we conclude that the transcripts are consistent and thus T_u and T_v are adjacent in $\mathcal{G}_G(W)$. □

By Theorem 8.1 it now follows that the probability that W accepts on input G, given the best oracle, is $\text{MaxClique}(\mathcal{G}_W(G))/N$ which by the above equals

$$\text{MaxClique}(G)/N\ .$$

Furthermore, given a proof π which makes W accept G with probability p, the accepting random strings of W constitute a clique of size pN in $\mathcal{G}_W(G)$. These accepting random strings can be found in polynomial time and they encode vertices of G (which form a clique in G). □

We now generalize the above construction to get verifiers which indicate the existence of large cliques in layered graphs. An (L, M, N)-*layered graph* is an N-vertex graph in which the vertices are arranged in L layers so that there are no edges between vertices in the same layer, and there are at most M vertices in each layer. We use a convention by which, whenever a layered graph is given to some algorithm, a partition into layers is given along with it (i.e., is implicit in the encoding of the graph).

THEOREM 8.3 (clique verifier for layered graphs). *There exists a verifier, denoted W, of logarithmic randomness complexity and logarithmic query length that, on input an (L, M, N)-layered graph G, has free-bit complexity $\log_2 M$, average free-bit complexity $\log_2(N/L)$, and satisfies*

$$\mathtt{ACC}\,[\,W(G)\,] = \text{MaxClique}(G)/L\ .$$

Furthermore, $\mathcal{G}_W(G)$ is isomorphic to G, where the isomorphism is easily computable. Lastly, given a proof/oracle π, we can construct in polynomial time a clique of size pL in G, where p is the probability that W accepts G with oracle access to π.

Proof. On input an (L, M, N)-layered graph G, the verifier W works with proofs consisting of two parts. The first part assigns every layer (i.e., every integer $i \in [L]$) a vertex in the layer (i.e., again we use a redundant encoding by which the answers are vertex names rather then an index between 1 and the number of vertices in the layer). The second part assigns to pairs of nonadjacent (in G) vertices a binary value, which again is represented as one of the two vertices. On input G and access to oracle π, the verifier W acts as follows:

—Picks uniformly a layer i in $\{1, \ldots, L\}$.
—Queries π at i and obtains as answer a vertex u. If u is not in the ith layer of G, then the verifier rejects. (Otherwise, it continues as follows.)
—For every $\{u, v\} \in E(\overline{G})$, the verifier W queries the oracle at $\{u, v\}$ and rejects if $\pi(\{u, v\}) \neq u$. (Actually, it is not necessary to query the oracle on pairs of vertices belonging to the same layer.)
—If the verifier did not reject by now (i.e., all queries were answered by u), then it accepts.

Properties of W. Here W tosses $\log_2 L$ coins. Once the first query of W is answered, specifying a vertex u, the only pattern it may accept in the remaining queries is $(u, u, \ldots, u)$. Thus, the free-bit complexity of W is $\log_2 M$, accounting for the first query which may be answered arbitrarily in $\{1, \ldots, m\}$, where $m \leq M$ is the number of vertices in the chosen layer. The average free-bit complexity is $\log_2(N/L)$ (as N/L is the average number of vertices in a layer of the graph G). Again, we can prove that $\mathcal{G}_W(G) = G$ and the theorem follows.

Proof. Here, the accepting transcripts of W, on input G, correspond to a choice of a layer i and a vertex in the ith layer (since, once a vertex is specified by the first

answer, there is only one accepting way to answer the other queries). Thus, a generic accepting transcript has the form

$$T_u \stackrel{\text{def}}{=} (i, (i, u), (\{u, v_1\}, u), \ldots, (\{u, v_d\}, u)),$$

where i is the layer selected by the verifier, u is a vertex in the ith layer of G, and $\{v_1, \ldots, v_d\}$ is the set of nonneighbors of u. Again, T_u is the only accepting transcript in which the verifier's first query is answered with vertex u, and for each vertex u, the transcript T_u is accepting. Again, we consider the 1-1 mapping ϕ that maps T_u to u and show that it is an isomorphism between $\mathcal{G}_W(G)$ and G.

Suppose that T_u and T_v are adjacent in $\mathcal{G}_G(W)$. Then, by definition of the FGLSS graph, these transcripts are consistent. We first note that u and v cannot appear in the same layer of G (otherwise the first query in the transcript would yield conflicting answers). Again, the same two-vertex query cannot appear in both (accepting) transcripts, and we conclude that $(\phi(T_u), \phi(T_v)) = (u, v) \in E(G)$. Suppose, on the other hand, that $(u, v) \in E(G)$. Clearly, u and v belong to different layers and, as before, the query (u, v) does not appear in either T_u or T_v. Since no other two-vertex query may appear in both transcripts, we conclude that the transcripts are consistent and thus T_u and T_v are adjacent in $\mathcal{G}_G(W)$. □

The theorem follows as before. □

Remark 8.4. The clique verifier W, presented in the proof of Theorem 8.3, is adaptive: the answer to its first query determines (all) of the other queries. We wonder if it is possible to construct a non-adaptive clique verifier with properties as claimed in Theorem 8.3.

8.2. Reversing the FGLSS reduction. We are interested in problems exhibiting a gap in Max-Clique size between positive and negative instances. Recall that $\overline{\text{MaxClique}}(G) = \text{MaxClique}(G)/N$ is the fraction of nodes in a maximum clique of N-node graph G. Also recall from section 2.4 that the $\mathsf{Gap}\text{-MaxClique}_{c,s}$ promise problem is (A, B), where A is the set of all graphs G with $\overline{\text{MaxClique}}(G) \geq c(N)$, and B is the set of all graphs G with $\overline{\text{MaxClique}}(G) < s(N)$. The *gap* of this problem is defined to be c/s. As a direct consequence of Theorem 8.2, we get the following.

COROLLARY 8.5. *For all functions c, s: $\mathcal{Z}^+ \to [0, 1]$ we have* $\mathsf{Gap}\text{-MaxClique}_{c,s} \in \text{FPCP}_{c,s}[\log, 0, \text{poly}]$.

The above corollary transforms the gap in the promise problem into a gap in a pcp system. However, the accepting probabilities in this pcp system are very low (also on yes instances). Below, we use Theorem 8.3 to obtain pcp systems with perfect (resp., almost-perfect) completeness for this promise problem. We start by presenting two randomized reductions of the promise problem to a layer version. Alternative methods are presented in section 11 (cf. Proposition 11.6).

PROPOSITION 8.6 (layering the clique promise problem).

(1) (obtaining a perfect layering). *There exists a polynomial-time randomized transformation, T, of graphs into layered graphs so that, on input a graph G, and integers C and L, the transformation outputs a subgraph $H = T(G, C, L)$ of G in L layers such that if* $\text{MaxClique}(G) \geq C$, *then*

$$\Pr[\,\text{MaxClique}(H) < L\,] < L \cdot 2^{-\frac{C}{2L}}.$$

Furthermore, with probability $1 - L \cdot 2^{-N/3L}$, no layer of H contains more than $2 \cdot \frac{N}{L}$ nodes.

(2) (using logarithmic randomness). *There exists a polynomial-time randomized transformation, T, of graphs into layered graphs so that, on input a graph G, and integers C and L, the transformation outputs a subgraph $H = T(G, C, L)$ of G in L layers such that if* $\mathrm{MaxClique}(G) \geq C$, *then*

$$\Pr[\,\mathrm{MaxClique}(H) \leq (1-\epsilon)\cdot L\,] < \frac{L}{\epsilon C}$$

for every $\epsilon \in [0,1]$. Furthermore, the transformation uses logarithmically many coins. Also, with probability $1 - \frac{L}{\epsilon N}$, at most ϵL layers of H contain more than $2 \cdot \frac{N}{L}$ nodes.

Proof. The *first transformation* consists of assigning to each vertex of G a randomly chosen layer of H. Namely, we construct the graph H, which is a subgraph of G, by uniformly selecting for each vertex v a layer $l(v) \in [L]$ and copying only the edges of G which connect vertices placed in different layers (of H). The construction can be carried out in random polynomial time and we show that if the original graph has a clique of size C, then with high probability the resulting graph has a clique of size L, provided $C \gg 2L\log_2 L$.

CLAIM 1. *Suppose that G has a clique of size C, denoted S. Then, the probability that all vertices in S were placed in less than L layers is at most $L \cdot 2^{-\frac{C}{2L}}$.*

Proof. We start by bounding, for each i, the probability that no vertex of S is placed in the ith layer. For each $v \in S$, we introduce the 0-1 random variable ζ_v so that $\zeta_v = 1$ if v is placed in the ith layer (i.e., $l(v) = i$) and $\zeta_v = 0$ otherwise. Let $t \stackrel{\mathrm{def}}{=} C/L$. Then, $\mathbf{E}[\sum_{v\in S}\zeta_v] = t$. Using a multiplicative Chernoff bound [75], we get

$$\begin{aligned}\Pr[\,\forall v \in S : l(v) \neq i\,] &= \Pr\left[\sum_{v\in S}\zeta_v = 0\right] \\ &< 2^{-\frac{t}{2}}.\end{aligned}$$

Call the ith layer *bad* if no vertex of S is placed in it. By the above, the probability that there exists a bad layer is smaller than $L \cdot 2^{-\frac{t}{2}}$, and the claim follows. □

It is left to bound the probability that a particular layer contains more than twice the expected number of vertices. Using again a multiplicative Chernoff bound, this probability is at most $2^{-N/3L}$ and the first part of the proposition follows.

The *second transformation* consists of selecting randomly a universal$_2$ hashing function (a.k.a., pairwise independent hash function) mapping the vertices of the graph G into the layer-set $[L]$. Namely, suppose that the function h was chosen; then we construct the graph H, which is a subgraph of G, by placing a vertex v (of G) in layer $h(v)$ of H, and copying only the edges of G which connect vertices placed in different layers (of H). The construction can be carried out in polynomial time using only logarithmic randomness (for the selection of the hashing function). We show that if the original graph has a clique of size C, then with high probability the resulting graph has a clique of size almost L, provided $L \ll C$.

CLAIM 2. *Suppose that G has a clique of size C, denoted S. Then, the probability that all vertices in S were placed in less than $(1-\epsilon)\cdot L$ layers is at most $\frac{L}{\epsilon C}$.*

Proof. Again, we bound, for each i, the probability that no vertex of S is placed in the ith layer. For each $v \in S$, we introduce the 0-1 random variable ζ_v so that $\zeta_v = 1$ if $h(v) = i$ and $\zeta_v = 0$ otherwise. Let $t \stackrel{\mathrm{def}}{=} C/L$ and $\zeta \stackrel{\mathrm{def}}{=} \sum_{v\in S}\zeta_v$. Then, $\mathbf{E}[\zeta] = t$ (which is greater than 1; otherwise the claim holds vacuously). Using the

pairwise independence of h and Chebyshev's inequality, we get

$$\begin{aligned}\Pr[\,\forall v \in S : h(v) \neq i\,] &= \Pr[\,\zeta = 0\,] \\ &\leq \frac{\mathbf{Var}[\sum_{v\in S}\zeta_v]}{t^2} \\ &< \frac{C/L}{t^2} = \frac{1}{t}.\end{aligned}$$

Call the ith layer *bad* if no vertex of S is placed in it. By the above, the expected number of bad layers is smaller than $L \cdot \frac{1}{t}$, so by Markov inequality the probability that more than ϵL layers are bad is at most $1/\epsilon t$. The claim follows. □

Again, it is left to bound the probability that a particular layer contains more than $M \stackrel{\text{def}}{=} 2N/L$. Using Chebyshev's inequality again, this probability is at most L/N. Thus, the expected number of layers having more than M vertices is at most L^2/N, and it follows that the probability that ϵL layers contain more than M vertices each is at most $\frac{L^2/N}{\epsilon L} = \frac{L}{\epsilon N}$. The second part of the proposition follows. □

Combining Theorem 8.3 and Proposition 8.6, we obtain the following. (Refer to section 2.3 for what it means for a promise problem to reduce to a complexity class.)

PROPOSITION 8.7 (reversing the FGLSS reduction, general form). *For any polynomial-time computable, positive functions* $c, s, \epsilon\colon \mathcal{Z}^+ \to [0,1]$ *we have*

(1) (randomized reduction to a pcp with perfect completeness):

$$\textsf{Gap-MaxClique}_{c,s} \leq_R^K \text{FPCP}_{1,s'}[\log, f'],$$

where $f'(N) \stackrel{\text{def}}{=} \log_2(1/c(N)) + \log_2\log_2 N + 2$ *and* $s'(N) \stackrel{\text{def}}{=} 2\log_2 N \cdot \frac{s(N)}{c(N)}$.

(2) (a pcp with almost-perfect completeness):

$$\textsf{Gap-MaxClique}_{c,s} \in \text{FPCP}_{1-4\epsilon,s'}[\log, f'],$$

where $f'(N) \stackrel{\text{def}}{=} 1 + \log_2(1/c(N)) + 2\log_2(1/\epsilon(N))$ *and* $s'(N) \stackrel{\text{def}}{=} \frac{1}{\epsilon(N)^2} \cdot \frac{s(N)}{c(N)}$.

Proof. For the *second part*, we construct a verifier for the promise problem as follows. On input an N-vertex graph G, the verifier computes $C \stackrel{\text{def}}{=} N \cdot c(N)$, $\epsilon \stackrel{\text{def}}{=} \epsilon(N)$, and $L \stackrel{\text{def}}{=} \epsilon^2 C$. It invokes the second transformation of Proposition 8.6, obtaining an (L, N, N)-layered graph $H = T(G, C, L)$. (We stress that this transformation requires only logarithmically many coin tosses.) Next, the verifier modifies H into H' by omitting (the minimum number of) vertices so that no layer of H' has more than $2N/L$ vertices. Finally, the verifier invokes the clique-verifier W of Theorem 8.3 on input H'.

The free-bit complexity of the verifier constructed above is $\log_2(2N/L) = 1 + \log_2(1/c(N)) + 2\log_2(1/\epsilon(N))$. Suppose that G is a no-instance of the promise problem. Using $\text{MaxClique}(H') \leq \text{MaxClique}(G)$ and Theorem 8.3, it follows that the constructed verifier accepts G with probability at most $\frac{\text{MaxClique}(H')}{L} \leq \frac{s(N)}{\epsilon^2(N)\cdot c(N)}$. Suppose, on the other hand, that G is a yes-instance of the promise problem. Then, with probability at least $1 - \frac{L}{\epsilon C} = 1 - \epsilon$ we have $\text{MaxClique}(H) \geq (1-\epsilon)\cdot L$, and with probability at least $1 - \frac{L}{\epsilon N} > 1 - \epsilon$ we have $\text{MaxClique}(H') \geq \text{MaxClique}(H) - \epsilon L$. Thus, with probability at least $1 - 2\epsilon$, we have $\text{MaxClique}(H') \geq (1-2\epsilon)\cdot L$. It follows that the constructed verifier, when given oracle access to an appropriate proof, accepts G with probability at least $1 - 4\epsilon$.

For the *first part*, we define a promise problem which refers to gaps in cliques of layered graphs. Specifically, we have the following.

DEFINITION. *For any function* $\ell : \mathcal{Z}^+ \to \mathcal{Z}^+$ *and* $s : \mathcal{Z}^+ \to [0,1]$*, we define the promise problem* $\mathsf{Gap}{-}\mathrm{CLG}_{\ell,s}$ *as the pair* (A, B)*, where:*

(1) A *is the set of all* $(\ell(N),\, 2N/\ell(N)\,,N)$*-layered graphs* G *with* $\mathrm{MaxClique}(G) = \ell(N)$*, and*

(2) B *is the set of all* $(\ell(N),\, 2N/\ell(N)\,,N)$*-layered graphs* G *with* $\mathrm{MaxClique}(G) < s(N) \cdot \ell(N)$*.*

The gap *of this problem is defined to be* $1/s$*.*

Using the first transformation of Proposition 8.6, we obtain $\mathsf{Gap}\text{-}\mathrm{MaxClique}_{c,s} \leq_R^K \mathsf{Gap}{-}\mathrm{CLG}_{\ell,s'}$, where $\ell(N) = \frac{c(N)\cdot N}{2\log_2 N}$ and $s'(N) = \frac{s(N)\cdot N}{\ell(N)} = 2\log_2 N \cdot \frac{s(N)}{c(n)}$. On the other hand, Theorem 8.3 asserts that $\mathsf{Gap}{-}\mathrm{CLG}_{\ell,s'} \in \mathrm{FPCP}_{1,s'}[\log, f']$, where $f'(N) \stackrel{\text{def}}{=} \log_2(2N/\ell(N))$. Observing that $f'(N) = 1 + \log_2 \frac{2\log_2 N}{c(N)}$ (which equals $\log_2(1/c(N)) + \log_2\log_2 N + 2$), the proposition follows. □

Each of the two parts of Proposition 8.7 shows that the well-known method of obtaining clique-approximation results from efficient pcp systems (cf. [40, 25, 86, 41, 23]) is "complete" in the sense that, if clique approximation can be shown NP-hard, then this can be done via this method. The precise statement is given in Theorems 8.10 and 8.11 (below). As a preparatory step, we first provide an easier-to-use form of the above proposition. The restriction that f be a constant is only for notational simplicity (as otherwise, given f as a function of $N = \|G\|$, one needs to repharse it as a function of $n = |x|$).

PROPOSITION 8.8 (reversing the FGLSS reduction, easy to use form). *Let* $f > 0$ *be a constant and let* c, s: $\mathcal{Z}^+ \to [0,1]$ *be polynomial-time computable so that*

$$\frac{c(N)}{s(N)} \geq N^{\frac{1}{1+f}}.$$

Then, for every $\epsilon > 0$*, we have*

(1) (randomized reduction to a pcp with perfect completeness):

$$\mathsf{Gap}\text{-}\mathrm{MaxClique}_{c,s} \leq_R^K \overline{\mathrm{FPCP}}[\log, f+\epsilon];$$

(2) (a pcp with almost-perfect completeness):

$$\mathsf{Gap}\text{-}\mathrm{MaxClique}_{c,s} \in \overline{\mathrm{FPCP}}_{1-o(1)}[\log, f+\epsilon].$$

Proof. We merely invoke Proposition 8.7 and calculate the amortized free-bit complexity of the resulting verifier. We may assume that $s(N) \geq 1/N$. Thus (using $c(N)/s(N) \geq N^{\frac{1}{1+f}}$), we have $c(N) \geq N^{\frac{1}{1+f}}/N = N^{\frac{-f}{1+f}}$ and $1/c(N) \leq N^{\frac{f}{1+f}}$.

For part 1, we let $\alpha(N) \stackrel{\text{def}}{=} 2\log_2 N$ and set $f'(N) \stackrel{\text{def}}{=} \log_2(1/c(N)) + \log_2 \alpha(N)$ and $s'(N) \stackrel{\text{def}}{=} \alpha(N) \cdot \frac{s(N)}{c(N)}$. By invoking Proposition 8.7 (part 1) we find that

$$\mathsf{Gap}\text{-}\mathrm{MaxClique}_{c,s} \leq_R^K \mathrm{FPCP}_{1,s'}[\log, f'],$$

and

$$\mathsf{Gap}\text{-}\mathrm{MaxClique}_{c,s} \leq_R^K \overline{\mathrm{FPCP}}[\log, \overline{f'}]$$

for $\overline{f'} = \frac{f'}{\log(1/s')}$ follows. It now remains to argue that for any $\epsilon > 0$, $\overline{f'} \leq f + \epsilon$.

Using the lower bounds on $c(N)$ and $c(N)/s(N)$, we obtain $f'(N) \leq \frac{f}{1+f}\log_2 N + \log_2 \alpha(N)$ and $\log(1/s'(N)) \geq \frac{1}{1+f}\cdot\log_2 N - \log_2\alpha(N)$. Selecting a sufficiently small $\delta > 0$ and using $\log_2\alpha(N) < \delta\cdot\log_2 N$, we get

$$\begin{aligned}\overline{f'} &\leq \frac{\frac{f}{1+f}\log_2 N + \log_2\alpha(N)}{\frac{1}{1+f}\log_2 N - \log_2\alpha(N)}\\ &< \frac{\frac{f}{1+f}+\delta}{\frac{1}{1+f}-\delta},\end{aligned}$$

and so part 1 follows. For part 2, we let α be a slowly decreasing function s.t. $\alpha(N) = o(1)$ but $\log_2(1/\alpha(N)) = o(\log N)$. We set $f'(N) \stackrel{\text{def}}{=} \log_2(1/c(N)) + 2\log_2(1/\alpha(N))$ and $s'(N) \stackrel{\text{def}}{=} \frac{1}{\alpha(N)^2}\cdot\frac{s(N)}{c(N)}$. By invoking Proposition 8.7 (part 2) we get $\textsf{Gap-MaxClique}_{c,s} \in \text{FPCP}_{1-\alpha,s'}[\log, f']$. Since $\alpha(N) = o(1)$, we conclude that

$$\textsf{Gap-MaxClique}_{c,s} \in \overline{\text{FPCP}}_{1-o(1)}[\log, \overline{f'}]$$

for $\overline{f'} = \frac{f'}{\log_2(1/s')}$. Again, it remains to argue that for any $\epsilon > 0$, $\overline{f'} \leq f + \epsilon$. Using the lower bound on $c(N)$ and $c(N)/s(N)$, we obtain $f'(N) \leq \frac{f}{1+f}\log_2 N - 2\log_2\alpha(N)$ and $\log_2(1/s'(N)) = 2\log_2\alpha(N) + \frac{1}{1+f}\log_2 N$. Selecting a sufficiently small $\delta > 0$ and using $\log_2(1/\alpha(N)) < \delta\cdot\log_2 N$, we get

$$\begin{aligned}\overline{f'} &\leq \frac{\frac{f}{1+f}\log_2 N + 2\log_2(1/\alpha(N))}{\frac{1}{1+f}\log_2 N - 2\log_2(1/\alpha(N))}\\ &< \frac{\frac{f}{1+f}+\delta}{\frac{1}{1+f}-\delta},\end{aligned}$$

and part 2 follows. □

8.3. Main consequences. Let us first state the FGLSS reduction.

THEOREM 8.9 (the FGLSS reduction, revisited). *Let $f > 0$ be a constant and $c, s\colon \mathcal{Z}^+ \to [0,1]$. Then, for every $\epsilon > 0$,*

$$\overline{\text{FPCP}}_{1-o(1)}[\log, f] \leq_R^K \textsf{Gap-MaxClique}_{c,s},$$

where $c(N)/s(N) \geq N^{1/(1+f+\epsilon)}$. Furthermore, in case the proof system is of perfect completeness, we have $c(N) = N^{-f/(1+f+\epsilon)}$ and $s(N) = N^{-(1+f)/(1+f+\epsilon)}$.

Proof. We first amplify the gap of the pcp verifier (cf. Corollary 11.3) and then apply the bare FGLSS reduction (see Theorem 8.1 and [40]) to the amplified verifier. Specifically, for any problem Π in $\overline{\text{FPCP}}[\log, f]$, we first obtain $\Pi \leq_R^K \text{FPCP}_{1,2^{-t}}[(1+\epsilon)\cdot t, f\cdot t]$, where $t(n) = \gamma\log_2 n$ (with the constant γ determined by the constant $\epsilon > 0$). The FGLSS reduction now yields a graph of size $N \stackrel{\text{def}}{=} 2^{(1+\epsilon+f)\cdot t(n)}$ with gap $2^{t(n)}$ (which can be written as $N^{\frac{1}{1+\epsilon+f}}$). Specifically, the clique size for a yes-instance (resp., no-instance) is at least $2^{(1+\epsilon)\cdot t(n)} = N^{\frac{1+\epsilon}{1+\epsilon+f}}$ (resp., at most $2^{\epsilon\cdot t(n)} = N^{\frac{\epsilon}{1+\epsilon+f}}$).

A similar procedure may be applied for any Π in $\overline{\text{FPCP}}_{1-o(1)}[\log, f]$. Specifically, by definition, for some function m, $\Pi \in \text{FPCP}_{c,2^{-m}\cdot c}[\log, m\cdot f]$, for $c(n) = 1 - o(1)$ (but we are not going to use the bound on c). Using Proposition 11.1 and Proposition 11.2 (part 2), we first obtain $\Pi \leq_R^K \text{FPCP}_{c',2^{-t}\cdot c'}[(1+\epsilon)\cdot t, f\cdot t]$, where

$c'(n) = c(n)^{t(n)/m(n)}$ and $t(n) = \gamma \log_2 n$ (with the constant γ determined by the constant $\epsilon > 0$). The FGLSS reduction now yields a graph of size $N \stackrel{\text{def}}{=} 2^{(1+\epsilon+f)\cdot t(n)}$ with gap $2^{t(n)}$ as above. □

Interestingly, the gap (for MaxClique) created by the FGLSS reduction is independent of the location of the gap in the pcp system. The main result of this section follows.

THEOREM 8.10. *Let f be a constant. Then the following statements are equivalent:*

(1) *For all $\epsilon > 0$, it is the case that* NP *reduces to* Gap-MaxClique$_{c,s}$ *with gap $c(N)/s(N) = N^{1/(1+f+\epsilon)}$.*

(2) *For all $\epsilon > 0$, it is the case that* NP *reduces to* $\overline{\text{FPCP}}[\log, f + \epsilon]$.

In both items the reduction is randomized. Furthermore, the equivalence holds for both Karp and Cook reductions.

Proof. The direction (2) ⇒ (1) follows again by Theorem 8.9. The reverse direction follows by part 1 of Proposition 8.8. □

An alternative statement is provided by the following theorem. Here the second item (existence of pcp systems with certain parameters) is weaker than in the previous theorem, but this allows the (1) ⇒ (2) direction to be proven via a deterministic reduction (instead of the randomized reduction used in the analogous proof above). Recall that $\overline{\text{FPCP}}_{1-o(1)}[\cdot, f]$ is the class of problems having a proof system with almost-perfect completeness (i.e., $c = 1 - o(1)$) and amortized free-bit complexity f.

THEOREM 8.11. *Let f be a constant. Then the following statements are equivalent:*

(1) *For all $\epsilon > 0$, it is the case that* NP *reduces to* Gap-MaxClique$_{c,s}$ *with gap $c(N)/s(N) = N^{1/(1+f+\epsilon)}$.*

(2) *For all $\epsilon > 0$, it is the case that* NP *reduces to* $\overline{\text{FPCP}}_{1-o(1)}[\log, f + \epsilon]$.

In both items the reduction is randomized and the equivalence holds for both Karp and Cook reductions. Furthermore, if item 1 *holds, with respect to deterministic reductions, so does item* 2*. Thus, if item* 1 *holds with a deterministic Karp reduction, then* NP $\subseteq \overline{\text{FPCP}}_{1-o(1)}[\log, f + \epsilon]$.

Proof. The direction (2) ⇒ (1) follows by applying Theorem 8.9. The reverse direction follows by part 2 of Proposition 8.8. □

8.4. More consequences. The equivalence between clique and FPCP described above turns out to be a useful tool in the study of the hardness of the Clique and Chromatic Number problems. Here we describe some applications. The first application is merely a rephrasing of the known reductions from the MaxClique problem to the Chromatic Number problem in a simpler and more convenient way. The remaining applications use the fact that the equivalence between FPCP and MaxClique allows us to easily shift gaps, in the MaxClique problem, from one place to another. Loosely speaking, these applications use the fact that the complexity of the promise problem Gap-MaxClique$_{c,s}$ remains unchanged when changing the parameters c and s so that the $\frac{\log_2 c(N)}{\log_2 s(N)}$ remains invariant. We stress that the ratio $c(N)/s(N)$ does not remain invariant.

REPHRASING REDUCTIONS FROM MAXCLIQUE TO CHROMATIC NUMBER. Starting with the work of Lund and Yannakakis [71], there have been several works on showing the hardness of approximating the Chromatic Number, which reduce the MaxClique problem to the Chromatic Number problem; see section 2.4.3 for a description. Yet none of these results could be stated cleanly in terms of a reduction

from MaxClique to Chromatic Number without loss of efficiency, i.e., the theorems could not be stated as saying "if approximating MaxClique to within a factor of N^α is NP-hard, then approximating Chromatic Number to within a factor of $N^{h(\alpha)}$ is NP-hard." The reason for the lack of such a statement is that these reductions use the structure of the graph produced by applying an FGLSS reduction to an FPCP result and are hence really reductions from FPCP to Chromatic Number rather than reductions from MaxClique to Chromatic Number. However, now that we know that FPCP and MaxClique are equivalent, we can go back and rephrase the old statements. Thus results of [71, 66, 23, 45] can be summarized as follows.

For every $\alpha, \epsilon, \gamma > 0$,

$$\mathsf{Gap}\text{-MaxClique}_{N^{\alpha-1},N^{\epsilon-1}} \leq_R^K \mathsf{Gap}\text{-ChromNum}_{N^{-(\epsilon+\gamma)},N^{-h(\alpha)}},$$

where

(1) $h(\alpha) = \min\{\frac{1}{6}, \frac{\alpha}{5-4\alpha}\}$ [71].
(2) $h(\alpha) = \min\{\frac{1}{11}, \frac{\alpha}{5+\alpha}\}$ [66].
(3) $h(\alpha) = \min\{\frac{1}{4}, \frac{\alpha}{3-2\alpha}\}$ [23].
(4) $h(\alpha) = \min\{\frac{1}{3}, \frac{\alpha}{2-\alpha}\}$ [45].

We note that it is an open problem whether one can get a reduction in which $h(\alpha) \to 1$ as $\alpha \to 1$. We also note that Fürer's reduction [45] is randomized while the rest are deterministic.

Reductions among MaxClique problems. Next we present an invariance of the Gap-Clique problem with respect to shifting of the gaps. The following result has also been independently observed by Feige in [37], where he uses a randomized graph product to show the result. Our description uses the properties of fpcp and its equivalence to clique approximation.

Theorem 8.12. *Let $k, \epsilon_1, \epsilon_2$ be real numbers such that $k \geq 1$ and $0 \leq \epsilon_1 < \epsilon_2 \leq 1$. Then the following hold:*

(1) $\mathsf{Gap}\text{-MaxClique}_{N^{-\epsilon_2},N^{-k\epsilon_2}} \leq_D^K \mathsf{Gap}\text{-MaxClique}_{N^{-\epsilon_1},N^{-k\epsilon_1}}$. *(Deterministic.)*
(2) $\mathsf{Gap}\text{-MaxClique}_{N^{-\epsilon_1},N^{-k\epsilon_1}} \leq_R^K \mathsf{Gap}\text{-MaxClique}_{1/2\cdot N^{-\epsilon_2},2\cdot N^{-k\epsilon_2}}$.

Proof. Part (1) is proved via a well-known graph theoretic trick. Let G be an instance of $\mathsf{Gap}\text{-MaxClique}_{N^{-\epsilon_2},N^{-k\epsilon_2}}$ with N nodes. We take the graph product of G with a complete graph on m nodes to get a graph H on $M = mN$ nodes. (By a graph product of two graphs $G_1(V_1, E_1)$ and $G_2(V_2, E_2)$ we mean a graph with vertex set $V_1 \times V_2$ where vertices (u_1, u_2) and (v_1, v_2) are connected iff $(u_i, v_i) \in E_i$ for both $i = 1, 2$.) We choose m so that if G has a clique of size $N^{1-\epsilon_2}$, then H has a clique of size $M^{1-\epsilon_1}$. Specifically, setting $m = N^{\frac{\epsilon_2-\epsilon_1}{\epsilon_1}}$, the requirement is satisfied (as a clique of size $N^{1-\epsilon_2}$ in G yields a clique of size $m \cdot N^{1-\epsilon_2} = N^{\frac{\epsilon_2-\epsilon_1}{\epsilon_1}+1-\epsilon_2} = M^{\frac{\epsilon_1}{\epsilon_2}\cdot\frac{\epsilon_2(1-\epsilon_1)}{\epsilon_1}}$ in H.) Under this choice of m we will show that if G has no cliques of size $N^{1-k\epsilon_2}$, then H has no cliques of size $M^{1-k\epsilon_1}$. This will complete the proof of part 1.

Suppose H has a clique of size $M^{1-\epsilon_1}$. Then, by construction, G must have a clique of size

$$\frac{M^{1-\epsilon_1}}{m} = \frac{N^{1-\epsilon_1}}{m^{\epsilon_1}} = N^{1-\epsilon_1-\frac{\epsilon_2-\epsilon_1}{\epsilon_1}\cdot\epsilon_1},$$

and the claim follows.

For part (2) we use the equivalence between FPCP and gaps in MaxClique and apply amplification properties of FPCP. Let $c(N) = N^{-\epsilon_1}$ and $s(N) = N^{-k\epsilon_1}$. Then,

using Corollary 8.5 (for line 1 below), Proposition 11.1 (for line 2), and part (2) of Proposition 11.2 (for line 3), we get

$$\begin{aligned}
&\mathsf{Gap}\text{-MaxClique}_{N^{-\epsilon_1},N^{-k\epsilon_1}}\\
&\quad\in\ \mathrm{FPCP}_{c,s}[\log_2 N, 0, N^2]\\
&\quad\subseteq\ \mathrm{FPCP}_{c^t,s^t}[t\cdot\log_2 N, 0, N^2]\quad\text{(for any integer constant } t\geq 1)\\
&\quad\leq_R^K\ \mathrm{FPCP}_{\frac{1}{2}\cdot c^t,2\cdot s^t}[\log_2(N^2/s^t), 0, N^2].
\end{aligned}$$

The choice of the integer t will be determined later.

Now, we go back to the Clique-Gap promised problem. Applying the FGLSS reduction to the pcp class $\mathrm{FPCP}_{\frac{1}{2}\cdot c^t,2\cdot s^t}[\log_2(N^2/s^t), 0, N^2]$, we obtain an instance of $\mathsf{Gap}\text{-MaxClique}_{\frac{1}{2}N^{-\epsilon_1 t},2N^{-k\epsilon_1 t}}$ on an M-vertex graph, where $M=\frac{N^2}{s^t}=N^{2+k\epsilon_1 t}$.

To clarify the last assertion and the rest of the proof, we introduce the notation $\mathsf{Gap}\text{-MaxClique}_{\alpha(N),\beta(N)}(N)$ which makes explicit the size parameter to which the promise problem refers. Thus, letting $\gamma\stackrel{\text{def}}{=}\frac{t}{2+tk\epsilon_1}$, we have obtained

$$\mathsf{Gap}\text{-MaxClique}_{N^{-\epsilon_1},N^{-k\epsilon_1}}(N)\ \leq_R^K\ \mathsf{Gap}\text{-MaxClique}_{\frac{1}{2}M^{-\gamma\epsilon_1},2M^{-k\cdot\gamma\epsilon_1}}(M),$$

(with M polynomial in N). Now, part 2 follows by setting t so that $\gamma=\frac{t}{2+tk\epsilon_1}\geq\frac{\epsilon_2}{\epsilon_1}$ and $t=\lceil\frac{2\epsilon_2}{(1-k\epsilon_2)\epsilon_1}\rceil$ will do. (Actually, we get $\mathsf{Gap}\text{-MaxClique}_{N^{-\epsilon_1},N^{-k\epsilon_1}}(N)\ \leq_R^K\ \mathsf{Gap}\text{-MaxClique}_{\frac{1}{2}M^{-\epsilon_2'},2M^{-k\epsilon_2'}}(M)$, for $\epsilon_2'\geq\epsilon_2$, but this can be corrected by invoking item 1.) □

The following theorem was first shown by Blum [26] using the technique of randomized graph products. Instead, we use the gap-shifting idea to show that a seemingly very weak approximator to the clique (say, $N^{1-\epsilon}$-approximation algorithm for some $\epsilon>0$) can be used to obtain a very good approximator to the clique number in graphs which are guaranteed to have very large cliques. In particular, using such an algorithm, if a graph has a clique of size $\frac{N}{k}$, then a clique of size $\frac{N}{k^{1/\epsilon}}$ can be found in such a graph in polynomial time. As observed by Blum, this can be translated into significantly better algorithms for approximate coloring of a 3-colorable graph than known currently (see item 1 in Corollary 8.15 below). Here we derive the theorem using FPCP and the gap-shifting techniques. The parameters are generalized so as to be able to conclude, say, that even if we have a $\frac{N}{2^{\sqrt{\log_2 N}}}$-approximation (for MaxClique), then we can obtain nontrivially good algorithms for 3-coloring (see item 2 in Corollary 8.15).

THEOREM 8.13. *Let $\alpha\in[0,1]$, $\beta\in[0,1/2)$, and $k>1$. Define $\epsilon:\mathcal{Z}^+\to\mathcal{R}^+$, $c\in\mathcal{R}^+$, and $g:\mathcal{Z}^+\to\mathcal{R}^+$ so that*

$$\begin{aligned}
\epsilon(N)&=\frac{\alpha}{\log_2^\beta N},\\
c&=\frac{2}{\log_2 k},\\
\text{and }\ \log_2 g(N)&=\left(\frac{c^\beta\log_2 k}{\alpha}\right)^{1/(1-\beta)}\log_2^{\beta/(1-\beta)} N.
\end{aligned}$$

Then there is a randomized $\mathrm{poly}(N^{2+c\log_2 g(N)})$-time reduction of (N-vertex) instances of

$$\mathsf{Gap}\text{-MaxClique}_{1/k,1/g}$$

to M-vertex instances of

$$\textsf{Gap-MaxClique}_{\frac{1}{2}M^{-\epsilon(M)},2M^{-1+\epsilon(M)}}.$$

Remark 8.14. Observe that $g(N) = N^{o(1)}$. Also, for $\beta = 0$ we have $\epsilon(N) = \alpha$ and $g(N) = k^{\frac{1}{\alpha}}$. Thus, the theorem states that given a $\frac{1}{4}M^{1-2\alpha}$ approximator for clique, one can solve $\textsf{Gap-MaxClique}_{1/k,1/k'}$ in polynomial time, where $k' = k^{\frac{1}{\alpha}}$.

Proof. As usual we first reduce Gap-MaxClique to FPCP and then amplify.

$$\begin{aligned}
&\textsf{Gap-MaxClique}_{1/k,1/g}\\
&\quad\in\ \text{FPCP}_{1/k,1/g}[\log_2 N, 0, N^2]\\
&\quad\subseteq\ \text{FPCP}_{(1/k)^t,(1/g)^t}[t\log_2 N, 0, N^2] \text{ (for any function } t : \mathcal{Z}^+ \to \mathcal{Z}^+.)\\
&\quad\leq_R^K\ \text{FPCP}_{\frac{1}{2}(1/k)^t,2(1/g)^t}[\log_2 N^2 g^t, 0, N^2].
\end{aligned}$$

We now show that by setting $t = c\log_2 N$ and using the FGLSS reduction, the above reduces in poly(M)-time to $\textsf{Gap-MaxClique}_{\frac{1}{2}M^{-\epsilon},2M^{-\epsilon+1}}$ in an M vertex graph, where $M = N^2 g(N)^t$.

In case the graph is a no-instance, the size of the clique is most $2(1/g(N))^t \cdot M = 2N^2$. In case the graph is a yes-instance, the clique size is at least $\frac{1}{2}(1/k)^t \cdot M$. Thus it suffices to show that $2N^2 \leq 2M^{\epsilon(M)}$ and $2k^t \leq 2M^{\epsilon(M)}$, respectively. Taking logs in both cases it suffices to show that

$$2\log_2 N \leq \epsilon(M)\log_2 M, \tag{16}$$

$$t\log_2 k \leq \epsilon(M)\log_2 M. \tag{17}$$

We first lower bound the right-hand side of both equations.

$$\begin{aligned}
\epsilon(M)\log_2 M &= \alpha \log_2^{1-\beta} M\\
&\geq \alpha \log_2^{1-\beta}(g(N)^t)\\
&\geq \alpha t^{1-\beta}\log_2^{1-\beta} g(N)\\
&= \alpha \cdot (c\log_2 N)^{1-\beta} \cdot \left(c^\beta \frac{\log_2 k}{\alpha}\log_2^\beta N\right)\\
&= c\log_2 N \log_2 k.
\end{aligned}$$

Inequality (16) now follows from the fact that $c\log_2 k = 2$. Inequality (17) follows from the fact that $t = c\log_2 N$. ∎

The following result was derived as a corollary by Blum [26] and shows the application of the above theorem to coloring graphs with low-chromatic number with relatively small number of colors. We warn the reader that the corollary does not follow directly from the above theorem; this is because it uses a Levin reduction[10] from the search version of Chromatic Number to the search version of the clique problem. However, it is possible to define search versions of all the gap problems above appropriately and verify that all the reductions work for the search problems as well (i.e., they are in fact Levin reductions). Thus the following can be derived as a corollary to the above.

[10] A Levin reduction is a polynomial-time many-to-one reduction which is augmented by corresponding polynomial-time witness transformations.

COROLLARY 8.15. *Let k be an integer.*

(1) *For $\epsilon > 0$, given an $N^{1-\epsilon}$ approximator to the clique, one can color any k-colorable graph on M nodes with $O(k^{1/\epsilon} \log M)$ colors in polynomial time.*
(2) *For $\epsilon(N) = \omega((\log N)^{-1/2})$, given an $N^{1-\epsilon(N)}$ approximator to the clique, one can color any k-colorable graph on M nodes with $M^{o(1)}$ colors in time $M^{O(\log M)}$.*

9. On the limitations of some common approaches. In this section we provide lower bounds on the free-bit complexity of two tasks which are central to all existing ("low-complexity") probabilistically checkable proofs. Specifically, we consider the task of checking that a string (given by oracle access) is "close" to a valid codeword and the task of checking that one oracle is an encoding of a projection of a string encoded by a second oracle. Here a string is considered *close* to the code if its distance from some codeword is less than half the distance of the code. Loosely speaking, we show that each of these tasks has amortized free-bit complexity of at least *one* (and this is tight by the codes and tests presented in section 7). Furthermore, we show that the amortized free-bit complexity of performing both tasks (with respect to the same given oracles) is at least *two* (and this also is tight by section 7).

Our original motivation in proving these lower bounds was to indicate that a paradigm shift is required in order to improve over our PCP systems of amortized free-bit complexity 2 (for NP). In retrospect, the paradigm shifts have amounted to the relaxation of the codeword test in [55] and to the relaxation of the projection test in [56]. Thus, our lower bounds may be considered as a justification for these (somewhat unnatural) relaxations.

In particular, the lower bound on the complexity of the codeword test relies on the particular interpretation of "closeness" used above (i.e., being at distance less than *half* the distance of the code). This requirement is not essential as can be seen in section 3.4, where we show that relaxed codeword tests, in which closeness means slightly less than the distance of the code, also suffice. Håstad's relaxation of the codeword test is different, yet it also suffices for the purpose of constructing PCP systems of amortized free-bit complexity 1 (for NP) [55]. The lower bound on the complexity of the projection test seems more robust. Yet, as shown by Håstad in [56], the projection requirements can be by-passed as well, yielding pcp systems of amortized free-bit complexity tending to 0.

9.1. The tasks. Our definitions of the various tasks/tests are quite minimal and do not necessarily suffice for PCP applications. However, as we are proving lower bounds this only makes our results stronger.

Loosely speaking, the first task consists of testing that an oracle encodes a valid codeword, or is "close" to a valid codeword, with respect to an error-correcting code of nontrivial distance (i.e., distance greater than 1). The condition regarding the distance of the code is essential since the task is easy with respect to the identity map (which is a code of distance 1). We remark that testing "closeness" to codewords with respect to codes of large distance is essential in all known pcp constructions [12, 40, 9, 8, 21, 41, 23].

The *absolute distance* between two words $w, u \in \{0,1\}^n$, denoted $\Delta(w,u)$, is the number of bits on which w and u disagree. We say that the code $E : \{0,1\}^* \mapsto \{0,1\}^*$ has *absolute distance* d if, for every m and every $x \neq y \in \{0,1\}^m$, the absolute distance between $E(x)$ and $E(y)$ is at least $d(m)$. The absolute distance between a word w and a code E, denoted $\Delta_E(w)$, is defined as the minimum absolute distance between w and a codeword of E.

DEFINITION 9.1 (codeword test). *Let $E : \{0,1\}^m \to \{0,1\}^n$ be a code of absolute distance $d > 1$. A* codeword test *(with respect to E) is an oracle machine, T, such that $T^{E(a)}(R)$ accepts for all a, R. The error probability of T is defined as the maximum accepting probability of T over oracles A of absolute distance at least $\lfloor d/2 \rfloor$ from the code E, namely,*

$$\max_{A \in \{0,1\}^n \ s.t. \ \Delta_E(A) \geq \lfloor d/2 \rfloor} \left\{ \Pr_R \left[T^A(R) \ accepts \right] \right\}.$$

(Nothing is required with respect to noncodewords which are "close" to the code.)

The second task is defined with respect to a "projection function" π and a pair of codes E_1 and E_2. Loosely speaking, the task consists of checking if the string E_1-encoded by the first oracle is mapped by π to the string that is E_2-encoded by the second oracle.

DEFINITION 9.2 (projection test). *Let $E_1 \colon \{0,1\}^m \to \{0,1\}^n$ and $E_2 \colon \{0,1\}^k \to \{0,1\}^{n'}$ be two codes and let $\pi : \{0,1\}^m \to \{0,1\}^k$ be a function. A* projection test *(with respect to the above) is a two-oracle machine, T, such that $T^{E_1(a), E_2(\pi(a))}(R)$ accepts for all a, R. The error probability of T is defined as the maximum accepting probability of T over oracle pairs $(E_1(a), E_2(b))$ where $b \neq \pi(a)$, namely,*

$$\max_{a,b \ s.t. \ \pi(a) \neq b} \left\{ \Pr_R \left[T^{E_1(a), E_2(b)}(R) \ accepts \right] \right\}.$$

(Nothing is required with respect to noncodewords.)

Finally, we consider a test T which combines the two tests above, namely, T takes two oracles A and B and performs a codeword test on A and a projection test on the pair (A, B).

DEFINITION 9.3 (combined test). *Let $E_1 \colon \{0,1\}^m \to \{0,1\}^n$ be a code of absolute distance $d > 1$, let $E_2 \colon \{0,1\}^k \to \{0,1\}^{n'}$ be two codes, and let $\pi : \{0,1\}^m \to \{0,1\}^k$ be a function. A* combined test *for (E_1, E_2, π) is a two-oracle machine T such that $T^{E_1(a), E_2(\pi(a))}(R)$ accepts on all a, R. The error probability of T is defined as the maximum accepting probability of T over oracle pairs (A, B), where either $\Delta_{E_1}(A) \geq \lfloor d/2 \rfloor$ or $A = E_1(a)$, $B = E_2(b)$ but $\pi(a) \neq b$, namely,*

$$\max_{(A,B) \in S} \left\{ \Pr_R \left[T^{A,B}(R) \ accepts \right] \right\},$$

where $S \stackrel{\text{def}}{=}$

$$\{(A,B) : (\Delta_{E_1}(A) \geq \lfloor d/2 \rfloor) \text{ or } (\exists a, b \ s.t. \ A = E_1(a) \text{ and } B = E_2(b) \text{ and } \pi(a) \neq b)\}.$$

(Nothing is required with respect to noncodeword pairs, (A, B), which are "close" to some pair $(E_1(a), E_2(b))$ with $\pi(a) \neq b$.)

Conventions and notations. The *pattern* of test T on access to oracle A (resp., oracles A and B) when using coin-sequence R consists of (R and) the sequence of queries and answers made by T. Namely, this pattern, denoted $\mathsf{pattern}_T(A; R)$ (resp., $\mathsf{pattern}_T(A, B; R)$), is defined as the sequence $(R, q_1, a_1, \ldots, q_t, a_t)$, where q_i is the ith query made by T on coin-sequence R and after receiving the answers $a_1, \ldots, a_{i-1}$. We include the queries in the pattern for sake of clarity (but they can be easily reconstructed from the coin sequence and the answers). In case T uses two oracles,

we may assume that the queries specify to which oracle they are addressed. For simplicity, we assume in the rest of this subsection that the test has access to one oracle, denoted A.

The set $\mathsf{Acc}_T(R)$ is defined to be the set of accepting patterns of T on coin-sequence R. Clearly,

$$\mathsf{Acc}_T(R) = \{\mathsf{pattern}_T(A;R) : T^A(R) \text{ accepts}\}.$$

Recall that T is said to have free-bit complexity f if for each possible coin-sequence R it holds that $|\mathsf{Acc}_T(R)| \leq 2^f$. We say that T has *average free-bit complexity* f_{av} if $\mathbf{E}_R\left[|\mathsf{Acc}_T(R)|\right] \leq 2^{f_{\text{av}}}$, when the expectation is taken uniformly over all possible coin sequences. The amortized free-bit complexity of a test is defined as $\frac{f_{\text{av}}}{\log_2(1/\epsilon)}$, where f_{av} is the average free-bit complexity of the test and ϵ is its error probability.

9.2. Lower bound for the codeword test.

PROPOSITION 9.4. *For any code of absolute distance greater than* 1*, the Codeword Test has amortized free-bit complexity of at least* $1 - o(1)$.

The amortization in the above proposition is to be understood as taking place on a fixed number of free bits whereas the length of the oracle grows. Actually, we can allow both the oracle length and the free-bit count to grow, provided that the logarithm of the number of codewords grows faster than the free-bit complexity. Alternatively, we can consider a fixed oracle length and a fix bound on the number of free bits. Actually, this is done in the following technical lemma from which the above proposition follows.

LEMMA 9.5. *Let* $E : \{0,1\}^m \mapsto \{0,1\}^n$ *be a code of absolute distance* $d > 1$*, and let* T *be a codeword test with respect to* E *having average free-bit complexity* f_{av}*. Then,* T *has error probability at least* $\max(2 - 2^{f_{\text{av}}}, \frac{1}{F} - \frac{1}{M})$*, where* $F = 2^{f_{\text{av}}}$ *and* $M = 2^m$.

In particular, if $f_{\text{av}} = 0$, then the error is 1, and for $f_{\text{av}} \geq 1$ the error is at least $\frac{1}{F} - \frac{1}{M}$.

Proof. Fix an arbitrary coin-sequence R, and let F_R denote the cardinality of the set $\mathsf{Acc}_T(R)$.

Let a_1, a_2 be selected independently and uniformly in $\{0,1\}^m$, and consider the codewords $E(a_1)$ and $E(a_2)$. With probability $\frac{1}{M}$ we have $a_1 = a_2$ and otherwise $\Delta(E(a_1), E(a_2)) \geq d$. From a_1 and a_2, we construct an oracle $A(a_1, a_2)$ as follows: if $a_1 = a_2$, then $A = E(a_1)$. Otherwise, we construct $A(a_1, a_2)$ so that it agrees with the value of the bits of both $E(a_i)$'s, whenever they are the same, and so that it is at distance $\lceil d/2 \rceil$ from $E(a_1)$. This can be done as follows: let S be the set of positions on which $E(a_1)$ and $E_2(a_2)$ disagree and let S' be a subset of S of cardinality $\lceil d/2 \rceil$. Then $A(a_1, a_2)$ equals $E(a_1)$ on all positions not in S' (and equals $E(a_2)$ on the positions in S').

We claim that, when $a_1 \neq a_2$, the oracle $A \stackrel{\text{def}}{=} A(a_1, a_2)$ is at distance at least $\lfloor d/2 \rfloor$ from the code (i.e., $\Delta_E(A) \geq \lfloor d/2 \rfloor$). This can be proved as follows: consider any $a \in \{0,1\}^m$ and observe that, by the triangle inequality,

$$\Delta(A, E(a)) \geq \Delta(E(a_1), E(a)) - \Delta(E(a_1), A) \geq d - \lceil d/2 \rceil = \lfloor d/2 \rfloor.$$

We now claim that

$$\Pr_{a_1,a_2}\left[T^{A(a_1,a_2)}(R) \text{ accepts}\right] \geq \frac{1}{F_R},$$

where the probability is taken uniformly over all possible choices of $a_1, a_2 \in \{0,1\}^m$. The key observation is that if $\mathsf{pattern}_T(E(a_1); R)$ equals $\mathsf{pattern}_T(E(a_2); R)$, then $\mathsf{pattern}_T(A(a_1, a_2); R)$ will be equal to $\mathsf{pattern}_T(E(a_1); R)$ (since no query of $T(R)$ falls in the set S, defined above). Thus, since $T^{E(a_1)}(R)$ accepts, $T^{A(a_1,a_2)}(R)$ must accept, too. This suggests to lower bound the probability that $T^{A(a_1,a_2)}(R)$ accepts by the probability that $\mathsf{pattern}_T(E(a_1); R) = \mathsf{pattern}_T(E(a_2); R)$. Consider an enumeration, $\alpha_1, \ldots, \alpha_{F_R}$, of the patterns in $\mathsf{Acc}_T(R)$ and denote by p_i the probability that $\mathsf{pattern}_T(E(a); R)$ equals the ith pattern in this enumeration, when a is uniformly selected in $\{0,1\}^m$ (i.e., $p_i \stackrel{\text{def}}{=} \Pr_a[\mathsf{pattern}_T(E(a); R) = \alpha_i]$). Thus, when a_1 and a_2 are picked at random, the probability that $\mathsf{pattern}_T(E(a_1); R) = \mathsf{pattern}_T(E(a_2); R)$ is $\sum_{i=1}^{F_R} p_i^2$. Subject to the condition $\sum_i p_i = 1$, the quantity $\sum_{i=1}^{F_R} p_i^2$ is lower bounded by $\frac{1}{F_R}$ (with an equality occurring when the p_i's are equal).

The following observations now bound the error of T:

$$\begin{aligned}
&\Pr_{a_1,a_2}\left[T^{A(a_1,a_2)}(R) \text{ accepts and } a_1 \neq a_2\right] \\
&\geq \Pr_{a_1,a_2}\left[T^{A(a_1,a_2)}(R) \text{ accepts}\right] - \Pr_{a_1,a_2}[a_1 = a_2] \\
&\geq \frac{1}{F_R} - \frac{1}{M}.
\end{aligned}$$

All of the above holds for any coin-sequence R. Now, we let R be uniformly chosen and get

$$\begin{aligned}
\Pr_{R,a_1,a_2}\left[T^{A(a_1,a_2)}(R) \text{ accepts and } a_1 \neq a_2\right] &\geq \mathbf{E}_R\left[\frac{1}{F_R}\right] - \frac{1}{M} \\
&\geq \frac{1}{F} - \frac{1}{M}.
\end{aligned}$$

(The last inequality follows by Jensen's inequality.) Thus, there must exist oracles a_1 and a_2 with $a_1 \neq a_2$ such that

$$\Pr_R\left[T^{A(a_1,a_2)}(R) \text{ accepts}\right] \geq \frac{1}{F} - \frac{1}{M},$$

but the oracle $A(a_1, a_2)$ above satisfies $\Delta_E(A(a_1, a_2)) \geq \lfloor d/2 \rfloor$, implying that the error of T is at least $\frac{1}{F} - \frac{1}{M}$.

To prove that the error is at least $2 - 2^{f_{\text{av}}}$, we observe that if $F_R = 1$ for some coin-sequence R, then $\mathsf{pattern}_T(E(a_1); R) = \mathsf{pattern}_T(E(a_2); R)$, for every two $a_1, a_2 \in \{0,1\}^m$. It follows that for every $a_1 \neq a_2$, given access to the oracle $A(a_1, a_2)$ and using coin-sequence R, the test T accepts (and is wrong in doing so). Thus, for every $a_1 \neq a_2$,

$$\Pr_R\left[T^{A(a_1,a_2)}(R) \text{ accepts}\right] \;\geq\; \Pr_R[F_R = 1] \;=\; 1 - \Pr_R[F_R > 1],$$

and the error bound follows by using $\Pr_R[F_R - 1 > 0] \leq \mathbf{E}_R[F_R - 1] = F - 1$. □

Proof of Proposition 9.4. Let T be a test for the code $E : \{0,1\}^* \to \{0,1\}^*$ so that E maps m-bit strings into $n(m)$-bit strings. Suppose that T has average free-bit complexity $f(m)$ and error $\epsilon(m)$, as a function of m (the length of strings encoded by the oracle). We first assume that $f(m) \geq 1$. Using Lemma 9.5 (and letting

$\rho(m) \stackrel{\text{def}}{=} 2^{f(m)-m}$), we lower bound the amortized free-bit complexity of T as follows:

$$\begin{aligned}\frac{f(m)}{\log_2(1/\epsilon(m))} &\geq \frac{f(m)}{-\log_2(1/2^{f(m)} - 1/2^m)} \\ &= \frac{f(m)}{f(m) - \log_2(1-\rho(m))} \\ &> \frac{f(m)}{f(m)+\rho(m)} \\ &> 1 - \rho(m).\end{aligned}$$

(For the last inequality, we have assumed $f(m) \geq 1$.) Thus, for this case, the proposition follows by our convention that the number of codewords (denoted 2^m) grows faster than exponential in the free-bit complexity $f(m)$ (i.e., $\rho(m) = \frac{2^{f(m)}}{2^m} \to 0$ with $n \to \infty$). Finally, we need to address the case in which $f(m) \geq 1$ does not hold. We consider two subcases. In the first subcase, we assume that $f(m) \to 0$ for some infinite subsequence of the m's. For these m's, we use the assertion of Lemma 9.4 that $\epsilon(m) \geq 2 - 2^{f(m)}$. Setting $g(m) \stackrel{\text{def}}{=} 2^{f(m)} - 1$, we lower bound the amortized free-bit complexity by

$$\begin{aligned}\frac{f(m)}{\log_2(1/\epsilon(m))} &\geq \frac{\log_2(1+g(m))}{-\log_2(1-g(m))} \\ &\to \frac{g(m)}{g(m)}.\end{aligned}$$

For the other subcase, we have $f(m) \geq t$, for some constant $t > 0$. Applying T for t times we get a test T' with average free-bit complexity $t \cdot f(m) \geq 1$ and error $\epsilon'(m) = \epsilon(m)^t$, which maintains the amortized free-bit complexity of T (since $\frac{f(m)}{-\log_2 \epsilon(m)} = \frac{t \cdot f(m)}{-\log_2 \epsilon'(m)}$). Applying the above analysis to T', the proposition follows. □

9.3. Lower bound for the projection test. A *projection function* is a function $\pi : \{0,1\}^* \mapsto \{0,1\}^*$ having the property that for every m there exists a k so that π maps $\{0,1\}^m$ onto $\{0,1\}^k$.

PROPOSITION 9.6. *For any pair of codes used in the two oracles and any projection function, the Projection Test has amortized free-bit complexity of at least* $1 - o(1)$.

Again, the proposition is proved by a technical lemma. Actually, the lemma refers to any function $\pi : \{0,1\}^m \mapsto \{0,1\}^k$, and its conclusion depends on the cardinality of the range of π (which in case of a projection function equals 2^k). Abusing notations we let $\pi(S) \stackrel{\text{def}}{=} \{\pi(a) : a \in S\}$.

LEMMA 9.7. *Let* $E_1 : \{0,1\}^m \mapsto \{0,1\}^n$, $E_2 : \{0,1\}^k \mapsto \{0,1\}^{n'}$ *and* $\pi : \{0,1\}^m \mapsto \{0,1\}^k$ *be as in Definition* 9.2, *and let* T *be a projection test with respect to them having average free-bit complexity* f_{av}. *Then,* T *has error probability at least* $\frac{1}{F} - \frac{1}{K}$, *where* $K = |\pi(\{0,1\}^m)|$ *and* $F = 2^{f_{\text{av}}}$. *Furthermore, if* $K > 1$, *then* T *has error probability at least* $2 - 2^{f_{\text{av}}}$.

Proof. Fixing an arbitrary coin-sequence R, let $F_R \stackrel{\text{def}}{=} |\{\mathsf{Acc}_T(R)\}|$. We consider the behavior of the test T when given oracle access to a pair of randomly and independently selected codewords. Specifically, let $S \subset \{0,1\}^m$ be a set of K strings such that for every $b \in \pi(\{0,1\}^m)$ there exists an $a \in S$ satisfying $\pi(a) = b$. We consider the behavior of T when given access to the oracles $E_1(a)$ and $E_2(\pi(a'))$, where a and a' are independently and uniformly selected in S. With probability $\frac{1}{K}$, we have

$\pi(a) = \pi(a')$. On the other hand we claim that, given access to such pair of random oracles, T accepts with probability at least $\frac{1}{F_R}$. Once the claim is proven, the lemma follows (as in the proof of the previous lemma).

Consider the set of all F_R possible accepting patterns of T on access to oracles, $E_1(a)$ and $E_2(\pi(a))$, where $a \in S$. Each such pattern consists of a pair (α, β), where α (resp., β) denotes the transcript of the test's interaction with $E_1(a)$ (resp., $E_2(\pi(a))$). Enumerating all possible F_R patterns, we denote by p_i the probability that the ith pattern occurs, when T is given access to the oracle-pair $(E_1(a), E_2(\pi(a)))$, where a is uniformly selected in S. Namely,

$$p_i \stackrel{\text{def}}{=} \Pr_{a \in S}\left[\mathsf{pattern}_T(E_1(a), E_2(\pi(a)); R) = (\alpha_i, \beta_i)\right],$$

where (α_i, β_i) is the ith accepting pattern for $T(R)$. Clearly,

(18)

$$\Pr_{a,a' \in S}\left[\mathsf{pattern}_T(E_1(a), E_2(\pi(a)); R) = \mathsf{pattern}_T(E_1(a'), E_2(\pi(a')); R) = (\alpha_i, \beta_i)\right] = p_i^2.$$

We now claim that the probability that a pair of independently chosen random oracles (i.e., $(E_1(a), E_2(b))$ selected by uniformly selecting $a, a' \in S$ and setting $b = \pi(a')$) leads to the ith pattern is at least p_i^2, namely,

$$\Pr_{a,a' \in S}\left[\mathsf{pattern}_T(E_1(a), E_2(\pi(a')); R) = (\alpha_i, \beta_i)\right] \geq p_i^2. \tag{19}$$

Equation (19) is proven by a cut-and-paste argument. Suppose

$$\mathsf{p} \stackrel{\text{def}}{=} \mathsf{pattern}_T(E_1(a), E_2(\pi(a)); R) \;=\; \mathsf{p}' \stackrel{\text{def}}{=} \mathsf{pattern}_T(E_1(a'), E_2(\pi(a')); R)$$

and consider a computation of $T^{E_1(a), E_2(\pi(a'))}(R)$. Proceeding by induction, and assuming that the first t queries are answered as in p, we show that the $t+1$st query (in our "hybrid" computation) is identical to the $t+1$st query in $\mathsf{p} = \mathsf{p}'$. If this query is directed to the first oracle, then it is answered by $E_1(a)$ (as in p) and otherwise it is answered by $E_2(\pi(a'))$ (as in p'). In both cases the answer matches the $t+1$st answer in $\mathsf{p} = \mathsf{p}'$. We conclude that whenever $\mathsf{p} = \mathsf{p}'$, the computation of $T^{E_1(a), E_2(\pi(a'))}(R)$ encounters the same pattern (p). Thus, the probability that the computation of $T^{E_1(a), E_2(\pi(a'))}(R)$ encounters the ith pattern is lower bounded by the expression in Eq. (18), and Eq. (19) follows. (We remark that for nonadaptive tests, the probability that the ith pattern is encountered equals $\sum_{i=1}^{F_R} p_i' p_i''$, where p_i' (resp., p_i'') is the sum of all p_j's satisfying $\alpha_j = \alpha_i$ (resp., $\beta_j = \beta_i$). Actually, the same holds for any test which selects its queries for each oracle independently of answers obtained from the other oracle.)

Using Eq. (19), we get

$$\begin{aligned}\Pr_{a,a' \in S}\left[\mathsf{pattern}_T(E_1(a), E_2(\pi(a')); R) \in \mathsf{Acc}_T(R)\right] &\geq \sum_{i=1}^{F_R} p_i^2 \\ &\geq \frac{1}{F_R},\end{aligned}$$

and the main part of the lemma follows. Again, the "furthermore" part follows by observing that for $F_R = 1$, $\mathsf{pattern}_T(E_1(a), E_2(\pi(a)); R) = \mathsf{pattern}_T(E_1(a'), E_2(\pi(a')); R)$, for every two $a, a' \in \{0,1\}^m$. Again this implies that, for every $a_1 \neq a_2$, given access to the oracle-pair $(E_1(a), E_2(\pi(a')))$ and using coin-sequence R, the test T (wrongly) accepts. □

9.4. Lower bound for the combined test.

PROPOSITION 9.8. *For any pair of codes used in the two oracles, so that the first code has absolute distance greater than* 1*, and for any projection function, the Combined Test has amortized free-bit complexity of at least* $2 - o(1)$.

Again, the proposition is proved by a technical lemma. Loosely speaking, the lemma asserts that a combined test of free-bit complexity $2f$ must have error probability at least $\frac{1}{8} \cdot 2^{-f}$. The lower bound extends to the case where $2f$ is a bound on the average free-bit complexity; the error probability in this case can be lower bounded by $\frac{3}{64} \cdot 2^{-f}$; see details below. It follows that the amortized free-bit complexity of such a test must be at least $\frac{2f}{f+5} \approx 2$ (for large f's). The restriction to large f's does not really weaken the result. Suppose on the contrary that there exists a test with amortized free-bit complexity f_{am}. Then, for any sufficiently large t, we can obtain a test with free-bit complexity $2f \stackrel{\text{def}}{=} t \cdot f_{\text{am}}$ and error 2^{-t}. By the above, $\frac{t \cdot f_{\text{am}}}{t} \geq \frac{2f}{f+5} \approx 2$ (as f is now large).

LEMMA 9.9. *Let* $E_1 : \{0,1\}^m \mapsto \{0,1\}^n$ *be a code of absolute distance greater than* 1*,* $E_2 : \{0,1\}^k \mapsto \{0,1\}^{n'}$*, and let* $\pi : \{0,1\}^m \mapsto \{0,1\}^k$ *be a projection function. Suppose that* T *is a combined codeword and projection test with respect to the above having free-bit complexity* $2f$*. Then,* T *has error probability at least* $\frac{1}{8F} - \frac{1}{2K} - \frac{1}{4M}$*, where* $K = 2^k$*,* $F = 2^f$*, and* M *is the minimum, over all* $b \in \{0,1\}^k$*, of the number of* $a \in \{0,1\}^m$ *projected by* π *to* b *(i.e.,* $M \stackrel{\text{def}}{=} \min_{b \in \{0,1\}^k}\{|\{a : \pi(a) = b\}|\}$*). Furthermore, if* $2f < 1$ *and* $\max\{M, K\} > 1$*, then* T *has error probability* 1*.*

Proof. The "furthermore" part follows immediately by any of the furthermore parts of Lemma 9.5 or 9.7 (as 2^{2f} must be an integer and so $2f < 1$ implies $f = 0$). The proof of the main part of the lemma uses both strategies employed in the proofs of Lemmas 9.5 and 9.7. We consider two cases. The first case is that for some $E_2(b)$, half of the possible (coin-sequence) R's have at most F accepting patterns with respect to the coin-sequence R and second oracle $B = E_2(b)$. In this case we employ the strategy used in the proof of Lemma 9.5, restricted to oracles constructed by combining two uniformly selected codewords $E_1(a_i)$'s satisfying $\pi(a_i) = b$. The second case is that for every $b \in \{0,1\}^k$, for half of the possible (coin-sequence) R's, the number of accepting patterns with respect to the coin-sequence R and second oracle $B = E_2(b)$ is at least F. In this case we show that many possible B's must fit into fewer than $\frac{F^2}{F}$ accepting patterns and we may employ the strategy used in the proof of Lemma 9.7. Details follow.

In the following, $\delta \in [0,1]$ is a constant to be determined later. (In the above motivating discussion we have used $\delta = 1/2$, but a better bound follows by letting δ be larger.)

Case 1. There exists $b \in \{0,1\}^k$ so that for at least $(1-\delta)$ fraction of the possible (coin-sequence) R's, hereafter called *good*, the number of accepting patterns with respect to the coin-sequence R and second oracle (fixed to) $B = E_2(b)$ is at most F.

Fixing this b, we consider M possible a's satisfying $\pi(a) = b$. Employing the argument of Lemma 9.5, we get that for each of these *good* R's, a random oracle A (constructed using two uniformly chosen a's as above) is wrongly accepted with probability at least $\frac{1}{F} - \frac{1}{M}$. By an averaging argument, it follows that there exists a pair of oracles (A, B) on which T errs with probability at least

$$(1-\delta) \cdot \left(\frac{1}{F} - \frac{1}{M}\right). \tag{20}$$

Case 2. For every $b \in \{0,1\}^k$, for at least a δ fraction of the possible (coin-sequence) R's, the number of accepting patterns with respect to the coin-sequence R and second oracle $B = E_2(b)$ is at least F.

Let $\gamma < \delta$ be a parameter to be determined later. By a counting argument, for at least a $\frac{\delta-\gamma}{1-\gamma}$ fraction of the possible R's, hereafter called *good*, there exists a set, denoted Π_R, of at least $\gamma \cdot 2^k$ possible $b \in \{0,1\}^k$ so that there are at least F accepting patterns which are consistent with coin-sequence R and second oracle fixed to $B = E_2(b)$. (Namely, let g denote the fraction of good R's. Then $g + (1-g)\cdot\gamma \geq \delta$ and $g \geq \frac{\delta-\gamma}{1-\gamma}$ follows.)

Let $S \subset \{0,1\}^m$ be a set of 2^k strings, defined as in the proof of Lemma 9.7, so that π maps S onto $\{0,1\}^k$. Fixing a good coin-sequence R, we adapt the strategy used in the proof of Lemma 9.7 as follows. We consider a set $S_R \subseteq S$ of $|\Pi_R|$ strings so that π maps S_R onto Π_R, and enumerate the accepting patterns which occur when the test, using coins R, is given access to an oracle-pair $(E_1(a), E_2(\pi(a)))$, where a is uniformly chosen in S_R. We first claim that there are at most F such patterns. Namely, we have the following.

CLAIM. *For any good R,* $|\{\mathsf{pattern}_T(E_1(a), E_2(\pi(a)); R) : a \in S_R\}| \leq F$.

Proof. By definition of Π_R, for each $b \in \Pi_R$, there are at least F accepting patterns consistent with the coin-sequence R and the second-oracle $E_2(b)$ (and out of them only one fits the first oracle $E_1(a)$, where $a \in S_R$ and $\pi(a) = b$). By a cut-and-paste argument, if (R, α, β) and (R, α', β) are accepting patterns for second-oracle $E_2(b)$, and if (R, α, β) is an accepting pattern for second-oracle $E_2(b')$, then (R, α', β) is also an accepting pattern for second-oracle $E_2(b')$. It follows that the accepting patterns of two $E_2(b)$'s either collide or do not intersect. Thus, the number of accepting patterns for the various $(E_1(a), E_2(\pi(a)))$'s, where $a \in S_R$, is at most $\frac{F^2}{F} = F$ and the claim follows. □

Now we consider what happens if one selects independently and uniformly $a, a' \in S$. Following the proof of Lemma 9.7, with probability $\frac{1}{K}$, we have $\pi(a) = \pi(a')$ (and otherwise $\pi(a) \neq \pi(a')$). On the other hand, given access to such a pair of random oracles, the test accepts with probability at least $\gamma^2 \cdot \frac{1}{F}$. (The γ^2 factor is due to the probability that $a, a' \in S_R$, whereas the $\frac{1}{F}$ factor corresponds to the analysis which supposes that a and a' are uniformly selected in S_R.)

The above analysis holds for any good coin-sequence R. Using the lower bound on the fraction of good R's, it follows that for a $\frac{\delta-\gamma}{1-\gamma}$ fraction of the R's, the probability that the test errs, on coin-sequence R when given access to a random pair of oracles (selected as above), is at least $\frac{\gamma^2}{F} - \frac{1}{K}$. By an averaging argument, there exists a pair of oracles for which the test errs with probability

$$\frac{\delta-\gamma}{1-\gamma} \cdot \left(\frac{\gamma^2}{F} - \frac{1}{K}\right). \tag{21}$$

Setting $\delta = \frac{3}{4}$ and $\gamma = 1/2$ we lower bound the expressions in Eqs. (20) and (21) by $\frac{1}{4F} - \frac{1}{4M}$ and $\frac{1}{8F} - \frac{1}{2K}$, respectively, and the lemma follows. □

To prove a bound for the case of average free-bit complexity $2f$, we first apply Markov's inequality and conclude that all but an ϵ fraction of the coin sequences have at most $G^2 \stackrel{\text{def}}{=} \frac{F^2}{\epsilon}$ accepting patterns (in which this fixed coin-sequence appears). (We can use any $0 < \epsilon < 1$.) We then consider only those coin sequences (and apply the same argument as above to each of them). The averaging argument at the end of the above proof then yields that there exists an oracle pair on which T errs on at least a $\frac{1}{8G} - \frac{1}{2K} - \frac{1}{4M}$ fraction of these coin sequences. It follows that this oracle makes T err with probability at least $(1-\epsilon)\cdot(\frac{1}{8G} - \frac{1}{2K} - \frac{1}{4M})$ (which equals $(1-\epsilon)\cdot(\frac{\sqrt{\epsilon}}{8F} - \frac{1}{2K} - \frac{1}{4M})$). Using $\epsilon = \frac{1}{4}$, we get a lower bound of $\frac{3}{64F} - \frac{3}{8K} - \frac{3}{16M}$.

Part III: PCP: Properties and transformations.

10. The complexity of PCP and FPCP. In this section we present several results regarding the complexity of languages acceptable by probabilistically checkable proofs having, respectively, small query complexity, small amortized query complexity, and small free-bit complexity. Thus, in the current section, notations such as $\mathrm{PCP}_{c,s}[r,q]$ stand for classes of languages. The results can be extended to classes of promise problems having such probabilistically checkable proofs.

In this section, $\mathrm{MIP}_{c,s}[r,p]$ denotes the class of languages accepted by a (one-round) p-prover interactive proof system in which r is the randomness complexity, c is a lower bound on the probability of accepting yes-instances, and s is an upper bound on the probability of accepting no-instances. The corresponding class for probabilistically checkable proofs is $\mathrm{PCP}_{c,s}[r,q]$, where q denotes the number of queries. In both classes only binary queries are allowed (indeed this is less standard for MIP).

10.1. MIP versus PCP. The first part of the following lemma is folklore and is stated here for sake of completeness.

LEMMA 10.1. *For all admissible functions c, s, r, p,*

(1) $\mathrm{MIP}_{c,s}[r,p] \subseteq \mathrm{PCP}_{c,s}[r,p]$.

(2) $\mathrm{MIP}_{c,s}[r,p] \subseteq \mathrm{MIP}_{c,2s}[r,p-1]$.

Proof. Part (1) follows from the definition of PCP and MIP. Part (2) is shown as follows. Let V be an (r,p)-restricted MIP verifier. We define V', an $(r,p-1)$-restricted verifier who on input x behaves as follows:

- V' tosses coins $\overline{c}$ for V.
- V' refers the first $p-1$ queries of V to the corresponding $p-1$ provers obtaining answers (bits) $a_1,\ldots,a_{p-1}$, respectively.
- V' accepts if and only if there exists $a_p \in \{0,1\}$ such that V would accept answers $a_1,\ldots,a_p$ on input x and random string $\overline{c}$.

Suppose that provers $P_1,\ldots,P_p$ convince V to accept x with probability δ. Then, the provers $P_1,\ldots,P_{p-1}$ convince V' to accept x with probability at least δ (because if $V(x)$ accepts the transcript $(\overline{c},a_1,\ldots,a_p)$ then $V'(x)$ will accept the transcript $(\overline{c},a_1,\ldots,a_{p-1})$). This justifies the bound on the completeness probability of V'. Suppose, on the other hand, that provers $P_1,\ldots,P_{p-1}$ cause V' to accept x with probability δ. Consider a uniformly selected strategy for another prover, denoted P_p (i.e., choose a random response for every question). Then, the probability that provers $P_1,\ldots,P_p$ cause V to accept input x is at least $\frac{1}{2}\cdot\delta$ (because if $V'(x)$ accepts the transcript $(\overline{c},a_1,\ldots,a_{p-1})$, then there exists a value $a_p \in \{0,1\}$ so that $V(x)$ will accept the transcript $(\overline{c},a_1,\ldots,a_p)$, and with probability one-half P_p's answer equals this a_p). This justifies the bound on the soundness probability of V'. □

Containments of PCP systems in MIP systems are more problematic. The reader is referred to a paper by Ta-Shma [83]. That paper also contains a proof of the following result due to Bellare, Goldreich, and Safra:

$$\mathrm{PCP}_{c,s}(\log,q) \subseteq \mathrm{MIP}_{c,q^q\cdot s}(\log,q).$$

Here we only consider the nonadaptive case and obtain a different bound on the soundness parameter.

PROPOSITION 10.2. *Suppose $L \in \mathrm{PCP}_{c,s}(r,q)$ with a nonadaptive verifier. Then $L \in \mathrm{MIP}_{c',s'}(r+O(\log q),q)$, where $c' = c + p\cdot(1-c)$, $s' = s + p\cdot(1-s)$ for any $p \geq \lfloor q/2\rfloor/(1+\lfloor q/2\rfloor)$.*

For $q=3$, we may set $p=0.5$ and obtain $c' = (c+1)/2$ and $s' = (s+1)/2$.

Proof. We start with a nonadaptive PCP verifier of q queries and construct a q-prover system as follows. First we uniformly select coin tosses for the PCP verifier, which defines q queries (here is where we use nonadaptivity). Next,

- with probability p we select a query uniformly among these q queries and forward it to all q provers. We accept iff all provers answer in the same manner.
- with probability $1-p$ we simulate the PCP system as follows. We uniformly select $i \in [q]$ and refer the jth query of the verifier to the $(i+j)$th prover. We accept iff the PCP verifier would have accepted.

Clearly, by setting all MIP provers to equal the good oracle (of the PCP system), inputs in the language are accepted with probability at least $p \cdot 1 + (1-p) \cdot c = c + p \cdot (1-c)$.

We now bound the acceptance probability of the MIP system for an input not in the language. Fix an arbitrary sequence of MIP provers. Let δ denote the probability, taken over the queries selected by the PCP verifier as above, that the q MIP provers differ on a random query. Define an oracle so that on each query it equals the majority of the prover's answers (ties, in case of even q, are broken arbitrarily). Then, the probability that the MIP system accepts is bounded above by

$$p \cdot (1-\delta) + (1-p) \cdot (s + \lfloor q/2 \rfloor \cdot \delta)\,. \tag{22}$$

To justify the second term consider the simulation of the PCP system (which takes place with probability $1-p$). In case the answers given by all MIP provers equal the corresponding answers of the PCP oracle (defined above), we bound the acceptance probability by soundness of the PCP system. Otherwise, there must be a query on which the relevant MIP prover differs from the PCP oracle. For each query this happens with probability at most $\frac{\lfloor q/2 \rfloor}{q}$ (as, by definition, only a minority of provers differ from the oracle). Using the union bound, Eq. (22) follows. Using the definition of p, we have

$$\begin{aligned} p \cdot (1-\delta) + (1-p) \cdot (s + \lfloor q/2 \rfloor \cdot \delta) &= p + (1-p) \cdot s - \delta \cdot (p - (1-p) \cdot \lfloor q/2 \rfloor) \\ &\leq s + p \cdot (1-s), \end{aligned}$$

and the proposition follows. ∎

10.2. Query complexity and amortized query complexity. The following proposition explores the limitations of probabilistically checkable proof systems which use logarithmic randomness and up to three queries. Some of the qualitative assertions are well known; for example, when considering perfect completeness, three queries are the minimum needed (and sufficient [8]) to get above P.

PROPOSITION 10.3 (PCP systems with logarithmic randomness and at most three queries).

(1) (PCP with one query is weak). *For all admissible functions* $s, c : \mathcal{Z}^+ \to [0,1]$, *so that* s *is strictly smaller than* c, $\mathrm{PCP}_{c,s}[\log, 1] = \mathrm{P}$.
(2) (one-sided error pcp with two queries is weak). *For all admissible functions* $s : \mathcal{Z}^+ \to [0,1]$ *strictly less than* 1, $\mathrm{PCP}_{1,s}[\log, 2] = \mathrm{P}$.
(3) (two-sided error pcp with two queries is not weak). *There exists* $0 < s < c < 1$ *so that* $\mathrm{PCP}_{c,s}[\log, 2] = \mathrm{NP}$. *Furthermore, this holds for some* $c > 0.9$ *and* $s < \frac{73}{74}c$.
(4) (one-sided error pcp with three queries is not weak). $\mathrm{PCP}_{1,0.85+\epsilon}[\log, 3] = \mathrm{NP}$, $\forall \epsilon > 0$.

(5) (one-sided error pcp with three queries is not very strong). *For every* $s < 0.18$, $\mathrm{PCP}_{1,s}[\log, 3] = \mathrm{P}$. *Furthermore,* $\forall s \leq 0.299$, $\mathbf{na}\mathrm{PCP}_{1,s}[\log, 3] = \mathrm{P}$, *where* $\mathbf{na}\mathrm{PCP}$ *is a restriction of* PCP *in which the verifier is required to be nonadaptive.*

We remark that $\mathrm{PCP}_{1,0.8999}[\log, 3] = \mathrm{NP}$ with a nonadaptive verifier was presented in an earlier version of this paper [20]. Using Proposition 10.2, we have $\mathrm{MIP}_{1,0.95}[\log, 3] = \mathrm{NP}$.

Proof of Proposition 10.3, *part* 1. An oracle π maximizing the acceptance probability can be constructed by scanning all possible random pads (random strings) and setting $\pi(q)$ so that it "satisfies" the majority of random pads for which the verifier makes query q. □

Proof of Proposition 10.3, *part* 2. The folklore proof commonly deals only with the nonadaptive case. In general, the verifier V, demonstrating that $L \in \mathrm{PCP}_{1,s}[\log, 2]$, may be adaptive. We assume, without loss of generality, that V always makes at least one query. Thus, after making the first query, V decides whether to accept, reject, or make an additional query and accept only a specific answer for it. Thus, the computation of V on input x, random pad $\overline{c}$, and access to a generic oracle can be captured by two Horn clauses, each corresponding to a different answer value for the first query. Specifically, suppose that V queries the oracle at location i and upon receiving value σ accepts iff location j has value τ. Then we write the Horn clause $\pi_i^\sigma \rightarrow \pi_j^\tau$, where π_i^τ is a boolean variable representing the event that ith oracle location has value τ. (In case V always accepts (resp., rejects) after obtaining value σ from oracle location i, we write the clause $\pi_i^\sigma \rightarrow \mathbf{T}$ (resp., $\pi_i^\sigma \rightarrow \mathbf{F}$).) In addition, for every i, we write the Horn clauses $\pi_i^0 \rightarrow (\neg\pi_i^1)$ and $(\neg\pi_i^0) \rightarrow \pi_i^1$. Thus, the computation of V on input x and access to a generic oracle can be captured by a Horn formula, denoted ϕ_x, in which Horn clauses correspond to the various (polynomially many) possible (random pad, first-answer) pairs. Furthermore, ϕ_x can be constructed in polynomial time given x (and V). Using a (polynomial-time) decision procedure for satisfiability of Horn formulae, we are done. (Alternatively, we can use the linear-time decision procedure for 2-SAT due to Even, Itai, and Shamir [35].) □

Proof of Proposition 10.3, *part* 4. To see that $\mathrm{PCP}_{1,s}[\log, \mathrm{poly}] \subseteq \mathrm{NP}$, for every $s < 1$, consider a nondeterministic machine which tries to guess an oracle which makes the verifier (of the above system) always accept. The other direction (of part 4) is shown in Theorem 4.5. □

Proof of Proposition 10.3, *part* 3. To see that $\mathrm{PCP}_{c,s}[\log, \mathrm{poly}] \subseteq \mathrm{NP}$, for every $s < c$, consider a nondeterministic machine which tries to guess an oracle which makes the verifier accept with probability at least c. The $\mathrm{NP} \subseteq \mathrm{PCP}_{c,s}[\log, 2]$ result follows from the hardness of approximating Max2SAT. Specifically, suppose that $L \leq_D^K \mathsf{Gap\text{-}2SAT}_{c,s}$. Then we can present a $\mathrm{PCP}_{c,s}[\log, 2]$ system for L as follows. On input x, the verifier in this system performs the reduction (of L to the promise problem) obtaining a 2CNF formula ϕ_x. Next it uniformly selects a clause of ϕ_x and queries the oracle for the values of the variables in this clause (accepting accordingly). Using Theorem 4.6 (part 3), $\mathrm{NP} \leq_D^K \mathsf{Gap\text{-}2SAT}_{c,s}$ for some $c > 0.9$ and $s < \frac{73}{74} \cdot c$, and $\mathrm{NP} \subseteq \mathrm{PCP}_{c,s}[\log, 2]$ follows. □

Remark 10.4. The ratio c/s has been subsequently increased to $(10/9) - \epsilon$, for any $\epsilon > 0$ (cf., [84, 57]).

Proof of Proposition 10.3, *part* 5. The result for general verifiers follows from Lemma 4.11 and the fact that MaxSAT can be approximated to within a $0.795 = 0.75 + \frac{0.18}{4}$ factor in polynomial time (cf. [84]). The (tedious) proof of the nonadaptive

case can be found in earlier versions of this paper [20]. The paper of Trevisan et al. [84] contains a stronger result which holds for all verifiers; that is, $\mathrm{PCP}_{1,0.367}[\log, 3] = \mathrm{P}$. □

The latter result (i.e., $\mathrm{PCP}_{1,0.367}[\log, 3] = \mathrm{P}$) is weaker than what can be proven for MIP proof systems (see next corollary). This contrast may provide a testing ground to separate PCP from MIP, a question raised by [21].

COROLLARY 10.5. *For $s < 1/2$, $\mathrm{MIP}_{1,s}[\mathsf{coins} = \log, \mathsf{provers} = 3] = \mathrm{P}$.*

Proof. Combining (the two parts of) Lemma 10.1 and (part 2 of) Proposition 10.3, we have $\mathrm{MIP}_{1,s}[\log, 3] \subseteq \mathrm{MIP}_{1,2s}[\log, 2] \subseteq \mathrm{PCP}_{1,2s}[\log, 2] \subseteq \mathrm{P}$. □

A general result that relates the query complexity of a probabilistically checkable proof system and the ratio between the acceptance probabilities of yes-instances and no-instances follows.

LEMMA 10.6. *For all admissible functions c, s, q, r, l such that $c/s > 2^q$,*

$$\mathrm{PCP}_{c,s}[r, q] \subseteq \mathrm{RTIME}\left(\mathrm{poly}\left(\frac{n}{c - 2^q s}\right)\right).$$

Furthermore, $\mathrm{PCP}_{c,s}[r, q] \subseteq \mathrm{PSPACE}$, and if r and q are both logarithmically bounded, then $\mathrm{PCP}_{c,s}[r, q] = \mathrm{P}$.

Proof. Let $L \in \mathrm{PCP}_{c,s}[r, q]$ and let V be a verifier demonstrating this fact. Observe that for $x \in L$, the probability that V accepts x, given access to a random oracle, is at least $\frac{c}{2^q}$. On the other hand, for $x \notin L$, the probability that V accepts x, given access to any oracle, is at most $s < \frac{c}{2^q}$. Thus, we can decide if x is in L by simulating the execution of V with access to a random oracle and estimating the acceptance probability over V's random choices and all possible oracles. In particular, we can estimate this probability up to an $\epsilon \stackrel{\mathrm{def}}{=} \frac{1}{2} \cdot (s - \frac{c}{2^q})$ additive term, with very high probability, by taking $\mathrm{poly}(1/\epsilon)$ samples. Alternatively, we can compute this probability in polynomial space. Finally, in case r and q are both logarithmically bounded, we can (exactly) compute the probability that V accepts x, given access to a random oracle. To this end we loop through all possible random pads for V and, for each pad, consider all possibilities of setting the oracle bits examined by V. Thus, for $s < \frac{c}{2^q}$, we get a deterministic polynomial-time decision procedure. □

The last assertion in the above lemma (i.e., $\mathrm{PCP}_{c,s}[\log, q] = \mathrm{P}$ for $c/s > 2^q$) cannot be strengthen by omitting the (logarithmic) bound on q since $\mathrm{NP} = \mathrm{PCP}_{1,0}[0, \mathrm{poly}]$. On the other hand, recalling the definition of $\overline{\mathrm{PCP}}$ we immediately get the following.

COROLLARY 10.7. *Let $\epsilon : \mathcal{Z}^+ \to [0, 1]$ be an admissible function strictly greater than 0. Then, for every admissible function $c : \mathcal{Z}^+ \to [0, 1]$,*

$$\overline{\mathrm{PCP}}_c[\log, 1 - \epsilon] = \mathrm{P}.$$

In particular, this holds for $c = 1$.

Proof. $L \in \overline{\mathrm{PCP}}_c[\log, 1 - \epsilon]$ implies that for some logarithmically bounded function m, we have $L \in \mathrm{PCP}_{c,2^{-m} \cdot c}[\log, (1 - \epsilon) \cdot m]$ and the corollary follows. □

PCP WITH SUPER-LOGARITHMIC RANDOMNESS. The above results are focused on pcp systems with logarithmic randomness. Proof systems with unrestricted randomness (as considered in the next proposition) may also provide some indication to the effect of very low query complexity. The results we obtain are somewhat analogous to those of Proposition 10.3. Recall that $\mathrm{PCP}_{1,1/2}[\mathrm{poly}, \mathrm{poly}]$ equals NEXPT (nondeterministic exponential time) [11]. Thus, the power of pcp systems with polynomial randomness has to be compared against NEXPT.

PROPOSITION 10.8 (general PCP systems with at most three queries).

(1) (PCP with one query is relatively very weak). *For all admissible functions* $s, c : \mathcal{Z}^+ \to [0,1]$*, so that* $c(n) - s(n)$ *is nonnegligible,*[11]

$$\mathrm{PCP}_{c,s}[\mathrm{poly}, 1] \subseteq \mathrm{AM},$$

where AM is the class of languages having one-round Arthur–Merlin proof systems (*cf.* [10]).

(2) (one-sided error pcp with two queries is relatively weak). *For all admissible functions* $s : \mathcal{Z}^+ \to [0,1]$ *strictly less than* 1, $\mathrm{PCP}_{1,s}[\mathrm{poly}, 2] \subseteq \mathrm{PSPACE}$.

(3) (two-sided error pcp with two queries is not weak). *On the other hand, there exists* $0 < s < c < 1$ *so that* $\mathrm{PCP}_{c,s}[\mathrm{poly}, 2] = \mathrm{NEXPT}$.

(4) (one-sided error pcp with three queries is not weak). $\mathrm{PCP}_{1,0.85+\epsilon}[\mathrm{poly}, 3] = \mathrm{NEXPT}$, $\forall \epsilon > 0$.

(5) (one-sided error pcp with three queries is not very strong). $\forall s < \frac{1}{8}$, $\mathrm{PCP}_{1,s}[\mathrm{poly}, 3] = \mathrm{PSPACE}$.

The first part of the proposition may be hard to improve since, as indicated in Proposition 10.9, part 6, graph nonisomorphism is in $\mathrm{PCP}_{1,1/2}[\mathrm{poly}, 1]$.

Proof of Proposition 10.8, *part* 1. We first observe that a 1-query pcp system is actually a one-round interactive proof system (cf. [53]). (The completeness and soundness bounds are as in the pcp system.) Using well-known transformations we obtain the claimed result. Specifically, we first reduce the error of the interactive proof by parallel repetition, next transform it into an Arthur–Merlin interactive proof [54], and finally transform it into an Arthur–Merlin interactive proof of perfect completeness [46]. We stress that all the transformations maintain the number of rounds up to a constant and that the constant-round Arthur–Merlin hierarchy collapses to one round [10]. □

Proof of Proposition 10.8, *parts* (3) *and* (4). For these parts we observe that the proof systems used in the corresponding parts of the proof of Proposition 10.3 do "scale up." Specifically, it is easy to see that the outer verifier used for all proof systems in this paper does scale up, yielding a canonical outer verifier of randomness complexity $O(\log(T(n))$ for any language in $\mathrm{Ntime}(T(n))$, provided $n < T(n) < 2^{\mathrm{poly}(n)}$. Furthermore, all inner verifiers used in the paper operate on constant sized oracles and so the composed verifier maintains the time and randomness complexities of the outer verifier. In particular, the verifier used for establishing Theorem 4.5 can be scaled up to yield part 4. The same holds for the verifier used for establishing part (3) of Proposition 10.3. (Note that although the exposition of the proof in Proposition 10.3 is in terms of reducing NP to Max2SAT, what actually happens is that the verifier used to establish the NP-hardness of Max2SAT (cf. section 4.2) is implemented by a verifier which makes only two queries (out of a constant number of possibilities).) □

Proof of Proposition 10.8, *part* 2. Following the strategy of the proof of the analogous part in Proposition 10.3, we obtain a polynomial-space reduction of $L \in \mathrm{PCP}_{1,s}[\mathrm{poly}, 2]$ to the set of satisfiable 2-Horn formulae (i.e., Horn formulae in which each clause has at most two literals). Namely, on input x, the reduction uses space

[11] A function $f : \mathcal{Z}^+ \to \mathcal{Z}^+$ is called nonnegligible if there exists a positive polynomial p so that $\forall n : \ f(n) > \frac{1}{p(n)}$.

poly($|x|$) and produces a Horn formula ϕ_x (of size exponential in $|x|$) so that $x \in L$ iff ϕ_x is satisfiable. Using a polylogarithmic decision procedure for satisfiability of 2-Horn formulae[12], we can decide if ϕ_x is satisfiable using poly($|x|$) space. □

Proof of Proposition 10.8, *part* 5. The result follows by the furthermore part of Lemma 10.6 (i.e., $\mathrm{PCP}_{c,s}[\mathrm{poly}, q] = \mathrm{PSPACE}$ for $c/s > 2^q$). □

10.3. Free-bit complexity. The class $\mathrm{FPCP}_{c,s}[r, f]$ is defined analogously to the class $\mathrm{PCP}_{c,s}[r, q]$ except that we consider the free-bit complexity (denoted f) instead of the query complexity (denoted q). The following proposition demonstrates the limitations of probabilistically checkable proof systems with free-bit complexity bounded by 1. We do not believe that similar limitations hold for amortized free-bit complexity.[13]

The first three items refer to proof systems with logarithmic randomness. The *second* item shows that such systems with perfect completeness and free-bit complexity 1 only exists for P (and are hence weak). In contrast, the *first* item shows the crucial role of perfect completeness in the former negative result: specifically, proof systems with two-sided error (nonperfect completeness) having free-bit complexity *zero* suffice for $\mathcal{NP}$. The *third* item asserts that the second item cannot be strengthened with respect to increasing the free-bit complexity. Proof systems with unrestricted randomness (as considered in the last three items) may also provide some indication to the effect of very low free-bit complexity. The last item can be viewed as (weak) evidence that the result in the fourth item cannot be "drastically improved" (e.g., to yield $\mathrm{FPCP}_{1,s}[\mathrm{poly}, 0] \subseteq \mathrm{BPP}$).

We make essential use of the ability to efficiently generate accepting computations, and the results may not hold otherwise.[14]

PROPOSITION 10.9 (PCP systems with low free-bit complexity). *Let* $s : \mathcal{Z}^+ \to [0, 1]$ *be an admissible function strictly smaller than* 1. *Then we have the following.*

(1) (PCP with logarithmic randomness and 0 free bit).

(1.1) *There exists* $s < 0.794$ *so that*

$$\mathrm{NP} \subseteq \mathrm{FPCP}_{\frac{1}{4},\frac{s}{4}}[\log, 0] .$$

Thus, $\mathrm{NP} = \overline{\mathrm{FPCP}}_{\frac{1}{4}}[\log, 0]$.

[12]For example, consider the following procedure. Given a 2-Horn formula, we construct a directed graph in which the vertices are the literals of the formula and there is a directed edge from literal x to literal y if the formula contains the clause $x \to y$. One can easily verify that the formula is not satisfied iff there exists a variable for which every truth assignment yields a contradiction (i.e., "forcing paths" to contradicting values; cf. [35]). Thus, a nondeterministic logspace machine can guess this variable and check that both possible truth assignments (to it) yield contradictions. The latter checking reduces to guessing the variable for which a conflicting assignment is implied and verifying the conflict via s-t directed connectivity. Since the latter task is in $\mathcal{NL}$, we are done. (Actually, 2SAT is complete for co$\mathcal{NL}$; see [60].)

[13]The conjecture was stated for systems with perfect completeness and has been subsequently proven by Håstad [56] (who proved that $\mathrm{NP} = \overline{\mathrm{FPCP}}_1[\log, \epsilon]$ for every $\epsilon > 0$). For systems with two-sided error probability, we knew that they can recognize $\mathcal{NP}$ languages using zero free bits; see below.

[14]We note, however, that the more relaxed notion of free bits may be less relevant to proving hardness of approximation results.

(1.2) *For every* $\epsilon > 0$, $\mathrm{NP} \subseteq \mathrm{FPCP}_{1-\epsilon,1-\frac{16}{15}\cdot\epsilon}[\log, 0]$.
(1.3) *For every* $\epsilon > 0$, $\mathrm{FPCP}_{1-\epsilon,1-2\cdot\epsilon}[\log, 0] \subseteq \mathrm{P}$.
(2) (limitations of PCP with logarithmic randomness and 1 free bit). $\mathrm{FPCP}_{1,s}[\log, 1] = \mathrm{P}$. *Also,* $\mathrm{FPCP}_{1,1-(1/\,\mathrm{poly})}[\mathsf{coins} = \mathrm{poly}\,;\, \mathsf{free} = 1\,;\, \mathsf{pflen} = \mathrm{poly}] \subseteq \mathrm{BPP}$.
(3) ("tightness" of item 2). *There exists* $s < 0.794$ *so that*
(3.1) $\mathrm{NP} \subseteq \mathrm{FPCP}_{1,s}[\log, 2]$;
(3.2) $\mathrm{NP} \subseteq \mathrm{FPCP}_{1,\frac{1+s}{2}}[\log, f]$ *where* $f = \log_2 3$ (i.e., $2^f = 3$);
(3.3) $\mathrm{NP} \subseteq \mathrm{FPCP}_{\frac{1}{2},\frac{s}{2}}[\log, 1]$.
(4) (general pcp with 0 free bit). $\mathrm{FPCP}_{1,s}[\mathrm{poly}, 0] \subseteq \mathrm{coNP}$.
(5) (general pcp with 1 free bit). $\mathrm{FPCP}_{1,s}[\mathrm{poly}, 1] \subseteq \mathrm{PSPACE}$.
(6) (examples for pcp with 0 free bit). *Graph nonisomorphism,* GNI, *has a PCP system with perfect completeness and soundness bound* $1/2$, *in which the verifier makes a single query and this query is free, namely,*

$$\mathtt{GNI} \in \mathrm{FPCP}_{1,1/2}[\mathsf{coins} = \mathrm{poly}\,;\, \mathsf{free} = 0\,;\, \mathsf{query} = 1].$$

The same holds for QNR (*"quadratic nonresiduosity" (cf.* [53])) *the set of integer pairs* (x, N) *so that* x *is a quadratic nonresidue modulo* N.

Proof of Proposition 10.9, *part* 3. The first claim of part 3 is justified by Theorem 5.4. Applying Proposition 11.9 to this verifier (which indeed satisfies the condition of this proposition) yields the second claim of part 3. Applying Proposition 11.8 to the same verifier (with $k = 1 < f = 2$), the third claim of part 3 follows. □

Proof of Proposition 10.9, *part* 1. Applying Proposition 11.8 (with $k = f = 2$) to the the verifier of Theorem 5.4, the first claim of part 1 follows. To prove the second claim, we apply Proposition 11.10 to the first claim and obtain $\mathrm{NP} \subseteq \mathrm{FPCP}_{1-\delta\cdot(1-0.25),1-\delta\cdot(1-0.2)}[\log, 0]$ (which holds for any δ). Substituting $\delta = (\frac{4}{3})\epsilon$, the second claim follows.

The last claim follows by the relationship between the Minimum Vertex Cover problem and the class $\mathrm{FPCP}_{c,s}[\log, 0]$; see the proof of Proposition 5.6. Specifically, consider the FGLSS reduction/graph of a proof system witnessing $L \in \mathrm{FPCP}_{1-\epsilon,1-2\epsilon}[\log, 0]$ (actually consider the complement graph where one asks about the size of the independent set). Then, for each $x \in L$ this graph has a vertex cover of density at most ϵ, whereas for $x \notin L$ this graph has no vertex cover of density 2ϵ. Using Gavril's approximation algorithm (cf. [48]), these two cases are distinguishable in polynomial time and so the third claim follows. □

Proof of Proposition 10.9, *part* 4. Let $L \in \mathrm{PCP}_{1,s}[\mathrm{poly}, 0]$ and V be a verifier demonstrating this fact. By definition, for every possible sequence of coin tosses for V, there exists at most one accepting configuration (of oracle answers to the queries made by V). Furthermore, by definition this accepting configuration (if it exists) can be generated in polynomial time from the coin sequence. Following is a nondeterministic procedure that accepts $\overline{L}$. It starts by guessing two sequences of coin tosses for V, generating the corresponding accepting configurations and checking whether they are consistent. (The input is accepted by this nondeterministic procedure iff the two coin sequences guessed yield conflicting configurations.) Clearly, if $x \in L$, then, for all possible pairs of coin sequences, accepting configurations exist and are consistent (since an oracle which *always* makes V accept x does exist). Thus, $x \in L$ is never accepted by the nondeterministic procedure. On the other hand, if all pairs of coin sequences yield accepting and mutually consistent configurations, then an oracle which

always makes V accept x emerges. Thus, for every $x \notin L$ there exists a guess which makes the nondeterministic procedure accept x. □

Proof of Proposition 10.9, *parts* 2 *and* 5. Here we consider proofs with free-bit complexity 1. Thus, for each possible sequence of coin tosses, there exist at most two accepting configurations (which again can be efficiently found given the coin sequence). We refer to these two possible accepting configurations as the 1-configuration and the 2-configuration of the coin sequence. In case a specific coin sequence has less than two accepting configurations, we introduce dummy configurations so that now each coin sequence has two associated configurations. Given an input x to such a pcp system, we consider the following 2CNF formula representing all possible computations of the verifier with a generic oracle. For each possible sequence of coin tosses, $\overline{c}$, we introduce a pair of boolean variables, $\pi^1_{\overline{c}}$ and $\pi^2_{\overline{c}}$, representing which of the two associated configurations is encountered (e.g., $\pi^1_{\overline{c}} = T$ means that the 1-configuration is encountered). To enforce that a single accepting configuration is encountered we introduce the clauses $(\pi^1_{\overline{c}} \vee \pi^2_{\overline{c}})$ and $((\neg\pi^1_{\overline{c}}) \vee (\neg\pi^2_{\overline{c}}))$. In addition, in case the σ-configuration of $\overline{c}$ is not accepting (but rather a dummy configuration) we introduce the clause $(\neg\pi^\sigma_{\overline{c}})$ thus "disallowing" a computation in which it is encountered. Finally, for each pair of coin sequences we introduce clauses disallowing inconsistencies. Namely, suppose that the σ-configuration of $\overline{c}$ is inconsistent with the τ-configuration of $\overline{c}'$, then we introduce the clause $((\neg\pi^\sigma_{\overline{c}}) \vee (\neg\pi^\tau_{\overline{c}'}))$, which is logically equivalent to $\neg(\pi^\sigma_{\overline{c}} \wedge \pi^\tau_{\overline{c}'})$. The resulting 2CNF formula, ϕ_x, is satisfiable if and only if there exists an oracle which causes V to accept x with probability 1. Thus, given x, we need to test if ϕ_x is satisfiable. We consider two cases.

(1) In case V uses logarithmically many coins, the 2CNF formula ϕ_x can be generated from x in polynomial time. Using a polynomial-time decision procedure for satisfiability of 2CNF formulae, we conclude that $\mathrm{FPCP}_{1,s}[\log, 1] = \mathrm{P}$. Furthermore, using Proposition 11.2, we can randomly reduce

$$\mathrm{FPCP}_{1,1-(1/\,\mathrm{poly})}[\mathrm{poly}, \mathsf{free} = 1, \mathsf{pflen} = \mathrm{poly}]$$

to

$$\mathrm{FPCP}_{1,1-(1/\,\mathrm{poly})}[\log, \mathsf{free} = 1]\ ,$$

and

$$\mathrm{FPCP}_{1,1-(1/\,\mathrm{poly})}[\mathrm{poly}, \mathsf{free} = 1, \mathsf{pflen} = \mathrm{poly}] \subseteq \mathrm{BPP}$$

follows. This establishes part 2.

(2) In general (V may make polynomially many coin tosses), the 2CNF formula ϕ_x may have exponential (in $|x|$) length. Yet it can be generated from x in polynomial space. Using a polylogarithmic-space decision procedure for satisfiability of 2CNF formulae,[15] we can decide if ϕ_x is satisfiable using $\mathrm{poly}(|x|)$ space. Part 5 (i.e., $\mathrm{FPCP}_{1,s}[\mathrm{poly}, 1] \subseteq \mathrm{PSPACE}$) follows. □

Proof of Proposition 10.9, *part* 6. We merely note that the interactive proof presented in [52] for graph nonisomorphism[16] constitutes a 1-query pcp system with

[15] For example, note that 2CNF formulae can be written in Horn form and use the procedure described in the proof of Proposition 10.8, part 2.

[16] On input a pair of graphs, G_0 and G_1, the verifier uniformly selects $i \in \{0, 1\}$ and generates a random isomorphic copy of G_i, denoted H. This graph H is the single query made by the verifier, which accepts if and only if the answer equals i.

perfect completeness and soundness bound 1/2. Furthermore, the query made by the verifier has a unique, acceptable answer and thus the free-bit complexity of this system is zero. The same holds for the interactive proof presented in [53] for quadratic nonresiduosity QNR, which is actually the inspiration for the proof in [52]. □

10.4. Query complexity versus free-bit complexity. The following proposition quantifies the intuition that not all queries are "undetermined" (i.e., that the free-bit complexity is lower than the query complexity). Furthermore, as a corollary we obtain that the amortized (average) free-bit complexity is at least one unit less than the amortized query complexity.

PROPOSITION 10.10. *For admissible functions c, s, r, q such that $r(n), q(n) = O(\log n)$,*

$$\mathrm{PCP}_{c,s}[r,q] \subseteq \mathrm{PCP}_{c,s}[\,\mathsf{coins} = r\,;\,\mathsf{free}_{\mathrm{av}} = q - \log_2(1/s)\,]. \tag{23}$$

Furthermore, for every admissible function t, $\mathrm{PCP}_{c,s}[r,q] \subseteq \mathrm{FPCP}_{c,(2^t+1)\cdot s}[r, q-t]$.

Proof. Let $L \in \mathrm{PCP}_{c,s}[r,q]$ and let V be the verifier demonstrating this. Fix an input $x \in \Sigma^n$, and let $r = r(n), q = q(n), s = s(n)$. For a random string $R \in \{0,1\}^r$, let F_R^x denote the number of accepting patterns of V, i.e., $F_R^x = |\mathsf{pattern}_V(x;R)|$. We first claim that if $\mathbf{E}_R[F_R^x] > 2^q \cdot s$, then $x \in L$. This is true since a random oracle π is accepted with probability at least $\mathbf{E}_R[F_R^x \cdot 2^{-q}]$, and so if the claim were not to hold we would have reached contradiction to the soundness condition (i.e., $x \notin L$ is accepted with probability strictly larger than s).

We now construct a verifier, denoted V', witnessing $L \in \mathrm{FPCP}^{\mathrm{av}}_{c,s}[r, q-\log_2(1/s)]$. On input x, the verifier first computes $\mathbf{E}_R[F_R^x]$ (by scanning all possible R's and generating all accepting patterns for each of them). If $\mathbf{E}_R[F_R^x]) > 2^q \cdot s$, then V' accepts x (without querying the oracle). Otherwise (i.e., if $\mathbf{E}_R[F_R^x]) \leq 2^q \cdot s$), then V' simulates V and accepts if V accepts. It follows that the average free-bit complexity of V' on input x equals the corresponding quantify for V, provided the latter is at most $q - \log_2(1/s)$, and equals zero otherwise. The first part of the proposition follows.

To establish the second part, for some $t = t(n)$, we construct a verifier V'' which, on input x, proceeds as follows. First, V'' computes $q \stackrel{\mathrm{def}}{=} \mathbf{E}_R[F_R^x]$ and accepts if $q > s2^q$ (just as V'). In case $q \leq s2^q$, the new verifier proceeds differently: it randomly selects R as V does and computes F_R^x. If $F_R^x > 2^{q-t}$, then V'' accepts and otherwise it invokes V on input x and coins R. Clearly, this guarantees that the free-bit complexity of V'' is at most $q-t$. To analyze the soundness of V'', note that when $\mathbf{E}_R[F_R^x] \leq s2^q$, it follows that $\Pr_R[F_R^x > 2^{q-t}] \leq 2^t \cdot s$ (Markov inequality). Thus, the soundness error of V'' is at most $s + 2^t s$ and the second part follows. □

By computing the amortized average free-bit complexity of the class of languages in the right-hand side of Eq. (23) above, we obtain the following consequence.

COROLLARY 10.11. *For admissible functions c, r, q with $r(n), q(n) = O(\log n)$,*

$$\overline{\mathrm{PCP}}_c[\,r,\,q\,] \subseteq \overline{\mathrm{FPCP}}^{\mathrm{av}}_c[\,r,\,q-1\,],$$

where $\overline{\mathrm{FPCP}}^{\mathrm{av}}_{\cdot}[\,\cdot,\,f\,]$ denotes a class analogous to $\overline{\mathrm{FPCP}}_{\cdot}[\,\cdot,\,f\,]$ in which average free-bit complexity is measured instead of (worst-case) free-bit complexity.

Proof. For some function m, we have

$$\overline{\mathrm{PCP}}_c[\,r,\,q\,] \subseteq \mathrm{PCP}_{c,c\cdot 2^{-m}}[r, qm] \subseteq \mathrm{FPCP}^{\mathrm{av}}_{c,c\cdot 2^{-m}}[r, qm-m] \subseteq \overline{\mathrm{FPCP}}^{\mathrm{av}}_c[\,r,\,q-1\,],$$

where the second inclusion is due to Eq. (23). □

The above corollary clinches the argument that the amortized query complexity is incapable of capturing the approximability of the clique function. Suppose that, for some g (e.g., $g = \frac{3}{2}$), MaxClique is NP-hard to approximate to within an $N^{1/(1+g)}$ factor, but it can be approximated to within an $N^{1/(1+g-\delta)}$ factor in polynomial time, for every $\delta > 0$ (actually, it suffices to postulate that MaxClique can be approximated to within an $N^{1/g}$ factor in polynomial time). Furthermore, supposed that the hardness result is demonstrated by showing that $\mathrm{NP} \subseteq \overline{\mathrm{PCP}}[\log, g-\epsilon]$, for every $\epsilon > 0$. Then, using the above corollary, we get $\mathrm{NP} \subseteq \overline{\mathrm{FPCP}}^{\mathrm{av}}[\log, g-1-\epsilon]$, for every $\epsilon > 0$, and an NP-hardness result of clique approximation[17] up to an $N^{1/(1+(g-1-\epsilon)+\epsilon)} = N^{1/g}$ follows, in contradiction to our hypothesis that such approximations could be achieved in polynomial time. To summarize, attempts to establish the factor $N^{1/(g+1)}$, for which it is NP-hard to approximate MaxClique via amortized query complexity, will always fall at least one unit away from the truth, whereas amortized free-bit complexity will yield the right answer.

11. Transformations of FPCP systems. We present several useful transformations which can be applied to pcp systems. These fall into two main categories:

(1) Transformations which amplify the (completeness versus soundness) gap of the proof system, while preserving (or almost preserving) its amortized free-bit complexity.
(2) Transformations which move the gap location (or, equivalently, the completeness parameter). The gap itself is almost preserved but moving it changes the free-bit complexity (and thus the amortized free-bit complexity is not preserved). Specifically, moving the gap "up" requires increasing the free-bit complexity, whereas moving the gap "down" allows us to decrease the free-bit complexity.

Most of these transformations are analogous to transformations which can be applied to graphs with respect to the MaxClique approximation problem. In view of the relation between FPCP and the clique promise problem (shown in section 8), this analogy is hardly surprising.

In this section, we use a more extensive FPCP notation which refers to promise problems (rather than to languages) and introduce an additional parameter—the proof length. Specifically, $\mathrm{FPCP}_{c,s}[r, f, l]$ refers to randomness complexity r, free-bit complexity f, and proof-length l.

11.1. Gap amplifications maintaining amortized free-bit complexity. We start by stating the simple fact that the ratio between the completeness and soundness bounds (also referred to as gap) is amplified (i.e., raised to the power k) when one repeats the pcp system (k times). Note, however, that if the original system is not perfectly complete, then the completeness bound in the resulting system gets decreased.

PROPOSITION 11.1 (simple gap amplification). *For all* $c, s : \mathcal{Z}^+ \to [0,1]$ *and* $k : \mathcal{Z}^+ \to \mathcal{Z}^+$,

$$\mathrm{FPCP}_{c,s}[r, f, l] \subseteq \mathrm{FPCP}_{c^k,s^k}[kr, kf, l].$$

Proof. Let $(Y, N) \in \mathrm{FPCP}_{c,s}[r, f, l]$ and let V be a verifier witnessing this with query complexity $q : \mathcal{Z}^+ \to \mathcal{Z}^+$. Given $k : \mathcal{Z}^+ \to \mathcal{Z}^+$, we define a verifier $V^{(k)}$ as

[17] Here we use the observation that the FGLSS reduction works also for amortized *average* free-bit complexity.

follows: on input $x \in \{0,1\}^n$, let $r = r(n), k = k(n), f = f(n), l = l(n)$, and $q = q(n)$.

- $V^{(k)}$ picks k random strings $\overline{c}^{(1)}, \ldots, \overline{c}^{(k)}$ uniformly and independently in $\{0,1\}^r$.
- For $i = 1$ to k, verifier $V^{(k)}$ simulates the actions of V on input x and random string $\overline{c}^{(i)}$. Verifier $V^{(k)}$ accepts if V accepts on each of these k instances.

Clearly, $V^{(k)}$ tosses kr coins and examines the l-bit long oracle in at most kq bits, where at most kf of these are free. For every x, if the probability that V accepts x, given access to oracle π, is p, then the probability that $V^{(k)}$ accepts x, given access to π, is exactly p^k. Thus, $(Y, N) \in \mathrm{FPCP}_{c^k, s^k}[kr, kf, l]$, and oracles can be transformed (by identity) from one pcp system to the other. □

Next, we show that in some sense the randomness complexity of a proof system need not be higher than logarithmic in the length of the proofs/oracles employed. Specifically, we show how to randomly reduce languages proven by the first kind of systems into languages proven by the second kind. Thus, whenever one is interested in the computational complexity of languages proven via pcp systems, one may assume that the system is of the second type. Recall that $\leq_R^K$ denotes a randomized Karp reduction.

PROPOSITION 11.2 (reducing randomness). *There exists a constant $\gamma > 0$ so that*

(1) (for perfect completeness): *for every two admissible functions $s, \epsilon : \mathcal{Z}^+ \to [0,1]$,*

$$\mathrm{FPCP}_{1,s}[r, f, l] \leq_R^K \mathrm{FPCP}_{1,s'}[r', f, l],$$

where $s' = (1+\epsilon) \cdot s$ and $r' = \gamma + \log_2(l/\epsilon^2 s)$.

(2) (for two-sided error): *for every four admissible functions $c, s, \epsilon_1, \epsilon_2 : \mathcal{Z}^+ \to [0,1]$,*

$$\mathrm{FPCP}_{c,s}[r, f, l] \leq_R^K \mathrm{FPCP}_{c',s'}[r', f, l],$$

where $c' = 1 - (1+\epsilon_1) \cdot (1-c) \geq c - \epsilon_1$, $s' = (1+\epsilon_2) \cdot s$ and $r' = \gamma + \max\{-\log_2(\epsilon_1^2(1-c)),\ \log_2(l) - \log_2(\epsilon_2^2 s)\}$.

Proof. The proof is reminiscent of Adleman's proof that $\mathcal{RP} \subseteq \mathrm{P/poly}$ [1]. Suppose we are given a pcp system for which we want to reduce the randomness complexity. The idea is that it suffices to choose the random pad for the verifier out of a relatively small set of possibilities (instead of from all 2^r possibilities). Furthermore, most small sets (i.e., sets of size linear in l) are good for this purpose. This suggest randomly mapping an input x for the original pcp system into an input (x, R) for the new system, where R is a random set of $m = O(l)$ possible random pads for the original system. The new verifier will select a random pad uniformly in R, thus using only $\log_2 |R|$ random coins, and run the original verifier using this random pad. Details follow.

We start with the simpler case stated in part 1. Let $(Y, N) \in \mathrm{FPCP}_{1,s}[r, f, l]$ and let V be a verifier demonstrating this fact. The random reduction maps $x \in \{0,1\}^n$ to (x, R), where R is a uniformly chosen m multisubset of $\{0,1\}^r$ for $l \stackrel{\mathrm{def}}{=} l(n)$, $r \stackrel{\mathrm{def}}{=} r(n)$, $s \stackrel{\mathrm{def}}{=} s(n)$, $\epsilon \stackrel{\mathrm{def}}{=} \epsilon(n)$, and $m \stackrel{\mathrm{def}}{=} \frac{\gamma l}{\epsilon^2 s}$. (The constant γ is chosen to make the Chernoff bound, used below, hold.) On input (x, R), the new verifier V' uniformly selects $\overline{c} \in R$ and invokes V with input x and random pad $\overline{c}$. Clearly, the complexities of V' are as claimed above. Also, assuming that V always accepts x, when given access to an oracle π, then, for every possible pair (x, R) to which x is mapped, V' always accepts

(x, R) when given access to the oracle π. It remains to upper bound, for each $x \notin L$ and most R's, the probability that V' accepts (x, R) when given access to an arbitrary oracle.

Fixing any $x \notin L$ and any oracle π, we bound the probability that V', give access to π, accepts (x, R) for most R's. A set R is called *bad* for x with respect to π if for more than an s' fraction of the $\overline{c} \in R$ the verifier V accepts x when given access to π and random pad $\overline{c}$. Let $R = (\overline{r}^{(1)}, \ldots, \overline{r}^{(m)})$ be a uniformly selected multiset. For every $i \in [m]$ (a possible random choice of V'), we define a 0-1 random variable ζ_i so that it is 1 iff V on random pad $\overline{r}^{(i)}$ and access to oracle π accepts the input x. Clearly, the ζ_i's are mutually independent and each equals 1 with probability $\delta \leq s$. Using a multiplicative Chernoff bound (cf. [75, Theorem 4.3]), the probability that a random R is bad (for x w.r.t. π) is bounded by

$$\Pr\left[\sum_{i=1}^{m} \zeta_i \geq (1+\epsilon) \cdot ms\right] < 2^{-\Omega(\epsilon^2 \cdot ms)}.$$

Thus, by the choice of m, the probability that a random R is bad for x, with respect to any fixed oracle, is smaller than $\frac{1}{4} \cdot 2^{-l}$. Since there are only 2^l relevant oracles, the first part of the proposition follows.

For the second part of the proposition, we repeat the same argument, except that now we need to take care of the completeness bound in the resulting pcp system. This is done similarly to the way we deal with the soundness bound, except that we do not need to consider all possible oracles; it suffices to consider the best oracle for each $x \in Y$. When applying the multiplicative Chernoff bound it is important to note that, since we are interested in the rejection event, the relevant expectation is $m \cdot (1-c)$ (and not $m \cdot c$). Thus, as long as $m \geq \frac{2\gamma}{\epsilon_1^2(1-c)}$, at least 3/4 of the possible sets R cause V' to accept $x \in Y$ with probability at least $1 - (1+\epsilon_1) \cdot (1-c) = c - (1-c)\epsilon_1$. The second part of the proposition follows. □

Combining Propositions 11.1 and 11.2, we obtain a randomized reduction of pcp systems which yields the effect of Proposition 11.1 at much lower (and in fact minimal) cost in the randomness complexity of the resulting pcp system. This reduction is analogous to the well-known transformation of Berman and Schnitger [25]. The reduction (in either forms) plays a central role in deriving clique approximation results via the FGLSS method: applying the FGLSS reduction to proof systems obtained via the second item (below), one derives graphs of size $N \stackrel{\text{def}}{=} 2^{(1+\epsilon+f)\cdot t}$ with clique gap 2^t (which can be rewritten as $N^{1/(1+f+\epsilon)}$). For sake of simplicity, we only state the case of perfect completeness.

COROLLARY 11.3 (probabilistic gap amplification at minimal randomness cost).

(1) (Combining the two propositions.) *For every admissible $k : \mathcal{Z}^+ \to \mathcal{Z}^+$,*

$$\begin{aligned}&\mathrm{PCP}_{1,1/2}[\,\mathsf{coins} = r\,;\,\mathsf{query} = q\,;\,\mathsf{free} = f\,;\,\mathsf{pflen} = l\,]\\ &\leq_R^K \mathrm{FPCP}_{1,2^{-k+1}}[r + \log_2 q + O(1) + k, kf, l]\,.\end{aligned}$$

(2) (Using amortized free-bit complexity.) *For every $\epsilon > 0$, there exists a constant c so that*

$$\overline{\mathrm{FPCP}}[\log,\, f, l\,] \leq_R^K \mathrm{FPCP}_{1,2^{-t}}[(1+\epsilon)\cdot t, f \cdot t, l],$$

where $t(n) = c \log_2 n$.

Proof. Suppose that $(Y,N) \in \mathrm{FPCP}_{1,1/2}[r,f,l]$. Clearly, $l \le 2^r \cdot q$, where $q(n) = \mathrm{poly}(n)$ is the query complexity of the verifier. Then, applying Proposition 11.1, we get $(Y,N) \in \mathrm{FPCP}_{1,1/2^k}[kr, kf, 2^r \cdot q]$. Applying part 1 of Proposition 11.2, we obtain $(Y,N) \le_R^K \mathrm{FPCP}_{1,\frac{1}{2^{k-1}}}[r', kf]$, where $r' = O(1) + \log_2(2^r q/2^{-k}) = O(1) + r + k + \log_2 q$. The first part of the corollary follows.

Suppose now that a language L has a proof system as in the hypothesis of the second part. Then, there exists a logarithmically bounded function m so that $L \in \mathrm{FPCP}_{1,1/2^m}[r, mf, l]$, where $r(n) \le \alpha \cdot \log_2 n$ and $l(n) \le n^\beta$ for some constants α and β. Invoking a similar argument (to the above), we get $L \le_R^K \mathrm{FPCP}_{1,\frac{1}{2^{km-1}}}[r', k \cdot mf]$, where $r'(n) = O(1) + km + (\alpha+\beta) \cdot \log_2 n$. Now, setting $k(n)$ so that $k(n) \cdot m(n) \ge \frac{\alpha+\beta}{\epsilon} \cdot \log_2 n$, the corollary follows. □

An alternative gap amplification procedure which does not employ randomized reductions is presented below. This transformation increases the randomness complexity of the pcp system more than the randomized reduction presented above (i.e., $r' \approx O(r) + 2k$ rather than $r' \approx r + k$ as in item 1 of Corollary 11.3). The transformation is used to obtain in-approximability results under the assumption $\mathrm{P} \ne \mathrm{NP}$ (rather than under $\mathrm{NP} \not\subseteq \mathrm{BPP}$). Again, we only state the case of perfect completeness.

PROPOSITION 11.4 (deterministic gap amplification at low randomness cost). *For every $\epsilon, s > 0$ and every admissible function $k : \mathcal{Z}^+ \to \mathcal{Z}^+$,*

$$\mathrm{FPCP}_{1,s}[r,f,l] \subseteq \mathrm{FPCP}_{1,s^k}[O(r) + (2+\epsilon) \cdot k \cdot \log(1/s), (1+\epsilon) \cdot kf, l].$$

Actually, the constant in the O notation is $\min\{1, \frac{2+(4/\epsilon)}{\log_2(1/s)}\}$.

We use random walks on expander graphs for error reduction (cf. [2, 30]). The value of the constant multiplier of $k \log(1/s)$ in the randomness complexity of the resulting pcp system depends on the expander graph used. Specifically, using a degree d expander graph with second eigenvalue λ yields a factor of $\frac{\log_2 d}{1+\log_2 \lambda}$. Thus, it is essential to use Ramanujan graphs [70] in order to obtain the claimed constant of $2+\epsilon$.

Proof of Proposition 11.4. For simplicity assume $s = 1/2$. The idea is to use a "pseudorandom" sequence generated by a random walk on an expander graph in order to get error reduction at moderate randomness cost. Specifically, we will use a Ramanujan expander graph of constant degree d and second eigenvalue $\lambda \approx 2\sqrt{d}$ (cf. [70]). The constant d will be determined so that $d > 2^{4+\frac{8}{\epsilon}}$ (and $d < 2^{6+\frac{8}{\epsilon}}$). It is well known that a random walk of length t in an expander avoids a set of density ρ with probability at most $(\rho + \frac{\lambda}{d})^t$ (cf. [2, 61]). Thus, as a preparation step we reduce the error probability of the pcp system to

$$p \stackrel{\mathrm{def}}{=} \frac{\lambda}{d} = \frac{2}{\sqrt{d}}. \tag{24}$$

This is done using the trivial reduction of Proposition 11.1. We derive a proof system with error probability p, randomness complexity

$$r' \stackrel{\mathrm{def}}{=} r \cdot \log_2(1/p) = r \cdot \log_2(\sqrt{d}/2) = O(r), \tag{25}$$

and free-bit complexity

$$f' \stackrel{\mathrm{def}}{=} f \cdot \log_2(1/p) = f \cdot \log_2(\sqrt{d}/2). \tag{26}$$

(In case we start with soundness error s, where $s > p$, the multiplier will be $\log_{1/s}(1/p)$ instead of $\log_2(1/p)$.) Now we are ready to apply the expander walk technique. Using an expander walk of length t, we transform the proof system into one in which the randomness complexity is $r' + (t-1) \cdot \log_2 d$, the free-bit complexity is $tf' = tf \cdot \log_2(\sqrt{d}/2)$, and the error probability is at most $(2p)^t = (4/\sqrt{d})^t = 2^{-k}$, where $k \stackrel{\text{def}}{=} t \cdot \log_2(\sqrt{d}/4)$. Using $\log_2 d > \frac{8}{\epsilon} + 4$, we can bound the randomness complexity by

$$\begin{aligned} r' + t \log_2 d &= r' + \frac{\log_2 d}{\frac{1}{2} \cdot (\log_2 d) - 2} \cdot k \\ &< r' + (2+\epsilon) \cdot k. \end{aligned}$$

and the free-bit complexity by

$$\begin{aligned} tf \cdot \log_2(\sqrt{d}/2) &= \frac{\frac{1}{2} \cdot (\log_2 d) - 1}{\frac{1}{2} \cdot (\log_2 d) - 2} \cdot kf \\ &< (1+\epsilon) \cdot kf. \end{aligned}$$

The proposition follows. □

Using Proposition 11.4, we obtain the following corollary which is used in deriving clique in-approximability results under the P $\neq$ NP assumption, via the FGLSS method: applying the FGLSS reduction to proof systems obtained via this corollary, one derives graphs of size $N \stackrel{\text{def}}{=} 2^{(2+\epsilon+f)\cdot t}$ with clique gap 2^t (which can be rewritten as $N^{1/(2+f+\epsilon)}$).

COROLLARY 11.5. *For every $\epsilon > 0$, there exists a constant c so that*

$$\overline{\text{FPCP}}[\log,\ f, l\,] \subseteq \text{FPCP}_{1,2^{-t}}[(2+\epsilon)\cdot t, (1+\epsilon)\cdot f \cdot t, l],$$

where $t(n) = c \log_2 n$.

11.2. Trading off gap location and free-bit complexity. The following transformation is analogous to the randomized layering procedure for the clique promise problem (i.e., Proposition 8.6). The transformation increases the acceptance probability bounds at the expense of increasing the free-bit complexity.

PROPOSITION 11.6 (increasing acceptance probabilities and free-bit complexity).

(1) (Using a randomized reduction which preserves the randomness of the proof system.) *For all admissible functions $c, s : \mathcal{Z}^+ \to [0,1]$, and $r, f, m : \mathcal{Z}^+ \to \mathcal{Z}^+$,*

$$\text{FPCP}_{c,s}[r, f] \leq_R^K \text{FPCP}_{c',s'}[r, f + \log_2 m],$$

where $c' = 1 - 4(1-c)^m$ and $s' = m \cdot s$. In case $c' > 1 - 2^{-r}$, we then have $c' = 1$.

(2) (Inclusion which moderately increases the randomness of the proof system.) *For all admissible functions $c, s : \mathcal{Z}^+ \to [0,1]$, and $r, f, m : \mathcal{Z}^+ \to \mathcal{Z}^+$,*

$$\text{FPCP}_{c,s}[r, f] \subseteq \text{FPCP}_{c',s'}[r', f + \log_2 m],$$

- *where if* $m \leq 1/c$, *then* $r' = 2 \cdot \max\{r, \log m\}$, $c' = \frac{m}{2} \cdot c$ *and* $s' = m \cdot s$;
- *and otherwise* (*i.e., for* $m > 1/c$), $r' = O(\max\{r, \log m\} + mc)$, $c' = 1 - 2^{-\Theta(mc)}$ *and* $s' = m \cdot s$.

Proof. Suppose we are given a pcp system for which we want to increase the acceptance probability bound in the completeness condition. The idea is to allow the new verifier to select m random pads for the original verifier and query the oracle as to which pad to use. A straightforward implementation of this idea will increase the randomness complexity of the verifier by a factor of m. Instead, we use two alternative implementations which yield the two parts of the proposition. In both implementations the free-bit complexity increases by $\log_2 m$ and the soundness bound increases by a factor of m.

The first implementation employs a technique introduced by Lautemann (in the context of $\mathcal{BPP}$) [68]. Using a randomized reduction, we supply the new verifier with a sequence of m possible "shifts" that it may effect. The new verifier selects one random pad for the original verifier and generates m shifts of this pad. Now, the new verifier queries the oracle as to which of these shifts it should use as a random pad for the original verifier. Details follow.

We first present a random reduction mapping $x \in \{0,1\}^n$ to (x, S), where S is a uniformly chosen m multisubset of $\{0,1\}^r$, for $r \stackrel{\text{def}}{=} r(n)$. On input (x, S), the new verifier V' uniformly selects $\overline{c} \in \{0,1\}^r$ and queries the oracle on $(x, \overline{c})$ receiving an answer $i \in [m]$. Intuitively, V' asks which shift of the random pad to use. Finally, V' invokes V with input x and random pad $\overline{c} \oplus \overline{s}_i$, where $\overline{s}_i$ is the ith string in S. Clearly, the complexities of V' are as claimed above. Also, assuming that V accepts x with probability δ, we get that, for every S, verifier V' accepts (x, S) with probability at most $m \cdot \delta$. On the other hand suppose that, when given access to oracle π, verifier V accepts x with probability δ. It follows that there exists a set R of $\delta 2^r$ random pads for V so that if V uses any $\overline{c} \in R$ (and queries oracle π), then it accepts x. Fixing any $\overline{c} \in \{0,1\}^r$, we ask what is the probability, for a uniformly chosen $S = \{\overline{s}_i : i \leq m\}$, that there exists an $i \in [m]$ so that $\overline{c} \oplus \overline{s}_i \in R$. Clearly, the answer is $1 - (1-\delta)^m$. Thus, for uniformly chosen $S \in (\{0,1\}^r)^m$ and $\overline{c} \in \{0,1\}^r$,

$$\Pr[\, \exists i \in [m] \ \text{ s.t. } \ \overline{c} \oplus \overline{s}_i \in R \,] = 1 - (1-\delta)^m.$$

By Markov inequality, with probability at least $3/4$, a uniformly chosen $S = \{\overline{s}_i\}$ has the property that for at least $1 - 4 \cdot (1-\delta)^m$ of the $\overline{c}$'s (in $\{0,1\}^r$) there exists an $i \in [m]$ so that $\overline{c} \oplus \overline{s}_i \in R$. Part 1 of the proposition follows.

To prove part 2 of the proposition, we use an alternative implementation of the above idea, which consists of letting the new verifier V' generate a "pseudorandom" sequence of possible random pads by itself. V' will then query the oracle as to which random pad to use, in the simulation of V, and complete its computation by invoking V with the specified random pad. To generate the "pseudorandom" sequence we use the sampling procedure of [18]. Specifically, for $m \leq 1/c$ we merely generate a pairwise independent sequence of uniformly distributed strings in $\{0,1\}^r$, which can be done using randomness $\max\{2r, 2\log_2 m\}$. Otherwise (i.e., for $m > 1/c$), we use the construction of [18] to generate $\Theta(cm)$ such related sequences, where the sequences are related via a random walk on a constant degree expander. Part 2 follows. □

The following corollary exemplifies the usage of the above proposition. In case $c(n) = n^{-\alpha}$ and $r(n) = O(\log n)$, we obtain perfect completeness while preserving the gap (up to a logarithmic factor) and increasing the free-bit complexity by

a $\log_2 1/c$ additive term. Thus, the corollary provides an alternative way of deriving the reverse-FGLSS transformation (say, Proposition 8.7) from the simple clique verifier of Theorem 8.2. Specifically, one may apply the following corollary to the simple clique verifier of Theorem 8.2, instead of combining the layered-graph verifier (of Theorem 8.3) and the graph-layering process of Proposition 8.6.

COROLLARY 11.7. *For all admissible $r, f : \mathcal{Z}^+ \to \mathcal{Z}^+$, so that $\forall n : \ r(n) \geq 2$,*

$$\mathrm{FPCP}_{c,s}[r,f] \ \leq_R^K \ \mathrm{FPCP}_{1,r\cdot\frac{s}{c}}[r, f + \log_2 r + \log_2(1/c)].$$

(Compare to item 1 of Proposition 8.7.)

We conclude this subsection with another transformation which is reminiscent of an assertion made in section 8. The following transformation has an opposite effect than the previous one, reducing the free-bit complexity at the expense of lowering the bounds on acceptance probability.

PROPOSITION 11.8 (decreasing acceptance probabilities and free-bit complexity). *For all admissible functions $c, s : \mathcal{Z}^+ \to [0,1]$, and $r, f, k : \mathcal{Z}^+ \to \mathcal{Z}^+$ so that $k \leq f$, if $L \in \mathrm{FPCP}_{c,s}[r,f]$, then $L \in \mathrm{FPCP}_{\frac{c}{2^k},\frac{s}{2^k}}[r+k, f-k]$. Furthermore, in case each random pad in the original pcp system has at least 2^k accepting configurations, the average free-bit complexity of the resulting system is $f_{\mathrm{av}} - k$, where f_{av} is the average free-bit complexity of the original system.*

Proof. Let V be a verifier satisfying the condition of the proposition. We construct a new verifier V' that on input $x \in \{0,1\}^n$, setting $r = r(n)$, $k = k(n)$, and $f = f(n)$, acts as follows. Verifier V' uniformly selects a random-pad $\overline{c} \in \{0,1\}^r$ for V and generates all possible accepting configurations with respect to $V(x)$ and random-pad $\overline{c}$. In case there are less than 2^k accepting configurations we add *dummy configurations* to reach the 2^k count. We now partition the set of resulting configurations (which are accepting and possibly also dummy) into 2^k parts of about the same size (i.e., some parts may have one configuration more than others). Actually, if we only care about average free-bit complexity, then any partition of the accepting configurations into 2^k nonempty parts will do. The new verifier, V', uniformly selects $i \in [2^k]$, thus specifying one of these parts, denoted A_i. Next, V' invokes V with random-pad $\overline{c}$ and accepts if and only if the oracle's answers form an accepting configuration which is in A_i (i.e., resides in the selected portion of the accepting configurations). (We stress that in case $\overline{c}$ has less than 2^k accepting configurations and the selected A_i does not contain any accepting configuration, then V' rejects on coins $(i, \overline{c})$.) Clearly, the randomness complexity of the new verifier is $r + k$.

To analyze the other parameters of V', we fix any $x \in \{0,1\}^n$. For sake of simplicity, we first assume that the number of accepting configurations of V for any random pad is a power of 2. Then the number of accepting configurations of V' for any random-pad $(\overline{c}, i) \in \{0,1\}^r \times [2^k]$ is 2^{m-k}, where 2^m is the number of accepting configurations of V on random-pad $\overline{c}$. Thus, the free-bit complexity of V' is $f - k$. Finally, we relate the acceptance probability of V' to that of V. This is done by reformulating the execution of V' with oracle π as consisting of two steps. First V' invokes V with access to π. If V reaches a rejecting configuration, then V' rejects as well; otherwise (i.e., when V reaches an accepting configuration), V accepts with probability 2^{-k} (corresponding to uniformly selecting $i \in [2^k]$). It follows that on input x and access to oracle π, the verifier V' accepts with probability $\frac{\delta}{2^k}$, where δ denotes the probability that V accepts input x when given access to oracle π.

In general, our simplifying assumption that the number of accepting configurations of V is a power of 2 may not hold and the analysis becomes slightly more cumbersome. Firstly, the number of accepting configurations of V' for a random-pad $(\overline{c}, i)$ is either $\lceil M/2^k \rceil$ or $\lfloor M/2^k \rfloor$, where M is the number of accepting configurations of V on random-pad $\overline{c}$. Thus, in the worst case the number of accepting configurations for V' (on random-pad $(\overline{c}, i)$) is $\lceil M/2^k \rceil$, and it follows that the free-bit complexity of V' is $\log_2 \lceil 2^f/2^k \rceil = f - k$. Furthermore, the expected number of accepting configurations (for a fixed $\overline{c}$ and uniformly chosen $i \in [2^k]$) is exactly $M/2^k$ (even if $M < 2^k$). Thus, if the extra condition holds, then the free-bit complexity of V' equals $f_{\text{av}} - k$. Finally, observe that the argument regarding the acceptance probabilities remains unchanged (and actually it does not depend on the partition of the accepting configurations into 2^k nonempty parts). The proposition follows. □

11.3. Other effects on acceptance probabilities and free-bit complexity. Following is an alternative transformation which reduces the free-bit complexity. However, unlike Proposition 11.8, the following does not decrease the acceptance parameters. Furthermore, the transformation increases the soundness parameter and so does *not* preserve the gap (between the completeness and soundness parameters).

PROPOSITION 11.9 (decreasing free-bit complexity without decreasing acceptance probabilities). *Let $c, s : \mathcal{Z}^+ \to [0,1]$ be admissible functions and $r, f, k : \mathcal{Z}^+ \to \mathcal{Z}^+$. Suppose $L \in \text{FPCP}_{c,s}[r, f]$ with a verifier for which the first k oracle-answers for each random pad allow at most 2^{f-k} accepting configurations. Then $L \in \text{FPCP}_{c',s'}[r + k, f']$, where $c' = 1 - \frac{1-c}{2^k}$, $s' = 1 - \frac{1-s}{2^k}$, and $f' = \log_2(2^{f-k} + 2^k - 1)$.*

The above can be further generalized, yet the current paper only utilizes the special case in which $c = 1$ (specifically, in the proof of part 3 of Proposition 10.9, we use $f = 2$ and $k = 1$ obtaining $f' = \log_2 3$, $c' = 1$, and $s' = \frac{1+s}{2}$).

Proof. The proof is similar to the proof of Proposition 11.8. Again, we consider a verifier V, as guaranteed by the hypothesis, and a random-pad $\overline{c}$, and let A_i be the set of (at most 2^{f-k}) accepting configurations which are consistent with the ith possibility of k oracle-answers to the first k queries. Denote the ith possibility by α_i (i.e., all configurations in A_i start with α_i). We construct a new verifier, V', which uniformly selects a random-pad $\overline{c}$ for V and $i \in [2^k]$ (specifying a part A_i as above). The verifier V' makes the first k queries of V and, if the answers differ from α_i, then V' halts and accepts.[18] Otherwise, V' continues the emulation of V and accepts iff V accepts.

Clearly, V' uses $r + k$ coin tosses. The accepting configurations of V' on random-pad $(\overline{c}, i)$ are those in A_i, as well as the "truncated V configurations" α_j, for $j \neq i$. Thus, there are at most $2^{f-k} + 2^k - 1$ accepting configurations. Suppose $V^\pi(x)$ accepts with probability p; then V' accepts input x with oracle access to π with probability $(1 - 2^{-k}) + 2^{-k} \cdot p = 1 - \frac{1-p}{2^k}$. The proposition follows. □

Finally, we present a simplified version of the above transformation. Here the acceptance probabilities are increased without affecting the free-bit complexity (either way).

PROPOSITION 11.10 (increasing acceptance probabilities while preserving free-bit complexity). *Let $c, s, \delta : \mathcal{Z}^+ \to [0,1]$ be admissible functions and $r, f : \mathcal{Z}^+ \to \mathcal{Z}^+$. Then*

$$\text{FPCP}_{c,s}[r, f] \subseteq \text{FPCP}_{c',s'}[r + \log(1/\delta), f],$$

where $c' = 1 - \delta \cdot (1 - c)$ and $s' = 1 - \delta \cdot (1 - s)$.

[18] In contrast, the verifier constructed in the proof of Proposition 11.8 rejects in case of such a mismatch.

Proof. Let V be a verifier for $L \in \mathrm{FPCP}_{c,s}[r,f]$. We construct a new verifier, V', which with probability δ invokes V and otherwise accepts regardless of the input. The proposition follows. □

Appendix. The coding theory bound. We provide here the coding theory bound used in the proof of Lemma 3.11. It is a slight extension of bounds in [73, Ch. 17] which consider only vectors of weight exactly w rather than at most w. For sake of completeness, we include a proof of this bound. In discussing binary vectors, the weight is the number of ones in the vector and the distance between two vectors is the number of places in which they disagree.

LEMMA A.1. *Let $B = B(n,d,w)$ be the maximum number of binary vectors of length n, each with weight at most w, and any two being distance at least d apart. Then $B \le (1-2\beta)/(4\alpha^2 - 2\beta)$, provided $\alpha^2 > \beta/2$, where $\alpha = (1/2) - (w/n)$ and $\beta = (1/2) - (d/n)$.*

Proof. Consider an arbitrary sequence $v_1, \ldots, v_M$ of n-vectors which are at mutual distance at least $n/2$. Let us denote by $v_{i,j}$ the jth entry in the ith vector, by w_i the weight of the ith vector, and by $\overline{w}$ the average value of the w_i's. Define

$$S \stackrel{\mathrm{def}}{=} \sum_{i=1}^{M}\sum_{j=1}^{M}\sum_{k=1}^{n} v_{i,k}v_{j,k}.$$

Then, on one hand,

$$\begin{aligned} S &= \sum_{i=1}^{M}\sum_{k=1}^{n} v_{i,k}^2 + \sum_{1\le i\ne j\le M}\sum_{k=1}^{n} v_{i,k}v_{j,k} \\ &\le \sum_i w_i + \sum_{1\le i\ne j\le M} \frac{w_i + w_j - d}{2} \\ &= M\overline{w} + M(M-1)\cdot(\overline{w} - (d/2)), \end{aligned}$$

where the inequality follows from observing that, for $i \ne j$,

$$\begin{aligned} w_i + w_j &= 2|\{k : v_{i,k} = v_{j,k} = 1\}| + |\{k : v_{i,k} \ne v_{j,k}\}| \\ &\ge 2\sum_{k=1}^{n} v_{i,k}v_{j,k} + d. \end{aligned}$$

On the other hand, $S = \sum_{k=1}^{n} |\{i : v_{i,k} = 1\}|^2$. This allows to lower bound S by the minimum of $\sum_k x_k^2$ subject to $\sum_k x_k = M\overline{w}$. The minimum is obtained when all x_k's are equal and yields

$$S \ge n \cdot \left(\frac{M\overline{w}}{n}\right)^2.$$

Confronting the two bounds, we get

$$\frac{M\cdot\overline{w}^2}{n} \le M\cdot\overline{w} - (M-1)\cdot\left(\frac{d}{2}\right)$$

which yields $(\frac{\overline{w}^2}{n} - \overline{w} + \frac{d}{2})M \le \frac{d}{2}$. Letting $\overline{\alpha} = (1/2) - (\overline{w}/n)$ and using

$$\overline{\alpha}^2 \ge \alpha^2 > \beta/2\,,$$

we get

$$M \leq \frac{1-2\beta}{4\overline{\alpha}^2 - 2\beta},$$

and the lemma follows by observing that the bound maximizes when $\alpha = \overline{\alpha}$. □

FAST GOSSIPING BY SHORT MESSAGES*

JEAN-CLAUDE BERMOND†, LUISA GARGANO‡, ADELE A. RESCIGNO‡, AND UGO VACCARO‡

Abstract. Gossiping is the process of information diffusion in which each node of a network holds a packet that must be communicated to all other nodes in the network. We consider the problem of gossiping in communication networks under the restriction that communicating nodes can exchange up to a fixed number p of packets at each round. In the first part of the paper we study the extremal case $p = 1$ and we exactly determine the optimal number of communication rounds to perform gossiping for several classes of graphs, including Hamiltonian graphs and complete k-ary trees. For arbitrary graphs we give asymptotically matching upper and lower bounds. We also study the case of arbitrary p and we exactly determine the optimal number of communication rounds to perform gossiping under this hypothesis for complete graphs, hypercubes, rings, and paths. Finally, we investigate the problem of determining sparse networks in which gossiping can be performed in the minimum possible number of rounds.

Key words. gossiping, graphs, networks

1. Introduction.

Gossiping (also called total exchange or all-to-all communication) in distribution systems is the process of distributing information known to each processor to every other processor of the system. This process of information dissemination is carried out by means of a sequence of message transmissions between adjacent nodes in the network.

The gossiping problem was originally introduced by the community of discrete mathematicians, to which it owes most of its terminology, as a combinatorial problem in graphs. Nonetheless, it was soon realized that, once cast in more realistic models of communication, gossiping is a fundamental primitive in distributed memory multiprocessor systems. There are a number of situations in multiprocessor computation, such as global processor synchronization, where gossiping occurs. Moreover, the gossiping problem is implicit in a large class of parallel computation problems, such as linear system solving, the discrete Fourier transform, and sorting, where both input and output data are required to be distributed across the network [6, 9, 18]. Due to the interesting theoretical questions it poses and its numerous practical applications, gossiping has been widely studied under various communication models. Hedetniemi, Hedetniemi, and Liestman [15] provide a survey of the area. Two more recent survey papers collecting the latest results are [10, 17]. Readers could also profit from seeing the book [24].

The great majority of the previous work on gossiping has considered the case in which the packets known to a processor at any given time during the execution of the gossiping protocol can be freely concatenated and the resulting (longer) message can be transmitted in a constant amount of time; that is, it has been assumed that the time required to transmit a message is independent of its length. While this assumption is reasonable for short messages, it is clearly unrealistic when the size of the messages becomes large. Notice that most of the gossiping protocols proposed in the literature require the transmission, in the last rounds of the execution of the protocol, of messages of size $\Theta(n)$, where n is the number of nodes in the network. Therefore, it would be interesting to have gossiping protocols that require only the transmission of bounded length messages between processors. In this paper we consider the problem of gossiping in communication networks under the restriction that communicating nodes can exchange up to a fixed number p of packets in each round.

1.1. The model. Consider a communication network modeled by a graph $G = (V, E)$ where the node set V represents the set of processors of the network and E represents the set of communication lines between processors.

Initially each node holds a packet that must be transmitted to any other node in the network by a sequence of *calls* between adjacent processors. During each call, communicating nodes can exchange up to p packets, where p is an a priori fixed integer. We assume that each processor can participate in at most one call at a time. Therefore, we can see the gossiping process as a sequence of *rounds*: during each round a disjoint set of edges (matching) is selected and the nodes that are end vertices of these edges make a call. This communication model is usually referred to as *telephone model* [15] or *full-duplex* 1-*port* (F_1) [20]. We denote by $g_{F_1}(p, G)$ the minimum possible number of rounds to complete the gossiping process in the network G subject to the above conditions. Another popular communication model is the *mail model* [15] or *half-duplex* 1-*port* (H_1) [20], in which in each round any node can either send a message to one of its neighbors or receive a message from it, but not simultaneously. The problem of estimating $g_{H_1}(p, G)$ has been considered in [4]. Analogous problems in bus networks have been considered in [11, 16]. Optimal bounds on $g_{H_1}(1, G)$ when the edges of G are subject to random failures are given in [7]. Packet routing in interconnection networks in the F_1 model has been considered in [1].

1.2. Results. We first study the extremal case in which gossiping is to be performed under the restriction that communicating nodes can exchange *exactly* one packet in each round. We provide several lower bounds on the gossiping time $g_{F_1}(1, G)$ and we provide matching upper bounds for Hamiltonian graphs, complete trees, and complete bipartite graphs. For general graphs we provide asymptotically tight upper and lower bounds.

Subsequently, we study the case of arbitrary p and we compute $g_{F_1}(p, G)$ exactly for complete graphs, hypercubes, rings, and paths. Our result for hypercubes allows us to improve the corresponding result in the H_1 model given in [4].

Finally, we investigate the problem of finding the sparsest networks in which gossiping can be performed in the minimum possible number of rounds.

All logarithms in this paper are to the base 2.

2. Gossiping by exchanging one packet at a time. In this section we study $g_{F_1}(1, G)$, that is, the minimum possible number of rounds to complete gossip in a graph G under the condition that at each round communicating nodes can exchange

exactly one packet.

In order to avoid overburdening the notation, we will simply write $g(G)$ to denote $g_{F_1}(1, G)$.

2.1. Lower bounds on $g(G)$. In this section we give some lower bounds on the time needed to complete the gossiping process.

LEMMA 2.1. *For any graph $G = (V, E)$, with $|V| = n$, let $\mu(G)$ be the size of a maximum matching in G; then*

$$g(G) \geq \left\lceil \frac{n(n-1)}{2\mu(G)} \right\rceil. \tag{1}$$

Proof. For any node $v \in V$ the packet initially resident in v must reach each of the remaining $n-1$ nodes. Therefore, during the gossiping process, at least $n(n-1)$ packet transmissions must be executed over the edges of G. Since in each communication round at most $\mu(G)$ calls are performed and each call allows the transmission of two packets (one in each direction), the bound follows. □

LEMMA 2.2. *Let $X \subset V$ be a vertex cutset of the graph $G = (V, E)$ whose removal disconnects G into the connected components $V_1, \ldots, V_d$; then*

$$g(G) \geq \left\lceil \sum_{i=1}^{d} \frac{\max\{|V_i|, n - |V_i|\}}{|M_X|} \right\rceil, \tag{2}$$

where $|M_X|$ is the size of a maximum matching M_X in G such that any edge in it has one endpoint in X and the other in $V - X$.

Proof. Consider a component V_i, for some $1 \leq i \leq d$. Nodes in V_i can receive the packets of nodes in $V - V_i$ only by means of calls between a node in X and one in V_i; moreover, at least $n - |V_i|$ calls are needed between nodes in X and nodes in V_i to bring all packets in $V - V_i$ to nodes in V_i. Analogously, packets of nodes in V_i can reach nodes in $V - V_i$ only by means of calls between a node in X and one in V_i, and at least $|V_i|$ such calls are needed. Therefore, for each $i = 1, \ldots, d$, at least $\max\{|V_i|, n - |V_i|\}$ calls must take place between nodes in X and nodes in V_i. We then get that at least $\sum_{i=1}^{d} \max\{|V_i|, n - |V_i|\}$ calls are needed between nodes in X and nodes in $V - X = \cup_{i=1}^{d} V_i$. Since at most $|M_X|$ such calls can take place during each round, we get the desired lower bound of

$$\left\lceil \frac{\sum_{i=1}^{d} \max\{|V_i|, n - |V_i|\}}{|M_X|} \right\rceil$$

on the time necessary to gossip in G. □

Remark 2.1. The bound in Lemma 2.2 can sometimes be improved by observing that after the last call has been done between a node in some V_i and a node in X, the last exchanged message has still to reach all the other nodes of V_i (or of $V - V_i$). Therefore, we can add to the lower bound (2) the minimum of the eccentricities of the subgraphs induced by the V_i's and the $V - V_i$'s.

COROLLARY 2.1. *Let $\alpha(G)$ be the independence number of G; then*

$$g(G) \geq \left\lceil \frac{\alpha(G)(n-1)}{n - \alpha(G)} \right\rceil. \tag{3}$$

Proof. Let Y denote an independent set of G. Applying Lemma 2.2 with cutset $X = V - Y$ and connected components $V_1, \ldots, V_{|Y|}$, each consisting of just one element of Y, we get

$$g(G) \geq \left\lceil \sum_{i=1}^{|Y|} \frac{n - |V_i|}{|M_X|} \right\rceil \geq \left\lceil \sum_{i=1}^{|Y|} \frac{n - |V_i|}{|X|} \right\rceil = \left\lceil \sum_{i=1}^{|Y|} \frac{n-1}{n - |Y|} \right\rceil = \left\lceil \frac{|Y|(n-1)}{n - |Y|} \right\rceil.$$

Choosing an independent set of maximum size $|Y| = \alpha(G)$ we get (3). □

Let T be a tree and v one of its nodes; we indicate the connected components into which the node set of T is split by the removal of v by $V_1(v), \ldots, V_{\deg(v)}(v)$, ordered so that $|V_1(v)| \geq \cdots \geq |V_{\deg(v)}(v)|$.

COROLLARY 2.2. *Let T be a tree on n nodes of maximum degree $\Delta = \max_{v \in V} \deg(v)$; then*

$$g(T) \geq \max_{v\,:\,\deg(v)=\Delta} L(v),$$

where

$$L(v) = \begin{cases} (\deg(v) - 1)n + 1 & \text{if } |V_1(v)| \leq n/2, \\ (\deg(v) - 2)n + 1 + 2|V_1(v)| & \text{if } |V_1(v)| > n/2. \end{cases}$$

Proof. Given a node v, Lemma 2.2 with $X = \{v\}$ gives

$$\begin{aligned} g(T) &\geq \sum_{i=1}^{\deg(v)} \max\{|V_i(v)|, n - |V_i(v)|\} \\ &= \sum_{i=2}^{\deg(v)} n - |V_i(v)| + \begin{cases} |V_1(v)| & \text{if } |V_1(v)| > n/2, \\ n - |V_1(v)| & \text{if } |V_1(v)| \leq n/2, \end{cases} \\ &= L(v). \end{aligned}$$

Direct computation shows that if $\deg(v) > \deg(w)$ then $L(v) > L(w)$, thus proving that the maximum is always attained at a node of maximum degree. □

2.2. Upper bounds. In this section we will determine $g(G)$ exactly for several classes of graphs, including Hamiltonian graphs and complete k-ary trees. We will also provide good upper bounds for general graphs.

2.2.1. Hamiltonian graphs. We first note that in any graph $G = (V, E)$ the size of a maximum matching $\mu(G)$ is at most $\lfloor |V|/2 \rfloor$. Therefore, from Lemma 2.1 we get that the gossiping time $g(G)$ of *any* graph with n nodes is always lower-bounded by

$$g(G) \geq \begin{cases} n - 1 & \text{if } n \text{ is even}, \\ n & \text{if } n \text{ is odd}. \end{cases} \tag{4}$$

We will show that this lower bound is attained by Hamiltonian graphs.

Let $C_n = (V, E)$ denote the ring of length n; we assume that the vertex set is $V = \{0, \ldots, n-1\}$ and the edge set is $E = \{(v, w) \ : \ 1 = |v - w| (\text{mod } n)\}$.[1]

[1] Here and in the rest of the paper with $x = a \pmod b$ we denote the unique integer $0 \leq x < b$ such that $x = qb + a$.

Gossiping-even(C_n)
Round $t = 1$**:** Each node v sends its own packet to the node w such that $(v, w) \in M_1$.
Round $t = 2$**:** Each node v sends its own packet to the node w such that $(v, w) \in M_2$.
Round t**,** $3 \leq t \leq n-1$**:** For each node v let w be the node such that $(v, w) \in M_t$; node v sends a new packet to w; namely, v sends the packet it first received from among those v has neither received from w nor sent to w in any previous round.

FIG. 1. *Gossiping algorithm in C_n, n even.*

Gossiping-odd(C_n)
Round t**,** $1 \leq t \leq n$**:** For each node $v \neq t-1$ let w be the neighbor of v in M_t; node v sends to w the packet that v first received from among those that it neither got from w nor sent to w in a previous round (v's own packet is considered to be received before any other packet).

FIG. 2. *Gossiping algorithm in C_n, n odd.*

LEMMA 2.3. $$g(C_n) \leq \begin{cases} n-1 & \text{if } n \text{ is even,} \\ n & \text{if } n \text{ is odd.} \end{cases}$$

Proof. We distinguish two cases according to the parity of the number n of nodes.

Case n even. We shall give a gossiping protocol on the ring C_n that requires $n-1$ rounds. First, for each integer t, define the perfect matching in C_n given by

$$M_t = \begin{cases} \{(v, w) \ : \ v \text{ is even and } w = v+1\} & \text{if } t \text{ is even,} \\ \{(v, w) \ : \ v \text{ is odd and } w = v+1 (\text{mod } n)\} & \text{if } t \text{ is odd;} \end{cases} \tag{5}$$

notice that M_t and M_{t+1} are disjoint for each t. The gossiping algorithm is shown in Figure 1.

It is immediate to see that each node receives a new packet at each round (this can be formally proved by induction on t). Therefore, at the end of round $n-1$ of algorithm **Gossiping-even**(C_n) each node has received all the packets of the other $n-1$ nodes.

Case n odd. Define the following maximum matchings M_t in C_n for each $t = 1, \ldots, n$:

$$M_t = \{(v, w) \ : \ v - t + 1 \, (\text{mod } n) \text{ is odd, } w = v + 1 (\text{mod } n), \text{ and } v \neq t-1 \neq w\}. \tag{6}$$

We give in Figure 2 a gossiping protocol on C_n that requires n rounds. It is easy to see that at each round $t = 1, \ldots, n$ each node different from $t-1$ receives a new packet. Therefore, at the end of round n of algorithm **Gossiping-odd**(C_n), each node has received all the packets of the other $n-1$ nodes. □

Example 2.1. For $n = 6$ we have $M_1 = M_3 = M_5 = \{(1, 2), (3, 4), (50)\}$ and $M_2 = M_4 = \{(0, 1), (2, 3), (4, 5)\}$. Each column of Table 1 shows the set of nodes whose packets are known by v at the end of round t, for each $0 \leq v \leq 5$ and $1 \leq t \leq 5$.

TABLE 1

$t\backslash v$	0	1	2
1	$\{5,0\}$	$\{1,2\}$	$\{1,2\}$
2	$\{5,0,1\}$	$\{0,1,2\}$	$\{1,2,3\}$
3	$\{4,5,0,1\}$	$\{0,1,2,3\}$	$\{0,1,2,3\}$
4	$\{4,5,0,1,2\}$	$\{5,0,1,2,3\}$	$\{0,1,2,3,4\}$
5	$\{3,4,5,0,1,2\}$	$\{5,0,1,2,3,4\}$	$\{5,0,1,2,3,4\}$

$t\backslash v$	3	4	5
1	$\{3,4\}$	$\{3,4\}$	$\{5,0\}$
2	$\{2,3,4\}$	$\{3,4,5\}$	$\{4,5,0\}$
3	$\{2,3,4,5\}$	$\{2,3,4,5\}$	$\{4,5,0,1\}$
4	$\{1,2,3,4,5\}$	$\{2,3,4,5,0\}$	$\{3,4,5,0,1\}$
5	$\{1,2,3,4,5,0\}$	$\{1,2,3,4,5,0\}$	$\{3,4,5,0,1,2\}$

TABLE 2

$t\backslash v$	0	1	2	3	4
1	$\{0\}$	$\{1,2\}$	$\{1,2\}$	$\{3,4\}$	$\{3,4\}$
2	$\{4,0\}$	$\{1,2\}$	$\{1,2,3\}$	$\{2,3,4\}$	$\{3,4,0\}$
3	$\{4,0,1\}$	$\{0,1,2\}$	$\{1,2,3\}$	$\{2,3,4,0\}$	$\{2,3,4,0\}$
4	$\{3,4,0,1\}$	$\{0,1,2,3\}$	$\{0,1,2,3\}$	$\{2,3,4,0\}$	$\{2,3,4,0,1\}$
5	$\{3,4,0,1,2\}$	$\{0,1,2,3,4\}$	$\{0,1,2,3,4\}$	$\{1,2,3,4,0\}$	$\{2,3,4,0,1\}$

For $n = 5$ we have $M_1 = \{(1,2),(3,4)\}$, $M_2 = \{(2,3),(4,0)\}$, $M_3 = \{(3,4),(0,1)\}$ $M_4 = \{(4,0),(1,2)\}$, and $M_5 = \{(0,1),(2,3)\}$. Each column of Table 2 shows the set of nodes whose packets are known by v at the end of round t, for each $0 \le v \le 4$ and $1 \le t \le 5$.

THEOREM 2.1. *For any Hamiltonian graph G on n vertices,*

$$g(G) = \begin{cases} n-1 & \text{if } n \text{ is even,} \\ n & \text{if } n \text{ is odd.} \end{cases}$$

Proof. If G is Hamiltonian, from Lemma 2.3 we get that gossiping along the edges of the Hamiltonian cycle requires time matching the lower bound (4), and the theorem holds. □

2.3. Trees. In this section we investigate the gossiping time in trees. We first give an upper bound on the gossiping time in *any* tree and afterwards compute the exact gossiping time of rooted k-ary trees.

Consider a tree $T = (V, E)$. We recall that for each node v the set $V_1(v)$ denotes the largest of the connected components into which T splits after the removal of v. Let

$$\vartheta = \max |V_1(v)|,$$

where the maximum is taken over all the internal nodes v having exactly $\deg(v) - 1$ leaves as neighbors; notice that any internal node u with less than $d(u) - 1$ leaves as neighbors has $|V_1(u)| \le \vartheta - 1$.

Let *pre-leaf* denote a node v such that $|V_1(v)| = \vartheta$ and denote by π the maximum degree of a node in the subgraph consisting only of the edges (u, f) where f is either a leaf or a pre-leaf of T. Finally, let λ be the maximum number of leaves connected to a common node and $\Delta = \max_{v \in V} \deg(v)$.

Gossiping-tree(T)
Phase 1
[*Color each edge* (u,v) *of* T *with color* $c(u,v)=c(v,u)\in\{0,\dots,\Delta-1\}$.]
Round t**, for** $t=1,\dots,\Delta(\vartheta-1)$**:** For each node u, if there is an edge (u,v) such that $c(u,v)=t-1(\mathrm{mod}\ \Delta)$, then u sends a new packet to v; namely, u sends to v a packet from among those that u has neither sent to v nor received from v in a previous round, if such a packet exists; otherwise u sends nothing.
Phase 2
[*Give to each edge* (u,f)*, where* f *is a leaf or a pre-leaf, a color* $c'(u,f)\in\{0,\dots,\pi-1\}$.]
Round $\Delta(\vartheta-1)+t$**, for** $t=1,\dots,\pi$**:** For each leaf or pre-leaf f, if there is an edge (u,f) with $c'(u,f)=t-1$, then u sends to f a packet from among those that u has neither sent to f nor received from f in a previous round, if any.
Phase 3
[*Give to each edge* (u,f)*, where* f *is a leaf of* T*, a color* $c''(u,f)\in\{0,\dots,\lambda-1\}$.]
Round $\Delta(\vartheta-1)+\pi+t$**, for** $t=1,\dots,(n-\vartheta-1)\lambda$**:** For each leaf f, if the edge (u,f) on f has $c''(u,f)=t-1(\mathrm{mod}\ \lambda)$, then u sends to f any packet f does not know.

FIG. 3. *Gossiping algorithm in a tree* T.

THEOREM 2.2. *For any tree* $T=(V,E)$ *on* n *nodes,* $g(T)\le(\vartheta-1)\Delta+\pi+(n-\vartheta-1)\lambda$.

Proof. Consider the gossiping algorithm **Gossiping-tree**(T) given in Figure 3. For any $e\in E$, the edge coloring $c(e)$ and the partial edge colorings $c'(e)$ and $c''(e)$ used in **Gossiping-tree**(T) are each intended so that no two edges sharing a vertex are assigned the same color.

We now prove the correctness of algorithm **Gossiping-tree**(T). Let us say that the edge (u,v) of T is *saturated* from u to v at time t of **Gossiping-tree**(T) if no packet is sent from u to v at *any time* $t'\ge t$, that is, if by time $t-1$ node v has received the packet of each node w connected to v through u. We need the following property of **Gossiping-tree**(T).

PROPERTY 2.1. *In any round* t *of Phase* 1 *of the algorithm* **Gossiping-tree**(T)*, if the edge* (u,v) *has color* $c(u,v)=t-1(\mathrm{mod}\ \Delta)$ *and it is not saturated from* u *to* v *at time* t*, then* u *sends a new packet to* v *at round* t.

Proof. The proof is by induction on the time unit t. Let $t\le\Delta$: at time unit t, for each edge (u,v) of color $c(u,v)=t-1\in\{0,\dots,\Delta-1\}$, nodes u and v exchange a call for the first time and have at least their own packet to send each other.

Now let $t>\Delta$ and suppose that the hypothesis holds for each $t'<t$.

Consider an edge (u,v) such that $c(u,v)=t-1(\mathrm{mod}\ \Delta)$. Suppose by contradiction that at time t the edge (u,v) is not saturated from u to v, but u has no packets to send to v among those u has not received through v. That is, all packets known to u and not received through v have already been sent from u to v.

In particular, node u has already sent to v all the packets it has received from its other neighbors, call them $w_1,\dots,w_k$. Notice that the last call from u to v has taken place at time $t-\Delta$. For each w_i, let τ_i be the only integer such that both

$t-\Delta < \tau_i < t$ and $c(u,w_i) = \tau_i - 1 (\mathrm{mod}\ \Delta)$ hold. If the edge (u,w_i) is not saturated at time τ_i, we know by the inductive hypothesis that u has received a packet from w_i at time τ_i. We can have two cases: the first case is that all the edges (u,w_i) are saturated at time $\tau_i < t$. This immediately implies that (u,v) is saturated at time t, contradicting our assumption that (u,v) was not saturated from u to v at time t. The second case is that at least one edge (u,w_i) is not saturated at time τ_i; in such a situation we know by the inductive hypothesis that u has received a new packet from w_i at time τ_i that can now be forwarded to v, again getting a contradiction. □

We can now complete the proof of the theorem by showing that at the end of **Gossiping-tree**(T) each node knows all the other $n-1$ packets. Property 2.1 shows that a new packet is sent from u to v at each round t of **Phase 1** such that $c(u,v) = t-1 \ (\mathrm{mod}\ \Delta)$, until the edge (u,v) is saturated and no more packets need to be sent from u to v. Therefore, for any internal node u and for any Δ consecutive rounds, u receives a new packet from each neighbor v such that (v,u) is not saturated from v to u. We recall that ϑ is the maximum number of packets that any internal node needs to get from one neighbor and that this maximum is attained with equality only if u is a pre-leaf. Therefore, by round $\Delta(\vartheta-1)$, any node u which is not a pre-leaf gets all the necessary $n-1$ packets, while a pre-leaf gets $n-2$ packets during the $\Delta(\vartheta-1)$ rounds of Phase 1, and the remaining packet during some round of Phase 2.

Analogously, during Phase 1 any leaf f gets $\vartheta-1$ packets. It is obvious that f receives a new packet during Phase 2; moreover, during Phase 3 the leaf f receives a new packet for any λ consecutive rounds, thus getting the remaining $n-\vartheta-1$ packets that it needs to complete the gossip. □

Let δ denote the minimum degree of an internal node in T. It is easy to see that we can upper-bound ϑ by $n-\delta$. Therefore, from Theorem 2.2 we have the following upper bound on $g(T)$ that is expressed only in terms of degree properties of the nodes in T.

COROLLARY 2.3. *For any tree $T=(V,E)$ on n nodes, $g(T) \le (n-\delta)\Delta + (\delta-1)\lambda$.*

Given a connected graph $G=(V,E)$, denote by $\mathcal{T}$ the set of all spanning trees of G, and for any vertex $v \in V$, denote by $\deg_T(v)$ the degree of v in $T \in \mathcal{T}$. Define $d(G) = \min_{T\in\mathcal{T}} \max_{v\in V} \deg_T(v)$. The following corollary is immediate.

COROLLARY 2.4. *For any connected graph $G=(V,E)$ with n vertices,*

$$g(G) \le (n-1)d(G). \tag{7}$$

We point out that, although the problem of computing $d(G)$ is NP-hard, there exists an efficient algorithm to compute a spanning tree of maximum degree at most $d(G)+1$ (see [12]). From Corollaries 2.2 and 2.4 we have that for any tree with n nodes and maximum degree Δ it holds that $n\Delta - n + 1 \le g(T) \le n\Delta - \Delta$. Let us now consider the tree $S_{n,\Delta}$ of Figure 4. If $\Delta = n-1$, then $S_{n,n-1}$ is the star on n nodes, and from Corollary 2.2 and Theorem 2.2 we have $g(S_{n,n-1}) = (n-1)^2$. If $\Delta > 2$ is constant with respect to $n > 2\Delta$ then from Corollary 2.2 and Theorem 2.2 we get $\Delta(n-1) - (\Delta-1) \le g(S_{n,\Delta}) \le \Delta(n-1) - 2$. It is not difficult to obtain a specific gossiping algorithm attaining the lower bound, hence the bound (7) is asymptotically tight.

In [7] it was conjectured that for any G, $g_{H_1}(1,G) = \Omega(n\ d(G))$ holds; Ravi [22] has proved the following theorem.

THEOREM 2.3 (see [22]). *For any graph G, $g(G) = \Theta(n\ d(G))$.*

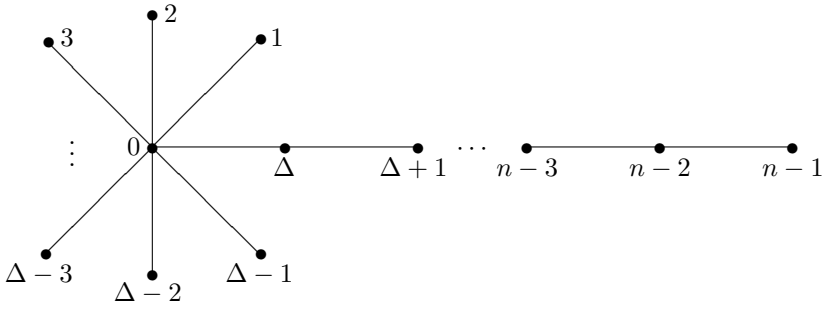

FIG. 4. *Tree* $S_{n,\Delta}$.

Proof. Given a vertex cutset X of $G = (V, E)$, from Lemma 2.2 we know that

$$g(G) \geq \left\lceil \sum_{i=1}^{c(X)} \frac{\max\{|V_i|, n - |V_i|\}}{|M_X|} \right\rceil,$$

where $V_1, \ldots, V_{c(X)}$ are the connected components induced in G by $V - X$ and M_X is a maximum matching between X and $V - X$ in G. Noticing that $|M_X| \leq |X|$ and $\max\{|V_i|, n - |V_i|\} \geq n/2$ for each i,

$$g(G) \geq \frac{n}{2} \frac{c(X)}{|X|}. \tag{8}$$

It was proved by Fürer and Raghavachari (see [12, Section 5]) that there exists a vertex cutset $Y \subset V$ such that

$$d(G) \leq \frac{c(Y)}{|Y|} + 1.$$

Using the above inequality and the lower bound (8), we have

$$g(G) \geq \frac{n}{2} \left(d(G) - 1 \right).$$

The above inequality, together with Corollary 2.4, implies that $g(G) = \Theta(n\ d(G))$. □

We remark that the same reasoning as in Theorem 2.3 allows us to prove that for any p

$$g_{F_1}(p, G) = \Omega(n\ d(G)/p).$$

We shall now compute the exact gossiping time of k-ary trees, that is, rooted trees in which each internal node has exactly k sons. Let $T_{k,n}$ denote *any* k-ary tree with n nodes.

Let us first notice that for $n = k + 1$ the tree $T_{k,n}$ is the star $S_{k+1,k}$. Consider then a tree $T_{k,n}$ with $n \geq 2k + 1$ nodes. Let u be a node of $T_{k,n}$ whose sons are all leaves. By Corollary 2.2 we get

$$g(T_{k,n}) \geq \max_v L(v) \geq L(u) = \begin{cases} kn + 1 & \text{if } n = 2k + 1, \\ (k + 1)(n - 1) - k & \text{if } n \geq 3k + 1. \end{cases} \tag{9}$$

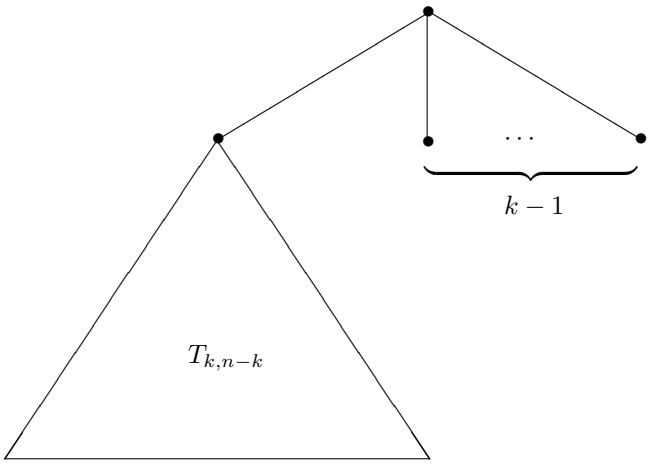

FIG. 5.

We show now that (9) holds with equality. Applying Theorem 2.2 to $T_{k,n}$ we get that

$$g(T_{k,n}) \leq (\vartheta - 1)\Delta + \pi + (n - \vartheta - 1)\lambda = (\vartheta - 1)(k+1) + \pi + (n - \vartheta - 1)k. \tag{10}$$

Unless exactly $k-1$ sons of the root are leaves (cf. the tree in Figure 5), $T_{k,n}$ has $\vartheta = n - k - 1$ and $\pi \leq \Delta = k + 1$; that, by (10) and (9), gives

$$g(T_{k,n}) = (n-k-2)(k+1) + k + 1 + k^2 = (k+1)(n-1) - k.$$

Consider the remaining case when $T_{k,n}$ is the tree of Figure 5. The only pre-leaf is the root, and $\vartheta = n - k$. If $n \geq 3k + 1$ we have $\pi = k$, and from (10) we get

$$g(T_{k,n}) \leq (n-k-1)(k+1) + k + (k-1)k = (n-1)(k+1) - k;$$

if $n = 2k + 1$ we have $\pi = \Delta = k + 1$ and $g(T_{k,2k+1}) \leq kn + 1$.

Therefore, we have proved the following result.

THEOREM 2.4. *For any k-ary tree on n nodes $T_{k,n}$,*

$$g(T_{k,n}) = \begin{cases} k^2 & \text{if } n = k+1, \\ 2k^2 + k + 1 & \text{if } n = 2k+1, \\ (k+1)(n-1) - k & \text{if } n \geq 3k+1. \end{cases}$$

The particular case $k = 1$ of the above result deserves to be explicitly stated.

COROLLARY 2.5. *Let P_n be the path on n nodes. We have*

$$g(P_n) = \begin{cases} 1 & \text{if } n = 2, \\ 4 & \text{if } n = 3, \\ 2n - 3 & \text{if } n \geq 4. \end{cases}$$

2.4. Complete bipartite graphs. Let $K_{r,s} = (V(K_{r,s}), E(K_{r,s}))$ be the complete bipartite graph on the node set $V(K_{r,s}) = \{a_0, \ldots, a_{r-1}\} \cup \{b_0, \ldots, b_{s-1}\}$, with $r \geq s$, $\{a_1, \ldots, a_{r-1}\} \cap \{b_0, \ldots, b_{s-1}\} = \emptyset$, and edge set $E(K_{r,s}) = \{a_0, \ldots, a_{r-1}\} \times \{b_0, \ldots, b_{s-1}\}$. In the next theorem we determine the gossiping time of $K_{r,s}$.

THEOREM 2.5. *For each r and s with $r \geq s \geq 1$, it holds that* $g(K_{r,s}) = \lceil (r+s-1)r/s \rceil$.

Proof. The lower bound $g(K_{r,s}) \geq \lceil (r+s-1)r/s \rceil$ is an immediate consequence of Corollary 2.1 since the complete bipartite graph has $\alpha(K_{r,s}) = r$.

In order to give a gossiping algorithm in $K_{r,s}$ requiring $\lceil (r+s-1)r/s \rceil$ communication rounds, we define the matchings

$$M_j = \{(b_i, a_{i+j \pmod r}) \ : \ 0 \leq i \leq s-1\}$$

for $j = 0, \ldots, r-1$. The algorithm is shown in Figure 6.

According to the protocol, at the end of **Phase 1** of **Gossiping-bipartite**$(K_{r,s})$ each node a_i (resp., b_i) knows the message of each b_i (resp., a_i). Consider now **Phase 2**. It is immediate to see that during the first $s-1$ rounds of **Phase 2** each of the b_i's receives the packet of each b_j for $j \neq i$, thus completing its knowledge. Moreover, after the $\lceil r(r+s-1)/s \rceil - r = \lceil r(r-1)/s \rceil$ rounds of **Phase 2** each node a_i has been involved in a call at least $r-1$ times and has then received the packet of each of the a_j, for $j \neq i$, thus completing its knowledge. □

Gossiping-bipartite$(K_{r,s})$
Phase 1
round t**, for** $t = 1, \ldots, r$**:** For each edge $(b_i, a_{i+t-1 \pmod r}) \in M_{t-1}$ nodes b_i and $a_{i+t-1 \pmod r}$ exchange their own packets.
Phase 2
round t**, for** $t = r+1, \ldots, \lceil r(r+s-1)/s \rceil$**:**
For each edge $(b_i, a_j) \in M_{(t-1-r)s \pmod r}$ node b_i sends to a_j any packet that a_j has not received in a previous round;
if $t \leq r+s-1$ then b_i receives from a_j the packet of $b_{i+t-r \pmod s}$.

FIG. 6. *Gossiping algorithm in $K_{r,s}$.*

2.5. Generalized Petersen graphs. In section 2.2.1 we have seen that Hamiltonian graphs have the minimum possible gossiping time among all graphs with n nodes. It is natural to wonder whether there are non-Hamiltonian graphs on n vertices with gossiping time equal to n if n is odd and $n-1$ if n is even. A quick check shows that this is not the case for rectangular grids $G_{t,s}$ with both t and s odd.[2] In fact, we know that $\alpha(G_{t,s}) = \lceil \frac{s \cdot t}{2} \rceil$, and from Corollary 2.1, we get $g(G_{t,s}) \geq s \cdot t + 1$. Moreover, it is also easy to check that the gossiping time of the Petersen graph on 10 vertices is at least 10. Therefore, one could be tempted to conjecture that the gossiping time $g(G)$ of a graph G is equal to the minimum possible only if G is Hamiltonian. This conjecture, although nice sounding, would be wrong, as the following classes of graphs, including the generalized Petersen graphs (GPGs), show.

Let $P_{k,\pi}$ be the graph consisting of two cycles of size k connected by a perfect matching in the following way: given a permutation π of $\{0, \ldots, k-1\}$ the graph $P_{k,\pi} = (V(P_{k,\pi}), E(P_{k,\pi}))$ has vertex set $V(P_{k,\pi}) = \{a_0, \ldots, a_{k-1}\} \cup \{b_0, \ldots, b_{k-1}\}$ and edge set

[2] It is well known that all rectangular grids $G_{t,s}$ are Hamiltonian except when t and s are both odd.

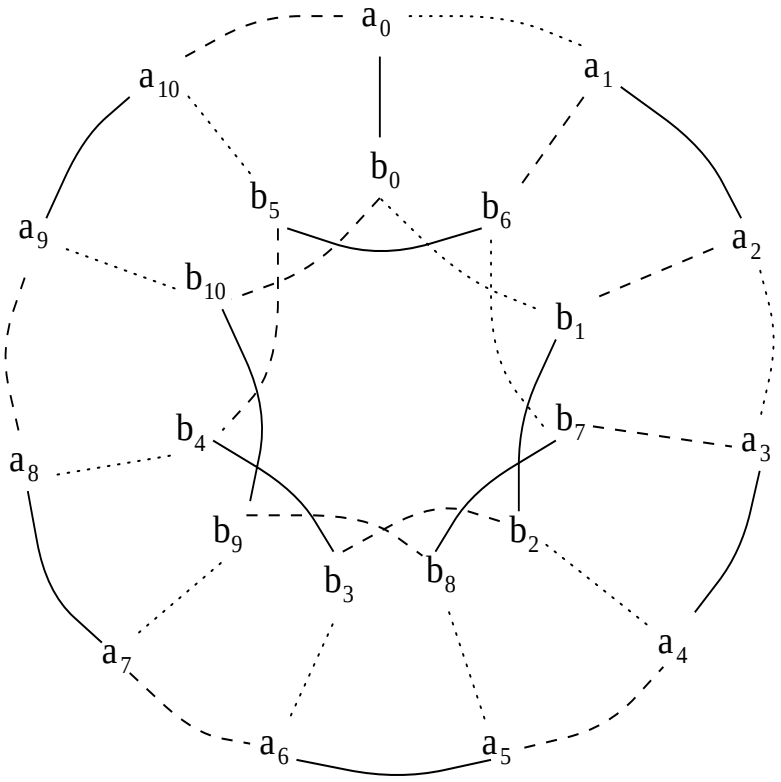

FIG. 7. *A 3-coloration of the GPG with* $n = 11$ *and* $s = 2$.

$$E(P_{k,\pi}) = \{(a_i, a_{i+1(\mathrm{mod}\ k)}) \ : \ 0 \le i < k\}$$
$$\cup \{(b_i, b_{i+1(\mathrm{mod}\ k)}) \ : \ 0 \le i < k\} \cup \{(a_i, b_{\pi(i)}) \ : \ 0 \le i < k\}.$$

The Petersen graph has $k = 5$ and $\pi(i) = 3i \,(\mathrm{mod}\ 5)$, for $i = 0, 1, 2, 3, 4$; GPGs have k odd and $\pi(s \cdot i \,(\mathrm{mod}\ k)) = i,\ i = 0, \ldots, k-1$, for a fixed integer s.

From Lemma 2.1 we know that $g(P_{k,\pi}) \ge |V(P_{k,\pi})| - 1 = 2k - 1$. We will show that for any k and π such that $P_{k,\pi}$ is 3-edge-colorable, we have the equality

$$g(P_{k,\pi}) = 2k - 1.$$

Each cubic GPG, other than the Petersen graph itself, is 3-edge-colorable [2]. Moreover, the class of 3-edge-colorable $P_{k,\pi}$'s includes the family of non-Hamiltonian GPGs with $k = 5 \,(\mathrm{mod}\ 6)$ and $s = 2$ (see [2] and references therein quoted). For an example of a 3-coloration of a GPG, see Figure 7.

The gossiping algorithm is described in Figure 8; it assumes that the edges of the graph are colored with the three colors 1, 2, and 3. It is easy to prove by induction on q that all the calls of **Phase** q, for $q \le (k-1)/2$, can actually be done. Therefore, after the first $(k-1)/2$ phases, each node a_i has the packet of $a_{i \pm j(\mathrm{mod}\ k)}$ for $j = 0, \ldots, (k-1)/2$; that is, it knows the packet of each other node in its own cycle; moreover, it knows the packet of $(k-1)/2$ nodes in the cycle on $\{b_0, \ldots, b_{k-1}\}$. Analogously, each b_i knows the packet of each other node in its own cycle and of $(k-1)/2$ nodes in $\{a_0, \ldots, a_{k-1}\}$.

Gossiping-3-color$(P_{k,\pi})$
Phase q $(1 \le q \le (k-1)/2)$ *[each phase consists of three communication rounds]*:
round t $(t = 1, 2, 3)$: make a call between the endpoints of each edge of color t.
Calls are made so that:
when an edge $(a_i, a_{i+1(\mathrm{mod}\ k)})$ is used, then a_i receives the packet of $a_{i+q(\mathrm{mod}\ k)}$, and $a_{i+1(\mathrm{mod}\ k)}$ receives the packet of $a_{i+1-q(\mathrm{mod}\ k)}$;
when an edge $(b_i, b_{i+1(\mathrm{mod}\ k)})$ is used, then b_i receives the packet of $b_{i+q(\mathrm{mod}\ k)}$, and $b_{i+1(\mathrm{mod}\ k)}$ receives the packet of $b_{i+1-q(\mathrm{mod}\ k)}$;
when the edge $(a_i, b_{\pi(i)})$ is used, then a_i receives the packet of some b_j, $0 \le j \le k-1$, and $b_{\pi(i)}$ receives the packet of some a_j, $0 \le j \le k-1$.
Phase $3(k-1)/2 + q$ $(1 \le q \le (k+1)/2)$ *[the phase consists of one communication round]*:
node a_i (resp., $b_{\pi(i)}$), for $i = 0, \ldots, k-1$, sends to $b_{\pi(i)}$ (resp., a_i) the packet of some a_j (resp., b_j) it has not already sent to it.

FIG. 8. *Gossiping algorithm in* $P_{k,\pi}$.

Therefore, the calls between nodes in $\{a_0, \ldots, a_{k-1}\}$ and in $\{b_0, \ldots, b_{k-1}\}$ of the last $(k+1)/2$ communication rounds allow completion of the knowledge of each node in the graph.

3. Gossiping by exchanging more than one packet at a time. In this section we shall study the minimum number of time units $g_{F_1}(p, G)$ necessary to perform gossiping in a graph G, under the restriction that at each time instant communicating nodes can exchange up to p packets, p fixed but arbitrary otherwise. We assume that p is smaller than the number of nodes of the graph G; otherwise, the problem is equivalent to the classical one. Again, for ease of notation, we shall write $g(p, G)$ to denote $g_{F_1}(p, G)$.

3.1. Lower bounds. First, we shall present a simple lower bound on $g(p, G)$ based on elementary counting arguments. Nonetheless, we shall prove in the sequel that the obtained lower bound is tight for complete graphs with an even number of nodes and for hypercubes. In order to derive the lower bound, let us define $I(p, t)$ as the maximum number of packets a vertex can have possibly received after t communication rounds in *any* graph. Since at each round i, with $1 \le i \le t$, any vertex can receive at most $\min\{p, 2^{i-1}\}$ packets, it follows that

$$I(p, t) = 1 + \sum_{i=1}^{t} \min\{p, 2^{i-1}\}, \tag{11}$$

or equivalently,

$$I(p, t) = 1 + \sum_{i=1}^{\lceil \log p \rceil} 2^{i-1} + p(t - \lceil \log p \rceil) = 2^{\lceil \log p \rceil} + p(t - \lceil \log p \rceil) \tag{12}$$

for any $t \ge \lceil \log p \rceil$. Therefore, for any graph $G = (V, E)$, the gossiping time $g(p, G)$ is always lower bounded by the smallest integer $t^\star$ for which $I(p, t^\star) \ge |V|$. Since $t^\star$

is obviously greater than or equal to $\lceil \log |V| \rceil \geq \lceil \log p \rceil$, we can use (12) and obtain

$$g(p,G) \geq \lceil \log p \rceil + \left\lceil \frac{1}{p}\left(|V| - 2^{\lceil \log p \rceil}\right) \right\rceil.$$

Moreover, notice that if the number of nodes in the graph is odd, then at each round there is a node that does not receive any message. This implies that after any round t there exists a node that can have possibly received at most $I(p,t-1)$ packets. Therefore,

$$g(p,G) \geq \lceil \log p \rceil + \left\lceil \frac{1}{p}\left(|V| - 2^{\lceil \log p \rceil}\right) \right\rceil + 1.$$

The above arguments give the following lemma.

LEMMA 3.1. *For any graph $G=(V,E)$, $|V|=n$, and integer p such that $2^{\lceil \log p \rceil} \leq n$, we have*

$$g(p,G) \geq \begin{cases} \lceil \log p \rceil + \left\lceil \frac{1}{p}\left(n - 2^{\lceil \log p \rceil}\right) \right\rceil & \text{if } n \text{ is even,} \\ \lceil \log p \rceil + \left\lceil \frac{1}{p}\left(n - 2^{\lceil \log p \rceil}\right) \right\rceil + 1 & \text{if } n \text{ is odd.} \end{cases}$$

Using similar arguments, we can also generalize the lower bound (1) that we established in section 2.1 for $p=1$ to general values of p.

LEMMA 3.2. *Let $G=(V,E)$ be a graph with n vertices and let $\mu(G)$ be the size of a maximum matching in G. For any integer p such that $2^{\lceil \log p \rceil} \leq n$,*

$$g(p,G) \geq \lceil \log p \rceil + \left\lceil \frac{1}{p}\left(\frac{n(n-1)}{2\mu(G)} - 2^{\lceil \log p \rceil} + 1\right) \right\rceil.$$

Remark 3.1. Given a gossiping algorithm $\mathcal{A}$ for a graph G that uses messages of size not larger than p, we can easily derive from it an algorithm $\mathcal{B}$ to gossip in G with messages of size $q < p$. Indeed, if a message of size $> q$ is sent during a call of $\mathcal{A}$, then we can split this call into more calls, each transmitting up to q packets. For example, we can use this observation to derive the following bound:

$$g(p,G) \leq \lfloor \log p \rfloor + 1 + 2(g(2p,G) - \lfloor \log p \rfloor - 1) = 2g(2p,G) - \lfloor \log p \rfloor - 1. \tag{13}$$

Bound (13) can be proved by noticing that during the first $\lfloor \log p \rfloor + 1$ calls of the algorithm attaining $g(2p,G)$, the exchanged messages necessarily have size less than or equal to p. From this observation and Theorem 2.5, it follows, for example, that for the complete bipartite graph $g(2,K_{r,s}) \geq (g(1,K_{r,s})+1)/2 = \lceil (r+s-1)r/(2s) \rceil + 1$; it is not difficult to derive an algorithm similar to the one in Figure 6 attaining the equality.

3.2. Rings and paths. Let $g(\infty,G)$ denote the gossiping time of the graph G in the absence of any restriction on the size of the messages. It is obvious that for each p, $g(p,G) \geq g(\infty,G)$ holds; it is possible to see that equality holds for any $p \geq 2$ when G is either the ring C_n or the path P_n on n nodes.

It is well known that [17]

$$g(\infty,P_n) = 2\left\lceil \frac{n}{2} \right\rceil - 1 \quad \text{and} \quad g(\infty,C_n) = \begin{cases} n/2 & \text{if } n \text{ is even,} \\ (n+3)/2 & \text{if } n \text{ is odd.} \end{cases}$$

We just point out that it is easy to see that the algorithms attaining $g(\infty, C_n)$ and $g(\infty, P_n)$ do not need to send more than two packets at a time. Therefore, the following results hold.

THEOREM 3.1. *For each $n \geq 3$ and $p \geq 2$,*

$$g(p, C_n) = g(2, C_n) = \begin{cases} n/2 & \text{if } n \text{ is even,} \\ (n+3)/2 & \text{if } n \text{ is odd.} \end{cases}$$

THEOREM 3.2. *For each $n \geq 2$ and $p \geq 2$,*

$$g(p, P_n) = g(2, P_n) = 2\left\lceil \frac{n}{2} \right\rceil - 1.$$

3.3. Complete graphs. In this section we study the gossiping time of the complete graph K_n on n nodes. We shall denote by $\{0, 1, \ldots, n-1\}$ the vertex set of K_n. We recall that $g(\infty, K_n)$ is equal to $\lceil \log n \rceil$ if n is even, and $\lceil \log n \rceil + 1$ if n is odd.

THEOREM 3.3. *For each even integer n and integer p such that $2^{\lceil \log p \rceil} \leq n$,*

$$g(p, K_n) = \lceil \log p \rceil + \left\lceil \frac{n - 2^{\lceil \log p \rceil}}{p} \right\rceil.$$

Proof. The lower bound follows from Lemma 3.1. We now give a gossiping algorithm for K_n that uses the optimal number of rounds. For each node v, with v even and $0 \leq v \leq n-1$, define the sequence of nodes v_t as

$$v_t = \begin{cases} v + 2^t - 1 \pmod n & \text{if } 1 \leq t \leq \lceil \log p \rceil, \\ v + 2^{\lceil \log p \rceil} - 1 + \tau p + 1 \pmod n & \text{if } t = \lceil \log p \rceil + \tau, \text{ with } \tau \geq 1 \text{ and } p \cdot \tau \text{ odd,} \\ v + 2^{\lceil \log p \rceil} - 1 + \tau p \pmod n & \text{if } t = \lceil \log p \rceil + \tau, \text{ with either } p \text{ or } \tau \geq 1 \text{ even.} \end{cases} \tag{14}$$

Note that for each t the set $M_t = \{(v, v_t) \ : \ v \text{ even}, 0 \leq v < n\}$ is a perfect matching between even and odd nodes. Finally, for each integer $\tau \geq 1$, for each even node v, with $0 \leq v \leq n-1$, define

$$P_{\text{even}}(v, \tau) = \begin{cases} \{v + i (\text{mod} n) : 1 \leq i \leq p\} & \text{if } p \text{ and } \tau \text{ are odd,} \\ \{v + i (\text{mod} n) : 0 \leq i \leq p-1\} & \text{otherwise,} \end{cases} \tag{15}$$

and for each odd node v, with $0 \leq v \leq n-1$,

$$P_{\text{odd}}(v, \tau) = \begin{cases} \{v - i (\text{mod} n) : 1 \leq i \leq p\} & \text{if } p \text{ and } \tau \text{ are odd,} \\ \{v - i (\text{mod} n) : 0 \leq i \leq p-1\} & \text{otherwise.} \end{cases} \tag{16}$$

Consider the gossiping algorithm given in Figure 9 and let $I_n(v, t)$ denote the set of nodes whose packets are known by v by the end of round t. For each node v the size of $I_n(v, t)$ doubles at each round of **Phase 1** and increases by p in every round of **Phase 2**. Indeed, it is immediate to see that for each $t = 1, \ldots, \lceil \log p \rceil$

$$I_n(v, t) = \begin{cases} \{v + i (\text{mod} n) : 0 \leq i \leq 2^t - 1\} & \text{if } v \text{ is even,} \\ \{v - i (\text{mod} n) : 0 \leq i \leq 2^t - 1\} & \text{if } v \text{ is odd,} \end{cases} \tag{17}$$

Gossiping-even(p, K_n)
Phase 1
Round t, $1 \le t \le \lceil \log p \rceil$: For each even node v
nodes v and v_t exchange all the packets they know.

Phase 2
Round $t = \lceil \log p \rceil + \tau$, $1 \le \tau \le \left\lceil \frac{n-2^{\lceil \log p \rceil}}{p} \right\rceil$: For each even node v
node v sends to v_t the packets of nodes in $P_{\text{even}}(v, \tau)$ and
node v_t sends to v the packets of nodes in $P_{\text{odd}}(v_t, \tau)$.

FIG. 9. *Gossiping algorithm in K_n, n even.*

and for each $\tau = 1, \ldots, \left\lceil \frac{n-2^{\lceil \log p \rceil}}{p} \right\rceil$

(18)
$$I_n(v, \lceil \log p \rceil + \tau) = \begin{cases} \{v + i (\mathrm{mod} n) : 0 \le i \le 2^{\lceil \log p \rceil} + \tau p - 1\} & \text{if } v \text{ is even,} \\ \{v - i (\mathrm{mod} n) : 0 \le i \le 2^{\lceil \log p \rceil} + \tau p - 1\} & \text{if } v \text{ is odd.} \end{cases}$$

Hence, $I_n\left(v, \lceil \log p \rceil + \left\lceil \frac{n-2^{\lceil \log p \rceil}}{p} \right\rceil\right) = \{0, \ldots, n-1\} = V$ for each node v. ∎

Remark 3.2. A close look at the algorithm **Gossiping-even**(p, K_n) reveals that the calls are always made between even and odd nodes. Therefore, the same protocol works in the complete bipartite graphs $K_{r,r}$ from which we get that for any p and r

$$g(p, K_{r,r}) = g(p, K_{2r}) = \lceil \log p \rceil + \left\lceil \frac{1}{p}\left(2r - 2^{\lceil \log p \rceil}\right) \right\rceil.$$

We now consider the case of complete graphs with odd number of nodes.

THEOREM 3.4. *For each odd integer N and integer p such that $2^{\lceil \log p \rceil} \le N + 1$,*

$$\lceil \log p \rceil + \left\lceil \frac{N - 2^{\lceil \log p \rceil}}{p} \right\rceil + 1 \le g(p, K_N) \le \lceil \log p \rceil + \left\lceil \frac{N + 1 - 2^{\lceil \log p \rceil}}{p} \right\rceil + 2.$$

Proof. The lower bound follows from Lemma 3.1. To prove the upper bound, we show that the algorithm **Gossiping-odd**(p, K_N) given in Figure 10 completes gossiping in K_N in $\lceil \log p \rceil + \left\lceil \frac{N+1-2^{\lceil \log p \rceil}}{p} \right\rceil + 2$ rounds. The algorithm **Gossiping-odd**(p, K_N) is described in terms of the algorithm **Gossiping-even**(p, K_n), where $n = N + 1$.

Let V_t, $P_{\text{even}}(v, \tau)$, and $P_{\text{odd}}(v, \tau)$ be defined as in (14), (15), and (16), respectively. In order to show the correctness of **Gossiping-odd**(p, K_N), let us first consider **Phase 1**. At round t, for $1 \le t \le \lceil \log p \rceil$, node $N + 1 - 2^t$ does not receive the information of the nodes in $I_n(N, t) - \{N\}$. It is easy to see that the nodes that *do not have* the packets of *all* the nodes in $I_n(v, t)$ are the nodes in the set X_t defined by $X_1 = \emptyset$, and

$$\begin{aligned} X_t = X_{t-1} \cup \{ & v + 2^t - 1 \ (\mathrm{mod}\ n) \ : \ v \in X_{t-1} \text{ even } \} \\ & \cup \{ v - 2^t + 1 \ (\mathrm{mod}\ n) \ : \ v \in X_{t-1} \text{ odd } \} \cup \{N + 1 - 2^t\} \end{aligned}$$

Gossiping-odd(p, K_N)
Phase 1

Round t, $1 \le t \le \lceil \log p \rceil$: For each even node v, with $v \ne N+1-2^t$, nodes v and v_t exchange all the packets they know;
Round $t = \lceil \log p \rceil + 1$: each node v with $v \in \{3+4i \ : \ 0 \le i \le 2^{\lceil \log p \rceil - 2} - 2\} \cup \{N-3-4i \ : \ 0 \le i \le 2^{\lceil \log p \rceil - 2} - 1\}$ receives from $v+2$ a message containing the packets of all the nodes in $\{N - 2^{\lceil \log p \rceil - 1} + 1, \ldots, N-1\}$.

Phase 2

Round $t = \lceil \log p \rceil + 1 + \tau$, $1 \le \tau \le \left\lceil (N+1-2^{\lceil \log p \rceil})/p \right\rceil$: For each even v with $v_{t-1} \ne N$ node v sends to v_{t-1} the packets of nodes in $P_{\text{even}}(v, \tau)$ and v_{t-1} sends to v the packets of nodes in $P_{\text{odd}}(v_{t-1}, \tau)$.
Round $t = \lceil \log p \rceil + \left\lceil (N+1-2^{\lceil \log p \rceil})/p \right\rceil + 2$: Each node v such that $v_{t-1} = n-1$ for some $t = \lceil \log p \rceil + 1 + \tau$ with $1 \le \tau \le \left\lceil (N+1-2^{\lceil \log p \rceil})/p \right\rceil + 1$ receives from $v+1$ a message containing the packets of the nodes in $P_{\text{odd}}(N, \tau)$.

FIG. 10. *Gossiping algorithm in K_N, N odd.*

for $2 \le t \le \lceil \log p \rceil$. This gives

$$X_t = \{3+4i \ : \ 0 \le i \le 2^{t-2} - 2\} \cup \{N-3-4i \ : \ 0 \le i \le 2^{t-2} - 1\} \tag{19}$$

for $t = 2, \ldots, \lceil \log p \rceil$.

Moreover, each node in X_t has at least those packets of all nodes in $I(v,t) - I(N, t-1)$. Therefore, at the end of round $\lceil \log p \rceil$, each node in $X_{\lceil \log p \rceil}$ lacks at most the packets of the nodes in $I(N, \lceil \log p \rceil - 1) = \{N - 2^{\lceil \log p \rceil - 1} + 1, N - 2^{\lceil \log p \rceil - 1} + 2, \ldots, N-1\}$, and the calls of round $\lceil \log p \rceil + 1$ between each node $v \in X_{\lceil \log p \rceil}$ and $v+2 \notin X_{\lceil \log p \rceil}$ assure that each node knows the packets of all nodes in $I(v, \lceil \log p \rceil)$.

Now consider **Phase 2**. It is immediate that at round t each node receives p new packets, except for the even node v such that $v_{t-1} = N$. Hence, after the calls of round $\lceil \log p \rceil + \left\lceil \frac{n - 2^{\lceil \log p \rceil}}{p} \right\rceil + 2$, each node knows the packet of each of the other $N-1$ nodes. □

For N odd, we believe that the true value of $g(p, K_N)$ is $\lceil \log p \rceil + \left\lceil \frac{N - 2^{\lceil \log p \rceil}}{p} \right\rceil + 1$; we can verify this equality for small values of N and p. In case $p = 2$, Theorem 3.1 and Lemma 3.1 tell us that $g(2, K_N) = (N+3)/2 = g(2, C_N)$, for each odd $N \ge 2$. Moreover, we can prove the following theorem.

THEOREM 3.5. *If p is a multiple of 4 then $g(p, K_N) = \lceil \log p \rceil + \left\lceil \frac{N - 2^{\lceil \log p \rceil}}{p} \right\rceil + 1$.*

Proof. Execute the first $\lceil \log p \rceil$ rounds of **Gossiping-odd**(p, K_N): from (19) we know that the nodes that have not received the packets of all nodes in $I_n(v, \lceil \log p \rceil)$ are those in the set

$$X_{\lceil \log p \rceil} = \{3+4i \ : \ 0 \le i \le 2^{\lceil \log p \rceil - 2} - 2\} \cup \{N-3-4i \ : \ 0 \le i \le 2^{\lceil \log p \rceil - 2} - 1\}. \tag{20}$$

Continue the gossiping process as follows.

Round $t = \lceil \log p \rceil + \tau$, $1 \le \tau \le \left\lceil (N - 2^{\lceil \log p \rceil})/p \right\rceil - 1$: For each even v with $v_t \ne N$, v sends to v_t the packets of nodes in $P_{\text{even}}(v, \tau)$ and v_t sends to v the packets of nodes in $P_{\text{odd}}(v_t, \tau)$.

The set $X_{\lceil \log p \rceil + \tau}$ of the nodes that at round $\lceil \log p \rceil + \tau$ do not have the packets of all nodes in $I_n(v, \lceil \log p \rceil + \tau)$ satisfies

$$X_{\lceil \log p \rceil + \tau} = X_{\lceil \log p \rceil + \tau - 1} \cup \{v \ : \ v_t \in X_{\lceil \log p \rceil} \cup \{N\}\}.$$

We can then deduce that for each $\tau \leq \left\lceil (N - 2^{\lceil \log p \rceil})/p \right\rceil - 1$,

$$\begin{aligned} X_{\lceil \log p \rceil + \tau} = &\{3 + 4i \ : \ 0 \leq i \leq 2^{\lceil \log p \rceil - 2} + \tau p/4 - 1\} \\ &\cup \{N - 3 - 4i \ : \ 0 \leq i \leq 2^{\lceil \log p \rceil - 2} + \tau p/4 - 2\}. \end{aligned}$$

Now consider the matchings $M = \{(v, v+1) \ : \ v \text{ is even}\}$ and $M' = \{(v, v+3) \ : \ v \text{ is even}\}$; it is easy to see that gossiping can be completed in two more rounds by exchanging calls during rounds $\lceil \log p \rceil + \left\lceil \frac{N - 2^{\lceil \log p \rceil}}{p} \right\rceil$ and $\lceil \log p \rceil + \left\lceil \frac{N - 2^{\lceil \log p \rceil}}{p} \right\rceil + 1$ along the edges of M and M' if $N = 1 (\mathrm{mod}\ 4)$ or the edges of M' and M if $N = 3 (\mathrm{mod}\, 4)$, respectively. □

3.4. Hypercube. In the next theorem we shall determine $g(p, G)$ for any p when the graph G is the d-dimensional hypercube H_d with 2^d nodes.

THEOREM 3.6. *For each integer* $p < 2^d$, $\quad g(p, H_d) = \lceil \log p \rceil + \left\lceil \frac{1}{p}\left(2^d - 2^{\lceil \log p \rceil}\right) \right\rceil$.

Proof. The lower bound follows from Lemma 3.1. We now prove the matching upper bound. Let p be fixed. Denote by t_d the minimum integer such that $I(p, t_d) \geq 2^d$, where $I(p, t_d)$ is given in (11). We shall show that there exists a gossiping protocol that requires t_d rounds. Notice that $t_d = \lceil \log p \rceil + \left\lceil \frac{1}{p}\left(2^d - 2^{\lceil \log p \rceil}\right) \right\rceil$.

The proof is by induction on d. The assertion is trivially true for $d = 1$; suppose that there exists a gossiping protocol in H_d that takes t_d rounds to be completed and that satisfies the additional property that after any round $t \leq t_d - 1$ each vertex knows exactly $I(p, t)$ packets. We shall exhibit a gossiping protocol in H_{d+1} that takes t_{d+1} rounds to be completed and that also satisfies the aforesaid additional property.

Case 1: $I(p, t_d) = 2^d$. This implies that in the last round of the gossiping protocol in H_d—the t_dth—each vertex must receive exactly $\min\{p, 2^{d-1}\}$ packets. Consider the following protocol in the $(d+1)$-dimensional hypercube H_{d+1}: split H_{d+1} into two hypercubes of dimension d according to the value of its $(d+1)$th dimension; during the first t_d rounds gossip separately in each d-dimensional subcube according to the protocol whose existence is guaranteed by the induction hypothesis. After t_d rounds each vertex has received all the information of the subcube it belongs to; i.e., according to the hypothesis of this case, each vertex has received exactly $I(p, t_d) = 2^d$ packets. Now, in successive rounds, exchange packets along dimension $d+1$ in H_{d+1} by sending either all 2^d packets in one round, if $p > 2^d$, or p packets per round except in the last one, where one sends $2^d - p\lfloor 2^d/p \rfloor$ (if nonzero) packets. It is clear that this protocol requires t_{d+1} rounds to be completed. Moreover, for each t, with $0 \leq t \leq \lfloor 2^d/p \rfloor$, after round $t_d + t \leq t_{d+1} - 1$ each node in H_{d+1} knows exactly $I(p, t_d) + pt = I(p, t_d + t)$ packets. Hence the protocol for H_{d+1} satisfies the inductive hypothesis.

Case 2: $I(p, t_d) > 2^d$. This implies that $p < 2^{d-1}$; otherwise it is easy to check that one would have $t_d = d$ and $I(p, t_d) = 1 + \sum_i 2^{i-1} = 2^d$. Consider the protocol in H_d whose existence is implied by the induction hypothesis. By inductive hypothesis at round $t_d - 1$ each vertex has received $I(p, t_d - 1)$ packets, and in the last round, receives α packets, with $\alpha < p$; otherwise, we

would be again in Case 1.

Let $\mathcal{M} = \cup_{i=1}^{2^{d-1}}(x_i, y_i)$ be the perfect matching used in the last round, i.e., the round t_d, of the protocol on H_d, and let A_i (resp., B_i) be the set of new packets that x_i (resp., y_i) receives in this last round. Note that $A_i \cap B_i = \emptyset$ and $|A_i| = |B_i| = \alpha$. For what follows, let C_i and D_i be two sets of packets such that $|C_i| = |D_i| = p - \alpha$ and $C_i \cap A_i = \emptyset$, $D_i \cap A_i = \emptyset$, $C_i \cap B_i = \emptyset$, $D_i \cap B_i = \emptyset$, and $C_i \cap D_i = \emptyset$. Such sets exist since $|A_i| + |B_i| + |C_i| + |D_i| = 2p < 2^d$. Consider now the following gossiping protocol in H_{d+1}. Split H_{d+1} according to the value of the $(d+1)$th dimension in two subcubes H_d and H'_d of dimension d; during the first $t_d - 1$ rounds, gossip in H_d and H'_d separately. At the end of this phase each vertex knows $2^d - \alpha$ packets. Now, for each node x in H_d, denote by x' its neighbor in H'_d. In the next round, exchange p packets along dimension $d+1$ in such a way that x_i (resp., y_i, x'_i, y'_i) sends to x'_i (resp., y'_i, x_i, y_i) p packets including C_i (resp., D_i, C'_i, D'_i) and not D_i (resp., C_i, D'_i, C'_i).

In the next round, exchange p packets along the matching $\mathcal{M}$ in such a way that x_i (resp., y_i) sends to y_i (resp., x_i) packets in $B_i \cup C'_i$ (resp., $A_i \cup D'_i$), and x'_i (resp., y'_i) sends to y'_i (resp., x'_i) all packets in $B'_i \cup C_i$ (resp., $A'_i \cup D_i$). After the above $t_d + 1$ rounds we are sure that each vertex x_i (resp., x'_i) knows all the packets of the subcube it belongs to, and so we can finish the protocol by sending packets along dimension $d+1$ in such a way that p new packets are received during each round (except possibly the last final round). Therefore, for each t, with $1 \le t \le 1 + \lfloor 2^d/p \rfloor$, each node in H_{d+1} after round $t_d + t - 1 \le t_{d+1} - 1$ knows exactly $I(p, t_d - 1) + p\,t = I(p, t_d + t - 1)$ packets. Hence this protocol in H_{d+1} satisfies all the induction hypothesis. □

Remark 3.3. It is worth pointing out that the obvious inequality

$$g_{H_1}(p, G) \le 2 g_{F_1}(p, G) \tag{21}$$

and the above theorem allow us to improve the upper bound on $g_{H_1}(p, H_d)$ given by Theorem 4 of [4] for all values of p which are not powers of two. Indeed, the authors of [4] have $g_{H_1}(p, H_d) \le 2d + 2^{d+1}/p - 2/p$, while from Theorem 3.6 and (21), we get Theorem 3.7.

THEOREM 3.7. *For each integer* $p < 2^d$,

$$g_{H_1}(p, H_d) \le 2\lceil \log p \rceil + 2 \left\lceil \frac{1}{p}\left(2^d - 2^{\lceil \log p \rceil}\right) \right\rceil.$$

4. p-optimal graphs. In this section we consider the problem of estimating the minimum possible number of edges in any graph in which gossiping can be performed in the minimum possible number of rounds. We consider only networks with an even number of nodes. More formally, for any even integer n and integer p such that $2^{\lceil \log p \rceil} \le n$, let us denote by $g(p, n)$ the minimum gossiping time of any graph with n nodes, that is (cf. Theorem 3.3),

$$g(p, n) := \min_{G\,:\,|V(G)|=n} g(p, G) = \lceil \log p \rceil + \left\lceil \frac{n - 2^{\lceil \log p \rceil}}{p} \right\rceil,$$

and by $\mathcal{M}(p, n)$, the quantity

$$\mathcal{M}(p,n) := \min\{m \ : \text{ there exists } G=(V,E) \text{ with } |V|=n,\ |E|=m,\ g(p,G)=g(p,n)\}.$$

Our objective is to find significant bounds on the function $\mathcal{M}(p,n)$. From a practical point of view, an interconnection network G having gossiping time $g(p,G)=g(p,n)$ and $\mathcal{M}(p,n)$ edges represents the most economical network, if our main concern is the number of communication lines, that still preserves the communication capabilities of the complete graph, as far as gossiping is concerned. The analogous problem of estimating the minimum possible number of edges in a network in which broadcasting can be performed in minimum time has been extensively studied (see [5, 13] and references therein quoted). Estimating $\mathcal{M}(p,n)$ seems a much harder task. Even when p is unbounded, only few results are known [21].

DEFINITION 4.1. *Given a graph $G(V,E)$ on n nodes and an integer p such that $2^{\lceil \log p \rceil} \leq n$ we say that G is p-optimal if $g(p,G)=g(p,n)$ and $|E|=\mathcal{M}(p,n)$, that is, if G is a sparsest graph among all the graphs with n nodes and minimum gossiping time $g(p,n)$.*

We first consider the special cases $p=1$ and $p=2$ that admit a very simple solution, and afterwards we consider the general case, that is, $p \geq 3$.

4.1. Sending $p \leq 2$ items per round. We have shown in sections 2.2 and 3.2 that for the ring C_n on n nodes

$$g(1,C_n)=g(1,n)=2\left\lceil \frac{n}{2} \right\rceil - 1 \text{ and } g(2,C_n)=g(2,n)=\begin{cases} n/2 & \text{if } n \text{ is even,} \\ (n+3)/2 & \text{if } n \text{ is odd.} \end{cases}$$

Consider any connected graph (tree) G with n nodes and $m \leq n-1$ edges. The lower bound given in Corollary 2.2 tells us that $g(1,G) \geq 2n-3$. Moreover, it is easy to verify that the inequality $g(1,G) \leq 2g(2,G)-1$ holds. The above two inequalities imply that $g(1,G) > g(1,n) = n-1$ for each $n \geq 3$ and $g(2,G) \geq (g(1,G)+1)/2 \geq (2n-2)/2 = n-1 \geq g(2,n)$ for each $n \geq 2$ with $n \neq 3$. It is easy to see that P_3 is also optimal for $p=2$. We have then proved the following theorem.

THEOREM 4.1. *$\mathcal{M}(1,2)=\mathcal{M}(2,2)=1$, $\mathcal{M}(1,3)=3$, $\mathcal{M}(2,3)=2$, and for each $n \geq 4$*

$$\mathcal{M}(1,n)=\mathcal{M}(2,n)=n.$$

4.2. Sending $p \geq 3$ items per round. In this section we study p-optimal graphs for $p \geq 3$. We recall that such graphs are to be sought among those graphs having gossiping time equal to $g(p,n)$. Let us first recall that for each $p \geq 3$ the ring C_n is not p-optimal; indeed, from the results of section 3.2 we have $\min_q g(q,C_n) = g(2,C_n) > g(p,n)$.

We have proved in section 3.4 that the hypercube H_d has minimum gossiping time for each value of p; moreover, it was shown in [21] that H_d is p-optimal for each $p \geq 2^{d-1}$ (equivalently, for p unbounded); that is, H_d has the minimum number of edges among all the networks with gossiping time $g(\infty,2^d)=d$. A natural question is whether the hypercube is p-optimal for other values of $p < 2^{d-1}$. The results of section 4.3 will imply a negative answer to the above question.

Let $d(p,n)$ be the minimum possible degree a node can have in any p-optimal graph on n nodes.

THEOREM 4.2. $d(p,n) \geq \lfloor \log p \rfloor + 1 - \left\lfloor \log \left(\left\lceil \frac{n-2^{\lceil \log p \rceil}}{p} \right\rceil p - n + 2^{\lceil \log p \rceil} + 1 \right) \right\rfloor$.

Proof. Denote by $r(p,t)$ the maximum number of items a node can receive with a call made at round t, and by $I(p,t) = 1 + \sum_{i=1}^{t} r(p,i)$, the maximum possible number of items a node can have received by round t. We recall that $I(p,0) = r(p,1) = 1$ and

$$r(p,t) = \max\{2^{t-1}, p\}$$

and

$$I(p,t) = \begin{cases} 2^t & \text{if } t \leq \lfloor \log p \rfloor + 1, \\ 2^{\lfloor \log p \rfloor + 1} + (t - \lfloor \log p \rfloor - 1)p & \text{if } t > \lfloor \log p \rfloor + 1. \end{cases}$$

Fix any gossiping protocol $\mathcal{P}$ that completes in $g(p,n)$ rounds. We denote by $r(p,t,v)$ the number of items node v receives at round t of $\mathcal{P}$ and let

$$I(p,t,v) = 1 + \sum_{i=1}^{t} r(p,i,v);$$

obviously $r(p,t,v) \leq r(p,t)$ and $I(p,t,v) \leq I(p,t)$ for each $t = 1, \ldots, g(p,n)$.

In order to prove the desired lower bound on $d(p,n)$ we show that any node has to make calls with at least $\lfloor \log p \rfloor + 1 - \left\lfloor \log \left(\left\lceil \frac{n-2^{\lceil \log p \rceil}}{p} \right\rceil p - n + 2^{\lceil \log p \rceil} + 1 \right) \right\rfloor$ *different* neighbors during the first $\lfloor \log p \rfloor + 1$ rounds of the protocol $\mathcal{P}$.

Fix a node v and suppose that v communicates with $\lfloor \log p \rfloor + 1 - \ell$ different neighbors during the first $\lfloor \log p \rfloor + 1$ rounds of $\mathcal{P}$. This means that there exist ℓ rounds, say $\tau_1, \ldots, \tau_\ell$, such that for each $i = 1, \ldots, \ell$ at round τ_i, v is either idle or makes a call with a node that will communicate again with v at some round δ_i with $\tau_i < \delta_i \leq \lfloor \log p \rfloor + 1$; we can bound $r(p, \tau_i, v)$ as follows.

i) If v does not participate in any call at round τ_i, then $r(p, \tau_i, v) = 0$.

ii) If v makes calls with a particular node, say w, at both rounds τ_i and δ_i, then at time δ_i node v will not receive again what it received at time τ_i from w, nor will it receive what it sent to w at time τ_i. Therefore, $r(p, \delta_i, v) \leq I(p, \delta_i - 1, w) - r(p, \tau_i, v) - r(p, \tau_i, w)$; that is,

$$r(p, \tau_i, v) + r(p, \delta_i, v) \leq I(p, \delta_i - 1, w) \leq 2^{\delta_i - 1} = r(p, \delta_i).$$

By i) and ii) we get that for each round $t \geq \lfloor \log p \rfloor + 1$,

$$\begin{aligned} I(p,t,v) = 1 + \sum_{i-1}^{t} r(p,i,v) &\leq I(p,t) - \sum_{i=1}^{\ell} 2^{\tau_i - 1} \\ &= 2^{\lfloor \log p \rfloor + 1} + (t - \lfloor \log p \rfloor - 1)p - \sum_{i=1}^{\ell} 2^{\tau_i - 1}. \end{aligned}$$

Recalling that n is even and the graph has minimum gossiping time $g(p,n) = \lceil \log p \rceil + \left\lceil \frac{n-2^{\lceil \log p \rceil}}{p} \right\rceil = \lfloor \log p \rfloor + 1 + \left\lceil \frac{n-2^{\lfloor \log p \rfloor + 1}}{p} \right\rceil$, the following inequality must be satisfied:

$$n \leq I(p, g(p,n)) - \sum_{i=1}^{\ell} 2^{\tau_i - 1} = 2^{\lfloor \log p \rfloor + 1} - \sum_{i=1}^{\ell} 2^{\tau_i - 1} + \left\lceil \frac{n - 2^{\lfloor \log p \rfloor + 1}}{p} \right\rceil p.$$

Noticing that $\sum_{i=1}^{\ell} 2^{\tau_i - 1} \leq \sum_{i=1}^{\ell} 2^{i-1} = 2^\ell - 1$, we get

$$\ell \leq \left\lfloor \log \left(\left\lceil \frac{n - 2^{\lfloor \log p \rfloor + 1}}{p} \right\rceil p - n + 2^{\lfloor \log p \rfloor + 1} + 1 \right) \right\rfloor$$

and the desired bound on $d(n,p)$ follows. □

4.3. A family of graphs with $O(\frac{n}{2} \log p)$ edges. In section 3.3 we have proved that $g(p, K_n) = g(p,n)$ for any even n and any p. Moreover, it is easy to see that in order to implement the gossiping protocol of Figure 9, only $O\left(n\left(\frac{n}{p} + \log p\right)\right)$ edges of K_n are needed. This implies that $\mathcal{M}(p,n) = O\left(n\left(\frac{n}{p} + \log p\right)\right)$. Actually, we can prove a much better bound. We will construct for any p and even n a graph $G_{p,n}$ with n nodes, $n(\lceil \log p \rceil + 1)/2$ edges, and optimal gossiping time $g(p, G_{p,n}) = g(p,n)$.

Let p be an even integer and define the sequence of integers $\mathbf{s}_p$ as follows: $\mathbf{s}_2 = (-1, 1)$ and for each $p = 2^m + q$ with $q \leq 2^m$, if $\mathbf{s}_{2^m} = (s_1, \ldots, s_{m+1})$, then

$$\mathbf{s}_p = (s_1, \ldots, s_{m+1}, s_{m+2}) \quad \text{with } s_{m+2} = \begin{cases} p + s_{m+1} & \text{if } m \text{ is even,} \\ -(p - s_{m+1}) & \text{if } m \text{ is odd.} \end{cases}$$

If p is odd define $\mathbf{s}_p = \mathbf{s}_{p+1}$.

Example 4.1. $\mathbf{s}_2 = (-1,1)$, $\mathbf{s}_3 = \mathbf{s}_4 = (-1,1,-3)$, $\mathbf{s}_5 = \mathbf{s}_6 = (-1,1,-3,3)$, $\mathbf{s}_7 = \mathbf{s}_8 = (-1,1,-3,5)$, $\mathbf{s}_9 = \mathbf{s}_{10} = (-1,1,-3,5,-5)$, $\mathbf{s}_{11} = \mathbf{s}_{12} = (-1,1,-3,5,-7)$. Let the node set be $V_n = \{0, 1, \ldots, n-1\}$. All operations on nodes will be performed modulo n. Define the matching

$$M_{p,n}(t) = \{(v, v + s_t) \mid v \in V_n \text{ is odd}\} \quad \text{for } t = 1 \ldots, \lceil \log p \rceil + 1,$$

and the graph $G_{p,n} = (V_n, E_{p,n})$ with $E_{p,n} = \cup_{t=1}^{\lceil \log p \rceil + 1} M_{p,n}(t)$; Figure 11 shows $G_{6,14}$.

One can check that at the end of the algorithm **Gossiping**$(G_{p,n})$, given in Figure 12, any node knows the packets of all the other nodes in $G_{p,n}$. Therefore, using Theorem 4.2, we get Theorem 4.3.

THEOREM 4.3. *For each integer p and even integer $n \geq 2^{\lceil \log p \rceil}$*

$$\tfrac{n}{2}\left(\lfloor \log p \rfloor + 1 - \left\lfloor \log \left(\left\lceil \tfrac{n - 2^{\lceil \log p \rceil}}{p} \right\rceil p - n + 2^{\lceil \log p \rceil} + 1 \right) \right\rfloor\right) \leq \mathcal{M}(p,n) \leq \tfrac{n}{2}(\lceil \log p \rceil + 1).$$

COROLLARY 4.1. *For each $p \geq 2$ and even integer n such that $n - 2^{\lceil \log p \rceil}$ is a multiple of p,*

$$\frac{n}{2}(\lfloor \log p \rfloor + 1) \leq \mathcal{M}(p,n) \leq \frac{n}{2}(\lceil \log p \rceil + 1).$$

COROLLARY 4.2. *For each integer $q \geq 1$ and integer $r \geq 2$,*

$$\mathcal{M}(2^q, r2^q) = r2^{q-1}(q+1).$$

It is possible to improve the lower bound given in Theorem 4.2 proving that $d(2^q - 1, n) \geq q + 1 - \lfloor \log (\lceil (n-1)/(2^q - 1) \rceil (2^q - 1) - n + 2) \rfloor$, which together with Theorem 4.3 implies the following corollary.

COROLLARY 4.3. *For each integer $q \geq 1$ and odd integer r,*

$$\mathcal{M}(2^q - 1, r(2^q - 1) + 1) = (r(2^q - 1) + 1)(q+1)/2.$$

FIG. 11.

Gossiping($G_{p,n}$)

Let $\mathbf{s}_p = (s_1, \ldots, s_{\lceil \log p \rceil + 1})$;
At round t, $t = 1, \ldots, \lceil \log p \rceil + 1$, each node sends $\max\{2^{t-1}, p\}$ new items to its neighbor in $M_{p,n}(t)$;
At round $t = \lceil \log p \rceil + 1 + \tau$, $\tau = 1, \ldots, g(p,n) - \lceil \log p \rceil - 1$, consider the matching

$$M_{p,n}(t) = \begin{cases} M_{p,n}(\lceil \log p \rceil) & \text{if } \tau \text{ is odd,} \\ M_{p,n}(\lceil \log p \rceil + 1) & \text{if } \tau \text{ is even;} \end{cases}$$

then each node sends p new items (or fewer than p in the last round) to its neighbor in $M_{p,n}(t)$.

FIG. 12. *Gossiping algorithm in* $G_{p,n}$.

5. Concluding remarks and open problems. We have considered the problem of gossiping in communication networks under the restriction that communicating nodes can exchange up to a fixed number p of packets at each round. In the extremal case $p = 1$ we have given optimal algorithms to perform gossiping in several classes of graphs, including Hamiltonian graphs, paths, complete k-ary trees, and complete bipartite graphs. For arbitrary graphs we gave asymptotically matching upper and lower bounds.

In the case of arbitrary p we have determined the optimal number of communication rounds to perform gossiping under this hypothesis for complete graphs, hypercubes, rings, paths, and complete bipartite graphs $K_{r,r}$.

Several open problems remain in the area. We list the most important of them here.

• It would be interesting to determine the computational complexity of computing $g_{F_1}(1, G)$ ($g_{F_1}(p, G)$) for general graphs; it is very likely that it is NP-hard. (We know that computing $g_{F_1}(\infty, G)$ is NP-hard; see [20].)

• We have left open the problem of determining the gossiping time $g_{F_1}(1, G_{t,s})$, and more generally $g_{F_1}(p, G_{t,s})$, of rectangular grids $G_{t,s}$ with both t and s odd. We know from Corollary 2.1 that $g_{F_1}(1, G_{t,s}) \geq st + 1$. Does equality hold? We can prove that $g_{F_1}(1, G_{3,3}) = 10$. A general upper bound on $g_{F_1}(1, G_{t,s})$ can be obtained by observing that $G_{t,s} = P_t \times P_s$, where P_t and P_s are the paths on t and s nodes, respectively, and $\times$ denotes the cartesian graph product. Now, given two graphs $G = (V, E)$ and $H = (W, F)$, it is easy to see that $g_{F_1}(1, G \times H) \leq \min\{g_{F_1}(1, G) + |V| g_{F_1}(1, H),\ g_{F_1}(1, H) + |W| g_{F_1}(1, G)\}$, which, together with Corollary 2.5, immediately gives $g_{F_1}(1, G_{t,s}) \leq 2ts - 3 - \max\{t, s\}$.

• We know from (4) that for any graph G with n vertices one has $g_{F_1}(1, G) \geq n$ if n is odd, $g_{F_1}(1, G) \geq n - 1$ if n is even, and from Theorem 2.1, we get that the equality holds for Hamiltonian graphs. It would be interesting to characterize the class of graphs for which this lower bound is tight. We know from the results of section 2.5 that this class is larger than the class of the Hamiltonian graphs.

• In view of the possible NP-hardness of computing $g(p, G)$ for arbitrary graphs, it would be interesting to design efficient algorithms to compute gossiping protocols that complete in time "close" to $g(p, G)$. Such algorithms have recently been provided for $g(\infty, G)$ (see [14, 23]). However, the techniques used there do not seem to apply to the case of bounded p.

• We have given fairly tight bounds on the function $\mathcal{M}(p, n)$. It would be interesting to study the analogous quantity $\mathcal{M}_c(p, n)$ equal to the minimum number of edges in any graph in which gossiping can be performed in quasi-optimal time $g(p, n) + c$, where c is a small constant. In particular, we ask whether $\mathcal{M}_1(p, n) = O(n)$.

Acknowledgments. The authors wish to thank R. Ravi for the proof of Theorem 2.3. They also want to thank Levon Khachatrian and Jonny Bond for interesting discussions. The first author would like to thank the Dipartimento di Informatica ed Applicazioni, Università di Salerno, Italy, where part of this research was conducted, for inviting him.

APPROXIMATION ALGORITHMS FOR THE FEEDBACK VERTEX SET PROBLEM WITH APPLICATIONS TO CONSTRAINT SATISFACTION AND BAYESIAN INFERENCE*

REUVEN BAR-YEHUDA†‡, DAN GEIGER†, JOSEPH (SEFFI) NAOR†§, AND RON M. ROTH†

Abstract. A *feedback vertex set* of an undirected graph is a subset of vertices that intersects with the vertex set of each cycle in the graph. Given an undirected graph G with n vertices and weights on its vertices, polynomial-time algorithms are provided for approximating the problem of finding a feedback vertex set of G with smallest weight. When the weights of all vertices in G are equal, the performance ratio attained by these algorithms is $4-(2/n)$. This improves a previous algorithm which achieved an approximation factor of $O(\sqrt{\log n})$ for this case. For general vertex weights, the performance ratio becomes $\min\{2\Delta^2, 4\log_2 n\}$ where Δ denotes the maximum degree in G. For the special case of planar graphs this ratio is reduced to 10. An interesting special case of weighted graphs where a performance ratio of $4-(2/n)$ is achieved is the one where a prescribed subset of the vertices, so-called *blackout* vertices, is not allowed to participate in any feedback vertex set.

It is shown how these algorithms can improve the search performance for constraint satisfaction problems. An application in the area of Bayesian inference of graphs with blackout vertices is also presented.

1. Introduction.

Let $G=(V,E)$ be an undirected graph and let $w: V(G) \to \mathbb{R}^+$ be a weight function on the vertices of G. A *cycle* in G is a path whose two terminal vertices coincide. A *feedback vertex set* of G is a subset of vertices $F \subseteq V(G)$ such that each cycle in G passes through at least one vertex in F. In other words, a feedback vertex set F is a set of vertices of G such that by removing F from G, along with all the edges incident with F, a forest is obtained. A *minimum feedback vertex set of a weighted graph* (G,w) is a feedback vertex set of G of minimum weight. The weight of a minimum feedback vertex set will be denoted by $\mu(G,w)$.

The *weighted feedback vertex set (WFVS) problem* is defined as finding a minimum feedback vertex set of a given weighted graph (G,w). The special case where w is the constant function 1 is called the *unweighted feedback vertex set (UFVS) problem.* Given a graph G and an integer k, the problem of deciding whether $\mu(G,1) \le k$ is known to be NP-complete [GJ79, pp. 191–192]. Hence, it is natural to look for efficient approximation algorithms for the feedback vertex set problem, particularly

in view of the recent applications of such algorithms in artificial intelligence, as we show in the sequel.

Suppose A is an algorithm that finds a feedback vertex set F_A for any given undirected weighted graph (G, w). We denote the sum of weights of the vertices in F_A by $w(F_A)$. The *performance ratio of A for (G, w)* is defined by $R_A(G, w) = w(F_A)/\mu(G, w)$. When $\mu(G, w) = 0$ we define $R_A(G, w) = 1$ if $w(F_A) = 0$ and $R_A(G, w) = \infty$ if $w(F_A) > 0$. The *performance ratio $r_A(n, w)$ of A for w* is the supremum of $R_A(G, w)$ over all graphs G with n vertices and for the same weight function w. When w is the constant function 1, we call $r_A(n, 1)$ the *unweighted performance ratio of A*. Finally, the *performance ratio $r_A(n)$ of A* is the supremum of $r_A(n, w)$ over all weight functions w defined over graphs with n vertices.

An approximation algorithm for the UFVS problem that achieves an unweighted performance ratio of $2 \log_2 n$ is essentially contained in a lemma due to Erdős and Pósa [EP62]. This result was improved by Monien and Schulz [MS81], where they achieved a performance ratio of $O(\sqrt{\log n})$.

In section 2, we provide an approximation algorithm for the UFVS problem that achieves an unweighted performance ratio of at most $4 - (2/n)$. Our algorithm draws upon a theorem by Simonovits [Si67], and our analysis uses a result by Voss [Vo68]. Actually, we consider a generalization of the UFVS problem, where a prescribed subset of the vertices, called *blackout vertices*, is not allowed to participate in any feedback vertex set. This problem is a subcase of the WFVS problem wherein each allowed vertex has unit weight and each blackout vertex has infinite weight. Our interest in graphs with blackout vertices is motivated by the *loop cutset* problem and its application to the updating problem in Bayesian inference which is explored in section 4.

In section 3, we present two algorithms for the WFVS problem. We first devise a primal-dual algorithm which is based on formulating the WFVS problem as an instance of the *set cover* problem. The algorithm has a performance ratio of 10 for weighted planar graphs and $4 \log_2 n$ for general weighted graphs. This ratio is achieved by extending the Erdős-Pósa lemma to weighted graphs. The second algorithm presented in section 3 achieves a performance ratio of $2\Delta^2(G)$ for general weighted graphs, where $\Delta(G)$ is the maximum degree of G. This result is interesting for low-degree graphs.

A notable application of approximation algorithms for the UFVS problem in artificial intelligence due to Dechter and Pearl is as follows [DP87, De90]. We are given a set of variables $x_1, x_2, \ldots, x_n$, where each x_i takes its values from a finite domain D_i. Also, for every $i < j$ we are given a constraint subset $R_{i,j} \subseteq D_i \times D_j$ which defines the allowable pairs of values that can be taken by the pair of variables (x_i, x_j). Our task is to find an assignment for all variables such that all the constraints $R_{i,j}$ are satisfied. With each instance of the problem we can associate an undirected graph G whose vertex set is the set of variables, and for each constraint $R_{i,j}$ which is *strictly* contained in $D_i \times D_j$ (i.e., $R_{i,j} \neq D_i \times D_j$) there is an edge in G connecting x_i and x_j. The resulting graph G is called a *constraint network* and it is said to represent a *constraint satisfaction problem*.

A common method for solving a constraint satisfaction problem is by backtracking, that is, by repeatedly assigning values to the variables in a predetermined order and then backtracking whenever reaching a dead end. This approach can be improved as follows. First, find a feedback vertex set of the constraint network. Then, arrange the variables so that variables in the feedback vertex set precede all other variables and

apply the backtracking procedure. Once the values of the variables in the feedback vertex set are determined by the backtracking procedure, the algorithm switches to a polynomial-time procedure SOLVE-TREE that solves the constraint satisfaction problem in the remaining forest. If SOLVE-TREE succeeds, a solution is found; otherwise, another backtracking phase occurs.

The complexity of the above modified backtracking algorithm grows exponentially with the size of the feedback vertex set: if a feedback vertex set contains k variables, each having a domain of size 2, then the procedure SOLVE-TREE might be invoked up to 2^k times. A procedure SOLVE-TREE that runs in polynomial time was developed by Dechter and Pearl, who also proved the optimality of their tree algorithm [DP88]. Consequently, our approximation algorithm for finding a small feedback vertex set reduces the complexity of solving constraint satisfaction problems through the modified backtracking algorithm. Furthermore, if the domain size of the variables varies, then SOLVE-TREE is called a number of times which is bounded from above by the product of the domain sizes of the variables whose corresponding vertices participate in the feedback vertex set. If we take the logarithm of the domain size as the weight of a vertex, then solving the WFVS problem with these weights optimizes the complexity of the modified backtracking algorithm in the case where the domain size is allowed to vary.

2. The UFVS problem. The best approximation algorithm prior to this work for the UFVS problem attained a performance ratio of $O(\sqrt{\log n})$ [MS81]. We now use some results of [Si67] and [Vo68] in order to obtain an approximation algorithm for the UFVS problem which attains a performance ratio ≤ 4. In fact, we actually consider a slight generalization of the UFVS problem where we mark each vertex of a graph as either an *allowed vertex* or a *blackout vertex*. In such graphs, feedback vertex sets cannot contain any blackout vertices. We denote the set of allowed vertices in G by $A(G)$ and the set of blackout vertices by $B(G)$. Note that when $B(G) = \emptyset$, this problem reduces to the UFVS problem. A feedback vertex set can be found in a graph G with blackout vertices if and only if every cycle in G contains at least one allowed vertex. A graph G with this property will be called a *valid graph*. The motivation for dealing with this modified problem is clarified in section 4 where we use the algorithm developed herein to reduce the computational complexity of Bayesian inference.

Throughout this section, G denotes a valid graph with a nonempty set of vertices $V(G)$ which is partitioned into a nonempty set $A(G)$ of allowed vertices, a possibly empty set $B(G)$ of blackout vertices, and a set of edges $E(G)$ possibly with parallel edges and self-loops. We use $\mu_a(G)$ as a shorthand notation for $\mu(G, w)$ where w assigns unit weight to each allowed vertex and an infinite weight to each blackout vertex. A *neighbor* of v is a vertex $u \in V(G)$ which is connected to v by an edge in $E(G)$. The degree $\Delta_G(v)$ of v in G is the number of edges that are incident with v in G. A self-loop at a vertex v contributes 2 to the degree of v. The degree of G, denoted $\Delta(G)$, is the largest among all degrees of vertices in G. A vertex in G of degree 1 is called an *endpoint*. A vertex of degree 2 is called a *linkpoint* and a vertex of any higher degree is called a *branchpoint*. A graph G is called *rich* if every vertex in $V(G)$ is a branchpoint. The notation $\Delta_a(G)$ will stand for the largest among all degrees of vertices in $A(G)$ (a degree of a vertex in $A(G)$ takes into account all incident edges, including those that lead to neighbors in $B(G)$). In a rich valid graph we have $\Delta_a(G) \geq 3$.

Two cycles in a valid graph G are *independent* if their vertex sets share only blackout vertices. Note that the size of any feedback vertex set of G is bounded from

below by the largest number of pairwise independent cycles that can be found in G. A cycle Γ in G is called *simple* if it visits every vertex in $V(G)$ at most once. Clearly, a set F is a feedback vertex set of G if and only if it intersects with every simple cycle in G. A graph is called a *singleton* if it contains only one vertex. A singleton is called *self-looped* if it contains at least one self-loop; for a singleton we have $\mu(G,1) = 1$ if it is self-looped and $\mu(G,1) = 0$ otherwise.

A graph G is connected if for every two vertices there is a connecting path in G. Every graph G can be uniquely decomposed into isolated connected components $G_1, G_2, \ldots, G_k$. Similarly, every feedback vertex set F of G can be partitioned into feedback vertex sets $F_1, F_2, \ldots, F_k$ such that F_i is a feedback vertex set of G_i. Hence, $\mu_a(G) = \sum_{i=1}^{k} \mu_a(G_i)$.

A 2-3-*subgraph* of a valid graph G is a subgraph H of G such that the degree in H of every vertex in $A(G)$ is either 2 or 3. The degree of a vertex belonging to $B(G)$ in H is not restricted. A 2-3-subgraph exists in any valid graph which is not a forest. A *maximal* 2-3-*subgraph* of G is a 2-3-subgraph of G which is not a subgraph of any other 2-3-subgraph of G. A maximal 2-3-subgraph can be easily found by applying depth-first search (DFS) on G.

A linkpoint v in a 2-3-subgraph H is called a *critical linkpoint* if v is an allowed vertex, and there is a cycle Γ in G such that $V(\Gamma) \cap V(H) \cap A(G) = \{v\}$. We refer to such a cycle Γ in G as a *witness cycle of* v. Note that we can assume a witness cycle to be simple and, so, verifying whether a linkpoint v in H is a critical linkpoint is easy: remove the set of vertices $(V(H) \cap A(G)) - \{v\}$ from G, with all incident edges, and apply a breadth-first search (BFS) to check whether there is a cycle through v in the remaining graph.

A cycle in a valid graph G is *branchpoint-free* if it does not pass through any allowed branchpoints; that is, a branchpoint-free cycle passes only through allowed linkpoints and blackout vertices of G.

The rest of this section is devoted to showing that the following algorithm correctly outputs a vertex feedback set and achieves an unweighted performance ratio less than 4.

ALGORITHM SUBG-2-3(*Input:* valid graph G; *Output:* feedback vertex set F of G);
if G is a forest then
    $F \leftarrow \emptyset$;
else begin:
    Using DFS, find a maximal 2-3-subgraph H of G;
    Using BFS, find the set X of critical linkpoints in H;
    Let Y be the set of allowed branchpoints in H;
    Find a set W that covers all branchpoint-free cycles of H which
        are not covered by X;
    $F \leftarrow X \cup Y \cup W$;
end.

Note that if $B(G) = \emptyset$, then all branchpoint-free cycles are isolated cycles in H and so W consists of one vertex of each such cycle.

We elaborate on how the set W is computed when $B(G) \neq \emptyset$. Let H' be a graph obtained from H by removing the set X along with its incident edges. Let H_b be the subgraph of H' induced by the allowed linkpoints and blackout vertices of H'. For every isolated cycle in H_b, we arbitrarily choose an allowed linkpoint from that cycle to W. Next, we replace each maximal (with respect to containment) chain of allowed

linkpoints in H_b by an edge, resulting in a graph H_b^*. We assign unit cost to all edges corresponding to a chain of allowed linkpoints, and a zero cost to all other edges, and compute a minimum-cost spanning forest T of H_b^*. We now add to W one linkpoint from each chain of allowed linkpoints in H_b that corresponds to an edge in $H_b^* - T$. It is now straightforward to verify that the complexity of SubG-2-3 is linear in $|E(G)|$.

The following two lemmas, which generalize some claims used in the proof of Theorem 1 in [Si67], are used to prove that SubG-2-3 outputs a feedback vertex set of a valid graph G.

LEMMA 1. *Let H be a maximal 2-3-subgraph of a valid graph G and let Γ be a simple cycle in G. Then, one of the following holds:*

(a) *Γ is a witness cycle of some critical linkpoint of H or*

(b) *Γ passes through some allowed branchpoint of H or*

(c) *Γ is a cycle in H that consists only of blackout vertices or allowed linkpoints of H.*

Proof. Let Γ be a simple cycle in G and assume to the contrary that neither of (a)–(c) holds. This implies in particular that Γ cannot be entirely contained in H. We distinguish between two cases: (1) Γ does not intersect with H and (2) Γ intersects with H only in blackout vertices and allowed linkpoints of H.

Case 1. In this case we could join Γ and H to obtain a 2-3-subgraph H^* of G that contains H as a proper subgraph. This however contradicts the maximality of H.

Case 2. If Γ intersects with H only in blackout vertices, then as in Case 1, we can join Γ and H and contradict the maximality of H. Suppose now that Γ intersects with H in some allowed linkpoints of H. Note that in such a case Γ must intersect with H in at least two distinct allowed linkpoints of H, or else Γ would be a witness cycle of the only intersecting (critical) linkpoint. Since Γ is not contained in H by assumption, we can find two allowed linkpoints v_1 and v_2 in $V(\Gamma) \cap V(H)$ that are connected by a path P along Γ such that $V(P) \cap V(H) \cap A(G) = \{v_1, v_2\}$ and P is not entirely contained in H. Joining P and H, we obtain a 2-3-subgraph of G that contains H as a proper subgraph, thus contradicting the maximality of H. □

LEMMA 2. *Let H be a maximal 2-3-subgraph of G and let Γ_1 and Γ_2 be witness cycles in G of two distinct critical linkpoints in H. Then Γ_1 and Γ_2 are independent cycles, namely, $V(\Gamma_1) \cap V(\Gamma_2) \subseteq B(G)$.*

Proof. Let v_1 and v_2 be the critical linkpoints associated with Γ_1 and Γ_2, respectively, and assume to the contrary that $V(\Gamma_1) \cap V(\Gamma_2)$ contains an allowed vertex $u \in A(G)$. Then, there is a path P in G that runs along parts of the cycles Γ_1 and Γ_2, starting from v_1, passing through u, and ending at v_2. Since Γ_1 and Γ_2 are witness cycles, we have $V(P) \cap V(H) \cap A(G) = \{v_1, v_2\}$. And, since v_1 and v_2 are distinct critical linkpoints, the vertex u cannot possibly coincide with either of them. Therefore, the path P is not entirely contained in H. Joining P and H we obtain a 2-3-subgraph of G that contains H as a proper subgraph, thus reaching a contradiction. □

THEOREM 3. *For every valid graph G, the set F computed by* SubG-2-3 *is a feedback vertex set of G.*

Proof. Let Γ be a simple cycle in G. We follow the three cases of Lemma 1 to show that $V(\Gamma) \cap F \neq \emptyset$.

(a) *Γ is a witness cycle of some critical linkpoint of H.* By construction, all critical linkpoints of H are in F.

(b) *Γ passes through some allowed branchpoint of H.* By construction, all allowed branchpoints of H are in F.

(c) Γ *is a cycle in* H *that consists only of blackout vertices or allowed linkpoints of* H. When $V(\Gamma)$ contains a critical linkpoint, then SubG-2-3 selects that linkpoint into the feedback vertex set F. Otherwise, the cycle Γ must be entirely contained in the graph H_b that was used to create W. We now show that W covers all cycles in H_b. Assume the contrary and let Γ be a cycle in H_b that is not covered by W. Recall that in the construction of H_b^*, each chain of allowed linkpoints in Γ was replaced by an edge with a unit cost. Let Γ^* be the resulting cycle in H_b^*. Since W does not cover Γ, all unit-cost edges in Γ^* were necessarily chosen to the minimum-cost spanning forest T. On the other hand, since T does not contain any cycles, there must be at least one zero-cost edge of Γ^* which is not contained in T. Hence, by deleting one of the unit-cost edges of Γ^* from T and inserting instead a particular zero-cost edge of Γ^* into T, we can obtain a new spanning forest T' for H_b^*. However, the cost of T' is smaller than that of T, which contradicts our assumption that T is a minimum-cost spanning forest. □

A *reduction graph* G' of an undirected graph G is a graph obtained from G by a sequence of the following transformations:

- Delete an endpoint and its incident edge.
- Connect two neighbors of a linkpoint v (other than a self-looped singleton) by a new edge and remove v from the graph with its two incident edges.

A reduction graph of a valid graph G is not necessarily valid, since the reduction process may generate a cycle consisting of blackout vertices only. We will be interested in reduction sequences in which each transformation yields a valid graph.

Lemma 4. *Let* G' *be a reduction graph of* G. *If* G' *is valid, then* $\mu_a(G') = \mu_a(G)$.

Proof. Let $H_1 = G, H_2, \ldots, H_{t-1}, H_t = G'$ be a sequence of reduction graphs where each H_i is obtained by a removal of one linkpoint and possibly some endpoints from H_{i-1}. Since G' is valid, each H_i is a valid graph as well. Let v_i be the linkpoint that is removed from H_i to obtain H_{i+1}.

First we show that $\mu_a(G') \geq \mu_a(G)$. Suppose F is a feedback vertex set of H_{i+1} for some i, $1 \leq i < t$ and let Γ be a cycle in H_i that passes through v_i. A reduction of Γ obtained by replacing the linkpoint v_i on Γ by an edge connecting the neighbors of v_i yields a cycle $\hat{\Gamma}$ in H_{i+1}. The vertex set of $\hat{\Gamma}$ intersects the set F. Hence, F is also a feedback vertex set of H_i which implies that $\mu_a(H_{i+1}) \geq \mu_a(H_i)$.

Now we show that $\mu_a(G') \leq \mu_a(G)$. Suppose F is a minimal feedback vertex set of H_i. If F does not contain v_i, then F is also a feedback vertex set of H_{i+1}. Otherwise, write $F = \{v_i\} \cup F'$. We claim that the set F' cannot fail to cover more than one cycle in H_{i+1}. If it failed, then there would be two distinct cycles Γ_1 and Γ_2 in H_i that contain v_i, in which case the cycle in H_i induced by $(V(\Gamma_1) \cup V(\Gamma_2)) - \{v_i\}$ would not be covered by F, thus contradicting the fact that F is a feedback vertex set of H_i. It follows by this and the minimality of F that the set F' fails to cover *exactly* one cycle in H_{i+1}. This cycle contains at least one allowed vertex u because H_{i+1} is a valid graph. Therefore, the set $F' \cup \{u\}$ is a feedback vertex set of H_{i+1}. Hence, $\mu_a(H_{i+1}) \leq \mu_a(H_i)$. □

A reduction graph G^* of a graph G is *minimal* if and only if G^* is a valid graph and any proper reduction graph G' of G^* is not valid.

Lemma 5. *If* G^* *is a minimal reduction graph of* G, *then* G^* *does not contain blackout linkpoints, and every feedback vertex set of* G^* *contains all allowed linkpoints of* G^*.

Proof. Recall that G^* is a valid graph. If G^* contains a blackout linkpoint, then its removal creates a valid reduction graph which contradicts the minimality of G^*.

Now assume F is a feedback vertex set of G^* and v is an allowed linkpoint which is not in F. If the removal of v yields a graph that is not valid, then v must have been included in F. If the removal of v yields a valid graph, then G^* is not minimal. □

The next lemma is needed in order to establish the performance ratio of SubG-2-3. It is a variant of Lemma 4 in [Vo68].

LEMMA 6. *Let G be a valid graph with no blackout linkpoints and such that no vertex has degree less than 2. Then, for every feedback vertex set F of G which contains all linkpoints of G,*

$$|V(G)| \;\leq\; (\Delta_a(G)+1)\,|F| \;-\; 2\,.$$

Proof. Suppose $F = V(G)$. In this case we have $|V(G)| \leq 3|V(G)| - 2 \leq (\Delta_a(G)+1)|V(G)| - 2$ and, therefore, the lemma holds trivially. So we assume from now on that $|F| < |V(G)|$.

Let E_F denote the set of edges in $E(G)$ whose terminal vertices are all vertices in F. Define $X = V - F$ and let E_X denote the set of edges in $E(G)$ whose terminal vertices are all vertices in X. Also, let $E_{F,X}$ denote the set of those edges in G that connect vertices in F with vertices in X. Clearly, E_F, E_X, and $E_{F,X}$ form a partition on $E(G)$. Now, the graph obtained by deleting F from G is a nonempty forest on X and, therefore, $|E_X| \leq |X| - 1$. However, each vertex in X is a branchpoint in G because all linkpoints are assumed to be in F and there are no vertices of degree less than 2. Therefore,

$$3\,|X| \;\leq\; \sum_{v\in X} \Delta_G(v) \;=\; |E_{F,X}| \;+\; 2\,|E_X| \;\leq\; |E_{F,X}| \;+\; 2\,(|X|-1)$$

i.e.,

$$|E_{F,X}| \;\geq\; |X| \;+\; 2 \;=\; |V(G)| \;-\; |F| \;+\; 2\,.$$

On the other hand,

$$\Delta_a(G)\,|F| \;\geq\; \sum_{v\in F} \Delta_G(v) \;=\; |E_{F,X}| \;+\; 2\,|E_F|\,.$$

Combining the last two inequalities we obtain

$$|V(G)| \;\leq\; (\Delta_a(G)+1)\,|F| \;-\; 2\,|E_F| \;-\; 2\,. \qquad \square$$

The main claim of this section now follows.

THEOREM 7. *The unweighted performance ratio of* SubG-2-3 *is at most* $4 - (2/|V(G)|)$.

Proof. Let F be the feedback vertex set computed by SubG-2-3 for a valid graph G which is not a forest. We show that $|F| \;\leq\; 4\,\mu_a(G) \;-\; 2$. The theorem follows immediately from this inequality.

Let H, X, Y, and W be as in SubG-2-3. Suppose $\mu_a(G) = 1$. Then, all cycles in G pass through some allowed vertex v in G and, so, no vertex other than v can be a critical linkpoint in H. Now, if v is a linkpoint in H, then H is a cycle. Otherwise, one can readily verify that H must contain exactly two branchpoints. In either case we have $|F| \leq 2$. We assume from now on that $\mu_a(G) \geq 2$.

For every $v_i \in X$, let Γ_i be some witness cycle of v_i in G. By Lemma 2, the cycles Γ_i are pairwise independent. Therefore, the minimum number of vertices needed to cover such cycles is $|X|$.

Let $\{\Gamma_j^*\}$ be the set of branchpoint-free cycles in H that do not contain any critical linkpoints of H. Note that each cycle Γ_j^* is independent with any witness cycle Γ_i. We now claim that any smallest set W' of vertices of $V(H)$ that intersects with the vertex set of each Γ_j^* must be of size $|W|$. To see this, note that W' contains only allowed linkpoints of H. If we remove from H_b^* all the edges that correspond to linkpoints belonging to W', then we clearly end up with a forest. By construction, the minimum number of edges (or allowed linkpoints) needed to be removed from H_b^* so as to make it into a forest is $|W|$.

Recalling that every cycle Γ_j^* is independent with any witness cycle Γ_i, the set W' cannot possibly intersect with any of the cycles Γ_i. Hence, in order to cover the cycles $\{\Gamma_i\} \cup \{\Gamma_j^*\}$ in G, we will need at least $|X| + |W'|$ vertices. Therefore,

$$\mu_a(G) \;\geq\; |X| + |W'| \;=\; |X| + |W| \;.$$

On the other hand, we recall that $|F| = |X| + |Y| + |W|$.

We distinguish between the following two cases.

Case 1. $|Y| \leq 2|X| + 2|W|$. Here we have

$$|F| \;=\; |X| + |Y| + |W| \;\leq\; 3|X| + 3|W| \;\leq\; 3\mu_a(G) \;\leq\; 4\mu_a(G) - 2 \;.$$

Case 2. $|Y| > 2|X| + 2|W|$. Let F^* be a feedback vertex set of G of size $\mu_a(G)$ and let W' be a smallest subset of F^* that intersects with the vertex set of each Γ_j^*. Clearly, W' consists of allowed linkpoints of H, and, as we showed earlier in this proof, $|W'| = |W|$. Let H_1 be the subgraph of H obtained by removing all critical linkpoints of H and all linkpoints in W'. With each deleted linkpoint, we also remove recursively all resulting endpoints from H while obtaining H_1. Thus, a deletion of a linkpoint from H can decrease the number of branchpoints by 2 at most. Hence, the number of branchpoints left in H_1 is at least $|Y| - 2|X| - 2|W| > 0$. Furthermore, the graph H_1 does not contain any endpoints.

Let H_1^* be a minimal reduction graph of H_1 and let H_2 be a valid graph obtained by removing all singleton components from H_1^*. Since H_1 does not contain any endpoints, the number of branchpoints of H_1 is preserved in H_1^* and in H_2. Therefore, the graph H_2 contains at least $|Y| - 2|X| - 2|W|$ branchpoints. On the other hand, since H_1^* is a minimal reduction and due to Lemma 5, there are no blackout linkpoints in H_1^* and every feedback vertex set of H_1^* contains all allowed linkpoints of H_1^*. Furthermore, the graphs H_1^* and H_2 do not contain any endpoints.

It follows that we can apply Lemma 6 to H_2 and any feedback vertex set of H_2, thus obtaining

$$|Y| - 2|X| - 2|W| \;\leq\; 4\mu_a(H_2) - 2 \;\leq\; 4\mu_a(H_1^*) - 2 \;=\; 4\mu_a(H_1) - 2 \;,$$

where the equality is due to Lemma 4. Therefore,

$$\begin{aligned} |F| &= |X| + |Y| + |W| \\ &\leq 4|X| + 4|W| + |Y| - 2|X| - 2|W| \\ &\leq 4(|X| + |W| + \mu_a(H_1)) - 2 \;. \end{aligned} \tag{1}$$

Recall that W' was chosen as a subset of a smallest feedback vertex set F^* of G. Let X' be a smallest subset of F^* that covers the witness cycles $\{\Gamma_i\}$ and let Z' be a smallest subset of F^* that covers the cycles of H_1. Since H_1 does not contain any of the critical linkpoints of H, each witness cycle Γ_i is independent with any cycle in

H_1 and, so, we have $X' \cap Z' = \emptyset$. It also follows from our previous discussion that $X' \cap W' = \emptyset$. In addition, by construction of H_1 we have $W' \cap Z' = \emptyset$. It thus follows that

$$|X| + |W| + \mu_a(H_1) \;\leq\; |X'| + |W'| + |Z'| \;\leq\; |F^*| \;=\; \mu_a(G)\ .$$

Combining with (1), we obtain the desired result. □

3. WFVS. In this section, we consider the approximation of the WFVS problem described in section 1. That is, given an undirected graph G and a weight function w on its vertices, find a feedback vertex set of (G, w) with minimum weight. As in the previous section, we assume that G may contain parallel edges and self-loops.

A *weighted reduction graph* G' of an undirected graph G is a graph obtained from G by a sequence of the following transformations.

- Delete an endpoint and its incident edge.
- Let u and v be two adjacent vertices such that $w(u) \leq w(v)$ and v is a linkpoint. Connect u to the other neighbor of v, and remove v from the graph with its two incident edges.

The following lemma can be easily verified. (See, e.g., the proof of Lemma 4.)

LEMMA 8. *Let (G', w') be a weighted reduction graph of (G, w). Then, $\mu(G', w') = \mu(G, w)$.*

A weighted reduction graph G^* of a graph G is *minimal* if and only if any weighted reduction graph G' of G^* is equal to G^*. A graph is called *branchy* if it has no endpoints and, in addition, its set of linkpoints induces an independent set; i.e., each linkpoint is either an isolated self-looped singleton or connected to two branchpoints. Clearly, any minimal weighted reduction graph must be branchy. We note that the complexity of transforming a graph into a branchy graph is linear in $|E(G)|$.

We are now ready to present our algorithms for finding an approximation for a minimum-weight feedback vertex set of a given weighted graph. In section 3.1 we give an algorithm that achieves a performance ratio of $4 \log_2 |V(G)|$. In section 3.2 we present an algorithm that achieves a performance ratio of $2\Delta^2(G)$.

3.1. The primal-dual algorithm. The basis of the first approximation algorithm is the next lemma which generalizes a lemma due to Erdős and Pósa [EP62, Lemma 3]. That lemma was obtained by Erdős and Pósa while estimating the smallest number of edges in a graph which contains a given number of pairwise independent cycles. Later on, in [EP64], they provided bounds on the value of $\mu(G, 1)$ in terms of the largest number of pairwise independent cycles in G. Tighter bounds on $\mu(G, 1)$ were obtained by Simonovits [Si67] and Voss [Vo68].

LEMMA 9. *The shortest cycle in any branchy graph G with at least two vertices is of length $\leq 4 \log_2 |V(G)|$.*

Proof. Let t be the smallest even integer such that $2 \cdot 2^{t/2} > |V(G)|$. Apply BFS on G of depth t starting at some vertex v. We now claim that the search hits some vertex twice and so there exists a cycle of length $\leq 2t$ in G. Indeed, if it were not so, then the induced BFS tree would contain at least $2 \cdot 2^{t/2}$ distinct vertices of G, which is a contradiction. □

In each iteration of the proposed algorithm, we first find a minimal weighted reduction graph, and then find a cycle Γ with the smallest number of vertices in the minimal weighted reduction graph. The algorithm sets δ to be the minimum among the weights of the vertices in $V(\Gamma)$. This value of δ is subtracted, in turn, from the weight of each vertex in $V(\Gamma)$. Vertices whose weight becomes zero are added to the

feedback vertex set and deleted from the graph. Each such iteration is repeated until the graph is exhausted.

ALGORITHM MINIWCYCLE(*Input:* (G, w); *Output:* feedback vertex set F of (G, w));
$F \leftarrow \emptyset$; $(H, w_H) \leftarrow (G, w)$;
While H is not a forest do begin:
  Find a minimal weighted reduction graph $(H', w_{H'})$ of (H, w_H);
  Find a cycle Γ' in H' with the smallest number of vertices;
  Set $\delta \leftarrow \min_{v \in V(\Gamma')} w_{H'}(v)$;
  Set $w_{H'}(v) \leftarrow w_{H'}(v) - \delta$ for every $v \in V(\Gamma')$;
  Let $X = \{v \in V(\Gamma') \ : \ w_{H'}(v) = 0\}$;
  Remove X (with all incident edges) from H';
  $(H, w_H) \leftarrow (H', w_{H'})$;
  $F \leftarrow X \cup F$;
end.

Finding a shortest cycle can be done by running BFS from each vertex until a cycle is found and then selecting the smallest. A more efficient approach for finding the shortest cycle is described in [IR78].

It is not hard to see that MINIWCYCLE computes a feedback vertex set of G. We now analyze the algorithm employing techniques similar to those used in [Ho82], [Ho83], and [KhVY94]. We note that the algorithm can also be analyzed using the local ratio theorem of Bar-Yehuda and Even [BaEv85].

THEOREM 10. *The performance ratio of algorithm* MINIWCYCLE *is at most* $4 \log_2 |V(G)|$.

Proof. We assume that $|V(G)| > 1$. Given a feedback vertex set F of (G, w), let $\mathbf{x} = [x_v]_{v \in V(G)}$ be the indicator vector of F, namely, $x_v = 1$ if $v \in F$ and $x_v = 0$ otherwise. We denote by $\mathcal{C}$ the set of cycles in G. The problem of finding a minimum-weight feedback vertex set of (G, w) can be formulated in terms of $\mathbf{x}$ by an integer programming problem as follows:

$$\begin{gathered} \text{minimize} \quad \textstyle\sum_{v \in V(G)} w(v) \cdot x_v \\ \text{ranging over all nonnegative integer vectors } \mathbf{x} = [x_v]_{v \in V(G)} \text{ such that} \\ \displaystyle\sum_{v \in V(\Gamma)} x_v \ \geq \ 1 \quad \text{for every} \quad \Gamma \in \mathcal{C} \ . \end{gathered} \tag{2}$$

Let $\mathcal{C}_v$ denote the set of cycles passing through vertex v in G and consider the following integer programming *packing* problem:

$$\begin{gathered} \text{maximize} \quad \textstyle\sum_{\Gamma \in \mathcal{C}} y_\Gamma \\ \text{ranging over all nonnegative integer vectors } \mathbf{y} = [y_\Gamma]_{\Gamma \in \mathcal{C}} \text{ such that} \\ \displaystyle\sum_{\Gamma \in \mathcal{C}_v} y_\Gamma \ \leq \ w(v) \quad \text{for every} \quad v \in V \ . \end{gathered} \tag{3}$$

Clearly, the linear relaxation of (3) is the dual of the linear relaxation of (2), with y_Γ, $\Gamma \in \mathcal{C}$, being the dual variables.

Let $(H', w_{H'})$ be a minimal weighted reduction graph computed at some iteration of algorithm MINIWCYCLE. Then, for each cycle $\Gamma' \in H'$, we associate a unique cycle $\Gamma \in G$ as follows: if all vertices in $V(\Gamma')$ belong to G, then $\Gamma = \Gamma'$. Otherwise, we "unfold" the transformation steps performed in obtaining H' from H in backward order, i.e., from H' back to H: in each such step we add to Γ' chains of linkpoints

(connecting vertices in Γ') that were deleted. When this process finishes, the cycle Γ' of H' transforms into a cycle Γ of G.

We now show that MiniWCycle can be interpreted as a primal-dual algorithm. We first show that it computes a dual feasible solution for (3) with a certain maximality property. The initial dual feasible solution is the one in which all the dual variables y_Γ are zero.

Let Γ'_i be a cycle chosen at iteration i of MiniWCycle and let Γ_i be the associated cycle in G. We may view the computation of iteration i of MiniWCycle as setting the value of the dual variable y_{Γ_i} to the weight δ of a lightest vertex in $V(\Gamma'_i)$. The updated weight $w_{H'}(v)$ of every $v \in V(\Gamma'_i)$ is precisely the slack of the dual constraint

$$\sum_{\Gamma \in \mathcal{C}_v} y_\Gamma \;\leq\; w(v) \tag{4}$$

that corresponds to v.

It is clear that by the choice of δ, the values of the dual variables y_Γ at the end of iteration i of MiniWCycle satisfy the dual constraints (4) corresponding to vertices $v \in V(\Gamma'_i)$. It thus follows that the dual constraints hold for all vertices $v \in V(H')$ at iteration i.

Let v be a vertex that was removed from H to obtain H' in iteration i of MiniWCycle. It remains to show that the dual constraint (4) corresponding to such a vertex holds in each iteration j of the algorithm for every $j \geq i$.

We show this by backward induction on j. By the previous discussion it follows that the constraints corresponding to vertices that exist in the last iteration all hold. Suppose now that the dual constraints corresponding to vertices in $V(H')$ in iteration j are not violated. We show that the dual constraints corresponding to vertices in $V(H) - V(H')$ in that iteration are also not violated. Let c be a chain of linkpoints in H in iteration j, and let v_1 and v_2 be the two branchpoints adjacent to c. Let u be a vertex of minimum weight among v_1, v_2, and the vertices in c. We note that the weighted reduction procedure deletes all vertices in c except possibly for one representative, depending on whether u is in c or is one of its adjacent branchpoints. We now observe that the set of cycles that passes through a linkpoint in c is the same for all linkpoints in c and is contained in the set of cycles that pass through v_1 and is also contained in the set of cycles that pass through v_2. This implies that if the dual constraint corresponding to u is not violated, then the dual constraints corresponding to any vertex in c is also not violated.

The algorithm essentially constructs a primal solution $\mathbf{x}$ from the dual solution $\mathbf{y}$: it selects into the feedback vertex set all vertices for which (i) the corresponding dual constraints are tight and (ii) in the iteration the constraint first became tight, the corresponding vertex belonged to the graph. As stated earlier, this construction yields a feasible solution.

Let $\mathbf{x}^* = [x^*_v]_{v \in V(G)}$ and $\mathbf{y}^* = [y^*_\Gamma]_{\Gamma \in \mathcal{C}}$ denote the optimal primal and dual fractional solutions, respectively. It follows from the duality theorem that

$$\sum_{v \in V(G)} w(v) \cdot x_v \;\geq\; \sum_{v \in V(G)} w(v) \cdot x^*_v \;=\; \sum_{\Gamma \in \mathcal{C}} y^*_\Gamma \;\geq\; \sum_{\Gamma \in \mathcal{C}} y_\Gamma \,. \tag{5}$$

Hence, to prove the theorem it suffices to bound the ratio between the LHS and the RHS of (5). First note that $y_\Gamma \neq 0$ only for cycles Γ in G that are associated with cycles Γ' that were chosen at some iteration of MiniWCycle. By the above

construction of $\mathbf{x}$, it is clear that the dual variable y_Γ of each such cycle Γ contributes its value to at most $V(\Gamma')$ vertices. Hence,

$$\sum_{v \in V(G)} w_v \cdot x_v \;\leq\; \sum_{v \in V(G)} \sum_{\Gamma \in \mathcal{C}_v} y_\Gamma \;\leq\; \sum_{\Gamma \in \mathcal{C}} y_\Gamma \cdot |V(\Gamma')| \,.$$

Now, in each iteration, the graph H' is a branchy graph. Therefore, by Lemma 9, we have that $|V(\Gamma')| \leq 4 \log_2 |V(G)|$. Hence the theorem is proved. □

PROPOSITION 11. *For planar graphs, the weighted performance ratio of* MINIWCYCLE *is at most* 10.

Proof. We first notice that the weighted reduction process preserves planarity and, therefore, at each iteration of algorithm MINIWCYCLE we remain with a planar graph.

We claim that every rich planar graph G must contain a face of length at most 5. Assume the contrary. By summing up the lengths of all the faces, we get that $2|E| \geq 6|Z|$, where Z denotes the set of faces of G. By Euler's formula,

$$|E| - |V| + 2 = |Z|.$$

Hence, $2|E| \leq 3|V| - 6$. However, since the degree of each vertex is at least 3, we get that $2|E| \geq 3|V|$, which is a contradiction. Furthermore, this implies that a branchy planar graph must contain a cycle of length at most 10. □

3.2. Low-degree graphs. The algorithm presented in this section is based on the following variant of Lemma 6.

LEMMA 12. *Let G be a branchy graph. Then, for every feedback vertex set F of G,*

$$|V(G)| \;\leq\; 2\Delta^2(G) \cdot |F|.$$

Proof. Let F be a feedback vertex set of G. We can assume without loss of generality that F contains only branchpoints, since this assumption can only decrease $|F|$. Let G' be the minimal (unweighted) reduction graph of G; i.e., G' contains only branchpoints or isolated self-looped singletons. Clearly, F is also a feedback vertex set of G'. Thus, G' and F satisfy the conditions of Lemma 6 ($\Delta_a = \Delta$), yielding that

$$|V(G')| \;\leq\; (\Delta(G') + 1) \cdot |F| \;-\; 2 \,.$$

Since G' is a branchy graph, the number of linkpoints in G can be at most $\Delta(G') \cdot |V(G')|/2$. Hence,

$$|V(G)| \;\leq\; \frac{(\Delta(G) + 2) \cdot |V(G')|}{2}$$

and, so,

$$|V(G)| \;\leq\; \frac{(\Delta(G) + 2) \cdot (\Delta(G) + 1) \cdot |F|}{2} \;\leq\; 2\Delta^2(G) \cdot |F|. \qquad \square$$

We now present a weighted greedy algorithm for finding a feedback vertex set in a graph G.

ALGORITHM WGREEDY(*Input:* (G, w); *Output:* feedback vertex set F of (G, w));
$F \leftarrow \emptyset$; $i \leftarrow 1$; $(H, w_H) \leftarrow (G, w)$;
while H is not a forest do begin:
    Find a minimal weighted reduction graph $(H'_i, w_{H'_i})$ of (H, w_H);
    $\alpha_i \leftarrow \min_{v \in V(H'_i)} w_{H'_i}(v)$;
    $U_i \leftarrow \{u \in V(H'_i) \mid w_{H'_i}(u) = \alpha_i\}$;
    $F \leftarrow F \cup U_i$;
    remove U_i from H'_i with its incident edges;
    $(H, w_H) \leftarrow (H'_i, w_{H'_i})$;
    $i \leftarrow i + 1$;
end.

For a subset $S \subseteq V$, let $w(S)$ denote the sum of weights of the vertices in S. We now prove the following theorem.

THEOREM 13. *Let G be a branchy graph. Denote by F the feedback vertex set computed by algorithm* WGREEDY*, and by F^* a minimum-weight feedback vertex set in G. Then, $w(F) \leq 2\Delta^2(G) \cdot w(F^*)$.*

Proof. Assume that the number of iterations the *while* loop is executed in algorithm WGREEDY is p. We define the following weight functions $w_1, \ldots, w_p$ on $V(G)$. The weight function w_i is defined, for $1 \leq i \leq p$, as follows:

$$\text{for all } v \in V(G): \quad w_i(v) = \begin{cases} \alpha_i - \alpha_{i-1} & \text{if } v \in V(H'_i), \\ 0 & \text{otherwise,} \end{cases}$$

where $\alpha_0 = 0$.

For a subset S, let $w_i(S)$ denote the sum of weights of the vertices in S, where the weight function is w_i. Clearly,

$$w(F) \;=\; \sum_{i=1}^{p} w(U_i) \;=\; \sum_{i=1}^{p} w_i(F).$$

Suppose that at one of the weighted reduction steps of algorithm WGREEDY, a chain c of equal weight linkpoints was reduced to a single vertex, say, v, which either belongs to c or is one of the two branchpoints adjacent to c. Suppose further that v was added to F. If F^* also contains a vertex from the chain c, then without loss of generality we can assume that this vertex can be replaced by v.

Let $u \in F^*$. Obviously, $u \in H'_1$. We claim that if $u \notin F$, then $u \in H'_i$ for all $i = 1, 2, \ldots, p$. Assume this is not the case. Then, with respect to the order in which vertices entered F in algorithm WGREEDY, let u be the first vertex such that $u \in F$, $u \notin F^*$, and u was removed from the graph in a weighted reduction step. This means that u was at the time of its removal a linkpoint that had an adjacent vertex u' with smaller weight. But then, by exchanging u for u' in F^*, we obtain a feedback vertex set which has smaller weight, contradicting the optimality of F^*. Hence, for a vertex $u \in F^*$, $w(u) \;\geq\; \sum_{i=1}^{p} w_i(u)$. Therefore,

$$w(F^*) \;\geq\; \sum_{i=1}^{p} w_i(F^*)\,.$$

Notice that in the graph H'_i, the weight function w_i assigns the same weight to all vertices. Hence, by Lemma 12, we have that $w_i(F) \leq 2\Delta^2(H'_i) \cdot w_i(F^*)$ for all $i = 1, 2, \ldots, p$. Since $\Delta(H'_i) \leq \Delta(G)$ for all i, the theorem follows. □

It follows from Lemma 8 that the performance ratio of algorithm WGREEDY for (G, w) is at most $2\Delta^2(G)$ for *any* graph G.

4. The loop cutset problem and its application. In section 4.1 we consider a variant of the WFVS problem for directed graphs and in section 4.2 we describe its application to Bayesian inference.

4.1. The loop cutset problem. The underlying graph of a directed graph D is the undirected graph formed by ignoring the directions of the edges in D. A *loop* in D is a subgraph of D whose underlying graph is a cycle. A vertex v is a *sink* with respect to a loop Γ if the two edges adjacent to v in Γ are directed into v. Every loop must contain at least one vertex that is not a sink with respect to that loop. Each vertex that is not a sink with respect to a loop Γ is called an *allowed vertex with respect to* Γ. A *loop cutset* of a directed graph D is a set of vertices that contains at least one allowed vertex with respect to each loop in D. Our problem is to find a minimum-weight loop cutset of a given directed graph D and a weight function w. We denote by $\mu(D, w)$ the sum of weights of the vertices in such a loop cutset. Greedy approaches to the loop cutset problem have been suggested by [SuC90] and [St90]. Both methods can be shown to have a performance ratio as bad as $\Omega(n/4)$ in certain planar graphs [St90]. An application of our approximation algorithms to the loop cutset problem in the area of Bayesian inference is described later in this section.

The approach we take is to reduce the weighted loop cutset problem to the weighted feedback vertex set problem solved in the previous section. Given a weighted directed graph (D, w), we define the *splitting* weighted undirected graph (D_s, w_s) as follows. Split each vertex v in D into two vertices v_{in} and v_{out} in D_s such that all incoming edges to v become undirected incident edges with v_{in} and all outgoing edges from v become undirected incident edges with v_{out}. In addition, we connect v_{in} and v_{out} by an undirected edge. Set $w_s(v_{\text{in}}) = \infty$ and $w_s(v_{\text{out}}) = w(v)$. For a set of vertices X in D_s, we define $\psi(X)$ as the set obtained by replacing each vertex v_{in} or v_{out} in X by the respective vertex v in D from which these vertices originated.

Our algorithm can now be easily stated.

ALGORITHM LOOPCUTSET (*Input:* (D, w); *Output:* loop cutset F of (D, w));
Construct (D_s, w_s);
Apply MINIWCYCLE on (D_s, w_s) to obtain a feedback vertex set X;
$F \leftarrow \psi(X)$.

Note that each loop in D is associated with a unique cycle in D_s, and vice versa, in a straightforward manner. Let $I(\Gamma)$ denote the loop image of a cycle Γ in D_s, and $I^{-1}(K)$ denote the cycle image of a loop K in D. It is clear that the mapping I is $1-1$ and onto.

The next lemma shows that algorithm LOOPCUTSET outputs a loop cutset of (D, w).

LEMMA 14. *Let (D, w) be a directed weighted graph and (D_s, w_s) be its splitting graph. Then* (i) *if F is a feedback vertex set of (D_s, w_s) having finite weight, then $\psi(F)$ is a loop cutset of (D, w), and $w_s(F) = w(\psi(F))$;* (ii) *if U is a loop cutset of D, then the set U_s obtained from U by replacing each vertex $v \in U$ by vertex $v_{out} \in D_s$ is a feedback vertex set of D_s, and $w(U) = w_s(U_s)$.*

Proof. We prove (i). The proof of (ii) is similar. Let Γ be a loop in D. To prove the lemma we show that an allowed vertex with respect to Γ belongs to $\psi(F)$. Let $I^{-1}(\Gamma)$ be the unique cycle image of Γ in D_s. Since F is a cycle cover of D_s having finite weight, there must be a vertex $v_{\text{out}} \in F$ in $I^{-1}(\Gamma)$. Now, it is clear that vertex $v \in \Gamma$ from which v_{out} originated is an allowed vertex with respect to Γ as needed. To complete the proof, by the finiteness of $w_s(F)$ we must have $w_s(F) = w(\psi(F))$, since $w_s(v_{\text{out}}) = w(v)$ for each vertex in F. ∎

It follows from Lemma 14 that $\mu(D, w) = \mu(D_s, w_s)$. In addition, due to Theorem 10 applied to the graph D_s, and since the number of vertices in D_s is twice the number of vertices in D, we get the following bound on the performance ratio of algorithm LoopCutset.

THEOREM 15. *The performance ratio of* LoopCutset *is at most* $4\log_2(2|V(D)|)$.

We now show that in the unweighted loop cutset problem we can achieve a performance ratio better than 4. In this case, for each vertex $v \in D$, the weight of $v_{\text{in}} \in D_s$ is one unit, and the weight of $v_{\text{out}} \in D_s$ is ∞. This falls within the framework considered in section 2, since vertices with infinite weight in D_s can be treated as blackout vertices. We can therefore apply SubG-2-3 in the LoopCutset algorithm instead of applying MiniWCycle and obtain the following improved performance ratio.

THEOREM 16. *When using* SubG-2-3*, the unweighted performance ratio of* LoopCutset *is at most* $4 - (2/|V(D)|)$.

Proof. We have

$$w(\psi(F)) = w_s(F) \leq 4\mu(D_s, w_s) - 2,$$

where the equality is due to Lemma 14, and the inequality is due to Theorem 7. Since $\mu(D_s, w_s) = \mu(D, w) \leq |V(D)|$, the claim is proved. ∎

4.2. An application. We conclude this section with an application of approximation algorithms for the loop cutset problem.

Let $P(u_1, \ldots, u_n)$ be a probability distribution where each u_i draws values from a finite set called the *domain* of u_i. A directed graph D with no directed cycles is called a *Bayesian network of* P if there is a 1-1 mapping between $\{u_1, \ldots, u_n\}$ and vertices in D such that u_i is associated with vertex i and P can be written as follows:

$$P(u_1, \ldots, u_n) = \prod_{i=1}^{n} P(u_i \mid u_{i_1}, \ldots, u_{i_{j(i)}}) \,, \tag{6}$$

where $i_1, \ldots, i_{j(i)}$ are the source vertices of the incoming edges to vertex i in D.

It is worth noting that Bayesian networks are useful knowledge representation schemes for many artificial intelligence tasks. Bayesian networks allow a wide spectrum of independence assumptions to be considered by a model builder so that a practical balance can be established between computational needs and adequacy of conclusions. For a complete exploration of this subject see [Pe88].

Suppose now that some variables $\{v_1, \ldots, v_l\}$ among $\{u_1, \ldots, u_n\}$ are assigned specific values $\{\mathbf{v}_1, \ldots, \mathbf{v}_l\}$, respectively. The *updating problem* is to compute the probability $P(u_i \mid v_1 = \mathbf{v}_1, \ldots, v_l = \mathbf{v}_l)$ for $i = 1, \ldots, n$. In principle, such computations are straightforward because each Bayesian network defines the joint probability distribution $P(u_1, \ldots, u_n)$ from which all conditional probabilities can be computed by dividing the appropriate sums. However, such computations are inefficient both in time and space unless they use conditional independence assumptions defined by (6). We shall see next how our approximation algorithms for the loop cutset problem reduce the computations needed for solving the updating problem.

A *trail* in a Bayesian network is a subgraph whose underlying graph is a simple path. A vertex b is called a *sink* with respect to a trail t if there exist two consecutive edges $a \to b$ and $b \leftarrow c$ on t. A trail t is *active by a set of vertices* Z if (1) every sink with respect to t either is in Z or has a descendant in Z and (2) every other vertex along t is outside Z. Otherwise, the trail is said to be *blocked* by Z.

Verma and Pearl [VePe88] have proved that if D is a Bayesian network of $P(u_1, \ldots, u_n)$ and all trails between a vertex in $\{r_1, \ldots, r_l\}$ and a vertex in $\{s_1, \ldots, s_k\}$ are blocked by $\{t_1, \ldots, t_m\}$, then the corresponding sets of variables $\{u_{r_1}, \ldots, u_{r_l}\}$ and $\{u_{s_1}, \ldots, u_{s_k}\}$ are independent conditioned on $\{u_{t_1}, \ldots, u_{t_m}\}$. Furthermore, Geiger and Pearl [GP90] proved a converse to this theorem. Both results are presented and extended in [GVP90].

Using the close relationship between blocked trails and conditional independence, Kim and Pearl [KiP83] developed an algorithm UPDATE-TREE that solves the updating problem on Bayesian networks in which every two vertices are connected with at most one trail. UPDATE-TREE views each vertex as a processor that repeatedly sends messages to each of its neighboring vertices. When equilibrium is reached, each vertex i contains the conditional probability distribution $P(u_i \mid v_1 = \mathbf{v}_1, \ldots, v_l = \mathbf{v}_l)$. The computations reach equilibrium regardless of the order of execution in time proportional to the length of the longest trail in the network.

Pearl [Pe86] solved the updating problem on any Bayesian network as follows. First, a set of vertices S is selected such that any two vertices in the network are connected by at most one *active* trail in $S \cup Z$, where Z is any subset of vertices. Then, UPDATE-TREE is applied once for each combination of value assignments to the variables corresponding to S, and, finally, the results are combined. This algorithm is called the method of *conditioning* and its complexity grows exponentially with the size of S. Note that according to the definition of active trails, the set S in Pearl's algorithm is a loop cutset of the Bayesian network. In this paper we have developed approximation algorithms for finding S.

When the domain size of the variables varies, then UPDATE-TREE is called a number of times which is bounded from above by the product of the domain sizes of the variables whose corresponding vertices participate in the loop cutset. If we take the logarithm of the domain size as the weight of a vertex, then solving the weighted loop cutset problem with these weights optimizes Pearl's updating algorithm in the case where the domain sizes are allowed to vary.

5. Discussion. It is useful to relate the feedback vertex set problem with the vertex cover problem in order to establish lower bounds on the performance ratios attainable for the feedback vertex set problem. A vertex cover of an undirected graph is a subset of the vertex set that intersects with each edge in the graph. The vertex cover problem is to find a minimum-weight vertex cover of a given graph. There is a simple polynomial reduction from the vertex cover problem to the feedback vertex set problem: Given a graph G, we extend G to a graph H by adding a vertex v_e for each edge $e \in E(G)$ and connecting v_e with the vertices in G with which e is incident in G. It is easy to verify that there always exists a minimum feedback vertex set in H whose vertices are all in $V(G)$ and this feedback vertex set is also a minimum vertex cover of G. In essence, this reduction replaces each edge in G with a cycle in H, thus transforming any vertex cover of G to a feedback vertex set of H.

Due to this reduction, it follows that the performance ratio obtainable for the feedback vertex set problem cannot be better than the one obtainable for the vertex cover problem. The latter problem has attracted a lot of attention over the years but has so far resisted any approximation algorithm that achieves in general graphs a constant performance ratio less than 2. We note that the above reduction retains planarity. However, for planar graphs, Baker [Bak94] provided a polynomial approximation scheme (PAS) for the vertex cover problem. For the UFVS problem, there are examples showing that 4 is the tightest constant performance ratio of algorithm SUBG-2-3.

Another consequence of the above reduction is a lower bound on the unweighted performance ratio of the greedy algorithm, GreedyCyc, for the feedback vertex set problem. In each iteration, GreedyCyc removes a vertex of maximal degree from the graph, adds it to the feedback vertex set, and removes all endpoints in the graph. A similar greedy algorithm for the vertex cover problem is presented in [Jo74] and in [Lo75]. The latter algorithm was shown to have an unweighted performance ratio no better than $\Omega(\log |V(G)|)$ [Jo74]. Due to the reduction to the cycle cover problem, the same lower bound holds also for GreedyCyc, as demonstrated by the graphs of [Jo74]. A tight upper bound on the worst-case performance ratio of GreedyCyc is unknown.

Finally, one should notice that the following heuristics may improve the performance ratios of our algorithms. For example, in each iteration MiniWCycle chooses to place in the cover all zero-weight vertices found on the smallest cycle. This choice might be rather poor especially if many weights are equal. It may be useful in this case to perturb the weights of the vertices before running the algorithm. Similarly, in algorithm SubG-2-3, there is no point in taking blindly all branchpoints of H. An appropriate heuristic here may be to pick the branchpoints one by one in decreasing order of residual degrees. Furthermore, the subgraph H itself should be constructed such that it contains as many high-degree vertices as possible.

Remark. In a preliminary version of this paper, presented in [BaGNR94], we conjectured that a constant performance ratio is attainable by a polynomial-time algorithm for the WFVS problem. This has been recently verified in [BaBF95, BeG96] where a performance ratio of 2 is obtained.

Acknowledgment. We would like to thank David Johnson for bringing [EP62] to our attention and Samir Khuller for helpful discussions.

PLANAR INTEGER LINEAR PROGRAMMING IS NC EQUIVALENT TO EUCLIDEAN GCD*

D. F. SHALLCROSS†, V. Y. PAN‡, AND Y. LIN-KRIZ§

Abstract. It is not known if planar integer linear programming is P-complete or if it is in NC, and the same can be said about the computation of the remainder sequence of the Euclidean algorithm applied to two integers. However, both computations are NC equivalent. The latter computational problem was reduced in NC to the former one by Deng [*Mathematical Programming: Complexity and Application*, Ph.D. dissertation, Stanford University, Stanford, CA, 1989; *Proc. ACM Symp. on Parallel Algorithms and Architectures*, 1989, pp. 110–116]. We now prove the converse NC-reduction.

Key words. integer linear programming, Euclidean algorithm, greatest common divisor, parallel computational complexity

1. Introduction.

Our main result is the proof of the NC-equivalence of the planar integer linear programming problem and the computation of the Euclidean remainder sequence, defined by the Euclidean algorithm for two integers, which terminates with their greatest common divisor (GCD). Hereafter, we will refer to these two major computational problems as 2-ILP and EUGCD, respectively. Both 2-ILP and EUGCD, as well as k-ILP, that is, the integer linear programming with k variables, for a fixed k, belong to the class P; specifically, sequential Boolean time $O(k^{9k}L\log L)$ suffices for solving k-ILP [7], [8], [12], and time $O(L^2)$ suffices for EUGCD [1], [11], where L denotes the input length (size).

On the other hand, very little is known about parallel complexity of both k-ILP and EUGCD. In particular, it is not known if either of these problems belongs to NC or if either of them is P-complete. (We recall that a computational problem is in NC if it can be solved by using $O((\log L)^c)$ time and $O(L^c)$ processors for a fixed c independent of the input length L; NC-reduction (or reduction in NC) of one problem to another is the reduction under the above bounds on time and on the processor number; NC-equivalence is the existence of NC-reductions in both directions; a P-complete problem is one whose solution in NC would imply the NC solution of all problems in P (see [4, Chapter 7], [5], [6], [10])).

There are relatively few computational problems for which, like for k-ILP and EUGCD, we neither know if they belong to NC nor if they are P-complete. Several computational problems of this kind are related to k-ILP and EUGCD via NC-reductions (see [2], [3], and Figure 1). These problems include GCD (computing the GCD of two integers), SGCD (solution of the set equation $m\mathbf{Z}+n\mathbf{Z}=d\mathbf{Z}$), expanding

the continued fraction for the ratio of two integers, computing the sequence of their convergents, and reduction of a lattice of k dimensions for a fixed k.

Deng in [2], [3] proved NC-reduction from EUGCD to Opt-2-ILP, which is the (stronger) optimization version of 2-ILP (see Definition 1). (In Figure 1, we use 2-ILP for the feasibility integer linear programs.) The NC-reduction in the opposite direction, from Opt-2-ILP to EUGCD, turned out to be more elusive. Lin-Kriz and Pan in [13] established NC-equivalence between Opt-2-ILP and the problem they called REU, thus abbreviating relative EUGCD. REU amounts to solving both EUGCD and EUMOD*, the special case of MOD*, where MOD* denotes the problem of computing MOD*$(c, b_1, ..., b_n) = (...((c \bmod b_1) \bmod b_2)...) \bmod b_n$, for any set of natural numbers c, b_1, b_2, ..., b_n, whereas EUMOD* is the same problem where $b_1 > b_2$, $b_{i+2} = b_i \bmod b_{i+1}$, $i = 1, 2,...,n-2$; that is, in the input set for EUMOD*, the values b_3, ..., b_n have been generated as the successive remainders computed by the Euclidean algorithm for b_1 and b_2.

Although MOD* is a P-complete problem [9], we do not know if EUMOD* is in NC or if it is P-complete, so that the works [2], [3], and [13] still left establishing NC-equivalence between Opt-2-ILP and EUGCD as a research challenge. [13] proposed to try to reduce EUMOD* to EUGCD in NC, which would resolve the issue, but this has not worked so far.

The work on the version of [13] submitted for journal publication has brought in an additional coauthor (David Shallcross) and a stronger result, which ended up in the appearance of [14]. This paper combines the work of these two papers.

In this paper, we rely on applying a sequence of appropriate dissections and unimodular transformations of triangles, a method previously used in [16] to count the number of integer points in a polygon. We show that, used correctly, these techniques are powerful enough to arrive at the desired NC-reduction of Opt-2-ILP to EUGCD, which completes the long-awaited proof of NC-equivalence of these two problems.

2. Preliminaries. Hereafter, **Z**, **Q**, and **R**, as usual, denote the sets of integers, rationals, and reals, respectively. For (column) vectors a, b, c, ... from $\mathbf{Z}^2$ and $\mathbf{Q}^2$, we will let (a_1, a_2), (b_1, b_2), (c_1, c_2), ... denote the pairs of their coordinates. $\lfloor x \rfloor$ and $\lceil x \rceil$ denote the two integers closest to a rational x such that $\lfloor x \rfloor \le x \le \lceil x \rceil$.

EUGCD denotes the computational problem which requires, for an input pair a_0, a_1 of positive integers, to compute a sequence of integers a_2, a_3, ..., a_{n+2} such that

$$a_{i+2} = a_i - a_{i+1} \left\lfloor \frac{a_i}{a_{i+1}} \right\rfloor, \ i = 0, 1, ..., n, \qquad a_{n+1} > a_{n+2} = 0. \tag{1}$$

This is intimately related to continued fractions, as we can write

$$\frac{a_0}{a_1} = \left\lfloor \frac{a_0}{a_1} \right\rfloor + \frac{1}{\left\lfloor \frac{a_1}{a_2} \right\rfloor + \frac{1}{\lfloor \frac{a_2}{a_3} \rfloor + \cdots \frac{1}{a_n / a_{n+1}}}}. \tag{2}$$

Note that

$$n = O(\log a_0). \tag{3}$$

We will promiscuously mix representations of triangles by their vertices and by their facets or sides, because either representation can be transformed into the other in NC by performing some basic linear algebra operations.

Define a *unimodular* matrix to be an integer matrix with determinant either 1 or -1. Multiplying a unimodular matrix by an integer vector gives an integer vector, and since the inverse of a unimodular matrix is also unimodular, only an integer vector can multiply a unimodular matrix to give an integer vector.

DEFINITION 1. *An instance of Opt-2-ILP is the following: given $A \in \mathbf{Z}^{m \times 2}$, $v \in \mathbf{Z}^m$, $u = (u_1, u_2)^T \in \mathbf{Z}^2$, find $x = (x_1, x_2)^T \in \mathbf{Z}^2$ such that $Ax \le v$ that maximizes $u^T x = u_1 x_1 + u_2 x_2$, where v^T denotes the transpose of a vector v. That is, less formally, given a polygon P in $\mathbf{R}^2$ as an intersection of half-planes and a linear objective function, find the integer point that maximizes that function over all integer points in the polygon.*

We observe that a unimodular transformation of a triangle transforms a solution of Opt-2-ILP over this triangle to a solution of Opt-2-ILP over its image.

3. NC reduction of Opt-2-ILP to Opt-2-ILP over a triangle of a special form. The next two lemmas are from [13] (compare also [2], [3]); we clarify their proofs.

LEMMA 3.1. *Opt-2-ILP is NC-reducible to Opt-2-ILP over triangles.*

Proof. For an instance of Opt-2-ILP with feasible region P given in the usual manner as the intersection of half-planes, we may, in NC, compute the representation of P as a polygon given by vertices and edges. We will next show a relatively simple (although far from being the most efficient) method for doing this in NC. For every pair of half-planes compute the point where their boundary lines intersect (if they do intersect). For each such point, check whether it lies in each of the remaining half-planes and reject infeasible points. Eliminate duplicates. Finally, declare two points (now vertices) to be adjacent if they both lie on the boundary of the same half-plane. If unbounded P are allowed as input, we can add explicit bounds on the components of any finite optimal solution (see [15, Corollary 17.1c]).

We next triangulate this polygon in NC by taking an arbitrary vertex a, and, for each adjacent pair of vertices b, c, neither equal to a, producing the triangle abc. By

a note above, we can obtain in NC the equations of the sides of any triangle from its vertices. Now we solve the original optimization problem by, in parallel, solving the linear number of optimization problems over the triangles and taking the best of the optima. □

LEMMA 3.2. *Opt-2-ILP over triangles is NC-reducible to solving the following pair of computational problems*: *GCD and Opt-2-ILP over triangles of the form* $T =$*convex hull*(α, β, γ) *where* $\alpha = (\alpha_1, \alpha_2)^T$, $\beta = (\beta_1, \beta_2)^T$, $\gamma = (\gamma_1, \gamma_2)^T$ *are three points in* $\mathbf{Q}^2$ *such that* $\alpha_1 = \beta_1 < \gamma$, $\alpha_2 > \beta_2$, $\alpha_2 > \gamma$, *and* α *is the solution to the linear programming relaxation of the original Opt-2-ILP.*

Proof. We will rely on the proof of Lemma 5.2 of [13], which we will essentially reproduce with slightly changed notation for the triangles and their vertices and with some unnecessary claims removed.

We shall apply (unimodular) linear transformations

$$U \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} ax + by \\ cx + dy \end{pmatrix},$$

where $U = \left(\begin{smallmatrix} u_{11} & u_{12} \\ u_{21} & u_{22} \end{smallmatrix}\right)$ is a 2×2 matrix of the matrix class

$$GL_2(\mathbf{Z}) = \left\{ \begin{pmatrix} g_{11} & g_{12} \\ g_{21} & g_{22} \end{pmatrix} \ : \ g_{11}, g_{12}, g_{21}, g_{22} \in \mathbf{Z} \text{ and } g_{11}g_{22} - g_{21}g_{12} = \pm 1 \right\} .$$

Clearly, every such a transformation (with $U \in GL_2(\mathbf{Z})$) will map all the integral points into integral points; furthermore, if $U \in GL_2(\mathbf{Z})$, then $U^{-1} \in GL_2(\mathbf{Z})$, since

$$(\det\ U)U^{-1} = \begin{pmatrix} u_{22} & -u_{12} \\ -u_{21} & u_{11} \end{pmatrix}$$

and since

$$\det(U^{-1}) = \frac{u_{11}u_{22} - u_{12}u_{21}}{\det\ U} = 1 .$$

Now let A_0, B_0, C_0 denote the vertices of the triangle $T_0 = (A_0B_0C_0)$, which is the feasibility region of the input Opt-2-ILP. We now seek a linear transformation with the matrix $U \in GL_2(\mathbf{Z})$ that transforms the triangle $T_0 = (A_0B_0C_0)$ into a triangle $T = (ABC)$ satisfying the requirements of Lemma 3.2. Without loss of generality, we may assume that A_0 is an optimum for the LP relaxation of the input ILP and that all the angles of the triangle $T_0 = (A_0B_0C_0)$ are less than $\frac{\pi}{2}$ (Figure 2).

Next, we will transform the triangle $T_0 = (A_0B_0C_0)$ into a triangle $T = (ABC)$ so that $A - B$ will lie on the Y-axis and A (the image of A_0) will be the optimum point of correspondingly transformed linear program (see Figure 3). To formalize this stage, we let $A_0 - B_0 = \left(\begin{smallmatrix} z \\ t \end{smallmatrix}\right) = \vec{A_0B_0}$ denote the vector directed from B_0 to A_0, and we will seek a matrix

$$M = \begin{pmatrix} m_{11} & m_{12} \\ m_{21} & m_{22} \end{pmatrix} \in GL_2(\mathbf{Z})$$

such that

$$\begin{pmatrix} m_{11} & m_{12} \\ m_{21} & m_{22} \end{pmatrix} \begin{pmatrix} z \\ t \end{pmatrix} = \begin{pmatrix} 0 \\ v \end{pmatrix};$$

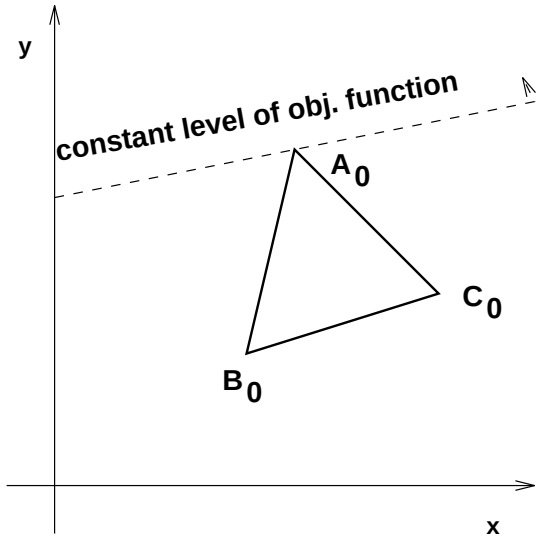

FIG. 2. *An arbitrary triangle* $A_0B_0C_0$.

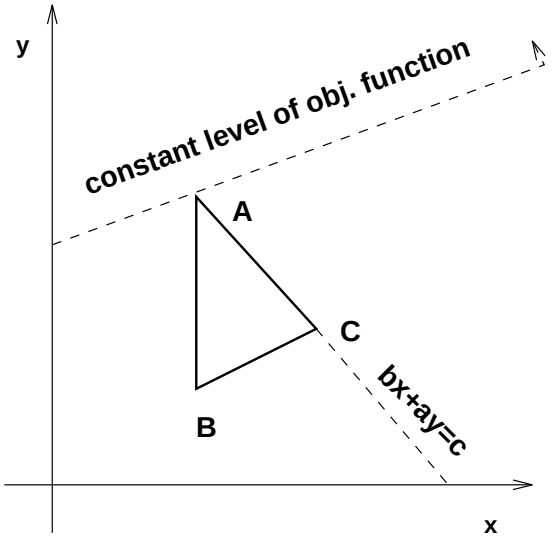

FIG. 3. *Triangle* $A_0B_0C_0$ *shifted to triangle* ABC.

that is,

$$m_{11}z + m_{12}t = 0 \ ,$$

$$m_{21}z + m_{22}t = v \ ,$$

$$m_{11}m_{22} - m_{12}m_{21} = \pm 1 \ .$$

Let $v = gcd(z,t)$. We can compute m_{21}, m_{22} by using the Euclidean algorithm or any algorithm that computes $v = gcd(z,t)$, since (as this can be immediately verified)

$$m_{11} = \frac{t}{v}\ , \quad m_{12} = -\ \frac{z}{v}\ ,$$

$$m_{11}m_{22} - m_{12}m_{21} = \frac{t}{v}\ m_{22} + \frac{z}{v}\ m_{21} = 1\ .$$

Let $T = (ABC)$ denote the resulting triangle.

During the entire transformation process, the image of A_0 (at the end represented by A'') remains the optimum of the correspondingly transformed linear program. Indeed, let $f(x, y) = ux + vy$ denote the objective function; then

$$ux + vy = \begin{pmatrix} u & v \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} u & v \end{pmatrix} M^{-1} M \begin{pmatrix} x \\ y \end{pmatrix},$$

and $M\binom{x}{y} = \binom{x'}{y'}$ is the optimum point in the new coordinate system, which is the image of the original optimum point. The vector $(u \quad v)M^{-1}$ is easy to calculate ($M^{-1} \in GL_2(\mathbf{Z})$ is the inverse of M), and it represents the direction of the constant level of the transformed objective function. Therefore, the optimum point and the optimum value are the transformation invariants.

Now we immediately observe that the requirements of Lemma 3.2 hold, except that we have yet to prove that $a > b$ in the equation for the edge $AC\ :\ bx + ay = c$ (Figure 3). Let k_{AC} denote the slope of AC; then all we need to prove is that $-\ \frac{\pi}{4} < k_{AC} \le 0$. We use the customary notation for the unimodular group of 2×2 matrices:

$$SL_2(\mathbf{Z}) = \left\{ \begin{pmatrix} s_{11} & s_{12} \\ s_{21} & s_{22} \end{pmatrix}\ :\ s_{11}s_{22} - s_{21}s_{12} = 1 \right\}\ .$$

Let $\alpha, \beta \in SL_2(\mathbf{Z})$ denote two such matrices:

$$\alpha = \begin{pmatrix} 1 & 0 \\ -1 & 1 \end{pmatrix}\ , \qquad \beta = \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix}\ ,$$

where $\alpha^{-1} = \beta$. Denote $\vec{CA} = C - A = \binom{g}{h}$; then

$$\text{(a)} \qquad \alpha \begin{pmatrix} g \\ h \end{pmatrix} = \begin{pmatrix} g \\ h - g \end{pmatrix}\ ,$$

$$\text{(b)} \qquad \beta \begin{pmatrix} g \\ h \end{pmatrix} = \begin{pmatrix} g \\ h + g \end{pmatrix}\ .$$

We can always assume that $g > 0$; otherwise we would have multiplied the resulting vector $\left[\begin{smallmatrix} g \\ h \end{smallmatrix}\right]$ by $\left(\begin{smallmatrix} -1 & 0 \\ 0 & 1 \end{smallmatrix}\right) \in GL_2(\mathbf{Z})$. If $h \ge g$, then we will multiply it by $\alpha^{\lfloor \frac{h}{g} \rfloor}$ and will arrive at the vector $\left[\begin{smallmatrix} g \\ h_1 \end{smallmatrix}\right]$, where $h_1 = h - g\lfloor \frac{h}{g} \rfloor < g$, as is required. Similarly, if $h < 0$, then we will multiply $\left[\begin{smallmatrix} g \\ h \end{smallmatrix}\right]$ by $\beta^{\lfloor \frac{-h}{g} \rfloor}$ and will arrive at $\left[\begin{smallmatrix} g \\ h_2 \end{smallmatrix}\right]$, where $h_2 = h + g\lfloor \frac{-h}{g} \rfloor > 0$. Thus, the requirements of Lemma 3.2 are satisfied for the triangle ABC. □

4. Restriction of the problem to the boundary of the convex hull of all the integer points of a superscribed right triangle. We will use the following definitions.

DEFINITION 2. *Hereafter, a triangle T of the form $\{(x_1, x_2) : ax_1 + bx_2 \le c, x_1 \ge g, x_2 \ge h\}$, for five integers $a > 0$, $b > 0$, c, g, h, will be called a* right triangle.

DEFINITION 3. *For any set S, let δS denote the boundary of the convex hull of the integer points in S.*

To solve Opt-2-ILP over a triangle of Lemma 3.2, we will reduce (in NC) this problem to solving EUGCD and to solving Opt-2-ILP over a few right triangles with integer slopes (see the next sections). To solve the latter problem in NC (see section 6), we will need the following lemma.

LEMMA 4.1. *Let a, b be positive integers, and let c, d, e, f, g be integers such that*

$$T = \{(x_1, x_2) : ax_1 + bx_2 \le c,\ dx_1 + ex_2 \le f,\ x_1 \ge g\}$$

is a nonempty bounded triangle. Let $u \in \mathbf{Z}^2$ be such that maximum over T of $u^T x$ occurs at the vertex $x^* = (g, (c - ag)/b)$. (This is the upper-left-hand corner of T.) Then the maximum over $T \cap \mathbf{Z}^2$ of $u^T x$ occurs among the integer points of $\delta T'$, the boundary of the convex hull H of integer points in the right triangle T', where

$$T' = \{(x_1, x_2) : ax_1 + bx_2 \le c,\ x_1 \ge g,\ x_2 \ge h\},$$

and h is an integer chosen so that $T \subset T'$.

Proof. If x^* defined above was an integer, then $x = x^*$ would optimize $u^T x$ over $T \cap \mathbf{Z}^2$ and would be a vertex on $\delta T'$. Otherwise let $x = z^*$ maximize $u^T x$ over $T \cap \mathbf{Z}^2$. Now suppose that $z^* \notin \delta T'$, but rather $z^* = (z_1^*, z_2^*) \in$ interior H, and we shall obtain a contradiction. (See Figure 4.)

Let K be the open wedge $\{(x_1, x_2) : x_1 < z_1^*,\ az_1^* + bz_2^* < ax_1 + bx_2\}$, and let P be the parallelogram $K \cap T'$. For all $x \in P$, $x_2 > z_2^*$, so P is in fact a subset of T. All points of K (and hence all of P) have a better objective value than z^*. In particular, by choice of z^*, P contains no integer points.

Since x^* is a vertex of T' but not an integer point, $x^* \notin H$. Thus since $z^* \in$ interior H, the diagonal of P from z^* to x^* intersects $\delta T'$ at some point t on an edge between two integer points w and y. Because they are integer points, neither w nor y can lie in P. They are in T', so they cannot lie anywhere else in K, but because the edge between them contains a point of P, one of these, say y, satisfies $y_1 < z_1^*$, $ay_1 + by_2 < az_1^* + bz_2^*$, and the other, w, satisfies $w_1 > z_1^*$, $aw_1 + bw_2 > az_1^* + bz_2^*$. Furthermore, either $w_2 > z_2^*$ or else $y_2 > z_2^*$.

Let $\bar{x} = w + y - z^*$. By the above, and since w and y are in T', we can see that $\bar{x}_1 > g$, and $a\bar{x}_1 + b\bar{x}_2 < c$. We can also see that $\bar{x}_2 > h$, so that $\bar{x} \in T'$. The points w and y are opposite vertices of a parallelogram with integer vertices y, $\bar{x}$, w, and z^* in T'. Since the point t between w and y lies on the boundary of the convex hull of integer points of T', we have the desired contradiction. Thus x^* lies on the boundary of H. ∎

5. Recursive partition of a triangle into unimodular images of right triangles.

LEMMA 5.1. *For integers k, l, $p > 0$, $q > 0$, r, the right triangle*

$$S = \left\{(x_1, x_2) : x_2 \le \frac{r}{q} - \frac{p}{q}x_1,\ x_1 \ge l,\ x_2 \ge k\right\}$$

(if nonempty) is the union (with disjoint interiors) of the right triangle

$$R = \left\{(x_1, x_2) : x_2 \le l' - \left\lfloor \frac{p}{q} \right\rfloor x_1,\ x_1 \ge l,\ x_2 \ge k\right\},$$

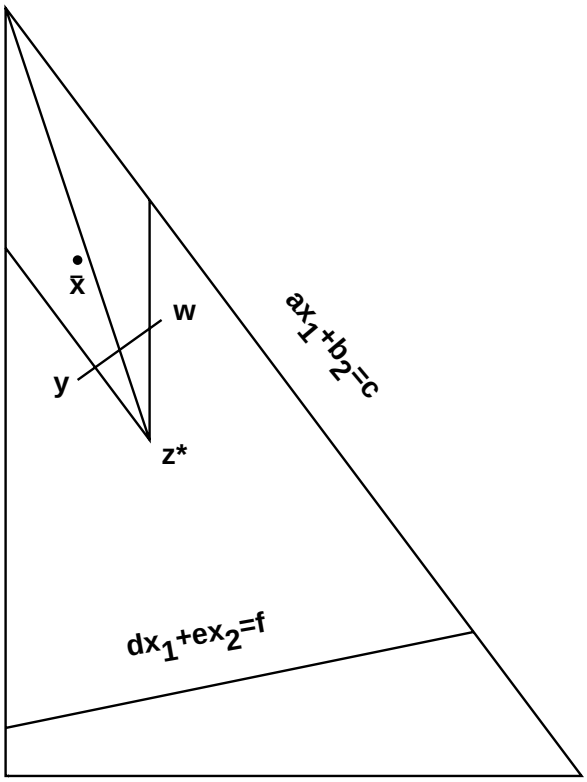

FIG. 4.

sharing the horizontal edge with the triangle S, and the unimodular image $U = MW$ of the triangle

$$W = \left\{ (x_1, x_2) : x_2 \le \frac{r}{q'} - \frac{p'}{q'} x_1,\ x_1 \ge l',\ x_2 \ge k' \right\},$$

where $p' = q$, $q' = p - q\lfloor \frac{p}{q} \rfloor$, $l' = k(\frac{q'}{p}) + \lfloor \frac{p}{q} \rfloor r/p$, $k' = l$, and

$$M = \begin{pmatrix} 0 & 1 \\ 1 & -\left\lfloor \frac{p}{q} \right\rfloor \end{pmatrix}.$$

Proof. We just divide S along the line of slope $-\lfloor \frac{p}{q} \rfloor$ that goes through the point $(\frac{r}{p} - (\frac{q}{p})k, k)$, the lower-right-hand corner of S. (See Figure 5.) This gives $S = R \cup U$ where R is as above, and

$$U = \left\{ (x_1, x_2) : l' - \left\lfloor \frac{p}{q} \right\rfloor x_1 \le x_2 \le \frac{r}{q} - \frac{p}{q} x_1,\ x_1 \ge l \right\}.$$

Now perform an elementary unimodular transformation $(x_1, x_2) \to (x_1, \lfloor \frac{p}{q} \rfloor x_1 + x_2)$ to map U to the triangle

$$V = \left\{ (x_1, x_2) : l' \le x_2 \le \frac{r}{q} - \left(\frac{p}{q} - \left\lfloor \frac{p}{q} \right\rfloor \right) x_1,\ x_1 \ge l \right\}.$$

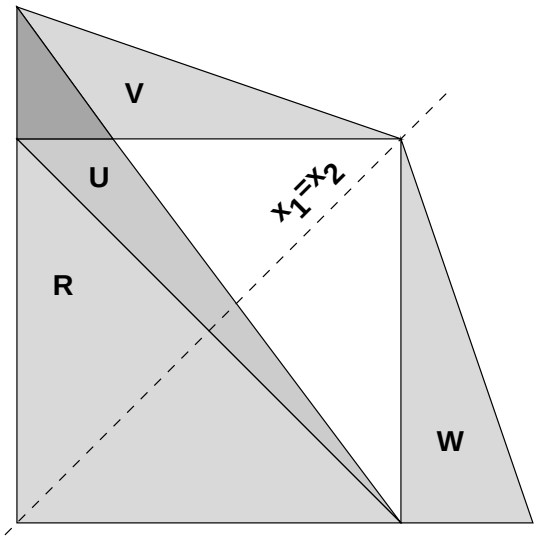

FIG. 5. *Lemma* 5.1 *for* $k = l = 0$.

Notice that we have $(\frac{p}{q}) - \lfloor \frac{p}{q} \rfloor = \frac{q'}{p'}$. Reflecting V over the line $x_1 = x_2$ gives us W above. □

LEMMA 5.2. *Given a sequence* $a_0, a_1, \ldots, a_{n+1}$ *of integers satisfying* (1) *and three rationals* h, k_0, *and* l_0 *such that* $a_0 l_0 + a_1 k_0 \leq h$, *we can compute in NC three sequences of rationals* k_i, l_i, *and unimodular matrices* M_i *such that if*

$$T^* = \{(x_1, x_2) : a_0 x_1 + a_1 x_2 \leq h,\ x_1 \geq l_0,\ x_2 \geq k_0\}$$

and

$$V_i = \left\{ (x_1, x_2) : x_2 \leq l_{i+1} - \left\lfloor \frac{a_i}{a_{i+1}} \right\rfloor x_1,\ x_1 \geq l_i,\ x_2 \geq k_i \right\},$$

then

$$T^* = \bigcup_{i=0}^{n} M_i V_i.$$

Proof. First we give recursions for the sequences k_i, l_i, and M_i. Then we will show that these sequences actually meet the requirements of the lemma.

Let

$$M_0 = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix},$$

and, for $0 \leq i < n$,

$$k_{i+1} = l_i, \tag{4}$$

$$l_{i+1} = k_i \frac{a_{i+2}}{a_i} + \left\lfloor \frac{a_i}{a_{i+1}} \right\rfloor \frac{h}{a_i}, \tag{5}$$

$$\tilde{M}_i = \begin{pmatrix} 0 & 1 \\ 1 & -\left\lfloor \frac{a_i}{a_{i+1}} \right\rfloor \end{pmatrix}, \tag{6}$$

$$M_{i+1} = M_i \tilde{M}_i. \tag{7}$$

Due to (3)–(7), the maximum magnitude μ of l_i and of the entries of M_i (over all i) satisfies the relation

$$\log \mu = (\log(a_0 + a_1))^{O(1)}. \tag{8}$$

For $0 \le i \le n$, define the triangle

$$S_i = \left\{ (x_1, x_2) : x_2 \le \frac{h}{a_{i+1}} - \frac{a_i}{a_{i+1}} x_1,\ x_1 \ge l_i, x_2 \ge k_i \right\},$$

so $S_0 = T^*$. Applying Lemma 5.1, for $S = S_i$, $p = a_i$, $q = a_{i+1}$, $r = h$, $V = V_i$, $l = l_i$, $k = k_i$, $l' = l_{i+1}$, $W = S_{i+1}$, $p' = a_{i+1}$, $q' = a_{i+2}$, $M = \tilde{M}_i$, we can see that S_i is the union of the two triangles (with disjoint interiors) V_i and $\tilde{M}_i S_{i+1}$, where $S_{n+1} = \emptyset$. By induction, we easily deduce that $T = \bigcup_{i=0}^{n-1} M_i V_i$.

Now, due to (8), and since the values k_i and l_i are defined by a linear recurrence with coefficients depending only on h and the a_i, we may compute these values k_i and l_i in NC using the prefix algorithm on their transformation matrix. Similarly, the prefix algorithm allows one to compute in NC the M_i as the products of the $\tilde{M}_i$. □

Remark. If we let $u_i = (h - a_{i+1}k_i)/a_i$, then it can be verified, for $i \ge 2$, that

$$l_i = \left\lfloor \frac{a_{i-1}}{a_i} \right\rfloor u_{i-1} + l_{i-2},$$

$$u_i = \left\lfloor \frac{a_{i-1}}{a_i} \right\rfloor l_{i-1} + u_{i-2}.$$

Thus, if h, k_0, and l_0 are integers, u_0 and l_1 can be expressed as fractions with denominator a_0, and all later terms can be expressed as fractions with denominator $a_0 a_1$. Likewise, if h, k_0, and l_0 are fractions with denominators d_h, d_k, and d_l, all terms can be expressed as fractions with denominator $d_h d_k d_l a_0 a_1$.

6. Final reduction of Opt-2-ILP to EUGCD.

LEMMA 6.1. *Opt-2-ILP over a triangle of the form T = convex hull(α, β, γ), where α, β, and γ are points in $\mathbf{Q}^2$ such that $\alpha_1 = \beta_1 < \gamma_1$, $\alpha_2 > \beta_2$, and $\alpha_2 \ge \gamma_2$, and with objective vector $u \in \mathbf{Z}^2$ such that $u^T\alpha > u^T\beta$ and $u^T\alpha > u^T\gamma$, can be NC-reduced to EUGCD.*

Proof. Given such a triangle by its vertices, we easily convert it in NC to the representation used in the statement of Lemma 4.1 for T. We then trivially produce the parameters for the triangle T' in the statement of that lemma. Using one call to EUGCD, we produce the sequence $a_0, a_1, \ldots, a_n, a_{n+1}$ according to the relation (1), loosely speaking, the continued fraction representation of the slope a_0/a_1 of T'. We now apply Lemma 5.2 to T', computing in NC the unimodular matrices M_i and right triangles V_i with integer slopes such that $T' = \cup_i M_i V_i$. According to Lemma 4.1, the maximum of $u^T x$ over $x \in T$ occurs in $\delta T'$ and so in $T \cap \delta T'$. The set $\delta T'$ is contained in $\cup_i \delta(M_i V_i)$, so $T \cap \delta T'$ is contained in $T \cap \cup_i \delta(M_i V_i)$, which equals $\cup_i (T \cap M_i \delta V_i)$.

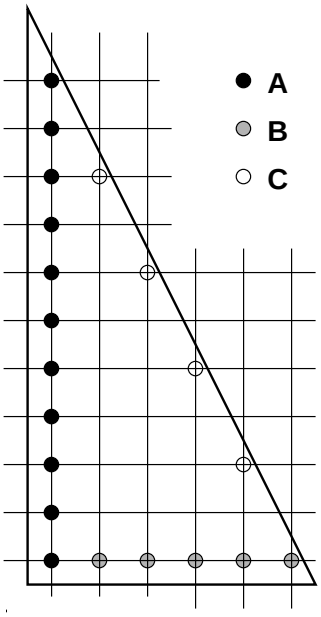

FIG. 6.

Each δV_i can be expressed simply as the union of three pieces A_i, B_i, C_i, each consisting of an arithmetic sequence of integer points, as follows:

$$\delta V_i = A_i \cup B_i \cup C_i,$$

$$A_i = \left\{ (\lceil l_i \rceil, \lceil k_i \rceil + j), \right.$$
$$\left. j = 0, \ldots, \lfloor l_{i+1} \rfloor - \left\lfloor \frac{a_{i+1}}{a_i} \right\rfloor \lceil k_i \rceil - \lceil k_i \rceil \right\},$$

$$B_i = \left\{ (\lceil l_i \rceil + j, \lceil k_i \rceil), \right.$$
$$\left. j = 0, \ldots, \frac{\lfloor l_{i+1} \rfloor - \lceil k_i \rceil}{\left\lfloor \frac{a_{i+1}}{a_i} \right\rfloor} - \lceil l_i \rceil \right\},$$

$$C_i = \left\{ \left(\lceil l_i \rceil + j, \lfloor l_{i+1} \rfloor - \left\lfloor \frac{a_{i+1}}{a_i} \right\rfloor \lceil l_i \rceil - \left\lfloor \frac{a_{i+1}}{a_i} \right\rfloor j \right), \right.$$
$$\left. j = 0, \ldots, \frac{\lfloor l_{i+1} \rfloor - \lceil k_i \rceil}{\left\lfloor \frac{a_{i+1}}{a_i} \right\rfloor} - \lceil l_i \rceil \right\}.$$

(See Figure 6.) Naturally, $M_i \delta V_i$ is the union of $M_i A_i$, $M_i B_i$, and $M_i C_i$. Thus we can maximize $u^T x$ over $x \in T$ by taking the maximum (for $i = 0, 1, ..., n$) of the maxima of $u^T x$ over x in $T \cap M_i A_i$, in $T \cap M_i B_i$, and in $T \cap M_i C_i$. □

THEOREM 6.2. *Opt-2-ILP can be NC-reduced to EUGCD.*

Proof. By Lemma 3.1, Opt-2-ILP can be NC-reduced to Opt-2-ILP over triangles. By Lemma 3.2, Opt-2-ILP over triangles can be NC-reduced to EUGCD plus Opt-2-ILP over triangles of a particular form. Finally, by Lemma 6.1 Opt-2-ILP can be NC-reduced to EUGCD. □

Since [2], [3] give a reduction of EUGCD to Opt-2-ILP, we obtain that Opt-2-ILP and EUGCD are NC-equivalent.

ALL HIGHEST SCORING PATHS IN WEIGHTED GRID GRAPHS AND THEIR APPLICATION TO FINDING ALL APPROXIMATE REPEATS IN STRINGS*

JEANETTE P. SCHMIDT†

Abstract. Weighted paths in directed grid graphs of dimension $(m \times n)$ can be used to model the string edit problem, which consists of obtaining optimal (weighted) alignments between substrings of A, $|A| = m$, and substrings of B, $|B| = n$. We build a data structure (in $O(mn \log m)$ time) that supports $O(\log m)$ time queries about the weight of any of the $O(m^2 n)$ best paths from the vertices in column 0 of the graph to all other vertices. Using these techniques we present a simple $O(n^2 \log n)$ time and $\Theta(n^2)$ space algorithm to find all (the locally optimal) approximate tandem (or nontandem) repeats xy within a string of size n. This improves (by a factor of $\log n$) upon several previous algorithms for this problem and is the first algorithm to find *all locally optimal* repeats. For edit graphs with weights in $\{0, -1, 1\}$, a slight modification of our techniques yields an $O(n^2)$ algorithm for the cyclic string comparison problem, as compared to $O(n^2 \log n)$ for the case of general weights.

Key words. string matching, tandem repeats, edit-distance, dynamic programming

AMS subject classification. 68P99

1. Introduction.

An approximately repeated pattern in a string A is a substring x followed by a substring y, so that x and y match approximately. If x and y are adjacent in A the repeat is called a tandem repeat. An important motivation for the *approximate* tandem repeat problem is found in molecular biology. From a computational point of view, DNA can be viewed as a string over a four letter alphabet (the four nucleotides), while a protein can be viewed as a string over a twenty letter alphabet (the twenty amino acids). Adjacent repeated patterns, or tandem repeats, occur frequently and play an important role in both DNA and protein sequences. Although the function of the repeating patterns that appear on the DNA or protein level is not always well understood, they have been associated with several important properties. For example, researchers have recently discovered that the tips of chromosomes are made up of telomeres, consisting of many repetitions of the same pattern. Each time the cell divides a fixed number of such repetitions is lost. The number of remaining repetitions appears to hold the cell's clock and to determine the number of divisions the cell can still undergo. On the protein level repetitions have been associated with structural properties and have helped determine the secondary structure of proteins, that is, its local folding pattern. As is inevitably the case in biological applications, the repetitions occurring in both DNA and protein sequences are not exact. It is therefore natural to look for approximately repeated patterns.

A very general measure of an approximate match between two strings can be expressed as a shortest (or longest) path in weighted grid graphs. An (m, n) grid graph $G = (V, E)$ is a directed (acyclic) weighted graph whose vertices are the $(m+1) \times (n+1)$

points of the grid with rows $0 \ldots m$ and columns $0 \ldots n$. Vertex (i, j) has a directed edge to $(i+1, j)$, $(i+1, j+1)$, and $(i, j+1)$, provided that these endpoints are within the boundaries of the grid (Figure 1).

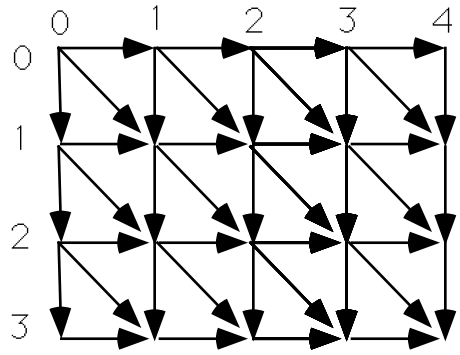

FIG. 1. *A* 3×4 *grid graph.*

The string edit problem is modeled by a grid graph and consists of obtaining an optimal alignment between a substring A' of $A = A_1 \ldots A_m$ and B' of $B = B_1 \ldots B_n$ (i.e., transforming A' into B' by performing a "least cost" series of weighted edit operations on A'). An alignment of $A_i^c = A_{i+1} \ldots A_c$ with $B_{i'}^{c'} = B_{i'+1} \ldots B_{c'}$ corresponds to a path from (i, i') to (c, c') in the graph. An edge $\langle (k, l), (k+1, l) \rangle$ (resp., $\langle (k, l), (k, l+1) \rangle$) on this path with weight w corresponds to skipping over character A_{k+1} (resp., character B_{l+1}), which incurs a penalty of w, while edge $((k, l), (k+1, l+1))$ with weight w' corresponds to aligning A_{k+1} and B_{l+1} with penalty (reward) w', which can be either positive or negative. The weight w of a given edge can be specified directly in the grid graph, or as is frequently the case in biological applications, is given by a penalty matrix (which specifies the substitution cost for each pair of characters and the deletion cost for each character from the alphabet). Depending on whether a positive weight corresponds to a penalty or a reward a best alignment of A_i^c with $B_{i'}^{c'}$ is given by a shortest (resp., longest) weighted path from (i, i') to (c, c') in the grid graph. Since edges can assume negative weights in either case, finding the longest or shortest path is analogous. We will henceforth assume that best alignments correspond to longest (i.e., highest scoring) paths. Computing such paths and hence a best alignment with arbitrary substitution/deletion weights can be done by standard dynamic programming in $O(|A_i^c||B_{i'}^{c'}|)$ time. If weights are arbitrary this is also optimal [H-88].

When trying to identify repetitions in a string we may initially seek the pair $(A_i^c, A_{i'}^{c'})$ whose score is highest among all such pairs. It turns out that under standard similarity measures it appears to be much easier to find "the highest scoring" repeated pattern when the patterns, A_i^c and $A_{i'}^{c'}$, are allowed to overlap (i.e., when c' is not required to be greater than or equal to i). This is discussed in more detail in section 2. In many applications, however, including the ones mentioned earlier, one is really interested in finding nonoverlapping repeated patterns. This problem was addressed in [M-92], [KM-93], and [B-94] using a general penalty matrix, and, among others, in [ML-84], [AP-83], and [C-81] for exact repetitions. In [KM-93] a recursive algorithm is described that reports "the highest scoring" nonoverlapping approximate repeat in $O(n^2 \log^2 n)$ time and $O(n^2 \log n)$ space. A modification of their algorithm was given by [B-94], which reduced the space to $O(n^2)$. [LS-93] study the problem of finding

good tandem repeats under the Levenshtein distance, in which matching characters score 0 and deletions/substitutions of characters score 1, and report repeated patterns whose edit distance is less than k in time $O(kn \log k \log (n/k))$. (The complexity stated in [LS-93] is actually $O(kn \log k \log n)$, but a more careful analysis of the algorithm given there gives the slightly stronger bound stated above.) The algorithm presented in this article is designed for arbitrary penalty matrices, runs in $O(n^2 \log n)$ time, and uses $O(n^2)$ space. Another major advantage of our algorithm over [KM-93], [B-94], in addition to its improved running time, is that it reports all "locally optimal" repeats, and not just the highest scoring pair. This is formally defined in section 3.

The remainder of this article is organized as follows. In section 2 we address the problem of finding highest scoring paths in grid graphs and introduce the notion of *locally optimal* alignments (and paths), as defined in [ES-83]. In section 3 we show how to efficiently compute the highest scoring paths from all points on column zero to all other points in the grid graph. In section 4 we show how the techniques developed in sections 2 and 3 can be applied to solve the approximate *tandem* repeat problem. In section 5 we show how the algorithm can be modified to report locally optimal nontandem repeats. Finally, in section 6 we discuss an application to grid graphs with unit weights.

2. High scoring paths in grid graphs. In this section we review some standard string matching problems and the (dynamic programming) techniques for solving them. We also define the notion of locally optimal alignments and give a general framework for obtaining such alignments. Finally, we show how the notion of locally optimal alignments applies to approximate repeats in a string, and we give an example to explain why the "trivial" solution for identifying repetitions does not give the desired results.

Finding the best alignment between a string A and a string B is one of many string editing problems that occur in a number of applications. To solve this problem alignments between substrings of A and substrings of B are examined. Let $score(A_j^r, B_\ell^t)$ denote the score of the best alignment between $A_j^r = A_{j+1} \dots A_r$ and $B_\ell^t = B_{\ell+1} \dots B_t$. The standard dynamic programming solution for finding $score(A, B)$ defines $T[r, t]$ as $score(A_0^r, B_0^t)$ and computes $T[r, t]$ from the T values of the points in $\{(r-1, t), (r-1, t-1), (r, t-1)\}$ which are contained in the grid. $T[0, 0]$ is initialized to zero, and the solution, $score(A, B)$, is given in $T[m, n]$. Another common problem consists of seeking the substring of B that best matches A. This corresponds to finding a highest scoring path from row zero to row m in the grid. The only difference in the dynamic programming is that now $T[r, t]$ holds the maximum in $\{score(A_0^r, B_\ell^t) \mid \ell \in [0, t]\}$. The computation of $T[r, t]$, for $r > 0$, given the T values of the relevant points in $\{(r-1, t), (r-1, t-1), (r, t-1)\}$, remains the same. The change in the computation is reflected in the initial assignments $T[0, t] = 0$, for $t \in [0, m]$ (assuming as usual that horizontal edges in the graph carry negative weights). The solution $\max_{0 \le \ell \le t \le m} score(A, B_\ell^t)$ is given in $\max_{t \in [0,m]} T[m, t]$.

A somewhat harder problem occurs when no restrictions on the substrings from A and B are given and one seeks to find substrings of A which align well with substrings of B. This latter problem is called the local alignment problem, since "local" pieces of the two strings are matched. Provided that the score of the alignment of two empty strings is defined as 0, and only pairs whose alignment scores above 0 are of interest, [SW-81] showed that essentially the same dynamic $O(n^2)$ programming solution can still be used. $T[r, t]$ would now hold the maximum in $\{score(A_j^r, B_\ell^t) \mid j \in [0, r], \ell \in [0, t]\}$. Note that if none of the suffixes of A_0^r and B_0^t can be aligned with a strictly

positive score, $T[r,t]$ would be set to $score(A_r^r, B_t^t) = 0$. The score for the highest scoring pair is given in $\max_{r\in[0,m],t\in[0,n]} T[r,t]$, but generally this is not the only pair of interest. The question of what other pairs of matching substrings from A and B to report, or in other words what pairs of substrings should be considered locally optimal, has been analyzed in [ES-83] and [WE-87], among others. We will adopt the definition of local optimality as given in Erickson and Sellers [ES-83], which we now describe.

DEFINITION 2.1. *The pair (A_j^r, B_ℓ^t) is locally optimal and satisfies the threshold if the following three conditions hold.*

1. $score(A_j^r, B_\ell^t) \geq$ *threshold;*
2. $\forall r' \geq j$ *and* $t' \geq \ell$, $\quad score(A_j^r, B_\ell^t) \geq score(A_j^{r'}, B_\ell^{t'})$;
3. $\forall j' \leq r$ *and* $\ell' \leq t$, $\quad score(A_{j'}^r, B_{\ell'}^t) \leq score(A_j^r, B_\ell^t)$.

Locally optimal alignments with any threshold $\tau > 0$ can be found in two passes of dynamic programming, each pass as just described. In the first pass each endpoint (r,t) records a pair of indexes (j,ℓ) which maximizes $score(A_j^r, B_\ell^t)$, by setting $S[r,t] = (j,\ell)$. This is easily done during the computation of $T[r,\ell]$, since (j,ℓ) satisfies $score(A_j^r, B_\ell^t) = T[r,t]$. The second pass is a (backward) dynamic programming on the transposed grid graph, where values $T^b[j,\ell]$ hold the maximum in $\{score(A_j^r, B_\ell^t) \mid r \in [j,m], t \in [\ell,n]\}$. Each point (j,ℓ) records a pair of indexes (r,t) which maximizes $score(A_j^r, B_\ell^t)$ $(r \geq j, t \geq \ell)$ by setting $E[j,\ell] = (r,t)$. It is not difficult to verify that if the above maxima are unique, a pair (A_j^r, B_ℓ^t) is *locally optimal* (according to Definition 2.1) if and only if $S[r,t] = (j,\ell)$ and $E[j,\ell] = (r,t)$. After the two dynamic programming passes, the locally optimal pairs and (with some extra standard bookkeeping) their alignments can be reported. When the suffixes of A_0^r and A_0^t (resp., prefixes of A_j^m and B_ℓ^n) yielding the best alignment are not unique one can either use a tie-breaking rule (such as the maximum j and maximum ℓ) or record all pairs (j,ℓ) (resp., (r,t)) yielding the highest score. In the latter case $S[r,t]$ and $E[j,\ell]$ hold a set of points. A pair (A_j^r, B_ℓ^t) would be considered locally optimal if $(j,\ell) \in S[r,t]$ and $(r,t) \in E[j,\ell]$.

Similar questions, as just described, are of considerable interest when comparing the string A to itself. Due to the symmetric nature of the grid graph corresponding to the comparison of a string with itself, the analysis can be limited to the upper triangular grid graph. In addition, the diagonal of the grid graph is initialized to zero, to exclude the possibility of the uninteresting case corresponding to any character A_j matching itself in an alignment.

Consider hence the (upper triangular) $(n+1)\times(n+1)$ grid graph obtained when comparing string $A = A_1, \ldots, A_n$ with itself. An approximate repeat (A_j^r, A_ℓ^t) with $\ell \geq r$ corresponds to the highest scoring path in the (upper triangular) grid graph from point (j,ℓ) to point (r,t). If $score(A_j^r, A_\ell^t)$ is above the (predetermined) threshold, the pair (A_j^r, A_ℓ^t) would be considered an approximate repeat in A. If $\ell = r$, so that there is no gap between the two substrings, the repeat is tandem. All approximate *tandem* repeats (A_j^c, A_c^t) correspond to a path in the (upper triangular) grid graph from a point on column c to a point on row c. If pairs (A_j^r, A_ℓ^t) are included for which $\ell < r$ (indicating that the strings overlap), the problem changes drastically. Finding the best scoring (possibly overlapping) repeat reduces to finding the substrings A_j^r and A_ℓ^t, for which the weight of the optimal path from (j,ℓ) to (r,t) in the (upper triangular) grid graph is highest among all such pairs, or alternatively finding the pairs of substrings whose alignments are locally optimal . The above problem can be directly solved by (one or two passes of) dynamic programming on a triangular grid graph,

as just described for square matrices. One problem in including these overlapping repeats is that in many applications nonoverlapping repeats are sought. In addition, these overlapping repeats present an "unfair competition" in the search for the best repeats. The best tandem repeat (or highest scoring path from some column c to some row c) might be very different than the best path starting at an earlier column c'. More precisely, the overlapping repeats may "hide" interesting tandem repeats. Consider, for example, the string $A = IRQIQLWLRQIWIRLRQL$, compared to itself. Figure 2 shows a penalty matrix and the resulting (upper triangular) dynamic programming matrix of A versus A. With the specified penalty matrix the (highest scoring) tandem repeat $IRQI\lfloor QLWLR\rfloor\lceil QIWIR\rceil LRQL$ would not be found. The alignments that would be found (given a threshold value 3) would be the (approximate) nontandem repeat $\lfloor IRQI\rfloor QLWLRQIWIR\lceil LRQL\rceil$, the (approximate) nontandem repeat $\lfloor \mathbf{IR}Q\mathbf{IQL}\rfloor WLRQIW\lceil \mathbf{IRL}R\mathbf{QL}\rceil$, and the long overlapping repeat $\lfloor IRQIQLW\lceil LRQI\rfloor WIRLRQL\rceil$, whose alignments are shown in Figure 2.

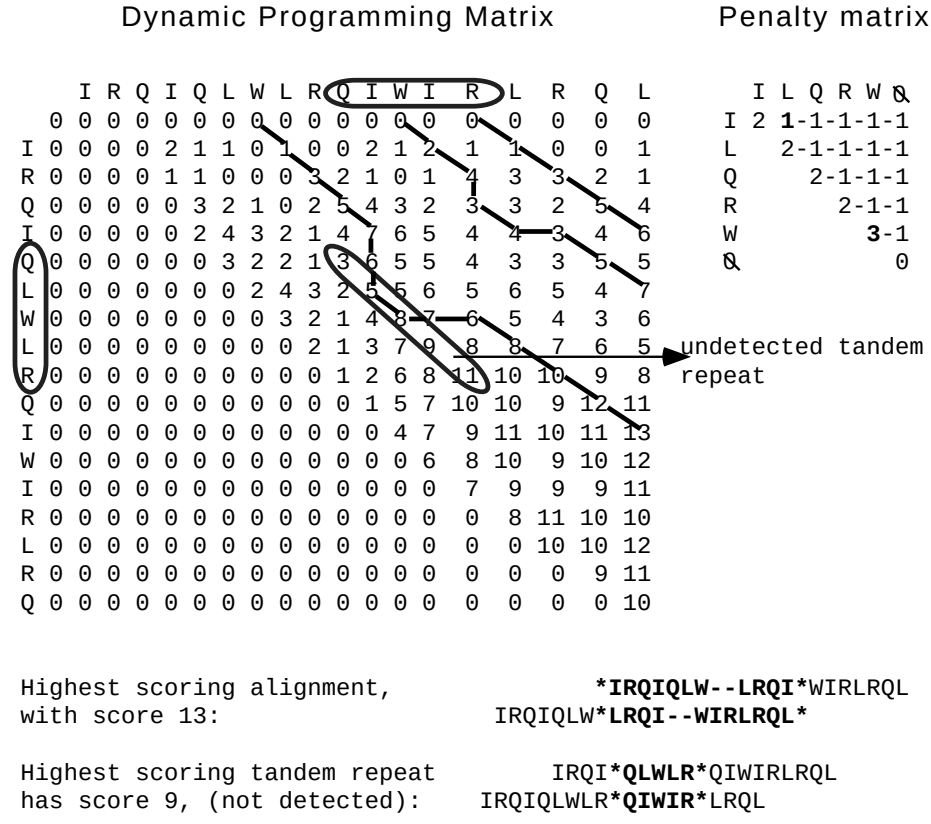

FIG. 2. *Example of a tandem repeat, not detected in a global search.*

It is worth noting that overlapping repeats are of independent interest, as they might indicate that a smaller string is (approximately) repeated several times. It appears that a different scoring method might be needed to detect both many repetitions of the same string and nonoverlapping repeats in the same search.

Note that a simple (but expensive) solution to the problem of finding nonover-

lapping repeats is to compare A_0^c with A_c^n, for $c = 1 \ldots n$. The comparison of A_0^c and A_c^n is modeled by a (rectangular) grid graph G_c of size $(c+1) \times (n-c+1)$. For nonoverlapping, but not necessarily tandem repeats one simply needs to find, for each c, the pair (A_j^r, A_ℓ^t) $(0 \le j \le r \le c$, and $c \le \ell \le t \le n)$ for which $score(A_j^r, A_\ell^t)$ is maximal, or more generally, find all locally optimal such pairs. Tandem repeats in this comparison have midpoint c and are of the form (A_j^c, A_c^t); they correspond to paths that must start anywhere in column 0 of G_c and must end anywhere in the last row (row c) of G_c. To compute the score of the highest scoring tandem repeat, the dynamic programming would be adapted as follows. $T_c[r,t]$ (defined for $r \le c$ and $t \ge c$) would hold the maximum score in $\{score(A_j^r, A_c^t) \mid j \in [0,r]\}$, and $S_c[r,t]$ would hold the index j (as a representative for the pair (j,c)), maximizing the score. The score of the best repeat is $\max_t T_c[c,t]$. Adapting Definition 2.1 to the problem of tandem repeats, we would seek all pairs (A_j^c, A_c^t) for which $score(A_j^c, A_c^t)$ is both $\max_{j' \le c} score(A_{j'}^c, A_c^t)$ and $\max_{t' \ge c} score(A_j^c, A_c^{t'})$. An equivalent definition is given below.

DEFINITION 2.2. *A tandem repeat (A_j^c, A_c^t) is locally optimal among all such repeats if the best match for A_j^c is A_c^t and vice versa. Formally, $score(A_j^c, A_c^t) = \max_{t' \ge c} score(A_j^c, A_c^{t'})$ and $score(A_j^c, A_c^t) = \max_{j' \le c} score(A_{j'}^c, A_c^t)$.*

As in the general case, locally optimal tandem repeats can be easily identified in two passes of dynamic programming. We first compute $T_c[r,t]$ and $S_c[r,t]$, as just defined. We then compute $T_c^b[j,\ell]$ (defined for $j \le c$ and $\ell \ge c$), which holds the maximum score in $\{score(A_j^c, A_\ell^t) \mid t \in [\ell, n]\}$, and $E_c[j,\ell]$, which holds the index t (representing the pair (c,t)) maximizing the score. Here the score of the best repeat is given in $\max_j T^b[j,c]$. A *tandem repeat* is locally optimal if $S_c[c,t] = j$ and $E_c[j,c] = t$.

The straightforward algorithm outlined above would identify all locally optimal tandem repeats and all locally optimal nonoverlapping repeats in $O(n^3)$ time. Our algorithm will report the same set of repeats in $O(n^2 \log n)$ time. We will treat tandem and nontandem repeats separately. Our main algorithm is tailored to tandem repeats. We then show how to modify the algorithm (without a penalty in either time or space) to report nontandem repeats as well.

A key component of our scheme is a data structure for implicitly computing in $O(mn \log m)$ time all $O(m^2 n)$ best paths from vertices $(i,0)$ (for $i \in [0,m]$) to *all other reachable vertices* in an (m,n) grid graph. In the same time bound we will also compute the weight of the $O(mn)$ best paths from vertices $(i,0)$ (for $i \in [0,m]$) to the jth row in the grid graph (for $j \ge i$). This feature appears to be essential for a fast algorithm that identifies all repeats above a given score in a string A. The methods exhibited in this article can be viewed as another example of speeding up dynamic programming by keeping and computing only a select subset of important values, as shown on several instances in the seminal articles [EG-92] and [EGa-92].

3. Computing the all source highest scoring paths in a grid graph.

3.1. Preliminary definitions. Suppose we wish to compute the highest scoring path from each of the vertices $(i,0), i \in [0,m]$, to all other vertices, or just even to all vertices on the last row of the grid graph. The latter problem has been studied in [AALM-90, AP-88] as a tool to design a parallel algorithm for computing the highest scoring path from $(0,0)$ to (m,n). They named the $O(mn)$ matrix whose $[i,j]$ entry holds the highest scoring path from node $(i,0)$ to node (m,j) in the grid graph the $DIST$ matrix. ([AALM-90] actually used this notion to denote the $(n+m)(n+m)$ highest scoring paths from the left and upper boundaries of the grid to the bottom

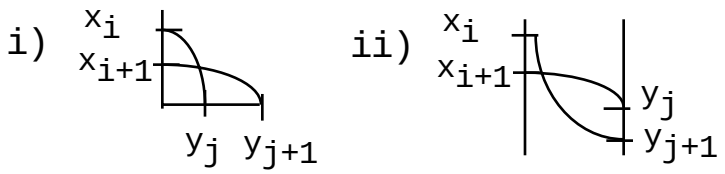

FIG. 3. *Paths that must cross.*

and right boundaries of the grid.) All our results apply to that definition as well, but for notational convenience it will be simpler to consider the smaller $DIST$ matrices.

Although [AALM-90] introduced $DIST$ matrices in the context of parallel algorithms, it turns out that $DIST$ matrices are interesting in sequential computations as well. Indeed, they were used in both [KM-93] and [B-94].

Instead of just computing one $DIST$ matrix, we will define and compute $m+1$ $DIST$ matrices associated with an (m,n) grid graph. These matrices will be denoted by $DIST_0, \ldots, DIST_m$ and are formally defined below.

DEFINITION 3.1. *Let* $DIST_\ell = [0 \ldots \ell, 0 \ldots n]$ *denote the* $(\ell+1) \times (n+1)$ *matrix, with* $DIST_\ell[i,j]$ *storing the weight of the highest scoring path from vertex* $(i,0)$ *to vertex* (ℓ, j).

None of the methods outlined in the previous sections allow us to compute all the entries in a $DIST$ matrix efficiently. Note, however, that the highest scoring path from column 0 to vertex (j,ℓ) in the grid graph corresponds to the maximum value in column j of the matrix $DIST_\ell$. Using the methods outlined in the previous section it is easy to see that the n column maxima of $DIST_\ell$ can be computed in $O(\ell n)$ time (without explicitly computing the entries of the $DIST$ matrix). Similarly using (backwards) dynamic programming, the ℓ row maxima can be computed in $O(\ell n)$ time. The naive computation of all the row and column maxima of the $m+1$ $DIST$ matrices would require $O(m^2 n)$ time. If, however, the entries of the $DIST$ matrices had been somehow precomputed their row and column maxima can be computed quickly. Indeed, Aggarwal and Park [AP-88] observed that $DIST$ matrices are Monge arrays (defined below), and [AKMSW-87] had shown that if all entries of a Monge array M can be accessed in $O(1)$ time, the m row maxima and n column maxima of M can be computed in $O(n)$ time (assuming $m \leq n$).

Following their terminology, we have the following definition.

DEFINITION 3.2. *A matrix* $M[0 \ldots m, 0 \ldots n]$ *is Monge if either condition* 1 *or* 2 *below holds for all* i, j*:*

1. $M[i,j] + M[i+1,j+1] \geq M[i,j+1] + M[i+1,j]$;
2. $M[i,j] + M[i+1,j+1] \leq M[i,j+1] + M[i+1,j]$.

The fact that $DIST$ matrices are Monge arrays (obeying property 2) is easily seen by noticing that the highest scoring paths from $x_i = (i,0)$ to $y_j = (\ell, j)$ and from $x_{i+1} = (i+1, 0)$ to $y_{j+1} = (\ell, j+1)$ (whose weights are recorded in $DIST_\ell[i,j]$ and $DIST_\ell[i+1, j+1]$) must cross (see Figure 3). These two paths can be piecewise combined to obtain a path from x_i to y_{j+1} and a path from x_{i+1} to y_j. The sum of the weights of the two highest scoring paths from x_i to y_{j+1} and x_{i+1} to y_j is by definition given by $DIST_\ell[i, j+1] + DIST_\ell[i+1, j]$. It immediately follows that $DIST_\ell[i,j] + DIST_\ell[i+1, j+1] \leq DIST_\ell[i, j+1] + DIST_\ell[i+1, j]$. For similar reasons (see Figure 3) we also have that $DIST_\ell[i+1, j] + DIST_{\ell+1}[i,j] \leq DIST_\ell[i,j] + DIST_{\ell+1}[i+1, j]$ (and hence the arrays $X_j[\ell, i] = DIST_\ell[i,j]$ are also Monge arrays, this time obeying property 1) (see Figure 3).

[AP-88] and [AALM-90] developed a recursive parallel algorithm to efficiently compute all the values in the matrix $DIST_m$. Its sequential counterpart takes $O(mn \log m)$ time and is also the best known sequential algorithm for computing $DIST_m$. We need to compute the values in $m+1$ $DIST$ matrices. If all entries of these matrices were to be output, $O(m^2 n)$ would be an obvious lower bound for the problem. This, however, turns out not to be necessary in our applications. Instead we will build a data structure in $O(mn \log m)$ time that will allow us to answer a query about the weight of the highest scoring path between $(i, 0)$ and (ℓ, j) in $O(\log \ell)$ time (for any $i \leq \ell$ and $j \in [0, n]$). Reporting *all entries* of a given $DIST$ matrix will take only $O(1)$ time per entry. The data structure will also allow us to report the n column maxima of matrix $DIST_\ell$ in $O(n + \ell \log n)$ time and the ℓ row maxima of matrix $DIST_\ell$ in $O(\ell + n \log \ell)$ time. If $m \leq n$, the total time to report all row and column maxima of the $m+1$ $DIST$ matrices is hence dominated by the time to construct the data structure and is achieved in $O(mn \log m)$ time. (For $m > n$ the time is $O(m^2 \log n)$.)

Our computation of the matrices $DIST_\ell$ proceeds as follows. Iteratively, for all values of $\ell \in [0, m]$, a representation for the matrix $DIST_\ell$ is constructed. Each such representation is computed in $O(n \log \ell)$ time from the representation of the previous $DIST$ matrix, $DIST_{\ell-1}$. Given the representation of $DIST_{\ell-1}$ the additional space required to construct the representation of $DIST_\ell$ is $O(n \log \ell)$. Hence if all representations are to be kept the total space used would be $O(mn \log m)$. In many applications, however (for example, if only the row maxima or the column maxima of the matrices $DIST_\ell$ are of interest), the representation of $DIST_{\ell-1}$ does not have to be kept after the representation of $DIST_\ell$ has been computed. We will prove the following theorems in sections 3.2–3.4.

THEOREM 3.3. *Given an (m, n) grid graph G with arbitrarily weighted edges, a representation of the m $DIST_\ell$ matrices can be computed in $O(nm \log m)$ time and $O(nm \log m)$ space. Any entry in any one of the $DIST_\ell$ matrices can thereafter be retrieved in $O(\log \ell)$ time. Retrieving an entire column of $DIST_\ell$ takes only $O(1)$ time per column entry.*

The following theorem states that row and column maxima can be computed efficiently in the above representation.

THEOREM 3.4. *Given an $m \times n$ grid graph G with arbitrary weights, all the row maxima and column maxima of the matrices $DIST_\ell$, for $\ell \in [0, m]$, can be computed in $O(nm \log m)$ time if $m \leq n$ (and $O(m^2 \log n)$ time otherwise) and $O(mn)$ space.*

3.2. Data structure used to represent the matrices $DIST_\ell$ and proof of Theorem 3.3. The data structure used to represent matrix $DIST_\ell$ is a collection $B_\ell^0, \ldots, B_\ell^n$ of $n+1$ binary trees of height $\lceil \log(\ell + 1) \rceil$. Each tree B_ℓ^j has exactly $(\ell+1)$ leaves and its tree edges are labeled by real numbers. B_ℓ^j is the tree "belonging" to vertex (ℓ, j) and its $\ell + 1$ leaves are in 1-1 correspondence (in left to right order) with the $\ell + 1$ vertices $(i, 0)$, $i \in [0, \ell]$.

In particular, *the weight of the highest scoring path from vertex $(i, 0)$ to vertex (ℓ, j) (corresponding to $DIST_\ell(i, j)$) is given by the sum of the weights of the edges on the path from the root to leaf i in B_ℓ^j (and can hence be retrieved in $O(\log \ell)$ time).*

The tree B_ℓ^j hence encodes column j of $DIST_\ell$. Note that the second part of Theorem 3.3 is readily achieved by the above representation of the $DIST$ matrices. To complete the proof of Theorem 3.3 it remains to show that the trees B_ℓ can be efficiently computed.

The structure of all trees B_ℓ is the same. B_ℓ is a subtree of the perfectly balanced

binary tree with $2^{\lceil \log(\ell+1) \rceil}$ leaves, containing only the paths to leaves $0 \dots \ell$. The tree path from the root to node i is hence (structurally) the same in all trees $B_\ell^j, j \in [0 \dots n]$ (and remains the same in trees $B_{\ell'}$ for which $\lceil \log(\ell'+1) \rceil = \lceil \log(\ell+1) \rceil$). In addition to the labels on the tree edges, each internal node x, whose left subtree is a complete binary tree, carries a label that holds the sum of the labels of the edges from x to the rightmost child in the left subtree of x.

OBSERVATION 3.5. *The ℓ highest scoring paths from nodes $(i,0), i = 1 \dots \ell$, to (ℓ, j) (i.e., the values in the jth column of the matrix $DIST_\ell$) can be output in $O(\ell)$ time by traversing the tree B_ℓ^j. Furthermore, if $c = 2^{\lceil \log(\ell+1) \rceil - 1}$ the highest scoring path from $(c,0)$ to (ℓ, j) can be retrieved in $O(1)$ time (for each j) by accessing the label of the root of B_ℓ^j.*

Note also that after traversing (and adding weights on) a path from the root to an internal node x, the highest scoring path "to the middle child" of x can be retrieved in $O(1)$ time.

We proceed to show how to construct the trees $B_{\ell+1}^0 \dots B_{\ell+1}^n$ from the trees $B_\ell^0 \dots B_\ell^n$ in $O(n \log \ell)$ time.

DEFINITION 3.6. *Denote by $B_\ell^j(i)$ the sum of the weights from the root to leaf i in B_ℓ^j. $B_\ell^j(i)$ is hence equal to $DIST_\ell[i,j]$, the highest scoring path from vertex $(i,0)$ to vertex (ℓ, j).*

The values $B_\ell^j(i) = DIST_\ell[i,j]$ are related by the following recurrence.

OBSERVATION 3.7. *Let $w_{i,j}^{k,l}$ be the weight of the edge from point (i,j) to point (k,l) in the grid graph $((k,l) \in \{(i,j+1),(i+1,j+1),(i+1,j)\})$; then:*

$$\forall\ i, \ell, j \geq 0,\ i \leq \ell + 1,\ j \leq n - 1,$$
$$B_{\ell+1}^{j+1}(i) = \max \begin{cases} B_\ell^{j+1}(i) + w_{\ell,j+1}^{\ell+1,j+1}, \\ B_\ell^j(i) + w_{\ell,j}^{\ell+1,j+1}, \\ B_{\ell+1}^j(i) + w_{\ell+1,j}^{\ell+1,j+1}, \end{cases}$$
$$B_0^{j+1}(0) = B_0^j(0) + w_{0,j}^{0,j+1},\ B_{\ell+1}^0(i) = B_\ell^0(i) + w_{\ell,0}^{\ell+1,0},\ \text{and}\ B_0^0 = 0.$$

Given the trees B_ℓ^{j+1}, B_ℓ^j, and $B_{\ell+1}^j$, the tree $B_{\ell+1}^{j+1}$ can be constructed in $O(\log \ell)$ time by adding $O(\log \ell)$ nodes to the existing structures. To construct $B_{\ell+1}^j$ we observe that the following lemma must hold.

LEMMA 3.8. *For each $j \in [0,n]$, the interval $[0, \ell+1]$, corresponding to the source vertices (rows) of the matrix $DIST_{\ell+1}$ can be partitioned into three intervals $[0, i_1)$, $[i_1, i_2)$, and $[i_2, \ell+1]$, $0 \leq i_1 \leq i_2 \leq \ell+1$, so that a highest scoring path from $(i,0)$ to $(\ell+1, j+1)$ goes through $(\ell, j+1)$ if $i \in [0, i_1)$, goes through (ℓ, j) if $i \in [i_1, i_2)$, and goes through $(\ell+1, j)$ if $i \in [i_2, \ell+1]$. (Notice that $\ell+1$ is always contained in the third interval, as the only path from $(\ell+1, 0)$ to $(\ell+1, j+1)$ goes through $(\ell+1, j)$.) Formally, there are indexes $0 \leq i_1 \leq i_2 \leq \ell+1$ so that*

$$B_{\ell+1}^{j+1}(i) = \begin{cases} B_\ell^{j+1}(i) + w_{\ell,j+1}^{\ell+1,j+1}, & i \in [0, i_1), \\ B_\ell^j(i) + w_{\ell,j}^{\ell+1,j+1}, & i \in [i_1, i_2), \\ B_{\ell+1}^j(i) + w_{\ell+1,j}^{\ell+1,j+1}, & i \in [i_2, \ell+1]. \end{cases}$$

Proof. We first give a quick proof derived from the fact that certain highest scoring paths need not cross. We then proceed to a formal proof using the Monge property which will also indicate why the points i_1 and i_2 should be efficiently computable. Suppose that a partition as described in Lemma 3.8 was not possible; then there are two points $(0,i)$ and $(0,i')$ $(i > i')$ such that all highest scoring paths from

$(\ell+1, j+1)$ to $(0, i)$ and from $(\ell+1, j+1)$ to $(0, i')$ immediately separate and then cross. These paths can be combined to obtain a pair of paths (with same score) to $(0, i)$ and $(0, i')$ that overlap up to the crossing point and hence do not immediately separate—a contradiction. The lemma can also be proven formally using the fact that $DIST$ arrays are Monge arrays, which directly implies that the following monotonicity properties hold.

Monotonicity properties. For any fixed $j < \ell$ and for all $i < \ell$, the following inequalities hold:

1. $h\_dif_i = B_\ell^{j+1}(i) - B_\ell^j(i) \geq B_\ell^{j+1}(i+1) - B_\ell^j(i+1) = h\_dif_{i+1}$,
2. $v\_dif_i = B_\ell^j(i) - B_{\ell+1}^j(i) \geq B_\ell^j(i+1) - B_{\ell+1}^j(i+1) = v\_dif_{i+1}$,
   and (adding the inequalities)
3. $d\_dif_i = B_\ell^{j+1}(i) - B_{\ell+1}^j(i) \geq B_\ell^{j+1}(i+1) - B_{\ell+1}^j(i+1) = d\_dif_{i+1}$.

The sequences (h_dif_i), (v_dif_i), and (d_dif_i), $i = 0 \ldots \ell$, are hence nonincreasing. In addition, $d\_dif_i = h\_dif_i + v\_dif_i$.

Combining the above definitions of h_dif, v_dif, and d_dif with Observation 3.7, we obtain that

$$B_{\ell+1}^{j+1}(i) = B_\ell^{j+1}(i) + w_{\ell,j+1}^{\ell+1,j+1} \quad \text{iff} \begin{cases} h\_dif_i \geq w_{\ell,j}^{\ell+1,j+1} - w_{\ell,j+1}^{\ell+1,j+1} \text{ and} \\ d\_dif_i \geq w_{\ell+1,j}^{\ell+1,j+1} - w_{\ell,j+1}^{\ell+1,j+1}, \end{cases}$$

$$B_{\ell+1}^{j+1}(i) = B_\ell^j(i) + w_{\ell,j}^{\ell+1,j+1} \quad \text{iff} \begin{cases} h\_dif_i \leq w_{\ell,j}^{\ell+1,j+1} - w_{\ell,j+1}^{\ell+1,j+1} \text{ and} \\ v\_dif_i \geq w_{\ell+1,j}^{\ell+1,j+1} - w_{\ell,j}^{\ell+1,j+1}, \end{cases}$$

$$B_{\ell+1}^{j+1}(i) = B_{\ell+1}^j(i) + w_{\ell+1,j}^{\ell+1,j+1} \quad \text{iff} \begin{cases} v\_dif_i \leq w_{\ell+1,j}^{\ell+1,j+1} - w_{\ell,j}^{\ell+1,j+1} \text{ and} \\ d\_dif_i \leq w_{\ell+1,j}^{\ell+1,j+1} - w_{\ell,j+1}^{\ell+1,j+1}. \end{cases}$$

Since h_dif_i and d_dif_i are nonincreasing it follows that $B_{\ell+1}^{j+1}(i) = B_\ell^{j+1}(i) + w_{\ell,j+1}^{\ell+1,j+1}$ holds in the interval $[0, i_1)$ for some $i_1 \geq 0$. The proof for the other cases is analogous.

Note that the values i_1 and i_2 in the lemma are generally not unique, but i_1, for example, can be chosen either as the smallest index for which $h\_dif_i < w_{\ell,j}^{\ell+1,j+1} - w_{\ell,j+1}^{\ell+1,j+1}$ or $d\_dif_i < w_{\ell+1,j}^{\ell+1,j+1} - w_{\ell,j+1}^{\ell+1,j+1}$, denoted by i_1^{max}, or it can be chosen as the smallest index for which $h\_dif_i \leq w_{\ell,j}^{\ell+1,j+1} - w_{\ell,j+1}^{\ell+1,j+1}$ or $d\_dif_i \leq w_{\ell+1,j}^{\ell+1,j+1} - w_{\ell,j+1}^{\ell+1,j+1}$, denoted by i_1^{min}. Alternatively, i_1 can be chosen as any index in $[i_1^{min}, i_1^{max}]$.

Henceforth we will assume that $i_1 = i_1^{max}$ and $i_2 = i_2^{max}$. □

LEMMA 3.9. *Tree $B_{\ell+1}^{j+1}$ can be computed from the trees B_ℓ^{j+1}, B_ℓ^j, and $B_{\ell+1}^j$ in $O(\log \ell)$ steps.*

Proof. To compute $B_{\ell+1}^{j+1}$ from the trees B_ℓ^j, B_ℓ^{j+1}, and $B_{\ell+1}^j$ the first step will consist of finding the breakpoints i_1 and i_2 (Lemma 3.8). To do so, we first perform a search on the trees B_ℓ^{j+1} and B_ℓ^j, mimicking a binary search on the values $h\_dif_i = (B_\ell^{j+1}(i) - B_\ell^j(i)), i = 0 \ldots \ell$, to determine i' the smallest i (if any) for which $h\_dif_i < w_{\ell,j}^{\ell+1,j+1} - w_{\ell,j+1}^{\ell+1,j+1}$. Clearly $i_1 \leq i'$; in fact, if the interval $[i_1, i_2)$ is not empty then $i_1 = i'$. This is so because if i_1 were less than i' we would have $h\_dif_{i_1} \geq w_{\ell,j}^{\ell+1,j+1} - w_{\ell,j+1}^{\ell+1,j+1}$, while $d\_dif_{i_1} < w_{\ell+1,j}^{\ell+1,j+1} - w_{\ell,j+1}^{\ell+1,j+1}$. But if $[i_1, i_2)$ is not empty then $v\_dif_{i_1} \geq w_{\ell+1,j}^{\ell+1,j+1} - w_{\ell,j}^{\ell+1,j+1}$. But since $d\_dif_{i_1} = h\_dif_{i_1} + v\_dif_{i_1}$, the above three inequalities cannot all hold, and $[i_1, i_2)$ not empty implies that $i_1 = i'$. Therefore, instead of determining the threshold value for d_dif_i, we proceed with a binary search

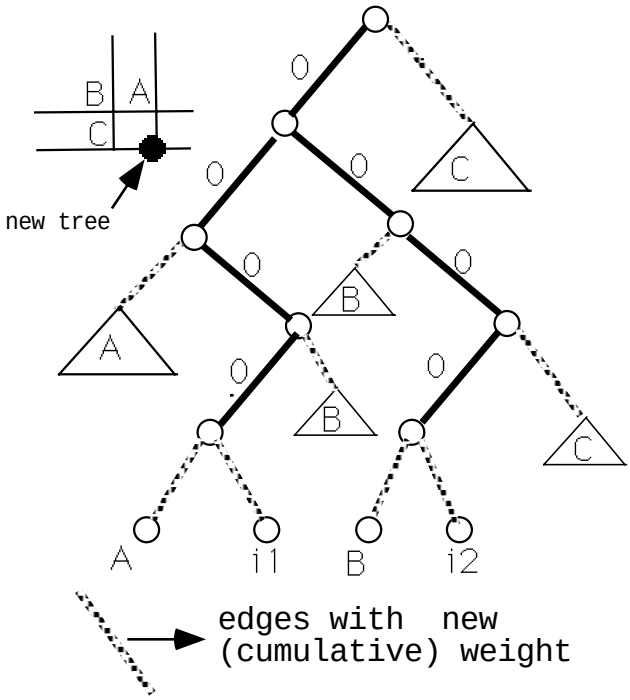

FIG. 4. *The tree $B_{\ell+1}^{j+1}$, as pasted together from subtrees of B_ℓ^{j+1} (marked A), subtrees of B_ℓ^j (marked B), and subtrees of $B_{\ell+1}^j$ (marked C) and $O(\log \ell)$ additional nodes.*

on $v\_dif_i = (B_\ell^j(i) - B_{\ell+1}^j(i)), i = 0 \dots \ell$, to find i'' the smallest i (if any) for which $v\_dif(i) < w_{\ell+1,j}^{\ell+1,j+1} - w_{\ell,j}^{\ell+1,j+1}$. For similar reasons as before, if $[i_1, i_2)$ is not empty then $i_2 = i''$. In addition, if $i'' > i'$ then $[i_1, i_2)$ cannot be empty. Hence if $i'' > i'$ we are done; otherwise the middle interval is empty and $i_1 = i_2$. The breakpoint (say i_1) between paths going through $(\ell+1, j)$ and those going through $(\ell, j+1)$ is determined by an additional binary search on $d\_dif(i) = (B_\ell^{j+1}(i) - B_{\ell+1}^j(i)), i = 0 \dots \ell$, to determine the smallest $i \in [0, \ell]$ for which $d\_dif_i < w_{\ell+1,j}^{\ell+1,j+1} - w_{\ell,j+1}^{\ell+1,j+1}$. If no such i exists, $i1 = i_2 = \ell + 1$.

After the points i_1 and i_2 have been determined, we have to construct the new tree $B_{\ell+1}^{j+1}$. (Generally, the structure of the paths to leafs $0 \dots \ell$ is the same in trees $B_{\ell+1}^{j+1}$ and B_ℓ^{j+1}. The only exception occurs when B_ℓ^{j+1} is a complete binary tree, in which case the paths in $B_{\ell+1}^{j+1}$ have an additional first edge.) $B_{\ell+1}^{j+1}$ should "contain" the portion of the tree B_ℓ^{j+1} to leaves in $[0, i_1)$ with additional weight $w_{\ell,j+1}^{\ell+1,j+1}$ and should "contain" the portion of the tree B_ℓ^j to leaves in $[i_1, i_2)$ with additional weight $w_{\ell,j+1}^{\ell+1,j+1}$, as well as the portion of the tree $B_{\ell+1}^j$ to leaves in $[i_2, \ell+1]$ with additional weight $w_{\ell+1,j}^{\ell+1,j+1}$. To construct the tree $B_{\ell+1}^{j+1}$ we start by creating a new root and new nodes along the path leading to the parent of leaf i_1 as well as the path leading to the parent of i_2. All edges on these new paths will carry a label with value 0 (see Figure 4).

Denote the path to the parent of i_1 in $B_{\ell+1}^{j+1}$ by P_1 and the path to the parent of i_2 by P_2. To complete the tree $B_{\ell+1}^{j+1}$ the appropriate subtrees from B_ℓ^{j+1}, B_ℓ^j, and

$B^j_{\ell+1}$ are attached to $P1$ and $P2$, and the edges to these subtrees must be labeled with the proper weights. Each node on $B^{j+1}_{\ell+1}$ is in a natural 1-1 correspondence with a node on $B^j_{\ell+1}$. Let L be the least common ancestor of leaf $\ell+1$ and leaf ℓ in $B^j_{\ell+1}$. With the exception of the nodes on the path from L to leaf $\ell+1$ all nodes also have a corresponding node on B^{j+1}_ℓ and B^j_ℓ. Let x be a node (internal or leaf) in B^{j+1}_ℓ, and let $B^{j+1}_\ell(x)$ denote the sum of weights on the path from the root to node x. The missing *left* subtrees of $P1$ are taken from B^{j+1}_ℓ. The label of the edge from $p \in P1$ to such a subtree rooted at x is set to $B^{j+1}_\ell(x) + w((\ell, j+1), (\ell+1, j+1))$. The missing right subtrees of $P2$ are taken from $B^j_{\ell+1}$. The label from $p \in P2$ to such a right subtree rooted at x is set to $B^j_{\ell+1}(x) + w((\ell+1, j), (\ell+1, j+1))$. All other subtrees are taken from B^j_ℓ, and the label of these edges is set to $B^j_\ell(x) + w((\ell, j), (\ell+1, j+1))$. Notice that $B^{j+1}_\ell(x)$ is only computed for children of nodes lying on the path to leaf i_1, and these values can therefore be computed in $O(\log \ell)$ time. A similar claim holds for the values $B^j_\ell(x)$ and $B^j_{\ell+1}(x)$ needed in the construction of $B^{j+1}_{\ell+1}$. In addition, each node on P_1 and P_2 that has a complete binary tree as its left subtree must compute the sum of the labels of the path to the rightmost child of this left subtree. Depending on which of the three intervals this child belongs to, this vertex label is computed (in $O(1)$ amortized time) from the labels on the new tree edges, and the vertex labels of the corresponding node in trees B^{j+1}_ℓ, B^j_ℓ, or $B^j_{\ell+1}$. The tree $B^{j+1}_{\ell+1}$ is hence constructed in $O(\log \ell)$ time and the weights on its edges and vertices satisfy the required properties. The construction of the tree $B^0_{\ell+1}$ from B^0_ℓ is slightly different (and in fact simpler) and is readily seen to be achievable in $O(\log \ell)$ time. The new nodes created are those on the path to leaf $\ell+1$. The trees B^j_0 have one leaf each and B^{j+1}_0 is constructed in $O(1)$ time from B^j_0. □

We are now ready to summarize the proof of Theorem 3.3.

THEOREM 3.3. *Given an (m, n) grid graph G with arbitrarily weighted edges, a representation of the m $DIST_\ell$ matrices can be computed in $O(nm \log m)$ time and $O(nm \log m)$ space. Any entry in any one of the $DIST_\ell$ matrices can thereafter be retrieved in $O(\log \ell)$ time. Retrieving an entire column of $DIST_\ell$ takes only $O(1)$ time per column entry.*

Proof. The representation of $DIST_\ell$ is the collection of subtrees $B^0_\ell \ldots B^n_\ell$. $DIST_\ell(i, j)$ corresponds to the weight of the path to leaf $B^j_\ell(i)$ in tree B^j_ℓ and can hence be retrieved in $O(\log \ell)$ time. By Lemma 3.9 this collection can be computed from the collection $B^0_{\ell-1} \ldots B^n_{\ell-1}$ in $O(n \log \ell)$ steps and $O(n \log \ell)$ space. The m $DIST$ matrices are hence computed in $O(nm \log m)$ time and space. To retrieve all entries of column c of $DIST_\ell$ it suffices to compute the weight of the paths to $B^c_\ell(0), B^c_\ell(2) \ldots B^c_\ell(\ell)$, which is readily achieved in $O(\ell)$ time by traversing the tree B^c_ℓ. □

3.3. Reconstructing the highest scoring paths. Given the properties established in section 3.2 it is easy to augment the grid graph with two indices per grid point enabling one to produce a (reverse) highest scoring path between a given vertex and any vertex in column 0 in time proportional to the number of vertices on the path. Each vertex in the grid graph simply records the two threshold values i_1 and i_2. To reconstruct a highest scoring path from endpoint $(\ell+1, j+1)$ to a starting point $(i, 0)$ each vertex on the path (starting with $(\ell+1, j+1)$) in turn compares i to its threshold values and determines the vertex preceding $(\ell+1, j+1)$ on the highest scoring path as follows. Whenever $i \geq i_2$ the previous vertex is $(\ell+1, j)$, whenever

$i_1 \le i < i_2$ the previous vertex is (ℓ, j) and whenever $i < i_1$ the previous vertex is $(\ell, j+1)$, until vertex $(i, 0)$ is reached.

LEMMA 3.10. *Given the row and column maxima of the matrix $DIST_\ell$, the score and endpoint of a highest scoring path from any point on row ℓ to column 0 and from any point on column 0 to row ℓ can be reported in $O(1)$ time. By augmenting each gridpoint with the two threshold values, these paths can be output in time linear in the length of the path.*

Proof. If the maximum score in row r of $DIST_\ell$ is obtained at $DIST_\ell[r, j]$, then the highest scoring path from point $(r, 0)$ to row ℓ in the grid has value $DIST_\ell[r, j]$ and ends at (ℓ, j). If the maximum score in column r of $DIST_\ell$ is obtained at $DIST_\ell[j, r]$ then the highest scoring path from point (ℓ, r) to column 0 in the grid has value $DIST_\ell[j, r]$ and ends at $(j, 0)$. The lemma follows. □

We proceed to show in the next section how to compute row and column maxima efficiently.

3.4. Row maxima in the *DIST* matrices and proof of Theorem 3.4. In order to compute the row (or column) maxima of the $DIST$ matrices we could use the algorithm described in [AKMSW-87]. They showed that if all entries of a Monge array M can be accessed in $O(1)$ time the m row maxima of M can be computed in $O(n)$ time (if $m < n$). In our model each entry is accessible in $O(\log m)$ time, which immediately yields an $O(n \log m)$ algorithm for computing all the row (as well as column) maxima. It turns out that in our model a much simpler and (by a constant factor) faster algorithm based on a simple binary search that takes advantage of the fact that some entries can be accessed in $O(1)$ time, also takes $O(n \log m)$ time. To compute the row maxima j_c of row $c = 2^{\lceil \log \ell + 1 \rceil - 1}$ in $O(n)$ time, we find the minimum of the $n+1$ values $B^\ell_j(c), j = 0 \ldots n$. Note that each $B^\ell_j(c)$ can be accessed in $O(1)$ time, since c is the rightmost child of the left subtree of the root. The row maxima of rows $i > c$ must lie in columns $j_i \le j_c$ while those in rows below c will lie in columns $j_i \ge j_c$. The row maxima for rows $i > c$ can be found in the right subtrees of the root of the trees $B^j_\ell, j = 1 \ldots j_c$, while the row maxima for rows $i < c$ can be found in the left subtrees of the trees $B^j_\ell, j = j_c \ldots n$. Furthermore, after traversing (and adding weights on) a path from the root to a node x, if x is at height r in the tree, the highest scoring path to the 2^{r-1}st child of x (generally "the middle child" of x) can be retrieved in $O(1)$ time. The m row maxima can therefore be computed in $O(n \log m)$ time (or $O(m + n \log m)$ if $m > n$).

The column maxima are computed in a similar (even simpler) fashion, in $O(m \log n + n)$ time.

We can now summarize the proof of Theorem 3.4 and its corollary.

THEOREM 3.4. *Given an $m \times n$ grid graph G with arbitrary weights, all the row maxima and column maxima of the matrices $DIST_\ell$ for $\ell \in [0, m]$ can be computed in $O(nm \log m)$ time if $m \le n$ (and $O(m^2 \log n)$ time otherwise).*

Proof. Using the algorithm of [AKMSW-87] this follows immediately from the fact that entries in $DIST_\ell$ can be accessed in $O(\log m)$ time. We have also shown that a simpler algorithm achieves the same complexity. Since the representation of $DIST_{\ell-1}$ need not be kept after the representation of $DIST_\ell$ is completed, the space requirement is only $O(mn)$.

3.5. Formal presentation of algorithm. Figure 5 gives high level pseudocode for the computation of the trees B^k_ℓ (encoding high scoring paths) and the computation of the table $Col\_to\_row\_max$, whose $[j, \ell]$ entry stores the highest scoring path from point j on the origin column to row ℓ.

```
Procedure Compute_high_scoring_paths(M[r_0 ... m, k_0 ... n])
1.   for ℓ ← r_0 to m
2.       {for k ← k_0 to n
3.            { Compute tree B_ℓ^k
4.              /* B_ℓ^k encodes the paths from points on column k_0 to (k, l) */
5.            }
6.        Compute all row maxima in DIST_ℓ    /* these correspond to best paths */
7.                                  /* to row ℓ from all points (j, k_0), j ← r_0 ... ℓ */
8.        and record in (Col_to_row_max[j, ℓ].score, Col_to_row_max[j, ℓ].index)
9.        for j ← r_0 to ℓ
10.           { Output "the best path from point (j, k_0) to row ℓ has a score of
11.             Col_to_row_max[j, ℓ].score and ends at Col_to_row_max[j, ℓ].index."
12.           }
13.      }
```

FIG. 5. *Computing the highest scoring paths from column k_0 to all other points in $M[r_0 \cdots m, k_0 \cdots m]$.*

4. Identifying tandem repeats. We now show how the above construction can be used to identify approximate repeats in a string A. We would like to report all approximate repeats that are "locally optimal" as defined in Definition 2.2 in section 2.

Recall that a tandem repeat (A_j^i, A_i^t) is locally optimal if the best match for A_j^i is A_i^t and vice versa. Alternatively, (A_j^i, A_i^t) is locally optimal if a best path from point (j, i) to row i is to (i, t) and a best path from column i to (i, t) starts from point (j, i). It immediately follows from the above definition that there are no more than $n(n-1)$ approximate tandem repeats xy that are locally optimal. (Each substring s of A can participate in at most two locally optimal repeats, one of the form sy, the other of the form xs.)

Our algorithm will report the set of locally optimal approximate repeats with weight above some predetermined threshold T.

All locally optimal approximate tandem repeats with midpoint c correspond to locally optimal paths in the grid graph that start at column c and end at row c (see Figure 6).

To identify the repeats we use an algorithm that can be viewed as an adaptation of the algorithm of [ML-84] to the approximate repeat problem together with the methods developed in section 3. Observe that all paths in the grid graph that correspond to approximate repeats either (a) cross column $n/2$ or (b) cross row $n/2$ or (c) lie entirely in the upper triangular grid graph delimited by the three points $(0, 0)$, $(0, n/2)$, $(n/2, n/2)$ or in the triangular grid graph delimited by the three points $(n/2, n/2)$, $(n/2, n)$, and (n, n) (see Figure 6).

We first find approximate repeats of types (a) and (b) and then recursively apply the algorithm to the two subcases corresponding to (c).

To find the approximate repeats that cross column $n/2$ we use the construction of section 3 twice. First, for each k, we find the highest scoring paths from nodes $(k, n/2)$ $(k = 1 \ldots c)$ to row c, by constructing the trees $B1_c^j$ $(j = n/2 \ldots n)$ and computing the c row maxima. We compute and record the best path from each point $(k, n/2)$ to row c in the table $Col\_to\_row\_max[k, c]$, as a pair (s, i), where s is the score of the highest scoring path to row c and i is the largest index for which the path from $(k, n/2)$ to (c, i) has score s. (This corresponds to computing the maximum in row

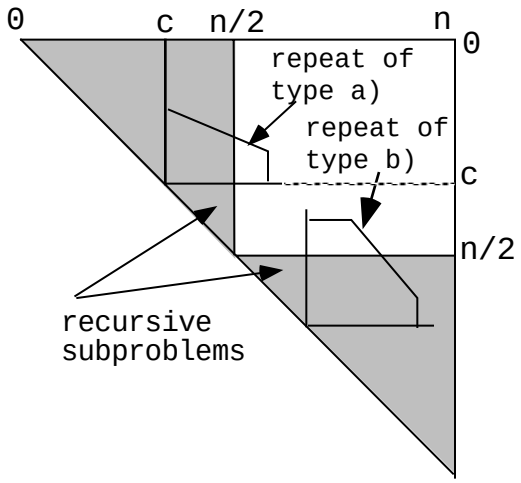

FIG. 6. *The four "types" of repeats examined by the algorithm.*

k of $DIST_c$, using a tie breaking rule.) We then use the construction (with minor modifications) to construct the highest scoring paths (in the grid graph with reversed edges) from nodes $(k, n/2)$ to (the relevant parts of) columns $n/2 \ldots 0$ by constructing the trees $B2_c^j$ $(j = 0 \ldots c)$. $B2_c^j(k)$ is the weight of the highest scoring path from (j, c) to $(k, n/2)$ and is computed for $k \in [j \cdots c]$. We compute and record the best path from each point $(k, n/2)$ to column c in $Col\_to\_col\_max[k, c]$.

Any approximate repeat whose path crosses column $n/2$ at $(k, n/2)$ is composed of two pieces: a highest scoring path from $(k, n/2)$ to row c, and a highest scoring path (in the grid graph with reversed edges) from $(k, n/2)$ to column c. We have computed and stored all these $O(n^2)$ values in $Col\_to\_col\_max[k, c]$ and $Col\_to\_row\_max[k, c]$ (for $k = 1 \ldots n/2$ and $c = k \ldots n/2$) in $O(n^2 \log n)$ time. Combining the two paths we obtain the best approximate repeat from column c to row c that crosses column $n/2$ at row k. We then repeat the above procedure to find "best tandem repeats" whose alignment path crosses row $n/2$. Finally we recursively find the repeats that lie entirely in the upper triangular grid graphs of $M[1 \cdots n/2, 1 \cdots n/2]$ and of $M[n/2 \cdots n, n/2 \cdots n]$. It is easy to verify that a repeat that is locally optimal will always correspond to such a "best repeat." Unfortunately, not all such "best repeats" will correspond to locally optimal repeats. We address this problem later. Note that the above algorithm will identify at most $O(n^2)$ candidate repeats that cross column $n/2$ (and $O(n^2)$ repeats that cross row $n/2$). The time taken to identify these candidates is $O(n^2 \log n)$. The algorithm then proceeds recursively as outlined in Figure 6 to find repeats that are contained in the two triangular grid graphs of size $n/2$. This yields an algorithm of complexity $T(n) = O(n^2 \log n) + 2T(n/2)$, which gives $T(n) = O(n^2 \log n)$. The number of candidate repeats identified is at most $C(n) = O(n^2) + 2C(n/2)$, which is $O(n^2)$.

Figure 7 summarizes how the above-described candidate set is constructed. The "highest scoring tandem repeat" corresponds to the element with maximum score in this set. A slightly modified *Compute_High_Scoring_paths* procedure (from Figure 5) is used in Figure 7 for each of the following four computations. To compute the highest scoring paths: (a) from points on the origin column c_0 to rows $r_0 \ldots r_0 + t$ we will refer to *Compute_High_Scoring_paths_col_to_row* and store the best path from (p, c_0) to row

r in $Col\_to\_row\_max[p, r]$; (b) for the highest scoring paths (in the reverse graph) from points on the origin column c_0 to columns $c_0 \ldots c_0 - t$ we will refer to *Compute_High_Scoring_paths_col_to_col* and store the best path from (p, c_0) to column c in $Col\_to\_col\_max[p, c]$; (c) for the highest scoring paths from points on the origin row r_0 to rows $r_0 \ldots r_0 + t$ we will refer to *Compute_High_Scoring_paths_row_to_row* and store the best path from (r_0, k) to row r in $Row\_to\_row\_max[k, r]$; finally, to compute the highest scoring paths from points on the origin row r_0 to columns $c_0 + t \ldots c_0$ we will call *Compute_High_Scoring_paths_row_to_col* and store the best path from (r_0, k) to column c in $Row\_to\_col\_max[k, c]$. Note that the procedure *Compute_High_Scoring_paths* in Figure 5 corresponds to *Compute_High_Scoring_paths_col_to_row*.

```
Procedure Construct_Candidates(r0, n0)

25. Output "a best repeat is given by path from (indxr, c) to (c, indxc) with score s";
```

FIG. 7. *Computing the highest scoring repeat.*

Although the candidate set certainly contains the set of all locally optimal repeats above the threshold score, it may also contain approximate repeats that are not locally optimal. The simplest such case occurs when two repeats x, y and x, y' (or x', y) are reported, in which case only one can be locally optimal. A trickier case occurs when the repeat x, y was reported, and there is a repeat x', y (x is a suffix of x') with higher

score which was, however, not reported because a repeat x', y' was detected with even higher score. By simply examining the candidate repeats it is not possible to detect whether x, y is indeed locally optimal. We proceed to show how to determine whether a given candidate repeat is locally optimal.

4.1. Detecting locally optimal repeats. All repeats in this section will refer to repeats with the same midpoint c, i.e., repeats corresponding to highest scoring paths from column c to row c. As discussed in section 2, to show that a tandem repeat corresponding to a highest scoring path from (i, c) to (c, j) is locally optimal, it suffices to show that the highest scoring path from (i, c) to row c ends at (c, j) and that the highest scoring path from (c, j) to column c (in the transposed graph) ends at (i, c). Suppose that the path from (i, c) to (c, j) was reported in the previous algorithm and that this path crosses column $n/2$ at row k. This path has the property that it is the highest scoring path from (i, c) to row c *through point* $(k, n/2)$ and the highest scoring path from (c, j) column c *through* $(k, n/2)$. The above path corresponds to a locally optimal repeat if and only if the highest scoring path from (i, c) to row c indeed goes through $(k, n/2)$ and so does the highest scoring path from (c, j) to column c.

Consider the following highest scoring paths matrices $R1_c^{n/2}$ and $R2_c^{n/2}$ for repeats with midpoint c that cross column $n/2$. $R1_c^{n/2}[k, j]$ is the weight of the repeat corresponding to the highest scoring path from column c through point $(k, n/2)$ to (c, j), while $R2_c^{n/2}[k, i]$ is the weight of the highest scoring path from (i, c) through $(k, n/2)$ to row c. "The best repeat" through column $n/2$ ending at (c, j) corresponds to the maximum value in column j of the matrix $R1_c^{n/2}$, while the best repeat through column $n/2$ starting at (i, c) corresponds to the maximum value in column i of $R2_c^{n/2}$. Given $Col\_to\_col\_max[c, k]$ and the trees $B1_c$ (resp., $Col\_to\_row\_max[c, k]$ and $B2_c$) we can compute a given value in the matrix $R1_c^{n/2}$ (resp., $R2_c^{n/2}$) in $O(\log n)$ time, by observing that $R1_c^{n/2}[k, j] = Col\_to\_col\_max[c, k] + B1_c^j(k)$ and $R2_c^{n/2}[k, i] = Col\_to\_row\_max[c, k] + B2_c^i(k)$. $B1_c^j(k)$ (resp., $B2_c^i(k)$) is computable in $O(\log n)$ time by traversing the path from the root to leaf k in tree $B1_c^j$ (resp., $B2_c^i(k)$).

Note that $R1_c^{n/2}$ and $R2_c^{n/2}$ have the same properties as a $DIST$ array and are therefore Monge arrays. To compute all the column maxima of the matrices $R1_c^{n/2}$ and $R2_c^{n/2}$ we could use the algorithm given in [AKMSW-87]. Alternatively, we can again also use a simpler algorithm, by taking advantage of the fact that if accessed in the right order, entries of $R1_c^{n/2}$ and $R2_c^{n/2}$ can be accessed in $O(1)$ time. Let $j_0 = 3n/4$ be the index of the middle element in the relevant portion of row c. We can find the maximum (over k) of $Col\_to\_col\_max[c, k] + B1_c^{j_0}(k)$ in $O(n)$ time (by accessing all the values in the tree $B1_c^{j_0}$). If this maximum is obtained at point $(k_0, n/2)$ then the maxima for $j < j_0$ will be at points $(k, n/2)$, with $k \geq k_0$, and those for $j > j_0$ will be at points $(k, n/2)$, with $k \leq k_0$. This clearly gives an $O(n \log n)$ time algorithm for finding all the column maxima in $R1_c^{n/2}$, and hence the total time to compute the column maxima in all matrices $R1_c^{n/2}$, $c = 1 \ldots n/2$, is $O(n^2 \log n)$. The column maxima in the matrices $R2_c^{n/2}$ are computed in the same manner.

Notice that if the computation is to use no more than $O(n^2)$ space we would first compute the $O(n^2)$ values $Col\_to\_row\_max[c, k]$ and $Col\_to\_col\_max[c, k]$ (as well as those in $Row\_to\_row\_max[c, k]$ and $Row\_to\_max\_max[c, k]$). At this point the "best tandem repeat" crossing row $n/2$ and column $n/2$ has been determined. We then recompute the trees B_c^j to determine the column maxima of $R1$ and $R2$ to find all

locally optimal repeats. The computation then recursively continues as shown in Figure 7 (lines 22 and 23).

Throughout the computation each point (c, r) will remember the best repeat (above the threshold) ending at (c, r) found so far, by setting $S[c, r] = j$ and setting $T[c, r]$ to the weight of the path from (j, c) to (c, r). Similarly, each point (j, c) will also record the best repeat starting at (j, c) found so far, by setting $E[j, c] = r$ and setting $T[j, c]$ to the weight of the path from (j, c) to (c, r). (Each gridpoint will hence store exactly two pairs of values, corresponding to the best repeat starting at that point and the best repeat ending at that point.) A repeat corresponding to a path from (j, c) to (c, r) will be reported at the end of the algorithm if $E[j, c] = r$ and $S[c, r] = j$.

5. Locally optimal nontandem repeats. As mentioned in the introduction, [KM-93] have addressed the problem of finding the (not necessarily adjacent) nonoverlapping repeat in a string. Their algorithm takes $O(n^2 \log^2 n)$ time. Our algorithm can easily be modified to address this problem as well, and can report all locally optimal repeats as defined in section 3.

The algorithm described in section 4, modified as described below, can be used to identify such repeats.

1. In addition to computing the highest scoring path from point $(k, n/2)$ to row c (resp., column c), one also computes the highest scoring path from $(k, n/2)$ *up to* row c (resp., column c). This is easily done by simply computing the maximum of $Col\_to\_row\_max[k, c']$ (resp., $Col\_to\_col\_max[k, c']$) over all $c' \leq c$. The best nontandem repeat through $(k, n/2)$ starting at (i, c) is then the highest scoring path from (i, c) to $(k, n/2)$ followed by the highest scoring path from $(k, n/2)$ to a row $c' \leq c$.
2. In addition to repeats that cross column $n/2$ and those that cross row $n/2$, and the recursive subproblems, one also needs to examine repeats that correspond to paths that lie entirely in the subgrid delimited by points $(0, n/2)$, $(0, n)$, $(n/2, n)$, and $(n/2, n/2)$; see Figure 6. For each point (i, j) in this square subgrid we need to find the highest scoring path starting anywhere in this subgrid and ending at (i, j). Note that this corresponds to a local alignment of the first half of the string with the second half. This can hence be easily achieved by running a forward and backward dynamic programming as explained in section 2.

A nontandem repeat corresponding to a path from (i, j) to (i', j') is reported, after all iterations are completed, if $E[i, j] = (i', j')$ and $S[i', j'] = (i, j)$. Note that the number of locally optimal nontandem repeats is also bounded by $O(n^2)$.

6. Grid graphs corresponding to edit graphs with unit weights. In this section we show how to efficiently use the methods of section 3 in a restricted scoring scheme. Two types of edit graphs with unit weights have been extensively studied in the literature. The first type corresponds to the Levenshtein measure [L-66]; in this measure matching symbols score 0, while substitutions/deletions score 1. This measure has been proven to provide combinatorial leverage not found in other scoring schemes when seeking alignments with a weight below a given threshold k, for example, in [LV-88], [My-86], [LS-93], and [LMS-94]. A seemingly similar but in fact much more sensitive measure is obtained when deletions and substitutions have (*constant*) weight $-S$, for some integer S, and matching symbols have (*constant*) integer weight M (typically for very small integers S and M), and a maximum cost alignment is sought. A maximum weight alignment in this second model will favor long alignments

with k deletions/substitutions over short alignments with (say) the same number of substitutions; in particular, alignments with a score above 0 will have a fraction of $\frac{S}{M+S}$ matching symbols.

The methods developed in section 3 can be modified to compute some representation of the matrices $DIST_\ell, \ell = 1 \ldots, m$, of an (m, n) grid graph in $O(mn)$ time. In the current special case a representation of $DIST_\ell$ can be computed in $O(n)$ time, when given an appropriate representation of $DIST_{\ell-1}$. The representation will allow us to augment the grid graph as outlined in section 3.3, so that any highest scoring path can be produced in time proportional to its length. However, general queries about the score of a highest scoring path will also require $O(n)$ time and hence will require as much time to be answered as it takes to produce the path itself. We will show that this limited capability, while not yielding a faster algorithm for the approximate repeat problem, does yield a faster algorithm for the cyclic string comparison (defined in the next subsection).

It is easy to see that if all horizontal and vertical edges in a grid graph have weight $-S$, and diagonal edges have weight M or $-S$, then $DIST_\ell[i, j+1] \geq DIST_\ell[i, j] - S$ and $DIST_\ell[i, j] \geq DIST_\ell[i, j+1] - S - M$. It immediately follows that $DIST_\ell[i, j+1] - DIST_\ell[i, j]$ assumes integer values in $[-S, S+M]$. Similarly, it is not hard to see that $DIST_\ell[i, j] - DIST_{\ell+1}[i, j]$ assumes integer values in $[-S-M, S]$. Instead of actually computing the values $DIST_\ell[i, j], i = 1 \ldots \ell$, we will only compute the differences $DIST_\ell[i, j+1] - DIST_\ell[i, j], i = 1 \ldots \ell$, and $DIST_\ell[i, j] - DIST_{\ell+1}[i, j], i = 1 \ldots \ell$. Since these differences assume at most $2S + M = O(1)$ values and are nonincreasing for $i \in [0, m]$, they can be represented as a list of $O(1)$ elements $I_0, I_1, \ldots, I_P$, $P = 2S+M+1$, such that $(DIST_\ell[i, j+1] - DIST_\ell[i, j]) = -S+j$ in the interval $[I_j, I_{j+1})$.

THEOREM 6.1. *Given a grid graph G with edge weights in $\{-S, M\}$ (for integer values M and S) and in which all horizontal and vertical edges have weight S, the row maxima and column maxima of the matrix $DIST_n$ can be computed in $O(nm)$ time.*

Proof (sketch). Let i' be the smallest $i \in [0, \ell]$ for which $DIST_\ell[i, j+1] - S < DIST_\ell[i, j] + w_{\ell,j}^{\ell+1,j+1}$, or $\ell + 1$ if there is no such i. Let i'' be the smallest $i \in [0, \ell]$ for which $DIST_\ell[i, j] + w_{\ell,j}^{\ell+1,j+1} < DIST_{\ell+1}[i, j] - S$, or $\ell + 1$ if there is no such i. If $i'' \geq i'$ then let $i_1 = i'$ and $i_2 = i''$. Otherwise let i_2 be the smallest i for which $DIST_\ell[i, j+1] - DIST_{\ell+1}[i, j] < 0$, and set $i_1 = i_2$.

Given the intervals in which $DIST_\ell[i, j+1] - DIST_\ell[i, j]$ is constant and the intervals in which $DIST_\ell[i, j] - DIST_{\ell+1}[i, j]$ is constant, the values i_1 and i_2 can clearly be computed in $O(1)$ time. Given these values we can, as in the case of general weight matrices, break down the general recurrence from Observation 3.7 into the following three cases.

$$DIST_{\ell+1}[i, j+1] = \begin{cases} DIST_\ell[i, j+1] - S, & i \in [0, i_1), \\ DIST_\ell[i, j] + w_{\ell,j}^{\ell+1,j+1}, & i \in [i_1, i_2), \\ DIST_{\ell+1}[i, j] - S, & i \in [i_2, \ell+1]. \end{cases}$$

Note, however, that the above equalities cannot be used directly to actually compute $DIST_{\ell+1}[i, j+1]$, as $DIST_\ell[i, j+1]$ is not directly available; only the differences $DIST_\ell[i, j+1] - DIST_\ell[i, j]$ and $DIST_\ell[i, j] - DIST_{\ell+1}[i, j]$ are available, which was sufficient for computing the breakpoints i_1 and i_2. From the above equalities, given the differences $DIST_\ell[i, j+1] - DIST_\ell[i, j]$, $DIST_\ell[i, j] - DIST_{\ell+1}[i, j]$, the differences $DIST_\ell[i, j+1] - DIST_{\ell+1}[i, j]$ and $DIST_{\ell+1}[i, j] - DIST_{\ell+1}[i, j]$ can now be computed in $O(S + M) = O(1)$ time (for each point $(\ell + 1, j + 1)$). In addition, each node $(\ell + 1, j + 1)$ in the grid can be augmented as in section 3.3 with the threshold

values i_1 and i_2 that indicate whether the highest scoring path to $(i, 0)$ for a given i is to go through $(\ell, j+1)$, (ℓ, j), or $(\ell+1, j)$. After computing the above representation of the matrix $DIST_\ell$ from $DIST_{\ell-1}$, one could compute all values in that matrix in $O(\ell n)$ time. and at the same time compute all the row and column maxima. Alternatively, one could compute the values in any row i in $O(n)$ time. Note that $DIST[i, 0] = (m-i)S$ for any i. We can hence compute the n values in this row from the differences $DIST_m(i, j+1) - DIST_m(i, j)$ in $O(n)$ time. □

6.1. Application to the cyclic string comparison problem. Given two strings A and B the cyclic string comparison problem consists of finding the cyclic shift of A which can be best aligned with B. Formally, if $B = B_1 \dots B_n$, we wish to find the i for which the optimal alignment of $A = A_i, A_{i+1}, \dots A_m, A_1, \dots A_{i-1}$ with $B_1, \dots B_n$ gives the best score. For general weight matrices, this problem was addressed in [Ma-90] where an $O(mn \log m)$ algorithm was presented. The techniques in [AALM-90] result in a parallel algorithm for that problem. [LMS-94] have shown how to solve the cyclic string comparison problem under the Levenshtein measure in $O(n+km)$ time provided that the cost of the best alignment is bounded by k. Here we consider the problem when all values in the weight matrix are restricted to an interval $[-S, M]$ for positive constants S and M. The cyclic string comparison problem can be reduced to the following highest scoring paths problem. Consider computing the $(2m \times n)$ grid graph of the comparison of the string AA (A concatenated with A) with B. Consider the matrix $DIST_m$ of that grid graph. The weights of the best alignments of the cyclic shifts of A with B are given by the values $DIST_{m+i}[i, n], i = 0 \dots m-1$. After computing the representation of the $DIST$ matrices described in the previous section in $O(mn)$ time, each value $DIST_{m+i}[i, n]$ can be computed in $O(n)$ time. The cyclic shift of A that best matches B and its alignment with B can hence be produced in $O(mn)$ time.

7. Conclusions. The algorithms presented in this paper allow the quick computation of certain highest scoring paths in grid graphs. We have given two string matching applications in which such paths can help solve interesting sequence comparison problems, while improving upon previous algorithms by a factor of $O(\log n)$. It would be interesting to find additional applications for these methods. An interesting question that remains open is whether approximate repeats can be found quicker in the simple scoring schemes considered in the last section.

Acknowledgments. I would like to thank Dina Kravets and Gad Landau for discussions on the subject, and Raffaele Giancarlo for valuable comments on an earlier version of this manuscript.

BOUNDING THE POWER OF PREEMPTION IN RANDOMIZED SCHEDULING*

RAN CANETTI† AND SANDY IRANI‡

Abstract. We study on-line scheduling in overloaded systems. Requests for jobs arrive one by one as time proceeds; the serving agents have limited capacity and not all requests can be served. Still, we want to serve the "best" set of requests according to some criterion. In this situation, the ability to *preempt* (i.e., abort) jobs in service in order to make room for better jobs that would otherwise be rejected has proven to be of great help in some scenarios.

We show that, surprisingly, in many other scenarios this is not the case. In a simple, generic model, we prove a polylogarithmic lower bound on the competitiveness of randomized and preemptive on-line scheduling algorithms. Our bound applies to several recently studied problems. In fact, in certain scenarios our bound is quite close to the competitiveness achieved by known *deterministic, nonpreemptive* algorithms.

Key words. randomized algorithms, scheduling, preemption, lower bounds

1. Introduction.

Scheduling problems pervade many aspects of system design and management. Consider, for instance, the following problems.

(a) A system with several processors is assigned jobs of varying duration and load, where each job is to be performed on a single processor. The jobs arrive one by one and each job must be assigned to a processor before the next job is known. The goal is to assign the jobs to processors "in the best possible way."

(b) A set of gateways connects a network of computers to a set of peripheral devices. At any point in time, a node in the network may request a connection to a particular type of device for some period of time. The bandwidth required for the different connections vary. The goal is, again, to assign connections to gateways "in the best possible way."

(c) A communication network with guaranteed bandwidth policy (e.g., asynchronous transfer mode (ATM) [23]) services many different types of traffic. Requests for connections between nodes in the network arrive and depart through time. The durations, priorities, and bandwidth requirements of connections vary (e.g., e-mail, video, etc.). Connections should be allocated bandwidth and routed "in the best possible way."

A prominent characteristic of all these scenarios is that the scheduling algorithm learns about the incoming requests as they enter the system one by one, and must decide how to handle each task without knowledge of future tasks. Any such algorithm which must make decisions without complete knowledge of the entire input sequence is said to be an *online* algorithm.

Two natural optimization problems arise from these and other related scenarios. First, we may assume that all requests will be served and aim at minimizing the maximum load on any serving agent (e.g., processor, gateway, link) at any point in time. We call this problem *load balancing*. Alternatively, we may consider a situation where the capacity of the system is limited and not all requests can be served. Here the goal is to schedule the subset of requests with maximum value according to some criterion. We call this problem *admission control*. Both optimization problems have been studied in several models. The load balancing problem emerging from example (a) above is an old problem introduced in [14] and extensively studied since [1, 6, 9, 16]. The admission control problem emerging from this example is studied in [10, 11, 22]. The load balancing problem emerging from example (b) is studied in [5, 7] and from example (c) in [1]. The admission control problem emerging from example (c) has been extensively studied (e.g., [2, 3, 12, 13, 8]). In this work we address admission control problems. (We refer the reader to [10] for an exposition of the importance of admission control.)

A natural question in such scenarios has to do with the power of *preemption.* The ability to alter previous decisions in certain ways has proven to be very powerful (say, when algorithms are allowed to reassign a job to a different server at some cost [20, 19, 15]). We address the following notion of preemption, natural in limited capacity scenarios. We allow a job to be aborted in the middle of execution in order to make room for a more valuable job that would otherwise be rejected. However, no credit is accrued for uncompleted jobs. Preempting jobs in the middle of execution may be problematic in some scenarios (say, when service is guaranteed upon admission). In other scenarios, preemption seems to be acceptable and even very helpful (say, in systems that support real-time jobs, e.g., [21]).

It has been demonstrated that an appropriate use of preemption helps considerably to enhance the *throughput* in certain settings [8]. We study the following question. To what extent can the ability to preempt jobs enhance the performance in more general cases (e.g., when the criteria for performance are different, or when the setting is different)?

We provide some surprising answers to this question by demonstrating that preemption does not help much (if at all) in a large variety of on-line admission control problems. First we consider a generic model for on-line admission control. In this model we show a lower bound on the competitiveness of any *randomized, preemptive* on-line scheduling algorithm. This bound applies, via several reductions, to a large variety of models, and in particular to the admission control problems emerging from the three examples above. We elaborate on the different scenarios where our result applies in section 1.1.

We describe our generic model. A server is given a sequence of job requests, arriving one by one as time proceeds. The server can serve only one job at a time. Each job is characterized by its arrival time, its *duration* (known upon arrival), and its *value.* A job has to be either rejected or served immediately for the specified duration. The server can *preempt* (i.e., abort) jobs in service. The value gained from a sequence is the sum of the values of completed jobs. No value is gained for preempted jobs. We consider randomized scheduling algorithms (or *schedulers*). A scheduler is f-competitive if for any sequence S of jobs the value gained by the best (off-line) schedule on S, divided by the value gained by the online scheduler on S, is at most f. Note that f may be a function of the request sequence, rather than a constant. In this model, we prove the following bound.

THEOREM 1. *Any randomized, preemptive scheduler has a competitive ratio of at best*

$$\frac{1}{10}\sqrt{\frac{\log \mu}{\log \log \mu}},$$

where μ is any of the following two measures:

(i) $\mu = \mu_v$, *the ratio between the largest and smallest values of a job in the request sequence;*

(ii) $\mu = \mu_d$, *the ratio between the largest and smallest durations of a job in the request sequence.*

We actually prove a stronger fact than suggested by the theorem: for any randomized preemptive scheduler $\mathcal{A}$ and for any μ, we construct a sequence S which simultaneously satisfies $\mu_d(S) \leq \mu$ and $\mu_v(S) \leq \mu$, such that the competitiveness of $\mathcal{A}$ on S is $1/10\sqrt{\log \mu / \log \log \mu}$. An identical bound applies also to scenarios where more than one job can be served at a time. In section 5 we describe a simple, randomized, preemptive $O(\log(\min\{\mu_d, \mu_v\}))$-competitive scheduler in our generic model, thus demonstrating that our bound is at most a roughly quadratic factor from optimality.

Many previously studied scheduling problems can be reduced to this generic model. In particular, our bound applies to the setting in which Awerbuch, Azar, and Plotkin show a scheduler with competitiveness logarithmic in μ_d and μ_v [2]. Their scheduler is both *deterministic* and *nonpreemptive.* Thus, in their setting, the combined power of randomization and preemption results in at most a roughly quadratic improvement. (We note, however, that the scheduler in [2] does not apply to the setting of Theorem 1.)

Our proof of the bound is nontrivial and occupies most of this paper. It involves techniques which we believe are of independent interest. For each randomized scheduler, we construct a request sequence on which the scheduler performs poorly relative to the best strategy. We stress that the sequence is fixed for this scheduler; that is, the sequence does not change in different runs of the scheduler. The sequence is constructed one request at a time via an interaction with the scheduler, $\mathcal{A}$. Each next request is generated based on the probability distribution of the job that $\mathcal{A}$ currently has in service. More specifically, at each step we keep a set of threshold values. We generate the next request depending on whether the probability that $\mathcal{A}$ has some specific job in service is above or below one of the thresholds. Our adversarial strategy is a randomized adaptation of a simple deterministic lower bound. Our technique may prove useful in transforming similar deterministic lower bounds into randomized ones.

1.1. Applications of the bound. We describe how our lower bound applies to several recently studied admission control problems. In section 4 we formally state and prove these applications.

Consider the setting of example (a) above. A system consists of a set of processors, each with limited capacity. Jobs of varying load, duration, and value arrive through time, each with a deadline. At all times the sum of the loads of the jobs in service on a given processor must not exceed its capacity. A scheduler must decide which jobs to execute (and on which processor) in order to complete the set of jobs with the largest total value before their deadlines. Via a simple reduction, our lower bound applies to this setting, with any number of processors, where μ is either μ_d or μ_v. A lower bound of $\Omega(\sqrt{\mu_v})$ on the competitive ratio of any *deterministic* preemptive scheduler

is shown in [11, 18], where the value of a job is arbitrary. However, their bound does not apply to randomized schedulers. Our bound holds even for the cases where:

(1) a single job cannot occupy more than a predefined fraction δ of the capacity, for any $\delta > 0$ (see Corollary 1);

(2) each job has a value equal to its duration, as opposed to having an arbitrary value;

(3) all jobs have the same value.

In the last two cases, the bound holds with respect to μ_d and μ_l, where μ_l is the ratio of largest to smallest load of a job in the input sequence. (See Corollaries 2 and 3.) Surprisingly, our bound does *not* apply when the value of each job equals its load times its duration. In fact, constant competitive algorithms exist in this case [10, 11, 22, 17, 18, 8]. We suggest an explanation for this phenomenon below.

We note that example (b) given at the beginning of the introduction is a generalization of this multiprocessor scheduling problem. The bound applies, yielding similar results.

Next we address *call control* and *virtual circuit routing* problems. Here we have a communication network with guaranteed bandwidth policy in which the links have limited capacities. Requests for connections (or *calls*) arrive through time, where each call has its source and destination nodes, as well as duration, bandwidth requirement, and value. The scheduler must route accepted calls within the capacity limitations of the links; that is, the sum of the bandwidth of calls using each link must be at all times less than its capacity.

Awerbuch, Azar, and Plotkin show a deterministic, nonpreemptive $O(\log \mu)$-competitive scheduler in this model, where $\mu = \mu_d \cdot \mu_v \cdot n$ and n is the number of nodes in the network [2]. They also show that this is the best that any deterministic, nonpreemptive scheduler can achieve. Their scheduler has the drawback that every job is constrained to require bandwidth at most $1/\log \mu$ of the capacity of any edge. Awerbuch et al. remove this constraint for networks with a tree topology via a randomized, nonpreemptive scheduler [3]. Awerbuch et al. improve the bounds for trees and give randomized, nonpreemptive schedulers for meshes [4].

Garay and Gopal initiated the study of preemptive call control in [12]. They show constant competitive preemptive schedulers for simple networks and value functions. Garay et al. show competitive schedulers on a single link and a line network, for the special case that at most one call can be accommodated on any link, and for several specific ways for determining the value of a call [13]. Bar-Noy et al. generalize their results by showing constant competitive schedulers on a single link when the value of a call is the bandwidth times the duration and every call has a bandwidth requirement which is at most a limited fraction of the capacity of the link [8]. Their strategies apply also to line networks if all calls have infinite durations. (Here the bandwidth times the duration of a call reflects the "amount of information" contained in the call. Thus, preemption helps when the quantity to be maximized is the throughput of the link.)

We provide a lower bound of $1/10\sqrt{\log \mu / \log \log \mu}$ on the competitiveness of any preemptive, randomized scheduler for any network, when the value of a call is arbitrary. The bound holds even when a single call cannot occupy more than a predefined fraction δ of the link capacity (for any $\delta > 0$), and even if the value of a call is its duration or if all calls have the same value (see Corollary 4).

Furthermore, if the network has no cycles then the bound applies with $\mu = \min\{\mu_d, D\}$, where D is the diameter of the network. In this case, the bound holds

even when the value of a call equals the duration times bandwidth, or the distance from source to destination, or the distance times duration, or the distance times duration times bandwidth (see Corollary 6).

We suggest the following explanation of this "dichotomy." The bandwidth times duration measures the "amount of information" contained in a call, whereas the bandwidth times duration times distance measures the "work" invested in a call. It can thus be said that, in the single link case, when the value of a job is directly proportional to the information contained in it then the bound does not apply and constant competitive algorithms exist. If the value of a job is determined in any other way then the bound applies. In more complex networks (even in a line of links), the bound applies even when the value of a call is directly proportional to the amount of information, or to the work invested.

Organization. In section 2 we formally define our generic model. In section 3 we state and prove the basic lower bound as stated in Theorem 2. (In section 3.1 we first prove a weaker version of the bound; the proof of this weaker version is simpler and offers intuition for the proof of the full bound.) In section 4 we state and prove several corollaries of the bound. In section 5 we demonstrate the tightness of the bound by sketching a scheduler in our model, with logarithmic competitiveness.

2. The model. We formalize the generic model described in the Introduction. A *server* is given a sequence of job requests, arriving one by one as time proceeds. We assume that time is discrete, although several requests may arrive at a single time unit. The server can serve at most one job at a time. Each job c is characterized by its arrival time t_c, its duration d_c (known upon arrival), and its *value* v_c. The scheduling of jobs is subject to the following rules. A job has to be either served immediately for the specified duration or rejected. The server can *preempt* (i.e., abort) a job in service. The server accrues an additive gain of v_c for each completed job c. No gain is accrued for preempted jobs.[1]

A sequence $S = c_1, \ldots, c_n$ of job requests is *timely* if $t_{c_i} \geq t_{c_j}$ for every $i > j$. Say that S is *feasible* if no two jobs intersect in time; that is, for no $i \neq j$ we have $t_i < t_j < t_i + d_i$. The *gain* of S is $G(S) \stackrel{\triangle}{=} \sum_{c \in S} v_c$. The *optimal feasible gain* of S is $\mathcal{O}(S) = \max_{\{S' \subseteq S | S' \text{ feasible}\}} G(S')$, where $S' \subseteq S$ means that S' is a subsequence of S.

For a scheduling algorithm $\mathcal{A}$, let $\mathcal{A}(S, r) \subseteq S$ be the sequence of jobs completed by $\mathcal{A}$ on sequence S and random input r. Algorithm $\mathcal{A}$ is a valid *scheduler* if whenever S is timely, $\mathcal{A}(S, r)$ is feasible for all r.

DEFINITION 1. *Let $\mu_1(\cdot), \ldots, \mu_t(\cdot)$ be a set of measure functions from request sequences into the reals. A scheduler $\mathcal{A}$ is* f-competitive with respect to $\mu_1(\cdot), \ldots, \mu_t(\cdot)$ *if for all large enough m and for all timely sequences S with $\max_{i=1}^{t}\{\mu_i(S)\} \leq m$ we have*

$$f(m) \geq \frac{\mathcal{O}(S)}{\mathrm{E}_r(G(\mathcal{A}(S, r)))},$$

where $\mathrm{E}_r(G(\mathcal{A}(S, r)))$ denotes the expected value of $G(\mathcal{A}(S, r))$ when r is uniformly chosen from the set of random inputs of $\mathcal{A}$. We stress that the sequence S does not depend on the random choices of $\mathcal{A}$ (i.e., using standard terminology, the adversary is *oblivious*).

[1] It may be helpful to visualize each job c as a rectangle with length d_c and height v_c/d_c; the rectangle is located on the number line so that its left edge is at point t_c. The area of the rectangle is v_c. Thus the goal is to maximize the total area of completed jobs. See Figure 3.1.

We sometimes use $\mathrm{E}G\mathcal{A}(S)$ to shorthand $\mathrm{E}_r(G(\mathcal{A}(S,r)))$. We also say that $\frac{\mathcal{O}(S)}{\mathrm{E}G\mathcal{A}(S)}$ is the *competitive ratio of* $\mathcal{A}$ *on sequence* S. Below we use the following simple observation. For a sequence S, a scheduler $\mathcal{A}$, and a job $c \in S$, let I_c denote the binary random variable having value 1 iff job c is completed in a run of $\mathcal{A}$ on S. Then,

$$\mathrm{E}_r(G(\mathcal{A}(S,r))) = \mathrm{E}_r\left(\sum_{c\in S} I_c \cdot v_c\right) = \sum_{c\in S} E_r(I_c)\cdot v_c = \sum_{c\in S} v_c \cdot \mathrm{Prob}(\mathcal{A} \text{ completes } c).$$

That is, the expected gain of the scheduler is the sum over all jobs in the input sequence of the probability that the job is completed times its value.

3. The lower bound. Let $g(x) = \frac{1}{10}\cdot\sqrt{\frac{\log(x)}{\log\log(x)}}$. Let $\mu_d(S)$ (resp., $\mu_v(S)$) be the ratio between the largest and smallest durations (resp., value) of a job in the request sequence S. We prove the following bound.

THEOREM 2. *Any randomized, preemptive on-line scheduler is at best g-competitive, with respect to measures μ_d and μ_v.*

For the proof we construct, for each scheduling algorithm $\mathcal{A}$ and infinitely many values m, a timely sequence S with $\max\{\mu_d(S),\mu_v(S)\} \le m$, and we show a feasible "off-line schedule" $S' \subseteq S$ such that $\frac{G(S')}{\mathrm{E}G\mathcal{A}(S)} \ge g(m)$. We first present a very rough description of the construction. Say that two jobs are of the same *type* if they have the same duration and value. The sequence S consists of several different types of jobs. Let $p_i(t)$ denote the probability that a job of type i is being served by $\mathcal{A}$ at the end of time unit t. Let $\vec{p}(t) = \langle p_0(t),\ldots,p_k(t)\rangle$, where the number of different types of jobs is $k+1$. Since at most one job can be scheduled at a time, we have $\sum_{i=0}^{k} p_i(t) \le 1$ for all t. Given $\mathcal{A}$, $\vec{p}(t)$ is a function only of the prefix of S consisting of the jobs requested up to time t.

The construction of the sequence S can be pictured as an interactive game between the scheduler and an adversary, where in each time unit t the adversary generates some requests based on $\vec{p}(t-1)$ and the jobs requested so far. Next the scheduler generates $\vec{p}(t)$ based on the new requests and the history of the interaction, subject to the conditions that $\sum_{i=0}^{k} p_i(t) \le 1$, and $p_i(t) \le p_i(t-1)$ unless a new i-job is requested at time t. (Here we give the scheduler some extra "leeway" by letting it know in advance all the jobs requested during the entire time unit.) Sequence S is now the concatenation of the jobs requested by the adversary in the game. We stress that S is fixed for each scheduler; it does not depend on the random choices of the scheduler in a specific run.

The adversary strategy in the above game consists of several recursive applications of roughly the same scheme. In order to better present the construction and analysis, we first describe a simpler adversary that consists of only one application of this scheme. This simpler adversary, called a 1-*adversary*, shows a weaker result than Theorem 2, namely, that no valid scheduler is less than $(\frac{\mathrm{e}+1}{\mathrm{e}} - o(1))$-competitive (where e is the base of natural logarithms).

3.1. A 1-adversary. A 1-*adversary* generates, for each scheduler $\mathcal{A}$ and each value m, a sequence S with $\mu_d(S) = m^2$ and $\mu_v(S) = m$, and a feasible "off-line schedule" $S' \subseteq S$ such that $\frac{G(S')}{\mathrm{E}G\mathcal{A}(S)} \ge \frac{\mathrm{e}+1}{\mathrm{e}}\cdot\left(1 - O(\frac{1}{m})\right)$.

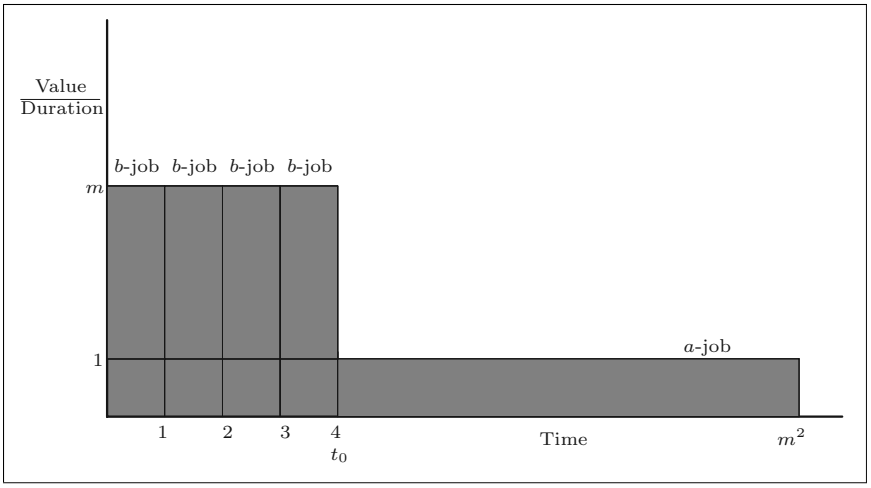

FIG. 3.1. *A* 1*-adversary. b-jobs are requested until time* t_0.

The 1-adversary uses only two types of jobs: *a-jobs* have duration m^2 and value m^2; *b-jobs* have duration 1 and value m. The sequence S is constructed as follows. The adversary first requests an a-job at time 0. Next, at each time $t = 0, \ldots, t_0$ (where t_0 is computed below) a b-job is requested. Note that any feasible subsequence of S consists of either the a-job or some of the b-jobs (see Figure 3.1).

Setting an appropriate "stopping time," t_0, is the crux of the adversarial strategy. If the scheduler were deterministic (or alternatively, if the adversary could see the random choices of the scheduler), then computing t_0 would be simple. If $\mathcal{A}$ preempts the a-job in favor of some b-job, the input sequence would stop. This way, $\mathcal{A}$ gains m while the optimal schedule is the a-job, with gain at least m^2. If $\mathcal{A}$ never preempts the a-job then we set $t_0 = m^2$ (that is, b-jobs are requested during the entire duration of the a-job), and the optimal schedule is all the b-jobs with gain m^3. In any case, the competitive ratio of $\mathcal{A}$ on S would be m.

However, the random choices of $\mathcal{A}$ are not known. Instead, the adversary will, at the onset of any time unit $t+1$, compute $p_a(t)$, the probability that $\mathcal{A}$ still serves the a-job. If $p_a(t)$ is large enough (i.e., above some threshold described below) then another b-job is requested. Otherwise the request sequence is stopped. The threshold is computed as follows. Let $\mathcal{O}_b(t)$ denote the maximum gain that can be accrued from the requested b-jobs up to time t (that is, $\mathcal{O}_b(t) = t \cdot m$ for time t where $p_a(t)$ has not yet dropped below the threshold). Let the threshold at time t be $f(\mathcal{O}_b(t))$ (that is, $f(t \cdot m)$), where the *threshold function* $f(\cdot)$ is:

$$f(x) = \begin{cases} 1 - \alpha \mathrm{e}^{\frac{x}{m^2}} & \text{if } x \le m^2, \\ 1 - \alpha \mathrm{e} & \text{if } x > m^2 \ , \end{cases}$$

and $\alpha = \frac{1}{\mathrm{e}+1}$. The adversarial strategy can now be described as follows. `First, request an` a`-job and a` b`-job at time 0. Next, at each time` $t = 1, \ldots, m^2 - 1$ `do: if` $p_a(t-1) \ge f((t-1)m)$ `request a` b`-job; else end the request sequence.`

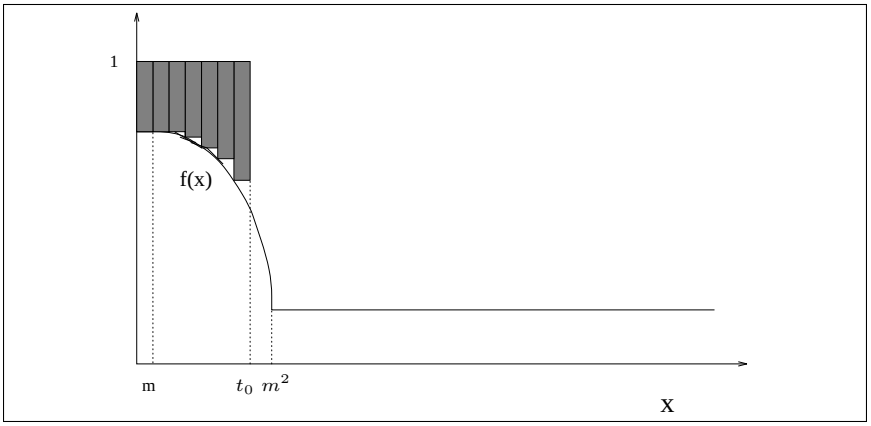

FIG. 3.2. *A* 1*-adversary. The shaded area shows the expected gain of the algorithm from type-b jobs.*

We suggest the following explanation for our choice of the threshold function. Let t_0 be the first time that $p_a(t)$ drops below the threshold. It will be seen that the competitive ratio of the algorithm is roughly at least the reciprocal of

$$f(x) + \frac{1}{m^2}\int_0^x (1 - f(y))dy \quad \text{if } x \le m^2, \tag{3.1}$$

$$1 - f(x) \quad \text{if } x > m^2\ , \tag{3.2}$$

where $x = t_0 \cdot m$ and $f(\cdot)$ is the threshold function in use (see Figure 3.2). This choice of $f(x)$ ensures that expression (3.1) evaluates to the same minimal value for all x. In particular, for any α the function $f(x) = 1 - \alpha e^{\frac{x}{m^2}}$ solves the differential equation

$$\frac{d}{dx}\left[f(x) + \frac{1}{m^2}\int_0^x (1 - f(y))dy\right] = 0,$$

thus making sure that (3.1) doesn't change for $0 \le x \le m^2$. The choice of α is such that $1 - \alpha = \alpha e$; that is, $f(0) = f(m^2) = 1 - f(x)$ for all $x > m^2$. Thus (3.1) has the same value also for $x > m^2$. Consequently, the competitive ratio of $\mathcal{A}$ on S will be roughly the same (minimal) value for all values of t_0.

Analysis of the operation of $\mathcal{A}$ on S. We consider three cases.

Case 1. $t_0 \le m$. In this case the best feasible subsequence of S is the a-job, with gain m^2 (that is, $\mathcal{O}(S) = m^2$). The expected gain of $\mathcal{A}$ is computed as follows. The probability that $\mathcal{A}$ completes the a-job is $p_a(t_0)$. The probability that $\mathcal{A}$ completes the b-job offered at time t is $p_b(t) \le 1 - p_a(t)$. Using the observation from the end of section 2, we have

$$\mathrm{E}G\mathcal{A}(S) \le m^2 p_a(t_0) + m\sum_{t=0}^{t_0}(1 - p_a(t)).$$

It follows from the adversary strategy that $p_a(t_0) < f(t_0 \cdot m)$, and $p_a(t) \ge f(t \cdot m)$ for all $t < t_0$. Thus,

$$\mathrm{E}G\mathcal{A}(S) \le m^2 f(t_0 \cdot m) + m\left(\sum_{t=0}^{t_0-1}(1 - f(t \cdot m))\right) + m \cdot p_b(t_0) \tag{3.3}$$

$$\le m^2 f(t_0 \cdot m) + \int_0^{t_0 m}(1 - f(x))dx + m \tag{3.4}$$

$$= m^2(1 - \alpha \mathrm{e}^{\frac{t_0}{m}}) + \int_0^{t_0 m} \alpha \mathrm{e}^{\frac{x}{m^2}} dx + m \tag{3.5}$$

$$= m^2(1 - \alpha \mathrm{e}^{\frac{t_0}{m}}) + m^2\alpha(\mathrm{e}^{\frac{t_0}{m}} - 1) + m \tag{3.6}$$

$$= m^2(1 - \alpha) + m. \tag{3.7}$$

(See Figure 3.2.) Thus, in this case the competitive ratio of $\mathcal{A}$ is at best $\frac{m^2}{m^2(1-\alpha)+m} = \frac{1}{1-\alpha} - O(\frac{1}{m})$.

Case 2. $m < t_0 < m^2 - 1$. In this case the best feasible subsequence of S is all the b-jobs, with gain $t_0 m$. For the expected gain of $\mathcal{A}$, we now have

$$\begin{aligned}
\mathrm{E}G\mathcal{A}(S) &\le m^2 f(t_0 \cdot m) + m\left(\sum_{t=0}^{t_0-1}(1 - f(t \cdot m))\right) + m \cdot p_b(t_0) \\
&\le m^2(1 - \alpha\mathrm{e}) + m\left(\sum_{t=0}^{m-1} \alpha \mathrm{e}^{\frac{t}{m}}\right) + m\left(\sum_{t=m}^{t_0-1} \alpha\mathrm{e}\right) + m \\
&\le \left[m^2(1 - \alpha\mathrm{e}) + \int_0^{m^2} \alpha \mathrm{e}^{\frac{x}{m^2}} dx\right] + (t_0 m - m^2)\alpha e + m \\
&\le m^2(1 - \alpha) + (t_0 m - m^2)\alpha e + m \\
&\le t_0 m \alpha \mathrm{e} + m.
\end{aligned}$$

(The derivation of the third row from the second is done using the same integral as in (3.4)–(3.7); the derivation of the fifth row from the fourth uses the fact that $1 - \alpha = \alpha\mathrm{e}$.) Thus, in this case the competitive ratio of $\mathcal{A}$ is at least $\frac{1}{\alpha\mathrm{e}} - O(\frac{1}{m})$.

Case 3. $t_0 = m^2 - 1$. The difference from Case 2 is that here $p_a(t)$ may never go below the threshold. However, this does not help the scheduler. The best feasible subsequence of S is all the b-jobs, with gain m^3. Bounding the expected gain of the scheduler, we have (since $p_a(t) > 1 - \alpha\mathrm{e}$ for all t):

$$\mathrm{E}G\mathcal{A}(S) \le m^2 p_a(m^2 - 1) + m \sum_{t=1}^{m^2-1}(1 - p_a(t)) \le m^2 + m^3(\alpha\mathrm{e}).$$

Thus, the bound on the competitive ratio of $\mathcal{A}$ is the same as in the previous case.

In all three cases, the competitive ratio of $\mathcal{A}$ on S is at least $\min\left\{\frac{1}{1-\alpha}, \frac{1}{\alpha\mathrm{e}}\right\} - O(\frac{1}{m}) = \frac{\mathrm{e}+1}{\mathrm{e}} - O(\frac{1}{m})$. A straightforward calculation shows that any $m \ge 8$ is enough for showing a nontrivial bound (that is, a bound more than 1).

3.2. Proof of Theorem 1.

Outline. Roughly speaking, the scheme described in section 3.1 used the b-jobs to make sure that $\mathcal{A}$ accrues only a fraction of the value of the a-job requested. The same scheme can be used recursively to make sure that $\mathcal{A}$ accrues only a fraction of the value of each b-job requested. That is, use a third type of jobs, called c-jobs, with smaller duration and value than b-jobs. The c-jobs have the property, however, that the total

TABLE 3.1
Summary of main notation.

Notation	Meaning	Page
i-job	a job of duration $d_i = k^{4i}$ and value $v_i = k^{2+2i}$	1002
i-period	the time period between two consecutive multiples of d_i	1002
i-small job	a j-job with $j < i$	1002
$\mathcal{O}_i(t)$	off-line gain from i-small jobs in this i-period until time t	1002
$p_i(t)$	Prob(a j-job is running at time t)	1002
$q_i(t)$	Prob(a j-job is running at time $t \mid$ no higher index job is running)	1002
i-step	the time interval between two subsequent increases in $\mathcal{O}_{i+1}(t)$	1005
i-height of τ	the amount of increase in $\mathcal{O}_{i+1}(t)$ during i-step τ	1005
$EG\mathcal{A}(S)$	the expected gain of $\mathcal{A}$ from sequence S	997
$EG\mathcal{A}_\tau(S)$	the expected gain of $\mathcal{A}$ from jobs in S requested during step τ	1005

value of a series of consecutive c-jobs scheduled back-to-back for the duration of a single b-job is greater than the value of the b-job. For each requested b-job recursively apply the above scheme, using the c-jobs. Consequently, the "effective gain" that the scheduler accrues from each b-job is only a fraction of its real value. Thus, a better threshold function can now be used with respect to the a-job, forcing $\mathcal{A}$ to accrue only a smaller fraction of the optimal gain of the entire sequence. The adversary used for proving Theorem 2 uses this idea, implementing several levels of recursion. Throughout the proof we introduce various notation. Table 3.1, summarizing the main definitions, will hopefully facilitate the reading.

Construction of a k-adversary. Define ADV_k, an adversary implementing k levels of recursion, as follows. ADV_k requests $k+1$ different types of jobs. The value of a job of type i (where $i = 0, \ldots, k$) is $v_i = k^{2+2i}$ and its duration is $d_i = k^{4i}$. Thus, $\frac{v_{i+1}}{v_i} = k^2$. (Using the terms of section 3.1, the lower index jobs play the role of the b-jobs and the higher index jobs play the role of the a-jobs.) Let an *i-period* be the time period in between two consecutive integer multiples of d_i. A job is said to be *i-small* if it is a j-job with $j < i$. Let the *partial gain function* $\mathcal{O}_i(t)$ denote the maximum (off-line) gain that can be obtained by scheduling only i-small jobs that have been requested by the adversary since the beginning of the current i-period through time t. ADV_k employs k threshold functions $f_1(\cdot), \ldots, f_k(\cdot)$, defined below. The ith threshold at time t is $f_i(\mathcal{O}_i(t))$.

At each time t, the threshold values are compared with the following values, derived from the behavior of the scheduler. Recall that $p_i(t)$ denotes the probability that the scheduler has a job of type i running at time t. Let $q_k(t) = p_k(t)$; for $i \le k$, let $q_i(t)$ denote the probability that the scheduler has a job of type i running at time t, conditioned on the event that no j-job with $j > i$ is currently running. That is,

$$q_i(t) = \frac{p_i(t)}{1 - \sum_{j=i+1}^{k} p_j(t)}.$$

ADV_k thus operates as follows. At time $t = 0$, request $k+1$ jobs, one of each type. At each other time $t+1$, run procedure $\text{ADVSTRATEGY}(k, q_k(t))$, described in Figure 3.3 below.

Let the ith threshold function be:

$$f_i(x) = \begin{cases} 1 - \alpha_i e^{\frac{\beta_{i-1}}{v_i} \cdot x} & \text{if } x \le v_i, \\ 1 - \alpha_i e^{\beta_{i-1}} & \text{if } x > v_i \ , \end{cases}$$

ADVSTRATEGY$(i, q_i(t))$:
(1) **if** d_i divides t **then**

Request an i-job;
(2) **if** $i > 0$ and $q_i(t) \geq f_i(\mathcal{O}_i(t))$ **then**
call ADVSTRATEGY$(i-1, q_{i-1}(t))$
end

FIG. 3.3. *At each time unit t,* ADV$_k$ *runs* ADVSTRATEGY$(k, q_k(t))$.

where β_i and α_i are defined as follows. Let $\beta_0 = 1$ and

$$\beta_i = \beta_{i-1}\left[\frac{e^{\beta_{i-1}}}{1+\beta_{i-1}\cdot e^{\beta_{i-1}}}\right] + \gamma, \tag{3.8}$$

where $\gamma = \frac{2}{k^2}$. Let $\alpha_i = 1 - (\beta_i - \gamma) = \frac{1}{1+\beta_{i-1}\cdot e^{\beta_{i-1}}}$. Note that the 1-adversary of section 3.1 is identical to ADV$_1$, with $v_0 = m = k^2$ and $v_1 = m^2$.

Some intuition. We suggest the following explanation to the operation of the adversary. The condition in step (1) makes sure that the times at which an i-job may be requested are d_i time units apart. Thus, only a single i-job can be requested during an i-period, and the duration of an i-job is a full i-period. (Namely, i-jobs are requested "back-to-back.") The condition in step (2) of each level i controls whether to call the $(i-1)$st level. Roughly, the $(i-1)$st level is called if the probability that an i-job is being served by $\mathcal{A}$ at time t, given that all the j-jobs for $j = i+1, \ldots, k$ were preempted, is more than the threshold. This condition corresponds to the condition of section 3.1 regarding whether to request any further b-jobs.

Also here, the threshold functions are chosen so that in each level i the scheduler will have the same expected gain regardless of when $q_i(t)$ "dips" below the threshold. The competitive ratio of the scheduler against ADV$_i$ is later shown to be roughly bounded by the reciprocal of

$$f_i(x) + \beta_{i-1}\frac{1}{v_i}\int_0^x (1 - f_i(y))dy \quad \text{if } x \leq v_i, \tag{3.9}$$

$$\beta_{i-1}(1 - f_i(v_i)) \quad \text{if } x > v_i\ , \tag{3.10}$$

where $f_i(\cdot)$ is the ith threshold function in use, and $x = \mathcal{O}_i(t)$. (The value $1/\beta_i$ represents a lower bound on the competitive ratio of a scheduler against ADV$_i$. See Lemma 1 below.) For every α_i and β_i, the choice of $f_i(x)$ ensures that expression (3.9) evaluates to the same (minimal) value for all $x \leq v_i$, using a differential equation in the same way as in section 3.1. The α_i's and β_i's are determined as follows. We set $\beta_0 = 1$. Next, for any $i > 0$, α_i is chosen so that the competitive ratios at $x \leq v_i$ and at $x > v_i$ are equal; using (3.9) and (3.10) this translates to $f_i(0) = \beta_{i-1}(1 - f_i(v_i))$, or (by the definition of $f_i(x)$):

$$\alpha_i = \frac{1}{\beta_{i-1}\mathrm{e}^{\beta_{i-1}} + 1} \tag{3.11}$$

(for $i = 1$ this condition identifies with the corresponding condition in section 3.1: $\alpha_1 = \frac{1}{\mathrm{e}+1}$). Next, β_i can be computed by evaluating (3.9) at any value of x (and adding a small "error term" γ). Setting, say, $x = 0$ and using (3.11), we get $\beta_i = f_i(0) + \gamma = 1 - \alpha_i + \gamma = 1 - \frac{1}{\beta_{i-1}\mathrm{e}^{\beta_{i-1}}+1} + \gamma$. The recursion relation (3.8) follows.

Analysis of ADV_k.

LEMMA 1. *Let $k \geq 0$. Let $\mathcal{A}$ be a scheduler and let S be the request sequence generated via an interaction between $\mathcal{A}$ and ADV_k. Then, the competitive ratio of $\mathcal{A}$ on S is at best $\frac{1}{\beta_k+\delta}$, where $\delta \stackrel{\triangle}{=} \frac{3}{k-1}$.*

In order to derive Theorem 2 from Lemma 1, we need the following technical lemma.

LEMMA 2. *Let β_k be as defined in* (3.8). *Then $\beta_k \leq 4/\sqrt{k}$.*

Proof. We will verify inductively that

$$\beta_i \leq 4/\sqrt{i} \quad \text{for } i \leq k. \tag{3.12}$$

Plugging $\beta_0 = 1$ into (3.8) with $i = 1$, we get that $\beta_1 \leq \frac{3}{4}$. Since β_i decreases with i, we know that (3.12) holds whenever $3/4 \leq 4/\sqrt{i}$. Thus, we only have to worry about the cases where $3/4 > 4/\sqrt{i}$. Since the function

$$F(x) = x\left[\frac{e^x}{1+xe^x}\right]$$

is increasing in x, we can use the upper bound on β_i from the inductive hypothesis to obtain an upper bound for β_{i+1} as follows:

$$\frac{4}{\sqrt{i}}\left[\frac{e^{\frac{4}{\sqrt{i}}}}{1+\frac{4}{\sqrt{i}}e^{\frac{4}{\sqrt{i}}}}\right] + \gamma \geq \beta_i\left[\frac{e^{\beta_i}}{1+\beta_i \cdot e^{\beta_i}}\right] + \gamma \geq \beta_{i+1}.$$

Plugging in $\gamma = \frac{2}{k^2} \geq \frac{2}{i^2}$, it just has to be verified that

$$\frac{4}{\sqrt{i+1}} \geq \frac{4}{\sqrt{i}}\left[\frac{e^{\frac{4}{\sqrt{i}}}}{1+\frac{4}{\sqrt{i}}e^{\frac{4}{\sqrt{i}}}}\right] + \frac{2}{i^2}.$$

After some algebraic manipulation, it can be seen that this is equivalent to

$$\frac{i}{i+1} - \frac{1}{i^{\frac{3}{2}}} + \frac{1}{4i^3} \geq e^{\frac{8}{\sqrt{i}}}\left(1 - \frac{4}{\sqrt{i+1}} + \frac{2}{i^2}\right)^2.$$

From the Taylor expansion of e^x, we can verify that $e^x \leq (1+x+\frac{3}{4}x^2)$ for any $x \leq 1$. Using the fact that $4/\sqrt{i} < 3/4$, we can assume that $i \geq 28$. Using both of these facts, it is not hard to verify that $4/\sqrt{i} - 1/7 \leq 4/\sqrt{i+1}$. Plugging all of these back into the above inequality establishes (3.12). ∎

Now, to establish Theorem 2, we first compute the maximum possible value for k (namely, the maximum possible number of recursion levels), and we note that a sequence S generated by ADV_k has $\mu_v(S) = \frac{v_0}{v_k} = k^{2k}$ (and $\mu_d(S) = \frac{v_k}{v_o} = k^{4k}$). Thus, given that $\mu(S) = m$ we can employ ADV_k, where $k = \lfloor \frac{\log m}{4 \log\log m} \rfloor$.

Theorem 2 always holds for $\sqrt{\frac{\log m}{\log\log m}} \leq 10$, since the competitive ratio is always at least 1. Thus, if we use $k = \lfloor \frac{\log m}{4\log\log m} \rfloor$, we can assume that $k \geq 25$. Using this lower bound on k, the fact that $\delta = \frac{3}{k-1}$ and the result from Lemma 2, we can bound $\beta_k + \delta$ by $\frac{5}{\sqrt{k}}$. Using Lemma 1 and plugging in $k = \lfloor \frac{\log m}{4\log\log m} \rfloor$, establishes Theorem 2. ∎

Proof of Lemma 1. Consider a sequence S generated via an interaction between $\mathcal{A}$ and ADV_k. We introduce the following notation. A time unit t is called *i-critical* if $\mathcal{O}_{i+1}(t) > \mathcal{O}_{i+1}(t-1)$. A time interval $\tau = [t_s, t_f]$ is called an i-step if t_s and $t_f + 1$ are i-critical and $t_s+1, \ldots, t_f$ are not i-critical. For every i, the sequence S partitions time into a sequence of i-steps. Let the *i-height* of τ be $h_i(\tau) = \mathcal{O}_{i+1}(t_s) - \mathcal{O}_{i+1}(t_s - 1)$. (Note that if $\tau = [t_s, t_f]$ is the first i-step in an i-period then the i-height of τ is v_i.) The optimal gain from sequence S is the sum of the k-heights of all the k-steps in the duration of S.

Roughly, we will show that the expected gain of $\mathcal{A}$ from the jobs requested during each k-step is at most β_k times the k-height of this step. However, we first distinguish between the main contribution to the competitive ratio of $\mathcal{A}$ and several special cases which result in additional, small "error terms." These error terms, encapsuled in the term δ defined above, result from three classes of requests. These classes are defined below and are taken care of in Lemma 4.

A j-job c is said to be *final for level i* if $j < i$ and c is the last j-job to be requested in its i-period. A j-job is *final* if it is final for some level i where $i > j$. A j-job c is a *step-2 job for level i* if $i > j$ and c is requested during the *second* i-step in its i-period. A job is *step-2* if it is step-2 for some level i with $i > j$. A j-job c is said to be *high-probability* if $q_j(t) \geq f_j(\mathcal{O}_j(t))$ for all times t in its duration. (High probability jobs correspond, in principle, to Case 3 in the analysis of a 1-adversary in section 3.1. This is the case where the probability that a job is running never falls below the threshold.) A job is *regular* if it is neither a step-2, final, nor high-probability job.

Let $\text{E}G\mathcal{A}_\tau(S)$ denote the expected gain of $\mathcal{A}$ from the *regular* jobs requested by ADV_k during some step τ. That is, $\text{E}G\mathcal{A}_\tau(S) = \sum_{c \in S_\tau} v_c \cdot \text{Prob}\ (\mathcal{A}\ \text{completes}\ c)$, where S_τ is the sequence of regular jobs requested during τ. Lemma 3 states that $\text{E}G\mathcal{A}_\tau(S)$ is at most β_k times the k-height of each k-step τ. We know that $\mathcal{O}(S) = \sum_{\{k\text{-steps } \tau\}} h_k(\tau)$. It follows that the expected gain of $\mathcal{A}$ from S due to regular jobs is at most $\beta_k \cdot \mathcal{O}(S)$. Lemma 4 states that the total gain of $\mathcal{A}$ from all the nonregular jobs in S is at most $\delta \cdot \mathcal{O}(S)$. Lemma 1 follows. □

On the structure of S. In the proofs of Lemmas 3 and 4, we use the following observations regarding the structure of S. The first job requested in each i-period is an i-job. The rest of the jobs in this i-period are i-small. Each i-period can be partitioned into i-steps (any i-step is contained within a single i-period). The first i-step in an i-period occurs due to the request of the i-job and has i-height v_i. This i-step can be partitioned to several $(i-1)$-steps. In the second i-step (if there is one), the optimal gain due to the i-small jobs exceeds the gain of the i-job for the first time. If this happens, then the optimal schedule in the i-period contains only i-small jobs instead of the i-job. As a result, any additional increase in $\mathcal{O}_{i+1}$ within this i-period causes the same increase in $\mathcal{O}_i$, and any subsequent i-step τ is also an $(i-1)$-step. Furthermore, $h_i(\tau) = h_{i-1}(\tau)$. Note that if there is a second i-step τ, then τ is also an $(i-1)$-step, but it is not necessarily the case that $h_i(\tau) = h_{i-1}(\tau)$ for the second i-step. This is because the arrival of an i-small job may cause the optimal gain from i-small jobs to exceed the value of the i-job by only a small amount.

LEMMA 3. *Let $k \geq 0$. Let $\mathcal{A}$ be a scheduler and let S be the request sequence generated via an interaction between $\mathcal{A}$ and ADV_k. Let τ be a k-step. Then,*

$$\text{E}G\mathcal{A}_\tau(S) \leq \beta_k \cdot h_k(\tau). \tag{3.13}$$

Proof. Outline. We prove the lemma by induction on k. The lemma trivially holds for ADV_0 (using one type of job), since $\beta_0 = 1$. Also, the case of ADV_1 was analyzed in section 3.1.

Let $k > 0$ and assume that there exists a scheduler $\mathcal{A}$ and a k-step τ such that (3.13) is violated. We construct a scheduler $\mathcal{A}'$ with the following property that contradicts the induction hypothesis. Consider the sequence S' generated via the interaction of $\mathcal{A}'$ with ADV_{k-1}. Then there exists a $(k-1)$-step τ' in S' such that

$$\text{EG}\mathcal{A}'_{\tau'}(S') > \beta_{k-1} \cdot h_{k-1}(\tau'), \tag{3.14}$$

where $\text{EG}\mathcal{A}'_{\tau'}(S')$ is defined similarly to $\text{EG}\mathcal{A}_\tau(S)$, with respect to $\mathcal{A}'$, S', and τ'.

Construction of $\mathcal{A}'$. Consider the sequence S generated by ADV_k interacting with $\mathcal{A}$. First a $(k-1)$-period of S, starting at time t_*, is chosen in a way described below. Roughly, $\mathcal{A}'$ will imitate the operation of $\mathcal{A}$ starting at time t_*, conditioned on the event that $\mathcal{A}$ has preempted the k-job. More precisely, let $p_i(t)$ (resp., $p'_i(t)$) denote the probability that $\mathcal{A}$ (resp., $\mathcal{A}'$) has a job of type i scheduled at time unit t. Scheduler $\mathcal{A}'$ is constructed so that when playing against ADV_{k-1} for the duration of a $(k-1)$-period, the following probability vector $\vec{p}'(t) = p'_0(t), \ldots, p'_{k-1}(t)$ is maintained:

$$p'_i(t) = \frac{p_i(t+t_*)}{1 - p_k(t+t_*)}. \tag{3.15}$$

Scheduler $\mathcal{A}'$ can always be implemented since $\sum_{i=0}^{k-1} p'_i(t) \le 1$, and $p'_i(t) > p'_i(t-1)$ only if an i-job is requested at time t. In choosing t_* we distinguish two cases.

Case 1. Step τ is not the first k-step. Then τ is also a $(k-1)$-step and is contained in a $(k-1)$-period. Let t_* be the beginning of this $(k-1)$-period. In the analysis, we will divide this case into two subcases, depending on whether the step is the second k-step or not.

Case 2. Step τ is the first k-step. The first k-step is partitioned into several $(k-1)$-steps, $\tau_1, \ldots, \tau_l$. Let τ_* be the $(k-1)$-step contained in τ that maximizes the ratio

$$\max_{1 \le i \le l} \left\{ \frac{\text{EG}\mathcal{A}_{\tau_i}(S)}{(1 - p_k(e_{\tau_i})) \cdot h_{k-1}(\tau_i)} \right\}$$

among all the $(k-1)$-steps contained in τ, where e_{τ_i} is the latest ending time of a regular job requested during τ_i (note that e_{τ_i} may be later than the end of τ_i). For convenience, we assume that the initial k-job is not included in the first $(k-1)$-step. Let t_* be the beginning of the $(k-1)$-period containing τ_*. Note that $\mathcal{A}'$ may perform very poorly on request sequences different than those generated by ADV_{k-1}. The only purpose of $\mathcal{A}'$ is to contradict the induction hypothesis.

Analysis of scheduler $\mathcal{A}'$. It can be seen from (3.15) and the adversary strategy (Figure 3.3) that at each time t in the interaction of ADV_{k-1} with $\mathcal{A}'$, ADV_{k-1} requests exactly the same jobs that ADV_k requests at time $t + t_*$ when interacting with $\mathcal{A}$; this holds with the following two exceptions. First, ADV_k may request an initial k-job at time t_*, where ADV_{k-1} does not. Second, the sequence S may end before S', if $p_k(t)$ falls below the threshold for some time t. Let $\hat{S}$ denote the subsequence of S starting at time t_* with the initial k-job removed (if there is one). Then, $\hat{S}$ is a prefix of S'. Furthermore, for any $(k-1)$-step τ in $\hat{S}$ we have $h_{k-1}(\tau) = h_{k-1}(\tau')$, where τ' is the $(k-1)$-step in S' that corresponds to τ. We consider the above two cases of determining t_*.

Case 1a. Step τ is the second k-step. All jobs requested in this step are step-2 jobs and are thus not regular. Thus, $\mathrm{E}G\mathcal{A}_\tau(S) = 0$. (Step-2 jobs are accounted for in Lemma 4.)

Case 1b. Step τ is neither the first nor the second k-step. Then, τ is a $(k-1)$-step as well. Let τ' be the $(k-1)$-step that corresponds to τ in S'. Then, $h_k(\tau) = h_{k-1}(\tau) = h_{k-1}(\tau')$. We show below that the probability that $\mathcal{A}$ completes each regular job $c \in S$ is at most $\frac{\beta_k}{\beta_{k-1}}$ times the probability that $\mathcal{A}'$ completes the corresponding job $c' \in S'$ during τ'. Thus, if (3.13) is violated with respect to τ then (3.14) holds with respect to step τ'.

Scheduler $\mathcal{A}$ completes an i-job c with probability $p_i(e_c)$, and $\mathcal{A}'$ completes c' with probability $\frac{p_i(e_c)}{1-p_k(e_c)}$, where e_c is the time at which c ends. It remains to show that $1 - p_k(e_c) \le \frac{\beta_k}{\beta_{k-1}}$. Since c is not a final job, we have that $p_k(e_c) \ge f_k(\mathcal{O}_k(e_c))$. Since τ is not the first k-step, the optimal gain has already exceeded v_k, and $\mathcal{O}_k(e_c) > v_k$. Thus, $f_k(\mathcal{O}_k(e_c)) = 1 - \alpha_k \mathrm{e}^{\beta_{k-1}}$ and $1 - p_k(e_c) \le \alpha_k \mathrm{e}^{\beta_{k-1}} \le \frac{\beta_k}{\beta_{k-1}}$.

Case 2. Step τ is the first k-step. Let ${\tau_*}'$ be the $(k-1)$-step that corresponds to τ_* with respect to S'. We show that if $\mathrm{E}G\mathcal{A}'_{{\tau_*}'}(S') \le \beta_{k-1} \cdot h_{k-1}({\tau_*}')$ then $\mathrm{E}G\mathcal{A}_\tau(S) \le \beta_k \cdot v_k$. We proceed in two steps: first we show (3.17), where t_0 is defined below. Next we show (3.18).

Showing (3.17), we first express $\mathrm{E}G\mathcal{A}_\tau(S)$ in terms of the expected gain of $\mathcal{A}$ in the $(k-1)$-steps $\tau_1, \ldots, \tau_l$ contained in τ. Assume that the initial k-job is not a high-probability job. In this case, there is a time t such that $p_k(t) < f_k(\mathcal{O}_k(t))$. Let $t_0 = t$ if t happens before the end of τ; otherwise t_0 is the first time unit after the end of τ. Thus,

$$\mathrm{E}G\mathcal{A}_\tau(S) \le v_k \cdot f_k(\mathcal{O}_k(t_0)) + \sum_{i=1}^{l} \mathrm{E}G\mathcal{A}_{\tau_i}(S). \tag{3.16}$$

Inequality (3.16) is satisfied even if the initial k-job is a high-probability job. In this case, the contribution of this job is not included in $\mathrm{E}G\mathcal{A}_\tau(S)$; it is considered in Lemma 4.

Scheduler $\mathcal{A}'$ completes each job $c' \in S'$ requested during τ_* with probability at least $\frac{1}{(1-p_k(e_c))}$ times the probability that $\mathcal{A}$ completes the corresponding job $c \in S$. Since $e_c \le e_{\tau_*}$, we have $\mathrm{E}G\mathcal{A}_{\tau_*}(S) \le (1 - p_k(e_{\tau_*})) \cdot \mathrm{E}G\mathcal{A}'_{{\tau_*}'}(S')$. Recall that $\mathrm{E}G\mathcal{A}'_{{\tau_*}'}(S') \le \beta_{k-1} \cdot h_{k-1}({\tau_*}')$, and $h_{k-1}({\tau_*}') = h_{k-1}(\tau_*)$. Thus,

$$\mathrm{E}G\mathcal{A}_{\tau_*}(S) \le (1 - p_k(e_{\tau_*})) \cdot \beta_{k-1} \cdot h_{k-1}(\tau_*).$$

It follows from the choice of τ_* that $\mathrm{E}G\mathcal{A}_{\tau_i}(S) \le (1 - p_k(e_{\tau_i}))\beta_{k-1} \cdot h_{k-1}(\tau_i)$ for all steps τ_i. Thus, (3.16) implies that

$$\mathrm{E}G\mathcal{A}_\tau(S) \le v_k \cdot f_k(\mathcal{O}_k(t_0)) + \sum_{i=1}^{l} (1 - p_k(e_{\tau_i})) \cdot \beta_{k-1} \cdot h_{k-1}(\tau_i). \tag{3.17}$$

It remains to show that

$$v_k \cdot f_k(\mathcal{O}_k(t_0)) + \sum_{i=1}^{l} (1 - p_k(e_{\tau_i})) \cdot \beta_{k-1} \cdot h_{k-1}(\tau_i) \;\le\; \beta_k \cdot v_k. \tag{3.18}$$

First, we show that

$$v_k \cdot f_k(\mathcal{O}_k(t_0)) + \sum_{i=1}^{l} (1 - p_k(s_{\tau_i})) \cdot \beta_{k-1} \cdot h_{k-1}(\tau_i) \le (\beta_k - \gamma) \cdot v_k, \tag{3.19}$$

where s_{τ_i} is the starting time of step τ_i, and $\gamma = \frac{2}{k^2}$ is a small "error term." Next we show that

$$\sum_{i=1}^{l}(p_k(s_{\tau_i}) - p_k(e_{\tau_i})) \cdot \beta_{k-1} \cdot h_{k-1}(\tau_i) \le \gamma \cdot v_k. \tag{3.20}$$

Showing (3.19), we have

$$\begin{aligned}
&v_k \cdot f_k(\mathcal{O}_k(t_0)) + \sum_{i=1}^{l}(1 - p_k(s_{\tau_i})) \cdot \beta_{k-1} \cdot h_{k-1}(\tau_i) \\
&\le v_k \cdot f_k(\mathcal{O}_k(t_0)) + \beta_{k-1} \cdot \sum_{i=1}^{l}(1 - f_k(\mathcal{O}_k(s_{\tau_i}))) \cdot h_{k-1}(\tau_i) \\
&\le v_k \cdot f_k(\mathcal{O}_k(t_0)) + \beta_{k-1} \cdot \int_0^{\mathcal{O}_k(t_0)}(1 - f_k(y))dy = (*).
\end{aligned}$$

The last derivation uses a standard transformation from a sum to an integral. We integrate only up to $\mathcal{O}_k(t_0)$, since either t_0 is after the end of τ, or the only jobs requested at or after time t_0 are final jobs. Let $x = \mathcal{O}_k(t_0)$. Since this is the first k-step we have $x \le v_k$; thus, $f_k(x) = 1 - \alpha_k e^{\frac{\beta_{k-1}x}{v_k}}$. Thus:

$$\begin{aligned}
(*) &= v_k \cdot f_k(x) + \beta_{k-1} \cdot \int_0^x (1 - f_k(y))dy \\
&= \left(1 - \alpha_k e^{\frac{\beta_{k-1}x}{v_k}}\right) v_k + \beta_{k-1} \int_0^x \alpha_k e^{\frac{\beta_{k-1}y}{v_k}} dy \\
&= \left(1 - \alpha_k e^{\frac{\beta_{k-1}x}{v_k}}\right) v_k + \beta_{k-1} \frac{v_k}{\beta_{k-1}} \alpha_k \left(e^{\frac{\beta_{k-1}x}{v_k}} - 1\right) \\
&= (1 - \alpha_k)v_k \\
&= (\beta_k - \gamma)v_k.
\end{aligned}$$

To show (3.20), let w_i denote the largest j such that a j-job is requested on the first time unit of τ_i. Rewriting the left-hand side of (3.20) we get

$$\beta_{k-1}\sum_{i=1}^{l} h_{k-1}(\tau_i)\cdot(p_k(s_{\tau_i})-p_k(e_{\tau_i})) \le \beta_{k-1}\sum_{j=0}^{k-1} v_j \cdot \sum_{\{i\,:\,w_i=j\}}(p_k(s_{\tau_i})-p_k(e_{\tau_i})) = (**).$$

Observe that $p_k(t)$ is a nonincreasing function, and that for any w_{i_1}, w_{i_2} with $i_1 > i_2$, step τ_{i_1} begins only after all the jobs requested during τ_{i_2} have ended. Thus, $\sum_{\{i \mid w_i=j\}}(p_k(s_{\tau_i}) - p_k(e_{\tau_i})) \le 1$. Since $v_{w_i} = k^{2+2w_i}$ and $\beta_{k-1} \le 1$, we have

$$(**) \le \beta_{k-1}\sum_{j=0}^{k-1} v_j \cdot 1 \le 2 \cdot v_{k-1}\cdot \le \frac{2}{k^2} \cdot v_k = \gamma \cdot v_k. \qquad \square$$

LEMMA 4. *Let $k \ge 0$. Let $\mathcal{A}$ be a scheduler and let S be the request sequence generated by an interaction between $\mathcal{A}$ and* ADV$_k$. *Then, the total gain of $\mathcal{A}$ from all the step-2, final, and high-probability jobs in S is at most $\frac{3}{k-1}\mathcal{O}(S)$.*

Proof. We first bound the gain of $\mathcal{A}$ from the final and step-2 jobs. The gain achievable, even by the optimal schedule, from all the step-2 jobs for level i requested within a given i-period is at most v_{i-1}. For each i-job and every $j < i$, there is at most one final j-job. Let n_i be the total number of i-jobs in S. The optimal gain achievable from the jobs that are either final or step-2 for level i is thus at most

$$n_i \left(v_{i-1} + \sum_{j=0}^{i-1} v_j \right) \leq 2n_i v_i \sum_{j=0}^{i-1} \frac{1}{k^{2(i-j)}} \leq \frac{2n_i v_i}{k^2 - 1}.$$

For every i, the sequence of all i-jobs in S is a feasible subsequence of S, with gain $n_i v_i$. Therefore, $\mathcal{O}(S) \geq \max_i(n_i v_i)$. The sum of the values of all final and step-2 jobs is thus at most:

$$\sum_{i=0}^{k} \frac{2n_i v_i}{k^2 - 1} \leq (k+1) \max_i \frac{2n_i v_i}{k^2 - 1} \leq \frac{2}{k-1} \mathcal{O}(S).$$

Next we bound the gain achievable from the high-probability jobs which are not final. Consider a high-probability i-job c which is not final. We first show that an $(i-1)$-job is requested in each $(i-1)$ period for the duration of c. To see why this is true, recall that an $(i-1)$ job is requested in an $(i-1)$-period if at the first time unit t in this period $q_j(t) \geq f_j(\mathcal{O}_j(t))$ for all $j \geq i$. If c is not final, then $q_j(t) \geq f_j(\mathcal{O}_j(t))$ for all $j > i$ and for all times t in the duration of c. If c is high-probability then $q_i(t) \geq f_i(\mathcal{O}_i(t))$ for all times t in the duration of c.

Consequently, k^4 jobs of type $(i-1)$ are requested in the duration of c. The total value of these $(i-1)$-jobs is k^2 times the value of c. Let g_i be the number of all nonfinal high-probability i-jobs in S. We know that $k^2 v_i g_i \leq v_{i-1} n_{i-1}$. Therefore, the total gain from all nonfinal high-probability jobs is at most

$$\sum_{i=1}^{k} v_i g_i \leq \frac{1}{k^2} \sum_{i=1}^{k} v_{i-1} n_{i-1} \leq \frac{1}{k} \max_i v_i n_i \leq \frac{1}{k} \mathcal{O}(S). \qquad \square$$

4. Applications of the bound. In this section, we present a series of corollaries showing how the lower bound of Theorem 2 can be generalized and extended to related problems. The proofs of most corollaries are very similar techniques. For clarity, we give a full proof of the first corollary (Corollary 1). Next we describe our general technique in abstract terms. For the rest of the proofs we merely state how certain parameters of the general technique should be set.

4.1. Multiprocessor scheduling. We first describe how the bound in Theorem 2 can be generalized to situations where more than a single job can be served at a time. Each job c has a load l_c, and a feasible sequence is one in which the sum of the loads of any set of overlapping jobs is at most the capacity U of the server. The bound holds even if there is more than one server (each with capacity U) and even if there is an upper bound on the load that any single job may require.

Recall that μ_d, μ_l, and μ_v denote the ratio of maximum to minimum duration, load and value of a job, respectively. Let $g(x) = \frac{1}{8}\sqrt{\frac{\log x}{\log \log x}}$.

COROLLARY 1. *Let $\delta < 1$. Theorem 2 holds even when there are m servers, each with capacity U, and even if $l_c \leq \delta U$ for each job c.*

Proof. We assume the existence of a scheduler $\mathcal{A}'$ that contradicts the corollary. Based on $\mathcal{A}'$, we then construct scheduler $\mathcal{A}$ that contradicts Theorem 2. $\mathcal{A}$ keeps a

copy of $\mathcal{A}'$ running. On a sequence S of requests, $\mathcal{A}$ generates for $\mathcal{A}'$ a sequence S' constructed as follows.

Construction of $\mathcal{A}$. Let α be chosen so that $1/\alpha = \lceil 1/\delta \rceil$. Upon receiving a request c with duration d_c and value v_c, $\mathcal{A}$ generates a set S'_c of $N_c = m/\alpha$ requests for $\mathcal{A}'$. Each request in S'_c has the same duration as c, has value $v_{c'} = \alpha v_c/m$ and load $l_{c'} = U\alpha$. Note that if all jobs from S'_c are scheduled, they use up the entire capacity of the system. Furthermore, the sum of the values of all the jobs in S'_c is equal to $N_c v_{c'} = v_c$.

Let $n_c(t)$ denote the expected number of jobs in S'_c scheduled by $\mathcal{A}'$ at time t. $\mathcal{A}$ will accept and preempt jobs so as to maintain the invariant that at all times t, the probability that $\mathcal{A}$ has job c scheduled is $n_c(t)/N_c$. In showing how $\mathcal{A}$ achieves this we assume that $\mathcal{A}'$ has the property that after the arrival of a set of jobs S'_c, the entire capacity of all m servers is being used. No generality is lost by this assumption, since $\mathcal{A}'$ can always decide to preempt jobs later in favor of an incoming job. Now suppose that $\mathcal{A}$ has a job $\tilde{c}$ running during time unit $t-1$ and jobs $c_1, c_2, \ldots, c_k$ arrive at time t. $\mathcal{A}$ will preempt $\tilde{c}$ with probability $(n_{\tilde{c}}(t-1) - n_{\tilde{c}}(t))/n_{\tilde{c}}(t-1)$. If $\mathcal{A}$ preempts its current job or did not have any jobs running during time $t-1$, then it accepts job c_i with probability $n_{c_i}(t)/\sum_{j=1}^{k} n_{c_j}(t)$. It can be verified by induction on t that the invariant holds.

Analysis of $\mathcal{A}$. Given a feasible subsequence $\hat{S} \subseteq S$, the following feasible subsequence $\hat{S}' \subseteq S'$ satisfies $\mathcal{O}(\hat{S}) \leq \mathcal{O}(\hat{S}')$: for every $c \in \hat{S}$, include all the jobs from S'_c in $\hat{S}'$. Thus $\mathcal{O}(S) \leq \mathcal{O}(S')$.

Let e_c be the ending time of job c. The expected gain of $\mathcal{A}'$ from the jobs in S'_c is $v_{c'} n_c(e_c) = v_c n_c(e_c)\alpha/m$. The expected gain of $\mathcal{A}$ from job c is $v_c n_c(e_c)/N_c = v_c n_c(e_c)\alpha/m$. Thus, the expected gain of $\mathcal{A}$ on its input sequence S is equal to the expected gain of $\mathcal{A}'$ on the constructed sequence S'. Since $\mu_d(S) = \mu_d(S')$ and $\mu_v(S) = \mu_v(S')$, the existence of $\mathcal{A}'$ contradicts Theorem 2. □

The remaining corollaries are proven using a reduction technique similar to the proof of Corollary 1. We first describe this technique in more general terms. Next, we state the corollaries and fill in the necessary details in the proofs.

Assume the existence of a scheduler $\mathcal{A}'$ that contradicts some corollary. Based on $\mathcal{A}'$, we then construct scheduler $\mathcal{A}$ that contradicts Theorem 2. $\mathcal{A}$ keeps a copy of $\mathcal{A}'$ running. Given a sequence S of requests, $\mathcal{A}$ gives $\mathcal{A}'$ a sequence S' constructed as follows. Upon receiving a request c in S, $\mathcal{A}$ generates a set S'_c of N_c requests for $\mathcal{A}'$, each of value $v_{c'}$ and load $l_{c'}$. The duration of each job in S'_c is exactly d_c. The parameters of the constructed requests depend on the reduction. However, they will always have the property that the total load of the N_c jobs in S'_c equals the capacity of the system. The sum of the values of all the jobs in S'_c is equal to v_c (i.e., $N_c v_{c'} = v_c$). $\mathcal{A}$ maintains the invariant that at all times t the probability that $\mathcal{A}$ has job c scheduled is $n_c(t)/N_c$. Thus, we can deduce that $\mathcal{O}(S) \leq \mathcal{O}(S')$. Also, given a feasible subsequence $\hat{S} \subseteq S$, we can obtain a feasible subsequence $\hat{S}' \subseteq S'$ such that $G(\hat{S}) \leq G(\hat{S}')$: for every $c \in \hat{S}$, include all the jobs from S'_c in $\hat{S}'$.

As in the previous proof, the expected gain of $\mathcal{A}'$ from the jobs in S'_c is $v_{c'} n_c(e_c)$. Consequently, the expected gain of $\mathcal{A}$ from job c is $v_c n_c(e_c)/N_c$.

The next two corollaries show that the bound applies also when some specific value functions are used.

COROLLARY 2. *Assume jobs have arbitrary load and duration, and the value of a job is its duration. Then, any randomized, preemptive on-line scheduler is at best* $g/2$*-competitive for measures* μ_d *and* μ_l.

Proof. We choose $N_c = v_c/d_c$, $l_{c'} = \frac{U d_c}{v_c}$, and $d_{c'} = d_c$. The expected gain of $\mathcal{A}'$ from jobs in S'_c is $d_c n_c(e_c)$, and the expected gain of $\mathcal{A}$ from job c is $v_c n_c(e_c)/N_c = d_c n_c(e_c)$. Thus, the expected gain of $\mathcal{A}$ on its input sequence S is equal to the expected gain of $\mathcal{A}'$ on the constructed sequence S'. Since $\mu_d(S) = \mu_d(S')$ and $\mu_l(S') \leq \mu_d(S) \cdot \mu_v(S)$, we have that $\max\{g(\mu_d(S')), g(\mu_l(S'))\} \leq 2\max\{g(\mu_d(S)), g(\mu_v(S))\}$. Thus, if $\mathcal{A}'$ is $g/2$-competitive with respect to measures μ_d and μ_l, then $\mathcal{A}$ is g-competitive with respect to measures μ_d and μ_v, contradicting Theorem 2.

We remark that the construction can be adapted to the cases where there is a bound δU (for any $\delta \leq 1$) on the load of a single job and where there are m servers. This is accomplished in a similar manner as in Corollary 1, that is, by increasing the number of jobs by a factor of m/δ and reducing the load of each job by a factor of δ. □

COROLLARY 3. *Assume jobs have arbitrary load and duration, and the value of all jobs is* 1. *Then, any randomized, preemptive on-line scheduler is at best g-competitive for measures μ_l and μ_d.*

Proof. We choose $N_c = v_c$, $l_{c'} = \frac{U}{v_c}$, and $d_{c'} = d_c$. The expected gain of $\mathcal{A}'$ from the S'_c jobs is $n_c(e_c)$, and the expected gain of $\mathcal{A}$ from job c is $v_c n_c(e_c)/N_c = n_c(e_c)$. Thus, the expected gain of $\mathcal{A}$ on its input sequence S is equal to the expected gain of $\mathcal{A}'$ on the constructed sequence S'. Since $\mu_d(S) = \mu_d(S')$ and $\mu_l(S') = \mu_v(S)$, the existence of $\mathcal{A}'$ contradicts Theorem 2.

Again, the construction can be adapted as in Corollary 1 to the cases where there is a bound δU (for any $\delta \leq 1$) on the load of a single job and where there are m servers. □

4.2. Bandwidth allocation. Next we address bandwidth allocation problems. Job scheduling for the uniprocessor model discussed above is identical to the bandwidth allocation (call control) model on a single link, when load is translated to bandwidth. We generalize the result to work for an arbitrary network as follows.

COROLLARY 4. *Assume calls have arbitrary values. Then, any randomized, preemptive call control algorithm for any network has a competitive ratio of at best g for measures μ_d and μ_v.*

Proof. Pick any pair of nodes s and t in the network. Let F be the value of the maximum flow from s to t, where $u(e)$ is the capacity of an edge. Let ϵ be the greatest common divisor of all the edge capacities. We will only request calls between s and t with bandwidth at most ϵ. Thus, the set of paths between s and t can be treated as a single edge with capacity F.

We use the same reduction above, choosing $N_c = F/\epsilon$, $v_{c'} = v_c\epsilon/F$, $d_{c'} = d_c$, and $l_c = \epsilon$. The expected gain of $\mathcal{A}'$ from the c' jobs is $v_c n_c(e_c)\epsilon/F$, and the expected gain of $\mathcal{A}$ from job c is $v_c n_c(e_c)/N_c = v_c n_c(e_c)\epsilon/F$. Thus, the expected gain of $\mathcal{A}$ on its input sequence S is equal to the expected gain of $\mathcal{A}'$ on the constructed sequence S'. Since $\mu_d(S) = \mu_d(S')$ and $\mu_v(S) = \mu_v(S')$, the existence of $\mathcal{A}'$ contradicts Theorem 2. □

COROLLARY 5. *Any randomized, preemptive call control algorithm for any network has a competitive ratio of at best g for measures μ_d and μ_l, even if the value of a call is its duration, or if the values of all calls are* 1.

Proof. Use the techniques of the proof of Corollary 4 to extend Corollaries 2 and 3 to general networks. □

Next we concentrate on networks with no cycles, namely trees. Corollaries 4 and 5 apply. In addition, here the bound can be shown to apply to other natural ways for determining a call value. Let r_c denote the distance in the tree between the two

endpoints of the call c. Let D be the diameter of the tree. (D can be regarded as the ratio between the lengths of the longest and shortest paths in a network.)

COROLLARY 6. *Suppose we have a tree network with diameter D. Then any randomized, preemptive call control algorithm for this network has a competitive ratio of at best $\Omega(g)$ for measures μ_d and D, even with the following criteria for call value.*

(i) $v_c = l_c d_c$.

(ii) $v_c = r_c$.

(iii) $v_c = r_c l_c$.

(iv) $v_c = r_c d_c$.

(v) $v_c = r_c l_c d_c$.

Remarks. (1) Note that although D is not a parameter of the input sequence, it describes the network which is part of the input to the problem. The definition of competitiveness in section 2 can be adapted accordingly. (2) Method (i) for determining the value of a call measures the amount of information potentially contained in a call. Measure (iv) measures the amount of "work" invested in a call. The fact that the bound holds for these measures stands in contrast to the single-edge and multiprocessor cases. There, constant competitive algorithms exist for similar measures (see, e.g., [8]).

Proof. We construct a reduction to Theorem 2. Assume that D, as well as v_c and v_c/d_c for each job c requested of $\mathcal{A}$, are powers of 2 (and d_c is an integer). Such a situation can be achieved by rescaling and rounding, with a loss of at most a factor of 4 in effectiveness. That is, first rescale v_c and d_c to be all integers. Next, D and v_c for each call c are rounded to the largest power of two smaller than D.

(i) Assume the existence of an $o(g)$-competitive scheduler $\mathcal{A}'$ on a tree network with diameter $D = \mu_d(S) \cdot \mu_v(S)$, where the value of a call c is $l_c \cdot d_c$. We construct a scheduler $\mathcal{A}$ that contradicts Theorem 2.

$\mathcal{A}$ first chooses a simple path of length D in the network on which $\mathcal{A}'$ operates and numbers the nodes along the path $0, 1, \ldots, D$. For each requested job c, scheduler $\mathcal{A}$ requests a set S'_c of v_c/d_c calls for $\mathcal{A}'$, where the ith call starts at node $[(i-1) \cdot \frac{Dd_c}{v_c}]$ and ends at node $[i \cdot \frac{Dd_c}{v_c}]$. (That is, $N_c = v_c/d_c$ and each generated call c' is of length $r_{c'} = D\frac{d_c}{v_c}$. All these calls can be served "back to back" on the path.) All generated calls have $l_{c'} = 1$. Next, $\mathcal{A}$ maintains the property that call c is in service with probability proportional to the fraction of the corresponding c' calls currently served by $\mathcal{A}'$.

The expected gain of $\mathcal{A}'$ from the jobs in S'_c is $d_c n_c(e_c)$, and the expected gain of $\mathcal{A}$ from job c is $v_c n_c(e_c)/N_c = d_c n_c(e_c)$. Thus, the expected gain of $\mathcal{A}$ on its input sequence S is equal to the expected gain of $\mathcal{A}'$ on the constructed sequence S'. Since $\mu_d(S) = \mu_d(S')$ and $\mu_v(S) \cdot \mu_d(S) \geq D$, the existence of $\mathcal{A}'$ contradicts Theorem 2.

(ii) As in the proof of (i), $\mathcal{A}$ picks a path of length D in the tree. The vertices of this path are labeled $\{0, \ldots, D\}$. $N_c = 1$, $l_c = 1$, $d_c = d_{c'}$. The endpoints of the call in S'_c are node 0 and node v_c. Thus, $v_c = r_{c'} = v_{c'}$. Since $\mu_d(S) = \mu_d(S')$ and $\mu_v(S) = D$, the existence of $\mathcal{A}'$ contradicts Theorem 2.

(iii) The construction for (ii) works here since for all c, $l_c = 1$.

(iv) As in the proof of (i), $\mathcal{A}$ picks a path of length D in the tree. The vertices of this path are labeled $\{0, \ldots, D\}$. $N_c = 1$, $l_c = 1$, $d_c = d_{c'}$. The endpoints of the call in S'_c are 0 and node v_c/d_c. Thus, $r_{c'} = v_c/d_c$ and $v_c = r_c d_{c'} = v_{c'}$. Since $\mu_d(S) = \mu_d(S')$ and $\mu_v(S) \cdot \mu_d(S) \geq D$, the existence of $\mathcal{A}'$ contradicts Theorem 2.

(v) The construction for (iv) works here since for all c, $l_c = 1$. ∎

5. Tightness of the bound. We sketch two simple preemptive, randomized schedulers in the basic model defined in section 2. The first is $O(\log \mu_v)$-competitive and the second is $O(\log \mu_d)$-competitive. Depending on whether $\mu_d \leq \mu_v$, we can implement the appropriate one to obtain an $O(\log \mu)$-competitive scheduler for $\mu = \min\{\mu_v, \mu_d\}$. In both cases we use a technique of [3].

For the $O(\log \mu_v)$-competitive scheduler, let m (resp., M) be the minimum (resp., maximum) possible value of a job. Let $k = \lceil \log(M/m) \rceil$ and let $v_0, \ldots, v_k$ satisfy $v_0 = m$, $v_k = M$, and $v_i/v_{i-1} \leq 2$. The scheduler first picks $1 \leq i \leq k$ at random. Next, it rejects all jobs whose value does not fall between v_{i-1} and v_i. Jobs with value between v_{i-1} and v_i are scheduled as follows: accept an incoming job if it terminates before the currently running job. This scheduler is 2-competitive over the sequence of jobs in the chosen range. Thus, the competitive ratio of the randomized algorithm is $4 \log_2 \mu_v = 4 \log_2(M/m)$.

For the $O(\log \mu_d)$-competitive scheduler, let d (resp., D) be the minimum (resp., maximum) possible duration of a job. Let $k = \lceil \log(D/d) \rceil$ and let $d_0, \ldots, d_k$ satisfy $d_0 = m$, $d_k = M$, and $d_i/d_{i-1} \leq 2$. The scheduler first picks $1 \leq i \leq k$ at random. Next, it rejects all jobs whose duration does not fall between d_{i-1} and d_i. Jobs with duration between d_{i-1} and d_i are scheduled as follows: accept an incoming job if there is no currently running job or if the new job has at least twice the value of the currently running job.

We first show that the competitive ratio of this scheduler is 14-competitive, assuming that all jobs have the same duration. Then we employ the above [3] technique to argue that the competitive ratio of this scheduler is $O(\log_2 \mu_d) = O(\log_2(M/m))$.

Assume all jobs have the same duration. First we observe that the total value of all jobs which the scheduler preempts is at most the total value of the jobs which the scheduler completes. This follows from the fact that the scheduler only preempts a job in favor of a job which is at least twice the value of the currently running job. Next we bound the gain from jobs which the scheduler rejects (i.e., never schedules). Each rejected job intersects in time with a running job. (The running job can later be either completed or rejected.) It can be seen that the maximum gain from rejected jobs that intersect each running job c is at most $6v_c$. Thus the maximum gain from rejected jobs is at most 6 times the total gain from completed or preempted jobs. Altogether, the maximum gain from rejected, preempted, and completed jobs is at most 14 times the gain from completed jobs.

In the above construction it is assumed that the scheduler would know μ_d and μ_v in advance. We remark that this can be avoided by "rerandomizing" every time a job is introduced which increases μ_d or μ_v. We do not elaborate here.

6. Open questions. The first question we leave open is to close the quadratic gap for our generic scheduling problem. A logarithmic lower bound would not only match the upper bound shown in section 5 but would also match the other logarithmic upper bounds discussed in section 1.1.

Although much of the recent work in online routing in communication networks addresses the limited capacity problem, most of the work on the more traditional load balancing problems relates to makespan minimization. Despite the general lack of attention, the limited capacity problem seems to be well suited to many of the applications for the variety of scheduling paradigms in the literature. This points out an important and largely unexplored area in online scheduling. For example, there has been little which addresses admission control problems related to either example (a) or (b) at the beginning of the introduction. Although the work of [10], [11], and

[22] is an important step in this direction, that work addresses a very special case. Thus, generalizing these results to apply to more complex models is an important and relevant new direction for research.

Acknowledgments. We are grateful to the hospitality of Zvi Galil and Columbia University that enabled us to carry out this work during the summer of 1994. We also thank the anonymous referees for their very helpful comments.

SURFACE APPROXIMATION AND GEOMETRIC PARTITIONS*

PANKAJ K. AGARWAL† AND SUBHASH SURI‡

Abstract. Motivated by applications in computer graphics, visualization, and scientific computation, we study the computational complexity of the following problem: given a set S of n points sampled from a bivariate function $f(x, y)$ and an input parameter $\varepsilon > 0$, compute a piecewise-linear function $\Sigma(x, y)$ of minimum complexity (that is, an xy-monotone polyhedral surface, with a minimum number of vertices, edges, or faces) such that $|\Sigma(x_p, y_p) - z_p| \leq \varepsilon$ for all $(x_p, y_p, z_p) \in S$. We give hardness evidence for this problem, by showing that a closely related problem is *NP-hard*. The main result of our paper is a polynomial-time approximation algorithm that computes a piecewise-linear surface of size $O(K_o \log K_o)$, where K_o is the complexity of an optimal surface satisfying the constraints of the problem.

The technique developed in our paper is more general and applies to several other problems that deal with partitioning of points (or other objects) subject to certain geometric constraints. For instance, we get the same approximation bound for the following problem arising in machine learning: given n "red" and m "blue" points in the plane, find a minimum number of *pairwise disjoint* triangles such that each blue point is covered by some triangle and no red point lies in any of the triangles.

Key words. approximation algorithms, dynamic programming, levels of detail, machine learning, terrains, simplification, visualization

1. Introduction.

In scientific computation, visualization, and computer graphics, the modeling and construction of surfaces is an important area. A small sample of some recent papers [1, 2, 4, 8, 11, 14, 22, 23] on this topic gives an indication of the scope and importance of this problem. Rather than delve into any specific problem studied in these papers, we focus on a general, abstract problem that seems to underlie them all.

In many scientific and computer graphics applications, computation takes place over a surface in three dimensions. The surface is generally modeled by piecewise linear (or sometimes piecewise cubic) patches, whose vertices lie either on or in the close vicinity of the actual surface. In order to ensure that all local features of the surface are captured, algorithms for an automatic generation of these models generally sample at a dense set of regularly spaced points. Demands for real-time speed and reasonable performance, however, require the models to have as small a combinatorial complexity as possible. A common technique employed to reduce the complexity of the model is to somehow "thin" the surface by deleting vertices with relatively "flat" neighborhoods. Only ad hoc and heuristic methods are known for this key step. Most of the thinning methods follow a set of local rules (such as deleting edges or vertices whose incident faces are almost coplanar), which are applied in an arbitrary order

until they are no longer applicable. Not surprisingly, these methods come with no performance guarantee, and generally no quantitative statement can be made about the surface approximation computed by them.

In this paper, we address the complexity issues of the surface approximation problem for surfaces that are xy-monotone. These surfaces represent the graphs of continuous bivariate functions $f(x, y)$, and they arise quite naturally in many scientific applications. One possible approach for handling arbitrary surfaces is to break them into monotone pieces and apply our algorithm individually on each piece. Let us formally define the main problem studied in our paper.

Let f be a continuous function of two variables x and y, and let S be a set of n points sampled from f. A continuous piecewise-linear function Σ is called an *ε-approximation* of f, for $\varepsilon > 0$, if

$$|\Sigma(x_p, y_p) - z_p| \leq \varepsilon$$

for every point $p = (x_p, y_p, z_p) \in S$. Given S and ε, the *surface-approximation* problem is to compute a piecewise-linear function Σ that ε-approximates f with a minimum number of breakpoints. The breakpoints of Σ can be arbitrary points of $\mathbb{R}^3$, and they are not necessarily points of S. In many applications, f is generally a function hypothesized to fit the observed data—the function Σ is a computationally efficient substitute for f. The parameter ε is used to achieve a complexity–quality tradeoff: the smaller the ε, the higher the fidelity of the approximation. (The graph of a piecewise-linear function of two variables is also called a *polyhedral terrain* in computational geometry literature; the breakpoints of the function are the vertices of the terrain.)

Although there is a vast literature on the surface-approximation problem in the graphics community, the state of theoretical knowledge of this problem appears to be rather slim. The provable performance bounds are known only for convex surfaces. For this special case, an $O(n^3)$ time algorithm is presented by Mitchell and Suri [17] for computing an ε-approximation of a convex polytope of n vertices in $\mathbb{R}^3$. Their algorithm produces an approximation of size $O(K_o \log n)$, where K_o is the size of an optimal ε-approximation. Extending their work, Clarkson [7] has proposed an $O(K_o n^{1+\delta})$ expected time randomized algorithm for computing an approximation of size $O(K_o \log K_o)$, where δ can be an arbitrarily small positive number. Recently Brönnimann and Goodrich [5] have refined Clarkson's algorithm and have given a polynomial-time algorithm for computing an approximation of size $O(K_0)$.

In this paper, we study the approximation problem for surfaces that correspond to graphs of bivariate functions. We give evidence that the surface approximation may be hard, by showing that a closely related problem is *NP-hard*. In particular, we prove that it is *NP-hard* to decide whether the set of sample points can be ε-approximated with k triangles whose projections on the $z = 0$ plane are pairwise disjoint. (The latter problem relaxes the *continuity* requirement of the surface approximation.)

The main result of our paper, however, is a polynomial-time algorithm for computing an ε-approximating surface of a guaranteed quality. If an optimal ε-approximating surface of f has K_o vertices, then our algorithm produces a surface with $O(K_o \log K_o)$ vertices. (The number of vertices, edges, and faces are linearly related by Euler's formula, and so the approximation holds for any of the three measures.) Observe that we are dealing with two approximation measures here: ε, which measures the absolute z difference between f and the "simplified" surface Σ, and the ratio between the sizes of the optimal surface and the output of our algorithm. For lack of better terminology,

we use the term "approximation" for both measures. Notice, though, that ε is an input (user-specified) parameter, and $\log K_o$ is the approximation guarantee provided by the analysis of our algorithm.

The key to our approximation method is an algorithm for partitioning a set of points in the plane by *pairwise disjoint* triangles. This is an instance of the geometric set-cover problem, with an additional *disjointness* constraint on the covering objects (triangles). Observe that the disjointness condition on covering objects precludes the well-known *greedy* method for set covering [12, 15]; in fact, we can show that a greedy solution has size $\Omega({K_o}^2)$ in the worst case. Let us now reformulate our surface-approximation problem as a constrained geometric partitioning problem.

Let $\bar{p}$ denote the orthogonal projection of a point $p \in \mathbb{R}^3$ onto the xy-plane $z = 0$. In general, for any set $A \subset \mathbb{R}^3$, we use $\bar{A}$ to denote the orthogonal projection of A onto the xy-plane. Then, in order to get an ε-approximation of f, it suffices to find a set of triangles in 3-space so that (i) the projections of these triangles on plane $z = 0$ are pairwise disjoint and they cover the projected set of points $\bar{S}$, and (ii) the vertical distance between a triangle and any point of S directly above/below it is at most ε. Our polynomial-time algorithm produces a family of $O(K_o \log K_o)$ such triangles. We stitch together these triangles to produce the desired surface Σ. The "stitching" process introduces at most a constant factor more triangles.

The geometric partition framework also includes several extensions and generalizations of the basic surface-approximation problem. For instance, we can formulate a stronger version of the problem by replacing each sample point by a horizontal triangle (or any polygon). Specifically, we are given a family of *horizontal* triangles (or polygons) in 3-space, whose projections on the xy-plane are pairwise disjoint. We want a piecewise-linear, ε-approximating surface whose maximum vertical distance from *any* point on the triangles is ε. Our approximation algorithm works equally well for this variant of the problem—this variant addresses the case when some local features of the surface are known in detail; unfortunately, our method works only for horizontal features.

Finally, let us mention the *planar bichromatic partition* problem, which is of independent interest in the machine learning literature. Given a set R of "red" points and another set B of "blue" points in the plane, find a minimum number of pairwise disjoint triangles so that each blue point lies in a triangle and no red point lies in any of the triangles. Our algorithm gives a solution with $O(K_o \log K_o)$ triangles. It can also be used to construct a linear decision tree of size $O(K_o \log K_o)$, which is consistent with respect to R and B, where K_o is the size of an optimal linear decision tree.

The running time of our algorithms, though polynomial, is quite high, and at the moment has only theoretical value. These being some of the first results in this area, however, we expect that the theoretical time complexity of these problems would improve with further work. Perhaps some of the ideas in our paper may also shed light on the theoretical performance of some of the "practical" algorithms that are used in the trade.

2. A proof of NP-hardness. We first show that the planar bichromatic partition problem is *NP-hard*, by a reduction from the planar 3-SAT. Later we extend the proof to the surface approximation by pairwise disjoint triangles. We do not know whether they are in *NP* since the coordinates of the triangles in the solution may require very high precision. We recall that the 3-SAT problem consists of n variables $x_1, \ldots, x_n$, and m clauses $C_1, \ldots, C_m$, each with three literals C_{i1}, C_{i2}, C_{i3}, where

C_{ij} is either x_k or $\bar{x}_k$. The problem is to decide whether the boolean formula

$$F = \bigwedge_{i=1}^{m} (C_{i1} \vee C_{i2} \vee C_{i3})$$

has a truth assignment. An instance of 3-SAT is called *planar* if its variable-clause graph is planar. In other words, F is an instance of the planar 3-SAT if the graph $G(F) = (V, E)$ is planar (see [13]), where V and E are defined as follows:

$$V = \{x_1, x_2, \ldots, x_n\},$$
$$E = \{(x_j, C_i) \mid x_i \text{ or } \bar{x}_i \text{ appears in } C_i\}.$$

THEOREM 2.1 (planar bichromatic partition problem). *The following problem is* NP-hard. *Given a set R of "red" points, another set B of "blue" points in the plane, and an integer parameter k, do there exist k pairwise disjoint triangles containing all the blue points and none of the red points?*

Proof. Our construction is similar to the one used by Fowler, Paterson, and Tanimoto [10], who prove the intractability of certain planar geometric covering problems (without the disjointness condition); see also [3, 9] for similar constructions. We first describe our construction for the bichromatic partition problem. To simplify the proof, our construction allows three or more points to lie on a line—the construction can be modified easily to remove these degeneracies.

Let F be a boolean formula, and let $G = (V, E)$ be a straight-line planar embedding of the graph $G(F)$. We construct an instance of the bichromatic partition problem whose solution determines whether F is satisfiable.

We start by placing a "blue" point at each clause node C_j, $1 \le j \le m$. Let x_i be a variable node, and let $e_{i1}, e_{i2}, \ldots, e_{il}$ be the edges incident to it. In the plane embedding of G, the edges e_{ij} form a "star" (see Figure 1 (i)). We replace this star by its Minkowski sum with a disk of radius δ, for a sufficiently small $\delta > 0$. Before performing the Minkowski sum, we shrink each edge e_{ij} by 2δ at its endpoint C_{ij}, so that different "star-shaped polygons" meeting at a clause node do not overlap (see Figure 1 (ii)). Let P_i denote the star-shaped polygon corresponding to x_i. In the polygon P_i, there is a tube corresponding to each edge e_{ij}. The tube consists of two copies of e_{ij}, each translated by distance δ, plus a circular arc s_{ij} near the clause node C_j.

We place an even number of (say, $2k_i$) "blue" points on the boundary of P_i, as follows. We put two points a_{ij} and b_{ij} on the circular arc s_{ij} near its tip. If C_j contains the literal x_i, we put six points on the straight-line portion of P_i's boundary, three each on translated copies of the edge e_{ij}. On each copy, we move the middle point slightly inwards so as to replace the original edge of P_i by a path of length 2. On the other hand, if C_j contains the literal $\bar{x}_i$, we put four points on the straight-line portion of P_i's boundary, two each on translated copies of the edge e_{ij}. Thus, the number of blue points added on the tube corresponding to the edge e_{ij} is either six or eight. ($2k_i$ is the total number of points put along P_i.) Let B denote the set of all blue points placed in this way, and let $k = \sum_{i=1}^{n} k_i$.

Finally, we scatter a large (but polynomially bounded) number of "red" points so that

(i) any segment connecting two blue points that are not adjacent along the boundary of some P_i contains a red point, and

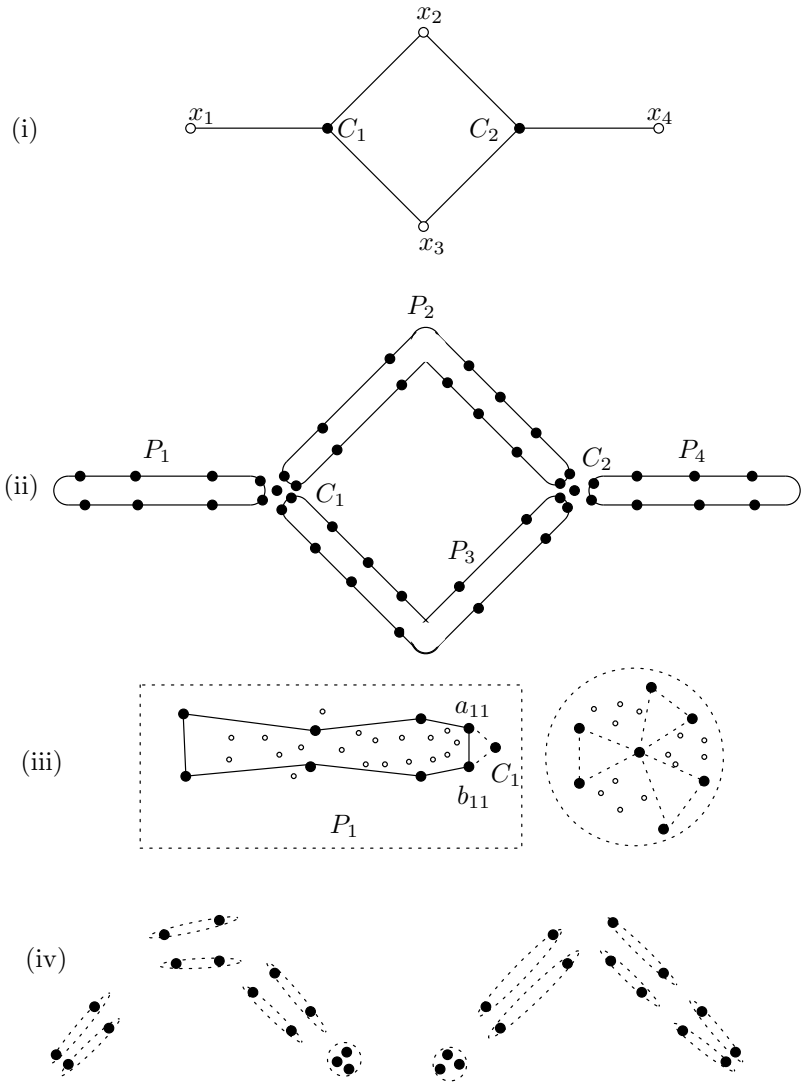

FIG. 1. (i) *An instance of planar* 3*-SAT:* $F = (x_1 \vee \bar{x}_2 \vee x_3) \wedge (x_2 \vee \bar{x}_3 \wedge x_4)$. (ii) *Corresponding instance of bichromatic partition.* (iii) *Details of* P_1 *and* C_1*; only some of the red points lying near* P_1 *and* C_1 *are shown.* (iv) *Two possible coverings of blue points on* P_2.

(ii) any triangle with three blue points as its vertices contains at least one red point unless the triangle is defined by $a_{ij}b_{ij}C_j$ for some edge $e_{ij} \in E$. (See Figure 1 (iii).)

Let R be a set of red points satisfying the above two properties.

We claim that the set of blue points B can be covered by k pairwise disjoint triangles, none of which contains any red point, if and only if the formula F has a truth assignment. Our proof is similar to the one in Fowler, Paterson, and Tanimoto [10]; we only sketch the main ideas. The red points act as enforcers, ensuring that only those blue points that are adjacent on the boundary of a P_i can be covered by a single triangle. Thus, the minimum number of triangles needed to cover all the points on P_i

is k_i. Further, there are precisely two ways to cover these points using k_i triangles: in one covering, a_{ij} and b_{ij} are covered by a single triangle for those clauses only in which $x_i \in C_j$, and, in the other covering, a_{ij} and b_{ij} are covered by a single triangle for those clauses only in which $\bar{x}_i \in C_j$; see Figure 4 (iv). We regard the first covering as setting $x_i = 1$, and the second covering as setting $x_i = 0$.

Suppose $x_i = 1$. For any clause C_j that contains x_i, the points a_{ij} and b_{ij} are covered by a single triangle, and we can cover the clause point corresponding to C_j by the same triangle. The same holds if $x_i = 0$ and the clause C_j contains $\bar{x}_i$. In other words, the clause point of C_j can be covered for free if C_j is satisfied. Thus, the set of blue points B can be covered by k triangles if and only if the clause point for each clause C_j is covered for free, that is, the formula F has a truth assignment. This completes our proof of *NP*-hardness of the planar bichromatic partition problem. □

REMARK. The preceding construction is degenerate in that most of the red points lie on segments connecting two blue points. There are several ways to remove these collinearities; we briefly describe one of them. For each polygon P_i, replace every blue point b on P_i by two blue points b', b'', placed very close to b. (We do not make copies of "clause points" C_j, $1 \le j \le m$.) For every pair of blue points b_j, b_l that we did not want to cover by a single triangle in the original construction, we place a red point in the convex hull of b'_j, b''_j, b'_l, b''_l. If there are $4k_i$ blue points on the boundary of P_i, they can be covered by k_i triangles, and there are exactly two ways to cover these blue points by k_i triangles, as earlier. Following a similar, but more involved, argument, we can prove that the set of all blue points can be covered by $\sum_{i=1}^{n} k_i$ triangles if and only if F is satisfiable.

THEOREM 2.2. *The following problem is* NP-hard. *Given a set S of n points sampled from a bivariate function $f(x, y)$, a real parameter $\varepsilon > 0$, and an integer k, can the points of S be ε-approximated by k triangles whose projections on the plane $z = 0$ are pairwise disjoint?*

Proof. Our construction is similar in spirit to the one for the bichromatic partition problem, albeit slightly more complex in detail. We use points of three colors: red, white, and black. The "white" points lie on the plane $z = 0$, the "black" points lie on the plane $z = 2A$, and the "red" points lie between $z = 0$ and $z = A$, where A is a sufficiently large constant. To maintain a connection with the previous construction, the black and white points play the role of blue points, while the red points play the role of enforcers as before, restricting the choice of "legal" triangles that can cover the black or white points. We will describe the construction in the xy-plane, which represents the orthogonal projection of the actual construction. The actual construction is obtained simply by vertically translating each point to its correct plane, depending on its color.

We start out again by putting a "black" point at each clause node C_j. Then, for each variable x_i, we construct the "star-shaped" polygon P_i; this part is identical to the previous construction. We replace each of the two straight-line edges of P_i by "concave chains," bent inward, and also make a small "dent" at the tip of the circular arc s_{ij}, as shown in Figure 2. We place 12 points on each arm of P_i, alternating black and white, as follows. At the tip of the circular arc s_{ij}, we put a white point c_{ij} at the outer endpoint of the dent and a black point d_{ij} at the inner endpoint of the dent (Figure 2 (ii)). The rest of the construction is shown in Figure 2 (i): we put two more points a_{ij}, b_{ij} on the circular arc and four points $\alpha_{ij}^l, \beta_{ij}^l$ $(1 \le l \le 4)$ on each of the two concave chains. The two points surrounding c_{ij}, d_{ij}, namely, a_{ij} and b_{ij}, are such that any segment connecting them to any point on the two concave chains lies inside

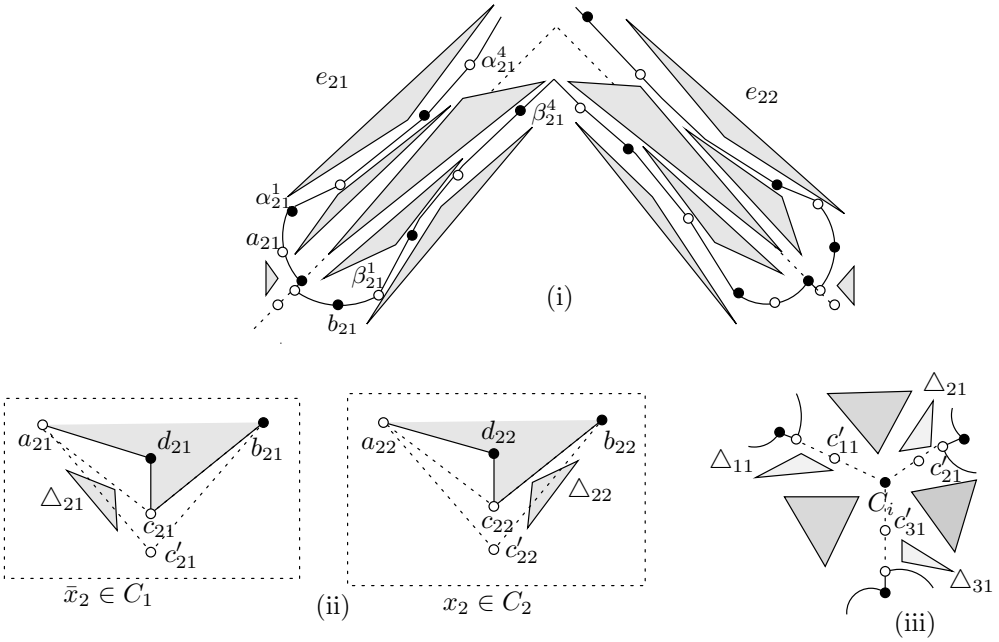

FIG. 2. *Placing points on the polygon P_2 corresponding to Figure* 1. (i) *Modified P_2 and points on P_2.* (ii) *Points and triangles in the neighborhood of c_{21}, c_{22}.* (iii) *Points and triangles near C_1.*

P_i. Next, corresponding to each edge e_{ij} of the graph $G(F)$, we put a "white" point c'_{ij} on the segment joining c_{ij} and the clause point C_j, very close to c_{ij}, such that

$$d(c_{ij}, c'_{ij}) \leq \frac{\varepsilon}{2A} d(c_{ij}, C_j)\,.$$

(See Figure 2 (iii).) This condition says that, in the final construction when the black and white points have been translated to their correct z-plane, the vertical distance between c'_{ij} and the segment $C_j c_{ij}$ is no more than ε—recall that ε is the input measure of approximation.

This completes the placement of white and black points. The only remaining part of the construction is the placement of "red" points, which we now describe.

We add a set of triangles, each containing a large (but polynomially bounded) number of red points—the role of these triangles is to restrict the choice of legal triangles that can cover black/white points. The set of triangles associated with P_i is labeled T_i. The construction of T_i is detailed in Figure 2 (i). Specifically, for an edge e_{ij}, if $x_i \in C_j$, then we add a small triangle that intersects the segment $b_{ij}c'_{ij}$ but not $b_{ij}c_{ij}$. On the other hand, if $\bar{x}_i \in C_j$, then we add a small triangle that intersects $a_{ij}c'_{ij}$ but not $a_{ij}c_{ij}$. Next, we add a small number of triangles inside P_i, near its concave chains, so that at most three consecutive points along P_i may be covered by one triangle without intersecting any triangle of T_i. We ensure that one of these triangles intersects the triangle $\triangle\alpha^1_{ij}a_{ij}d_{ij}$, so that $\{\alpha^1_{ij}, a_{ij}, d_{ij}\}$ cannot be covered by a single triangle. We also place three triangles near each clause C_j, each containing a large number of red points; see Figure 2 (iii). Finally, we translate black and white points in the z-direction, as described earlier. Let $\{\tau_1, \ldots, \tau_t\}$ be the set of all "red" triangles. We move all points in τ_i vertically to the plane $z = \frac{A}{4}(1 + \frac{2i}{t})$.

Now, suppose that polygon P_i has $3k_i$ white or black points on its boundary.

Then, there are two ways to cover the points of P_i with k_i legal (nonintersecting) triangles: one in which a_{ij}, d_{ij}, c_{ij} are covered by a single triangle, and one in which b_{ij}, d_{ij}, c_{ij} are covered by a triangle. These coverings are associated with the true and false settings of the variable x_i. Let P denote the set of all points constructed, and let $k = \sum_{i=1}^{n} k_i$. Let t denote the total number of "red" triangles. Recall also that m is the number of clauses in F.

We claim that the set of points P can be ε-approximated with $k+m+t$ triangles if and only if F has a truth assignment, provided that ε is sufficiently small. The claim follows from the observations that it is always better to cover all red points lying in a horizontal triangle τ_i by τ_i itself, and that a clause C_j requires one triangle to cover its points if and only if one of the literals in C_j is set true; otherwise it requires two triangles. (For instance, if C_j contains the literal x_i and x_i is set true, then the triangle a_{ij}, d_{ij}, c_{ij} can be enlarged slightly to cover c'_{ij}. The remaining three points for the clause C_j can be covered by one additional triangle.) The rest of the argument is the same as for the bichromatic partition problem. Finally, we can perturb the points slightly so that no four of them are coplanar. □

REMARK. Our proof has some technical problems if the approximating surface is required to be continuous. While the surface approximation and the approximation by disjoint triangles seem closely related, we can only claim to have proved the hardness for the latter. In the remainder of the paper, however, we develop algorithms for the continuous version of the surface approximation; of course, our algorithmic results hold for the problem of approximation by triangles as well.

3. A canonical trapezoidal partition. We introduce an abstract geometric partitioning problem in the plane, which captures the essence of both the surface-approximation problem and the bichromatic partition problem. The abstract problem deals with trapezoidal partitions under a boolean constraint function $\mathcal{C}$ satisfying the "subset restriction" property. More precisely, let $\mathcal{C}$ be a boolean function from compact, connected subsets of the plane to $\{0, 1\}$ satisfying the following property:

$$\mathcal{C}(U) = 1 \implies \mathcal{C}(V) = 1 \qquad \text{for all} \quad V \subseteq U \subseteq \mathbb{R}^2. \tag{3.1}$$

For technical reasons, we choose to work with "trapezoids" instead of triangles, where the top and bottom edges of each trapezoid are parallel to the x-axis. The trapezoids and triangles are equivalent for the purpose of approximation: each triangle can be decomposed into two trapezoids, and each trapezoid can be decomposed into two triangles.

Given a set of n points P in the plane, a family of trapezoids $\mathbf{\Delta} = \{\Delta_1, \ldots, \Delta_m\}$ is called a *valid trapezoidal partition* (a *trapezoidal partition*, for brevity) of P with respect to a boolean constraint function $\mathcal{C}$ if the following conditions hold:

(i) $\mathcal{C}(\Delta) = 1$, for all $\Delta \in \mathbf{\Delta}$;
(ii) $\mathbf{\Delta}$ covers all the points: $P \subset \bigcup_{i=1}^{m} \Delta_i$; and
(iii) the trapezoids in $\mathbf{\Delta}$ have pairwise disjoint interiors.

We can cast our bichromatic partition problem in this abstract framework by setting $P = B$ (the set of "blue" points) and, for a trapezoid $\tau \subset \mathbb{R}^2$, defining $\mathcal{C}(\tau) = 1$ if and only if τ is empty of red points, that is, $\tau \cap R = \emptyset$. In the surface-approximation problem, we set $P = \bar{S}$ (the orthogonal projection of S on the plane $z = 0$), and a trapezoid $\tau \subset \mathbb{R}^2$ has $\mathcal{C}(\tau) = 1$ if and only if τ can be vertically lifted to a planar trapezoid $\hat{\tau}$ in $\mathbb{R}^3$ so that the vertical distance between $\hat{\tau}$ and any point of S directly above/below it is at most ε.

The space of optimal solutions for our abstract problem is potentially infinite—the vertices of the triangles in our problem can be anywhere in the plane. For our approximation results, however, we show that a restricted choice of trapezoids suffices.

Given a set of n points P in the plane, let $\mathcal{L}(P)$ denote the set consisting of the following lines: the horizontal lines passing through a point of P, and the lines passing through two points of P. Thus, $|\mathcal{L}(P)| = O(n^2)$. We will call the lines of $\mathcal{L}(P)$ the *canonical lines* determined by P. We say that a trapezoid $\Delta \subset \mathbb{R}^2$ is *canonical* if all of its edges belong to lines in $\mathcal{L}(P)$. A trapezoidal partition $\mathbf{\Delta}$ is *canonical* if all of its trapezoids are canonical (see Figure 3). The following lemma shows that by limiting ourselves to canonical trapezoidal partitions only, we sacrifice at most a constant (multiplicative) factor in our approximation.

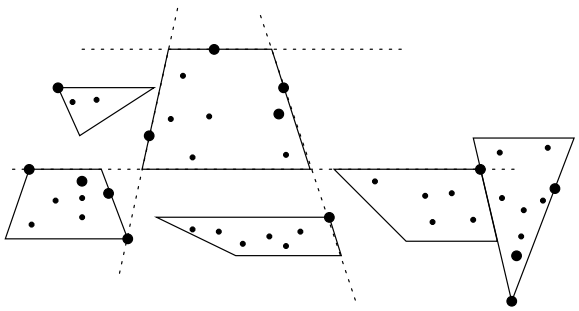

FIG. 3. *A canonical trapezoidal partition.*

LEMMA 3.1. *Any trapezoidal partition of P with k trapezoids can be transformed into a canonical trapezoidal partition of P with at most $4k$ trapezoids.*

Proof. We give a construction for transforming each trapezoid $\Delta \in \mathbf{\Delta}$ into four trapezoids $\Delta_i \subseteq \Delta$, for $1 \leq i \leq 4$, with pairwise disjoint interiors, so that Δ_i together cover all the points in $P \cap \Delta$. By (3.1), the new set of trapezoids is a valid trapezoidal partition of P. Our construction works as follows.

Consider the convex hull of the points $P_\Delta = P \cap \Delta$. If the convex hull itself is a trapezoid, we return that trapezoid. Otherwise, let ℓ, r, t, b denote the left, right, top, and bottom edges of Δ, as shown in Figure 4 (i). We perform the following four steps, which constitute our transformation algorithm.

(i) We shrink the trapezoid Δ by translating each of its four bounding edges towards the interior, until it meets a point of P_Δ. Let $\Delta' \subseteq \Delta$ denote the smaller trapezoid thus obtained (Figure 4 (i)). Let p_ℓ, p_r, p_t, p_b, respectively, denote a point of P_Δ lying on the left, right, top, and bottom edges of Δ'; we break ties arbitrarily if more than one point lies on an edge.

(ii) We partition Δ' into two trapezoids, Δ_L and Δ_R, by drawing the line segment $p_u p_b$, as shown in Figure 4 (ii).

(iii) We next partition Δ_L into two trapezoids Δ_{LU} and Δ_{LB}, by drawing the maximal horizontal segment through p_ℓ. Let p'_ℓ denote the right endpoint of this segment. Similarly, we partition Δ_R into Δ_{RU} and Δ_{RB}, lying, respectively, above and below the horizontal line segment $p_r p'_r$.

(iv) We rotate the line supporting the left boundary of Δ_{LU} around the point p_ℓ in clockwise direction until it meets a point of the set $P \cap \Delta_{LU}$. Let q_ℓ denote the intersection of this line and the top edge of Δ_{LU}. We set $\Delta_1 = p_\ell q_\ell p_u p'_\ell$ (Figure 4 (iv)). (If $q_\ell = p_u$, then Δ_1 is a triangle, which we regard as a degenerate trapezoid; e.g., Δ_4 in Figure 4 (iii).) The top and bottom edges of

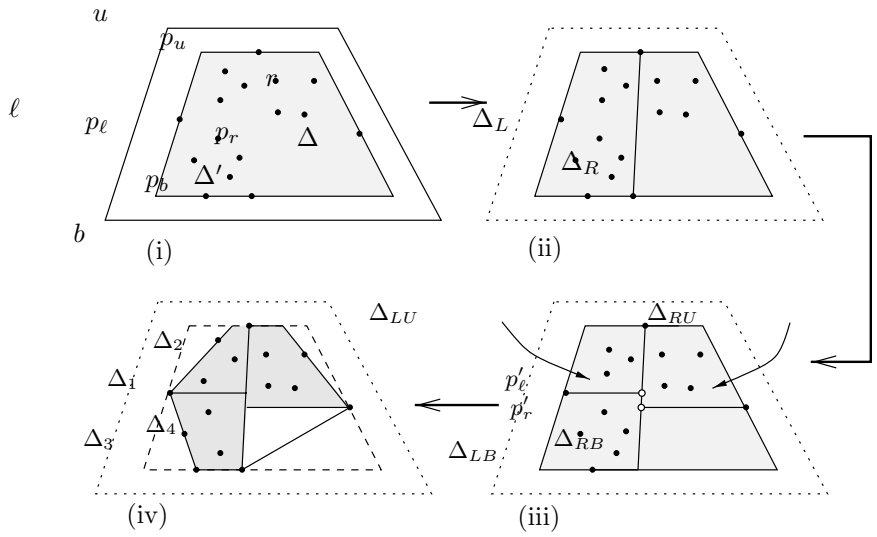

FIG. 4. *Illustration of the canonicalization.*

Δ_1 contain p_u and p_ℓ, respectively, the left edge contains p_ℓ and q_ℓ, and the right edge is determined by the pair of points p_u and p_b. Thus, the trapezoid Δ_1 is in canonical position. The three remaining trapezoids $\Delta_2, \Delta_3, \Delta_4$ are constructed similarly.

In the above construction, if any of the four trapezoids Δ_i does not cover any point of P_Δ (e.g., Δ_4 in Figure 4 (iv)), then we can discard it. Thus, an arbitrary trapezoid of the partition $\mathbf{\Delta}$ can be transformed into at most four canonical trapezoids. This completes the proof of the lemma. □

4. Greedy algorithms. At this point, we can obtain a weak approximation result using the canonical trapezoidal partition. Roughly speaking, we can use the greedy set-cover heuristic [7, 15], ignoring the disjointness constraint, and then refine the heuristic output to produce disjoint trapezoids. Unfortunately, the last step can increase the complexity of the solution quite significantly.

THEOREM 4.1. *Given a set P of n points in the plane and a boolean constraint function $\mathcal{C}$ satisfying* (3.1) *that can be evaluated in polynomial time, we can compute an $O({K_o}^2 \log^2 n)$-size trapezoidal partition of P respecting $\mathcal{C}$ in polynomial time, where K_o is the size of an optimal trapezoidal partition.*

Proof. Consider the set Ξ of all valid, canonical trapezoids in the plane; the set Ξ has $O(n^6)$ trapezoids. We form the geometric set-system

$$X = (P, \quad \{\, P \cap \Delta \mid \Delta \in \Xi \;\&\; \mathcal{C}(\Delta) = 1 \,\}) .$$

X can be computed by testing whether each $\Delta \in \Xi$ is valid. We compute a set cover of X using the greedy algorithm [12, 15] in polynomial time. The greedy algorithm returns a set R consisting of $O(K_o \log^2 n)$ trapezoids, not necessarily disjoint. In order to produce a disjoint cover, we first compute the arrangement $\mathcal{A}(R)$ of the plane induced by R. Then, we decompose each face of $\mathcal{A}(R)$ into trapezoids by drawing a horizontal segment through each vertex until the segment hits an edge of the arrangement. The resulting partition is a trapezoidal partition of P. The number

of trapezoids in the partition is $O(K_o \log n)$, since the arrangement $\mathcal{A}(R)$ has this size. The total running time of the algorithm is polynomial. □

REMARK. (i) The canonical form of trapezoids is used only to construct a finite family of trapezoids to search for an approximate solution. A direct application of the definition in the previous subsection gives a family of $O(n^6)$ canonical trapezoids. By using a slightly different canonical form, we can reduce the size of canonical triangles to $O(n^4)$.

(ii) One can show that the number of trapezoids produced by the above algorithm is $\Omega({K_o}^2)$ in the worst case.

5. A recursively separable partition. We now develop our main approximation algorithm. The algorithm is based on dynamic programming, and it depends on two key ideas: a *recursively separable* partition and a *compliant* partition.

A trapezoidal partition $\mathbf{\Delta}$ is called *recursively separable* if the following hold:

(i) $\mathbf{\Delta}$ consists of a single trapezoid, or

(ii) there exists a line ℓ such that (i) ℓ does not intersect the interior of any trapezoid in $\mathbf{\Delta}$, (ii) $\mathbf{\Delta}^+ = \mathbf{\Delta} \cap \ell^+$ and $\mathbf{\Delta}^- = \mathbf{\Delta} \cap \ell^-$ are both nonempty, where ℓ^+ and ℓ^- are the two half-planes defined by ℓ, and (iii) each of $\mathbf{\Delta}^+$ and $\mathbf{\Delta}^-$ is recursively separable.

The following key lemma gives an upper bound on the penalty incurred by our approximation algorithm if only recursively separable trapezoidal partitions are used.

LEMMA 5.1. *Let P be a finite set of points in the plane and let $\mathbf{\Delta}$ be a trapezoidal partition of P with k trapezoids. There exists a recursively separable partition $\mathbf{\Delta}^\star$ of P with $O(k \log k)$ trapezoids. In addition, each separating line is either a horizontal line passing through a vertex of $\mathbf{\Delta}$ or a line supporting an edge of a trapezoid in $\mathbf{\Delta}$.*

Proof. We present a recursive algorithm for computing $\mathbf{\Delta}^\star$. Our algorithm is similar to the binary space partition algorithm proposed by Paterson and Yao [18]. We assume that the boundaries of the trapezoids in $\mathbf{\Delta}$ are also pairwise disjoint—this assumption is only to simplify our proof.

At each recursive step of the algorithm, the subproblem under consideration lies in a trapezoid T. (This containing trapezoid may degenerate to a triangle, or it may even be unbounded.) The top and bottom edges of T (if they exist) pass through the vertices of $\mathbf{\Delta}$, while the left and right edges (if they exist) are portions of edges of $\mathbf{\Delta}$. Initially T is set to an appropriately large trapezoid containing the family $\mathbf{\Delta}$. Let $\mathbf{\Delta}_T$ denote the trapezoidal partition of $P \cap T$ obtained by intersecting $\mathbf{\Delta}$ with T, and let V_T be the set of vertices of $\mathbf{\Delta}_T$ lying in the interior of T. An edge of $\mathbf{\Delta}_T$ cannot intersect the left or right edge of T, because they are portions of the edge of T. Therefore, each edge of $\mathbf{\Delta}_T$ either lies in the interior of T or intersects only the top and bottom edges of T.

If $|\mathbf{\Delta}_T| = 1$, we return $\mathbf{\Delta}_T$ and stop. Otherwise, we proceed as follows. If there is a trapezoid $\triangle \in \mathbf{\Delta}_T$ that completely crosses T (that is, its vertices lie on the top and bottom edges of T), then we do the following. If $\triangle$ is the leftmost trapezoid of $\mathbf{\Delta}_T$, then we partition T into two trapezoids T_1, T_2 by drawing a line through the right edge of Δ, so that T_1 contains $\triangle$ and T_2 contains the remaining trapezoids of Δ_T. If $\triangle$ is not the leftmost trapezoid of $\mathbf{\Delta}_T$, then we partition T into T_1, T_2 by drawing a line through the left edge of Δ.

If every trapezoid Δ in $\mathbf{\Delta}_T$ has at least one vertex in the interior of T, and so the previous condition is not met, then we choose a point $v \in V_T$ with a median y-coordinate. We partition T into trapezoids T_1, T_2 by drawing a horizontal line ℓ_v passing through v. Each trapezoid $\Delta \in \mathbf{\Delta}_T$ that crosses ℓ_v is partitioned into two

trapezoids by adding the segment $\Delta \cap \ell_v$. At the end of this dividing step, let $\mathbf{\Delta}_1$ and $\mathbf{\Delta}_2$ be the set of trapezoids that lie in T_1 and T_2, respectively. We recursively refine $\mathbf{\Delta}_1$ and $\mathbf{\Delta}_2$ into separable partitions $\mathbf{\Delta}_1^\star$ and $\mathbf{\Delta}_2^\star$, respectively, and return $\mathbf{\Delta}_T^\star = \mathbf{\Delta}_1^\star \cup \mathbf{\Delta}_2^\star$. This completes the description of the algorithm.

We now prove that $\mathbf{\Delta}^*$ satisfies the properties claimed in the lemma. It is clear that $\mathbf{\Delta}^*$ is recursively separable and that each separating line of $\mathbf{\Delta}^*$ either supports an edge of $\mathbf{\Delta}$ or is horizontal. To bound the size of $\mathbf{\Delta}^*$, we charge each trapezoid of $\mathbf{\Delta}^*$ to its bottom-left vertex. Each such vertex is either a bottom-left vertex of a trapezoid of $\mathbf{\Delta}$ or it is an intersection point of a left edge of a trapezoid of $\mathbf{\Delta}$ with the extension of a horizontal edge of another trapezoid of $\mathbf{\Delta}$. There are only k vertices of the first type, so it suffices to bound the number of vertices of the second type. Since the algorithm extends a horizontal edge of a trapezoid of $\mathbf{\Delta}_T$ only if every trapezoid of $\mathbf{\Delta}_T$ has at least one vertex in the interior of T, and we always extend a horizontal edge with a median y-coordinate, it is easily seen that the number of vertices of the second type is $O(k \log k)$. This completes the proof. □

REMARK. Given a family $\mathbf{\Delta}$ of k pairwise disjoint orthogonal rectangles partitioning P, we can find a set of $O(k)$ recursively separable rectangles that forms a *rectangular* partition of P—this uses the *orthogonal* binary space partition algorithm of Paterson and Yao [19].

6. An approximation algorithm. Lemma 5.1 applies to any trapezoidal partition of P. In particular, if we start with a canonical trapezoidal partition $\mathbf{\Delta}$, then the output partition $\mathbf{\Delta}^\star$ is both canonical and recursively separable, and each separating line in $\mathbf{\Delta}^\star$ belongs to the family of canonical lines $\mathcal{L}(P)$. For lack of a better term, we call a trapezoidal partition of P that satisfies these conditions a *compliant partition*. Lemmas 3.1 and 5.1 together imply the following useful theorem.

THEOREM 6.1. *Let P be a set of n points in the plane and let $\mathcal{C}$ be a boolean constraint function satisfying the condition* (3.1). *If there is a trapezoidal partition of P respecting $\mathcal{C}$ with k trapezoids, then there is a compliant partition of P also respecting $\mathcal{C}$ with $O(k \log k)$ trapezoids.*

In the remainder of this section, we give a polynomial-time algorithm, using dynamic programming, for constructing an optimal compliant partition. By Theorem 6.1, this partition has $O(K_o \log K_o)$ trapezoids. Recall that the set $\mathcal{L} = \mathcal{L}(P)$ consists of all canonical lines determined by P.

Consider a subset of points $R \subseteq P$ and a canonical trapezoid Δ containing R. Let $\sigma(R, \Delta)$ denote the size of an optimal compliant partition of R in Δ; the size of a partition is the number of trapezoids in the partition. Theorem 6.1 gives the following recursive definition of σ:

$$\sigma(R, \Delta) = \begin{cases} 1 & \text{if } \mathcal{C}(\Delta) = 1, \\ \min_{\ell} \{\sigma(R^+, \Delta^+) + \sigma(R^-, \Delta^-)\} & \text{otherwise,} \end{cases}$$

where the minimum is over all those lines $\ell \in \mathcal{L}$ that are either horizontal and intersect Δ or intersect both the top and bottom edges of Δ; ℓ^+ and ℓ^- denote the positive and negative half-planes induced by ℓ, $R^+ = R \cap \ell^+$ and $R^- = R \cap \ell^-$. The goal of our dynamic programming algorithm is to compute $\sigma(P, T)$ for some canonical trapezoid T enclosing all the points P. We now describe how the dynamic programming systematically computes the required partial answers.

Every canonical trapezoid Δ in the plane can be described (uniquely) by a 6-tuple $(i, j, k_1, k_2, l_1, l_2)$ consisting of integers between 1 and n. The first two numbers fix

two points p_i and p_j through which the lines containing the top and bottom edges of Δ pass; the second pair fixes the points p_{k_1}, p_{k_2} through which the line containing the left edge of Δ passes; and the third pair fixes the points p_{l_1}, p_{l_2} through which the line containing the right edge of Δ passes. (In case of ties, we may choose the points closest to the corners of Δ.) We use the notation $\Delta(i, j, k_1, k_2, l_1, l_2)$ for the trapezoid associated with the 6-tuple $(i, j, k_1, k_2, l_1, l_2)$. If the 6-tuple does not produce a trapezoid, then $\Delta(i, j, k_1, k_2, l_1, l_2)$ is undefined.

Let $P(i, j, k_1, k_2, l_1, l_2) = P \cap \Delta(i, j, k_1, k_2, l_1, l_2)$. We use the abbreviated notation $\sigma(i, j, k_1, k_2, l_1, l_2)$ to denote the size of an optimal compliant partition for the points contained in $\Delta(i, j, k_1, k_2, l_1, l_2)$:

$$\sigma(i, j, k_1, k_2, l_1, l_2) = \sigma\Big(P(i, j, k_1, k_2, l_1, l_2),\ \Delta(i, j, k_1, k_2, l_1, l_2)\Big).$$

The quantity $\sigma(i, j, k_1, k_2, l_1, l_2)$ is undefined if the trapezoid $\Delta(i, j, k_1, k_2, l_1, l_2)$ is undefined. If the points in P are sorted in increasing order of their y-coordinates, then $\Delta(i, j, k_1, k_2, l_1, l_2)$ is defined only for $i \geq j$. Our dynamic programming algorithm computes the σ values as follows.

If $\mathcal{C}(\Delta(i, j, k_1, k_2, l_1, l_2)) = 1$, then

$$\sigma(i, j, k_1, k_2, l_1, l_2) = 1\,.$$

Otherwise,

$$\sigma(i, j, k_1, k_2, l_1, l_2) \;=\; \min \left\{ \begin{array}{l} \min\limits_{i \leq u \leq j} \{\sigma(i, u, k_1, k_2, l_1, l_2) + \sigma(u+1, j, k_1, k_2, l_1, l_2)\} \\ \min\limits_{v_1, v_2} \{\sigma(i, j, k_1, k_2, v_1, v_2) + \sigma(i, j, v_1, v_2, l_1, l_2)\} \end{array} \right\},$$

where the last minimum varies over all pairs of points v_1, v_2 such that the line passing through them intersects both the top and the bottom edges of $\Delta(i, j, k_1, k_2, l_1, l_2)$.

If Ξ denotes the set of all canonical trapezoids, then $|\Xi| = O(n^6)$; each 6-tuple is associated with at most one unique trapezoid. If $Q(n)$ denotes the time to decide whether $\mathcal{C}(\Delta) = 1$ for an arbitrary trapezoid Δ, then we can initially compute all trapezoids for which $\mathcal{C}(\Delta) = 1$ in total time $O(n^6 Q(n))$; for these trapezoids, we initially set $\sigma(\Delta) = 1$. For all the remaining trapezoids in Ξ, we use the recursive formula presented above to compute their σ. Computing σ for a trapezoid requires computing the minimum of $O(n^2)$ quantities. Thus the total running time of the algorithm is $O(n^8)$. The following theorem states the main result of our paper.

THEOREM 6.2. *Given a set P of n points in the plane and a boolean constraint $\mathcal{C}$ satisfying condition* (3.1)*, we can compute a geometric partition of P with respect to $\mathcal{C}$ using $O(K_o \log K_o)$ trapezoids, where K_o is the number of trapezoids in an optimal partition. Our algorithm runs in worst-case time $O(n^8 + n^6 Q(n))$, where $Q(n)$ is the time to decide whether $\mathcal{C}(R) = 1$ for any subset $R \subseteq P$.*

REMARK. By computing σ's in a more clever order and exploiting certain geometric properties of a geometric partition, the time complexity of the above algorithm can be improved by one order of magnitude. This minor improvement, however, doesn't seem worth the effort needed to explain it.

Theorem 6.2 immediately implies polynomial-time approximation algorithms for the surface-approximation and the planar bichromatic partition problem. In the case of the surface-approximation problem, deciding $\mathcal{C}(\Delta)$ for a trapezoid Δ requires checking whether there is a plane π in $\mathbb{R}^3$ such that the vertical distance between π and the points covered by Δ is at most ε. This problem can be solved in linear time using the

fixed-dimensional linear programming algorithm of Megiddo [16]. (A more practical algorithm, running in time $O(n \log n)$, is the following. Let $A \subseteq P$ denote the set of points covered by the trapezoid Δ. For a point $p \in A$, let p^+ and p^-, respectively, denote the point p translated vertically up and down by ε. Let $A^+ = \{p^+ \mid p \in A\}$ and $A^- = \{p^- \mid p \in A\}$. Then, $\mathcal{C}(\Delta) = 1$ if and only if sets A^+ and A^- can be separated by a plane. The two sets are separable if their convex hulls are disjoint. This can be tested in $O(n \log n)$ time; for instance, see the book by Preparata and Shamos [20].

THEOREM 6.3. *Given a set S of n points in $\mathbb{R}^3$ and a parameter $\varepsilon > 0$, in polynomial time we can compute an ε-approximate polyhedral terrain Σ with $O(K_o \log K_o)$ vertices, where K_o is the number of vertices in an optimal terrain. Our algorithm runs in $O(n^8)$ worst-case time.*

In the planar bichromatic partition problem, deciding whether $\mathcal{C}(\Delta) = 1$ requires checking whether Δ contains any point from the red set R. This can clearly be done in $O(n)$ time. Alternatively, R can be preprocessed in time $O(n^{2+\delta} \log^{O(1)} n)$, for any $\delta > 0$, into a triangle range-searching data structure, which can determine in $O(\log n)$ time whether a query trapezoid contains any point of R; see, e.g., [6]. Our main purpose, however, is to only establish a polynomial-time bound for the approximation algorithm.

THEOREM 6.4. *Given a set R of "red" points and another set B of "blue" points in the plane, we can find in polynomial time a set of $O(K_o \log K_o)$ pairwise disjoint triangles that cover B but do not contain any red point; K_o is the number of triangles in an optimal solution.*

In view of the remark following Theorem 6.1, given a set R of "red" points and another set B of "blue" points in the plane, we can find in polynomial time a set of $O(K_o)$ disjoint orthogonal rectangles that cover B but do not contain any red point. In this case, the time complexity improves by a few orders of magnitude, because there are only $O(n^4)$ canonical rectangles and each rectangle is subdivided into two rectangles by drawing a horizontal or vertical line passing through one of the points. Omitting all the details, the running time in this case is $O(n^5)$. Hence, we obtain the following result.

THEOREM 6.5. *Given a set R of "red" points and another set B of "blue" points in the plane, we can find in polynomial time a set of $O(K_o)$ pairwise disjoint orthogonal rectangles that cover B but do not contain any red point; K_o is the number of rectangles in an optimal solution.*

We conclude this section by noting that Theorem 6.4 can be used to construct small size linear decision trees in the plane. A *linear decision tree* in $\mathbb{R}^d$ is a full binary tree, of which each leaf is labeled $+1$ or -1 and each interior node v is associated with a $(d-1)$-hyperplane h_v; the left (resp., right) child of v is also associated with the half-space lying above (resp., below) h_v. T is used to classify a point $p \in \mathbb{R}^d$ by traversing a path of T, starting from the root, as follows. Suppose v is the node being currently visited. If v is a leaf, return the label of v. Otherwise, if p lies above (resp., below) h_v, we recursively visit the left (resp., right) child of v. T is *consistent* with B and R if it assigns $+1$ to all the points of B and -1 to all the points of R. Each leaf of T corresponds to a convex polyhedron, which is the intersection of the half-spaces associated with its ancestors, and these regions induce a convex partition of $\mathbb{R}^d$. For $d \leq 3$, a convex polyhedron can be triangulated into a linear number of simplices. Hence, for $d \leq 3$, the size of an optimal linear decision tree that is consistent with R and B is $\Omega(K_o)$, where K_o is the size of an optimal bichromatic partition for R and B. See [21] for a survey of known results on decision trees.

Using Theorem 6.4, we can construct a linear decision tree of size $O(K_o \log K_o)$ for R and B as follows. Let $\mathbf{\Delta}$ be the partition computed by the above algorithm. If $\mathbf{\Delta}$ consists of a single trapezoid, say τ, then we construct a linear decision tree with four interior nodes, each associated with the line supporting one of the edges of τ. The leaves of the tree partition the plane into five regions, of which one is τ itself. The leaf corresponding to τ is labeled $+1$ and the others are labeled -1. If $|\mathbf{\Delta}| > 1$, then there is a separating line ℓ; let $\mathbf{\Delta}^+$ (resp., $\mathbf{\Delta}^-$) be the subset of trapezoids lying above (resp., below) ℓ. We associate the root with ℓ, recursively construct the decision trees for $\mathbf{\Delta}^+$ and $\mathbf{\Delta}^-$, and attach them as the left and right subtrees of the root. Putting everything together, we obtain the following result.

THEOREM 6.6. *Given a set R of "red" points and another set B of "blue" points in the plane, we can construct in polynomial time a linear decision tree of size $O(K_o \log K_o)$, which is consistent with R and B; K_o is the size of an optimal linear decision tree that is consistent with R and B.*

7. Extensions. We can extend our algorithm to a slightly stronger form of surface approximation. In the basic problem, the implicit function (surface) is represented by a set of sample points S. What if the sample consists of two-dimensional compact, connected pieces? In this section, we show an extension of our algorithm that deals with the case when the sample consists of a set $\mathcal{T}$ of n *horizontal triangles* with pairwise disjoint xy-projection. (Since any polygon can be decomposed into triangles, this case also handles polygons.) Our goal is to compute a polyhedral terrain Σ, so that the vertical distance between any point in $T_i \in \mathcal{T}$ and Σ is at most ε. We produce a terrain Σ with $O(K_o \log K_o)$ vertices, where K_o is again the number of vertices in an optimal such surface.

Let $\mathcal{T} = \{T_1, \ldots, T_n\}$ be the input set of n horizontal triangles in $\mathbb{R}^3$ with the property that their vertical projections on the plane $z = 0$ are pairwise disjoint. We will consistently use the following notational convention: for an object $s \in \mathbb{R}^3$, $\bar{s}$ denotes its orthogonal projection on the plane $z = 0$, and for a subset $g \subseteq \bar{s}$, $\hat{g}$ denotes the portion of s in $\mathbb{R}^3$ such that $g = \bar{\hat{g}}$. Abusing the notation slightly, we say that a set Ξ of trapezoids (or triangles) in $\mathbb{R}^3$ *ε-approximates* $\mathcal{T}$ within a region $Q \subseteq \mathbb{R}^2$ if the vertical distance between $\mathcal{T}$ and Ξ in Q is at most ε and the vertical projections of trapezoids of Ξ are pairwise disjoint on $z = 0$.

Let S denote the set of vertices of the triangles in $\mathcal{T}$, and let $\bar{S}$ be their orthogonal projection on $z = 0$. We set $P = \bar{S}$, as the set of points in our abstract problem. The constraint function is defined as follows. Given a trapezoid $\Delta \in \mathbb{R}^3$, we have $\mathcal{C}(\Delta) = 1$ if and only if the vertical distance between Δ and any point in $\bigcup_{i=1}^{n} T_i$ directly above/below Δ is at most ε. (Thus, while the point set P includes only the vertices of $\mathcal{T}$, the constraint set takes into consideration the whole triangles.) The constraint $\mathcal{C}$ satisfies (3.1), and it can be computed in polynomial time.

It is also clear that the size of an optimal trapezoidal partition of P with respect to $\mathcal{C}$ is a lower bound on the size of a similar partition for $\mathcal{T}$, the set of triangles. We first apply Theorem 6.3 to obtain a family $\mathbf{\Delta}$ of $O(k \log k)$ trapezoids that ε-approximates P with respect to $\mathcal{C}$; clearly $k \leq K_o$. The next step of our algorithm is to extend $\mathbf{\Delta}$ to a polyhedral terrain that ε-approximates the triangles of $\mathcal{T}$. Care must to be exercised in this step if one wants to add only $O(k \log k)$ new trapezoids. In the second step, we work with the projection of $\mathcal{T}$ and Δ in the plane $z = 0$.

Let $\bar{\mathbf{\Delta}} = \{\bar{\Delta} \mid \Delta \in \mathbf{\Delta}\}$ and $\bar{\mathcal{T}} = \{\bar{T} \mid T \in \mathcal{T}\}$. Let R be the set of connected components of the closure of $\bigcup_{T \in \mathcal{T}} \bar{T} \setminus \bigcup_{\Delta \in \mathbf{\Delta}} \bar{\Delta}$. That is, R is the portion of $\bigcup_{T \in \mathcal{T}} \bar{T}$ lying in the common exterior of $\bar{\mathbf{\Delta}}$, as shown in Figure 5 (i). R is a collection

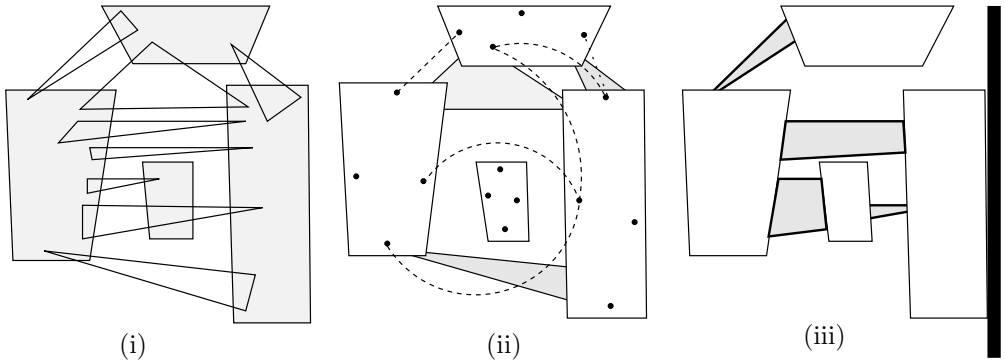

FIG. 5. (i) $\bar{\mathcal{T}}$ *and* $\bar{\mathbf{\Delta}}$*;* (ii) R_1 *and* G*;* (iii) R_2 *and* Q_i*'s.*

of *simple* polygons, each of which is contained in a triangle of $\bar{\mathcal{T}}$. Since the corners of the triangles of $\bar{\mathcal{T}}$ are covered by $\bar{\mathbf{\Delta}}$, the vertices of all polygons in R lie on the boundary of $\bar{\mathbf{\Delta}}$, and each edge of R is contained in an edge of $\bar{\mathbf{\Delta}}$ or of $\bar{\mathcal{T}}$. Let $R_1 \subseteq R$ be the subset of polygons that touch at least three edges of trapezoids in $\bar{\mathbf{\Delta}}$, and let $R_2 = R - R_1$.

For each polygon $P_i \in R_1$, we compute a set of triangles that ε-approximate $\mathcal{T}$ within P_i. For a vertex $v \in P_i$, lying on the boundary of a trapezoid $\bar{\Delta}$, let $\hat{v}$ denote the point on Δ whose xy-projection is v. Let $\bar{T}_i$ be the triangle containing P_i. We triangulate P_i and, for each triangle $\triangle abc$ in the triangulation, we pick $\triangle \hat{a}\hat{b}\hat{c}$. Since T_i is parallel to the xy-plane, it can be proved that the maximum vertical distance between $\triangle \hat{a}\hat{b}\hat{c}$ and T_i is ε. We repeat this step for all polygons in R_1. The number of triangles generated in this step is proportional to the number of vertices in the polygons of R_1, which we bound in the following lemma.

LEMMA 7.1. *The total number of vertices in the polygons of* R_1 *is* $O(k \log k)$.

Proof. Each vertex of a polygon in R_1 is either (i) a vertex of a trapezoid in $\bar{\mathbf{\Delta}}$, or (ii) an intersection point of an edge of $\bar{\mathbf{\Delta}}$ with an edge of a triangle in $\mathcal{T}$. There are only $O(k \log k)$ vertices of type (i), so it remains to bound the number of vertices of type (ii).

We construct an undirected graph $G = (V, E)$, as follows. Let $\Gamma = \{\gamma_1, \ldots, \gamma_t\}$ be the set of edges in $\bar{\mathbf{\Delta}}$.[1] To avoid confusion, we will call the edges of Γ *segments* and those of E *arcs*. For each segment γ_i, we place a point i close to γ_i, inside the trapezoid bounded by γ_i. The set of resulting points forms the node set V. If there is an edge pq of a polygon in R_1 such that $p \in \gamma_i$ and $q \in \gamma_j$, we add the arc (i, j) to E; see Figure 5 (ii). It is easily seen that G is a planar graph and that $|E| = O(k \log k)$. Fix a pair of segments $\gamma_1, \gamma_2 \in \Gamma$ such that $(1, 2) \in E$. Let $E_{12} = \{p_1q_1, p_2q_2, \ldots\}$ be the set of edges in R_1, sorted either left to right or top to bottom, as the case may be, that are incident to γ_1 and γ_2. Let $|E_{12}| = m_{ij}$. Assume that for every $1 \leq i \leq m_{ij}$, p_i lies on γ_1 and q_i lies on γ_2. The number of vertices of type (ii) is obviously $2\sum_{(i,j)\in E} m_{ij}$. We call two edges $p_iq_i,\ p_jq_j \in E_{12}$ *equivalent* if the interior of the convex hull of p_iq_i and p_jq_j does not intersect any trapezoid of $\bar{\mathbf{\Delta}}$. This equivalence relation partitions E_{12} into equivalent classes, each consisting of a contiguous subsequence of E_{12}. Let μ_{ij} denote the number of equivalence classes in E_{ij}.

[1] The segments of Γ may overlap, because the trapezoids of $\bar{\mathbf{\Delta}}$ can touch each other. If a segment γ_i of Γ is an edge of two trapezoids, then no edge of R_1 can be incident to γ_i.

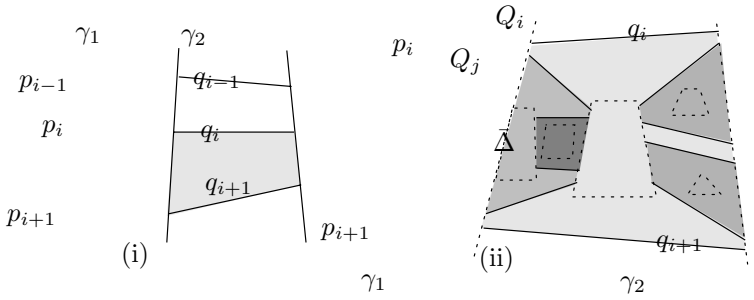

FIG. 6. (i) *Edges in one equivalent class of* E_{12}*, and* (ii) *edges in different equivalent classes.*

CLAIM 1. *There are at most two edges in each equivalence class of* E_{12}*.*

Proof. Assume for the sake of a contradiction that three edges $p_{i-1}q_{i-1}$, p_iq_i, and $p_{i+1}q_{i+1}$ belong to the same equivalence class. Further, assume that the triangle $\bar{T} \in \bar{\mathcal{T}}$ bounded by p_iq_i lies below p_iq_i (see Figure 6 (i)). Since the quadrilateral Q defined by p_iq_i and $p_{i+1}q_{i+1}$ does not contain any trapezoid of $\bar{\mathbf{\Delta}}$, $p_{i+1}q_{i+1}$ is also an edge of $\bar{T}$ and $Q \subseteq \bar{T}$. But then Q is a connected component of R and it touches only two edges of $\bar{\mathbf{\Delta}}$, thereby implying that p_iq_i is not an edge of a polygon of R_1, a contradiction. ∎

Thus,

$$\sum_{(i,j)\in E} m_{ij} \;\le\; 2\sum_{(i,j)\in E} \mu_{ij} \;=\; 2|E| + \sum_{(i,j)\in E} (\mu_{ij}-1) \;=\; O(k\log k) + \sum_{(i,j)\in E} (\mu_{ij}-1)\,.$$

Next, we bound the quantity $\sum_{(i,j)\in E}(\mu_{ij}-1)$. Let E_{12}^j and E_{12}^{j+1} be two consecutive equivalence classes of E_{12}, let p_iq_i be the bottom edge of E_{12}^j, and let $p_{i+1}q_{i+1}$ be the top edge of E_{12}^{j+1}. The quadrilateral $Q_{12}^j = p_iq_iq_{i+1}p_{i+1}$ contains at least one trapezoid $\bar{\Delta}$ of $\bar{\mathbf{\Delta}}$. We call $p_iq_i, p_{i+1}q_{i+1}$ the *triangle edges* of Q, and p_ip_{i+1}, q_iq_{i+1} the *trapezoidal edges* of Q. The triangle edges of Q_{12}^j are adjacent in E_{12}. Let

$$\mathcal{Q} = \bigcup \{Q_{ij}^l \mid (i,j) \in E \text{ and } l < \mu_{ij}\}$$

be the set of resulting quadrilaterals. Since $|\mathcal{Q}| = \sum_{(i,j)\in E}(\mu_{ij}-1)$, it suffices to bound the number of quadrilaterals in $\mathcal{Q}$.

Consider the planar subdivision induced by $\mathcal{Q}$ and call it $\mathcal{A}(\mathcal{Q})$. The number of faces in the subdivision is proportional to the number of quadrilaterals in $\mathcal{Q}$, so we bound the number of faces in the subdivision. For each bounded face $f \in \mathcal{A}(\mathcal{Q})$, let $Q(f)$ be the smallest quadrilateral of $\mathcal{Q}$ that contains f. Since the boundaries of quadrilaterals do not cross, $Q(f)$ is well defined.

CLAIM 2. *Every face* f *of* $\mathcal{A}(\mathcal{Q})$ *can be uniquely associated with a trapezoid* $\Delta \in \bar{\mathbf{\Delta}}$ *such that* $\Delta \subseteq f$*.*

Proof. The claim is obviously true for the unbounded face, so assume that f is a bounded face. If $Q_i = Q(f)$ does not contain any other quadrilateral of $\mathcal{Q}$, then $f = Q_i$. As mentioned above, Q_i, and therefore f, contains a trapezoid of $\bar{\mathbf{\Delta}}$. We associate this trapezoid with f. If there is more than one trapezoid lying in f, we arbitrarily choose one of them.

If $Q_i = Q(f)$ contains another quadrilateral of $\mathcal{Q}$, let $Q_j \in \mathcal{Q}$ be the largest quadrilateral that lies inside Q_i; that is, ∂Q_j is a part of ∂f. If neither of the

trapezoidal edges of Q_j lies in the interior of Q_i, then the trapezoidal edges of both Q_i, Q_j lie on the same segments of Γ, say, γ_1, γ_2. Consequently, the triangle edges of both Q_i, Q_j belong to E_{12}, which is impossible, because then the triangle edges of Q_i are not adjacent in E_{12}. Hence, one of the trapezoidal edges of Q_j lies in the interior of Q_i. Let $\bar{\Delta}$ be the trapezoid bounded by this edge. Since the triangle edges of Q_j lie outside $\bar{\Delta}$ and the interior of $\bar{\Delta}$ does not intersect any edge of R_1, $\bar{\Delta}$ lies in f. We associate $\bar{\Delta}$ with f. It can be verified that $\bar{\Delta}$ is not associated with any other face. This completes the proof of Claim 2. □

By Claim 2, the number of faces in $\mathcal{A}(\mathcal{Q})$ is at most $|\bar{\mathbf{\Delta}}| = O(k \log k)$. Hence,

$$\sum_{(i,j)\in E} (\mu_{ij} - 1) = |\mathcal{Q}| = O(k \log k),$$

as required. □

Next, we partition the polygons of R_2 into equivalence classes in the same way as we partitioned the edges of E_{12} in the proof of Lemma 7.1. That is, we call two polygons $\tau_1, \tau_2 \in R_2$ *equivalent* if (i) their endpoints lie on the same pair of edges in $\bar{\mathbf{\Delta}}$, and (ii) the interior of the convex hull of $\tau_1 \cup \tau_2$ does not intersect any trapezoid of $\bar{\mathbf{\Delta}}$. Using the same argument as in the proof of the above lemma, the following lemma can be established.

LEMMA 7.2. *The edges of R_2 can be partitioned into $O(k \log k)$ equivalence classes.*

For each equivalence class $E_i \subseteq R_2$, let Q_i be the convex hull of E_i—observe that Q_i is a convex quadrilateral, as illustrated in Figure 5 (iii). Each quadrilateral Q_i can be ε-approximated using at most three triangles in $\mathbb{R}^3$ in the same way as we approximated each polygon P_i of R_1. By Lemma 7.2, the total number of triangles created in this step is also $O(k \log k)$.

Putting together these pieces, we obtain the following lemma.

LEMMA 7.3. *The family of trapezoids $\mathbf{\Delta}$ can be supplemented with $O(k \log k)$ additional trapezoids in $\mathbb{R}^3$ so that all the triangles of $\mathcal{T}$ are ε-approximated. The orthogonal projection of all the trapezoids on the plane $z = 0$ is pairwise disjoint.*

The area not covered by the projection of trapezoids found in the preceding lemma, of course, can be approximated without any regard to the triangles of $\mathcal{T}$. The final surface has $O(K_o \log K_o)$ trapezoids and it ε-approximates the family of triangles $\mathcal{T}$. We finish with a statement of our main theorem in this section.

THEOREM 7.4. *Given a set of n horizontal triangles in $\mathbb{R}^3$, with pairwise disjoint projection on the plane $z = 0$ and a parameter $\varepsilon > 0$, we can compute in polynomial time an ε-approximate polyhedral terrain of size $O(K_o \log K_o)$ for $\mathcal{T}$, where K_o is the size of an optimal ε-approximate terrain.*

8. Closing remarks. We presented an approximation technique for certain geometric covering problems with a disjointness constraint. Our algorithm achieves a logarithmic performance guarantee on the size of the cover, thus matching the bound achieved by the "greedy set cover" heuristic for arbitrary sets and no disjointness constraint. Applications of our result include polynomial-time algorithms to approximate a monotone, polyhedral surface in 3-space, and to approximate the disjoint cover by triangles of red-blue points. We also proved that these problems are *NP-hard*.

The surface-approximation problem is an important problem in visualization and computer graphics. The state of theoretical knowledge on this problem appears to be rather slim. Except for the convex surfaces, no approximation algorithms with good performance guarantees are known [7, 17]. For the approximation of convex

polytopes, it turns out that one does not need *disjoint* covering, and therefore the greedy set-cover heuristic works.

We conclude by mentioning some open problems. An obvious open problem is to reduce the running time of our algorithm for it to be of any practical value. Finding efficient heuristics with good performance guarantees seems hard for most of the geometric partitioning problems and requires further work. A second problem of great practical interest is to ε-approximate general polyhedra—this problem arises in many real applications of computer modeling. To the best of our knowledge, the latter problem remains open even for the special case where one wants to find a minimum-vertex polyhedral surface that lies between two monotone surfaces. The extension of our algorithm presented in Section 7 does not work because we do not know how to handle the last fill-in stage.

Acknowledgments. The authors thank Joe Mitchell, Prabhakar Raghavan, and John Reif for several helpful discussions.

RANDOMIZED DATA STRUCTURES FOR THE DYNAMIC CLOSEST-PAIR PROBLEM*

MORDECAI GOLIN†, RAJEEV RAMAN‡, CHRISTIAN SCHWARZ§, AND MICHIEL SMID¶

Abstract. We describe a new randomized data structure, the *sparse partition*, for solving the dynamic closest-pair problem. Using this data structure the closest pair of a set of n points in D-dimensional space, for any fixed D, can be found in constant time. If a frame containing all the points is known in advance, and if the floor function is available at unit cost, then the data structure supports insertions into and deletions from the set in expected $O(\log n)$ time and requires expected $O(n)$ space. This method is more efficient than any deterministic algorithm for solving the problem in dimension $D > 1$. The data structure can be modified to run in $O(\log^2 n)$ expected time per update in the algebraic computation tree model. Even this version is more efficient than the best currently known deterministic algorithm for $D > 2$. Both results assume that the sequence of updates is not determined in any way by the random choices made by the algorithm.

1. Introduction.

We consider the *dynamic closest-pair problem*: we are given an initially empty set S of points in D-dimensional space and want to keep track of the closest pair of points in S, as S is being modified by insertions and deletions of individual points. We assume that D is an arbitrary constant and that distances are measured in the L_t-metric for some fixed t, $1 \le t \le \infty$. Recall that in the L_t-metric, the distance $d_t(p, q)$ between two points $p = (p^{(1)}, \ldots, p^{(D)})$ and $q = (q^{(1)}, \ldots, q^{(D)})$ in D-dimensional space is defined by

$$d_t(p, q) := \left(\sum_{i=1}^{D} |p^{(i)} - q^{(i)}|^t \right)^{1/t}$$

if $1 \le t < \infty$, and for $t = \infty$ it is defined by

$$d_\infty(p, q) := \max_{1 \le i \le D} |p^{(i)} - q^{(i)}|.$$

Throughout this paper, t will be implicit, and we will write $d(p, q)$ for $d_t(p, q)$.

The precursor to this problem is the classical *closest-pair problem* which is to compute the closest pair of points in a static set S, $|S| = n$. Shamos and Hoey [20] and

Bentley and Shamos [2] gave $O(n \log n)$-time algorithms for solving the closest-pair problem in the plane and in arbitrary but fixed dimension, respectively. This running time is optimal in the algebraic computation tree model [1]. If we allow randomization as well as the use of the (nonalgebraic) floor function, we find algorithms with better (expected) running times for the closest-pair problem. Rabin, in his seminal paper [16] on randomized algorithms, gave an algorithm for this problem which ran in $O(n)$ expected time [16, 5]. Since then, alternative methods with the same running time have been discovered. In addition to the randomized incremental algorithm presented in [11], there is a different approach, described by Khuller and Matias [12], which uses a randomized "filtering" procedure. This method is at the heart of our dynamic algorithm.

There has been a lot of work on maintaining the closest pair of a dynamically changing set of points. When we were restricted to the case where only insertions of points are allowed (sometimes known as the *on-line closest-pair problem*), a series of papers culminated in an optimal data structure due to Schwarz, Smid, and Snoeyink [23]. Their data structure required $O(n)$ space and supported insertions in $O(\log n)$ time.

The existing results are not as satisfactory when deletions must be performed. If only deletions are to be performed, Supowit [24] gave a data structure with $O(\log^D n)$ amortized update time which uses $O(n \log^{D-1} n)$ space. When both insertions and deletions are allowed, Smid [22] described a data structure which uses $O(n \log^D n)$ space and runs in $O(\log^D n \log \log n)$ amortized time per update. Another data structure due to Smid [21], with improvements stemming from results of Salowe [17] and Dickerson, Drysdale, and Sack [7], uses $O(n)$ space and requires $O(\sqrt{n} \log n)$ time for updates. Very recently, after a preliminary version of this paper was presented, Kapoor and Smid [13] devised a deterministic data structure of linear size which achieves polylogarithmic amortized update time, namely, $O(\log^{D-1} n \log \log n)$ for $D \geq 3$ and $O(\log^2 n/(\log \log n)^\ell)$ for the case $D = 2$, where ℓ is an arbitrary nonnegative integer constant.

In this paper we discuss a randomized data structure, the *sparse partition,* which solves the dynamic closest-pair problem in arbitrary fixed dimension using $O(\log n)$ expected time per update. The data structure needs $O(n)$ expected space. This time bound is obtained assuming that the floor function can be computed in constant time and that the algorithm has prior knowledge of a frame which contains all the points in S at any time (this assumption enables the algorithm to create and use dynamic hash tables). Without either of the above assumptions, we obtain an $O(\log^2 n)$ expected update time in the algebraic computation tree model. Even this version of the randomized algorithm is more efficient than the currently best-known deterministic algorithms for solving the problem for $D > 2$ and almost matches the running time of the recently developed method of Kapoor and Smid [13] in the case $D = 2$. Indeed, our algorithm is the first to obtain polylogarithmic update time using linear space for the dynamic closest-pair problem.

Our results require that the updates are generated by an *oblivious* adversary, who fixes a worst-case sequence of operations in advance and reveals it to the data structure in an on-line manner. Hence, the adversary's knowledge of the internal state of the data structure (which is a random variable) is limited to that which can be obtained a priori, and, in particular, the sequence of updates is not determined in any way by the random choices made by the algorithm.

Given a set S of points, the sparse partition that stores S will be a randomly

chosen one from many possible structures. In one version of the data structure, the probability that a particular structure is the one that is being used will depend only on the set S that is being stored and not upon the sequence of insertions and deletions that were used to construct S. In this sense, the data structure is reminiscent of skip lists or randomized search trees [15, 19].

The paper is organized as follows. In section 2, we give an implementation-independent definition of the sparse partition, give a static algorithm to build it, and show how to augment this data structure to find the closest pair in constant time. A grid-based implementation of the sparse partition is given in section 3, and algorithms for updating the sparse partition are given in section 4. In section 5, we show how to modify the grid-based data structure in order to obtain an algorithm which fits in the algebraic computation tree model. Section 6 contains extensions of the method. We show how to modify the data structure to achieve $O(n)$ worst-case space rather than that which is only expected, at the cost of making the update time bound amortized. We also give high probability bounds for the running time of a sequence of update operations. Section 7 contains some concluding remarks.

2. Sparse partitions. We start with some notation. Let S be a set of n points in D-dimensional space. The *minimal distance* of S is $\delta(S) := \min\{d(p,q) : p,q \in S,\ p \neq q\}$. A *closest pair* in S is a pair $p,q \in S$ such that $d(p,q) = \delta(S)$. The distance of p to its nearest neighbor in S is denoted by $d(p,S) := \min\{d(p,q) : q \in S \setminus \{p\}\}$. For convenience, we often speak of *the* closest pair, although there might be more than one. This causes no problems since, as we shall see, our data structure not only allows us to find a single closest pair but also to report all pairs of points attaining the minimal distance in time proportional to their number.

We now describe an idealized version of our data structure. Although the final data structure will be different in many significant ways, the idealized description may offer some insight into the working of the final data structure. For now, assume that the points are in general position and define the *sparseness* of a point $p \in S$ as being simply $d(p,S)$. We will assume the existence of a data structure which, for some fixed $\delta > 0$, maintains a set T of points under insertions, deletions, and queries of the form "is $d(p,T) > \delta$?" for an arbitrary point p, and "enumerate all $q \in T$ with $d(p,q) \leq \delta$." Insertions, deletions, and the former query are assumed to take constant time, while the latter query takes constant time per element reported.

Our idealized data structure partitions the points of S based on their sparseness. Suppose the set S initially contains n points, and we preprocess S to obtain a distance threshold δ such that between $1/3$ and $2/3$ of the points have sparseness greater than δ. This preprocessing can be done in $O(n)$ expected time as follows: simply pick a random $p \in S$, compute $\delta = d(p,S)$, and check how many points have sparseness greater than δ. The fundamental observation of [12] is that p's position in a list of the points in S ordered by sparseness is also random, and hence $O(1)$ such random trials suffice on average to compute a suitable threshold.

We now perform a sequence of cn updates to S for some sufficiently small constant $c > 0$. Let S' denote the set of points in S at any time during this sequence of updates whose sparseness is greater than δ. Since the sparseness of a point changes only when its nearest neighbor in S changes, and a point can only be the nearest neighbor of $O(1)$ points in the set, each update can only change the sparseness of $O(1)$ other points. Hence, during this sequence of updates, S' will continue to contain a constant fraction of points in S. Furthermore, no point in S' will be part of a closest pair in S. At the end of this sequence of updates we can recompute a suitable threshold in linear time,

the cost of which can be amortized over the $\Theta(n)$ updates since the last threshold computation. Applying the partitioning idea recursively to the set $S \setminus S'$ then leads, modulo some details, to a solution to the closest-pair problem with $O(\log n)$ expected amortized time per update—in essence, there will be $O(\log n)$ levels of recursion, and each update results in $O(1)$ amortized expected work per level of recursion.

The most significant problem with this idealized approach is that the "distance threshold" queries that we postulated appear difficult to answer in reality. However, we can quite easily answer the *approximate* versions of these queries, which can distinguish between the cases $d(p,T) > (1+\epsilon)\delta$ and $d(p,T) \leq \delta$ for some fixed $\epsilon > 0$ but may give an arbitrary answer for values in between (a grid-based implementation using the floor function will doubtless occur to a reader familiar with Rabin's algorithm [16]). This causes many problems with the above approach which we have not been able to overcome in a direct manner. The main differences are that the sets "sieved out" at each level have to be more carefully defined and that the rebuilding rules now contain probabilistic components rather than being purely deterministic as above. A few more complications arise when we go from the grid-based algorithm to the algebraic one.

We now present an abstract framework which captures all the properties that we need from the sets sieved out at each level and prove some basic facts about these sets in the abstract framework.

DEFINITION 2.1. *Let S be a set of points in D-space. A* sparse partition *for the set S is a sequence of 5-tuples $(S_i, S'_i, p_i, q_i, \delta_i)$, $1 \leq i \leq L$, where L is a positive integer, such that the following hold.*

(a) *For $i = 1, \ldots, L$,*
  (a.1) *$S_i \neq \emptyset$;*
  (a.2) *$S'_i \subseteq S_i \subseteq S$;*
  (a.3) *$p_i, q_i \in S_i$ and $p_i \neq q_i$ if $|S_i| > 1$;*
  (a.4) *$\delta_i = d(p_i, q_i) = d(p_i, S_i)$.*

(b) *For all $1 \leq i \leq L$, and for all $p \in S_i$,*
  (b.1) *if $d(p, S_i) > \delta_i/2$ then $p \in S'_i$;*
  (b.2) *if $d(p, S_i) \leq \delta_i/4D$ then $p \notin S'_i$.*

(c) *For all $1 \leq i < L$ and for all $p \in S_i$,*
  if $p \in S_{i+1}$, then there is a point $q \in S_i$ such that $d(p,q) \leq \delta_i/2$ and $q \in S_{i+1}$.

(d) *$S_1 = S$ and for $1 \leq i \leq L-1$, $S_{i+1} = S_i \setminus S'_i$.*

For each i, we call the points of S'_i the sparse points *in S_i, and the set S'_i the* sparse set. *Each 5-tuple itself is also called a* level *of the partition.*

Conditions (b.1) and (b.2) govern the decision on whether a point of S_i is in the sparse set S'_i or not. The threshold values given in (b.1) and (b.2) depend on the nearest neighbor distance $d(p_i, S_i)$ of the point $p_i \in S_i$, which will be called the *pivot* in the following. For a point $p \in S_i$ such that $d(p_i, S_i)/4D < d(p, S_i) \leq d(p_i, S_i)/2$, the decision may be arbitrary as far as the results of this section are concerned and will be made precise by the implementation later. Condition (c) is used while implementing updates to the sparse partition efficiently. Some readers may now wish to adjourn to section 3 and read up to the end of the proof of Lemma 3.2, where a concrete implementation of a sparse partition is discussed, before continuing with the rest of this section.

LEMMA 2.1. *Any sparse partition for S satisfies the following properties:*

(1) *The sets S'_i, for $1 \leq i \leq L$, are nonempty and pairwise disjoint. For any $1 \leq i \leq L$, $S_i = \bigcup_{j \geq i} S'_j$. In particular, $\{S'_1, S'_2, \ldots, S'_L\}$ is a partition of S.*

(2) *For any* $1 \le i < L$, $\delta_{i+1} \le \delta_i/2$. *Moreover,* $\delta_L/4D < \delta(S) \le \delta_L$.

Proof. Part (1) is obvious. To prove the first part of (2), let $1 \le i < L$. Since $p_{i+1} \in S_{i+1}$, we know from condition (c) in Definition 2.1 that there is a point $q \in S_i$ such that $d(p_{i+1}, q) \le \delta_i/2$ and $q \in S_{i+1}$. Therefore,

$$\delta_{i+1} = d(p_{i+1}, S_{i+1}) \le d(p_{i+1}, q) \le \delta_i/2.$$

To prove the second part of (2), let p, q be a closest pair in S. Let i and j be such that $p \in S'_i$ and $q \in S'_j$. Assume w.l.o.g. that $i \le j$. Then it follows from (1) that p and q are both contained in S_i. It is clear that $\delta(S) = d(p, q) = d(p, S_i)$. Condition (b.2) in Definition 2.1 implies that $d(p, S_i) > \delta_i/4D$, and from the first part of (2), we conclude that $\delta(S) > \delta_i/4D \ge \delta_L/4D$. The inequality $\delta(S) \le \delta_L$ obviously holds, because δ_L is a distance between two points of S. □

DEFINITION 2.2. *Let S_i be some set of points and let $(S_i, S'_i, p_i, q_i, \delta_i)$ be a* 5*-tuple chosen randomly from some distribution. This* 5*-tuple is called* uniform *if, for all $p \in S_i$, $\Pr[p = p_i] = 1/|S_i|$. Now let $(S_i, S'_i, p_i, q_i, \delta_i)$, $1 \le i \le L$, be a sparse partition for the set S chosen randomly from some distribution on all of the sparse partitions on $S_1 = S$. The set S is said to be* uniformly stored *by the sparse partition if all its* 5*-tuples are uniform.*

We now give an algorithm that, given an input set S, stores it uniformly as a sparse partition.

ALGORITHM *Sparse_Partition*(S)

(i) $S_1 := S$; $i := 1$.

(ii) Choose a random point $p_i \in S_i$. Calculate $\delta_i = d(p_i, S_i)$. Let $q_i \in S_i$ be such that $d(p_i, q_i) = \delta_i$.

(iii) Choose S'_i to satisfy (b.1), (b.2), and (c) in Definition 2.1.

(iv) If $S_i = S'_i$ stop; otherwise set $S_{i+1} := S_i \setminus S'_i$, set $i := i + 1$ and goto (ii).

LEMMA 2.2. *Let S be a set of n points in $\mathbb{R}^D$. Run Sparse_Partition(S) and let $(S_i, S'_i, p_i, q_i, \delta_i)$, $1 \le i \le L$, be the* 5*-tuples constructed by the algorithm. Then this set of* 5*-tuples is a uniform sparse partition for S, and we have* $\mathrm{E}(\sum_{i=1}^{L} |S_i|) \le 2n$.

Proof. The output generated by algorithm *Sparse_Partition*(S) obviously fulfills the requirements of Definitions 2.1 and 2.2. To prove the bound on the size of the structure, we first note that $L \le n$ by Lemma 2.1. Define $S_{L+1} := S_{L+2} := \cdots := S_n := \emptyset$. Let $s_i := \mathrm{E}(|S_i|)$ for $1 \le i \le n$. We will show that $s_{i+1} \le s_i/2$, from which it follows that $s_i \le n/2^{i-1}$. By the linearity of expectation, we get $\mathrm{E}(\sum_{i=1}^{L} |S_i|) \le \sum_{i=1}^{n} n/2^{i-1} \le 2n$.

It remains to prove that $s_{i+1} \le s_i/2$. If $s_i = 0$, then $s_{i+1} = 0$ and the claim holds. So assume $s_i > 0$. We consider the conditional expectation $\mathrm{E}(|S_{i+1}| \mid |S_i| = l)$. Let $r \in S_i$ such that $d(r, S_i) \ge \delta_i$. Then, condition (b.1) of Definition 2.1 implies that $r \in S'_i$; i.e., $r \notin S_{i+1}$.

Take the points in S_i and label them $r_1, r_2, \ldots, r_l$ such that $d(r_1, S_i) \le d(r_2, S_i) \le \cdots \le d(r_l, S_i)$. The point p_i is chosen randomly from the set S_i, so it can be any of the r_j's with equal probability. Thus $\mathrm{E}(|S_{i+1}| \mid |S_i| = l) \le l/2$, from which it follows that $s_{i+1} = \sum_l \mathrm{E}(|S_{i+1}| \mid |S_i| = l) \cdot \Pr(|S_i| = l) \le s_i/2$. □

We remark that the procedure *Sparse_Partition* is the essential component of Khuller and Matias's algorithm [12], where it was used as a filtering procedure to compute δ_L and only kept track of the current set S_i. Our dynamic algorithm stores the sets S_i and S'_i at all the levels. As we now show, the minimal distance is closely related to the sparse sets S'_i, i.e., the points that were thrown away in each step of the iteration in [12]. This enables us to use the sparse partition to find $\delta(S)$ quickly.

DEFINITION 2.3. *Let $S'_1, S'_2, \ldots, S'_L$ be the sparse sets of a sparse partition for S. For any $p \in \mathbb{R}^D$ and $1 \le i \le L$, define the* restricted distance

$$d_i^*(p) := \min\left(\delta_i,\, d\big(p,\, \bigcup_{1\le j\le i} S'_j\big)\right),$$

i.e., the smaller of δ_i and the minimal distance between p and all points in $S'_1 \cup S'_2 \cup \cdots \cup S'_i$.

For convenience, we define, for all $i \le 0$, $S'_i := \emptyset$, $\delta_i := \infty$, and $d_i^*(p) := \infty$ for any point p.

LEMMA 2.3. *Let $p \in S$ and let i be the index such that $p \in S'_i$.*

(1) *$d_i^*(p) > \delta_i/4D$.*

(2) *If $q \in S'_j$, where $1 \le j < i - D$, then $d(p,q) > \delta_i$.*

(3) *$d_i^*(p) = \min\big(\delta_i,\, d(p, S'_{i-D} \cup S'_{i-D+1} \cup \cdots \cup S'_i)\big)$.*

Proof. The proof of (1) is obvious. To prove (2), let $q \in S'_j$, where $1 \le j < i - D$. Since $d(p,q) > \delta_j/4D$, Lemma 2.1 implies that

$$d(p,q) > \frac{\delta_j}{4D} \ge \frac{\delta_{i-D-1}}{4D} \ge \frac{2^{D+1}\delta_i}{4D} \ge \delta_i.$$

(3) follows immediately from (2). □

LEMMA 2.4.

$$\delta(S) = \min_{1\le i\le L} \min_{p\in S'_i} d_i^*(p) = \min_{L-D\le i\le L} \min_{p\in S'_i} d_i^*(p).$$

Proof. The value $d_i^*(p)$ is always the distance between two points in S. Therefore, $\delta(S) \le \min_{1\le i\le L} \min_{p\in S'_i} d_i^*(p)$. Let p, q be a closest pair, with $p \in S'_i$ and $q \in S'_j$. Assume w.l.o.g. that $j \le i$. Clearly, $d(p,q) = d(p, \bigcup_{\ell\le i} S'_\ell) \ge d_i^*(p)$. This implies that $\delta(S) \ge \min_{1\le i\le L} \min_{p\in S'_i} d_i^*(p)$, proving the first equality.

It remains to prove that we can restrict the value of i to $L-D, L-D+1, \ldots, L$. We know from Lemma 2.3(1) that $\min_{p\in S'_i} d_i^*(p) > \delta_i/4D$. Moreover, we know from Lemma 2.1(2) that for $i < L-D$, $\delta_i/4D \ge \delta_{L-D-1}/4D \ge (2^{D+1}/4D)\cdot\delta_L \ge \delta_L \ge \delta(S)$. □

Now we are ready to describe how to find the closest pair using the sparse partition. According to the characterization of $\delta(S)$ in Lemma 2.4, we will augment the sparse partition with a data structure which stores, for each level $i \in \{1, \ldots, L\}$, the set of restricted distances $\{d_i^*(p) : p \in S'_i\}$.

The data structure that we use for this purpose is a *heap*. (See, e.g., [6, Chapter 7].) A heap storing n items can be built in linear time, and the operations *insert*(item), *delete*(item), and *change_key*(item, key)—which changes the key of the item item to the value key—are supported in $O(\log n)$ time. Also, operation *find_min*(H) can be performed in $O(1)$ time, and *find_all_min*(H), which returns all A items with minimum key, can be performed in time $O(A)$.

So, for each $i \in \{1, \ldots, L\}$, we maintain a min-heap H_i which stores items having the restricted distances $\{d_i^*(p) : p \in S'_i\}$ as their keys. How we compute these values depends on the way we implement the sparse partition, which will be described in the following sections, where we also describe the exact contents of our heap items.

LEMMA 2.5. *Let $S'_1, S'_2, \ldots, S'_L$ be the sparse sets of a sparse partition for S, and for each $1 \le i \le L$, let the set $\{d_i^*(p) : p \in S'_i\}$ of restricted distances be stored*

in a min-heap H_i. Then the minimum distance $\delta(S)$ can be found in constant time. Moreover, all point pairs attaining this minimum distance can be reported in time proportional to their number.

Proof. For $i \leq 0$, define H_i as the empty heap. Lemma 2.4 characterizes $\delta(S)$ as a minimum of certain restricted distances. In particular, Lemma 2.4 says that $\delta(S)$ can only be stored in one of the heaps $H_{L-D}, H_{L-D+1}, \ldots, H_L$. To find $\delta(S)$ it is therefore enough to take the minima of these $D+1$ heaps and then to take the minimum of these $D+1$ values. Moreover, we can report all closest pairs in time proportional to their number as follows: in all of the at most $D+1$ heaps whose minimum key is $\delta(S)$, we report all items whose key is equal to $\delta(S)$. From the discussion of heaps above, this can be done in time proportional to the number of items that are reported. □

We close this section with an abstract description of our data structure.

The closest-pair data structure for set S.

- A data structure storing S uniformly as a sparse partition according to Definitions 2.1 and 2.2.
- The heaps H_1, H_2, ..., H_L, where H_i stores the set of restricted distances $d_i^*(p)$, cf. Definition 2.3, for all points p in the sparse set S_i'.

In the rest of the paper, we discuss two different ways to implement the data structure. First, we describe a grid-based implementation. Since this data structure is the most intuitive one, we describe the update algorithms for this structure. Then we define the other variant of the data structure. Concerning implementation details and update algorithms, we then only mention the changes that have to be made in comparison with the grid-based implementation in order to establish the results.

3. A grid-based implementation of the sparse partition. Let S be a set of n points in D-space. To give a concrete implementation of a sparse partition for S, we only have to define the set S_i', i.e., the subset of sparse points in S_i for each i.

3.1. The notion of neighborhood in grids. We start with some definitions. Let $\delta > 0$. We use $\mathcal{G}_\delta$ to denote the grid with mesh size δ and a lattice point at $(0, 0, \ldots, 0)$. Hypercubes of the grid are called *boxes*. More precisely, a box has the form

$$[i_1\delta : (i_1+1)\delta) \times [i_2\delta : (i_2+1)\delta) \times \cdots \times [i_k\delta : (i_k+1)\delta)$$

for integers $i_1, \ldots, i_k$. We call $(i_1, \ldots, i_k)$ the *index* of the box. Note that with this definition of a box as the product of half-open intervals, every point in $\mathbb{R}^D$ is contained in exactly one grid box. The neighborhood of a box b in the grid $\mathcal{G}_\delta$, denoted by $N(b)$, consists of b itself plus the collection of $3^D - 1$ boxes bordering on it. Let p be any point in $\mathbb{R}^D$ and let $b_\delta(p)$ denote the box of $\mathcal{G}_\delta$ that contains p. The *neighborhood of p in $\mathcal{G}_\delta$*, denoted by $N_\delta(p)$, is defined as the neighborhood of $b_\delta(p)$; i.e., $N_\delta(p) := N(b_\delta(p))$. Let V be a set of points in $\mathbb{R}^D$. The *neighborhood of p in $\mathcal{G}_\delta$ relative to V* is defined as

$$N_\delta(p, V) := N_\delta(p) \cap (V \setminus \{p\}).$$

We say that p *is sparse in $\mathcal{G}_\delta$ relative to V* if $N_\delta(p, V) = \emptyset$, i.e., if, besides p, there are no points of V in $N_\delta(p)$. In cases where V and δ are understood from the context we will simply say that p is *sparse.*

The following observations follow directly from the definitions.

LEMMA 3.1. *Let V be a set of points in $\mathbb{R}^D$, and let p and q be arbitrary points in $\mathbb{R}^D$.*

(N.1) *If $N_\delta(p, V) = \emptyset$, then $d(p, V) > \delta$.*

(N.2) *If $q \in N_\delta(p, V)$, then $d(p, q) \leq 2D\delta$.*

(N.3) $q \in N_\delta(p) \iff p \in N_\delta(q)$.

We are now in a position to define the sets S'_i precisely. For $i \geq 1$, let

$$S'_i := \{p \in S_i \,:\, p \text{ sparse in } \mathcal{G}_{\delta_i/4D} \text{ relative to } S_i\}. \tag{1}$$

For convenience, we now modify the abstract definition of the sparse partition given in Definition 2.1 and replace it by one which is defined in terms of grid neighborhoods. Recall that in Definition 2.1 S'_i was not fully specified; the definition only gave conditions, specifically (b.1), (b.2), (c), and (d), which S'_i had to satisfy. We now replace those conditions by equation (1); with this new definition the sparse partitions are totally specified and we will be able to use them in section 4 to develop and later analyze our update algorithms.

DEFINITION 3.1. *A sparse partition for the set S is a sequence of 5-tuples $(S_i, S'_i, p_i, q_i, \delta_i)$, $1 \leq i \leq L$, where L is a positive integer, such that*

1. *For $i = 1, \ldots, L$,*
   - (a) $\emptyset \neq S_i \subseteq S$;
   - (b) $p_i, q_i \in S_i$ *and* $p_i \neq q_i$ *if* $|S_i| > 1$;
   - (c) $\delta_i = d(p_i, q_i) = d(p_i, S_i)$;
   - (d) $S'_i = \{p \in S_i \,:\, N_{\delta_i/4D}(p, S_i) = \emptyset\}$.
2. $S_1 = S$ *and for* $1 \leq i \leq L-1$, $S_{i+1} = S_i \setminus S'_i$.

LEMMA 3.2. *Let $(S_i, S'_i, p_i, q_i, \delta_i)$, $1 \leq i \leq L$, be a set of 5-tuples satisfying Definition 3.1. Then this set of 5-tuples also satisfies Definition 2.1.*

Proof. We only have to prove conditions (b) and (c) of Definition 2.1. Let $1 \leq i \leq L$ and let $p \in S_i$. First assume that $p \notin S'_i$. Then there is a point $q \in S_i$ which is in the neighborhood of p. By (N.2), $d(p, S_i) \leq d(p, q) \leq 2D \cdot \delta_i/4D = \delta_i/2$. This proves condition (b.1). To prove (b.2), assume that $p \in S'_i$. Then, the neighborhood of p relative to S_i is empty. Hence, by (N.1), $d(p, S_i) > \delta_i/4D$.

To prove (c), let $1 \leq i < L$ and let $p \in S_{i+1} = S_i \setminus S'_i$. It follows that there is a point $q \in S_i$ such that $q \in N_{\delta_i/4D}(p)$. By the symmetry property (N.3), this is equivalent to $p \in N_{\delta_i/4D}(q)$ and therefore $q \in S_{i+1}$. From condition (b.1), we also have $d(p, q) \leq \delta_i/2$.

In Figure 1 we provide an example of a sparse partition based on Definition 3.1. □

We now come to some additional properties of the sparse partition as defined in Definition 3.1 that will be used in the dynamic maintenance of the data structure. For this purpose, we give some additional facts about neighborhoods.

We start with some notation. Let p be a point in $\mathbb{R}^D$. We number the 3^D boxes in the neighborhood of p as follows. The number of a box is a D-tuple over $\{-1, 0, 1\}$. The jth component of the D-tuple is -1, 0, or 1, depending on whether the jth coordinate of the box (i.e., its lower left coordinate) is smaller than, equal to, or greater than the corresponding coordinate of $b_\delta(p)$. We call this D-tuple the *signature* of a box. We denote by $b_\delta^\Psi(p)$ the box with signature Ψ in $N_\delta(p)$.

We now define the notion of *partial neighborhood* of a point p. (See Figure 2.) For any signature Ψ, we denote by $N_\delta^\Psi(p)$ the part of p's neighborhood that is in the neighborhood of $b_\delta^\Psi(p)$. Note that $N_\delta^\Psi(p)$ contains all the boxes $b_\delta^{\Psi'}(p)$ of $N_\delta(p)$ whose signature Ψ' differs from Ψ by at most 1 for each coordinate—these are exactly the

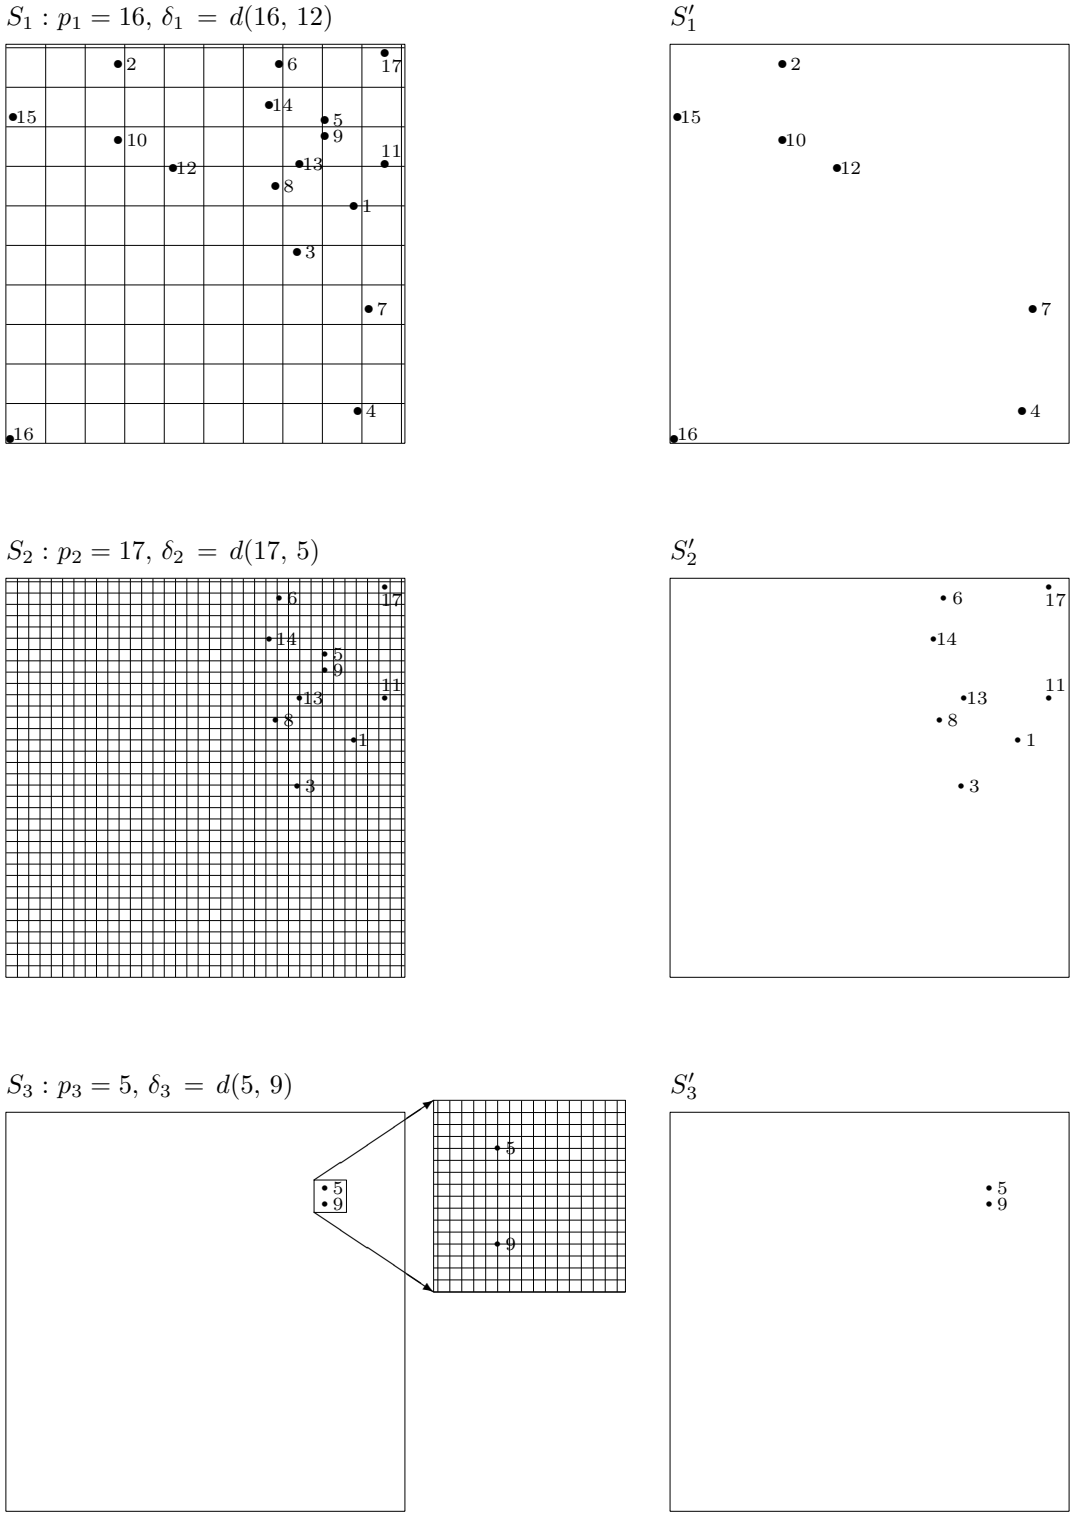

FIG. 1. *A sparse partition. Although the sets S'_i are also stored in grids, we have not shown the corresponding grids.*

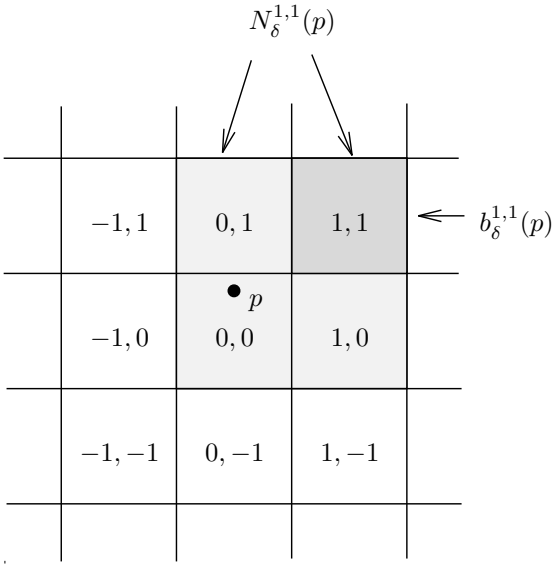

FIG. 2. *The neighborhood of a point p in $\mathcal{G}_\delta$. The dark shaded area denotes the box $b_\delta^{1,1}(p)$ in the upper right corner of p's neighborhood. This box also belongs to $N_\delta^{1,1}(p)$, the partial neighborhood of p with signature $1,1$. The light shaded area shows the other three boxes of $N_\delta^{1,1}(p)$.*

boxes bordering on $b_\delta^\Psi(p)$ including $b_\delta^\Psi(p)$ itself. In particular, $N_\delta^{0,\dots,0}(p) = N_\delta(p)$; i.e., the partial neighborhood with signature $0,\dots,0$ is the whole neighborhood of p.

The following properties will let us relate the neighborhoods of a point in different grids and more specifically in the different grids that correspond to different levels of the same sparse partition.

LEMMA 3.3. *Let $0 < \delta' \le \delta''/2$ be real numbers and let $p \in \mathbb{R}^D$. Then the following hold.*

(N.4) $N_{\delta'}(p) \subseteq N_{\delta''}(p)$.

(N.5) *For any signature $\Psi \in \{-1,0,1\}^D$: $b_{\delta'}^\Psi(p) \subseteq N_{\delta''}^\Psi(p)$.*

Proof. For any grid size δ and $1 \le j \le D$, denote by $h_\delta^{L,j}, h_\delta^{l,j}, h_\delta^{r,j}, h_\delta^{R,j}$ the jth coordinates of the four hyperplanes bounding the grid boxes of p's neighborhood in the j-direction, ordered from "left" to "right." See Figure 3.

Let $q = (q^{(1)}, q^{(2)}, \dots, q^{(D)}) \in \mathbb{R}^D$, and let $\Psi = (\alpha_1, \dots, \alpha_D) \in \{-1,0,1\}^D$ be a signature. Then $q \in b_\delta^\Psi(p)$ in $\mathcal{G}_\delta$ if and only if for all $1 \le j \le D$,

$$\begin{aligned} h_\delta^{l,j} \le q^{(j)} \le h_\delta^{r,j} &\qquad \text{if } \alpha_j = 0,\\ h_\delta^{r,j} \le q^{(j)} \le h_\delta^{R,j} &\qquad \text{if } \alpha_j = 1,\\ h_\delta^{L,j} \le q^{(j)} \le h_\delta^{l,j} &\qquad \text{if } \alpha_j = -1. \end{aligned}$$

Also, $q \in N_\delta^\Psi(p)$ if and only if for all $1 \le j \le D$,

$$\begin{aligned} h_\delta^{L,j} \le q^{(j)} \le h_\delta^{R,j} &\qquad \text{if } \alpha_j = 0,\\ h_\delta^{l,j} \le q^{(j)} \le h_\delta^{R,j} &\qquad \text{if } \alpha_j = 1,\\ h_\delta^{L,j} \le q^{(j)} \le h_\delta^{r,j} &\qquad \text{if } \alpha_j = -1. \end{aligned}$$

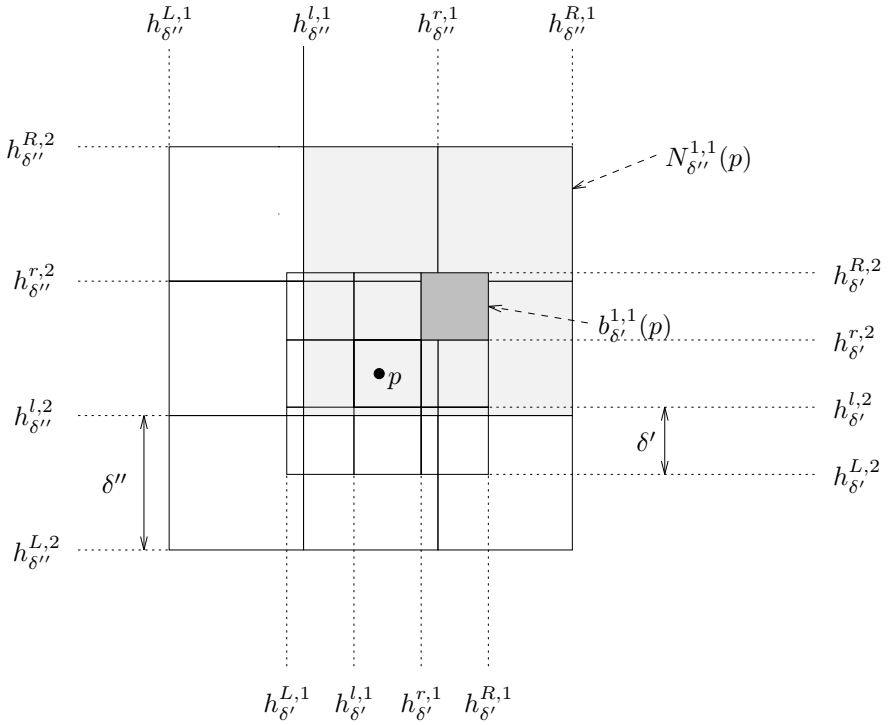

FIG. 3. *The neighborhoods of a point p in grids $\mathcal{G}_{\delta'}$ and $\mathcal{G}_{\delta''}$ where $\delta' \leq \delta''/2$.*

Figure 3 shows the neighborhoods of p in the two grids $\mathcal{G}_{\delta'}$ and $\mathcal{G}_{\delta''}$.

Now observe that, since $\delta' \leq \delta''/2$,

$$h^{L,j}_{\delta'} \geq h^{L,j}_{\delta''}, \tag{2}$$

$$h^{R,j}_{\delta'} \leq h^{R,j}_{\delta''} \tag{3}$$

for $1 \leq j \leq D$. These facts are equivalent to $N_{\delta'}(p) \subseteq N_{\delta''}(p)$, which is claim (N.4).

Furthermore, by the definition of the hyperplanes w.r.t. p,

$$h^{r,j}_{\delta'} \geq h^{l,j}_{\delta''}, \tag{4}$$

$$h^{l,j}_{\delta'} \leq h^{r,j}_{\delta''} \tag{5}$$

for $1 \leq j \leq D$. This proves claim (N.5): $b^{\Psi}_{\delta'}(p) \subseteq N^{\Psi}_{\delta''}(p)$. □

NOTATION. Consider a set S which is stored in a set of 5-tuples $(S_i, S'_i, p_i, q_i, \delta_i)$, $1 \leq i \leq L$, according to Definition 3.1. Since we will only use grids $\mathcal{G}_{\delta_i/4D}$ for the data structures that store level i of the partition, we will use the abbreviations $\mathcal{G}_i := \mathcal{G}_{\delta_i/4D}$ and $N_i(p) := N_{\delta_i/4D}(p)$ from now on. We use the same convention for the neighborhood relative to a set.

COROLLARY 3.1. *Let p be an arbitrary point of $\mathbb{R}^D$, and let $(S_i, S'_i, p_i, q_i, \delta_i)$, $1 \leq i \leq L$, be a sparse partition. Then for any $1 \leq i < j \leq L$, $N_j(p) \subseteq N_i(p)$.*

Proof. Apply (N.4) from Lemma 3.3 with $\delta'' = \delta_i/4D, \delta' = \delta_j/4D$, noting that $\delta' \leq \delta''/2$ by Lemma 2.1. □

In particular, if $N_i(p, S_i) = \emptyset$ for a point $p \in \mathbb{R}^D$, i.e., if p is sparse in $\mathcal{G}_i$ relative to S_i, then since $S_{i+1} \subseteq S_i$, Corollary 3.1 implies $N_{i+1}(p, S_{i+1}) = \emptyset$, which means

that p is also sparse in $\mathcal{G}_{i+1}$ relative to S_{i+1}. This property will be crucial to our update algorithms.

The following lemma will also be useful later on.

LEMMA 3.4. *Let $(S_i, S_i', p_i, q_i, \delta_i)$, $1 \le i \le L$, be a sparse partition. Then for any $p \in S \setminus S_{i+1}, 1 \le i < L$,*

$$N_i(p, S) = \emptyset.$$

Proof. We use induction on i. If $i = 1$, then for any $p \in S \setminus S_2 = S_1'$, $N_1(p, S) = N_1(p, S_1) = \emptyset$ by definition. Now let $i > 1$ and assume that, for any $p \in S \setminus S_i$, we have $N_{i-1}(p, S) = \emptyset$.

1. If $p \in S \setminus S_i$, then $N_i(p, S) \subseteq N_{i-1}(p, S) = \emptyset$ by Corollary 3.1 and our induction hypothesis, respectively.
2. If $p \in S_i'$, then $N_i(p, S_i) = \emptyset$ by definition. It remains to show that $N_i(p, S \setminus S_i) = \emptyset$. This is true because if there were a point $q \in S \setminus S_i$ such that $q \in N_i(p)$, then by the symmetry property (N.3) we have $p \in N_i(q)$, contradicting $N_i(q, S) = \emptyset$, which was shown in item 1 above.

We have thus shown that $N_i(p, S) = \emptyset$ for any $p \in S \setminus S_{i+1} = (S \setminus S_i) \cup S_i'$. □

3.2. Storing a point set according to a grid. We now explain how to store the point sets involved in the sparse partition of our input set S. Let δ be a grid size and $V \subseteq S$ be a subset of S. We store each nonempty box in the grid $\mathcal{G}_\delta$ in a hash table, using the index of the box in $\mathcal{G}_\delta$ as a key. Associated with each box b, we store a list containing the points in $V \cap b$ in arbitrary order. We call this *storing V according to $\mathcal{G}_\delta$*, and the data structure itself is called the *box dictionary*.

The dynamic perfect hashing algorithm of [10] allows us to store a set of integer-valued keys in linear space such that the information stored at a given key can be accessed in $O(1)$ worst-case time and permits a key to be inserted or deleted in $O(1)$ expected time. This algorithm needs to know in advance the range of integers from which the keys to be inserted or deleted may be drawn, but this range can easily be computed from δ if we know a frame containing all the points in S.

If V is stored according to $\mathcal{G}_\delta$, then we can answer the question *"are any points of V in box b?"* in $O(1)$ worst-case time. Moreover, if the answer is yes, we can report all points in $V \cap b$ in time proportional to their number. By checking all boxes in the neighborhood of an arbitrary point q, we can check in $O(1)$ time if q is sparse in the grid $\mathcal{G}_\delta$ relative to V, and by doing this for each point in V we can, in linear time, find the subset $V' \subseteq V$ of sparse points in V.

3.3. The complete data structure. Recall that, when discussing a sparse partition, we use $\mathcal{G}_i$ as a short form for the grid of mesh size $\delta_i/4D$. Our data structure now consists of the following:

For each $1 \le i \le L$,

- the pivot $p_i \in S_i$, its nearest neighbor q_i in S_i and $\delta_i = d(p_i, q_i)$,
- S_i stored according to $\mathcal{G}_i$,
- S_i' stored according to $\mathcal{G}_i$,
- the heap H_i.

Note that this means that S_i and S_i' are kept in two separate grid data structures defined on $\mathcal{G}_i$. We now add some more details to the description. Let b be a box of $\mathcal{G}_i$ which is nonempty w.r.t. S_i or S_i'. The list of points in $S_i \cap b$ will be called $\mathcal{L}(b)$, and the list of points in $S_i' \cap b$ will be called $\mathcal{L}'(b)$. Each element of $\mathcal{L}(b)$ is a record containing the following information:

$p \in \mathcal{L}(b)$: record | *point:* p | *upper:*$\uparrow p$ in S_{i-1} | $lower : \uparrow p$ in S_{i+1} |

Here, "$\uparrow p$ in V" means a pointer to the representation of point p in the data structure storing V. The pointers are nil if the corresponding representation of the point does not exist.

Each element of $\mathcal{L}'(b)$ is a record with the following information:

$p \in \mathcal{L}'(b)$: record | *point:* p | $it : \uparrow it(p)$ in H_i | $left : \uparrow p$ in S_i |

Here, "$\uparrow it(p)$ in H_i" means a pointer to the heap item $it(p)$ with key $d_i^*(p)$. (See below.) Note that each list $\mathcal{L}'(b)$ normally contains at most one point, by the sparseness property of the set S_i', but may temporarily contain more than one point during an update.

Now let us turn to the heaps. The key of an item in heap H_i is the value $d_i^*(p)$ for some $p \in S_i'$. Let q—if it exists—be such that $d_i^*(p) = d(p,q) < \delta_i$, and let l be such that $0 \le l \le D$ and $q \in S_{i-l}'$. Then the heap item $it(p)$ of H_i contains the following information:

item $it(p) \in H_i$: record | *key:* $d_i^*(p)$ | *point:* $\uparrow p$ in S_i' | *point*2: $\uparrow q$ in S_{i-l}' |

If the point q does not exist, i.e., if $d_i^*(p) = \delta_i$, then the pointer *point*2 is nil.

We are now in a position to describe a complete procedure which constructs the sparse partition and its auxiliary data structures. It will be convenient to have two slight variants of the procedure. The first, called $Build(T, j)$, takes as arguments a set of points T and an integer j and stores set T uniformly in levels $j, j+1, \ldots$ of a sparse partition. The second, $Near\_Build(T, p, j)$, again stores the given set of points T uniformly in levels $j, j+1, \ldots$ of a sparse partition but uses the given point $p \in T$ as the pivot for level j. In all invocations of $Near\_Build$, p will be chosen at random from T.

ALGORITHM $Near\_Build(T, p, j)$

1. $i := j$; $S_i := T$; $p_i := p$.
2. Calculate $\delta_i := d(p_i, S_i)$. Let $q_i \in S_i$ be such that $d(p_i, q_i) = \delta_i$.
3. Store S_i according to $\mathcal{G}_i$.
4. Compute $S_i' := \{p \in S_i : p \text{ sparse in } \mathcal{G}_i \text{ relative to } S_i\}$.
5. Store S_i' according to $\mathcal{G}_i$.
6. Compute the restricted distances $\{d_i^*(p) : p \in S_i'\}$ and, using a linear time algorithm, construct a heap H_i containing these values with the minimal value at the top.
7. If $S_i = S_i'$ stop; otherwise set $S_{i+1} := S_i \setminus S_i'$; choose a random point $p_{i+1} \in S_{i+1}$; set $i := i+1$; and goto 2.

ALGORITHM $Build(T, j)$

Choose a random point $p \in T$ and call $Near\_Build(T, p, j)$.

For the sake of simplicity, we did not mention in this algorithm how to establish the above-described links between the various parts of the data structure. The links between heap items and points in a list $\mathcal{L}'(b)$, i.e., points stored in a sparse set S_i', can be installed during the construction of the heaps. The pointers between representations of a point p in subsequent nonsparse sets S_i, S_{i+1} can be established easily in step 7 when S_{i+1} is obtained by stripping off the sparse set S_i' from S_i.

LEMMA 3.5. *Let $(S_i, S_i', p_i, q_i, \delta_i), 1 \le i \le L$, be a sparse partition, and let $p \in S_i'$ for some $i \in \{1, \ldots, L\}$. If we have the data structures storing the sets S_j' according to $\mathcal{G}_j$ available for $1 \le j \le i$, then the value $d_i^*(p)$ can be computed in $O(1)$ time.*

Proof. We know from Lemma 2.3(2) that if $d_i^*(p) = d(p,q)$ with $d(p,q) < \delta_i$ then q must be in one of the sets $S'_i, S'_{i-1}, \ldots, S'_{i-D}$. Furthermore, there are only a constant number of boxes in the grids $\mathcal{G}_j$, $i - D \le j \le i$, in which the point q can possibly appear: since the boxes in the grids $\mathcal{G}_j$ have side length $\delta_j/4D \ge \delta_i/4D$, these are the grid boxes that are within $4D$ boxes of the box in which p is located. Finally, because of the sparseness of the sets S'_j, there can be at most one point in each grid box and using the hash tables storing S'_j, $i - D \le j \le i$, we can find all points contained in these boxes and compute $d_i^*(p)$ in $O(1)$ time. □

LEMMA 3.6. *Let T be a set of points in $\mathbb{R}^D$. The procedures $Build(T, j)$ and $Near\_Build(T, p, j)$ complete in $O(|T|)$ expected time and produce sparse partitions of $O(|T|)$ expected size.*

Proof. For $k = 0, 1, \ldots$, consider the kth iteration of algorithm $Build(T, j)$ for which the loop index i has value $j+k$. Step 2 can be performed in $O(|S_i|)$ deterministic time by calculating the distance between p_i and all other points in S_i. Steps 3 and 5 build the grid data structures for S_i and S'_i and take $O(|S_i|)$ and $O(|S'_i|)$ expected time, respectively. By the discussion at the end of subsection 3.2, step 4, which computes S'_i from S_i, can be performed in $O(|S_i|)$ deterministic time. This implicitly includes the work of step 7.

Since we have the data structures for S'_l, $j \le l \le j + k$, available in the kth iteration of the algorithm, we can apply Lemma 3.5 to conclude that computing the restricted distances $\{d_i^*(p) : p \in S'_i\}$ in step 6 takes $O(|S'_i|)$ worst-case time. The heap H_i can be constructed within the same time bound.

Therefore, the expected running time of the algorithm is bounded by $O(\mathrm{E}(\sum_i |S_i|))$, which is also the amount of space used. Lemma 2.2 shows that this quantity is $O(|T|)$.

The analysis for $Near\_Build$ is similar. □

Recall that given this data structure, we can find the closest pair in S in $O(1)$ time by Lemma 2.5.

4. Dynamic maintenance of the data structure. In this section, we show how to maintain the sparse partition when the input set S is modified by insertions and deletions of points. The algorithms for insertions and deletions turn out to be very similar. We will demonstrate the ideas that are common to both update operations when we treat insertions. Then we give the deletion algorithm.

4.1. The insertion algorithm. We start with an intuitive description of the insertion algorithm. Let S be the current set of points, and assume we want to insert the point q. Further assume that S is already uniformly stored in the sparse partition. Our goal is to randomly build a sparse partition which uniformly stores $S \cup \{q\}$.

If we were to build a uniform sparse partition of $S \cup \{q\}$ from scratch then q would be the pivot of S_1 with probability $1/(|S_1| + 1)$; otherwise one of the points in S is chosen at random as the pivot. By assumption, p_1 (the pivot of S_1) is a random element of $S_1 = S$. Therefore, to generate a pivot for $S_1 \cup \{q\}$ it suffices to retain p_1 as pivot with probability $|S_1|/(|S_1|+1)$ and to choose q with probability $1/(|S_1|+1)$. If q is chosen, then we discard everything and run $Near\_Build(S_1 \cup \{q\}, q, 1)$, terminating the procedure. The latter event happens, however, only with probability $1/(|S_1| + 1)$ and so its expected cost is $O(1)$.

Assume now that p_1 remains unchanged as the pivot. We now check to see if q_1—the nearest neighbor of p_1—and hence, δ_1, have to be changed. First note that q can be the nearest neighbor of at most $3^D - 1 \le 3^D$ points in S_1. (See [8].) This means that δ_1 changes only if p_1 is one of these points. Since the updates are assumed to be independent of the coin flips of the algorithm, and since p_1 is chosen uniformly from

S_1, it follows that the probability of δ_1 changing is at most $3^D/|S_1|$. If δ_1 changes, we run $Build(S_1 \cup \{q\}, 1)$ and terminate the procedure. The expected cost of this is $O(1)$. The previous two steps are called "check for rebuild" in the later part of this section.

Assume now that p_1, q_1, and δ_1 remain unchanged. Let us denote $S \cup \{q\}$ by $\widetilde{S}$. We now need to determine the set $\widetilde{S}_2$, which contains the nonsparse points in $\widetilde{S}_1 = \widetilde{S}$. If q is sparse in S_1, it will go into $\widetilde{S}'_1$, and nothing further needs to be done; that is, the tuples $(S_i, S'_i, p_i, q_i, \delta_i)$ and $(\widetilde{S}_i, \widetilde{S}'_i, \widetilde{p}_i, \widetilde{q}_i, \widetilde{\delta}_i)$ are identical for $2 \le i \le L$. So, in this case, we can terminate the procedure. Otherwise, $\widetilde{S}_2$ contains q and possibly some points from S'_1. The set of points which are deleted from S'_1 due to the insertion of q is called $down_1$. This completes the construction of the first 5-tuple. Two of the three cases that may occur while constructing the first 5-tuple are given in Figures 4 and 5. The algorithm for constructing the new 5-tuples for $\widetilde{S}_i, i > 1$ follows the same general idea. We now describe more formally how to construct the new 5-tuples for $\widetilde{S}_i, i \ge 1$ and extend the notion of the set $down_1$ from the first level to the other levels of the sparse partition.

Let $i \ge 1$ and take $down_0 := \emptyset$. The following invariant holds if the algorithm attempts to construct the 5-tuple for $\widetilde{S}_i$ without having performed a rebuilding yet.

INVARIANT $\mathsf{INS}(i)$

(a) For $1 \le j < i$,

(a.1) $q \in \widetilde{S}_j$ and the set of 5-tuples $(\widetilde{S}_j, \widetilde{S}'_j, \widetilde{p}_j, \widetilde{q}_j, \widetilde{\delta}_j)$ satisfies Definitions 3.1 (sparse partition) and 2.2 (uniformity), where $\widetilde{p}_j = p_j, \widetilde{q}_j = q_j, \widetilde{\delta}_j = \delta_j$;

(a.2) $\widetilde{S}_{j+1} = \widetilde{S}_j \setminus \widetilde{S}'_j$.

(b) The sets $down_j, 0 \le j < i$, have been computed and $\widetilde{S}_i = S_i \cup down_{i-1} \cup \{q\}$.

Note that at the beginning of the algorithm, $\mathsf{INS}(1)$ holds because $down_0 = \emptyset$. We will show later that 3^D is an upper bound on the size of the union of all the $down$ sets. Thus each single $down$ set has size at most 3^D.

Now let us construct the 5-tuple for $\widetilde{S}_i$. From invariant $\mathsf{INS}(i)$ (b), we have $\widetilde{S}_i = S_i \cup down_{i-1} \cup \{q\}$. As discussed above, to construct the first 5-tuple we had to take the new point q as new pivot with probability $1/(1+|S_1|)$. In general, constructing $(\widetilde{S}_i, \widetilde{S}'_i, \widetilde{p}_i, \widetilde{q}_i, \widetilde{\delta}_i)$ from $(S_i, S'_i, p_i, q_i, \delta_i)$ requires that up to $3^D + 1$ points (q as well as the points in $down_{i-1}$) be considered as new pivots and also increases the chance of one of these points being closer to the old pivot than the pivot's previous nearest neighbor. This would result in a rebuilding (see Figure 6), but as the probabilities only increase by a constant factor, the effect is negligible.

If no rebuilding takes place, we determine $\widetilde{S}'_i$, the set of sparse points in $\widetilde{S}_i$. We define the set $down_i$, which consists of the points of S that were already sparse at some level $j \le i$ but that will not be sparse at level i due to the insertion of q, as follows. Let $D_i := S'_i \cup down_{i-1}$. Then

$$down_i := N_i(q, D_i) = \{x \in D_i \,:\, x \in N_i(q)\}. \tag{6}$$

The set D_i is called the "candidate set" for $down_i$. We can compute $\widetilde{S}'_i$ as follows: throw out from D_i all elements that belong to $down_i$ and add q, if it is sparse in $\widetilde{S}_i$. (We shall prove later that the set $\widetilde{S}'_i$ computed in this way actually *is* the set of sparse points in $\widetilde{S}_i$.)

We have constructed the 5-tuple $(\widetilde{S}_i, \widetilde{S}'_i, \widetilde{p}_i, \widetilde{q}_i, \widetilde{\delta}_i)$ and can now compute $\widetilde{S}_{i+1} = \widetilde{S}_i \setminus \widetilde{S}'_i$, the next subset of our new sparse partition for $\widetilde{S}$. If $q \in \widetilde{S}'_i$ then, by the

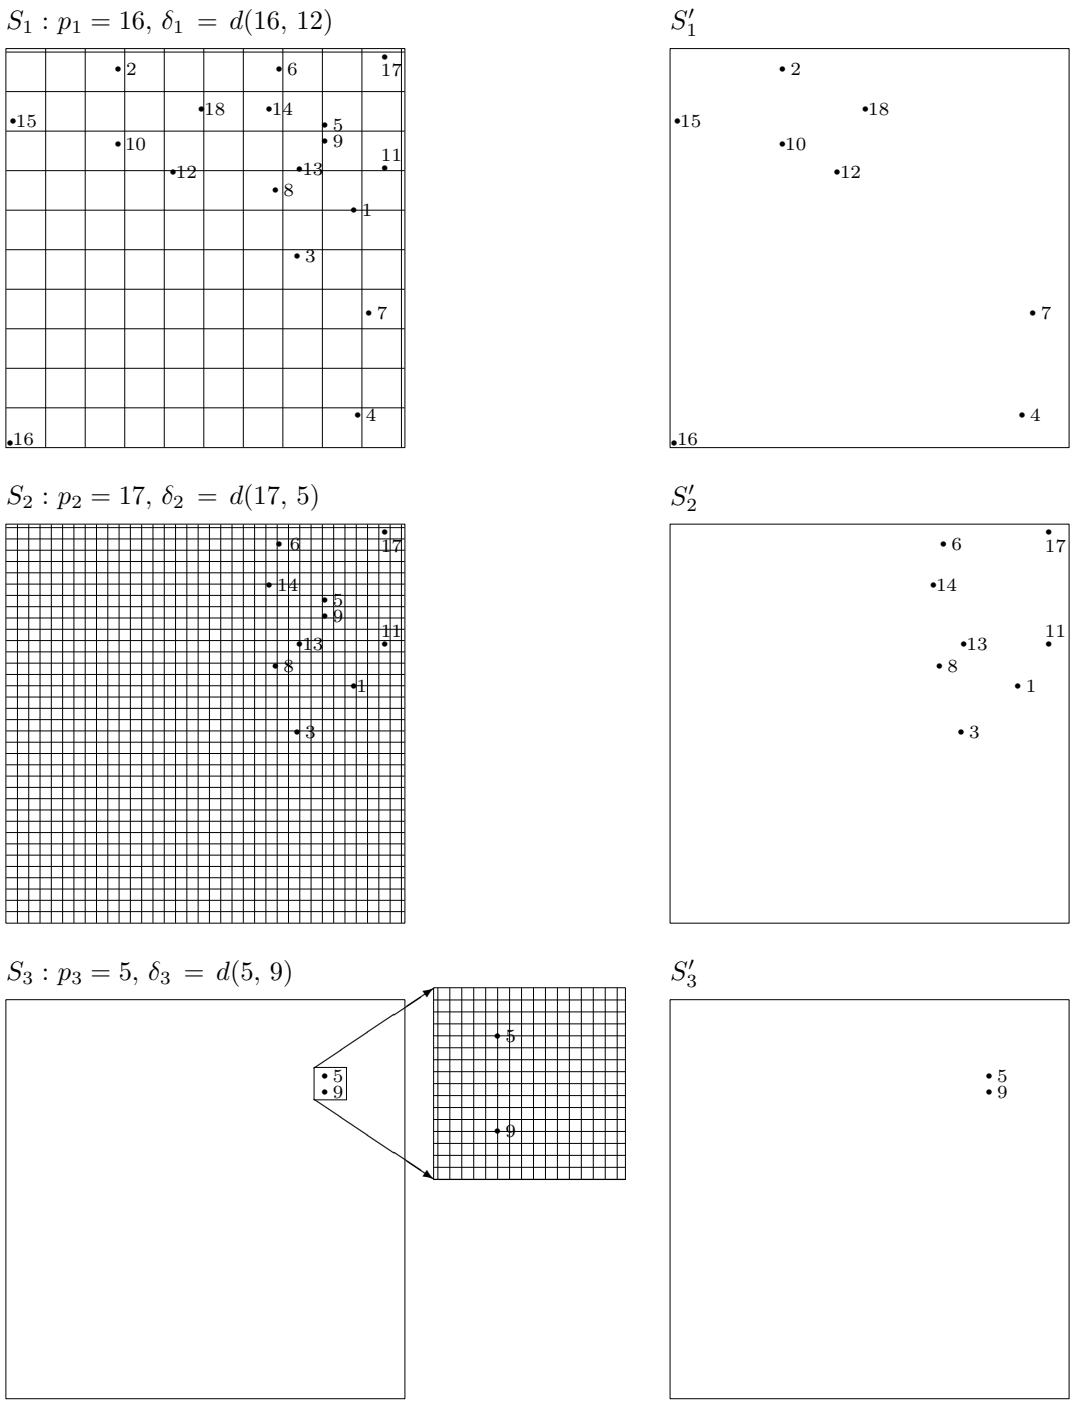

FIG. 4. *This is the sparse partition that resulted when point* 18 *was inserted into the sparse partition of the previous example. Point* 18 *was not chosen to be the pivot and was sparse in* S_1 *with the old pivot* $p_1 = 16$. *Thus* $18 \in S_1'$.

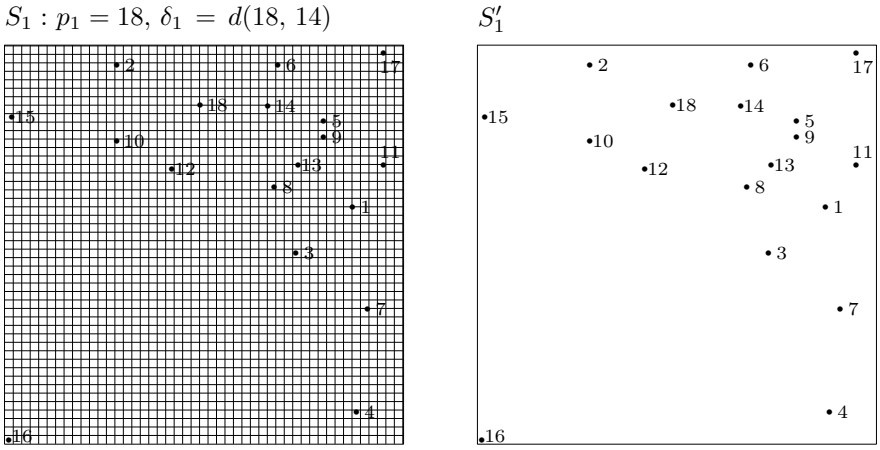

FIG. 5. *This is the sparse partition that results when the same point* 18 *is inserted as in the previous example but with point* 18 *now being chosen to be the pivot, something that occurs with probability* 1/18. *Note that in this case every point in* S_1 *becomes sparse so the partition only has one level.*

definition of the *down* sets, $down_i = \emptyset$ and $S_{i+1} = \widetilde{S}_{i+1}$. This means that the levels $i+1, \ldots, L$ of the sparse partition remain unchanged, and we are finished with the construction of the sparse partition for $\widetilde{S}$. Otherwise, $q \in \widetilde{S}_{i+1}$. So q and the points in $down_i$ are not sparse in $\widetilde{S}_i$ and we can add q and $down_i$ to S_{i+1}, giving the set $\widetilde{S}_{i+1}$. The invariant $\mathsf{INS}(i+1)$ holds, as we will prove later. We then continue with level $i+1$.

After the sparse partition has been updated, it remains to update the heaps. It is clear that the new point q has to be inserted into the heap structure appropriately. To see what kind of changes will be performed for the points of S, let us examine the point movements between the different levels of the sparse partition due to the insertion of q more closely. Let us look at level i, where $i \geq 1$. From invariant $\mathsf{INS}(i)$ (b) (respectively, $\mathsf{INS}(i+1)$ (b)), the points in $down_{i-1}$ (respectively, $down_i$) move at least down to level i (respectively, level $i+1$). The construction rule for $\widetilde{S}'_i$ now implies $\widetilde{S}'_i \setminus \{q\} = (S'_i \cup down_{i-1}) \setminus down_i$. Thus we have the following lemma.

LEMMA 4.1. *Let* p *be a point in* S*:*

(i) $p \in down_i \setminus down_{i-1} \iff p \in S'_i$ *and* $p \notin \widetilde{S}'_i$,
(ii) $p \in down_{i-1} \setminus down_i \iff p \notin S'_i$ *and* $p \in \widetilde{S}'_i$,
(iii) $p \in down_{i-1} \cap down_i \iff p \notin S'_i$ *and* $p \notin \widetilde{S}'_i$.

That is, the points in (i) *start moving* at level i, the points in (ii) *stop moving* at level i, and the points in (iii) *move through* level i. For all the points satisfying (i) or (ii), we have to update the heaps where values associated with these points disappear (i) or enter (ii).

The complete insertion algorithm is given in Figure 7.

It remains to describe the procedures that actually perform the heap updates. Before we do this, however, we will show that steps 1–3 in lines (3)–(21) of the algorithm actually produce a sparse partition for the new set $\widetilde{S}$.

LEMMA 4.2. *Assume algorithm Insert*(q) *has computed* 5*-tuples* $(\widetilde{S}_j, \widetilde{S}'_j, \widetilde{p}_j, \widetilde{q}_j, \widetilde{d}_j)$, $1 \leq j < i$, *and a set* $\widetilde{S}_i$ *that satisfy* $\mathsf{INS}(i)$. *Then if no rebuilding occurs, the* i*th*

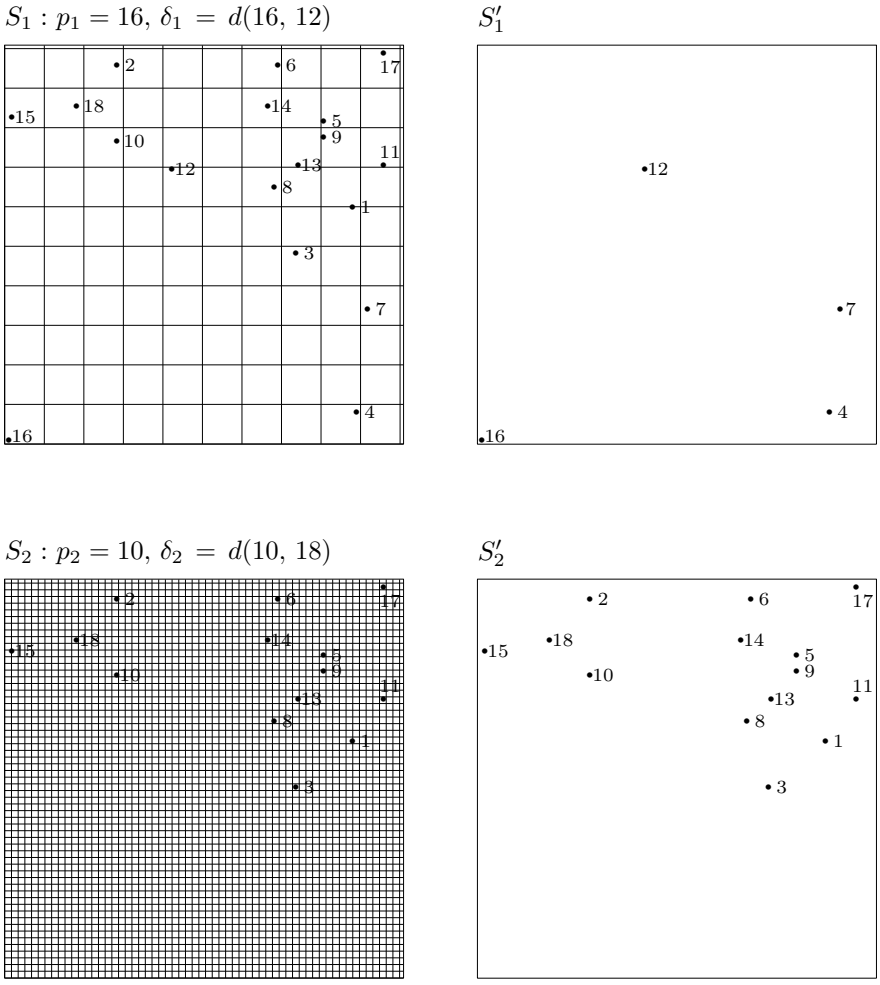

FIG. 6. *In this diagram a different point* 18 *is added to the first sparse partition. This point* 18 *is not sparse; it has neighbors* 2, 15, *and* 10. *In fact, because of the insertion of* 18, *these three points, which used to be sparse, are no longer sparse and are therefore placed in* $down_1$. *When the algorithm reached* S_2 *it then decided, probabilistically, that* 10 *should be the new pivot of that level. After making* 10 *the pivot, it found that all points were sparse and so terminated the algorithm.*

iteration of the algorithm constructs the 5*-tuple* $(\widetilde{S}_i, \widetilde{S}'_i, \widetilde{p}_i, \widetilde{q}_i, \widetilde{\delta}_i)$ *and the set* $\widetilde{S}_{i+1}$, *which satisfy* $\mathsf{INS}(i+1)$ (a.1)–(a.2). *Furthermore, if* $q \notin \widetilde{S}'_i$, *then* $\mathsf{INS}(i+1)$ (b) *also holds.*

Proof. Let us first prove (a.1), saying that the 5-tuple $(\widetilde{S}_i, \widetilde{S}'_i, \widetilde{p}_i, \widetilde{q}_i, \widetilde{\delta}_i)$ satisfies Definitions 3.1 and 2.2, with $\widetilde{p}_i = p_i, \widetilde{q}_i = q_i$, and $\widetilde{\delta}_i = \delta_i$. The 5-tuple is certainly uniform, and it retains the pivot as well as the pivot's nearest neighbor when the algorithm has passed step 2 (check for rebuild) of the algorithm without a rebuilding; cf. the discussion at the beginning of this section.

It remains to show that $N_i(p, \widetilde{S}_i) = \emptyset \iff p \in \widetilde{S}'_i$ for any $p \in \widetilde{S}_i$; see Definition 3.1, 1(d). We have $\widetilde{S}_i = S_{i+1} \cup S'_i \cup down_{i-1} \cup \{q\}$ from invariant $\mathsf{INS}(i)$ (b). Since $N_i(p, \widetilde{S}_i) \neq \emptyset$ for $p \in S_{i+1}$, it remains to prove the claim for $p \in D_i = S'_i \cup down_{i-1}$

(1) **Algorithm** Insert (q);
(2) **begin**
(3) **1. initialize:** $i := 1$; $down_0 := \emptyset$; $h := \infty$
(∗ From invariant $\mathsf{INS}(i)$ (b), we know that $\widetilde{S}_i = S_i \cup down_{i-1} \cup \{q\}$. We want to determine $\widetilde{S}'_i$. Before that, we check if the data structure has to be rebuilt. ∗)
2. check for rebuild:

(26) **forall** $p \in down_{\ell-1} \setminus down_\ell$ **do**
(27) addtoheap(p, ℓ)
(28) **od**;
(29) **od**;
(30) **if** $q \in \widetilde{S}'_{\min\{i,h\}}$ **then**
(31) addtoheap$(q, \min\{i, h\})$
(32) **fi**;
(33) **end**;

FIG. 7. *Algorithm Insert*(q). *The heap update procedures* addtoheap *and* removefromheap *called in step* 4 *will be given later.*

and $p = q$. Note that since $D_i \subseteq S \setminus S_{i+1}$ we have $N_i(p, S) = \emptyset$ by Lemma 3.4 and, therefore, for any $p \in D_i$,

$$\begin{aligned} N_i(p, \widetilde{S}_i) = \emptyset &\iff q \notin N_i(p) \\ &\iff p \notin N_i(q) && \text{by symmetry (N.3)} \\ &\iff p \notin \mathit{down}_i && \text{by definition of } \mathit{down}_i \\ &\iff p \in \widetilde{S}'_i && \text{by definition of } \widetilde{S}'_i. \end{aligned}$$

If $p = q$, then $N_i(p, \widetilde{S}_i) = \emptyset \iff q \in \widetilde{S}'_i$ by lines (17)–(19).

Next, we show that $\widetilde{S}_{i+1} = \widetilde{S}_i \setminus \widetilde{S}'_i$. After line (16), we have $\widetilde{S}_{i+1} = S_{i+1} \cup \mathit{down}_i$ and $\widetilde{S}'_i = (S'_i \cup \mathit{down}_{i-1}) \setminus \mathit{down}_i$, and at the end of step 3, q has been added to exactly one of these sets. Thus $\widetilde{S}_{i+1} \cup \widetilde{S}'_i = (S_{i+1} \cup S'_i) \cup \mathit{down}_{i-1} \cup \{q\} = S_i \cup \mathit{down}_{i-1} \cup \{q\}$ which equals $\widetilde{S}_i$ by $\mathsf{INS}(i)$ (b). Since $\widetilde{S}_{i+1}$ and $\widetilde{S}'_i$ are disjoint, it follows that $\widetilde{S}_{i+1} = \widetilde{S}_i \setminus \widetilde{S}'_i$.

Finally, if $q \notin \widetilde{S}'_i$, $\mathsf{INS}(i+1)$ (b) holds because $\widetilde{S}_{i+1} = S_{i+1} \cup \mathit{down}_i \cup \{q\}$ by lines (16) and (20). □

COROLLARY 4.1. *At the end of step* 3 *of algorithm Insert, we have computed a uniform sparse partition for* $\widetilde{S}$ *according to Definitions* 3.1 *and* 2.2.

Proof. Refer to Figure 7. Let $\hat{\imath}$ denote the value of i after the last completion of step 3. This in particular means that for each level $1 \le j < \hat{\imath}$, no rebuilding has yet occurred and $q \notin \widetilde{S}'_j$. By induction on the number of levels, $\mathsf{INS}(\hat{\imath})$ (a)–(b) hold. (We have already seen that $\mathsf{INS}(1)$ vacuously holds, forming the base of the induction. The induction step is established by Lemma 4.2.)

Invariant $\mathsf{INS}(\hat{\imath})$ (a) implies that the 5-tuples at levels $1, \ldots, \hat{\imath} - 1$ satisfy Definitions 3.1 and 2.2. Now the last iteration at level $\hat{\imath}$ is either a rebuilding or produces a 5-tuple such that $q \in \widetilde{S}'_{\hat{\imath}}$.

In the former case, the algorithm $\mathit{Build}(\widetilde{S}_{\hat{\imath}}, \hat{\imath})$ computes a uniform sparse partition for $\widetilde{S}_{\hat{\imath}}$, and the result is a uniform sparse partition for the set $\widetilde{S}$.

In the latter case, another application of Lemma 4.2 establishes $\mathsf{INS}(\hat{\imath}+1)$ (a). Let $\widetilde{L}$ denote the number of levels of the partition at the end of step 3. If $\widetilde{L} = \hat{\imath}$, then all the levels have been reconstructed and satisfy Definitions 3.1 and 2.2. Otherwise, if $\widetilde{L} > \hat{\imath}$, then some levels of the partition have not been reconstructed and thus $\widetilde{L} = L$. In this case, the 5-tuples for $\widetilde{S}_j$ are the old 5-tuples for S_j, $\hat{\imath} < j \le L$, which fulfill the desired property anyway. Therefore, all the 5-tuples $(\widetilde{S}_i, \widetilde{S}'_i, \widetilde{p}_i, \widetilde{q}_i, \widetilde{\delta}_i)$, $1 \le i \le \widetilde{L}$, are uniform and $\widetilde{S}_{i+1} = \widetilde{S}_i \setminus \widetilde{S}'_i$ for $1 \le i < \widetilde{L}$. It follows that this set of 5-tuples is a uniform sparse partition for $\widetilde{S}$. □

Having established the correctness of the algorithm, we now go into the implementation details in order to establish the running time. First, as promised, we examine the sizes of the *down* sets. The crucial fact which enables us to estimate the total size of the *down* sets is that at any level of the partition, only the new point q can make a previously sparse point nonsparse. We express this in the following lemma.

LEMMA 4.3. *Let the sets* $\mathit{down}_j, 1 \le j \le i$, *be defined, and let* $p \in \mathit{down}_j$ *for a level* $j \in \{1, \ldots, i\}$. *Then*

(1) $p \in N_j(q)$ *and*

(2) $N_j(p, S) = \emptyset$.

Proof. The first claim is obvious from the definition of down_j; cf. equation (6). The second claim is true because $p \in \mathit{down}_j$ implies $p \in S \setminus S_{j+1}$, and by Lemma 3.4, $N_j(p, S) = \emptyset$ for each $p \in S \setminus S_{j+1}$. □

LEMMA 4.4. *Let the sets $down_0, \ldots, down_i$ be as defined in equation* (6). *Then*

$$\Big| \bigcup_{1 \le j \le i} down_j \Big| \le 3^D.$$

Proof. Assume that $p \in down_j$ for some $j \le i$. Then $p \in N_j(q)$ and $N_j(p, S) = \emptyset$ by Lemma 4.3. Moreover, let $\Psi \in \{-1, 0, 1\}^D$ be such that $p \in b_j^\Psi(q)$. The partial neighborhood $N_j^\Psi(q)$ is the intersection of q's neighborhood with the neighborhood of p in the grid $\mathcal{G}_j$. Refer to Figures 2 and 3. Since $N_j(p, S) = \emptyset$, $N_j^\Psi(q)$ contains no point of $S \setminus \{p\}$.

Now consider a point $p' \in down_\ell$ for any $\ell > j$. From Lemma 4.3, we know that $p' \in N_\ell(q)$. Furthermore, assume that p' is in the box of q's neighborhood with signature Ψ; i.e., $p' \in b_\ell^\Psi(q)$. Since $\delta_\ell \le \delta_{j+1} \le \delta_j/2$ by Lemma 2.1(2), Lemma 3.3 (property (N.5)) gives $p' \in N_j^\Psi(q)$, from which it follows that p' must be identical to p.

This means that at levels $j + 1 \le \ell \le i$, there cannot be any point in $down_\ell$ with signature Ψ except p itself. (Note that a point can be in several *down* sets.) It follows that for each $\Psi \in \{-1, 0, 1\}^D$, there is at most one point p in S which satisfies $p \in down_j \wedge p \in b_j^\Psi(q)$. □

Computing the *down* sets in constant time. We have just shown that the total size of the *down* sets is constant, implying in particular that each single *down* set has constant size. Now we show that, given the candidate set $D_i = S_i' \cup down_{i-1}$, where S_i' is stored according to grid $\mathcal{G}_i$, we can compute $down_i$ in constant time. According to equation (6), we want to find all $p \in S_i' \cup down_{i-1}$ such that $p \in N_i(q, S_i' \cup down_{i-1})$. How do we find these points? The elements in S_i' are already stored at that level, whereas the elements in $down_{i-1} \cup \{q\}$ are not. We tentatively insert these points into the data structure storing the sparse set S_i' and then search in the neighborhood of q. This proves that we can find $down_i$ in constant time.

Performing the changes in the data structures storing the sparse partition. Of course, the changes from $(S_i, S_i', p_i, q_i, \delta_i)$ to $(\widetilde{S}_i, \widetilde{S}_i', \widetilde{p}_i, \widetilde{q}_i, \widetilde{\delta}_i)$ also have to be performed in the data structures that actually store the 5-tuple. We will now fill in these details.

The operations that we have to take care of are computing the new sparse set $\widetilde{S}_i'$ in lines (16) and (18) and computing the new set $\widetilde{S}_{i+1}$ in lines (16) and (20) of algorithm Insert.

To compute $\widetilde{S}_i' = (S_i' \cup down_{i-1}) \setminus down_i$, we just have to insert and delete a constant number of points in the data structure storing the sparse set S_i'. To insert a point p into $\widetilde{S}_i'$ (respectively, $\widetilde{S}_{i+1}$), we add p to the list $\mathcal{L}'(b)$ (respectively, $\mathcal{L}(b)$) where b is the box containing p. We also have to insert the box b into the box dictionary of the grid data structure, if it was not there before. This takes $O(1)$ expected time. (The same holds for the deletion of a box from the box dictionary.)

Now let us turn to the deletion of points. Note that during the insertion algorithm, deletions are performed in the sparse sets S_i'; more specifically there may be points that are in S_i' but are not in $\widetilde{S}_i'$. We can easily delete those points because we know that the lists $\mathcal{L}'(b)$ can only contain a constant number of points: at most one point at the start of the operation by the sparseness property, plus the points in $down_{i-1}$ that might have been tentatively inserted into the list. We remark here that instead of actually deleting the points of $down_i$ from the data structure storing the sparse set, we only *mark* them as deleted. The reason for this is that in step 4 when we

update the heaps we need to access both the old set S_i' and the new set $\widetilde{S}_i'$. The actual deletions will be performed after step 4 has been completed.

The lists $\mathcal{L}(b)$ for the nonsparse set S_{i+1} can contain more than a constant number of points. However, observe that a point is only deleted from a nonsparse set S_{i+1} during the insertion algorithm if a rebuilding occurs.

To sum up, performing the changes from the old 5-tuple $(S_i, S_i', p_i, q_i, \delta_i)$ to the new 5-tuple $(\widetilde{S}_i, \widetilde{S}_i', \widetilde{p}_i, \widetilde{q}_i, \widetilde{\delta}_i)$ of the sparse partition takes $O(1 + |down_{i-1}| + |down_i|)$ expected time.

LEMMA 4.5. *Steps* 1–3 *of algorithm Insert*(q) *take expected time* $O(\log n)$.

Proof. Consider one iteration of the steps 2 and 3. If no rebuilding occurs, the running time of step 2 is constant. (Recall that we assume that we can obtain a random number of $O(\log n)$ bits in constant time.) By the discussion in the two paragraphs before the lemma, the expected running time of step 3 at level i is $O(1 + |down_{i-1}| + |down_i|) = O(1)$.

We now give a probabilistic analysis for the insertion time, taking rebuildings into account. We show that the expected running time over all iterations of steps 1–3 is $O(\log n)$. The expectation is taken both over the new random choices and over the expected state of the old data structure.

Let the initial set of tuples be $(S_i, S_i', p_i, q_i, \delta_i)$, $1 \le i \le n$, padding the sequence out with empty tuples if necessary. Let T_i be the time to construct $\widetilde{S}_i$ from S_i assuming no rebuilding has taken place while constructing $\widetilde{S}_1, \ldots, \widetilde{S}_{i-1}$. Clearly, the overall running time X satisfies $X \le \sum_{i=1}^{n} T_i$. For $1 \le i \le n$, we have the following: with probability at most $\min(1, c/|S_i|)$ for some constant c, a rebuilding happens at level i and, therefore, $\mathrm{E}(T_i) = O(|S_i|)$ in this case. Otherwise, $\mathrm{E}(T_i) = O(1)$. These expected time bounds stem from the running times of the hashing algorithms that are used to rebuild or to update the structure, respectively. Since the random choices made by the hashing algorithms are independent of the coin flips made by our algorithms Insert and Build to choose the pivots, we can multiply the probabilities of the events with the expected running times that are valid for the event and so obtain that the expected value of T_i is $O(1)$, independently of the previous state of the data structure.

We now note that $\mathrm{E}(\sum_{i=k}^{n} T_i) = O(|S_k|)$ for any $1 \le k \le n$. This is because either a rebuild occurs at level k, requiring $O(|S_k|)$ expected time, and we are done. Otherwise $\mathrm{E}(T_k) = O(1)$ and by induction, $\mathrm{E}(\sum_{i=k+1}^{n} T_i) = O(|S_{k+1}|)$. Since $|S_{k+1}| \le |S_k| - 1$ (the pivot at level N is always sparse) we can choose the constant within the Big-Oh large enough to conclude that $\mathrm{E}(\sum_{i=k}^{n} T_i) = O(|S_k|)$ in this case as well.

Let $N = \lceil \log n \rceil$. From the above discussion,

$$\begin{aligned}\mathrm{E}(X) &\le \sum_{i=1}^{N} \mathrm{E}(T_i) + \mathrm{E}\left(\sum_{i=N+1}^{n} T_i\right) \\ &\le O(\log n) + O(\mathrm{E}(|S_{N+1}|)) = O(\log n)\end{aligned}$$

since $\mathrm{E}(|S_{\lceil \log n \rceil + 1}|)$ is $O(1)$. □

Remark. Note that not only is the running time at each level of the sparse partition a random variable, but also the number of levels is a random variable, and its value can be as high as n. This means in particular that the running times of consecutive update operations are not independent.

Discussion of the heap updates. We are now ready to discuss step 4 of the insertion algorithm. Heap updates are necessary when points move to a different level due to the insertion of q.

```
(1)   proc removefromheap(p, h);
(2)   begin
(3)       (* p starts moving at level i, i.e., p ∈ S'_i, but p ∉ S̃'_i *)
(4)       DELETE(H_i, it(p));
(5)       for ℓ := i to min{i + D, h} do
(6)           forall r ∈ S'_ℓ ∩ S̃'_ℓ such that d(r, p) < δ_ℓ do
(7)               CHANGE_KEY(it(r), d*_ℓ(r))
(8)           od
(9)       od;
(10)  end;
```

FIG. 8. *Procedure removefromheap*(p, h).

Assume point p moves to a different level. Then heap updates are necessary (i) when p starts moving at level i and (ii) when p stops moving at some level j, where $i < j$. In the first case, we basically perform a deletion of the heap values associated with p, while in the second case we perform the corresponding reinsertions into the heap structure. Note that the latter case does not occur if the data structure has been rebuilt at some level $i < l \leq j$. In this case, the rebuilding algorithm inserts the values associated with p into the heap structure.

Note that at each level i a point can be associated with only a constant number of heap values, which are located in the heaps $H_\ell, i \leq \ell \leq i + D$. From Lemma 2.3(3), we know that $d_i^*(p) = \min\left(\delta_i, d(p, S'_{i-D} \cup \cdots \cup S'_i)\right)$. Thus a point $p \in S'_i$ can be associated with a heap in two different ways: either there is a value $d_i^*(p)$ in H_i or for each $i \leq \ell \leq i + D$ there may be points $r \in S'_\ell$ such that $d(r, p)$ gives rise to $d_\ell^*(r)$ in H_ℓ.

Recall that $\widetilde{L}$ denotes the last level of the sparse partition *after* the update. In our heap update procedures given below, we want to rearrange the heaps such that heap $H_j, 1 \leq j \leq \widetilde{L}$, contains the values

$$\left\{ d_j^*(p) = \min\left(\widetilde{\delta}_j, d(p, \widetilde{S}'_{j-D} \cup \cdots \cup \widetilde{S}'_j)\right) \ : \ p \in \widetilde{S}'_j \right\}.$$

At the moment, the heaps contain the restricted distances w.r.t. the old sparse partition, except for the levels that have been rebuilt. We therefore take care that we only rearrange heaps at levels that have not been rebuilt. In step 4, a parameter h occurs. It denotes the last level that has not been rebuilt if such a rebuilding has taken place. Otherwise, $h = \infty$. The heap update procedures are shown in Figures 8 and 9.

LEMMA 4.6. *After step* 4 *of algorithm Insert*(q)*, the heap* H_i *stores the set* $\{d_i^*(p) \ : \ p \in \widetilde{S}'_i\}$ *for all levels* $1 \leq i \leq \widetilde{L}$*. Also, the running time of the procedures* addtoheap *and* removefromheap *is* $O(1)$ *plus the time spent on the heap operations. The number of heap operations that are performed in step* 4 *is constant.*

Proof. Recall that at the beginning of step 4 the new sparse partition is computed, and since the elements of S'_i that are not in $\widetilde{S}'_i$ have only been marked deleted, we have both sparse sets at hand at each level.

Notation. For each level i, we call points that remain sparse, i.e., the points in $S'_i \cap \widetilde{S}'_i$, the *passive* points and the points that cease or start being sparse, i.e., the points in $(S'_i \setminus \widetilde{S}'_i) \cup (\widetilde{S}'_i \setminus S'_i)$, the *active* points.

Claim. Exactly those restricted distances which can change due to the change of the sparse partition and which have not been handled by rebuilding have been treated by the procedures shown in Figures 8 and 9.

```
(1)   proc addtoheap(p, h);
(2)   begin
(3)       (* p stops moving at level j, i.e., p ∉ S'_j, but p ∈ S̃'_j *)
(4)       compute d*_j(p); let r be such that d*_j(p) = d(r, p) if it exists;
(5)       it(p) := new item; it(p).key := d*_j(p); it(p).point := p; it(p).point2 := r;
(6)       INSERT(H_j, it(p));
(7)       for ℓ := j to min{j + D, h} do
(8)           forall r ∈ S'_ℓ ∩ S̃'_ℓ such that d(r, p) < δ_ℓ do
(9)               CHANGE_KEY(it(r), d*_ℓ(r))
(10)          od
(11)      od;
(12)  end;
```

FIG. 9. *Procedure addtoheap*(p, h).

Proof of claim. At the beginning of step 4, we know h, the index of the last level for which heap H_h has to be reconstructed, if a rebuilding has taken place. In this case, the data structure has been rebuilt at level $h+1$. (Otherwise $h = \infty$.) We can therefore guarantee that our heap update procedures do not treat levels whose heaps have already been correctly computed by a rebuilding.

Now consider the levels where the heaps have to be rearranged. Heap H_i contains the restricted distances of points $p \in S'_i$ to points in $S'_{i-D} \cup \cdots \cup S'_i$. For the active points, the claim is clear: these are the points in the symmetric difference of S'_i and $\widetilde{S}'_i$. By Lemma 4.1, these are exactly the points in the symmetric difference of $down_{i-1}$ and $down_i$. Our heap update procedures are called exactly for these points and the restricted distances of these points are deleted in line (4) of removefromheap and inserted in line (6) of addtoheap, respectively.

For a passive point p, we only have to examine, at levels $j = i, \ldots, i-D$, the points that are

1. active at level j and
2. closer to p than the threshold distance δ_i.

These are exactly the points that are treated in lines (5)–(9) of removefromheap and in lines (7)–(11) of addtoheap.

Also note that for every point that is treated by the heap update procedures, either the corresponding heap item is deleted, if it belongs to the set of points that ceases being sparse at that level, or its restricted distance according to the new sparse partition is computed (and inserted if it is a point that starts being sparse). This establishes the correctness of the heap update procedures and step 4 of algorithm Insert.

Now let us look at the running time of the heap update procedures. Each restricted distance can be computed in $O(1)$ time by Lemma 3.5. Moreover, from the proof of Lemma 3.5 we know that the restricted distances can be computed by searching the area of at most $4D$ boxes away from p in the grids that store the sparse sets $S'_{i+l}, 0 \le l \le D$. Outside this area, the restricted distance of a point r cannot be affected by removal or insertion of p. Since we assume that the dimension D is fixed, the total number of heap operations carried out by the procedure is constant, and the time spent by the procedure not counting the heap operations is also constant. □

LEMMA 4.7. *Algorithm Insert*(q) *correctly maintains the data structure and takes expected time* $O(\log n)$.

Proof. From Lemma 4.2, steps 1–3 establish that $S \cup \{q\}$ is stored uniformly as a sparse partition. Also, from Lemma 4.6, the heaps are maintained correctly by step 4. This proves the correctness of the algorithm.

As shown in Lemma 4.5, steps 1–3 have expected cost $O(\log n)$. Now consider step 4. From Lemma 4.4 we know that the heap update procedures are only called for a constant number of points. Since by Lemma 4.6 one procedure call only performs $O(1)$ heap operations and, apart from these operations, performs only $O(1)$ additional work, the total time for step 4 is $O(\log n)$. ∎

4.2. The deletion algorithm. Now we come to the algorithm that deletes a point q from the data structure. Let $\widetilde{S}$ denote $S \setminus \{q\}$. Deletion is basically the reverse of insertion and may involve some points becoming sparse at their current levels due to the deletion of q, thus causing them to move up a few levels. In particular, points which move to lower levels during an insertion of q move back to their old levels when q is deleted directly afterward (provided no rebuilding takes place).

An insertion ends at the level where the new point q is sparse. Therefore, assuming that $q \in S'_\ell$, we have to delete q from S'_ℓ and also from all the sets S_i, $1 \le i \le \ell$. Note that in order to be able to delete q efficiently from the nonsparse sets S_i containing it, we linked the occurrence of a point in S_i to its occurrence in S_{i-1} and vice versa, if the corresponding level exists.

Although it looks natural to implement a deletion starting at the level ℓ where q is sparse and then walking up the levels, it is much easier to implement the deletion algorithm in a top-down fashion, as in the insertion algorithm. In the insertion algorithm, we collected in $down_i$ the points that were sparse at some level $j \le i$ but that were no longer sparse at level i due to the insertion of q. Now we want to collect in up_i the points that are nonsparse at level i but will be sparse there after a deletion.

The deletion algorithm starts at the top level and moves downward, as algorithm Insert. We define $up_0 := \emptyset$. Let $i \ge 1$. The following invariant, which is analogous to invariant $\mathsf{INS}(i)$ in algorithm Insert, holds if the algorithm attempts to construct the 5-tuple for $\widetilde{S}_i$ without having performed a rebuilding yet.

Invariant $\mathsf{DEL}(i)$

(a) This invariant is identical to $\mathsf{INS}(i)$, saying that the new 5-tuples at the levels $1, \ldots, i-1$ satisfy Definitions 3.1 and 2.2.

(b) The sets $up_j, 0 \le j < i$, have been computed and $\widetilde{S}_i = (S_i \setminus up_{i-1}) \setminus \{q\}$.

Note that at the start of the algorithm, $\mathsf{DEL}(1)$ holds because $up_0 = \emptyset$.

To construct the 5-tuple for $\widetilde{S}_i$, the deletion algorithm first checks if a rebuilding has to be performed, as does the insertion algorithm. Having done that, it constructs the new sparse set $\widetilde{S}'_i$ and, along with it, the nonsparse set $\widetilde{S}_{i+1}$. $\widetilde{S}'_i$ is computed from the previous sparse set S'_i by adding the points of up_i and deleting the points of up_{i-1}. Also, we obtain $\widetilde{S}_{i+1}$ by deleting the points of up_i from S_{i+1}. Now, q is still in $\widetilde{S}'_i$ or $\widetilde{S}_{i+1}$, depending on whether it was previously in S'_i or S_{i+1}, respectively. Deleting q from the set containing it finishes the computation of $\widetilde{S}'_i$ and $\widetilde{S}_{i+1}$. If q was sparse at level i, then $S_{i+1} = \widetilde{S}_{i+1}$ and the construction of the new sparse partition is complete. (Note that up_i must be empty in this case.) Otherwise, we go into the next iteration and construct the 5-tuple for $\widetilde{S}_{i+1}$.

When the new sparse partition is computed, the heaps have to be updated. Analogously to the insertion algorithm, (i) $p \in up_{i-1} \setminus up_i$ means p *starts moving* at level i, i.e., $p \in S'_i$ and $p \notin \widetilde{S}'_i$, (ii) $p \in up_i \setminus up_{i-1}$ means p *stops moving* at level i, i.e., $p \notin S'_i$ and $p \in \widetilde{S}'_i$, and (iii) $p \in up_{i-1} \cap up_i$ means that p *moves through* level i, i.e., $p \notin S'_i$

(1) **Algorithm** Delete (q);
(2) **begin**
(3) **1. initialize:** $i := 1$; $up_0 := \emptyset$; $h := \infty$
($*$ From invariant $\mathsf{DEL}(i)$ (b), we know that $\widetilde{S}_i = (S_i \setminus up_{i-1}) \setminus \{q\}$. $*$)
2. check for rebuild:
(4) ($*$ we do not need to flip a coin for a new pivot $*$)
(5) **if** q or an element of up_{i-1} is the pivot p_i or the nearest neighbor of p_i
(6) **then** $Build(\widetilde{S}_i, i)$; $h := i - 1$; goto **4.**
(7) **fi**; ($*$ $d_i = d(p_i, S_i) = d(p_i, \widetilde{S}_i)$ $*$)
3. Determine $\widetilde{S}'_i$:
(8) compute $up_i = \left\{p \in S_i \ : \ N_i(p, S_i) = \{q\}\right\}$;
(9) $\widetilde{S}'_i := (S'_i \cup up_i) \setminus up_{i-1}$; $\widetilde{S}_{i+1} := S_{i+1} \setminus up_i$; ($*$ now $\widetilde{S}_{i+1} \cup \widetilde{S}'_i = \widetilde{S}_i \cup \{q\}$ $*$)
(10) **if** $q \in \widetilde{S}'_i$ **then**
(11) delete q from $\widetilde{S}'_i$; goto **4.** ($*$ q is sparse in $\widetilde{S}_i$, and so $\widetilde{S}_{i+1} = S_{i+1}$ $*$)
(12) **fi**; ($*$ q is not sparse in $\widetilde{S}_i$ $*$)
(13) delete q from $\widetilde{S}_{i+1}$;
(14) $i := i + 1$; goto **2.**
4. Update heaps:
Completely analogous to algorithm Insert. At levels $1 \le \ell \le \min\{i, h\}$, we execute the heap update procedures for the points in the symmetric difference of up_{i-1} and up_i, and for the deleted point q, if we are on a level where q contributes a heap value.
(15) **end**;

FIG. 10. *Algorithm Delete*(q).

and $p \notin \widetilde{S}'_i$. As before, the points that start or stop moving cause heap updates. The deletion algorithm is described in Figure 10.

From the similarity of invariants $\mathsf{INS}(i)$(b) and $\mathsf{DEL}(i)$(b), it is easy to see that the arguments used in Lemma 4.4 to derive the bound on the size of the *down* sets carry over to the *up* sets, and thus we obtain $|\bigcup_{1 \le i \le L} up_i| \le 3^D$.

The computation of the *up* sets is slightly different from the computation of the *down* sets. In order to compute the *down* sets efficiently, we gave an alternative but equivalent definition for these sets (equation (6)) and showed that the alternative definition could be efficiently realized. The difficulty there was that the points in $down_i$ could come from the set $S \setminus S_{i+1} = S'_1 \cup \cdots \cup S'_i$, and there seemed to be no direct way of extracting the points of $down_i$ from this set. In contrast to the insertion case, the points that are nonsparse at level i but will be sparse there after a deletion are all contained in S_i. We can compute the set up_i in constant time as follows. From $\mathsf{DEL}(i)$(b), it follows that $p \in up_i$ if and only if $N_i(p, S_i) = \{q\}$. Checking this condition means finding all points in S_i having only q in their neighborhood. Using the symmetry property (N.3), this can be done in $O(1)$ time.

LEMMA 4.8. *Algorithm Delete*(q) *correctly maintains the data structure and takes expected time* $O(\log n)$.

Proof. The proofs of correctness and running time are analogous to those for the insertion algorithm and are therefore omitted. □

We summarize the results of this section in the following theorem:

THEOREM 4.1. *There exists a data structure which stores a set S of n points in $\mathbf{R}^D$ such that the minimal distance $\delta(S)$ can be found in $O(1)$ time, and all point pairs*

attaining $\delta(S)$ can be reported in time proportional to their number. The expected size of the structure is $O(n)$, and we can maintain the data structure as S is modified by insertions or deletions of arbitrary points in $O(\log n)$ expected time per update. The algorithms run on a RAM and use randomization. The bounds are obtained under the assumption that we know a frame that contains all the points that are in the set S at any time, that the floor function can be computed in constant time, and that the updates do not depend upon the random choices made by the data structure.

5. An algebraic computation tree implementation. The solution from the previous section uses a somewhat inelegant model, which is an uneasy marriage of the unit-cost RAM and the algebraic computation tree. This algorithm may also be a poor one to use in practice, as the integers (box indices) which are computed as intermediate results may be so large that they cannot be manipulated in constant time by the hashing routines. Even if we implement the box dictionary by search trees, dividing point coordinates by very small numbers (interpoint distances) may lead to numerical problems.

We now present an algorithm which fits into the algebraic computation tree model. It can be verified that the algorithm requires only addition, subtraction, comparison, and multiplication of real numbers to maintain the closest pair (although computing the actual value of the minimum distance $\delta(S)$ in the L_t-metric for $1 < t < \infty$ will require the tth root function as well). However, it is well known that the floor function used by the previous algorithm is very powerful: the maximum-gap problem requires $\Omega(n \log n)$ time in the algebraic computation tree model but can be solved in $O(n)$ time by adding this function. Hence, we may expect some increase in the time complexity of the operations, and this does indeed turn out to be the case.

Note that the floor function was only used to compute the grid box containing a given point. Therefore, we will modify the algorithm Theorem 4.1 by using a degraded grid for which we only need algebraic functions. The method we use already appears in [9] and [11]. We sketch the structure here and refer to these papers or [18] for details.

Consider a standard grid of mesh size δ. Fixing the origin as a lattice point, we divide the space into slabs of width δ in each dimension. Since we can identify a slab using the floor function, this gives rise to an *implicit* storage of the slabs. To avoid the use of the floor function, we store these slabs *explicitly* by keeping a dictionary for the coordinates of its endpoints in each dimension.

In contrast to the standard grid, a degraded grid is defined in terms of the point set stored in it. To emphasize this, we use the notation $\mathcal{DG}_{\delta,V}$ for a degraded δ-grid defined by the points of a set $V \subseteq \mathbf{R}^D$ in comparison with the grid $\mathcal{G}_\delta$. In a degraded δ-grid $\mathcal{DG}_{\delta,V}$, all boxes have sides of length at least δ, and the boxes that contain a point of V have sides of length at most 2δ. See Figure 11.

The degraded grid can be maintained under insertions and deletions of points in logarithmic time, and the box containing a point can be identified in logarithmic time as well.

In order to implement our data structure, we only have to define the sparse sets S'_i. The alignment of boxes in slabs enables us to transfer the notion of neighborhood directly from standard grids to degraded grids. The neighborhood of a box consists of the box itself plus the $3^D - 1$ boxes bordering on it.

Consider a degraded δ-grid $\mathcal{DG}_{\delta,V}$. As in the grid case, the neighborhood of a point $p \in \mathbf{R}^D$ is defined as the neighborhood of the box $b_{\delta,V}(p)$ that contains p; i.e., $N_{\delta,V}(p) := N(b_{\delta,V}(p))$. The notion of partial neighborhood is also defined analogously.

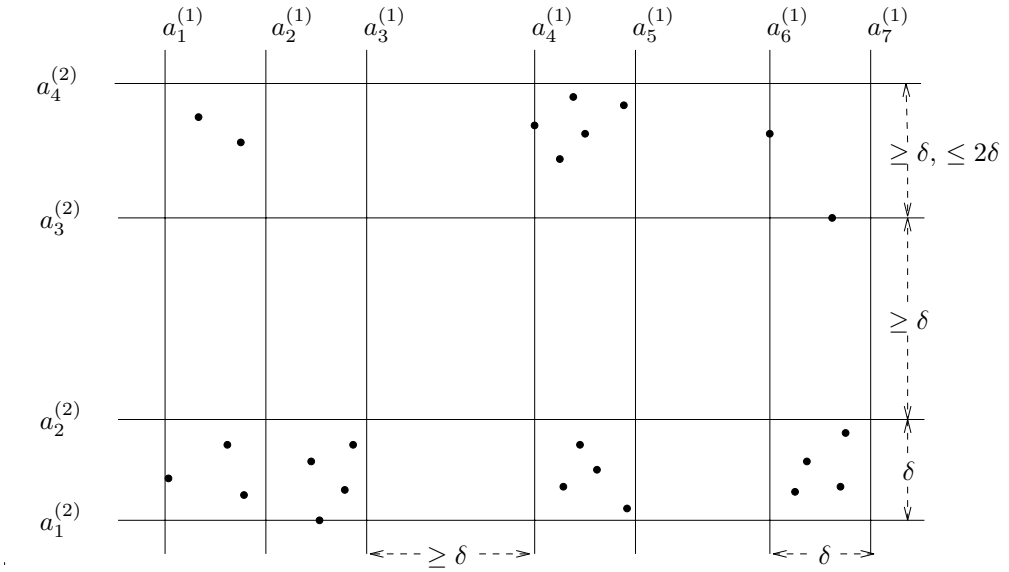

FIG. 11. *Example of a degraded δ-grid. It is dependent on the set stored in it.*

See Figure 2. We number the 3^D boxes in the neighborhood of a point p as described there, giving each box a *signature* $\Psi \in \{-1, 0, 1\}^D$. The box with signature Ψ is denoted by $b^{\Psi}_{\delta,V}(p)$. The boxes of p's neighborhood which are adjacent to $b^{\Psi}_{\delta,V}(p)$ form the *partial neighborhood of p with signature* Ψ, denoted by $N^{\Psi}_{\delta,V}(p)$.

We now define the neighborhood of a point relative to a set of points. For any set $\widehat{V}$, the neighborhood of p in $\mathcal{DG}_{\delta,V}$ relative to $\widehat{V}$, denoted by $N_{\delta,V}(p, \widehat{V})$, is defined as $N_{\delta,V}(p, \widehat{V}) := N_{\delta,V}(p) \cap (\widehat{V} \setminus \{p\})$. Note that in this definition the set $\widehat{V}$ need not be identical to the *defining set* V of the degraded grid. As before, we say that a point p is *sparse* in the degraded grid relative to $\widehat{V}$ if $N_{\delta,V}(p, \widehat{V}) = \emptyset$.

The basis of correctness and running time of the grid algorithms were the neighborhood properties (N.1)–(N.5). We now adapt these to handle degraded grids. Two changes are needed. First, we change the constants in response to the fact that a nonempty box might now have side length up to 2δ. Second, although we defined the neighborhood relative to a set $\widehat{V}$ independently of the defining set V of the degraded δ-grid, a lot of properties will only continue to hold if $\widehat{V} \subseteq V$. This is because boxes of a degraded δ-grid $\mathcal{DG}_{\delta,V}$ that do not contain a point of the defining set V may be unbounded. For example, this may cause a point $q \in \widehat{V}$ to be in the neighborhood $N_{\delta,V}(p)$ of a point $p \in \mathbf{R}^D$ even if it is arbitrarily far away from p.

LEMMA 5.1. *Let V be a set of points in $\mathbf{R}^D$, and let $p, q \in V$. Consider a degraded δ-grid $\mathcal{DG}_{\delta,V}$.*

(N.1') *If $q \notin N_{\delta,V}(p)$, then $d(p, q) > \delta$.*

(N.2') *If $q \in N_{\delta,V}(p)$, then $d(p, q) \leq 4D\delta$.*

(N.3') $q \in N_{\delta,V}(p) \iff p \in N_{\delta,V}(q)$.

LEMMA 5.2. *Let $0 < \delta' \leq \delta''/4$ be real numbers. Consider a degraded δ'-grid $\mathcal{DG}_{\delta',V'}$ and a degraded δ''-grid $\mathcal{DG}_{\delta'',V''}$, and let $p, q \in V'$. Then*

(N.4') $q \in N_{\delta',V'}(p) \implies q \in N_{\delta'',V''}(p)$.

(N.5') *For any signature $\Psi \in \{-1, 0, 1\}^D$, let $q \in b^{\Psi}_{\delta',V'}(p)$. Then $q \in N^{\Psi}_{\delta'',V''}(p)$.*

Proof. Refer to the proof of (N.4) and (N.5). By the organization of the degraded grid boxes in slabs, the argument carries over directly, except that we have to care about the width of the slabs. Since $p, q \in V'$, the slabs containing p and q w.r.t. each coordinate have width at most $2\delta'$. Since $\delta' \leq \delta''/4$, equations (2) and (3) hold, which proves (N.4'). Once (N.4') is proved, stating that the neighborhood in the smaller grid is contained in the neighborhood of the larger grid, (N.5') follows completely analogous to (N.5) by equations (4) and (5), because these equations hold by the definition of the hyperplanes employed in the proof. See Figure 3. □

Now we are ready to define our degraded grid-based sparse partition. Let $g_i := \delta_i/16D$. We store the set S_i in a degraded g_i-grid $\mathcal{DG}_{g_i,S_i}$. Analogously to equation (1) for standard grids, we define

$$S_i' := \{p \in S_i : p \text{ sparse in } \mathcal{DG}_{g_i,S_i} \text{ relative to } S_i\}. \tag{7}$$

The sparse set S_i' will also be stored in a degraded g_i-grid $\mathcal{DG}_{g_i,S_i}$. Defining the sets S_i' for each i by equation (7) yields a definition of a sparse partition analogous to the one given in Definition 3.1 for the grid case.

We adapt the abstract definition of the sparse partition (Definition 2.1) to degraded grids by changing "$\delta_i/2$" to "$\delta_i/4$" and "$\delta_i/4D$" to "$\delta_i/16D$." The bounds in Lemma 2.1 then become $\delta_i \leq \delta_{i+1}/4$ and $\delta_L/16D \leq \delta(S) \leq \delta_L$, respectively. The constants in the other lemmas of section 2 are changed analogously. Using a proof completely analogous to the one of Lemma 3.2, using (N.1')–(N.3') instead of (N.1)–(N.3), we get Lemma 5.3.

LEMMA 5.3. *Using the definition for S_i' given in equation* (7)*, we get a sparse partition according to Definition* 2.1*, with the constants changed as outlined above.*

The degraded grid-based data structure. For each $1 \leq i \leq L$, we have

- the pivot $p_i \in S_i$, its nearest neighbor q_i in S_i, and $\delta_i = d(p_i, q_i)$,
- S_i stored in a degraded g_i-grid $\mathcal{DG}_{g_i,S_i}$,
- S_i' stored in a degraded g_i-grid $\mathcal{DG}_{g_i,S_i}$,
- the heap H_i.

Now let us examine the update algorithms. In section 4, we defined the sets $down_i$. The definition remains the same here, with the notion of neighborhood in degraded grids. The *down* sets describe the point movements between the levels of the sparse partition during an insertion. Similarly, the *up* sets contain the points that move to a different level during a deletion.

Due to the point movements between the levels, the defining set of the degraded grid at level i may contain extra points additional to the ones of S_i. We therefore use a distinguished name for the defining set of the degraded grid at level i; we call it V_i.

When the insertion algorithm reaches level i without having yet performed a rebuilding, it brings along the points of $down_{i-1}$ and the new point q, see section 4. Therefore, $V_i = S_i \cup down_{i-1} \cup \{q\}$. It is important to see that, as for the sets S_i, we have

$$V_1 \supseteq V_2 \supseteq \cdots \supseteq V_L. \tag{8}$$

In the deletion algorithm, no additional point is introduced at any level except in the sparse sets S_i'. We therefore have $V_i = S_i$. (Points which vanish from level i because they move upward may be deleted from the defining set V_i at the end of the deletion algorithm.)

Remark. The defining set V_i may differ from the nonsparse set at level i only *during an update algorithm.* After completion of an update operation, these sets are

equal. In particular, the update algorithms maintain the degraded grid $\mathcal{DG}_{\delta,S_i}$ for *both* S_i *and* S_i'. That is, a point p which is new in S_i due to an update is also added to the degraded δ-grid storing the sparse set S_i', even if it is not contained in S_i'.

In the remainder of this section, we discuss the analysis of the insertion algorithm. The crucial point is the estimate on the size of the *down* sets. We transfer the relevant results to the degraded grid case, using the adapted neighborhood properties (N.4'), (N.5') given in Lemma 5.2. These properties hold with a restriction to the defining set of the degraded grid, whereas the original properties (N.4), (N.5) were valid without restriction to any point set. The nesting property (8) allows us to carry over the results nevertheless.

Analogously to the grid case, we use the following convention to describe neighborhoods in the sparse partition. For any point p, we let $N_i(p) := N_{g_i,V_i}(p)$. We use the analogous notation for the neighborhood relative to a set.

For the following statements, let $(S_i, S_i', p_i, q_i, \delta_i), 1 \le i \le L$, be a sparse partition as defined above, where V_i denotes the defining set of the degraded grid at level i.

The results corresponding to Corollary 3.1 and Lemma 3.4, obtained using (N.4'), are as follows.

- For any $1 \le i < j \le L$ and any $p \in V_j$, $\quad N_j(p, V_j) \subseteq N_i(p, V_i)$.
- For any $p \in (S \setminus S_{i+1}) \cap V_i, 1 \le i < L$, $\quad N_i(p, S \cap V_i) = \emptyset$.

Now assume that algorithm Insert(q) processes the levels $1, \ldots, i$ without a rebuilding, and the sets $down_j, 1 \le j \le i$, are defined according to equation (6). The corresponding statement to Lemma 4.3, which is obtained by using the above two statements, follows.

(9) Let $p \in down_j$ for a $j \in \{1, \ldots, i\}$. Then $p \in N_j(q)$ and $N_j(p, S \cap V_j) = \emptyset$.

With these preparations, we can prove that Lemma 4.4 remains valid; i.e.,

$$\Big| \bigcup_{1 \le j \le i} down_j \Big| \le 3^D.$$

We recall the proof of Lemma 4.4 together with the changes that are needed. The proof is now done with (9) and (N.5') replacing Lemma 4.3 and (N.5), respectively.

Assume that $p \in down_j$ for some $j \le i$. Then $p \in N_j(q)$ and $N_j(p, S \cap V_j) = \emptyset$ by (9). Let $\Psi \in \{-1, 0, 1\}^D$ be a signature such that $p \in b_j^\Psi(q)$. Refer to Figures 2 and 3. Note that the boxes $b_j^\Psi(q)$ and $b_j(q)$ have side lengths between g_j and $2g_j$ in the degraded g_j-grid, because both p and q are in V_j. The partial neighborhood $N_j^\Psi(q)$ is equal to $N_j(q) \cap N_j(p)$. Since $N_j(p, S \cap V_j) = \emptyset$ by (9), $N_j^\Psi(q)$ contains no point of $(S \cap V_j) \setminus \{p\}$.

Now consider a point $p' \in down_\ell$ for any $\ell > j$. Then $p', q \in V_\ell$, and we have $p' \in N_\ell(q)$ by (9). Assume that $p' \in b_\ell^\Psi(q)$. Since $\delta_\ell \le \delta_{j+1} \le \delta_j/4$, (N.5') gives $p' \in N_j^\Psi(q)$. We also have $p' \in V_j$, because $p' \in V_\ell$ and $V_\ell \subseteq V_j$ by the nesting property (8). However, we know from above that $N_j^\Psi(q)$ contains no point of $S \cap V_j$ except p. Therefore, $p' = p$.

This shows that, for each signature $\Psi \in \{-1, 0, 1\}^D$, all boxes $b_j^\Psi(q), 1 \le j \le i$, together contribute at most one element to the union $\bigcup_{1 \le j \le i} down_j$, which completes the proof.

Now let us turn to the running time of the algorithm. In Theorem 4.1, the box dictionary, which stores the indices of the nonempty grid boxes, was implemented using perfect hashing. Clearly, we can also store these indices in a balanced binary

search tree. Since identifying the box containing a given point now takes $O(\log n)$ time anyway on a structure of size n, the cost of searching for that box in the box dictionary (also $O(\log n)$) may be ignored. As we are now doing in logarithmic time what previously took constant time, the overall running time is also increased by a logarithmic factor. We conclude with Theorem 5.1.

THEOREM 5.1. *There exists a data structure which stores a set S of n points in $\mathbf{R}^D$ such that the minimal distance $\delta(S)$ can be found in $O(1)$ time, and all point pairs attaining $\delta(S)$ can be reported in time proportional to their number. The expected size of the structure is $O(n)$, and we can maintain the data structure as S is modified by insertions or deletions of arbitrary points in $O(\log^2 n)$ expected time per update. The data structure is randomized and fits in the algebraic decision tree model. The time bounds are obtained assuming that the updates do not depend upon the random choices made by the data structure.*

Note that the degraded grid not only depends on g_i, as in the grid case, but also on the set S_i stored in it (respectively, on the set $V_i \supset S_i$ during the insertion algorithm). Actually, it even depends on the way S_i has developed by updates. This means that this data structure no longer has the property that its distribution is independent of the history of updates. This does not affect the analysis of the algorithms, however.

6. Extensions. The data structure, as described so far, uses $O(n)$ *expected* space. In this section, we give a variant of the data structure that achieves linear space in the worst case. The update time bounds on this structure are amortized in that they will bound the expected running time of a sequence of update operations. We also show that this variant executes an update sequence quickly with high probability.

6.1. A data structure with linear space in the worst case. Recall that the space requirements are bounded by the sum of the sizes of the nonsparse sets $S_1, \ldots, S_L$ of the sparse partition, whose expected value was shown to be $O(n)$. To turn this into a worst-case bound, our first step is to slightly modify the algorithm *Sparse_Partition* given in section 2.

The modification is as follows: after picking the pivot of the grid randomly we determine the set of sparse points induced by this random choice. If at least half of the points are sparse, we call the pivot *good* and retain it as the pivot. Otherwise, we discard it and make a new random choice, continuing this process until a good pivot is found. We then continue on to the next set, making sure it has a good pivot as well, etc. Note that if all of the pivots in the sparse partition are good then, for all i, $|S_i'| \geq |S_i|/2$ so $|S_{i+1}| < |S_i|/2$, $\sum_{j>i} |S_j| = O(|S_i|)$ and the data structure will use $O(n)$ space. Furthermore, since $|S_{i+1}| \leq |S_i|/2$, the sparse partition has only $O(\log n)$ levels.

Note that at least half of the elements of a set are good pivots, and so at most two trials are needed on average until a good pivot is found. Using the same data structures as before to implement the sparse partition, we can easily prove that Lemma 6.1 holds.

LEMMA 6.1. *Let S be a set of n points in $\mathbf{R}^D$. The modified version of algorithm Sparse_Partition produces a sparse partition for S of worst-case size $O(n)$ in $O(n)$ expected time.*

Note that the above lemma only discusses creating the sparse partition itself and does not discuss creating the auxiliary data structures. However, this additional work can be completed within the same time bound, and therefore we do not discuss it. In the next section, in which we discuss high probability bounds, we will need to distinguish between constructing the sparse partition itself on the one hand and the

complete data structure on the other. For the remainder of this section we assume that the procedures *Build* and *Near_Build* have been modified as above to produce sparse partitions of worst-case linear size.

We now move on to the update algorithms. The idea will be to maintain a sparse partition all of whose pivots are good or at least not too far from being good. We make the following observations.

1. The uniformity property (Definition 2.2) is lost. However, since at least half of the elements are good pivots, the probability of an element being the pivot right after the construction of a new sparse partition is $2/n$ for a set of size n.
2. Updates can gradually unbalance the data structure in the sense that more than a constant proportion of the elements at that level can become non-sparse. In the earlier version of the algorithm the uniformity condition guaranteed that the data structure was, probabilistically, well balanced. Lacking the uniformity condition we enforce the balance of the sparse partition "by hand" to ensure that the data structure uses linear space. That is, we count the number of update operations that affect a level of the data structure, rebuilding after this count has reached a suitable constant fraction of the cardinality of the set at that level at the time of the last rebuilding. This will ensure that $|S_i'|$ is always at least some constant proportion of $|S_i|$. In the sequel we call these rebuildings *amortized* to distinguish them from the *probabilistic* rebuildings that can be caused by a particular update.

We now sketch the modifications to the update algorithms, using the notation from section 4. We associate two variables, $last_i$ and $count_i$, with level i of the current sparse partition. $last_i$ equals $|S_i|$ after the last (amortized or probabilistic) rebuilding that affected S_i, i.e., the last rebuilding performed at a level $j \leq i$. $count_i$ denotes the number of update operations since the last rebuilding that affected level i. In what follows, $c > 1$ is a sufficiently large constant.

In the insertion algorithm (Figure 7), let q be the newly inserted point, and suppose we are at level i, $down_{i-1}$ has been computed, and $\widetilde{S}_i = S_i \cup down_{i-1} \cup \{q\}$. Only step 2 (checking for rebuild) is changed as follows:

1. $count_i := count_i + 1$; **if** $count_i \geq last_i/c$ **then** $Build(\widetilde{S}_i, i)$; stop;
2. **if** q or an element of $down_{i-1}$ is closer to the pivot p_i than its previous nearest neighbor
   then $Build(\widetilde{S}_i, i)$; stop;

The first item is the amortized rebuilding discussed above, and the second item is one component of the probabilistic rebuilding in the original algorithm. Note that the first part of that rebuild step—which ensured the uniformity of the pivots by probabilistically deciding whether to make one of the elements in $down_{i-1} \cup \{q\}$ the new pivot—does not appear here. Since we do not have complete uniformity here anyway (bad elements cannot be pivots), we treat a newly inserted element as if it were a bad element.

In the deletion algorithm (Figure 10), suppose again that we are at level i, up_{i-1} has been computed, and we have $\widetilde{S}_i = (S_i \setminus up_{i-1}) \setminus \{q\}$. Only step 2 is changed as follows:

1. $count_i := count_i + 1$; **if** $count_i \geq last_i/c$ **then** $Build(\widetilde{S}_i, i)$; stop;
2. **if** q or an element of up_{i-1} is either the pivot p_i or its nearest neighbor q_i
   then $Build(\widetilde{S}_i, i)$; stop;

It is clear that the above modifications do not affect the correctness of the update

algorithms. We now analyze its cost. First note that immediately after a rebuilding $|S_i'| \geq |S_i|/2$. A single update may only add or subtract a constant number of items to or from S_i and S_i'. Thus if c is taken to be large enough, the amortized rebuildings guarantee that $|S_i'| > |S_i|/4$ always holds, ensuring that (i) the data structure has $O(\log n)$ levels and (ii) the size of the structure is $O(n)$. (Note that the constant number of points that can be moved at each step depends upon the dimension D, so c must be chosen dependent upon D as well.)

As long as no rebuilding occurs, the algorithm uses a constant number of dictionary operations at each level. Since there are $O(\log n)$ levels the total expected cost of all dictionary operations is $O(\log n)$. The heap updates cost $O(\log n)$ time as before. Thus the total expected time required for an update operation which does not perform a rebuilding is $O(\log n)$.

Recall now that there are two types of rebuildings: amortized and probabilistic. We start by analyzing the amortized rebuildings. Note that an amortized rebuilding occurs on a set S_i of size m only if a sequence of $\Theta(m)$ updates has occurred without a rebuilding of S_i. Since a rebuilding costs $O(m)$ expected time each of the sequence of $\Theta(m)$ updates incurs an $O(1)$ amortized cost for the rebuilding of S_i. Summing over all $O(\log n)$ levels in the data structure gives an amortized expected cost of $O(\log n)$ per update operation.

For the probabilistic rebuildings, we will show that for each update which affects a set S_i of size m, the probability of a rebuilding is at most c'/m for some fixed constant c'. Since the expected cost of a rebuilding is $O(m)$ this means that the expected cost of rebuilding a set at a given level at any particular step will be $O(1)$. Summing over all $O(\log n)$ levels yields a total expected cost of $O(\log n)$ per update.

To show that the probability of a rebuilding is at most c'/m for some c' we note that immediately after a rebuilding the probability of rebuilding a set S_i of size m is c'/m where $c' = 2$. Between rebuildings, an adversary gains knowledge about the possible pivots of the data structure permitting him to force a rebuilding with an appropriately chosen insert or delete command. However, we have already seen that an adversary can only exclude at most a constant number of points from being a pivot in each update operation. Thus, if c is taken to be large enough that after m/c updates at a level of initial size m, the adversary still must consider $|S_i|/4$ possible good pivots, this implies that the probability of a probabilistic rebuilding (i.e., item 2 of the modified updates) is still $O(1/m)$. This proves the following theorem.

THEOREM 6.1. *The data structure of Theorem* 4.1 *can be modified to use $O(n)$ worst-case space. The modified data structure has $O(\log n)$ amortized expected update time, and the time complexities of all other operations are unchanged.*

Applying the same modifications to the data structure of Theorem 5.1 we get Theorem 6.2.

THEOREM 6.2. *The data structure of Theorem* 5.1 *can be modified to use $O(n)$ worst-case space. The modified data structure has $O(\log^2 n)$ amortized expected update time, and the time complexities of all other operations are unchanged.*

6.2. High probability bounds. The previous theorem yields the expected running time of the dynamic closest-pair algorithm on a sequence of updates. We now discuss the probability that the running time of the data structure of Theorem 6.2 on such an update sequence deviates significantly from its expectation. In what follows we say that an event occurs with *n-polynomial probability* if, for any fixed $s > 0$, it occurs with probability $1 - O(n^{-s})$. A process is said to take $O(f(n))$ time with n-polynomial probability if, for any fixed $s > 0$, the process takes at most $c(s)f(n)$ time

for sufficiently large n, where $c(s)$ is a constant dependent upon s, with probability $1 - O(n^{-s})$.

THEOREM 6.3. *Let S be a set of n points in $\mathbf{R}^D$. The data structure of Theorem 6.2 performs a sequence of n updates on S in $O(n \log^2 n)$ time with n-polynomial probability.*

Remark. We can also prove that the data structure of Theorem 6.1 processes a sequence of $\Theta(n)$ updates, starting with a set of size n, in $O(n \log^2 n)$ time with n-polynomial probability; see [18] for details.

Proof. First note that the theorem is obviously correct if we only count the costs of the part of the updates that do not include rebuildings. The nonrebuilding part of the update consists of $O(1)$ heap operations, each costing $O(\log n)$ time for a total of $O(\log n)$ time, and of $O(\log n)$ dictionary operations each costing $O(\log n)$ time for a total of $O(\log^2 n)$ time. (Recall that our data structure has $O(\log n)$ levels in the worst case for a set of size n.) Hence, if no rebuilding occurs, an update takes $O(\log^2 n)$ time in the worst case.

We now analyze the rebuilding cost and show that rebuilding a sparse partition for a set of size m will require $O(m \log n)$ time with n-polynomial probability. First note that during the rebuilding of a level the chance of a random pivot being a good one is at least $1/2$; the probability of not finding a good pivot after k trials is therefore at most 2^{-k}, so with n-polynomial probability only $O(\log n)$ pivots need to be checked before finding a good one. At first sight, it appears as if even checking if a single pivot is good should take $O(m \log n)$ time, since checking to see if a point is sparse appears to require $O(1)$ queries to the box dictionary, each costing $O(\log n)$ time.

However, if we only want to check if a pivot is good, we can avoid queries to the box dictionary as follows: during the building of the degraded grid data structure, we can link each nonempty box with the nonempty boxes in its neighborhood, where we mean the occurrences of the boxes in the box dictionary (not only in the geometric representation, which is trivial). We can use these pointers to find the sparse points of the point set which is being stored *in linear time*, as follows: walk through the list of nonempty boxes of the grid. With the help of the above-described pointers, we can access the point lists associated with the neighboring boxes in constant time, replacing the queries in the box dictionary. (This faster method was not mentioned earlier as computing the sparse points of a set was never previously a bottleneck.) Thus we can identify the sparse points and decide whether the pivot is good in $O(m)$ time; it is only in the computing of the restricted distances where we will need $\Theta(m \log n)$ time.

We conclude that a good pivot can be found and the grid for that level built and processed in $O(m \log n)$ time with n-polynomial probability. Since the levels decrease geometrically in size, good pivots for all succeeding levels of the partition can also be found in $O(m \log n)$ time with n-polynomial probability. The remainder of the *Build* procedure takes $O(m \log n)$ time as before.

We now analyze the amortized and probabilistic rebuildings separately, studying the amortized ones first. Actually, using the same reasoning as developed in the previous subsection, we find that an amortized rebuilding of set S_i of size m is only performed if $\Theta(m)$ previous updates did not rebuild S_i. Now rebuilding S_i requires $O(m \log n)$ time with n-polynomial probability, so with n-polynomial probability the amortized rebuilding cost per update of S_i is $O(\log n)$. Since there are $O(\log n)$ levels, this adds up to $O(n \log^2 n)$ time with n-polynomial probability.

Before analyzing the cost of the probabilistic rebuildings, i.e., the rebuildings caused by a deletion of a pivot or insertion/deletion of the nearest neighbor to a pivot,

it will help to quickly review what we are trying to study. As we start with a data structure which contains n points and then make n updates to it, the data structure contains at most $2n$ items at any update step. Since $|S_i'| > |S_i|/4$ we have $|S_{i+1}| < 3|S_i|/4$ so the data structure never contains more than $L = \log_{4/3}(2n) = \Theta(\log n)$ levels. Now suppose that $|S_i| = m$. Then as described in the previous subsection S_i is rebuilt with probability $O(1/m)$. The cost of rebuilding S_i will be $O(m \log n)$ with n-polynomial probability. Let $m_{i,t}$ denote the size of S_i at the end of update $t-1$ for $1 \le i \le L$ and $1 \le t \le n$. If S_i does not exist at the end of update $t-1$ set $m_{i,t} = 1$ by convention. Now define the random variables

$$X_{i,t} = \begin{cases} m_{i,t} & \text{with probability } 1/m_{i,t}, \\ 0 & \text{with probability } 1 - 1/m_{i,t}. \end{cases}$$

Then the cost of probabilistically rebuilding S_i at update t, counting both degraded grid and heap operations, is $O(X_{i,t} \log n)$ with n-polynomial probability by the above discussion. Hence the total cost of probabilistic rebuildings over all updates is bounded by $O(M \log n)$ with n-polynomial probability, where $M = \sum_{i,t} X_{i,t}$. We now show that M itself is $O(n \log n)$ with n-polynomial probability. The proof of Theorem 6.3 will follow.

The first complication we encounter in bounding M is that the $X_{i,t}$ are *not* independent because the $m_{i,t}$ depend upon each other. Nevertheless, since $|S| \le 2n$ and the amortized rebuilding ensures that $|S_{i+1}| < 3|S_i|/4$, the relation

$$m_{i,t} \le \max\{1, 2 \cdot (3/4)^{i-1} \cdot n\} \tag{10}$$

must always hold. We sidestep the dependence issue by showing that, for *any* values of $m_{i,t}$ that satisfy equation (10), M has n-polynomial probability of being $O(n \log n)$. This allows us to assume that we are given some *fixed* (but arbitrary) values $m_{i,t}$ which satisfy (10), and that the variables $X_{i,t}$ are as defined above and *independent* of each other.

The following lemma is obtained by a straightforward modification of the proof of the Chernoff bound given in [14, p. 68].

LEMMA 6.2. *Let $Y_1, \ldots, Y_k$ be independent random variables, and let $a_1, \ldots, a_k \in [1, A]$ for some $A \ge 1$. For $i = 1, \ldots, k$ suppose that*

$$Y_i = \begin{cases} a_i & \textit{with probability } 1/a_i, \\ 0 & \textit{with probability } 1 - 1/a_i, \end{cases}$$

and let $Y = \sum_{i=1}^{k} Y_i$. Then for any $\delta > 0$,

$$\Pr[Y > (1+\delta)k] < \left[\frac{e^{\delta}}{(1+\delta)^{(1+\delta)}}\right]^{k/A}. \tag{11}$$

Proof. Let $\lambda = (\ln(1+\delta))/A$ and note that $\lambda > 0$. Then

$$\begin{aligned} \Pr[Y > (1+\delta)k] &= \Pr[e^{\lambda Y} > e^{\lambda(1+\delta)k}] \\ &\le \frac{\mathrm{E}(e^{\lambda Y})}{e^{\lambda(1+\delta)k}} \\ &= \frac{\prod_{i=1}^{k} \mathrm{E}(e^{\lambda Y_i})}{e^{\lambda(1+\delta)k}} \\ &= \frac{\prod_{i=1}^{k} (\frac{1}{a_i} e^{\lambda a_i} + 1 - \frac{1}{a_i})}{e^{\lambda(1+\delta)k}}. \end{aligned}$$

However, $f(x) = e^{\lambda x}/x + 1 - 1/x$ can easily be seen to be an increasing function of x, for $x > 0$. Therefore,

$$\Pr[Y > (1+\delta)k] \le \frac{\left(\frac{1}{A}e^{\lambda A} + 1 - \frac{1}{A}\right)^k}{e^{\lambda(1+\delta)k}} \le \frac{(1+\delta/A)^k}{(1+\delta)^{(1+\delta)k/A}} < \left[\frac{e^{\delta}}{(1+\delta)^{(1+\delta)}}\right]^{k/A}. \qquad \square$$

Let s be a given positive integer. We apply Lemma 6.2 to $X_i = \sum_{t=1}^{n} X_{i,t}$ for each $1 \le i \le 5 \log\log n$, noting that $m_{i,t} \le 2n$ for this range of i. By choosing $\delta = c \cdot \log n / \log\log n - 1$ for sufficiently large $c > 0$ and $A = 2n$, we obtain that, for all $1 \le i \le 5 \log\log n$,

$$\Pr[X_i > c \cdot n \cdot \log n / \log\log n] < n^{-s-1}. \tag{12}$$

We now apply Lemma 6.2 to $X_i = \sum_{t=1}^{n} X_{i,t}$ for each $5 \log\log n < i \le L$, noting that $m_{i,t} \le n/\log n$ for this range of i. By choosing $\delta = c' - 1$ for sufficiently large $c' > 1$ and $A = n/\log n$, we obtain that, for all $5 \log\log n < i \le L$,

$$\Pr[X_i > c' \cdot n] < n^{-s-1}. \tag{13}$$

From (12) and (13) we conclude that $M = \sum_{i=1}^{n} X_i = O(n \log n)$ with probability at least $1 - n^{-s}$, and hence $M = O(n \log n)$ with n-polynomial probability. $\square$

7. Concluding remarks. In this paper, we have given the first solution to the fully dynamic closest pair problem which achieves linear space and polylogarithmic update time simultaneously. After a preliminary version of this paper was published, Kapoor and Smid [13] achieved this goal with a deterministic method which has amortized update time $O(\log^{D-1} n \log\log n)$ for $D \ge 3$ and $O(\log^2 n/(\log\log n)^{\ell})$ for the case $D = 2$, where ℓ is an arbitrary nonnegative integer constant. Also, Callahan and Kosaraju [4] gave a deterministic data structure achieving $O(\log^2 n)$ update time while using linear space for any fixed dimension. Finally, Bespamyatnikh [3] gave an optimal deterministic solution for the dynamic closest pair problem: for any fixed dimension, his technique achieves $O(\log n)$ update time and uses $O(n)$ space.

SEPARATING EXPONENTIALLY AMBIGUOUS FINITE AUTOMATA FROM POLYNOMIALLY AMBIGUOUS FINITE AUTOMATA*

HING LEUNG†

Abstract. We resolve an open problem raised by Ravikumar and Ibarra [*SIAM J. Comput.*, 18 (1989), pp. 1263–1282] on the succinctness of representations relating to the types of ambiguity of finite automata. We show that there exists a family of nondeterministic finite automata $\{A_n\}$ over a two-letter alphabet such that, for any positive integer n, A_n is exponentially ambiguous and has n states, whereas the smallest equivalent deterministic finite automaton has 2^n states, and any smallest equivalent polynomially ambiguous finite automaton has $2^n - 1$ states.

Key words. nondeterministic finite automata, ambiguity, succinctness of representation

AMS subject classification. 68Q68

PII. S0097539793252092

1. Introduction.

In their 1989 paper [RI89] Ravikumar and Ibarra raised some interesting questions relating the type of ambiguity of finite automata to the succinctness in their number of states. They considered the following five classes of finite automata: deterministic finite automata (DFA), nondeterministic finite automata (NFA), unambiguous NFA (UFA), finitely ambiguous NFA (FNA), and polynomially ambiguous NFA (PNA). Formal definitions of these classes are given in section 2 of this paper.

Let C_1 and C_2 be any two of the above five classes of finite automata. We say that C_1 can be polynomially converted to C_2 (written $C_1 \leq_P C_2$) if there exists a polynomial p such that for any finite automaton in C_1 with n states we can find an equivalent finite automaton in C_2 with at most $p(n)$ states. C_1 is said to be polynomially related to C_2 (written $C_1 =_P C_2$) if $C_1 \leq_P C_2$ and $C_2 \leq_P C_1$. C_1 is said to be separated from C_2 if $C_1 \neq_P C_2$. We write $C_1 <_P C_2$ if $C_1 \leq_P C_2$ and $C_1 \neq_P C_2$.

It is immediate that DFA $\leq_P$ UFA, UFA $\leq_P$ FNA, FNA $\leq_P$ PNA, and PNA $\leq_P$ NFA.

The following is known: DFA $<_P$ NFA [MF71], [Mo71], DFA $<_P$ UFA [Sc78], [SH85], [RI89], UFA $<_P$ FNA [Sc78], [RI89], and UFA $<_P$ NFA [SH85]. It is unknown whether FNA $<_P$ NFA. Ravikumar and Ibarra conjecture that FNA $<_P$ PNA and that PNA $<_P$ NFA [RI89].

In this paper, we prove that PNA $<_P$ NFA which immediately implies that FNA $<_P$ NFA. The other conjecture that FNA $<_P$ PNA still remains open.

In summary, we have

$$\text{DFA} <_P \text{UFA} <_P \text{FNA} \leq_P \text{PNA} <_P \text{NFA}.$$

Specifically, we show that there exists a family of NFAs $\{A_n \mid n \geq 1\}$ over a two-letter alphabet such that, for any positive integer n, A_n is exponentially ambiguous

and has n states, whereas the smallest equivalent DFA has 2^n states and any smallest equivalent PNA has $2^n - 1$ states.

Our results show that any PNA equivalent to A_n cannot do better in the number of states than the smallest equivalent DFA obtained by the subset construction except for the saving of the dead state.

Another way to interpret our results is as follows: let us first define that an NFA is "strongly" ambiguous if there is a useful state q (that is, q can be reached from some starting state and can reach some final state) and a string w such that M can process w starting from state q and ending also with state q in more than one way. Then by a characterization in [IR86] our results show that A_n is strongly ambiguous with n states, whereas the smallest equivalent DFA has 2^n states and any smallest equivalent NFA that is not strongly ambiguous has $2^n - 1$ states.

Section 2 presents the definitions and some basic results. Section 3 presents the family of NFAs $\{A_n\}$ and proves the main result of this paper by a series of lemmas.

2. Preliminaries. We assume that the reader is familiar with the basic definitions and notations in finite automata theory and the Myhill–Nerode theorem [HU79] as well as the basics of graph theory [Ha69].

Let w be a string, and L a language. We denote by w^R the reverse of w and by L^R the set of strings v^R where $v \in L$.

Throughout this paper, we assume a model of NFA that is slightly more general than the one defined in [HU79] in that we allow a set of starting states instead of only one starting state. Thus, an NFA M is a 5-tuple $(Q, \Sigma, \delta, Q_I, Q_F)$ where Q is the set of states, Σ is the alphabet set, $\delta : Q \times \Sigma \longrightarrow 2^Q$ is the transition function, Q_I is the set of starting states, and Q_F is the set of final states.

Given an NFA M, we define the ambiguity of a string w to be the number of different accepting paths for w in M. Note that a string w is in the language of M if and only if the ambiguity of w is not zero. The ambiguity function $amb_M : \mathbb{N}_0 \longrightarrow \mathbb{N}_0$ is defined such that $amb_M(n)$ is the maximum of the ambiguities of strings that are of length n or less. Remark: amb_M is nondecreasing.

M is called unambiguous if the ambiguity of any string is either zero or one. M is called finitely (respectively, polynomially, exponentially) ambiguous if amb_M can be bounded by a constant (respectively, polynomial, exponential) function f; that is, for all $n \in \mathbb{N}_0$, $amb_M(n) \leq f(n)$.

It is easy to see that $amb_M(n) \leq s_1 s^n$ where s_1 is the cardinality of Q_I and s is the cardinality of Q. Thus, every NFA must be exponentially ambiguous.

M is called strictly exponentially ambiguous [IR86] if M is exponentially ambiguous but not polynomially ambiguous. It is known [IR86] that M is strictly exponentially ambiguous if and only if there is a useful state q and there is a string w such that M can process w starting from state q and ending also with state q in more than one way.

3. Main result. For any positive integer n, we define an NFA $A_n = (Q, \Sigma, \delta, \{q_1\}, \{q_1\})$ where $Q = \{q_1, q_2, \ldots, q_n\}$, q_1 is the only starting state and the only final state, $\Sigma = \{0, 1\}$, and δ (see Figure 1) is defined as follows:

- $\delta(q_1, 0) = \{q_1, q_2\}$,
- $\delta(q_i, 0) = \{q_{i+1}\}$ for $2 \leq i \leq n-1$,
- $\delta(q_n, 0) = \{q_1\}$,
- $\delta(q_1, 1) = \emptyset$,
- $\delta(q_i, 1) = \{q_i\}$ for $2 \leq i \leq n$.

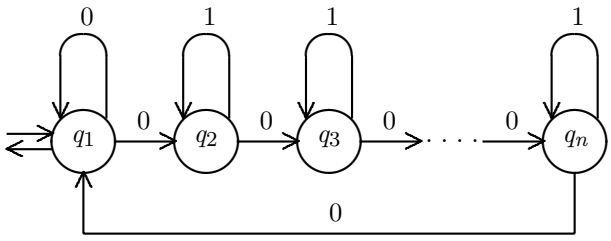

FIG. 1. *Transition diagram of* A_n.

We denote the language of A_n by L_n, which is $(0 + (01^*)^{n-1}0)^*$. It is easy to see that $L_n = L_n^R = L_n^*$.

It is argued in section 2 that every NFA is exponentially ambiguous. Thus A_n is exponentially ambiguous. Moreover, A_n is strictly exponentially ambiguous since the ambiguity of 0^m is at least $2^{\lfloor m/n \rfloor}$.

We will prove that any DFA recognizing L_n has at least 2^n states (Lemma 2), any UFA recognizing L_n has at least $2^n - 1$ states (Lemma 4), and any PNA recognizing L_n also has at least $2^n - 1$ states (Theorem 1).

First, we present some definitions. Given a language L and a string x, $\mathit{prefix}(L) \stackrel{\text{def}}{=} \{w \mid \exists w',\ ww' \in L\}$ and $x^{-1}(L) \stackrel{\text{def}}{=} \{w \mid xw \in L\}$. The two operations *prefix* and x^{-1} commute since both $x^{-1}(\mathit{prefix}(L))$ and $\mathit{prefix}(x^{-1}(L))$ equal $\{w \mid \exists w',\ xww' \in L\}$.

Let *kill_non_*q_1 denote $0(10)^{n-1}$, *accept* denote 0^{n-1}, and *reset* denote *accept kill_non_*q_1. The intuitive concepts of the strings *kill_non_*q_1, *accept*, and *reset* are reflected in the following properties: for any $P \subseteq Q$, $\delta(P, \mathit{kill\_non\_}q_1) = P - \{q_2, \ldots, q_n\}$. For any nonempty subset $P \subseteq Q$, observe that $q_1 \in \delta(P, \mathit{accept})$ and $\delta(P, \mathit{reset}) = \{q_1\}$. Equivalently, for any $x \in \mathit{prefix}(L_n)$, $x\ \mathit{accept} \in L_n$ and $(x\ \mathit{reset})^{-1}(L_n) = L_n$.

For any $P \subseteq Q$, let $w_P \in \Sigma^*$ be $w_1 0 w_n 0 w_{n-1} 0 \ldots 0 w_1$ where $w_i = \epsilon$ if $q_i \in P$ and $w_i = 1$ otherwise; and let $u_P \in \Sigma^*$ be $0^{n-1}\ w_P$. The meaning of w_P and u_P can be understood as the strings that satisfy Lemma 1 and Corollary 1, respectively, given below. The following properties (Lemma 1 and Corollaries 1 and 2) of the strings w_P and u_P are very crucial in proving the main theorem of the paper.

LEMMA 1. *For any* $P \subseteq Q$, *we have*

(1) $\delta(P, w_P) = P$;

(2) *for any* $q \in P$, $\delta(q, w_P) \supseteq \{q\}$;

(3) $\delta(Q - P, w_P) = \emptyset$.

Proof. The proof of Lemma 1, which is quite long but straightforward, is given in the appendix. ∎

COROLLARY 1. *For any* $P \subseteq Q$, $\delta(q_1, u_P) = P$.

Proof. $\delta(q_1, u_P) = \delta(q_1, 0^{n-1}\ w_P) = \delta(Q, w_P) = \delta(P, w_P) \bigcup \delta(Q - P, w_P) = \delta(P, w_P) = P$ by parts (1) and (3) of Lemma 1. ∎

COROLLARY 2. *For any* $P, P' \subseteq Q$, $u_P w_{P'} \in \mathit{prefix}(L_n)$ *if and only if* $P \bigcap P' \neq \emptyset$.

Proof. Suppose $P \bigcap P' \neq \emptyset$. Let $q \in P \bigcap P'$. Then $\delta(q_1, u_P w_{P'}) = \delta(P, w_{P'}) \supseteq \delta(q, w_{P'}) \supseteq \{q\} \neq \emptyset$ by Corollary 1 and part (2) of Lemma 1. Since all states in A_n are useful, $u_P w_{P'} \in \mathit{prefix}(L_n)$.

Suppose $P \bigcap P' = \emptyset$. Then $P \subseteq Q - P'$ and $\delta(q_1, u_P w_{P'}) = \delta(P, w_{P'}) \subseteq \delta(Q - P', w_{P'}) = \emptyset$ by Corollary 1 and part (3) of Lemma 1. Thus we have that $u_P w_{P'} \notin \mathit{prefix}(L_n)$. ∎

With the basic properties established, we begin to prove the first result that the smallest DFA recognizing L_n has 2^n states.

LEMMA 2. *The smallest DFA recognizing L_n has 2^n states.*

Proof. By Corollary 1, all subsets of states can be realized in the subset construction. We show that any two different subsets of states are not equivalent; then we are done by the Myhill–Nerode theorem. Let $P \neq P' \subseteq Q$. Let q_i be the state with the largest subscript such that q_i belongs only to exactly one of P and P'. That is, for any q_j where $i+1 \leq j \leq n$, either q_j belongs to both P and P' or q_j does not belong to any one of P and P'. If $i = 1$, then P and P' can be distinguished by the empty string. Assume that $1 < i \leq n$. Then P and P' can be distinguished by $(10)^{n+1-i}$. □

The next result (Lemma 4) that we want to establish is that a smallest UFA recognizing L_n cannot do better in the number of states than a smallest DFA besides the saving of the dead state. Some technical definitions and a technical lemma (Lemma 3) are needed first.

Let M_n be a $2^n - 1 \times 2^n - 1$ matrix over the field of characteristic 2 with rows and columns indexed by the nonempty subsets of Q such that $M_n(P, P') = 1$ if $u_P\ w_{P'}\ accept \in L_n$, and $M_n(P, P') = 0$ otherwise. By Corollary 2 and the property of *accept*, $M_n(P, P') = 1$ if $P \bigcap P' \neq \emptyset$ and $M_n(P, P') = 0$ otherwise.

LEMMA 3. *The rank of M_n is $2^n - 1$.*

Proof. Equivalently, we can index rows and columns of M_n by n-bit positive binary numbers in the order of increasing values such that any n-bit positive binary number $b_n b_{n-1} \ldots b_1$ corresponds to the nonempty subset $P \subseteq Q$ with the property that for any $1 \leq i \leq n$, $q_i \in P$ if and only if $b_i = 1$. Note that the indices range from binary number of value 1 to binary number of value $2^n - 1$. Thus, $M_n(\alpha, \beta) = 1$ if there is some i such that the ith bits of α and β are both 1, and $M_n(\alpha, \beta) = 0$ otherwise.

We are going to show by induction on n that M_n has rank $2^n - 1$. For $n = 1$, then $M_n = [1]$, which is a 1×1 matrix of rank $2^1 - 1 = 1$.

Suppose that the statement is true for $n = k$. Consider $n = k + 1$. We observe that the matrix M_{k+1} (see Figure 2) can be characterized as follows:

- The matrix M_{k+1} is symmetric. (Reason: According to the definition given above for $M_n(\alpha, \beta)$, it is immediate that $M_n(\alpha, \beta) = M_n(\beta, \alpha)$.)
- The middle row and the middle column both have $2^k - 1$ zeros followed by 2^k ones. (Reason: The middle row has an index of a one followed by k zeros. On the other hand, the first $2^k - 1$ column indices are binary numbers that begin with zero, and the last 2^k column indices are binary numbers that begin with one. Thus, by definition, the middle row has $2^k - 1$ zeros followed by 2^k ones. Since M_{k+1} is symmetric, the middle column also has $2^k - 1$ zeros followed by 2^k ones.)
- Separated by the middle row and the middle column, we have four square submatrices of sizes $2^k - 1 \times 2^k - 1$ each. Let us name the upper-left, upper-right, lower-left, and lower-right submatrices as UL, UR, LL, and LR. Then UL, UR, and LL are the same as M_k, and LR is a matrix of ones. (Reason: Elements in LR correspond to row and column indices that both begin with one. Thus LR is a matrix of ones. For elements in other submatrices, either the row or column index begins with zero. Thus the element values are determined by the remaining k bits of the row and column indices, which behave in the same way as the row and column indices of M_k. Hence, UL,

$$M_{k+1} = \left[\begin{array}{c|c|c} UL & \begin{matrix}0\\ \vdots\\ 0\end{matrix} & UR \\ \hline 0\cdots 0 & 1 & 1\cdots 1 \\ \hline LL & \begin{matrix}1\\ \vdots\\ 1\end{matrix} & LR \end{array}\right] = \left[\begin{array}{c|c|c} M_k & \begin{matrix}0\\ \vdots\\ 0\end{matrix} & M_k \\ \hline 0\cdots 0 & 1 & 1\cdots 1 \\ \hline M_k & \begin{matrix}1\\ \vdots\\ 1\end{matrix} & \begin{matrix}1\cdots 1\\ \vdots\\ 1\cdots 1\end{matrix} \end{array}\right]$$

FIG. 2. *Structure of M_{k+1}.*

$$M_{k+1} = \left[\begin{array}{c|c|c} UL & \begin{matrix}0\\ \vdots\\ 0\end{matrix} & UR \\ \hline 0\cdots 0 & 1 & 1\cdots 1 \\ \hline LL & \begin{matrix}0\\ \vdots\\ 0\end{matrix} & LR \end{array}\right] = \left[\begin{array}{c|c|c} M_k & \begin{matrix}0\\ \vdots\\ 0\end{matrix} & \begin{matrix}0\cdots 0\\ \vdots\\ 0\cdots 0\end{matrix} \\ \hline 0\cdots 0 & 1 & 1\cdots 1 \\ \hline M_k & \begin{matrix}0\\ \vdots\\ 0\end{matrix} & M_k \end{array}\right]$$

FIG. 3. *Structure of M_{k+1} (after transformations).*

UR, and LL are the same as M_k.)

We want to apply elementary row operations to show that M_{k+1} can be transformed to an identity matrix. By subtracting the middle row from each of the rows in the lower half of the matrix, LL remains unchanged whereas the rest of the entries in the lower half become all zeros. Note that the middle column now has all zeros except a one in the middle. Let us swap the lower half of the matrix with the upper half. See Figure 3 for the current structure of M_{k+1}.

By induction, we can apply elementary row operations to the upper half such that UL becomes an identity matrix, and the rest of the entries in the upper half are zeros. With UL being the identity matrix and zeros elsewhere in the upper half, we apply again elementary row operations so that LL becomes all zeros whereas LR remains the same as M_k. See Figure 4 for the current structure of M_{k+1}.

Next, again by induction, we can transform LR to identity matrix since the rest of the entries in the lower half are all zeros. Finally subtract each of the rows in the lower half from the middle row; the middle row becomes a row with all zeros except a one in the middle position. Therefore, an identity matrix is obtained and the rank of M_{k+1} is thus $2^{k+1}-1$. □

LEMMA 4. *A smallest UFA recognizing L_n has 2^n-1 states.*

Proof. First, by removing the dead state from the DFA obtained by the subset construction, we have a UFA with 2^n-1 states. Next we are going to use a technique introduced in [Sc78] to show that any UFA would require at least 2^n-1 states.

Let U be a UFA recognizing L_n with the finite set of states denoted by K. Let R be a matrix over the field of characteristic 2 with rows indexed by K and columns indexed by the nonempty subsets of Q such that $R(k,P)=1$ if U can reach a final state starting from state $k \in K$ on consuming w_P *accept*, and $R(k,P)=0$ otherwise.

We claim that any row in M_n is a linear combination of the rows in R. Given a nonempty subset P of Q, let $K' \subseteq K$ be the set of states reached by U from the set of starting states on consuming u_P. For any $k_1 \neq k_2 \in K'$ and for any nonempty subset

$$M_{k+1} = \left[\begin{array}{c|c|c} UL & \begin{matrix}0\\ \vdots\\ 0\end{matrix} & UR \\ \hline 0\cdots 0 & 1 & 1\cdots 1 \\ \hline LL & \begin{matrix}0\\ \vdots\\ 0\end{matrix} & LR \end{array}\right] = \left[\begin{array}{c|c|c} I_k & \begin{matrix}0\\ \vdots\\ 0\end{matrix} & \begin{matrix}0\cdots 0\\ \vdots\\ 0\cdots 0\end{matrix} \\ \hline 0\cdots 0 & 1 & 1\cdots 1 \\ \hline \begin{matrix}0\cdots 0\\ \vdots\\ 0\cdots 0\end{matrix} & \begin{matrix}0\\ \vdots\\ 0\end{matrix} & M_k \end{array}\right]$$

FIG. 4. *Structure of M_{k+1} (after transformations).*

P' of Q, $R(k_1, P')$ and $R(k_2, P')$ cannot both have value one; that is, at most one of $R(k, P')$, for $k \in K'$, is 1. Otherwise, there are two different accepting paths for $u_P w_{P'}$ *accept* in U, which contradicts the assumption that U is unambiguous. Thus, the row indexed by P in M_n is the sum of the rows indexed by K' in R.

Therefore, the rank of M_n is less than or equal to the rank of R. Hence, K must have at least $2^n - 1$ states so that the rank of R is at least $2^n - 1$. □

We need Lemma 5 below to prove Lemma 6, which is the main technical lemma that helps us to show that a smallest PNA recognizing L_n has $2^n - 1$ states (Theorem 1). In fact, Lemma 5 can be viewed as a generalization of Lemma 4.

LEMMA 5. *Any UFA recognizing L such that prefix(L) = prefix(L_n) requires at least $2^n - 1$ states.*

Proof. Since L is regular, there exists a finite set of strings $\{\gamma_1, \ldots, \gamma_h\} \subseteq \Sigma^*$ such that for any $z \in$ *prefix*(L), exactly one of $z\gamma_i$, for $1 \le i \le h$, is in L.

Let X be a $2^n - 1 \times h(2^n - 1)$ matrix over the field of characteristic 2 with rows indexed by the nonempty subsets of Q and columns indexed by $\{(P, i) \mid \emptyset \ne P \subseteq Q,\ 1 \le i \le h\}$ such that $X(P, (P', i)) = 1$ if $u_P w_{P'} \gamma_i \in L$, and $X(P, (P', i)) = 0$ otherwise.

We claim that the rank of X is $2^n - 1$. We define X' to be a $2^n - 1 \times 2^n - 1$ matrix over the field of characteristic 2 with rows and columns indexed by the nonempty subsets of Q such that the column indexed by P is the sum of the h columns in X indexed by $\{(P, i) \mid 1 \le i \le h\}$.

We want to show that X' is the same matrix as M_n. That is, we want to show that $X'(P, P') = 1$ if $P \bigcap P' \ne \emptyset$ and $X'(P, P') = 0$ otherwise.

Suppose $P \bigcap P' \ne \emptyset$. By Corollary 2, $u_P w_{P'} \in$ *prefix*(L_n) = *prefix*(L). By the definition of γ_i's, exactly one of $u_P w_{P'} \gamma_i$, for $1 \le i \le h$, is in L. That is, exactly one of $X(P, (P', i))$, for $1 \le i \le h$, is 1. Hence, $X'(P, P') = 1$.

Suppose $P \bigcap P' = \emptyset$. By Corollary 2, $u_P w_{P'} \notin$ *prefix*(L_n) = *prefix*(L). Therefore, $u_P w_{P'} \gamma_i \notin L$ for $1 \le i \le h$. Hence, $X(P, (P', i)) = 0$ for $1 \le i \le h$ and $X'(P, P') = 0$.

By Lemma 3, the rank of X' is $2^n - 1$. Since each column of X' is obtained by a linear combination of the columns of X, the rank of X must be bigger than or equal to the rank of X'. Thus, the rank of X is at least $2^n - 1$. Moreover since the number of rows in X is $2^n - 1$, the rank of X is at most $2^n - 1$. Therefore, the rank of X is $2^n - 1$.

Finally, since the rank of X is $2^n - 1$ and by using the same technique as in the proof of Lemma 4, a smallest UFA for L must have at least $2^n - 1$ states. □

The following lemma is a generalization of Lemma 5, which is the special case where $x = \epsilon$.

LEMMA 6. *Let U be a UFA with the number of states less than 2^n-1 which accepts L such that prefix$(L) \subseteq$ prefix(L_n). Then for all $x \in$ prefix(L_n), $x^{-1}($prefix$(L)) \subset x^{-1}($prefix$(L_n))$.*

Proof. From prefix$(L) \subseteq$ prefix(L_n), it is immediate that $x^{-1}($prefix$(L)) \subseteq x^{-1}($prefix$(L_n))$ for any arbitrary x. We want to show that $x^{-1}($prefix$(L)) \neq x^{-1}($prefix$(L_n))$ for any $x \in$ prefix(L_n).

Suppose to the contrary that $x^{-1}($prefix$(L)) = x^{-1}($prefix$(L_n))$ for some $x \in$ prefix(L_n). Thus, $z^{-1}($prefix$(L)) = z^{-1}($prefix$(L_n))$ where $z = x$ *reset*. Since z^{-1} and *prefix* commute, prefix$(z^{-1}(L)) =$ prefix$(z^{-1}(L_n))$. Let L' be $z^{-1}(L)$. Then we obtain prefix$(L') =$ prefix(L_n) since $z^{-1}(L_n) = L_n$ by the property of *reset*.

We are going to construct a UFA U' with less than $2^n - 1$ states to recognize L' which is a contradiction, because of Lemma 5.

The transition diagram for U' is the same as that of U. The set of starting states for U' is defined to be the set of states reached by U on consuming z from the set of starting states of U. The set of final states for U' is again the same as that of U. It is clear that the language accepted by U' is $L' = z^{-1}(L)$. Also, U' cannot be ambiguous otherwise U is also ambiguous. Moreover, the number of states in U' is the same as the number of states in U; therefore, it is less than $2^n - 1$. ∎

We are ready to prove the main result of this paper.

THEOREM 1. *A smallest PNA recognizing L_n has $2^n - 1$ states.*

Proof. By removing the dead state from the DFA obtained by the subset construction, we have a UFA, which is polynomially ambiguous, with $2^n - 1$ states.

Let M be a PNA for L_n with the smallest number of states. Then every state in M must be useful.

Consider the transition diagram of M. Since the strongly connected components form a partial ordering with respect to reachability, there must exist one strongly connected component, denoted T, that cannot be reached from other strongly connected components.

We claim that T must have at least $2^n - 1$ states. Suppose to the contrary that it has less than $2^n - 1$ states.

T must have some starting states in it. Otherwise it is not useful which contradicts the definition of M. Let the set of starting states of M that appears in T be $\{p_1, \ldots, p_k\}$.

Let $1 \leq i \leq k$. We define an NFA T_{p_i} such that p_i is now the only starting and final state, and the transition diagram for T_{p_i} is T. We want to check that Lemma 6 can be applied to the language of T_{p_i}. First, T_{p_i} has less than $2^n - 1$ states. Next, T_{p_i} is a UFA; otherwise by the characterization given in section 2, M is strictly exponentially ambiguous, a contradiction. Let $w \in$ prefix$(L(T_{p_i}))$. Then p_i must reach a nonempty subset of states in T on consuming w. Since all states in M are useful, w is therefore in prefix(L_n). Hence, prefix$(L(T_{p_i})) \subseteq$ prefix(L_n).

Consider the set of UFAs $\{T_{p_i} \mid 1 \leq i \leq k\}$. Let $x_0 = \epsilon \in$ prefix(L_n). For $1 \leq i \leq k$, we define x_i to be a string chosen arbitrarily from

$$(x_0 x_1 \ldots x_{i-1})^{-1}(\text{prefix}(L_n)) - (x_0 x_1 \ldots x_{i-1})^{-1}(\text{prefix}(L(T_{p_i})).$$

Thus, $x_0 x_1 \ldots x_i \in$ prefix(L_n) for $0 \leq i \leq k$. The existence of x_i, for $1 \leq i \leq k$, is then guaranteed by Lemma 6. Let x be $x_1 \ldots x_k$. By the way x_i's are defined, $x \notin$ prefix$(L(T_{p_i}))$ for $1 \leq i \leq k$. Thus, each UFA T_{p_i}, $1 \leq i \leq k$, reaches the empty set from the starting state p_i on consuming x since all states in T_{p_i} are useful.

Let $z = x$ *reset*. Since $x \in$ *prefix*(L_n), then $z^{-1}(L_n) = L_n$ by the property of *reset*.

Let us consider M again. From the set of starting states, M reaches a subset of states, denoted P, on consuming z. Since $z \in$ *prefix*(L_n) and $L(M) = L_n$, P is not empty. Moreover, by the previous discussions, P does not include any state in T.

We define another NFA M' by removing the set of states in T from the state set of M and let P be the new set of starting states, whereas the set of final states is the set of final states of M minus the set of states in T. By the facts that M accepts L_n and $z^{-1}(L_n) = L_n$, M' must also accept L_n. But this is a contradiction since M' is now a PNA accepting L_n with a smaller number of states than M.

Therefore, T cannot have less than $2^n - 1$ states. Hence, M has at least $2^n - 1$ states. □

Remark. We can prove the same results for the related family of automata B_n, defined as the same as A_n except that all states in B_n are final.

Appendix (Proof of Lemma 1).

LEMMA 1. *For any $P \subseteq Q$, we have*

(1) $\delta(P, w_P) = P$;

(2) *for any $q \in P$, $\delta(q, w_P) \supseteq \{q\}$*;

(3) $\delta(Q - P, w_P) = \emptyset$.

Proof. Given a state $q_i \in Q$, we define *shift*(q_i) to be q_{i+1} if $1 \leq i \leq n-1$, and q_1 if $i = n$. Given $P \subseteq Q$, we extend the definition of *shift* such that *shift*$(P) = \{$*shift*$(q) \mid q \in P\}$. Moreover, for any $q \in Q$ and $P \subseteq Q$, we define *shift*$^0(q) = q$ and *shift*$^0(P) = P$. Note that *shift*$^n(q) = q$ and *shift*$^n(P) = P$.

We begin by proving part (1) of the lemma that $\delta(P, w_P) = P$.

Observe that $\delta(P, w_1) = P$. This is because if $q_1 \in P$, then $w_1 = \epsilon$ and $\delta(P, w_1) = \delta(P, \epsilon) = P$. Otherwise if $q_1 \notin P$, then $w_1 = 1$ and $\delta(P, w_1) = \delta(P, 1) = P$ since $q_1 \notin P$.

Therefore, $\delta(P, w_P) = \delta(P, 0w_n0w_{n-1} \ldots 0w_1)$.

We want to show by induction that $\delta(P, 0w_n0w_{n-1} \ldots 0w_{n-i+1}) =$ *shift*$^i(P)$ for $0 \leq i \leq n$. Then we are done since $\delta(P, 0w_n0w_{n-1} \ldots 0w_1) =$ *shift*$^n(P) = P$.

Base. $i = 0$. $\delta(P, \epsilon) = P =$ *shift*$^0(P)$.

Induction hypothesis. Assume that the statement is true for $0 \leq k \leq n-1$.

Induction step. By induction, we have $\delta(P, 0w_n0w_{n-1} \ldots 0w_{n-k+1}0w_{n-k}) = \delta(\delta(P, 0w_n0w_{n-1} \ldots 0w_{n-k+1}), 0w_{n-k}) = \delta($*shift*$^k(P), 0w_{n-k})$. The induction proof is completed if we can verify that $\delta($*shift*$^k(P), 0w_{n-k}) =$ *shift*$^{k+1}(P)$.

Case 1. ($q_{n-k} \in P$). Then $w_{n-k} = \epsilon$ and $q_n \in$ *shift*$^k(P)$. Thus, $\delta($*shift*$^k(P), 0w_{n-k})$ $= \delta($*shift*$^k(P), 0) =$ *shift*$^{k+1}(P)$ since $q_n \in$ *shift*$^k(P)$.

Case 2. ($q_{n-k} \notin P$). Then $w_{n-k} = 1$ and $q_n \notin$ *shift*$^k(P)$. Thus, $\delta($*shift*$^k(P), 0w_{n-k})$ $= \delta($*shift*$^k(P), 01) =$ *shift*$^{k+1}(P)$ since $q_n \notin$ *shift*$^k(P)$.

We finish the proof of part (1) of the lemma. Next, we prove part (2) of the lemma that for any $q \in P$, $\delta(q, w_P) \supseteq \{q\}$.

Observe that $\delta(q, w_1) = \{q\}$. This is because if $q_1 \in P$, then $w_1 = \epsilon$ and $\delta(q, w_1) = \delta(q, \epsilon) = \{q\}$. Otherwise if $q_1 \notin P$, then $w_1 = 1$ and $\delta(q, w_1) = \delta(q, 1) = \{q\}$ since $q \neq q_1$ by the facts that $q_1 \notin P$ and $q \in P$.

Therefore, $\delta(q, w_P) = \delta(q, 0w_n0w_{n-1} \ldots 0w_1)$.

We want to show by induction that $\delta(q, 0w_n0w_{n-1} \ldots 0w_{n-i+1}) \supseteq$ *shift*$^i(\{q\})$ for $0 \leq i \leq n$. Then we are done since $\delta(q, 0w_n0w_{n-1} \ldots 0w_1) \supseteq$ *shift*$^n(\{q\}) = \{q\}$.

Base. $i = 0$. $\delta(q, \epsilon) = \{q\} =$ *shift*$^0(\{q\})$. Thus, $\delta(q, \epsilon) \supseteq$ *shift*$^0(\{q\})$.

Induction hypothesis. Assume that the statement is true for $0 \leq k \leq n-1$.

Induction step. By induction, we have $\delta(q, 0w_n0w_{n-1}\dots0w_{n-k+1}0w_{n-k}) = \delta(\delta(q, 0w_n0w_{n-1}\dots0w_{n-k+1}), 0w_{n-k}) \supseteq \delta(shift^k(\{q\}), 0w_{n-k})$. The induction proof is complete if we can verify that $\delta(shift^k(\{q\}), 0w_{n-k}) \supseteq shift^{k+1}(\{q\})$.

Case 1. ($q_n = shift^k(q)$). Then $w_{n-k} = \epsilon$ since $q_{n-k} = q \in P$. Thus, $\delta(shift^k(\{q\}), 0w_{n-k}) = \delta(shift^k(\{q\}), 0) = \delta(q_n, 0) = \{q_1\} = shift(\{q_n\}) = shift(shift^k(\{q\})) = shift^{k+1}(\{q\})$. Hence, $\delta(shift^k(\{q\}), 0w_{n-k}) \supseteq shift^{k+1}(\{q\})$.

Case 2. ($q_n \neq shift^k(q)$). Then no matter whether $w_{n-k} = \epsilon$ or $w_{n-k} = 1$, we always have $\delta(shift^k(\{q\}), 0w_{n-k}) \supseteq shift^{k+1}(\{q\})$.

We finish the proof of part (2) of the lemma. Finally, we prove part (3) of the lemma that $\delta(Q - P, w_P) = \emptyset$.

We claim that $\delta(Q-P, w_1 0w_n0w_{n-1}0\dots0w_2) = \emptyset$. Hence, $\delta(Q-P, w_P) = \delta(Q-P, w_1 0w_n0w_{n-1}0\dots0w_20w_1) = \delta(\delta(Q-P, w_1 0w_n0w_{n-1}0\dots0w_2), 0w_1) = \delta(\emptyset, 0w_1) = \emptyset$.

First observe that $\delta(Q - P, w_1) = Q - P - \{q_1\}$. This is because if $q_1 \in P$ then $w_1 = \epsilon$ and $q_1 \notin Q-P$. Thus $\delta(Q-P, w_1) = \delta(Q-P, \epsilon) = Q-P = Q-P-\{q_1\}$ since $q_1 \notin Q - P$. Otherwise if $q_1 \notin P$ then $w_1 = 1$. Thus $\delta(Q - P, w_1) = \delta(Q - P, 1) = Q - P - \{q_1\}$.

Next we want to show by induction that for $1 \leq i \leq n$, $\delta(Q-P-\{q_1\}, 0w_n0w_{n-1}\dots 0w_{n-i+2}) = shift^{i-1}(Q-P)-\{q_1, q_2, \dots, q_i\}$. Then we are done since by taking $i = n$, we have $\delta(Q - P - \{q_1\}, 0w_n0w_{n-1}\dots0w_2) = shift^{n-1}(Q - P) - \{q_1, q_2, \dots, q_n\} = \emptyset$.

Base. $i = 1$. $\delta(Q - P - \{q_1\}, \epsilon) = Q - P - \{q_1\} = shift^0(Q - P) - \{q_1\}$.

Induction hypothesis. Assume that the statement is true for $1 \leq k \leq n - 1$.

Induction step. By induction, we have $\delta(Q-P-\{q_1\}, 0w_n0w_{n-1}\dots0w_{n-k+2}0w_{n-k+1}) = \delta(shift^{k-1}(Q - P) - \{q_1, q_2, \dots, q_k\}, 0w_{n-k+1})$. The induction proof is completed if we can verify that $\delta(shift^{k-1}(Q - P) - \{q_1, q_2, \dots, q_k\}, 0w_{n-k+1}) = shift^k(Q - P) - \{q_1, q_2, \dots, q_k, q_{k+1}\}$.

Case 1. ($q_{n-k+1} \in P$). Then $w_{n-k+1} = \epsilon$ and $q_n \notin shift^{k-1}(Q - P)$. Thus, $shift^{k-1}(Q-P) = shift^{k-1}(Q-P)-\{q_n\}$. Hence, $\delta(shift^{k-1}(Q-P)-\{q_1, q_2, \dots, q_k\}, 0w_{n-k+1}) = \delta(shift^{k-1}(Q - P) - \{q_n, q_1, q_2, \dots, q_k\}, 0) = shift^k(Q - P) - \{q_1, q_2, \dots, q_k, q_{k+1}\}$.

Case 2. ($q_{n-k+1} \notin P$). Then $w_{n-k+1} = 1$. Thus, $\delta(shift^{k-1}(Q-P)-\{q_1, q_2, \dots, q_k\}, 0w_{n-k+1}) = \delta(shift^{k-1}(Q-P)-\{q_1, q_2, \dots, q_k\}, 01) = shift^k(Q-P)-\{q_1, q_2, \dots, q_k, q_{k+1}\}$.

We finish the proof of the claim and hence part (3) of the lemma. □

Acknowledgments. The author thanks Andreas Weber for many fruitful discussions and comments throughout this work. He also thanks Jonathan Goldstine and Detlef Wotschke for their valuable discussions.

AN $\Omega(\sqrt{\log \log n})$ LOWER BOUND FOR ROUTING IN OPTICAL NETWORKS *

LESLIE ANN GOLDBERG†, MARK JERRUM‡, AND PHILIP D. MACKENZIE§

Abstract. Optical communication is likely to significantly speed up parallel computation because the vast bandwidth of the optical medium can be divided to produce communication networks of very high degree. However, the problem of contention in high-degree networks makes the routing problem in these networks theoretically (and practically) difficult. In this paper we examine Valiant's *h-relation routing problem*, which is a fundamental problem in the theory of parallel computing. The h-relation routing problem arises both in the direct implementation of specific parallel algorithms on distributed-memory machines and in the general simulation of shared-memory models such as the PRAM on distributed-memory machines. In an h-relation routing problem each processor has up to h messages that it wishes to send to other processors and each processor is the destination of at most h messages. We present a lower bound for routing an h-relation (for any $h > 1$) on a complete optical network of size n. Our lower bound applies to any randomized distributed algorithm for this task. Specifically, we show that the expected number of communication steps required to route an arbitrary h-relation is $\Omega(h + \sqrt{\log \log n})$. This is the first known lower bound for this problem which does not restrict the class of algorithms under consideration.

1. Introduction.

In current distributed-memory parallel computers, a number of processors equipped with private local memory communicate by sending messages via a network of communication links. Current technology restricts the network to be of low degree: each processor in the network can communicate directly with only a few others, and the remainder must be reached indirectly by routing messages along a sequence of links. The emerging technology of optical communication challenges the assumption that the network must be of low degree. In particular, the huge bandwidth of the optical medium can be divided so that each processor has its own channel for receiving messages and each processor can send on any channel. Even though such an interconnection network is a complete graph, there remains the problem of contention: no processor can receive messages simultaneously from two other processors without corruption. The problem of avoiding contention is much more difficult in high-degree networks (such as optical networks) than in traditional low-degree networks.

The problem of routing in optical networks is captured mathematically by the OCPC model. In an n-processor *completely connected Optical Communication Paral-*

lel Computer (n-OCPC) n processors with local memory are connected by a complete network. A computation on this computer consists of a sequence of communication steps. During each communication step each processor can perform some local computation and then send one message to any other processor. If a processor is sent a single message during a communication step then it receives this message successfully, but if it is sent more than one message then the transmissions are garbled and it receives none of them.

Eshaghian [5, 6] first studied the computational aspects of parallel architectures with complete optical interconnection networks. The OCPC model is an abstract model of computation which formalizes important properties of such architectures. It was first introduced by Anderson and Miller [1] and Eshaghian and Kumar [7] and has subsequently been studied by several authors including Valiant [22], Geréb-Graus and Tsantilas [12], and Gerbessiotis and Valiant [11] (though not always under the name OCPC). Aside from its importance as a model for optical communication, the OCPC has the attraction of being a clean, mathematically appealing model that allows us to study a single issue, namely the resolution of contention between independent processors, in isolation from other factors. It has recently been observed that the n-processor OCPC is equivalent to an ERCW PRAM with n global memory cells. Thus our results carry over to that model. For details, see [20].

In this paper we study a fundamental communication problem for multiprocessor computers: that of routing h-relations. This problem arises both in the direct implementation of specific parallel algorithms [1], and in the simulation of shared-memory models, such as the PRAM, on more realistic distributed-memory models [22]. An *h-relation* routing problem [22] is a communication problem in which each processor has up to h messages that it wishes to send to other processors. The destinations of these messages can be arbitrary except that each processor is the destination of at most h messages. The goal is to design a fast algorithm for the n-OCPC that can route an arbitrary h-relation.

Anderson and Miller [1] have observed that an h-relation can easily be routed in h communication steps if all of the processors are given *total* information about the h-relation to be routed. A more interesting (and more realistic) situation arises if we assume that each processor initially knows only about the messages that it wants to send, and that processors learn about the rest of the h-relation only through receiving messages from other processors. This is the usual assumption, and the one that will be made here.

Valiant [22], building on work of Anderson and Miller [1], developed a randomized algorithm that routes an arbitrary h-relation in $O(h + \log n)$ steps, on average. Subsequently, Goldberg, Jerrum, Leighton, and Rao [13] presented a more complex randomized algorithm for the same task that runs in $O(h + \log \log n)$ steps and has failure probability $n^{-\alpha}$ for any constant α. The latter algorithm is asymptotically the fastest known, and it would be interesting to discover whether it is the best possible. Our attention therefore turns to lower bounds.

Goldberg et al. [13] proved a lower bound for a restricted class of algorithms known as *direct*, in which a processor may only send messages directly to their final destination. (Thus the only freedom a processor has is in its choice of *when* to attempt to send its messages.) They proved that for any (randomized) direct algorithm there is a 2-relation that takes $\Omega(\log n)$ steps to route with success probability $\frac{1}{2}$, thus showing that even in a completely connected network it is advantageous to route messages indirectly. Subsequently, MacKenzie, Plaxton, and Rajaraman [19] generalized this

result by showing that for any (randomized) direct algorithm and any $h \geq 2$ there is an h-relation that takes $\Omega(h + \log h \log n)$ expected steps to route. (This bound is tight as the randomized direct algorithm of Geréb-Graus and Tsantilas [12] routes h-relations in $O(h + \log h \log n)$ expected steps.)

Obtaining a lower bound for *unrestricted* algorithms has proved a much greater challenge, owing, no doubt, to the rich variety of strategies that are available to a nondirect algorithm. (Some of the possibilities will be glimpsed in section 2.) Indeed, no lower bound beyond the trivial $\Omega(h)$ was previously known. The new result in this paper is a lower bound on the number of steps required to route 2-relations on an n-OCPC. We prove that for any randomized algorithm there is a 2-relation such that the expected number of steps required to route the relation is $\Omega(\sqrt{\log\log n})$. (See Theorem 3.1 for a precise statement of the result.) Our result implies that for any $h > 1$ the number of steps required to route an arbitrary h-relation is $\Omega(h + \sqrt{\log\log n})$. We note that our lower bound also holds for routing $c+1$-relations in the c-collision OCPC model studied by Dietzfelbinger and Meyer auf der Heide [2].

Our proof technique is based on one used in MacKenzie [18] (see also [16]). The technique is a novel extension to the *random restriction method* which Furst, Saxe, and Sipser [10] used to prove circuit lower bounds. In this extension the choice of *which* inputs to randomly restrict at each stage depends on a careful analysis of the appropriate step of the algorithm under consideration. Although the random restriction method was first used to obtain a deterministic lower bound, we obtain a randomized lower bound by proving that the induction hypothesis in the random restriction method holds with high probability (and not merely with nonzero probability). Other randomized lower bounds were obtained by this method in Hastad [15].

The gap between the current upper and lower bounds on routing h-relations deserves comment. Section 4 indicates why a lower bound of the form $\Omega(\sqrt{\log\log n})$ is the limit of the current technique. An example presented in that section points to an issue that must be faced in any attempt to improve the current lower bound. It appears that some new idea is necessary to make further progress on this front.

2. Some preliminary observations. Imagine that two processors p and q wish to deliver a single message each to a common destination processor within $O(\log\log n)$ steps. Assume that p and q do not know each other's identity. A simple strategy is for p and q each to flip a coin and attempt to transmit its packet to the destination processor if the coin comes up "heads." After $O(\log\log n)$ steps, the probability that p and q have failed to transmit their packets is at least $(\log n)^{-O(1)}$. If $n^{\Omega(1)}$ pairs of processors simultaneously employ this strategy to deliver their messages to separate destinations, the probability that they all succeed is negligible. Some more subtle approach is required.

One possibility, suggested by Rao, is the following. Suppose the processors are assigned binary sequence numbers, and that the numbers assigned to p and q are $p_1p_2\ldots p_r$ and $q_1q_2\ldots q_r$, where $r \sim \log n$. By simultaneously sending messages to processors $p_1p_2\ldots p_{r/2}0\ldots0$ and $q_1q_2\ldots q_{r/2}0\ldots0$, respectively, processors p and q may discover whether their sequence numbers differ in the first $r/2$ bits. After about $\log\log n$ experiments of this general form, and using binary search, p and q can agree on a bit position at which their sequence numbers differ; this bit can then be used to determine a priority for the processors, and hence resolve the conflict. Note that this method (with slight modification) could be used by $n^{\Omega(1)}$ pairs of processors simultaneously. Observe that p and q are not sending messages in order to get the content of the message to another processor but to learn some information about the

competing processor.

A second strategy is replication of messages. In $O(\log \log n)$ binary replication steps, p and q can each prime a set of $\Theta(\log n)$ processors with the message they are required to transmit. These two sets of processors then use the naive coin-flipping strategy to attempt to send their cloned messages to a common target set of size $\Theta(\log n)$. In just a constant number of attempts, the probability that either a p-message or a q-message fails to get through is reduced to $n^{-\Omega(1)}$ where the implicit constant is arbitrary. Finally, the messages in the target set can be funneled into the destination processor by a procedure which is an inverse of the cloning phase. Note that the failure probability is much smaller here than for the naive strategy and can be expected to remain small when many pairs of processors simultaneously attempt to send to distinct targets.

These two examples indicate the subtle strategies that are available to indirect algorithms. With these in mind, it is possible to give a little of the flavor of the lower bound argument. After t-steps, some set of processors (of size at most exponential in t) will be aware that processor p or q has a packet to send. Viewing the situation crudely, these "agents" for p and q can act in one of two modes, or possibly a mixture: (a) they can send messages to some narrow set of destinations that is only weakly dependent on the identity of the source processor, or (b) they can send to a wide destination set, or one that is strongly dependent on the identity of the source processor.

The first strategy sketched above operates purely in mode (a), while the second strategy relies on mode (b) to recruit the processors that are required in the replication phase. The key point is that the effectiveness of mode (a) is limited by the collisions that inevitably occur, while mode (b) is limited in its ability to "advance messages toward their destination." The lower bound proof to be described in section 3 analyzes the tradeoff between these modes. That both strategies described above are effective suggests that the whole range of the tradeoff must be examined and explains some of the technical complexity of the proof.

3. The lower bound argument.

3.1. Definitions and goals. Our goal is to establish the following.

THEOREM 3.1. *Let A be a randomized algorithm that routes 2-relations on an n-OCPC. Then there is a 2-relation on which the expected number of communication steps used by A is at least $\sqrt{\log \log n}/4$.*[1]

The first step in the proof of Theorem 3.1 will be to reduce to the case of deterministic A. A certain restricted class of 2-relations (to be defined presently) will be termed "relevant." We will use a weak form of a theorem of Yao (as stated in [9]) to show that Theorem 3.1 reduces to proving the following.

THEOREM 3.2. *Let A be a deterministic algorithm that allegedly routes 2-relations in $T = \sqrt{\log \log n/2}$ steps. Let the input to A be drawn u.a.r. from the set of relevant 2-relations. Then the probability that A successfully routes the input is at most $\frac{1}{2}$.*

To define the class of relevant 2-relations, we make the following definitions, which will be explained below. (For the purpose of the proof, we define "h-relation" in a restricted way. In the h-relations that we consider, a processor can receive up to h messages but can send at most one message.)

DEFINITION. *A* partial h-relation *is a function from the set $\{1, \ldots, n\}$ of processors to $\{0, 1, *\}$.*

[1] All logarithms in this paper are to the base 2.

DEFINITION. *An* h-relation *is a partial* h*-relation in which no processor is mapped to* "$*$."

Intuitively, we think of the n-OCPC as being partitioned into $n^{4/5}$ *ranges* containing $n^{1/5}$ processors each. If an h-relation maps a processor to 1 then this processor has a message to send, and if it maps a processor to 0 then this processor does not have a message to send. The destination of each message is the first processor in the range containing the sending processor. We can now make the following definitions.

DEFINITION. *A* relevant 2-relation *is an* h*-relation in which exactly two processors in each range are mapped to* "1."

DEFINITION. *A partial* h*-relation* f *is a* refinement *of a partial* h*-relation* f' *(this is denoted by* $f \leq f'$*) if* $f'(p) = 1$ *implies* $f(p) = 1$*, and* $f'(p) = 0$ *implies* $f(p) = 0$.

DEFINITION. *A* partial relevant 2-relation *is a partial* h*-relation that has a refinement which is a relevant* 2*-relation.*

DEFINITION. f_* *is the partial* h*-relation that maps every processor to* "$*$."

3.2. Generating a random 2-relation. Algorithm RANDOMSET can be used to randomly generate a relevant 2-relation one processor at a time. It is called with a partial relevant 2-relation f and a set P of processors which are mapped to "$*$" by f. The processors in P are randomly mapped to "0" or "1" in such a way that the resulting function f' is a partial relevant 2-relation and the following claim holds.

```
Function RANDOMSET(f, P)
    Let f' = f
    For each p ∈ P
        Let s = | { q | q is in the range of p and f(q) = "*" } |
        If no processors in the same range as p are mapped to "1" by f
                With probability 2/s set f'(p) = 1
                With probability 1 − 2/s set f'(p) = 0
        If one processor in the same range as p is mapped to "1" by f
                With probability 1/s set f'(p) = 1
                With probability 1 − 1/s set f'(p) = 0
        Otherwise set f'(p) = 0
    Return f'
End RANDOMSET
```

CLAIM 3.3. *An* h*-relation* f *generated solely by calls to RANDOMSET is a relevant* 2*-relation generated uniformly at random (u.a.r.) from the set of relevant* 2*-relations.*

Proof. The proof is straightforward. ∎

3.3. Defining the knowledge set and t-good partial h-relations. Now we make some definitions that deal with the running of a deterministic algorithm A on an n-OCPC when the input is an h-relation f.

DEFINITION. *The* $(0, f)$-trace *of processor* p *is the tuple* $\langle p, f(p)\rangle$*. The* (t, f)-trace *of processor* p *(for* $t > 0$*) is the tuple* $\langle p, f(p), \lambda_1, \ldots, \lambda_t\rangle$ *in which* λ_j *is the message that processor* p *receives at step* j *if such a message exists and* λ_j *is the null symbol otherwise.*

Note that we lose no generality by assuming that if p sends a message on step t then it sends its entire $(t-1)$-trace. (Since each processor is allowed to know the algorithms that the other processors run we can simulate an algorithm which sends different messages by an algorithm which sends traces using the same pattern of communications.)

DEFINITION. *Processor p is a* direct (t, f)-receiver *of processor q if either $p = q$ or when A is run with input f, p receives a message from q in the first t steps.*

DEFINITION. *Processor p is an* indirect (t, f)-receiver *of q if either p is a direct (t, f)-receiver of q, or when A is run with input f, there is some processor k and some time step $t' < t$ such that k is an indirect (t', f)-receiver of q and p receives a message from k during steps $t' + 1, \ldots, t$.*

DEFINITION. *A set S of processors is a* (t, g)-dependency set *of a processor p if g is a partial h-relation and for any relevant 2-relations f_1 and f_2 which refine g and have $f_1(q) = f_2(q)$ for every processor $q \in S$, the (t, f_1)-trace of p is the same as the (t, f_2)-trace of p.*

The intuition behind the above definition is that p is not dependent on processors outside S, since these could not affect its trace. Note that if S' and S'' are (t, g)-dependency sets of a processor p then so is $S' \cap S''$, so p has a unique (t, g)-dependency set of minimum size.

DEFINITION. *The* (t, g)-knowledge set *of a processor p is the smallest (t, g)-dependency set of p.*

Suppose that g is a partial h-relation and that f is a relevant 2-relation which refines g. Note that if $g(p) =$ "$*$" and q has a (t, g)-dependency set which excludes p then q cannot be an indirect (t, f)-receiver of p. Also note that if $g(p) \neq$ "$*$" then p is not in the (t, g)-knowledge set of any processor. We now define the following constants and functions of n.

DEFINITION. $k_i = 3^i$, $s_0 = n^{1/5}$, $w_i = s_i^{1/k_i}/21k_i^2$, $r_i = s_i^4$, *and* $s_i = w_{i-1}^{1/7}$ (*for* $i \geq 1$).

Recall that $T = \sqrt{\log \log n/2}$. We will use the following facts.

FACT 3.4. *For large enough n and $t \leq T$, $s_t \geq 2^{\log^{1/3} n}$.*

Proof. Note that for $t \geq 1$ we have

$$s_t = (7/3)^{-1/7} 9^{-t/7} {s_{t-1}}^{1/(7 \cdot 3^{t-1})}.$$

Let $\alpha(t)$ denote $1/(7^t 3^{\binom{t}{2}})$. It is easy to prove (by induction on t) that

$$s_t \geq (7/3)^{-2/7} 9^{-2t/7} {s_0}^{\alpha(t)}.$$

Therefore

$$s_T \geq (7/3)^{-2/7} 9^{-2T/7} 2^{\alpha(T) \log n/5}.$$

To see that the claim follows, note that $3^{\binom{T}{2}} \leq (\log n)^{(\log 3)/4}$ and $(\log 3)/4 < 2/3$. □

FACT 3.5. *For large enough n and $t < T$, $3k_t \leq w_t^{1/7}$.*

Proof. Using Fact 3.4, for large enough n and $t < T$ we have

$$3k_t = k_{t+1} \leq 3^{\sqrt{\log \log n}} \leq 2^{\log^{1/3} n} \leq s_{t+1} = w_t^{1/7}. \qquad \square$$

FACT 3.6. $r_t / w_t^{4/7} > s_t^3$.

Proof. The proof is immediate from the definitions. □

DEFINITION. *A* t-good *partial h-relation is a partial h-relation f which satisfies the following three conditions.*

1. *r_t ranges have s_t processors that are mapped to "$*$" by f, and no processors that are mapped to "1" by f, while the remaining ranges have no processors mapped to "$*$" by f, and two processors that are mapped to "1" by f.*

2. *The (t, f)-knowledge set of each processor p has size at most one.*
3. *Each processor q is in the (t, f)-knowledge set of at most k_t processors.*

Condition 2 captures a crucial idea, which can be traced to Fich, Meyer auf der Heide, and Wigderson [8], and may be expressed informally as follows. Suppose that A is run on input g, where g is a 2-relation that refines f. Then the entire state of the n-OCPC at time t depends in a particularly simple way on the restriction of g to the processors p with $f(p) =$ "$*$."

3.4. Refining partial 2-relations with CONSTRUCT. At the heart of our proof is a randomized procedure CONSTRUCT(t, f) that takes a time t and a partial 2-relation f and returns a new partial 2-relation f' that is a refinement of f. Aside from the parameters t and f, CONSTRUCT depends implicitly on the algorithm A, in particular on the action of A at time step $t + 1$. (The approach here is similar to that used by MacKenzie in the context of lower bounds for load balancing [18].) The procedure CONSTRUCT has two important properties, the first of which is concerned with invariance. Namely, we will show that if $t < T$ and CONSTRUCT is called with parameters (t, f), where f is t-good, then with high probability, CONSTRUCT will return a partial 2-relation f' that is $(t + 1)$-good. The second property is that CONSTRUCT is unbiased. Specifically, suppose that GENERATE is a procedure that starts with the partial 2-relation $f_0 = f_*$ and applies CONSTRUCT T times to generate a sequence of partial relevant 2-relations $f_0 = f_* \geq f_1 \geq \cdots \geq f_T \geq f$ in which each $f_t =$ CONSTRUCT(t, f_{t-1}) is a refinement of f_{t-1}, and f is a relevant 2-relation generated u.a.r. from the set of refinements of f_T. We will show that the relevant 2-relation f produced by GENERATE is uniformly distributed. From invariance, we will also be able to conclude that with high probability the partial 2-relation f_T is T-good.

Before describing algorithm CONSTRUCT, we note that the proof of Theorem 3.2 follows quickly from the properties of CONSTRUCT that we have described, provided we are prepared to set aside a minor technical complication, which is dealt with later in this section. With high probability, the partial 2-relation f_T produced by GENERATE has many ranges with no processors mapped to "1" by f_T. In these ranges the target processor has a (T, f_T)-knowledge set of size at most one; thus the target processor can have received at most one of the messages destined for it.

We now describe algorithm CONSTRUCT which is called with a time t and a partial 2-relation f, and which randomly refines f based on the action of algorithm A at step $t + 1$. Let the jth range be denoted by R_j and let S_j denote the set of processors in R_j that are mapped to "$*$" by f. Let J be the set of indices j such that $|S_j| > 0$.

DEFINITION. *A processor p* zero-affects *a processor q if there is a processor p' such that p is in the (t, f)-knowledge set of p', and for any relevant 2-relation g which refines f and has $g(p) = 0$: when A is run with input g, processor p' sends to q on step $t + 1$.*

The notion of p *one-affecting* processor q is defined analogously. Whenever it is the case that a processor p is zero-affected or one-affected by a processor q, there is a risk that the $(t + 1, f)$-knowledge set of p will grow to size greater than one. Recall that the aim of CONSTRUCT is to produce a refinement f' of f that is $(t + 1)$-good; in particular this entails arranging that the $(t + 1, f')$-knowledge set of p has size at most one. CONSTRUCT's strategy is to nominate, for each range R_j with $j \in J$, a certain subset of S_j. The subsets are chosen in such a way that each processor p is affected by at most one processor in the subsets. Then CONSTRUCT randomly

selects a refinement f' of f such that the undetermined part of f' lies precisely over the union of the subsets that were nominated.

We now describe CONSTRUCT in detail. Let W'_j be a subset of S_j which is as large as possible and has the property that if two processors p_1 and p_2 are in W'_j and zero-affect the same processor q, then two processors in $S_j - W'_j$ also zero-affect processor q. Let W''_j be a subset of W'_j which is as large as possible and has the property that if two processors p_1 and p_2 are in W''_j and one-affect the same processor q, then all processors in W''_j one-affect processor q.

For each processor p in range R_j we define the set AFFECTS(p) as follows.

1. If p is in the (t, f)-knowledge set of any processor q then put q in AFFECTS(p).
2. If p zero-affects any processor q and there are not two processors in $S_j - W'_j$ which zero-affect q then put q in AFFECTS(p).
   (The intuition here is that if there are two processors in $S_j - W'_j$ which zero-affect q and all of the processors in $S_j - W'_j$ are mapped to "0" there will be a collision at processor q at step $t + 1$ so q will not be affected by p.)
3. If p one-affects any processor q and there is some processor in W''_j which does not one-affect q then put q in AFFECTS(p).
   (The intuition here is that if every processor in W''_j one-affects q and all of the processors in $S_j - W''_j$ are mapped to "0" there will be a collision at processor q at step $t + 1$ so q will not be affected by p.)

Let W_j be a subset of W''_j which is as large as possible and has the property that for any two processors p_1 and p_2 in W_j, AFFECTS(p_1) $\cap$ AFFECTS(p_2) is empty. (Intuitively, at this point, we would like each processor to be affected by at most one processor in each W_j.)

In CONSTRUCT, we will split J into groups $J_1, J_2, \ldots, J_\ell$ each of size $r_t/w_t^{4/7}$, with the last group possibly smaller. For each group J_i CONSTRUCT will construct a set V_i containing some of the processors from up to one of the ranges in J_i. The sets will have the property that if two processors p and p' are in $\bigcup_i V_i$, then AFFECTS(p)$\cap$ AFFECTS(p') is empty. Intuitively, this means that no processor could be affected by two processors in $\bigcup_i V_i$. We will let V denote $\bigcup_i V_i$. CONSTRUCT will produce f' by making random assignments to the processors which are not in V. We will say that algorithm CONSTRUCT is *successful* if each set V_i has size $w_t^{1/7}$.

```
Function CONSTRUCT(t, f)
    For each i ∈ {1, ..., ℓ}
        Let V_i = ∅
        For each j ∈ J_i
            Let S = ∅
            Let S' = ∅
            While |S| < w_t^{1/7} and |W_j − S − S'| > 0
                Let p be the lowest numbered processor in W_j − S − S'
                If there is no p' ∈ V_1 ∪ ··· ∪ V_{i−1} such that
                    AFFECTS(p) ∩ AFFECTS(p') ≠ ∅ Then
                    Let S = S ∪ {p}
                Else
                    Let S' = S' ∪ {p}
            Let f = RANDOMSET(S_j − S, f)
            If f maps any processor in S_j − S to "1" Then
                Let f = RANDOMSET(S, f)
                Next j
```

```
            Else
                Let V_i = S
                For each remaining j' ∈ J_i
                    Let f = RANDOMSET(S_{j'}, f)
                Next i
        Let f' = f
        Return f'
    End CONSTRUCT
```

3.5. Analysis of CONSTRUCT.

CLAIM 3.7. *If f is t-good then $|\text{AFFECTS}(p)| \leq 3k_t$ for each p.*

Proof. Since f is t-good, each p is in the (t, f) knowledge set of at most k_t processors. Each of these k_t processors can cause p to zero-affect at most one other processor and to one-affect at most one other processor. □

CLAIM 3.8. *If f is t-good then each processor q is in at most 3 sets* AFFECTS(p) *with $p \in W_j''$.*

Proof. Since f is t-good, the (t, f)-knowledge set of q has size at most one. Therefore, q is added to at most one set AFFECTS(p_1) using the first part of the definition of AFFECTS(p). By the construction of W_j', q is added to at most one set AFFECTS(p_2) using the second part of the definition of AFFECTS(p). Finally, by the construction of W_j'', q is added to at most one set AFFECTS(p_3) using the third part of the definition of AFFECTS(p). □

CLAIM 3.9. *If f is t-good then for each $j \in J$ we have $|W_j'| \geq |S_j|/(2k_t + 1)$.*

Proof. We use the following procedure, which we call Procedure A.

```
Procedure A
    For each j ∈ J
        Let S' = ∅
        Let S = S_j
        While |S| > 0
        Select a processor p ∈ S
            Let S = S − p
            Let S' = S' ∪ {p}
            For each processor q which p zero-affects
                Let Z = {v | v zero-affects q and v ∈ S}
                If Z > 1 Then
                    Let p_1, p_2 be two processors in Z
                    Let S = S − {p_1, p_2}
                Else
                    If Z = 1 Then
                        Let p_1 be the processor in Z
                        Let S = S − {p_1}
End A
```

Using Procedure A we can construct a set $S' \subseteq S_j$ such that if two processors p_1 and p_2 are in S' and zero-affect the same processor q, then two processors in $S_j - S'$ also zero-affect processor q. Procedure A starts by setting $S = S_j$. Since f is t-good each processor $p \in S$ zero-affects at most k_t processors. So for each iteration of the while loop at most $2k_t + 1$ processors are removed from S with exactly one of them placed in S'. Thus $|S'| \geq |S_j|/(2k_t + 1)$. By the definition of W_j', we have $|W_j'| \geq |S'| \geq |S_j|/(2k_t + 1)$. □

CLAIM 3.10. *If f is t-good then for each $j \in J$ we have $|W_j''| \geq |W_j'|^{1/k_t}/k_t$.*

Proof. For $p \in W'_j$, let $D(p)$ be the set of processors which p one-affects. Then $|D(p)| \leq k_t$. A *sunflower* is defined as a collection of sets such that if an element is in two of the sets, then it is contained in all of the sets. The Erdös–Rado theorem ([4]; see also [17]) says the following: let t and m be positive integers and let F be a family of sets such that every element of F has size at most t and $|F| > t!(m-1)^t$. Then F contains a sunflower of size m. If we let F be the family of sets $D(p)$ for $p \in W'_j$, then F contains a sunflower of size $(|W'_j|/k_t!)^{1/k_t} \geq |W'_j|^{1/k_t}/k_t$. If two processors p_1 and p_2 correspond to two sets in this sunflower and they one-affect the same processor q, then (by the definition of *D(p)* and sunflower) all p corresponding to sets in this sunflower one-affect q, and since W''_j is the largest set of processors which satisfy this property, $|W''_j| \geq |W'_j|^{1/k_t}/k_t$. □

A construction similar to the one used in the proof of Claim 3.10 was used by Grolmusz and Ragde [14].

CLAIM 3.11. *If f is t-good then for each $j \in J$ we have $|W_j| \geq |W''_j|/7k_t$.*

Proof. Construct a graph $G = (W''_j, E)$ where $(p,q) \in E$ if AFFECTS(p) ∩ AFFECTS(q) is nonempty. Then an independent set S in this graph has the property that for p_1, p_2 in S, AFFECTS(p_1) ∩ AFFECTS(p_2) is empty. Then W_j is simply the largest independent set in this graph. By Turán's theorem, $|W_j| \geq |W''_j|^2/(|W''_j| + 2|E|)$. By Claims 3.7 and 3.8, for each $p \in W''_j$, $|\text{AFFECTS}(p)| \leq 3k_t$, and each q is in at most 3 sets AFFECTS(p). Thus each $p \in W''_j$ is an endpoint of at most $6k_t$ edges in E and therefore $|E| \leq 3k_t\,|W''_j|$. We conclude that $|W_j| \geq |W''_j|/7k_t$. □

A construction similar to the one used in the proof of Claim 3.11 was used by Fich, Meyer auf der Heide, and Wigderson [8].

COROLLARY 3.12. *If f is t-good then for each $j \in J$ we have $|W_j| \geq w_t$.*

Proof. Since f is t-good, $|S_j| = s_t$. Then the corollary follows from Claims 3.9, 3.10, and 3.11. □

CLAIM 3.13. *If f is t-good then the number of groups used by algorithm* CONSTRUCT *is $w_t^{4/7}$.*

Proof. This follows from the definition of t-good and from the fact that the size of the groups is $r_t/w_t^{4/7}$. □

CLAIM 3.14. *If f is t-good and $t < T$ then the while loop in algorithm* CONSTRUCT *always terminates with $|S| = w_t^{1/7}$.*

Proof. We will show that if f is t-good then $|S| < w_t^{1/7}$ implies $|W_j - S - S'| > 0$. Suppose that some vertex p in W_j cannot be added to S. Then for some $p' \in V_1 \cup \cdots \cup V_{i-1}$ we have AFFECTS(p) ∩ AFFECTS(p') ≠ ∅. But the size of each set V_α is at most $w_t^{1/7}$ and i is at most the number of groups, which is equal to $w_t^{4/7}$ by Claim 3.13. Furthermore, for each $p' \in V_1 \cup \cdots \cup V_{i-1}$, $|\text{AFFECTS}(p')| \leq 3k_t$. So at most $3k_t w_t^{5/7}$ members of R_j will be put in S'. By Fact 3.5, $3k_t w_t^{5/7} < w_t - w_t^{1/7}$ for $t < T$ and large enough n. We conclude using Corollary 3.12 that if $|S| < w_t^{1/7}$ then $|W_j - S - S'| > w_t - (w_t^{1/7}) - (w_t - w_t^{1/7}) = 0$. □

CLAIM 3.15. *If f is t-good and $t < T$ then the probability that* CONSTRUCT *is successful is at least $1 - n^{-2}$.*

Proof. We have already shown in the proof of Claim 3.14 that if f is t-good and $t < T$ then the while loop in algorithm CONSTRUCT always terminates with $|S| = w_t^{1/7}$. It remains to show that with probability at least $1 - n^{-2}$ each group i has a range j such that the function f returned by the call "Let f = RANDOMSET($S_j - S, f$)" does not map any processor in $S_j - S$ to "1." Assume that this is true for groups 1 to $i-1$. For $1 \leq v \leq i-1$, let X_v be the random variable equal to the index of the

first such range in group v. For $1 \le j \le r_t/w_t^{4/7}$, let $Y_{i,j}$ be a binary random variable which is 1 when range j is such a range for group i. Let $Z_i = \sum_{j=1}^{r_t/w_t^{4/7}} Y_{i,j}$. Note that Z_i is zero if and only if group i does not have such a range. Note that for $j \neq j'$, $Y_{i,j}$ and $Y_{i,j'}$ are independent. By construction, for any $b_1, \ldots, b_{i-1} \in [1, r_t/w_t^{4/7}]$, using the facts that $s_t \ge 2^{\log^{1/3} n}$ (from Fact 3.4), and $r_t/w_t^{4/7} > s_t^3$ (from Fact 3.6), and assuming n is large,

$$
\begin{aligned}
&\Pr(Z_i = 0 | X_{i-1} = b_{i-1}, \ldots, X_1 = b_1) \\
&\quad = \Pr\left(\sum_{j=1}^{r_t/w_t^{4/7}} Y_{i,j} = 0 | X_{i-1} = b_{i-1}, \ldots, X_1 = b_1 \right) \\
&\quad = \Pr\left(\bigcap_{j=1}^{r_t/w_t^{4/7}} (Y_{i,j} = 0) | X_{i-1} = b_{i-1}, \ldots, X_1 = b_1 \right) \\
&\quad = \prod_{j=1}^{r_t/w_t^{4/7}} \Pr(Y_{i,j} = 0 | X_{i-1} = b_{i-1}, \ldots, X_1 = b_1) \\
&\quad = \left(1 - \frac{\binom{w_t^{1/7}}{2}}{\binom{s_t}{2}} \right)^{r_t/w_t^{4/7}} \\
&\quad \le \left(1 - \frac{1}{s_t^2} \right)^{s_t^3} \\
&\quad \le e^{-s_t} \\
&\quad \le n^{-3}.
\end{aligned}
$$

The probability of failing in any group can then be bounded by

$$
\begin{aligned}
&\sum_{i=1}^{w_t^{4/7}} \Pr(Z_i = 0 | Z_{i-1} = 1, \ldots, Z_1 = 1) \\
&\quad = \sum_{i=1}^{w_t^{4/7}} \sum_{b_1, \ldots, b_{i-1} \in [1, r_t/w_t^{4/7}]} \Pr(Z_i = 0 | X_{i-1} = b_{i-1}, \ldots, X_1 = b_1) \\
&\qquad\qquad \Pr(X_{i-1} = b_{i-1}, \ldots, X_1 = b_1) \\

$$

COROLLARY 3.16. *If f is t-good and algorithm* CONSTRUCT *is successful then after* CONSTRUCT *is executed r_{t+1} ranges have s_{t+1} processors that are mapped to "$*$" by f', and no processors that are mapped to "1" by f', while the remaining ranges*

have no processors mapped to "$*$" *by* f'*, and two processors that are mapped to* "1" *by* f'

Proof. The proof is immediate from the definition of successful and from Claim 3.13. □

CLAIM 3.17. *If* f *is* t*-good then after* CONSTRUCT *is executed every processor* q *that is in the* $(t+1, f')$*-knowledge set of a processor* p *has* $p \in \text{AFFECTS}(q)$.

Proof. By the definition of dependency sets, we can form a $(t+1, f')$ dependency set D of p by taking the union of the (t, f)-knowledge set of p and the (t, f)-knowledge sets of all processors p' satisfying the following: there is some refinement g of f which is a relevant 2-relation and on which p' sends to p on step $t+1$. Note that D is the union of the (t, f)-knowledge set of p and the set of processors that zero-affect p and the set of processors that one-affect p. If q is in the (t, f)-knowledge set of p then p is in AFFECTS(q) by the first part of the definition of AFFECTS. Suppose that q_1 is a processor in some range j which zero-affects p and that $p \notin \text{AFFECTS}(q_1)$. By the second part of the definition of AFFECTS we know that there are two processors in $S_j - W'_j$ which zero-affect p. If both of these are mapped to "0" by f' then for any refinement of f' processor p has a conflict at step $t+1$ so $D - q_1$ is a $(t+1, f')$-dependency set of p. If, on the other hand, one of these is mapped to "1" by f' then algorithm CONSTRUCT maps every member of the range of q_1 to "0" or "1" so $D - q_1$ is a $(t+1, f')$-dependency set of p. (Recall that if $f'(q_1) \neq$ "$*$" then q_1 cannot be in the $(t+1, f')$-knowledge set of any processor.) Similarly, suppose that q_2 is a processor in some range j which one-affects p and that $p \notin \text{AFFECTS}(q_2)$. By the third part of the definition of AFFECTS we know that every processor in W''_j one-affects p. If all of the processors in $S_j - W''_j$ are mapped to "0" by f' then for any refinement of f' that is a relevant 2-relation processor p has a conflict at step $t+1$ so $D - q_2$ is a $(t+1, f')$-dependency set of p. If, on the other hand, one of these is mapped to "1" by f' then algorithm CONSTRUCT maps every member of the range of q_2 to "0" or "1" so $D - q_2$ is a $(t+1, f')$-dependency set of p. □

CLAIM 3.18. *If* f *is* t*-good and algorithm* CONSTRUCT *is successful then after* CONSTRUCT *is executed the* $(t+1, f')$*-knowledge set of every processor* p *has size at most one.*

Proof. We know from Claim 3.17 that every processor p has a $(t+1, f')$-dependency set D which contains only those processors q such that $p \in \text{AFFECTS}(q)$. Suppose that two processors q and q' have $f'(q) = f'(q') =$ "$*$." (If a processor q is not mapped to "$*$" by f' then it is not in the $(t+1, f')$-knowledge set of any processor so it is not in the $(t+1, f')$-knowledge set of p.) Then q must be in some $W_j \subset W''_j \subset W'_j$ and q' must be in some $W_{j'} \subset W''_{j'} \subset W'_{j'}$ and both q and q' are in the set V constructed by algorithm CONSTRUCT. If $j = j'$, then the definition of W_j guarantees that $\text{AFFECTS}(q) \cap \text{AFFECTS}(q') = \emptyset$, implying that p is in just one of these sets, and thus either q or q' is not in D. If, on the other hand, $j \neq j'$ by the construction of V, $\text{AFFECTS}(q) \cap \text{AFFECTS}(q') = \emptyset$, implying p is in just one of these sets, and thus either q or q' is not in D. Thus $|D| \leq 1$. □

CLAIM 3.19. *If* f *is* t*-good then after* CONSTRUCT *is executed each processor* q *is in the* $(t+1, f')$*-knowledge set of at most* k_{t+1} *processors.*

Proof. Let q be a processor which is in the $(t+1, f')$-knowledge set of a processor p. By Claim 3.17, $p \in \text{AFFECTS}(q)$. But by Claim 3.7, $|\text{AFFECTS}(q)| \leq 3k_t = k_{t+1}$. The claim follows. □

LEMMA 3.20. *If* $t < T$ *and* CONSTRUCT *is called with parameters* (t, f)*, where* f *is* t*-good, then with probability at least* $1 - n^{-2}$ CONSTRUCT *will return a partial*

2-*relation* f' *that is* $(t+1)$-*good.*

Proof. The proof follows from Claims 3.15, 3.18, and 3.19 and Corollary 3.16. □

3.6. Function GENERATE. We use the following function, which calls CONSTRUCT to generate a sequence of partial relevant 2-relations $f_0 = f_* \geq f_1 \geq \cdots \geq f_T \geq f$ in which each f_t is a refinement of f_{t-1}, f is a refinement of f_T, and f is a relevant 2-relation generated u.a.r.

```
Function GENERATE
    Let f_0 = f_*
    Let f = f_0
    Let t = 0
    While t ≤ T Do
        If for some p, f(p) = "*" Then
            Let f_t = CONSTRUCT(t, f)
        Else
            Let f_t = f
        t = t + 1
        f = f_t
    Let P = {p | f(p) = "*"}
    Return RANDOMSET(f, P)
End GENERATE
```

LEMMA 3.21. *The relevant* 2-*relation* f *produced by* GENERATE *is uniformly distributed.*

Proof. The lemma follows from Claim 3.3. □

LEMMA 3.22. *With probability at least* $1 - n^{-1}$, *the partial* 2-*relation* f_T *is* T-*good.*

Proof. Let Z_t be a random variable which is equal to 1 when CONSTRUCT succeeds at step t. Then the probability of failing at any step $t \leq T$ can then be bounded by

$$\sum_{t=1}^{T} \Pr(Z_t = 0 \mid Z_{t-1} = 1, \ldots, Z_1 = 1).$$

By Lemma 3.20, this is at most Tn^{-2} which is at most n^{-1}. □

We now prove the following theorem.

THEOREM 3.2. *Let* A *be a deterministic algorithm that allegedly routes* 2-*relations in* $T = \sqrt{\log\log n/2}$ *steps. Let the input to* A *be drawn u.a.r. from the set of relevant* 2-*relations. Then the probability that* A *successfully routes the input is at most* $\frac{1}{2}$.

Proof. We will generate a relevant 2-relation by running algorithm GENERATE. By Lemma 3.21, algorithm GENERATE generates relevant 2-relations u.a.r. GENERATE also produces a sequence $f_0 \geq \cdots f_T \geq \cdots f$ in which f is the final relevant 2-relation. By Lemma 3.22, f_T will be T-good with probability at least $1 - 1/n$.

Suppose that f_T is T-good. Then there is a range R that has a set S of s_T processors which are mapped to "$*$" by f_T. R has no processors which are mapped to "1" by f_T. Let d denote the first processor in range R. (d is the destination of the messages in range R.) The (T, f_T)-knowledge set of d contains at most one processor. There are three cases which must be examined concerning f_T.

Case 1. The (T, f_T)-knowledge set of d contains a processor q which is a member of S: we wish to bound the probability that A succeeds, given that f_T is in Case 1. Let $\mathcal{F}_1$ denote the set of relevant 2-relations which refine f_T and map q to "1" and

let $\mathcal{F}_0$ denote the set of relevant 2-relations which refine f_T and map q to "0." One can see by examining algorithm RANDOMSET that the probability that f is in $\mathcal{F}_1$ is $2/s_T$ and the probability that f is in $\mathcal{F}_0$ is $1 - 2/s_T$. We now examine the following subcases concerning f.

Case 1A. f is in $\mathcal{F}_1$: we wish to bound the probability that A succeeds, given that f is in $\mathcal{F}_1$. There is a particular trace τ which is the (T, f')-trace of d for every input h-relation $f' \in \mathcal{F}_1$. Since A runs in T steps processor d uses this trace τ to deduce the pair of messages that were destined for d in every input h-relation that is in $\mathcal{F}_1$. But there are $s_T - 1$ such pairs of messages, each of which is equally likely to come up in a randomly chosen member of $\mathcal{F}_1$. So the probability that A is successful given that f is in $\mathcal{F}_1$ is at most $1/(s_T - 1)$.

Case 1B. f is in $\mathcal{F}_0$: we wish to bound the probability that A succeeds, given that f is in $\mathcal{F}_0$. There is a particular trace τ which is the (T, f')-trace of d for every input h-relation $f' \in \mathcal{F}_0$. Since A runs in T steps processor d uses this trace τ to deduce the pair of messages that were destined for d in every input h-relation that is in $\mathcal{F}_0$. But there are $\binom{s_T-1}{2}$ such pairs of messages, each of which is equally likely to come up in a randomly chosen member of $\mathcal{F}_1$. So the probability that A is successful given that f is in $\mathcal{F}_1$ is at most $1/\binom{s_T-1}{2}$.

Therefore the probability that A succeeds given that f_T is in Case 1 is at most $(2/s_T)(1/(s_T - 1)) + (1 - 2/s_T)(1/\binom{s_T-1}{2})$ which is at most $2/\binom{s_T-1}{2}$.

Case 2. The (T, f_T)-knowledge set of d contains a processor q which is not a member of S: similar arguments to those used in Case 1 show that the probability that A succeeds given that f_T is in Case 2 is at most $1/\binom{s_T}{2}$.

Case 3. The (T, f_T)-knowledge set of d is the empty set: similar arguments to those used in Case 1 show that the probability that A succeeds given that f_T is in Case 3 is at most $1/\binom{s_T}{2}$.

Finally, we conclude that the probability that A successfully routes f in T steps is at most the sum of $1/n$ (an upper bound on the probability that f_T is not T-good, by Lemma 3.22) and $(1 - 1/n) \times 2/\binom{s_T-1}{2}$ (an upper bound on the probability that A succeeds given that f_T is T-good). We can use Fact 3.4 to show that this quantity is at most $1/2$.

Therefore, with probability at least $1/2$, an f drawn u.a.r. from the set of relevant 2-relations will not be routed by algorithm A in T steps. □

COROLLARY 3.23. *Let A be a deterministic algorithm that routes 2-relations. Let the input to A be drawn u.a.r. from the set of relevant 2-relations. Then the expected number of communication steps used by A is at least $\sqrt{\log \log n}/4$.*

Proof. The corollary follows from the fact that $\sqrt{\log \log n}/4 \leq (1/2)(T+1)$. □

The following weak form of a theorem of Yao is stated (and proved) in Fich, Ragde, and Wigderson's paper [9].

THEOREM 3.24 (see [23]). *Let T_1 be the expected running time for a given probabilistic algorithm solving problem P, maximized over all possible inputs. Let T_2 be the average running time for a given input distribution, minimized over all possible deterministic algorithms to solve P. Then $T_1 \geq T_2$.* □

We now prove the following theorem.

THEOREM 3.1. *Let A be a randomized algorithm that routes 2-relations on an n-OCPC. Then there is a 2-relation on which the expected number of communication steps used by A is at least $\sqrt{\log \log n}/4$.*

Proof. Corollary 3.23 shows that the average running time for the uniform distribution on relevant 2-relations, minimized over all deterministic algorithms, is at least

$\sqrt{\log\log n}/4$. Theorem 3.1 now follows from Theorem 3.24. □

4. The prospect for tightening the bound. Recall the situation in which two processors p and q each have a single message to transmit to a common destination. Consider the following OCPC "algorithm" which is a parallel version of a strategy consider in section 2. In $\Theta(\sqrt{\log\log n})$ steps, p and q recruit $k = \Theta\big(\exp(\sqrt{\log\log n}\,)\big)$ "agents" to help discover a bit position at which the binary sequence numbers for p and q differ. This is done using the method of section 2 but with k-way search in place of binary search: a p-agent and a q-agent simultaneously attempt to transmit a message to processors with sequence numbers of the form $0\ldots0p_{i+1}\ldots p_{i+r/k}0\ldots0$ and $0\ldots0q_{i+1}\ldots q_{i+r/k}0\ldots0$, respectively, and hence discover whether the sequence numbers of p and q differ on a particular block of r/k bits. This would seem to give an $O(\sqrt{\log\log n}\,)$ algorithm for delivering the messages.

Of course, the catch is that a p-agent that finds a block on which the sequence numbers of p and q differ is unable to alert the other p-agents to the discovery, at least not sufficiently quickly to obtain an improvement over the original binary search strategy. Unfortunately, the lower bound argument presented here is oblivious to a cheating "algorithm" in which an agent that finds an appropriate block broadcasts its discovery to the other agents in one step. The problem is that in the lower bound argument, the behavior of a processor is considered to be a function of a partial 2-relation f that provides far more information than a processor could in reality know.

Acknowledgments. The authors thank Satish Rao and Mike Sipser for useful discussions.

COMPUTING MATRIX EIGENVALUES AND POLYNOMIAL ZEROS WHERE THE OUTPUT IS REAL*

DARIO BINI† AND VICTOR Y. PAN‡

Abstract. Surprisingly simple corollaries from the Courant–Fischer minimax characterization theorem enable us to devise a very effective algorithm for the evaluation of a set S interleaving the set E of the eigenvalues of an $n \times n$ real symmetric tridiagonal (rst) matrix T_n (as well as a point that splits E into two subsets of comparable cardinalities). Furthermore, we extend this algorithm so as to approximate all the n eigenvalues of T_n at *nearly optimal* sequential and parallel cost, that is, at the cost of staying within polylogarithmic factors from the straightforward lower bounds. The resulting improvement of the known processor bound in NC algorithms for the rst-eigenproblem is roughly by factor n. Our approach extends the previous works [M. Ben-Or and P. Tiwari, *J. Complexity*, 6(1990), pp. 417–442] and [M. Ben-Or et al., *SIAM J. Comput.*, 17(1988), pp. 1081–1092] for the approximation of the zeros of a polynomial having only real zeros, and our algorithm leads to an alternative and simplified derivation of the known record parallel and sequential complexity estimates for the latter problem.

1. Introduction.

1.1. The problem. The problem of approximating the eigenvalues of an $n \times n$ Hermitian or real symmetric matrix A is one of the central problems of practical matrix computations [GL], [Par]. The first step of its solution in all the customary algorithms is the reduction of the input matrix A to the real symmetric tridiagonal (rst) form; this step can be effectively parallelized [Pan87], [BP94, Proposition 5.4, p. 325].

In the present paper, we consider the remaining eigenvalue problem for an $n \times n$ rst-matrix T_n. From technical and theoretical points of view, this problem is closely related to approximating the zeros of polynomials having only real zeros. In computing practice, such polynomials usually appear as the characteristic polynomials of Hermitian (or real symmetric) matrices, which also cover the class of orthogonal polynomials. Given the coefficients of an nth-degree polynomial $p(\lambda)$ having only real zeros, $\lambda_1, \ldots, \lambda_n$, we may compute the entries of an $n \times n$ rst-matrix T_n that has the characteristic polynomial $p(\lambda)$ and the eigenvalues $\lambda_1, \ldots, \lambda_n$. In Appendix A and also in [BP94, pp. 117–120], we achieve this by applying the extended Euclidean scheme to $p(\lambda)$ and $p'(\lambda)$, whereas, for a given T_n, we may compute the coefficients of $p(\lambda)$ by applying a simpler algorithm, which we present in section 5. In the practice of matrix computations, the reduction of the rst-eigenvalue problem to computing

the coefficients of the characteristic polynomial $p(\lambda)$ is avoided because of the numerical stability problems (in particular, the value $|p(0)| = |\det T_n|$ can be very large); this does not apply, however, to computing the *values* of $p(\lambda)$, which is a customary auxiliary step of the rst-eigenvalue computation [Par], [GL, pp. 437–440].

1.2. Our results (outline). Our main result is a new parallel NC algorithm for approximating the eigenvalues of an rst-matrix T_n given its entries. We assume the customary arithmetic and Boolean PRAM models of parallel computation (where in each parallel step each nonidle processor performs one arithmetic or, respectively, Boolean operation), and we deduce *nearly optimum* upper bounds on parallel time and the number of processors required by our algorithm. (By nearly optimum we mean upper bounds that are within polylogarithmic factors from the known, and in our case straightforward, lower bounds.) This is a dramatic improvement of the previous best parallel solution, based on the reduction of the problem to approximating the zeros of $p(\lambda)$ and on the solution of the latter problem by means of the algorithm of [BOT]. Our approach avoids using extended Euclidean computations involved in the algorithm of [BOT], and this gives us the edge over [BOT].

The sequential version of our algorithm, as well as its extension to the sequential and parallel approximation of the zeros of $p(\lambda)$ given the coefficients, supports the same complexity estimates as the algorithm of [BOT] does, and in the sequential case, these upper estimates are nearly optimal too. Our approach, however, may be considered conceptually simpler and easier to comprehend, as the reader may observe from the comparison of our techniques with ones of [BOT], made in the beginning of section 2.

1.3. Our complexity estimates. To estimate the sequential and parallel cost, we will write $O_A(t,p)$ and $O_B(t,p)$ for the algorithms that require $O(t)$ parallel steps using p arithmetic processors and $O(t)$ parallel steps using p bit-serial processors, respectively. The bounds $O_A(t,sp)$ and $O_B(t,sp)$ imply the bounds $O_A(st,p)$ and $O_B(st,p)$, respectively, for $s \geq 1$, according to Brent's scheduling principle of parallel computing [Br]. (In particular, $O_A(t,p)$ and $O_B(t,p)$ imply the sequential arithmetic cost bound $O_A(tp,1)$ and the sequential Boolean cost bound $O_B(tp,1)$, respectively.) Under this notation, our algorithm supports approximating the eigenvalues of T_n (whose entries have magnitudes at most 2^m), within the absolute error bound 2^{-h}, at the arithmetic and Boolean parallel cost bounded by $O_A(\log^2 n(\log^2 b + \log n)\log\log n, n/\log\log n)$ and $O_B(\log^2 n \log(nb)(\log^2 b + \log n)\log\log n \log\log(nb), n^2 b/\log\log n)$, respectively, and at the sequential cost bounded by $O_A(n\log^2 n(\log^2 b + \log n), 1)$ and $O_B(n^2 b \log^2 n \log(nb)(\log^2 b + \log n)\log\log(nb), 1)$, respectively, where $b = m + h$. For approximating all the n zeros of a polynomial $p(\lambda)$ having only real zeros, the same sequential cost bounds hold, but the parallel cost bounds change (in particular, to $O_A(\log^2 n(\log^2 b + \log n), (n/\log b)^2)$ under the arithmetic PRAM model) since we need to add the cost of performing the extended Euclidean algorithm that supports the transition from $p(\lambda)$ to T_n. In section 8, we comment on some ways to further minor improvements.

1.4. A parallel modification. Our major concern in this paper is about the computational complexity estimates. On the other hand, caring more about numerical stability of lower precision computations than about decreasing their asymptotic complexity, we have modified our main algorithm in [BP92] (cf. our Remark 5.1 in section 5 and comments in section 8). In the parallel NC algorithm of [BP92], we only need about $n/\log n$ times more processors but achieve substantially improved

numerical stability, which makes the algorithm competitive with the known alternative practical algorithms for the symmetric eigenvalue problem. In [B] and in [BG1], further progress in this direction has been obtained.

1.5. Organization of the paper. We will organize our paper as follows: in section 2, we deduce some properties of interlacing sets by using the Cauchy interlace theorem for the matrix eigenvalues. In section 3, for each eigenvalue of T_n, we compute either its approximation within a fixed error bound or an interval containing this eigenvalue but no other eigenvalues of T_n. In section 4, given an interval containing only one eigenvalue, we compute an approximation to this eigenvalue within the required precision by means of Newton's method and of the bisection of the exponents. In section 5, we describe an algorithm for the simultaneous computation of the values of the characteristic polynomial and its derivative at a set of points. In section 6, we summarize the construction of sections 2–5 and devise an algorithm for the approximation of all the eigenvalues. In section 7, we estimate the bit-complexity of the algorithm. In section 8, we briefly discuss some results that appeared more recently, after this paper had been submitted for publication—in particular, some results related to the complexity estimates and to practical performance of the algorithm of the present paper. In section A.1 of the appendix, we discuss the relations between the polynomial root-finding problem and the problem of the computation of the eigenvalues of a matrix, and in section A.2, the reduction of a Hermitian or real symmetric matrix to the tridiagonal form.

2. Interlacing sets and splitting points for the set of the eigenvalues. In the following, all logarithms are to the base 2.

Hereafter, T_n denotes an $n \times n$ rst-matrix having diagonal entries $a_1, \dots, a_n$, subdiagonal entries $b_1, \dots, b_{n-1}$, and a set Λ of n eigenvalues, $\Lambda = \{\lambda_1 \le \cdots \le \lambda_n\}$. Without loss of generality, suppose that $b_1 \dots b_{n-1} \neq 0$. (Indeed, if $b_j = 0$ for some j, the eigenvalue problem would be split into two eigenvalue problems of smaller dimensions.) We assume that $|a_i|$, $|b_i| \le 2^m$, m is a positive integer, and then, by virtue of Gerschgorin's theorem ([GL, p. 341]),

$$-3(2^m) \le \lambda_i \le 3(2^m). \tag{2.1}$$

We say that the set $R = \{r_0, \dots, r_k\}$ *interleaves* the set $Q = \{q_1, \dots, q_k\}$ and that R is an *interlacing set* for Q if $r_0 \le q_1 \le r_1 \le q_2 \le \cdots \le q_{k-1} \le r_{k-1} \le q_k \le r_k$, where, in particular, we will allow $r_0 = -\infty$ and/or $r_k = +\infty$, and then we will write $R = \{r_i, \dots, r_{k-j}\}$, where $i, j = 0, 1$. We say that s is a *splitting point of the level* (g, h) for the set Q if $q_g < s < q_h$.

In this section, we will prove some simple corollaries from Cauchy's interlace theorem [Par, p. 186] or from the Courant–Fischer minimax characterization [GL, p. 411]. Later on, they will lead us to simple algorithms for the evaluation of the interlacing sets and splitting points for the set of the eigenvalues of T_n. Using such sets and/or points will enable us to devise divide-and-conquer algorithms for approximating the eigenvalues of T_n, and we will specify such an algorithm in section 6.

It is instructive to compare these results with the techniques of [BOT] and [BFKT] dealing with a polynomial $p(\lambda)$ that has only real zeros and can be considered as the characteristic polynomial of T_n. Specifically, the algorithm of [BOT] relies on computing the Sturm and pseudoremainder sequences associated with $p(\lambda)$ and defining a set S of real points that interleaves the set of the zeros of $p(\lambda)$. Computing such a set S is the central (and also most innovative, most intricate, and most involved) part of

the algorithm of [BOT], and here we will introduce our main innovation too: we will replace the major techniques of [BOT] by some simple corollaries from Cauchy's interlace theorem or the Courant–Fischer minimax characterization theorem, and then, we will immediately arrive at a set interleaving the set of the eigenvalues Λ of T_n.

Technically, it may also be interesting that Cauchy's theorem or the Courant–Fischer minimax characterization may replace Sturm sequences in at least one more application. Namely, in [BFKT], the Sturm sequences have been used for computing a splitting point (rather than the interleaving set) for the set of the zeros of $p(\lambda)$; then again, some simple corollary from Cauchy's theorem or the Courant–Fischer minimax characterization will give us a simple algorithm for computing such a splitting point for the eigenvalues of T_n, and this computation is more effective than one of [BFKT]. We will give more comments later on, after the statement of our Corollary 2.1.

Hereafter, $\mathrm{Diag}(B_1, \dots, B_s)$ denotes the block diagonal matrix having diagonal blocks $B_1, \dots, B_s$.

We will rely on the following result, known as Cauchy's interlace theorem.

THEOREM 2.1. *If A_r denotes an $r \times r$ principal submatrix of an $n \times n$ real symmetric matrix A, then the eigenvalues $\lambda_1 \le \lambda_2 \le \cdots \le \lambda_n$ of A and the eigenvalues $\mu_1 \le \mu_2 \le \cdots \le \mu_r$ of A_r satisfy the following relations:*

$$\lambda_i \le \mu_i \le \lambda_{i+n-r}, \quad i = 1, \dots, r.$$

Proof. The latter relations hold for $r = n-1$ (see Corollary 8.1-4 to the Courant–Fischer theorem in [GL, p. 411]). In the general case, it is sufficient to apply these relations to a sequence $A = A_n, A_{n-1}, A_{n-2}, \dots, A_r$ of principal submatrices of A such that A_i is a principal submatrix of A_{i+1}. An alternative proof can be found on pp. 186–187 of [Par]. □

We are ready to prove the following basic result.

THEOREM 2.2. *The eigenvalues of T_n satisfy the following relations:*

(a) *If nk is a multiple of $2(k+1)$ and if $\{\mu_1 < \mu_2 < \cdots < \mu_{\frac{k}{k+1}n}\}$ is the set of all the eigenvalues of the $k \times k$ principal submatrices $\tilde{T}_i$ of T_n, $i = 1, \dots, \frac{n}{k+1}$, $\tilde{T}_i$ containing the (s,s) entries a_s of T_n for $s = (i-1)(k+1)+j$, $j = 1, \dots, k$, then*

$$\lambda_{\frac{nk}{2(k+1)}} \le \mu_{\frac{nk}{2(k+1)}} \le \lambda_{\frac{n(k+2)}{2(k+1)}}.$$

(b) *If $1 \le j \le n-2$ and if $\{\gamma_1 \le \gamma_2 \le \cdots \le \gamma_{n-1}\}$ is the set of all the eigenvalues of the two principal submatrices of T_n,*

$$T_j = \begin{pmatrix} a_1 & b_1 & & \\ b_1 & a_2 & \ddots & \\ & \ddots & \ddots & b_{j-1} \\ & & b_{j-1} & a_j \end{pmatrix}, \quad \hat{T}_{n-j-1} = \begin{pmatrix} a_{j+2} & b_{j+2} & & \\ b_{j+2} & a_{j+3} & \ddots & \\ & \ddots & \ddots & b_{n-1} \\ & & b_{n-1} & a_n \end{pmatrix},$$

then

$$\lambda_i \le \gamma_i \le \lambda_{i+1}, \quad i = 1, \dots, n-1.$$

In other words, part (a) *defines a splitting point of the level $(\frac{nk}{2(k+1)}, \frac{n(k+2)}{2(k+1)})$ for the set of the eigenvalues of T_n, and part* (b) *defines an interlacing set for this set of the eigenvalues.*

Proof. Theorem 2.2 immediately follows from Theorem 2.1. In particular, to prove part (a), apply Theorem 2.1 to the $r \times r$ principal submatrix of T_n (where $r = n - \frac{n}{k+1}$) obtained by deleting the $(i(k+1))$th rows and columns of T_n for $i = 1, 2, \ldots, \frac{n}{k+1}$. This submatrix is the block diagonal matrix $\mathrm{Diag}(\tilde{T}_1, \ldots, \tilde{T}_{\frac{n}{n+1}})$. To prove part (b), apply Theorem 2.1 to the $(n-1) \times (n-1)$ principal submatrix of T_n obtained by deleting the ith row and column of T_n; this submatrix is the 2×2 block diagonal matrix $\mathrm{Diag}(T_j, \hat{T}_{n-j-1})$. □

Remark 2.1. To extend part (a) to the case of any n, apply Theorem 2.2 to the tridiagonal matrix

$$\begin{pmatrix} T_n & O \\ O & qI_s \end{pmatrix}$$

for an appropriate $s < 2k+2$ and any fixed real q, where I_s is the $s \times s$ identity matrix.

Apply part (a) of Theorem 2.2 for $k = 1$, then modify it by replacing $\tilde{T}_i$ by the 1-by-1 matrices (a_{2i}) for $i = 1, \ldots, \frac{n}{2}$, and thus arrive at Corollary 2.1.

COROLLARY 2.1. *If n is a multiple of 4, $\{\sigma_1 \le \sigma_2 \le \cdots \le \sigma_{\frac{n}{2}}\} = \{a_{2i-1}, i = 1, \ldots, \frac{n}{2}\}$, $\{\theta_1 \le \theta_2 \le \cdots \le \theta_{\frac{n}{2}}\} = \{a_{2i}, i = 1, \ldots, \frac{n}{2}\}$, then*

$$\lambda_{\frac{n}{4}} \le \sigma_{\frac{n}{4}} \le \lambda_{\frac{3}{4}n}, \quad \lambda_{\frac{n}{4}} \le \theta_{\frac{n}{4}} \le \lambda_{\frac{3}{4}n}.$$

Corollary 2.1 in a weaker form has been proven in [BFKT], where it states some properties of the zeros of the polynomials generated by the Euclidean scheme for the two polynomials $p(\lambda) = \det(\lambda I - T_n)$ and $p'(\lambda)$ and where it is used in order to solve the root-finding problem in NC for a polynomial having only real zeros. The result of part (b) of Theorem 2.2 has been proven in [BOT], still in terms of the zeros of the polynomials generated by the Euclidean scheme. The proofs in both papers [BFKT] and [BOT] are quite intricate, whereas the matrix formulation of these properties is a straightforward consequence of Theorem 2.1, and the results can be immediately extended to polynomial zeros (as we pointed out in the introduction).

Let us again apply the Courant–Fischer theorem in order to obtain still another interlacing set for the set Λ of the eigenvalues of T_n; this time, we will rely on a suitable rank-one modification of the matrix T_n (cf. Remark 2.1 at the end of this section).

THEOREM 2.3. *Let $\{\phi_1 \le \phi_2 \le \cdots \le \phi_n\}$ be the set of all the eigenvalues of the matrices $S_k = T_k - \mathrm{Diag}(0, \ldots, 0, b_k)$, $R_{n-k} = \hat{T}_{n-k} - \mathrm{Diag}(b_k, \ldots, 0)$, where T_k and $\hat{T}_{n-k}$ are defined in Theorem 2.2. Set $\phi_{n+1} = \phi_n + 2b_k$, $\phi_0 = \phi_1 + 2b_k$.*

If $b_k > 0$, then

$$\phi_i \le \lambda_i \le \phi_{i+1}, \quad i = 1, \ldots, n.$$

If $b_k < 0$, then

$$\phi_{i-1} \le \lambda_i \le \phi_i, \quad i = 1, \ldots, n.$$

Proof. Theorem 2.3 follows from Theorem 8.1-5 of [GL, p. 412], applied to the matrix equation

$$T_n = \mathrm{Diag}(S_k, R_{n-k}) + 2b_k \mathbf{e}\mathbf{e}^T,$$

where $\mathbf{e} = (e_i)$, $e_i = 1/\sqrt{2}$ for $i = k$, and $i = k+1$, $e_i = 0$ elsewhere. □

A different proof of Theorem 2.3 is given in [Cu] and [BNS], where this theorem is used for separating the eigenvalues of an rst-matrix as a basis for devising practically effective divide-and-conquer algorithms for approximating the eigenvalues and eigenvectors of rst-matrices. As in [BNS] and [Cu], we may extend our algorithm to computing the eigenvectors of T_n, although our approach does not require us to compute the eigenvectors if we only need to compute the eigenvalues.

Remark 2.2. The algorithm supporting our asymptotic complexity estimates can be based on Theorems 2.2 or 2.3 as well. Application of Theorem 2.3 leads to some advantages for practical computation, particularly due to the possibility of using the so-called secular function (cf. [Cu], [BP92]).

3. Computing the number of the eigenvalues in the intervals of nearly interlacing sets. With a set interleaving the zeros of $p(\lambda)$ (and the eigenvalues of T_n) available, the subsequent approximations to these zeros (and to these eigenvalues) are obtained by using more customary techniques of [BOT]; for the sake of completeness, we will elaborate a modification of these techniques in this section and in section 4. (Some additional care is required here since we actually start not with an interlacing set but with its approximation.) The resulting algorithm consists of three main stages. At the first stage, specified in this section, we approximate some eigenvalues of T_n within a required error bound and cover each remaining eigenvalue by a real line interval containing no other eigenvalues of T_n. Such an eigenvalue may lie arbitrarily close to the end of the interval and, consequently, to other eigenvalues of T_n. However, the second stage ensures sufficiently strong isolation of all such eigenvalues from each other (by means of the bisection and the double exponential sieve algorithms). In the third stage, we rapidly approximate the isolated eigenvalues by means of Newton's iteration. The second and the third stages are described in section 4.

Now, let the set $\{d_0, \dots, d_n\}$ interleave the set Λ of the eigenvalues of T_n,

$$d_0 < \lambda_1 \le d_1 \le \lambda_2 \le d_2 \le \cdots \le d_{n-1} \le \lambda_n < d_n. \tag{3.1}$$

Let the pairs, d_i^-, d_i^+, of approximations to the real points d_i be given for $i = 1, \dots, n-1$, such that for a fixed Δ, we have

$$d_i^+ - d_i^- = 2\Delta, \quad d_i^- \le d_i \le d_i^+, \quad i = 0, \dots, n; \tag{3.2}$$

that is, the values d_i lie in the intervals

$$\mathcal{I}_i = \{\lambda : \ d_i^- \le \lambda \le d_i^+\}, \ i = 0, \dots, n. \tag{3.3}$$

Let us be given Δ, d_i^-, $d_i^+ = d_i^- + 2\Delta$ for $i = 0, \dots, n$, and the black box subroutine for the exact evaluation of the value at point λ of the characteristic polynomial of T_n,

$$p(\lambda) = \det(T_n - \lambda I). \tag{3.4}$$

In this section, for every eigenvalue λ_j of T_n (for $j = 1, \dots, n$), either we will compute its approximation, within the absolute error bound 2Δ, or we will determine that the interval

$$\mathcal{K}_j = \{\lambda : \ d_{j-1}^+ \le \lambda \le d_{j-}^-\} \tag{3.5}$$

contains λ_j and no other eigenvalues of T_n. This problem was solved in [BOT]; we propose an alternative solution.

With no loss of generality, we assume that

$$p(d_i^-)\ p(d_i^+) \neq 0, \quad i = 0, \dots, n, \tag{3.6}$$

and we will use the next definition and simple auxiliary results implied by (3.1)–(3.6).

DEFINITION 3.1. *The number of the eigenvalues of T_n in a real interval $\mathcal{I}$ is called the index of $\mathcal{I}$ and is denoted $c(\mathcal{I})$.*

PROPOSITION 3.1. *Any interval $\mathcal{K}_j$ cannot contain more than one eigenvalue of T_n.*

PROPOSITION 3.2. *$d_i^- \le \lambda_{i+1} \le d_{i+1}^+$, for $i = 0, 1, \dots, n-1$.*

COROLLARY 3.1. *If $\mathcal{I}_i \cap \mathcal{I}_{i+1} \cap \cdots \cap \mathcal{I}_{i+h} \neq \oslash$, then the points $\tilde{\lambda}_{i+j} = \frac{1}{2}(d_{i+j}^- + d_{i+j-1}^+)$ approximate λ_{i+j} within the absolute error bound 2Δ for $j = 1, 2, \dots, h$. Moreover, $h \le c(\mathcal{I})$, where $\mathcal{I} = \{\lambda :\ d_i^- \le \lambda \le d_{i+h}^+\}$. Furthermore, $c(\mathcal{I}) \le h + 2$, if in addition, $\mathcal{I}_{i-1} \cap \mathcal{I}_i = \mathcal{I}_{i+h} \cap \mathcal{I}_{i+h+1} = \oslash$.*

We will also use the following simple fact.

PROPOSITION 3.3. *Let $p(a)p(b) \neq 0$, $\mathcal{I} = \{\lambda :\ a \le \lambda \le b\}$. Then $p(a)p(b) < 0$ if and only if $c(\mathcal{I})$ is odd.*

ALGORITHM 3.1.

Input: Positive rational Δ, an integer n, and a set of rational numbers $D = \{d_i^-, d_i^+,\ \ i = 1, \dots, n-1\} \cup \{d_0^+ = -3(2^{-m}),\ \ d_n^- = 3(2^m)\}$ such that (3.1), (3.2), and (3.6) hold, and $d_0^+ \le \lambda_1,\ \ \lambda_n \le d_n^-$ (compare (2.1)).

Output: For every j, $j = 1, \dots, n$, either the interval $\mathcal{K}_j$ of (3.5) containing a unique eigenvalue λ_j of T_n or an approximation $\tilde{\lambda}_j$ to λ_j such that $|\lambda_j - \tilde{\lambda}_j| < 2\Delta$.

Stage 1 (form the union of the overlapping intervals): For $i = 0$ and for every i such that $d_i^+ < d_i^-$, determine the maximum $h = h(i)$ such that $d_{i+j-1}^+ \ge d_{i+j}^-$, for $j = 1, \dots, h$, letting $h(i) = 0$ if $d_i^+ < d_{i+1}^-$. Output $\tilde{\lambda}_{i+j} = (d_{i+j}^- + d_{i+j-1}^+)/2$, $j = 1, \dots, h$. (By virtue of Corollary 3.1, $|\lambda_{i+j} - \tilde{\lambda}_{i+j}| \le 2\Delta$.) Save the values $\eta_i = (d_i^- + d_i^+)/2$, $\nu_{i+h+1} = (d_{i+h}^- + d_{i+h}^+)/2$ as candidates for being approximations to λ_i and λ_{i+h+1}. Write

$$\mathcal{J}_{i,h} = \{\lambda :\ d_i^- \le \lambda \le d_{i+h}^+\} = \bigcup_{j=0}^{h} \mathcal{I}_{i+j} \tag{3.7}$$

and observe that

$$\lambda_i \le d_i^+ = d_i^- + 2\Delta,$$

$$\lambda_{i+h+1} \ge d_{i+h}^- \ge d_{i+h}^+ - 2\Delta,$$

so that

$$|\lambda_i - \eta_i| \le \Delta \ \text{ if } \ \lambda_i \in \mathcal{J}_{i,h},$$

$$|\lambda_{i+h+1} - \nu_{i+h+1}| \le \Delta \ \text{ if } \ \lambda_{i+h} \in \mathcal{I}_{i,h}.$$

Stage 2 (define the indices of the intervals $\mathcal{K}_j$ of (3.5) and $\mathcal{J}_{i,h}$ of (3.7)): Compute $p(d_i^-)$ and $p(d_i^+)$ for all i. Recall the relations (3.5)–(3.7), Propositions 3.1 and 3.3, and Corollary 3.1. For all i and j, define

$$c(\mathcal{K}_j) = \begin{cases} 0 & \text{if } p(d_{j+1}^-)\ p(d_j^+) > 0, \\ 1 & \text{otherwise,} \end{cases}$$

$$c(\mathcal{J}_{i,h}) = h+1 \ \text{ if } \begin{cases} \text{either } h \text{ is even and } p(d_i^-)p(d_{i+h}^+) < 0, \\ \text{or } h \text{ is odd and } p(d_i^-)p(d_{i+h}^+) > 0; \end{cases}$$

$$\text{otherwise, either } \ c(\mathcal{J}_{i,h}) - h = 0 \ \text{ or } \ c(\mathcal{J}_{i,h}) - h = 2. \tag{3.8}$$

Output the set of indices j such that $c(\mathcal{K}_j) = 1$, in which case $\lambda_{j-1} \in \mathcal{K}_j$.

Stage 3 (choose approximations among the candidate values): By the beginning of this stage, for every j, $j = 1, \dots, n$, it has been determined whether

$$\lambda_j \in \mathcal{K}_{j+1} \ (\text{see Stage 2})$$

or

$$|\lambda_j - \tilde{\lambda}_j| \le 2\Delta \ \ (\text{for } \tilde{\lambda}_j \ \text{ defined in Stage 1}),$$

or, otherwise, at least one of the next two bounds hold:

$$|\lambda_j - \eta_j| \le \Delta,$$

$$|\lambda_j - \nu_j| \le \Delta.$$

It remains to distinguish between the two latter cases and to choose an approximation to λ_j by one of the two candidates ν_j and η_j. This process relies on the two following simple rules:

(a) For every interval $\mathcal{J}_{i,h}$, of the two candidate values η_i and ν_{i+h+1}, exactly $c(\mathcal{J}_{i,h}) - h$ values should be selected as approximations within Δ to λ_i and/or λ_{i+h} (due to the observations made at the end of the description of Stage 1).

As soon as we decide about selecting one of the two candidate values η_i and ν_{i+h+1}, we apply the latter rule in order to decide if we should or should not select another of the two candidates (recall that we know the parity of $c(\mathcal{K}_j) - h$).

(b) For every j, $j = 1, \dots, n$, of the two consecutive candidate values ν_j and η_j, separated by the single interval $\mathcal{K}_j$, exactly $1 - c(\mathcal{K}_j)$ values should be selected as an approximation to the eigenvalue λ_j of T_n. (Indeed, $d_{j-1}^- < \nu_j < d_{j-1}^+ < d_j^- < \eta_j < d_j^+$ and $d_{j-1}^- \le \lambda_j \le d_j^+$, so that either $d_{j-1}^+ \le \lambda_j \le d_j^-$, and then $c(\mathcal{K}_j) = 1$, or $d_{j-1}^- \le \lambda_j \le d_{j-1}^+$, and then $|\nu_j - \lambda_j| \le \Delta$, or $d_j^- \le \lambda_j \le d_j^+$, and then $|\eta_j - \lambda_j| \le \Delta$.)

Rule (b) implies that neither of the values ν_j and η_j should be selected if $c(\mathcal{K}_j) = 1$; otherwise, we choose exactly one of them as an approximation to λ_j.

Recursive application of rules (a) and (b) completely defines the selection of the approximations to λ_j among all the candidate values η_j and ν_j for all j provided that we are given the values $p(d_i^+)$ and $p(d_i^-)$ for all i and that we know whether the leftmost interval $\mathcal{J}_{j,h}$ contains λ_j. The latter inclusion can be easily checked by using (3.1), (3.2), and Propositions 3.1–3.3. We shall decrease the parallel time of this

selection process by using the following equivalent procedure (the equivalence can be easily verified by inspection).

To select an approximation to λ_j by η_j or by ν_j, first partition the set S of all the intervals $\mathcal{J}_{i,h}$ satisfying (3.8) into the maximal subsets whose consecutive intervals are only interleaved with intervals $\mathcal{K}_j$ having indices 0 and with intervals $\mathcal{J}_{i,h}$ having indices $h+1$. Number the intervals in each maximal subset from left to right by $1, 2, \ldots$. For each subset, let $N(i,h)$ denote the number assigned to the interval $\mathcal{J}_{i,h}$ in this enumeration. Let $\delta = 0$ if there is no interval $\mathcal{K}_j$ having index 1 to the left of the subset and let $\delta = 1$ otherwise. Then determine the indices of the intervals of the subset as follows:

$$c(\mathcal{J}_{i,h}) = h + 1 + (-1)^{\delta + N(i,h)}. \tag{3.9}$$

Select both η_i and ν_{i+h+1} as approximations within Δ to λ_i and λ_{i+h+1} if $c(\mathcal{J}_{i,h}) = h+2$ and select none of them if $c(\mathcal{J}_{i,h}) = h$ (according to rule (a)).

Finally, for every i such that $c(\mathcal{J}_{i,h}) = h+1$, apply rule (b) to select one of the η_i and ν_{i+h+1} as an approximation within Δ to λ_i or to λ_{i+h+1}, respectively.

4. Approximation to the eigenvalues by using Newton's iterations, double exponential sieve, and the bisection method. In this section we will complement Algorithm 3.1 with an algorithm that approximates (within a fixed absolute output error Δ) an eigenvalue λ_j of T_n given a pair of real c and d, such that the interval $\mathcal{K} = \{\lambda : c \le \lambda \le d\}$ contains only this eigenvalue of T_n. We will apply the techniques of [BOT] and [R] based on the following result of [R].

THEOREM 4.1. *Let $p(x) = a_n \prod_{i=1}^{n}(x - \xi_i)$ be a polynomial. Let $x^{(0)} \in \mathbf{C}$ be such that $|x^{(0)} - \xi_1| \le |x^{(0)} - \xi_2| \le \cdots \le |x^{(0)} - \xi_n|$. If*

$$|x^{(0)} - \xi_1| < \frac{1}{5n^2}|x^{(0)} - \xi_2|, \tag{4.1}$$

then the sequence $x^{(i+1)} = x^{(i)} - p(x^{(i)})/p'(x^{(i)})$, $i = 0, 1, \ldots$, generated by Newton's method, converges to ξ_1; moreover, $|x^{(i)} - \xi_1| \le 2^{3-2^i}|x^{(0)} - \xi_1|$.

If we have an initial approximation $x^{(0)}$ such that $c < x^{(0)} < d$ and

$$|x^{(0)} - \lambda_j| \le \frac{1}{5n^2}\min\{x^{(0)} - c,\ d - x^{(0)}\}, \tag{4.2}$$

then we may invoke Theorem 4.1 and use Newton's iteration, thus arriving at the desired approximation to λ_j in $\lceil \log\log(0.8\frac{d-c}{\Delta n^2})\rceil$ Newton's steps. This observation leads us to the next procedure, which consists of the double exponential sieve process (Stages 2 and 3), bisection (Stage 4), together ensuring (4.1), and Newton's iteration (Stage 5), which outputs a real point $\tilde{\lambda}$ such that

$$|\tilde{\lambda} - \lambda| \le \Delta, \quad \lambda = \lambda_j. \tag{4.3}$$

ALGORITHM 4.1.

Input: Natural numbers $c < d$ such that $c < \lambda < d$ and a positive rational Δ.

Output: A rational $\tilde{\lambda}$ such that $|\lambda - \tilde{\lambda}| < \Delta$.

Stage 1. If $d - c < 2\Delta$, then output $\tilde{\lambda} = \frac{c+d}{2}$ and stop. Otherwise, set $\beta = 0$, compute $p(c)$ and $p((c+d)/2)$, set $c_0 = c$, $d_0 = d$, and restrict further computations to the interval $[c, \frac{c+d}{2}]$ if $p(c)p((c+d)/2) < 0$ and to the interval $[\frac{c+d}{2}, d]$ otherwise. Suppose, with no loss of generality, that $p(c) < 0$, $p((c+d)/2) > 0$, and perform the following stages.

Stage 2. Set $\gamma_0 = (c_0 + d_0)/2$ and apply the *bisection of the exponents* (also called the double exponential sieve) procedure to the interval $[c_0, (c_0 + d_0)/2]$; that is, successively evaluate $p(\gamma_i)$ for $\gamma_i = c_0 + (d_0 - c_0)2^{-2^i}$, $i = 1, 2, \ldots$, until either $\gamma_i - c_0 < 2\Delta$ or $\gamma_i - c_0 < \beta$ or $p(\gamma_i) \le 0$. In the first case, output $(c_0 + \gamma_i)/2$ and stop; in the second case, set $d_0 = \gamma_i$, $x_0 = (c_0 + \gamma_i)/2$ and go to Stage 4; otherwise, set $\beta = \gamma_i - c_0$ and go to the next stage. (Note that the second case may only occur for $\beta \ge 2\Delta > 0$, that is, not at the first pass through Stage 2.)

Stage 3. Set $c_1 = \gamma_i$ and $d_1 = \gamma_{i-1}$. (Note that $d_1 - c_1 \ge c_1 - c_0 \ge 2\Delta$.) Compute $p((c_1 + d_1)/2)$. If $p((c_1 + d_1)/2) < 0$, then set $c_0 = (c_1 + d_1)/2$, $d_0 = d_1$ and go to the next stage (in this case, $\lambda \in [c_0, d_0]$ and $d_0 - c_0 < \min\{c_0 - c,\ d - d_0\}$). Otherwise, set $c_0 = c_1$, $d_0 = (c_1 + d_1)/2$, and go to Stage 2.

Stage 4. Apply $\lceil \log(5n^2) \rceil$ bisection steps to $[c_0, d_0]$ in order to find a starting point $x^{(0)}$ satisfying (4.1).

Stage 5. Apply $\lceil \log\log(0.8\frac{d_0 - c_0}{\Delta n^2}) \rceil$ Newton's steps (starting with $x^{(0)}$) in order to arrive at an approximation $\tilde{\lambda}$ to λ such that $|\tilde{\lambda} - \lambda| < \Delta$.

Since β only grows, whereas $d_0 - c_0$ decreases by at least two times, in each recursive call to Stages 2 and 3, there can only be $O(\log^2(m + \log(\Delta^{-1})))$ such calls, and there can only be $O(\log(m + \log(\Delta^{-1})))$ Newton's iteration steps at Stage 5 provided that $-3(2^m) < c < d < 3(2^m)$.

5. Computing the values of the characteristic polynomial and its derivative at a set of points. We will concurrently apply Algorithm 4.1 to all the selected intervals, each containing a single eigenvalue of T_n. At any of the $O(\log^2(m + \log(\Delta^{(-1)})))$ steps we will have to compute the values $p(\lambda)$ and $p'(\lambda)$ at a set of at most n points. In this section we will devise an algorithm for computing the values of the characteristic polynomial $p(\lambda) = p_n(\lambda) = \det(T_n - \lambda I)$ of T_n and of its first derivative at a given set of n points.

Due to the tridiagonal structure of the matrix T_n, we have the following three-term recurrence for the polynomials $p_i(\lambda) = \det(T_i - \lambda I)$:

$$p_0(\lambda) = 1, \quad p_1(\lambda) = a_1 - \lambda,$$

$$p_{i+1}(\lambda) = (a_{i+1} - \lambda)\, p_i(\lambda) - b_i^2 p_{i-1}(\lambda), \quad i = n-1, n-2, \ldots, 1, \tag{5.1}$$

or in the equivalent matrix form,

$$\begin{pmatrix} p_{i+1}(\lambda) \\ p_i(\lambda) \end{pmatrix} = \begin{pmatrix} a_{i+1} - \lambda & -b_i^2 \\ 1 & 0 \end{pmatrix} \begin{pmatrix} p_i(\lambda) \\ p_{i-1}(\lambda) \end{pmatrix},$$

so that

$$\begin{pmatrix} p_{i+1}(\lambda) \\ p_i(\lambda) \end{pmatrix} = F_i \ldots F_0 \begin{pmatrix} 1 \\ 0 \end{pmatrix}, \tag{5.2}$$

$$F_j = \begin{pmatrix} a_{j+1} - \lambda & -b_j^2 \\ 1 & 0 \end{pmatrix}, \quad j = 0, \ldots, i, \quad b_0 = 0. \tag{5.3}$$

Now, we will compute the coefficients of $p(\lambda)$. At this stage, we do not have to restrict our computation to the real or complex case; we may allow the input entries of T_n from any field $\mathbf{F}$.

ALGORITHM 5.1.

Input: A positive integer $n = 2^h$ (compare Remark 2.1), and $a_1, \dots, a_n, b_1, \dots, b_{n-1}$ (the entries of T_n, being the elements of a field $\mathbf{F}$).

Output: $\alpha_0, \dots, \alpha_n \in \mathbf{F}$, such that $p(\lambda) = \det(T_n - \lambda I) = \sum_{i=0}^{n} \alpha_i \lambda^i$.

Computation: First set $H_j^{(0)} = F_j$, $j = 0, \dots, n-1$; then, for $i = 1, 2, \dots, \log n = h$, compute $H_j^{(i)} = H_{2j+1}^{(i-1)} H_{2j}^{(i-1)}$, $j = 0, \dots, 2^{-i}n - 1$, output the coefficients of the polynomial $p(\lambda) = (1 \;\; 0) H_0^{(h)} \binom{1}{0}$.

The ith level of the computation is essentially reduced to $8n/2^i$ multiplications of the entries of the matrices $H_j^{(i)}$, which are polynomials of degrees at most 2^i, and to four additions of the products. Over the complex or real fields $\mathbf{F}$, this means the $O_A(\log n, n)$ cost bound at each level i [AHU], [BM]; that is, the overall cost of Algorithm 5.1 is $O_A(\log^2 n, n)$.

Given the coefficients of $p(\lambda)$, and therefore, of $p'(\lambda)$, we may compute the values of both $p(\lambda)$ and $p'(\lambda)$ on a fixed set of n points, at the cost $O_A(\log^2 n \log\log n, n/\log\log n)$ (see [AHU], [BM], [RT]).

Now recall that we apply Newton's iteration to approximate the n eigenvalues of T_n. Each Newton's iteration step essentially amounts to computing the ratio $p(x)/p'(x)$ at n points, which now means the cost $O_A(\log^2 n \log\log n, n/\log\log n)$, and this is also an estimate for the cost of performing Algorithm 3.1.

Remark 5.1. Given the matrix T_n and a scalar x, $p(\lambda)$ can be evaluated at $\lambda = x$ at the cost $O_A(\log n, n)$. It is sufficient to apply Algorithm 5.1 replacing λ by $\lambda + x$ and performing the computation modulo λ. The same computation modulo λ^2 outputs the linear polynomial $p(x) + p'(x)\lambda$. Thus, given an $n \times n$ rst-matrix T_n, we may compute $p(\lambda)$ and $p'(\lambda)$ at $O(n)$ points at the cost $O_A(\log n, n^2)$, avoiding the evaluation of the coefficients of $p(\lambda)$. Even though the number of processors grows, the numerical stability of the computations is greatly improved in this way, which is the basis of the practical modification of our algorithm presented in [BP92]. The latter algorithm actually uses a slightly different modification of Algorithm 5.1, which yields the same output values of $p(\lambda)$ and $p'(\lambda)$ at the same computation cost but in, numerically, a more stable way. Besides improved numerical stability, we have also modified (in [BP92]) the isolation stage so as to bound the *relative* output errors, which is important for practical implementation.

6. The main algorithm. By using the tools and steps described in the preceding sections, we will now devise our main algorithm for the approximation of the eigenvalues of an $n \times n$ rst-matrix T_n with integer entries. This is a divide-and-conquer algorithm, which recursively reduces the original computational problem to two problems of half-size.

ALGORITHM 6.1.

Input: Two positive integers m and n, positive u; n integers $a_1, \dots, a_n$ and $n-1$ nonzero integers $b_1, \dots, b_{n-1}$, such that n is a power of 2 (compare Remark 2.1), $|a_i|$, $|b_i| \le 2^m$. (This input defines an rst-matrix T_n and the tolerance 2^{-u} to the output errors.)

Output: Reals $\gamma_1, \dots, \gamma_n$ such that $|\gamma_i - \lambda_i| < 2^{-u}$, where λ_i are the eigenvalues of T_n, $i = 1, \dots, n$.

Stage 1. Compute the coefficients of the characteristic polynomial of T_n by applying Algorithm 5.1.

Stage 2. Apply Algorithm 6.1 to the input set

$$u+1,\ m,\ \frac{n}{2},\ a_1,\dots,a_{\frac{n}{2}-1},a_{\frac{n}{2}}-b_{\frac{n}{2}},b_1,\dots,b_{\frac{n}{2}-1},$$

which defines an rst-matrix $S_{\frac{n}{2}}$, and to the input set

$$u+1,\ m,\ \frac{n}{2},\ a_{\frac{n}{2}+1}-b_{\frac{n}{2}},a_{\frac{n}{2}+2},\dots,a_n,b_{\frac{n}{2}},\dots,b_{n-1},$$

which defines an rst-matrix $R_{\frac{n}{2}}$, thus obtaining approximations $\delta_1 \le \delta_2 \le \cdots \le \delta_n$ to the eigenvalues of $S_{\frac{n}{2}}$ and $R_{\frac{n}{2}}$ within the absolute error bound $\Delta = 2^{-u-1}$. (The matrices $S_{\frac{n}{2}}$ and $R_{\frac{n}{2}}$ have been defined in Theorem 2.3.)

Stage 3. Recall that the set of all the eigenvalues of $S_{\frac{n}{2}}$ and $R_{\frac{n}{2}}$ interleaves the set $\{\lambda_i\}$ (see Theorem 2.3), set $d_i^+ = \delta_i + \Delta$, $d_i^- = \delta_i - \Delta$, and apply Algorithms 3.1 and 4.1, to obtain $\gamma_1,\dots,\gamma_n$ such that $|\gamma_i - \lambda_i| < 2^{-u}$.

The overall cost of performing the algorithm is $O_A(\log^3 n \log\log n(\log^2 b + \log n), n/\log\log n)$, $b = u+m$, but this bound can be decreased to $O_A(\log^2 n \log\log n(\log^2 b + \log n), n/\log\log n)$, since we need the output of Algorithm 4.1 with a precision lower than b bits until we arrive at the stage of approximating the eigenvalues of the original matix T_n (see the details in [BOT]).

Remark 6.1. An equivalent version of Algorithm 6.1 can be obtained by replacing the matrices $S_{\frac{n}{2}}$ and $R_{\frac{n}{2}}$ at Stage 3 by the matrices $T_{\frac{n}{2}}$ and $\hat{T}_{\frac{n}{2}-1}$ of part (b) of Theorem 2.2.

7. Bit-complexity estimates. We will prove the following result.

THEOREM 7.1. *Algorithm* 6.1 *can be implemented at the Boolean cost bounded by* $O_B(\log(nb)\log^2 n(\log^2 b + \log n)\log\log n \log\log(bn), n^2\frac{b+\log n}{\log\log n})$, *where* $|a_i|$, $|b_i| \le 2^m$, $b = m+u$.

The most expensive computations in Algorithm 6.1 are the evaluation of the coefficients of the characteristic polynomial $p(\lambda)$ of T_n at Stage 1, performed by means of Algorithm 5.1, and the evaluation at Stage 3 of the values of $p(\lambda)$ and $p'(\lambda)$ on a set of n points, performed by means of the multipoint polynomial evaluation algorithm of [AHU], [BM].

We will use the following auxiliary result.

THEOREM 7.2. *Let* n *be a power of* 2, k *a positive integer,* $p = 2^{nk/2}+1$, $u(x)$ *and* $v(x)$ *two polynomials with coefficients in* $\mathbf{Z}_p$ *(*$\mathbf{Z}_p$ *is the ring of integers with arithmetic modulo* p*),* $\deg v(x) = n_2 \le \deg u(x) = n_1 = O(n)$. *Then the coefficients of the polynomial*

$$w(x) = u(x)v(x)$$

can be computed modulo p *at the Boolean cost* $O_B(\log n \log(nk)\log\log(nk), n^2k)$. *Moreover, if the polynomial* $v(x)$ *is monic, the coefficients of the two polynomials* $q(x)$ *and* $r(x)$ *such that*

$$u(x) = v(x)q(x) + r(x)$$

and degree$(r(x)) < n_2$ *can be computed modulo* p *at the Boolean cost bounded by* $O_B(\log n \log\log n \log(nk)\log\log(nk), \frac{n^2k}{\log\log n})$.

Proof. We just need to combine the known estimates from [AHU] and [RT]. The Boolean cost of each arithmetic operation in $\mathbf{Z}_p$ is $O_B(\log d \log\log d, d)$, $d = \lceil \log p \rceil$

(see [AHU, p. 226], [RT]). Moreover, $2^{jk} \neq 1 \bmod p$, $j = 1, \ldots, n-1$, and $2^{nk} = 1 \bmod p$; that is, 2^k is a primitive nth root of 1 in $\mathbf{Z}_p$, and any integer power of 2, in particular, n, has its inverse in $\mathbf{Z}_p$. Therefore, in $\mathbf{Z}_p$, we may compute the product of a pair of nth-degree polynomials, by means of three FFTs, at the arithmetic cost $O_A(\log n, n)$ and, therefore, at the Boolean cost $O_B(\log n \log(nk) \log\log(nk), n^2 k)$. Finally, no divisions are needed for computing $q(x)$ and $r(x)$, since $v(x)$ is monic, and the computation can be performed in $\mathbf{Z}_p$ by using the polynomial division algorithm of [RT]. We arrive at the cost bounds $O_A(\log n \log\log n, n/\log\log n)$ and, therefore,

$$O_B(\log n \log(nk) \log\log n \log\log(nk), n^2 k/\log\log n). \qquad \square$$

Now, recall that the ith stage of Algorithm 5.1 (which evaluates the coefficients of the characteristic polynomial of T_n) consists in evaluating $8(n/2^i)$ products of pairs of polynomials of degrees at most 2^{i-1} and having integer coefficients whose absolute values are less than $2^{i+m2^{i+1}}$, for $i = 1, 2, \ldots, \log n$. Such coefficients are well defined by their values modulo $p = 2^{nk/2} + 1$, already for $k = 4m + 4$. Therefore, we may use integer arithmetic modulo p, apply Theorem 7.2, and deduce that the cost of performing Algorithm 5.1 is given by

$$O_B(\log^2 n \log(nm) \log\log(nm), n^2 m).$$

This bound is dominated by the cost bound of Theorem 7.1, since $b = m + u$, $u > 0$, and Brent's principle enables us to multiply the time bound by $s = \log\log n$ and simultaneously divide the processor bound by s.

Now, consider the evaluation of $p(x)$ and $p'(x)$ at a set of points $\gamma_1, \gamma_2, \ldots, \gamma_n$. We first observe that $|\gamma_i| \leq 2^{m+2}$, since γ_i, for $i = 1, \ldots, n$, are approximations, within absolute errors at most $2^{-u} \leq 1$, to the eigenvalues of rst-matrices having the 1-norms at most $3(2^m)$. Moreover, we may consider γ_i a binary value, $\gamma_i = y_i/2^{u+\log n}$, where y_i is an integer, $|y_i| \leq 2^{m+2+u+\log n}$, since we are looking for an approximation within the absolute error bound $2^{-u-\log n}$. Therefore, the evaluation of $p(\gamma_i)$ and $p'(\gamma_i)$ can be kept within the set of integers in the following way.

Consider $Q(y) = \sum_{i=-1}^{n} \alpha_i 2^{(u+\log n)(n-i)} y^i$, where $p(x) = \sum_{i=0}^{n} \alpha_i x^i$. The polynomial $Q(y)$ has integer coefficients, each represented with at most $n(m+u+2\log n)$ bits, and satisfies the following relation: $Q(y) = 2^{(u+\log n)n} p(x)$, $y = 2^{u+\log n} x$. Moreover, the size of the integers $Q(y_i)$ is bounded as follows:

$$|Q(y_i)| \leq 2^{n(2m+2u+3\log n+2)} = 2^{nk/2}, \quad k = O(m+u+\log n). \tag{7.1}$$

Now, we apply the known algorithm for multipoint polynomial evaluation [AHU], [BM], where we use integer arithmetic modulo $p = 2^{nk/2} + 1$ in the following way.

Recursively compute the coefficients of the monic polynomials $S_i^{(j)}$ of degrees 2^j,

$$S_k^{(0)} = y - y_k, \quad k = 1, \ldots, n,$$

$$S_i^{(j)} = S_{2i-1}^{(j-1)} S_{2i}^{(j-1)}, \quad i = 1, \ldots, \frac{n}{2^j}, \quad j = 1, \ldots, \log n - 1.$$

Recursively compute the coefficients of the polynomials $r_k^{(j)}$ of degrees at most $n/2^j$,

$$r_1^{(0)} = Q(y),$$

$$r_{2i-1}^{(j)} = r_i^{(j-l)} \bmod S_{2i-1}^{(\log n - j)},$$

$$r_{2i}^{(j)} = r_i^{(j-l)} \bmod S_{2i}^{(\log n - j)},$$

$i = 1, \dots, 2^{j-1}$, $j = 1, \dots, \log n$, such that $r_k^{(\log n)} = Q(y_k)$, $k = 1, \dots, n$. Combining the relations (7.1) and Theorem 7.1 and recalling that $b = m + \mu$, we deduce that such a multipoint polynomial evaluation can be performed at the overall cost

$$O_A(\log^2 n \log\log n, n/\log\log n)$$

and, consequently,

$$O_B(\log^2 n \log\log n \log(nb) \log\log(nb), n^2 b/\log\log n).$$

Therefore, Algorithm 6.1 can be carried out at the cost

$$O_B(\log^2 n \log(nb)(\log^2 b + \log n) \log\log n \log\log(nb), n^2 b/\log\log n),$$

performing a total of

$$O(n^2 b \log^2 n \log(nb)(\log^2 b + \log n) \log\log(nb))$$

bit-operations.

8. Discussion. We keep our results and proofs in their original form (cf. also [BP91]) assuming the PRAM models, though this assumption is not pertinent to the efficiency of our algorithms. Since the time of the submission of the present paper, some related results have appeared. The recent divide-and-conquer algorithms of [P95], [P96] approximate within 2^{-b} all the n complex zeros of any nth-degree polynomial, with its zeros in the unit disc, by using $O(n \log^2 b \log^2 n)$ arithmetic operations or $O((b+n)n^2 \log^2 n \log(bn) \log\log(bn))$ bit-operations; moreover, these algorithms have NC- and processor-efficient parallelization. The latter complexity bounds apply to any polynomial and are only slightly inferior to the current record bounds of the [BOT] and the present paper, which are restricted to the case where all the zeros of $p(x)$ are real. Combining the results of [P95], [P96] with the known algorithms for computing the coefficients of the characteristic polynomial of a general $n \times n$ matrix A gives an NC- and processor-efficient algorithm for the unsymmetric eigenvalue problem for A. On the other hand, the algorithms of [P95], [P96] do not extend directly to approximating the eigenvalues of unsymmetric matrices; extension of the divide-and-conquer techniques to the latter problem is a challenging open problem of practical importance.

Some minor improvements of the parallel complexity estimates of the present paper are possible, for instance, due to the recent improvement of parallel polynomial division achieved in [BP93] or via replacement of some integer divisions by multiplications.

The algorithm of this paper has several attractive features for its practical application; in particular, its computational cost is low, and its rapid convergence is guaranteed even where the input rst-matrix has clustered eigenvalues. The only major obstacle for the practical implementation is the stage of fast multipoint polynomial evaluation, which is known to be numerically unstable. There are two ways out of this difficulty, not counting recent progress in improving multipoint polynomial evaluation

(cf. [P95a], [PSLT], [PZHY]). One way, elaborated upon in [BP92], [B], and [BG1], proceeds by replacing the latter stage by slower but numerically stable computation. Another way, proposed and elaborated in [GE], relies on replacing the stage of multipoint polynomial evaluation by solving the associated secular equation by means of the multipole algorithm of [Ro85]. Unfortunately, [GE] deceptively claims its contribution to decreasing the known estimates for the computational complexity of the symmetric tridiagonal eigenproblem. In fact, the paper [GE] contains neither computational complexity estimates nor proper analysis of the case of clustered eigenvalues (effectively treated by the techniques of [BOT], [BP91], and [BP92]). Furthermore, [GE] fails to inform its readers about the existence of the *much earlier* papers [BOT], [BP91], and [BP92], with faster algorithms for the rst-eigenvalues, whereas comparison and, perhaps, combination of the techniques and the results of these papers with ones of [GE] could be informative and useful for the study of the symmetric tridiagonal eigenproblem. We also recall the papers [R93] (as the rediscovery of [BOT]) and [R97], whose main result (on multipoint polynomial evaluation) repeats one of [PSLT] and [PZHY].

Appendix A.

A.1. Reduction of approximating polynomial zeros to approximating matrix eigenvalues. Let $p(x)$ be a polynomial of a degree n having integer coefficients in the range from 2^m to 2^m and having only real zeros. There exist many $n \times n$ rst-matrices T_n whose characteristic polynomials are proportional to $p(x)$, that is, equal to $p(x) = p_n(x)$ after their appropriate normalization. We may specify T_n much better if, in addition to $p_n(x)$, we will fix the characteristic polynomials $p_{n-1}(x)$ of T_{n-1}, the $(n-1) \times (n-1)$ leading principal submatrix of T_n, and apply the extended Euclidean algorithm to $p_n(x)$ and $p_{n-1}(x)$. Suppose that we have chosen $p_{n-1}(x)$ such that this algorithm performs all its $n-1$ recursive steps, producing the $(n-1-i)$th-degree polynomial in the ith step, for $i = 1, \dots, n-1$. (This holds, in particular, if $p(x)$ has only real zeros and if $p_{n-1}(x) = -p'(x)$.) Then, due to (5.1), $p(x) = p_n(x)$ is the characteristic polynomial of an rst-matrix T_n whose entries a_i, b_i satisfy (5.1) for all i, and such a matrix T_n is defined uniquely, except that we may vary the signs of b_i as we like.

Let us analyze the complexity and errors of these computations assuming that $p_{n-1}(x) = -p'(x)$. Then the computation by the extended Euclidean algorithm can be performed at the cost bounded by $O_A(n \log^2 n, 1)$ [AHU] or $O_A(\log^3 n, n^2/\log n)$ [BP94]. Combining these bounds with the cost bounds of Algorithm 6.1 implies the estimates $O_A(n \log^2 n(\log^2 b + \log n), 1)$ and $O_A(\log^2 n(\log^2 b + \log n), (n/\log b)^2/\log n)$ for the sequential and parallel arithmetic complexity of approximating the zeros of a polynomial having only real zeros (compare [BOT]), and similarly, the sequential and parallel Boolean complexity estimates for approximating the zeros of $p(x)$ can be reduced to the estimates for Boolean complexity of the extended Euclidean computations and approximating the eigenvalues of T_n. The estimates for the sequential Boolean complexity and for the parallel Boolean time of the latter stage dominate the respective estimates for the overall complexity of approximating the zeros of $p(x)$, whereas the opposite is true for the bit-serial processor bound.

We will conclude this part of the appendix with two theorems that will enable us to bound the precision of the entries of T_n remaining within a prescribed tolerance to the errors of approximating the eigenvalues of T_n. As before, let a_i, $i = 1, \dots, n$, and b_j, $j = 1, \dots, n-1$, denote the diagonal and the subdiagonal entries of T_n, respectively. We do not assume any bounds on a_i and b_j but will deduce them.

THEOREM A.1. *The entries of T_n have absolute values at most $2^{m+1.5}$.*

Proof. Due to the Cauchy well-known bounds on the magnitudes of polynomial zeros, the zeros of $p(x)$ have absolute values at most $1+2^m < 2^{m+1}$. Due to Theorem 2.1, for $r = 1$, the diagonal entries of T_n, that is, $a_1, \dots, a_n$, have absolute values at most 2^{m+1}. By applying Theorem 2.1 with $r = 2$, we deduce that the eigenvalues of all the 2×2 submatrices

$$\begin{pmatrix} a_i & b_i \\ b_i & a_{i+1} \end{pmatrix}$$

have absolute values at most 2^{m+1}, that is, $|a_i a_{i+1} - b_i^2| \le 2^{2m+2}$; whence $|b_i| \le 2^{m+1.5}$. □

On the other hand, the eigenvalues of T_n are not very sensitive to the pertubation of the entries.

THEOREM A.2. *Let $\tilde{T}_n$ be an rst-matrix having diagonal and subdiagonal entries $\tilde{a}_i$, $i = 1, \dots, n$, and $\tilde{b}_j$, $j = 1, \dots, n-1$, respectively, such that $|\tilde{a}_i - a_i|$, $|\tilde{b}_j - b_j| \le 2^{-\nu}$, $i = 1, \dots, n$; $j = 1, \dots, n-1$. Then for any eigenvalue λ_i of T_n, there exists an eigenvalue $\tilde{\lambda}_i$ of $\tilde{T}_n$ such that $|\tilde{\lambda}_i - \lambda_i| \le 3(2^{-\nu})$.*

Proof. Theorem A.2 follows from the Bauer–Fike theorem (see [GL, p. 342]) applied for the Euclidean norm, since $\|\tilde{T} - T\|_2 \le 3(2^{-\nu})$. □

From the above theorems, we deduce that the rst-matrix $\tilde{T}_n$ obtained by setting $\tilde{a}_i = \lceil 2^\nu a_i \rceil$, $\tilde{b}_j = \lceil 2^\nu b_j \rceil$ has integer entries with absolute values at most $2^{\nu+m+1.5}$; furthermore, its eigenvalues, divided by $2^{-\nu}$, yield approximations $\tilde{\lambda}_i$ to the eigenvalues of T_n such that $|\tilde{\lambda}_i - \lambda_i| \le 3(2^{-\nu})$. Thus, to insure the latter bound, it suffices to compute the entries of T_n with the precision of $\lceil \nu + m + 1.5 \rceil$ bits.

A.2. Reduction of a Hermitian or real symmetric matrix to the tridiagonal form. Various randomized techniques are well known [GL] for the reduction of an $n \times n$ Hermitian or real symmetric matrix A to an rst-matrix T_n via similarity transformations (which leave invariant the eigenvalues and the characteristic polynomial of A). In [P87] and [BP94, Proposition 5.4, p. 325], a parallel implementation of such a tridiagonal reduction is shown and is analyzed. In particular, in the implementation of [BP94], tridiagonal reduction is essentially reduced

(a) to computation of the $2n + 1$ scalars $h_i = \vec{p}^T A^i \vec{q}$, $i = 0, 1, \dots, 2n$, for two random column vectors $\vec{p}$ and $\vec{q}$, and

(b) to the LDL^T (triangular) factorization of the associated Hankel matrix $H = (h_{i,j})$, $h_{i,j} = h_{i+j}$, $i, j = 0, 1, \dots, n-1$.

The overall computational cost of such a reduction can be bounded by $O_A(\log^2 n, n^3/\log n)$ or, alternatively, by $O_A(\log^3 n, P(n)/\log n)$, provided that a pair of $n \times n$ matrices can be multiplied at the cost bounded by $O_A(\log n, P(n)/\log n)$, $P(n) = O(n^{2.38})$.

Acknowledgments. The authors thank Prasoon Tiwari for kindly supplying a copy of [BOT] and the referee for helpful comments.

COMPUTATIONAL COMPLEXITY AND KNOWLEDGE COMPLEXITY*

ODED GOLDREICH†, RAFAIL OSTROVSKY‡, AND EREZ PETRANK§

Abstract. We study the computational complexity of languages which have interactive proofs of logarithmic knowledge complexity. We show that all such languages can be recognized in $\mathcal{BPP}^{\mathcal{NP}}$. Prior to this work, for languages with greater-than-zero knowledge complexity only trivial computational complexity bounds were known. In the course of our proof, we relate statistical knowledge complexity to perfect knowledge complexity; specifically, we show that, for the honest verifier, these hierarchies coincide up to a logarithmic additive term.

Key words. zero knowledge, interactive proofs, knowledge complexity, randomness, complexity classes, cryptography.

AMS subject classification. 68Q15

1. Introduction.

The notion of knowledge complexity was introduced in the seminal paper of Goldwasser, Micali, and Rackoff [GMR-85, GMR-89]. Knowledge complexity is intended to measure the *computational advantage* gained by interaction. A formulation of knowledge complexity, for the case that it is not zero, has appeared in [GP-91]. A very appealing suggestion, made by Goldwasser, Micali, and Rackoff, is to characterize languages according to the knowledge complexity of their interactive proof systems [GMR-89].

The lowest level of the knowledge-complexity hierarchy is the class of languages having interactive proofs of knowledge complexity zero, better known as zero knowledge. Actually, there are three hierarchies extending the three standard definitions of zero knowledge: *perfect*, *statistical*, and *computational*. Assuming the existence of one-way functions, the third hierarchy collapses; that is, the zero level of the *computational* knowledge-complexity hierarchy contains all languages having interactive proof systems [GMW-86, IY-87, B+ 88], and thus contains all levels of the (computational) knowledge-complexity hierarchy. In this paper we will be only interested in the other two hierarchies. Previous works have provided information only concerning the zero level of these hierarchies (see, for example, Fortnow [F-89] and Aiello and Håstad [AH-87]). Our main result is an upper bound on the computational complexity of languages having logarithmic (statistical) knowledge complexity; namely, we show that such languages are contained in $\mathcal{BPP}^{\mathcal{NP}}$.

We consider the (statistical) knowledge-complexity hierarchy to be a very natural

one. Its lowest level resides in the second level of the polynomial-time hierarchy (cf. [F-89, AH-87, B-85]), whereas as a whole it covers all of $\mathcal{PSPACE}$ (cf. [LFKN-90, Sh-90]). Another hierarchy with a similar feature, which also deserves investigation, is the hierarchy of languages classified by the number of rounds in their ("shortest") interactive proof system. Interestingly, the latter hierarchy has a multiplicative collapse (cf. [BM-88]), whereas no such result is known for the knowledge-complexity hierarchy.

1.1. Background on knowledge complexity. Loosely speaking, an interactive-proof system for a language L is a two-party protocol, by which a powerful *prover* can "convince" a probabilistic polynomial-time *verifier* of membership in L but will fail (with high probability) when trying to fool the verifier into "accepting" nonmembers [GMR-89]. An interactive proof is called *zero knowledge* if the interaction of any probabilistic polynomial-time machine with the predetermined prover, on common input $x \in L$, can be "simulated" by a probabilistic polynomial-time machine (called the *simulator*), given only x [GMR-89]. We say that a probabilistic machine M *simulates* an interactive proof if the output distribution of M is *statistically close* to the distribution of the real interaction between the prover and the verifier.

The formulation of zero knowledge presented above is known as *statistical* (almost-perfect) zero knowledge. Alternative formulations of zero knowledge are *computational* zero knowledge and *perfect* zero knowledge. In this paper we concentrate on statistical zero knowledge and the knowledge-complexity hierarchy that generalizes it.

Loosely speaking, the knowledge complexity of a protocol Π is the number of oracle bits that are needed to simulate the protocol efficiently. Namely, we say that a prover leaks (at most) $k(\cdot)$ bits of knowledge to verifier V if there is a probabilistic polynomial-time oracle machine ("simulator") M such that on any input $x \in L$, machine M makes at most $k(|x|)$ oracle queries, and the output distribution of $M(x)$ is statistically close to the distribution of the conversations in the interaction between the prover and V. For a formal definition and further discussion, see section 2.2.

The knowledge complexity of a language is the minimum knowledge complexity of an interactive proof system for that language. We consider the knowledge complexity of a language to be a very natural parameter. Furthermore, the question of how this parameter relates to the complexity of deciding the language is a very fundamental question.

1.2. Previous work. The complexity of recognizing zero-knowledge languages was first bounded by Fortnow [F-89]. He showed that any language that admits a zero-knowledge interactive proof is in the class co$\mathcal{AM}$. Subsequently, Aiello and Håstad [AH-87] showed that these languages are also in $\mathcal{AM}$.

Bellare and Petrank [BP-92] bounded the computational complexity of languages which have *short* interactive proofs with *low* knowledge complexity. Specifically, they showed that if a language L has a $g(n)$-round interactive proof which leaks at most $k(n)$ bits of knowledge and if $k(n) \cdot g(n) = O(\log n)$, then the language can be recognized in $\mathcal{BPP}^{\mathcal{NP}}$. This result does not apply to the general class of low knowledge-complexity languages, since these languages might not have interactive proofs which are both of small round complexity and low knowledge complexity.

1.3. This work. In this work we extend the result of [BP-92], showing that any language having an interactive proof with logarithmic knowledge complexity can be recognized in $\mathcal{BPP}^{\mathcal{NP}}$. We recall that $\mathcal{BPP}^{\mathcal{NP}}$ is contained in the third level of the polynomial-time hierarchy ($\mathcal{PH}$). It is believed that $\mathcal{PH}$ is a proper subset of

$\mathcal{PSPACE}$. Thus, assuming $\mathcal{PH} \subsetneq \mathcal{PSPACE}$, our result yields the first proof that there exist languages in $\mathcal{PSPACE}$ which cannot be proven by an interactive proof that yields $O(\log n)$ bits of knowledge. In other words, there exist languages which do have interactive proofs but only interactive proofs with super-logarithmic knowledge complexity. We stress that prior to our work there was no indication that would contradict the possibility that all languages in $\mathcal{PSPACE}$ have interactive proofs which yield only *one bit of knowledge*.

Our proof that languages of logarithmic knowledge complexity are in $\mathcal{BPP}^{\mathcal{NP}}$ consists of two parts. In the first part, we show that the $\mathcal{BPP}^{\mathcal{NP}}$ procedure described by Bellare and Petrank [BP-92] is applicable for recognizing languages that have interactive proofs of logarithmic *perfect* knowledge complexity. To this end, we use a more careful analysis than the one used in [BP-92]. In the second part of our proof, we transform interactive proofs of *statistical* knowledge complexity $k(n)$ into interactive proofs of *perfect* knowledge complexity $k(n) + O(\log n)$. This transformation refers only to knowledge complexity with respect to the honest verifier, but this suffices since the first part of our proof applies to the knowledge complexity with respect to the honest verifier. Yet, the transformation is interesting for its own sake, and a few words are in place.

The question of whether statistical zero knowledge equals perfect zero knowledge is one of the most fundamental open problems regarding zero knowledge. The question has been open also for the case of zero knowledge with respect to the honest verifier. Our transformation implies, as a special case, that any statistical zero-knowledge interactive proof can be modified into an interactive proof of perfect knowledge complexity bounded by a logarithmic function. Following the conference presentation of our work, Aiello, Bellare, and Venkatesan showed that statistical zero knowledge coincides with negligible *on the average* perfect knowledge complexity [ABV-95]. Their result is stronger in two respects; it refers to all verifiers, not only the honest verifier, and it bounds the perfect knowledge complexity by a negligible function rather than by a logarithmic one. On the other hand, their result is weaker as it refers to a much more liberal notion of (perfect) knowledge complexity, that is, "average" knowledge complexity rather than "worst-case" knowledge complexity (as considered here).

1.4. Organization. In section 2, we present the main definitions referred to in the rest of the paper. These include the definition of an interactive proof system as well as the definition of its knowledge complexity. Section 3 provides an overview to our proof that languages having (statistical) knowledge complexity bounded by a logarithmic function reside in $\mathcal{BPP}^{\mathcal{NP}}$. The first part of our proof (i.e., the case of perfect knowledge complexity) is presented in section 4. The second part of our proof (i.e., the transformation of statistical knowledge complexity to perfect knowledge complexity) is presented in section 5. Some concluding remarks appear in section 6.

In Appendix A, we discuss a flaw in Fortnow's paper [F-89]. We stress that the main result of [F-89] as well as its main techniques remain valid.

2. Preliminaries. Throughout this paper we use n to denote the length of the input x. A function $f : \mathsf{N} \to [0, 1]$ is called *negligible* if for every positive polynomial p and all sufficiently large n's $f(n) < \frac{1}{p(n)}$. We will say that two distribution ensembles indexed by strings are *statistically close* if the statistical distance between them is a negligible function of the length of the index.

2.1. Interactive proofs. Let us recall the concept of interactive proofs presented by [GMR-89]. For formal definitions and motivating discussions the reader is

referred to [GMR-89]. A protocol between a (computationally unbounded) *prover* P and a (probabilistic polynomial-time) *verifier* V constitutes an *interactive proof* for a language L if there exists a negligible function $\epsilon : \mathsf{N} \to [0,1]$ such that the following hold.

1. *Completeness.* If $x \in L$ then
$$\Pr[(P,V)(x) \text{ accepts}] \geq 1 - \epsilon(n).$$
2. *Soundness.* If $x \notin L$ then for any prover P^*
$$\Pr[(P^*,V)(x) \text{ accepts}] \leq \epsilon(n).$$

2.2. Knowledge complexity. Throughout the rest of the paper, we only refer to knowledge complexity *with respect to the honest verifier*, namely, the ability to simulate the honest verifier's view of its interaction with the prover. (In the stronger definition, one considers the ability to simulate the point of view of *any efficient verifier* while interacting with the prover.)

We let $(P,V)(x)$ denote the random variable that represents V's view of the interaction with P on common input x. The view contains the verifier's random tape as well as the sequence of messages exchanged between the parties.

We begin by briefly recalling the definitions of perfect and statistical zero knowledge. A protocol (P,V) is *perfect zero knowledge* (resp., *statistical zero knowledge*) over a language L if there is a probabilistic polynomial-time simulator M such that for every $x \in L$ the random variable $M(x)$ is distributed identically to $(P,V)(x)$ (resp., the statistical difference between $M(x)$ and $(P,V)(x)$ is a negligible function in $|x|$).

Next, we present the definitions of perfect (resp., statistical) knowledge complexity which we use in the sequel. These definitions extend the definition of perfect (resp., statistical) zero knowledge, in the sense that knowledge complexity zero is exactly zero knowledge. Actually, there are two alternative formulations of knowledge complexity, called the *oracle version* and the *fraction version*. These formulations coincide at the zero level and differ by at most an additive constant otherwise [GP-91]. For further intuition and motivation see [GP-91]. It will be convenient to use both definitions in this paper.

By the *oracle formulation*, the knowledge complexity of a protocol (P,V) is the number of oracle (bit) queries that are needed to simulate the protocol efficiently as described in the following definition.

DEFINITION 2.1 (knowledge complexity—oracle version). *Let* k: $\mathsf{N} \to \mathsf{N}$. *We say that an interactive proof* (P,V) *for a language* L *has* perfect (resp., statistical) knowledge complexity $k(n)$ in the oracle sense *if there exists a probabilistic polynomial-time oracle machine* M *and an oracle* A *such that*

1. *on input* $x \in L$, *machine* M *queries the oracle* A *for at most* $k(|x|)$ *bits;*
2. *for each* $x \in L$, *machine* M^A *produces an output with probability at least* $\frac{1}{2}$, *and given that* M^A *halts with an output,* $M^A(x)$ *is* identically distributed (resp., statistically close) *to* $(P,V)(x)$.

In the *fraction formulation*, the simulator is not given any explicit help. Instead, one measures the density of the largest subspace of the simulator's executions (i.e., coins) which is identical (resp., statistically close) to the (P,V) distribution.

DEFINITION 2.2 (knowledge complexity—fraction version). *Let* ρ: $\mathsf{N} \to (0,1]$. *We say that an interactive proof* (P,V) *for a language* L *has* perfect (resp., statistical) knowledge complexity $\log_2(1/\rho(n))$ in the fraction sense *if there exists a probabilistic polynomial-time machine* M *with the following* good subspace *property. For any* $x \in L$

there is a subset of M's possible random tapes, denoted S_x, such that the following hold.

1. *The set S_x contains at least a $\rho(|x|)$ fraction of the set of all possible coin tosses of $M(x)$.*
2. *Conditioned on the event that $M(x)$'s coins fall in S_x, the random variable $M(x)$ is* identically distributed (resp., statistically close) *to $(P,V)(x)$. Namely, for the perfect case this means that for every $\bar{c}$,*

$$\text{Prob}(M(x,\omega)=\bar{c}\,|\,\omega\in S_x) = \text{Prob}((P,V)(x)=\bar{c}),$$

where $M(x,\omega)$ denotes the output of the simulator M on input x and coin tosses sequence ω.

As mentioned above, these two measures are almost equal.

THEOREM (see [GP-91]). *The fraction measure and the oracle measure are equal up to an additive constant.*

Since none of our results is sensitive to a difference of an additive constant in the measure, we ignore this difference in the subsequent definition as well as in the statement of our results.

DEFINITION 2.3 (knowledge-complexity classes). $\mathcal{PKC}(k(\cdot))$ (resp., $\mathcal{SKC}(k(\cdot))$) *denotes the class of languages having interactive proofs of* perfect (resp., statistical) *knowledge complexity $k(\cdot)$.*

2.3. The simulation-based prover. An important ingredient in our proof is the notion of a simulation-based prover, introduced by Fortnow [F-89]. Consider a simulator M that outputs conversations of an interaction between a prover P and a verifier V. We define a new prover P^*, called *the simulation-based prover*, which selects its messages according to the conditional probabilities induced by the simulation. Namely, on a partial history h of a conversation, P^* outputs a message α with probability

$$\text{Prob}(P^*(h)=\alpha) \stackrel{\text{def}}{=} \text{Prob}(M_{|h|+1}=h\circ\alpha \;\big|\; M_{|h|}=h),$$

where M_t denotes the distribution induced by M on t-long prefixes of conversations. (Here, the length of a prefix means the number of messages in it.)

It is important to note that the behavior of P^* is *not* necessarily close to the behavior of the original prover P. Specifically, if the knowledge complexity is greater than zero and we consider the simulator guaranteed by the fraction definition, then P^* and P might have quite a different behavior. Our main objective will be to show that even in this case P^* still behaves in a manner from which we can benefit.

3. Overview. Using Definition 2.3, we state the main result of this paper as follows.

MAIN THEOREM. $\mathcal{SKC}(O(\log(\cdot))) \subseteq \mathcal{BPP}^{\mathcal{NP}}$.

We recall that all that was previously known regarding the $\mathcal{SKC}(\cdot)$ hierarchy is $\mathcal{SKC}(0) \subseteq \mathcal{AM} \cap \text{co}\mathcal{AM}$ and $\mathcal{BPP} \subseteq \mathcal{SKC}(k) \subseteq \mathcal{SKC}(k+1) \subseteq \mathcal{PSPACE}$ for every $k : \mathsf{N} \mapsto \mathsf{N}$.

The Main Theorem is proven in two stages:

1. $\mathcal{PKC}(O(\log(\cdot))) \subseteq \mathcal{BPP}^{\mathcal{NP}}$ (see Theorem 1);
2. $\mathcal{SKC}\,(k(\cdot)) \subseteq \mathcal{PKC}\,(k(\cdot) + O(\log(\cdot)))$ for every $k : \mathsf{N} \mapsto \mathsf{N}$ (see Theorem 2).

In the rest of this section we make several remarks regarding the above theorems and provide an overview to their proofs.

3.1. On the definitions underlying our results.

Remark 1. Usually, the definition of interactive proofs is robust in the sense that setting the error probability to be bounded away from $\frac{1}{2}$ does not change their expressive power, since the error probability can be reduced by repetitions. However, this standard procedure is NOT applicable when knowledge complexity is measured, since (even sequential) repetitions may increase the knowledge complexity. The question is, thus, what is the *right* definition. The definition used in section 2.1 is quite standard and natural; it is certainly less arbitrary then setting the error to be some favorite constant (e.g., $\frac{1}{3}$) or function (e.g., 2^{-n}). Yet, our techniques yield nontrivial results also in case one defines interactive proofs with nonnegligible error probability (e.g., constant error probability). For example, languages having interactive proofs with error probability $\frac{1}{4}$ and perfect knowledge complexity 1 are also in $\mathcal{BPP}^{\mathcal{NP}}$. For more details see Appendix B.

Remark 2. In the definition used in section 2.1 we have allowed two-sided error probability, rather than insisting on "perfect completeness" (as is sometimes done). This strengthens our Main Theorem but weakens the statistical-to-perfect transformation (i.e., Theorem 2), since a transformation for the case of one-sided error implies a transformation for the two-sided case,[1] whereas the converse is not clear.

Remark 3. The definitions of knowledge complexity in section 2.2 refer to simulations of the honest verifier. Analogous definitions of knowledge complexity refer to simulations of arbitrary polynomial-time verifiers (cf. [GP-91]). Let us denote the corresponding classes by $\mathcal{PKC}^*(\cdot)$ and $\mathcal{SKC}^*(\cdot)$. Clearly, $\mathcal{PKC}^*(k(\cdot)) \subseteq \mathcal{PKC}(k(\cdot))$ and $\mathcal{SKC}^*(k(\cdot)) \subseteq \mathcal{SKC}(k(\cdot))$ for every $k : \mathsf{N} \mapsto \mathsf{N}$. Thus, our Main Theorem is only strengthened by referring to the honest-verifier classes, whereas Theorem 2 is arguably weaker than an analogous statement referring to the arbitrary-verifier classes.

3.2. The perfect case—Overview. Our proof of Theorem 1 follows the procedure suggested in [BP-92], which in turn follows the approach of [F-89, BMO-90, Ost-91] while introducing a new "uniform generation" procedure which builds on ideas of [Si-83, St-83, GS-89, JVV-86].

Suppose that (P, V) is an interactive proof of perfect knowledge complexity $k(n) = O(\log n)$ for the languages L, and let M be the simulator guaranteed by the fraction formulation (i.e., Definition 2.2). We consider the conversations of the original verifier V with the simulation-based-prover P^* (see the definition in section 2.3). We show that the probability that the interaction (P^*, V) is accepting is negligible if $x \notin L$ and greater than a polynomial fraction if $x \in L$. Our proof differs from [BP-92] in the analysis of the case $x \in L$ (and thus we get a stronger result although we use the same procedure). This separation between the cases $x \notin L$ and $x \in L$ can be amplified by sequential repetitions of the protocol (P^*, V). So it remains to observe that we can sample the (P^*, V) interactions in probabilistic polynomial time having access to an NP-oracle. This observation originates from [BP-92] and is justified as follows. Clearly, V's part of the interaction can be produced in polynomial time. Also, by the uniform generation procedure of [BP-92] we can implement P^* by a probabilistic polynomial-time oracle machine that has access to an NP-oracle. Thus, it remains only to analyze the accepting probability of (P^*, V) on input x.

[1] Suppose one is given a transformation for the one-sided case. Then, given a two-sided interactive proof of some statistical knowledge complexity one could first transform it to a one-sided error proof system of the same knowledge complexity (cf. [GMS-87]). Applying the transformation for the one-sided case to the resulting one-sided error-proof system yields an (one-sided error) interactive proof with the desired knowledge complexity.

The case $x \notin L$ follows trivially from the soundness condition of V. The challenging case is when $x \in L$. If $k(n) = 0$ this case is easy since P^* behaves exactly as P and so the completeness condition guarantees that x will be accepted with very high probability. However, in case $k(n) > 0$ this argument is not valid and the simulator-based prover may behave very differently from the prescribed prover. Note that it is possible to define a prover P^{**} based on the behavior of the simulator on the "good subspace" and that P^{**} will indeed behave as P. However, it is not clear if P^{**} can be implemented in a relatively efficient manner (e.g., by a probabilistic polynomial-time machine that has access to an NP-oracle). Thus, we need to analyze the behavior of (P^*, V) on $x \in L$. For the sake of simplicity, we consider here only the special case in which $(P, V)(x)$ is always accepting (i.e., "perfect" completeness). Recall that the deviation of P^* from the behavior of P is due to the fact that behavior of the former is conditioned on the entire probability space of the simulator, whereas the latter is conditioned on the "good subspace." In each case the next prover move is determined by the set of all simulator coins which match the current history of the interaction. For P^* this is the set of all coin tosses which may produce this history, whereas for P this is the set of all good coin tosses (i.e., coins in the "good subspace") which produce this history. We first observe that the key parameter for the analysis of P^* is the ratio between the size of the residual probability space of the simulator and the size of the residual space of good coins. Actually, we consider the reciprocal of the above ratio. We observe that the *expected value* of the latter ratio may only increase as a function of the history length, where the expectation is taken over all possible histories of fixed length as produced by a (P^*, V) interaction. Finally, we observe that the expected value of the ratio for a full interaction is a lower bound on the probability that P^* makes V accept the input, whereas for the empty interaction the ratio equals 2^{-k}.

3.3. The transformation—Overview. Our proof of Theorem 2 refers to the oracle formulation of knowledge complexity (see Definition 2.1). Suppose we are given a simulator which produces output that is *statistically close* to the real prover–verifier interaction. We will change both the interactive proof and its simulation *so that they produce exactly the same distribution.* We will take advantage of the fact that the prover in the interactive proof and the oracle that "assists" the simulator are both infinitely powerful. Thus, the modification to the prover's program and the augmentation to the oracle need not be efficiently computable. We stress that the modification to the simulator itself will be efficiently computable. Also, we maintain the original verifier (of the interactive proof), and thus the resulting interactive proof is still sound. Furthermore, the resulting interaction will be statistically close to the original one (on any $x \in L$) and, therefore, the completeness property of the original interactive proof is maintained (although the error probability here may increase by a negligible amount).

The key question is how can we modify the two relevant distributions so that they become identical rather than statistically close. The easy case is when some conversation is more likely in the simulation (than in the original prover–verifier interaction). This case is handled by providing the oracle with a candidate conversation and having the oracle decide probabilistically whether we should output this conversation or not. Thus, we can use one additional oracle query in order to lower the probability of conversations produced by the original simulator. However, the challenging case is when some conversation is less probable in the simulation (than in the original interaction). Using the oracle to produce such conversations is too costly, in terms of

query complexity, unless we consider average-case query complexity (as in [ABV-95]). Thus, we need a different approach. Our approach is to modify the original prover so that it truncates conversations at a point where they become less probable in the simulation. This truncation is also probabilistic. A new simulator, with the help of an augmented oracle, will have to detect the truncation point and produce truncated conversations with the same probability as they are produced in interaction with the new prover. In order to specify the truncation point we need to get a t-ary value from the oracle, where t is the total number of bits in the interaction. This is implemented using $\log_2 t$ queries giving rise to the additive logarithmic factor in the result of the theorem.

4. The perfect case. In this section we prove that the Main Theorem holds for the special case of *perfect* knowledge complexity.

THEOREM 1. $\mathcal{PKC}(O(\log n)) \subseteq \mathcal{BPP}^{\mathcal{NP}}$.

As stated above, our proof follows the procedure suggested in [BP-92]. Suppose that (P, V) is an interactive proof of perfect knowledge complexity $k(n) = O(\log n)$ for the languages L, and let M be the simulator guaranteed by Definition 2.2. Let us denote by P^* the simulation-based prover (for M); see section 2.3. Then the following holds.

LEMMA 4.1 (see [BP-92]). *P^* can be implemented by a probabilistic polynomial-time oracle machine that has access to an NP-oracle.*

LEMMA 4.2 (analysis of the behavior of P^*).

1. *If $x \in L$ then the probability that (P^*, V) outputs an accepting conversation is at least $\frac{1}{2} \cdot 2^{-k(|x|)}$.*
2. *If $x \notin L$ then the probability that (P^*, V) outputs an accepting conversation is negligible (in $|x|$).*

Remark. In [BP-92], a weaker lemma is proven. Specifically, they show that the probability that (P^*, V) outputs an accepting conversation on $x \in L$ is related to $2^{-k(|x|)\cdot t(|x|)}$, where $t(\cdot)$ is the number of rounds in the protocol. We stress that our lemma does not refer to the number of rounds which may be polynomial in $|x|$, whereas the weaker form of [BP-92] is meaningful only for logarithmic number of rounds (i.e., $t(n) = O(\log n)$).

4.1. Proof of Theorem 1. Combining Lemma 4.1 with the fact that V is probabilistic polynomial time and using Lemma 4.2, we obtain a probabilistic polynomial-time oracle machine A that when given access to an NP-oracle satisfies, for some polynomial p, the following statements.

1. If $x \in L$ then $\text{Prob}(A^{NP}(x)=1) \geq \frac{1}{p(|x|)}$.
2. If $x \notin L$ then $\text{Prob}(A^{NP}(x)=1) \leq \frac{1}{2p(|x|)}$.

(For example, $p(n) = 2^{k(n)+1}$ will do.) Using standard amplification, we conclude that $L \in \mathcal{BPP}^{\mathcal{NP}}$. □

4.2. Proof of Lemma 4.2. The second part of the lemma follows from the soundness property of V; namely, the probability that V accepts $x \notin L$ is negligible no matter what the prover does. We thus concentrate on the first part. We fix an arbitrary $x \in L$ for the rest of the proof and allow ourselves not to mention it in the sequel discussion and notation. Let $k = k(|x|)$ and q be the number of coin tosses made by M. We denote by $\Omega \stackrel{\text{def}}{=} \{0,1\}^q$ the set of all possible coin tosses, and by S the "good subspace" of M (i.e., S has density 2^{-k} in Ω and for ω chosen uniformly in S the simulator outputs exactly the distribution of the interaction (P, V)).

4.2.1. Motivation. Consider the conversations that are output by the simulator on coins $\omega \in S$. The probability of getting such a conversation when the simulator is run on ω uniformly selected in Ω is at least 2^{-k}. We *claim* that the probability to get these conversations in the interaction (P^*, V) is also at least 2^{-k}. This is not obvious, since the distribution produced by (P^*, V) may not be identical to the distribution produced by M on a uniformly selected $\omega \in \Omega$. Nor is it necessarily identical to the distribution produced by M on a uniformly selected $\omega \in S$. However, the prover's moves in (P^*, V) are distributed as in the case that the simulator selects ω uniformly in Ω, whereas the verifier's moves (in (P^*, V)) are distributed as in the case that the simulator selects ω uniformly in S. Thus, it should not be too surprising that the above claim can be proven.

However, we need more than the above claim. It is not enough that the (P^*, V) conversations have an origin in S, they must be *accepting* as well. (Note that this is not obvious since M simulates an interactive proof that may have two-sided error.) Again, the density of the accepting conversations in the "good subspace" of M is high, yet we need to show that this is the case also for the (P^*, V) interaction. Actually, we will show that the probability than a (P^*, V) conversation is accepting and "has an origin" in S is at least $\frac{1}{2} \cdot 2^{-k}$.

4.2.2. Preliminaries. Let us begin the formal argument with some notations. For each possible history of the interaction h, we define subsets of the random tapes of the simulator (i.e., subsets of Ω) as follows. Ω_h is the set of $\omega \in \Omega$ which causes the simulator to output a conversation with prefix h. S_h is the subset of ω's in Ω_h which are also in S. A_h is the set of ω's in S_h which are also accepting. Thus, letting $M_t(\omega)$ denote the t-message long prefix output by the simulator M on coins ω, we get

$$\begin{aligned}
\Omega_h &\stackrel{\text{def}}{=} \{\omega : M_{|h|}(\omega) = h\},\\
S_h &\stackrel{\text{def}}{=} \Omega_h \cap S,\\
A_h &\stackrel{\text{def}}{=} \{\omega \in S_h : M(\omega) \text{ is accepting}\}.
\end{aligned}$$

Let C be a random variable representing the (P^*, V) interaction, and χ be an indicator so that $\chi(\bar{c}) = 1$ if the conversation $\bar{c}$ is accepting and $\chi(\bar{c}) = 0$ otherwise. Our aim is to prove that $\text{Prob}(\chi(C) = 1) \geq \frac{1}{2} \cdot 2^{-k}$. Note that

$$\begin{aligned}
\text{Prob}(\chi(C) = 1) &= \sum_{\bar{c}} \text{Prob}(C = \bar{c}) \cdot \chi(\bar{c})\\
&\geq \sum_{\bar{c}} \text{Prob}(C = \bar{c}) \cdot \frac{|A_{\bar{c}}|}{|\Omega_{\bar{c}}|}.
\end{aligned}$$

The last expression is exactly the expectation value of $\frac{|A_c|}{|\Omega_c|}$. Thus, it suffices to show that

$$\text{Exp}_{\bar{c}} \left(\frac{|A_{\bar{c}}|}{|\Omega_{\bar{c}}|} \right) > \frac{1}{2} \cdot 2^{-k}, \tag{1}$$

where the expectation is over the possible conversations $\bar{c}$ as produced by the interaction (P^*, V). Once equation (1) is proven, we are done. Denote the empty history by λ. To prove equation (1) it suffices to prove that

$$\text{Exp}_{\bar{c}} \left(\frac{|A_{\bar{c}}|}{|\Omega_{\bar{c}}|} \cdot \frac{|A_{\bar{c}}|}{|S_{\bar{c}}|} \right) \geq \frac{|A_\lambda|}{|\Omega_\lambda|} \cdot \frac{|A_\lambda|}{|S_\lambda|} \tag{2}$$

since using equation (1), $\frac{|A_\lambda|}{|S_\lambda|} > \sqrt{\frac{1}{2}}$ and $\frac{|S_\lambda|}{|\Omega_\lambda|} \geq 2^{-k}$, we get

$$\begin{aligned}\mathrm{Exp}_{\bar{c}}\left(\frac{|A_{\bar{c}}|}{|\Omega_{\bar{c}}|}\right) &\geq \frac{|A_\lambda|}{|\Omega_\lambda|}\cdot\frac{|A_\lambda|}{|S_\lambda|}\\ &= \left(\frac{|A_\lambda|}{|S_\lambda|}\right)^2\cdot\frac{|S_\lambda|}{|\Omega_\lambda|}\\ &> \frac{1}{2}\cdot 2^{-k}.\end{aligned}$$

The proof of equation (2) is by induction on the number of rounds. Namely, for each round i we show that the expected value of $\frac{|A_h|}{|\Omega_h|}\cdot\frac{|A_h|}{|S_h|}$ over all possible histories h of i rounds (i.e., length i) is greater or equal to the expected value of this expression over all histories h' of $i-1$ rounds. In order to show the induction step we consider two cases:

1. the current step is by the prover (i.e., P^*); and
2. the current step is by the verifier (i.e., V).

In both cases we show, for any history h,

$$\mathrm{Exp}_m\left(\frac{|A_{h\circ m}|}{|\Omega_{h\circ m}|}\cdot\frac{|A_{h\circ m}|}{|S_{h\circ m}|}\right) \geq \frac{|A_h|}{|\Omega_h|}\cdot\frac{|A_h|}{|S_h|}, \tag{3}$$

where the expectation is over the possible current moves m, given history h, as produced by the interaction (P^*, V).

4.2.3. A technical claim. The following technical claim is used for deriving the inequalities in both cases.

CLAIM 4.3. *For $1 \leq i \leq n$, let x_i and y_i be positive reals. Then,*

$$\sum_{i=1}^{n}\frac{{x_i}^2}{y_i} \geq \frac{(\sum_{i=1}^{n} x_i)^2}{\sum_{i=1}^{n} y_i}.$$

Proof. The Cauchy–Schwarz inequality asserts

$$\left(\sum_{i=1}^{n}{a_i}^2\right)\cdot\left(\sum_{i=1}^{n}{b_i}^2\right) \geq \left(\sum_{i=1}^{n} a_i\cdot b_i\right)^2.$$

Setting $a_i \stackrel{\mathrm{def}}{=} \sqrt{y_i}$ (we can do this since y_i is positive) and $b_i \stackrel{\mathrm{def}}{=} \frac{x_i}{a_i}$ and rearranging the terms, we get the desired inequality. □

4.2.4. Prover step (denoted α). Using the fact that P^* is a simulation-based prover for M, we observe that given history h, the prover P^* sends α as its next message with probability exactly $\frac{|\Omega_{h\circ\alpha}|}{|\Omega_h|}$. Thus,

$$\begin{aligned}\mathrm{Exp}_\alpha\left(\frac{|A_{h\circ\alpha}|}{|\Omega_{h\circ\alpha}|}\cdot\frac{|A_{h\circ\alpha}|}{|S_{h\circ\alpha}|}\right) &= \sum_\alpha \frac{|\Omega_{h\circ\alpha}|}{|\Omega_h|}\cdot\frac{|A_{h\circ\alpha}|}{|\Omega_{h\circ\alpha}|}\cdot\frac{|A_{h\circ\alpha}|}{|S_{h\circ\alpha}|}\\ &= \frac{1}{|\Omega_h|}\cdot\sum_\alpha\frac{|A_{h\circ\alpha}|^2}{|S_{h\circ\alpha}|}\\ &\geq \frac{|A_h|}{|\Omega_h|}\cdot\frac{|A_h|}{|S_h|}.\end{aligned}$$

The inequality is justified by using Claim 4.3 and noting that $\sum_\alpha |A_{h\circ\alpha}| = |A_h|$ and $\sum_\alpha |S_{h\circ\alpha}| = |S_h|$.

4.2.5. Verifier step (denoted β). Using the perfectness of the simulation, when restricted to the good subspace S, we observe that given history h the verifier V sends β as its next message with probability exactly $\frac{|S_{h\circ\beta}|}{|S_h|}$. Thus,

$$\begin{aligned}\mathrm{Exp}_\beta\left(\frac{|A_{h\circ\beta}|}{|\Omega_{h\circ\beta}|}\cdot\frac{|A_{h\circ\beta}|}{|S_{h\circ\beta}|}\right)&=\sum_\beta\frac{|S_{h\circ\beta}|}{|S_h|}\cdot\frac{|A_{h\circ\beta}|}{|\Omega_{h\circ\beta}|}\cdot\frac{|A_{h\circ\beta}|}{|S_{h\circ\beta}|}\\&=\frac{1}{|S_h|}\cdot\sum_\beta\frac{|A_{h\circ\beta}|^2}{|\Omega_{h\circ\beta}|}\\&\geq\frac{|A_h|}{|\Omega_h|}\cdot\frac{|A_h|}{|S_h|}.\end{aligned}$$

The inequality is justified by using Claim 4.3 and noting that $\sum_\beta|A_{h\circ\beta}|=|A_h|$ and $\sum_\beta|\Omega_{h\circ\beta}|=|\Omega_h|$.

Having proven equation (3) for both cases, equation (2) follows and so does the lemma. □

5. The transformation. In this section we show how to transform *statistical* knowledge complexity into *perfect* knowledge complexity, incurring only a logarithmic additive term.

THEOREM 2. *For every (poly-time computable)* $k:\mathsf{N}\mapsto\mathsf{N}$,

$$\mathcal{SKC}\left(k(\cdot)\right)\subseteq\mathcal{PKC}\left(k(\cdot)+O(\log(\cdot))\right).$$

We stress again that these knowledge-complexity classes refer to the honest verifier and that we don't know whether such a result holds for the analogous knowledge-complexity classes referring to arbitrary (polynomial-time) verifiers.

The rest of this section is devoted to proving the above theorem. All the numbered claims appearing below are quite evident from the corresponding definitions and so the reader may skip their proofs (which are provided for sake of completeness). This holds also with respect to Claim 5.3.

5.1. Preliminaries. Let $L\in\mathcal{SKC}(k(\cdot))$, and let (P,V) be the guaranteed interactive proof. Without loss of generality, we may assume that all messages are of length 1. Here we use the oracle formulation of knowledge complexity (see Definition 2.1). Recall that Definition 2.1 only guarantees that the simulator produces output with probability at least $\frac{1}{2}$. Yet, employing Proposition 3.8 of [GP-91], we get that there exists an oracle machine M that, after asking $k(n)+2\log\log n$ queries, *always* produces an output so that the output is statistically close to the interaction of (P,V). Let A denote the associated oracle and let $M'\stackrel{\mathrm{def}}{=}M^A$. When we talk in the sequel of modifying M', what we actually mean is modifications to the code of M and augmentations of the oracle A. All the modifications in the code correspond to operations that can be performed in probabilistic polynomial time.

Let P' be the simulation-based prover induced by M'. Similarly, let V' be the simulator-based verifier induced by M'. A simulator-based verifier is defined analogously to the simulator-based prover. It is a fictitious entity which does not necessarily coincide with V. Thus, $M'(x)$ and $(P',V')(x)$ are identically distributed. In the rest of the presentation, we fix a generic input $x\in L$ and omit it from the notation.

Notation. Let $[A,B]_i$ be a random variable representing the i-message (i-bit) long prefix of the interaction between A and B (the common input x is implicit in

the notation). We denote by $A(h)$ the random variable representing the message sent by A after interaction history h. Thus, if the ith message is sent by A, we can write $[A,B]_{i-1} \circ A([A,B]_{i-1}) = [A,B]_i$. By $X \stackrel{s}{=} Y$ we denote the fact that the random variables X and Y are statistically close.

Using these notations we may write for every $h \in \{0,1\}^i$ and $\sigma \in \{0,1\}$,

$$\text{Prob}(P'(h) = \sigma) \;=\; \text{Prob}\left([M']_{i+1} = h \circ \sigma \mid [M']_i = h\right)$$

and, similarly,

$$\text{Prob}(V'(h) = \sigma) \;=\; \text{Prob}\left([M']_{i+1} = h \circ \sigma \mid [M']_i = h\right).$$

CLAIM 5.1 (analysis of the behavior of (P',V)). *The distribution induced by (P',V) is statistically close to the distributions induced by both $M' = (P',V')$ and (P,V).*

Proof. By definition, the distributions produced by $M' = (P',V')$ and (P,V) are statistically close. Thus, we have

$$[P,V]_i \stackrel{s}{=} [P',V']_i \quad \text{for every } i. \tag{4}$$

We prove that $[P',V]$ is statistically close to $[P',V']$ by induction on the length of the interaction. We stress that we will use the induction hypothesis only once in our proof of the induction step, and thus the statistical distance grows at most linearly with the number of induction steps. Since the number of induction steps is polynomial, the statistical distance at the last induction step (i.e., between the random variables representing the full interaction) is negligible. (Note that for every negligible function μ and any polynomial p the function $\mu'(n) \stackrel{\text{def}}{=} p(n) \cdot \mu(n)$ is negligible.)

We now prove the induction step. Assuming that $[P',V]_i \stackrel{s}{=} [P',V']_i$, we wish to prove it for $i+1$. We distinguish two cases. In case the $i+1$st move is by the prover, we get

$$\begin{aligned}
[P',V]_{i+1} &= [P',V]_i \circ P'([P',V]_i) \\
&\stackrel{s}{=} [P',V']_i \circ P'([P',V']_i) \\
&= [P',V']_{i+1},
\end{aligned}$$

where $\stackrel{s}{=}$ follows by the induction hypothesis. (Actually, we also use the fact that the statistical distance can only decrease when the same probabilistic process is applied to two random variables; specifically, the process here is $R(x) \stackrel{\text{def}}{=} x \circ P'(x)$.) In case the $i+1$st move is by the verifier, we get

$$\begin{aligned}
[P',V]_{i+1} &= [P',V]_i \circ V([P',V]_i) \\
&\stackrel{s}{=} [P',V']_i \circ V([P',V']_i) \\
&\stackrel{s}{=} [P,V]_i \circ V([P,V]_i) \\
&= [P,V]_{i+1} \\
&\stackrel{s}{=} [P',V']_{i+1},
\end{aligned}$$

where the first $\stackrel{s}{=}$ is justified by the induction hypothesis and the other two by equation (4). ∎

5.2. Motivating discussion. Note that the statistical difference between the interaction (P', V) and the simulation $M' = (P', V')$ is due solely to the difference between the proper verifier (i.e., V) and the verifier induced by the simulator (i.e., V'). This difference is due to V' putting too much probability weight on certain moves and thus also too little weight on their sibling messages (recall that a message in the interaction consists of a single bit). In what follows we deal with two cases.

The first case is when this difference between the behavior of V' (induced by M') and the behavior of the verifier V is "more than tiny." This case receives most of our attention. We are going to use the oracle in order to move weight from a verifier message β that gets too much weight (after a history h) to its sibling message $\beta \oplus 1$ that gets too little weight in the simulation. Specifically, when the new simulator M'' invokes M' and comes up with a conversation that has $h \circ \beta$ as a prefix, the simulator M'' (with the help of the oracle) will output a conversation with the prefix $h \circ (\beta \oplus 1)$ instead of outputting the original conversation. The simulator M'' will do this with probability that exactly compensates for the difference between V' and V. This leaves one problem. How does the new simulator M'' come up with a conversation that has a prefix $h \circ (\beta \oplus 1)$? The cost of letting the oracle supply the rest of the conversation (after the known prefix $h \circ (\beta \oplus 1)$) is too high. We adopt a "brutal" solution in which we truncate all conversations that have $h \circ (\beta \oplus 1)$ as a prefix. The truncation takes place both in the interaction (P'', V), where P'' stops the conversation after $\beta \oplus 1$ (with a special STOP message) and in the simulation where the oracle recognizes cases in which the simulator M'' should output a truncated conversation. These changes make M'' and V behave exactly the same on messages for which the difference between V' and V is more than tiny. Naturally, V immediately rejects when P'' stops the interaction abruptly, so we have to make sure that this change does not foil the ability of P'' to convince V on an input $x \in L$. It turns out that these truncations happen with negligible probability since such truncation is needed only when the difference between V and V' is more than tiny. Thus, P'' convinces V on $x \in L$ almost with the same probability as P' does.

The second possible case is that the difference between the behavior of V and V' is tiny. In this case, looking at a full conversation $\bar{c}$, we get that the tiny differences sum up to a small difference between the probability of $\bar{c}$ in the distributions of M' and of (P', V). We correct these differences by lowering the probabilities of all conversations in the new simulator. The probability of each conversation is lowered so that its relative weight (relative to all other conversations) is equal to its relative weight in the interaction (P'', V). Technically, this is done by M'' not producing an output in certain cases that M' did produce an output.

Technical remark. The oracle can be used to allow the simulator to toss bias coins even when the simulator does not "know" the bias. Suppose that the simulator needs to toss a coin so that it comes up *head* with probability $\frac{N}{2^m}$, where $N < 2^m$ and both N and m are integers. The simulator supplies the oracle with a uniformly chosen $r \in \{0,1\}^m$ and the oracle answers *head* if r is among the first N strings in $\{0,1\}^m$ and *tail* otherwise. A similar procedure is applicable for implementing a lottery with more than two a priori known values. Using this procedure, we can get extremely good approximations of probability spaces at a cost related to an a priori known upper bound on the size of the support (i.e., the oracle answer is logarithmic in the size of the support).

5.3. Weak, good, critical, and cocritical conversations. Motivated by the above discussion we make the following definitions.

DEFINITION. *Let* $\epsilon \stackrel{\text{def}}{=} \frac{1}{4t}$, *where* t *is the number of rounds in the interaction* (P,V). *(This setting guarantees that* $(1-\epsilon)^t \geq \frac{3}{4}$.*)*

- *Let* h *be a partial history of the interaction and* β *be a possible next move by the verifier. We say that* β *is* weak *with respect to* h *if*

$$\text{Prob}(V'(h)=\beta) < (1-\epsilon)\cdot\text{Prob}(V(h)=\beta).$$

- *A conversation* $\bar{c}=(c_1,...,c_t)$ *is* i*-weak if* c_i *is weak with respect to* $(c_1,...,c_{i-1})$, *otherwise it is* i-good. (*Note that a conversation can be* i*-weak only if the* i*th move is a verifier move.*)
- *A conversation* $\bar{c}=(c_1,...,c_t)$ *is* i-critical *if it is* i*-weak but* j*-good for every* $j<i$. *A conversation* $\bar{c}$ *is* i-cocritical *if the conversation obtained from* $\bar{c}$, *by complementing (only) the* i*th bit, is* i*-critical.* (*Note that a conversation can be* i*-critical only for a single* i, *yet it may be* i*-cocritical for many* i*'s.*)
- *A conversation is* weak *if it is* i*-weak for some* i, *otherwise it is* good.

We first show that weak conversations occur with negligible probability.

CLAIM 5.2 (rarity of weak conversations). (P',V) *outputs weak conversations with negligible probability.*

Proof. Recall that $[P',V] \stackrel{\text{s}}{=} [P',V']$ and that the same holds also for prefixes of the conversations. Namely, for any $1 \leq i \leq t$, $[P',V]_i \stackrel{\text{s}}{=} [P',V']_i$. Let us define a prefix $h \in \{0,1\}^i$ of a conversation to be *bad* if either

$$\text{Prob}([P',V']_i=h) < \left(1-\frac{\epsilon}{2}\right)\cdot\text{Prob}([P',V]_i=h)$$

or

$$\text{Prob}([P',V']_i=h) > \left(1+\frac{\epsilon}{2}\right)\cdot\text{Prob}([P',V]_i=h).$$

The claim follows by combining two elementary facts.

FACT 5.2.1. *The probability that* (P',V) *outputs a conversation with a bad prefix is negligible.*

Proof. For any $i \leq t$, define B_i to be the set of bad prefixes of length i. By the statistical closeness of $[P',V]_i$ and $[P',V']_i$, we get that

$$\Delta \stackrel{\text{def}}{=} \sum_{h\in B_i} |\text{Prob}([P',V]_i=h) - \text{Prob}([P',V']_i=h)| \;\leq\; \gamma$$

for some negligible fraction γ. On the other hand,

$$\Delta \;=\; \sum_{h\in B_i} \text{Prob}([P',V]_i=h)\cdot\left|1-\frac{\text{Prob}([P',V']_i=h)}{\text{Prob}([P',V]_i=h)}\right| \;>\; \text{Prob}([P',V]_i\in B_i)\cdot\left|\pm\frac{\epsilon}{2}\right|.$$

Thus, $\text{Prob}([P',V]_i \in B_i) < \frac{2\gamma}{\epsilon}$ and the fact follows.

FACT 5.2.2. *If a conversation* $\bar{c}=(c_1,...,c_t)$ *is weak then it contains a bad prefix.*

Proof. Suppose that $\beta \stackrel{\text{def}}{=} c_{i+1}$ is weak with respect $h \stackrel{\text{def}}{=} (c_1,...,c_i)$. If h is a bad prefix then we are done. Otherwise it holds that

$$\text{Prob}([P',V']_i=h) \leq \left(1+\frac{\epsilon}{2}\right)\cdot\text{Prob}([P',V]_i=h).$$

Using the fact that β is weak with respect to h, we get

$$\begin{aligned}\text{Prob}([P',V']_{i+1}=h\circ\beta) &< \left(1+\frac{\epsilon}{2}\right)\cdot(1-\epsilon)\cdot\text{Prob}([P',V]_{i+1}=h\circ\beta)\\ &< \left(1-\frac{\epsilon}{2}\right)\cdot\text{Prob}([P',V]_{i+1}=h\circ\beta),\end{aligned}$$

which implies that $h\circ\beta$ is a bad prefix.

Combining Facts 5.2.1 and 5.2.2, Claim 5.2 follows. □

5.4. Dealing with weak conversations. We start by modifying the prover P', resulting in a modified prover denoted P'', that stops once it gets a verifier message which is weak with respect to the current history; otherwise, P'' behaves as P'.

DEFINITION (modified prover - P''). *For any $h\in\{0,1\}^*$ and $\beta\in\{0,1\}$,*

$$P''(h\circ\beta)=\begin{cases}\text{STOP} & \text{if } \beta \text{ is weak with respect to } h,\\ P'(h\circ\beta) & \text{otherwise.}\end{cases}$$

We assume that the verifier V stops and rejects immediately upon receiving an illegal message from the prover (and in particular upon receiving this STOP *message).*

Next, we modify the simulator, M', so that it outputs either good conversations or truncated conversations which are originally i-critical. Jumping ahead, we stress that such truncated i-critical conversations will be generated from both i-critical and i-cocritical conversations. The modified simulator, denoted M'', proceeds as follows. (We stress that P'' is not necessarily the simulator-based prover of M''.)

DEFINITION (modified simulator - M''). *First, M'' invokes M' and obtains a conversation $\bar{c}=(c_1,...,c_t)$. Next, it queries the augmented oracle on $\bar{c}$. The oracle answers probabilistically and its answers are of the form (i,σ), where $i\in\{1,...,t\}$ and $\sigma\in\{0,1\}$. Finally, M'' halts outputting $(c_1,...,c_{i-1},c_i\oplus\sigma)$.*

In case $\sigma=1$ the output of M'' is NOT a prefix of the output it has obtained from M'. Furthermore, i may be smaller than t, in which case M'' outputs a truncated conversation which, as we see below, is always i-critical; otherwise, M'' outputs a nontruncated conversation. Observe that the oracle message contains $1+\log_2 t$ bits, where t is the length of the interaction between P' and V. It remains to specify the oracle's answer distribution. We first remark that the oracle only returns pairs (i,σ) for which one of the following three conditions holds

1. $\bar{c}$ is good, $i=t$ and $\sigma=0$ (if $\bar{c}$ is good and is not j-cocritical for any j then the oracle always answers this way);
2. $\bar{c}$ is i-critical and $\sigma=0$;
3. $\bar{c}$ is i-cocritical and $\sigma=1$. (Hence, $(c_1,...,c_{i-1},c_i\oplus 1)$ is i-critical.)

To motivate the definition of the augmented oracle, we first consider two special cases. In the first case, the conversation generated by M' is i-critical for some i but is not j-cocritical for any $j<i$. In this case the oracle always answers $(i,0)$ and consequently the simulator always outputs the i-bit long prefix. However, this prefix is still being output with too low probability. This will be corrected by the second case hereby described. In this case, the conversation $\bar{c}$ generated by M' is good and i-cocritical for a single i. This means that the i-bit long prefix is given too much probability weight, whereas the prefix obtained by complementing the ith bit gets too little weight. To correct this, the oracle outputs $(i,1)$ with probability q and $(t,0)$ otherwise, where q will be specified. What happens is that M'' will output the "i-complemented prefix" with higher probability than with which it has appeared in M'. The value of q is determined as follows. Denote $p\stackrel{\text{def}}{=}\text{Prob}(V(c_1,...,c_{i-1})=c_i\oplus 1)$ and

$p' \stackrel{\text{def}}{=} \text{Prob}(V'(c_1,...,c_{i-1})=c_i \oplus 1)$. Then, setting q so that $p'+(1-p')\cdot q = p$ (i.e., $q = \frac{p-p'}{1-p'}$) allows the simulator to output the prefix $(c_1,...,c_{i-1},c_i \oplus 1)$ with the right probability (i.e., as in a (P'',V) interaction). In the general case, the conversation generated by M' may be i-cocritical for many i's as well as j-critical for some (*single*) j. In case it is j-critical, it can be i-cocritical only for $i<j$.

DEFINITION (the augmented oracle answers). *Let us consider the sequence of indices $(i_1,...,i_l)$ for which the generated conversation $\bar{c}$ is critical or cocritical (i.e., the conversation is i_k-cocritical for all $k<l$ and is either i_l-critical or i_l-cocritical). We consider two cases. In both cases the q_k's are set as in the above example; namely, $q_k = \frac{p_k-p'_k}{1-p'_k}$, where $p_k \stackrel{\text{def}}{=} \text{Prob}(V(c_1,...,c_{i_k-1})=c_{i_k}\oplus 1)$ and $p'_k \stackrel{\text{def}}{=} \text{Prob}(V'(c_1,...,c_{i_k-1})=c_{i_k}\oplus 1)$.*

1. *The generated conversation $\bar{c}=(c_1,...,c_t)$ is i_k-cocritical for every $k<l$ and is i_l-critical. In this case, the distribution of the oracle answers is as follows. For every $k<l$, the pair $(i_k,1)$ is returned with probability $(\prod_{j<k}(1-q_j))\cdot q_k$, whereas the pair $(i_l,0)$ appears with probability $\prod_{j<l}(1-q_j)$. We stress that no other pair appears in this distribution (and indeed the reader can easily verify that these probabilities sum up to 1).*
2. *The generated conversation $\bar{c}=(c_1,...,c_t)$ is i_k-cocritical for every $k\le l$. In this case, the distribution of the oracle answers is as follows. For every $k\le l$, the pair $(i_k,1)$ is returned with probability $(\prod_{j<k}(1-q_j))\cdot q_k$, whereas the pair $(t,0)$ appears with probability $\prod_{j\le l}(1-q_j)$. Again, no other pair appears in this distribution. In particular, if $l=0$ then the oracle always returns the pair $(t,0)$.*

CLAIM 5.3 (analysis of the behavior of P'' and M'').

1. $[P'',V] \stackrel{\text{s}}{=} [P',V]$.
2. *Let $\bar{c}$ be an arbitrary conversation of (P'',V). Then*

$$\text{Prob}\,(M''=\bar{c}) \;\ge\; (1-\epsilon)^t \cdot \text{Prob}\,([P'',V]=\bar{c})\,.$$

Recall that $(1-\epsilon)^t \ge \frac{3}{4}$ (by definition of ϵ).

Proof. The weak conversations are negligible in the output distribution of (P',V) (see Claim 5.2). The only difference between $[P'',V]$ and $[P',V]$ originates from a different behavior of P'' on weak conversations; specifically, P'' truncates them while P' does not. Yet, the distribution on the good conversations remains unchanged. Therefore, the distribution of $[P'',V]$ is statistically close to the distribution of $[P',V]$, and we are done with part 1.

We start the proof of part 2 by writing again the probability that (P'',V) outputs $\bar{c}$ as the product of the conditional probabilities of the t steps. Namely,

$$\prod_{i=1}^{t} \text{Prob}\,([P'',V]_{i+1}=h_i\circ c_{i+1} \mid [P'',V]_i=h_i)\,,$$

where $h_i \stackrel{\text{def}}{=} (c_1,...,c_i)$. We do the same for the probability that M'' outputs a conversation $\bar{c}$. We will show by induction that each step of any conversation is produced by M'' with at least $(1-\epsilon)$ times the probability of the same step in the (P'',V)-interaction. Once we have shown this, we are done. Clearly this claim holds for the null prefix. To prove the induction step, we consider the two possibilities for the party making the $i+1$st step.

$i+1$st step is by the prover. Consider the conditional behavior of M'' given the history so far. We will show that this behavior is identical to the behavior of P'' on

the same partial history. A delicate point to note here is that we may talk about the behavior of M'' on a prefix h_i only if this prefix appears with positive probability in the output distribution $[M'']_i$. However, by the induction hypothesis any prefix that is output by $[P'', V]_i$ appears with positive probability in $[M'']_i$.

We partition the analysis into two cases.

1. First, we consider the case in which the last message of the verifier is weak with respect to the history that precedes it. Namely, $h = h' \circ \beta$ and β is weak with respect to h'. In this case, both in the interaction (P'', V) and in the simulation M'', the next message of the prover is set to STOP with probability 1. Namely,

$$\text{Prob}\left(M'' = h \circ \text{STOP} \mid [M'']_i = h\right) \;=\; 1 \;=\; \text{Prob}\left(P''(h) = \text{STOP}\right).$$

2. The other possible case is that the last message of the verifier is not weak with respect to its preceding history. In this case, the simulator M'' behaves like M' and the prover P'' behaves like P'. (Note that the changes in critical and cocritical steps apply only to verifier steps.) Thus,

$$\begin{aligned}\text{Prob}\left([M'']_{i+1} = h \circ \alpha \mid [M'']_i = h\right) \;&=\; \text{Prob}\left([M']_{i+1} = h \circ \alpha \mid [M']_i = h\right)\\ &=\; \text{Prob}\left(P'(h) = \alpha\right)\\ &=\; \text{Prob}\left(P''(h) = \alpha\right).\end{aligned}$$

To summarize, the conditional behavior of M'' in the prover steps and the conditional behavior of P'' are exactly equal.

$i+1$st step is by the verifier. Again, we consider the conditional behavior of M'' given the history so far. Let us recall the modification applied to M' when deriving M''. This modification changes the conditional probability of the verifier steps in the distribution of M' in order to add weight to steps having low probability in the simulation. We note that this modification is made only in critical or cocritical steps of the verifier. Consider a history h_i which might appear in the interaction (P'', V) and a possible response β of V to h_i. Again, by the induction hypothesis, h_i has a positive probability to be output by the simulation M'' and, therefore, we may consider the conditional behavior of M'' on this history h_i. There are three cases to be considered, corresponding to whether either β or $\beta \oplus 1$ or none is weak with respect to h_i.

We start with the simplest case in which neither β nor $\beta \oplus 1$ is weak (w.r.t. h_i). In this case, the behavior of M'' is identical to the behavior of M' since the oracle never sends the message $(i+1, \sigma)$ in this case. However, by the fact that β is not weak, we get that

$$\begin{aligned}(1-\epsilon) \cdot \text{Prob}(V(h) = \beta) \;&\le\; \text{Prob}\left([M']_{i+1} = h \circ \beta \mid [M']_i = h\right)\\ &=\; \text{Prob}\left([M'']_{i+1} = h \circ \beta \mid [M'']_i = h\right)\end{aligned}$$

and we are done with this simple case.

We now turn to the case in which β is weak (w.r.t. h_i). In this case, given that M'' has produced the prefix h_i, it produces $h_i \circ \beta$ whenever M' produces the prefix $h_i \circ \beta$. Furthermore, with conditional probability q (as defined above), M'' produces the prefix $h_i \circ \beta$ also in case M' produces the prefix $h_i \circ (\beta \oplus 1)$. As above, we define

$$\begin{aligned}p \;&\stackrel{\text{def}}{=}\; \text{Prob}\left(V(h_i) = \beta\right),\\ p' \;&\stackrel{\text{def}}{=}\; \text{Prob}\left(V'(h_i) = \beta\right).\end{aligned}$$

Since V' is the simulation-based verifier (for M'), we may also write

$$p' = \text{Prob}\left([M']_{i+1} = h_i \circ \beta \mid [M']_i = h_i\right). \tag{5}$$

Also, recall that q was defined as $\frac{p-p'}{1-p'}$. Now, using these notations,

$$\begin{aligned}\text{Prob}\left([M'']_{i+1} = h_i \circ \beta \mid [M'']_i = h_i\right) &= \text{Prob}\left([M']_{i+1} = h_i \circ \beta \mid [M']_i = h_i\right) \\ &\quad + \frac{p-p'}{1-p'} \cdot \text{Prob}\left([M']_{i+1} = h_i \circ (\beta \oplus 1) \mid [M']_i = h_i\right).\end{aligned}$$

Using equation (5), we get

$$\begin{aligned}&= p' + \frac{p-p'}{1-p'} \cdot (1-p') \\ &= p \\ &= \text{Prob}\left(V(h) = \beta\right).\end{aligned}$$

Finally, we turn to the case in which $\beta \oplus 1$ is weak (w.r.t. h_i). This means that β is cocritical in $\bar{c}$. Given that M'' has produced the prefix h_i, it produces $h_i \circ \beta$ only when M' produces the prefix $h_i \circ \beta$ and, furthermore, M'' does so only with probability $1-q$ (where q is again as defined above). We denote p and p' with respect to the critical message $\beta \oplus 1$. Namely,

$$\begin{aligned}p &\stackrel{\text{def}}{=} \text{Prob}\left(V(h_i) = \beta \oplus 1\right), \\ p' &\stackrel{\text{def}}{=} \text{Prob}\left(V'(h_i) = \beta \oplus 1\right) \\ &= \text{Prob}\left([M']_{i+1} = h_i \circ (\beta \oplus 1) \mid [M']_i = h_i\right).\end{aligned}$$

Thus, recalling that $q = \frac{p-p'}{1-p'}$, we get

$$\begin{aligned}\text{Prob}\left([M'']_{i+1} = h_i \circ \beta \mid [M'']_i = h_i\right) &= \left(1 - \frac{p-p'}{1-p'}\right) \cdot \text{Prob}\left([M']_{i+1} = h_i \circ \beta \mid [M']_i = h_i\right) \\ &= \frac{1-p}{1-p'} \cdot (1-p') \\ &= 1-p \\ &= \text{Prob}\left(V(h_i) = \beta\right).\end{aligned}$$

This completes the proof of Claim 5.3. □

5.5. Lowering the probability of some simulator outputs. By virtue of the modification of M' into M'', we have arrived at a situation in which every conversation appears in the output of M'' with probability which cannot be much smaller than the probability that the conversation appears in $[P'', V]$. Specifically, by part 2 of Claim 5.3 (and by $(1-\epsilon)^t \geq \frac{3}{4}$), we have for every $\bar{c}$

$$\text{Prob}\left(M'' = \bar{c}\right) \geq \frac{3}{4} \cdot \text{Prob}\left([P'', V] = \bar{c}\right). \tag{6}$$

Thus, all that is required is to lower the probabilities that the (modified) simulator outputs each conversation $\bar{c}$ to exactly $\frac{3}{4} \cdot \text{Prob}([P'', V] = \bar{c})$. This can be done by "sieving" the output of M'' using an additional query to the (further-augmented) oracle. Specifically, the modified simulator, denoted M''', runs M'' to obtain a conversation

$\bar{c}$. (Note that M'' always produces output.) Using a further-augmented oracle, M''' outputs $\bar{c}$ with probability

$$p_{\bar{c}} \stackrel{\text{def}}{=} \frac{3}{4} \cdot \frac{\text{Prob}([P'', V] = \bar{c})}{\text{Prob}([M''] = \bar{c})}$$

and halts without output otherwise. Note that $p_{\bar{c}} \leq 1$ holds due to equation (6).

CLAIM 5.4 (analysis of the behavior of M''').

1. *M''' produces output with probability $\frac{3}{4}$.*
2. *The output distribution of M''' (i.e., in case it has output) is identical to the distribution $[P'', V]$.*

Proof. The probability that M''' produces an output is exactly

$$\sum_{\bar{c}} \text{Prob}\left([M''] = \bar{c}\right) \cdot p_{\bar{c}} \;=\; \frac{3}{4}.$$

As for Part (2), we note that the probability that a conversation $\bar{c}$ is output by M''' is exactly $\frac{3}{4} \cdot \text{Prob}\left([P'', V] = \bar{c}\right)$. Since the simulator halts with an output with probability exactly $\frac{3}{4}$, we get that given that M''' halts with an output, it outputs $\bar{c}$ with probability exactly $\text{Prob}\left([P'', V] = \bar{c}\right)$ and we are done. ∎

5.6. Final details. An important point not explicitly addressed so far is whether all the modifications applied to the simulator preserve its ability to be implemented by a probabilistic polynomial-time machine with bounded access to an oracle. Specifically, an issue ignored so far is the ability to efficiently implement the probabilistic choices required of the augmented oracle. A hint toward resolving this problem was given in the technical remark at the end of the motivating subsection (section 5.2). Namely, probabilities of the form $\frac{N}{2^m}$ can be implemented by uniformly selecting a string in $\{0,1\}^m$ and sending it to the oracle which responds with either 0 or 1. However, this only allows to approximate probabilities which are not of the above form. In particular, one can obtain approximations up to exponentially small deviation error. We first comment that such approximations suffice through the entire analysis except for the construction of M''' which must satisfy Claim 5.4 (where the probabilistic behavior must be exact).

Thus, M''' must be implemented with more care. But before we do this, we modify P'' so that it makes its random choices (in case it has any) by flipping a polynomial number of unbiased coins.[2] This modification may change the behavior of P'' slightly, but the deviation can be made so small that the above assertions (specifically Claim 5.3) still hold.

We now turn to the implementation of M'''. Consider the specific "sieving probability" we need to implement when going from M'' to M'''. Namely, $p_{\bar{c}} = \frac{3}{4} \cdot \frac{a/b}{c/d}$, where $\frac{a}{b} = \text{Prob}([P'', V] = \bar{c})$ and $\frac{c}{d} = \text{Prob}([M''] = \bar{c})$. A key observation is that c is the number of coin tosses which lead M'' to output $\bar{c}$. Observing that b is the size of probability space for $[P'', V]$ and using the above modification to P'', we may rewrite $p_{\bar{c}}$ as $\frac{3ad}{4b} \cdot \frac{1}{c} = \frac{e}{c2^f}$, where e and $f = \text{poly}(n)$ are some nonnegative integers.

[2] The implementation of P'' was not discussed explicitly. It is possible that P'' uses an infinite number of coin tosses to select its next message (either 0 or 1). However, an infinite number of coin tosses is not really needed since rounding the probabilities so that a polynomial number of coins suffices, causes only exponentially small rounding errors.

We now note that the oracle can enable the simulator to sieve conversations with probability $\frac{e}{c}$ for any $0 \leq e \leq c$ in the following way. M''' sends to the oracle the random tape ω that it has tossed for M'', and the oracle sieves only e out of the possible c random tapes which lead M'' to output $\bar{c}$. The general case of $p_{\bar{c}} = \frac{e}{c2^f}$ is dealt with by writing $p_{\bar{c}} = \frac{q}{c} + \frac{r}{c2^f}$, where $q = \lfloor \frac{e}{2^f} \rfloor$ and $r = e - q2^f < 2^f$. To implement this sieve, M''' supplies the oracle with a uniformly chosen f-bit long string (in addition to ω). The oracle sieves out q random tapes (of M'') as before and uses the extra bits in order to decide on the sieve in case ω equals a specific (different) random tape. Formally, the process is implemented as follows.

DEFINITION (implementing M''' with an oracle). *Let $f = \mathrm{poly}(n)$. For every possible $\bar{c}$, let $p_{\bar{c}} = \frac{q(\bar{c})}{|\Omega_{\bar{c}}|} + \frac{r(\bar{c})}{2^f \cdot |\Omega_{\bar{c}}|}$, where $\Omega_{\bar{c}}$ is the set of random tapes which makes M'' produce $\bar{c}$ and $0 \leq r(\bar{c}) < 2^f$. Let $G_{\bar{c}} \subseteq \Omega_{\bar{c}}$ be a subset of cardinality $q(\bar{c})$, $a_{\bar{c}} \in \Omega_{\bar{c}} \setminus G_{\bar{c}}$ and $R_{\bar{c}} \subseteq \{0,1\}^f$ be a subset of cardinality $r(\bar{c})$. Then, M''' uniformly selects a random tape ω for M'' and a string $r \in \{0,1\}^f$. Machine M''' queries the oracle on (ω, r) and outputs $M''(\omega)$ if the oracle responds with 1 (otherwise M''' halts with no output). The oracle determines $\bar{c} = M''(\omega)$ and responds 1 if either $\omega \in G_{\bar{c}}$ or $(\omega = a_{\bar{c}}) \wedge (r \in R_{\bar{c}})$, otherwise the oracle responds 0.*

We conclude the proof of Theorem 2 by observing that the following statements hold.

- (P'', V) is an interactive proof system for L. (The completeness condition follows by Claim 5.1 and part 1 of Claim 5.3 which together yield $[P'', V] \stackrel{\mathrm{s}}{=} [P, V]$. Note that we may incur an additional, negligible, completeness error.)
- (P'', V) has *perfect* knowledge complexity $k(n) + 2\log_2 \log_2 n + 2 + \log_2 t = k(n) + O(\log n)$. (The perfectness of the simulator M''' follows by Claim 5.4, whereas the query count follows from the construction: the double-logarithmic term is due to the modification in section 5.1, a $1 + \log_2 t$ term is introduced in the construction of M'', and an additional last query is due to M'''.)

This completes the proof of Theorem 2. □

6. Concluding remarks. We consider our main result as a very first step toward a classification of languages according to the knowledge complexity of their interactive proof systems. In an early version of this paper we suggested two challenges. The first challenge was to provide evidence that NP-complete languages cannot be proven within low (say logarithmic or even constant) knowledge complexity, by showing that languages having logarithmic knowledge complexity are in co$\mathcal{AM}$ (rather than in $\mathcal{BPP}^{\mathcal{NP}}$). Recall that NP is unlikely to be in co$\mathcal{AM}$—see [BHZ-87]. Indeed, following our work and using some of our results, Petrank and Tardos have recently shown that languages having logarithmic knowledge complexity are in $\mathcal{AM} \cap \mathrm{co}\mathcal{AM}$ [PT-96]. The second challenge, still opened, is to try to provide indications that there are languages in $\mathcal{PSPACE}$ which do not have interactive proofs of linear (rather than logarithmic) knowledge complexity. The reader can easily envision more moderate and more ambitious challenges in this direction.

Another interesting question is whether each level of the knowledge-complexity hierarchy contains strictly more languages than previous levels or if some partial collapse occurs. For example, it is open whether the constant knowledge-complexity classes collapse to the zero level.

Regarding our transformation of statistical knowledge complexity into perfect knowledge complexity (i.e., Theorem 2), a few interesting questions arise. First, can the cost of the transformation be reduced to below $O(\log n)$ bits of knowledge? A

result for the special case of statistical zero knowledge will be almost as interesting. Second, can one present an analogous transformation that preserves *one-sided error probability* of the interactive proof? (Note that our transformation introduces a negligible error probability into the completeness condition.) Finally, can one present an analogous transformation that applies to knowledge complexity *with respect to arbitrary verifiers*? (Our transformation applies only to knowledge complexity *with respect to the honest verifier*.)

Appendix A. A flaw in [F-89]. In [F-89], Fortnow presents a constructive method for proving that $\mathcal{SZK} \stackrel{\text{def}}{=} \mathcal{SKC}(0)$ is contained in co-$\mathcal{AM}$. Given an interactive proof (P, V) for a language L and a (statistical) zero-knowledge simulator M (for the honest verifier V), he constructs a two-round protocol (P', V'). This protocol was claimed to constitute an interactive proof system for $\overline{L}$. This claim, as we are going to show, is wrong. Yet, the result $\mathcal{SZK} \subseteq$ co-$\mathcal{AM}$ does hold, since the work of Aiello and Håstad contains the necessary refinements which enable us to present a modified AM-protocol for $\overline{L}$ (see [AH-87, H-94]). Furthermore, Fortnow's basic approach is valid, and indeed it was used in subsequent works (e.g., [AH-87, BMO-90, Ost-91, BP-92, OW-93]).

Fortnow's basic approach starts with the observation that the simulator M must behave differently on $x \in L$ and $x \notin L$. Clearly, the difference cannot be recognized in polynomial time, unless $L \in \mathcal{BPP}$. Yet, stronger recognition devices such as interactive proofs should be able to tell the difference. Fortnow suggests a characterization of the simulator's behavior on $x \in L$ and uses this characterization in his protocol for $\overline{L}$, yet this characterization is wrong. Aiello and Håstad present a refinement of Fortnow's characterization [AH-87]; their characterization is correct and can be used to show that $\mathcal{SZK} \subseteq \mathcal{AM}$ (which is the goal of their paper) as well as $\mathcal{SZK} \subseteq$ co-$\mathcal{AM}$.

Fortnow's characterization. Given an interactive proof (P, V) for L and a simulator M and fixing a common input $x \in \{0,1\}^*$, the following sets are defined. Let us denote by t the number of random bits that the verifier V uses on input x, and by q the number of random bits used by the simulator M. For every conversation prefix h, we consider the set of the verifier's coin tosses which are consistent with h (the conversation so far). We denote this set by R_1^h. Namely, suppose $h = (\alpha_1, \beta_1, ..., \alpha_i, \beta_i)$ or $h = (\alpha_1, \beta_1, ..., \alpha_i, \beta_i, \alpha_{i+1})$. Then, $r \in R_1^h$ iff $V(x, r, \alpha_1, ..., \alpha_j) = \beta_j$ for every $j \leq i$, where $V(x, r, \bar{\alpha})$ denotes the message sent by V on input x random tape r and prover message sequence $\bar{\alpha}$. The set R_1^h depends only on the verifier V. Next, we consider sets R_2^h which are subsets of the corresponding R_1^h's. Specifically, they contain only r's that can appear with h in an accepting conversation output by the simulator M. Namely, $r \in R_2^h$ iff $r \in R_1^h$ and there exists $\omega \in \{0,1\}^q$ so that $M(x, \omega)$ is an accepting conversation with prefix h. (Here $M(x, \omega)$ denotes the conversation output by M on input x and simulator random tape ω.)

Motivation. For simplicity, suppose that the simulation is perfect (i.e., M witnesses that (P, V) is *perfect* zero knowledge) and that (P, V) has one-sided error (i.e., "perfect completeness"). Then, for every $x \in L$ and every possible h, we must have $R_2^h = R_1^h$ (otherwise the simulation is not perfect). However, if $x \notin L$ then there must exist h's so that R_2^h is much smaller than R_1^h. Otherwise the simulator-based prover (for M) will always convince V to accept x, thus violating the soundness condition of (P, V). The problem with the above dichotomy is that it is "too existential" and thus it is not clear how to use it. Instead Fortnow claimed a dichotomy which is more quantitative.

A false characterization. Let $\mathrm{pref}(\bar{c})$ denote the set of all message prefixes in the conversation $\bar{c}$:

- if $x \in L$ then

$$\mathrm{Prob}_\omega(\forall h \in \mathrm{pref}(M(x,\omega)) \ : \ \left|R_2^h\right| \approx_1 \left|R_1^h\right|) \ > \ \frac{3}{4};$$

- if $x \notin L$ then

$$\mathrm{Prob}_\omega(\forall h \in \mathrm{pref}(M(x,\omega)) \ : \ \left|R_2^h\right| \approx_2 \left|R_1^h\right|) \ < \ \frac{1}{4},$$

where the probability (in both cases) is taken uniformly over $\omega \in \{0,1\}^q$. We did not specify what is meant by $\approx_i$. One may substitute $\alpha \approx_1 \beta$ by $\alpha \geq \frac{1}{2} \cdot \beta$ and $\alpha \approx_2 \beta$ by $\alpha \geq \frac{1}{4} \cdot \beta$. The gap between the two is needed for the approximate lower/upper bound protocols.

A counterexample. The mistake is in the second item of the characterization. The false argument given in [F-89] confuses between the probability distribution of conversations output by the simulator and the probability distribution of the conversations between a simulator-based prover (denote P^*) and the verifier. These distributions are not necessarily the same (note that we are in the case $x \notin L$). Consequently, the probability that "good" conversations (i.e., conversations for which $|R_2| \approx |R_1|$ for all prefixes) occur in the (P^*, V) interaction is not the same as the probability that the simulator outputs "good" conversations. This point is ignored in [F-89] and leads there to the false conclusion that the characterization holds. Below, we present an interactive proof (P, V) and a (perfect) zero-knowledge simulator for which the characterization fails.

The interactive proof that we present is for the empty language Φ. This interactive proof is perfect zero knowledge for the trivial reason that the requirement is vacuous. Yet, we present a simulator for this interactive proof which, for every $x \in \{0,1\}^* = \overline{\Phi}$, outputs "good" conversation with probability close to 1. Thus, the characterization fails.

The interactive proof (from the verifier's point of view – input $x \in \{0,1\}^n$).

- The verifier uniformly selects $\alpha \in \{0,1\}^n$ and sends α to the prover.
- The verifier waits for the prover's message $\beta \in \{0,1\}^n$.
- Next, the verifier uniformly selects $\gamma \in \{0,1\}^n$ and sends γ to the prover.
- The verifier accepts iff either $\alpha = 0^n$ or $\beta = \gamma$.

Regardless of the prover's strategy, the verifier accepts each $x \in \{0,1\}^n$ with negligible probability; specifically, $2^{-n} + (1 - 2^{-n}) \cdot 2^{-n}$. Thus, the above protocol indeed constitutes an interactive proof for the empty language Φ.

The simulator operates as follows (on input $x \in \{0,1\}^n$ and parameter ϵ).

- With probability $1 - \epsilon$, the simulator M outputs a conversation uniformly distributed in $0^n \times \{0,1\}^{2n}$.
- With probability ϵ, the simulator M outputs a conversation uniformly distributed in $(\{0,1\}^n - 0^n) \times \{0,1\}^{2n}$.

The parameter ϵ is set to be negligible, say, $\epsilon = 2^{-n}$.

Claim. In contradiction to the characterization, for every $x \in \{0,1\}^* = \overline{\Phi}$,

$$\mathrm{Prob}_\omega(\forall h \in \mathrm{pref}(M(x,\omega)) \ : \ \left|R_2^h\right| = \left|R_1^h\right|) \ \geq \ 1 - \epsilon,$$

where the probability is taken uniformly over $\omega \in \{0,1\}^q$.

Proof. Recall that all conversations are $3n$-bit long strings and for a conversation $\alpha\beta\gamma \in \{0,1\}^{3n}$ the verifier coins are $\alpha\gamma$. Note that with probability $1-\epsilon$, the simulator outputs a conversation of the form $0^n\beta\gamma$. Thus, it suffices to show that every conversation of the form $0^n\beta\gamma$ satisfies $R_2^h = R_1^h$ for each prefix (i.e., $h \in \{\lambda, 0^n, 0^n\beta, 0^n\beta\gamma\}$). First observe that $R_1^\lambda = \{0,1\}^{2n} = R_2^\lambda$, since for every $\alpha\gamma \in \{0,1\}^{2n}$ the simulator outputs the accepting conversation $\alpha\gamma\gamma$ with nonzero probability. Similarly, $R_1^{0^n} = 0^n\{0,1\}^n = R_2^{0^n}$ (here we use $\alpha = 0^n$). Next, for every $\beta \in \{0,1\}^n$ we have $R_1^{0^n\beta} = 0^n\{0,1\}^n = R_2^{0^n\beta}$, since for every $\gamma \in \{0,1\}^n$ the simulator outputs the accepting conversation $0^n\beta\gamma$ with nonzero probability. (Here we use the fact that the verifier always accepts when $\alpha = 0^n$.) Similarly, $R_1^{0^n\beta\gamma} = 0^n\gamma = R_2^{0^n\beta\gamma}$. □

Conclusion. The source of trouble is that the definition of the set R_2^h does not take into account the probability weight assigned by the simulator to ω's that witness the assertion "the simulator outputs an accepting conversation that starts with h." Indeed, this is exactly the nature of the refinement suggested by Aiello and Håstad [AH-87].

Appendix B. Interactive proofs with nonnegligible error probabilities. As explained in Remark 1 of section 3.1, the notion of an interactive proof with bounded knowledge complexity is not robust under changes in the allowed error probability. Throughout the paper, we use the natural definition of interactive proofs in which the error probability is negligible. However, our techniques yield nontrivial results also in the case where one defines interactive proofs with some specific nonnegligible error probability. In this appendix we explain how such assertions may be obtained and state such results for two special cases.

Denote by $\epsilon_c(n)$ an upper bound on the probability that the verifier rejects an input x although $x \in L$ and the prover plays honestly. This is the error probability related to the completeness condition. Similarly, denote by $\epsilon_s(n)$ an upper bound on the probability that the verifier accepts $x \notin L$ when the prover follows its optimal strategy (not necessarily following the protocol). This is the error probability related to the soundness condition. We say that an interactive proof has error probabilities (ϵ_s, ϵ_c) if its error probability in the soundness condition is bounded by ϵ_s and its error probability in the completeness condition is bounded by ϵ_c.

B.1. The perfect case. In this subsection, we consider the restricted case of *perfect* knowledge complexity and derive Theorem B.1 which is the analogue of Theorem 1 for the case that the error probabilities are not negligible. Following the definitions in section 4, we denote the simulation-based prover by P^*.

Let us follows the steps of the proof of our main theorem and observe which assertions hold for the case of nonnegligible error probability. We begin by observing that the following generalization of Lemma 4.2 holds.

LEMMA B.1. *Let (P,V) be an interactive proof for L with error probabilities $(\epsilon_s(n), \epsilon_c(n))$ and with knowledge complexity $k(n)$, then the following hold.*

1. *If $x \in L$ then the probability that (P^*,V) outputs an accepting conversation is at least $(1-\epsilon_c(n))^2 \cdot 2^{-k(n)}$, where $n = |x|$.*
2. *If $x \notin L$ then the probability that (P^*,V) outputs an accepting conversation is at most $\epsilon_s(n)$, where $n = |x|$.*

The proof of this lemma is identical to the proof of Lemma 4.2, except that here $\frac{|A_\lambda|}{|S_\lambda|} \geq 1 - \epsilon_c(n)$. As explained in section 4, an efficient machine with access to an NP-oracle can sample conversations in (P^*,V). By Lemma B.1, this would yield an

accepting conversation with probability at most $\epsilon_s(n)$ in the case $x \notin L$ and at least $(1-\epsilon_c(n))^2 \cdot 2^{-k(n)}$ when $x \in L$. In case these two probabilities differ sufficiently (i.e., by more then a polynomial fraction), we can use standard amplification techniques to get a probabilistic algorithm that determines whether $x \in L$ with error probability less than $\frac{1}{3}$ (or negligible, or 2^{-n}). To summarize, we get the following theorem for perfect knowledge complexity.

THEOREM B.1. *If a language L has an interactive proof with perfect knowledge complexity $k(n)$ and error probabilities (ϵ_s, ϵ_c) and if there exists a positive polynomial $p(n)$ such that*

$$(1-\epsilon_c(n))^2 \cdot 2^{-k(n)} \;>\; \epsilon_s(n) + \frac{1}{p(n)},$$

then $L \in \mathcal{BPP}^{\mathcal{NP}}$.

Examples. Theorem B.1 implies, for example, that if a language L has an interactive proof of knowledge complexity 1 and error probability $\frac{1}{4}$ (both in the soundness condition and in the completeness condition), then L is in $\mathcal{BPP}^{\mathcal{NP}}$. Another interesting example is the case of one-sided error (i.e., $\epsilon_c = 0$). Theorem B.1 implies that, for any polynomial $p(\cdot)$, if a language L has a one-sided error interactive proof (P, V) of knowledge-complexity at most $\log_2 p(\cdot)$ and error probability $\epsilon_s \leq \frac{1}{2p(\cdot)}$, then L is in $\mathcal{BPP}^{\mathcal{NP}}$.

B.2. The general (statistical) case. Unfortunately, the analogue result for statistical knowledge complexity is not as clean and has various different formulations according to possible properties of the error probabilities. Let us explain how such results can be obtained and give a specific example for the special case in which $\epsilon_c = 0$; i.e., the original interaction has one-sided error.

Recall that the proof for the negligible error-probability case uses the transformation from statistical to perfect knowledge complexity (i.e., Theorem 2) and then uses Theorem 1. This transformation increases the knowledge complexity by a logarithmic additive term. In view of Lemma B.1, it is desirable not to increase the knowledge complexity without concurrently decreasing the error probability. Thus, before applying the transformation, we reduce the error probability by iterating the protocol as many times as possible while maintaining logarithmic knowledge complexity.

Specifically, we start with a protocol (P, V) of statistical knowledge complexity $k(\cdot)$ and denote by $l(\cdot)$ the total length of the conversation in this protocol. Also, fix an input x of length n, and let $l = l(n)$, $k = k(n)$, $\epsilon_s = \epsilon_s(n)$, and $\epsilon_c = \epsilon_c(n)$. We begin by running the original protocol (P, V) sequentially $t \stackrel{\text{def}}{=} \lceil (\log_2 l)/k \rceil$ times. These repetitions yield a new protocol (P', V') whose length is $t \cdot l$, its knowledge-complexity is bounded by $t \cdot k < k + \log_2 l$, and its error probability decreases. To compute the decrease in the error probabilities, we partition the analysis into two cases according to whether the original protocol has one-sided error or not.

If the original interaction has one-sided error, i.e., the verifier always accepts when $x \in L$, then the new verifier V' accepts only if ALL repetitions of the original protocols end up accepting. The error probabilities in this case decrease from $(\epsilon_s, 0)$ to $(\epsilon_s^t, 0)$. In the case where the original interactive proof was not one sided, the verifier counts the number of original interactions that end up with the original verifier accepting. The new verifier accepts if this number is greater than $\frac{\epsilon_s + (1-\epsilon_c)}{2} \cdot t$. In order to compute the new error probabilities we may apply the Chernoff bound and get an upper bound on the new error probabilities which depends on t, on the difference between $1 - \epsilon_c$ and ϵ_s, and, of course, on ϵ_s and ϵ_c themselves.

Next, we apply the transformation of section 5 and get a new interactive proof (P'', V'') for L which has knowledge complexity $(k + \log l) + 2 + 2\log_2 \log_2 n + \lceil \log_2(l \cdot t) \rceil$, where the additional $2 + 2\log_2 \log_2 n + \lceil \log_2(l \cdot t) \rceil$ term comes from the transformation. Finally, if the resulting parameters of (P'', V'') satisfy the conditions stated in Theorem B.1, then we get that the language L is in $\mathcal{BPP}^{\mathcal{NP}}$. Let us provide full details for the special (yet important) case of one-sided error (i.e., $\epsilon_c = 0$).

In the special case of one-sided error, we end up using Theorem B.1 for an interactive proof with knowledge complexity $(k + \log l) + 2 + 2\log_2 \log_2 n + \lceil \log_2(l \cdot t) \rceil$ and error probabilities $({\epsilon_s}^t, \epsilon)$, where ϵ is a negligible fraction (introduced by the transformation). Thus, we get the following theorem for statistical knowledge complexity.

THEOREM B.2. *Suppose that a language L has an interactive proof of statistical knowledge complexity $k(n)$, one-sided error probability $\epsilon_s(n)$, and with length $l(n)$ so that there exists a polynomial $p(n)$ for which the following inequality holds:*

$$\frac{1}{8 \cdot (\log_2 n)^2 \cdot 2^{k(n)} \cdot l(n)^2 \cdot \left\lceil \frac{\log_2 l(n)}{k(n)} \right\rceil} \geq \epsilon_s(n)^{\lceil (\log_2 l(n))/k(n) \rceil} + \frac{1}{p(n)}.$$

Then $L \in \mathcal{BPP}^{\mathcal{NP}}$.

For $l(n) \leq 2^{k(n)}$ the condition simplifies to $2^{-3k(n)} \geq 8(\log_2 n)^2 \cdot \epsilon_s(n) + 1/\mathrm{poly}(n)$, whereas for $l(n) > 2^{k(n)}$ the condition simplifies to

$$\frac{1}{8 \cdot (\log_2 n)^3 \cdot l(n)^3} \geq \epsilon_s(n)^{\lceil (\log_2 l(n))/k(n) \rceil} + \frac{1}{\mathrm{poly}(n)}.$$

Acknowledgment. We thank Leonard Shulman for providing us with a simpler proof of Claim 4.3.

THE COMPLEXITY OF PLANAR COUNTING PROBLEMS*

HARRY B. HUNT III†, MADHAV V. MARATHE‡, VENKATESH RADHAKRISHNAN§, AND RICHARD E. STEARNS†

Abstract. We prove the #P-hardness of the counting problems associated with various satisfiability, graph, and combinatorial problems, when restricted to planar instances. These problems include 3SAT, 1-3SAT, 1-EX3SAT, MINIMUM VERTEX COVER, MINIMUM DOMINATING SET, MINIMUM FEEDBACK VERTEX SET, X3C, PARTITION INTO TRIANGLES, AND CLIQUE COVER. We also prove the NP-completeness of the AMBIGUOUS SATISFIABILITY problems [J. B. Saxe, *Two Papers on Graph Embedding Problems*, Tech. Report CMU-CS-80-102, Dept. of Computer Science, Carnegie Mellon Univ., Pittsburgh, PA, 1980] and the D^P-completeness (with respect to random polynomial reducibility) of the unique satisfiability problems [L. G. Valiant and V. V. Vazirani, *NP is as easy as detecting unique solutions*, in Proc. 17th ACM Symp. on Theory of Computing, 1985, pp. 458–463] associated with several of the above problems, when restricted to planar instances. Previously, very few #P-hardness results, no NP-hardness results, and no D^P-completeness results were known for counting problems, ambiguous satisfiability problems, and unique satisfiability problems, respectively, when restricted to planar instances.

Assuming $\mathsf{P} \neq \mathsf{NP}$, one corollary of the above results is that there are no ϵ-approximation algorithms for the problems of maximizing or minimizing a linear objective function subject to a planar system of linear inequality constraints over the integers.

Key words. planar, 3SAT, graphs, #P-complete, D^P-complete, NP-complete

AMS subject classifications. 68Q15, 68R10.

1. Introduction.

A number of papers in the literature, including [1, 5, 16, 20, 21, 25, 26], have considered the complexity of counting problems, proving many such problems to be #P-complete. Other papers have studied the complexity of ambiguous and unique satisfiability problems [23, 27], proving such problems to be NP-hard and D^P-hard,[1] respectively. Still other papers [3, 4, 5, 6, 15] have considered the complexity of decision problems when restricted to planar instances, proving many such problems to be NP-hard. In this paper, we combine these lines of research and prove for the first time that *even when restricted to planar instances*, many counting problems remain #P-complete, many ambiguous satisfiability problems remain NP-complete, and many unique satisfiability problems remain D^P-hard.

Previously, very few #P-hardness results, no NP-hardness results, and no D^P-completeness results were known for counting problems, ambiguous satisfiability problems, and unique satisfiability problems, respectively, when restricted to planar in-

[1]Throughout this paper, all the D^P-hardness results are with respect to random polynomial time reductions.

stances. Such results are presented for several satisfiability, graph, and combinatorial problems. These results show that planar counting, planar ambiguous satisfiability, and planar unique satisfiability problems are *as hard as* arbitrary such problems, with respect to polynomial time and random polynomial time reducibilities. The results in this paper both extend the results in the literature and also provide additional tools for proving hardness results for planar problems for various complexity classes. These tools include parsimonious and weakly parsimonious crossover boxes, the NP-hardness of various basic planar satisfiability problems, and the NP-hardness of the planar ambiguous satisfiability problems. (Henceforth, we denote the restriction of a problem Π to planar instances by PL-Π.) The particular results presented here include the following.

1. The problem 3SAT has a parsimonious planar crossover box. Among other things, this implies that the problem #PL-3SAT is #P-complete, the problem AMBIGUOUS-PL-3SAT is NP-complete, and the problem UNIQUE-PL-3SAT is D^P-complete.

2. The problem 3SAT is simultaneously polynomial time, planarity-preserving, and parsimoniously reducible to each of the basic CNF satisfiability problems listed in Table 1.1. (Previously, 3SAT was only known to be so reducible to the problem 1-EX3SAT [3].)

3. There exist polynomial time, weakly parsimonious, and planarity-preserving reductions from the problem 1-EX3MONOSAT to several graph problems including MINIMUM VERTEX COVER, MINIMUM DOMINATING SET, and MINIMUM FEEDBACK VERTEX SET.

4. Using the results 1, 2, and 3, variants of known reductions, and new reductions, we show that for all of the problems PL-Π in Table 1.1, the problem #PL-Π is #P-hard. Similarly, we show that for many of the problems in Table 1.1, the problems AMBIGUOUS PL-Π and UNIQUE PL-Π are NP-hard and D^P-hard, respectively.

5. All of the #P-hardness results for planar counting problems in Table 1.1 can easily be shown to hold, even when the input to the problem consists of a formula f and one of its satisfying assignments, a graph G and one of its minimum vertex covers, a graph G and one of its dominating sets, etc.

Thus the #P-hardness of the problems #PL-Π in Table 1.1 is not simply a corollary of the NP-hardness of the problem PL-Π, since the problems #PL-Π are #P-hard even when restricted to sets of instances for which the problems PL-Π are trivially polynomial time solvable. Moreover, quoting from [27] we note that "whether the number of solutions of all NP-complete problems are nevertheless polynomial time interreducible (i.e., whether NP-completeness implies #P-completeness) is still open."

Corollaries of our results and their proofs include the following.

1. The problems #1-VALID 3SAT and #1-VALID PL-3SAT are #P-complete. (It is trivially seen that every instance of the problem 1-VALID 3SAT is satisfiable by the assignment making all variables equal to 1. See Definition 2.10.)

2. The problems AMBIGUOUS 1-VALID 3SAT and AMBIGUOUS 1-VALID PL-3SAT are NP-complete. The problems UNIQUE 1-VALID 3SAT and UNIQUE 1-VALID PL-3SAT are Co-NP-complete.

3. Assuming $P \neq NP$, there are no ϵ-approximation algorithms for the problems of maximizing or minimizing a linear objective function subject to a planar system of inequalities over the integers.

Table 1.1 gives a summary of our #P-hardness results. The rest of the paper is organized as follows. Section 2 contains definitions and preliminaries. Section 3

discusses the complexity of #Pl-3Sat and other basic CNF satisfiability problems. These problems are used to prove the #P-hardness of other problems discussed in the subsequent sections. Section 4 discusses the complexity of various counting problems for planar graphs. Section 5 contains the ambiguous and unique satisfiability results and the result on the nonapproximability of the objective functions of integer linear programs. Finally, section 6 consists of conclusions and open problems.

Table 1.1

Summary of NP- and #P-hardness results for planar instances. The third column summarizes the decision complexity of the problems while the fourth column summarizes the complexity of the counting versions. A star (*) denotes a result obtained in this paper. The numbers in square brackets are the references where the corresponding results are proved.

2. Definitions and preliminaries. In this section we review the basic definitions and notation used in this paper. Additional definitions can be found in [3, 5, 19, 23].

Definition 2.1. *A* search problem Π *consists of a set* D_Π *of objects called* instances, *and for each instance* $I \in D_\Pi$, *a set* $S_\Pi[I]$ *of objects called* solutions *for* I. *An algorithm is said to* solve *a search problem* Π *if, given* $I \in D_\Pi$ *as input, the algorithm outputs* no *if* $S_\Pi[I] = \phi$ *and outputs an* $s \in S_\Pi[I]$ *otherwise.*

Definition 2.2. *The* enumeration problem *associated with a search problem* Π *is the problem of determining, given* $I \in D_\Pi$, *the cardinality of* $S_\Pi[I]$.

Definition 2.3. *The class* #P *consists of all enumeration problems associated with search problems* Π *such that there is a nondeterministic algorithm for solving* Π *such that, for all* $I \in D_\Pi$, *the number of distinct accepting sequences for* I *by the algorithm equals* $|S_\Pi[I]|$ *and the length of the longest accepting computation of the algorithm on* $I \in D_\Pi$ *is bounded by a polynomial in the length of* I.

Definition 2.4. *A reduction* [5] $f : D_\Pi \to D_{\Pi'}$ *is parsimonious if and only if* $\forall I \in D_\Pi$ *the number of solutions of* I *is equal to the number of solutions of* $f(I)$.

Definition 2.5. *A reduction* f *is weakly parsimonious if and only if* $|S(I)| = g(I)|S(f(I))|$, *where* $|S(I)|$ *and* $|S(f(I))|$ *denote the number of solutions of* I *and* $f(I)$, *respectively, and* $g(I)$ *is a polynomial time computable function represented using binary notation.*

An enumeration problem is said to be #P-hard if each problem in #P is polynomial time parsimoniously or weakly parsimoniously Turing reducible to it. If, in addition, the enumeration problem is in #P, the problem is said to be #P-complete.

DEFINITION 2.6. #3SAT *is the problem of computing the number of satisfying assignments of a Boolean formula F in conjunctive normal form with at most three literals per clause.*

The following basic results on the complexity of counting problems are used in this paper.

THEOREM 2.7 (see [5, 25]). *The problems* #3SAT *and* #GRAPH 3-COLORING *are* #P*-complete.*

DEFINITION 2.8. *The* bipartite graph *associated with a CNF satisfiability problem is defined as follows. The clauses and variables in a formula are in one to one correspondence with the vertices of the graph. There is an edge between a clause node and a variable node if and only if the variable appears in the clause. A CNF formula is planar if and only if its associated bipartite graph is planar.*

DEFINITION 2.9. (1) EX3SAT *is the restriction of the problem* 3SAT *to formulas in which each clause has exactly three literals.*

(2) 1-3SAT *is the problem of determining if a CNF formula in which each clause has no more than three literals has a satisfying assignment such that exactly one literal per clause is satisfied.*

(3) 1-EX3SAT *is the problem of determining if a CNF formula in which each clause has exactly three literals has a satisfying assignment such that exactly one literal per clause is satisfied.*

(4) 1-EX3MONOSAT *is the restriction of* 1-EX3SAT *to formulas having no negated literals.*

DEFINITION 2.10 (see [24]). *A relation $R(x_1, x_2, \ldots, x_n)$ is* 1-valid *if and only if $(1, 1, \ldots, 1) \in R$. A CNF formula f is* 1-valid *if the formula is satisfied when all the variables in the formula are set to true.*

DEFINITION 2.11. *Given a Boolean formula F and an assignment $\mathbf{v}$ to the variables of F, the notation $\mathbf{v}[F]$ denotes the value of F under $\mathbf{v}$.*

DEFINITION 2.12. (1) EXACT COVER BY 3-SETS (X3C): *An instance of this problem consists of a set X with $3m$ elements and a collection C of three-element subsets of X. The question is: does there exist a subcollection C' of C such that every element of X occurs in exactly one set in C'?*

(2) HITTING SET: *An instance of this problem consists of a collection C of subsets of a finite set S and a positive integer $K \leq |C|$. The question is: is there a subset $S' \subseteq S$ with $|S'| \leq K$ such that S' contains at least one element from each subset in C?*

As in the case of 3SAT, we can associate a bipartite graph $G = (S, T, E)$ with an instance of each of the above problems. For example, PL-X3C is defined as follows. Each element in C has a corresponding vertex in S, each element in X has a corresponding vertex in T, and a vertex in S is joined to a vertex in T if and only if the set corresponding to the vertex in S contains the element corresponding to the vertex in T.

DEFINITION 2.13. (1) DOMINATING SET: *An instance of this problem consists of an undirected graph $G = (V, E)$ and an integer $K \leq |V|$. The question is: is there a dominating set of size at most K in G; i.e., is there a subset V' of V, $|V'| \leq K$, such that for each $u \in V - V'$ there is a $v \in V'$ such that $(u, v) \in E$?*

(2) CLIQUE COVER: *An instance of this problem consists of an undirected graph $G = (V, E)$ and an integer $K \leq |V|$. The question is: is there a clique cover of size*

at most K in G; i.e., can the graph be partitioned into at most K sets of nodes such that each set is a clique?

(3) PARTITION INTO CLAWS: *An instance of this problem consists of an undirected graph $G = (V, E)$, $|E| = m$. The question is: is there a way to partition the edges of the graph into sets $E_1, \ldots, E_s$, $s = m/3$, such that each E_i induces a subgraph isomorphic to $K_{1,3}$ (i.e., a claw)?*

(4) FEEDBACK VERTEX SET: *An instance of this problem consists of a directed graph $G = (V, E)$ and an integer $K \leq |V|$. The question is: is there a feedback vertex set of size at most K in G; i.e., does there exist a subset V' of V of size at most K such that V' contains at least one vertex from every cycle in G?*

DEFINITION 2.14. *Let Π denote a CNF satisfiability problem. Then the associated* ambiguous version *of Π, denoted by* AMBIGUOUS-Π, *is the problem of determining, given an instance I of Π and an assignment $\mathbf{v}$ to the variables of I such that $\mathbf{v}[I] = 1$, if there is an additional assignment of values to the variables of I satisfying I. The associated* unique version *of Π, denoted by* UNIQUE-Π, *is the problem of determining if the given instance I of Π has exactly one satisfying assignment.*

More generally, let Π be any decision problem. Henceforth, when applicable, we denote the restriction of Π to planar instances by PL-Π, the counting version of Π by #Π, the ambiguous version of Π by AMBIGUOUS-Π, and the unique version of the problem by UNIQUE-Π. For example, recalling Definition 2.12 and the discussion immediately following it,

(i) PL-X3C is the problem X3C restricted to instances (X, C) for which the bipartite graph $G = (S, T, E)$ is planar;

(ii) #X3C is the problem of computing, given (X, C), the number of distinct subsets $C' \subseteq C$ such that each element of X occurs in exactly one set in C';

(iii) AMBIGUOUS-X3C is the problem of determining, given (X, C, C'), where $C' \subseteq C$ and each element of X occurs in exactly one set in C', if there exists another subset $C'' \subseteq C$ that is an exact cover of the elements in X.

Finally, henceforth, by *reduction*, we mean a polynomial time many-one reduction.

3. Basic planar counting problems. In this section, we prove that the problem PL-3SAT has a parsimonious crossover box. Specifically, we show that the crossover box in [15] is parsimonious. One immediate corollary is that the problem #PL-3SAT is #P-hard. We also prove that the problem 3SAT is planarity-preserving and parsimoniously reducible to each of the basic SAT problems listed in Table 1.1.

DEFINITION 3.1. *A* crossover box *for a satisfiability problem Π is a formula f_c with four distinguished variables a, a_1, b, b_1, which can be laid out on the plane with the distinguished variables on the outer face, such that*

(1) *the* old variables *a and b are opposite to the corresponding* new variables *a_1 and b_1,*

(2) *each assignment to a and b can be extended to a satisfying assignment of f_c,*

(3) *for any satisfying assignment of f_c, $a \equiv a_1$ and $b \equiv b_1$.*

The crossover box is parsimonious *if and only if for each assignment to the old variables, there is exactly one extension of this assignment to the variables in the crossover box such that f_c is satisfied.*

THEOREM 3.2. *The problem* 3SAT *has a parsimonious planar crossover box. Hence,* 3SAT *is parsimoniously reducible to* PL-3SAT *and* #PL-3SAT *is* #P*-complete.*

Proof. The crossover box described here is the same as the one given in [15]. Here we prove that the crossover box also preserves the number of solutions. For expository purposes, we describe the crossover box in two steps. The first step is to consider the

following formula:

$$f_c = (\overline{a_2} + \overline{b_2} + \alpha) \wedge (a_2 + \overline{\alpha}) \wedge (b_2 + \overline{\alpha}) \bigwedge$$

$$(\overline{a_2} + b_1 + \beta) \wedge (a_2 + \overline{\beta}) \wedge (\overline{b_1} + \overline{\beta}) \bigwedge$$

$$(a_1 + b_1 + \gamma) \wedge (\overline{a_1} + \overline{\gamma}) \wedge (\overline{b_1} + \overline{\gamma}) \bigwedge$$

$$(a_1 + \overline{b_2} + \delta) \wedge (\overline{a_1} + \overline{\delta}) \wedge (b_2 + \overline{\delta}) \bigwedge$$

$$(\alpha + \beta + \gamma + \delta) \bigwedge$$

$$(\overline{\alpha} + \overline{\beta}) \wedge (\overline{\beta} + \overline{\gamma}) \wedge (\overline{\gamma} + \overline{\delta}) \wedge (\overline{\delta} + \overline{\alpha}) \bigwedge$$

$$(a_2 + \overline{a}) \wedge (a + \overline{a_2}) \wedge (b_2 + \overline{b}) \wedge (b + \overline{b_2}).$$

Following [15], we give an intuitive explanation of formula f_c. Clauses 1, 2, and 3 imply that $(\alpha \leftrightarrow (a_2 \wedge b_2))$; clauses 4, 5, and 6 imply $(\beta \leftrightarrow (a_2 \wedge \overline{b_1}))$; clauses 7, 8, and 9 imply $(\gamma \leftrightarrow (\overline{a_1} \wedge \overline{b_1}))$; clauses 10, 11, and 12 imply $(\delta \leftrightarrow (\overline{a_1} \wedge b_2))$. Clause 13 (the four literal clause) implies that at least one of α, β, γ, or δ is true. Clauses 14, 15, 16, 17 imply that $(\alpha+\gamma) \rightarrow (\overline{\beta} \wedge \overline{\delta})$ and $(\beta+\delta) \rightarrow (\overline{\alpha} \wedge \overline{\gamma})$. Finally, clauses 18 and 19 imply $(a \leftrightarrow a_2)$ and $(b \leftrightarrow b_2)$. It can now be verified that the formula f_c implies $(a_1 \leftrightarrow a)$ and $(b_1 \leftrightarrow b)$. For example, consider an assignment $\mathbf{v}$ such that $\mathbf{v}[a_1] = \mathbf{v}[b_1] = 0$. Then f_c implies that $\mathbf{v}[\beta] = \mathbf{v}[\delta] = \mathbf{v}[\alpha] = \mathbf{v}[a_2] = \mathbf{v}[b_2] = 0$ and $\mathbf{v}[\gamma] = 1$. We leave it to the reader to verify the other three cases. Thus, in any satisfying assignment to f_c, the new variables $a_1, a_2, b_1, b_2, \alpha, \beta, \gamma$, and δ are *functionally* dependent on a and b. In other words, given an assignment to the variable a and b there is a unique way to extend this assignment so as to satisfy all the clauses in f_c. Thus f_c is a parsimonious crossover box. Even though the formula itself is a parsimonious planar crossover box, it is unsuitable for a reduction to Pl-3Sat because it has one clause with four literals, namely, $(\alpha + \beta + \gamma + \delta)$. The second step is to obtain the formula f_c' by replacing this clause with the formula $(\alpha + \delta + \xi) \wedge (\overline{\xi} + \beta + \gamma)$. The planarity of the formula f_c' is demonstrated in Figure 3.1. This step also preserves numbers of satisfying assignments as demonstrated by the following claim.

Claim 3.3. (1) *Exactly one of $\alpha, \beta, \gamma, \delta$ is true in any satisfying assignment to f_c.* (2) *ξ is functionally dependent on α, β, γ, and δ. Thus a satisfying assignment for f_c can be extended in a unique way to a satisfying assignment to the formula f_c'.*

Proof. We prove the claim for the case when α is true. The other three cases are similar. As already discussed, clauses 14, 15, 16, 17 imply that $(\alpha+\gamma) \rightarrow (\overline{\beta} \wedge \overline{\delta})$ and $(\beta + \delta) \rightarrow (\overline{\alpha} \wedge \overline{\gamma})$. Consider a satisfying assignment $\mathbf{v}$ such that $\mathbf{v}[\alpha] = 1$. Then the above discussion implies that $\mathbf{v}[\beta] = \mathbf{v}[\delta] = 0$. Now, since $(\beta \leftrightarrow (a_2 \wedge \overline{b_1}))$ and $\mathbf{v}[\beta] = 0$, we have $\mathbf{v}[a_2] = 1$ and $\mathbf{v}[b_1] = 1$. Since $(\gamma \leftrightarrow (\overline{a_1} \wedge \overline{b_1}))$ and $\mathbf{v}[b_1] = 1$ it implies that $\mathbf{v}[\gamma] = 0$. This forces $\mathbf{v}[\xi] = 0$. □

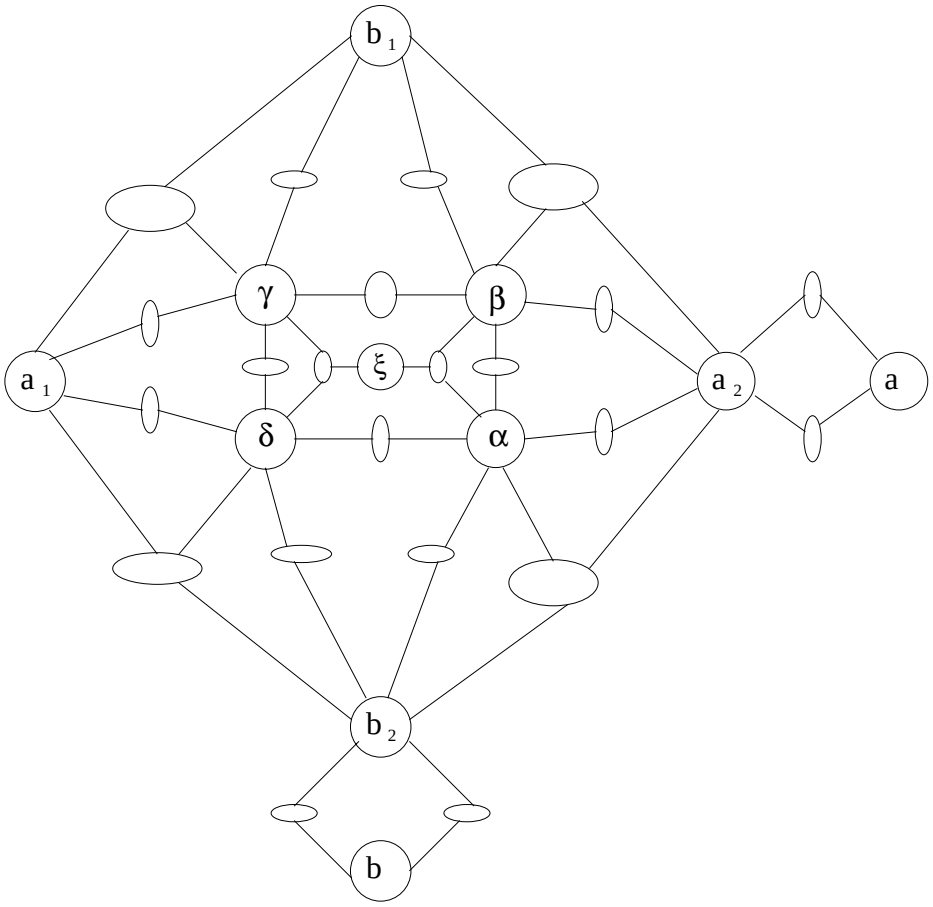

FIG. 3.1. *The parsimonious planar crossover box for* 3SAT. *The clauses are denoted by ellipses and the variables are denoted by circles.*

Thus, the satisfying assignments to f_c' satisfy f_c. It can now be seen that in a satisfying assignment to the variables of f_c', the values of a_1, a_2, b_1, b_2, α, β, γ, δ, and ξ are all functionally dependent on a and b. Therefore, f_c' is a parsimonious crossover box.

We can now describe the reduction given in [15] from 3SAT to PL-3SAT. For any 3CNF formula, lay the formula in the plane, possibly with certain edge pairs crossing over at "crossover points." This layout is a planar graph with vertex set consisting of the variables, clauses, and crossover points. In this layout, we add a new variable node on the edge between two crossover points or between a crossover point and a clause node, as shown in Figure 3.2. The resulting graph is bipartite where the first set of nodes consists of the variable nodes and the second set consists of the clause nodes and the crossover points. Each edge is between a variable and a crossover point, or between a variable and a clause. Also, each crossover point has four distinct variables as neighbors. We now replace each crossover point with the crossover box in Figure 3.1, where a_2, b_2, α, β, γ, δ, and ξ are given distinct names in each replacement. Here a, b, a_1, and b_1 are identified with the neighbors of the crossover point in cyclic order in the layout. The new layout is planar and the

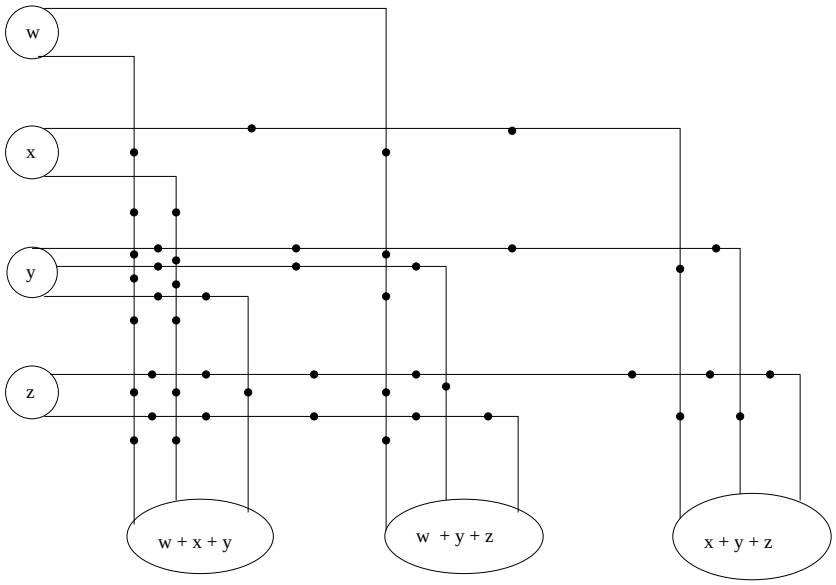

FIG. 3.2. *Figure showing how new variables are introduced in the bipartite graph for* 3SAT *to obtain an instance of* PL-3SAT. *In the example, the instance of* 3SAT *is given by* $F = (w + x + y) \wedge (w + y + z) \wedge (x + y + z)$. *The circles denote original variables, ellipses denote the original clauses, and the black dots denote new variables added. Each crossover of edges is replaced by a crossover box shown in Figure* 3.1.

new formula has the same number of solutions as the original, since in any satisfying assignment the new variables are functionally dependent on the old. □

Next, we strengthen Theorem 3.2 by showing that counting the number of satisfying assignments of a planar 3CNF formula is #P-complete, even when the input consists of a planar 3CNF formula F and an assignment $\mathbf{v}[F]$ to the variables of F which satisfies F.

THEOREM 3.4. *Given an instance* F *of* PL-3SAT *and an assignment* $\mathbf{v}$ *to the variables of* F *such that* $\mathbf{v}[F] = 1$, *the problem of counting the number of satisfying assignments of* F *is* #P*-complete.*

Proof. Step 1. Given an arbitrary planar 3CNF formula $f(x_1, x_2, \ldots, x_n)$, we first construct a new formula $f_1(x_1, x_2, \ldots, x_n, x_{n+1})$, where $f_1 = (f \wedge x_{n+1}) \bigvee [\overline{x_1} \wedge \overline{x_2} \wedge \cdots \wedge \overline{x_n} \wedge \overline{x_{n+1}}]$.

Obviously, an assignment $\mathbf{v}$, such that $\mathbf{v}[x_1] = \mathbf{v}[x_2] = \cdots = \mathbf{v}[x_n] = \mathbf{v}[x_{n+1}] = 0$, satisfies f_1. Hence f_1 is always satisfiable. Also, the number of satisfying assignments of f_1 is one more than the number of satisfying assignments of f. Therefore, knowing the number of satisfying assignments of f_1 tells us the number of satisfying assignments of f.

Step 2. Convert $f_1(x_1, x_2, \ldots, x_n, x_{n+1})$ into an equivalent 3CNF formula $f_2(x_1, x_2, \ldots, x_n, x_{n+1}, x_{n+2}, \ldots, x_{n+p})$, where $x_{n+2}, \ldots, x_{n+p}$ are new variables. This is done in the standard way as follows. Obtain a parse tree of f_1. For each non-leaf node in the parse tree introduce new variables $y_1, y_2, \ldots, y_m$, where y_m is the variable corresponding to the root of the parse tree. Each node of the parse tree corresponds to an operator applied to one or two inputs. Let the children of a non-leaf node i be j and k.

Case 1. If the operator at node i is an AND operator, construct a new 3CNF formula equivalent to the formula $y_i \equiv (y_j \wedge y_k)$.

Case 2. If the operator is an OR operator, construct a 3CNF formula equivalent to the formula $y_i \equiv (y_j + y_k)$.

Case 3. If the operator is a NOT operator, construct a 3CNF formula equivalent to the formula $y_i \equiv \overline{y_j}$.

The final 3CNF formula f_2 is a conjunction of all the 3CNF formulas along with y_m. Now it is easy to see that f_2 is satisfiable if and only if f_1 is satisfiable and the reduction is parsimonious. (The new variables are functionally dependent on the old.)

Step 3. Next, lay out f_2 on a plane and replace each crossover in the layout by the crossover box described in Theorem 3.2. Let f_3 be the resulting planar 3CNF formula. By Theorem 3.2, the reduction from f_2 to f_3 is parsimonious. Thus the number of satisfying assignments of f_3 is one more than the number of satisfying assignments of f. The theorem now follows. □

Next we extend this result to prove that counting the number of satisfying assignments of a 1-*valid* planar 3CNF formula is #P-hard.

THEOREM 3.5. *The problem* #1-VALID PL-3SAT *is* #P*-complete.*

Proof. Given an arbitrary PL-3CNF formula $f(x_1, x_2, \ldots, x_n)$ and a satisfying assignment $\mathbf{v}$ such that $\mathbf{v}[\mathrm{f}] = 1$, we construct a new formula $f_1(x_1, x_2, \ldots, x_n, y_1, \ldots, y_p)$, where $y_1, \ldots, y_p$ are new variables. The formula f_1 is constructed as follows. Let $x_{l_1}, x_{l_2}, \ldots, x_{l_p}$ be the variables in f such that $\mathbf{v}[x_{l_1}] = \mathbf{v}[x_{l_2}] = \cdots = \mathbf{v}[x_{l_p}] = 0$. Then replace $\overline{x_{l_i}}$ by y_i and x_{l_i} by $\overline{y_i}$, $1 \leq i \leq p$. Obviously, the formula f_1 is 1-valid and the reduction is parsimonious. □

Karp and Luby [14] presented randomized fully polynomial time approximation schemes for several #P-complete problems, including #DNF. Since then, substantial research has been done in the area of approximation algorithms for various counting problems. Saluja, Subramanium, and Thakur [22] give a logical characterization of the counting problems that have a polynomial time random approximation scheme. Our #P-hardness of #PL-3SAT and other problems immediately raise the question of approximating the optimal values of these counting problems. The parsimonious reduction from 3SAT to PL-3SAT implies that, given a deterministic polynomial time algorithm A to approximately count the number of satisfying assignments of a planar 3CNF formula, we can construct a deterministic polynomial time algorithm A' with the same performance guarantee to approximately count the number of satisfying assignments of an arbitrary 3CNF formula.

Intuitively Theorem 3.2 and the above observation mean that counting the number of satisfying assignments of a planar 3CNF formula is *as hard as* counting the number of satisfying assignments of an arbitrary 3CNF formula with respect to polynomial time reducibility. We remark that the result holds even for 1-VALID PL-3CNF formulas.

Next, we prove the #P-hardness of other basic satisfiability problems. First we prove two lemmas.

LEMMA 3.6. *Let F be the planar monotone formula $(c + d + e) \wedge (c + e + f) \wedge (d + e + f)$. Then there is a unique satisfying assignment $\mathbf{v}$ to the variables of F such that each clause has exactly one true literal, namely, $\mathbf{v}[c] = \mathbf{v}[d] = \mathbf{v}[f] = 0$; and $\mathbf{v}[e] = 1$.*

Proof. The proof is by inspection. □

LEMMA 3.7. *The following* EX3CNF *formula is planar and has exactly one satisfying assignment, namely, the assignment $\mathbf{v}$ defined by $\mathbf{v}[x_i] = 0 (1 \leq i \leq 9)$:*

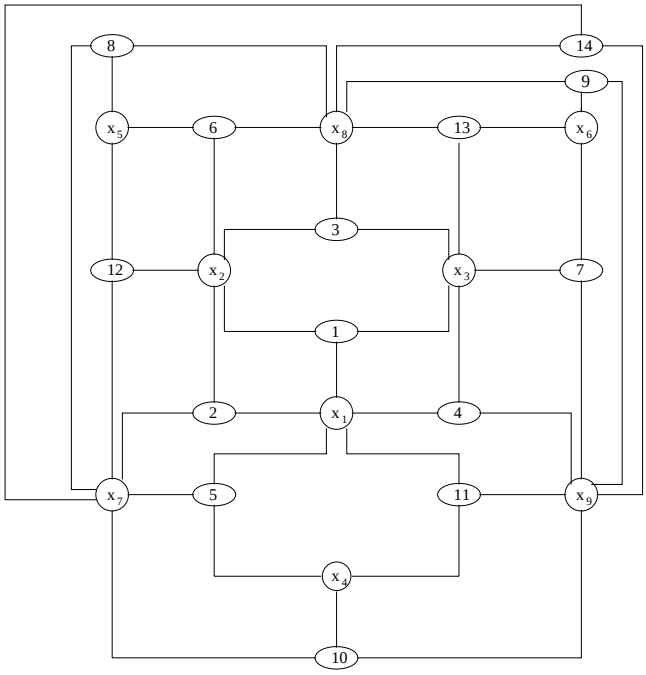

FIG. 3.3. PL-EX3SAT *formula as described in Lemma* 3.7. *Ellipses denote the clauses in* G. *The clauses are numbered in the order in which they appear in Lemma* 3.7.

$G(x_1, \ldots, x_9) = (\overline{x}_1 + \overline{x}_2 + \overline{x}_3) \wedge (\overline{x}_1 + x_2 + x_7) \wedge (\overline{x}_2 + x_3 + x_8) \wedge (\overline{x}_3 + x_1 + x_9) \wedge (\overline{x}_4 + x_1 + x_7) \wedge (\overline{x}_5 + x_2 + x_8) \wedge (\overline{x}_6 + x_3 + x_9) \wedge (\overline{x}_7 + x_5 + x_8) \wedge (\overline{x}_8 + x_6 + x_9) \wedge (\overline{x}_9 + x_4 + x_7) \wedge (\overline{x}_1 + \overline{x}_4 + \overline{x}_9) \wedge (\overline{x}_2 + \overline{x}_5 + \overline{x}_7) \wedge (\overline{x}_3 + \overline{x}_6 + \overline{x}_8) \wedge (\overline{x}_7 + \overline{x}_8 + \overline{x}_9)$.

Proof. Planarity is demonstrated by Figure 3.3. The given assignment $\mathbf{v}$ satisfies G since each clause of G contains a negated literal.

Suppose G is true. Let $\mathbf{u}$ be any truth assignment to the variables in G. Then, $x_7 \rightarrow x_8$ by clauses 6, 8, and 12; $x_8 \rightarrow x_9$ by clauses 7, 9, and 13; $x_9 \rightarrow x_7$ by clauses 5, 10, and 11. Therefore, $(x_7 + x_8 + x_9) \rightarrow (x_7 \wedge x_8 \wedge x_9)$. Hence by clause 14, $\mathbf{u}[x_7] = \mathbf{u}[x_8] = \mathbf{u}[x_9] = 0$. Given this, $x_1 \rightarrow x_2$ by clause 2; $x_2 \rightarrow x_3$ by clause 3; and $x_3 \rightarrow x_1$ by clause 4. Therefore, $(x_1 + x_2 + x_3) \rightarrow (x_1 \wedge x_2 \wedge x_3)$. Hence by clause 1, $\mathbf{u}[x_1] = \mathbf{u}[x_2] = \mathbf{u}[x_3] = 0$. But this implies that $\mathbf{u}[x_4] = \mathbf{u}[x_5] = \mathbf{u}[x_6] = 0$ by clauses 5, 6, and 7. Hence in any satisfying assignment $\mathbf{u}$ of G, $\mathbf{u}[x_i] = 0$ $(1 \leq i \leq 9)$. □

Next we give planarity-preserving parsimonious reductions from 3SAT to the basic SAT problems listed in Table 1.1. Without loss of generality, we assume that the given instance of the CNF formula does not have any single literal clause.

THEOREM 3.8. *There exist planarity-preserving parsimonious reductions from* 3SAT *to each of the following problems:* EX3SAT, 1-3SAT, 1-EX3SAT, 1-EX3MONOSAT *and* X3C.

Proof. 3SAT $\rightarrow$ EX3SAT: Let f be a 3CNF formula with clauses $c_j (1 \leq j \leq k)$. For $1 \leq j \leq k$, let c'_j be c_j, if c_j is a three-literal clause. If $c_j = (l_{j1} + l_{j2})$, let c'_j be $(l_{j1} + l_{j2} + x_9^j) \wedge G(x_1^j, \ldots, x_9^j)$.

G is defined as in Lemma 3.7 and x_i^j $(1 \leq i \leq 9)$ are distinct new variables. Let

$$g = \bigwedge_{j=1}^{k} c'_j.$$

Then by Lemma 3.7, Figure 3.3, and direct inspection of the definitions of the formulas c'_j, the reduction mapping f into g is seen to be a planarity-preserving and parsimonious reduction of the problem 3SAT to the problem EX3SAT.

3SAT $\rightarrow$ 1-EX3SAT[2]: Let f be a 3CNF formula with clauses $c_j (1 \leq j \leq m)$.

(1) For each three-literal clause $c_j = (z_p + z_q + z_r)$ of f, let $c'_j = (z_p + u^j + v^j) \wedge (\overline{z_q} + u^j + w^j) \wedge (v^j + w^j + t^j) \wedge (\overline{z_r} + v^j + x^j)$, where u^j, v^j, w^j, t^j, and x^j are distinct new variables local to c'_j.

(2) For each two-literal clause $c_j = (z_p + z_q)$ of f, let $c'_j = (z_p + u^j + v^j) \wedge (\overline{z_q} + u^j + w^j) \wedge (v^j + w^j + t^j) \wedge (\overline{a^j} + v^j + x^j) \wedge (a^j + d^j + e^j) \wedge (a^j + e^j + f^j) \wedge (d^j + e^j + f^j)$, where u^j, v^j, w^j, t^j, x^j, a^j, d^j, and e^j are all new variables local to c'_k. Let

$$f' = \bigwedge_{j=1}^{m} c'_j.$$

To see the planarity of this reduction, see Figure 3.4. We claim that f' is exactly-one satisfiable *if and only if* the original formula f is satisfiable. Moreover, the reduction is planarity-preserving and parsimonious. To prove that the reduction is parsimonious, it suffices to show the following two claims.

CLAIM 3.9. *No assignment of truth values to the variables of clause c_j $(1 \leq j \leq m)$ of f which does not satisfy c_j can be extended to an assignment of truth values to the variables of the formula c'_j that exactly-one satisfies c'_j.*

Proof. Let $c_j = (z_p + z_q + z_r)$ and $\mathbf{u}$ be an assignment to the variables such that $\mathbf{u}[z_p] = \mathbf{u}[z_q] = \mathbf{u}[z_r] = 0$. Let $\mathbf{v}$ be an exactly-one satisfying assignment to the variables of c'_j such that $\mathbf{v}[z_p] = \mathbf{v}[z_q] = \mathbf{v}[z_r] = 0$ (i.e., $\mathbf{v}$ is an extension of $\mathbf{u}$). Then, the clauses $(\overline{z_q} + u^j + w^j)$ and $(\overline{z_r} + v^j + x^j)$ imply that $\mathbf{v}[u^j] = \mathbf{v}[w^j] = \mathbf{v}[v^j] = \mathbf{v}[x^j] = 0$. It follows that $\mathbf{v}$ does not exactly-one satisfy the clause $(z_p + u^j + w^j)$ of c'_j.

Let $c_j = (z_p + z_q)$ and $\mathbf{u}$ be an assignment to the variables such that $\mathbf{u}[z_p] = \mathbf{u}[z_q] = 0$. Let $\mathbf{v}$ be an exactly-one satisfying assignment to the variables of c'_j such that $\mathbf{v}[z_p] = \mathbf{v}[z_q] = 0$. Then, the clauses $(z_p + u^j + v^j)$ and $(\overline{z_q} + u^j + w^j)$ imply that $\mathbf{v}[u^j] = \mathbf{v}[w^j] = 0$ and $\mathbf{v}\ [v^j] = 1$. But given this, the clause $(\overline{a^j} + v^j + x^j)$ implies that $\mathbf{v}[a^j] = 1$. Lemma 3.6 now implies that $\mathbf{v}$ does not exactly-one satisfy c'_j. □

CLAIM 3.10. *For each satisfying assignment to the variables of the clause c_j $(1 \leq j \leq m)$ of f, there is exactly one way the assignment can be extended to the variables of the formula c'_j so as to exactly-one satisfy c'_j.*

Proof. When $c_j = (z_p + z_q + z_r)$, we need to verify that the only exactly-one satisfying assignments c'_j are the following:

1. $z_p = 1,\ z_q = 0,\ z_r = 0,\ u^j = 0, v^j = 0,\ w^j = 0,\ t^j = 1,\ x^j = 0;$
2. $z_p = 0,\ z_q = 1,\ z_r = 0,\ u^j = 1,\ v^j = 0,\ w^j = 0,\ t^j = 1,\ x^j = 0;$
3. $z_p = 0,\ z_q = 0,\ z_r = 1,\ u^j = 0,\ v^j = 1,\ w^j = 0,\ t^j = 0,\ x^j = 0;$

[2] Although they claim to have a parsimonious reduction, the reduction actually given in [3] is *not* parsimonious.

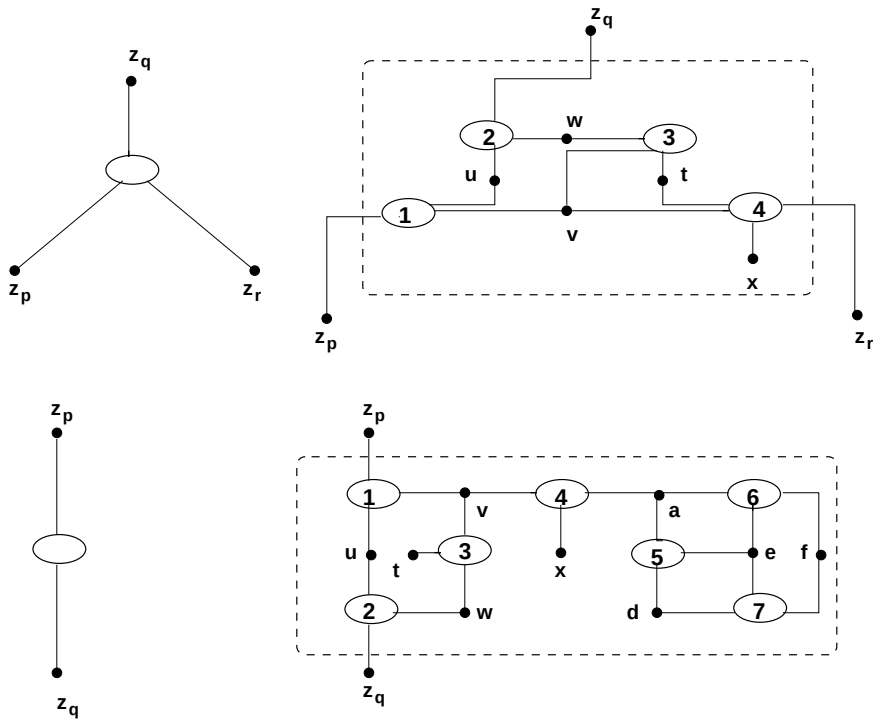

FIG. 3.4. *Figure illustrating the reduction from* 3SAT *to* 1-EX3SAT. (a) *shows how to transform a three-literal clause.* (b) *shows how to transform a two-literal clause. The clauses are numbered in the order in which they appear in the reduction outlined in the proof of Theorem* 3.8. *Note that the reduction is a local replacement–type reduction and hence preserves planarity.*

4. $z_p = 1$, $z_q = 1$, $z_r = 0$, $u^j = 0$, $v^j = 0$, $w^j = 1$, $t^j = 0$, $x^j = 0$;
5. $z_p = 1$, $z_q = 0$, $z_r = 1$, $u^j = 0$, $v^j = 0$, $w^j = 0$, $t^j = 1$, $x^j = 1$;
6. $z_p = 0$, $z_q = 1$, $z_r = 1$, $u^j = 1$, $v^j = 0$, $w^j = 0$, $t^j = 1$, $x^j = 1$;

and

7. $z_p = 1$, $z_q = 1$, $z_r = 1$, $u^j = 0$, $v^j = 0$, $w^j = 1$, $t^j = 0$, $x^j = 1$.

When $c_j = (z_p + z_q)$, we need to verify that the only exactly-one assignments of c'_j are the following:

1. $z_p = 1$, $z_q = 0$, $u^j = 0$, $v^j = 0$, $w^j = 0$, $t^j = 1$, $x^j = 0$, $c^j = 0$, $d^j = 0$, $e^j = 1$, $f^j = 0$;
2. $z_p = 0$, $z_q = 1$, $u^j = 1$, $v^j = 0$, $w^j = 0$, $t^j = 1$, $x^j = 0$, $c^j = 0$, $d^j = 0$, $e^j = 1$, $f^j = 0$; and
3. $z_p = 1$, $z_q = 1$, $u^j = 0$, $v^j = 0$, $w^j = 1$, $t^j = 0$, $x^j = 0$, $c^j = 0$, $d^j = 0$, $e^j = 1$, $f^j = 0$. □

1-EX3SAT → 1-EX3MONOSAT: Let f be an instance of 1-EX3SAT. Let

$$f = \bigwedge_{j=1}^{m} c_j.$$

For each c_j, construct c'_j as follows. Replace each negated literal of the form $\overline{z_p}$ appearing in the clause c_j by a distinct new variable y_p^j in c_j, then add the clauses $(z_p + y_p^j + a_p^j) \wedge (a_p^j + d_p^j + e_p^j) \wedge (a_p^j + f_p^j + e_p^j) \wedge (d_p^j + f_p^j + e_p^j)$. Note that for each negated

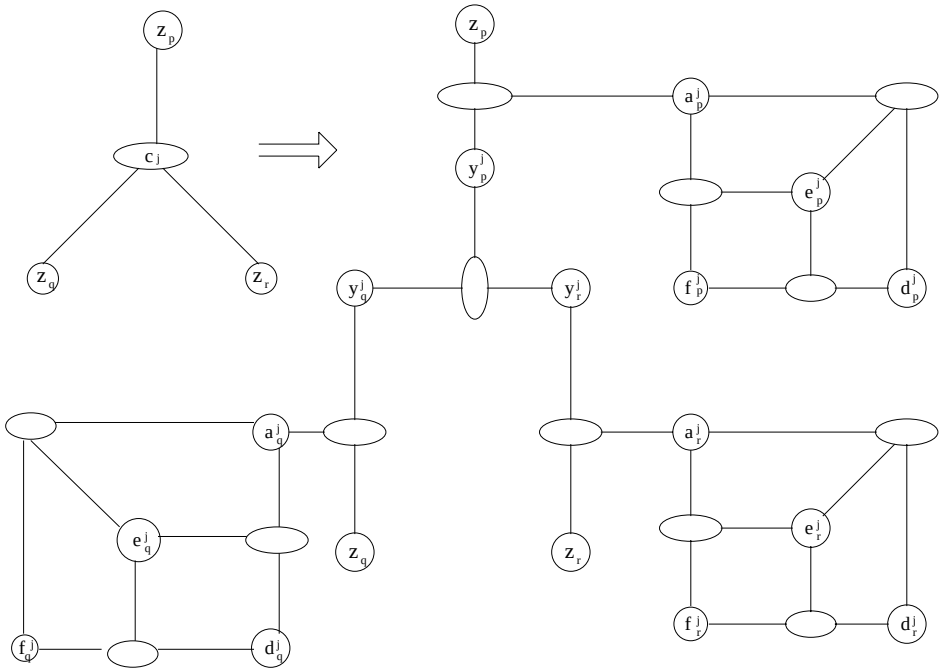

FIG. 3.5. *Figure illustrating the reduction from* 1-EX3SAT *to* 1-EX3MONOSAT. *The figure illustrates the construction for a three-literal clause c_j which contains all negated literals.*

literal, we introduce new copies of the auxiliary variables $a_p^j, \ldots, f_p^j$. See Figure 3.5 for an example.

Let

$$f' = \bigwedge_{j=1}^{m} c'_j.$$

Then f' is an instance of 1-EX3MONOSAT obtained from f. The result follows from Lemma 3.6 and the fact that for all variables x and y, $(x+y)$ is exactly-one satisfiable *if and only if* $x = \overline{y}$.

1-EX3MONOSAT $\rightarrow$ X3C: Although Dyer and Frieze [3] do not observe this, the reduction given in their paper [3] from 1-EX3SAT to X3C is actually parsimonious. The reduction presented here is essentially the same as that given in [3], except that we start from an instance of 1-EX3MONOSAT. Thus in our reduction, we do not have to take care of negated literals. We now describe the reduction. Each variable is represented by a cycle of 3 element sets. If the variable occurs r times in the 1-EX3SAT instance, then there are $2r$ sets, with each successive pair of sets sharing an element. This cycle is augmented with r additional sets and $2r$ elements by adding a 3-set to one of the external elements in each pair. The 3 elements now corresponding to an appearance of v_j will be called a connector. The variable v_j is set to true if and only if all three connector elements are covered by the cycle when v_j appears in the corresponding clause. Figure 3.6 illustrates the variable component. Next, consider each clause c_i. Each c_i is represented by a configuration shown in Figure 3.7. This has 12 elements and 9 sets. Of the 12 elements, 3 are internal and the rest are grouped in groups of 3. Each group of 3 elements is called a terminal of c_i. Finally, we connect a

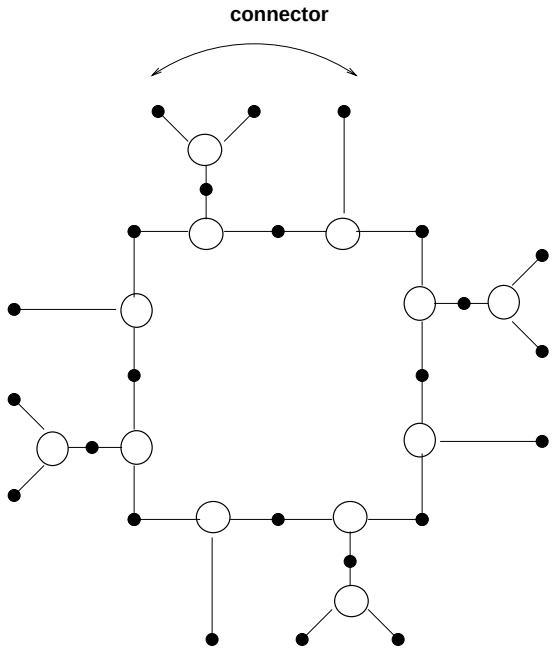

FIG. 3.6. *Variable configuration for reduction to* X3C. *The black dots represent element nodes, while the ellipses denote the triples.*

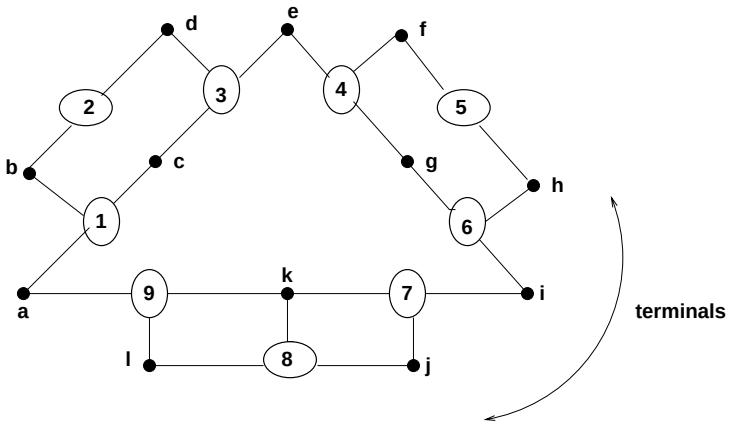

FIG. 3.7. *Figure illustrating the clause configuration. The sets* $\{l, a, b\}, \{d, c, f\}, \{j, i, h\}$ *represent the three terminals. The vertices labeled* c, g, k *are the internal elements.*

clause component to the variable component as follows. For each $v_j \in c_i$ we identify three distinct connector elements with one of the terminals in c_i. The construction is depicted in Figure 3.8. Let G denote the graph obtained as a result of the construction. Planarity of G follows by the fact that each component replacing a variable and a clause is planar and the components are joined in a planarity-preserving way. We first prove that there is an exact cover of c_i configuration if and only if exactly one terminal is covered externally, when we restrict the covering such that either none or all 3 of the elements in each terminal are covered externally. But the configuration has the

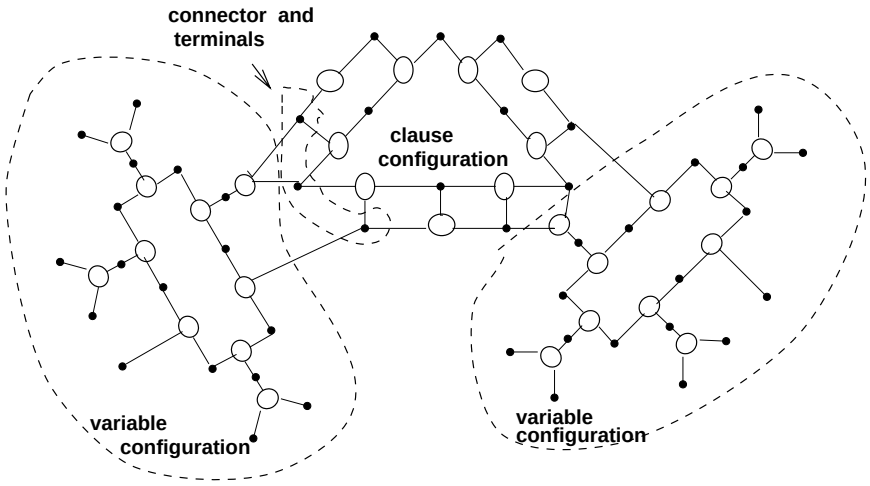

FIG. 3.8. *Figure illustrating the way the clause and variable configurations are attached.*

property that each of the 3 internal elements appear in 3 of the 9 sets and no 2 appear in the same set. It follows that if this configuration forms part of an exact cover by 3-sets, then exactly 3 of the sets must be used, hence 9 of the 12 elements will be covered internally. Moreover, this can only be done so that exactly 1 of the terminals will be left uncovered. This uncovered terminal is covered by sets in the variable configuration and amounts to setting the literal true. It can then be argued that the exact cover by 3-sets has a solution if and only if the corresponding 1-EX3MONOSAT instance is satisfiable. It is easily verified that the reduction is parsimonious. This is because the clause configuration forces precisely 1 literal to be set to true and the other 2 literals to be false. Moreover, for each satisfying assignment of 1-EX3MONOSAT, there is exactly 1 way the sets can be chosen so as to have an exact cover. Hence, the reduction is parsimonious. □

COROLLARY 3.11. *The problems* PL-EX3SAT, PL-1-EX3SAT, *and* PL-1-EX3MONOSAT *are* NP*-complete. The problems* #PL-EX3SAT, #PL-1-3SAT, #PL-1-EX3SAT, #PL-1-EX3MONOSAT, *and* #PL-X3C *are* #P*-complete.*

4. Planar graph problems.

4.1. Overview of our proofs. In this section we give parsimonious/weakly parsimonious and planarity-preserving reductions from PL-1-EX3MONOSAT to various graph problems. The problems considered here are MINIMUM VERTEX COVER, MINIMUM DOMINATING SET, CLIQUE COVER, FEEDBACK VERTEX SET, PARTITION INTO CLAWS, PARTITION IN TRIANGLES, and BIPARTITE DOMINATING SET. Previously, reductions showing that these problems were NP-hard frequently did not preserve the number of solutions. Central to the proofs is the reduction (called $RED1$) from 1-EX3MONOSAT to 3SAT with the property that every formula is mapped to a formula in which all satisfying assignments satisfy exactly one literal in each three-literal clause. This in turn enables us to obtain (weakly) parsimonious reductions from EX1-3MONOSAT to the problems considered here.

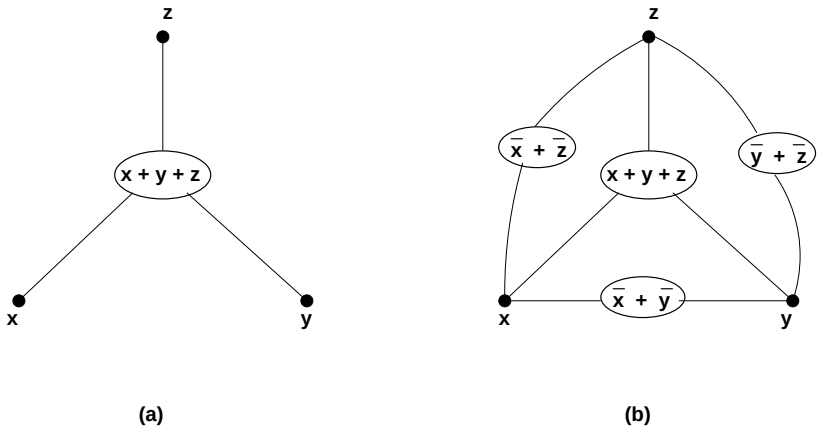

FIG. 4.1. *Figure illustrating the reduction RED*1 *discussed in section* 4.2. *Observe that the reduction is planarity-preserving.*

4.2. Reduction RED1. Let *RED*1 be a mapping from an instance

$$f = \bigwedge_{j=1}^{m} c_j$$

of 1-EX3MONOSAT to an instance

$$f' = \bigwedge_{j=1}^{m} c'_j$$

of 3SAT, where for $c_j = (x + y + z)$, $c'_j = (x + y + z) \wedge (\overline{x} + \overline{y}) \wedge (\overline{x} + \overline{z}) \wedge (\overline{z} + \overline{y})$.

LEMMA 4.1. *The formula* f' *has the following properties.*

(1) *The satisfying assignments of* f' *are* exactly *the exactly-one satisfying assignments of* f.

(2) *In any satisfying assignment of* f', *all but one clause in* c'_j *is exactly-one satisfiable.*

(3) *Each variable in the formula* f' *occurs at least twice negated and at least once unnegated.*

(4) *RED*1 *is planarity-preserving. (See Figure* 4.1.*)*

(5) *RED*1 *is parsimonious.*

Proof. The proof is by inspection. □

We call each of the c'_j a *clause group.* Observe that each c'_j has four clauses; one is a three-literal clause and the others are two-literal clauses.

4.3. Weakly parsimonious reductions and basic graph problems.

THEOREM 4.2. *There exists a planarity-preserving and weakly parsimonious reduction from* 1-EX3MONOSAT *to each of the following problems:* (1) MINIMUM VERTEX COVER, (2) MINIMUM DOMINATING SET, (3) MINIMUM FEEDBACK VERTEX SET, *and* (4) SUBGRAPH ISOMORPHISM.

Proof. (1) MINIMUM VERTEX COVER: The reduction is from 1-EX3MONOSAT and is similar to the one given in [5] for proving NP-hardness of MINIMUM VERTEX COVER. Let f be a 1-EX3MONOSAT formula. Apply *RED*1 to f to obtain f'. Next,

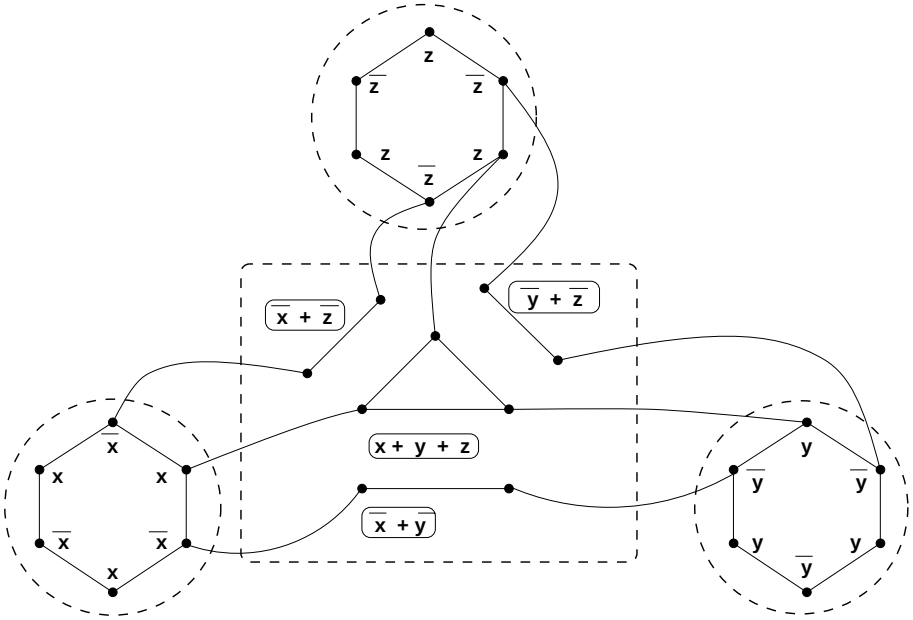

FIG. 4.2. *Figure illustrating the reduction from* 1-EX3MONOSAT *to* VERTEX COVER *and the transformation of a clause group* $(x + y + z) \wedge (\overline{x} + \overline{y}) \wedge (\overline{x} + \overline{z}) \wedge (\overline{z} + \overline{y})$. *The dotted enclosures depict how to locally transform the clauses as well as the variables so as to preserve planarity of the resulting graph.*

starting from f', construct an instance $G(V, E)$ of the vertex cover problem as shown in Figure 4.2 as follows.

1. Consider a clause group $c'_j = (x + y + z) \wedge (\overline{x} + \overline{y}) \wedge (\overline{x} + \overline{z}) \wedge (\overline{z} + \overline{y})$. Corresponding to the clause $(x + y + z)$, construct a triangle with vertices $\{x, y, z\}$ and edges $\{(x, y), (x, z), (y, z)\}$. Corresponding to a clause of the form $(\overline{x} + \overline{y})$ add the edge $\{(x, y)\}$. Call this the clause graph.

2. For each variable x that appears i times we construct a simple cycle with $2i$ vertices. Let the odd-numbered variables represent the negated occurrences and the even-numbered variables represent the unnegated occurrences. Call this the variable graph.

3. Join the vertices of the clause graph to the vertices of the variable graph as follows. Consider a clause group c'_j. Corresponding to a clause, join the triangle vertices x, y, and z to the corresponding unnegated occurrences of x, y, and z in the cycles. Corresponding to a clause of the form $(\overline{x} + \overline{y})$, join the two vertices x, y to the negated occurrence of the variables x and y, respectively. Repeat the procedure for each clause group.

Now set $K = 1/2 \sum C_i + 2m + 3m$, where C_i is the length of the cycle of the variable i and m is the number of clause groups in f'. The reduction is illustrated in Figure 4.2.

CLAIM 4.3. (1) *The formula f' is satisfiable if and only if the graph G has a vertex cover of size K.*

(2) *The reduction is planarity-preserving and weakly parsimonious.*

Proof. Part 1. Observe that for any vertex cover, one needs to pick at least half of the nodes from each cycle, two of the three nodes from each triangle, and one from the

simple edge for each two-literal clause. (Recall that there are $3m$ two-literal clauses in f'.) The sum is exactly K. Given this observation, the proof is similar to the one given in [5].

Part 2. It can be easily verified by observing in Figure 4.2 that the reduction is planarity-preserving. To see that for each distinct satisfying assignment of f', there are 2^m distinct vertex covers of size K, note that, by Lemma 4.1, for each satisfying assignment, all but one clause in each clause group has only one true literal. This forces the choice of vertices from the clause graph for all clauses having only one true literal. For each satisfying assignment and for each clause group there is one clause in the clause group in which both the literals are true. For each such clause any of the two vertices can be included in the vertex cover. Since there are m clause groups, we have m such clauses and hence we have 2^m different vertex covers for each satisfying assignment. □

Note that our reduction shows that counting the number of vertex covers of size $\leq k$ is #P-hard even if there are *no* vertex covers of size strictly less than k. For the next two results, we use such an instance of #-vertex cover for our reductions.

(2) Minimum Dominating Set: The reduction is from the Minimum Vertex Cover problem. The reduction in [13] from Vertex Cover to Dominating Set can easily be modified to get a parsimonious reduction. Let $G_1 = (V_1, E_1)$, $V_1 = \{v_1, \ldots, v_n\}$ be an instance of the Minimum Vertex Cover problem. We construct an instance $G_2 = (V_2, E_2)$ of the Minimum Dominating Set problem as follows. There is one vertex in V_2 corresponding to every vertex in V_1. For each edge in G_1 we also introduce two additional vertices and join them to the two endpoints of the original edge. Formally, $V_2 = U_1 \cup U_2$ and $E_2 = A_1 \cup A_2$, where

$$U_1 = \{u_i \mid v_i \in V_1\},$$

$$U_2 = \{x_1^{ij}, x_2^{ij} \mid (v_i, v_j) \in E_1\},$$

$$A_1 = \{(u_i, u_j) \mid (v_i, v_j) \in E_1\},$$

$$A_2 = \{(u_i, x_1^{ij}), (x_1^{ij}, u_j), (u_i, x_2^{ij}), (x_2^{ij}, u_j) \mid (v_i, v_j) \in E_1\}.$$

Claim 4.4. *G_1 has a minimum vertex cover of size k if and only if G_2 has a minimum dominating set of size k. Furthermore, the reduction is planarity-preserving and parsimonious.*

Proof. It is easy to see that the reduction is planarity-preserving. Consider a minimum vertex cover $VC = \{v_{i_1}, v_{i_2}, \ldots, v_{i_k}\}$ of G_1. Corresponding to VC we claim that there is exactly one dominating set in the graph G_2, namely, the vertex set $DS = \{u_{i_1}, u_{i_2}, \ldots, u_{i_k}\}$. First note that for each edge in the original graph G we have four new edges and two new vertices in G_2. Consider a pair of nodes of the form x_1^{ij}, x_2^{ij} connected to the nodes u_i and u_j. It is clear that the only way to dominate both x_1^{ij}, x_2^{ij} by using only one node is to include one of u_i or u_j in the dominating set. We need to consider two cases. First consider the case when exactly one of v_i or v_j is in VC. Then it is clear that there is exactly one dominating set DS in G_2 corresponding to VC. When both v_i and v_j are in VC, the minimality of VC implies that at least one edge incident on v_i and at least one edge incident on v_j are covered solely by v_i and v_j, respectively. This implies that both u_i and u_j have to be in

any feasible dominating set of G_2. Thus we have exactly one dominating set DS in G_2 corresponding to the vertex cover VC in G_1. Conversely, consider a minimum dominating set $DS = \{u_{i_1}, u_{i_2}, \ldots, u_{i_k}\}$ of size k in G_2. Consider an edge (v_i, v_j) in G. If u_i and u_j are not in DS, then by construction of G_2, both x_1^{ij} and x_2^{ij} are in DS. But we could then construct a new dominating set DS' of G_2, where

$$DS' = DS - \{x_1^{ij}, x_2^{ij}\} \cup \{u_i\}.$$

Clearly $|DS'| < |DS|$, which is a contradiction to the assumption that DS is a minimum dominating set. Thus, DS does not contain any vertex from the set U_2. We now claim that $VC = \{v_{i_1}, v_{i_2}, \ldots, v_{i_k}\}$ is a vertex cover of G. The claim follows by observing that corresponding to each edge $(v_i, v_j) \in E_1$, at least one of the vertices $u_i, u_j, x_1^{ij}, x_2^{ij}$ are in the set DS. We have already argued that $x_1^{ij}, x_2^{ij} \notin DS$. Thus one of u_i, u_j is in DS. The corresponding vertex in VC is seen to cover the edge (v_i, v_j). □

(3) Feedback Vertex Set: The reduction is from the Minimum Vertex Cover problem. Starting from an instance $G_1(V_1, E_1)$ of the Minimum Vertex Cover problem, we construct the graph G_2 that is identical to the one given for the Minimum Dominating Set problem. By arguments similar to those given in the proof of the Minimum Dominating Set problem, it is easy to see that the G_1 has a minimum vertex set of size K if and only if G_2 has a feedback vertex set of size K and the reduction is parsimonious.

(4) Subgraph Isomorphism: This follows directly by taking the graph H to be a simple cycle on n nodes, and the weakly parsimonious reduction from 3Sat to the Hamiltonian Circuit problem given in Provan [20]. □

Corollary 4.5. *The problems* #Pl-Minimum Vertex Cover, #Pl-Minimum Dominating Set, #Pl-Minimum Feedback Vertex Set, *and* #Pl-Subgraph Isomorphism *are* #P*-complete.*

4.4. Parsimonious reductions and other graph problems. In this section we briefly discuss why the reductions studied by [6, 15] and [3, 4] from X3C to various other graph problems are parsimonious and planarity-preserving.

Theorem 4.6. *There exist planarity-preserving and parsimonious reductions from* X3C *to each of the problems* (1) Minimum Clique Cover, (2) Partition into Claws, (3) Bipartite Dominating Set, (4) Partition into Triangles, *and* (5) Minimum Hitting Set.

Proof. (1) Minimum Clique Cover: The reduction is the same as given in [3, 5]. Given an instance $I(X, C)$ of X3C such that $|X| = 3p$ and $|C| = m$, we construct an instance G of the Minimum Clique Cover problem such that G has a clique cover with cliques of size 3 if and only if I has a solution. The reduction consists of replacing each triple in the instance of I by a triangle and by replacing an edge from a triple to an element by a set of triangles. The reduction is illustrated in Figure 4.3. Formally, for each element, we have a vertex in G. Corresponding to each triple $t_i = \{x_i, y_i, z_i\}$ and the associated edges $(t_i, x_i), (t_i, y_i), (t_i, z_i)$, we create the subgraph as shown in Figure 4.3. The graph G obtained by carrying out the above reduction for each triple has $3p+9m$ vertices and $18m$ edges. The reduction is planarity-preserving, as each component is planar and they are joined in a planarity-preserving way. We claim that I has a solution if and only if G has a clique cover of size $(p + 3m)$. In particular, as shown in [3, 5], if $t_1, \ldots, t_p$ is the set of triples in an exact cover, then

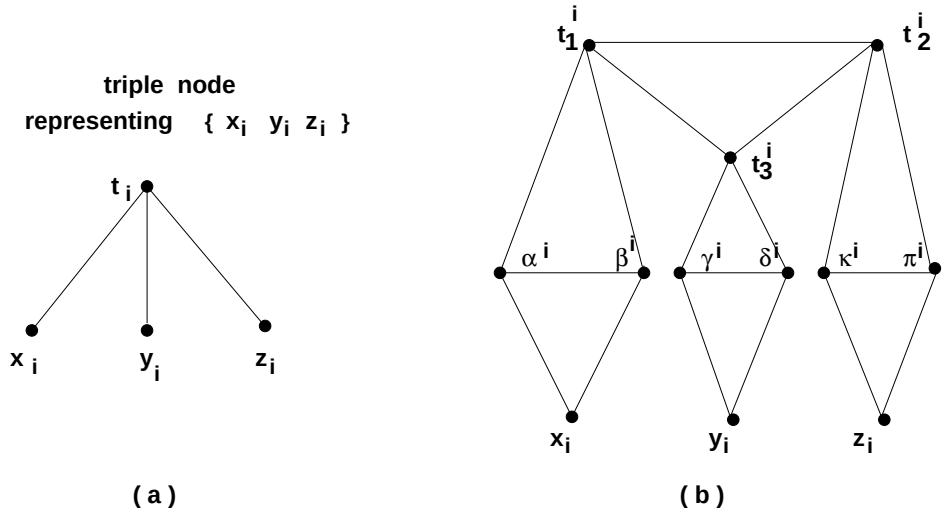

FIG. 4.3. *Figure illustrating the reduction from* X3C *to* CLIQUE COVER.

the corresponding clique cover is constructed by taking

$$\{\alpha^i, \beta^i, x_i\}, \{\gamma^i, \delta^i, y_i\}, \{\kappa^i, \pi^i, z_i\}, \{t_1^i, t_2^i, t_3^i\}$$

whenever $t_i = \{x_i, y_i, z_i\}$ is in the exact cover and by taking the cliques

$$\{\alpha^i, \beta^i, t_1^i\}, \{\gamma^i, \delta^i, t_2^i\}, \{\kappa^i, \pi^i, t_3^i\}$$

when the corresponding triple t_i is not in the exact cover. Conversely, since G has $3p + 9m$ vertices, if G has a clique cover of size $p + 3m$ it implies that each clique consists of exactly three vertices. (Recall that we do not have cliques of size 4 in G.) The corresponding exact cover is given by choosing those $t_i \in C$ such that the triangles t_1^i, t_2^i, t_3^i are in the clique cover. Finally, we prove that the reduction is parsimonious. First note that if the triple triangle $\{t_1^i, t_2^i, t_3^i\}$ is not chosen then we have to choose the triangles $\{\alpha^i, \beta^i, t_1^i\}, \{\gamma^i, \delta^i, t_2^i\}, \{\kappa^i, \pi^i, t_3^i\}$ so as to cover the triple vertices. Second, once the triangle $\{t_1^i, t_2^i, t_3^i\}$ is chosen there is exactly one way for the auxiliary nodes (and thus the element nodes) to be covered, namely, the lower triangle corresponding to the covering triple, i.e., choosing the triangles

$$\{\alpha^i, \beta^i, x_i\}, \{\gamma^i, \delta^i, y_i\}, \{\kappa^i, \pi^i, z_i\}.$$

These observations immediately imply that the reduction is parsimonious.

(2) PARTITION INTO CLAWS: The reduction is from X3C and is the same as the one given in [3]. The reduction consists of the following steps.

1. Construct the bipartite graph $G(C \cup X, E)$ corresponding to the given instance $I(X, C)$ of X3C.

2. As in [3], we assume that each element vertex appears in either two or three sets; i.e., the element vertices have a degree 2 or 3.

3. For each element of degree 3, we add an extra edge and for each element of degree 2, we add two extra edges. This is shown in Figure 4.4. Let G_1 denote the resulting graph.

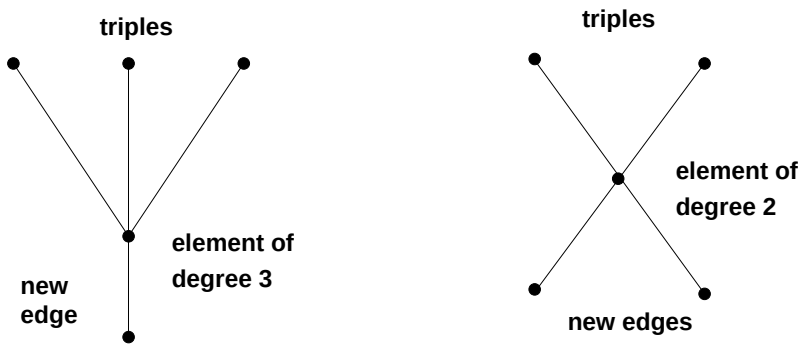

FIG. 4.4. *Figure illustrating the reduction from* X3C *to* PARTITION INTO CLAWS.

Clearly the reduction is planarity-preserving. We now recall the proof in [3] to show that the edges of G_1 can be partitioned into a disjoint set of claws. Note that each element vertex is adjacent to either 1 or 2 vertices of degree 1, so it follows that each element node must be the center of at least one claw. But each such element node has degree 4 and hence can be the center of exactly one claw. After removing the claws from G_1 the resulting graph G_2 has the property that all element nodes have degree 1. This implies that the only way to partition G_2 into claws is for each triple to have a degree of 0 or 3. Thus the triples with degree 3 induce a solution for the X3C in an obvious way. Conversely, given a solution for I, the above argument can be reversed to yield a partition of the edges in G_1 into claws. The following observations immediately imply that the reduction is parsimonious.

1. There is a unique way to pick the claws in G_1 with the element nodes as centers.

2. In G_2, each triple vertex has degree 3 or 0 and each element node has degree 1 in G_2.

(3) BIPARTITE DOMINATING SET: Reduction from X3C. The construction is similar to that in [3]. Let $I(X, C)$ be an instance of PL-X3C with each element occurring in at most three triples. We first construct the bipartite graph G associated with I. Next, we attach a 2-claw ($K_{1,2}$) to each triple vertex in G as shown in Figure 4.5. (In [3], they add a path of length 2.) Let G' denote the graph obtained as a result of the transformation. The construction is depicted in Figure 4.5. Since G is bipartite and we added a claw as shown in Figure 4.5, it follows that G' is also bipartite. Also note that the reduction is planarity-preserving and thus G' is planar. Let the number of triples be m and the number of elements be $3p$. Then we set $k = p + m$. Now by arguments similar to those in [3], it is easy to see that G' has a dominating set of size k if and only if I has an exact cover of size p. We prove the reduction is parsimonious. Consider a solution $S(I)$ for I. Since each triple in the solution covers three distinct element nodes, these element nodes cannot be used to dominate the vertices in G' without increasing the cardinality of the solution for G'. This means that for each of the p triples chosen in the solution $S(I)$, we have exactly one node in G' that can be used in the dominating set so as to dominate all the element nodes. Moreover, due to the constraints on the size of the dominating set in G', it follows that we can select exactly one vertex per claw (the vertex with degree 3 and marked a) in the dominating set. These observations imply that the reduction is parsimonious.

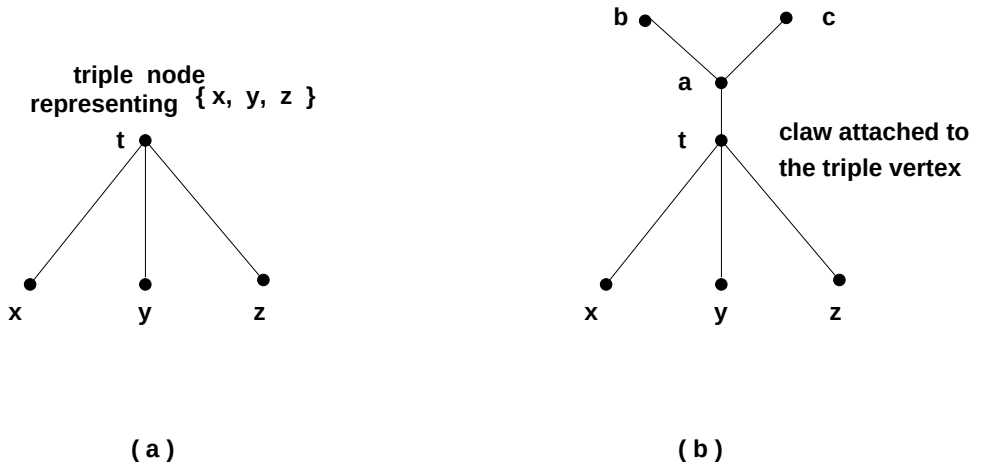

FIG. 4.5. *Figure illustrating the parsimonious reduction from* X3C *to* BIPARTITE DOMINATING SET. *It is easy to see that the reduction preserves planarity of the graph.*

(4) PARTITION INTO TRIANGLES: The reduction is from X3C and is the same as the reduction described in the proof of CLIQUE COVER. Given that the resulting graph has no cliques of size 4, the proof follows.

(5) MINIMUM HITTING SET: As given in [5], each instance of vertex cover can be seen to be an instance of a hitting set, in which every edge (u, v) corresponds to the set $\{u, v\}$. The elements of the set are simply the nodes of the graph. The result now follows by noting that there is a weakly parsimonious reduction from 3SAT to MINIMUM VERTEX COVER. □

COROLLARY 4.7. *The problems* #PL-MINIMUM CLIQUE COVER, #PL-PARTITION INTO CLAWS, #PL-BIPARTITE DOMINATING SET, #PL-PARTITION INTO TRIANGLES, *and* #PL-MINIMUM HITTING SET *are* #P*-complete.*

THEOREM 4.8. *Let* Π *be one of the problems in Table* 1.1. *It is* #P*-complete to count the number of solutions to* Π*, even when one is given an instance of* Π *and a solution which is guaranteed to satisfy* Π.

Proof. Starting from a 3CNF formula obtained in the proof of Theorem 3.4, we now do the same set of reductions discussed in the earlier theorems to obtain an instance of the problem Π. Since we know that the 3CNF formula is satisfiable, it follows that the instance of Π has a solution. □

5. Unique and ambiguous planar problems. Our parsimonious planar crossover box for 3SAT can also be used to show that additional problems for planar CNF formulas are *as hard as* the corresponding problems for arbitrary CNF formulas, with respect to polynomial time or random polynomial time reducibilities. We briefly describe these results. We first recall the definitions of D^P and random polynomial time reductions from [19, 27].

DEFINITION 5.1. $\mathsf{D}^P = \{L_1 - L_2 \mid L_1, L_2 \in \mathsf{NP}\}$. *Intuitively, a problem is in* D^P *if it can be solved by asking one question in* NP *and one question in* Co-NP.

DEFINITION 5.2. *Problem A is reducible to problem B by a randomized polynomial time reduction if there is a randomized polynomial time Turing machine T and a polynomial p such that*

(1) $\forall x,\ [x \notin A \rightarrow T[x] \notin B]$;

(2) $\forall x,\ [x \in A \rightarrow T[x] \in B$ *with probability at least* $1/p(|x|)]$. □

THEOREM 5.3. UNIQUE-PL-3SAT *is* D^P*-complete under randomized polynomial time reductions.*

Proof. We modify the proof of the D^P-completeness of UNIQUE SAT in [27], so that whenever their reduction outputs a boolean formula f, our reduction outputs the planar formula $\text{PL}(f)$ obtained by applying the parsimonious planar crossover box to f. The formula $\text{PL}(f)$ has exactly the same number of satisfying assignments as f. In particular, $\text{PL}(f)$ is uniquely satisfiable if and only if f is uniquely satisfiable. □

A second example is the following.

THEOREM 5.4. AMBIGUOUS-PL-3SAT *is* NP*-complete.*

Proof. Given an instance of an arbitrary 3CNF formula f, we first construct a new formula using the same construction as in Step 1 of Theorem 3.4. As pointed out in the proof of Theorem 3.4, the new formula is ambiguously satisfiable if and only if the original formula is satisfiable. We then do the same sequence of reductions as in Theorem 3.4 to obtain a planar formula that is ambiguously satisfied if and only if the original formula is satisfied. □

Using the ideas similar to those in the proof of Theorem 3.5, we can prove the following theorem.

THEOREM 5.5. AMBIGUOUS-1-VALID PL-3SAT *is* NP*-complete.*

COROLLARY 5.6. UNIQUE-1-VALID PL-3SAT *is* Co-NP*-complete.*

Proof. To prove the membership in Co-NP, consider an arbitrary formula $F(x_1, \ldots, x_n)$, which is an instance of 1-VALID PL-3SAT. By the definition of 1-VALID formulas, an assignment $\mathbf{v}$ to the variables such that $\mathbf{v}[x_1] = \mathbf{v}[x_2] = \cdots \mathbf{v}[x_n] = 1$ satisfies $F(x_1, \ldots, x_n)$. Now consider the formula $H(x_1, \ldots, x_n) = F(x_1, x_2, \ldots, x_n) \wedge (\overline{x_1} \vee \overline{x_2} \ldots \overline{x_n})$. F is uniquely satisfiable if and only if H is unsatisfiable. To prove Co-NP-hardness, given a formula $f(x_1, x_2, \ldots, x_n)$, we construct a formula g such that

$$g(x_1, \ldots, x_{n+1}) = [f(x_1, x_2, \ldots, x_n) \wedge x_{n+1}] \bigvee (\overline{x_1} \wedge \overline{x_2} \ldots \overline{x_{n+1}}).$$

Now using ideas similar to those in the proof of Theorem 3.5, we obtain a planar formula g_1 with the following properties:

(1) g_1 is 1-valid.

(2) g_1 is uniquely satisfiable *if and only if* f is unsatisfiable. □

Combining our parsimonious planar crossover box for 3SAT and the reductions to prove Theorem 3.8, we get that exact analogues of Theorems 5.3–5.5 hold for each of the problems EX3SAT, 1-3SAT, 1-EX3SAT, and 1-EX3MONOSAT. Thus, we have the following corollary.

COROLLARY 5.7. *Let* Π *be one of the following problems:* EX3SAT, 1-3SAT, 1-EX3SAT*, or* 1-EX3MONOSAT. *Then the problem* AMBIGUOUS-PL-Π *is* NP*-complete and the problem* UNIQUE-PL-Π *is* D^P*-complete under randomized polynomial time reductions.*

As a corollary of our parsimonious reductions, the unique versions of many graph problems are also D^P-complete.

COROLLARY 5.8. *Let* Π *be one of the problems* PL-PARTITION INTO TRIANGLES, PARTITION INTO CLAWS*, or* BIPARTITE DOMINATING SET. *Then the problem* AMBIGUOUS-Π *is* NP*-complete and the problem* UNIQUE-Π *is* D^P*-complete under randomized polynomial reductions.*

Proof. Given that each reduction in the sequence of reductions 3SAT $\rightarrow$ PL-3SAT $\rightarrow$ PL-EX1-3SAT $\rightarrow$ PL-X3C is parsimonious, that UNIQUE 3SAT is D^P-complete,

and that the reduction from X3C to each of the problems mentioned above is parsimonious, the proof of the corollary is similar to the proof of Theorem 5.4. □

5.1. Nonapproximability results for integer linear programming. Next, we give an application of our result that AMBIGUOUS PL-3SAT is NP-complete and prove that it is not possible to approximate the optimal value of the objective function of an integer linear program.

An instance of an integer linear program consists of a system of linear inequalities and an objective function which is to be maximized (minimized); i.e., maximize (minimize) $\mathbf{c}x$ subject to the constraints $\mathbf{A}x \leq \mathbf{b}$. The variables x are allowed to take only integer values. We say that a minimization problem Π is ϵ-approximable, $\epsilon > 1$ (or has an ϵ-approximation) if there is a polynomial time algorithm that, given an instance $I \in \Pi$, finds a solution which is within a factor ϵ of an optimal solution for I.

THEOREM 5.9. *Unless* P = NP, *given an instance of the integer linear program problem and a feasible solution, the maximum (minimum) value of the objective function is not polynomial time ϵ-approximable for any $\epsilon > 1$, even when the bipartite graph associated with the set of constraints is planar.*

Proof. We prove the theorem for the maximization version of the problem. The proof for the minimization version is similar and hence omitted.

Step 1. Given a 3SAT formula $f(x_1, x_2, \ldots, x_n)$, we construct a formula

$$g(x_1, \ldots, x_{n+1}) = [f(x_1, x_2, \ldots, x_n) \wedge x_{n+1}] \vee (\overline{x_1} \wedge \overline{x_2} \ldots \overline{x_{n+1}}).$$

It follows that for any assignment $\mathbf{v}$, $\mathbf{v}[g(x_1, \ldots, x_{n+1})] = 1$ if and only if either (i) $\mathbf{v}[f(x_1, x_2, \ldots, x_n)] = 1$ and $\mathbf{v}[x_{n+1}] = 1$, *or* (ii) $\mathbf{v}[x_1] = \mathbf{v}[x_2] = \cdots \mathbf{v}[x_{n+1}] = 0$.

Step 2. Starting from $g(x_1, \ldots, x_{n+1})$, we construct a PL-3SAT formula $\hat{g}(x_1, x_2, \ldots, x_{n+1}, t_1, \ldots, t_m)$ such that $\hat{g}(x_1, x_2, \ldots, x_{n+1}, t_1, \ldots, t_m)$ is satisfiable if and only if $g(x_1, x_2, \ldots, x_{n+1})$ is satisfiable.

The construction can be carried out as in Step 2 in the proof of Theorem 3.4. We therefore omit the details here.

Step 3. Let $\hat{g} = G_1 \wedge G_2 \ldots G_r$. Construct a new 1-EX3-MONOSAT formula h from $\hat{g}$ such that $\hat{g}$ is satisfiable if and only if h is satisfiable. Let $h = C_1 \wedge C_2 \ldots C_p$. Replace each clause $C_i = (x_{i_1} + x_{i_2} + x_{i_3})$ by the inequality $(x_{i_1} + x_{i_2} + x_{i_3}) \geq 1$. All the inequalities corresponding to the clauses make up the constraints. We also add constraints that $\forall i,\ x_i \in \{0, 1\}$. The objective function is now simply x_{n+1}. It is easy to verify that the maximum value of the objective function is exactly 1 if $f(x_1, x_2, \ldots, x_n)$ is satisfiable and is 0 otherwise. Hence it follows that unless P = NP the integer linear program problem has no polynomial time ϵ-approximation algorithm for any $\epsilon > 1$. □

6. Conclusions and open problems. We showed that for many problems Π studied in the literature, the problems #PL-Π, AMBIGUOUS-PL-Π, and UNIQUE-PL-Π are *as hard as* the respective problems #Π, AMBIGUOUS-Π, and UNIQUE-Π with respect to polynomial time or random polynomial time reducibilities. We note that the problem #PL-HAMILTONIAN-CYCLE was proved to be #P-complete by Provan [20]. We can give an alternate proof of the #P-hardness of #PL-HAMILTONIAN-CYCLE by a reduction from a variant of $RED1$. The reduction is significantly more complicated than that in [20]. Consequently, we omit it here.

As corollaries of our results, we have shown that many planar problems are complete for the classes NP, #P, and D^P. Our results and their proofs provide the following general tools for proving hardness results for planar problems.

1. We have shown how parsimonious and weakly parsimonious crossover boxes can be used to prove the #P-hardness of many planar counting problems. These ideas were used to prove the #P-hardness of problem #1-Valid Pl-3Sat.

2. We extended the class of basic planar CNF satisfiability problems that are known to be NP-complete. Previously, only Pl-3Sat [15] and Pl-1-Ex3Sat [3] were known to be NP-hard. We expect that the variants of the problem Pl-3Sat shown to be NP-hard here will be useful in proving hardness results for many additional planar problems. In particular, we have already shown that the problem Pl-1-3MonoSat and its variant *RED*1 are especially useful in proving the #P-hardness of many planar graph problems.

3. We have shown that the problem Ambiguous-Pl-3Sat can be used to prove the nonapproximability of linear integer programming. Recently, there has been a lot of research in the area of approximability of graph and combinatorial problems, and the tools for showing negative results are few. Our proof of the nonapproximability of the minimum or maximum objective value of an integer linear program is direct and significantly different from the proof given in Kann [12] or Zuckerman [28]. Moreover, in [9], we show how to use the NP-completeness of Ambiguous-Pl-3Sat to show the nonapproximability of several constrained optimization problems even when restricted to *planar instances*. (The results in [12, 28] do not hold for planar instances.)

Finally, the results presented here and their proofs suggest a number of open problems including the following.

1. Can natural planar problems be found that are complete for additional complexity classes such as PSPACE, #PSPACE, MAX SNP, MAX Π_1, etc.? (In recent papers [8, 9, 17, 10], we partially answer this question by showing that a number of problems are complete for the classes PSPACE, #PSPACE, MAX-SNP, MAX Π_1, even when restricted to planar instances.)

2. Valiant [25] has shown that the problem #2Sat is #P-complete. How hard is the problem #Pl-2Sat? We conjecture that the problem is #P-complete, but it seems to us that different techniques than the ones used here are required to prove this. Recently Vadhan has affirmatively proved the conjecture [29].

3. We have shown that many unique satisfiability problems are complete for D^P, even when restricted to planar instances. Using our parsimonious reductions, we then proved the D^P-completeness of a number of graph problems for planar graphs. A number of such problems for planar graphs remain open. For example, how hard is the problem Unique-Pl-Hamiltonian Circuit?

4. Do results similar to the ones proved in this paper hold for other restricted classes of graphs, e.g., intersection graphs of unit disks and squares? Such graphs have been studied extensively by [2, 7, 18] in the context of image processing, VLSI design, geometric location theory, and network design.

Acknowledgments. We thank the anonymous referee for invaluable suggestions. These suggestions significantly improved the quality of presentation and helped us in correcting a number of errors in the earlier draft. We thank Salil Vadhan for providing a draft of his paper [29].

GUARANTEEING FAIR SERVICE TO PERSISTENT DEPENDENT TASKS*

AMOTZ BAR-NOY†, ALAIN MAYER‡, BARUCH SCHIEBER§, AND MADHU SUDAN¶

Abstract. We introduce a new scheduling problem that is motivated by applications in the area of access and flow control in high-speed and wireless networks. An instance of the problem consists of a set of *persistent tasks* that have to be scheduled repeatedly. Each task has a demand to be scheduled "as often as possible." There is no *explicit* limit on the number of tasks that can be scheduled concurrently. However, such limits are imposed implicitly because some tasks may be in conflict and cannot be scheduled simultaneously. These conflicts are presented in the form of a conflict graph. We define parameters which quantify the *fairness* and *regularity* of a given schedule. We then proceed to show lower bounds on these parameters and present fair and efficient scheduling algorithms for the case where the conflict graph is an interval graph. Some of the results presented here extend to the case of perfect graphs and circular-arc graphs as well.

Key words. fairness, dining philosophers problem, scheduling, interval graphs

1. Introduction.

In this paper we consider a new form of a scheduling problem that is characterized by the following two features.

Persistence. A task does not simply terminate once it is scheduled. Instead, each task must be scheduled infinitely many times. The goal is to schedule every task as frequently as possible.

Dependency. Some tasks conflict with each other and hence cannot be scheduled concurrently. These conflicts are represented by a conflict graph. This graph imposes constraints on the sets of tasks that may be scheduled concurrently. Note that these constraints are not based simply on the cardinality of the sets but rather on the identity of the tasks within the sets.

We consider both the problems of *allocation*, i.e., how often should a task be scheduled and *regularity*, i.e., how evenly spaced are lengths of the intervals between successive schedulings of a specific task. We present a more formal description of this problem next and discuss our primary motivation immediately afterward. While all our definitions are presented for general conflict graphs, our applications, bounds, and algorithms are for special subclasses—perfect graphs, interval graphs, and circular arc graphs.

Problem statement. An instance of the scheduling problem consists of a conflict graph G with n vertices. The vertices of G are the tasks to be scheduled, and the edges of G define pairs of tasks that cannot be scheduled concurrently. The output of the scheduling algorithm is an infinite sequence of subsets of the vertices, $I_1, I_2, \ldots$, where I_t lists the tasks that are scheduled at time t. Note that I_t must be an independent set of G for all t.

In the form above, it is hard to analyze the running time of the scheduling algorithm. We consider instead a finite version of the above problem and use it to analyze the running time.

Input. *A conflict graph G and a time t.*

Output. *An independent set I_t denoting the set of tasks scheduled at time unit t.*

The objective of the scheduling algorithm is to achieve a *fair* allocation and a *regular* schedule. We next give some motivation and describe the context of our work. As we will see, none of the existing measures can appropriately capture the "goodness" of a schedule in our framework. Hence we proceed to introduce measures which allow a better presentation of our results.

1.1. Motivation.

Session scheduling in high-speed local-area networks. The main motivation for this work arises from the session scheduling problem on a network called MetaRing. MetaRing [CO93] is a recent high-speed local-area ring network that allows "spatial bandwidth reuse"; i.e., in contrast to other ring networks which may only allow one source destination pair to communicate on the ring at a time, the MetaRing can allow several such pairs to communicate with each other, provided the pairs do not use the same link for the communication. This concurrent access and transmission of user sessions is implemented using only minimal intermediate buffering of packets. A typical use of the MetaRing network involves several users trying to establish "sessions." A session is simply a source destination pair, where the source wishes to send data over to the destination. The data are generated over time and need to be shipped over at regular intervals, if not immediately. In the general setting, the set of sessions can change dynamically. We restrict our attention to the static case. This restriction is justified by the fact that sessions typically last for a long while. As a result of the minimal intermediate buffering, a session can send its data over only if it has exclusive use of all the links in its route. Consequently, sessions whose routes share a link are in conflict. These conflicts must be regulated by breaking the data sent in a session into units of quotas that are transmitted according to some schedule. This schedule has to be *efficient* and *fair*. Efficient means that the total number of quotas transmitted (throughput) is maximized. Fair means that the throughput of *each* session is maximized, and that the time between successive activation of a session is minimized, so that large buffers at the source nodes can be avoided. It has been recognized [CCO93] that the access and flow control in such a network should depend on locality in the conflict graph. However, no firm theoretical basis for an algorithmic framework has been proposed up to now. To express this problem as our scheduling problem we create a circular-arc graph, the vertices of which are the sessions, and in which vertices are adjacent if the corresponding paths associated with the sessions intersect. Since an independent set in this graph is a collection of mutually nonconflicting sessions, they can all communicate simultaneously. Thus a schedule is a sequence of independent sets in this graph. Our goal will be to produce such a schedule which is efficient and fair, in a sense to be made precise later.

Time sharing in wireless networks. A second naturally occurring scenario where our model can be applied is in the scheduling of base-station transmissions in a cellular network. We now describe this setting in detail. Most indoor designs of wireless networks are based on a *cellular* architecture with a very small cell size (see, e.g., [Goo90].) The cellular architecture comprises two levels—a stationary level and a mobile level. The stationary level consists of fixed base stations that are interconnected through a backbone network. The mobile level consists of mobile units that communicate with the base stations via wireless links. The geographic area within which mobile units can communicate with a particular base station is referred to as a cell. Neighboring cells overlap with each other, thus ensuring continuity of communications. The mobile units communicate among themselves, as well as with the fixed information networks, through the base stations and the backbone network. The continuity of communications is a crucial issue in such networks. A mobile user who crosses boundaries of cells should be able to continue its communication via the new base station. To ensure this, base stations periodically need to transmit their identity using the wireless communication. In some implementations the wireless links use infrared waves. Therefore, two base stations, the cells of which overlap, are in conflict and cannot transmit their identity simultaneously. These conflicts have to be regulated by a time-sharing scheme. This time sharing has to be *efficient* and *fair*. Efficient means that the scheme should accommodate the maximal number of base stations. Fair means that the time between two consecutive transmissions of the same base station should be less than the time it takes a user to cross its corresponding cell. Once again this problem can be posed as our graph scheduling problem in which the vertices of the graph are the base stations and an edge indicates that the base stations belong to overlapping cells. Independent sets again represent lack of conflict and a schedule will thus be a sequence of independent sets.

1.2. Relationship to past work. Previous research on scheduling problems in our framework considered either persistence of the tasks or dependency among the tasks but not both.

An early work by Liu and Layland [LL73] considers persistent scheduling of tasks in a single processor environment. In their problem, tasks have deadlines which specify a time limit in which the ith scheduling of a given task must have occurred. They give an algorithm which achieves full processor utilization for this task. More recently, the problem of scheduling persistent tasks has been studied in the work of Baruah et al. [BCPV96]. Their setting is closer to ours, and we describe their problem in detail. They considered the problem of scheduling a set of n tasks with given (arbitrary) frequencies on m machines. (The case $m = 1$ is equivalent to an instance of our problem in which the conflict graph is a clique.) To measure *regularity* of a schedule for their problem they introduced the notion of *P-fairness*. A schedule for this problem is P-fair (proportionate-fair) if at each time t for each task i the absolute value of the difference in the number of times i has been scheduled and $f_i t$ is strictly less than 1, where f_i is the frequency of task i. They provided an algorithm for computing a P-fair solution to their problem. Their problem fails to capture our situation for two reasons. First, we would like to constrain the sets of tasks that can be scheduled concurrently according to the topology of the conflict graph and not according to their cardinality. Moreover, in their problem every feasible frequency requirement can be scheduled in a P-fair manner. For our scheduling problem, we show that such a P-fair schedule cannot always be achieved. To deal with feasible frequencies that cannot be scheduled in a P-fair manner, we define weaker versions of regularity.

The dependency property captures most of the work done based on the well-known "dining philosophers" paradigm (see, for example, [Dijk71], [Lyn80], [CM84], [AS90], [CS92], and [BP92]). In this setting, Lynch [Lyn80] was the first to explicitly consider the *response time* for each task. The goal of successive works was to make the response time of a node depend only on its local neighborhood in the conflict graph (see, e.g., [BP92]). While response time in terms of a node's degree is adequate for "one-shot" tasks, it does not capture our requirement that a task should be scheduled in a regular and fair fashion over a period of time.

1.3. Notations and definitions. A *schedule* S is an infinite sequence of independent sets $I_1, I_2, \ldots, I_t, \ldots$. Let $S(i,t)$ denote the indicator variable that represents the schedule; it is 1 if task i is scheduled at time t and 0 otherwise. Let $f_i^{(t)}(S) = \sum_{\tau=1}^{t} S(i,\tau)/t$. We refer to $f_i^{(t)}(S)$ as the *prefix frequency* of task i at time t in schedule S. Let $f_i(S) = \liminf_{t\to\infty}\{f_i^{(t)}(S)\}$. We refer to $f_i(S)$ as the *frequency* of task i in schedule S. We say that a schedule S is *periodic* with *period* T, if $I_j = I_{T+j} = I_{2T+j} = \cdots$ for all $1 \le j \le T$. In periodic schedules we will refer to $f_i^{(T)}(S)$ as the frequency of task i. (In both $f_i^{(t)}(S)$ and $f_i(S)$ we drop the index S whenever the identity of the schedule S is clear from the context.)

DEFINITION 1. *A vector of frequencies* $\hat{f} = (f_1, \ldots, f_n)$ *is* feasible *if there exists a schedule* S *such that the frequency of the* i*th task in schedule* S *is at least* f_i.

DEFINITION 2. *A schedule* S realizes *a vector of frequencies* $\hat{f}$ *if the frequency of the* i*th task in schedule* S *is at least* f_i. *A schedule* S c-approximates *a vector of frequencies* $\hat{f}$ *if the frequency of the* i*th task in schedule* S *is at least* f_i/c.

A measure of fairness. Fairness is determined via a partial order $\prec$ that we define on the set of frequency vectors.

DEFINITION 3. *Given two frequency vectors* $\hat{f} = (f_1, \ldots, f_n)$ *and* $\hat{g} = (g_1, \ldots, g_n)$, $\hat{f} \prec \hat{g}$ *(*$\hat{f}$ *is less fair than* $\hat{g}$*) if there exists an index* i *and a threshold* f *such that* $f_i < f \le g_i$, *and for all* j *such that* $g_j \le f$, $f_j \le g_j$.

Less formally, if $\hat{f} \prec \hat{g}$, then $\hat{g}$ "performs" better for some task i and all tasks with frequency smaller than the ith task, i.e., those tasks that are least scheduled. It could be the case that $\hat{f}$ "performs" better for the other tasks; however, our concern in fair allocation is with the less frequently scheduled tasks.

In Appendix A we prove that the relation $\prec$ is indeed a partial order.

DEFINITION 4. *A vector of frequencies* $\hat{f}$ *is* max-min fair *if no feasible vector* $\hat{g}$ *satisfies* $\hat{f} \prec \hat{g}$.

Less formally, in a max-min fair frequency vector, one cannot increase the frequency of some task at the expense of less frequently scheduled tasks. This means that our goal is to let each task i have more of the resource as long as we have to take the resource away only from tasks which are better off, i.e., those that have more of the resource than task i.

Measures of regularity. We provide two measures by which one can evaluate a schedule for its *regularity*. We call these measures the *response time* and the *drift*.

Given a schedule S, the *response time* for task i, denoted r_i, is the largest interval of time for which task i waits between successive schedulings. More precisely,

$$r_i = \max\{t_2 - t_1 | 0 \le t_1 < t_2 \text{ s.t. } \forall_{t_1<t<t_2} S(i,t) = 0\}.$$

For any time t, the number of expected occurrences of task i can be expressed as $f_i t$. But note that if r_i is larger than $1/f_i$, it is possible that, for some period of time, a schedule allows a task to "drift away" from its expected number of occurrences. In

order to capture this, we introduce a second measure for the regularity of a schedule. We denote by d_i the *drift* of a task i. It indicates how much a schedule allows task i to drift away from its expected number of scheduled units:

$$d_i = \max_t \left\{ \left| f_i \cdot t - \sum_{r=1}^{t} S(i,r) \right| \right\}.$$

Note that if a schedule S achieves drift $d_i < 1$ for all i, then it is *P-fair* as defined in [BCPV96].

A schedule achieves its strongest form of regularity if each task i is scheduled every $1/f_i$ time units (except for its first appearance). We say that a schedule is *rigid* if for each task i there exists a starting point s_i such that the task is scheduled on exactly the time units $s_i + j(1/f_i)$ for $j \geq 0$.

Graph subclasses. A graph is *perfect* if for all its induced subgraphs the size of the maximum clique is equal to the chromatic number (cf. [Gol80]). A graph is an interval graph (circular-arc graph) if its vertices correspond to intervals on a line (circle), and two vertices are adjacent if the corresponding intervals intersect (cf. [Tuc71]).

1.4. Results. In section 2 we motivate our definition of max-min fairness and show several of its properties. First, we provide an equivalent (alternate) definition of feasibility which shows that deciding feasibility of a frequency vector is computable. Next, we prove that every graph has a *unique* max-min fair frequency vector. Then, we show that the task of even weakly approximating the max-min fair frequencies on general graphs is NP-hard. As we mentioned above, many practical applications of this problem arise from simpler networks such as buses and rings (i.e., interval conflict graphs and circular-arc conflict graphs). For the case of perfect graphs (and hence for interval graphs), we describe an efficient algorithm for computing max-min fair frequencies. We prove that the period T of a schedule realizing such frequencies on a perfect graph satisfies $T = 2^{O(n)}$ and that there exist interval graphs such that $T = 2^{\Omega(n)}$.

The rest of our results deal with the problem of finding the most "regular" schedule that realizes any feasible frequency vector. In section 3 we show the existence of interval graphs for which there is no P-fair schedule that realizes their max-min fair frequencies. In section 4 we describe an algorithm for computing a schedule that realizes any given feasible frequencies on interval graphs. The schedule computed by the algorithm achieves response time of $\lceil 4/f_i \rceil$ and drift of $O(\sqrt{\log T} n^{\epsilon})$. A slight modification of this algorithm yields a schedule that 2-approximates the given frequencies. The advantage of this schedule is that it achieves a bound of one on the drift and hence a bound of $\lceil 2/f_i \rceil$ on the response time. In section 5 we present an algorithm for computing a schedule that 12-approximates any given feasible frequencies on interval graphs and has the advantage of being rigid. All algorithms run in polynomial time. In section 6 we show how to transform any algorithm for computing a schedule that c-approximates any given feasible frequencies on interval graphs into an algorithm for computing a schedule that $2c$-approximates any given feasible frequencies on circular-arc graphs. The response time and drift of the resulting schedule are doubled as well.

Finally, in section 7 we summarize our results, list a number of open problems, and sketch what additional properties are required to obtain solutions for actual networks.

2. Max-min fair allocation. Our definition for max-min fair allocation is based on the definition used by Jaffe [Jaf81] and Bertsekas and Gallager [BG87] but differs

in one key ingredient, namely, our notion of feasibility. We study some elementary properties of our definition in this section. In particular, we show that our definition guarantees a unique max-min fair frequency vector for every conflict graph. We also show the hardness of computing the frequency vector for general graphs. However, for the special case of perfect graphs our notion turns out to be the same as that of [BG87].

The definition of [Jaf81] and [BG87] is considered as the traditional way of measuring throughput fairness in communication networks and is also based on the partial order $\prec$ as used in our definition. The primary difference between our definition and theirs is in the definition of *feasibility*. Bertsekas and Gallager [BG87] use a definition, which we call clique feasibility, that is defined as follows:

> a vector of frequencies $(f_1, \ldots, f_n)$ is *clique feasible* for a conflict graph G, if $\sum_{i \in C} f_i \leq 1$ for all cliques C in the graph G.

The notion of max-min fairness of Bertsekas and Gallager [BG87] is now exactly our notion, with feasibility replaced by clique feasibility.

The definition of [BG87] is useful for capturing the notion of fractional allocation of a resource such as bandwidth in a communication networks. However, in our application we need to capture a notion of integral allocation of resources, and hence their definition does not suffice for our purposes. By definition, every frequency vector that is feasible in our sense is clique feasible. However, the converse is not true. Consider the five-cycle conflict graph. For this graph the vector $(1/2, 1/2, 1/2, 1/2, 1/2)$ is clique feasible, but no schedule can realize this frequency vector.

2.1. An alternate definition of feasibility. Given a conflict graph G, let $\mathcal{I}$ denote the family of all independent sets in G. For $I \in \mathcal{I}$, let $\chi(I)$ denote the characteristic vector of I.

THEOREM 5. *A vector of frequencies $\hat{f}$ is feasible if and only if $\hat{f}$ is a convex combination of the $\chi(I)$'s; that is, there exist weights $\{\alpha_I\}_{I \in \mathcal{I}}$ such that $\sum_{I \in \mathcal{I}} \alpha_I = 1$ and $\sum_{I \in \mathcal{I}} \alpha_I \chi(I) = \hat{f}$.*

Proof. Claim 6 proves the easier direction. Claim 7 proves the other direction only for the case when $\hat{f}$ can be expressed as a rational convex combination of the independent sets. The proof for the case when $\hat{f}$ is not a rational convex combination is given in Appendix B. □

CLAIM 6. *If a frequency vector $\hat{f}$ is feasible then there exists a sequence of weights $\{\alpha_I\}_{I \in \mathcal{I}}$ such that $\sum_I \alpha_I = 1$ and $\sum_I \alpha_I \chi(I) = \hat{f}$.*

Proof. To obtain a contradiction assume otherwise. By continuity there exists an $\epsilon > 0$, such that the vector $(1 - \epsilon)\hat{f}$ cannot be expressed as a convex combination of the $\chi(I)$'s. Based on the definition of feasibility, there exists a schedule S which achieves a frequency of at least $\hat{f}$. In particular, there exists a time $T = T_\epsilon$ such that $f_i^{(T)} \geq f_i - \epsilon$ for all $1 \leq i \leq n$. Let α_I be the frequency of the independent set I in the first T time units in the schedule S. Then $\sum_I \alpha_I = 1$ and $\sum_I \alpha_I \chi(I) \geq (1 - \epsilon)\hat{f}$, contradicting the choice of ϵ. □

CLAIM 7. *If a frequency vector $\hat{f}$ can be expressed as a rational convex combination of the independent sets, then $\hat{f}$ is feasible.*

Proof. Suppose that there exist rational weights $\{\alpha_I\}_{I \in \mathcal{I}}$, such that $\sum_{I \in \mathcal{I}} \alpha_I = 1$ and $\sum_{I \in \mathcal{I}} \alpha_I \chi(I) = \hat{f}$. Express α_I as p_I/q_I where p_I and q_I are integral and let $T = \text{LCM}\{q_I\}$. Observe that $N_I \equiv \alpha_I T$ is integral. For each I we schedule N_I times the independent set I over a period of T intervals (in any arbitrary N_I units of time). It is clear that there are enough slots for each independent set to be scheduled N_I times. □

The main impact of Theorem 5 is that it shows that the space of all feasible frequencies is well behaved (i.e., it is a closed, connected, compact space). In addition, it shows that determining whether a frequency vector is feasible is a computable task (a fact that may not have been easy to see from the earlier definition). We now use this definition to observe the following interesting connection.

PROPOSITION 8. *Given a conflict graph G, the notions of feasibility and clique feasibility are equivalent if and only if G is perfect.*

Proof. The proof follows directly from well-known polyhedral properties of perfect graphs. (See [GLS87], [Knu94].) In the notation of Knuth [Knu94] the space of all feasible vectors is the polytope STAB(G), and the space of all clique-feasible vectors is the polytope QSTAB(G). The result follows from the theorem on page 38 in [Knu94] which says that a graph G is perfect if and only if STAB(G) = QSTAB(G). □

2.2. Uniqueness and computability of max-min fair frequencies. In this subsection we prove that the max-min fair frequency vector is unique. We also show that finding this vector (or even approximating it) is computationally hard.

THEOREM 9. *For any conflict graph there exists a unique max-min fair frequency vector.*

Proof. For a vector $\hat{f}$ let sort$\hat{f}$ denote the vector obtained by permuting the vector $\hat{f}$ so that its coordinates appear in nondecreasing order. Let the relation $\prec_{\text{lex}}$ on the feasible frequency vectors be the lexicographic ordering on sort$\hat{f}$. More precisely, $\hat{f} \prec_{\text{lex}} \hat{g}$ if either sort$\hat{f}$ = sort$\hat{g}$ or there exists an index $i \geq 1$ such that sort$\hat{f}_i <$ sort$\hat{g}_i$ and sort$\hat{f}_j$ = sort$\hat{g}_j$ for all $1 \leq j < i$. (Note that $\prec_{\text{lex}}$ is not a partial order since it is not antisymmetric.) It is easy to verify that if $\hat{f} \prec_{\text{lex}} \hat{g}$, and sort$\hat{f} \neq$ sort$\hat{g}$ then $f \prec g$. Let the vector $\hat{f}$ be a max-min fair vector. (Such a vector exists in the space of feasible vectors, since this space is compact.) The vector $\hat{f}$ is also larger according to the ordering $\prec_{\text{lex}}$ than any vector $\hat{g}$ such that sort$\hat{f} \neq$ sort$\hat{g}$. We now show that there is no vector $\hat{g}$ such that sort$\hat{f}$ = sort$\hat{g}$. This implies that it is the unique max-min fair frequency vector.

To obtain a contradiction, suppose that there exists a vector $\hat{g}$ such that sort$\hat{f}$ = sort$\hat{g}$. First observe that the vector $\hat{h} = (\hat{f} + \hat{g})/2$ is feasible. This is true because $\hat{f}$ and $\hat{g}$ can be expressed as a convex combination of the independent sets and $\hat{h}$ is a convex combination of $\hat{f}$ and $\hat{g}$. Thus $\hat{h}$ is a convex combination of the independent sets. Now assume without loss of generality that the indices of the vectors are arranged in increasing order of $f_i + g_i$. Let j be the smallest index such that $f_j \neq g_j$. Say f_j is the smaller of the two. Then $((\hat{f} + \hat{g})/2)_j$ is greater than f_j and for all vertices i with smaller frequencies, $f_i = ((\hat{f} + \hat{g})/2)_i$. This implies that $\hat{f} \prec_{\text{lex}} (\hat{f} + \hat{g})/2$, which is a contradiction. □

We now turn to the issue of the computability of the max-min fair frequencies. While we do not know the exact complexity of computing max-min fair frequencies (in particular, we do not know if deciding whether a frequency vector is feasible is in NP ∪ coNP), it does seem to be very hard in general. Here, we consider the subproblem of computing the smallest frequency assigned to any vertex by a max-min allocation and show the following theorem.

THEOREM 10. *There exists an $\epsilon > 0$ such that given a conflict graph on n vertices, approximating the smallest frequency assigned to any vertex in a max-min fair allocation to within a factor of n^{ϵ} is NP-hard.*

Proof. We relate the computation of max-min fair frequencies in a general graph to the computation of the fractional chromatic number of a graph. We then use the

recent hardness result for approximating the (fractional) chromatic number due to Lund and Yannakakis [LY93] to show that computing max-min fair frequencies in general graphs is very hard.

The fractional chromatic number problem (cf. [LY93]) is defined as follows.

> To each independent set I in the graph, assign a weight w_I, so as to minimize the quantity $\sum_I w_I$, subject to the constraint that for every vertex v in the graph the quantity $\sum_{I \ni v} w_I$ is at least 1. The quantity $\sum_I w_I$ is called the *fractional chromatic number* of the graph.

Observe that if the w_I's are forced to be integral, then the fractional chromatic number is the chromatic number of the graph.

The following claim shows a relationship between the fractional chromatic number and the assignment of feasible max-min fair frequencies.

CLAIM 11. *Let $(f_1, f_2, \ldots, f_n)$ be a feasible assignment of frequencies to the vertices in a graph G. Then $1/(\min_i f_i)$ is an upper bound on the fractional chromatic number of the graph. Conversely, if k is the fractional chromatic number of a graph, then a schedule that sets the frequency of every vertex to be $1/k$ is feasible.*

The proof of the above claim is straightforward given the definitions of fractional chromatic number and feasibility. We now show how to use the claim to prove the theorem.

The above claim, combined with the hardness of computing the fractional chromatic number [LY93], suffices to show the NP-hardness of deciding whether a given assignment of frequencies is feasible for a given graph. To show that the claim also implies the hardness of approximating the smallest frequency in the max-min fair frequency vector we inspect the Lund–Yannakakis construction a bit more closely. Their construction yields a graph in which every vertex participates in a clique of size k such that deciding if the (fractional) chromatic number is k or kn^ϵ is NP-hard. In the former case, the max-min fair frequency assignment to every vertex is at least $1/k$. In the latter case at least some vertex will have frequency smaller that $1/(kn^\epsilon)$. Thus this implies that approximating the smallest frequency in the max-min fair frequencies to within a factor of n^ϵ is NP-hard. □

2.3. Max-min fair frequencies on perfect graphs. We now consider perfect graphs. We show how to compute in polynomial time max-min fair frequencies for this class of graphs and give bounds on the period of a schedule realizing such frequencies. As our main focus of the subsequent sections will be interval graphs, we will give our algorithms and bounds first in terms of this subclass and then show how to generalize the results to perfect graphs.

We start by describing an algorithm for computing max-min fair frequencies on interval graphs. As we know that clique feasibility equals feasibility (by Proposition 8), we can use an adaptation of [BG87].

ALGORITHM 1. *Let $\mathcal{C}$ be the collection of maximal cliques in the interval graph. (Notice that $\mathcal{C}$ has at most n elements and can be computed in polynomial time.) For each clique $C \in \mathcal{C}$ the algorithm maintains a* residual capacity *which is initially* 1. *To each vertex the algorithm associates a label* assigned/unassigned. *All vertices are initially unassigned. Dividing the residual capacity of a clique by the number of unassigned vertices in this clique yields the* relative *residual capacity. Iteratively, we consider the clique with the smallest current relative residual capacity and assign to each of the clique's unassigned vertices this capacity as its frequency. For each such vertex in the clique we mark it assigned and subtract its frequency from the residual*

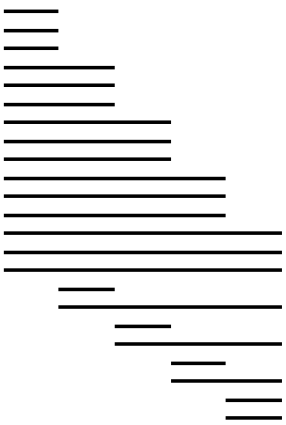

FIG. 1. *An interval graph with $n = 23$ intervals for which $T = LCM_{i=1}^{n}\{q_i\} \geq 2^{\frac{n+2}{5}-1}$.*

capacity of every clique that contains it. We repeat the process till every vertex has been assigned some frequency.

It is not hard to see that Algorithm 1 correctly computes max-min fair frequencies in polynomial time. We now use its behavior to prove a tight bound on the period of a schedule for an interval graph. The following theorem establishes this bound.

THEOREM 12. *Let $f_i = p_i/q_i$ be the frequencies in a max-min fair schedule for an interval graph G, where p_i and q_i are relatively prime. Then, the period for the schedule $T = LCM_{i=1}^{n}\{q_i\}$ satisfies, $T = 2^{O(n)}$. Furthermore, there exist interval graphs for which $T = 2^{\Omega(n)}$.*

We prove this theorem with the help of the following two lemmas.

LEMMA 13. *$LCM_{i=1}^{n}\{q_i\} \leq 2^{n/2}$.*

Proof. Let n_j denote the number of intervals that are assigned frequency $\frac{p_j}{q_j}$ in iteration j. That is, $\frac{p_j}{q_j}$ is the minimum relative residual capacity at iteration j. From the way the relative residual capacities are updated, it follows that q_i divides $\prod_{j=1}^{i} n_j$ for all $1 \leq i \leq n$. The lemma follows since assuming there were ℓ iterations, q_i divides $\prod_{j=1}^{\ell} n_j$, and $\prod_{j=1}^{\ell} n_j$ attains its maximum when $\ell = n/2$ and $n_i = 2$ for all $1 \leq i \leq \ell$. □

LEMMA 14. *There exists an interval graph for which $LCM_{i=1}^{n}\{q_i\} \geq 2^{\frac{n+2}{5}-1}$.*

Proof. We show an interval graph in which $\max_{i=1}^{n}\{q_i\} \geq 2^{\frac{n+2}{5}-1}$; the lemma follows since trivially $\mathrm{LCM}_{i=1}^{n}\{q_i\} \geq \max_{i=1}^{n}\{q_i\}$. For simplicity we assume that 5 divides $n + 2$. The reader may find it easier to follow the construction for $n = 23$ depicted in Figure 1. Let $x = \frac{3(n+2)}{5}$ and $y = \frac{n+2}{5} - 1$. In the construction x intervals start at 0 (the top 15 intervals in Figure 1), and two intervals start at i for all $1 \leq i \leq y$ (the bottom 8 intervals in Figure 1). Note that indeed $2y + x = n$. Out of the first x intervals, three intervals terminate at i for each $1 \leq i \leq y + 1$. Note that indeed $3(y + 1) = x$. For $1 \leq i \leq y$, out of the two intervals starting at i, one interval terminates at $i + 1$ and one continues until $y + 1$.

Now, since at 0 the size of the clique is x and at i the size of the clique is $x - 3i + (i - 1) + 2 = x - 2i + 1$, it follows that the algorithm for the frequency assignment handles the cliques from left to right and there are $y + 1$ different values for frequencies denoted by $w_0, \ldots, w_y$. We get

$$w_0 = \frac{1}{x},$$
$$w_1 = \frac{3w_0}{2} = \frac{3}{2x},$$
$$w_2 = \frac{3w_0 + w_1}{2} = \frac{9}{4x}.$$

In general, by induction we prove that $w_i = \frac{3}{x} \cdot \frac{2^i - 1}{2^i}$ for $1 \le i \le y$.

$$w_{i+1} = \frac{3w_0 + w_i}{2} = \frac{3}{2x} + \frac{3}{x} \cdot \frac{2^i - 1}{2^{i+1}} = \frac{3}{x} \cdot \frac{1}{2} + \frac{2^i - 1}{2^{i+1}} = \frac{3}{x} \cdot \frac{2^{i+1} - 1}{2^{i+1}}.$$

Since the denominator of w_y is greater than or equal to 2^y and neither 3 nor $2^y - 1$ has a common divisor with 2^y, it follows that $\max_{i=1}^{n}\{q_i\} \ge 2^{\frac{n+2}{5}-1}$. □

Algorithm 1 works for all graphs where clique feasibility determines feasibility, i.e., perfect graphs. However, the algorithm does not remain computationally efficient since it involves scanning all the cliques in the graph. Still, Theorem 12 can be directly extended to the class of perfect graphs. We now use this fact to describe a polynomial-time algorithm for assigning max-min fair frequencies to perfect graphs.

ALGORITHM 2. *This algorithm maintains the labelling procedure* assigned/unassigned *of Algorithm* 1. *At each phase, the algorithm starts with a set of assigned frequencies and tries to find the largest f such that all unassigned vertices can be assigned the frequency f. To compute f in polynomial time, the algorithm uses the fact that deciding if a given set of frequencies is feasible is reducible to the task of computing the size of the largest weighted clique in a graph with weights on vertices. The latter task is well known to be computable in polynomial time for perfect graphs. Using this decision procedure the algorithm performs a binary search to find the largest achievable f. (The binary search does not have to be too refined due to the upper bound on the denominators of the frequencies given in Theorem* 12.*) Having found the largest f, the algorithm finds a set of vertices which are saturated under f as follows: let ϵ be some small number, with the property that the difference between any two distinct assigned frequencies is more than ϵ. By Theorem* 12, $\epsilon = 2^{-n^2}$ *is sufficient. Now the algorithm raises, one at a time, the frequency of each unassigned vertex to $f + \epsilon$, while maintaining the other unassigned frequencies at f. If the so obtained set of frequencies is not feasible, then it marks the vertex as assigned and its frequency is assigned to be f. The algorithm now repeats the phase until all vertices have been assigned some frequency.*

3. Nonexistence of *P*-fair allocations. We show that a P-fair scheduling under max-min fair frequencies need not exist for every interval graph.

THEOREM 15. *There exist interval graphs G for which there is no P-fair schedule that realizes their max-min frequency assignment.*

Proof. In order to prove the theorem we produce a counterexample as follows. We choose a parameter k and for every permutation π of the elements $\{1, \ldots, k\}$, we define an interval graph G_π. We show a necessary condition that π must satisfy if G_π has a P-fair schedule. Last, we show that there exists a permutation π of 12 elements which does not satisfy this condition.

Given a permutation π on k elements, G_π consists of $3k$ intervals. For $1 \le 1 \le k$, define the intervals $A(i) = (i-1, i]$, $B(i) = (i, k+\pi(i)+1]$ and $C(i) = (k+i+1, k+i+2]$. Observe that the max-min frequency assignment to G_π is the following: all the tasks $B(1), \ldots, B(k)$ have frequency $1/k$; task $A(i)$ has frequency $(k-i+1)/k$ for $1 \le i \le k$; and task $C(i)$ has frequency i/k for $1 \le i \le k$. (See Figure 2.)

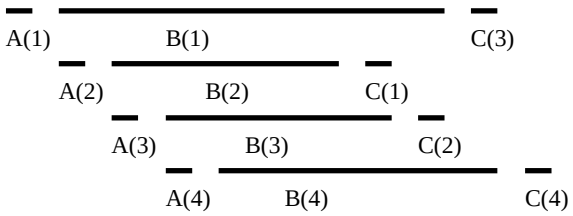

FIG. 2. *The graph G_π for $\pi = (3, 1, 2, 4)$.*

We now observe the properties of a P-fair schedule for the tasks in G_π. (i) The time period is k. (ii) The schedule is entirely specified by the schedule for the tasks $B(i)$. (iii) This schedule is a permutation σ of k elements, where $\sigma(i)$ is the time unit for which $B(i)$ is scheduled. To see what kind of permutations σ constitute P-fair schedules of G_π we define the notion of when a permutation is *fair* for another permutation.

DEFINITION 16. *A permutation σ_1 is* fair *for a permutation σ_2 if for all $1 \leq i, j \leq k$, σ_1 and σ_2 satisfy the conditions* cond_{ij} *defined as follows:*

$$\frac{ij}{k} - 1 < |\{\ell : \sigma_1(\ell) \leq j \text{ and } \sigma_2(\ell) \leq i\}| < \frac{ij}{k} + 1 \ .$$

CLAIM 17. *If a permutation σ is a P-fair schedule for G_π then σ is fair for the identity permutation and permutation π.*

Proof. For fixed i, we claim that the conditions cond_{ij} for $\sigma_1 = \sigma$ and σ_2 being the identity permutation are exactly the conditions for a P-fair allocation of $A(i+1)$. Similarly, the conditions cond_{ij} for $\sigma_1 = \sigma$ and $\sigma_2 = \pi$ are the conditions for a P-fair allocation of $C(k-i)$. Thus, a permutation σ represents a P-fair schedule for G_π if and only if σ is fair for both π and the identity permutation.

We now show why the conditions cond_{ij} for $\sigma_1 = \sigma$ and σ_2 being the identity permutation are exactly the conditions for a P-fair allocation of $A(i+1)$. The claim about the conditions cond_{ij} for $\sigma_1 = \sigma$ and $\sigma_2 = \pi$ is analogous. Recall that the frequency of task $A(i+1)$ is $(k-i)/k$ and that $A(i+1)$ can be scheduled only when tasks $B(\ell)$, for $1 \leq \ell \leq i$, are not scheduled. Consider the schedule up to time $j \leq k$. In order for the schedule to be P-fair, the number of occurrences of tasks $B(\ell)$, for $1 \leq \ell \leq \ell$, up to this time must be between $j - \frac{(k-i)j}{k} - 1 = \frac{ij}{k} - 1$ and $j - \frac{(k-i)j}{k} + 1 = \frac{ij}{k} + 1$. Note that the number of times these tasks are scheduled is the cardinality of the set $\{\ell : \sigma_1(\ell) \leq j \text{ and } \ell \leq i\}$, which translates to cond_{ij} for $\sigma_1 = \sigma$ and σ_2 being the identity permutation. □

Let $\pi = (1, 3, 4, 7, 8, 9, 11, 5, 12, 10, 2, 6)$ be a permutation on 12 elements. The following arguments show that no permutation σ is fair to both the identity permutation and the permutation π.

1. We define a *block* as any contiguous set of elements in the range 1 to 12. We say that σ places an element i in the block $[j, \ell]$.
2. Without loss of generality assume that σ places the element 1 in the block $[1, 6]$.
3. Consider the elements in the following six pairs $\{1, 2\}$, $\{3, 4\}$, $\{5, 6\}$, $\{7, 8\}$, $\{9, 10\}$, and $\{11, 12\}$. If the permutation σ is fair for the identity permutation, then it must place exactly one element of each pair in the block $[1, 6]$. To see this, note that if σ places both elements 1 and 2 in the block $[1, 6]$, then $|\{\ell : \sigma(\ell) \leq 6 \text{ and } \ell \leq 2\}| = 2$, violating $\text{cond}_{2,6}$. Thus only element 1 is in

block $[1,6]$. Inductively, it can be shown that if σ places both elements $2i-1$ and $2i$ for $1 < i \leq 6$ in the block $[1,6]$, then $\text{cond}_{2i,6}$ is violated.

4. A similar argument applied to π implies that σ must place exactly one element of each of the six pairs $\{1,3\}$, $\{4,7\}$, $\{8,9\}$, $\{11,5\}$, $\{12,10\}$, and $\{2,6\}$ in the block $[1,6]$ if σ is fair for π.
5. Arguments 2, 3, and 4 imply that the first half of σ consists of the elements $\{1,4,8,10,11,6\}$ and the second half consists of the elements $\{3,7,9,12,5,2\}$.
6. Again, since σ is fair for the identity permutation, σ must place exactly one of the elements of each of the triplets $\{1,2,3\}$, $\{4,5,6\}$, and $\{7,8,9\}$ in each of the blocks $[1,4]$, $[5,8]$, and $[9,12]$ in order not to violate conditions $\text{cond}_{3,4}$, $\text{cond}_{3,8}$, and $\text{cond}_{3,12}$.
7. Similarly, since σ is fair for π, σ must place exactly one of the elements of the triplet $\{\pi(7),\pi(8),\pi(9)\} = \{11,5,12\}$ in each of the blocks $[1,4]$, $[5,8]$, and $[9,12]$.
8. Since 1 appears in the block $[1,6]$ and both 2 and 3 appear in the block $[7,12]$, it follows from Argument 6 that exactly one of the elements 2 and 3 is placed in the block $[7,8]$ by σ.
9. A similar argument applied to the triplet $\{7,8,9\}$ implies that exactly one of 7 and 9 is placed in the block $[7,8]$ by σ.
10. Last, we examine the triplet $\{\pi(7),\pi(8),\pi(9)\} = \{11,5,12\}$. It follows from Argument 7 that one of 5 and 12 must appear in the block $[7,8]$.

Since σ cannot place three elements in a block of size two, we obtain the contradiction.

The proof of Theorem 15 follows. □

4. Realizing frequencies exactly. In this section we first show how to construct a schedule which realizes any feasible set of frequencies (and hence in particular max-min frequencies) exactly on an interval graph. We prove its correctness and give a bound of $\lceil 4/f_i \rceil$ on the response time for each interval i. We then proceed to introduce a potential function which can be used to yield a bound of $O(n^{\frac{1}{2}+\epsilon})$ on the drift for every interval. An easy consequence of our algorithm is for the special case in which the frequencies are of the form $1/2^i$, the drift can be bounded by 1 and thus the waiting time can be bounded by $\lceil 2/f_i \rceil$. This yields a 2-approximation algorithm with high regularity.

Input to the algorithm a unit of time t and a conflict graph G which is an interval graph. The graph G is represented by a set $I = \{I_1, \ldots, I_n\}$ of intervals on the unit interval $[0,1]$ of the x-coordinate, where $I_i = [i.s, i.e]$ for $1 \leq i \leq n$. Every interval I_i has a frequency $f_i = p_i/q_i$ with the following constraint: $\sum_{I_i \ni x} f_i \leq 1$ for all $0 \leq x \leq 1$. For simplicity, we assume from now on that these constraints on the frequencies are met with equality and that $t \leq T = \text{LCM}\{q_i\}$.

Output of the algorithm an independent set I_t defining the set of tasks scheduled for time t such that the scheduled S, given by $\{I_t\}_{t=1}^{T}$ realizes frequencies f_i.

The algorithm is recursive. Let s_i denote the number of times a task i has to appear in T time units, i.e., $s_i = Tp_i/q_i$. The algorithm has $\log T$ levels of recursion. In the first level we decide on the occurrences of the tasks in each half of the period. That is, for each task we decide how many of its occurrences appear in the first half of the period and how many in the second half. This yields a problem of a recursive nature in the two halves. In order to find the schedule at time t, it suffices to solve the problem recursively in the half which contains t. (Note that in case T is odd one of the halves is longer than the other.) Clearly, if a task has an even number of occurrences in T it would appear the same number of times in each half in order to minimize the

drift. The problem is with tasks that have an odd number of occurrences s_i. Clearly, each half should have at least $\lfloor s_i \rfloor$ of the occurrences. The additional occurrence has to be assigned to one of the halves in a way that both resulting subproblems would still be feasible. This is the main difficulty of the assignment and is solved in the procedure *sweep*.

Procedure sweep. In this procedure we compute the assignment of the additional occurrence for all tasks that have an odd number of occurrences. The input to this procedure is a set of intervals $I_1, \ldots, I_m$ (those having odd s_i's) with the restriction that each clique in the resulting interval subgraph is of even size. (Later, we show how to overcome this restriction.) The output is a partition of these intervals into two sets such that each clique is equally divided among the sets. This is done by a sweep along the x-coordinate of the intervals. During the sweep every interval will be assigned a variable which at the end is set to 0 or 1 (i.e., first half of the period or second half of the period). Suppose that we sweep point x. We say that an interval I_i is *active* while we sweep point x if $x \in I_i$. The assignment rules are stated in Algorithm 3.

ALGORITHM 3. *For each interval I_i that starts at x:*
If the current number of active intervals is even:
A new variable is assigned to I_i (I_i is unpaired*).*
Otherwise; the current number of active intervals is odd:
I_i is paired to the currently unpaired interval I_j, and it is assigned the negation of I_j's variable.
Comment: *No matter what value is later assigned to this variable, I_i and I_j will end up in opposite halves.*

ALGORITHM 4. *For each interval I_i that ends at x:*
If the current number of active intervals is even:
Nothing is done.
Otherwise; the current number of active intervals is odd:
If I_i is paired with I_j:
I_j is now paired with the currently unpaired interval I_k. Also, I_j's variable is matched with the negation of I_k's variable.
Comment: *This will ensure that I_j and I_k are put in opposite halves, or equivalently, I_i and I_k are put in the same halves.*
If I_i is unpaired:
Assign arbitrarily 0 *or* 1 *to I_i's variable.*

It will be proven later that these rules ensure that whenever the number of active intervals is even, then exactly half of the intervals will be assigned 0 and half will be assigned 1. We note that since the conflict graph is an interval graph we are assured that when we apply the above rules pairing up arbitrary intervals will not result in a circular dependency of the variables (e.g., $x = y = \bar{x}$).

Recall that we assumed that the size of each clique is even. To overcome this restriction we need the following simple lemma. For $x \in [0, 1]$, denote by C_x the set of all the input intervals (with odd and even s_i's) that contain x; C_x will be referred to as a clique.

LEMMA 18. *The period T is even if and only if $|\{i \ : \ I_i \in C \wedge s_i \text{ is odd}\}|$ is even for every clique C.*

Proof. Note that

$$\sum_{I_i \in C} f_i = 1 \Rightarrow \sum_{I_i \in C} s_i = T \Rightarrow \sum_{I_i \in C,\ s_i \text{ is odd}} s_i + \sum_{I_i \in C,\ s_i \text{ is even}} s_i = T.$$

Since the second summand is always even, T is even if and only if the first summand is also even. □

This lemma implies that if T is even then the size of each clique in the input to procedure *Sweep* is indeed even. If T is odd, then a dummy interval I_{n+1} which extends over all other intervals and which has exactly one occurrence is added to the set I before calling *sweep*. Again, by Lemma 18, we are sure that in this modified set I the size of each clique is even. This would increase the period by one. The additional time unit will be allotted only to the dummy interval and thus can be ignored. We note that to produce the schedule at time t we just have to follow the recursive calls that include t in their period.

Applying this algorithm to the max-min frequencies yields a polynomial in n algorithm. This is true because there are no more than $\log T$ such calls and because $T = 2^{O(n)}$ for max-min fair frequencies.

LEMMA 19. *The algorithm produces a correct schedule for every feasible set of frequencies.*

Proof. We need to prove that feasibility is maintained with every recursive step. We show that the following invariant is maintained by *sweep.*

> For every x for which the number of active intervals in C_x is even, exactly half of the intervals will be assigned 0 and half will be assigned 1.

This invariant is easily maintained when a new interval starts: if the current number of intervals is odd, then the new interval is paired up with the currently unpaired interval and thus will be scheduled in the opposite half of its partner. The invariant holds also when an interval ends since by our rules whenever an interval ends any two unpaired intervals are immediately paired up.

Now, if T is odd, then a dummy interval is added and hence *sweep* produces a feasible solution for $T + 1$. In this case the algorithm assigns the "smaller" half of T to the half to which *sweep* assigned the dummy interval and feasibility is maintained. □

LEMMA 20. *If the set of frequencies is of the form $1/2^i$ then the resulting schedule is P-fair (i.e., the drift can be bounded by 1) and the response time is bounded by $\lceil 2/f_i \rceil$.*

Proof. Since our algorithm always divides even s_i into equal halves, the following invariant is maintained: in recursion level j, if $s_i > 1$ then s_i is even. Also note that $T = 2^k$, where $\min_i f_i = 1/2^k$ and thus each s_i is of the form $2^{\psi_i - k}$. Now, following the algorithm, it can be easily shown that there is at least one occurrence of task i in each time interval of size $2^{k-\psi_i}$. This implies that $\lfloor \frac{t}{2^{k-\psi_i}} \rfloor \leq \sum_{r=1}^{t} S(i,r) \leq \lceil \frac{t}{2^{k-\psi_i}} \rceil$ and thus P-fairness follows. Since the drift is bounded by one the response time is bounded by $\lceil 2/f_i \rceil$. □

LEMMA 21. *The response time for every interval I_i is bounded by $\lceil 4/f_i \rceil$.*

Proof. Lemma 20 implies the case in which the frequencies are powers of two. Moreover, in case the frequencies are not powers of two, we can virtually partition each task into two tasks with frequencies a_i and b_i, respectively, so that $f_i = a_i + b_i$, a_i is a power of two, and $b_i < a_i$. Then, the schedule of the task with frequency a_i has drift 1. This implies that its response time is at most $\lceil 2/a_i \rceil \leq \lceil 4/f_i \rceil$. □

Remark. It can be shown that the bound of the above lemma is tight for our algorithm.

We summarize the results in this section in the following theorem.

THEOREM 22. *Given an arbitrary interval graph as a conflict graph, the algorithm exactly realizes any feasible frequency vector and guarantees that the response time is at most* $\lceil 4/f_i \rceil$.

4.1. Bounding the drift. Since the algorithm has $O(\log T)$ levels of recursion and each level may increase the drift by one, it follows that the maximum drift is bounded by $O(\log T)$. In this section we prove that we can decrease the maximum drift to be $O(\sqrt{\log T} n^{\epsilon})$ for any fixed ϵ, where n is the number of tasks. By Lemma 13 this implies that in the worst case the drift for max-min fair frequencies is bounded by $O(n^{\frac{1}{2}+\epsilon})$.

Our method to get a better drift is based on the following observation: at each recursive step of the algorithm two sets of tasks are produced such that each set has to be placed in a different half of the time interval currently considered. However, we are free to choose which set goes to which half. We use this degree of freedom to decrease the bound on the drift. To make the presentation clearer we assume that T is a power of two and that the time units are $0, \ldots, T-1$. The arguments can be modified to hold in the general case.

Consider a subinterval of size $T/2^j$ starting *after* time $t_\ell = i \cdot T/2^j - 1$ and ending at $t_r = (i+1) \cdot T/2^j - 1$ for $0 \le i \le 2^j - 1$. In the first j recursion levels we already fixed the number of occurrences of each task up to t_ℓ. Given this number, the drift d_ℓ at time t_ℓ is fixed. Similarly, the drift d_r at time t_r is also fixed. At the next recursion level we split the occurrences assigned to the interval $[t_\ell + 1, t_r]$, thus fixing the drift d_m at time $t_m = (t_\ell + t_r)/2$. Optimally, we would like the drifts after the next recursion level at each time unit $t \in [t_\ell + 1, t_r]$ to be the weighted average of the drifts d_ℓ and d_r. In other words, let $\alpha = (t - t_\ell)/(t_r - t_\ell)$; then we would like the drift at time t to be $\alpha d_r + (1-\alpha) d_\ell$. In particular, we would like the drift at t_m to be $(d_\ell + d_r)/2$. This drift can be achieved for t_m only if the occurrences in the interval $[t_\ell + 1, t_r]$ can be split equally. However, in case we have an odd number of occurrences to split, the drift at t_m is $(d_\ell + d_r)/2 \pm 1/2$, depending on our decision in which half interval to put the extra occurrence. Note that the weighted average of the drifts of all other points changes accordingly. That is, if the new d_m is $(d_\ell + d_r)/2 + x$, for $x \in \{\pm 1/2\}$, then the weighted average in $t \in [t_\ell + 1, (t_r + t_\ell)/2]$ is $\alpha d_r + (1-\alpha) d_\ell + 2\alpha x$, where $\alpha = (t - t_\ell)/(t_r - t_\ell) \le 1/2$, and the weighted average in $t \in [(t_r + t_\ell)/2 + 1, t_r]$ is $\alpha d_r + (1-\alpha) d_\ell + 2(1-\alpha)x$, where $\alpha = (t - t_\ell)/(t_r - t_\ell) > 1/2$.

Consider now the two sets of tasks S_1 and S_2 that we have to assign to the two subintervals (of the same size) at level k of the recursion. For each of the possible two assignments, we compute a "potential" based on the resulting drifts at time t_m. For a given possibility let $D[t_m, i, k]$ denote the resulting drift of task i at t_m after k recursion levels. Define the potential of t_m after k levels as $POT(t_m, k) = \sum_{i=1}^{n} D(t_m, i, j)^{\phi}$ for some fixed even constant ϕ. We choose the possibility with the lowest potential. We now prove that using this policy the drift of any task after $\log T$ steps is bounded by $O(\sqrt{\log T} \cdot n^{\frac{1}{\phi}})$.

Consider a time t and a task i. The drift of task i at t is the outcome of at most $\log T$ recursion levels. Define the drift of task i at t after k levels, denoted $D(t, i, k)$, as the weighted average drift at t given the fixed drifts after k levels. It is easy to see that the initial drift is zero, and the final weighted average drift is the actual drift at t. Also, in each level the drift may either stay the same (in case we have to split an even number of occurrences of task i) or is changed by $\pm x$ where $0 \le x \le 1/2$. Note that x is positive if and only if the change in the drift at the current median point closest to t is $+1/2$. We extend the definition of potentials to all time points t in the

obvious way; that is, $POT(t,k) = \sum_{i=1}^{n} D(t,i,k)^{\phi}$. We show that the potential after $\log T$ levels is bounded by $O(T^{\phi/2} \cdot n)$. This implies the desired bound on the drift of each task at t since the potential is the sum of the drifts to the power of ϕ.

LEMMA 23. *For all* $0 \le t \le T-1$, *and all* $1 \le k \le \log T$,

$$POT(t,k) \le POT(t,k-1) + c \cdot \sum_{i=1}^{n} D(t,i,k-1)^{\phi-2}$$

for some constant c.

Proof. The increment of the potential at time t at the kth level is bounded by the maximum over all disjoint sets $S_1, S_2 \subset \{1,\dots,n\}$ such that $|S_1| = |S_2|$ of

$$\begin{aligned}\min_{S_1,S_2} \Bigg\{ & \sum_{i\in S_1} [D(t,i,k-1)+x]^{\phi} + \sum_{i\in S_2} [D(t,i,k-1)-x]^{\phi}, \\ & \sum_{i\in S_2} [D(t,i,k-1)+x]^{\phi} + \sum_{i\in S_1} [D(t,i,k-1)-x]^{\phi} \Bigg\} \\ - & \sum_{i\in S_1\cup S_2} [D(t,i,k-1)]^{\phi}\end{aligned}$$

for some $0 \le x \le 1/2$. Since the minimum is always bounded by the average, the change is bounded by

$$\frac{1}{2}\left\{ \sum_{i\in S_1\cup S_2} [D(t,i,k-1)+x]^{\phi} + [D(t,i,k-1)-x]^{\phi} - 2[D(t,i,k-1)]^{\phi} \right\}.$$

Finally, the maximum over all disjoint sets $S_1, S_2 \subset \{1,\dots,n\}$ such that $|S_1| = |S_2|$ is achieved for $S_1 \cup S_2 = \{1,\dots,n\}$, and it is $O(\sum_{i=1}^{n} [D(t,i,k-1)+x]^{\phi-2})$. ∎

LEMMA 24. *For all* $0 \le t \le T-1$, *and all* $0 \le k \le \log T$,

$$\sum_{i=1}^{n} [D(t,i,k)]^{\phi-2} \le (c \cdot \log T)^{\frac{\phi}{2}-1} \cdot n,$$

where c *is the constant of Lemma* 23.

Proof. To obtain a contradiction assume that there exists $0 \le t \le T-1$ and $0 < k \le \log T$ for which the bound does not hold. Consider the minimum such k. By Lemma 23 and the minimality of k, we get that $POT(t,k) \le POT(t,k-1) + c \cdot \sum_{i=1}^{n} D(t,i,k-1)^{\phi-2}$. Reapplying Lemma 23 and since the function $D(t,i,k)$ is increasing in k we get $POT(t,k) \le kc \cdot \sum_{i=1}^{n} D(t,i,k-1)^{\phi-2}$. Finally by the minimality of k, $POT(t,k) \le kc \cdot (c \cdot \log T)^{\frac{\phi}{2}-1} \cdot n = c^{\frac{\phi}{2}} \cdot (\log T)^{\frac{\phi}{2}-1} \cdot n \cdot k$. By our definition $POT(t,k) = \sum_{i=1}^{n} D(t,i,k)^{\phi}$. By Hölder inequality

$$\sum_{i=1}^{n} D(t,i,k)^{\phi} \ge n \left(\frac{\sum_{i=1}^{n} D(t,i,k)^{\phi-2}}{n} \right)^{\frac{\phi}{\phi-2}}.$$

However, by our assumption

$$n \left(\frac{\sum_{i=1}^{n} D(t,i,k)^{\phi-2}}{n} \right)^{\frac{\phi}{\phi-2}} > n \left(\frac{(c \cdot \log T)^{\frac{\phi}{2}-1} n}{n} \right)^{\frac{\phi}{\phi-2}} = (c \cdot \log T)^{\frac{\phi}{2}} \cdot n.$$

Combining the two inequalities we get

$$(\log T)^{\frac{\phi}{2}} < (\log T)^{\frac{\phi}{2}-1} \cdot k.$$

But this inequality implies that $k > \log T$, which is a contradiction. □

THEOREM 25. *The maximum drift is bounded by* $O(\sqrt{\log T} \cdot n^{\epsilon})$ *for any fixed* ϵ.

Proof. By Lemmas 23 and 24, the potential $POT(t, \log T)$ for all $1 \leq t \leq T$ is bounded by $\log T \cdot O((\log T)^{\frac{\phi}{2}-1} \cdot n) = O((\log T)^{\frac{\phi}{2}} \cdot n)$. This implies the bound on each drift, since the potential is the sum of the drifts to the power of ϕ. The constant ϵ is chosen to be $\frac{1}{\phi}$. □

5. Realizing frequencies rigidly. In this section we show how to construct a schedule that 12-approximates any feasible frequency vector in a *rigid* fashion on an interval graph. We reduce our rigid schedule problem to the dynamic storage allocation problem. The dynamic storage allocation problem is defined as follows. We are given objects to be stored in a computer memory. Each object has two parameters: (i) its size, that is, the number of cells needed to store it, and (ii) the time interval in which it should be stored. Each object must be stored in adjacent cells. The problem is to find the minimal size memory that can accommodate at any given time all of the objects that are needed to be stored at that time. The dynamic storage allocation problem is a special case of the multicoloring problem on interval graphs defined below.

A *multicoloring* of a weighted graph G with the weight function $w : V \to \mathcal{N}$ is a function $F : V \to 2^{\mathcal{N}}$ such that (i) for all $v \in V$ the size of $F(v)$ is $w(v)$, and (ii) if $(v, u) \in E$ then $F(v) \cap F(u) = \emptyset$. The multicoloring problem is to find a multicoloring with minimal number of colors. This problem is known to be an NP-Hard problem [GJ79].

Two interesting special cases of the multicoloring problem are when the colors of a vertex must be either contiguous or "spread well" among all colors. We call the first case the cont-MC problem and the second case the spread-MC problem. More formally, in a solution to cont-MC if $F(u) = \{x_1 < \cdots < x_k\}$, then $x_{i+1} = x_i + 1$ for all $1 \leq i < k$. Whereas in a solution to spread-MC that uses T colors, if $F(u) = \{x_1 < \cdots < x_k\}$ then (i) k divides T and (ii) $x_{i+1} = x_i + T/k$, for all $1 \leq i < k$, and $x_k + T/k - T = x_1$.

It is not hard to verify that for interval graphs the cont-MC problem is equivalent to the dynamic storage allocation problem described above. Simply associate each object with a vertex in the graph and give it a weight equal to the number of cells it requires. Put an edge between two vertices if their time intervals intersect. The colors assigned to a vertex are interpreted as the cells in which the object is stored.

On the other hand, the spread-MC problem corresponds to the rigid schedule problem as follows. First, we replace the frequency $f(v)$ by a weight $w(v)$. Let $k(v) = \lceil -\log_2 f(v) \rceil$, and let $k = \max_{v \in V}\{k(v)\}$; then $w(v) = 2^{k-k(v)}$. Clearly, $f(v)/2 \leq w(v)/2^k \leq f(v)$. Now, assume that the output for the spread-MC problem uses T colors, and let the colors of v be $\{x_1 < \cdots < x_k\}$ where $x_2 - x_1 = \Delta$. We interpret this as follows: v is scheduled in times $x_1 + i\Delta$ for all $i \geq 0$. It is not difficult to verify that the resulting schedule is rigid and it 2-approximates the given frequencies.

Although the dynamic storage allocation problem is a special case of the multicoloring problem it is still known to be an NP-Hard problem [GJ79]. Using similar arguments it can be shown that the rigid scheduling problem is also NP-Hard. Therefore, we are looking for an approximation algorithm. In what follows we present an

approximation algorithm that produces a rigid scheduling that 12-approximates the given frequencies. For this we consider instances of the cont-MC and spread-MC problems in which the input weights are powers of two.

DEFINITION 26. *A solution for an instance of* cont-MC *is both* aligned *and* contiguous *if for all* $v \in V$, $F(v) = \{j \cdot w(v), \ldots, (j+1) \cdot w(v) - 1\}$ *for some* $j \geq 0$.

In [Kie91], Kierstead presents an algorithm for cont-MC that has an approximation factor 3. A careful inspection of this algorithm shows that it produces solutions that are both aligned and contiguous for all instances in which the weights are powers of two.

We show how to translate a solution for such an instance of the cont-MC problem that is both aligned and contiguous into a solution for an instance of the spread-MC problem with the same input weights.

For $0 \leq x < 2^k$, let $\pi(x)$ be the k-bit number the binary representation of which is the inverse of the binary representation of x.

PROPOSITION 27. *For* $1 \leq i \leq k$ *and* $0 \leq j < 2^{k-i} = \Delta$, $\{\pi(j2^i), \ldots, \pi(j2^i + 2^i - 1)\} = \{\pi(j2^i), \pi(j2^i) + \Delta, \ldots, \pi(j2^i) + (2^i - 1)\Delta\}$.

This proposition says that an output of cont-MC that uses c colors can be transformed into an output of spread-MC that uses at most $2c$ colors.

Consider an instance of the spread-MC problem in which all the input weights are powers of two. Apply the solution of Kierstead [Kie91] to solve the cont-MC instance with the same input. This solution is both aligned and contiguous and uses at most $3T'$ colors where T' is the number of colors needed by an optimal coloring. Let $T \geq 3T'$ be the smallest power of 2 that is greater than T'. It follows that $T \leq 6T'$. Applying the transformation of Proposition 27 on the output of the solution to cont-MC yields a solution to spread-MC with at most T colors. This in turn yields an approximation factor of at most 12 for the rigid scheduling problem, since $w(v)/T \geq f(v)/2$.

THEOREM 28. *The above algorithm computes a rigid schedule that* 12*-approximates any feasible frequency vector on an interval graph.*

6. Circular-arc graphs. In this section we show how to transform any algorithm $\mathcal{A}$ for computing a schedule that c-approximates any given feasible frequency vector on interval graphs into an algorithm $\mathcal{A}'$ for computing a schedule that $2c$-approximates any given feasible frequencies on circular-arc graphs.

Let $\hat{f}$ be a feasible frequency vector on a circular-arc graph G.

Step 1. Find the maximum clique C in G.

Let $G' = G - C$. Note that G' is an interval graph. Let $\hat{g_1}$ and $\hat{g_2}$ be the frequency vectors resulting from restricting $\hat{f}$ to the vertices of G' and C, respectively. Note that $\hat{g_1}$ and $\hat{g_2}$ are feasible on G' and C, respectively.

Step 2. Using $\mathcal{A}$, find schedules S_1 and S_2 that c-approximate $\hat{g_1}$ and $\hat{g_2}$ on G' and C, respectively.

Step 3. Interleave S_1 and S_2.

Clearly, the resulting schedule $2c$-approximates $\hat{f}$ on the circular-arc graph G. Note also that all the three steps can be computed in polynomial time.

7. Conclusions and future research. In this paper we have introduced a new scheduling problem. It is characterized by the persistence and interdependency of the tasks involved. We have developed new measures that quantify the fairness and regularity of a schedule. We have shown that every conflict graph has a unique max-min fair frequency assignment and that, in general, this assignment is hard even to approximate. However, for perfect graphs, it turns out that max-min fair frequencies

are easy to compute and we have given an algorithm for this purpose. The scheduling algorithms described in this paper exhibit a tradeoff between the accuracy with which given frequencies are realized and their regularity. Furthermore, we have shown that a drift of one (i.e., P-fairness) is not achievable even for simple interval conflict graphs. This can be viewed as an indication that the problem in this paper is inherently more complex than the one considered in [BCPV96].

Many open problems remain. The exact complexity of computing a max-min fair frequency assignment in general graphs is not known, and there is no characterization of when such an assignment is easy to compute. All the scheduling algorithms in the paper use the inherent linearity of interval or circular-arc graphs. It would be interesting to find scheduling algorithms for the wider class of perfect graphs. The algorithm for interval graphs that realizes frequencies exactly exhibits a considerable gap in its drift. It is not clear from which direction this gap can be closed.

Our algorithms assume a central scheduler that makes all the decisions. Both from a theoretical and practical point of view it is important to design scheduling algorithms working in more realistic environments such as high-speed local-area networks and wireless networks (as mentioned in section 1.1). The distinguishing requirements in such an environment include a distributed implementation via a local signaling scheme, a conflict graph which may change with time, and restrictions on space per node and size of a signal. The performance measures and general setting, however, remain the same. A first step toward such algorithms has been recently carried out by Mayer, Ofek, and Yung in [MOY96].

Appendix A. The partial order $\prec$. In this appendix we prove that the relation $\prec$ is a partial order. We first observe that the definition can be restated as $\hat{f} \prec \hat{g}$ if there exists an index i and a threshold f such that $f_i < f \leq g_i$ (the *index* property), and for all $1 \leq j \leq n$, $g_j \geq \min\{f, f_j\}$ (the *threshold* property). The following two claims establish that $\prec$ is a partial order.

CLAIM 29. *The relation $\prec$ is antisymmetric.*

Proof. To obtain a contradiction assume that there exist two vectors $\hat{f}$ and $\hat{g}$ such that $\hat{f} \prec \hat{g}$ and $\hat{g} \prec \hat{f}$. This implies that there exist two indices i and ℓ and two thresholds f and g such that

1. $f_i < f \leq g_i$, and for all $1 \leq j \leq n$, $g_j \geq \min\{f, f_j\}$;
2. $g_\ell < g \leq f_\ell$, and for all $1 \leq j \leq n$, $f_j \geq \min\{g, g_j\}$.

Since $g_\ell \geq \min\{f, f_\ell\}$, $f_\ell > g_\ell$, and $g > g_\ell$, it follows that $g > f$. Similarly, since $f_i \geq \min\{g, g_i\}$, $g_i > f_i$, and $f > f_i$, it follows that $f > g$. We get the contradiction. □

CLAIM 30. *The relation $\prec$ is transitive.*

Proof. Suppose that $\hat{f} \prec \hat{g}$ and $\hat{g} \prec \hat{h}$. We show that $\hat{f} \prec \hat{h}$. Since $\hat{f} \prec \hat{g}$ and $\hat{g} \prec \hat{h}$ there exist two indices i and ℓ and two thresholds f and g such that

1. $f_i < f \leq g_i$, and for all $1 \leq j \leq n$, $g_j \geq \min\{f, f_j\}$;
2. $g_\ell < g \leq h_\ell$, and for all $1 \leq j \leq n$, $h_j \geq \min\{g, g_j\}$.

We choose $h = \min\{f, g\}$ as the threshold for $\hat{f} \prec \hat{h}$. Now, for all $1 \leq j \leq n$,

$$h_j \geq \min\{g, g_j\} \geq \min\{g, \min\{f, f_j\}\} \geq \min\{\min\{f, g\}, f_j\} \geq \min\{h, f_j\} .$$
