We still have to prove that there exists an index with the desired property. Assume first that $h = f \leq g$; then we choose i as the index and we need to show that $f_i < h \leq h_i$. Since $h = f$ it follows that $f_i < h$. Since $h_i \geq \min\{g_i, g\}$, $h \leq g$, and $g_i \geq f = h$, it follows that $h_i \geq h$. Now assume that $h = g < f$; then we choose ℓ

as the index. Here we need to show that $f_\ell < h \le h_\ell$. Since $g \le h_\ell$ it follows that $h \le h_\ell$. Since $g_\ell \ge \min\{f, f_\ell\}$, $g > g_\ell$, and $h = g < f$, it follows that $h > f_\ell$. ∎

Appendix B. The complete proof of Theorem 5. We complete the proof of Theorem 5 for the case when $\hat{f}$ is not a rational convex combination.

CLAIM 31. *If a frequency vector $\hat{f}$ can be expressed as a convex combination of the independent sets, then $\hat{f}$ is feasible.*

Proof. Suppose that there exist weights $\{\alpha_I\}_{I\in\mathcal{I}}$ such that $\sum_{I\in\mathcal{I}} \alpha_I = 1$ and $\sum_{I\in\mathcal{I}} \alpha_I \chi(I) = \hat{f}$. We show how to obtain a schedule S that realizes the frequency vector $\hat{f}$. For every $k < \infty$, we pick $g_i^{(k)}$ to be a rational number between $f_i - 2^{-k}$ and f_i and apply Claim 7 to construct a schedule A_k of finite length, denoted $T(A_k)$, that realizes the frequency vector $\hat{g^{(k)}}$.

We go on to construct schedules $S_1, S_2, \ldots, S_k$ with the following properties.

Property 1. Schedule S_k has finite length $T(S_k)$.

Property 2. For each task $1 \le i \le n$, schedule S_k achieves a frequency of at least $f_i - 2^{-(k-1)}$ for task i.

Property 3. Schedule S_{k-1} is a prefix of schedule S_k.

Property 4. In the infinite schedule $S_kS_kS_k\cdots$ (i.e., the schedule given by concatenating the schedule S_k infinitely many times), for any task $1 \le i \le n$ and time $t > T(S_k)$, $f_i^{(t)}(S_kS_kS_k\cdots) \ge f_i - 2^{-(k-2)}$. (Recall that $f_i^{(t)}(S)$ is the prefix frequency of task i at time t in schedule S.)

Property 5. For any task $1 \le i \le n$ and time $t > T(S_{k-1})$, $f_i^{(t)}(S_k) \ge f_i - 2^{-(k-3)}$.

We construct the S_k's inductively. The base case S_1 exists trivially (every nonempty schedule satisfies the required properties). Assume the schedules $S_1, \ldots, S_{k-1}$ exist. Schedule S_k is given by the concatenation of n_1 schedulings of S_{k-1} followed by n_2 schedulings of A_k. We now show that under an appropriate choice of n_1 and n_2, the schedule S_k satisfies the above properties. Let D_i be the maximum among the drift of task i in the schedule S_{k-1} and the drift of task i in the schedule A_k. Let $D = \max_i\{D_i\}$. Let

$$n_1 = \left\lceil \frac{2^k D}{4T(S_{k-1})} \right\rceil \text{ and } n_2 = \left\lceil \frac{2n_1 T(S_{k-1})}{T(A_k)} \right\rceil.$$

Property 1. The period of S_k is

$$T(S_k) = n_1 T(S_{k-1}) + n_2 T(A_k)$$

which is finite since n_1 and n_2 are finite.

Property 2. The frequency of task i in S_k is at least

$$\frac{n_1 T(S_{k-1})(f_i - 2^{-(k-2)}) + n_2 T(A_k)(f_i - 2^{-k})}{n_1 T(S_{k-1}) + n_2 T(A_k)}$$

$$= f_i - 2^{-(k-1)} - \frac{n_1 T(S_{k-1}) 2^{-(k-1)} - n_2 T(A_k) 2^{-k}}{n_1 T(S_{k-1}) + n_2 T(A_k)}.$$

We wish to show that the above quantity is at least $f_i - 2^{-(k-1)}$. This simplifies to

$$n_2 \ge \frac{2n_1 T(S_{k-1})}{T(S_k)},$$

a condition which is satisfied by our choice of n_1 and n_2.

Property 3. Since $n_1 \geq 1$, it follows that S_{k-1} is a prefix of S_k.

Property 4. Since S_{k-1} is a prefix of S_k it follows that in the infinite schedule $S_kS_kS_k\ldots$, for any task $1 \leq i \leq n$ and time $t > T(S_k)$,

$$\begin{aligned} f_i^{(t)}(S_kS_kS_k\cdots) &= (f_i - 2^{-(k-1)})T(S_k) + (f_i - 2^{-(k-2)})[t - T(S_k)] - D_i \\ &= (f_i - 2^{-(k-2)})t + 2^{-(k-1)}T(S_k) - D_i. \end{aligned}$$

We wish to show that this is at least $t(f_i - 2^{-(k-2)})$. This condition simplifies to

$$2^{k-1}D_i \leq T(S_k) = n_1T(S_{k-1}) + n_2T(S_k).$$

Once again, the choice of n_1 and n_2 satisfies this condition.

Property 5. For any task $1 \leq i \leq n$ and time $T(S_{k-1}) < t \leq n_1T(S_{k-1})$, Property 4 of schedule S_{k-1} guarantees that $f_i^{(t)}(S_k) \geq f_i - 2^{-(k-3)}$. Now, consider $t > n_1T(S_{k-1})$. The number of times a task i is scheduled in S_k by time t is at least

$$(f - 2^{-(k-2)})n_1T(S_{k-1}) + (f - 2^{-k})(t - n_1T(S_{k-1})) - D_i$$

$$= (f - 2^{-(k-3)})t + 2^{-(k-2)}n_1T(S_{k-1}) + 7 \cdot 2^{-k}(t - n_1T(S_{k-1})) - D_i.$$

We wish to show that this quantity is at least $t(f-2^{-(k-3)})$. This inequality is implied by the condition $4n_1T(S_{k-1}) \geq 2^kD_i$, which is satisfied by the choice of n_1.

We use the sequences $S_1, \ldots, S_k, \ldots$ to define an infinite sequence S (which is essentially the limiting element of the sequence $\{S_i\}$). To determine which independent set to schedule at time t in S, we let k be the smallest index such that $T(S_k) \geq t$. We schedule the independent set scheduled by S_k at time t.

To see that S realizes the desired frequency vector $\hat{f}$, we prove that for every $\epsilon > 0$ there exists $T < \infty$ such that for all $t \geq T$ and for all tasks $1 \leq i \leq n$, $f_i^{(t)}(S) \geq f_i - \epsilon$.

Given $\epsilon > 0$, let k be the minimum integer such that $2^{-(k-2)} \leq \epsilon$ and let $T = T(S_k) + 1$. Given $t \geq T$, let k' be the largest index such that $t > T(S_{k'})$. Clearly, $k' \geq k$. Observe that for any $j < \infty$, S_j is a prefix of S. Thus, the prefix of schedule S up to time t is a prefix of $S_{k'+1}$. By Property 5 of $S_{k'+1}$, $f_i^{(t)}(S_{k'+1}) \geq f_i - 2^{-(k'-2)} \geq f_i - 2^{-(k-2)} \geq f_i - \epsilon$. □

Acknowledgment. We would like to thank Don Coppersmith and Moti Yung for many useful discussions.

TIME–SPACE LOWER BOUNDS FOR DIRECTED *st*-CONNECTIVITY ON GRAPH AUTOMATA MODELS*

GREG BARNES† AND JEFF A. EDMONDS‡

Abstract. Directed *st*-connectivity is the problem of detecting whether there is a path from a distinguished vertex s to a distinguished vertex t in a directed graph. We prove time–space lower bounds of $ST = \Omega(\frac{n^2 \log n}{\log(n \log n/S)})$ and $S^{\frac{1}{2}}T = \Omega(m(n \log n)^{\frac{1}{2}})$ for directed *st*-connectivity on Cook and Rackoff's jumping automaton for graphs (JAG) model [*SIAM J. Comput.*, 9(1980), pp. 636–652], where n is the number of vertices and m the number of edges in the input graph, S is the space, and T the time used by the JAG. These lower bounds are simple and elegant, they approach the known upper bound of $T = O(m)$ when S approaches $\Theta(n \log n)$, and they are the first time–space tradeoffs for JAGs with an unrestricted number of jumping pebbles.

1. Introduction.

The *st*-connectivity problem is a fundamental one in computational complexity theory. The *st*-connectivity problem for *directed* graphs (STCON) is the prototypical complete problem for nondeterministic logarithmic space [20]. Both STCON and the corresponding problem for undirected graphs, USTCON, are DLOG-hard—any problem solvable deterministically in logarithmic space can be reduced to either problem [16, 20]. Understanding the complexity of *st*-connectivity is, therefore, a key to understanding the relationship between deterministic and nondeterministic space bounded complexity classes. For example, showing that there is no deterministic logarithmic space algorithm for directed connectivity would separate the classes DSPACE($\log n$) and NSPACE($\log n$), while devising such an algorithm would prove that DSPACE($f(n)$) = NSPACE($f(n)$) for any constructible $f(n) = \Omega(\log(n))$ [20]. Unfortunately, determining the complexity of STCON remains a difficult open problem. In this paper we devise *time–space tradeoffs* for STCON, that is, bounds on the *simultaneous* time and space requirements of algorithms for directed connectivity. Such tradeoffs are an important step toward solving the complexity of STCON. Time–space tradeoffs are also important in their own right, since they give more insight into the resource requirements of a problem or class of problems than a bound on time or space alone.

Proving lower bounds on the time or space requirements of STCON for a general model of computation, such as a Turing machine, is beyond the reach of current techniques. Thus, it is natural to consider a *structured* model [9] whose basic operations are based on the structure of the graph, as opposed to being based on the bits in the

graph's encoding. A natural structured model for the problem of *st*-connectivity is the *jumping automaton for graphs*, or *JAG*, introduced by Cook and Rackoff [11]. A JAG moves a set of pebbles on the graph. There are two basic operations—moving a pebble along a directed edge in the graph and jumping a pebble from its current location to the vertex occupied by another pebble. Although the JAG model is structured, it is not weak. In particular, it is general enough that most known deterministic algorithms for graph connectivity can be implemented on it. Poon [18] introduces the more powerful node-named JAG (*NNJAG*), an extension of the JAG model where the computation is allowed to depend on the names of the nodes on which the pebbles are located.

Cook and Rackoff [11] prove a lower bound of $\Omega(\log^2 n/\log\log n)$ on the space required for a JAG to compute directed *st*-connectivity (STCON). Berman and Simon [8] extend this result to randomized JAGs, and Poon [18] extends it to a probabilistic version of the NNJAG. Tompa [23] shows lower bounds on the product of the time and space needed when using certain natural approaches to solve STCON. Many time–space lower bounds have been proved for *undirected st*-connectivity (USTCON) on various weak versions of the JAG model [7, 10, 11]. Edmonds was the first to prove a time–space lower bound for USTCON on the unrestricted JAG model [13].

The standard algorithms for STCON, breadth- and depth-first search, run in optimal time $\Theta(m+n)$ and use $\Theta(n\log n)$ space. At the other extreme, Savitch's theorem [20] provides a small space ($\Theta(\log^2 n)$) algorithm that requires time exponential in its space bound (i.e., time $n^{\Theta(\log n)}$). Barnes et al. [3] show the first sublinear space, polynomial time algorithm for STCON. The algorithm runs in time $2^{O(\log^2(n/S))}\cdot n^3$ given space S. All of these algorithms can be implemented on the standard JAG [11, 19]. Using the NNJAG's ability to access the names of the nodes in the graph, Poon [18] shows how to implement Immerman's and Szelepcsényi's nondeterministic $O(\log n)$-space algorithm for directed *st*-nonconnectivity [15, 22] on a nondeterministic NNJAG. It is not clear that this algorithm can be implemented on a standard nondeterministic JAG.

The paper proves lower bounds of $ST=\Omega(\frac{n^2\log n}{\log(n\log n/S)})$ and $S^{\frac{1}{2}}T=\Omega(m(n\log n)^{\frac{1}{2}})$ for STCON on the JAG model, where $S\le 2n\log n$ is the space and T the time used by a JAG. The first bound is proved on directed graphs with outdegree at most three. Neither bound puts a restriction on the number of states used by the JAG. These lower bounds approach the known upper bound of $T=O(m)$ when S approaches $\Theta(n\log n)$ and are the first time–space tradeoffs for JAGs with an unrestricted number of jumping pebbles. An earlier version of this paper [4] proved a bound of $S^{\frac{1}{3}}T=\Omega(m^{\frac{2}{3}}n^{\frac{2}{3}})$ on the more powerful NNJAG model. This bound has since been improved to $T=2^{\Omega(\log^2(n/S))}$ for most S by Achlioptas, Edmonds, and Poon [1] and Edmonds and Poon [14], matching the previously mentioned upper bound of Barnes et al. [3]. Even though the bounds of the current paper are weaker than those in Edmonds and Poon, the results are still worth studying, because they apply to JAGs with an infinite number of states, because it is more likely they can be extended to the USTCON problem and because they are simple and elegant. In addition, this paper strengthens the model in two ways. Hence, technically speaking, the results here are not subsumed by the results of Edmonds and Poon.

In the following section, we formally define the JAG model. In section 3, we describe the families of *layered* and *comb graphs*, the graphs we use to prove our lower bounds. In section 4 we prove the $ST=\Omega(\frac{n^2\log n}{\log(n\log n/S)})$ and $S^{\frac{1}{2}}T=\Omega(m(n\log n)^{\frac{1}{2}})$

lower bounds for the JAG model. Finally, section 5 presents some notes and a discussion of future work.

For a survey of the graph connectivity problem, see Wigderson [24].

2. Definitions. A JAG [11] is a finite automaton with p distinguishable pebbles and q states. The input to a JAG is an instance of STCON $\langle G, s, t\rangle$, where G is a directed graph on n vertices with maximum outdegree d, and s and t are two distinguished nodes in the graph. For each node in the input graph, the outgoing edges are given a unique label in $\{1, \ldots, d\}$. The JAG begins its computation in state Q_0, with one of the pebbles on the distinguished node t and the other $p-1$ on s.

The program of the JAG may depend nonuniformly on n and on the degree d of the graph. What the JAG does each time step depends on the current state, the list of the pebbles that are on the distinguished vertices s and t, and the partition of the pebbles not on s and t, according to which pebbles are on the same vertices. Based on this information, the automaton changes state and either *walks* or *jumps* a pebble. Walking a pebble consists of selecting a pebble $P \in \{1, \ldots, p\}$ at some vertex v and some label $l \in \{1, \ldots, d\}$ and moving P along the edge out of v with label l. If there is no edge out of v with that label, the pebble stays at v. Jumping a pebble consists of selecting two pebbles $P, P' \in \{1, \ldots, p\}$ and moving P to the node occupied by P'. A JAG that solves STCON enters an accepting state if and only if there is a path from s to t in the input graph.

The space used by a JAG is defined to be $S = p \log_2 n + \log_2 q$, where p is the number of pebbles and q is the number of states. This corresponds to the $\log_2 n$ bits needed to store which of the n nodes a pebble is on and the $\log_2 q$ bits needed to record the current state.

This paper strengthens the definition of the JAG. First, it does not count the number of states as part of the space and hence applies even when the JAG has an arbitrarily large number of states. Second, it allows the pebbles to back up opposite the direction of the directed edge to the node that it came from. This is done by keeping on a stack the path of nodes taken from the source node s to its current position. We will refer to such a JAG as a *many states, stack JAG*.

This new JAG model is provably stronger than the original model. To begin, it is surprising that one can prove lower bounds when the number of states is allowed to be arbitrarily large. These states can be used to remember everything the JAG ever learns about the input graph. Previous study had indicated that as the number of states increases, the time to compute STCON on a JAG becomes linear. Evidently, this is not the case.

In addition, one complaint about JAGs is that they cannot traverse directed trees easily. Cook and Rackoff prove an $\Omega(\log^2 n/\log\log n)$ space for trees. However, a general model of computation is able to traverse trees easily in $O(\log n)$ space by means of depth first search. The JAG is unable to do this because it is unable to move a pebble to the parent of its current location as this would involve walking along the edge in the backward direction. Clearly, the many states, stack JAG is able to do this.

3. Comb and layered graphs. We prove the $ST = \Omega(\frac{n^2 \log n}{\log(n \log n/S)})$ lower bound on a class of graphs known as *layered graphs*. A layered graph consists of l layers (later set to $\log(\frac{n}{p \log(n/p)})$) of vertices, plus the extra distinguished vertex t. The number of vertices in layer i is χ_i and they are denoted $v_{\langle i,1\rangle}, v_{\langle i,2\rangle}, \ldots, v_{\langle i,\chi_i\rangle}$. The first layer is special: it contains $\chi_1 = cn$ vertices for some constant c; these vertices are

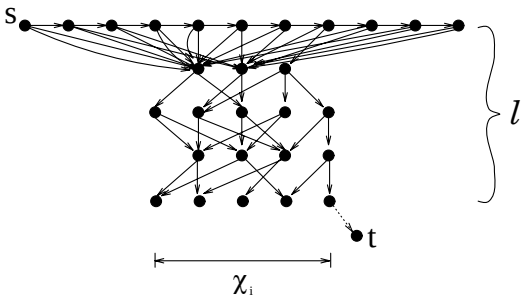

FIG. 1. *A layered graph.*

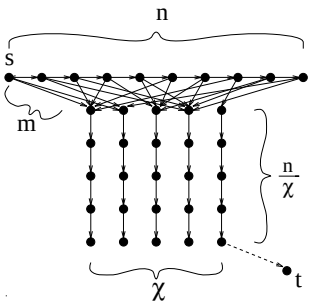

FIG. 2. *A comb graph.*

connected into a directed path using the *crossedges*, $(v_{\langle 1,1\rangle}, v_{\langle 1,2\rangle}), (v_{\langle 1,2\rangle}, v_{\langle 1,3\rangle}), \ldots, (v_{\langle 1,\chi-1\rangle}, v_{\langle 1,\chi_1\rangle})$; and the distinguished vertex s is the first vertex $v_{\langle 1,1\rangle}$ in this layer. Adjacent layers are connected as follows. Every vertex in layers 1 through $l-1$ has two *downedges* connecting it to two vertices on the next layer. We allow double edges, so it is of no concern if some vertex's two downedges go to the same vertex. Finally, there may or may not be an edge from a vertex on layer l to the distinguished vertex t. The edges are labeled in a straightforward way, say with 1 and 2 for the downedges of each node and 3 for the crossedges. See Figure 1 for an example of a layered graph. Note that no vertex in a layered graph has outdegree more than three, so the lower bound does not depend on the graph having a large number of edges.

We prove the $S^{\frac{1}{2}}T = \Omega(m(n\log n)^{\frac{1}{2}})$ lower bound on a different class of graphs known as *comb graphs*. A comb graph, illustrated in Figure 2, is composed of a *back*, χ *teeth*, and the distinguished node t. The back of the comb consists of a directed path of n nodes $v_1, \ldots, v_n$. The first node v_1 is the distinguished node s. The rth tooth consists of the directed path $u_{\langle r,1\rangle}, \ldots, u_{\langle r,l\rangle}$. The length of each tooth will be $l = \frac{n}{\chi}$ so that the total number of nodes in a comb graph is $2n+1$.

There are m $(\geq n)$ directed *connecting edges* $e_1, \ldots, e_m$ each going from a back node v_i to the top of one of the teeth in such a way that the outdegree of any two back nodes can differ by at most 1. The outdegree of the graph is then $\lceil \frac{m}{n} \rceil + 1$. More formally, for $j \in \{1, \ldots, m\}$, the connecting edge e_j is the $\lceil \frac{j}{n} \rceil$th edge emanating from back node $v_{1+(j-1) \bmod n}$ and has label $\lceil \frac{j}{n} \rceil$. We allow double edges, so it is of no concern if two edges from a back node go to the same tooth. If there is to be a directed path from s to t, then the node t is attached to the bottom of at least one of the teeth.

4. Lower bounds for JAGs. Intuitively, solving STCON for layered graphs is difficult because there are $cn \cdot 2^l$ possible paths from s to vertices on layer l. The JAG must potentially check each such path before it can be sure whether t is not connected to s. Of course, these paths will overlap in many places, but because the model is allocated a bounded amount of space, it is difficult for it to "remember" which subpaths have been traversed already. Therefore, many subpaths must be traversed many times before the JAG is sure they have all been traversed. Similarly, it is difficult for a JAG to "remember" which teeth in a comb graph have been traversed, so some teeth may get traversed many times before the JAG is sure that they all have been traversed.

There are two basic approaches to computing STCON on layered graphs. The first is the brute force approach. For each path from s to layer l, the JAG walks a pebble down the path. This requires at least $cn \cdot 2^l$ time steps.

The second approach is to learn enough about the downedges between the various layers, so that the subpaths starting at a vertex on layer i, for $i \in \{2, \ldots, l-1\}$, need to be traversed only once. For example, the JAG could move two pebbles to layer $i-1$ and then move the pebbles down two downedges, e and e', to layer i. If the pebbles collide, then e and e' point to the same vertex on layer i. With this knowledge, the JAG can avoid traversing all subpaths that begin with e', as long as it traverses all subpaths that begin with e. We show below that this strategy is not effective unless the JAG computes for at least $(\chi_i - 1)^2/(p-1)$ steps. In particular, if less time is used, there is a layered graph such that whenever the JAG moves two pebbles down two different edges to some layer, the pebbles never collide.

THEOREM 1. *Any many states, stack JAG that solves* STCON *on graphs with n vertices using p pebbles requires time $\Omega(\frac{n^2}{p \log(n/p)})$ (where the* log *on the bottom is at least* 1).

Since the space S used by a JAG is defined to be at least $p \log n$, the time–space tradeoff $ST = \Omega(\frac{n^2 \log n}{\log(n \log n/S)})$ follows. Note that the theorem sets no limit on the number of states in the JAG.

Proof. We will show that to solve STCON on layered graphs of size n, a JAG requires time $\mathrm{Min}(cn \cdot 2^l, c' \frac{n^2}{pl})$ for any $1 \le l \le c''n$ for some constants c, c', and c''. Putting $l = \log(\frac{n}{p \log(n/p)})$, we have $T = \Omega(\frac{n^2}{p \log(n/p)})$.

Suppose by way of contradiction that there is a JAG J that solves STCON on graphs of size n using p pebbles and using less time than the given bound. In order to bound how quickly the JAG can gain information, we will run J for this amount of time on graphs that have many more than n vertices. J is only supposed to run on graphs of size n, but because all the vertices in the input graph except s and t are indistinguishable during the computation of J, it is well defined how the computation would proceed if J were given a larger graph. We cannot expect J to solve STCON on this large graph, but we can run it for T time steps and see what happens.

More formally, the next move taken by a JAG is specified by the transition function. The input to this function is the following information: the current state, the list of the pebbles that are on the distinguished vertices s and t, and the partition of the pebbles not on s and t, according to which pebbles are on the same vertices. Call this information the current *configuration* of a JAG. A computation on an input graph is formally defined to be a sequence of such configurations. Given this definition, we can say that J's computation on two different graphs is identical, even if the graphs have a different number of vertices.

We run J on a set of larger graphs referred to as *k-tree graphs*, one k-tree graph for each $k \in \{1, \ldots, l\}$. A k-tree graph consists of a layered graph with k layers with the addition that each vertex $v_{\langle k,i \rangle}$ on the kth layer is the root of a directed binary tree of depth $l-k+1$, with edges directed down from the root. As with the layered graph, the downedges are labeled 1 and 2 and the crossedges are labeled 3. In addition, each k-tree graph has an isolated vertex t. The distinguished vertex s is defined to be $v_{\langle 1,1 \rangle}$ for every k-tree graph.

We prove by induction that for every $k \in \{1, \ldots, l\}$, there exists a k-tree G_k and a leaf vertex v_* of this graph such that during the computation of the JAG J on G_k, there is never a pebble on the vertex v_*. At the end of the proof, we need to find a graph with n vertices on which the JAG J gives the incorrect answer. We use the k-tree G_l, which is also a layered graph with n vertices, to find such a graph.

For the base case of the induction, $k = 1$, there is only one graph G_1 in the class of 1-trees, consisting of $\chi_1 = cn$ binary trees of depth l. This graph has $cn \cdot 2^l$ leaf vertices. Because JAG J uses fewer than $cn \cdot 2^l$ time steps, there must be some leaf vertex v_* that is never accessed in J's computation on G_1.

We are now ready to fix the number of vertices on each level of the k-tree graphs to be $\chi_i = \mathrm{Min}(2\chi_{i-1}, \sqrt{2(p-1)T_i}+1)$, where T_i is the number of time steps J walks a pebble from layer $i-1$ to layer i during this computation on the 1-tree. For each k, we will find a k tree on which the computation for J is identical as that on the 1-tree. Hence, T_i will be the number of time steps J walks a pebble from layer $i-1$ to layer i in each of these graphs.

For the inductive step, assume there is a $(k-1)$-tree, G_{k-1}, and a leaf v_* in G_{k-1} such that the computation of the JAG J on G_{k-1} never places a pebble on v_*. If χ_i is set to be $2\chi_{i-1}$, then we are done with the induction step, because G_{k-1} is already a k-tree with χ_i vertices at level i. Therefore, assume that $\chi_i = \sqrt{2(p-1)T_i}+1 < 2\chi_{i-1}$.

Think of G_{k-1} as follows. It has $k-1$ layers of a layered graph. Layer k has $2\chi_{i-1}$ vertices, the vertices in the second level of the binary trees rooted at layer $k-1$. Each of these vertices is the root of a directed binary tree of depth $l-k+1$. Denote these $2\chi_{i-1}$ disjoint binary trees by $\mathcal{T}_1, \ldots, \mathcal{T}_{2\chi_{i-1}}$. Denote the downedges going from layer $k-1$ to the roots of these trees by $e_1, \ldots, e_{2\chi_{i-1}}$.

The goal of the inductive step is to produce a k-tree G_k. Think of G_k as follows. Like G_{k-1}, it has $k-1$ layers of a layered graph. We will choose G_k so that G_{k-1} and G_k are identical on the first $k-1$ layers. Like G_{k-1}, G_k will have $2\chi_{i-1}$ downedges $e_1, \ldots, e_{2\chi_{i-1}}$ going from layer $k-1$ to layer k. Layer k of the k-tree, however, has only χ_i vertices, which are the roots of χ_i directed binary tree of depth $l-k+1$. Denote these χ_i binary trees by $\mathcal{T}'_1, \ldots, \mathcal{T}'_{\chi_i}$. What remains to be chosen in order to specify G_k are the connections between the downedges $e_1, \ldots, e_{2\chi_{i-1}}$, and the trees $\mathcal{T}'_1, \ldots, \mathcal{T}'_{\chi_i}$. These connections can be specified by choosing a partition of the trees $\mathcal{T}_1, \ldots, \mathcal{T}_{2\chi_{i-1}}$ into χ_i groups, $\mathcal{S}_1, \ldots, \mathcal{S}_{\chi_i} \subseteq \{\mathcal{T}_1, \ldots, \mathcal{T}_{2\chi_{i-1}}\}$. For $i \in \{1, \ldots, 2\chi_{i-1}\}$ and $h \in \{1, \ldots, \chi_i\}$, if $\mathcal{T}_i \in \mathcal{S}_h$, then the downedge e_i is connected to the root of the tree $\mathcal{T}'_h$ in the graph G_k. This can be thought of as collapsing the trees in the group $\mathcal{S}_h$ into the one tree $\mathcal{T}'_h$. See Figure 3.

We want to find a partition $\mathcal{S}_1, \ldots, \mathcal{S}_{\chi_i}$ with the property that the computation on the corresponding graph G_k is identical to that on G_{k-1}. Below, we show how to find a partition with the following property: for any two trees $\mathcal{T}_i$ and $\mathcal{T}_j$, if there is ever a time in the computation of J on G_{k-1} when one pebble is in $\mathcal{T}_i$ and another pebble is in $\mathcal{T}_j$, then these two trees will be in different groups in the partition. If this property is preserved, we can show that the sequence of configurations in the

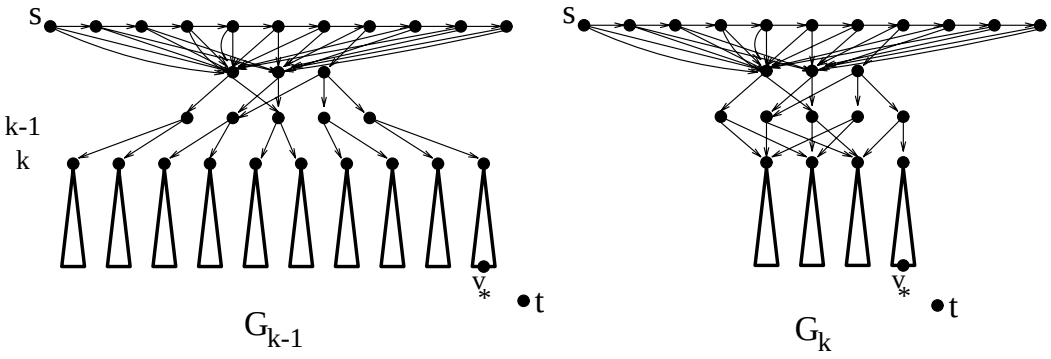

FIG. 3. *Collapsing the trees in G_{k-1} to form G_k.*

computation of J on G_{k-1} is the same as the sequence in the computation of J on a graph G_k. One difference between G_{k-1} and G_k is that in G_{k-1} the vertices in layer k all have indegree one. But the JAG model is defined so that it has no access to the indegree of a vertex. It is not hard to see that if the two computations were to deviate, the first deviation would occur because two pebbles collide in G_k that do not collide in G_{k-1}. To be more precise, if the two computations were to deviate, in the computation on G_k, one pebble must enter a tree T'_h via the downedge e_i, another pebble must enter the same tree via a different downedge e_j, and within this tree the two pebbles must meet. In the computation on G_{k-1}, which is the same up to this point, one pebble would enter the tree $\mathcal{T}_i$ via the downedge e_i, the other pebble would enter a different tree $\mathcal{T}_j$ via the downedge e_j, and clearly, these pebbles would not meet. Hence, the partition of the pebbles according to which pebbles are on the same vertices becomes different for the two computations. However, if we find a partition of the trees $\mathcal{S}_1, \ldots, \mathcal{S}_{\chi_i}$ with the desired property, such an event is not possible. It would mean that at some point during the computation on G_{k-1}, there is a pebble in the tree $\mathcal{T}_i$ and at the same time there is a pebble in the tree $\mathcal{T}_j$. By the property of the partition, these trees would be in different groups, e_i and e_j would be connected to different trees in G_k, and the pebbles entering these trees would not meet. It follows that the two sequences of configurations are the same.

The next step is to explain how a partition $\mathcal{S}_1, \ldots, \mathcal{S}_{\chi_i} \subseteq \{\mathcal{T}_1, \ldots, \mathcal{T}_{2\chi_{i-1}}\}$ with this property is found. Run the JAG J on the graph G_{k-1}, while maintaining an undirected graph H with vertex set $\{\mathcal{T}_1, \ldots, \mathcal{T}_{2\chi_{i-1}}\}$. The undirected edge $\{\mathcal{T}_i, \mathcal{T}_j\}$ is added to H if there is ever a time during the computation when one pebble is in the tree $\mathcal{T}_i$ and another pebble is in the tree $\mathcal{T}_j$.

We claim that H will contain at most $(p-1)T_i$ edges. A new edge can only be added to H if a pebble moves into some tree $\mathcal{T}_i$, i.e., a pebble is moved from layer $i-1$ to layer i. By definition, T_i is the number of such moves. During such a move, only one pebble is allowed to move. There are only $p-1$ other pebbles, so there are at most $p-1$ trees $\mathcal{T}_j$ already containing pebbles. Therefore, at most $p-1$ edges can be added to H at this step, one edge for each possible pair $\{\mathcal{T}_i, \mathcal{T}_j\}$. The following lemma shows that the chromatic number of H is then at most $\chi_i - 1$.

LEMMA 1. *Every undirected graph with no more than E edges has chromatic number at most $\sqrt{2E}$.*

H has at most $(p-1)T_i$ edges. Hence, by the lemma, it has chromatic number at most $\sqrt{2(p-1)T_i} = \chi_i - 1$.

Proof. Fix a graph. At most $\sqrt{2E}$ vertices have degree at least $\sqrt{2E}$. Give each of them its own color. The remaining vertices can be colored with the same $\sqrt{2E}$ colors—each vertex in turn is given a color that has not been assigned to one of its fewer than $\sqrt{2E}$ neighbors. □

Because H has chromatic number no more than $\chi_i - 1$, the vertices $\{\mathcal{T}_1, \ldots, \mathcal{T}_{2\chi_{i-1}}\}$ can be partitioned into $\chi_i - 1$ groups $\mathcal{S}_1, \ldots, \mathcal{S}_{\chi_i - 1}$ such that no edge of H has both ends in the same group. It follows that this partition has the required property.

To complete the induction step, we must find a leaf vertex of the k-tree that is never visited during the computation by J on the graph. Let $\mathcal{T}_*$ be the tree of G_{k-1} containing the leaf vertex v_*. Delete $\mathcal{T}_*$ from the group $\mathcal{S}_h$ that contains $\mathcal{T}_*$ and form a new group $\mathcal{S}_{\chi_i}$ containing only $\mathcal{T}_*$. This new partition also has the required property. Consider the leaf vertex of $\mathcal{T}'_*$ corresponding to the leaf vertex v_* of $\mathcal{T}_*$. The k-tree G_k defined by this new partition has the property that the only way to get from s to this leaf vertex is to traverse the downedge e_* and then to follow the path through the tree to the leaf. We can prove inductively that this path is unique and is defined by the same sequence of labeled edges in both G_{k-1} and G_k. Hence, it is reasonable to denote both the leaf vertex of G_{k-1} and this leaf vertex of G_k by v_*.

By the induction hypothesis, the computation of J on G_{k-1} never reaches the vertex v_*. By the stated property of the partition, the computation on G_k is identical to that on G_{k-1}. The same sequence of labels that must be traversed to reach v_* in G_k must be traversed to reach v_* in G_{k-1}. It follows that the computation on G_k never reaches the vertex v_*. This completes the inductive step.

After collapsing the k-tree graphs at each layer, we obtain a layered graph G_l. We claim that this graph contains at most n vertices. The number of vertices is $N = \sum_{i=1..l} \chi_i \le cn + \sum_{i=2..l} \sqrt{2(p-1)T_i} + 1$, where $\sum_{i=2..l} T_i = T \le c' \frac{n^2}{pl}$ is the total number of time steps. N is maximized when all the T_i's are equal to $\frac{T}{l-1}$. This gives $N \le cn + \sum_{k=2..l} \sqrt{2(p-1)c' \frac{n^2}{pl(l-1)}} + 1 \le cn + \sqrt{2c'}n + l - 1$, which is at most n for the appropriate choice of c, c', and c''.

By the induction proof, we know that there is a leaf vertex v_* in G_l that never contains a pebble during the computation of J. Let G'_l be the same graph as G_l except that there is a directed edge from the leaf v_* to the distinguished vertex t. Because J never places a pebble on vertex v_*, it can never detect whether there is an outgoing edge from v_* to t. Therefore, J's computation is the same on both G_l and G'_l, and hence J gives an incorrect answer for one of the graphs. Note that pebbles located on vertex t do not give the JAG any information about incoming edges. In fact, because t has no outgoing edges, pebbles on t can only move by jumping.

We now prove the second bound of $S^{\frac{1}{2}}T = \Omega(m(n \log n)^{\frac{1}{2}})$ for JAGs, using the comb graphs defined in section 3. Again, there are two basic approaches to computing STCON on comb graphs. One is the brute force approach. For each connecting edge, the JAG walks a pebble to the bottom of the tooth attached to it. This requires $m \times l$ time steps and two pebbles. The other approach is to learn enough about which connecting edges are attached to the same teeth, so that no tooth needs to be traversed more than once. The second approach requires $\Omega(\frac{\chi m}{p})$ time steps. This is proved by reducing the following *partition game* to the problem.

The partition game is parameterized by m, χ, and μ. The input consists of a partition of the edges $e_1, \ldots, e_m$ into χ nonempty groups. The player is able to specify two edges and query whether they are in the same group in the partition. The game is over when the player has determined a set C of μ or fewer edges that covers

the χ groups of the input partition; i.e., for each group, there is an edge in the group that is included in C.

LEMMA 2. *There are partitions for which the partition game requires at least* $\frac{1}{2}(\chi-1)(m-\mu)$ *queries.*

An upper bound of χm is easy for completely determining the partition. Query for each edge e_i whether e_1 and e_i are in the same group. These m queries determine all the edges that are in e_1's group in the partition. Delete these edges and repeat the process with the next edge, and so on.

Proof. The proof is by Impagliazzo [25]. The proof uses an adversary. The adversary maintains disjoint groups $P_1,\ldots,P_{\chi-1}\subseteq\{e_1,\ldots,e_m\}$ and an undirected graph H with m nodes, each node representing one of the connecting edges $e_i, 1\le i\le m$. (In the proof below, we refer to the connecting edges as nodes to avoid confusing them with the edges of H.) The adversary adds a node to the group P_r when it fixes the node to be in the rth group of the input partition, and it adds an edge $\{e_i,e_j\}$ to H when it reveals to the player that these nodes are in different groups. The adversary maintains the properties that two adjacent nodes in H are not in the same group and that the degree of every node in H that is not in one of the groups P_r is at most $\chi-2$.

When the player asks a question $\{e_i,e_j\}$ for the first time, the adversary does the following. For each of e_i and e_j, if it is not in some group P_r and has degree $\chi-2$ in H, then it is added to one of the groups that contains none of its neighbors in H. There are $\chi-1$ groups, so by the pigeonhole principle such a group exists. If e_i and e_j are both added to groups, it does not matter if they go into the same group. Now the adversary responds to the question. If e_i and e_j are in the same group, the adversary reveals this information. Otherwise, the adversary answers that e_i and e_j are in different groups and adds the edge $\{e_i,e_j\}$ to H.

A node is not added to a group until $\chi-1$ questions are asked about it. A single query involves two nodes, so $\frac{1}{2}(\chi-1)m'$ queries are required to place m' nodes in groups. Therefore, after $\frac{1}{2}(\chi-1)(m-\mu)-1$ queries, there are at least $\mu+1$ nodes not contained in any group P_r.

Assume the player completes the game with $\frac{1}{2}(\chi-1)(m-\mu)-1$ or fewer queries. At the end of the game, the player must specify a set C of μ nodes that covers each of the χ groups of the input partition. By the pigeonhole principle, there must be a node e_* that is among the $\mu+1$ nodes not contained in any group P_r and is not among the μ nodes in C specified by the player. The adversary then fixes the χth group P_χ to be a singleton group containing only e_*. Each of the nodes that has not yet been added to a group is added to one of the first $\chi-1$ groups that contains none of its neighbors in H (again, since these nodes have $\chi-2$ or fewer neighbors in H, such a group must exist). This defines a partition $P_1,\ldots,P_\chi$ that is consistent with all the answers given by the adversary. The player's set of nodes C must cover the χ groups, but it does not, since e_*, the only node in P_χ, is not in C. □

THEOREM 2. *Any many states, stack JAG that solves* STCON *on graphs with n vertices and m edges using p pebbles requires time $\Omega(mn^{\frac{1}{2}}/p^{\frac{1}{2}})$. We allow multiple edges. Hence, there is no restriction on m at all.*

As noted before, the space S used by a JAG is defined to be at least $p\log n$, so the time–space tradeoff $S^{\frac{1}{2}}T=\Omega(m(n\log n)^{\frac{1}{2}})$ follows.

Proof. We will show that to solve STCON on all comb graphs with n back nodes and m connecting edges requires time at least $\mathrm{Min}(\frac{m}{2}\times l, \frac{(\chi-1)(m/2)}{2(p-1)})$. If a JAG has

p pebbles, then setting χ to $n^{\frac{1}{2}}p^{\frac{1}{2}}$ gives the required bound $T = \Omega(mn^{\frac{1}{2}}/p^{\frac{1}{2}})$, since in a comb graph, $l = \frac{n}{\chi}$.

The proof reduces the above partition game to the STCON problem on comb graphs, where the parameter m in the game is the number of connecting edges in the comb graph, the parameter χ is the number of teeth in the comb graph, and the parameter μ is $\frac{m}{2}$. Suppose by way of contradiction that there is a JAG, J, that solves STCON on comb graphs with n back nodes and m connecting edges using p pebbles and in less than the stated time. Given J, we show that a player in the partition game can always beat the bound given in Lemma 2, a contradiction.

The game player beats the bound by simulating the execution of the JAG J on a comb graph G and using this simulation to construct its set C for the game. The graph G corresponds to the input partition in the game by partitioning the connecting edges into χ nonempty groups according to which edges point to which of the χ teeth. Note that the JAG cannot differentiate between the teeth. Hence, there is no particular order on the parts of the partition.

Initially, the game player knows neither the input partition nor the graph G. The player builds G "on the fly" in order to determine the information needed to simulate J's computation. This is done by repeatedly querying the input partition of the game and using the results of these queries to determine the structure of G and hence determine the next steps J will take. As J's computation proceeds, the player associates each pebble that is in a tooth with the connecting edge e_i through which it entered the tooth. If the pebble jumped into the tooth to pebble p_i, then it is associated with the connecting edge e_i that the pebble p_i was associated with when the jump occurred. Whenever there is one pebble associated with the connecting edge e_i and another pebble associated with e_j at the same time, J might learn whether e_i and e_j are connected to the same tooth. When this first happens, the game player queries $\{e_i, e_j\}$ and learns whether they are in the same group. If they are, the player implicitly connects the two connecting edges to the same tooth in the input graph, and if not, it implicitly connects them to two different teeth.

At any time t in the computation, G could be any graph in the set $\mathcal{G}_t$ of comb graphs that are consistent with the information revealed so far by the queries. The game player is able to continue this simulation on the incompletely specified G because J's computation is the same for every graph in $\mathcal{G}_t$. This follows from the following two observations. First, although the indegree of the nodes at the top of the teeth may be different for different graphs in $\mathcal{G}_t$, J has no access to the indegree of nodes. Second, when two pebbles enter teeth via two different connecting edges e_i and e_j, the answers to the queries ensure that they are either in the same tooth for every graph in $\mathcal{G}_t$ or in different teeth for every graph. Thus two pebbles meet during the computation on one of the graphs in $\mathcal{G}_t$ if and only if they meet during the computation on all such graphs.

The goal of the player is to construct the set C that covers the χ groups of the game's partition. Whenever there is a pebble associated with the connecting edge e_i that traverses down to the bottom of the tooth connected to e_i, the game player adds e_i to the set C. Intuitively, J must traverse all the teeth to be sure the input graph is not s-t connected, so the constructed set C must cover all the groups in the input partition to the game.

We now prove that given the JAG J, the player will never make more than $\frac{1}{2}(\chi - 1)(\frac{m}{2}) - 1$ queries during the computation and will add at most $\frac{m}{2}$ edges to C and that these edges will cover all groups in the game's input partition, which

will lead to a contradiction. First, at each step of J's computation only one pebble is allowed to move. This step causes the game player to make a query only if this pebble moves into the tooth attached to some edge e_i while there is another pebble already in a tooth attached to some other edge e_j. There are only $p-1$ other pebbles, so a step causes the game player to make at most $p-1$ queries. Since J uses no more than $\frac{(\chi-1)(\frac{m}{2})}{2(p-1)} - 1$ steps, no more than $\frac{1}{2}(\chi-1)(\frac{m}{2}) - 1$ queries will be made.

Second, the game player will add at most $\frac{m}{2}$ connecting edges to the set C. The number of JAG computation steps required to move a pebble into a tooth via a connecting edge and then to the bottom of the tooth is at least l, the length of the tooth. J's computation proceeds for fewer than $(\frac{m}{2})l$ steps, so this is done for at most $\frac{m}{2}$ connecting edges.

Finally, for every game input partition, the set C constructed by the player will cover all of the groups in the partition. By way of contradiction, suppose that for some partition there is a group P_r in the partition that is disjoint from C, and let the rth tooth be the one whose edges correspond to the group P_r. During the computation of J on G, a pebble can never traverse to the bottom of the rth tooth. If a pebble did, it must have entered the tooth via some connecting edge, and that edge must be in both C and P_r. It follows that a pebble is never on the bottom node $u_{\langle r,l\rangle}$ of this tooth.

Let G' be the same graph as G except that the node t is attached to the bottom of the rth tooth. J's computation is identical on the graphs G and G', because J must have a pebble on node $u_{\langle r,l\rangle}$ in order to know whether there is an outgoing edge from it to t (as noted in the proof of Theorem 1, pebbles located on node t do not give J any information about incoming edges). Because the computation is the same on G and G', the JAG J must give an incorrect answer for one of the graphs. But we assumed that J correctly solves STCON for all these graphs. Therefore, the set C will cover all the groups in the game's input partition. But this contradicts Lemma 2, since then the game player always finishes the game with fewer than the required number of queries. □

5. Open problems. The obvious open problems presented by this work are to improve the STCON lower bounds for the JAG and NNJAG. Subsequent to this work, Achlioptas, Edmonds, and Poon [1] and Edmonds and Poon [14] have shown a lower bound of time $T = 2^{\Omega(\log^2(n/S))}$ given space $S \leq n^{1-\Omega(1)}$ for the probabilistic NNJAG (or $T = 2^{\Omega(\log^2(n/S)/\log\log n)} \times (nS/\log n)^{\frac{1}{2}}$ otherwise). Not only does this greatly improve the current bounds, it shows that the upper bound of Barnes et al. [3] of time $2^{O(\log^2(n/S))} \times n^{O(1)}$ is optimal NNJAG.

There are a few directions in which these results could be extended. First, the small gap of $\log\log n$ between Barnes et al.'s upper bound and Edmonds and Poon's lower bound at the lower end of the space spectrum could be eliminated. Second, the lower or upper bounds for STCON could be improved at the higher end of the space spectrum.

Finally, better lower bounds are needed for the undirected version of s-t connectivity. There is a probabilistic upper bound of $S \cdot T \in m^{1.5}n^{.5}\log^{O(1)} n$ [5] that can be run on a JAG. It is interesting how close our lower bounds are to this upper bound. The current JAG lower bounds for USTCON are weak and only allow a small number of pebbles [13]. Our hope is that the techniques used in this paper can be applied to the undirected version of s-t connectivity. [12] discusses some ideas and difficulties in doing this.

Ultimately, one would like to prove lower bounds for STCON on a general model of computation. Any nontrivial bounds for general models would be a step in this direction. A more modest goal would be to add features to the JAG or NNJAG to make it more general (as Poon added node names to the JAG to devise the NNJAG [18]) and to prove the same bounds on these more general models.

Acknowledgments. We would like to thank Faith Fich for her extensive support and Paul Beame, Al Borodin, Russell Impagliazzo, and Hisao Tamaki for their helpful comments and suggestions. We would also like to thank a referee for adding another factor of $\log n$ to the first lower bound by having a different number of nodes χ_i on each level.

A CHERNOFF BOUND FOR RANDOM WALKS ON EXPANDER GRAPHS*

DAVID GILLMAN†

Abstract. We consider a finite random walk on a weighted graph G; we show that the fraction of time spent in a set of vertices A converges to the stationary probability $\pi(A)$ with error probability exponentially small in the length of the random walk and the square of the size of the deviation from $\pi(A)$. The exponential bound is in terms of the expansion of G and improves previous results of [D. Aldous, *Probab. Engrg. Inform. Sci.*, 1 (1987), pp. 33–46], [L. Lovász and M. Simonovits, *Random Structures Algorithms*, 4 (1993), pp. 359–412], [M. Ajtai, J. Komlós, and E. Szemerédi, *Deterministic simulation of logspace*, in Proc. 19th ACM Symp. on Theory of Computing, 1987].

We show that taking the sample average from one trajectory gives a more efficient estimate of $\pi(A)$ than the standard method of generating independent sample points from several trajectories. Using this more efficient sampling method, we improve the algorithms of Jerrum and Sinclair for approximating the number of perfect matchings in a dense graph and for approximating the partition function of a ferromagnetic Ising system, and we give an efficient algorithm to estimate the entropy of a random walk on an unweighted graph.

1. Introduction.

Let G be a connected undirected graph with positive weights on the edges. We consider the random walk on G, which at each time step chooses an edge leaving the current vertex with probability proportional to the weight on the edge. The random walk converges to a limiting distribution π on the vertices of G.[1] This model is equivalent to a finite reversible Markov chain.

Let A be a subset of vertices of G. We consider the amount of time t_n the random walk spends in A during the first n steps. It is well known that for almost every trajectory of the random walk, the fraction of time spent in A, t_n/n, converges to the limiting probability of A, $\pi(A)$ [Do, Theorem 6.1].

We quantify this rate of convergence. We are concerned with the probability that for a given n-step trajectory of the random walk, t_n/n will deviate by some specified amount from $\pi(A)$ (the *deviation probability*). Theorem 2.1 shows that this probability decays exponentially in the square of the amount of deviation, as a multiple of $1/\sqrt{n}$. This bound is of a similar form to that given by Chernoff [Ch] for the case of independent random variables (a very special case of random walk).

The exponent in the bound of Theorem 2.1 is proportional to the eigenvalue gap of the transition matrix of the random walk, which is directly related to the expansion of G [AM, Ta, Alo, SJ]. The bound also depends on the starting distribution of the random walk, which may introduce a factor of $|G|$. In this case $O(\log|G|)$ random

[1] We are interested in convergence in the following weak sense: let $P^{(k)}$ be the distribution of the random walk after k steps. Then $\frac{1}{n}\sum_{k=1}^{n} P^{(k)} \to \pi$. This holds even when G is bipartite.

walk steps suffice to get a good estimate of $\pi(A)$. When the random walk starts close to the stationary distribution the bound does not depend on $|G|$.

Theorem 2.1 is the first exponential bound on the deviation probability in terms of a computable quantity (in this case the eigenvalue gap). This result implies bounds on all higher moments of the fraction of time spent in A, and it quantifies the rate of convergence to $\pi(A)$ in each L^p norm, $1 \leq p < \infty$ [Kah]. It also sharpens a theorem of Ajtai, Komlós, and Szemerédi [AKS] (see also [CW] and [IZ]), which showed that the probability of a deviation of constant size decays exponentially in n. Aldous [Ald87] bounded the variance of the fraction of time spent in A in terms of the eigenvalue gap. Lovász and Simonovits [LS] gave a similar result for arbitrary measure spaces. Those results give quadratic bounds on the deviation probability via Chebyshev's inequality. Goldreich et al. [G*] have given a bound on the probability of not hitting A in n steps which decays exponentially in $n\pi(A)$.

Theorem 2.1 applies more generally to estimating the expectation of a nonnegative function on the vertices of G. $\pi(A)$ is the expectation of χ_A, the indicator function of A, and Theorem 2.1 states that the fraction of time spent in A is a good estimate of this expectation. We establish the analogous result for estimating the expectation $\mathrm{E}f$ of an arbitrary nonnegative function f on the vertices of G. In this case the bound depends on $\max_x |f(x)|$ as well as on the eigenvalue gap.

Approximation algorithms. Estimating $\pi(A)$ (or in some applications, $\mathrm{E}f$) is a fundamental problem for approximation algorithms in which A and G are exponentially large combinatorial sets such as sets of matchings of a graph [JS89]. The basic strategy is to generate random sample points in G and compute the fraction that are in A. The standard procedure is to use the rapid mixing property of the random walk on G to generate a single nearly random sample point from π. The random walk is repeated to generate the number of independent sample points Chernoff's bound requires [DFK, JS89, LS]. We compare this with the alternative procedure analyzed by Aldous in [Ald87], which was the first to generate a nearly random point in G and then to continue the random walk from that point, sampling every subsequent vertex. This procedure is commonly used in statistical biology and physics, usually without rigorous analysis of its reliability; for convenience we will refer to it as "Aldous's procedure" (AP).

We show in this paper that AP (sometimes in a modified form) requires fewer random walk steps than the standard procedure to ensure the same confidence in the resulting estimate of $\pi(A)$. A little intuition here will show why one would expect this to be the case. Let τ be the "relaxation time" of the random walk, which is the number of steps required to generate a single random point. The standard procedure picks up l sample points by taking τl random walk steps. We may as well assume that these sample points come from a single long random walk on the graph which visits the vertices $x_1, x_2, \ldots$. Then the sample points are $x_\tau, x_{2\tau}, \ldots, x_{l\tau}$. Now consider using AP on the same random walk. The estimate it gives is an average from the (highly dependent) sample points $x_{\tau+1}, x_{\tau+2}, \ldots, x_{l\tau}$. But this estimate is just an average of τ different estimates, each using the standard procedure with $l-1$ samples: for each fixed $i \leq \tau$ the ith estimate uses the sample points $x_{\tau+i}, x_{2\tau+i}, \ldots, x_{(l-1)\tau+i}$. It should not hurt each estimate much that it only samples $l-1$ points instead of l, whereas it should help that τ different (admittedly dependent) estimates are being averaged.

Stating the results more quantitatively, we analyze these procedures within the framework of (β, δ)-approximation algorithms; i.e., algorithms with input parameters

β and δ that with probability $1-\delta$ output an approximation of $\pi(A)$ with relative error β [KL]. We assume throughout that we can efficiently find one point $s \in G$ from which to start a random walk.

The main consequence of Theorem 2.1 for (β, δ)-approximation algorithms is that AP requires $O(\log(1/\pi(s)) + \log(1/\delta)/\beta^2)$ random walk steps. The first term is the relaxation time. The standard procedure (SP) requires $O(\log(1/\pi(s)) \log(1/\delta)/\beta^2)$. The constants in both cases depend on the eigenvalue gap and $\pi(A)$.

Unfortunately, the dependence on $\pi(A)$ favors the standard procedure when $\pi(A)$ is small (often in practice $\pi(A)$ is $O(1/n)$). This is because the bound in Theorem 2.1 is not optimal for small $\pi(A)$ in comparison with either the Chernoff bound for independent random variables or the variance bound of Aldous for Markov chains. For this reason the best procedure when $\pi(A)$ is small is to use AP with δ replaced by a constant, say $1/4$, to repeat this estimate $\log(1/\delta)$ times, and to take the median of the answers. The technique of using the median of several estimates is well known and was introduced by Jerrum, Valiant, and Vazirani in [JVV]. Our analysis of this modified procedure depends on an extension of the variance bound of Aldous.

We present a modified version of an approximation algorithm, due to Jerrum and Sinclair, for evaluating the partition function of a ferromagnetic Ising system. Our new version of the algorithm improves the running time from $O(|E|^3 m^7)$ to $O(|E|^2 m^6)$, where m is the number of vertices and E is the edge set of the system [JS91]. This algorithm makes calls to a (β, δ)-approximation routine for $\mathrm{E}f$ for different functions f. Part of the improved running time of the algorithm comes from replacing the standard sampling procedure by AP. The rest of the improvement comes from the observation that the errors from the different calls to the (β, δ)-approximation routine are independent and cancel one another out to some extent. Dyer and Frieze used the same observation in their algorithm for computing the volume of a convex body in Euclidean n-space [DF].

We are also able to improve an approximation algorithm, due to Jerrum and Sinclair, for counting the number of perfect matchings in a graph. Suppose the graph $H = (V, E)$ has $2m$ vertices. Our new version of the algorithm improves the running time from $O(q^3 m^6 |E| \log^2 m)$ to $O(q^2 m^5 |E| \log m)$, where q is an a priori upper bound on the ratio of the number of matchings with $m-1$ edges to the number of perfect (m-edge) matchings [JS89]. Polynomial bounds on q are known for large classes of graphs; for example, $q(m) = m^2$ for dense bipartite graphs and for regular periodic lattices [JS89, KRS]. Part of the improved running time of our new version of the algorithm comes from implementing AP. The algorithm makes calls to a $(\beta, O(1))$-approximation routine for different sets A. In addition, the new algorithm introduces a strategy of selecting only those sets A for which $\pi(A)$ is not too small. The importance of this is that the running time of the $(\beta, O(1))$-approximation routine depends inversely on $\pi(A)$.

Entropy estimation. In the special case where the edges of G are not weighted, Theorem 2.1 shows that one can compute the entropy of the random walk accurately from a very short realization of it. We view the random walk on G as an information source whose alphabet is the vertex set of G. It is convenient to state the result in this form, although it applies to any labelling of the vertices such that the Markov chain is unifilar. (A *unifilar* Markov chain is one in which each state has nonzero transition probability to at most one state of each label.) If G has constant eigenvalue gap and bounded degree then a good entropy estimate requires only $O(\log |G|)$ steps of the random walk.

This result quantifies the rate of convergence of the classical Shannon–McMillan asymptotic equipartition property [Ash]. The classical result assumes an ergodic information source with entropy H. It says, intuitively, that for large n, roughly 2^{Hn} of the n-bit strings each have probability roughly 2^{-Hn}. For purposes of encoding n-bit blocks of output from the source into blocks of some fixed shorter length greater than Hn, we give a bound on the exponent of the error probability. This is the first bound on the error exponent for fixed-length noiseless source coding in terms of a computable property of the underlying Markov chain. Previous bounds on the error exponent have been based on divergence and retain an asymptotic flavor. Large deviation methods for the source coding problem were used in [Nat, An].

Methods. The proof of Theorem 2.1 begins with Theorem 2.2, due to Höglund, which follows the method of Cramér [Cr] and Chernoff [Ch] of estimating the deviation probability in terms of the moment generating function of the number of visits to A [H, Theorem 5.5] (see also Nagaev [Nag, Theorem 6]). Höglund writes the moment generating function as an expression involving the largest eigenvalue of a perturbation of the transition matrix for the random walk. How hard it is to find a quantitative bound for this expression can depend on the transition matrix. Generally, the eigenvalues of a matrix may vary wildly under small perturbations of the matrix [SS, p. 166]. Höglund was able to use his method to derive a bound similar to Chernoff's for the case of Bernoulli trials (in which the transition matrix has identical rows).

Theorem 2.1 demonstrates the applicability of Höglund's approach to random walks on weighted graphs, where the transition matrix is similar to a symmetric matrix. We first bound the logarithm of the largest eigenvalue of a perturbation of the transition matrix by estimating its second derivative with respect to a perturbation parameter r. This bound uses Cauchy's estimate and the observation that the largest eigenvalue is an analytic function of r [Ahl, Kat]. The first bound leads to a bound on the probability of deviation in terms of r, and Theorem 2.1 follows by optimizing over r.

Overview. In section 2 we state and prove our main theorem. At the end of the section we compare similar recent results due to Kahale [Kah] and Dinwoodie [Di95a, Di95b]. In section 3 we give a general comparison of sampling procedures. There we prove an extension of the variance bound of Aldous (Proposition 3.2). In section 4 we describe an improved version of an approximation algorithm for the partition function of an Ising system, and we summarize our improvements to an algorithm for counting perfect matchings in a graph. Finally, in section 5 we discuss the use of random walks to estimate entropy of an information source generated by a random walk.

2. The main theorem. Let $G = (V, E)$ be a connected undirected graph. Let each edge $\{x, y\}$ in the edge set E be assigned a positive weight w_{xy}. We define the weight w_x of the vertex x by the formula $w_x = \sum_{\{x,y\}\in E} w_{xy}$.

A random walk on such a weighted graph is equivalent to a time-reversible finite Markov chain. The states of the Markov chain are the vertices of the graph. The Markov chain is defined by its *transition matrix* $P = (p_{xy})$; p_{xy} is the probability (independent of time) of moving to state y after entering state x, given by

$$p_{xy} = \begin{cases} \frac{w_{xy}}{w_x} & \text{if } \{x, y\} \in E, \\ 0 & \text{if not.} \end{cases}$$

By the classical theory of nonnegative matrices, the eigenvalues of P are $1 = \lambda_1 >$

$\lambda_2 \geq \cdots \geq \lambda_{|V|} \geq -1$, and $\lambda_{|V|} = -1$ if and only if G is bipartite [Se]. The strict separation of λ_1 and λ_2 follows from the connectedness of G. Let π denote the unique left eigenvector with eigenvalue 1. Properly normalized, $\pi(x) = w_x / \sum_{y \in V} w_y$ for all $x \in V$, and π is a probability distribution. We refer to π as the *stationary distribution*. For all probability distributions $\mathbf{d}$ on V, $\lim_{n\to\infty} \frac{1}{n} \sum_{k=0}^{n-1} P^k \mathbf{d} = \pi$. (When G is not bipartite, we have the stronger property that $P^n \mathbf{d} \to \pi$ for all $\mathbf{d}$.) Let $\epsilon := 1 - \lambda_2$ denote the *eigenvalue gap* of P. The eigenvalue gap is directly related to the expansion of G [AM, Ta, Alo, SJ]. In particular, if G is an expander ϵ will be large.

Let $x_0, x_1, \ldots$ be the sequence of vertices visited by the random walk on G, where x_0 is chosen according to some distribution $\mathbf{q}$ on the vertices. Let $A \subseteq V$. Let χ_A denote the indicator function $\chi_A(x) = 1$ if $x \in A$, and 0 otherwise. Let $t_n := \chi_A(x_1) + \cdots + \chi_A(x_n)$, the number of visits to A in n random walk steps.

We introduce some special notation. Let $\frac{\mathbf{q}}{\sqrt{\pi}}$ denote the vector with entries $\frac{\mathbf{q}}{\sqrt{\pi}}(x) = \frac{\mathbf{q}(x)}{\sqrt{\pi(x)}}$, and let $N_{\mathbf{q}} = \|\frac{\mathbf{q}}{\sqrt{\pi}}\|_2$. Let $\mathbf{1} = (11\cdots1)$ be the vector of all 1's. Logarithms are in base e unless otherwise subscripted.

We now state our main result, a large deviation bound for a random walk on a weighted graph, in terms of the eigenvalue gap.

THEOREM 2.1. *Consider the random walk on a weighted graph $G = (V, E)$ with initial distribution $\mathbf{q}$. Let $A \subseteq V$. Let t_n be the number of visits to A in n steps. For any $\gamma \geq 0$,*

$$\Pr[t_n - n\pi(A) \geq \gamma] \leq (1 + \gamma\epsilon/10n)\, N_{\mathbf{q}} e^{-\gamma^2\epsilon/20n}. \tag{2.1}$$

Remarks. (i) We may write $\mathrm{E}_\pi \chi_A$ for $\pi(A)$ in Theorem 2.1. As we will see, the proof of this theorem uses only that χ_A is a nonnegative function on the vertices of G such that $\|\chi_A\|_\infty \leq 1$. For an arbitrary nonnegative function f on the vertices of G, we may substitute f for χ_A in the definition of t_n. Equation (2.1) becomes

$$\Pr[t_n - n\mathrm{E}_\pi f \geq \gamma] \leq (1 + \gamma\epsilon/10n)\, N_{\mathbf{q}} e^{-(\gamma/\|f\|_\infty)^2\epsilon/20n}. \tag{2.2}$$

(ii) Applying the theorem to $G \setminus A$ gives the same bound on $\Pr[t_n - n\pi(A) \leq -\gamma]$.

Before proving Theorem 2.1, we lay the groundwork for our proof with Theorem 2.2, a simplified version of a result of Höglund [H, Theorem 5.5]. This result follows the strategy of Cramér [Cr] and Chernoff [Ch], which is to estimate the deviation probability in terms of the *moment generating function* $m(r) = \mathrm{E}e^{rt_n}$, evaluated at some $r > 0$. We will see that this strategy reduces the problem of estimating the left-hand side of (2.1) to a problem of analyzing a perturbation of the transition matrix P.

Let $P(r) = PE_r$, where $E_r = \mathrm{diag}(e^{r\chi_A})$ and r is any complex number (we will often restrict r to the nonnegative real line). $P(r)$ is equal to P except that for $j \in A$ the jth column vector of P is multiplied by e^r.

P and $P(r)$ are similar to symmetric matrices. Let M be the (symmetric) weighted adjacency matrix of G: the ijth entry of M is w_{ij} if $\{i, j\} \in \mathrm{E}$ and 0 otherwise. Let $D = \mathrm{diag}(1/w_i)$. Then

$$\begin{aligned} P &= \sqrt{D} S \sqrt{D^{-1}}, \text{ and} \\ P(r) &= \sqrt{DE_r^{-1}}\, S(r) \sqrt{E_r D^{-1}}, \end{aligned} \tag{2.3}$$

where $S := \sqrt{D} M \sqrt{D}$ and $S(r) := \sqrt{DE_r} M \sqrt{DE_r}$ are symmetric. By (2.3) the eigenvalues of $P(r)$ are real for $r \geq 0$, and they are equal to the eigenvalues of $S(r)$;

in this case let $\lambda(r)$ and $\lambda_2(r)$ denote the largest and second largest eigenvalues of $P(r)$, respectively. Note that $P(0) = P$, $\lambda(0) = 1$ (with left eigenvector π^T and right eigenvector $\mathbf{1}$), and $\lambda_2(0) = \lambda_2$. For $r \geq 0$, let the eigenvalue gap of $P(r)$ be denoted by $\epsilon_r = \lambda(r) - \lambda_2(r)$.

THEOREM 2.2. *Consider the random walk on a weighted graph $G = (V, E)$ with initial distribution $\mathbf{q}$. Let $A \subseteq V$. Let t_n be the number of visits to A in n steps. For any $\gamma \geq 0$ and $r \geq 0$,*

$$\Pr[t_n - n\pi(A) \geq \gamma] \leq e^{-r(n\pi(A)+\gamma) + n \log \lambda(r)} \, (\mathbf{q}\, P(r)^n \, \mathbf{1})/\lambda(r)^n \,. \tag{2.4}$$

Proof. By Markov's inequality,

$$\begin{aligned} \Pr[t_n \geq n\pi(A) + \gamma] &= \Pr[e^{rt_n} \geq e^{r(n\pi(A)+\gamma)}] \\ &\leq e^{-r(n\pi(A)+\gamma)} \mathrm{E}_{\mathbf{q}} e^{rt_n} \,, \end{aligned} \tag{2.5}$$

where $\mathrm{E}_{\mathbf{q}}$ denotes the expectation given that x_0 is chosen according to $\mathbf{q}$. This expectation can be evaluated by summing over all possible trajectories $x_0, x_1, \ldots, x_n$ (where t_n is understood to be a function of the trajectory):

$$\mathrm{E}_{\mathbf{q}} e^{rt_n} = \sum_{x_0,\ldots,x_n} e^{rt_n} \mathbf{q}(x_0) \prod_{i=1}^{n} p_{x_{i-1}x_i} = \mathbf{q}\, P(r)^n \, \mathbf{1} \,. \tag{2.6}$$

Combining (2.6) with inequality (2.5) we obtain

$$\Pr[t_n \geq n\pi(A) + \gamma] = e^{-r(n\pi(A)+\gamma) + n \log \lambda(r)} \, (\mathbf{q}\, P(r)^n \, \mathbf{1})/\lambda(r)^n. \tag{2.7}$$ □

Here are the reasons that this theorem is useful.

1. For matrices $P(r)$ satisfying (2.3), the fraction $(\mathbf{q}\, P(r)^n \, \mathbf{1})/\lambda(r)^n$ on the right-hand side of (2.4) is close to 1. In fact, this fraction turns out to measure how close the starting distribution $\mathbf{q}$ is to the stationary distribution π. We have the following lemma.

LEMMA 2.3. *For $0 \leq r \leq 1$, $(\mathbf{q}\, P(r)^n \, \mathbf{1})/\lambda(r)^n \leq (1 + r)\, N_{\mathbf{q}}$.*

2. The exponent $-r(n\pi(A) + \gamma) + n \log \lambda(r)$ in the right-hand side of (2.4) is negative for small r because, as we show below, $\frac{d \log \lambda}{dr}|_{r=0} = \pi(A)$, and because $\log \lambda(0) = 0$. Our goal then is to bound this exponent away from zero for some r in order that a meaningful bound on $\Pr[t_n - n\pi(A) \geq \gamma]$ will follow from Theorem 2.2. This is accomplished by Lemma 2.4.

LEMMA 2.4. *If r is a real number such that $0 \leq e^r - 1 \leq \epsilon/4$, then*

$$\log \lambda(r) \leq r\pi(A) + 5r^2/\epsilon \,.$$

Proof of Theorem 2.1. We combine (2.4), Lemma 2.3, and Lemma 2.4 to get

$$\Pr[t_n - n\pi(A) \geq \gamma] \leq (1 + r)\, N_{\mathbf{q}} \, e^{-n(r\gamma/n - 5r^2/\epsilon)} \,. \tag{2.8}$$

The expression $r\gamma/n - 5r^2/\epsilon$ is quadratic in r and is maximized when $r = \gamma\epsilon/10n$, which satisfies the condition of Lemma 2.4 that $e^r - 1 \leq \epsilon/4$ (we can assume $\gamma < n$, because otherwise Theorem 2.1 is trivially true). The maximum value is $\gamma^2\epsilon/20n^2$. Substituting into (2.8),

$$\Pr[t_n - n\pi(A) \geq \gamma] \leq (1 + \gamma\epsilon/10n)\, N_{\mathbf{q}} \, e^{-\gamma^2\epsilon/20n}.$$

This completes the proof. □

Proof of Lemma 2.3. Since the matrix $S(r)$ of (2.3) is symmetric, $\|S(r)\|_2 = \lambda(r)$. We have

$$\begin{aligned}(\mathbf{q}\,P(r)^n\,\mathbf{1})/\lambda(r)^n &= (\mathbf{q}\,\sqrt{DE_r^{-1}}\,S(r)^n\,\sqrt{E_rD^{-1}}\,\mathbf{1})/\lambda(r)^n \\ &\le e^{r/2}\,(\,\|\tfrac{\mathbf{q}}{\sqrt{\pi}}\|_2\,\|S(r)^n\|_2\,\|\sqrt{\pi}\|_2\,)/\lambda(r)^n \\ &\le e^{r/2}\,N_{\mathbf{q}} \\ &\le (1+r)\,N_{\mathbf{q}}\,. \qquad \square\end{aligned}$$

In the remainder of this section we prove Lemma 2.4. For each $r \ge 0$ we define the matrix $B(r) = \frac{1}{e^{-1}}(S(r+1)-S(r))$. $B(r) \le S(r)$ in each entry. Also, $(B(r))_{i,j} = (S(r))_{i,j}$ whenever $i \in A$ and $j \in A$, and $(B(r))_{i,j} = 0$ whenever $i \notin A$ and $j \notin A$. Fix r, $0 \le e^r - 1 \le \epsilon/4$. We may expand the function $\log\lambda(y)$ in a Taylor series of the following form about the point $y = r$ (see [W]):

$$\log\lambda(y) = \log\lambda(r) + m_r(y-r) + (y-r)^2\int_0^1 (1-t)V_{r+(y-r)t}\,dt\,, \tag{2.9}$$

where m_z and V_z are the first and second derivatives, respectively, of $\log\lambda(y)$ at the point $y = z$. m_0 is equal to $\sqrt{\pi}B(0)\sqrt{\pi} = \pi(A)$, the limit of the mean of t_n/n as $n \to \infty$. This follows from letting $\mathbf{1}(r)$ be the right eigenvector of $P(r)$ with eigenvalue $\lambda(r)$ and equating coefficients in the power series expansions of both sides of $P(r)\mathbf{1}(r) = \lambda(r)\mathbf{1}(r)$ [W, p. 69]. V_0 is the limit of the variance of t_n/n as $n \to \infty$ [Nag, equation (2.5)].

The lemma follows from (2.9) and the second part of the following.

Claim 1. If $0 \le e^r - 1 \le \epsilon/4$, then

(i) $\epsilon_r \ge 3\epsilon/4$,

(ii) $V_r \le 10/\epsilon$.

Proof. For part (i), it is enough to show that $\epsilon_r \ge \epsilon - (e^r - 1)$. Note that for $r \ge 0$, the matrices $P(r)$ and $S(r)$ have the same eigenvalues, $S(r)$ is nonnegative, and $S(r) \ge S$ in each entry. By the Perron–Frobenius theorem, $\lambda(r) \ge 1$ [Se]. Let $\mu < \lambda(r)$ be any other eigenvalue of $S(r)$. It will suffice to show that $\mu \le \lambda_2 + e^r - 1$.

The matrix S is diagonalizable; there exist a unitary matrix U and diagonal matrices D' and D_A such that

$$\begin{aligned}B(0) \;&=\; 1/2(SD_A \,+\, D_AS)\,, \\ D' \;&=\; U^TSU, \quad \text{and} \\ \|D'\|_2 \;&=\; \|D_A\|_2 \;=\; 1\,.\end{aligned}$$

If $\mu \le \lambda_2$ we are done. If not, the matrix product $U^T(S + (e^r-1)B(0) - \mu I)U$, which is equal to $(D' - \mu I)[I + (D'-\mu I)^{-1}1/2(e^r-1)(D'U^TD_AU + U^TD_AUD')]$, is singular. Therefore,

$$\begin{aligned}1 &\le 1/2\|(D'-\mu I)^{-1}(e^r-1)D'U^TD_AU\|_2 \\ &\quad + 1/2\|(D'-\mu I)^{-1}(e^r-1)U^TD_AUD'\|_2 \\ &\le (e^r-1)/(\mu-\lambda_2)\,.\end{aligned}$$

(The first inequality uses the continuity of the function $\lambda_2(\cdot)$.) This proves part (i).

Our strategy for part (ii) is to use Cauchy's estimate from complex analysis to bound V_r in terms of the maximum value attained by $\lambda(z)$ in a complex neighborhood

of r [Ahl]. We bound this maximum value indirectly: the convergence of a certain loop integral will imply that $\lambda(z)$ lies inside the loop.

For z in a small complex neighborhood of r we may write $S(z) = S(r) + (e^{z-r} - 1)B(r)$. A fundamental theorem of perturbation theory says that the matrix for the projection onto the eigenspace for $\lambda(z)$ is given by the operator-valued complex integral

$$-\tfrac{1}{2\pi i} \int_\Gamma (S(z) - \zeta I)^{-1}\, d\zeta\,,$$

where Γ is any circle with $\lambda(r)$, and no other eigenvalues of $S(r)$, in its interior [Kat, section II.1.4]. The important fact for us is that if $\lambda(z) \in \Gamma$ then the integrand will have a singularity at $\lambda(z)$. To avoid this we choose Γ to have center $\lambda(r)$ and radius $\epsilon_r/2$. The norm of the integrand is finite on Γ as long as the following holds [Kat, section II.3.1]:

$$\begin{aligned} |e^{z-r} - 1| &< \|B(r)(S(r) - (\lambda(r) - \epsilon_r/2)I)^{-1}\|_2^{-1} \\ &\le 2/\epsilon_r\,. \end{aligned} \tag{2.10}$$

For the range of r we are interested in, in order for (2.10) to hold it is enough that

$$|z - r| \,<\, 3\epsilon_r/8\,. \tag{2.11}$$

Whenever (2.11) holds $\lambda(z)$ does not lie on Γ. But by continuity of $\lambda(z)$, (2.11) must imply that $\lambda(z)$ lies *inside* Γ, and therefore $|\lambda(z) - \lambda(r)| \le \frac{\epsilon_r}{2}$. Comparing Taylor series for $\lambda(z)$ and $\log \lambda(z)$, we see that $V_r \le 2\,\frac{d^2\lambda}{dz^2}|_{z=r}$. Cauchy's estimate says that $\frac{d^2\lambda}{dz^2}|_{z=r}$ is at most $(\max\{\lambda(z) : |z - r| < \rho\})/\rho^2$. If we let $\rho = \frac{3\epsilon_r}{8}$ then $V_r \le 2\frac{\epsilon_r}{2}/(\frac{3\epsilon_r}{8})^2 = 64/9\epsilon_r$. By part (i), $V_r \le 10/\epsilon$, and this completes the proof of Claim 1. □

Recent work of Dinwoodie [Di95a, Di95b] has improved the exponent in the bound of Theorem 2.1 by a factor of $20/\pi(A)$ for γ/n less than a small constant and has extended it to nonreversible Markov chains for γ/n dependent on the eigenvalue gap. This resolves an open question in the earlier version of this paper [G93b]. These results use perturbation theory and power series expansions of the perturbed matrix $P(r)$, eigenvalue $\lambda(r)$, and eigenvector $\mathbf{1}(r)$. These results also extend to estimates of $\mathrm{E}f$ for real-valued functions f on V. In [Kah], Kahale has also improved the exponent in the bound of Theorem 2.1. The exponent in the bound in [Kah] is given as the largest zero of a polynomial in λ_2, γ/n, and $\pi(A)$ and is shown to be optimal on two-state Markov chains for each triple of values of λ_2, γ/n, and $\pi(A)$. This result uses perturbation theory and a proof that a certain two-state Markov chain is extremal for the deviation probability being estimated.

3. (β, δ)-approximation algorithms for $\pi(A)$. In this section we compare different (β, δ)-approximation algorithms for $\pi(A)$ that use random walks to generate sample points from G. Formally, the output t of a (β, δ)-approximation algorithm for $\pi(A)$ must satisfy, with probability at least $1-\delta$, $\pi(A)(1-\beta) \le t \le \pi(A)(1+\beta)$. The cost of an algorithm will be the total number of random walk steps taken (see the discussion of measures of cost at the end of the section). We assume we can efficiently find one point s in G from which to start a random walk.

Below we define SP, AP, and a modified Aldous's procedure (APm). We analyze the efficiency of AP in Proposition 3.1. APm uses a technique for increasing the

confidence of estimates introduced by Jerrum, Valiant, and Vazirani in [JVV, Lemma 6.1]. This technique, the so-called "median trick," improves an arbitrary $(\beta, 1/4)$-approximation algorithm to a (β, δ)-approximation algorithm by taking $12\log(1/\delta)$ independent estimates and using the median of the estimates. We use Proposition 3.2 and Lemma 6.1 of [JVV] to analyze APm.

Standard procedure (SP). Start the random walk at s and simulate it for k' steps, so that the final state is distributed according to **q'**. Take the final state as a sample point. Repeat this l' times by choosing the same starting point s and taking a walk of length k' each time. Let $t_{l'}$ be the number of sample points in A, and let $t = t_{l'}/l'$.

Aldous's procedure (AP). Choose positive integers k and l. Start the random walk at s and simulate it for k steps (the "delay"), so that the final state x_0 is distributed according to **q**. Starting from x_0, continue the random walk l more steps taking each subsequent point as a sample point. Let t_l be the number of sample points in A, and let $t = t_l/l$.

Aldous's procedure, modified (APm). Choose k and l and follow AP to get an estimate of $\pi(A)$. Repeat $12\log(1/\delta)$ times and let t be the median of the estimates.

For a distribution **d** on the vertices of G, let the *chi-square distance from* π be defined by $\chi^2_d = \sum_x \pi(x)(\frac{\mathbf{d}(x)}{\pi(x)} - 1)^2$. Let χ^2_s denote the chi-square distance from π of the initial distribution concentrated at s.

PROPOSITION 3.1. *The cost of estimating* $\pi(A)$ *to within* $\beta\pi(A)$ *with probability* $1 - \delta$ *using AP is at most*

$$\log(1/\pi(s))\,/\,\epsilon \;+\; 20\log(8/\delta)\,/\,(\epsilon\beta^2\pi(A)^2)\,.$$

Proof. Let $k = \log(1/\pi(s))\,/\,\epsilon$ and $l = 20\log(8/\delta)\,/\,(\epsilon\beta^2\pi(A)^2)$. In the notation of Theorem 2.1, $N_{\mathbf{q}} = 1 + \chi^2_{\mathbf{q}}$. According to a result of Fill [Fi, equation (2.11)], $\chi^2_{\mathbf{q}} \le \chi^2_s(1-\epsilon)^k$. Therefore, $N_{\mathbf{q}} \le 1 + \chi^2_s(1-\epsilon)^k \le e^{-\epsilon k}/\pi(s) \le 2$.[2] By Theorem 2.1 and the ensuing remark (ii),

$$\Pr[|t_l/l - \pi(A)| \ge \beta\pi(A)] \;\le\; 4N_{\mathbf{q}}e^{-\beta^2\pi(A)^2\epsilon l/20} \;\le\; \delta. \qquad \square$$

Let $\pi_{\min} = \min_x \pi(x)$. Proposition 4.2 of Aldous [Ald87] and Lemma 6.1 of Jerrum, Valiant, and Vazirani [JVV] show that the cost of AP, modified, is $O[(\log(1/\delta)\,/\,\epsilon)(\log(1/\pi_{\min}) + 1\,/\,(\beta^2\pi(A)))]$. The following proposition and its corollary serve to replace $\pi_{\min}$ by $\pi(s)$. This will be useful in the applications of the next section.

PROPOSITION 3.2. *Let* $\beta > 0$ *and* $\alpha \le \beta^2$. *Let AP be used with parameters* $k = \log(20/(\pi(s)\alpha\pi(A)^2))/\epsilon$ *and* $l = 10/(\epsilon\beta^2\pi(A))$ *to generate an estimate* t. *Then*

$$|\mathrm{E}[t - \pi(A)]| \;\le\; \alpha\pi(A)^2/20$$

and

$$\mathrm{E}(t - \pi(A))^2 \;\le\; \beta^2\pi(A)^2/4\,.$$

[2] Fill's result actually depends on the larger of λ_2 and $|\lambda_{|V|}|$, but it is possible to modify any random walk so that in fact λ_2 is the larger of the two. One converts it to a so-called "lazy" random walk which with probability 1/2 stays put at each step [LS]. The values of k and l increase by at most a factor of 2. The same remark applies to the application of [JS91, Theorem 6.1] below.

TABLE 3.1
Costs of procedures for estimating $\pi(A)$.

Algorithm	Cost
SP	$\frac{1}{\epsilon}\log\frac{1}{\delta}\,\log\frac{1}{\pi(s)}\,\frac{1}{\beta^2\pi(A)}$
AP	$\frac{1}{\epsilon}\,(\log\frac{1}{\pi(s)}\,+\,\log\frac{1}{\delta}\,\frac{1}{\beta^2\pi(A)^2})$
APm	$\frac{1}{\epsilon}\log\frac{1}{\delta}\,(\log\frac{1}{\pi(s)}\,+\,\frac{1}{\beta^2\pi(A)})$

Proof. Let $\|\mathbf{q}-\pi\|$ denote the total variation distance between $\mathbf{q}$ and π. Citing, for example, [JS91, Theorem 6], we have that $\|\mathbf{q}-\pi\| < \frac{1}{20}\alpha\pi(A)^2$. Let $x_1,\ldots,x_l$ be the random vertices of G sampled. Each x_i is distributed according to some $\mathbf{q}_i$, which also satisfies $\|\mathbf{q}_i-\pi\| < \frac{1}{20}\alpha\pi(A)^2$. By linearity of expectations,

$$|\mathrm{E}[t_l/l-\pi(A)]| \le \frac{1}{l}\sum_{i=1}^{l}|\mathbf{q}_i(A)-\pi(A)| \le \frac{1}{20}\alpha\pi(A)^2.$$

Now define a vector $\mathbf{b}$ by letting $\mathbf{b}_j = \mathrm{E}[(t_l/l-\pi(A))^2 \,|\, x_0 = j]$. Observe that $\|\mathbf{b}\|_\infty \le 1$; therefore, by Proposition 4.1 of [Ald87], $\mathrm{E}_\pi\mathbf{b} \le 2\pi(A)/(\epsilon l)$. We have

$$\begin{aligned}\mathrm{E}(t-\pi(A))^2 &\le \mathrm{E}_{\mathbf{q}}\mathbf{b}\\ &\le [\mathrm{E}_\pi\mathbf{b} + |\mathrm{E}_{\mathbf{q}}\mathbf{b} - \mathrm{E}_\pi\mathbf{b}|]\\ &\le [2\pi(A)/(\epsilon l) + \alpha\pi(A)^2/20]\\ &\le \beta^2\pi(A)^2/4\,. \qquad \square\end{aligned}$$

COROLLARY 3.3. *The cost of estimating $\pi(A)$ to within $\beta\pi(A)$ with probability $1-\delta$ using APm is at most*

$$12\log(1/\delta)[\log(20/(\pi(s)\alpha\pi(A)^2))/\epsilon + 10/(\epsilon\beta^2\pi(A))]\,.$$

Proof. Set k and l as in Proposition 3.2 with $\alpha = \beta^2$. By Chebyshev's inequality,

$$\begin{aligned}\Pr[|t-\pi(A)| \ge \beta\pi(A)] &\le (\,\mathrm{E}(t-\pi(A))^2\,)/(\beta^2\pi(A)^2)\\ &\le 1/4.\end{aligned}$$

The corollary follows from Lemma 6.1 of [JVV]. $\square$

The standard procedure can be used to estimate $\pi(A)$ to within $\beta\pi(A)$ with probability $1-\delta$ by choosing $k' = O((\log(1/\pi_{\min}))\,/\,\epsilon)$ and $l' = O(\log(1/\delta)\,/\,(\beta^2\pi(A)))$. This value of k' comes from the analysis of Sinclair and Jerrum in [SJ], and the value of l' comes from Chernoff's bound. The method used in Lemma 3 of [JS91] is easily seen to be generally applicable; this improves the $\pi_{\min}$ to $\pi(s)$ in the expression for k'.

The costs of the three procedures disregarding constants are shown in Table 3.1. APm improves SP by a factor of $\min(\log(1/\pi(s)),\, 1/(\beta^2\pi(A)))$. AP is within a factor of $O(1/\pi(A))$ of APm. APm incurs extra cost by repeating the initial stage of finding a nearly random starting point; therefore, AP becomes better for small δ when β and A are such that $1/(\beta^2\pi(A)^2) < \log(1/\pi(s))$.

Remarks. (i) The recent work of Dinwoodie [Di95b] has improved the exponent in the bound of Theorem 2.1 by a factor of $20/\pi(A)$ for γ/n less than some small constant. This makes the cost of AP proportional to $1/\pi(A)$ and not $1/\pi(A)^2$, for β less than some small constant.

(ii) The results of this section all have analogues for estimating the expectation $\mathrm{E}f$ of a nonnegative function f on the vertices of G. Corresponding to Proposition 3.2 is the following, which we state without proof.

PROPOSITION 3.4. *Let $\beta > 0$ and $\alpha \le \beta^2$. Let $k = \log(20/(\alpha\pi(s)(\mathrm{E}f)^2))/\epsilon$ and $l = 10\mathrm{Var}(f)/(\epsilon\beta^2(\mathrm{E}f)^2)$. Take a random walk on G starting in s, and let x_i, $i \ge 1$, stand for the $(i+k)$th vertex of the random walk. Let $t = \frac{1}{l}(f(x_1) + \cdots + f(x_l))$. Then*

$$|\mathrm{E}[t - \mathrm{E}f]| \le \alpha(\mathrm{E}f)^2/20$$

and

$$\mathrm{E}(t - \mathrm{E}f)^2 \le \beta^2(\mathrm{E}f)^2/4\,.$$

The running time for AP is proportional to $\|f\|_\infty/(\mathrm{E}f)^2$ instead of $1/\pi(A)^2$, and the running time of SP has the same dependence as APm on $\mathrm{Var}(f)$ and $(\mathrm{E}f)^2$ [JS91, Lemma 3].

(iii) *Measures of cost.* It can be argued that SP has the advantage of taking only a small fraction (around ϵ) of the number of sample points of either AP or APm. We have not considered the number of sample points in our measure of cost because in the cases we know of the cost of sampling a point is dominated by the cost of taking one step of the random walk. For example, in the case of the random walk on matchings treated below, to determine the transition probability from one matching to another it is necessary to know whether the number of edges is going up or down by one, or staying the same. Therefore, it adds only a constant cost to keep track of the size of the current matching (see [JS89]). The same sort of justification holds for the case of the Ising model considered below. Computing the value of f at a vertex is no more difficult than computing the next transition probability (see [JS91]). Situations may yet arise of having to estimate $\mathrm{E}f$ for complicated f, where the number of sample points will be an important part of the cost of an algorithm.

(iv) *Nondelayed samples.* Suppose instead of generating a random initial point we had begun sampling immediately from s. The question is raised in [Ald87, Example 4.2] whether such nondelayed samples give good estimates in polynomial time. Setting $k = 0$ in Proposition 3.1 yields $l = 20(\log(1/\pi(s)) + \log(1/\delta))/(\epsilon\beta^2\pi(A)^2)$. An upper bound on $\log(1/\pi(s))$ is $\log|G| + \log\max_{x,y}(\pi(x)/\pi(y))$, which is typically polynomial in the data. This shows that nondelayed samples give good estimates in polynomial time, as long as $\pi(A)$ is not too small. It is not hard to see that the most efficient estimate, using our analysis, comes from letting k be equal to the relaxation time as in the proof of Proposition 3.1.

4. Applications: Two approximation algorithms.

The subgraphs random walk for the Ising model. In this section we give a modified version of an algorithm, due to Jerrum and Sinclair, for computing the partition function Z of a ferromagnetic Ising system I on m points (definitions below). Our new version of the algorithm improves the running time from $O(|E|^3m^7)$ to $O(|E|^2m^6)$, where m is the number of vertices and E is the edge set of the system [JS91].

Our algorithm is a *fully polynomial randomized approximation scheme* (*fpras*) as described in [KL] and in subsequent work on approximation algorithms. That is, on input I and a real number $a > 0$ it runs in time polynomial in m and $1/a$ and outputs a number that with probability at least $3/4$ approximates Z with relative error of a. The algorithm of Jerrum and Sinclair was the first fpras for this problem.

Consider a graph $I = ([m], E)$, $[m] = \{1, 2, \ldots, m\}$, with a positive *interaction energy* V_{ij} associated to each edge $\{i, j\} \in E$. A *configuration* $\sigma = \{\sigma_i\}_{i=1}^m$ is an assignment of positive ($\sigma_i = +1$) or negative ($\sigma_i = -1$) *spin* to each *site* $i \in [m]$. The *energy* of a configuration is given by the Hamiltonian

$$H(\sigma) = -\sum_{\{i,j\}\in E} V_{ij}\sigma_i\sigma_j - B\sum_{k\in[m]} \sigma_k,$$

where B is an external field.

This is a *ferromagnetic Ising system*; the positivity constraint on the V_{ij} models the behavior of a ferromagnet. A central problem for Bayesian inference in statistical physics is to compute a probability normalizing constant called the *partition function*:

$$Z = Z(V_{ij}, B, \beta_T) := \sum_{\sigma\in\{-1,+1\}^m} e^{-\beta_T H(\sigma)},$$

where β_T is related to the temperature. For further motivation we refer to [JS91] and the references therein.

Physicists have long used random walks on the set of spin configurations to estimate Z, but these random walks are not rapidly mixing for certain values of β_T. However, the partition function has an alternate characterization. Consider the set of all subsets X of the edge set E. Each subset X can be identified with a subgraph of I (which may contain isolated vertices). Let $\mathrm{odd}(X)$ stand for the set of all odd-degree vertices in the subgraph identified with X. Let $\lambda_{ij} = \tanh \beta_T V_{ij}$ and $\mu = \tanh \beta_T B$. The *weight* of X is defined by

$$w(X) = \mu^{|\mathrm{odd}(X)|} \prod_{\{i,j\}\in X} \lambda_{ij}. \tag{4.1}$$

The "subgraphs-world" partition function is

$$Z' = \sum_{X\subseteq E} w(X). \tag{4.2}$$

The two partition functions are related by the formula

$$Z = AZ', \tag{4.3}$$

where $A = (2\cosh \beta_T B)^m \prod_{\{ij\}\in E} \cosh \beta_T V_{ij}$ (see [NM]).

Although the subgraphs have no physical meaning, it is natural in light of (4.3) to compute Z indirectly by computing Z'. We define a random walk on the set G of all subsets $X \subseteq E$. Fix $\mu = \mu(\beta_T)$. For each X the transition probabilities out of X are given by the following rules [JS91, p. 16]: pick an edge $e \in E$ uniformly at random, and then

1. set $Y = X \oplus e$ (the symmetric difference of X and e);
2. if $w(Y) \geq w(X)$ then move to Y with probability 1;

(1) $A := (2\cosh\beta_T B)^m \prod_{\{ij\}\in E} \cosh\beta_T V_{ij}$; and $Z'(1) := \prod_{\{i,j\}\in E}(1+\lambda_{ij})$; $\Pi := A \times Z'(1)$;
(2) $r :=$ the natural number satisfying $\frac{m-r}{m} > \tanh\beta_T B \geq \frac{m-r-1}{m}$;
(3) $\mu_0 := 1$; **for** $j = 0, 1, \ldots, r$, **do begin**
  (4) **if** $j \leq r$, **then** $\mu_{j+1} := \frac{m-j}{m}$; **else** $\mu_{j+1} := \tanh\beta_T B$;
  (5) Make a call to AP with parameters k and l and t as in Proposition 3.4: let $\alpha = a^2/2m^2$ and $\beta = a/\sqrt{2m}$, and assume a lower bound of $1/10$ on $\mathrm{E}f$. Use the random walk on G with parameter μ_j, and obtain an estimate t for $\mathrm{E}_{\mu_j} f$;
  (6) $\Pi := \Pi \times t$;
end;
(7) **halt** with output Π;

FIG. 4.1. *Algorithm for computing the partition function.*

3. if $w(Y) < w(X)$ then move to Y with probability $w(Y)/w(X)$, and stay at X otherwise.

It is easy to see that G is connected by the transitions that have positive probability. It is not hard to check that the unique stationary distribution $\pi = \pi^\mu$ is given by $\pi(X) = w(X)/Z'$ (the transition probabilities were chosen with this goal in mind, according to the well-known Metropolis rule).

We adhere to the strategy of Jerrum and Sinclair for computing $Z' = Z'(\mu)$. This is to notice that $Z'(1) = \prod_{\{i,j\}\in E}(1+\lambda_{ij})$, which is easy to compute. Then for a general $\mu \in [0,1]$, one bootstraps from $Z'(1)$ down to $Z'(\mu)$ by computing successive ratios $Z'(\mu')/Z'(\mu)$ as follows. Let $\mathrm{E}_\mu f$ be the expectation under π^μ. For $0 \leq \mu_1 < \mu_0 \leq 1$ define the function $f(X) = (\mu_1/\mu_0)^{|\mathrm{odd}(X)|}$. The expectation of f satisfies $\mathrm{E}_{\mu_0} f = Z'(\mu_1)/Z'(\mu_0)$ [JS91, p. 11]. Furthemore, Lemma 4 of [JS91] says that if $\mu_0 \leq \mu_1 + 1/m$, then $\mathrm{E}_{\mu_0} f \geq 1/10$.

Our $(a, 1/4)$ approximation scheme for computing the partition function is shown in Fig. 4.1. We let step (5) assume a lower bound of $\epsilon \geq (2m^4|E|^2)^{-1}$, as given by Sinclair in [Si]. This algorithm differs from the algorithm of Jerrum and Sinclair [JS89, p. 12] in two ways. First, we use AP rather than SP in step (5). Second, we choose $\beta = \theta(a/\sqrt{m})$ instead of $\beta = \theta(a/m)$ in step (5) and we observe that the accumulated errors in Π tend to cancel one another out. This observation has been used before by Dyer and Frieze. We formalize it in the following lemma, which essentially appears in [DF, page 10].

LEMMA 4.1. *Let $z_1, \ldots, z_m$ be independent nonnegative random variables with $\mathrm{E}z_i \leq \eta/2m^2$ for some $\eta \leq 1$, and $\mathrm{E}z_i^2 \leq \nu/m$ for some $\nu \leq 1$. Let $Y = \prod_{i=1}^m (1+z_i)$. Then $\mathrm{E}(Y-1)^2 \leq \eta/m + \nu + (\eta/m+\nu)^2$.*

Proof. Since $Y \geq 1$, $\mathrm{E}(Y-1)^2 = \mathrm{E}[Y^2 - 2Y + 1] \leq \mathrm{E}Y^2 - 1$. Therefore,

$$\begin{aligned}
\mathrm{E}(Y-1)^2 &\leq \mathrm{E}[\textstyle\prod_i (1+z_i)^2] - 1 \\
&= \textstyle\prod_i (1 + 2\mathrm{E}z_i + \mathrm{E}z_i^2) - 1 \\
&\leq (1 + \eta/m^2 + \nu/m)^m - 1 \\
&\leq e^{\eta/m+\nu} - 1 \\
&\leq \eta/m + \nu + (\eta/m+\nu)^2. \qquad \square
\end{aligned}$$

THEOREM 4.2. *Let $a \in (0,1)$. The output Π of our algorithm satisfies $\Pi(1-a) < Z < \Pi(1+a)$ with probability at least $3/4$. The running time is at most $500m^6|E|^2/a^2$ random walk steps.*

Remark. Theorem 2, Lemmas 3 and 4, and the remark at the end of section 4 of [JS91] give a bound of $O(m^7|E|^3/a^2)$ random walk steps to estimate Z with the algorithm of Jerrum and Sinclair.

Proof. Let t_j be the estimate of $\mathrm{E}_{\mu_j} f$ from the jth iteration of the **do** loop. Let $z_j = t_j/\mathrm{E}f - 1$. Let $Y = \prod_j (1 + z_j) = \Pi/Z$. By Proposition 3.4,

$$|\mathrm{E}_{\mu_j} z_j| \le a^2/40m^2$$

and

$$\mathrm{E}_{\mu_j} z_j^2 \le a^2/8m.$$

Assuming in the worst case that $r = m$, the z_j satisfy the assumptions of Lemma 4.1 with $\eta = a^2/20$ and $\nu = a^2/8$. By Chebyshev's inequality, $\Pr[|(\Pi/Z) - 1| \ge a] \le \mathrm{E}(Y-1)^2/a^2$; so by the lemma,

$$\Pr[|(\Pi/Z) - 1| \ge a] \le [a^2/20 + a^2/8 + (a^2/20 + a^2/8)^2]/a^2 \le 1/4\,. \qquad \square$$

Perfect matchings. In this subsection we summarize the improvements we have made to an approximation algorithm, due to Jerrum and Sinclair, for counting the number of perfect matchings in a graph $H = (V, E)$ on $2m$ vertices. A *matching* is a subset of E such that no two edges share a common endpoint. A *perfect matching* is a matching that contains m edges. Let M_j denote the set of matchings of size j in H.

In [Br] Broder gave the first fpras for counting perfect matchings in dense graphs. A full proof of the correctness of this algorithm awaited Jerrum and Sinclair, who also gave a faster algorithm in [JS89].

An upper bound $q(m) > |M_{m-1}|/\max(1, |M_m|)$ is assumed to be known for some fixed polynomial q. Thus H is said to be *q-amenable*. Jerrum and Sinclair have shown that all dense graphs are m^2-amenable and almost every random bipartite graph is m^{10}-amenable in the $B(n,p)$ model for any density p above the threshold for the existence of a perfect matching [JS89]. Kenyon, Randall, and Sinclair have shown that all bipartite Cayley graphs and all regular periodic lattices of any dimension are $O(m^2)$-amenable [KRS]. In general, $q(m) \ge m$.

Jerrum and Sinclair define a random walk on a weighted graph G whose vertex set is all matchings of H: $\bigcup_{1 \le j \le m} M_j$. The transition probabilities depend upon a certain real parameter c which varies at different stages in the algorithm. In each stage the transition probabilities are chosen according to the Metropolis rule to ensure that the stationary probabilities $\pi(M_j)$ are proportional to $c^j|M_j|$ for all j. See [JS89] for more details.

Our modified version of the algorithm of [JS89] also uses a random walk on G, and like the original algorithm, our version proceeds in $m - 1$ stages, each using a different value $c^{(j)}$ for c. Stage $j \ge 1$ calculates the ratio $|M_{j+1}|/|M_j|$. The algorithm multiplies the ratios together to obtain an estimate of $|M_m|$ ($|M_1|$ is simply the number of edges of H). Since each of these ratios satisfies $|M_{j+1}|/|M_j| = c\pi(M_{j+1})/\pi(M_j)$, the essential step of the algorithm is to estimate $\pi(M_{j+1})$ and $\pi(M_j)$.

Our version modifies the algorithm of Jerrum and Sinclair [JS89, Figure 2] in two ways. First, we use APm in our random walk calls to estimate the $\pi(M_j)$'s, instead of SP. Second, we introduce a new strategy for choosing the values of c which allows the algorithm to assume that both $\pi(M_{j+1})$ and $\pi(M_j)$ are $\Omega(1/m)$.

The idea behind the new strategy is as follows. By Theorem 5.1 of [JS89], the sequence $|M_1|, |M_2|, \ldots, |M_m|$ is log-concave. This means that $\log |E|^{-1} = \log(|M_0|/|M_1|)$

$\le \log(|M_1|/|M_2|) \le \cdots \le \log(|M_{m-1}|/|M_m|) \le \log q(m)$. Put $c_j = |M_{j-1}|/|M_j|$ for each j, and $c_{m+1} = q(m)$. Whenever $c \in [c_j, c_{j+1}]$, $\pi(M_j) \ge \pi(M_i)$ for all i. In particular, when $c = c_{j+1}$, $\pi(M_j)$ and $\pi(M_{j+1})$ are each at least $1/m$. Since all of our sampling procedures are more efficient when sampling large sets, we would like to choose $c = c_{j+1}$ at stage j of the algorithm. What our algorithm does is to increase c by a constant factor at each stage, so that $\log c$ is incremented through the range $[\log |E|^{-1}, \log q(m)]$ in constant-size steps. However, the algorithm also detects those areas of this range where the $\log(\pi(M_j)/\pi(M_{j+1}))$'s are clumped together, and in those areas it takes smaller steps. In the end the algorithm needs to try only $m + O(\log m)$ different values of c to ensure that each c_{j+1} is approximated well by one of them.

THEOREM 4.3. *Let $a \in (0, 1/2]$. If H is q-amenable then the output Π of our algorithm satisfies $\Pi(1-a) < M_m < \Pi(1+a)$ with probability at least $3/4$. Our algorithm uses $O(q^2 m^5 |E| \log m/a^2)$ random walk steps.*

Remarks. (i) The algorithm of Jerrum and Sinclair uses $O(q^3 m^6 |E| \log^2 m/a^2)$ random walk steps, assuming the lower bound on the eigenvalue gap given later by Sinclair in [Si].

(ii) We have tried to reduce the running time of our algorithm by another factor of $O(m)$ using Lemma 4.1. The problem we face is that we need very reliable estimates of each $c^{(j)}$ (as did Jerrum and Sinclair) to make sure that M_j and M_{j+1} would be large enough sets (in stationary probability) to sample from. The cost of these reliable estimates dominates the cost of each stage of the algorithm.

5. Entropy of sources. We now consider the special case of a random walk on an unweighted undirected graph G. We view the random walk as an information source whose alphabet is the vertex set V of G. Theorem 2.1 enables us to quantify the rate of convergence of the classical Shannon–McMillan asymptotic equipartition property for this information source. We will then be able to estimate the entropy of the source very quickly, in $O(\log |G|)$ steps when G has constant expansion and constant nonuniformity (defined below). For purposes of fixed-length noiseless coding of the source, this result will imply a bound on the error exponent in terms of the expansion of G.

Let G have eigenvalue gap ϵ. Define the *nonuniformity* ν of G by

$$\nu = \max_{x,y} \pi(x)/\pi(y).$$

Let M be twice the number of edges of G. Let $P = (p_{ij})$ be the transition matrix for the random walk on G. For all i, j, $p_{ij} = 1/d_i$, where d_i is the degree of vertex i. $\pi(i) = d_i / \sum_j d_j = d_i/M$; therefore, $M \ge \max_i 1/\pi(i) \ge \nu$. Let $x_0, x_1, \ldots$ be a random walk on G starting from the stationary distribution. Consider the random sequence $X = x_1, x_2, \ldots$ an information source.

The random walk as an information source. In general, the *entropy* $H(Y)$ of an information source $Y = y_1, y_2, \ldots$ is defined in terms of the ordinary Shannon entropy: $H(Y) = \lim_{n\to\infty} \mathrm{E}\, H[y_n | y_1, \ldots, y_{n-1}]$. In our case, in which there is an underlying stationary random walk on an unweighted graph, there is a simple formula:

$$\begin{aligned} H(X) = \mathrm{E}\, H(x_1|x_0) &= -\mathrm{E} \log_2 p_{x_0 x_1} \\ &= \mathrm{E}_\pi \log_2 d_{x_0}\,. \end{aligned} \tag{5.1}$$

The Shannon–McMillan theorem [Ash, Theorem 6.6.1] states that under an ergodicity assumption which is satisfied here, an information source Y has the *asymp-*

totic equipartition property (AEP): for a fixed length n of source sequences, there are asymptotically $2^{nH(Y)}$ source sequences each of asymptotic probability $2^{-nH(Y)}$, and the probability of the "bad" set of remaining sequences tends to zero as n tends to infinity. The next theorem establishes an upper bound on the probability of the "bad" set.

Consider the particular information source X and a finite sequence $x_1, \ldots, x_n$, generated by X. Define the *empirical entropy* V_n of this finite sequence by $V_n = -\frac{1}{n} \log_2 \Pr[x_1, \ldots, x_n]$.

THEOREM 5.1. *Let X be the information source generated by the random walk on G. Let $x_1, \ldots, x_n$ be a finite sequence generated by X, with empirical entropy V_n. Then*

$$\begin{aligned} &\Pr[|V_n - H(X)| \ \geq \ \gamma] \\ &\qquad \leq \ 4e^{-(\gamma - (\log_2 M)/n)^2 n\epsilon/20\log_2{}^2 \nu}. \end{aligned} \tag{5.2}$$

Proof. Define a nonnegative function g on the vertices of G by $g(x) = \log_2 d_x$. Set $f(x) = g(x) - \min_y g(y)$. Then $\|f\|_\infty = \log_2 \nu$ and by (5.1), $\mathrm{E}_\pi f = H(X) - \min_y g(y)$. Let $t_n = f(x_1) + \cdots + f(x_n)$. Then $V_n - \min_y g(y) = t_n/n + (\log_2 1/\pi(x_1))/n - (\log_2 d_{x_n})/n$. Using (2.2) and remark (i) following Theorem 2.1,

$$\begin{aligned} &\Pr[V_n - H(X) \ \geq \ \gamma] \\ &\quad = \ \Pr[t_n/n - (H(X) - \min_y g(y)) \\ &\qquad \geq \ \gamma - (\log_2 1/\pi(x_1))/n + (\log_2 d_{x_n})/n] \\ &\quad \leq \ 2\exp\left[-\left(\frac{\gamma - (\log_2 M)/n}{(\log_2 \nu)/n}\right)^2 \epsilon/20n\right] \\ &\quad \leq \ 2e^{-(\gamma - (\log_2 M)/n)^2 n\epsilon/20\log_2{}^2 \nu}. \end{aligned}$$

The inequality in the other direction is similar. □

Unifilar sources. Let $\chi : V(G) \to \{0, 1, \ldots, k-1\}$ be any labelling of the vertices of G such that the random walk on G is unifilar; that is, no vertex G is adjacent to two or more vertices of the same label. Let $Y = y_1, y_2, \ldots$ be the sequence of labels: $y_i = \chi(x_i)$. Then the entropy of the information source Y still satisfies (5.1): $H(Y) = \mathrm{E}_\pi \log_2 d_{x_0}$. The definition of empirical entropy for Y is also the same, and we immediately have the following generalization.

COROLLARY 5.2. *Let V_n denote the empirical entropy of $y_1, \ldots, y_n$. Then*

$$\begin{aligned} &\Pr[|V_n - H(Y)| \ \geq \ \gamma] \\ &\qquad \leq \ 4e^{-(\gamma - (\log_2 k|G|)/n)^2 n\epsilon/20\log_2{}^2 k}. \end{aligned} \tag{5.3}$$

□

Remarks. (i) The logarithm of the right-hand side of (5.3) gives an upper bound on the error exponent for fixed-length coding of the source Y. This appears to be the first such bound which applies for all n and is given in terms of a computable quantity (the eigenvalue gap). Large deviation methods were used in [Nat, An], giving asymptotic estimates of the error exponent.

(ii) Corollary 5.2 can be restated as follows: to estimate $H(Y)$ to within an additive error γ with probability at least $1 - \delta$ requires a random walk of length $\mathrm{O}(\log^2 k \log(1/\delta) \log k|G|/\epsilon\gamma^2)$. When the number of labels k is constant and G has constant expansion, this simplifies to $\mathrm{O}(\log(1/\delta) \log |G|/\gamma^2)$.

6. Further work. The main open problem is to give a lower bound on the probability of deviation estimated in Theorem 2.1. A lower bound must depend on the set A and not only on $\pi(A)$. For example, in the usual barbell graph, if A is all on one side of the "handle," the deviation probability will actually be larger than if A is equally distributed between the two sides of the graph [G93a, pp. 56–57].

It would be nice to be able to estimate the entropy of a random walk on a weighted graph. In [G93a], the author has shown that such a generalization would have applications to the problem of discriminating two hidden Markov chains from their output. The immediate difficulty is not the lack of a nice formula for entropy in this case, but the problem of estimating the expected value of a function on the edges of G. The random walk on G induces a Markov chain on the edges of G. The induced Markov chain is not time-reversible, so the Chernoff bound does not apply as it stands.

Ultimately it would be nice to be able to estimate the entropy of a `0-1` source generated by a (possibly nonunifilar) Markov chain whose states are labelled `0` and `1`.

Acknowledgments. My advisor Mike Sipser helped to formulate the problem of a central limit theorem for expander graphs and continually discussed the issues of this paper with me while my work progressed. Johan Håstad drew my attention to the paper of T. Höglund. László Lovász pointed out the potential application of a Chernoff bound to approximation algorithms. Nabil Kahale, Miklos Simonovits, Alistair Sinclair, and David Zuckerman, and Svante Janson made helpful comments. It is my pleasure to thank these people.

PROCESSOR-RING COMMUNICATION: A TIGHT ASYMPTOTIC BOUND ON PACKET WAITING TIMES*

E. G. COFFMAN, JR.†, NABIL KAHALE‡, AND F. T. LEIGHTON§

Abstract. We consider N processors communicating unidirectionally over a closed transmission channel, or ring. Each message is assembled into a fixed-length packet. Packets to be sent are generated at random times by the processors, and the transit times spent by packets on the ring are also random. Packets being forwarded, i.e., packets already on the ring, have priority over waiting packets. The objective of this paper is to analyze packet waiting times under a greedy policy within a discrete Markov model that retains the overall structure of a practical system but is simple enough so that explicit results can be proved. Independent, identical Bernoulli processes model message generation at the processors, and independently and identically distributed (i.i.d.) geometric random variables model the transit times. Our emphasis is on asymptotic behavior for large ring sizes, N, when the respective rate parameters have the scaling λ/N and μ/N. Our main result shows that, if the traffic intensity is fixed at $\rho = \lambda/\mu < 1$, then as $N \to \infty$ the expected time a message waits to be put on the ring is bounded by a constant. This result verifies that the expected waiting time under the greedy policy is within a constant factor of that under an optimal policy.

Key words. processor rings, processor interconnection networks, queuing networks, asymptotic analysis, routing algorithm analysis

1. Introduction.

Communication among N processors takes place counterclockwise along a slotted circular transmission channel, or *ring*. A processor generates messages, receives messages, and forwards messages between other processors. Each message is a *packet* of fixed duration. One time unit is required for a packet to be sent or forwarded from one processor to its counterclockwise neighbor. Packets are generated randomly at the processors according to i.i.d. arrival processes. The integer times spent by packets on the ring, packet *transit times*, are i.i.d. random variables. Packets being forwarded on the ring have priority; while a processor has a packet to be forwarded, it cannot place one of its own waiting packets on the ring. A packet waiting for transmission is held in a queue at the processor where it was generated.

The details defining a practical implementation of a processor ring are many and varied. Indeed, the applications and analysis of communication rings form a rather large and growing literature; see van Arem and van Doorn (1990), Barroso and Dubois (1993), and Georgiadis, Szpankowski, and Tassiulas (1997) for brief surveys and many references. As a concession to mathematical tractability, we adopt here the simple discrete Markov model in Fig. 1, where the ring is partitioned into *cells*, each capable of holding a single packet. The cells rotate counterclockwise past the processors in discrete steps, one step per unit of time. Packets are generated at each of the N

processors by a Bernoulli process at rate λ/N, $0 < \lambda < N$, per time unit (step); the total arrival rate is then λ. The packet transit times are geometrically distributed with rate parameter μ/N, $N > \mu > \lambda$. Thus, at any given step, a packet on the ring departs with probability μ/N and stays for at least one more step with probability $1 - \mu/N$, independent of how long the packet has already been on the ring. We will explain shortly the reason for the scaling of arrival and transit-time parameters by the ring size.

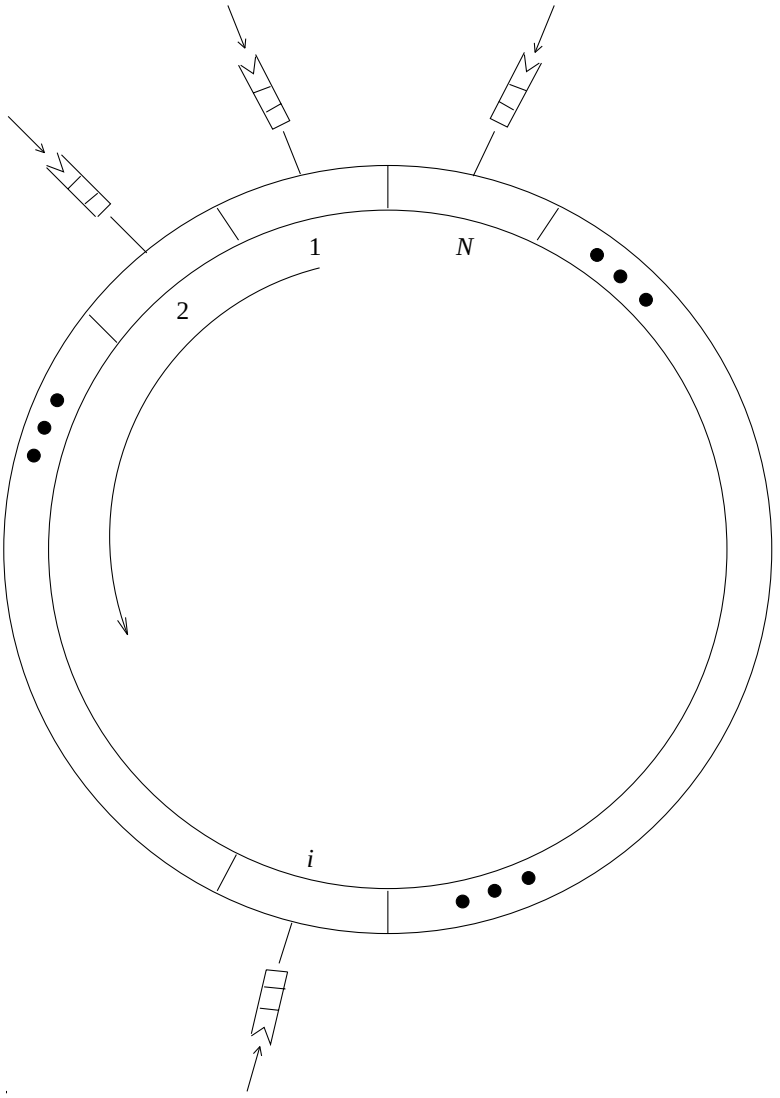

FIG. 1. *The rotating ring model.*

In each step, the ring system undergoes a transition according to the following sequence.

(i) The ring rotates one position while processor queues accept new arrivals, if any (at most one per queue in each step).

(ii) Packets on the ring that have completed their transit times are delivered, i.e., removed from their cells.

(iii) Each processor with a nonempty queue opposite an empty cell then puts a waiting packet into this cell.

This gives the *nonblocking* model; reversing (ii) and (iii) would give the *blocking* model: a departing packet can not be replaced in the same time step by a waiting packet. As we shall see, our asymptotic results apply to both models. The above sequence gives the *greedy* cell admission policy, placing waiting packets on the ring as soon as empty cells are available.

As discussed in Coffman et al. (1995), the greedy policy has the undesirable effect of occasionally "freezing out" certain processor queues for long periods of time; long trains of occupied cells pass by such processors, denying them access to the ring. The results of this paper will show that, for large rings within our probability model, the greedy rule is remarkably efficient, and that in fact, the above behavior is quite rare.

Our specific objective is to analyze packet waiting times under the greedy policy. (Hereafter, unless noted otherwise, waiting times always refer to times spent waiting in processor queues.) To prepare for the statement of our main theorem on waiting times, we need a little more notation. For a given admission policy, we denote the joint queue length at integer time t by $\mathbf{Q}(t) = (Q_1(t), \ldots, Q_N(t))$, where $Q_i(t)$ is the number in the ith processor queue at time t. The phrase "at time t" means at an instant just after t so that events, if any, occurring at t have already taken place. Define the N-bit vector $\mathbf{R}(t)$ whose ith bit is 1 if and only if a packet is in the ith cell at time t. Hereafter, the term *state* refers to a pair $\mathbf{Q}(t), \mathbf{R}(t)$ at some time t. It follows from the geometric law for transit times that the *ring process* $\{(\mathbf{Q}(t), \mathbf{R}(t)), t = 0, 1, \ldots\}$ is a Markov chain. It was shown by Coffman et al. (1995) that, if $\lambda < \mu$, then the ring process under the greedy rule is ergodic. Unfortunately, an exact analysis of the stationary behavior of this ring process seems quite difficult. Indeed, attempts to solve the balance equations have so far failed even for the case $N = 2$. Thus, we turn to asymptotic estimates for large ring sizes, N, with λ and μ fixed and $\lambda < \mu$. That is why we introduced the scalings λ/N and μ/N; as we allow N to increase, the traffic intensity will remain fixed at $\rho = \lambda/\mu$, the usual product of arrival rate and average service (transit) time.

With $\lambda < \mu$, let Q have the stationary distribution common to all queue lengths $Q_i(t)$, and let W be the waiting time of a packet in the stationary regime.

THEOREM 1.1. *Fix λ and μ with $\lambda < \mu$. Then, under the greedy policy,*

$$E[Q] = \Theta(1/N) \ .$$

Thus, by Little's theorem,

$$E[W] = \Theta(1) \ .$$

The lower bounds are easy to see, as follows. Consider the entire ring as an N-server system with a total arrival rate λ and maximum departure rate μ. Then, by Little's theorem, the arrival rate λ times the average time spent on the ring, i.e., N/μ, must be equal to the expected number of packets on the ring in the stationary regime, i.e., ρN. But if a positive fraction $\rho > 0$ of the ring is occupied on average, then there must be a positive average waiting time $E[W] = \Omega(1)$ to get on the ring and hence $E[Q] = \Omega(1/N)$.

In the usual way, *on-line* admission policies are those deciding packet admissions solely on the basis of information currently available about packets already in the system, waiting or on the ring. Such information can include, for example, queue

lengths and the elapsed times already spent in the system by packets. As we will see later, it is convenient to extend this class of admission policies by allowing decisions to depend also on the times and queues of future arrivals. *Hereafter, unless stated otherwise, the term* policy *refers to a policy in this extended class.* Note, in particular, that policies retain the on-line property with respect to transit times on the ring; i.e., we do not allow policies that base decisions on prior knowledge of remaining transit times.

We say that a policy A is optimal if, over any interval $[0, T]$, the sum of waiting times (in queue) under A is stochastically no larger than that under any other policy starting in the same initial state. We prove in the next section that the greedy policy is an optimal policy (the proof will need the geometric law for transit times). In the proof of Theorem 1.1, this result allows us to analyze a more tractable policy with the same asymptotic performance as the greedy rule; the more tractable policy exploits the fact that policies can base decisions on the times and queues of future arrivals.

Coffman et al. (1995) proved in an earlier paper that the growth of the expected waiting time in our model was sublinear in N, i.e., $E[W] = o(N)$. Our much stronger result shows that the expected waiting time is in fact bounded by a constant. So, by Little's theorem, an important practical implication of our result is that the expected size of a buffer needed to hold all waiting packets is bounded by a constant uniformly in N. The proof of Theorem 1.1 requires a much more intricate probabilistic analysis than the one in Coffman et al. (1995), where the law of large numbers was the basic tool. Here, we will need more powerful asymptotic bounds (e.g., those of Chernoff type) on the tail probabilities for sums of independent random variables and the excursions of Lindley processes (see, e.g., Prabhu (1965), p. 66); these appear as lemmas in section 3. The proof of the upper bound $E[Q] = O(1/N)$ is given in sections 4 and 5. The paper concludes in section 6 with a brief discussion of extensions and open problems.

2. Preliminaries. Consider the packet at the head of any given nonempty queue. Since transit times are geometrically distributed with parameter μ/N, the probability that this packet is placed on the ring in the current time step is at least μ/N; the conditional probability is precisely μ/N if the cell is occupied on arrival, and it is trivially 1 if the cell is empty. Thus, one expects that, in statistical equilibrium, the ith queue length Q_i is bounded stochastically for each i by the length of a single-server Markov (i.e., M/M/1) queue in discrete time with arrival and service rate parameters λ/N and μ/N. Moreover, this bound should hold independently for each queue. Indeed, these observations are but a special case of Theorem 2 in Coffman et al. (1995). An easy analysis of the discrete-time M/M/1 queue then proves the following lemma.

LEMMA 2.1. *For each i independently, Q_i is stochastically smaller than a nonnegative integer random variable L with $P(L = n) \sim (1 - \rho)\rho^n$ as $N \to \infty$ for every $n \geq 0$, and with*

$$P(L > n) = O(e^{-\nu n}) \ , \tag{2.1}$$

where $\nu = \ln 1/\rho > 0$.

Hereafter, we take the equivalent point of view that *the queues rotate past the ring of cells, which remains fixed.* As shown in Fig. 2, in any given time interval $[0, T]$, the ring process can be represented by events on a cylindrical lattice cut at some cell position and laid out as a rectangle. For simplicity, we assume that the cylinder is cut between cell N and cell 1. Along the top of the rectangle the $Q_i(0)$, $1 \leq i \leq N$,

give the initial state of the queues, and the bullets (•'s) indicate the initial cell states: a cell with a • at time 0 is empty; otherwise, it is occupied. Again, for simplicity, we assume queue 1 is at cell 1 at time 0. Within the rectangle, circles (∘'s) and bullets give a random sample of arrivals and departures, respectively. A • and ∘ can appear at the same lattice point. The probability of such an event is $O(1/N^2)$, and hence relatively low; for simplicity, the figures in this paper do not show samples where such coincidences occur.

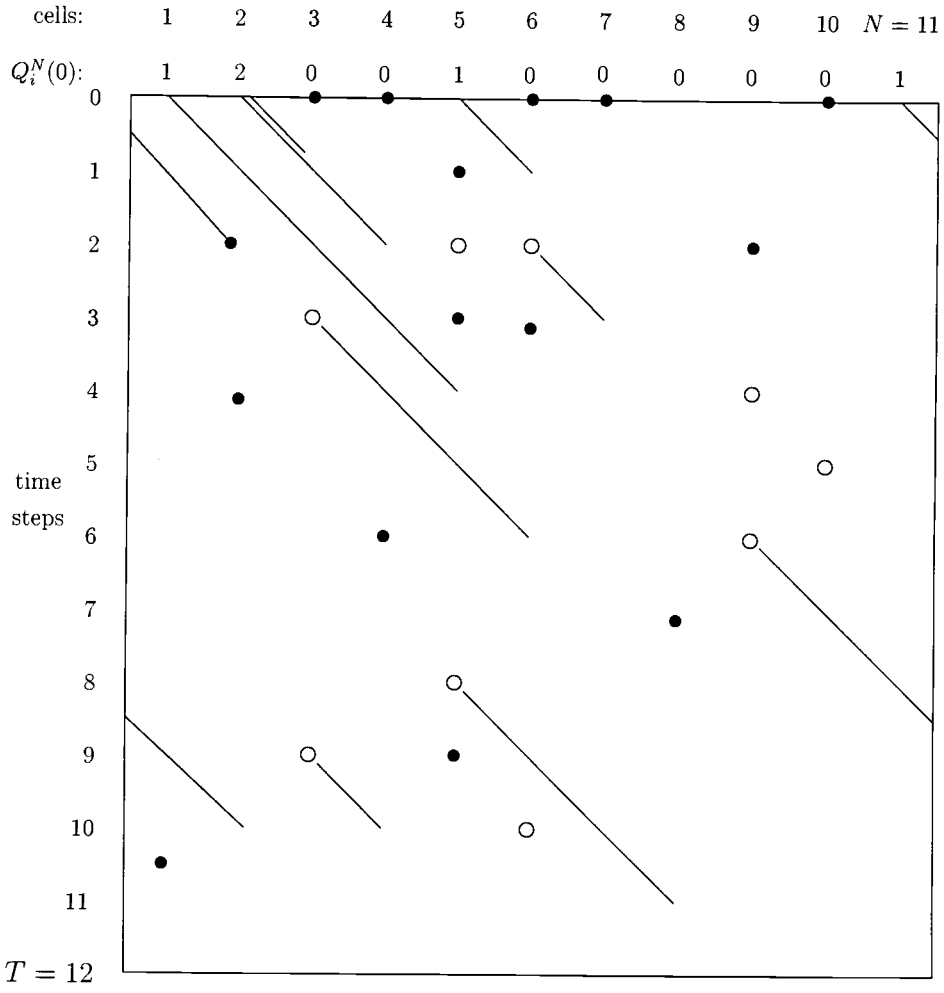

FIG. 2. *Greedy assignment.*

The greedy policy is represented by a suitable assignment of cells to circles (new arrivals) and to packets in the initial state. An example is shown in Fig. 2. The *motion* lines drawn between packets and assigned cells describe the trajectories of the packets in time and space; their vertical components correspond to waiting times. A motion line is broken into two pieces when it extends past cell N, one ending at the right boundary and one beginning at the same time at the left boundary.

To ensure that an assignment of circles and initial packets to cells is valid, one must check to see that the cell, say c, at which a motion line terminates, at time t say, is indeed empty at time t. Thus, if t', $0 \le t' < t$, is the time of the last departure (bullet) in cell c, then no other motion lines can terminate at cell c in the interval $[t', t]$.

We conclude this section with a proof that greedy is optimal in that it minimizes stochastically the sum S of waiting times over any given interval $[0, T]$. The proof uses the following simple relation between S and the queue lengths $Q_i(t)$ during $[0, T]$:

$$S = \sum_{t=0}^{T} \sum_{i=1}^{N} Q_i(t) \ . \tag{2.2}$$

THEOREM 2.1. *The greedy rule is an optimal admission policy.*

Proof. Consider ring operation over an interval $[0, T]$, and let A be an arbitrary policy. To compare total waiting times in $[0, T]$ under A and greedy, both starting in the same initial state, we compare both to an intermediate algorithm A*, which is artificial in that it sometimes returns packets to queues before they have completed their transit times. Under A* an occupied queue places a packet into the first available empty cell, just as with the greedy policy. But suppose that, under A* at some time t, a cell c occupied by packet φ is in front of a queue having a packet φ' that, under A, would have been in c at time t. Then at time t, φ and φ' change places under A*; φ joins the queue and φ' enters the cell.

At any given queue, the admissions under A* and greedy implement the same deterministic rule except at times when A* exchanges a packet in the queue with the packet in the cell in front of the queue. *But such an exchange does not change the state (any queue length or the state of any cell) of the ring process*; from the point of view of the ring process, the exchange has the effect of doing nothing, which is just what the greedy rule would do in the same circumstances. Thus, if A* and greedy start in the same initial state, then the joint queue-length process over $[0, T]$, and hence by (2.2) the sum of waiting times over $[0, T]$, is stochastically the same under A* and greedy.

It remains to show that the sum of waiting times over $[0, T]$ under A is at least as large stochastically as it is under A*. In fact, we prove the stronger deterministic result: for a given initial state, a given sequence of arrivals over $[0, T]$, and a given sample of the remaining transit times of all packets in the system during $[0, T]$, the sum of waiting times under A is at least that under A*. To see this, note first that, although A* may put a packet φ on and off the ring several times, eventually one of three events will occur: φ will depart, T steps will have been taken, or φ will be in a queue when the cell assigned to it under A catches up to it. In the last case, A* places φ on the ring making an exchange, if needed, and leaves it there until it departs or T steps have been made. Thus, every packet during $[0, T]$ has moved along the ring under A* at least as far as it has moved under A, and so the sum of waiting times under A* is deterministically at most the sum under A. □

3. Probability bounds. The reader may wish to skip this section at first reading, referring back to it as needed while reading section 5. We begin with a useful Chernoff bound that combines Theorems A.12 and A.13 of Alon and Spencer (1991), pp. 237–238.

LEMMA 3.1. *Let $Z = Z_1 + \cdots + Z_n$, where the Z_i are independent Bernoulli random variables with $P(Z_i = 1) = p_i$, $P(Z_i = 0) = 1 - p_i$. Then for any $\epsilon > 0$, there exists a $\beta > 0$ such that*

$$P((1-\epsilon)E[Z] < Z < (1+\epsilon)E[Z]) = 1 - O(e^{-\beta E[Z]}) \ . \tag{3.1}$$

Next, we consider a Lindley process, starting at the origin and defined by (x^+ denotes the positive part of x)

$$\zeta_0 = 0, \quad \zeta_i = (\zeta_{i-1} + U_i)^+, \tag{3.2}$$

with $U_i = X_i - Y_i$, where $\{X_i\}$ and $\{Y_i\}$ are independent sequences of i.i.d. random variables. In our application, Y_i is an integer in $\{0, \ldots, K\}$ with K a given integer constant independent of N, and X_i is the number of arrivals of a rate-$a\lambda/N$ Bernoulli process in bN time steps, where a and b are constants independent of N. Thus, for large N, X_i is approximately Poisson distributed with mean $ab\lambda$. It is easy to check that X_i and hence U_i has an exponential tail probability; i.e., there exists a $\kappa > 0$ such that

$$P(U_i > x) \le P(X_i > x) = O(e^{-\kappa x}) \ . \tag{3.3}$$

The process $\{\zeta_i\}$ is said to have negative drift if $E[Y_i] > E[X_i]$ and hence $E[U_i] < 0$. The next result follows from standard theory (e.g., see Asmussen (1987)). Let the X_i and U_i be distributed as X and U, respectively.

LEMMA 3.2. *If $E[U] < 0$, then $E[\zeta_i]$ is bounded by a constant uniformly in $i \ge 0$. The distributions of the ζ_i converge in total variation to the distribution of a random variable ζ with moments of all orders.*

In addition to Lemma 3.2, we will need certain probability bounds on excursions of $\{\zeta_i\}$. These will be derived in terms of corresponding bounds for the unrestricted process

$$\xi_i = \xi_{i-1} + U_i, \quad i \ge 1 \ , \tag{3.4}$$

with the U_i defined as before, and with a given initial state ξ_0. Hereafter, we assume a negative drift $E[U] < 0$.

The probability bound on excursions of $\{\xi_i\}$ that we will use in the analysis of $\{\zeta_i\}$ is developed as follows. Since $E[U] < 0$ and $P(U > 0) > 0$, there exists an $\alpha_0 > 0$ such that $E[e^{\alpha_0 U}] = 1$. Define the process $\xi_i^* = e^{\alpha_0 \xi_i}$, $i \ge 0$, with the property

$$E[\xi_{i+1}^* \mid \xi_i^*] = E[e^{\alpha_o U_i} \xi_i^* \mid \xi_i^*] = \xi_i^* E[e^{\alpha_0 U}] = \xi_i^* \ .$$

Together with our assumptions on U, this shows that $\{\xi_i^*\}$ is a uniformly integrable martingale, so we have

$$\begin{aligned} P\left(\sup_{i\ge 0} \xi_i \ge x\right) &= P\left(\sup_{i\ge 0} \xi_i^* \ge e^{\alpha_0 x}\right) \\ &\le e^{-\alpha_0 x} E[\xi_0^*] = E[e^{-\alpha_0 (x - \xi_0)}] \ , \end{aligned} \tag{3.5}$$

where the inequality follows from Doob's martingale inequality (see, for example, section 35 in Billingsley (1986)).

We now use (3.5) to get similar bounds for the *busy periods* of $\{\zeta_i\}$. In analogy with queueing applications, we say that steps i_1 through i_2, $i_2 > i_1$, comprise a busy period if $\{\zeta_i\}$ moves away from the origin at step $i_1 \ge 1$ and makes its first subsequent return to the origin at step i_2, i.e., $\zeta_{i_1 - 1} = 0$, $\zeta_j > 0$, $i_1 \le j < i_2$, and $\zeta_{i_2} = 0$. The process is *idle* while it resides at the origin. We want a probability bound on the

maximum value of the process during a busy period B. For this purpose, we make use of the fact that, away from the origin, $\{\zeta_i\}$ behaves as an unrestricted random walk. In particular, the conditional probability that, given the first jump $U_{i_1} > 0$, $\{\zeta_i\}$ exceeds level x before its next return to the origin is the same as the probability that, starting in state U_{i_1}, the unrestricted version $\{\xi_i\}$ exceeds level x before its first passage to a point at or below the origin. As an easy consequence of (3.3) and (3.5), we have that, for a randomly chosen busy period B of $\{\zeta_i\}$,

$$P\left(\sup_{i\in B}\zeta_i > x\right) \le E[e^{-\alpha_0(x-U)}|U>0] \le e^{-\alpha_0 x}E[e^{\alpha_0 X}|X>K] = O(e^{-\alpha_0 x}), \tag{3.6}$$

since $X \ge U \ge X - K$ and X is a binomial random variable with a mean bounded independently of N.

Our primary interest is in the behavior of $\{\zeta_i\}$ over a finite (and large) number of steps. It is convenient to let N denote the number of steps, since in later applications of the results below, N will also denote the ring size. For example, a bound on $P(\sup_{1\le i\le N}\zeta_i > \alpha \ln N)$, $\alpha > 0$, will be useful. To get such a bound, note that there are at most $N/2$ busy periods in the first N steps of $\{\zeta_i\}$. Then, by (3.6),

$$P\left(\sup_{1\le i\le N}\zeta_i > x\right) \le \frac{N}{2}P\left(\sup_{i\in B}\zeta_i > x\right) = O(e^{-\alpha_0 x+\ln N}) \ .$$

Thus, for any $\gamma > 0$, we can choose $x = x(N) = \alpha \ln N$ with $\alpha = \alpha(\gamma)$ sufficiently large that

$$P\left(\sup_{1\le i\le N}\zeta_i > \alpha\ln N\right) = O(e^{-\gamma\ln N}) = O(N^{-\gamma}) \ . \tag{3.7}$$

Consider next the duration D of busy period B.

LEMMA 3.3. *There exists an $\eta_0 > 0$ such that*

$$P(D > y) = O(e^{-\eta_0 y}) \ .$$

Proof. Let $\{U_i\}$ be the common sequence generating both $\{\zeta_i\}$ and $\{\xi_i\}$, $\zeta_0 = \xi_0 = 0$, and suppose the first busy period B_1 of $\{\zeta_i\}$ begins at step $\ell \ge 1$. Let D_1 be the duration of B_1. It is easy to check that, for any integer $y \ge 1$, the event $\{\zeta_i > 0 \text{ for all } i, \ell \le i \le \ell + y\}$ implies the event $\{\xi_{\ell+y} \ge \xi_\ell\}$. Busy periods are i.i.d. and $P(\xi_{\ell+y} \ge \xi_\ell)$ does not depend on ℓ, so

$$\begin{aligned} P(D > y) = P(D_1 > y) &\le P(\xi_{\ell+y} \ge \xi_\ell) \\ &\le P(\xi_y \ge 0). \end{aligned} \tag{3.8}$$

By Lemma 3.1, we obtain that, for any $\epsilon > 0$, there exists an $\alpha > 0$ such that

$$P(\xi_y > (1-\epsilon)E[\xi_y]) = O(e^{\alpha E[\xi_y]}) \ , \tag{3.9}$$

with $E[\xi_y] = yE[U] < 0$. To see this, we need only observe that the U_i and hence ξ_y can be expressed as sums of independent 0-1 random variables. Put $\epsilon = 1$ in (3.9) and conclude that, for some $\alpha_1 > 0$,

$$P(\xi_y \ge 0) = O(e^{\alpha_1 yE[U]}) \ . \tag{3.10}$$

Together with (3.8), this proves the lemma. □

4. Admission policy. The proof of Theorem 1.1 will use the admission policy of this section. Before presenting the policy, however, we will briefly review how it is applied in the general argument.

The proof of Theorem 1.1 estimates the expected value of the sum $S \equiv S(N,T)$ of waiting times under the greedy policy in an interval of length $T = \Theta(N^3)$, assuming that the state of the queues at the beginning of the interval is a sample from the stationary distribution. For convenience, we take $[0,T]$ as the interval. To make use of the estimate, observe that in the stationary regime, $E[Q_i(t)] = E[Q]$, so by (2.2) $E[S] = NTE[Q]$ and

$$E[Q] = \frac{E[S]}{NT} \ . \tag{4.1}$$

We will prove that, under the admission policy defined below, the sum $\tilde{S}$ of waiting times over $[0,T]$ satisfies $E[\tilde{S}] = O(N^3)$. By Theorem 2.1, $E[S] \le E[\tilde{S}]$, so substitution into (4.1) proves $E[Q] = O(1/N)$, since $T = \Theta(N^3)$. Then Theorem 1.1 is proved.

We now discuss the admission policy, Algorithm A, shown in Fig. 3, previewing as we go along the properties of the algorithm that must be proved in the probabilistic analysis of the next section. The algorithm is based on various constants and structures determined by λ and μ, which we describe first. The algorithm takes as input an $\epsilon > 0$ such that $\mu(1-2\epsilon) > \lambda$, and reserves a sequence of $2\epsilon N$ cells of the ring as nearly equally spaced as possible. (The lengths of adjacent intervals between reserved cells differ by at most 1.) Call the odd-numbered cells of this sequence *initialization* (I) cells, and the even-numbered cells *clean-up* (CU) cells. *Regular* cells are those that are neither I nor CU cells.

To avoid trivialities and to simplify notation, we assume in what follows that $(2\epsilon)^{-1}$ and ϵN are integers. The reserved (I and CU) cells partition the $(1-2\epsilon)N$ regular cells into $2\epsilon N$ groups C_j, with $(2\epsilon)^{-1} - 1$ cells per group. We also define a partition of the queues into $2\epsilon N$ groups G_j, $1 \le j \le 2\epsilon N$, with $(2\epsilon)^{-1}$ per group. The index j is taken mod $2\epsilon N$ if $j > 2\epsilon N$.

Algorithm A determines the schedule over the time interval $[0, N + bN^3]$, which is partitioned into an initial block B_0 of N steps followed by N^2 blocks $B_1, \ldots, B_{N^2}$ of bN steps each. The parameter b must be chosen sufficiently small; the probabilistic analysis of section 5 will give an upper bound in terms of μ and λ.

The algorithm is preceded by the following process: independently, at every cell and time step a mark ($\times$) is placed with probability μ/N; these marks are superposed on the input arrival pattern. If, by Algorithm A, a packet φ is placed in cell j at time t, then the first $\times$ after time t in column j signals the departure of φ from the ring (these particular $\times$'s correspond to bullets in Fig. 2). By the memoryless property of the geometric distribution of the times between successive $\times$'s in any column, this rule for determining departures yields geometric transit times on the ring, as desired.

With this set-up, the algorithm is as follows (see Fig. 3). First, the interval $[0,N]$ of B_0 is devoted solely to the accumulation of empty CU cells, to be used as described later, starting at time N. No admissions to the ring are scheduled during $[0,N]$. This is for convenience only; our asymptotic results would not change if such scheduling were allowed.

At time N, the algorithm partitions the empty CU cells into sequences σ_k, $1 \le k \le a \ln N$, as nearly equal in length as possible (see step 1 in Fig. 3), for a constant a sufficiently large to be determined by the probabilistic analysis. Apart from their

size and number, the sequences σ_k can be chosen arbitrarily from among the empty CU cells.

The remainder of step 1 assigns I cells starting at time N to just those packets in the initial state plus those that arrived in $[0, N]$. The jth I cell admits the packets in the ϵ^{-1} queues of $G_{2j-1} \cup G_{2j}$ at time N; it serves these queues in a round-robin sequence; i.e., a $(k+1)$st packet from one of the queues is not admitted until at least k visits have been made to the other queues (admitting a packet at each visit if one is there).

Note that the I cells work in parallel with the other cells that serve the arrivals in $B_1, \ldots, B_{N^2}$. The probabilistic analysis will use elementary bounds to show that the expected total waiting time of packets served by I cells is negligible, i.e., $o(N^3)$.

Almost all of the arriving packets in the B_i, $1 \le i \le N^2$, are assigned by the iterations of step 2 to regular cells during the interval $[N, N + bN^3]$ (see Fig. 3). Arrivals in B_i are assigned to cells at time $N + (i-1)bN$, $1 \le i \le N^2$. At this time, a regular cell is called *available* if its column segment in B_{i-1} has at least one $\times$, its column segments in B_{i-2} and B_{i-3} have no $\times$, and the cell has not already been assigned to an arrival in B_i (if $i = 2$, then the reference to B_{i-3} is omitted, and if $i = 1$, the references to both B_{i-2} and B_{i-3} are omitted). Examples are given in Fig. 4, which are referenced again at the end of this section. Step 2 scans the groups G_j in left-to-right order beginning with G_1. Assume for simplicity that the cell group C_j is lined up in front of the queues in G_j so that the last cell of C_j is in front of the last queue in G_j (recall that C_j has one fewer cell than G_j has queues). This is the alignment assumed in step 2 of Fig. 3.

For $j = 1, \ldots, 2\epsilon N$, the arrivals as yet unassigned to $G_1, \ldots, G_j$ are assigned in any order to the available cells of C_{j+1} until either the former or latter set is empty, whichever occurs first. At the end of this process, there may still be unassigned arrivals in B_i; these are called *leftover* packets. Also, there may have been instances where an arrival was assigned to a cell more than bN cells (time units) away. These assignments are discarded and the corresponding packets are left unassigned throughout $[0, N + bN^3]$. The restriction to cells that are both available (in the above limited sense) and not too far from the arrivals assigned to them guarantees that Algorithm A makes valid assignments. We will verify this fact after we describe the remainder of the algorithm.

The probabilistic analysis will show that, for each block B_i, the number of available cells in the C_j's is sufficiently large to ensure an $O(N)$ expected total waiting time for the arrivals assigned in step 2. Then, for all N^2 blocks, the total waiting time is $O(N^3)$, as desired. The analysis will then show that the assignment of an arrival to a cell more than bN columns away is so rare that its effect on total waiting time is negligible.

Finally, step 3 of the algorithm takes care of leftover packets by assigning them to the cells of the sequences σ_k. These assignments are organized so that, for each $k = 1, \ldots, a \ln N$, the leftover packets of B_k, $B_{k+a\ln N}$, $B_{k+2a\ln N}$, ... are all assigned to cells in the same sequence σ_k. Thus, for $r \ge 0$, the leftover packets in $B_{k+ra\ln N}, \ldots, B_{k+(r+1)a\ln N-1}$ are served in parallel by disjoint regions of the ring.

The probabilistic analysis will show that, except for a negligible fraction of the leftover packets, all of those admitted by the cells of σ_k from $B_{k+ra\ln N}$ for any $r \ge 0$ will have departed when it is time to start admitting the arrivals in $B_{k+(r+1)a\ln N}$ into the cells of σ_k. In addition, the analysis will show that the expected total wait of the leftover packets in B_i is $O(N)$, and hence the expected total wait for leftovers from all N^2 blocks is $O(N^3)$, as desired.

Algorithm A

Input: N, a, b, ϵ, an initial state and sets of arrivals and marks ($\times$'s) over $[0, N + bN^3]$

1. (i) At time N, the empty CU cells are partitioned into sequences σ_k, $1 \le k \le a \ln N$, whose lengths differ by at most 1.
   (ii) For $j = 1, \ldots, \epsilon N$, the jth I cell admits just those packets appearing in the ϵ^{-1} queues of $G_{2j-1} \cup G_{2j}$ at time N. For each j, these queues are served by a round-robin starting at time N.

For $i = 1, \ldots, N^2$, the following two steps are performed.

2. (i) Assume that the queues in G_j are aligned with the cells of C_j, at the time B_i begins. For $j = 1, \ldots, 2\epsilon N$, the as yet unassigned arrivals in the queues of $G_1, \ldots, G_j$ are assigned to the available cells in C_{j+1} until the former or the latter are exhausted, whichever occurs first ($C_{2\epsilon N+1} \equiv C_1$).
   (ii) Assignments just made that match an arrival to a cell more than bN columns (cells) away are removed.
3. Let integer k satisfy $1 \le k \le a$ and $i = ma + k$ for some integer $m \ge 0$. Then the leftover packets, if any, of B_i are admitted according to the greedy rule by the empty CU cells of σ_k; admissions stop when there are no more leftovers to admit or when the empty cells of σ_k have been exhausted, whichever occurs first.

FIG. 3. *An admission algorithm.*

It is easy to see that, if Algorithm A always makes valid assignments (loads packets into empty cells), then it is indeed a valid admission policy; the (future) arrivals in B_i are known when assignments are made at the beginning of B_i, but knowledge of future departure times is not used at any point. (This is obvious for steps 1 and 3; it is clear for step 2 as well, since cell availability at the beginning of B_i depends only on departures times in $B_1 \cup \cdots \cup B_{i-1}$.)

It remains to verify that, under Algorithm A, whenever an arrival reaches the cell to which it is assigned by the algorithm, the cell is empty. But suppose that cell j is the available cell assigned by step 2(i) to arrival φ in B_i and that it remains assigned to cell j after step 2(ii). (See Fig. 4 for examples.) Then the earliest that cell j can again become available occurs when assigning arrivals in B_{i+3}; no arrival of B_{i+1} or B_{i+2} can be assigned to cell j by the definition of cell availability and the fact that B_{i-1} has a $\times$ in column j. If cell j is indeed available during the scan of B_{i+3}, then there must be a $\times$ in B_{i+2}. This $\times$ must come after the admission of φ to cell j; otherwise the motion line of φ would span more than bN columns, and this would contradict step 2(ii), where such assignments are removed. Thus, this $\times$ in B_{i+2} guarantees that any packet already in cell j will have departed before cell j is re-used for an arrival in B_{i+3} or some later block.

5. Proof of Theorem 1.1. Recall the general approach outlined at the beginning of the previous section: we prove that $E[\tilde{S}] = O(N^3)$, where $\tilde{S}$ is the sum of the waiting times in $[0, N + bN^3]$ under Algorithm A. It is enough to show, as is done below, that the $O(N^3)$ bound holds for the packets considered by each of the three steps individually.

In what follows, when we say that an event occurs *with high probability*, we mean that it occurs with probability $1 - O(N^{-\gamma})$, where γ can be made as large as desired by a suitable choice of (usually hidden) constants. For example, by the geometric law for transit times V, we have

$$P(V \le dN \log N) = 1 - (1 - \mu/N)^{dN \log N} ,$$

and so $P(V \le dN \log N) \sim 1 - N^{-\mu d}$ as $N \to \infty$. Thus, we can say that transit times are $O(N \log N)$ with high probability; $\gamma = \mu d$ can be made as large as desired by increasing d. Note that m high-probability events occur *jointly* with high probability if m is at most some polynomial in N.

Step 1. Consider the ith queue length $Q_i(N)$ at time N and recall that $Q_i(0)$ has the stationary distribution. Algorithm A admits no packets to the ring in $[0, N]$, so $Q_i(N)$ is $Q_i(0)$ plus the number of arrivals in $[0, N]$ at queue i. At time N, $Q_i^*(N)$ counts the packets waiting at time N in queue i plus the packet, if any, in the I cell that serves queue i in step 1. We have $Q_i^*(N) \le Q_i(N) + 1$, so by Lemma 2.1 and the geometric law of interarrival times, there exists an $\eta > 0$ such that $P(Q_i^*(N) \ge k+1) \le P(Q_i(N) \ge k) = O(e^{-\eta k})$ independently for all queues. Let $\tilde{S}_i^{(1)}$ be the total waiting time of the packets counted by $Q_i(N)$, and let $\mathcal{C}$ be the joint event in which (i) for some $c > 0$ the first $Q_i(N) \wedge c \ln N$ packets waiting in queue i at time N have $O(N \log N)$ transit times, and (ii) at time N the packet, if any, in the I cell serving queue i has $O(N \log N)$ remaining transit time. By the geometric law for transit times, $\mathcal{C}$ has high probability.

Since each I cell serves a constant number of queues in a round-robin sequence, the kth packet in any queue must wait $k \cdot O(N \log N)$ time if $\mathcal{C}$ holds and $k \le c \ln N$. Since no packet can wait more than $bN^3 + N$ time, we obtain the bound

$$\begin{aligned} E[\tilde{S}_i^{(1)} | \mathcal{C}] &= \sum_{1 \le k \le c \ln N} k \cdot O(N \log N) \quad + \quad O(N^3) \cdot E(Q_i(N) - c \ln N)^+ \\ &= O(N \log^3 N) + O(N^{-\eta c}) \cdot O(N^3) \\ &= O(N \log^3 N) \end{aligned}$$

by choosing c large enough. If $\mathcal{C}$ does not hold, we use the $O(N^3)$ trivial bound for all packets to obtain $E[\tilde{S}_i^{(1)} | \overline{\mathcal{C}}] = O(N^3)$, since $E[Q_i(N)] = O(1)$. But $\overline{\mathcal{C}}$ has low probability, so $E[\tilde{S}_i^{(1)}] = O(N \log^3 N)$. Since $\mathcal{C}$ holds simultaneously for all i with high probability, we can conclude that

$$E[\tilde{S}^{(1)}] = N E[\tilde{S}_i^{(1)}] = O(N^2 \log^3 N) = O(N^3),$$

as desired.

Step 2. We analyze the left-to-right scan of the sets G_j in B_i and C_j in B_{i-1}, and bound first the expected total waiting time of the packets that are assigned in step 2(i). Define the Lindley process

$$\zeta_0 = 0, \quad \zeta_j = (\zeta_{j-1} + U_j)^+, \quad j = 1, \ldots, \epsilon N,$$

where $U_j = X_j - Y_j$, X_j is the number of arrivals in G_j and Y_j is the number of available columns in C_{j+1} at the start of the jth iteration in step 2. It is easy to see that, among the arrivals already scanned in $G_1, \ldots, G_j$, ζ_j gives the number as yet unassigned at the start of the $(j+1)$st iteration. Thus, $(2\epsilon)^{-1}(\zeta_1 + \cdots + \zeta_{2\epsilon N})$ is the cumulative waiting time $\tilde{S}_i^{(2)}$ of the arrivals assigned in B_i, not counting the times spent waiting by these arrivals in their initial and final blocks. The latter times are bounded by $2(2\epsilon)^{-1} = \epsilon^{-1}$, so

$$\tilde{S}_i^{(2)} \le (2\epsilon)^{-1}(\zeta_1 + \cdots + \zeta_{2\epsilon N}) + \epsilon^{-1}(X_1 + \cdots + X_{2\epsilon N}).$$

But $E[X_j] = \lambda b (2\epsilon)^{-1}$, and if $E[U_j] < 0$ then $E[\zeta_j] = O(1)$, by Lemma 3.2, so that $E[\tilde{S}_i^{(2)}] = O(N)$ and hence the expected total wait of assigned packets summed over all i is $O(N^3)$, as desired. Thus, it remains to prove that $E[U_j] < 0$.

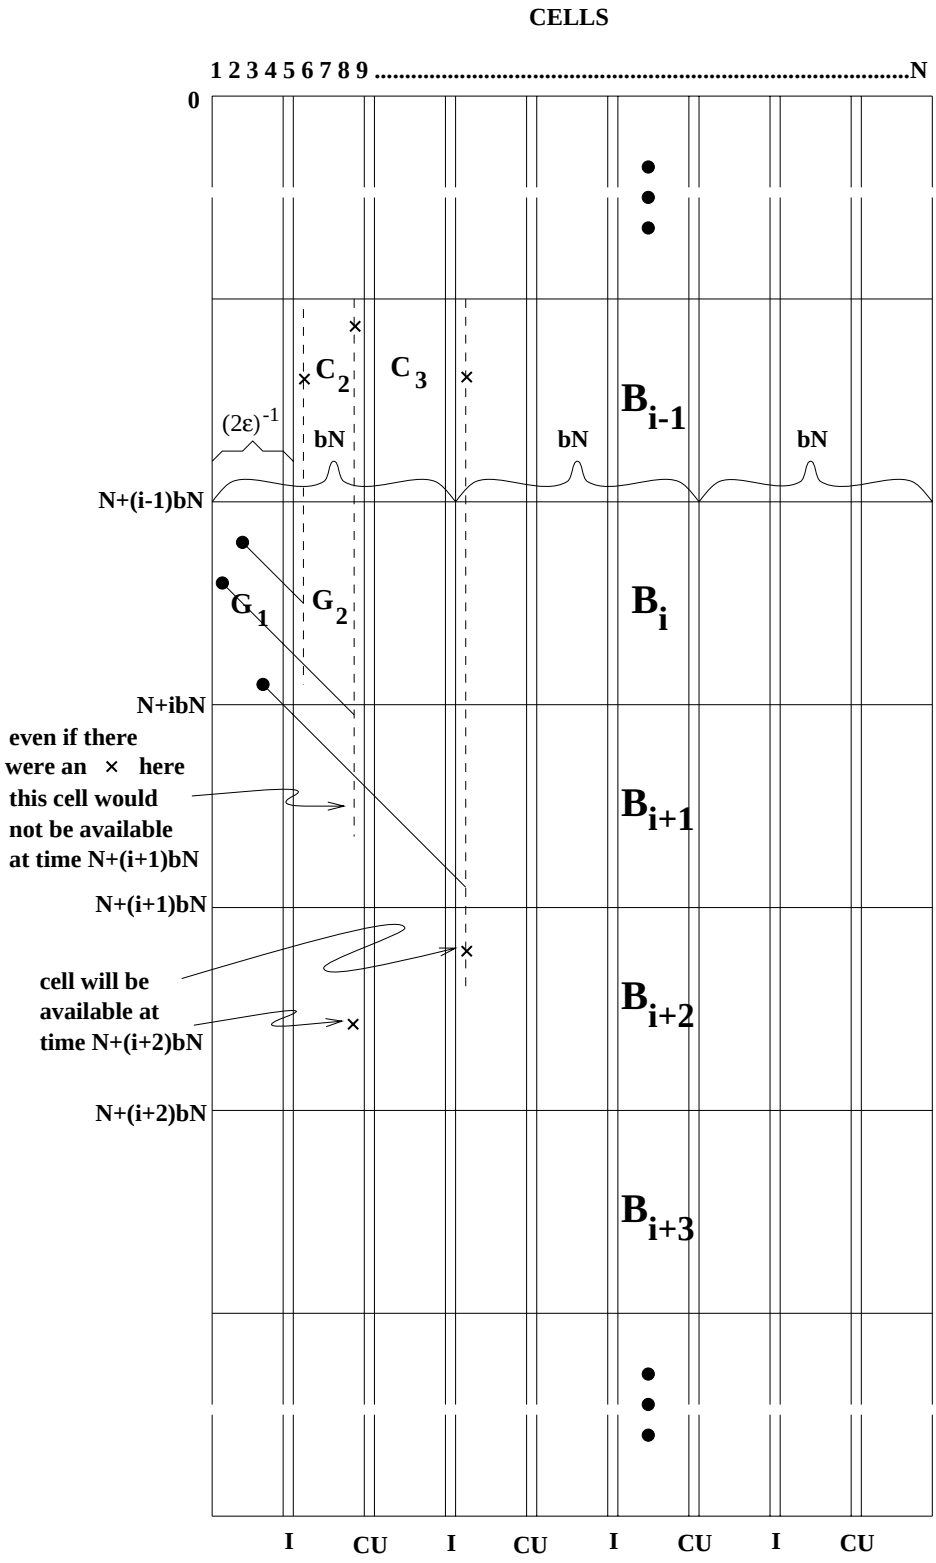

FIG. 4. *Admission algorithm.*

We need to verify that $P(A_k) > \lambda b/(1-2\epsilon)$, where A_k is the event in which column k is available when assignments to arrivals in B_i begin; for then, since there are $(2\epsilon)^{-1}-1$ columns in the C_j,

$$E[Y_j] > \frac{\lambda b}{1-2\epsilon}[(2\epsilon)^{-1}-1] = (2\epsilon)^{-1}\lambda b = E[X_j],$$

and hence $E[U_j] < 0$. We consider B_i for $i \geq 4$; the cases $i = 1, 2, 3$ are similar. We need only observe that A_k holds if there is at least one $\times$ in a column of B_{i-1} and none in B_{i-2} and B_{i-3}, so

$$P(A_k) = [1-(1-\mu/N)^{bN}](1-\mu/N)^{2bN} \sim (1-e^{-\mu b})e^{-2\mu b}$$

as $N \to \infty$. Then for all N sufficiently large,

$$b < \frac{1}{5}\frac{\mu(1-2\epsilon)-\lambda}{(1-2\epsilon)\mu^2}$$

is enough to ensure that $P(A_k) > \lambda b/(1-2\epsilon)$.

It remains to estimate the added total waiting time of the packets that were assigned but then unassigned in step 2. But by Lemma 3.3 the probability that a packet is assigned to a $\times$ at least bN columns (and hence $\Omega(N)$ groups C_j) away is exponentially small in N. It follows that the expected added total waiting time of such packets is $o(1)$, since the number and maximum wait of such packets are both bounded by polynomials in N. Thus, the expected total wait of all packets examined in step 2 is $E[\tilde{S}^{(2)}] = O(N^3)$, as desired.

Step 3. Let $k_i = (i-1) \bmod (a \ln N) + 1$, and note that, by step 3, the leftover packets of B_i should go into the cells of σ_{k_i}.

We argue first that, by an application of Lemma 3.1, at time N there are at least $\frac{\epsilon}{2}(1-e^{-\mu})N$ empty CU cells with very high probability (i.e., with probability $1-O(e^{-\Omega(N)})$); thus, with very high probability, any existing leftover packets are assigned to the $a \log N$ sequences σ_k, which have $\Omega(N^\beta)$ cells each for every β, $0 < \beta < 1$.

For definiteness, choose $\beta = 1/2$ and let $\mathcal{E}_i$ be the event in which the leftover packets of B_i number fewer than $N^{1/2}$ and each has a transit time at most $bN \cdot a \ln N - N$. In this event, the waiting time of each leftover packet is at most N and the leftover packets of B_i leave the CU cells of σ_{k_i} empty by the time the next set of leftover packets (those in $B_{i+a\ln N}$) have to be scheduled in the cells of σ_{k_i}. By (3.7) and the geometric law for transit times, $\mathcal{E}_i$ holds with high probability for all a large enough. There are only N^2 such events, so the combined event $\mathcal{E} = \bigcap_{i=0}^{N^2} \mathcal{E}_i$ also holds with high probability, where $\mathcal{E}_0$ is the event in which there exist at least $\frac{\epsilon}{2}(1-e^{-\mu})N$ empty CU cells at time N.

Now suppose $\mathcal{E}$ holds. Then, since a leftover packet waits at most N and there are N^2 blocks, the conditional expected total waiting time is $O(N^3)$ times the conditional expected number of leftover packets per block B_i, i.e., $O(N^3) \cdot E[\zeta_N|\mathcal{E}]$. But

$$E[\zeta_N|\mathcal{E}] = E[\zeta_N|\zeta_N \leq N^{1/2}] \leq E[\zeta_N] = O(1),$$

by Lemma 3.2, so the expected total waiting time of leftover packets is $O(N^3)$ when $\mathcal{E}$ holds.

Given that $\mathcal{E}$ does not hold, we use the trivial polynomial bounds $O(N^4)$ and $O(N^3)$ on the total number of leftover packets and the waiting time of each. Since $\mathcal{E}$ fails with low probability, a can be chosen large enough so that $P(\mathcal{E}) = 1 - O(N^{-4})$. Thus, the expected total waiting time of leftover packets is

$$O(N^3) + (1 - P(\mathcal{E}))O(N^7) = O(N^3)$$

and the theorem is proved. □

6. Final remarks. A close look at the analysis in section 5 shows that it is possible to prove a stronger version of Theorem 1.1 in which the dependence of the hidden multiplicative constant on λ and μ is specified: there exists a universal constant α such that, for N sufficiently large,

$$E[W] \leq \frac{\alpha}{(1-\rho)^2} \ . \tag{6.1}$$

The details of a proof of this result have been omitted because no new ideas are needed, and because the added clutter makes the proof significantly harder to follow. In broad outline, a proof can begin with the observation that if (6.1) can be proved for the expected waiting time $E[W^{(2)}]$ of packets assigned in step 2, then changing only the constant α, it must also hold for $E[W]$. This is not difficult to verify using the probability bounds of sections 2 and 3, and the arguments in section 5.

It is then not difficult to verify that, within a constant factor independent of λ and μ, $E[W^{(2)}]$ is the expected waiting time in a G/G/1 queue with arrivals in each time slot having a binomial distribution with mean λb and service times having a geometric distribution with rate parameter $\mu' \approx (1-2\epsilon)(1-e^{-\mu b})e^{-2\mu b}$. For large N, the queue is asymptotically an M/G/1 queue, so by classical results, we get (Kleinrock (1975), section 5.7)

$$E[W^{(2)}] = O\left(\frac{1}{(1-\rho')\mu'}\right),$$

where $\rho' = \lambda'/\mu'$ and $\lambda' = \lambda b$.

As in the analysis of Step 2 in section 5, we again choose $b = \Theta(\frac{\mu-\lambda}{\mu^2})$, and so $1 - \rho' = \Omega(1-\rho)$ and $\mu' = \Omega(\mu b) = \Omega(1-\rho)$. Thus, $E[W^{(2)}]$ and hence $E[W]$ has a bound of the form (6.1).

Asymptotics in N pose intriguing open problems for transit-time distributions other than the geometric. The uniform distribution on $\{1, \ldots, N-1\}$ is of particular interest; extensive simulations by Coffman et al. (1995) give convincing evidence that the bounds in Theorem 1.1 hold for this case as well, but no proof has yet been found.

Finally, in keeping with our Markov arrival and transit-time assumptions, it would be interesting to study asymptotic behavior in the generalization of rings to toroidal arrays of processors (see Leighton (1990, 1992)). Much is known about regular (open) arrays, as can be seen from the recent work of Mitzenmacher (1994) and Kahale and Leighton (1995), who give references to the earlier work on this problem. But the analysis of toroidal arrays seems to require different methods.

Acknowledgment. We are grateful to M. Harchol-Balter for improvements to an early version of this paper, and to I. Telatar and A. Weiss for helpful discussions. The second author also thanks DIMACS for its hospitality.

APPROXIMATION ALGORITHMS FOR PSPACE-HARD HIERARCHICALLY AND PERIODICALLY SPECIFIED PROBLEMS*

MADHAV V. MARATHE†, HARRY B. HUNT III‡, RICHARD E. STEARNS‡, AND VENKATESH RADHAKRISHNAN§

Abstract. We study the efficient approximability of basic graph and logic problems in the literature when instances are specified hierarchically as in [T. Lengauer, *J. Assoc. Comput. Mach.*, 36(1989), pp. 474–509] or are specified by one-dimensional finite narrow periodic specifications as in [E. Wanke, *Paths and cycles in finite periodic graphs*, in Lecture Notes in Comp. Sci. 711, Springer-Verlag, New York, 1993, pp. 751–760]. We show that, for most of the problems Π considered when specified using *k-level-restricted* hierarchical specifications or k-narrow periodic specifications, the following hold.

(i) Let ρ be any performance guarantee of a polynomial time approximation algorithm for Π, when instances are specified using standard specifications. Then $\forall \epsilon > 0$, Π has a polynomial time approximation algorithm with performance guarantee $(1 + \epsilon)\rho$.

(ii) Π has a polynomial time approximation scheme when restricted to planar instances.

These are the first polynomial time approximation schemes for PSPACE-hard hierarchically or periodically specified problems. Since several of the problems considered are PSPACE-hard, our results provide the first examples of natural PSPACE-hard optimization problems that have polynomial time approximation schemes. This answers an open question in Condon et al. [*Chicago J. Theoret. Comput. Sci.*, 1995, Article 4].

1. Introduction and motivation.

Many practical applications of graph theory and combinatorial optimization in CAD systems, mechanical engineering, VLSI design, and software engineering involve processing large objects constructed in a systematic manner from smaller and more manageable components [13]. An important example of this occurs in VLSI technology. Currently, VLSI circuits can consist of millions of transistors. But such large circuits usually have a highly regular design and consequently are defined systematically, in terms of smaller circuits. As a result, the graphs that abstract the structure and operation of the underlying circuits (designs) also have a regular structure and are defined systematically in terms of smaller graphs. Methods for describing large but regular objects by small descriptions are referred to as *succinct specifications*. Over the last 20 years several theoretical models have been put forward to succinctly represent objects such as graphs and circuits.

(See, for example, [5, 6, 11, 19, 23, 26, 27, 34, 48, 50, 52, 57].) Here, we study two kinds of succinct specifications, namely, hierarchical and periodic specifications.

Hierarchical specifications allow the overall design of an object to be partitioned into the design of a collection of modules, which is a much more manageable task than producing a complete design in one step. Such a top down (or hierarchical design) approach also facilitates the development of CAD systems, since low-level objects can be incorporated into libraries and can thus be made available as submodules to designers of large scale objects. Other areas where hierarchical specifications have found applications are VLSI design and layout [18, 19, 47, 55], finite element analysis, software engineering [13], and datalog queries (see [18, 29, 43] and the references therein). Periodic specifications can also be used to define large scale systems with highly regular structures. Using periodic specifications, large objects are described as repetitive connections of a basic module. Frequently, the modules are connected in a linear fashion, but the basic modules can also be repeated in two- or higher dimensional patterns. Periodic specifications are also used to model time variant problems, where the constraints or demands for any one period are the same as those for preceding or succeeding periods. Periodic specifications have applications in such diverse areas as operations/management [46], transportation planning [18, 43, 48], parallel programming [18, 26], and VLSI design [23, 24].

Typically, the kinds of hierarchical and periodic specifications studied in the literature are generalizations of standard specifications used to describe objects. An important feature of both these kinds of specifications is that they can be much more concise in describing objects than standard specifications. In particular, the size of an object can be exponential in the size of its periodic or hierarchical specifications. As a result of this, problems for hierarchically and periodically specified inputs often become PSPACE-hard, NEXPTIME-hard, etc.

In this paper, we concentrate our attention on

1. the hierarchical specifications of Lengauer [31, 34, 35] (referred to as L-specifications) and
2. the one-dimensional finite periodic specifications of Gale and Wanke [10, 58] (referred to as 1-FPN-specifications).

Both of these specifications have been used to model problems in areas such as CAD systems and VLSI design [35, 32, 36], transportation planning [10], parallel programming [58], etc. We give formal definitions of these specifications in sections 4 and 5.

Let Π be a problem posed for instances specified using *standard* specifications. For example, if Π is a satisfiability problem for CNF formulas, the standard specification is sets of clauses, with each clause being a set of literals. Similarly, if Π is a graph problem, the adjacency matrix representation or the adjacency list representation of the edges in the graph are standard specifications. For the rest of the paper, we use

1. L-Π to denote the problem Π, when instances are specified using the hierarchical specifications of Lengauer [35] (see Definition 4.1), and
2. 1-FPN-Π to denote the problem Π, when instances are specified using the one-dimensional finite periodic specifications of Wanke [58] (see Definition 5.1).

Thus for example, L-3SAT denotes the problem 3SAT when instances are specified using L-specifications, and 1-FPN-3SAT denotes the problem 3SAT when instances are specified using 1-FPN-specifications. For the rest of this paper, we use the term succinct specifications to mean both L-specifications and 1-FPN-specifications.

2. Summary of results. In this paper, we discuss a natural syntactic restriction on the L-specifications and call the resulting specifications *level-restricted* specifications. (For 1-FPN-specifications our notion of level-restricted specifications closely coincides with Orlin's notion of narrow specifications [48].) Most of the problems considered in this paper are PSPACE-hard even for level-restricted specifications (see [37, 44, 48]). Consequently, we focus our attention on devising polynomial time approximation algorithms for level-restricted L- or 1-FPN-specified problems. Recall that an approximation algorithm for a minimization problem[1] Π provides a *performance guarantee* of ρ if for every instance I of Π, the solution value returned by the approximation algorithm is within a factor ρ of the optimal value for I. A *polynomial time approximation scheme* (PTAS) for problem Π is a family of algorithms such that, given an instance I of Π, $\forall \epsilon > 0$, there is a polynomial time algorithm in the family that returns a solution which is within a factor $(1+\epsilon)$ of the optimal value for I. The main contributions of this paper include the following.

(i) We design polynomial time approximation algorithms (for arbitrary instances) and approximation schemes (for planar instances) for a variety of natural PSPACE-hard problems specified using level-restricted L- or 1-FPN-specifications. These are the first PTASs in the literature for "hard" problems specified using either L- or 1-FPN-specifications. To obtain our results we devise a new technique called the *partial expansion*. The technique has two desirable features. First, it works for a large class of problems and second, it works well for *both* L-specified and 1-FPN-specified problems.

(ii) For problems specified using level-restricted L- or 1-FPN-specifications, we devise polynomial time approximation algorithms with performance guarantees that are asymptotically equal to the best possible performance guarantees for the corresponding problems specified using standard specifications.

(iii) The results presented in this paper are a step towards finding sufficient syntactic restrictions on the L- or 1-FPN-specifications that allow us to specify a number of realistic designs in a succinct manner while making them amenable for rapid processing.

Our results provide the first examples of *natural* PSPACE-complete problems whose optimization versions have PTASs. Thus they affirmatively answer the question posed by Condon et al. [8] of whether there exist *natural* classes of PSPACE-hard optimization problems that have PTASs.

2.1. The meaning of approximation algorithms for succinctly specified problems. When objects are represented using L- or 1-FPN-specifications, there are several possible ways of defining what it means to "design a polynomial time approximation algorithm." Corresponding to each decision problem Π, specified using either L- or 1-FPN-specifications, we consider four variants of the corresponding optimization problem. We illustrate this with an example.

Example 1. Consider the minimum vertex cover problem, where the input is an L-specification of a graph G. We provide efficient algorithms for the following versions of the problem.

1. *The construction problem*: Output an L-specification of the set of vertices in the approximate vertex cover $\mathcal{C}$.
2. *The size problem*: Compute the size of the approximate vertex cover $\mathcal{C}$ for G.

[1] A similar definition can be given for maximization problems.

3. *The query problem*: Given any vertex v of G and the path from the root to the node in the *hierarchy tree* (see section 2 for the definition of hierarchy tree) in which v occurs, determine whether v belongs to the vertex cover $\mathcal{C}$.

4. *The output problem*: Output the approximate vertex cover $\mathcal{C}$.

Note that our algorithms for the four variants of the problem apply to the *same* vertex cover $\mathcal{C}$. Our algorithms for (1), (2), and (3) above run in time *polynomial in the size of the L-specification* rather than the size of the graph obtained by expanding the L-specification. Our algorithm for (4) runs in time linear in the size of the expanded graph but uses space which is only polynomial in the size of the L-specification. □

Analogous variants of approximation algorithms can be defined for problems specified using 1-FPN-specifications. Therefore, we omit this discussion.

These variants are natural extensions of the definition of approximation algorithms for problems specified using standard specifications. This can be seen as follows: when instances are specified using standard specifications, the number of vertices is polynomial in the size of the description. Given this, any polynomial time algorithm to determine if a vertex v of G is in the approximate minimum vertex cover can be easily modified to obtain a polynomial time algorithm that lists all the vertices of G in the approximate minimum vertex cover. Thus, in the case when inputs are specified using standard specifications, (3) can be used to solve (2) and (4) in polynomial time. The above discussion also shows that given an optimization problem specified using standard specifications, variants (1), (3), and (4) discussed above are polynomial time interreducible.

The approximation algorithms given in this paper have another desirable feature. For an optimization problem or a query problem, our algorithms use space and time, which is a low level polynomial in the size of the hierarchical or the periodic specification. This implies that for graphs of size N, which are specified using specifications of size $O(\text{polylog}\, N)$, the time and space required to solve problems is only $O(\text{polylog}\, N)$. Moreover, when we need to output the subset of vertices, subset of edges, etc. corresponding to a vertex cover, maximum cut, etc., in the expanded graph, our algorithms take essentially the same time but substantially less (often logarithmically less) space than algorithms that work directly on the expanded graph. The graphs obtained by expanding hierarchical or periodic descriptions are frequently too large to fit into the main memory of a computer [31]. This is another reason for designing algorithms which exploit the regular structure of the underlying graphs. Indeed, most of the standard algorithms in the literature assume that the input completely resides in the main memory. As a result, even the most efficient algorithms incur a large number of page faults while executing on the graphs obtained by expanding the hierarchical or periodic specifications. Hence, algorithms designed for solving problems for graphs or circuits represented in a standard fashion are often impractical for succinctly specified graphs. We refer the reader to [31, 36] for more details on this topic.

The rest of the paper is organized as follows. Section 3 contains discussion of related research. In sections 4, 5, and 6 we give the basic definitions and preliminaries. In section 7 we discuss our approximation algorithms for L-specified problems and 1-FPN-specified problems. Finally, in section 8, we give concluding remarks and directions for future research.

3. Related research. In the past, much work has been done on characterizing the complexity of various problems when instances are specified using L- or 1-FPN-specifications. For periodically specified graphs, several researchers [6, 7, 19, 26, 27, 29, 49, 50] have given efficient algorithms for solving problems such as determining

STRONGLY CONNECTED COMPONENTS, TESTING FOR EXISTENCE OF CYCLES, FINDING MINIMUM COST PATHS BETWEEN A PAIR OF VERTICES, BIPARTITENESS, PLANARITY, and MINIMUM COST SPANNING FORESTS. Orlin [50] and Wanke [58] discuss NP- and PSPACE-hardness results for infinite and finite periodically specified graphs.

For L-specified graphs, Lengauer and Wanke [32, 34, 35] and Williams [59] have given efficient algorithms to solve several graph-theoretic problems including 2-COLORING, MINIMUM SPANNING FORESTS, and PLANARITY TESTING. Lengauer and Wagner [37] show that the following problems are PSPACE-hard when graphs are L-specified: 3-COLORING, HAMILTONIAN CIRCUIT AND PATH, MONOTONE CIRCUIT VALUE PROBLEM, NETWORK FLOW, ALTERNATING GRAPH ACCESSIBILITY, and MAXIMUM INDEPENDENT SET. In [38], Lengauer and Wanke consider a more general hierarchical specification of graphs based on graph grammars and give efficient algorithms for several basic graph-theoretic problems specified using this specification. We refer the reader to [18, 43] for a detailed survey of the work done in the area of hierarchical and periodic specifications.

A substantial amount of research has been done on finding polynomial time approximation algorithms with provable worst case guarantees for NP-hard problems. In contrast, until recently little work has been done towards investigating the existence of polynomial time approximation algorithms for PSPACE-hard problems. As a step in this direction, in [40, 41] we have investigated the existence and nonexistence of polynomial time approximations for several PSPACE-hard problems for L-specified graphs. In [20], we considered geometric intersection graphs defined using the hierarchical specifications (HIL) of Bentley, Ottmann, and Widmayer [5]. There, we devised efficient PTASs for a number of problems for geometric intersection graphs specified using a restricted form of HIL.

Condon et al. [8, 9] also studied the approximability of several PSPACE-hard optimization problems. They characterize PSPACE in terms of probabilistically checkable debate systems and use this characterization to investigate the existence and nonexistence of polynomial time approximation algorithms for a number of basic PSPACE-hard optimization problems.

4. The L-specifications. This section discusses the L-specifications. The following two definitions are essentially from Lengauer [32, 35, 37].

DEFINITION 4.1. *An L-specification* $\Gamma = (G_1, \ldots, G_n)$ *of a graph is a sequence of labeled undirected simple graphs* G_i *called cells. The graph* G_i *has* m_i *edges and* n_i *vertices.* p_i *of the vertices are called pins. The other* $(n_i - p_i)$ *vertices are called inner vertices.* r_i *of the inner vertices are called nonterminals. The* $(n_i - r_i)$ *vertices are called terminals. The remaining* $n_i - p_i - r_i$ *vertices of* G_i *that are neither pins nor nonterminals are called explicit vertices.*

Each pin of G_i *has a unique label, its name. The pins are assumed to be numbered from* 1 *to* p_i*. Each nonterminal in* G_i *has two labels* (v, t)*, a name, and a type. The type* t *of a nonterminal in* G_i *is a symbol from* $G_1, \ldots, G_{i-1}$*. The neighbors of a nonterminal vertex must be terminals. If a nonterminal vertex* v *is of the type* G_j *in* G_i*, then* v *has degree* p_j *and each terminal vertex that is a neighbor of* v *has a distinct label* (v, l) *such that* $1 \leq l \leq p_j$*. We say that the neighbor of* v *labeled* (v, l) matches *the* l*th pin of* G_j*.*

Note that a terminal vertex may be a neighbor of several nonterminal vertices. Given an L-specification Γ, $N = \sum_{1 \leq i \leq n} n_i$ denotes the *vertex number*, and $M = \sum_{1 \leq i \leq n} m_i$ denotes the *edge number* of Γ. The size of Γ, denoted by $size(\Gamma)$, is $N + M$.

DEFINITION 4.2. *Let $\Gamma = (G_1, \ldots, G_n)$ be an L-specification of a graph $E(\Gamma)$ and let $\Gamma_i = (G_1, \ldots, G_i)$. The expanded graph $E(\Gamma)$ (i.e., the graph associated with Γ) is obtained as follows.*

$k = 1$: $E(\Gamma) = G_1$.

$k > 1$: Repeat the following step for each nonterminal v of G_k, say of the type G_j: delete v and the edges incident on v. Insert a copy of $E(\Gamma_j)$ by identifying the lth pin of $E(\Gamma_j)$ with the node in G_k that is labeled (v, l). The inserted copy of $E(\Gamma_j)$ is called a subcell of G_k.

Observe that the expanded graph can have multiple edges although none of the G_i have multiple edges. Here, however, we *only* consider *simple* graphs; i.e., there is at most one edge between a pair of vertices. This means that multi-edges are treated simply as single edges. We assume that Γ is not redundant in the sense that for each j, $1 \leq j \leq n$, there is a nonterminal v of type G_i in the definition of G_j, $j > i$.

The expansion $E(\Gamma)$ is the graph associated with the L-specification Γ with vertex number N. For $1 \leq i \leq n$, $\Gamma_i = (G_1, \ldots, G_i)$ is the L-specification of the graph $E(\Gamma_i)$. Note that the total number of nodes in $E(\Gamma)$ can be $2^{\Omega(N)}$. (For example, a complete binary tree with $2^{\Omega(N)}$ nodes can be specified using an L-specification of size $O(N)$.) To each L-specification $\Gamma = (G_1, \ldots, G_n)$, $n \geq 1$, we associate a labeled rooted unoriented tree $HT(\Gamma)$ depicting the insertions of the copies of the graphs $E(\Gamma_j)$ $(1 \leq j \leq n-1)$, made during the construction of $E(\Gamma)$ as follows (see Figure 4.1).

DEFINITION 4.3. *Let $\Gamma = (G_1, \ldots, G_n)$, $n \geq 1$, be an L-specification of the graph $E(\Gamma)$. The* hierarchy tree *of Γ, denoted by $HT(\Gamma)$, is the labeled rooted unordered tree defined as follows.*

1. *Let r be the root of $HT(\Gamma)$. The label of r is G_n. The children of r in $HT(\Gamma)$ are in* one-to-one *correspondence with the nonterminal vertices of G_n as follows. The label of the child s of r in $HT(\Gamma)$ corresponding to the nonterminal vertex (v, G_j) of G_n is (v, G_j).*

2. *For all other vertices s of $HT(\Gamma)$ and letting the label of $s = (v, G_j)$, the children of s in $HT(\Gamma)$ are in* one-to-one *correspondence with the nonterminal vertices of G_j as follows. The label of the child t of s in $HT(\Gamma)$ corresponding to the nonterminal vertex (w, G_l) of G_j is (w, G_l).*

Given the above definition, we can naturally associate a hierarchy tree corresponding to each Γ_i, $1 \leq i \leq n$. We denote this tree by $HT(\Gamma_i)$. Note that each vertex v of $E(\Gamma)$ is either *an explicit vertex of G_n* or *the copy of some explicit vertex v' of G_j $(1 \leq j \leq n)$ in exactly one copy C_j^v of the graph $E(\Gamma_j)$ inserted during the construction of $E(\Gamma)$*. This enables us to assign v of $E(\Gamma)$ to the unique vertex n_v of the $HT(\Gamma)$ given by

1. if v is a terminal vertex of G_n, then n_v is the root of $HT(\Gamma)$, and

2. otherwise, v belongs to the node n_v that is the root of the hierarchy tree $HT(\Gamma_j)$, corresponding to C_j^v.

Given $HT(\Gamma)$, the *level number* of a node in $HT(\Gamma)$ is defined as the length of the path from the node to the root of the tree.

As noted in [35], L-specifications have the property that for each copy (instance) of a nonterminal, a complete boundary description has to be given. Thus if a nonterminal has a lot of pins, copying it is costly. Another property of the definition of L-specifications is that nonterminals are adjacent only to terminals. These properties ensure that the size of the "frontier" (or the number of neighbors) of any nonterminal is polynomial in the size of the specification. These properties weaken the

L-specifications with respect to other notions of hierarchy involving a substitution mechanism that entails implicit connections to pins at a cell boundary [11, 57]. As a result, regular structures such as grids cannot be specified using small L-specifications (see [32]). In contrast, the graph glueing model of Galperin [11] allows a hierarchical description of pins; thus the size of the frontier can be exponentially large. As a result, graphs such as grids can be represented using descriptions of logarithmic size. However, as demonstrated in [11, 32, 34, 35, 57], these properties seem to be a prerequisite for the construction of efficient exact algorithms for L-specified problems. As subsequent sections show, these restrictions are also necessary in part for devising efficient approximation algorithms for L-specified problems. The size of the frontier also has a significant impact on the complexity of several basic succinctly specified problems. For example, several basic NP-hard problems become PSPACE-hard when specified using L-specifications (see [37, 44]). In contrast, in a recent paper we show that these problems typically become NEXPTIME-hard when specified using the graph glueing specifications of [11] (see [45]).

By noting Definition 4.1, it follows that an L-specification is a restricted form of a context-free graph grammar. The substitution mechanism glues the pins of cells to neighbors of nonterminals representing these cells, as described in Definition 4.2. Such graph grammars are known as *hyperedge replacement systems* [15] or *cellular graph grammars* [38]. Two additional restrictions are imposed on cellular graph grammars to obtain L-specified graphs. First, for each nonterminal there is only one cell that can be substituted. Thus there are no *alternatives* for substitution. Second, the index of the substituted cell has to be *smaller* than the index of the cell in which the nonterminal occurs. The acyclicity condition together with the "no alternatives" condition implies that an L-specification defines a unique finite graph. We observe that $HT(\Gamma)$ is the parse tree of the unique graph generated by the context-free graph grammar Γ.

Example 2. Figure 4.1 depicts the L-specification $G = (G_1, G_2, G_3)$ and the associate hierarchy tree $HT(G)$. Figure 4.2 depicts the graph $E(G)$ specified by G. The correspondence between pins of G_j and neighbors of G_j in G_i, $j < i$, is clear by the positions of the vertices and the pins. □

4.1. Level-restricted specifications. We discuss level-restricted L-specifications now. This is also discussed in [40, 41].

DEFINITION 4.4. *An L-specification $\Gamma = (G_1, \ldots, G_n)$, $n \geq 1$, of a graph G is 1-level-restricted if for all edges (u, v) of $E(\Gamma)$, either*

1. *n_u and n_v are the same vertex of $HT(\Gamma)$, or*
2. *one of n_u or n_v is the parent of the other in $HT(\Gamma)$.*

Extending the above definition we can define k-level-restricted specifications. An L-specification $\Gamma = (G_1, \ldots, G_n)$, $n \geq 1$, of a graph $E(\Gamma)$ is *k-level-restricted*, if for all edges (u, v) of $E(\Gamma)$, either

1. n_u and n_v are the same vertex of $HT(\Gamma)$ or
2. one of n_u or n_v is an ancestor of the other in $HT(\Gamma)$ and the length of the path between n_u and n_v in $HT(\Gamma)$ is no more than k.

We note that for any fixed $k \geq 1$, k-level-restricted L-specifications can still lead to graphs that are exponentially large in the sizes of their specifications. Moreover, L-specifications (see [30, 31, 32]) for several practical designs are *k-level-restricted* for small values of k. (For example, it is easy to define a complete binary tree with $2^{\Omega(N)}$ nodes by a 1-level-restricted L-specification of size $O(N)$. Note however, that the specification depicted in Figure 4.1 is not 1-level-restricted.) For the rest of the

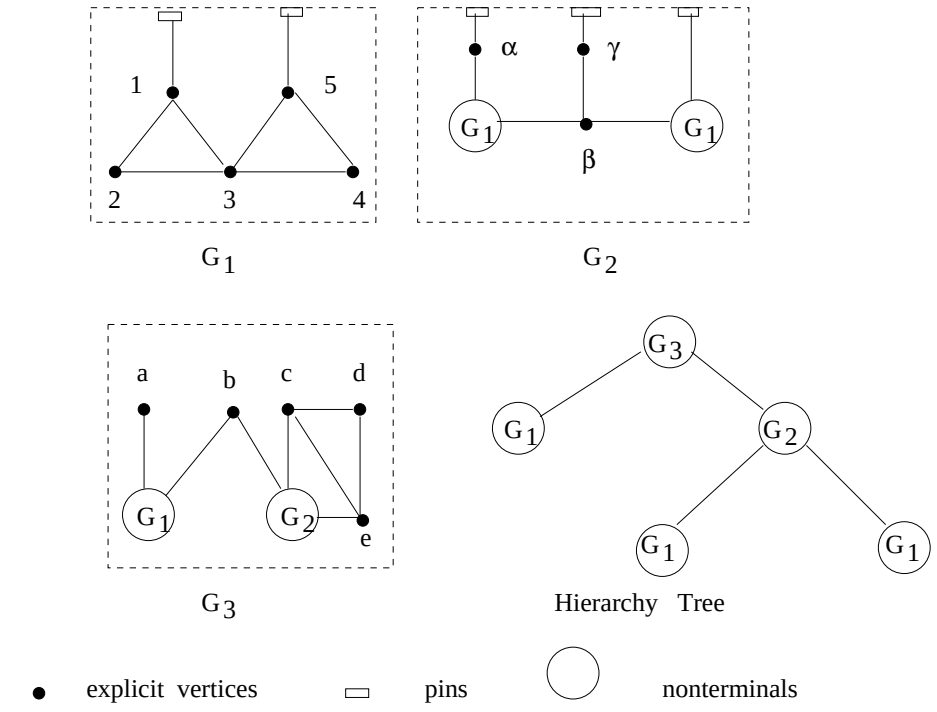

FIG. 4.1. *An L-specification G of a graph $E(G)$ and the associated hierarchy tree $HT(G)$. The mapping between the pins and its neighbors is clear by the relative positions of the pins and its neighbors.*

paper, given a problem Π specified using standard specifications, we use 1-L-Π to denote the problem specified using 1-level-restricted L-specifications and k-L-Π to denote the problem specified using k-level-restricted L-specifications.

5. 1-FPN-specifications. Next, we give the definition of one-dimensional periodic specifications due to Orlin [48], Wanke [58], and Höfting and Wanke [19]. For the rest of the paper $\mathbf{N}$ and $\mathbf{Z}$ denote the set of nonnegative integers and integers, respectively.

DEFINITION 5.1. *Let $G(V, E)$ (referred to as a static graph) be a finite directed graph such that each edge (u, v) has an associated nonnegative integral weight $t_{u,v}$. The undirected one-way infinite graph $G^{\infty}(V', E')$ is defined as follows:*

1. $V' = \{v(p) \mid v \in V$ *and* $p \in \mathbf{N}\}$,
2. $E' = \{(u(p), v(p + t_{u,v})) \mid (u, v) \in E$, $t_{u,v}$ *is the weight associated with the edge* (u, v) *and* $p \in \mathbf{N}\}$.

A one-dimensional periodic specification Γ *(referred to as* 1*-P-specification) is given by* $\Gamma = (G(V, E))$ *and specifies the graph* $G^{\infty}(V', E')$ *(referred to as a* 1*-P-specified graph).*

A 1*-P-specification* Γ *is said to be* narrow *or* 1-level-restricted *if* $\forall (u, v) \in E$, $t_{u,v} \in \{0, 1\}$. *This implies that* $\forall (u(p), v(q)) \in E'$, $|p - q| \leq 1$. *Similarly, a* 1*-P-specification is* k-narrow *or* k-level-restricted *if* $\forall (u, v) \in E$, $t_{u,v} \in \{0, 1, \ldots, k\}$.

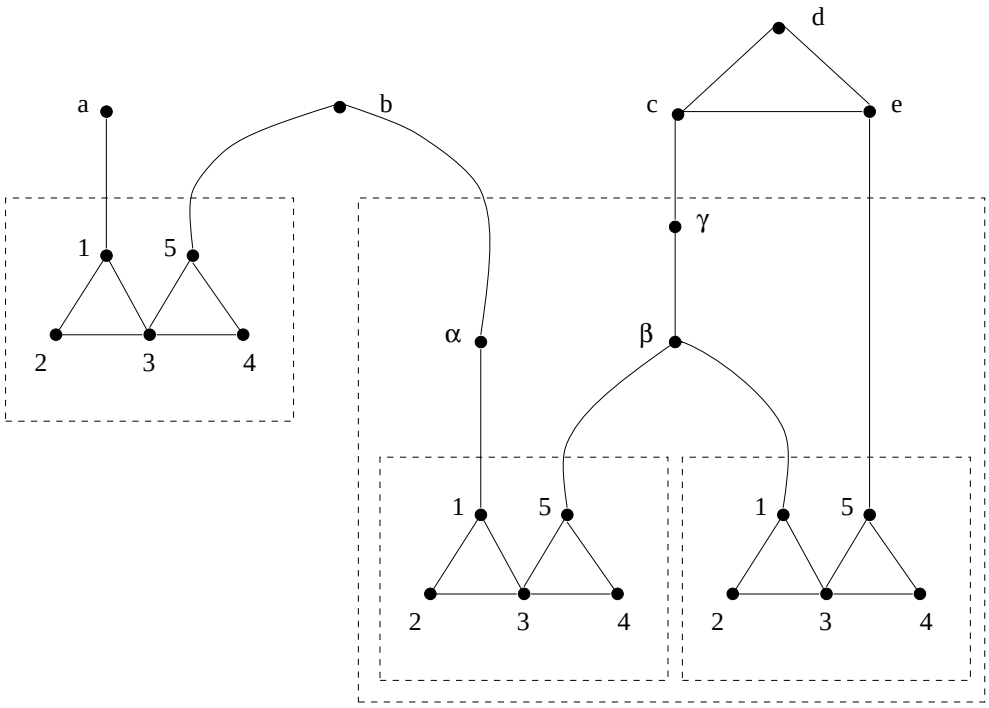

FIG. 4.2. *The graph $E(G)$ represented by G specified in Figure* 4.1.

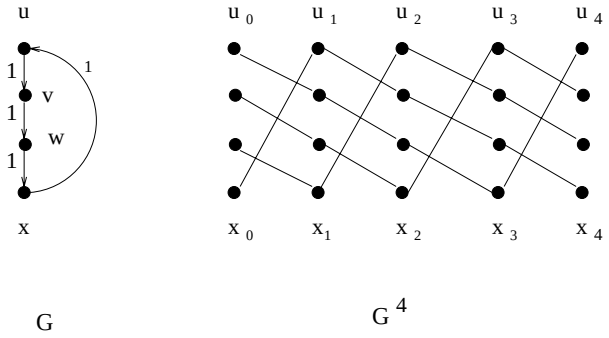

FIG. 4.3. *A static graph G, and the graph G^4 specified by the* 1*-FPN-specification* $\Gamma = (G, 4)$.

We note that if we replace **N** by **Z** in Definition 5.1, we obtain a *two-way* infinite periodically specified graph defined in Orlin [48]. It is sometimes useful to imagine a narrow periodically specified graph G^∞ as being obtained by placing a copy of the vertex set V at each integral point (also referred to as lattice point) on the X-axis (or the time line) and joining vertices placed on neighboring lattice points in the manner specified by the edges in E.

G^m is the subgraph of the infinite periodic graph G^∞ induced by the vertices associated with nonnegative lattice points less than or equal to m. Formally, we have the following definition.

DEFINITION 5.2. *Let $G(V, E)$ denote a static graph. Let $G^{\infty}(V', E')$ denote the one-way infinite* 1*-PN-specified graph as in Definition* 5.1. *Let $m \geq 0$ be an integer specified using binary numerals. Let $G^m(V^m, E^m)$ be a subgraph of $G^{\infty}(V', E')$ induced by the vertices $V^m = \{v(p) | v \in V$ and $0 \leq p \leq m\}$. A* 1*-FPN-specification is given by $\Gamma = (G(V, E), m)$ and specifies the graph G^m (referred to as a* 1*-FPN-specified graph).*

An example of a 1-FPN-specified graph appears in Figure 4.3. In [48], Orlin defined the concept of two-way infinite one-dimensional periodically specified 3CNF formulas and the associated 3SAT problem [12]. It is straightforward to restrict Orlin's definition along the lines of Definition 5.1 to define 1-FPN-specified satisfiability problems. As a consequence, we omit the definition here. (See [44, 48, 54] for formal definitions of periodically specified satisfiability problems.) We only give an example of a 1-FPN-specified 3CNF formula to illustrate the concept.

Example 3. Let $U = \{x_1, x_2, x_3\}$ be a set of static variables. Let C be a set of static clauses given by $(x_1(0) + x_2(0) + x_3(0)) \wedge (x_1(1) + x_3(0)) \wedge (x_3(1) + x_2(0))$. Let $F = (U, C, 3)$ be a 1-FPN-specification. Then F specifies the 3CNF formula $F^3(U^3, C^3)$ given by

$$(x_1(0) + x_2(0) + x_3(0)) \wedge (x_1(1) + x_3(0)) \wedge (x_3(1) + x_2(0)) \bigwedge$$

$$(x_1(1) + x_2(1) + x_3(1)) \wedge (x_1(2) + x_3(1)) \wedge (x_3(2) + x_2(1)) \bigwedge$$

$$(x_1(2) + x_2(2) + x_3(2)) \wedge (x_1(3) + x_3(2)) \wedge (x_3(3) + x_2(2)) \bigwedge$$

$$(x_1(3) + x_2(3) + x_3(3)).$$

6. Other preliminaries. Recall that a graph is said to be *planar* if it can be laid out in the plane in such a way that there are no crossovers of edges. For the rest of the paper, we use L-PL-Π, 1-L-PL-Π, and 1-FPN-PL-Π to denote the problem Π restricted to L-specified planar instances, 1-level-restricted L-specified planar instances, and 1-FPN-specified planar instances, respectively. As shown in Lengauer [35], given an L-specification Γ, there is a polynomial time algorithm to determine if $E(\Gamma)$ is planar. Similarly, as pointed out in [18], given a 1-FPN-specification Γ, there is a polynomial time algorithm to determine if $E(\Gamma)$ is planar. Thus for solving L- or 1-FPN-specified problems restricted to planar instances, we can assume without loss of generality that the inputs to our algorithms consist of planar instances.

Next, we define the problems MAX SAT(**S**). The definition is essentially an extension of the definition of SAT(**S**) given in Schaefer [56].

DEFINITION 6.1 (Schaefer [56]). *Let $\mathbf{S} = \{R_1, R_2, \ldots, R_m\}$ be a finite set of finite arity Boolean relations. (A Boolean relation is defined to be any subset of $\{0, 1\}^p$ for some integer $p \geq 1$. The integer p is called the* **arity** *of the relation.) An* **S-formula** *is a conjunction of clauses, each of the form $\hat{R}_i(\xi_1, \xi_2, \ldots)$, where $\xi_1, \xi_2, \ldots$ are distinct, unnegated variables whose number matches the arity of $R_i, i \in \{1, \ldots, m\}$, and $\hat{R}_i$ is the relation symbol representing the relation R_i. The* **S***-satisfiability problem is the problem of deciding whether a given* **S***-formula is satisfiable. Given an* **S***-formula F, the problem* MAX SAT(**S**) *is to determine the maximum number of simultaneously satisfiable clauses in F.*

As in Schaefer [56], given $\mathbf{S}$, $Rep(\mathbf{S})$ is the set of relations that are representable by existentially quantified $\mathbf{S}$-formulas with constants.

Recall from [39] that an $\mathbf{S}$-formula f is said to be planar if its associated bipartite graph is planar. The problem PL-3SAT [39] is the problem of determining if a given planar 3CNF formula is satisfiable. Lichtenstein [39] showed that the problem PL-3SAT is NP-complete.

Next, we define L-specified $\mathbf{S}$-formulas. Such formulas are built by defining larger $\mathbf{S}$-formulas in terms of smaller $\mathbf{S}$-formulas. Just as L-specifications of graphs can represent graphs that are exponentially larger than the specification, L-specified $\mathbf{S}$-formulas can specify formulas that are exponentially larger than the size of the specification.

DEFINITION 6.2. *An instance* $F = (F_1(X^1), \ldots, F_{n-1}(X^{n-1}), F_n(X^n))$ *of* L-SAT($\mathbf{S}$) *is of the form*

$$F_i(X^i) = \left(\bigwedge_{1 \le j \le l_i} F_{i_j}(X^i_j, Z^i_j) \right) \bigwedge f_i(X^i, Z^i)$$

for $1 \le i \le n$, *where* f_i *are* $\mathbf{S}$*-formulas,* $X^n = \phi$, X^i, X^i_j, Z^i, Z^i_j, $1 \le i \le n-1$, *are vectors of Boolean variables such that* $X^i_j \subseteq X^i$, $Z^i_j \subseteq Z^i$, $0 \le i_j < i$. *Thus,* F_1 *is just an* $\mathbf{S}$*-formula. An instance of* L-SAT($\mathbf{S}$) *specifies an* $\mathbf{S}$*-formula* $E(F)$, *which is obtained by expanding the* F_j, $2 \le j \le n$, *where the set of variables* Z*'s introduced in any expansion are considered distinct. The problem* L-SAT($\mathbf{S}$) *is to decide whether the formula* $E(F)$ *specified by* F *is satisfiable. The corresponding optimization problem denoted by* L-MAX-SAT($\mathbf{S}$) *is to find the maximum number of simultaneously satisfiable clauses in* $E(F)$.

Let n_i be the total number of variables used in F_i (i.e., $|X^i| + |Z^i|$) and let m_i be the total number of clauses in F_i. The size of F, denoted by $size(F)$, is equal to $\sum_{1 \le i \le n}(m_i n_i)$. Given a formula $E(F)$ specified by an L-specification F, $BG(E(F))$ denotes the bipartite graph associated with $E(F)$. We use $H[BG(E(F))]$ to denote the L-specification of $BG(E(F))$. It is easy to define level-restricted L-SAT($\mathbf{S}$) formulas along the lines of Definition 4.4. Hence we omit this definition here.

Example 4. Let $F = (F_1(x_1, x_2), F_2(x_3, x_4), F_3)$ be an instance of L-3SAT where each F_i is defined as follows:

$$F_1(x_1, x_2) = (x_1 + x_2 + z_1) \wedge (z_2 + z_3),$$

$$F_2(x_3, x_4) = F_1(x_3, z_4) \wedge F_1(z_4, z_5) \wedge (z_4 + z_5 + x_4),$$

$$F_3 = F_1(z_7, z_6) \wedge F_2(z_8, z_7).$$

The formula $E(F)$ denoted by F is $(z_7 + z_6 + z^1_1) \wedge (z^1_2 + z^1_3) \wedge (z_8 + z_4 + z^2_1) \wedge (z^2_2 + z^2_3) \wedge (z_4 + z_5 + z^3_1) \wedge (z^3_2 + z^3_3) \wedge (z_4 + z_5 + z_7)$.

We now extend the definition of PL-3SAT given in [39] to define the L-PL-3SAT.

DEFINITION 6.3. *The problem* L-PL-3SAT *is to decide whether the planar* 3*CNF formula* $E(F)$ *specified by an L-specification* F *is satisfiable. The corresponding optimization problem denoted by* L-PL-MAX-3SAT *is to find the maximum number of simultaneously satisfiable clauses in* $E(F)$.

Extensions of the above definition to 1-L-PL-3SAT,1-L-PL-MAX-3SAT, L-PL-SAT($\mathbf{S}$), L-PL-MAX-SAT($\mathbf{S}$), 1-L-PL-SAT($\mathbf{S}$), 1-L-PL-MAX-SAT($\mathbf{S}$), 1-FPN-PL-SAT($\mathbf{S}$), and 1-FPN-PL-MAX-SAT($\mathbf{S}$) are straightforward and are omitted.

Finally we state the following PSPACE-completeness results proved in a sequel paper [44]. The definitions of the problems mentioned in the following theorems can be found in [12].

THEOREM 6.4. *The following problems are PSPACE-complete for* 1*-level-restricted L-specified planar instances:* INDEPENDENT SET, VERTEX COVER, PARTITION INTO TRIANGLES, *and* SAT(**S**) *such that Rep*(**S**) *is the set of all finite arity Boolean relations.*

THEOREM 6.5. *The following problems are PSPACE-complete for* 1*-FPN-specified planar instances:* INDEPENDENT SET, VERTEX COVER, PARTITION INTO TRIANGLES, *and* SAT(**S**) *such that Rep*(**S**) *is the set of all finite arity Boolean relations.*

7. Approximation algorithms. The hardness results in Theorems 6.4 and 6.5 motivate the study of polynomial time approximation algorithms with good performance guarantees for these problems. We show that several basic combinatorial problems (including the ones in Theorems 6.4 and 6.5) have approximation algorithms with performance guarantees asymptotically equal to the best known performance guarantees, when instances are specified using standard specifications. As an immediate corollary, most of the problems shown to have PTASs in [3, 21] when instances are represented using standard specifications have PTASs when instances are specified by either k-level-restricted L-specifications or 1-FPN-specifications.

7.1. The basic technique: Partial expansion. We outline the basic technique behind the approximation algorithms for the 1-level-restricted L-specified problems. Consider one of the maximization problems Π in this paper. Let $\mathcal{A}$ be an approximation algorithm with performance guarantee $FBEST$ for Π when specified using standard specifications. Also, let $T(N)$ denote an increasing function that is an upper bound on the running time of $\mathcal{A}$ used to solve Π specified using standard specifications of size $O(N)$. Then, given a fixed $l \geq 1$, our approximation algorithm for 1-L-Π takes time $O(N \cdot T(N^{l+1}))$ and has a performance guarantee of $(\frac{l+1}{l}) \cdot FBEST$. Informally, the algorithm consists of $(l+1)$ iterations. During an iteration i we delete[2] all the explicit vertices which belong to nonterminals defined at level j, $j = i \mod (l+1)$. This breaks up the given hierarchy tree into a collection of disjoint trees. The algorithm finds a near-optimal solution for the vertex-induced subgraph[3] defined by each small tree and outputs the union of all these solutions as the solution for the problem Π. It is important to observe that the hierarchy tree can have an exponential number of nodes. Hence the deletion of nonterminals and the determination of near-optimal solutions for each subtree has to be done in such a manner that the whole process takes only polynomial time. This is achieved by observing that the subtrees can be divided into n distinct equivalence classes and that the number of subtrees in each equivalence class can be counted in polynomial time in the *size* of the specification.

We remark that our idea of dividing the graph into vertex (edge) disjoint subgraphs is similar to the technique used by Baker [3] for obtaining approximation schemes for planar graph problems.

7.2. Maximum independent set problem for 1-level-restricted L-specified planar graphs. We illustrate the technique by giving a PTAS for the MAXIMUM INDEPENDENT SET problem for 1-level-restricted L-specified planar graphs. The INDEPENDENT SET problem is defined as follows. Given a graph $G = (V, E)$ and a

[2]For the minimization problem, instead of deleting the vertices in the level, we consider the vertices as a part of both the subtrees.

[3]For a fixed l, the size of each subgraph is polynomial in the size of the specification.

positive integer $K \leq |V|$, is there an independent of size K or more for G, i.e., a subset $V' \subseteq V$ with $|V'| \geq K$ such that for each $u, v \in V'$ $(u, v) \notin E$? The optimization problem called the MAXIMUM INDEPENDENT SET PROBLEM (MIS) requires one to find an independent set of maximum size. In [40], we showed that given an L-specification that has edges between pins in the same cell, there is a polynomial time algorithm to construct a new L-specification such that there is no edge between pins in the *same* cell. Consequently, we assume without loss of generality that in the given L-specification there is no edge between two pins in the same nonterminal.

In the following description, we use $HIS(G_i)$ to denote the approximate independent set for the graph $E(\Gamma_i)$ obtained by our algorithm H-MIS. We also use F-MIS to denote the algorithm of Baker [3] for finding an approximate independent set in a planar graph specified using a standard specification. Before we discuss the details of the heuristic we define the concept of *partial expansion* of an L-specification. Recall that, for each nonterminal G_i there is a unique hierarchy tree $HT(G_i)$ rooted at G_i.

DEFINITION 7.1. *Let $\Gamma = (G_1, \ldots, G_n)$ be an L-specification of a graph $E(\Gamma)$. The partial expansion $PE(G_i^j)$ of the nonterminal G_i is constructed as follows:*

$j = 0$: $PE(G_i^j) = G_i -$ {all the explicit vertices defined in G_i}. (Thus the definition of $PE(G_i^j)$ now consists of a collection of the nonterminals and pins called in the definition of G_i.)

$j \geq 1$: Repeat the following step for each nonterminal G_r called by G_i: Insert a copy of $PE(G_r^{j-1})$ by identifying the lth pin of $PE(G_r^{j-1})$ with the node in G_i that is labeled (v, l). (Observe that the definition of $PE(G_i^j)$ consists of (i) *explicit vertices defined in all the nonterminals at depth r, $0 \leq r \leq j-1$, in $HT(G_i)$ and* (ii) *a* multiset *of nonterminals G_k, such that the nonterminal G_k occurs at depth $j+1$ in the hierarchy tree $HT(G_i)$.)*

Let $Ex(PE(G_i^j))$ denote the subgraph induced by the set of explicit vertices in the definition of $PE(G_i^j)$. Also let $V(E(\Gamma_i))$ denote the set of vertices in $E(\Gamma_i)$.

HEURISTIC H-MIS

- **Input:** A 1-level-restricted L-specification $\Gamma = (G_1, \ldots, G_n)$ of a planar graph G and an integer $l \geq 1$.

- **Output:** An L-specification of an independent set for $E(\Gamma)$ whose size is at least $(\frac{l}{l+1})^2$ times the size of an optimal independent set in $E(\Gamma)$.

1. **For** each $1 \leq i \leq l$, find a near-optimal independent set in $E(\Gamma_i)$ using F-MIS.
2. **For** each $l+1 \leq i \leq n-1$
   (a) Compute the partial expansion $PE(G_i^l)$ of G_i.
   (b) Find an independent set in the subgraph $Ex(PE(G_i^l))$ using heuristic F-MIS. Denote this by A_i^l.
   (c) Let $G_{i_1}, \ldots, G_{i_p}$ denote the multiset of nonterminals in $PE(G_i^l)$. Then the independent set for the whole graph for the iteration i denoted by $HIS(G_i)$ is given by

$$HIS(G_i) = A_i^l \cup \bigcup_{1 \leq r \leq p} HIS(G_{i_r}).$$

Remark. The explicit vertices in $PE(G_i^l)$ do not have an edge to any of the nonterminals $G_{i_1}, \ldots, G_{i_p}$. From this observation and the

definition of hierarchical specification, the independent set $HIS(G_i)$ can now be calculated as follows.

(d)
$$|HIS(G_i)| = |A_i^l| + \sum_{1 \le r \le p} |HIS(G_{i_r})|.$$

3. **For** each $0 \le i \le l$
   (a) Compute the partial expansion $PE(G_n^i)$ of G_n.
   (b) Find a near-optimal independent set of all the explicit vertices in $PE(G_n^i)$ using F-MIS. Denote this by A_n^i.
   (c) Let $G_{n_1}, \ldots, G_{n_p}$ denote the multiset of nonterminals in $PE(G_n^i)$. The independent set for the whole graph for the iteration i, denoted by $HIS_i(G_n)$, is given by
$$HIS_i(G_n) = A_n^i \cup \bigcup_{1 \le r \le p} HIS(G_{n_r}).$$
   Remark. By a remark similar to the one in step 2(c) of the algorithm, we have the following.

   (d)
$$|HIS_i(G_n)| = |A_n^i| + \sum_{1 \le r \le p} |HIS(G_{n_r})|.$$

4. The independent set $HIS(G)$ is the largest among all the independent sets $HIS_i(G_n)$ computed in step 3(c).
5. $|HIS(G)| = \max_{0 \le i \le l} |HIS_i(G_n)|$.

7.3. Analysis and performance guarantee. The correctness of H-MIS and the proof of its performance guarantee is based on the following intermediate results.

LEMMA 7.2. *The set $HIS(G)$ computed by the algorithm H-MIS in step* 4 *is an independent set.*

Proof. We first prove that the set for $1 \le i \le n-1$, $HIS(G_i)$, is an independent set. The proof is by induction on the depth of the hierarchy tree $HT(\Gamma)$.

Basis: If the depth is $\le l$, the proof follows by the correctness of algorithm F-MIS.

Induction: Assume that the lemma holds for all hierarchy trees of depth at most $m > l$. Consider a hierarchy tree of depth $m+1$. Step 2(c) of the algorithm computes a partial expansion $PE(G_i^l)$. This implies that the explicit vertices in $PE(G_i^l)$ do not have edges incident on the nonterminals in $PE(G_i^l)$. Thus, by the definition of 1-level-restricted L-specifications and partial expansion, it follows that the independent sets A_i^l and the sets $HIS(G_{i_r})$, $1 \le r \le p$, computed in steps 2(b) and 2(c) are disjoint. Also, the nonterminals in $PE(G_i^l)$ are at level $l+1$ in $HT(G_i)$ and have an associated hierarchy tree of depth $\le m$. Thus, by the induction hypothesis and the above stated observations, it follows that $HIS(G_m)$ computed in step 2(c) is an independent set. This completes the proof that $1 \le i \le n-1$, and $HIS(G_i)$ is an independent set.

A similar inductive argument proves that the set $HIS_i(G_n)$ computed in each iteration of step 3(c) is also an independent set. By step 4, we have that $HIS(G)$ is an independent set. □

LEMMA 7.3.

1. *In each iteration i, $l+1 \le i \le n-1$, of step* 2 *of algorithm H-MIS, all the explicit vertices in nonterminals at levels $j = l \mod (l+1)$ in the hierarchy tree $HT(G_i)$ are deleted.*

2. *In each iteration i of step* 3 *of algorithm H-MIS, all the explicit vertices in nonterminals at levels $j = i \mod (l+1)$ in the hierarchy tree $HT(G_n)$ are deleted.*

Proof of Part 1. Induction on the depth of the hierarchy tree associated with G_i.
Basis: If the depth is $l+1$, the proof follows directly by step 1 and the definition of partial expansion.
Induction: Assume that the lemma holds for all hierarchy trees of depth at most $m > (l+1)$. Consider a hierarchy tree of depth $m+1$. Step 2(c) of the algorithm computes the partial expansion $PE(G_i^l)$. This implies that all the explicit vertices at level l in the hierarchy tree $HT(G_i)$ were deleted. Each nonterminal occurring in the definition of $PE(G_i^l)$ is at level $l+1$ in $HT(G_i)$ and has an associated hierarchy tree of depth $\leq m$. The proof now follows by the induction hypothesis.

Proof of Part 2. Consider a hierarchy tree $HT(G_n)$. In iteration i of step 3 we compute $PE(G_n^i)$. This removes all the explicit vertices defined in nonterminals at level i. Also, by the definition of partial expansion it follows that all explicit vertices defined in nonterminals at levels 1 to i appear explicitly in the partially expanded graph. Therefore, the partially expanded graph now has nonterminals defined at level $i+1$ in the hierarchy tree $HT(G_n)$. The proof now follows as a consequence of part 1 of the lemma. □

Given the decomposition of $E(\Gamma)$ into a forest (as a result of removing explicit vertices in nonterminals at levels $j = i \mod (l+1)$ in the hierarchy tree $HT(G_n)$) we can associate a hierarchy tree with each of the subgraphs in the forest. Each such tree is a subtree of the original hierarchy tree $HT(\Gamma)$. Label each subtree by the type of nonterminal that is the root of the subtree. The proof of the following lemma is straightforward.

LEMMA 7.4.

1. *During each iteration i of step* 3 *of the algorithm H-MIS, the root of each subtree is labeled by one of the elements of the set $\{G_1, \ldots, G_{n-1}\}$.*

2. *For $1 \leq i \leq n$, let $H_1^i, \ldots, H_{r_i}^i$ be the set of graphs corresponding to the subtrees labeled G_i. Then for each i the graphs $H_1^i, \ldots, H_{r_i}^i$ are isomorphic.*

7.3.1. At least one good iteration exists. Next we prove that at least one iteration of step 3 has the property that the number of nodes of an optimal independent set that are deleted is a small fraction of the optimal independent set.

Let F_i denote the set of vertices obtained by deleting the explicit nodes in iteration i in step 3 of algorithm H-MIS. By Lemma 7.3 it follows that for each iteration i we did not consider the explicit vertices in levels $j_{i_1}, j_{i_2}, \ldots, j_{i_p}$ such that $1 \leq i_p \leq n$ and $j_{i_q} = i \mod (l+1)$, $1 \leq q \leq p$. Let S_i, $0 \leq i \leq l$, be the set of vertices not considered in iteration i of step 3. Let $IS(G_n)$ denote an optimum independent set in the graph $E(\Gamma)$. Let $IS_{opt}(S_i)$ denote the nodes in S_i included in the maximum independent set $IS(G_n)$.

LEMMA 7.5.

$$\max_{0 \leq i \leq l} |IS(F_i)| \geq \frac{l}{(l+1)} |IS(G_n)|.$$

Proof. By Lemma 7.3 and the algorithm H-MIS, it follows that

$$S_i \cap S_j = \phi, \quad \cup_{t=0}^{t=l} S_t = V(E(\Gamma)), \quad \text{and}$$

$$|IS_{opt}(S_0)| + |IS_{opt}(S_1)| + \cdots + |IS_{opt}(S_l)| = |IS(G_n)|.$$

Therefore,

$$\min_{0\le i\le l} |IS_{opt}(S_i)| \le |IS(G_n)|/(l+1),$$

$$\max_{0\le i\le l} |IS(F_i)| \ge |IS(G_n)| - \min_{0\le i\le l} |IS_{opt}(S_i)| \ge \frac{l}{(l+1)}|IS(G_n)|. \qquad \square$$

7.3.2. Performance guarantee and running time. We now prove that the above algorithm computes a near-optimal independent set. Given any $\epsilon > 0$, for some choice of positive integer l such that $(\frac{l}{l+1})^2 \ge (1-\epsilon)$, we show that algorithm H-MIS computes an independent set whose size is at least $(1-\epsilon)$ times the size of an optimal independent set. We first recall a similar lemma in [3] for planar graphs specified using standard specifications.

THEOREM 7.6 (see [3]). *For all fixed $l \ge 1$, given a planar graph G there is a linear time algorithm that computes an independent set $FIS(G)$ such that $|FIS(G)| \ge (\frac{l}{l+1}) \cdot |IS(G)|$, where $IS(G)$ denotes a maximum independent set in G.*

LEMMA 7.7. $|HIS_i(G_n)| \ge (\frac{l}{l+1}) \cdot |IS(F_i)|$.

Proof (induction on the number of nonterminals in the definition of Γ). The base case is fairly straightforward. Consider the induction step. By the definition of partial expansion it follows that

$$|IS(F_i)| = |IS(Ex(PE(G_n^i)))| + \sum_{1\le r\le p} |IS(PE(G_{n_r}))|.$$

From step 3(c) of the algorithm H-MIS we also know that

$$|HIS_i(G_n)| = |A_n^i| + \sum_{1\le r\le p} |HIS(G_{n_r})|.$$

From the induction hypothesis and Theorem 7.6 it follows that

$$A_n^i| \ge \left(\frac{l}{l+1}\right) \cdot |IS(Ex(PE(G_n^i)))| \quad \text{and}$$
$$|HIS(G_{n_r})| \ge \left(\frac{l}{l+1}\right) \cdot |IS(PE(G_{n_r}))|.$$

The lemma now follows. $\square$

THEOREM 7.8. $|HIS(G)| \ge (\frac{l}{l+1})^2 \cdot |IS(G)|$.

Proof. The proof follows from Lemma 7.5 and repeated application of Lemma 7.7. $\square$

THEOREM 7.9. *Let Γ be an L-specification with vertex number N. Given any $\epsilon > 0$, let $l \ge 1$ be an integer such that $(\frac{l}{l+1})^2 \ge (1-\epsilon)$. Then the approximation algorithm H-MIS runs in time $O(N^{l+2})$ and finds an independent set in $E(\Gamma)$ that is at least $(\frac{l}{l+1})^2$ times the size of an optimal independent set in $E(\Gamma)$.*

Proof. The performance guarantee follows by Theorem 7.8. Therefore, we only prove the claimed time bounds.

First consider step 1. Note that by Euler's formula, the number of edges in a planar graph with $O(N^l)$ vertices is also $O(N^l)$. Thus, the size of the graphs $E(\Gamma_i)$, $1 \le i \le l$, is $O(N^l)$. Hence the time required to compute the partial expansion is

$O(N^l)$. By Theorem 7.6, the time needed to compute an independent set in $E(\Gamma_i)$ is $O(N^l)$. Thus the total running time of step 1 is $O(N^l)$.

Next consider each iteration of step 2 of the algorithm H-MIS. Step 2(a) takes time $O(N^{l+1})$ since the size of the graph $PE(G_i^l)$ can be $O(N^{l+1})$. By Theorem 7.6, the time needed for executing step 2(b) is $O(N^l)$, since the number of nodes in $Ex(PE(G_i^l))$ can be $O(N^l)$. By Lemma 7.4, steps 2(c) and 2(d) together take time $O(N)$. Therefore, the total running time for executing one iteration of step 2 is $O(N^{l+1})$. Thus the total running time of step 2 is $nO(N^{l+1}) = O(N^{l+2})$.

A similar calculation shows that the total time needed to execute one iteration of step 3 is $O(N^{l+1})$. Thus the total time needed to execute step 3 is $(l+1)O(N^{l+1}) = O(N^{l+1})$.

Thus the total running time of the algorithm is $O(N^{l+2})$. □

7.4. L-specification of the solution and the query problem. In section 7.3, we showed how to solve the *size* problem for 1-L-MIS. We now discuss the *construction* problem. As noted in section 2.1 our algorithms for the four variants of the problem apply to the *same* independent set $HIS(G)$.

The L-specification of the solution can be easily constructed by slightly modifying the algorithm H-MIS as follows. Consider the iteration i of step 3 which gives the maximum independent set. Denote the iteration by i^*. The L-specification H of the solution consists of nonterminals $H_1, \ldots, H_n$. For $1 \leq j \leq n$ the explicit vertices of H_j are the explicit vertices in $PE(G_j^i)$ that are in the independent set. If $PE(G_j^l)$ calls nonterminals $G_{j_1}, \ldots, G_{j_m}$, then the nonterminal H_j calls the nonterminals $H_{j_1}, \ldots, H_{j_m}$. Observe that some of the nonterminals H_i may be redundant and these can be removed from the final specification. Given the L-specification of the solution, the query problem can be easily solved by examining if the given vertex occurs in the set of nodes specified by the L-specification of the solution. Given an L-specification of the solution, we can solve the output problem as follows. We traverse the hierarchy tree associated with H in a depth-first manner and output the vertices in the nonterminals visited during the traversal.

Observe that the only place we used planarity was to obtain a near-optimal solution for the maximum independent set problem for each partially expanded graph. In section 7.7 we use this observation to compute near-optimal solutions for problems for arbitrary 1-level-restricted L-specified graphs.

7.5. Other L-specified planar problems. Our technique can be applied to obtain efficient approximation algorithms for the following additional optimization problems: MINIMUM VERTEX COVER, MAXIMUM PARTITION INTO TRIANGLES, MINIMUM EDGE DOMINATING SET, MAXIMUM CUT, and MAX SAT($\mathbf{S}$) for any finite set of finite arity Boolean relations $\mathbf{S}$. The basic idea behind devising approximation schemes for these problems is similar to the ideas used to solve the MAXIMUM INDEPENDENT SET problem. Therefore, we only briefly discuss the method for MINIMUM VERTEX COVER and MAX SAT($\mathbf{S}$).

(1) MINIMUM VERTEX COVER. Given a graph $G = (V, E)$ and a positive integer $K \leq |V|$, is there a vertex cover of size K or less for G, i.e., a subset $V' \subseteq V$ with $|V'| \leq K$ such that for each edge $(u, v) \in E$ either u or v belongs to V'? The optimization problem requires one to find a vertex cover of minimum size.

In order to approximate the 1-L-PL-MINIMUM VERTEX COVER problem we do the following. Given an ϵ, we choose an l such that $(\frac{l+1}{l})^2 \leq (1+\epsilon)$. Next, we modify the definition of partial expansion so that instead of deleting the explicit vertices at levels

$(l+1)$ apart, we consider them in both sides of the partition. For each $0 \leq i < l$, the algorithm finds a near-optimal solution for the overlapping planar graphs induced by explicit vertices in levels $(jl+i)$ to $((j+1)l+i)$ for $j \geq 0$. The algorithm picks the best among all the vertex covers obtained for the different values of i. Let $OPT(G)$ denote an optimal vertex cover for G. The following lemma points out that the solution obtained is at most $(\frac{l+1}{l})^2$ times the optimal vertex cover. The proof of the lemma follows the same general argument given for the MAXIMUM INDEPENDENT SET problem.

LEMMA 7.10. *The size of the vertex cover obtained is no more than*

$$\left(\frac{l+1}{l}\right)^2 |OPT(G)|.$$

Proof. Consider an optimal solution $OPT(G)$ to the vertex cover problem. Then for some $0 \leq t < l$, at most $|OPT(G)|/l$ nodes in $OPT(G)$ are in levels congruent to t mod (l). Consider the iteration when the planar graphs are obtained by overlapping at levels congruent to t mod (l). Hence the size of an optimal vertex cover in this iteration is $(|OPT(G)| + |OPT(G)|/l)$. Now applying the known approximation scheme [3] for computing a near-optimal vertex cover for each of smaller subgraphs, we obtain a near-optimal vertex cover for the whole graph for iteration t. The size of the vertex cover obtained in this iteration is no more than $(|OPT(G)| + |OPT(G)|/l)\frac{l+1}{l}$. The reason is that the explicit vertices in the overlapping levels are counted twice, and the near-optimal vertex cover heuristic yields a vertex cover of size $(l+1)/l$ times the optimal vertex cover for each subgraph. Since the heuristic picks the minimum vertex over all values of i, it follows that the size of the vertex cover produced by the heuristic is no more than $(\frac{l+1}{l})^2|OPT(G)|$. □

(2) MAX SAT($\mathbf{S}$). In the following, we will assume that an instance F of 1-L-PL-MAX-SAT($\mathbf{S}$) is specified by $H[BG(E(F))]$ (i.e., the specification of the associated bipartite graph). The basic idea behind the approximation schemes for 1-L-MAX-PL-SAT($\mathbf{S}$) is as follows. For each i, $0 \leq i \leq 2l$, in increments of 2, we remove the explicitly defined clauses which are in levels j and $j+1$, such that $j = i \mod (l+1)$. This breaks the bipartite graph into a number of smaller bipartite graphs such that the formulas they denote do not share any variables or clauses. It is not difficult to modify the definition of partial expansion to obtain a decomposition as described above. Figure 7.1 shows how the variables in levels j and $j+1$ are redistributed. As in the case of the MAXIMUM INDEPENDENT SET problem, it is easy to see that there exists an iteration t, $0 \leq t \leq 2l$, such that at most $\frac{OPT}{(l+1)}$ clauses in OPT are deleted. Next, by the results in [21] the problem can be solved near-optimally for each smaller subformula. The union of the clauses satisfied for each small formula constitutes a solution for a given value of i. We pick the best solution for different values of i. This ensures that the best assignment to the variables over all values of i is at least $(\frac{l}{l+1})^2$ of an optimal assignment to the variables of the 1-L-PL-MAX-SAT($\mathbf{S}$) instance.

7.6. Extension to k-level-restricted instances. The technique used to solve various problems for 1-level-restricted L-specifications can be generalized to solve problems specified using k-level-restricted L-specifications. We only point out the essential differences. Again, for the purposes of illustration consider the problem k-L-PL-MIS. First note that we need to extend the definition of partial expansion so that we delete the explicit vertices in nonterminals at k consecutive levels. This implies that the time to compute $PE(G_i^l)$, $1 \leq i \leq n-1$, is $O(N^{l+k})$. The rest of the

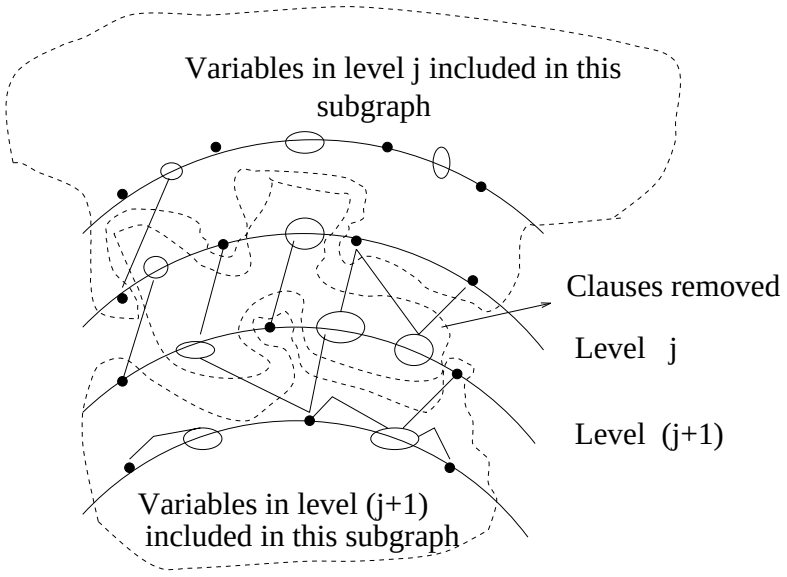

FIG. 7.1. *Basic idea behind the approximation algorithm for* 1-L-MAX-PL-SAT($\mathbf{S}$). *The black dots represent variables and the ellipses denote clauses. The figure depicts the set of clauses to be deleted and the redistribution of the variables.*

algorithm follows the same outline as that of H-MIS. The proof of correctness and the performance guarantee also follow similar arguments as in section 7.3. Thus the total running time of the algorithm is $O(N^{k+l+1})$ and its performance guarantee is $(\frac{l+1}{l})^2$. Hence we have the following theorem.

THEOREM 7.11. *For any fixed $k \geq 1$, there are PTASs for the problems* MAXIMUM INDEPENDENT SET, MINIMUM VERTEX COVER, MINIMUM EDGE DOMINATING SET, MAXIMUM PARTITION INTO TRIANGLES AND MAXIMUM CUT, *and* MAX SAT($\mathbf{S}$) *for each finite set of finite arity Boolean relations* $\mathbf{S}$, *when restricted to planar instances specified using k-level-restricted L-specifications.*

7.7. Extension to level-restricted arbitrary instances. Our results in sections 7.2–7.6 can be extended for problems on arbitrary graphs specified using k-level-restricted L-specifications. To do this, observe that to obtain the results in sections 7.2–7.6 we used planarity only to obtain approximation schemes for smaller subgraphs (formulas) obtained as a result of partial expansion. If the graphs were not planar we could use the best known approximation algorithms for solving the problem near-optimally and in turn get a performance guarantee which reflects this bound. For example, consider the problem 1-L-MAX-2SAT. Let $\epsilon > 0$ be the required performance guarantee. $l \geq 1$ is an integer satisfying the inequality $\frac{l}{l+1} \geq (1-\epsilon)$. For the problem MAX-2SAT, the recent work of Goemans and Williamson [14] provides an approximation algorithm with performance guarantee of 1.137. Using their algorithm as a subroutine to solve the small MAX-2SAT instances obtained as a result of partial expansion, we can devise an approximation algorithm for 1-L-MAX-2SAT with performance guarantee $\left(\frac{l+1}{l}\right)1.137$. A similar idea applies to other optimization problems considered. Again, it is easy to generalize our results for k-level-restricted L-specifications. Thus we have the following theorem.

Let Π be one of the following problems: MAXIMUM INDEPENDENT SET, MINIMUM VERTEX COVER, MINIMUM EDGE DOMINATING SET, MAXIMUM PARTITION INTO TRIANGLES, MAXIMUM CUT, and MAX-SAT($\mathbf{S}$) for finite set of Boolean relations $\mathbf{S}$, such that $Rep(\mathbf{S})$ is the set of all finite arity Boolean relations.[4]

THEOREM 7.12. *For all fixed $k \geq 1$, $\epsilon > 0$ and for all of the problems Π, there are polynomial time approximation algorithms with performance guarantee*[5] $(1+\epsilon) \cdot FBEST_{\Pi}$ *for problems Π, when specified using k-level-restricted L-specifications. Here $FBEST_{\Pi}$ denotes the best known performance guarantee of an algorithm for the problem Π for instances specified using standard specifications.*

Using the results of Arora et al. [2], Bellare, Goldreich, and Sudan [4] and Hunt, Marathe, and Stearns [22] we get the following theorem.

THEOREM 7.13. *Unless $\mathbf{P} = \mathbf{NP}$, the problems Π, when specified using k-level-restricted L-specifications, do not have PTASs.*

7.8. Approximation algorithms for 1-FPN-specified problems. Next, we briefly discuss how to extend our ideas developed in sections 7.2–7.7 in order to devise approximation schemes for several PSPACE-hard problems for 1-FPN-specified instances.

The basic idea is simple. Once again, we illustrate our ideas by describing our approximation algorithm for the problem 1-FPN-PL-MIS. Given a 1-FPN-specification $\Gamma = (G(V, E), m)$ of a planar graph G^m and an $\epsilon > 0$, we find the corresponding integer l that satisfies the inequality $(\frac{l}{l+1})^2 \geq (1 - \epsilon)$. For $0 \leq i \leq l$, we remove the vertices placed at the lattice points j such that $j = i \bmod (l + 1)$. This partitions the graph G^m into a number of smaller disjoint subgraphs, each induced by l consecutive lattice points.

Specifically, for a given i, let $l_p^i = \max\{0, (p-1)(l+1) + (i+1)\}$ and $r_p^i = \min\{m, p(l+1) + (i-1)\}$, where $0 \leq p \leq t_i$. Here $t_i = \lceil \frac{m-(i-1)}{(l+1)} \rceil$. Let the subgraph induced by vertices $v(j_p)$, where $l_p^i \leq j_p \leq r_p^i$, be denoted by $H(l_p^i, r_p^i)$. For a given $\epsilon > 0$, the graphs $H(l_p^i, r_p^i)$ are linear in the size of Γ. Figure 7.2 shows a schematic diagram of the vertices removed in a given iteration i. Next, we solve the MIS problem near-optimally on each of the subgraphs. This can be done by using the linear time algorithm stated in Theorem 7.6. The union of these independent sets is the independent set obtained in iteration i. The heuristic simply picks up the largest independent set obtained over all $l + 1$ iterations. By arguments similar to the ones we presented for approximating 1-L-PL-MIS (sections 7.2–7.4), it follows that the approximation algorithm has a performance guarantee of $(\frac{l+1}{l})^2$.

We note the following important point. If a near-optimal independent set were to be obtained for each subgraph $H(l_p^i, r_p^i)$, we would take an exponential amount of time in each iteration i. This is because $p = O(m)$. Hence we cannot afford to solve the problem explicitly for each subgraph. But observe that in each iteration i the subgraphs $H(l_p^i, r_p^i)$, $1 \leq p \leq \lceil \frac{m-(i-1)}{(l+1)} \rceil - 1$ are isomorphic. Hence we need to solve the MIS problem for the graphs $H(l_0^i, r_0^i), H(l_1^i, r_1^i)$, and $H(l_{t_i}^i, r_{t_i}^i)$, where $t_i = \lceil \frac{m-(i-1)}{(l+1)} \rceil$. Let $IS(H(l_p^i, r_p^i))$ denote the independent set obtained by the heuristic for the graph $H(l_p^i, r_p^i)$. Furthermore, let the approximate maximum independent set for the whole graph for a given iteration i be denoted by $IS(G^m(i))$. Then the size of $IS(G^m(i))$ is given by the following equation:

[4] Actually, our easiness results hold for all finite set of finite arity Boolean relations $\mathbf{S}$.

[5] For the sake of uniformity we assume that the performance guarantee is ≥ 1.

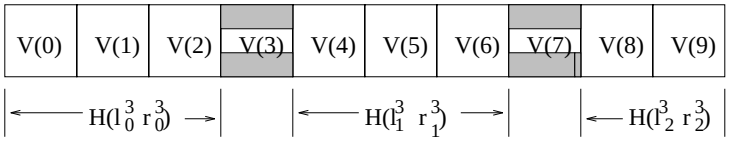

FIG. 7.2. *A schematic diagram showing the vertices to be removed in each iteration i while computing a near-optimal independent set for 1-FPN-specified planar graphs. In our example $i = 3$, $l + 1 = 4$, and $m = 9$. Each box represents a copy of the vertices in the original static graph. The shaded area represents the vertices that are removed.*

$$|IS(G^m(i))| = |IS(H(l_0^i, r_0^i))| + \left\lfloor \frac{m-(i-1)}{(l+1)} \right\rfloor |IS(H(l_1^i, r_1^i))| + |IS(H(l_{t_i}^i, r_{t_i}^i))|.$$

This completes the discussion of the approximation algorithm for 1-FPN-PL-MIS. By combining the above arguments along with those in sections 7.2–7.7, we can show that several other optimization problems can be approximated in a similar fashion. Again, it is easy to see that the technique extends to problems for arbitrary instances and also to problems for instances specified using k-narrow 1-FPN-specifications. Thus we have the following theorem.

THEOREM 7.14. *For all fixed $k \geq 1$, $\epsilon > 0$ and for all of the problems Π stated in section 7.7, there are polynomial time approximation algorithms with performance guarantee*[6] $(1+\epsilon) \cdot FBEST_\Pi$ *for problems Π, when specified using k-level-restricted 1-FPN-specifications. Here $FBEST_\Pi$ denotes the best known performance guarantee of an algorithm for the problem Π for instances specified using standard specifications.*

Observe that the technique used to devise approximation algorithms for problems restricted to k-narrow 1-FPN-specified instances is very similar to the technique used to devise approximation algorithms for k-level-restricted L-specified problems. But there are two important differences in the details of the algorithms.

1. In the case of algorithms for L-specified problems, the number of equivalence classes is $O(n)$, where n is the number of nonterminals. In contrast, the number of equivalence classes in the case of algorithms for 1-FPN-specified problems is only $O(1)$.

2. The size of the subgraphs for which the problem is solved near-optimally also differs significantly. Specifically, the number of explicit vertices in $PE(G_i^l)$ can be $O(N^l)$. Moreover, the time required to compute $PE(G_i^l)$ can be $O(N^{l+k})$. In contrast, the number of explicit vertices in each $H(l_p^i, r_p^i)$ is only $O(N)$ and the time required to construct each $H(l_p^i, r_p^i)$ is only $O(N)$. In both cases we use N to be the vertex number of the respective specifications Γ (N can be $O(size(\Gamma))$).

These important differences allow us to devise linear time approximation schemes for 1-FPN-specified problems.

8. Conclusions.

8.1. Summary. We have investigated the polynomial time approximability of several PSPACE-hard optimization problems for both L- and 1-FPN-specified instances. A general approach was given to obtain PTASs for several PSPACE-hard optimization problems for planar graphs specified using k-level-restricted L- or 1-FPN-specifications. We believe that the partial expansion technique can be used to obtain

[6] For the sake of uniformity we assume that the performance guarantee is ≥ 1.

efficient approximations for other problems specified using L- or 1-FPN-specifications as well as for problems specified using other succinct specifications.

In a companion paper [44], we investigate the decision complexity of various combinatorial problems specified using various kinds of L-specifications and 1-FPN-specifications. There we give a general method to obtain PSPACE-hard lower bounds for such problems, including the ones discussed here.

8.2. Open problems. We conclude with a list of open problems for future research.

1. Can we use the concept of probabilistically checkable debate systems [8, 9] to prove nonapproximability results for problems specified using arbitrary (not level-restricted) L-specifications?

Recently, Agarwal and Condon [1] have partially answered this question by showing that unless P = PSPACE, there is no PTAS for the problem L-MAX-3SAT. The result was proved by using the characterization of PSPACE in terms of random debate systems. In [22], we extended their result to hold for any L-MAX-SAT($\mathbf{S}$) such that *Rep*($\mathbf{S}$) denotes the set of all finite arity Boolean relations.

2. Recently, several researchers have considered logical definability of a number of optimization problems and defined appropriate classes such as MAX SNP, MAX Π_1, MAX NP, and MAX #P (cf. [25, 28, 51, 53]). All these researchers have assumed that the input is specified using standard specifications. What happens if the instances (finite or infinite) are specified succinctly ?

Some work has been done along these lines by Hirst and Harel [17]. Specifically, they considered infinite recursive versions of several NP optimization problems. They prove that some problems become highly undecidable (in terms of Turing degrees), while others remain on low levels of arithmetic hierarchy. As a corollary of their results they provide a method for proving (finitary) problems to be outside the syntactic class MAX NP and hence outside MAX SNP.

Acknowledgments. We thank the referees for invaluable comments that greatly improved the presentation. We also thank Anne Condon, Ashish Naik, Egon Wanke, Joan Feigenbaum, R. Ravi, S. S. Ravi, and Thomas Lengauer for many helpful conversations during the course of writing this paper.

APPROXIMATELY COUNTING HAMILTON PATHS AND CYCLES IN DENSE GRAPHS*

MARTIN DYER†, ALAN FRIEZE‡, AND MARK JERRUM§

Abstract. We describe fully polynomial randomized approximation schemes for the problems of determining the number of Hamilton paths and cycles in an n-vertex graph with minimum degree $(\frac{1}{2}+\alpha)n$, for any fixed $\alpha > 0$. We show that the exact counting problems are #P-complete. We also describe fully polynomial randomized approximation schemes for counting paths and cycles of all sizes in such graphs.

Key words. Hamilton cycles, fpras, dense

1. Introduction. Combinatorial counting problems have a long history, even from the computational viewpoint. For example, the classical matrix-tree theorem provides a good algorithm for determining the number of trees in a graph. However, it seems that few interesting combinatorial structures possess good counting algorithms. This intuition was made precise by Valiant [21] using the class #P. He showed that many problems for which the decision counterpart is easy were nevertheless complete for this class. Since it is unlikely that #P = P, exact counting is apparently intractable for many natural problems. For example, Valiant [20] showed that 0-1 permanent evaluation and counting the number of bases of a (suitably presented) matroid [21] were #P-complete. Many other problems have since been added to this list, for example, volume computation for polyhedra [6], counting linear extensions of a partial order [3], and counting Eulerian orientations of a graph [17].

The hardness of most counting problems has led to an interest in *approximate* counting. The most fruitful approach in this respect has been *randomized approximation*. This is based on the idea of a fully polynomial randomized approximation scheme (*fpras*) due to Karp and Luby [15]. Thus, if N is the true value, we must determine an estimate $\widehat{N}$ such that for given $\varepsilon, \delta > 0$

$$\Pr\left(1/(1+\varepsilon) < \widehat{N}/N < (1+\varepsilon)\right) > 1-\delta,$$

in time polynomial in the size of the input, ε^{-1} and $\log(\delta^{-1})$. Examples of problems amenable to this type of approximation are dense 0-1 permanent evaluation [4, 12], matchings [12], volume computation [7], counting Eulerian orientations [17], counting linear extensions of a partial order [16], and computing the partition function for the ferromagnetic Ising model [13]. The algorithms in the papers cited use a *random*

walk to generate an almost uniform random solution to the problem (e.g., a random matching), and then apply multistage statistical sampling methods to obtain the desired estimate.

One obvious requirement for such approximate counting to be possible is that the associated decision problem be easy. In fact, it appears from experience that it must be "very easy" in order to have a realistic hope that a randomized approximation scheme can be found.

In this paper, we add further entries to the small but growing list of randomly approximable hard counting problems: that of counting the number of Hamilton paths and cycles in "dense" graphs. Let $G = (V, E)$ be a graph, where $V = \{v_1, v_2, \ldots, v_n\}$. Denote the degree of vertex v_i by d_i, for $i = 1, 2, \ldots, n$. We will say that G is *dense* if $\min_i d_i \geq (\frac{1}{2} + \alpha)n$, where $0 < \alpha \leq \frac{1}{2}$ is a fixed constant. Under these circumstances it is known [5] that G must contain a Hamilton cycle. Moreover, the proof of this fact is easily modified to give a simple polynomial-time algorithm for constructing such a Hamilton cycle. This algorithm, which uses edges whose existence is guaranteed by the pigeonhole principle to "patch together" disjoint cycles, provides the required easy decision procedure.

We consider here the natural but more difficult problems of counting the *number* of Hamilton paths and cycles in such graphs. We show in section 4 that these problems are in fact #P-complete, so exact counting is presumably intractable. More positively, our main results in sections 2 and 3 establish the existence of *fpras's* for these counting problems when $\alpha > 0$. We may observe that if the degree condition is relaxed to $\min_i d_i \geq (\frac{1}{2} - \alpha_n)n$ with $\alpha_n = \Omega(n^{\kappa-1})$ for any fixed $\kappa > 0$, then the question of the existence of any Hamilton path or cycle becomes NP-complete,[1] and approximate counting is NP-hard. Thus our results establish quite precisely the difficulty of the counting problem except in the region where α is close to zero. Section 5 extends the positive results of the earlier sections to cover self-avoiding paths and cycles of all lengths.

The natural approach given previous successes in this area is to try to find a rapidly mixing Markov chain with state space the set of Hamilton cycles of a given dense graph, and possibly its Hamilton paths as well. Earlier attempts with this approach have proved fruitless. Somewhat surprisingly, the key lies in the fact that in dense graphs, Hamilton cycles form a substantial fraction of the set of 2-factors, a 2-*factor* being defined as a set of vertex-disjoint cycles which together contain all vertices of G. This is not obvious a priori and the main technical difficulty in the approach lies in obtaining a good upper bound on the ratio of 2-factors to Hamilton cycles in a dense graph. A direct attack—relating the number of 2-factors with k cycles to the number with $k+1$ cycles—appears unworkable. Instead, we introduce a weight function on 2-factors that allows us to argue about the distribution of total weight as a function of the number of cycles. By a rather delicate analysis, we are able to show that the Hamilton cycles carry sufficient weight for our purpose. In summary, we prove the following theorem.

THEOREM 1.1. *If G is dense then there are fpras's for*

(a) *approximating its number of Hamilton cycles,*

[1] This is true even if we insist on G being k-connected for any $k = o(n)$. The construction is from Bollobás [2]. Start with an arbitrary graph G and add a clique C of size $m = n^{1/\kappa}$ and an independent set I of size $m - 1$, and then join every vertex in C to every other vertex, to produce a graph Γ. Then G has a Hamilton path if and only if Γ has a Hamilton cycle. Also, Γ contains a Hamilton path if and only if G contains two vertex-disjoint paths that cover all its vertices.

(b) *approximating its number of Hamilton paths,*
(c) *approximating its number of cycles of all sizes,*
(d) *approximating its number of paths of all sizes.*

2. Outline approach. Our approach to constructing an fpras for Hamilton cycles in a dense graph G is via a randomized reduction to sampling and estimating 2-*factors* in G. An *almost uniform sampler* for 2-factors in a graph is a randomized algorithm that takes as input a graph G and $\delta > 0$ and as output a 2-factor Z (a random variable) such that

$$1/(1+\delta)N \leq \Pr(Z = F) \leq (1+\delta)/N,$$

where F is any 2-factor in G and N is the total number of 2-factors. The sampler is said to be *fully polynomial* if it runs in time polynomial in the size of G and $\log \delta^{-1}$. Using known techniques, 2-factors in a dense graph G may be efficiently sampled, and their number estimated.

THEOREM 2.1. *There exist both a fully polynomial randomized approximation scheme and a fully polynomial almost uniform sampler for the set of* 2*-factors in a dense graph.*

This result follows immediately from Corollary 4.2 of Jerrum and Sinclair [14], as will become clear once the notation used there has been explained. For convenience, the corollary in question is repeated below as Proposition 2.2.

PROPOSITION 2.2. *There exists a fully polynomial almost uniform sampler for* $\mathcal{G}(\mathbf{d}, X)$ *and a fully polynomial randomized approximation scheme for* $|\mathcal{G}(\mathbf{d}, X)|$*, provided the pair* $(\mathbf{d}, X)$ *satisfies* $e(\mathbf{d}) > d_{\max}(d_{\max} + x_{\max} - 1)$.

In Proposition 2.2, $\mathbf{d} = (d_1, \ldots, d_n)$ stands for a degree sequence on $V = \{v_1, v_2, \ldots, v_n\}$, and $X \subseteq V^{(2)}$ for the edge set of an "excluded" graph on vertex set V. The notation $\mathcal{G}(\mathbf{d}, X)$ stands for the set of graphs on vertex set V that have degree sequence $\mathbf{d}$ and avoid all edges in X. Finally, $e(\mathbf{d})$ is the number of edges in any graph with $\mathbf{d}$ as degree sequence, $d_{\max}$ is the largest component of $\mathbf{d}$, and $x_{\max}$ is the largest degree of any vertex in the excluded graph (V, X).

Proof of Proposition 2.2 (sketch). Our aim here is merely to indicate the algorithmic techniques used to sample from, and estimate the size of, $\mathcal{G}(\mathbf{d}, X)$. For a full proof, the reader is directed to [14].

Using a reduction due to Tutte [19], a graph Γ is constructed whose perfect matchings are in (constant) many-one correspondence with elements of $\mathcal{G}(\mathbf{d}, X)$. An algorithm of Jerrum and Sinclair [12], based on the simulation of a rapidly mixing Markov chain, is then used to sample or estimate the number of perfect matchings in Γ, as required. For this algorithm to be applicable, we require that Γ satisfy a certain condition; it is this condition, translated back through the reduction to the pair $(\mathbf{d}, X)$, that gives rise to the condition $e(\mathbf{d}) > d_{\max}(d_{\max} + x_{\max} - 1)$. □

Proof of Theorem 2.1. The set of 2-factors in a graph $G = (V, E)$ is equal to $\mathcal{G}(\mathbf{d}, X)$, where $\mathbf{d} = (2, 2, \ldots, 2)$, and $X = V^{(2)} - E$ is the complementary edge set to E. The result now follows from Proposition 2.2, since, for a dense G and n sufficiently large, $d_{\max} = 2$, $x_{\max} < \frac{1}{2}n - 1$, and $d_{\max}(d_{\max} + x_{\max} - 1) < n = e(\mathbf{d})$. □

Given Theorem 2.1, the reduction from Hamilton cycles to perfect matchings is easy to describe. We estimate first the number of 2-factors in G, and then the number of Hamilton cycles by standard sampling methods as a proportion of the number of 2-factors. Both counting and sampling phases run in polynomial time, by Theorem 2.1, provided only that G is dense. For the sampling phase to produce an

accurate estimate, it is necessary that the ratio of 2-factors to Hamilton cycles in G not be too large. This will be established in section 3.

We remark that it would be sufficient to be able to generate a random Hamilton cycle. We could then proceed alternatively by adding one edge at a time, giving a sequence of $M = O(n^2)$ graphs $G = G_0, G_1, \ldots, G_M = K_n$. We could then estimate the ratio of the number of Hamilton cycles in G_{i-1} to those in G_i for $i = 1, 2, \ldots, M$. The degree conditions can be used to show that each of these ratios is not too small and hence can be estimated efficiently. (This is similar to an idea in [4].)

The method of using random 2-factors to generate random Hamilton cycles was previously used by Frieze and Suen [9] in the context of *random digraphs* and more recently by Frieze, Jerrum, and Molloy [8] with regard to random regular graphs. It is interesting that the same method should be successful here also. It raises the intriguing possibility of using existing approaches to other random graph problems to guide the design of new randomized algorithms for restricted versions of the corresponding deterministic problem.

3. Many 2-factors are Hamiltonian. Let n be a natural number and $\beta = 10/\alpha^2$. Let $k_0 = \lfloor \beta \ln n \rfloor$, and for $1 \le k \le n$, define $g(k) = n^\beta k!(\beta \ln n)^{-k}$, and

$$f(k) = \begin{cases} g(k), & \text{if } k \le k_0, \\ g(k_0), & \text{otherwise.} \end{cases}$$

LEMMA 3.1. *Let f be the function defined above. Then*
(a) *f is nonincreasing and satisfies*

$$\min\{f(k-1), f(k-2)\} = f(k-1) \ge (\beta \ln n) k^{-1} f(k);$$

(b) *$f(k) \ge 1$, for all k.*

Proof. Observe that g is unimodal and that k_0 is the value of k minimizing $g(k)$; it follows that f is nonincreasing. When $k \le k_0$, we have $f(k-1) = g(k-1) = (\beta \ln n) k^{-1} g(k) = (\beta \ln n) k^{-1} f(k)$; otherwise, $f(k-1) = g(k_0) = f(k) \ge (\beta \ln n) k^{-1} f(k)$. In either case, the inequality in part (a) of the lemma holds.

Part (b) of the lemma follows from the chain of inequalities

$$\frac{1}{f(k)} \le \frac{1}{g(k_0)} \le \frac{(\beta \ln n)^{k_0}}{n^\beta k_0!} \le n^{-\beta} \sum_{k=0}^{\infty} \frac{(\beta \ln n)^k}{k!} = n^{-\beta} \exp(\beta \ln n) = 1. \qquad \square$$

LEMMA 3.2. *Suppose α is constant greater than 0. Let $G = (V, E)$ be an undirected graph of order n and minimum degree $(\frac{1}{2} + \alpha)n$. Then the number of 2-factors in G exceeds the number of Hamilton cycles by at most a polynomial (in n) factor, the degree of the polynomial depending only on α.*

Proof. For $1 \le k \le \lfloor n/3 \rfloor$, let Φ_k be the set of all 2-factors in G containing exactly k cycles, and let $\Phi = \cup_k \Phi_k$ be the set of all 2-factors. Define

$$\Psi = \big\{(F, F') : F \in \Phi_k, F' \in \Phi_{k'}, k' < k, \\ \text{and } F \oplus F' \cong C_6\big\},$$

where $\oplus$ denotes symmetric difference and C_6 is the cycle on six vertices. Observe that (Φ, Ψ) is an acyclic directed graph; let us agree to call its component parts *nodes* and *arcs* to avoid confusion with the vertices and edges of G. Observe also that if $(F, F') \in \Psi$ is an arc, then F' can be obtained from F by deleting three edges and

adding three others, and that this operation can decrease the number of cycles by at most two. Thus every arc $(F, F') \in \Psi$ is directed from a node F in some Φ_k to a node F' in Φ_{k-1} or Φ_{k-2}.

Our proof strategy is to define a positive weight function on the arc set Ψ such that the total weight of arcs leaving each node (2-factor) $F \in \Phi \setminus \Phi_1$ is at least one greater than the total weight of arcs entering F. This will imply that the total weight of arcs entering Φ_1 is an upper bound on the number of non-Hamilton 2-factors in G, and that the maximum total weight of arcs entering a single node in Φ_1 is an upper bound on the ratio $|\Phi \setminus \Phi_1|/|\Phi_1|$.

The weight function $w : \Psi \to \mathbb{R}^+$ we employ is defined as follows. For any arc (F, F') with $F' \in \Phi_k$: if the 2-factor F' is obtained from F by coalescing two cycles of lengths l_1 and l_2 into a single cycle of length $l_1 + l_2$, then $w(F, F') = (l_1^{-1} + l_2^{-1})f(k)$; if F' results from coalescing three cycles of length l_1, l_2, and l_3 into a single one of length $l_1 + l_2 + l_3$, then $w(F, F') = (l_1^{-1} + l_2^{-1} + l_3^{-1})f(k)$.

Let $F \in \Phi_k$ be a 2-factor with $k > 1$ cycles $\gamma_1, \gamma_2, \ldots, \gamma_k$, of lengths $n_1, n_2, \ldots, n_k$. We proceed to bound from below the total weight of arcs *leaving* F. For this purpose imagine that the cycles $\gamma_1, \gamma_2, \ldots, \gamma_k$ are oriented in some way, so that we can speak of each oriented edge (u, u') in some cycle γ_i as being "forward" or "backward." Since we are interested in obtaining a *lower* bound, it is enough to consider only arcs (F, F^+) from F of a certain kind: namely, those for which the 6-cycle $\gamma = F \oplus F^+$ is of the form $\gamma = (x, x', y, y', z, z')$, where $(x, x') \in F$ is a forward cycle edge, $(y, y') \in F$ is a forward edge in a cycle distinct from the first, and $(z, z') \in F$ is a backward cycle edge. The edge (z, z') may be in the same cycle as either (x, x') or (y, y'), or in a third cycle. Observe that (x', y), (y', z), and (z', x) must necessarily be edges of F^+. It is routine to check that any cycle $\gamma = (x, x', y, y', z, z')$ satisfying the above constraints does correspond to a valid arc from F. The fact that (z, z') is oriented in the opposite sense to (x, x') and (y, y') plays a crucial role in ensuring that the number of cycles decreases in the passage to F^+ when only two cycles are involved.

First, we estimate the number of cycles γ for which (x, x') is contained in a particular cycle γ_i of F. We might say that γ is *rooted* at γ_i. Assume, for a moment, that the vertices x, x', y, y' have already been chosen. There are at least $(\frac{1}{2} + \alpha)n - 5$ ways to extend the path (x, x', y, y'), first to z and then to z', which are consistent with the rules given above; let Z' be the set of all vertices z' so reachable. Denote by $G(x)$ the set of vertices adjacent to x. The number of ways of completing the path (x, x', y, y') to a valid 6-cycle is at least

$$\begin{aligned} |G(x) \cap Z'| &\geq |G(x)| + |Z'| - n \\ &\geq (\tfrac{1}{2} + \alpha)n + [(\tfrac{1}{2} + \alpha)n - 5] - n \\ &= 2\alpha n - 5 \\ &\geq \alpha n, \end{aligned}$$

for n sufficiently large. A lower bound on the number of 6-cycles γ rooted at γ_i now follows easily: there are n_i choices for (x, x'); then at least $(\frac{1}{2} + \alpha)n - n_i$ choices for (y, y'); and finally—as we have just argued—at least αn ways to complete the cycle. Thus the total number of 6-cycles rooted at γ_i is at least $\alpha n n_i[(\frac{1}{2} + \alpha)n - n_i]$.

We are now poised to bound the total weight of arcs leaving F. Each arc (F, F^+) defined by a cycle γ rooted at γ_i has weight at least $n_i^{-1} \min\{f(k-1), f(k-2)\}$, which, by Lemma 3.1, is bounded below by $(\beta \ln n)(kn_i)^{-1} f(k)$. Thus the total weight of

arcs leaving F is bounded as follows:

$$\sum_{F^+:(F,F^+)\in\Psi} w(F,F^+) \geq \sum_{i=1}^{k} \alpha n n_i[(\tfrac{1}{2}+\alpha)n - n_i]\frac{(\beta \ln n)f(k)}{kn_i} \tag{1}$$

$$= \alpha n^2[(\tfrac{1}{2}+\alpha)k - 1]\frac{(\beta \ln n)f(k)}{k}$$

$$\geq \alpha^2 \beta\, f(k) n^2 \ln n$$

$$\geq 10 f(k) n^2 \ln n, \tag{2}$$

where we have used the fact that $k \geq 2$. Note that the presence of a unique backward edge, namely (z, z'), ensures that each cycle γ has a distinguishable root, and hence that the arcs (F, F^+) were not overcounted in summation (1).

We now turn to the corresponding *upper* bound on the total weight of arcs $(F^-, F) \in \Psi$ *entering* F. It is straightforward to verify that the cycle $\gamma = (x, x', y, y', z, z') = F^- \oplus F$ must contain three edges—(x, x'), (y, y') and (z, z')—from a single cycle γ_i of F, the remaining edges coming from F^-. The labeling of vertices in γ can be made canonical in the following way: assume an ordering on vertices in V, and assign label x to the smallest vertex. The condition $(x, x') \in F$ uniquely identifies vertex x', and the labeling of the other vertices in the cycle γ follows.

Removing the three edges (x, x'), (y, y'), and (z, z') from γ_i leaves a triple of simple paths of lengths (say) $a-1$, $b-1$, and $c-1$: these lengths correspond (resp.) to the segment containing x, the segment containing x', and the remaining segment. Going round the cycle γ_i, starting at x' and ending at x, the vertices x, x', y, y', z, z' may appear in one of eight possible sequences:

$$x', y', y, z', z, x;$$
$$x', z, z', y, y', x;$$
$$x', z, z', y', y, x;$$
$$x', z', z, y, y', x;$$
$$x', y', y, z, z', x;$$
$$x', y, y', z', z, x;$$
$$x', z', z, y', y, x;$$
$$x', y, y', z, z', x.$$

For a given triple of lengths (a, b, c), each of the above sequences corresponds to at most n_i possible choices for the edges (x, x'), (y, y'), and (z, z'), yielding a maximum of $8n_i$ in total. To see this, observe that the edge (x, x') may be chosen in n_i ways (minimality of x fixes the orientation of the edge), and that the choice of (x, x') combined with the information provided by the sequence completely determines the triple of edges.

The eight sequences divide into five possible cases, as the first four sequences lead to equivalent outcomes (covered by case 1 below). Taken in order, the five cases are:

1. for at most $4n_i$ of the choices for the edges (x, x'), (y, y'), and (z, z'), $\gamma_i \oplus \gamma$ is a single cycle;
2. for at most n_i choices, $\gamma_i \oplus \gamma$ is a pair of cycles of lengths a and $b + c$;
3. for at most n_i choices, $\gamma_i \oplus \gamma$ is a pair of cycles of lengths b and $a + c$;
4. for at most n_i choices, $\gamma_i \oplus \gamma$ is a pair of cycles of lengths c and $a + b$;
5. for at most n_i choices, $\gamma_i \oplus \gamma$ is a triple of cycles of lengths a, b, and c.

The first case does not yield an arc (F^-, F), since the number of cycles does not decrease when passing from $F^- = F \oplus \gamma$ to F, but the other four cases do have to be reckoned with.

The total weight of arcs entering F can be bounded above as follows:

$$\begin{aligned}\sum_{F^-:(F^-,F)\in\Psi} w(F^-,F) &\le \sum_{i=1}^{k} n_i f(k) \sum_{\substack{a,b,c\ge 1\\ a+b+c=n_i}} \left[\left(\frac{1}{a}+\frac{1}{b}+\frac{1}{c}\right)+\right.\\ &\qquad \left.\left(\frac{1}{a}+\frac{1}{b+c}\right)+\left(\frac{1}{b}+\frac{1}{a+c}\right)+\left(\frac{1}{c}+\frac{1}{a+b}\right)\right]\\ &= \sum_{i=1}^{k} n_i f(k) \sum_{\substack{a,b,c\ge 1\\ a+b+c=n_i}} \left[\frac{6}{a}+\frac{3}{b+c}\right]\\ &\le \sum_{i=1}^{k} n_i f(k) n \sum_{a=1}^{n_i-1} \left[\frac{6}{a}+\frac{3}{n_i-a}\right]\\ &\le 9f(k)n^2 H_n, \qquad (3)\end{aligned}$$

where $H_n = \sum_{i=1}^{n} i^{-1} \le \ln n + 1$ is the nth harmonic number [10, eq. (6.60)]. Combining inequalities (2) and (3), we have

$$\begin{aligned}\sum_{F^+:(F,F^+)\in\Psi} w(F,F^+) \;-\; \sum_{F^-:(F^-,F)\in\Psi} w(F^-,F) &\ge 10f(k)n^2\ln n - 9f(k)n^2 H_n\\ &\ge f(k)n^2(\ln n - 9)\\ &\ge n^2(\ln n - 9),\end{aligned}$$

where the final inequality is by Lemma 3.1. Thus the total weight of arcs leaving F exceeds the total weight of arcs entering by at least 1, provided n is sufficiently large. The number of non-Hamilton 2-factors $|\Phi\setminus\Phi_1|$ is bounded above by the total weight of arcs entering Φ_1, which in turn is bounded—see inequality (3)—by $|\Phi_1|\times 9f(1)n^2H_n = |\Phi_1|\times O(n^{2+\beta})$. This establishes the lemma. □

4. Exact counting is #P-complete. Let #HC (resp., #HP) be the problem of counting the number of Hamilton cycles (resp., paths) in an undirected graph. It is known [21, 18] that #HC is #P-complete, and it follows, by an easy reduction, that #HP is also #P-complete.

THEOREM 4.1. *Both #HC and #HP are #P-complete when restricted to graphs G of minimum degree at least $(1-\alpha)n$, where n is the number of vertices in G, and $\alpha > 0$.*

Proof. We first present a Turing reduction from #HP to #HP such that all the target instances of #HP satisfy the required minimum degree condition. Let $G = (V, E)$ be an undirected graph of order n with vertex set V and edge set E, considered as an instance of #HP. A typical target instance of #HP is a graph G_t constructed from G by forming the disjoint union of G with the complete graph K_t on $t \ge n$ vertices, and connecting every vertex in G with every vertex in K_t.

Assume $t \ge 3$. For $1 \le k \le n$, denote by P_k the set of all covers of G by k vertex-disjoint oriented paths, where paths of length 0 are allowed. Each oriented Hamilton path P in G_t induces an element of $\cup_k P_k$ by restriction to G. Conversely, each element of P_k may be extended in precisely $t!\binom{t+1}{k}k! = (t+1)!\binom{t}{k-1}(k-1)!$ ways to an oriented Hamilton path in G_t: the vertices in K_t may be visited in $t!$ orders; there are $\binom{t+1}{k}$ ways to choose k positions in that order during which excursions to G can be made, including the two positions prior to and following the order, and $k!$ ways

to match those positions to the k oriented paths covering G. Thus the number p_t of oriented Hamilton paths in G_t can be expressed as the sum

$$p_t = \sum_{k=1}^{n} (t+1)! \binom{t}{k-1} (k-1)! |P_k|.$$

Note that p_t may be evaluated by one call to an oracle for #HP, since the number of oriented Hamilton paths is twice the number of unoriented paths. Using n such calls we may evaluate p_t for $t = t_0 + j$ and $j = 1, 2, \ldots, n$, where $t_0 = \lceil \alpha^{-1} n \rceil$ is chosen sufficiently large that every graph G_t with $t > t_0$ satisfies the minimum degree constraint. Recovering the values $\{(k-1)!|P_k| : 1 \le k \le n\}$ from $\{p_{t_0+j}/(t_0+j+1)! : 1 \le j \le n\}$ amounts to inverting the matrix

$$A = (A_{jk}) = \left(\binom{t_0 + j}{k-1} : 1 \le j, k \le n \right),$$

which may be expressed as the product $A = LU$ of a lower triangular matrix $L = (L_{jh})$ and upper triangular matrix $U = (U_{hk})$ defined as follows:

$$L_{jh} = \binom{j-1}{h-1} \quad \text{and} \quad U_{hk} = \binom{t_0+1}{k-h}.$$

The equality $A = LU$ is a direct consequence of the "Vandermonde convolution" formula [10, eq. (5.22)]

$$\sum_{h=1}^{n} \binom{j-1}{h-1} \binom{t_0+1}{k-h} = \binom{t_0+j}{k-1}.$$

Both L and U have unit diagonals and are hence nonsingular: indeed, their inverses have the following simple explicit forms, as can be verified by direct multiplication using standard identities involving sums of products of binomial coefficients [10, eqs (5.24), (5.25)]:

$$(L^{-1})_{hk} = (-1)^{h+k} \binom{h-1}{k-1}$$

and

$$(U^{-1})_{jh} = (-1)^{j+h} \binom{t_0 + h - j}{t_0 + 1}.$$

Since $A^{-1} = U^{-1} L^{-1}$, the values $\{|P_k| : 1 \le k \le n\}$ may be computed in polynomial time using two matrix multiplications involving integers of $O(n \log n)$ bits. Observe that $\frac{1}{2}|P_1|$ gives the number of (unoriented) Hamilton paths in G.

The hardness of #HC is now simple to verify. Given a graph $G = (V, E)$ with the minimum degree condition we add a new vertex x and edges (x, v) for all $v \in V$ to create G'. Note that G' satisfies the minimum degree condition as well. Removing x from a Hamilton cycle in G' creates a Hamilton path in G. This defines a bijection from the set of Hamilton cycles in G' to the set of Hamilton paths in G. □

5. Counting the number of cycles of all sizes. We will first consider approximating the total number of cycles in graphs with minimum degree $(\frac{1}{2} + \alpha)n$.

We first note that if we add a loop to each vertex and extend the definition of 2-factor to include loops as cycles of length one, then the argument of [14] may be

extended to this case (note that we still forbid cycles of length 2, i.e., double edges). Thus there exists both a fully polynomial randomized approximation scheme and a fully polynomial almost uniform sampler for the set of *partial* 2-factors in a dense graph. Let a partial 2-factor be *cyclic* if it consists of a single cycle of length at least three and a collection of loops. Clearly, the number of cyclic partial 2-factors is the same as the number of cycles.

The procedure for approximating the number of cycles of all sizes is as follows: we estimate first the number of partial 2-factors in G, and then the number of cyclic partial 2-factors by standard sampling methods as a proportion of the number of partial 2-factors. To produce an accurate estimate in polynomial time it is only necessary to show that the ratio of partial 2-factors to cyclic partial 2-factors is not too large. Let

$$\mathcal{F}_\ell = \{\text{partial 2-factors with } \ell \text{ loops}\} \quad \text{and} \quad f_\ell = |\mathcal{F}_\ell|.$$

For a given $F \in \mathcal{F}_\ell$ let $L = \{\text{loops of } F\}$, which we will now identify with the corresponding set of vertices. For $v \in L$ let d_v denote the number of neighbors of v in L and $D = \sum_{v\in L} d_v$.

If $v \in L$ then there are at least $2\alpha n - 2d_v$ ways of adding v to a cycle C of F by deleting an edge (a, b) of C and adding edges $(a, v), (v, b)$. Indeed, we go round each cycle C of F; if the successor b of a vertex a neighboring v is also a neighbor of v, then it forms an (a, b, v) triangle. The number of such triangles is at least $2\alpha n - 2d_v$.

So in total there are at least

$$\sum_{v\in L}(2\alpha n - 2d_v) = 2\ell\alpha n - 2D \tag{4}$$

$$\geq 2\ell(\alpha n - (\ell - 1)) \tag{5}$$

such augmentations.

Suppose first that $\ell \leq \ell_1 = \lfloor \alpha n/2 \rfloor$. Then (5) gives at least $\ell\alpha n$ augmentations of $F \in \mathcal{F}_\ell$ to an $F' \in \mathcal{F}_{\ell-1}$. Each $F' \in \mathcal{F}_{\ell-1}$ arises in at most n ways and so

$$\frac{f_{\ell-1}}{f_\ell} \geq \alpha\ell.$$

Putting $\ell_0 = \lceil 2/\alpha \rceil$ we see that

$$f_{\ell_1} + f_{\ell_1-1} + \cdots + f_{\ell_0+1} \leq f_{\ell_0} \leq f_{\ell_0} + f_{\ell_0-1} + \cdots + f_0. \tag{6}$$

Suppose next that $\ell > \ell_1$. Note first that since a graph with r vertices and s edges contains at least $r - s + 1$ distinct cycles, we see that L contains at least

$$\frac{D}{2} - \ell + 1 \tag{7}$$

distinct cycles.

Adding a cycle C contained in L to F and removing $|C|$ loops gives us a 2-factor in $\mathcal{F}_{\ell'}$ where $\ell' < \ell$. From (4) and (7) we see that there are at least[2]

$$\left(\frac{2\ell\alpha n - 2D}{4}\right)^+ + \left(\frac{D}{2} - \ell\right)^+ \geq \ell\left(\frac{\alpha n}{2} - 1\right) \tag{8}$$

$$\geq \frac{\ell\alpha n}{3} \tag{9}$$

[2] $x^+ = \max\{0, x\}$.

augmentations of either sort from F. Each $F' \in \mathcal{F}_{<\ell}$ arises in at most $n+n$ ways (accounting for both ways of reducing L), and so

$$\begin{aligned} f_\ell &\le \frac{6}{\alpha\ell}(f_{\ell-1} + f_{\ell-2} + \cdots + f_0) \\ &\le \theta(f_{\ell-1} + f_{\ell-2} + \cdots + f_0), \end{aligned}$$

where $\theta = 12/(\alpha^2 n)$, assuming $\ell > \ell_1$.

Thus

$$\frac{f_\ell + f_{\ell-1} + \cdots + f_0}{f_{\ell-1} + f_{\ell-2} + \cdots + f_0} \le 1 + \theta,$$

and so

$$f_\ell + f_{\ell-1} + \cdots + f_0 \le (1+\theta)^{\ell-\ell_1}\Sigma_1, \tag{10}$$

where $\Sigma_1 = f_{\ell_1} + f_{\ell_1-1} + \cdots + f_0$. We weaken (10) to

$$\begin{aligned} f_{\ell_1+k} &\le (1+\theta)^k \Sigma_1 \\ &\le e^{12\alpha^{-2}}\Sigma_1. \end{aligned} \tag{11}$$

It follows from (6) and (11) that

$$\frac{f_0 + f_1 + \cdots + f_n}{f_0 + f_1 + \cdots + f_{\ell_0}} \le 2 + 2ne^{12\alpha^{-2}}. \tag{12}$$

Now take an $F \in \mathcal{F}_\ell$ where $\ell \le \ell_0$ and fix its set of loops L. The number of partial 2-factors with this same L is at most a polynomial factor, $p(n)$ say, of the number of cycles of size $n-\ell$ through $V \setminus L$, by the results of section 3. (It is clear that because ℓ is small here, the required degree conditions are satisfied.) Thus, by (12), the ratio of partial 2-factors to cyclic partial 2-factors is $O(np(n))$ and we have proved the existence of an fpras for the number of cycles.

6. Paths and Hamilton paths. We obtain an fpras for counting the number of Hamilton paths in the following way. We add a vertex v_0 and join it by an edge to every vertex of G. Call this new graph G^*. The number of Hamilton cycles in G^* is equal to the number of Hamilton paths in G. Since G^* is dense we can approximate the latter quantity by approximating the former.

Similarly, to estimate the number of paths of all lengths, we compute an estimate c^* for the number of cycles in G^* and an estimate ρ^* for the proportion ρ of cycles which contain v_0. Since the number of cycles containing v_0 is the number of paths in G, this provides an estimate $\rho^* c^*$ for the number of paths. Also, this will give us an fpras provided ρ is not too small. But clearly, $\rho \ge 3/4$ and we are done.

7. Concluding remarks. We remark that it is not difficult to adapt the above methods to the corresponding *directed* case. Here we will have both minimum indegree and outdegree at each vertex guaranteed to be at least $(\frac{1}{2}+\alpha)n$. Also, we may similarly count the number of connected k-factors in G for any $k = o(n)$. (Hamilton cycles are, of course, connected 2-factors.)

We leave open the following questions. First, is it possible to count approximately as $\alpha \to 0$ in any fashion? Second, is there a random walk on Hamilton cycles and (in some sense) "near-Hamilton cycles" which is rapidly mixing? In other words, can we avoid the Tutte construction and the need for 2-factors with many cycles?

Finally, are there other interesting counting problems which are tractable on such dense graphs? Note that Annan [1] has recently found an fpras for the number of spanning forests in a dense graph. This can easily be modified to approximate the total number of (not necessarily spanning) trees in a dense graph. On the other hand, Jerrum [11] has recently shown that the problem of computing this number for a general graph is #P-complete.

Acknowledgment. We thank Alistair Sinclair for his comments on an earlier draft.

A SUBLINEAR SPACE, POLYNOMIAL TIME ALGORITHM FOR DIRECTED *s-t* CONNECTIVITY*

GREG BARNES†, JONATHAN F. BUSS‡, WALTER L. RUZZO§, AND BARUCH SCHIEBER¶

Abstract. Directed *s-t* connectivity is the problem of detecting whether there is a path from vertex s to vertex t in a directed graph. We present the first known deterministic sublinear space, polynomial time algorithm for directed *s-t* connectivity. For n-vertex graphs, our algorithm can use as little as $n/2^{\Theta(\sqrt{\log n})}$ space while still running in polynomial time.

1. Introduction.

The *s-t* connectivity problem, detecting whether there is a path from a distinguished vertex s to a distinguished vertex t in a directed graph, is a fundamental one, since it is the natural abstraction of many computational search processes, and a basic building block for more complex graph algorithms. In computational complexity theory, it has an additional significance: understanding its complexity is a key to understanding the relationship between deterministic and nondeterministic space-bounded complexity classes. In particular, the *s-t* connectivity problem for *directed* graphs (STCON) is the prototypical complete problem for nondeterministic logarithmic space [12]. Both STCON and the undirected version of the problem, USTCON, are DLOG-hard—any problem solvable deterministically in logarithmic space can be reduced to either problem [7, 12].

Establishing the deterministic space complexity of STCON would tell us a great deal about the relationship between deterministic and nondeterministic space-bounded complexity classes. For example, showing a deterministic logarithmic space algorithm for directed connectivity would prove that $\mathrm{DSPACE}(f(n)) = \mathrm{NSPACE}(f(n))$ for any constructible $f(n) = \Omega(\log(n))$ [12]. Unfortunately, this remains a difficult open problem. A fruitful intermediate step is to explore *time-space tradeoffs* for STCON, that is, the *simultaneous* time and space requirements of algorithms for directed connectivity. No nontrivial lower bounds are known for general models of computation (such as Turing machines) on either the space or the simultaneous space and time required to solve STCON, although Cook and Rackoff [5] and Tompa [13] have obtained lower bounds for restricted models. This paper presents new upper bounds for the problem.

The standard algorithms for connectivity, breadth- and depth-first search, run in optimal time $\Theta(m+n)$ and use $\Theta(n \log n)$ space. At the other extreme, Savitch's theorem [12] provides a small space ($\Theta(\log^2 n)$) algorithm that requires time exponential in its space bound (i.e., time $n^{\Theta(\log n)}$). Cook and Rackoff show an algorithm for their more restricted "JAG" model that is similar to, but more subtle than, Savitch's; it has essentially the same time and space performance.

Recent progress has been made on the time-space complexity of USTCON. Barnes and Ruzzo [3] show the first sublinear space, polynomial time algorithms for undirected connectivity. Nisan [8] shows that $O(\log^2 n)$ space and polynomial time suffice. Nisan, Szemerédi, and Wigderson [9] show the first USTCON algorithm that uses less space than Savitch's algorithm ($O(\log^{1.5} n)$ versus $\Theta(\log^2 n)$).

Prior to the present paper, there was no corresponding sublinear space, polynomial time algorithm known for STCON, and there was some evidence suggesting that none was possible. It has been conjectured [4] that no deterministic STCON algorithm can run in simultaneous polynomial time and polylogarithmic space. Tompa [13] shows that certain natural approaches to solving STCON admit no such solution. Indeed, he shows that for these approaches, performance degrades sharply with decreasing space. Space $o(n)$ implies superpolynomial time, and space $n^{1-\epsilon}$ for fixed $\epsilon > 0$ implies time $n^{\Omega(\log n)}$, essentially as slow as Savitch's algorithm.

The main result of our paper is a new deterministic algorithm for directed s-t connectivity that achieves polynomial time and sublinear space simultaneously. While not disproving the conjecture of [4], it shows that the behavior elicited from certain algorithms by Tompa is not intrinsic to the problem. Our algorithm can use as little as $n/2^{\Theta(\sqrt{\log n})}$ space while still running in polynomial time. As part of this algorithm, we present an algorithm that finds short paths in a directed graph in polynomial time and sublinear space. The *short paths problem* is a special case of STCON that retains many of the difficulties of the general problem and seems particularly central to designing small space algorithms for STCON. We are not aware of any previous algorithms that solve this problem in sublinear space and polynomial time. Interestingly, our algorithm for the short paths problem is a generalization of two well-known algorithms for STCON. In one extreme it reduces to a variant of the linear time breadth-first search algorithm, and in the other extreme it reduces to the $O(\log^2 n)$ space, superpolynomial time algorithm of Savitch.

Subsequent to the appearance of a preliminary version of this paper [1], Poon [11, Chap. 4] has shown an algorithm for the JAG model that is similar to this algorithm and achieves similar performance. In addition, Barnes and Edmonds [2] and Edmonds and Poon [6] have given improved lower bounds for STCON on the JAG model and the stronger Node-Named JAG (*NNJAG*) model of Poon [10]. Edmonds and Poon's lower bound is particularly strong, since it nearly matches the upper bounds in this paper when the machine uses space $n/2^{O(\sqrt{\log n})}$ or less, and thus suggests that the algorithm in this paper could provide an optimal time-space tradeoff for STCON.

Our algorithm to solve STCON in polynomial time and sublinear space is constructed from two algorithms with different time-space tradeoffs. The first performs a modified breadth-first search of the graph, while the second finds short paths. Alone, neither algorithm can solve STCON in simultaneous polynomial time and sublinear space. In the following two sections, we present the breadth-first search algorithm and the short paths algorithm. Section 4 shows how the two algorithms can be combined to yield the desired result. Section 5 presents some notes and concluding remarks.

For more information on graph connectivity, see the survey paper by Wigderson [15].

2. The breadth-first search tradeoff. Consider the tree constructed by a breadth-first search beginning at s. The tree can contain n vertices and thus requires $O(n \log n)$ space to store. Instead of constructing the entire tree, our modified breadth-first search generates a fraction of the tree.

Suppose we want our modified tree to contain at most n/λ vertices. We can do this by only storing (the vertices in) every λth level of the tree. Number the levels of the tree $0, 1, \ldots, n-1$, where a vertex v is on level l if the shortest path from s to v is of length l. Divide the levels into equivalence classes $C_0, C_1, \ldots, C_{\lambda-1}$ based on their number mod λ. Besides s, the algorithm stores only the vertices in one equivalence class C_j, where j is the smallest value for which C_j has no more than the average number of vertices, n/λ.

The algorithm constructs this partial tree one level at a time. It begins with level 0, which consists of s only, and generates levels j, $j+\lambda$, $j+2\lambda$, $\ldots$, $j+\lambda \cdot \lfloor n/\lambda \rfloor$. Given a set, S, of vertices, we can find all vertices within distance λ of S in time $n^{O(\lambda)}$ and space $O(\lambda \log n)$ by enumerating all possible paths of length at most λ and checking which paths exist in G. This can be used to generate the levels of the partial tree. Let V_i be the vertices in levels 0, j, $j+\lambda$, $\ldots$, $j+i\lambda$. Consider the set of vertices, U, that are within distance λ of a vertex in V_i. Clearly, U contains all the vertices in level $j+(i+1)\lambda$. However, U may also contain vertices in lower numbered levels. The vertices in level $j+(i+1)\lambda$ are those vertices in U that are not within distance $\lambda - 1$ of a vertex in V_i. Thus, to get V_{i+1} we add to V_i all vertices that are within distance λ but not $\lambda - 1$ of V_i.

Pseudocode for the algorithm appears in Figure 2.1. Note that to find an equivalence class with at most n/λ vertices, the algorithm just tries all classes in order, discarding a class if it generates too many vertices.

Referring to Figure 2.1, the algorithm's space bound is dominated by the number of vertices in S and S', and the space needed to test whether a vertex is within distance λ of a vertex in S. There are never more than $n/\lambda + 1$ vertices in S and S', so the algorithm uses $O((n \log n)/\lambda)$ space to store these vertices. The time bound is dominated by repeatedly testing whether a vertex is within distance λ of a vertex in S. This test is performed $O(n^3/\lambda)$ times—the innermost loop to find the vertices on the next level of the tree makes $O(n \cdot n/\lambda)$ such tests (testing for a path from the $O(n/\lambda)$ vertices in S to all other $O(n)$ vertices), and is executed $O(\lambda \cdot n/\lambda)$ times.

In summary, we have shown the following.

THEOREM 2.1. *For any n-vertex directed graph and any integer $\lambda, 1 \leq \lambda \leq n$, the breadth-first search algorithm presented above solves s-t connectivity in space $O((n \log n)/\lambda + S_{PATH}(\lambda, n))$ and time $O((n^3/\lambda) \cdot T_{PATH}(\lambda, n))$, where $S_{PATH}(\lambda, n)$ and $T_{PATH}(\lambda, n)$ denote the space and time bounds, respectively, of the algorithm used to test for a path of length at most λ between two vertices in an n-vertex graph.*

Note that we assume that testing for a path of length at most j, $j-1$, or $\lambda - 1$ will not take asymptotically more time or space than testing for a path of length at most λ. This is because the first three problems are easily reduced to the latter. To test for a path of length at most λ', $\lambda' < \lambda$, from some vertex in a set S to some vertex v, connect $\lambda - \lambda'$ new vertices, $v_1, v_2, \ldots, v_{\lambda-\lambda'}$, in a chain to v by adding the edges $(v, v_1), (v_1, v_2), (v_2, v_3), \ldots, (v_{\lambda-\lambda'-1}, v_{\lambda-\lambda'})$. There will be a path in the new graph from some vertex $u \in S$ to $v_{\lambda-\lambda'}$ of length at most λ if and only if there was a path in the original graph from u to v of length at most λ'.

```
Algorithm Bfs (integer: λ);
                                  {remember every λth level of the breadth-first search tree}
  for j = 0 to λ − 1 do begin          {first level to remember, apart from level 0}
    S = {s}.
    for all vertices, v do begin                    {Find vertices on the first level}
      if v within distance j of s and
          v not within distance j − 1 of s then
        if |S| > n/λ then try next j.   {Don't store more than n/λ vertices, + vertex s}
        else add v to S.
    end;
    for i = 1 to ⌊n/λ⌋ do begin
      S′ = ∅.
      for all vertices, v do begin                  {Find vertices on the next level. ⋆}
        if v within distance λ of some vertex in S and
            v not within distance λ − 1 of any vertex in S then
          if |S| + |S′| > n/λ then try next j.
          else add v to S′.
      end;
      S = S ∪ S′.
    end;
    if t within distance λ of a vertex in S then return (Connected);
    else return (Not Connected);
  end;
end Bfs.
```

FIG. 2.1. *Details of the breadth-first search algorithm.*

Using a straightforward enumeration of all paths, testing whether a vertex is within distance λ requires $n^{O(\lambda)}$ time and $O(\lambda \log n)$ space. This algorithm is not sufficient for our purposes. In particular, if λ is asymptotically greater than a constant, the algorithm uses superpolynomial time. If we restrict our input to graphs with bounded degree, there is a slight improvement. In a graph where the outdegree is bounded by d, the number of paths of length λ from a vertex is at most d^{λ}. For these graphs, λ can be $O(\log n)$ and the algorithm will run in polynomial time. Note that the overall algorithm still does not use sublinear space in this case, even though the subroutine for finding paths of length λ does.

The problem with this algorithm is its method of finding vertices within distance λ. Explicitly enumerating all paths is not very clever, and uses too much time. There is hope for improvement, though, since this method uses only $O(\lambda \log n)$ space, much less than the $O(\frac{n}{\lambda} \log n)$ used by the rest of the algorithm. Indeed, in the next section we give an algorithm that uses more space but runs much faster.

3. The short paths tradeoff. Consider the *bounded s-t connectivity problem* (*bounded* STCON).

DEFINITION 3.1. *For any real-valued function $f(n)$, the $f(n)$-*bounded *s-t* connectivity problem *is, given an n-vertex directed graph G and two distinguished vertices s and t, to determine whether there is a path in G from s to t of length less than or equal to $f(n)$.*

Solving bounded STCON for general $f(n)$ is at least as hard as solving STCON. We are interested in the *short paths problem*, informally defined as the bounded STCON problem where $f(n)$ is small. The short paths problem is a special case of STCON

that seems to retain many of the difficulties of the general problem. It is particularly interesting given the breadth-first search algorithm above, because a more efficient method of finding short paths would clearly lead to an improvement in that algorithm's time bound.

Our second tradeoff is an algorithm that solves the short paths problem for many $f(n)$ in sublinear space and polynomial time. As will become clear, we will eventually want $f(n) = 2^{\Theta(\sqrt{\log n})}$, but to simplify the following discussion, we begin with the more modest goal of finding a sublinear space, polynomial time algorithm for the short paths problem with $f(n) = \log^c n$, for some integer constant $c \geq 1$.

As noted before, we already have a sublinear space, polynomial time algorithm that searches to distance $\log n$ on bounded degree graphs; because there are a constant number of ways to leave each vertex, we can enumerate and test all paths of length $\log n$ in polynomial time. In a general graph, this approach will not work, because there can be up to $n-1$ possible edges from each vertex, and explicit enumeration can yield a superpolynomial number of paths of length $\log n$. We can avoid this problem by using a labeling scheme that limits the number of possible choices at each step of the path.

Suppose we divide the vertices into k sets, according to their vertex number mod k. Then, every path of length L ($L = f(n)$) can be mapped to an $(L+1)$-digit number in base k, where digit i has value j if and only if the ith vertex in the path is in set j. Conversely, each such number defines a set of possible paths of length L.

Given this mapping, our algorithm is straightforward: generate all possible $(L+1)$-digit k-ary numbers, and check for each number whether there is a path in the graph that matches it. For a given k-ary number, the algorithm uses approximately $2n/k$ space to test for the existence of a matching path in the graph, as follows. Suppose we are looking for a path from s to t and want to test the $(L+1)$-digit number $\langle s \bmod k, d_1, d_2, \ldots, d_{L-1}, t \bmod k\rangle$. We begin with a bit vector of size $\lceil n/k \rceil$, which corresponds to the vertex set d_1. Zero the vector, and then examine the outedges of s, marking any vertex v in set d_1 (by setting the corresponding bit in the vector) if we find an edge from s to v. When we are finished, the marked vertices in the vector are the vertices in d_1 that have a path from s that maps to the first two digits of the number. Using this vector, we can run a similar process to find the vertices in d_2 that have a path from s that maps to the first three digits of the number, and store them in a second vector of size $\lceil n/k \rceil$. In general, given a bit vector of length $\lceil n/k \rceil$ representing the vertices in d_i with a path from s that maps to the first $i+1$ digits of the number, we use the other vector to store the vertices in d_{i+1} with a path from s that maps to the first $i+2$ digits. Pseudocode for the algorithm appears in Figure 3.1. Notice that the algorithm as given does not solve the short paths problem, as it tests for the existence of a path from s to t of length *exactly* L, not *at most* L. Any such algorithm can easily be converted into an algorithm for the short paths problem by adding a self-loop to s. For simplicity, we omit this detail from our algorithms.

The algorithm uses space $O(n/k)$ to store the vectors, and $O(L \log k)$ to write down the path to be tested. Let D be the maximum number of edges from one set of vertices d_i to another set of vertices d_j (i and j can be the same). For all steps in each path, we do at most $O(n/k + D)$ work zeroing the vector and testing for edges from d_{i-1} to d_i. Since $D = O(n^2/k^2)$, the algorithm uses $O(k^L L \cdot n^2/k^2) = O(k^L n^3)$ time to test all L steps on each of the k^L paths.

Unfortunately, this does not reach our goal of polynomial time and sublinear space when $L = \log^c n$. With a distance as small as $\log n$, k^L is only polynomial if k

```
Algorithm SP (integer: k, L; vertex s, t);
                                {Test for a path of length L between s and t using space O(n/k)}
  Create V_0 and V_1, two ⌈n/k⌉ bit vectors.
  for all (L + 1)-digit numbers in base k,
      ⟨d_0 = s mod k, d_1, ..., d_{L-1}, d_L = t mod k⟩ do begin
    Set all bits in V_0 to zero, and mark s (set the corresponding bit to 1).
    for i = 1 to L do begin
      Set all bits in V_{i mod 2} to zero.
                                                {Find edges from d_{i-1} to d_i}
      for all u in d_{i-1} marked in V_{(i-1) mod 2} and all v in d_i do begin
        if (u, v) is an edge then
          mark v in V_{i mod 2}.
      end;
    end;
    if t is marked in V_{L mod 2} then return (Connected);
  end;
  return (Not Connected);
end SP.
```

FIG. 3.1. *Details of the short paths algorithm.*

is constant, and if k is constant, the algorithm does not use sublinear space. We *can* achieve polynomial time and sublinear space by reducing the distance the algorithm searches. For example, if $L = \log n / \log\log n$, k can be $\log^c n$ for any constant c, and the algorithm will run in $O(n/\log^c n)$ space and $O((\log n)^{c \log n / \log\log n} n^3) = O(n^{c+3})$ time.

The algorithm can be improved by invoking it recursively. Consider the loop in the algorithm that tests for edges between one set of vertices and the next. This loop, in effect, finds paths of length one from marked vertices in the first set to vertices in the second set. Instead of finding paths of length one, we can use the short paths algorithm to find paths of length L, yielding an algorithm that uses twice as much space, but finds paths of length L^2. In general, using $r \geq 1$ levels of recursion, the improved algorithm can find paths of length L^r using $O(r(n/k + L \log k))$ space. If we make a recursive call for every possible pair of vertices in $d_{i-1} \times d_i$, we get a time bound of $O((k^L L \cdot n^2/k^2)^r) = O(n^{2r+1} k^{rL})$, since $L^r = O(n)$. In Figure 3.2, we present the pseudocode for our recursive algorithm. This algorithm uses a further refinement to improve the time bound—one recursive call is used to find all vertices in d_i reachable from any reachable vertex in d_{i-1}.

Given the discussion above, the time used by the recursive algorithm is bounded by the following recurrence relation, where $T(j)$ is the time used by the algorithm with j levels of recursion. For an appropriately chosen constant c,

$$T(j) = \begin{cases} O(n^2/k^2) & \text{if } j = 0, \\ k^L L(T(j-1) + cn/k) & \text{if } j > 0. \end{cases}$$

In the base case, the algorithm does $O(n^2/k^2)$ work. At other levels, the algorithm makes $k^L L$ recursive calls to itself, as well as doing some auxiliary work, such as setting all vector entries to zero. Solving the recurrence relation for $j = r$ gives time $O((k^L L)^r \cdot n^2/k^2) = O(n^3 k^{rL})$.

In summary, we have shown the following.

```
Algorithm SPR (integer: k, L, r, d_s, d_t; vector V_s): vector;
                          {Return the vector of vertices in set d_t that are reachable by paths
                            of length L^r from vertices in set d_s that are marked in vector V_s}
  Create V_0, V_1, and V_t, three ⌈n/k⌉-bit vectors. Set all bits in V_t to zero.
  if r = 0 then                                                          {base case}
    for all u in d_s marked in V_s and all v in d_t do begin
      if (u, v) is an edge then
        mark v in V_t.
    end;
  else
    for all (L + 1)-digit numbers in base k,
        ⟨d_0 = d_s, d_1, ..., d_{L-1}, d_L = d_t⟩ do begin
      V_0 = V_s.
      for i = 1 to L do begin                                  {Find paths from d_{i-1} to d_i}
        V_{i mod 2} = SPR(k, L, r - 1, d_{i-1}, d_i, V_{(i-1) mod 2}).
      end;
      Set all bits in V_t that are set in V_{L mod 2}.
    end;
  return (V_t);
end SPR.
```

FIG. 3.2. *Details of the recursive short paths algorithm.*

THEOREM 3.2. *For arbitrary integers r, k, and L, such that $r \geq 1$, $L \geq 1$, $n \geq k \geq 1$, and $L^r \leq n$, the recursive short paths algorithm, presented above, can search to distance L^r in time $O(k^{rL}L^r \cdot n^2/k^2)$ $(= O(n^3 k^{rL}))$ and space $O(r(n/k + L \log k))$.*

We will close this section with a few notes on the algorithm. This recursive algorithm meets our goal of finding a sublinear space, polynomial time algorithm that detects paths of polylogarithmic length. For example, for $L = \log n / \log\log n$, $k = \log^r n$, and constant $r \geq 2$, the algorithm searches to distance $L^r = \omega(\log^{r-1} n)$ in time $O(n^3 k^{rL}) = O(n^{r^2+3})$ and space $O(rn/\log^r n)$. However, as mentioned in the introduction, this algorithm does not by itself give a polynomial time, sublinear space algorithm for STCON. The algorithm searches to distance L^r by testing k^{rL} numbers. If $L^r = n$, then k^{rL} is polynomial only if $k = O(1)$. But if $k = O(1)$, the algorithm does not use sublinear space.

The algorithm, which was designed to solve the short paths problem, actually solves bounded STCON, and is thus a general algorithm for s-t connectivity. In fact, given the appropriate parameters, the algorithm exhibits behavior and performance similar to the best-known previous algorithms for STCON. If we let $k = 1$, $L = n$, and $r = 1$, the algorithm is a somewhat inefficient variant of breadth-first search that uses $O(n)$ space and $O(n(n + m))$ time: the algorithm first finds all vertices at distance 1 from s, then distance 2, etc., until it has searched to distance n. At the other end of the time-space spectrum, Savitch's algorithm is just the special case of this algorithm where $k = n$, $L = 2$, and $r = \lceil \log n \rceil$—this is also the minimum space bound for the algorithm.

4. Combining the two algorithms. As an immediate consequence of the previous two sections, we have an algorithm for STCON using sublinear space and polynomial time: use the modified breadth-first search algorithm to find every $(\log^c n)$th level of the tree (for integer constant $c \geq 2$), with the recursive short paths algorithm

```
                                  {S is the set of vertices on previous tree levels. S' (initially
                                   the empty set) will be the set of vertices on the next level}
for i_1 = 0 to k - 1 do begin
   S_{i_1} = {all vertices whose vertex number mod k = i_1}.
   P = ∅.                          {P will be all vertices in S_{i_1} on the next tree level}
   for i_2 = 0 to k - 1 do begin
      S_{i_2} = {all vertices whose vertex number mod k = i_2}.
      Q = S ∩ S_{i_2}.             {Q is all vertices in S_{i_2} on previous tree levels}
      A = {all vertices in S_{i_1} within distance L^r of a vertex in Q}.
      B = {all vertices in S_{i_1} within distance L^r - 1 of a vertex in Q}.
      P = P ∪ (A - B).
   end;
   if |S| + |S' ∪ P| > n/L^r then try next j.
   else S' = S' ∪ P.
end;
```

FIG. 4.1. *Combining the two algorithms efficiently.*

(the version that checks for paths of length up to L^r) as a subroutine to find the paths between levels. With careful choices of the parameters k, L, and r, however, the algorithm can use even less space while still maintaining polynomial time.

In general, if we set λ in the breadth-first search algorithm to be L^r, the breadth-first search algorithm finds every (L^r)th level of the tree, and the short paths algorithm searches to distance L^r. Substituting the space bound for the short paths algorithm (see Theorem 3.2) for the term $S_{PATH}(\lambda, n)$ in the breadth-first search algorithm (see Theorem 2.1), we get a space bound for this algorithm of

$$O((n \log n)/L^r + r(n/k + L \log k)), \tag{4.1}$$

where the first term corresponds to the space used by the partial breadth-first tree, and the second to the space used to find short paths. Substituting the short paths time bound for the term $T_{PATH}(\lambda, n)$ in the breadth-first search time bound gives a time bound of

$$O((n^3/L^r) \cdot k^{rL} L^r \cdot n^2/k^2) = O(n^5 k^{rL-2}).$$

The above time bound applies when we call the short paths algorithm every time the breadth-first search algorithm needs to know whether one vertex is within distance L^r of another. The two algorithms can be combined more efficiently by noticing that the short paths algorithm can answer many short paths queries in one call; for any pair of sets, (Q, R), such that R is one of the k sets of vertices in the short paths algorithm and Q is a subset of one of the k sets, one call to the short paths algorithm can be used to find all vertices in R within distance L^r of a vertex in Q. Thus, the short paths algorithm only needs to be called $2k^2$ times to generate the next level of the tree, twice for each possible pair of the k sets in the short paths algorithm. Figure 4.1 gives the code that should be used in place of the loop in Figure 2.1 (marked with a $\star$) that finds vertices on the next level of the breadth-first search tree. Similar code should replace the earlier loop in Figure 2.1 that finds the vertices on the first level.

The improved version makes a total of $O(k^2 n/L^r)$ calls to the short paths algorithm, for a time bound of

$$O((k^2 n/L^r) \cdot k^{rL} L^r \cdot n^2/k^2) = O(n^3 k^{rL}). \tag{4.2}$$

We want to find the minimum amount of space the algorithm can use while still maintaining a polynomial running time. To maintain polynomial time, we must have, for some constant a,

$$k^{rL} = n^a. \tag{4.3}$$

For simplicity, we bound expression (4.1) from below by

$$\Omega(n/L^r + n/k). \tag{4.4}$$

(That is, we omit the $\log n$ factor in the first summand and the r factor in the second summand, and leave out the third summand altogether.) The minimum value of the bound (4.4) is reached when the denominators are equal. For any given k, the product rL is fixed; thus the quantity L^r reaches its maximum, and the bound reaches its minimum, when L is a constant. Substituting L^r for k in (4.3) and solving for r yields $r = \sqrt{(a/L)\log_L n} = \Theta(\sqrt{\log n})$, and thus $k = 2^{\Theta(\sqrt{\log n})}$.

Substituting these values, $\sqrt{\log n}$ for r, $2^{\Theta(\sqrt{\log n})}$ for k, and a constant for L, into the simplified space bound expression (4.4) gives a bound of $n/2^{\Theta(\sqrt{\log n})}$. Substituting these same values into the actual space bound expression (4.1) yields the same asymptotic space bound, $n/2^{\Theta(\sqrt{\log n})}$. Since this matches the minimum for the simplified expression, which was a lower bound for this expression, we cannot do any better, and this must be the minimum space bound for the algorithm when using polynomial time.

The results of this section are summarized in the following theorem and its corollary.

THEOREM 4.1. *The combined algorithm, described above, solves* STCON *in space* $O((n \log n)/L^r + r(n/k + L \log k))$ *and time* $O(n^3 k^{rL})$, *for any integers* r, k, *and* L *that satisfy* $n \geq k \geq 1, r \geq 1, L \geq 1$, *and* $L^r \leq n$.

COROLLARY 4.2. *The combined algorithm can solve* STCON *in time* $n^{O(1)}$ *and space* $n/2^{\Theta(\sqrt{\log n})}$.

Proof. Choose $r = \sqrt{\log n}$, $k = 2^{\Theta(\sqrt{\log n})}$, and $L = 2$ in Theorem 4.1. As discussed above, these choices minimize space while retaining polynomial time. □

5. Conclusions and future work. Letting $L = 2$ and $k = 2^r$, we obtain the following corollary.

COROLLARY 5.1. *The combined algorithm of section* 4 *can solve* STCON *using time* $2^{O(\log^2(n/S))} \cdot n^3$ *given space* S.

The recent lower bound of Edmonds and Poon [6] shows that no algorithm that runs on an NNJAG can do better than time $2^{\Omega((\log^2(n/S))/\log\log n)}$ given space S. Ignoring the $\log\log n$ factor in the lower bound, the two bounds therefore match when $S = n/2^{O(\sqrt{\log n})}$. For higher space bounds, Edmonds and Poon's bound does not improve the JAG lower bound in Barnes and Edmonds [2] of $ST = \Omega(n^2/\log(n/S))$ (where T is the time used by the JAG).

Note that only the $\log\log n$ factor separates the lower bound from the upper bound when small space is used. When the space used is larger, there is still a

significant gap between the upper and lower bounds (although the gap is not as large as Theorem 4.1 indicates, since the time bound in (4.2) is an overestimate). It is possible that the combined algorithm above is optimal for the NNJAG model, but to prove it, these gaps must be eliminated.

Given that the upper and lower bounds for the problem are now close for the JAG and NNJAG models, we should consider more general models of computation. To improve this algorithm, it seems likely that we must use methods for exploring a graph that cannot be mimicked by an NNJAG. On the other hand, finding a lower bound similar to Barnes and Edmonds's [2] or Edmonds and Poon's [6] on a more general model of computation would be a breakthrough and would help decide the question of the complexity of *DL* versus *NL*.

Acknowledgments. Allan Borodin pointed us toward the short paths problem. Uri Feige helped find the minimum space bound.

MONOTONE CIRCUITS FOR CONNECTIVITY HAVE DEPTH $(\log n)^{2-o(1)}$*

MIKAEL GOLDMANN† AND JOHAN HÅSTAD‡

Abstract. We prove that a monotone circuit of size n^d recognizing connectivity must have depth $\Omega((\log n)^2/\log d)$. For formulas this implies depth $\Omega((\log n)^2/\log\log n)$. For polynomial-size circuits the bound becomes $\Omega((\log n)^2)$ which is optimal up to a constant.

Key words. monotone circuits, circuit complexity, connectivity, lower bounds

AMS subject classification. 68Q15

1. Introduction.

1.1. Graph connectivity. Connectivity is the problem of determining if an undirected graph G is connected or not. This is a natural and fundamental problem which has been studied in numerous contexts. We refer the reader to Wigderson's survey of connectivity and its importance in complexity theory [9]. We consider the complexity of computing connectivity using monotone circuits with AND-gates and OR-gates of fan-in two. Typically, an n-node graph is encoded by $\binom{n}{2}$ variables $x_{i,j}$ that indicate whether $\{i,j\}$ is an edge in G or not. In [4] Karchmer and Wigderson proved that monotone circuits for the related problem (s,t)-connectivity (determining if there is an s,t-path in G) must have depth $\Omega((\log n)^2)$.[1] This is well known to be optimal. In spite of the two problems being very similar in nature, attempts to prove nontrivial bounds for connectivity were fruitless until Yao recently proved a lower bound of $\Omega((\log n)^{3/2}/\log\log n)$ [10].

While Karchmer and Wigderson used a top-down approach exploiting an equivalence between circuit depth and communication complexity (see [3]), Yao uses a bottom-up approach. In this article we modify his method to prove a lower bound of $\Omega((\log n)^2/\log\log n)$, and in the case of polynomial-size circuits the bound improves to optimal $\Omega((\log n)^2)$.

1.2. The method of approximation. The tool used by Yao in [10] is a modification of the method of approximation, originally designed by Razborov [7, 6] to prove lower bounds on the size of monotone circuits (also used in [1, 2]). The method is roughly as follows. One considers some subset of the inputs, called *test inputs*. Given some monotone circuit C one replaces each gate g by an approximator $\tilde{g}$ yielding a function $\tilde{C}$ that approximates the function that C computes. In order to prove a lower bound on the size of C one needs to show two things:

[1] All logarithms in this paper are to the base 2 unless we explicitly state otherwise.

1. g and $\tilde{g}$ agree on all but a tiny fraction of the test inputs,
2. C and $\tilde{C}$ disagree on a large fraction of the test inputs.

Since local errors are small but the total error is large, there must be many local errors; that is, C must have many gates.

Yao adapted the method of approximation to prove lower bounds on circuit depth. The key is to allow more and more powerful functions as approximators as one goes up the circuit. This way one can get good approximating functions at each level of the circuit. On the other hand, if there are not too many levels in the circuit, then the approximator one gets is still not powerful enough to agree with connectivity on most inputs.

Remark. The idea of having more powerful approximators as one goes up the circuit is also present in [5] and [8]. These papers prove lower bounds on the size of nonmonotone constant-depth circuits.

1.3. An overview of the paper. Recall the standard way to compute connectivity with $O(\log^2 n)$-depth monotone circuits. Let A_G be an $n \times n$ adjacency matrix of the undirected graph G and let I be the $n \times n$ identity matrix. Then G is connected if and only if $(A_G + I)^n$ (computed over the Boolean semiring $\langle \{0,1\}, \wedge, \vee \rangle$) is the all-one matrix. It is sufficient to look at $(A_G + I)^{2^{\lceil \log n \rceil}}$ which can be computed by $\lceil \log n \rceil$ squarings. Each squaring can be carried out by a $O(\log n)$-depth monotone circuit. If we look at an intermediate result, say $(A_G + I)^j$, then the u, v entry in this matrix tells us whether u and v are within distance 2^j in G or not. The intuition behind the proof is that this is more or less what a shallow monotone circuit can know about G: that some "small" sets of vertices are "close" to each other in G.

The basic approximators used have a parameter j that is coupled to the depth of the circuit that is to be approximated. A basic approximator checks if for some small subsets of the vertices all the vertices in each subset are within distance K^j in G (where K is a fixed parameter in the proof). For $j = 0$ the basic approximators are just checking edges in G, that is, looking at the inputs. Notice that the basic approximators correspond closely to the functions computed at the gates of the standard circuit above. The real approximators we use are disjunctions of basic approximators.

We wish to prove that some arbitrary shallow circuit C does not compute connectivity. Thus, we want to find an approximator that approximates C well. The proof proceeds in stages. At stage j we find approximators (with parameter j) for all the subfunctions computed by gates on level $j\epsilon \log n$ in C. As long as the circuit has depth $l\epsilon \log n$ where l is smaller than, say, $(\log_K n)/10$, the resulting approximator for the circuit only looks at local connectivity problems (checks if certain vertices are within distance $n^{1/10}$ in G) and therefore is poor at checking connectivity "globally."

In section 2 we present the approximators and prove some preliminary results about how they behave on certain "test inputs." We also prove some preliminary combinatorial lemmas.

In section 3 it is shown that monotone circuits of size n^d (where $d = o(\log n)$) for connectivity must have depth $\Omega((\log n)^2/\log d)$. By modifying the proof of this result we show in section 4 that monotone formulas for connectivity must have depth $\Omega((\log n)^2/\log\log n)$.

Finally, section 5 discusses the most obvious open problem: to show that computing connectivity with monotone formulas requires depth $\Omega((\log n)^2)$. We give some reasons why minor modifications to the method used in this paper probably will not be sufficient to prove this. In particular it is shown that there exists a circuit of depth $O((\log^2 n)/\log\log n)$ that when the method of approximation is applied to it, the

resulting function approximates connectivity well.

2. Test inputs and our approximating functions. As in Yao's paper we concentrate on two types of inputs:

1. Hamiltonian paths,
2. two disjoint cliques.

We use the abbreviation HP for the first type and 2C for the second. The goal is to show that an approximator for a shallow circuit either outputs 0 for a large fraction of HP or outputs 1 for a large fraction of 2C. We are interested in random instances of the two types and for HP we take the uniform distribution. A random instance of 2C is obtained by randomly and independently giving the labels 0 and 1 (each with probability 1/2) to each node. We then connect nodes with the same label. Thus, a random instance of HP is always connected while the probability that a random instance of 2C is connected is 2^{1-n} which for all practical purposes can be approximated with 0.

As mentioned in the introduction, we use approximations that are similar to Yao's. In other words, our method is bottom-up and starts with the inputs. We let the circuit do computation for $\epsilon \log n$ levels, and then we replace the functions computed by a nearby function. The information we concentrate on is the fact that certain subsets of vertices are known to be close to each other. The simplest case of this is an edge which is just saying that two vertices are at distance 1. To be able to formulate the general concept we need a little bit of notation.

DEFINITION 2.1. *Let $V = \{1, \dots, n\}$. A* partitioned subset *of V is a set $\mathbf{A} = \{A_1, \dots, A_k\}$ of disjoint subsets of V.*

Let $e(\mathbf{A}) = A_1 \cup \cdots \cup A_k$, and let the size of $\mathbf{A}$ *be $|e(A)|$.*

Let $s(\mathbf{A})$ be the number of sets in $\mathbf{A}$; i.e., $s(\mathbf{A}) = k$ in the given notation.

A partitioned set $\mathbf{A} = \{A_1, \dots, A_k\}$ is a subset *of another partitioned set $\mathbf{B} = \{B_1, \dots, B_l\}$ (written $\mathbf{A} \subseteq \mathbf{B}$) if $k \le l$ and (possibly after renumbering the parts of B) $A_i \subseteq B_i$ for $i = 1, 2, \dots, k$.*

A partitioned set $\mathbf{A}$ is finer *than a partitioned set $\mathbf{B}$ if for each $A_i \in \mathbf{A}$ there is a $B_j \in \mathbf{B}$ such that $A_i \subseteq B_j$. Conversely, we say that $\mathbf{B}$ is* coarser *than $\mathbf{A}$.*

It will be useful to have an estimate of the number of small partitioned subsets.

LEMMA 2.2. *Let $V = \{1, \dots, n\}$ and k be an integer. Then there are at most $(en)^k$ partitioned subsets of V of size at most k.*

Proof. We count by first picking a subset of V and then partitioning it. A set of size $s \le k$ can clearly be partitioned in at most $s^s \le k^k$ ways. Therefore, $k^k \sum_{s=0}^{k} \binom{n}{s}$ is an upper bound on the number of partitioned subsets of V. However,

$$\sum_{s=0}^{k} \binom{n}{s} \le \left(\frac{n}{k}\right)^k \sum_{s=0}^{n} \binom{n}{s} \left(\frac{k}{n}\right)^s = \left(\frac{n}{k}\right)^k \left(1 + \frac{k}{n}\right)^n \le \left(\frac{n}{k}\right)^k e^k,$$

which completes the proof. □

We will always have $|A_i| \ge 2$ and hence $|e(\mathbf{A})| \ge 2s(\mathbf{A})$.

The partitioned sets will play the role of minterms in our approximating functions. For a partitioned set $\mathbf{A}$ and integer r define the following function on graphs:

$$f^r_{\mathbf{A}}(G) = 1 \Leftrightarrow \bigwedge_{i=1}^{s(\mathbf{A})} \left(\bigwedge_{a,b \in A_i} d_G(a,b) \le r \right),$$

where $d_G(a,b)$ is the length of the shortest path in G between the nodes a and b. If a and b are not connected we define $d_G(a,b) = \infty$.

Our general approximating functions will be disjunctions of $f^r_{\mathbf{A}}$ for various $\mathbf{A}$ and r. Let $\mathcal{A} = \{\mathbf{A}^1, \ldots, \mathbf{A}^t\}$ be a collection of partitioned sets. Then we define

$$f^r_{\mathcal{A}} = \bigvee_{i=1}^{t} f^r_{\mathbf{A}^i}.$$

Also, for the empty set $\emptyset$ we define

$$f^r_{\emptyset} \equiv 1.$$

Boolean operations on functions $f^r_{\mathcal{A}}$ can almost be performed in the natural way. $f^r_{\mathcal{A}} \vee f^r_{\mathcal{B}}$ is of course $f^r_{\mathcal{A}\cup\mathcal{B}}$ so that is no problem. However, $f^r_{\mathcal{A}} \wedge f^r_{\mathcal{B}}$ is a little bit more complicated. By using the distributive law we need only to consider $f^r_{\mathbf{A}^i} \wedge f^r_{\mathbf{B}^j}$. If $e(\mathbf{A}^i)$ and $e(\mathbf{B}^j)$ are disjoint, this is just $f^r_{\mathbf{A}^i\cup\mathbf{B}^j}$, while if the two partitioned sets are not disjoint the resulting function might not be exactly representable and we can only find an approximation in our set of functions. Essentially we use $f^{r'}_{\mathbf{C}}$ where $e(\mathbf{C}) = e(\mathbf{A}^i) \cup e(\mathbf{B}^j)$ and the partition of $\mathbf{C}$ is the finest partition that is coarser than both $\mathbf{A}^i$ and $\mathbf{B}^j$ and r' is a suitable multiple of r. The fact that we are forced to increase r is one of the key reasons that we need to consider $\epsilon \log n$ levels at the time.

We start with an easy observation.

LEMMA 2.3. *$f^r_{\mathbf{A}}(G) = f^1_{\mathbf{A}}(G)$ for all $\mathbf{A}$ and all $r \geq 1$ and all graphs from $2C$.*

This is obvious since any two connected nodes are at distance 1.

In our arguments we want to keep our collections of partitioned sets small. One mechanism for doing this is to throw away any large partitioned set, and we need the following lemma.

LEMMA 2.4. *The probability that $f^r_{\mathbf{A}}(G) = 1$ for a random graph G from HP is at most*

$$\left(\frac{2r}{n - |e(\mathbf{A})|}\right)^{|e(\mathbf{A})|/2}.$$

Proof. Let $\mathbf{A} = \{A_1, \ldots, A_k\}$ and $a_i = |A_i|$. Define the notation $\mathbf{A}(i) = \{A_1, \ldots, A_i\}$ (this means that $\mathbf{A}(0) = \emptyset$). We have

$$\Pr[f^r_{\mathbf{A}}(G) = 1] = \prod_{i=1}^{k} \Pr[\, f^r_{\{A_i\}}(G) = 1 \mid f^r_{\mathbf{A}(i-1)}(G) = 1\,].$$

To estimate $\Pr[\, f^r_{\{A_i\}}(G) = 1 \mid f^r_{\mathbf{A}(i-1)}(G) = 1\,]$ let us assume that a random HP is found by randomly picking the places of all vertices one by one. We can pick the place for the first vertex in A_i in an arbitrary way, but for every other element of A_i there are at most $2r$ possible places which will satisfy the requirement. Since there are at least $n - e(\mathbf{A})$ remaining slots we get the bound

$$\begin{aligned}
\Pr[f^r_{\mathbf{A}}(G) = 1] &\leq \prod_{i=1}^{k} \left(\frac{2r}{n - |e(\mathbf{A})|}\right)^{a_i - 1} \\
&= \left(\frac{2r}{n - |e(\mathbf{A})|}\right)^{\sum_{i=1}^{k}(a_i - 1)} \\
&\leq \left(\frac{2r}{n - |e(\mathbf{A})|}\right)^{|e(\mathbf{A})|/2}.
\end{aligned}$$

The last inequality follows because $|e(\mathbf{A})| \geq 2k$. □

We will need a slightly more general statement of the lemma, and let us state this explicitly.

LEMMA 2.5. *Let $\mathbf{A}^i$, $i = 1, \ldots, d$, be a set of not necessarily disjoint partitioned sets and let $m = |\bigcup e(\mathbf{A}^i)|$. The probability that $\wedge_{i=1}^d f^r_{\mathbf{A}^i}(G) = 1$ for a random graph G from HP is at most*

$$\left(\frac{2r}{n-m}\right)^{m/2}.$$

Proof. The proof is almost identical to the proof of the previous lemma. Place the elements of $\bigcup e(\mathbf{A}^i)$ on the HP in random places. To satisfy that $\wedge_{i=1}^d f^r_{\mathbf{A}^i}(G) = 1$ at least half the elements will have at most $2r$ possible places to go. The lemma now follows. □

To avoid having too many large partitioned sets we will replace some collections by smaller collections and the concept of a sunflower is of central importance. Remember that the containment relation for partitioned sets respects the partition.

DEFINITION 2.6. *Let $\mathbf{A}^1, \ldots, \mathbf{A}^t$ be distinct partitioned sets. They form a t-*sunflower *with* core $\mathbf{C} = \{C_1, \ldots, C_k\}$ *if the following two conditions hold:*

1. $\mathbf{C} \subseteq \mathbf{A}^i$ *for* $1 \leq i \leq t$,
2. $e(\mathbf{A}^i) \cap e(\mathbf{A}^j) = e(\mathbf{C})$ *for* $1 \leq i < j \leq t$.

The petals *of a sunflower are the partitioned sets* $\mathbf{A}^i \setminus \mathbf{C} = \left\{ A \setminus e(\mathbf{C}) \mid A \in \mathbf{A}^i \right\}$.

Given a collection of partitioned sets that contain a sunflower with certain parameters, we will replace all the partitioned sets in the sunflower by the core. First note that this might create partitions with $|C_i| = 1$. These sets will simply be dropped when forming $f^r_{\mathbf{C}}$. We might also get an empty core and in such a case remember that $f^r_{\emptyset} \equiv 1$.

Replacing a t-sunflower by its core makes the corresponding function accept more inputs. We will not care that more HPs are accepted (they are actually quite a number). The reason is that we only worry about approximation errors that make the circuit accept less HP-inputs or more 2C-inputs. Thus, we need to check how many 2C-inputs get added by this procedure.

LEMMA 2.7. *Let $\mathbf{A}^1, \ldots, \mathbf{A}^t$ be partitioned sets which form a sunflower with core $\mathbf{C}$. Suppose that maximum of $|e(\mathbf{A}^i)| - |e(\mathbf{C})|$ is bounded by u; then the probability that a random element G of $2C$ satisfies $f^r_{\mathbf{C}}(G)$ while $f^r_{\mathbf{A}^i}(G) = 0$ for all i is bounded by $e^{-t2^{-u}}$.*

The process of replacing sunflowers by their core will be denoted *plucking*.

Proof of Lemma 2.7. We want to estimate the probability $\Pr[\vee_{i=1}^t f^1_{\mathbf{A}^i}(G) = 0 \mid f^1_{\mathbf{C}}(G) = 1]$. However, when G is drawn randomly under the condition that $f^1_{\mathbf{C}}(G) = 1$, then the events $f^1_{\mathbf{A}^i}(G) = 0$ are independent since $e(\mathbf{A}^i) \setminus e(\mathbf{C})$ is disjoint from $e(\mathbf{A}^j) \setminus e(\mathbf{C})$ when $i \neq j$.

$$\begin{aligned}
&\Pr[\vee_{i=1}^t f^1_{\mathbf{A}^i}(G) = 0 \mid f^1_{\mathbf{C}}(G) = 1] \\
&\quad = \prod_{i=1}^t \Pr[f^1_{\mathbf{A}^i}(G) = 0 \mid f^1_{\mathbf{C}}(G) = 1] \\
&\quad \leq (1 - 2^{-u})^t \\
&\quad \leq e^{-t2^{-u}}. \qquad \square
\end{aligned}$$

We need some information on the existence of sunflowers.

LEMMA 2.8. *We are given $\mathbf{A}^1, \ldots, \mathbf{A}^m$ that are distinct partitioned sets of size at most a, an integer t, and a partitioned set $\mathbf{B}$ of size b such that $\mathbf{B} \subseteq \mathbf{A}^i$ for $1 \leq i \leq m$. If $m \geq t^{a-b}(a-b)!a!/b!$, then there is a $\mathbf{C} \supseteq \mathbf{B}$ such that there is a t-sunflower with core $\mathbf{C}$.*

Proof. The proof is by induction on $a-b$. Since $\mathbf{A}^1, \ldots, \mathbf{A}^m$ are distinct we know that $a - b \geq 1$.

Base case ($a - b = 1$). The following greedy approach produces a t-sunflower. Pick an arbitrary partitioned set $\mathbf{A}^i$ and remove all sets $\mathbf{A}^j$ that intersect it outside $\mathbf{B}$. At first it might not seem like there can be any such $\mathbf{A}^j$. It is possible, however, that $e(\mathbf{A}^j) = e(\mathbf{A}^i)$, but the partitions are different. Since the partitions induced on $\mathbf{B}$ are the same, there may only be $\leq b = a - 1$ such sets. Since the total number of sets was at least ta we can repeat this $t - 1$ more times to get a t-sunflower with core $\mathbf{B}$.

Induction step ($a - b = i$).

Case 1. There is an element $x \notin \mathbf{B}$ appearing in at least $t^{a-b-1}(a-b-1)!a!/b!$ of the sets. There are at most $(b+1)$ ways to extend $\mathbf{B}$ by adding x to it, and there is at least one of these extensions, $\mathbf{B}'$, that is a subset of $t^{a-b-1}(a-b-1)!a!/(b+1)!$ of the $\mathbf{A}^i$. Since $a - |e(\mathbf{B}')| = i - 1$ one can use induction to find a t-sunflower among them with some core $\mathbf{C}$, where $\mathbf{B} \subseteq \mathbf{B}' \subseteq \mathbf{C}$.

Case 2. No element appears in more than $t^{a-b-1}(a-b-1)!a!/b!$ of the sets. Like in the base case we can pick a t-sunflower with $\mathbf{B}$ as its core in a greedy fashion. Each petal picked reduces the number of sets by at most $t^{a-b-1}(a-b)!a!/b!$ and thus we can pick t sets. □

Having established the basic preliminaries, let us repeat the outline of the proofs. We approximate the gates computed at levels $i\epsilon \log n$ by a function $f_{\mathcal{A}}^{K^i}$ where K will be a suitable number and $\mathcal{A}$ is a collection of partitioned sets of size $< K$ and which does not contain any sunflowers of certain parameters. For $i = 0$ there is no problem since the input $x_{i,j}$ is just $f_{\mathcal{A}}^1$ where $\mathcal{A}$ is just one partitioned set which contains the only set $\{i, j\}$. Let us now dive into the details and we start first with the case of when the circuits are of small size.

3. Polynomial size implies depth $\Omega((\log n)^2)$. The purpose of this section is to prove the following theorem.

THEOREM 3.1. *Given a monotone circuit of size n^d that computes connectivity, then the depth of this circuit is at least*

$$\frac{c(\log n)^2}{\log d}$$

for some universal constant c and sufficiently large n. Here d might be a function of n provided that it satisfies $d \in o((\log n)^{1/2})$.

In particular, the theorem implies that if the circuit is of polynomial size, then the depth is $\Omega((\log n)^2)$ and as is well known; this is tight.

To follow the general outline we just need to specify a couple of parameters. Set $\epsilon < 1/40$ such that $\epsilon \log n$ is an integer. The functions approximating the gates at level $i\epsilon \log n$ are functions $f_{\mathcal{A}}^{K^i}$, where

1. $K = 10d$;
2. $\mathcal{A}$ only contains partitioned sets of size at most K, and every sunflower has fewer than $2K2^K \log n$ petals.

Note that by Lemma 2.8 this implies that no collection of partitioned sets contains more than $(2K2^K \log n)^K (K!)^2 \leq n^\epsilon$ partitioned sets (for n sufficiently large).

Assume now that there is a circuit of size n^d and depth at most $\epsilon(\log n)^2/(4\log K)$ that computes connectivity. As described before, we will derive a contradiction by successively finding functions $f^r_{\mathcal{A}}$ that approximate the functions computed by gates in the circuit. The functions at the inputs ($i = 0$) are approximated perfectly, and the key is to go from i to $i+1$. Each gate at level $(i+1)\epsilon\log n$ is given by a circuit of depth $\epsilon\log n$ of gates at level $i\epsilon\log n$. There are at most n^d such gates and we approximate each gate separately.

Let us fix a gate at level $(i+1)\epsilon\log n$ and consider its $\epsilon\log n$ depth-defining circuit. The jth input is given by $f^{K^i}_{\mathcal{A}^j}$. We can convert the circuit to a depth-two circuit which is an $\vee$ of $\wedge$'s and such that the top fan-in is bounded by 2^{n^ϵ} and bottom fan-in is bounded by n^ϵ.

Since each $f^{K^i}_{\mathcal{A}^j}$ is conveniently represented as an $\vee$ of $\wedge$ we can just use the distributive law and compute each $\wedge$. This will produce a disjunction of functions g_α of the type $\wedge_{(j,k)\in\alpha} f^{K^i}_{\mathbf{A}^{j,k}}$ where the $\mathbf{A}^{j,k}$ are partitioned sets which might not be disjoint and α is a set of index pairs. We now proceed as follows.

1. Let $S_\alpha = \bigcup_{(j,k)\in\alpha} e(\mathbf{A}^{j,k})$.
2. Drop each g_α where $|S_\alpha| \geq K$.
3. Let $\mathbf{B}_\alpha$ be the finest partitioning of the set S_α that is coarser than $\mathbf{A}^{j,k}$ for all $(j,k) \in \alpha$.
4. Pluck the collection of $\mathbf{B}_\alpha$'s to form $f^{K^{i+1}}_{\mathcal{B}}$.

Let us look more closely at the approximations made. Dropping g_α with S_α large decreases the number of inputs that is accepted. We need to analyze the number of HPs dropped this way. This is done in Lemma 3.2.

When forming $\mathbf{B}_\alpha$ and increasing the value of allowable distances we accept more HPs. To see this, note that each set in $\mathbf{B}_\alpha$ is the union of at most $K-1$ sets $\mathbf{A}^{j,k}$. We must prove that any graph G that satisfies $\wedge_{(j,k)\in\alpha} f^{K^i}_{\mathbf{A}^{j,k}}(G) = 1$ also satisfies $f^{K^{i+1}}_{\mathbf{B}_\alpha}(G) = 1$. But for any pair $\{s,t\}$ of elements which are in the same set of $\mathbf{B}_\alpha$ there are elements $v_1 \ldots v_l$ with $l \leq K-1$ such that if we set $s = v_0$ and $t = v_{l+1}$ then for $r = 0, \ldots, l-1$ v_r and v_{r+1} are in the same set of $\mathbf{A}^{j,k}$ for some $(j,k) \in \alpha$. Since $\wedge_{(j,k)\in\alpha} f^{K^i}_{\mathbf{A}^{j,k}}(G) = 1$ we have $d_G(v_i, v_{i+1}) \leq K^i$ and hence $d_G(s,t) \leq K^{i+1}$. Since s and t were arbitrary, we conclude that $f^{K^{i+1}}_{\mathbf{B}_\alpha}(G) = 1$. By Lemma 2.3 we know that the subset of inputs from 2C that is accepted does not change when forming $\mathbf{B}_\alpha$.

Finally, plucking implies that we accept more inputs, and how many more inputs that are accepted from 2C is analyzed in Lemma 3.3.

We now prove the relevant lemmas.

LEMMA 3.2. *For sufficiently large n, the fraction of HP that satisfies any term dropped during step 2 of the construction is at most n^{-2d}.*

Proof. We find a small collection of functions h_β similar to g_α such that for any g_α dropped there is an h_β that covers g_α; that is, $g_\alpha(G) = 1 \Rightarrow h_\beta(G) = 1$ for some β.

For any dropped g_α find a minimal subset β of α such $|\bigcup_{(j,k)\in\beta} e(\mathbf{A}^{j,k})| \geq K$. Clearly there is such a β of size at most K. Let

$$h_\beta = \bigwedge_{(j,k)\in\beta} f^{K^i}_{\mathbf{A}^{j,k}}.$$

Then it clearly satisfies the property outlined above. Now we claim that

1. there are at most $2\binom{n^{2\epsilon}}{K}$ different h_β;

2. the probability that $h_\beta(G) = 1$ for a random HP G is at most $n^{-K/4}$ for sufficiently large n.

The first claim follows from the fact that each $\mathcal{A}^j$ contains at most n^ϵ partitioned sets and we need to choose at most K partitioned sets. The second claim follows from Lemma 2.5 (note that $r \le K^j \le K^{\log n/(4\log K)} \le n^{1/4}$). The lemma now follows since

$$2\binom{n^{2\epsilon}}{K} n^{-K/4} \le n^{-2d}$$

for $\epsilon < 1/40$ and sufficiently large n. □

Let us next estimate the number of inputs from 2C added under plucking.

LEMMA 3.3. *The fraction of* 2*C added in the above process is bounded by* $(e/n)^K$.

Proof. By Lemma 2.7, each time we replace a sunflower by its core we add a fraction n^{-2K} of 2C. This operation decreases the number of partitioned sets by at least one, and by Lemma 2.2 there are at most $(en)^K$ to begin with. The lemma now follows. □

Let us now finish the proof of the theorem. The output gate corresponds to $i = \log n/(4\log K)$ and hence it is approximated by a function $f_{\mathcal{A}}^{n^{1/4}}$. We have two cases

Case 1. We have the identically 0 function. In order for this to happen we must have lost all of HP. However, given that the circuit has size $\le n^d$ and using Lemma 3.2, the fraction of HP lost is at most $n^d \cdot n^{-2d} = n^{-d}$, which contradicts the assumption that all of HP has been lost.

Case 2. We get some function f which is not identically 0. There is a partitioned set $\mathbf{A}$ such that $|e(\mathbf{A})| \le K$ and $f_{\mathbf{A}}^{n^{1/4}}$ implies f. However, it is easy to see that the fraction of 2C accepted by $f_{\mathbf{A}}^{n^{1/4}}$, and thus by f is at least $2^{-K} = 2^{-10d}$. However, the total fraction of 2C added by the approximations is at most $n^d(e/n)^K = e^{10d}n^{-9d}$. For n sufficiently large, $e^{10d}n^{-9d} < 2^{-10d}$ and we have a contradiction.

4. Formulas require depth $\Omega((\log n)^2/\log\log n)$. The purpose of this section is to prove the following theorem.

THEOREM 4.1. *The depth of a monotone formula that computes connectivity is at least*

$$\Omega\left(\frac{(\log n)^2}{\log\log n}\right).$$

The outline is the same as in the other proof but we need to be more careful. In the sunflowers we remove, the number of petals we need is dependent on their sizes.

DEFINITION 4.2. *Let* $\mathbf{A}^1, \ldots, \mathbf{A}^t$ *be a sunflower with core* $\mathbf{C}$*, and say that the petal size* $|e(\mathbf{A}^i)| - |e(\mathbf{C})|$ *is at most* u*. We say that this is a* good *sunflower if* $t \ge 2^u(\log n)^2$.

Use the same ϵ as before. This time we use functions $f_{\mathcal{A}}^{K^i}$, where

1. $K = \lfloor \log n/(18\log\log n)\rfloor$,
2. $\mathcal{A}$ only contains partitioned sets of size at most K and no good sunflower.

Assume now that there is a circuit that has depth at most $\epsilon(\log n)^2/(4\log K)$ that computes connectivity. We proceed exactly as in the previous proof. In particular, the process of forming our approximations level by level is the same; i.e.,

1. let $S_\alpha = \bigcup_{(j,k)\in\alpha} e(\mathbf{A}^{j,k})$,

2. drop each g_α where $|S_\alpha| \geq K$,

3. let $\mathbf{B}_\alpha$ be the finest partition of the set S_α that is coarser than $\mathbf{A}^{j,k}$ for all $(j,k) \in \alpha$,

4. pluck the collection of $\mathbf{B}_\alpha$'s to form $f_{\mathcal{B}}^{K^{i+1}}$.

The crucial difference from the previous proof is that we need to work harder to estimate the number of HPs dropped at the first step. The crucial lemma follows.

LEMMA 4.3. *The fraction of HP dropped at a single gate is bounded by $n^{-K/8}$ for sufficiently large n.*

Proof. Again we form a small set of functions H that dominate the set of lost inputs.

Let $\gamma \subset \{1, \ldots, n^\epsilon\}$, and $|\gamma| = l \leq K$. Let $g_\gamma = \wedge_{j \in \gamma} f_{\mathcal{A}^j}^{K^i}$ and using the distributive law we can write

$$g_\gamma = \bigvee_{\delta} \bigwedge_{(j,k) \in \delta} f_{\mathbf{A}^{j,k}}^{K^i},$$

where δ ranges over all possible ways to pick $\mathbf{A}^{j,k}$ from $\mathcal{A}^j$ for each $j \in \gamma$. Call the term corresponding to δ h_δ and let H_γ be the set of terms in g_γ. We say that the *weight* of h_δ is $|\cup_{(j,k)\in\delta} e(\mathbf{A}^{j,k})|$. We call h_δ *heavy* if its weight is at least K and let H_γ^h be the set of heavy terms in H_γ. Finally, let $H = \cup_{|\gamma| \leq K} H_\gamma^h$. Now, H covers all sets dropped in step 2 for the following reason. For any α with $|S_\alpha| \geq K$ pick a subset β of size at most K such that $|\bigcup_{(j,k)\in\beta} e(\mathbf{A}^{j,k})| \geq K$. The term that corresponds to α is covered by the term $h_\beta = \wedge_{(j,k)\in\beta} f_{\mathbf{A}^{j,k}}^{K^i}$. Let γ be the projection of β on the first coordinate. Clearly, $h_\beta \in H_\gamma^h \subseteq H$.

It remains to analyze the fraction of HP that is accepted by any of the functions in H. For any $h \in H$ let s be its weight. By definition $s \geq K$, and since we only consider $|\gamma| \leq K$ we have $s \leq K^2$. First note that by Lemma 2.5 the fraction of HP that satisfies a term h_δ of weight s is at most $n^{-s/3}$ for n sufficiently large. Now we need the following lemma.

LEMMA 4.4. *Given γ, $|\gamma| = l \leq K$. The number of h in H_γ of weight s is at most*

$$F(s,l) = 2^{Ks + 2s\log\log n + 2s\log s + l(s\log s + s + 1)}.$$

Before we prove Lemma 4.4, let us just see how to complete the proof of Lemma 4.3. For a fixed γ we drop at most a fraction $\sum_{s=K}^{K^2} F(s,K) n^{-s/2}$ of HP. For n sufficiently large this quantity is bounded by

$$K^2 \cdot 2^{3K^2 \log\log n - (K/3)\log n} = K^2 \cdot n^{-K/6}.$$

There are fewer than $n^{\epsilon K}$ sets γ, and for n sufficiently large, we have that $K^2 \cdot n^{(\epsilon - 1/6)K} < n^{-K/8}$. □

Let us now prove Lemma 4.4.

Proof. We need the following useful technical lemma.

LEMMA 4.5. *We are given $\mathbf{A}^1, \ldots, \mathbf{A}^m$ that are distinct partitioned sets, a set R of size r such that $|R \cup e(\mathbf{A}^i)| \leq s$ for $1 \leq i \leq m$, and an integer t.*

If $m \geq (r+1)^r t^{s-r}(s-r)!s!/r!$, then there is a $\mathbf{C}$ such that there is a t-sunflower with core $\mathbf{C}$, and for each $\mathbf{A}^i$ in the sunflower, $|e(\mathbf{A}^i) \setminus e(\mathbf{C})| \leq s - r$.

Proof. We will find a subset of R and partition it to get a partitioned set $\mathbf{Q}$ such that for many of the sets $\mathbf{Q} \subseteq \mathbf{A}^i$ and $|e(\mathbf{A}^i) \setminus e(\mathbf{Q})| \leq s - r$, and then use Lemma 2.8.

Let $R^i = R \cap \mathbf{A}^i$, and let $\mathbf{R}^i$ be the partitioned set that $\mathbf{A}^i$ induces on R^i. Since $|R^i| \leq r$, $(r+1)^r$ is an upper bound on the number of distinct $\mathbf{R}^i$ that can be obtained. Therefore at least $m' = t^{s-r}(s-r)!s!/r!$ of the $\mathbf{A}^i$ must give the same partitioned set. Call this partitioned set $\mathbf{Q}$ and let $q = |e(\mathbf{Q})|$.

Without loss of generality $\mathbf{A}^1, \ldots, \mathbf{A}^{m'}$ all give $\mathbf{Q}$. Since for these, $\mathbf{Q} \subseteq \mathbf{A}^i$ and $|e(\mathbf{A}^i)| \leq s - r + q$, we can apply Lemma 2.8 with $a = s - r + q$, $b = q$, and $\mathbf{B} = \mathbf{Q}$. Provided that $m' \geq t^{s-r}(s-r)!(s-r+q)!/q!$ we are done. The right-hand side of this expression grows with q, so $m' \geq t^{s-r}(s-r)!s!/r!$ suffices, and we have completed the proof. □

Now we can establish Lemma 4.4 by induction on l. We want to show that the number of terms of size s of H_γ is bounded by $F(s,l)$. The base case $l = 1$ follows from Lemma 2.8 with $\mathbf{B}$ being the empty set. Obviously there are no terms of weight $s \geq K$. For weight $s < K$ we just need to observe that

$$(2^s(\log n)^2)^s s! \leq 2^{Ks+2s\log\log n + s\log s} \leq F(s,1).$$

For the induction step consider $\gamma = \{\gamma_1, \ldots, \gamma_l\}$, and let $\gamma' = \{\gamma_1, \ldots, \gamma_{l-1}\}$. To do the induction we need to analyze how many terms of size s in H_γ can be formed from a single term of size $r \leq s$ in $H_{\gamma'}$. Since $\mathcal{A}^{\gamma_l}$ does not contain any good sunflowers, by Lemma 4.5 with parameter $t = 2^{s-r}(\log n)^2$ we conclude that each term of size r in $H_{\gamma'}$ can give at most

$$\begin{aligned}&(r+1)^r(2^{s-r}(\log n)^2)^{s-r}(s-r)!s!/r! \\ &\quad \leq 2^{(s-r)^2+2(s-r)\log\log n+2(s-r)\log s+r\log r+r}\end{aligned}$$

different terms of size s in H_γ. The inequality is immediate except for $(s-r)!s!/r! \leq 2^{2(s-r)\log s}$, but this follows because the left-hand side has $2(s-r)$ factors that are all at most s. Also, note that a term of size r cannot give any terms of size $s > r + K$ since all $\mathbf{A} \in \mathcal{A}^{\gamma_l}$ have size at most K.

To get the total number of terms of size s we just use the inductive hypothesis to bound the number of terms of size r in $H_{\gamma'}$ and sum over $r \geq s - K$. Through simple calculation,

$$\begin{aligned}&\sum_{r=\max(0,s-K)}^{s} F(r,l-1)\cdot 2^{(s-r)^2+2(s-r)\log\log n+2(s-r)\log s+r\log r+r} \\ &\quad \leq F(s,l). \qquad \square\end{aligned}$$

The fraction of 2C lost by plucking is easy to estimate.

LEMMA 4.6. *The fraction of $2C$ inputs added at a single gate is bounded by $n^{-\log n}$ for sufficiently large n.*

Proof. By Lemma 2.7 and the definition of good sunflowers we know that plucking a single good sunflower adds a fraction at most $e^{-(\log n)^2}$ of 2C. Each time we pick a sunflower the number of partitioned sets decreases, and by Lemma 2.2 there are at most $(en)^K$ partitioned sets of size $\leq K$ before plucking starts. Thus, the fraction of 2C that gets added at a single gate is less than $e^{-(\log n)^2 + K\log n + O(K)}$, which is less than $n^{-\log n}$ for sufficiently large n. □

The proof of Theorem 4.1 is now completed in exactly the same way as Theorem 3.1 by using Lemmas 4.3 and 4.6 instead of Lemmas 3.2 and 3.3 and the fact that the size of the formula is at most $n^{\epsilon \log n/(4\log K)}$. For n sufficiently large there are less than $n^{\log n/(150\log\log n)}$ gates, and at each gate the error on HP is at most $n^{-K/8} \leq n^{-\log n/(145\log\log n)}$ and the error on 2C at each gate is at most $n^{-\log n}$.

5. Conclusion and open problems. Combining the results of the previous two sections shows that a monotone circuit of size n^d for connectivity must be of depth $\Omega((\log n)^2/\log d)$. Of course one would like to get $\Omega((\log n)^2)$ lower bounds for the depth even for formulas. We do believe that this is the correct answer, but we believe that it is hard to find a more or less straightforward extension of the current method. The following intuitive argument explains the problem.

An approximation argument seems to require partitioned sets[2] of size $\Omega(\log n)$. The reason is that if we drop a single partitioned set of size K then the fraction of HPs dropped is at least n^{-K}. Since we are discussing circuits of size $n^{c\log n}$ we cannot afford this if $K = o(\log n)$. Now suppose we are using some type of sunflowers and plucking. Consider a program that computes a predicate $D(s,t,i)$ recursively where s and t are vertices and i is a parameter. It sets $D(s,t,0)$ to true iff (s,t) is an edge. To compute $D(s,t,i)$ set $s = v_0$, $t = v_l$ and try n^2 ways of picking $v_1 \dots v_{l-1}$ and set $D(s,t,i)$ to true if for some attempt $D(v_i, v_{i+1}, i)$ are true for $i = 0, 1, \dots, i-1$. $D(s,t,i)$ should be thought of as a crude approximation that s and t are within distance l^i. This is not really true since we do not try all the values of the $l-1$ intermediate points. However, in an approximation scheme such as ours $D(s,t,i)$ is converted into the function $d_G(s,t) \le l^i$ by plucking (this argument is inductive on i). If we choose $l = \sqrt{\log n}$ then $D(s,t,i)$ can be computed in depth about $O(i \log n)$ and for $i = i_0 = 2\log n/\log\log n$ the approximation of $D(s,t,i)$ is whether s and t are connected and hence $\wedge_{t=2}^{n} D(1,t,i_0)$ is approximated by connectivity.

The problem arises because the plucking operation causes a significant increase in the fraction of HPs accepted. In our opinion, a major idea or a totally different approach seems to be needed to eliminate the $\log\log n$ factor.

Acknowledgment. The results described were obtained while visiting the Lab for Computer Science at MIT. We thank the LCS and in particular Mike Sipser for this opportunity. We are also grateful to the referees for careful reading and helpful suggestions.

COMPLEXITY ANALYSIS OF A PARALLEL LATTICE BASIS REDUCTION ALGORITHM*

C. HECKLER† AND L. THIELE‡

Abstract. Lattice basis reduction is an important problem in geometry of numbers with applications in combinatorial optimization, computer algebra, and cryptography. The well-known sequential LLL algorithm finds a short vector in $O(n^4 \log B)$ arithmetic operations on integers having binary length $O(n \log B)$, where n denotes the dimension of the lattice and B denotes the maximum L_2 norm of the initial basis vectors. In this paper a new analysis of the parallel algorithm of Roch and Villard is presented. It is shown that on an $n \times n$ mesh it needs $O(n^2 \log B)$ arithmetic operations on integers having binary length $O(n \log B)$. This improves the previous analysis and shows that an asymptotical speedup of n^2 is possible using n^2 processors.

Key words. lattice basis reduction, parallel algorithms, parallel computational complexity, size of the numbers

1. Introduction.

Lattice basis reduction, the problem of finding a basis of a lattice with "short" vectors, is an important problem in geometry of numbers with applications in combinatorial optimization, computer algebra, and cryptography (see, for example, [8, 7, 6]). In the field of basis reduction a major advance was reached in 1982 when A.K. Lenstra, H.W. Lenstra Jr., and L. Lovasz [7] developed the so-called LLL algorithm, which is a polynomial-time algorithm finding a "good" basis ("reduced basis") in $O(n^4 \log B)$ arithmetic operations on integers having binary length $O(n \log B)$, where n denotes the dimension of the lattice and B denotes the maximum L_2-norm of the initial basis vectors. Subsequently various variants have been developed; see, for example, [10, 11]. In 1992 Roch and Villard [9, 13] developed a parallel algorithm for n^2 processors, but the efficiency of that algorithm could not be proved. Moreover, larger numbers than in the sequential LLL algorithm can occur in this parallel algorithm. They show the bound $O(n^2 \log B)$ for the binary length of the integers. In this paper a new analysis of the parallel algorithm is presented. It is shown that on an $n \times n$ mesh it needs $O(n^2 \log B)$ arithmetic operations and communication steps on integers having binary length $O(n \log B)$. Thus, using n^2 processors an optimal speedup can be reached.

This paper is organized as follows: the next section gives a brief survey of the notation used in the paper. In section 3 the parallel algorithm is reviewed. The complexity in terms of the number of arithmetic operations is studied in section 4. Finally, in section 5 the size of the numbers of the serial and parallel algorithms and the binary complexity are considered.

A more practical algorithm using fast floating point arithmetic can be found in [3]. Implementation details and practical results of different parallel algorithms are given in [2].

2. Basic notation. We assume that the reader is familiar with the foundations of lattice basis reduction as described in section 1 of [7] (also see, for example, [11, 12]). Here we only describe our basic notation.

An n-dimensional lattice is a discrete subgroup of $\mathbf{R}^n$.

DEFINITION 2.1. *Let $b_1, b_2, \ldots, b_n \in \mathbf{R}^n$ be n linearly independent vectors. Then $L = L(b_1, \ldots, b_n) = \{\sum_{i=1}^{n} \lambda_i b_i | \lambda_i \in \mathbf{Z}, i = 1, \ldots, n\}$ is called a lattice with basis $(b_1, \ldots, b_n)$.*

Let us recall the Gram–Schmidt orthogonalization process. Let $\| \cdot \|$ denote the L_2-norm of a vector and let $(b_1, b_2, \ldots, b_n)$ be a basis, then the Gram–Schmidt orthogonalization $(b_1^*, b_2^*, \ldots, b_n^*)$ of mutually orthogonal vectors can be computed by $b_1^* = b_1$ and $b_i^* = b_i - \sum_{j=1}^{i-1} \mu_{i,j} b_j^*$ for $i = 2, \ldots, n$, where $\mu_{i,j} = \frac{b_i^T b_j^*}{||b_j^*||^2}$. Let be $\mu_{i,i} = 1$ and $\mu_{i,j} = 0$ for $i < j$, and let $M = (\mu_{i,j})_{1 \le i,j \le n}$ be the matrix of the Gram–Schmidt coefficients. Then M is a lower triangular matrix where all elements of the main diagonal are equal to 1 and the above equations can be expressed as $(b_1, \ldots, b_n) = (b_1^*, \ldots, b_n^*) M^T$.

The following procedure (designated "size reduction") is used to obtain a basis of the lattice with small Gram–Schmidt coefficients $|\mu_{i,j}| \le 0.5$.

ALGORITHM 2.2.

Size reduction of the basis $(b_1, \ldots, b_n)$ [7]

```
for i = 2 to n do
    reduce size of column i of the basis and of M^T:
      for j = i − 1 downto 1 do
          reduce size of coefficient μ_{i,j} of column i:
            let ⌈μ_{i,j}⌋ be the nearest integer to μ_{i,j}
            and let μ_j denote the column j of M^T:
            b_i ← b_i − ⌈μ_{i,j}⌋ b_j; μ_i ← μ_i − ⌈μ_{i,j}⌋ μ_j
      od
od
```

For technical reasons we use the following definition of a reduced basis (due to [12]) which is almost the same as the original one given in [7].

DEFINITION 2.3 (reduced basis [7, 12]). *A lattice basis $(b_1, \ldots, b_n)$ is called reduced if both of the following conditions are fulfilled:*

- $|\mu_{i,j}| \le \frac{1}{2}$ *for all* $1 \le j < i \le n$,
- $||b_{i-1}^*||^2 \le 2||b_i^*||^2$ *for all* $1 < i \le n$.

The idea of the LLL lattice basis reduction algorithm of [7] consists in iteratively computing the size reduction of one basis vector b_i and swapping b_i and b_{i-1} if the second condition of the above definition is not valid. The complexity of the LLL algorithm is given in the next theorem.

THEOREM 2.4 (sequential complexity [7]). *Let $B = \max_{i=1,\ldots,n} ||b_i||^2$ be the square of the length of the longest vector of the original basis. Given a basis $(b_1, \ldots, b_n)$ of a lattice with $b_i \in \mathbf{Z}^n$ for all $1 \le i \le n$, the sequential LLL algorithm of [7] computes a reduced basis of the same lattice in $O(n^4 \log B)$ arithmetic operations on integers having binary length $O(n \log B)$.*

3. The parallel algorithm. The main idea of the parallel algorithm of [9, 13] is to perform all possible swaps in one phase (see also [3, 4]) and to compute the size

reduction of the whole matrix. Strictly speaking, b_i and b_{i+1} are swapped for *all odd* indices i with $||b_i^*||^2 > 2||b_{i+1}^*||^2$ in one phase of the algorithm and for *all even* indices i in the next phase of the algorithm (see Algorithm 3.1). The concatenation of an odd and an even phase is called an *"all swap phase."*

ALGORITHM 3.1.

All-Swap Lattice Basis Reduction Algorithm [3, 4, 9, 13]
input: $b_1, b_2, \ldots, b_n$ a lattice basis
output: $b_1, b_2, \ldots, b_n$ a reduced basis
method:

```
Compute the Gram–Schmidt orthogonalization of
the basis, i.e. M and ‖b_i^*‖^2, i = 1, ..., n;
ordering ← odd;
while (any swap is possible) do
    Compute the size reduction of the basis (b_1, ..., b_n) and
    the Gram–Schmidt coefficients M;
    if (ordering = odd) then
        swap b_i and b_{i+1} for every odd index i with
        ||b_i^*||^2 > 2||b_{i+1}^*||^2;
        ordering ← even;
    else
        swap b_i and b_{i+1} for every even index i with
        ||b_i^*||^2 > 2||b_{i+1}^*||^2;
        ordering ← odd;
    fi;
    Repair the Gram–Schmidt orthogonalization
od.
```

In the serial case, $O(n^3)$ arithmetic operations are required for one phase. However, the two major steps of the algorithm, that is the orthogonalization of the basis (respectively, the repair of the orthogonalization) and the size reduction of the whole matrix, are well suited for parallelization. Thus, the following theorem holds.

THEOREM 3.2 (see [3, 4, 9, 13]). *An all-swap phase can be done in $O(n)$ parallel steps* (*according to the number of arithmetic operations and the number of communications of numbers*) *on a mesh-connected network of n^2 processors.*

4. Parallel complexity. In order to achieve a speedup of n^2 using n^2 processors in comparison with the LLL algorithm, it must be shown that a short vector can be found after at most $n \log B$ all-swap phases. The following analysis is taken from [3].

THEOREM 4.1 (parallel time complexity). *After at most $n \log B$ all-swap phases*[1] *the following situation holds for all i with $1 \le i \le n$:*

$$||b_1^*||^2 \cdot ||b_2^*||^2 \cdots ||b_i^*||^2 \le \tfrac{4}{3} \cdot c^{\frac{i(n-i)}{2}} \cdot (\det L)^{\frac{2i}{n}}$$

with $c = \frac{32}{9}$.

Proof. Consider the ratios

$$(1)\quad \frac{||b_1^*||^2}{c^{\frac{n-1}{2}}(\det L)^{\frac{2}{n}}} \cdot \frac{||b_2^*||^2}{c^{\frac{n-3}{2}}(\det L)^{\frac{2}{n}}} \cdots \frac{||b_i^*||^2}{c^{\frac{n-2i+1}{2}}(\det L)^{\frac{2}{n}}} = \frac{\prod_{j=1}^{i} ||b_j^*||^2}{c^{\frac{i(n-i)}{2}}(\det L)^{\frac{2i}{n}}} =: v(i).$$

[1] In the following log denotes the logarithm with basis $\frac{4}{3}$.

We are finished when all these ratios $v(i), 1 \le i \le n$, are less than $\frac{4}{3}$. Let max be the maximum of all these ratios, that is $max = \max\{v(i) | 1 \le i \le n\}$, and let max' be the maximum after one further all-swap phase.

It will be shown that every all-swap phase decreases the value of max by a factor less than $\frac{3}{4}$, that is $max' \le \frac{3}{4} max$, if $max > \frac{4}{3}$. In the beginning, $max \le B^n$ since $||b_i^*||^2 \le B$ holds for all $1 \le i \le n$. Therefore, all ratios are less than $\frac{4}{3}$ after at most $n \log B$ all-swap phases.

PROPOSITION 4.2. *If $max > \frac{4}{3}$ and $v(i) > \frac{3}{4} max$, the product $||b_1^*||^2 \cdot ||b_2^*||^2 \cdots ||b_i^*||^2$ and thereby $v(i)$ is decreased by a factor less than $\frac{3}{4}$ in one all-swap phase. All other ratios remain unchanged or decrease.*

Proof of the proposition. If two vectors b_j and b_{j+1} are swapped, the product $||b_1^*||^2 \cdot ||b_2^*||^2 \cdots ||b_j^*||^2$ is decreased by a factor less than $\frac{3}{4}$; all other products remain unchanged. See [7] for these facts. Thus, we have to show that $max \le \frac{4}{3}$ or b_i and b_{i+1} are swapped for all i with $v(i) > \frac{3}{4} max$ in one all-swap phase; that is, if $v(i) > \frac{3}{4} max$, then $||b_i^*||^2 > 2||b_{i+1}^*||^2$. If this swap condition holds for an even index i, it is also valid after one odd swapping phase.

If $v(n) > \frac{3}{4} max$, then $max < \frac{4}{3}$ since $v(n) = 1$.

Therefore, consider an index $i, 1 \le i \le n-1$, with $v(i) > \frac{3}{4} max$. We show in the following that the vectors b_i and b_{i+1} are swapped in this case.

If $v(i) > \frac{3}{4} max$, then $v(i) > \frac{3}{4} v(i+1)$. Using (1) we obtain

$$\frac{\frac{4}{3} (\det L)^{\frac{2}{n}} c^{\frac{n-2i-1}{2}}}{||b_i^*||^2} > \frac{||b_{i+1}^*||^2}{||b_i^*||^2}. \tag{2}$$

In the same way, if $v(i) > \frac{3}{4} max$ and $i > 1$, then $v(i) > \frac{3}{4} v(i-1)$ holds and therefore

$$||b_i^*||^2 > \frac{3}{4} c^{\frac{n-2i+1}{2}} (\det L)^{\frac{2}{n}}. \tag{3}$$

This relation is also valid for $i = 1$ if $max \ge 1$ and $v(1) > \frac{3}{4} max$.

However, it follows from (2), (3), and the choice of c that

$$\frac{\left(\frac{4}{3}\right)^2}{c} = \frac{1}{2} > \frac{||b_{i+1}^*||^2}{||b_i^*||^2}, \tag{4}$$

and therefore the swap condition is satisfied.

Thus, the proposition and the theorem have been proven. □

In particular, we have found a short vector as shown in the following corollary.

COROLLARY 4.3. *After at most $n \log B$ all-swap phases, the vector b_1 of the resulting lattice basis satisfies*

$$||b_1|| \le \frac{4}{3} c^{\frac{n-1}{4}} (\det L)^{\frac{1}{n}}.$$

Proof. Use Theorem 4.1 with $i = 1$ and $b_1 = b_1^*$. □

COROLLARY 4.4. *A short vector of a lattice can be found in $O(n^2 \log B)$ parallel steps using a network of n^2 processors. Thus, an asymptotical[2] optimal speedup of n^2 can be achieved in comparison with the serial LLL algorithm.*

Proof. See Corollary 4.3 and Theorems 3.2 and 2.4. □

[2] I.e., this holds for $n \to \infty$.

5. Size of the numbers and binary complexity. The time for one operation depends on the size of the numbers. If we start with an integral basis, that is $b_i \in \mathbf{Z}^n$ for all $1 \le i \le n$, all numbers occurring throughout the algorithm are rational with denominators less than B^n [7]. See [7, 5] for an analysis of the sizes of the numbers of the LLL algorithm. The bounds are summarized in Table 1. The known analysis of the parallel algorithm is reviewed in the next section. Then a new result for the parallel case is given.

5.1. Known analysis of the parallel case. In the parallel case the Gram–Schmidt orthogonalization is computed for the whole matrix whereby bigger numbers than in the serial case can occur where the orthogonalization is only computed for the reduced part of the basis.

THEOREM 5.1 (see [7]). *After the computation (or repair) of the Gram–Schmidt orthogonalization we have* $\mu_{i,j}^2 \le iB^n$.

In the parallel algorithm the size reduction is computed simultaneously for all columns. Therefore, the size reduction of each column is performed using nonreduced columns of the basis. This leads to the following theorem.

THEOREM 5.2. *Let* $\mu_{i,j}^2 \le M$ *for all* $1 \le j < i \le n$ *before the size reduction. Then the following inequalities are valid during the size reduction phase of the parallel algorithm (see also* [4, 13]*):*

$$\mu_{i,j}^2 \le 4^n M^n \qquad \text{for} \quad 1 \le j < i \le n, \tag{5}$$

$$\|b_i\|^2 \le nB4^n M^n \qquad \text{for} \quad 1 \le i \le n. \tag{6}$$

Proof. Consider the size reduction of column k. During the reduction of the element $\mu_{k,k-1}$ the computation $\mu_{k,i} \leftarrow \mu_{k,i} - \lceil \mu_{k,k-1} \rfloor \mu_{k-1,i}$ for $i = 1, \ldots, k-1$ is performed. In the case of a parallel execution, column $k-1$ is not size reduced. Therefore, only the estimation $|\mu_{k-1,i}| \le \sqrt{M}$ is possible. Thus, the new value of $|\mu_{k,i}|$ satisfies $|\mu_{k,i}| \le 2M$. The proposition follows by induction and with $\|b_i\|^2 = \sum_{j=1}^{i} \mu_{i,j}^2 \|b_j^*\|^2$. □

Using Theorems 5.1 and 5.2 the following result about the size of the numbers of the parallel lattice basis reduction algorithm can be derived.

COROLLARY 5.3. *During the parallel lattice basis reduction the following inequalities hold for all values of* $\|b_i\|^2$ *and* $\mu_{i,j}^2$ *(see also* [13]*):*

$$\mu_{i,j}^2 \le (4nB^n)^n \qquad \text{for} \quad 1 \le j < i \le n, \tag{7}$$

$$\|b_i\|^2 \le nB(4nB^n)^n \qquad \text{for} \quad 1 \le i \le n. \tag{8}$$

5.2. New results. Two examples for Theorems 5.1 and 5.2 are presented where large numbers do in fact occur. However, both situations never occur simultaneously. Therefore, a better analysis of the size of the numbers can be derived than the one given in Corollary 5.3. This new result is given in Theorem 5.7.

THEOREM 5.4. *The bound given in Theorem* 5.1 *is asymptotically tight.*

Proof. Consider the following $n \times n$ basis for some $D > 1 \in \mathbf{Z}$:

$$\begin{pmatrix} D & D+1 & \cdots & \cdots & D+1 & 0 \\ 0 & D & D+1 & \cdots & D+1 & 0 \\ \vdots & \ddots & \ddots & \ddots & \vdots & \vdots \\ 0 & \cdots & 0 & D & D+1 & 0 \\ 1 & \cdots & 1 & 1 & 1 & 1 \\ 0 & \cdots & \cdots & 0 & 0 & 1 \end{pmatrix}.$$

For the Gram–Schmidt orthogonalization of that basis we have

$$\mu_{n,n-1} = (-1)^{n-2} D^{n-2}.$$

The proof can be carried out by induction over n using "Givens" rotations for the computation of the Gram–Schmidt orthogonalization (see, for example, [1] for Givens rotations and [3] for the computation of the Gram–Schmidt orthogonalization via Givens rotations). □

THEOREM 5.5. *The bound for $\mu_{i,j}^2$ given in Theorem* 5.2 *is asymptotically tight.*

Proof. Consider the following $n \times n$ basis for some $D > 1 \in \mathbf{Z}$:

$$(b_1, \ldots, b_n) = \begin{pmatrix} 1 & D & \cdots & D \\ 0 & 1 & \ddots & \vdots \\ \vdots & \ddots & \ddots & D \\ 0 & \cdots & 0 & 1 \end{pmatrix}.$$

For the matrix of the Gram–Schmidt coefficients of the basis above we have that $M^T = (b_1, \ldots, b_n)$. By induction it can easily be shown that coefficients of the size D^{n-1} occur during the size reduction of column n. □

In order to prove that both cases given above cannot occur simultaneously, we use the following lemma.

LEMMA 5.6. *Consider the size reduction of column k, $2 \le k \le n$, that is of the elements $\mu_{k,k-1}, \ldots, \mu_{k,1}$. After the size reduction of the element $\mu_{k,k-i}$ with $1 \le i \le k-2$, $2^i - 1$ products of Gram–Schmidt coefficients were subtracted from each coefficient $\mu_{k,k-j}$, $j > i$. Each product only consists of (rounded) coefficients of* different *rows of the matrix M^{T} and only of coefficients of the rows $k-1, k-2, \ldots, k-i$ and $k-j$.*

Proof. The proof is done by induction over i.

Let $\mu_{x,y}^{(0)}$ denote $\mu_{x,y}$ before the size reduction of column k, and let $\mu_{x,y}^{(i)}$ denote $\mu_{x,y}$ after the size reduction of $\mu_{k,k-i}$.

$i = 1$: After the size reduction of $\mu_{k,k-1}$ the following is valid for $j > 1$:

$$\mu_{k,k-j}^{(1)} = \mu_{k,k-j}^{(0)} - \lceil \mu_{k,k-1}^{(0)} \rfloor \mu_{k-1,k-j}^{(0)}.$$

Thus, the proposition is true for $i = 1$.

After the size reduction of $\mu_{k,k-i-1}$ the following holds for $j > 1$:

$$\mu_{k,k-j}^{(i+1)} = \mu_{k,k-j}^{(i)} - \lceil \mu_{k,k-i-1}^{(i)} \rfloor \mu_{k-i-1,k-j}^{(0)}.$$

Now, the proposition for $i+1$ follows with the induction hypothesis for $\mu_{k,k-j}^{(i)}$ and $\mu_{k,k-i-1}^{(i)}$. □

Now the following theorem about the size of the numbers of the parallel lattice basis reduction can be shown.

THEOREM 5.7. *During the parallel size reduction phase the following inequalities hold:*

$$\mu_{i,j}^2 \le n^n (2B)^{2n} \qquad \text{for} \quad 1 \le j < i \le n, \tag{9}$$

$$\|b_i\|^2 \le nBn^n (2B)^{2n} \qquad \text{for} \quad 1 \le i \le n. \tag{10}$$

Proof. During the size reduction only sums with at most 2^n terms occur. Each term is a product of coefficients of *different* rows. With $\mu_{i,j}^2 \le \frac{\|b_i\|^2}{\|b_j^*\|^2}$ [7] we have

$$\prod \mu_{i,j}^2 \le \prod \frac{\|b_i\|^2}{\|b_j^*\|^2}.$$

With $\|b_i\|^2 \le nB$ [7] it follows that

$$\prod \|b_i\|^2 \le (nB)^n.$$

As $\|b_1^*\|^2 \cdots \|b_n^*\|^2 \ge 1$ and $\|b_i^*\|^2 \le B$ for all $1 \le i \le n$ (see [7]) and because in each product only different b_j^*'s occur we obtain

$$\prod \|b_j^*\|^2 \ge \frac{1}{B^n},$$

and therefore for each product the following inequalities are valid

$$\prod \mu_{i,j}^2 \le n^n B^{2n},$$
$$\left|\prod \mu_{i,j}\right| \le n^{n/2} B^n.$$

Each sum consists of at most 2^n products. Therefore we obtain for all values

$$|\mu| \le n^{n/2} (2B)^n,$$
$$\mu^2 \le n^n (2B)^{2n}.$$

Again, the proposition for the values of b_i follows with $\|b_i\|^2 = \sum_{j=1}^{i} \mu_{i,j}^2 \|b_j^*\|^2$. ∎

Table 1 summarizes the results with respect to the sizes of the numbers.

TABLE 1
Comparison of the sizes of the numbers.

	LLL [7, 5]	Parallel (old analysis)	Parallel (new analysis)
$\mu_{i,j}^2$ after Gram–Schmidt	$n2^n B$	nB^n	nB^n
$\|b_i\|^2$ after Gram–Schmidt	nB	nB	nB
$\mu_{i,j}^2$ during size reduction	$n2^{3n} B$	$(4nB^n)^n$	$n^n (2B)^{2n}$
$\|b_i\|^2$ during size reduction	$n^2 2^{3n} B^2$	$nB(4nB^n)^n$	$nBn^n (2B)^{2n}$

5.3. Further remarks. There is a special class of lattices (which are constructed for the solution of the subset sum problem) for which a better analysis of the size of the numbers in the parallel case is possible [13].

Joux [4] has presented a method for avoiding big numbers during the parallel size reduction. But also with that method a better analysis than the one given in Theorem 5.7 is not possible.

In practical experiments for the parallel algorithm of [13] and [2, 3] larger numbers than in the serial algorithm do not occur.

5.4. Binary complexity. The estimation of the sizes of the numbers and a detailed analysis by Kaltofen [5] lead to the following binary complexity of the LLL algorithm using standard arithmetic.

THEOREM 5.8 (see [5]). *The LLL algorithm has binary complexity* $O(n^5(\log B)^3 + n^6(\log B)^2)$.

The binary parallel complexity is given by the following theorem.

THEOREM 5.9. *The binary complexity of parallel lattice basis reduction using* n^2 *processors is* $O(n^4(\log B)^3)$.

Proof. The size of all numbers (numerators and denominators) is bounded by $O(n \log B)$. Thus the time for one arithmetic operation is at most $O(n^2(\log B)^2)$ using standard arithmetic. At most $O(n^2 \log B)$ arithmetic operations must be performed. □

ON THE FAULT TOLERANCE OF SOME POPULAR BOUNDED-DEGREE NETWORKS*

F. THOMSON LEIGHTON†, BRUCE M. MAGGS‡, AND RAMESH K. SITARAMAN§

Abstract. In this paper, we analyze the fault tolerance of several bounded-degree networks that are commonly used for parallel computation. Among other things, we show that an N-node butterfly network containing $N^{1-\epsilon}$ worst-case faults (for any constant $\epsilon > 0$) can emulate a fault-free butterfly of the same size with only constant slowdown. The same result is proved for the shuffle-exchange network. Hence, these networks become the first connected bounded-degree networks known to be able to sustain more than a constant number of worst-case faults without suffering more than a constant-factor slowdown in performance. We also show that an N-node butterfly whose nodes fail with some constant probability p can emulate a fault-free network of the same type and size with a slowdown of $2^{O(\log^* N)}$. These emulation schemes combine the technique of redundant computation with new algorithms for routing packets around faults in hypercubic networks. We also present techniques for tolerating faults that do not rely on redundant computation. These techniques tolerate fewer faults but are more widely applicable because they can be used with other networks such as binary trees and meshes of trees.

Key words. fault tolerance, network emulation, butterfly network

1. Introduction.

In this paper, we analyze the effect of faults on the computational power of bounded-degree networks such as the butterfly network, the shuffle-exchange network, and the mesh of trees. The main objective of our work is to devise methods for circumventing faults in these networks using as little overhead as possible and to prove lower bounds on the effectiveness of optimal methods. We consider both worst-case and random fault patterns, and we always assume that faulty components are totally disabled (e.g., a faulty node cannot be used to transport a packet of data through the network). We also assume that the faults in a network are static and detectable and that information concerning the location of faults can be used when reconfiguring the network to circumvent the faults. For simplicity, we restrict our attention to node faults since an edge fault can always be simulated by disabling the node at each end of the edge.

There are several ways to measure the effect of faults on a network. In this paper, we are primarily concerned with the amount by which a collection of faults can slow down some computation on the network. For example, if a butterfly network

containing some faults is to be used for packet routing, we are concerned with how many nodes can send and receive packets, and how much longer it takes the faulty butterfly to deliver all of the packets than it takes a fault-free butterfly to perform the same task. More generally, we are interested in the length of time it takes an impaired network to emulate a single step of a fault-free network of the same type and size. In particular, we define the *slowdown* caused by a set of faults in a network G to be the minimum value of S such that any computation that takes T steps on G when there are no faults can be performed in at most $S \cdot T$ steps on G when faults are present. One of our main goals is to understand the relationship between slowdown and the number of faults for commonly used networks. In particular, we prove bounds on the number of faults that can be tolerated without losing more than a constant factor in speed.

We have two approaches for emulating a fault-free network G on an isomorphic faulty network H. The first approach is to find an embedding of G into H that avoids the faults in H. The second approach uses redundant computation; i.e., we allow H to emulate some of the nodes of G in more than one place. At first glance this approach seems disadvantageous, since H ends up performing more work. As we shall see, however, the freedom to emulate a node of G in more than once place allows H to have results ready where and when they are needed and can greatly reduce the slowdown of the emulation.

1.1. Emulations based on embeddings. An *embedding* maps the nodes of G to nonfaulty nodes of H and the edges of G to nonfaulty paths in H. A good embedding is one with minimum load, congestion, and dilation, where the *load* of an embedding is the maximum number of nodes of G that are mapped to any single node of H, the *congestion* of an embedding is the maximum number of paths that pass through any edge e of H, and the *dilation* of an embedding is the length of the longest path. The load, congestion, and dilation of the embedding determine the time required to emulate each step of G on H. In particular, Leighton, Maggs, and Rao have shown [30] that if there is an embedding of G in H with load l, congestion c, and dilation d, then H can emulate any computation on G with slowdown $O(l + c + d)$.

In this paper, we are most interested in embeddings for which the load, congestion, and dilation are all constant (independent of the size of the network). In particular, we show in section 2 how to embed a fault-free N-input butterfly into an N-input butterfly containing $\log^{O(1)} N$ worst-case faults using constant load, congestion, and dilation. A similar result is also proved for the N-node mesh of trees. Hence, these networks can tolerate $\log^{O(1)} N$ worst-case faults with constant slowdown.

Previously, no connected bounded-degree networks were known to be able to tolerate more than a constant number of worst-case faults without suffering more than a constant-factor loss in performance. Indeed, it was only known that

1. any embedding of an N-node (two- or three-dimensional) array into an array of the same size containing more than a constant number of worst-case faults must have more than constant load, congestion, or dilation [22, 25, 31], and
2. the N-node hypercube can be reconfigured around $\log^{O(1)} N$ worst-case faults with constant load, congestion, and dilation [2, 12].

The embeddings that we use in section 2 are level preserving; i.e., nodes in a particular level of the fault-free network are mapped to nodes on the same level of the faulty network. We take a significant step toward proving the limitation of embedding techniques for the emulation of these networks by showing that no level-preserving embedding strategy with constant load, congestion, and dilation can tolerate more

than $\log^{O(1)} N$ worst-case faults. Whether or not there is a natural low-degree N-node network (the hypercube included) that can be reconfigured around more than $\log^{O(1)} N$ faults with constant load, congestion, and dilation using (not necessarily level-preserving) embedding techniques remains an interesting open question.

1.2. Fault-tolerant routing algorithms. In section 3, we shift our attention to the routing capabilities of hypercubic networks containing faults. The algorithms developed in this section are later used by the emulation schemes based on redundant computation. First we prove in section 3.1 that an N-input butterfly with f worst-case faults can support an $O(\log N)$-step randomized packet routing algorithm for the nodes in $N - 6f$ rows of the butterfly. The ability of the butterfly to withstand faults in this context is important because butterflies are often used solely for their routing abilities. Previously, it was known that expander-based multibutterfly networks can tolerate large numbers of worst-case faults without losing their routing powers [6, 28], but no such results were known for butterflies or other hypercubic networks. A corollary of this result is that an N-input butterfly with $N/12$ worst-case faults can support an $O(\log N)$-step randomized routing algorithm for a majority of its nodes. Note that the number of faults is optimal to within a constant factor, since it is possible to partition an N-input butterfly into connected components of size $O(\sqrt{N} \log N)$ with N faults. In section 3.2 we show that butterflies with faults can also be used for circuit switching. In particular, we show that even if a $2N$-input $O(1)$-dilated Beneš network contains $N^{1-\epsilon}$ worst-case faults (for any $\epsilon > 0$), there is still a set of $2N - o(N)$ inputs I and a set of $2N - o(N)$ outputs O such that for any one-to-one mapping $\phi : I \mapsto O$ it is possible to route edge-disjoint paths from i to $\phi(i)$ for all $i \in I$. This result substantially improves upon previous algorithms for fault-tolerant circuit switching in Beneš networks [41, 49], which dealt with a constant number of faults by adding an extra stage to the network.

1.3. Emulations using redundant computation. In section 4, we use the fault-tolerant routing algorithm from section 3.2 to show that an N-input butterfly with $N^{1-\epsilon}$ worst-case faults (for any constant $\epsilon > 0$) can emulate a fault-free butterfly of the same size with only constant slowdown. A similar result is proved for the shuffle-exchange network. These results are stronger than the reconfiguration results proved in section 2 because the number of faults tolerated is much larger. The approach used in section 4 differs from the embedding-based approaches in section 2 in that a single node of the fault-free butterfly is emulated by (possibly) several nodes in the faulty butterfly. Allowing redundant computation provides greater flexibility when embedding one network in another (thereby attaining greater fault tolerance) but also adds the complication of ensuring that replicated computations stay consistent (and accurate) over time. This technique was previously used in the context of (fault-free) work-preserving emulations of one network by another [19, 26, 38, 39, 40, 47].

The techniques developed in section 4 also have applications for hypercubes. For example, in section 4.4, we use them to show than an N-node hypercube with $N^{1-\epsilon}$ worst-case faults can emulate T steps of any normal algorithm [27] in $O(T + \log N)$ time. (The set of normal algorithms include FFT, bitonic sort, and other important ascend–descend algorithms.) Previously, such results were known only for hypercubes containing $\log^{O(1)} N$ faults [2, 12, 13]. Whether or not an N-node hypercube can tolerate more than $\log^{O(1)} N$ faults with constant slowdown for general computations remains an important unresolved question.

In section 5, we show that even if each node in an N-input butterfly fails indepen-

dently with probability $p = 1/\log^{(k)} N$, where $\log^{(k)}$ denotes the logarithm function iterated k times, the faulty butterfly can still emulate a fault-free N-input butterfly with slowdown $2^{O(k)}$, with high probability. For $k = O(\log^* N)$ the node failure probability is constant, and the slowdown is $2^{O(\log^* N)}$, which grows very slowly with N. Whether or not this result can be improved remains an interesting open question. Until recently, no results along these lines were known for the butterfly, unless routing is allowed through faulty nodes [5], which simplifies matters substantially. Tamaki [51] has recently discovered an emulation scheme with slowdown $O((\log\log N)^{8.2})$. He also introduced a class of bounded-degree networks called cube-connected arrays [52] and showed that an N-node network in this class with constant-probability random faults can emulate itself with expected slowdown approximately $\log\log N$. These networks can also tolerate up to $\log^{O(1)} N$ worst-case faults with approximately $\log\log N$ slowdown.

1.4. Additional previous work. There is a substantial body of literature concerning the fault tolerance of communication networks. We do not have the space to review all of this literature here, but we would like to cite the papers that are most relevant. In particular, [2, 5, 9, 14, 23, 24, 25, 35, 44, 52] show how to reconfigure a network with faults so that it can emulate a fault-free network of the same type and size. A fault-tolerant area-universal network is presented in [53]. References [4, 10, 11, 16, 17] show how to design a network H that contains G as a subnetwork even if H contains some faults. Algorithms for routing messages around faults appear in [1, 6, 8, 15, 24, 25, 28, 34, 36, 41, 43, 44, 49]. The fault-tolerance of sorting networks is studied in [7, 32]. Finally, [12, 56, 57] show how to perform certain computations in hypercubes containing faults.

1.5. Network definitions. In this section, we review the structure of some of the networks that we study in this paper. In all of these networks, the edges are assumed to be undirected (or bidirectional).

An N-input $(\log N)$-dimensional *butterfly* network has $N(\log N + 1)$ nodes arranged in $(\log N) + 1$ levels.[1] An 8-input butterfly is shown in Figure 1.1. Each node in the butterfly has a distinct label (w, i), where i is the *level* of the node $(0 \le i \le \log N)$ and w is a $(\log N)$-bit binary number that denotes the *row* of the node. All edges connect pairs of nodes on adjacent levels. Each node (w, i) is connected by a *straight edge* to node $(w, i + 1)$, provided that $i < \log N$. In the figure, straight edges are drawn horizontally. Each node (w, i) is also connected by a *cross edge* to node $(w', i + 1)$, where w and w' differ only in the bit in position i, provided that $i < \log N$. (The most significant bit is in position 0, and the least significant is in position $(\log N) - 1$.) In the figure, cross edges are drawn diagonally. The nodes in level 0 are called the *inputs* of the butterfly, and those in level $\log N$ are called the *outputs*. Sometimes the input and output nodes in each row are assumed to be the same node. In this case, the butterfly has only $N \log N$ nodes. Our results hold whether or not the butterfly wraps around in this way.

In an N-node *hypercube*, each node is labeled with a distinct $(\log N)$-bit binary number. Two nodes in the hypercube are connected by an edge if and only if their labels differ in exactly one bit. The hypercube is the only network considered in this paper in which the degree of each node is not constant.

As in the N-node hypercube, each node in an N-node *shuffle-exchange* network is labeled with a distinct $(\log N)$-bit binary number. An 8-node shuffle-exchange

[1] Throughout this paper, log denotes the base-2 logarithm function, $\log_2$.

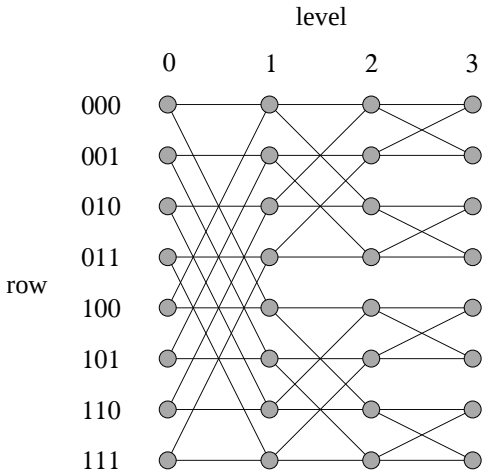

FIG. 1.1. *An* 8*-input butterfly network.*

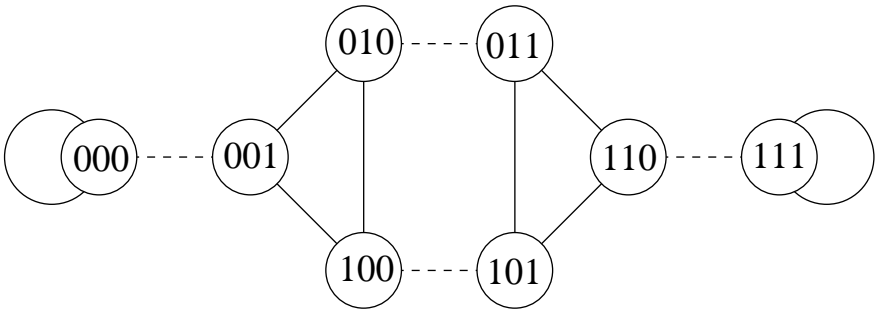

FIG. 1.2. *An* 8*-node shuffle-exchange network.*

network is shown in Figure 1.2. In the shuffle-exchange network, a node labeled u is connected by an *exchange* edge to the node labeled u', where u and u' differ only in the bit in the least significant position (position $(\log N)-1$). Node u is also connected by *shuffle* edges to the nodes labeled u_l and u_r, where u_l and u_r are the one-bit left and right cyclic shifts of u. (If $u_l = u_r$ then there is only one shuffle edge.) In the figure exchange edges are dotted and shuffle edges are solid.

An $N \times N$ *mesh of trees* network [27] is formed by first arranging N^2 nodes (but no edges) in a grid of N rows and N columns. Then for each row, an N-leaf complete binary tree, called a *row tree*, is added. The leaves of the row tree are the nodes of the corresponding row. Similarly, for each column an N-leaf *column tree* is added. The leaves of the column tree are the nodes of the column. Hence, the node at position (i, j) in the grid is a leaf of the ith row tree and jth column tree for $0 \le i, j \le N-1$.

A *circuit-switching network* is used to establish edge-disjoint paths (called circuits) between its inputs and outputs. We call the nodes in a circuit-switching network *switches* to signify that they are used only for routing and not for performing computation. Each switch in a circuit-switching network has a set of incoming edges and a set of outgoing edges. Inside the switch, the incoming edges can be connected to the outgoing edges in any one-to-one fashion. The switches at the first level of the network are called the *input switches*. The switches at the last level are called the

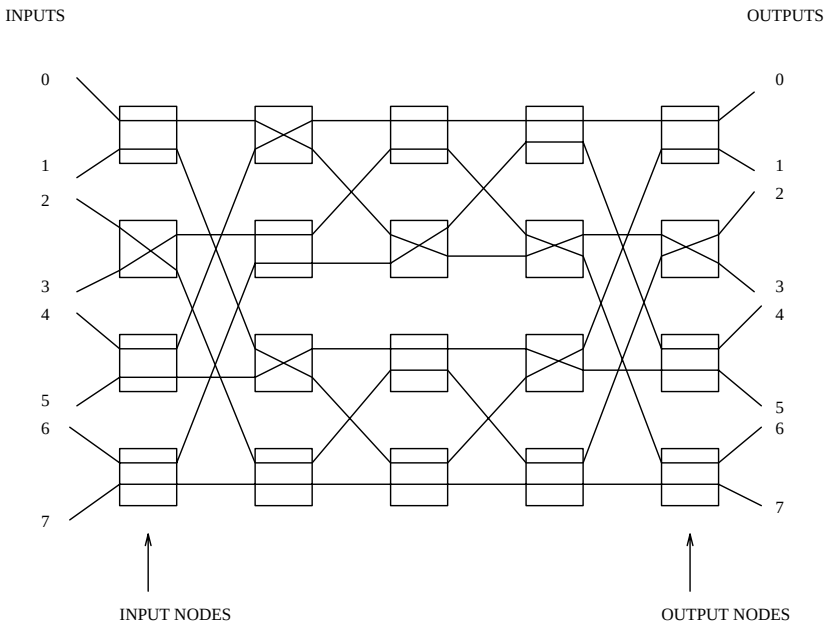

FIG. 1.3. *An 8-input (two-dimensional) Beneš network.*

output switches. The edges into each input switch are called *input edges*, or *inputs*. The edges out of each output switch are called *output edges*, or *outputs*. (Note, however, that in a butterfly network, we use the terms "inputs" and "outputs" to refer to nodes, not edges.) By setting the connections inside the switches, each input edge can be connected to an output edge via a path through the network.

A circuit-switching network with N inputs and N outputs is said to be *rearrangeable* if for any one-to-one mapping ϕ from the inputs to the outputs it is possible to construct edge-disjoint paths in the network connecting the ith input to the $\phi(i)$th output for $0 \leq i \leq N-1$.

The *Beneš* network is a classic example of a rearrangeable network. A $(\log N)$-dimensional Beneš network has $2N$ inputs and $2N$ outputs. Its switches are arranged in $2\log N + 1$ levels of N switches each. The first and last $\log N + 1$ levels each form a $(\log N)$-dimensional butterfly. Hence a Beneš network consists of two back-to-back butterflies sharing level $\log N$. We refer to the switches in levels 0, $\log N$, and, $2\log N$ as the *input switches*, *middle switches*, and *output switches*, respectively. Figure 1.3 shows an 8-input Beneš network in which the inputs are connected to the outputs according to the following mapping ϕ: $\phi(0) = 3$, $\phi(1) = 1$, $\phi(2) = 2$, $\phi(3) = 6$, $\phi(4) = 0$, $\phi(5) = 5$, $\phi(6) = 4$, $\phi(7) = 7$.

2. Emulation by embedding. In this section, we show how to embed a fault-free binary tree, butterfly, or mesh of trees into a faulty network of the same type and size with constant load, congestion, and dilation. As noted in the introduction, finding a constant load, congestion, and dilation embedding is the simplest way of emulating arbitrary computations of a fault-free network on a faulty network of the same type and size with only constant slowdown. We first consider embedding a complete binary tree in a complete binary tree with faults only at its leaves. This result also holds for fat-trees [21, 33] with faults at the leaves. We use this result to

find reconfigurations of butterflies and meshes of trees in which faults may occur at any node. The main result of this section is a proof that an N-node butterfly or mesh of trees network can tolerate $\log^{O(1)} N$ worst-case faults and still emulate a fault-free network of the same type and size with only constant slowdown.

2.1. The binary tree. In Theorem 2.1.2, we show that a fault-free 2^n-leaf complete binary tree can be embedded in another 2^n-leaf complete binary tree containing $S(n,b)$ or fewer faults at its leaves with load and congestion at most 2^b and dilation 1, where $S(n,b)$ is defined for $n \geq b \geq 0$ by the recurrence

$$S(n,b) = S(n-1,b) + S(n-1,b-1) + 1$$

for $n > b > 0$, with boundary conditions $S(n,0) = 0$ and $S(n,n) = 2^n - 1$ for $n \geq 0$. The following lemma provides a useful bound on the growth of $S(n,b)$.

LEMMA 2.1.1. *For all* $n \geq b \geq 1$, $\binom{n}{b} \leq S(n,b) \leq \binom{n+b}{b}$.

Proof. The proof is by induction on n. For $n = 1$, the only possible value of b is 1. In this case, $S(1,1) = 1$ and $\binom{1}{1} = 1 < \binom{2}{1}$. For $n > 1$, there are three cases to consider. First, for $b = 1$, $S(n,1) = n$, and $\binom{n}{1} = n < \binom{n+1}{1}$. Second, for $n = b$, $S(n,n) = 2^n - 1$ and $\binom{n}{n} \leq 2^n - 1 < \binom{2n}{n}$. Finally, for $n > b > 1$, the inequalities are proved inductively using the fact that $\binom{x}{y} = \binom{x-1}{y} + \binom{x-1}{y-1}$, for all $x > y > 0$, and $\binom{x}{y} + 1 \leq \binom{x+1}{y}$ for $x \geq y > 0$. ∎

Using the inequalities $(x/y)^y \leq \binom{x}{y} \leq (xe/y)^y$ for $x \geq y > 0$, we see that for any constant $b > 0$, $S(n,b) = \Theta(n^b)$.

THEOREM 2.1.2. *Given a* 2^n*-leaf complete binary tree* T *with a set of at most* $S(n,b)$ *worst-case faults at the leaves, where* $n \geq b \geq 0$*, it is possible to embed a fault-free* 2^n*-leaf complete binary tree* T' *in* T *so that*

1. *nodes on level* i *of* T' *are mapped to nonfaulty nodes on level* i *of* T*, for* $0 \leq i \leq n$;
2. *the congestion and the load of the embedding are at most* 2^b; *and*
3. *the dilation of the embedding is* 1.

Proof. The proof is by induction on n. For $n = 0$, the only possible value of b is 0 and $S(0,0) = 0$. In this case T is a single fault-free node and T' can be embedded in T with load 1, congestion 0, and dilation 0. For $n > 0$, there are three cases to consider. First, for $b = 0$, $S(n,0) = 0$, so T has no faults. In this case, T' can be embedded in T with load 1, congestion 1, and dilation 1. Second, for $b = n$, $S(n,n) = 2^n - 1$, so there is a single nonfaulty leaf l in T. In this case, all of the 2^n leaves of T' are mapped to l, and the rest of the tree is mapped to the path from the root of T to l. The embedding has load 2^n, congestion 2^n, and dilation 1. Finally, suppose that $n > b > 0$. If both 2^{n-1}-leaf subtrees of T have at most $S(n-1,b)$ faulty leaves, then we use the result inductively in both subtrees. Otherwise, if one 2^{n-1}-leaf subtree (say the left subtree) has $S(n-1,b)+1$ or more faults, then by the definition of $S(n,b)$ the other subtree (the right subtree) has at most $S(n-1,b-1)$ faulty leaves. Hence we can use induction to embed a 2^{n-1}-leaf complete binary tree on the right subtree with dilation 1 and load and congestion 2^{b-1}. By doubling the congestion and the load, we can embed two 2^{n-1}-leaf complete binary trees in the right subtree. This means that we can embed T' in T with dilation 1 and load and congestion 2^b using only the root and the right subtree of T. ∎

Rewriting the number of leaves as $N = 2^n$, we see that for any constant $b > 0$, it is possible to embed a fault-free N-leaf complete binary tree T' in an N-leaf

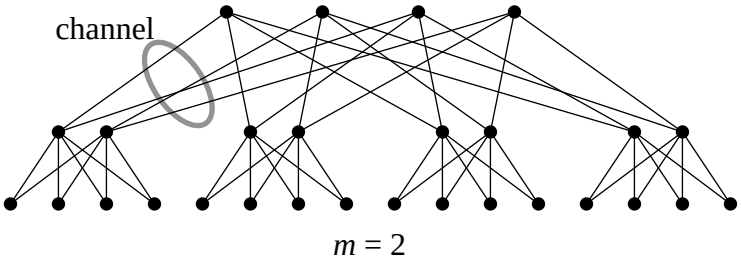

FIG. 2.1. *A 4-ary fat-tree network with depth $m = 2$ in which $r_0 = 4$, $r_1 = 2$, and $r_2 = 1$.*

complete binary tree T containing $S(\log N, b) = \Theta(\log^b N)$ faults with constant load, congestion, and dilation.

This result can be extended to a class of networks called *fat-trees*. A fat-tree of depth m is specified by a sequence of numbers $r_0, r_1, \ldots, r_m$, where $r_m = 1$. (Typically $r_0 \geq r_1 \geq \cdots \geq r_m$.) A fat-tree of depth 0 is a single node, which is both the root node and the leaf node of the tree. A fat-tree of depth m is constructed as follows. At the root of the fat-tree there is a set of r_0 nodes. The subtrees of the root are identical and are constructed recursively. Each is a fat-tree of depth $m - 1$ with number sequence $r_1, \ldots, r_m$. The r_0 root nodes of the fat-tree are connected to the r_1 root nodes of each subtree by a *channel* of edges. There may be any number of edges in the channel, and they may form any pattern of connections, but the channels to each subtree must be isomorphic. Figure 2.1 shows a fat-tree in which $r_0 = 4$, $r_1 = 2$, and $r_2 = 1$. In this figure, the root has four subtrees, as do the roots of these subtrees. Hence the figure shows a 4-ary fat-tree. This fat-tree was chosen for the figure because a fat-tree of this form has been shown to be area universal [33, 21, 30]. Corollary 2.1.3 is stated for binary fat-trees (i.e., fat-trees in which the root has two subtrees), but similar results can be proven for 4-ary fat-trees.

COROLLARY 2.1.3. *A $(\log N)$-depth binary fat-tree can be embedded in a level-preserving fashion in an isomorphic fat-tree with $S(\log N, b)$ worst-case faults at its leaves with load and congestion 2^b and dilation 1.*

Proof. Associate the nodes of the fat-tree with the nodes of an N-node complete binary tree as follows. Associate all root nodes of the fat-tree with the root of the complete binary tree. Recursively associate the nodes of the left (right) subtree of the fat-tree with the nodes of the left (right) subtree of the complete binary tree. Note that every leaf of the fat-tree is associated with a distinct leaf of the complete binary tree. Given a fat-tree F with some faulty leaves, let T be a complete binary tree whose leaf is faulty if and only if the corresponding leaf in F is faulty. A fault-free complete binary tree T' can be embedded in T by embedding subtrees of T' into subtrees of T using the procedure given in Theorem 2.1.2. The same embedding can be used to embed a fault-free fat-tree F' in F by embedding the corresponding subtrees of F' into the corresponding subtrees of F. The dilation and load are the same as that of the complete binary tree embedding. □

COROLLARY 2.1.4. *A* $(\log N)$*-dimensional butterfly can be embedded in a level-preserving fashion in an isomorphic butterfly with* $S(\log N, b)$ *worst-case faults at level* $\log N$ *with load and congestion* 2^b *and dilation* 1.

Proof. A $(\log N)$-dimensional butterfly is a binary fat-tree of depth $\log N$ with $r_i = 2^{\log N - i}$. The leaves of the fat-tree are the nodes in level $\log N$ of the butterfly. □

2.2. The mesh of trees and the butterfly. We can use Theorem 2.1.2 to show that the mesh of trees and the butterfly network can tolerate $\log^{O(1)} N$ worst-case faults with constant slowdown, even when a fault can occur at *any node* of the network. The proof uses the fact that both the mesh of trees and the butterfly can be viewed as a special kind of product graph, which we call an *external product graph*.

As external product graph is defined as follows. Let G be a graph in which some set of N nodes have been labeled as *external* nodes. For example, if G is a tree, the leaves could be the external nodes, or, if G is a butterfly, the nodes on level $\log N$ (the outputs) could be the external nodes. Given a graph G with N external nodes, the external product graph of G (denoted PG) is constructed as follows. Make $2N$ copies of G, $G_{i,j}$ for $i = 1, 2$ and $0 \leq j \leq N-1$. Number the external nodes of each copy from 0 to $N-1$. Now identify the kth external node in $G_{1,j}$ with the jth external node in $G_{2,k}$ for all $0 \leq j, k \leq N-1$. (By "identify" we mean make them the same node of the graph PG.) The resulting graph is the external product graph of G. As an example, when the graph G is a tree and its leaves are the external nodes, the graph PG is a mesh of trees network. As another example, when G is a butterfly and its outputs are external nodes, PG is a butterfly with twice the dimension.

We now show that if G can tolerate faults in its external nodes, then PG can tolerate faults at any of its nodes.

THEOREM 2.2.1. *If a graph* G' *can be embedded in a level-preserving fashion with load* l*, congestion* c*, and dilation* d *in an isomorphic graph* G *with* f *worst-case faults located in its external nodes, then it is possible to embed the product graph* PG' *in a level-preserving fashion with load* l^2*, congestion* lc*, and dilation* d *in an isomorphic graph* PG *with* $f/2$ *worst-case faults located in any of its nodes.*

Proof. Let PG and PG' be made up of graphs isomorphic to G called $G_{i,j}$ and $G'_{i,j}$, respectively, for $i = 1, 2$ and $1 \leq j \leq N$. Let CG and CG' also be graphs isomorphic to G. The jth external node of CG is declared to be faulty if and only if either $G_{1,j}$ or $G_{2,j}$ contains a fault. If PG has $f/2$ faults, then CG has at most f faults (since an external node of PG can appear both as the kth leaf of $G_{1,j}$ and as the jth leaf of $G_{2,k}$). Let Φ be a level-preserving embedding of the fault-free graph CG' into CG with load l, congestion c, and dilation d and define ϕ so that Φ maps the jth external node of CG' to the $\phi(j)$th external node of CG. We embed PG' into PG by mapping $G'_{i,j}$ to $G_{i,\phi(j)}$ using Φ to map the individual nodes of $G'_{i,j}$ to $G_{i,\phi(j)}$ for $i = 1, 2$ and $0 \leq j \leq N-1$. (Hence, the mapping Φ is used twice.) It follows from the definition of faults in CG that $G_{i,\phi(j)}$ is fault-free. Therefore, no nodes of PG' are mapped to faulty nodes of PG. We need to verify that our mapping is well defined, i.e., that it doesn't map an external node of PG' to more than one node of PG. The kth external node of $G'_{1,j}$ is the same as the jth external node of $G'_{2,k}$. The former is mapped to the $\phi(k)$th external node of $G_{1,\phi(j)}$ and the latter to the $\phi(j)$th external node of $G_{2,\phi(k)}$. These nodes are the same node of PG. Hence, the mapping is well defined. The dilation of the mapping is d. The number of copies $G'_{i,j}$ of PG' mapped to any particular $G_{i,\phi(j)}$ is at most l. Each copy can map l nodes onto any particular node of $G_{i,\phi(j)}$. Therefore, the load is at most l^2, and the congestion is at most lc. □

Theorem 2.2.1 is readily applied to the butterfly and mesh of trees networks. For simplicity, we state the result for a two-dimensional mesh of trees. The same techniques, however, can be used to show that any constant-dimension mesh of trees can tolerate $\log^{\Theta(1)} N$ worst-case faults with only constant slowdown.

THEOREM 2.2.2. *A $2 \log N$-dimensional butterfly can be embedded in a level-preserving fashion in a $2 \log N$-dimensional butterfly containing $S(\log N, b) = \Theta(\log^b N)$ worst-case faults with load and congestion 2^{2b} and dilation 1.*

Proof. The proof follows from Corollary 2.1.4 and Theorem 2.2.1. □

THEOREM 2.2.3. *An $N \times N$ mesh of trees can be embedded in a level-preserving fashion in an $N \times N$ mesh of trees containing $S(\log N, b) = \Theta(\log^b N)$ worst-case faults with load and congestion 2^{2b} and dilation 1.*

Proof. The proof follows from Theorems 2.1.2 and 2.2.1. □

The results of this subsection can also be shown by using the fact that the butterfly and the mesh of trees can be expressed as the layered cross product [18] of two complete binary trees (or variations thereof) [3] and proving a theorem analogous to Theorem 2.2.1 for layered cross product graphs.

2.3. Limitations of level-preserving embeddings. We do not know whether Theorems 2.1.2, 2.2.2, and 2.2.3 can be improved if the level-preserving constraint is removed. However, we can show that the bounds in Theorems 2.1.2, 2.2.2, and 2.2.3 are tight if the embedding is forced to be level preserving. The proof uses a construction called an arrow diagram.

Given an N-leaf binary tree T with faults at its leaves, an *arrow diagram* has arrows drawn from some nodes of T to their siblings, with no pairs of antiparallel arrows allowed. We define a *b-legal* arrow diagram as follows.

1. On any path from the root to a faulty leaf, there is an arrow from a node on the path to a node not on the path (called an outgoing arrow).
2. On any path with no outgoing arrow, there can be at most b incoming arrows.

An arrow diagram is called *legal* if it is b-legal for any $0 \leq b \leq n$.

Suppose that an adversary is allowed to place faults at the leaves of a 2^n-leaf complete binary tree. Let $T(n, b) + 1$ be the minimum number of faults needed by the adversary to make it impossible to construct a b-legal arrow diagram for the tree. Note that if a diagram is illegal for some set of faults then it cannot be made legal by adding another fault. Hence allowing more faults only makes the adversary more powerful. We bound the value of $T(n, b)$ as follows.

LEMMA 2.3.1. *For $n \geq b \geq 0$,*

$$T(n,b) \leq \begin{cases} 0 & \text{for } b = 0, \\ T(n-1,b) + T(n-1,b-1) + 1 & \text{for } 0 < b < n, \\ 2^n - 1 & \text{for } b = n. \end{cases}$$

Proof. First, suppose that $b = 0$. If the tree has one or more faults, then any legal arrow diagram must have at least one arrow. If the diagram has at least one arrow, then there must be a path from the root of the tree to a leaf having at least one incoming arrow and no outgoing arrow. Such a path can be recursively constructed as follows. Choose the arrow that is closest to the root of the tree, and let this arrow be directed from a node m' to its sibling m. The constructed path is the path from the root of the tree to m concatenated with the path constructed recursively in the subtree rooted at m. (If there is no arrow in the subtree rooted at m a path from m to any leaf of the subtree suffices.) Thus, a tree with a fault cannot have a 0-legal arrow diagram. Thus $T(n, 0) \leq 0$.

Next, let $n = b$. If there are 2^n faults, then every leaf is faulty, and it is not possible to draw an arrow diagram with an outgoing arrow on the path from the root to every faulty leaf. Thus, $T(n, n) \leq 2^n - 1$.

Finally, suppose that $0 < b < n$. We show that there is a way of placing $T(n-1, b) + T(n-1, b-1) + 2$ faults at the leaves such that in any legal arrow diagram either there must be at least $b+1$ incoming arrows on some path without any outgoing arrow or there must be a faulty leaf with no outgoing arrow in its path. We place $T(n-1, b) + 1$ worst-case faults in the left subtree and $T(n-1, b-1) + 1$ worst-case faults in the right subtree. Assume that it is possible to place arrows in the tree such that every path to a faulty leaf has an outgoing arrow and every path from the root to a leaf that has no outgoing arrows has at most b incoming arrows. We look at the placement of arrows in the left subtree. Since there are more than $T(n-1, b)$ faults, there must be a path from the root of this subtree to a leaf that has $b+1$ incoming arrows and no outgoing arrows or there must be path from the root of this subtree to a fault with no outgoing arrow. Either of these cases imply that the root of the left subtree must have an arrow from itself to its sibling. Now look at the right subtree. It cannot be the case that there is a path from the root of the right subtree to a faulty leaf with no outgoing arrow, since then there would be no outgoing arrow for the path from the root of T to this fault. Further, no path from the root of the right subtree to a leaf of the right subtree can have more than $b-1$ incoming arrows without having an outgoing arrow, since otherwise there would be a path from the root of the tree to that leaf with more than b incoming arrows without an outgoing arrow. Thus the right subtree must be $(b-1)$-legal. However, the right subtree has more than $T(n-1, b-1)$ worst-case faults. This is a contradiction. □

COROLLARY 2.3.2. *For all $n \geq b \geq 1$, $T(n, b) = O(n^b)$.*

Proof. The recurrence for $T(n, b)$ is bounded from above by the recurrence that we had for $S(n, b)$ in section 2.1 and hence $T(n, b) = O(S(n, b))$. Using Lemma 2.1.1, $T(n, b)$ is $O(n^b)$. □

THEOREM 2.3.3. *For any constants l and d, there is a constant $k = d + (l-1)2^d$ such that there is a way of placing $O(\log^k N)$ faults in the leaves of an N-leaf complete binary tree T such that there is no level-preserving embedding of an N-leaf fault-free complete binary tree T' in T with load l and dilation d.*

Proof. We begin by placing a set of faults of cardinality $O(\log^k N)$ at the leaves of T such that this fault pattern has no k-legal arrow diagram, where $k = d + (l-1)2^d$ and $N = 2^n$. This is possible because $T(n, k) + 1$ is $O(\log^k N)$. Now suppose for the sake of contradiction that there is an embedding of T' into T with load l and dilation d with the property that nodes on level i of T' are mapped to nodes on level i of T and no nodes of T' are mapped to faulty nodes of T. Annotate the tree T with arrows as follows. For any two siblings in the tree, draw an arrow from the sibling whose subtree has a smaller number of leaves of T' mapped to it to the sibling that has a larger number of leaves mapped to it. If the number of leaves mapped to each of the two subtrees is equal then no arrow is drawn.

We now show that the annotated tree is b-legal for some $b \leq k$, which is a contradiction. The path from the root of a tree to any faulty leaf must have an outgoing arrow, since no node of T' is mapped to a faulty leaf. Hence, the first criterion in the definition of a b-legal tree is satisfied. Let b be the maximum number of incoming arrows on a path without an outgoing arrow. We ignore the last d levels of the tree. Therefore, there is a path in T, $m_0, m_1, \ldots, m_{n-d}$, where m_0 is the root and m_i is a node in level i of the tree, that has at least $b-d$ incoming arrows without

any outgoing arrows. Let l_i, $0 \leq i \leq n-d$, denote the average number of leaves of T' that are embedded into each leaf of the subtree of T rooted at node m_i. Clearly, l_0 is 1. If there is no incoming arrow into node m_i, then the split of leaves of T' is even and hence $l_i = l_{i-1}$. Suppose there is an incoming arrow into node m_i from its sibling m'_i. Then $l_i > l_{i-1}$. Further, $l_i \geq l_{i-1} + 2^{-d}$. To see why, consider the subtrees of T' rooted at level $i+d$. The nodes in each of these subtrees can be mapped entirely within either the subtree rooted at m_i or entirely within the subtree rooted at m'_i but never to the nodes in both. To see why, note that if a node in one of these subtrees that was mapped to the subtree rooted at m_i and a neighbor at an adjacent level was mapped to the subtree rooted at m'_i, then the dilation of the edge between them would be more than d. (In fact, the dilation would have to be at least $2d+3$, since the subtrees are separated by a distance of $2d+2$, and any two nodes connected by an edge in T' must be mapped to different levels in T.) Thus, the subtree rooted at m_i must have at least 2^{n-i-d} more leaves of T' mapped to it than the subtree rooted at m'_i. Hence, $l_i \geq l_{i-1} + (2^{n-i-d}/2^{n-i}) = l_{i-1} + 2^{-d}$. Since there are at least $b-d$ incoming arrows on the path, $l_{n-d} \geq 1 + (b-d)2^{-d}$. Note that there is at least one leaf in the subtree rooted at m_{n-d} that has load at least l_{n-d}. Therefore, $l \geq l_{n-d}$. This implies that $b \leq d + (l-1)2^d = k$. But there can be no k-legal arrow placement for the fault pattern chosen for T. This is a contradiction. □

THEOREM 2.3.4. *For any constants l and d, there is a constant $k = d + (l-1)2^d$ such that there is a way of choosing $\Theta(\log^k N)$ faults in an N-input butterfly B such that there is no level-preserving embedding of an N-input butterfly B' in B with load l and dilation d.*

Proof. The proof is similar to that of Theorem 2.3.3. Let B be a butterfly with faults and let B' be the fault-free version of B. We can associate a tree T with B as follows: the root of T represents the entire butterfly B. Its children represent the two subbutterflies of dimension $\log N - 1$ (between levels 1 and $\log N$). Each child is subdivided recursively until each leaf of the tree T represents a distinct node in level $\log N$ of the butterfly B. We choose the same set of worst-case faults in the leaves of T as in Theorem 2.3.3. The faulty nodes of B are the nodes in level $\log N$ of B that correspond to the faulty leaves of T. Given a level-preserving embedding of B' into B with load l and dilation d, we can produce a b-legal placement of arrows in T in a manner similar to the previous proof. Given two siblings m and m', draw an arrow from m' to m if the there are more nodes in level $\log N$ of B' mapped to the subbutterfly of B represented by tree node m than the subbutterfly represented by tree node m'. Let m and m' be on level j of T. As before, due to dilation considerations, the smaller subbutterflies of B' spanning levels $j+d$ to n must be mapped entirely within the subbutterfly of B represented by m or within the subbutterfly represented by m' but never to both. The rest of the proof is similar to Theorem 2.3.3. □

The following theorem is stated for two-dimensional meshes of trees. An analogous theorem can be proved for any constant-dimension mesh of trees.

THEOREM 2.3.5. *For any constants l and d, there is a constant $k = d + (l-1)2^d$ such that there is a way of choosing $\Theta(\log^k N)$ faults in a $\sqrt{N} \times \sqrt{N}$ mesh of trees M such that there is no level-preserving embedding of a $\sqrt{N} \times \sqrt{N}$ mesh of trees M' in M with load l and dilation d.*

Proof. The proof is similar to that of Theorem 2.3.4. Let M be a mesh of trees with faults and let M' be the fault-free version of M. The nodes in level $\log N$ of M and M' are arranged in the form of a two-dimensional $\sqrt{N} \times \sqrt{N}$ mesh. We refer to these nodes as the mesh nodes. We can associate a tree T with the mesh nodes of M

as follows: the root of T represents the entire mesh. Divide the mesh vertically into two equal parts and let each child represent one of the halves. At the next level of the tree divide each of the halves horizontally into two equal parts. Divide alternately, either vertically or horizontally, until reaching individual mesh nodes, which are each represented by a distinct leaf of the tree. We choose the same set of worst-case faults in the leaves of T as in Theorem 2.3.3. The faulty nodes of M are the mesh nodes of M that correspond to the faulty leaves of T. Given a level-preserving embedding of M' into M with load l and dilation d, we can produce a b-legal placement of arrows in T in a manner similar to the previous proofs. Given two siblings m and m', draw an arrow from m' to m if there are more mesh nodes of M' mapped to the submesh of M represented by tree node m than the submesh represented by tree node m'. As before, due to dilation considerations, the smaller submeshes of M' must be mapped entirely within the submesh of B represented by m or within the submesh represented by m' but never to both. The rest of the proof is similar to Theorem 2.3.3. □

3. Fault-tolerant routing. In this section, we present algorithms for routing around faults in hypercubic networks. Section 3.1 presents algorithms for routing packets in a butterfly network with faulty nodes, while section 3.2 presents algorithms for establishing edge-disjoint paths between the inputs and outputs of an $O(1)$-dilated Beneš network with faulty switches.

3.1. Fault-tolerant packet routing. In this section we show how to route packets in an N-input butterfly network with f worst-case faults. In particular, we focus on the problem of routing packets between the nodes of the network in a one-to-one fashion. This type of routing is also called *permutation routing.* (See [37] for references to permutation routing algorithms.) In a permutation routing problem, every node is the origin of at most one packet and the destination of at most one packet. We show that there is some set of $N - 6f$ rows (where $0 \leq f \leq N/6$) such that it is possible to route any permutation between the nodes in these rows in $O(\log N)$ steps using constant-size queues, with high probability. The same result (without the high probability caveat) was previously shown for the expander-based multibutterfly network [28]. A special case of this result is that when $f \leq N/12$ we can route arbitrary permutations between a majority of nodes in the butterfly. Note that this is optimal to within constant factors since N faults on level $(\log N)/2$ partitions the butterfly into many disjoint small connected components.

It will be convenient for us to view the packets as being routed on a larger network with $4 \log N + 1$ levels and N rows. The network consists of four stages. Stage i consists of those nodes in levels $i \log N$ through $(i + 1) \log N$ for $0 \leq i \leq 3$. Note that each pair of consecutive stages shares a level of nodes. The nodes in stages 0 and 3 are connected by straight edges only. Stages 1 and 2 consist of a pair of back-to-back butterflies isomorphic to the Beneš network. In analogy with the Beneš network, the nodes in levels $\log N$, $2 \log N$, and $3 \log N$ are called input nodes, middle nodes, and output nodes, respectively. Note that this larger network can be embedded in a butterfly network so that the jth row of the larger network is mapped to the jth row of the butterfly, and at most one node from each stage of the larger network is mapped to each node of the butterfly. The embedding has load 4, congestion 4, and dilation 1.

We start by describing Valiant's algorithm [54] for permutation routing on a butterfly without faults. Each node in stage 0 is the source of at most one packet, and each node in stage 3 is the destination of at most one packet. (Thus in the underlying butterfly, each node is both the source and destination of at most one packet.) In

stage 0, a packet travels along its row to the input node in that row (say, m). In stage 1, the packet goes from m to a random middle node (say, m''). In stage 2, the packet goes from m'' to the output node m' in the row of its destination. In stage 3, the packet travels along the row of m' until it reaches its destination. Valiant showed that these paths, which have length at most $4 \log N$, also have congestion $O(\log N)$ with high probability. In networks such as the butterfly with $O(\log N)$ levels, as long as the (leveled) paths of the packets have congestion $O(\log N)$, a Ranade-type queuing protocol can be used to route the packets in $O(\log N)$ steps using constant-size queues, with high probability [29]. Therefore, it is sufficient to derive high-probability bounds on the congestion of the paths in a routing scheme.

Our goal is to identify a large set of "good" nodes in a faulty butterfly between which we can route permutations using an algorithm like Valiant's. A node in the four-stage network is faulty if the corresponding node in the underlying butterfly is faulty. Since stages 0 and 3 require a fault-free row, any node in a row with a fault is declared to be *bad*. Furthermore, in stage 1, every packet needs a sufficient number of random choices of middle nodes. For every input node m, let $REACH(m)$ be defined to be the set of middle nodes reachable from m using fault-free paths of length $\log N$ from level $\log N$ to level $2 \log N$. Also, for every output node m', let $REACH(m')$ be the set of middle nodes reachable using fault-free paths from level $3 \log N$ back to level $2 \log N$. Note that if m and m' lie in the same row, then $REACH(m) = REACH(m')$, because the fault pattern in stage 2 is the mirror image of the fault pattern in stage 1. If $|REACH(m)| < 4N/5$ for any input node m, then we declare m and all other nodes in its row to be bad. Any node not declared bad is considered *good*. Note that there are no faults in rows containing good nodes, and every good input or output node can reach at least $4N/5$ middle nodes via fault-free paths. A row in the underlying butterfly is good if the corresponding row in the four-stage network is good.

We now show that only $6f$ rows contain bad nodes. This follows from the fact that only f rows can contain faults and from the fact that $|REACH(m)| \geq 4N/5$ for all but $5f$ input nodes m. The latter fact is proved by setting $t = N/5$ in the following lemma, which will also be used in section 3.2.

LEMMA 3.1.1. *In an N-input butterfly with f worst-case faults, at least $N - fN/t$ input nodes (nodes in level 0) can each reach at least $N - t$ output nodes (nodes in level $\log N$) via fault-free paths of length $\log N$ for any $t \leq N$.*

Proof. For each input node i, let n_i represent the number of output nodes in level $\log N$ that i cannot reach. If the lemma were false, then we would have

$$\sum_{i=0}^{N-1} n_i \geq \left(\frac{fN}{t} + 1 \right) (t + 1).$$

A fault at any level of the butterfly lies on precisely N paths from input nodes to output nodes. Hence $\sum_{0=1}^{N-1} n_i = fN$. Combining the equation with the inequality yields $fN \geq (fN/t + 1)(t + 1)$, which is a contradiction. Hence the lemma must be true. □

In order to route any permutation between the good nodes, we use Valiant's algorithm except that in stage 1, in order to route a packet from input m to output m', we randomly select a middle node m'' from $REACH(m) \cap REACH(m')$. (One way to do this is to store at each input m a table containing information about $REACH(m) \cap REACH(m')$ for each output m'.) Since m and m' are good input and output nodes $|REACH(m) \cap REACH(m')|$ is at least $3N/5$. We now prove that the paths selected in this manner have congestion $O(\log N)$ with high probability.

LEMMA 3.1.2. *For any constant $k > 0$, the randomly selected paths have congestion $O(\log N)$ with probability at least $1 - 1/N^k$. Furthermore, these paths are leveled and have length at most $4 \log N$.*

Proof. The lengths of the paths are clearly at most $4 \log N$ since the paths traverse the butterfly four times, once in each stage. We bound the congestion as follows. Every good node sends and receives one packet. Thus, the congestion of any node in stages 0 and 3 is trivially at most $(\log N + 1)$. Consider a node s in level l of the butterfly in stage 1. There are $2^l(\log N + 1)$ packets that could pass through this node. A packet passes through this node if and only if it selects as a random middle node one of the $2^{\log N - l}$ middle nodes reachable from this node. Note that the set of possible choices of middle nodes for any input node m and output node m' is $REACH(m) \cap REACH(m')$. Since both m and m' are good nodes, $|REACH(m)| \geq 4N/5$ and $|REACH(m')| \geq 4N/5$. This implies that $|REACH(m) \cap REACH(m')| \geq 3N/5$. Thus the probability that the packet chooses a middle node that is reachable from s is at most $2^{\log N - l}/(3N/5)$. Therefore, the expected number of packets that passes through a node in stage 1 is at most $(2^l(\log N + 1))(2^{\log N - l})/(3N/5) = 5(\log N + 1)/3$. We can use Chernoff-type bounds [46] to show that the number of packets that pass through s in stage 1 is $O(\log N)$ with probability at least $1 - 1/2N^k$ for any constant k. The calculation for a node in stage 2 is exactly analogous. Thus the congestion is $O(\log N)$ with probability at least $1 - 1/N^k$. □

The following theorem summarizes the result presented in this section.

THEOREM 3.1.3. *In an N-input butterfly network with f worst-case faults, where $0 \leq f \leq N/6$, there is some set of $N - 6f$ "good" rows whose nodes can serve as the origins and destinations of any permutation routing problem. Furthermore, there is a routing algorithm such that, for any constant $k > 0$, there is a constant $C > 0$ such that the algorithm routes all the packets in any permutation (using routing tables) in at most in $C \log N$ steps using constant-size queues, with probability at least $1 - 1/N^k$.*

Proof. Lemma 3.1.1 shows how to identify the $N - 6f$ rows that are to serve as the sources and destinations of the packets. The lemma is applied for the case $t = N/5$. To route from an input node m to an output node m', a packet must select a random intermediate destination m'' that can be reached from both m and m'. The choice is made by consulting a table of all such m''. Lemma 3.1.2 shows that, with high probability, these paths have congestion $O(\log N)$. Finally, once the paths are selected, the algorithm for routing on leveled networks [29] can be applied to deliver the packets in $O(\log N)$ steps, with high probability using constant-size queues. □

3.1.1. Packet routing without routing tables. In the previous algorithm, every good input node m was required to store a table containing information about $REACH(m) \cap REACH(m')$ for every good output node m'. In this section, we show that is possible to route packets in a faulty butterfly without using such routing tables. The information about the placement of the faults is used only during the reconfiguration when the good and bad nodes are identified. This information is not needed for the routing itself. We assume that any packet that attempts to go through a fault is simply lost. We further assume that a node that receives a packet sends back an acknowledgement message (ACK) to the sender. Each ACK message follows the path of the corresponding packet in reverse. An ACK is generally smaller than a message and requires at most $O(\log N)$ bits to specify its path and the identity of the message that it is acknowledging. The algorithm for routing proceeds in rounds. There are a total of $(A \log \log N) + 1$ rounds (for some constant A). Each round consists of the following steps (R takes values from 0 to $A \log \log N$ and denotes the round number).

SEND-PACKET: In stage 0, if packet p has not yet been delivered to its destination, send 2^R identical copies of p to the input node m in its row. In stage 1, send each copy of the packet independently to a random middle node. In stage 2, send each copy to the appropriate output node m'. In stage 3, send each copy to the appropriate destination node in that row.

RECEIVE-PACKET: If a packet is received send an ACK along the same path that the packet came through but in reverse.

WAIT: Wait $B \log N$ steps before starting the next round.

THEOREM 3.1.4. *For any constant $k > 0$, there are constants A and B such that the algorithm routes any permutation on the nodes of the $N - 6f$ good rows of an N-input butterfly with f faults in $O(\log N \log\log N)$ steps using constant-size queues, with probability at least $1 - \frac{1}{N^k}$, without using routing tables.*

Proof. First we show that there is very little probability that a packet survives $A \log\log N$ rounds without reaching its destination, where A is an appropriately chosen constant. A packet can never encounter a fault in stages 0 and 3 since its source and destination rows are fault-free. Let m and m' denote the input and output nodes that the packet passes through, respectively. In stage 1, if the packet chooses any middle node in $REACH(m) \cap REACH(m')$ then it succeeds in reaching its destination. Since $|REACH(m) \cap REACH(m')| \geq 3N/5$ the probability of this happening is at least $3/5$. Suppose the packet did not get through after $A \log\log N$ rounds. Then $2^{A \log\log N} = \log^A N$ copies of the packet are transmitted in the last round. Note that the probability of each copy surviving is independent of the others. Hence the probability that none of these copies reach their destination is at most $(1-3/5)^{\log^A N}$, which is at most $1/N^{k+3}$, for any constant $k > 0$ and for an appropriate choice of the constant A. Thus, the probability that some packet does not reach its destination is at most $N \log N/N^{k+3}$, which is less than $1/N^{k+1}$.

Next we show that each round takes $O(\log N)$ time with high probability. We assume inductively that at the beginning of round i the total number of packets (counting each copy once) to be transmitted from any row in stage 0 of the algorithm or received by any row in stage 3 of the algorithm is at most $q \log N$ for some constant $q > 1$. Clearly the basis of the induction is true at the beginning of the first round since there are exactly $\log N$ packets sent by each row in stage 0 and received by each row in stage 3. The expected number of copies that are sent from a row in stage 0 or that are destined for a row in stage 4 that do not get through is at most $2q \log N/5$. The value of q is chosen such that the probability that more than $q \log N/2$ copies do not get through in any row can be shown to be small, i.e., at most $1/AN^{k+2}$, for any constants A and k, using Chernoff-type bounds. At the beginning of the next stage, each unsent copy is duplicated and hence, with high probability, the number of packets in any row in the next round is at most $q \log N$. Since there are $(A \log\log N)+1$ rounds, the probability that the inductive hypothesis does not hold in the beginning of any one round is at most $((A \log\log N) + 1)/AN^{k+2}$, which is less than $1/N^{k+1}$.

Now we assume that the inductive hypothesis is true and show that each round takes only $B \log N$ steps, for some constant B, with high probability. Consider any round i. From the inductive hypothesis, the congestion of any node in stage 0 or 3 is at most $q \log N$ which is $O(\log N)$. In stage 1, a node at level l can receive packets from any one of 2^l input nodes, each packet with probability 2^{-l}. The total number of packets that pass through an input node is at most $q \log N$ by our inductive hypothesis. Therefore, the expected number of packets that pass through a node at level l is $q \log N 2^l 2^{-l} = q \log N$. The value of q is chosen so that the probability that

any node gets more than $2q \log N$ packets can be shown to be at most $1/AN^{k+2}$, using Chernoff-type bounds. The analysis for stage 2 is similar. Thus we have shown that if the inductive hypothesis is true, the congestion of any node is $O(\log N)$ with high probability. Therefore, using the algorithm for routing on leveled networks [29] to schedule the packets, the routing completes in $C \log N$ steps with probability at least $1-2/AN^{k+2}$ for an appropriate constant C. The ACKs follow the paths of the packets in the reverse direction. Therefore, the congestion in any node due to ACKs can be no larger than the congestion due to packets and is also therefore $O(\log N)$. Since we are using the algorithm for routing on leveled networks to schedule the packets, the probability that some ACK does not reach its destination in $D \log N$ time is also at most $2/AN^{k+2}$ for some suitably large constant D. We choose the constant B in the algorithm to be at least $C + D$ so that the algorithm waits long enough for both the packet routing and the routing of ACKs to finish before starting the next round of routing. The probability that either the packet routing or the ACK routing fails to complete in some round is at most $4A \log \log N/AN^{k+2}$, which is less than $1/N^{k+1}$.

The probability that either some packet remains untransmitted after the last round or that the inductive hypothesis does not hold for some round or that some round fails to complete in $B \log N$ steps is at most $3/N^{k+1}$, which is less than $1/N^k$. Thus, the algorithm successfully routes every packet to its destination in $O(\log N \log \log N)$ steps with probability at least $1 - 1/N^k$. □

If the number of worst-case faults is smaller then there is a simpler way of routing in $O(\log N)$ steps without using routing tables or creating duplicate packets.

THEOREM 3.1.5. *Given an N-input butterfly with $N^{1-\epsilon}$ worst-case faults (for any constant $\epsilon > 0$), it is possible to identify $N - o(N)$ good rows in the butterfly such that any permutation routing problem on the good nodes can be routed in $O(\log N)$ steps using constant-size queues with probability greater than $1 - 1/N^k$, for any fixed constant k, without using routing tables.*

Proof. We define the "good" nodes in the butterfly as follows. A row is good if it contains no faults and the input in that row can reach all but $N^{1-\epsilon/2}$ middle nodes. (Previously a good input was required to reach all but $N/5$ middle nodes.) Using Lemma 3.1.1 with $f = N^{1-\epsilon}$ and $t = N^{1-\epsilon/2}$, we see that the number of good rows is least $N - N^{1-\epsilon/2}$. The algorithm is the same as the previous algorithm except that we don't create any duplicate packets and we now need only a constant number of routing rounds with high probability. This is because each unsent packet at each round has probability at most $\Theta(1/N^{\epsilon/2})$ of hitting a fault. Therefore, it is sufficient to have $\Theta(k/\epsilon)$ rounds (a constant) before every packet is delivered, with probability at least $1 - 1/N^k$. □

3.2. Fault-tolerant circuit switching. In this section, we examine the ability of the Beneš network to establish disjoint paths between its inputs and outputs when some of its switches fail. We assume that no path can pass through a faulty switch. The main result of this section is a proof that for arbitrarily small positive constants ϵ and δ, there is a constant b such that given a b-dilated $(\log N)$-dimensional Beneš network with $f = N^{1-\epsilon}$ worst-case switch failures, we can identify a set of $N - 4N^{1-\delta}$ input and output switches such that it is possible to route edge-disjoint paths in any permutation between the corresponding input and output edges. (A *b-dilated* Beneš network is one in which each edge is replaced by b parallel edges, and each 2×2 switch is replaced by a $2b \times 2b$ switch.) At each input switch, two of the b incoming edges are used as inputs, and at each output switch, two of the b outgoing edges are used as outputs.

In a $(\log N)$-dimensional Beneš network, levels 1 through $2\log N-1$ can be decomposed into two disjoint sub-Beneš networks of dimension $\log N - 1$, a top sub-Beneš network, and a bottom sub-Beneš network. Note that the two paths that originate from input edges that share an input switch cannot use the same sub-Beneš network. The same is true for paths that end on output edges that share the same output switch. A full permutation consists of a set of $2N$ input–output pairs to be connected by edge-disjoint paths. The standard algorithm for setting the switches in a Beneš network, due to Waksman [55], uses bipartite graph matching to split the set of $2N$ pairs into two sets of N pairs which are then each routed recursively in one of the smaller sub-Beneš networks.

We now present Waksman's algorithm with a twist. We call this algorithm RANDSET (for RANDom switch SETting). The way RANDSET differs from Waksman's algorithm is that it randomly chooses which of the two sets of N pairs to route through the top (and bottom) sub-Beneš network. The input to RANDSET is a permutation ϕ represented as a $2N \times 2N$ bipartite graph. The nodes of the graph represent the $2N$ input edges and the $2N$ output edges of the network. An edge in the bipartite graph from input i to output $\phi(i)$ indicates that a path must be routed from i to $\phi(i)$ in the network. The first step is to merge pairs of nodes in the bipartite graph that correspond to input edges (or output edges) that share the same input switch (or output switch). The result is a 2-regular $N \times N$ bipartite graph. The second step is to split the edges of this graph into two perfect matchings, M_0 and M_1. (See [42] for a nice proof that such a split is possible.) Next, we pick a binary value for random variable X at random. If $X = 0$ then we recursively route the paths in matching M_0 through the top sub-Beneš network and those in M_1 through the bottom sub-Beneš network. If $X = 1$ we do the opposite. The following lemma shows that RANDSET chooses the path from i to $\phi(i)$ uniformly from among all possible paths.

LEMMA 3.2.1. *For any i, the path chosen by algorithm RANDSET between input i and output $\phi(i)$ in a $2N$-input Beneš network passes through any of the N middle switches (switches in level $\log N$) with equal probability $(1/N)$.*

Proof. At the first stage, the path from i to $\phi(i)$ goes to the top or the bottom sub-Beneš network with probability $1/2$ depending on whether the matching that contains the edge corresponding to this input–output pair is chosen to be routed through the top or the bottom. The decisions made at the succeeding levels of the recursion are similar and independent of all other decisions. □

It is important to remember that given a permutation, the *paths themselves could be highly correlated* and determining one path gives some information about the others.

We classify the input and output switches of the Beneš network as either good or bad depending on whether they can reach a sufficiently large number of middle switches. In a fault-free Beneš network, there is a path from each input (and output) switch to each of the N middle switches. The middle switches in fact form the leaves of a complete binary tree with the input (or output) switch as the root. The faults could make some of these paths unusable. We declare an input (or output) switch *bad* if the number of middle switches that it cannot reach exceeds a certain threshold. The threshold is chosen so that it is possible to establish edge-disjoint paths between the *good* (i.e., not bad) inputs and outputs in any permutation. (The two inputs coming into an input (or output) switch are good or bad depending on whether the corresponding input (or output) switch is good or bad.)

Let $BAD(t)$ be the set of input and output switches for which more than t middle switches are unreachable. The first and last $\log N + 1$ levels of the Beneš network each

form a $\log N$-dimensional butterfly. Applying Lemma 3.1.1 to each of these butterflies separately, we know that $|BAD(t)| < 2fN/t$. (Note that these butterflies share the middle level of switches and hence might share some faults.)

THEOREM 3.2.2. *For any constants $0 < \delta < \epsilon \leq 1$, there exists a constant $b = \lceil 1 + (2-\epsilon)/(\epsilon - \delta) \rceil$ such that a $2N$-input b-dilated Beneš network with $N^{1-\epsilon}$ worst-case switch faults has a set of $N - 4N^{1-\delta}$ input switches and output switches between whose input and output edges it is possible to route any permutation using edge-disjoint paths.*

Proof. We declare any input or output switch in $BAD(N^{1+\delta-\epsilon}/2)$ to be bad. Since we need the number of good input switches and good output switches to be equal we may have to declare some extra input switches or output switches to be bad. From Lemma 3.1.1, we know that $|BAD(N^{1+\delta-\epsilon}/2)| \leq 4N^{1-\delta}$. Thus, the number of good input switches (or output switches) is at least $N - 4N^{1-\delta}$.

We now prove that we can route any permutation between the good inputs and good outputs using edge-disjoint paths. In this proof, we simply show that for every permutation such a set of paths *exists*, without showing how to compute these paths efficiently. Later, we give an efficient procedure for computing these paths.

Given a permutation ϕ on the good inputs and outputs, we select paths using RANDSET in b rounds. In the first round, we route all the paths using RANDSET. Some of these paths pass through faults in the network. The number of paths that pass through faults is at most $2N^{1-\epsilon}$, since each fault appears on at most two paths. These paths are not permissible and must be rerouted in the second round using RANDSET. Note that every good input switch (or output switch) has at most $N^{1+\delta-\epsilon}/2$ unreachable middle switches. Thus, from Lemma 3.2.1, the probability that any one of the paths hits a fault in the first $\log N + 1$ levels is at most $N^{-(\epsilon-\delta)}/2$. The probability that it hits a fault in the second $\log N + 1$ levels is also at most $N^{-(\epsilon-\delta)}/2$. The net probability that the path hits a fault is at most $N^{-(\epsilon-\delta)}$. Even though the probabilities that any two paths hit a fault is correlated, the expected number of paths that hit faults in the second round is at most $2N^{1-\epsilon}N^{-(\epsilon-\delta)}$. This implies that with nonzero probability RANDSET finds a set of paths such that at most $2N^{1-\epsilon-(\epsilon-\delta)}$ paths hit faults. Note that this also means that there *exists* a way of selecting the paths so that at most $2N^{1-\epsilon-(\epsilon-\delta)}$ paths hit faults. We select paths such that this criterion is satisfied and route the paths that hit faults again using RANDSET. We continue to do the rerouting until the expected number of paths that hit faults drops below 1. At this point, with nonzero probability RANDSET routes all of the paths without hitting any faults. In particular, such a set of paths exists. The expected number of paths that hit faults in the ith round is $2N^{1-\epsilon-(i-1)(\epsilon-\delta)}$. Thus, for $b = \lceil 1 + (2-\epsilon)/(\epsilon-\delta) \rceil$ the number of paths that hit faults at the end of the bth round is less than 1. Therefore, all paths are routed by the end of the bth round. Since we use at most b rounds of routing and since each edge of the Beneš network has been replaced by b edges, we obtain edge-disjoint paths for the permutation. □

3.2.1. Derandomizing RANDSET. In the proof of Theorem 3.2.2, we show the existence of edge-disjoint paths by using the fact that algorithm RANDSET finds them with nonzero probability. In this section we construct a deterministic algorithm that finds these paths using the technique due to Raghavan [45] and Spencer [50] to remove the randomness. Like Waksman's algorithm for finding the switch settings in a fault-free Beneš network with N input switches, the algorithm runs in $O(N \log N)$ time.

Let P be the random variable that denotes the number of paths that go through

faults at some round of rerouting. Let X be the binary random variable used by RANDSET to make its random decision to select which matching is to be routed through which sub-Beneš network. Let us further define two random variables P_l and P_r to denote the number of paths that RANDSET routes through faults in the left butterfly and the right butterfly, respectively. Let $U(P)$ be an upper bound on $E(P)$ that is defined as $U(P) = E(P_l) + E(P_r)$. In the proof of Theorem 3.2.2, we used the fact that with nonzero probability RANDSET finds a set of paths in which at most $U(P)$ paths hit faults. We define an algorithm DSET (for deterministic switch SETting) that deterministically finds such a set of paths. Algorithm DSET is the same as RANDSET except that instead of selecting a random value for X, we select the "better" choice for X as follows. We compute $U(P|(X = i)) = E(P_l|(X = i)) + E(P_r|(X = i))$ for $i = \{0, 1\}$. We then choose X to be the value of i that yields the minimum of the two values computed above.

THEOREM 3.2.3. *Given a (partial) permutation ϕ to be routed, algorithm DSET deterministically computes paths such that at most $U(P)$ paths hit faults, and DSET has the same asymptotic running time as RANDSET.*

Proof. We prove the theorem by induction on the size of the Beneš network. The base case is trivial. Now consider a $2N$-input Beneš network with a (partial) permutation ϕ to route. Let P_f and P_e denote the number of paths that hit faults in the first and last levels of the Beneš network, respectively. Also, let P_t and P_b denote the number of paths that hit faults in the top and bottom sub-Beneš networks (but not in the first or last levels of the Beneš network), let $P_{t,l}$ and $P_{t,r}$ denote the number of paths that hit faults in the left and right halves of the top sub-Beneš network, and let $P_{b,l}$ and $P_{b,r}$ denote the number of paths that hit faults in the left and right halves of the bottom sub-Beneš network. Finally, let i be the value chosen for X in step 2 of DSET. The total number of paths that hit faults P is bounded as follows:

$$P \le P_f + U(P_t|(X = i)) + U(P_b|(X = i)) + P_e \tag{3.1}$$

$$= P_f + E(P_{t,l}|(X = i)) + E(P_{t,r}|(X = i)) + E(P_{b,l}|(X = i)) + E(P_{b,r}|(X = i)) + P_e \tag{3.2}$$

$$= E(P_l|(X = i)) + E(P_r|(X = i)) \tag{3.3}$$

$$= U(P|(X = i)) \tag{3.4}$$

$$\le U(P). \tag{3.5}$$

These inequalities have the following explanation. Independent of the choice of i, P_f paths are blocked at the first level and P_e are blocked at the last. Once i is chosen, we know by induction that at most $U(P_t|(X = i))$ paths are blocked in the top sub-Beneš network and at most $U(P_b|(X = i))$ are blocked in the bottom sub-Beneš network. Hence inequality (3.1) holds. Equation (3.2) is derived by substituting the definitions of $U(P_t|(X = i))$ and $U(P_b|(X = i))$. Equation (3.3) is derived by observing that

$$E(P_l|(X = i)) = P_f + E(P_{t,l}|(X = i)) + E(P_{b,l}|(X = i))$$

and

$$E(P_r|(X = i)) = P_e + E(P_{t,r}|(X = i)) + E(P_{b,r}|(X = i)).$$

Equation (3.4) follows from the definition of $U(P|(X = i))$. Finally, (3.5) holds by the choice of i.

Now we deal with the question of how fast $U(P|(X = i))$ can be calculated in step 2 of DSET for $i \in \{0, 1\}$. For every switch m in the Beneš network, let $REACH(m)$ be the set of middle switches reachable from switch m using fault-free paths. We can precompute $|REACH(m)|$ as follows. The value for the middle switches are trivially known. We then compute the values for levels on both sides adjacent to levels where the values are known and continue in this manner. This takes only $O(N \log N)$ steps of precomputation and does not affect the asymptotic time complexity of the algorithm. Given the values of $|REACH(m)|$, the values of $U(P|(X = i))$ can be easily calculated by summing up the appropriate values of $|REACH(m)|$. This is an $O(N)$ time computation. Since step 1 of the algorithm takes N time just to set N switches in the first level, this does not affect the asymptotic time complexity. Hence using DSET yields the same asymptotic time complexity as RANDSET and takes time linear in the size of the Beneš network. □

4. Emulations on faulty butterflies. In this section, we show that for any constant $\epsilon > 0$, a $(\log N)$-dimensional butterfly with $N^{1-\epsilon}$ worst-case faults (the host H) can emulate any computation of a fault-free $(\log N)$-dimensional butterfly (the guest G) with only constant slowdown. We assume that a faulty node cannot perform computations and that packets cannot route through faulty nodes. For simplicity we assume that both the guest and host butterflies wrap around; i.e., the nodes of level 0 are identified with the nodes of level $\log N$.

We model the emulation of G by H as a pebbling process. There are two kinds of pebbles. With every node v of G and every time step t, we associate a *state pebble* (s-pebble) $\langle v, t\rangle$ that contains the entire state of the computation performed at node v at time t. The s-pebble contains local memory values, registers, stacks, and anything else that is required to continue the computation at v. We view G as a directed graph by replacing each undirected edge between nodes u and v by two directed edges: one from u to v and the other from v to u. With each directed edge e and every time step t, we associate a *communication pebble* (c-pebble) $[e, t]$ that contains the message transmitted along edge e at time step t.

The host H emulates each step t of G by creating an s-pebble $\langle v, t\rangle$ for each node v of G and a c-pebble $[e, t]$ for each edge e of G. A node of H can create an s-pebble $\langle v, t\rangle$ only if contains s-pebble $\langle v, t-1\rangle$ and all of the c-pebbles $[e, t-1]$, where e is an edge into v. It can create a c-pebble $[g, t]$ for an edge g out of v only if it contains an s-pebble $\langle v, t\rangle$. A node of H can also transmit a c-pebble to a neighboring node of H in unit time. A node of H is not permitted to transmit an s-pebble since an s-pebble may contain a lot of information. Note that H can create more than one copy of an s-pebble or c-pebble. The ability of H to create redundant pebbles is crucial to our emulation schemes. In our emulations, each node of H is assigned a fixed set of nodes of G to emulate and creates s-pebbles for them for each time step.

4.1. Assignment of nodes of G to nodes of H. We now show how to map the computation of G to the faulty butterfly H. The host H has $N^{1-\epsilon}$ arbitrarily distributed faults. We first divide H into subbutterflies of dimension $(\epsilon \log N)/2$ spanning levels $(i\epsilon \log N)/2$ through $((i + 1)\epsilon \log N)/2$ for integer $i = 0$ to $2/\epsilon - 1$. (Without loss of generality, we assume that $2/\epsilon$ and $\epsilon \log N/4$ are integers.) Note that every input node of a subbutterfly is also an output node of another subbutterfly and vice versa. Each band of $((\epsilon \log N)/2) + 1$ levels consists of $N^{1-\epsilon/2}$ disjoint subbutterflies. Thus, there are a total of $(2/\epsilon)N^{1-\epsilon/2}$ subbutterflies. The faults in the network may make some of these subbutterflies unusable. We identify "good" and "bad" subbutterflies according to the following rules.

Rule 1. A subbutterfly that contains a node that lies in a butterfly row in which there is a fault is a *bad* subbutterfly (even if the fault lies outside of the subbutterfly).

Rule 2. In order to apply Rule 2, we embed a Beneš network in the butterfly. The edges of the first stage of the Beneš network traverse the butterfly in increasing order of dimension and the edges of the second stage in decreasing order of dimension. The input switches, the middle switches, and the output switches of the Beneš network are all embedded in level 0 of the butterfly (which is the same as level $\log N$). For $\delta = 2\epsilon/3$, identify the set of bad inputs/outputs (they are the same set here) according to the procedure outlined in the proof of Theorem 3.2.2 in section 3.2. Any subbutterfly that contains a node that has a bad input/output at the end of its butterfly row is a bad subbutterfly.

LEMMA 4.1.1. *For any $\epsilon > 0$, the number of rows in which there is either a fault or a bad input or output is at most $N^{1-\epsilon} + 4N^{1-2\epsilon/3}$.*

Proof. The number of rows containing a fault is at most $N^{1-\epsilon}$, since there are at most $N^{1-\epsilon}$ faults. By Theorem 3.2.2, for $\delta = 2\epsilon/3$, the number of bad inputs and outputs (they are the same nodes) is at most $4N^{1-\delta} = 4N^{1-2\epsilon/3}$. □

LEMMA 4.1.2. *For any $\epsilon > 0$, at least half the subbutterflies of H are good for sufficiently large N.*

Proof. The total number of subbutterflies is $(2/\epsilon)N^{1-\epsilon/2}$. By Lemma 4.1.1, the number of rows containing either a fault or a bad input or output is at most $N^{1-\epsilon} + 4N^{1-2\epsilon/3}$. Since each bad row passes through $2/\epsilon$ different subbutterflies, the total number of subbutterflies identified as bad by Rules 1 and 2 cannot exceed $2(N^{1-\epsilon}+4N^{1-2\epsilon/3})/\epsilon$. Observe that $2(N^{1-\epsilon}+4N^{1-2\epsilon/3})/\epsilon \leq N^{1-\epsilon/2}/\epsilon$ for sufficiently large N. □

Now we divide the guest G into overlapping subbutterflies of dimension $(\epsilon \log N)/2$ and map them to the good subbutterflies of H. For any node v of G, at most three nodes of H receive the initial state of the computation of node v, i.e., s-pebble $\langle v, 0\rangle$. (A node v of G can appear as an input in one subbutterfly, an output in another, and a middle node in a third.) These nodes in H create the s-pebbles for v. The mapping proceeds as follows. Take the guest G and cut it into subbutterflies at levels $i\epsilon \log N/2$ for integers $i = 0$ to $2/\epsilon - 1$. Map each subbutterfly to a good subbutterfly of H so that each subbutterfly of H gets at most two subbutterflies of G. Now cut G again, this time at levels $(\epsilon/4 + i\epsilon/2)\log N$ for integers $i = 0$ to $2/\epsilon - 1$. Map the subbutterflies to good subbutterflies of H as before. At most eight nodes of G are mapped to each node of H.

4.2. Building constant congestion paths. We call the nodes v of G belonging to level $i\epsilon \log N/4$, for $i = 0$ to $4/\epsilon - 1$, *boundary nodes* since they lie on the boundary of some subbutterfly of G. Let the set of boundary nodes of G be denoted by $\mathcal{B}_\mathcal{G}$. Similarly we define the nodes in the levels where H was cut to form subbutterflies, i.e., level $i\epsilon \log N/2$ for $i = 0$ to $2/\epsilon - 1$, the boundary nodes of H. Let us denote this set $\mathcal{B}_\mathcal{H}$.

Let ϕ be the function that maps an s-pebble $\langle v, t\rangle$ to the node in H that creates it. The creation of $\langle v, t\rangle$ requires that node $\phi(\langle v, t\rangle)$ of H gets all the c-pebbles $[e, t]$ from some other node of H for every edge e into v. Suppose that $\langle v, t\rangle$ is mapped to some node $m = \phi(\langle v, t\rangle)$ in the interior (i.e., not on the boundary) of a good subbutterfly of H. Then the neighbors of m in H also create the s-pebbles of the neighbors of v in G. In this case m receives the required c-pebbles from its neighbors in H.

On the other hand, if the s-pebble for v is mapped to some node $m \in \mathcal{B}_\mathcal{H}$, the neighbors of m in H may not create the s-pebbles of the neighbors of v in G. However,

since every node v of G is mapped to at least two nodes of H, there is another node m' of H that also creates an s-pebble for v. In particular, *m' is necessarily a node in the center of a subbutterfly of H*, i.e., in level $\epsilon \log N/4$ of the subbutterfly. Node m' of H forwards a copy of the c-pebble $[e, t]$ to node m for each of the edges e into v.

To facilitate the transmission of c-pebbles, we use the results of section 3.2 to establish constant-congestion fault-free paths in H between all pairs of nodes m and m' of H that create the s-pebbles for the same node v in $\mathcal{B}_{\mathcal{G}}$. The number of paths originating in a row of H is simply the number of nodes mapped to subbutterfly boundaries in that row, which is at most $8 \cdot 2/\epsilon = 16/\epsilon$, i.e., a constant. Similarly the number of paths ending in any row is $16/\epsilon$. We can divide the paths into $8/\epsilon$ sets such that each set has at most two paths originating in a row and two paths ending in a row. Note that all paths start and end in rows that have good inputs and outputs for doing Beneš-type routing. Therefore, each set can be routed with dilation $4 \log N$ and with congestion $O(1)$ using the results of section 3.2. Since there are only a constant number of such sets the total congestion is also a constant.

4.3. The emulation. We now formally describe the emulation and prove its properties. Initially, nodes of H contain s-pebbles $\langle v, 0\rangle$ for nodes v of G. We say that H has emulated T steps of the computation of G if and only if for every node v of G, an s-pebble $\langle v, T\rangle$ has been created somewhere in H. The emulation algorithm is executed by every node m of H and proceeds as a sequence of macrosteps. Each macrostep consists of the following four substeps.

1. *Computation step.* For each node v of G that has been assigned to m, if m contains an s-pebble $\langle v, t-1\rangle$ and c-pebbles $[e, t-1]$ for every edge e into v and m has not already created an s-pebble $\langle v, t\rangle$, then it does so.
2. *Communication step.* For each node v whose s-pebble was updated from $\langle v, t-1\rangle$ to $\langle v, t\rangle$ in the computation step and for each edge g from v to a neighbor u of v, node m sends a c-pebble $[g, t]$ to its neighbor in H that creates s-pebbles for u (if such a neighbor exists).
3. *Routing step.* If m has any c-pebble that was created on the previous copy step or that was received on the previous routing step but whose final destination is not m, then m forwards the c-pebble to the next node on the pebble's path to its destination.
4. *Copy step.* If m is a node in the center level (level $\epsilon \log N/4$ in the subbutterfly) and in the communication step m received a c-pebble $[e, t]$ for an edge e into a node v that has been assigned to m, then m makes two copies of the c-pebble, one for each of the two nodes m' and m'' that also create s-pebbles for v. On the next routing step, m forwards each copy to the next node on the path from m to m' or m''.

LEMMA 4.3.1. *Each macrostep takes only a constant number of time steps to execute.*

Proof. At most eight s-pebbles mapped are to each node. Therefore, the computation step takes constant time. Every s-pebble that is updated can cause at most four c-pebbles to be sent in the communication step. Therefore, the communication step takes only constant time. Since only a constant number of paths passes through any node, only a constant number of c-pebbles enters a particular path at any macrostep, and every c-pebble that has not yet reached its destination moves in every macrostep, the number of c-pebbles entering any node during any macrostep is at most a constant. Thus, the routing step and the copy step both take only a constant number of time steps. □

THEOREM 4.3.2. *Any computation on a fault-free butterfly G that takes time T can be emulated in time $O(T + \log N)$ by H.*

Proof. We show that only $O(T + \log N)$ macrosteps are required to emulate a T-step computation of G. The final result then follows from Lemma 4.3.1.

The *dependency tree* of an s-pebble represents the functional dependency of this s-pebble on other s-pebbles and can be defined recursively as follows. As the base case, if $t = 0$, the dependency tree of $\langle v, t\rangle$ is a single node $\langle v, 0\rangle$. If $t > 0$, the creation of s-pebble $\langle v, t\rangle$ requires s-pebble $\langle v, t-1\rangle$ and a c-pebble $[e, t-1]$ for each edge e into node v in G. Each c-pebble is sent by an s-pebble $\langle u, t-1\rangle$ where u is a neighbor of v in G. The dependency tree of $\langle v, t\rangle$ is defined recursively as follows. The root of the tree is $\langle v, t\rangle$ and the subtrees of the root are the dependency trees of $\langle v, t-1\rangle$ and all s-pebbles $\langle u, t-1\rangle$.

Let the emulation of T steps of G take T' macrosteps on H. Let $\langle v, T\rangle$ be an s-pebble that was updated in the last macrostep. We now look at the dependency tree of $\langle v, T\rangle$. We choose a *critical path*, $s_T, s_{T-1}, \ldots, s_0$, of tree nodes from the root to the leaves of the tree as follows. The first node on the path s_T is $\langle v, T\rangle$. Let ϕ be the function that maps an s-pebble $\langle v, t\rangle$ to the node in H that creates it. The creation of s_T requires the s-pebble $\langle v, T-1\rangle$ and c-pebbles $[e, T-1]$. If the s-pebble $\langle v, T-1\rangle$ was created after all the c-pebbles were received then choose s_{T-1} to be $\langle v, T-1\rangle$. Otherwise, choose the s-pebble that sent the c-pebble that arrived last at node $\phi(\langle v, T\rangle)$. After choosing s_{T-1}, we choose the rest of the sequence recursively in the subtree with s_{T-1} as the root. The last s-pebble on the path s_0 is one that was present initially, i.e., at time step 0. We define a quantity l_i as follows. If $\phi(s_i)$ and $\phi(s_{i-1})$ are the same node or neighbors in H, then $l_i = 1$. Otherwise, l_i is the length of the path by which a c-pebble generated by s_{i-1} is sent to s_i. For every tree node s, we can associate a time (in macrosteps) $\tau(s)$ when that s-pebble was created. From the definition of our critical path and because a c-pebble moves once in every macrostep, $\tau(s_i) - \tau(s_{i-1}) = l_i$. Thus,

$$T' = \sum_{0<i\le T} (\tau(s_i) - \tau(s_{i-1})) = \sum_{0<i\le T} l_i.$$

Now suppose that some l_i is greater than one. This corresponds to a long path taken by some c-pebble to go from $\phi(s_{i-1})$ in the center level of a subbutterfly of H to $\phi(s_i)$ in $\mathcal{B}_{\mathcal{H}}$. Thus l_i is the length of one of the constant congestion paths and is at most $(4 \log N)+1$. (In fact, the paths are somewhat shorter, but $(4 \log N)+1$ is a convenient quantity to work with.) The key observation is that since $\phi(s_{i-1})$ is a node in the center level, working down the tree from s_{i-1} there can be no long paths until we reach an s-pebble mapped to the boundary $\mathcal{B}_{\mathcal{H}}$; i.e., $l_{i-j} = 1$ for $1 \le j \le (\epsilon \log N)/4 - 1$. Thus, the extra path length of $4 \log N$ can be amortized over $(\epsilon \log N)/4$ s-pebbles. Hence, $T' = \sum_{0<i\le T} l_i \le (16/\epsilon + 1)T + 4 \log N + 1 = O(T + \log N)$. □

We can extend these results to the shuffle-exchange network using Schwabe's proof [26, 47] that an N-node butterfly can emulate an N-node shuffle-exchange network with constant slowdown, and vice versa.

THEOREM 4.3.3. *Any computation on a fault-free N-node shuffle-exchange network G that takes time T can be emulated in $O(T + \log N)$ time by an N-node shuffle-exchange network H with $N^{1-\epsilon}$ worst-case faults for any constant $\epsilon > 0$.*

Proof. Schwabe [26, 47] shows how to emulate any computation of a butterfly on a shuffle-exchange network with constant slowdown and vice versa. First we use Schwabe's result to map the computation of a butterfly B to the faulty shuffle-exchange network H. Any node of B that is mapped to a faulty node of H is declared

faulty. If there are any routing paths required by the emulation that pass through a faulty node of H, we declare the nodes of B that use this path to be faulty. The faulty nodes of B do no computation, and H is not required to emulate them. Hence, the faulty shuffle-exchange network H can emulate the faulty butterfly network B with constant slowdown. The number of faults in B is only a constant factor larger than $N^{1-\epsilon}$, since both the load and the congestion of the paths used in Schwabe's emulation are constant. Now we use Theorem 4.3.2 to emulate a fault-free butterfly B' on B. Finally, use Schwabe's result (in the other direction) to emulate the fault-free shuffle-exchange network G on the fault-free butterfly B'. Each of these emulations has constant slowdown. Therefore, the entire emulation of G on H has constant slowdown. □

4.4. Emulating normal algorithms on the hypercube. Many practical computations on the hypercube are structured. The class of algorithms in which every node of the hypercube uses exactly one edge for communication at every time step and all of the edges used in a time step belong to the same dimension of the hypercube are called *leveled algorithms* (also known as *regular algorithms* [13]). A useful subclass of leveled algorithms are *normal algorithms*. A normal algorithm has the additional restriction that the dimensions used in consecutive time steps are consecutive. Many algorithms including bitonic sort, FFT, and tree-based algorithms like branch-and-bound can be implemented on the hypercube as normal algorithms [27]. An additional property of normal algorithms is that they can be emulated efficiently by bounded-degree networks such as the shuffle-exchange network and the butterfly. We state a result due to Schwabe [48] to this effect.

LEMMA 4.4.1. *An N-node butterfly can emulate any normal algorithm of an N-node hypercube with constant slowdown.*

We also require the following well-known result concerning the embedding of a butterfly in a hypercube. (See [20] for the stronger result that the butterfly is a subgraph of the hypercube.)

LEMMA 4.4.2. *An N-node butterfly can be embedded in an N-node hypercube with constant load, congestion, and dilation.*

THEOREM 4.4.3. *An N-node hypercube with $N^{1-\epsilon}$ worst-case faults (for any $\epsilon > 0$) can emulate T steps of any normal algorithm on an N-node fault-free hypercube in $O(T + \log N)$ steps.*

Proof. Let the faulty N-node hypercube be H and the fault-free N-node hypercube be G. H emulates any normal algorithm of G by using a sequence of constant slowdown emulations. Let an N-node butterfly B be embedded in H in the manner of Lemma 4.4.2. Any node of B that is mapped to a faulty node of H is considered faulty. (And H is not required to emulate these faulty nodes.) Since this is a constant load embedding, the number of faulty nodes in B is $O(N^{1-\epsilon})$. Clearly, H can emulate any computation of B with constant slowdown using the constant load, congestion, and dilation embedding of B in H. Let B' be a fault-free N-node butterfly. From Theorem 4.3.2, B can emulate B' with a constant slowdown. Now, from Lemma 4.4.1, B' can emulate any normal algorithm of G with a constant slowdown. Putting all these emulations together, we obtain a constant slowdown emulation of any normal algorithm on G on the faulty hypercube H. □

5. Random faults. In this section we show that an N-input host butterfly H can sustain many random faults and still emulate a fault-free N-input guest butterfly G with little slowdown. In particular, we show that if each node in H fails independently with probability $p = 1/\log^{(k)} N$, where $\log^{(k)}$ denotes the logarithm function

iterated k times, the slowdown of the emulation is $2^{O(k)}$, with high probability. For any constant k this slowdown is constant. Furthermore, for $k = O(\log^* N)$ the node failure probability p is constant, and the slowdown is $2^{O(\log^* N)}$. Previously, the most efficient self-emulation scheme known for an N-input butterfly required $\omega(\log \log N)$ slowdown [51].

The proof has the following outline. We begin by showing that the host H can emulate another N-input butterfly network B_k with constant slowdown. As in H, some of the nodes in B_k may fail at random (in which case it is not necessary for H to emulate them), but B_k is likely to contain fewer faults than H. In turn, B_k can emulate another butterfly B_{k-1} with even fewer faults. Continuing in this fashion, we arrive at B_1, which, with high probability, contains so few faults that it can emulate the guest G with constant slowdown. There are $k+1$ emulations, and each incurs a constant factor slowdown, so the total slowdown is $2^{O(k)}$.

5.1. Emulating a butterfly with fewer faults. We begin by explaining how H emulates B_k. The first step is to cover the N-input butterfly B_k with overlapping $(\log^{(k)} N)^2$-input subbutterflies. For ease of notation, let $M_k = (\log^{(k)} N)^2$. (For simplicity, we assume that $\log M_k$ is an integral multiple of 4.) For each i from 0 to $4(\log N/\log M_k) - 4$, there is a band of disjoint M_k-input subbutterflies spanning levels $(i \log M_k)/4$ through $((i+4)\log M_k)/4$. We call these subbutterflies the *band* i subbutterflies. Note that each band i subbutterfly shares $M_k^{3/4}$ rows with $M_k^{1/4}$ different band $i-1$ subbutterflies and $M_k^{3/4}$ rows with $M_k^{1/4}$ different band $i+1$ subbutterflies.

Each M_k-input subbutterfly in B_k is emulated by the corresponding subbutterfly in H. We say that an M_k-input subbutterfly in B_k *fails* if more than $\alpha\sqrt{M_k}\log M_k$ nodes inside the corresponding M_k-input subbutterfly in H fail, where α is a constant that will be determined later. If a subbutterfly in B_k fails, then H is not required to emulate any of the nodes that lie in that subbutterfly. As we shall see, if it does not fail, then the corresponding subbutterfly in H contains few enough faults that we can treat them as worst-case faults and apply the technique from section 4 to reconfigure around them. The following lemma bounds the probability that a subbutterfly in B_k fails.

LEMMA 5.1.1. *For $\alpha > 4e$, an M_k-input subbutterfly in B_k fails with probability at most $1/\log^{(k-1)} N$.*

Proof. An M_k-input subbutterfly fails if the corresponding M_k-input subbutterfly in H contains too many faults. An M_k-input subbutterfly in H contains a total of $M_k(1+\log M_k) \le 4(\log^{(k)} N)^2(\log^{(k+1)} N)$ nodes, each of which fails with probability $1/\log^{(k)} N = 1/\sqrt{M_k}$. Thus, the expected number of nodes that fail is at most $2\sqrt{M_k}\log M_k = 4(\log^{(k)} N)(\log^{(k+1)} N)$. Since each node fails independently, we can bound the probability that more than $\alpha\sqrt{M_k}\log M_k$ nodes fail using a Chernoff-type bound. For $\alpha > 4e$, the probability that more than $\alpha\sqrt{M_k}\log M_k$ nodes fail is at most $2^{-\alpha\sqrt{M_k}\log M_k}$ (for a proof, see [46]). Since $\alpha\sqrt{M_k}\log M_k > \log^{(k)} N$, this probability is at most $2^{-\log^{(k)} N} = 1/\log^{(k-1)} N$. □

The next lemma shows that if a subbutterfly in B_k does not fail, then the corresponding subbutterfly in H can emulate it with constant slowdown.

LEMMA 5.1.2. *If an M_k-input subbutterfly in B_k does not fail, then the corresponding subbutterfly in H can emulate it with constant slowdown.*

Proof. Since the number of faults in an M_k-input subbutterfly that does not fail is most $\alpha\sqrt{M_k}\log M_k$, we can treat them as worst-case faults and apply Theorem 4.3.2 with $\epsilon \approx 1/2$. □

The next lemma shows that the host H can emulate any computation performed by an N-input butterfly network B_k with constant slowdown. Recall that H is not required to emulate nodes in B_k that lie in subbutterflies in B_k that have failed.

LEMMA 5.1.3. *The host H can emulate B_k with constant slowdown.*

Proof. By Lemma 5.1.2, each M_k-input subbutterfly in B_k that has not failed can be emulated by the corresponding subbutterfly in H with constant slowdown using the technique of section 4. (Note that each node in B_k may be emulated by as many as four different subbutterflies in H.) In order to emulate the entire network B_k, it is also necessary to emulate the connections between the subbutterflies. As in section 4, let $M_k^{1-\epsilon}$ denote the number of faults in an M_k-input subbutterfly of H. For a subbutterfly that has not failed, $\epsilon \approx 1/2$. By Lemma 4.1.1, the number of rows in the subbutterfly containing either a fault or an input or output that is bad for Beneš routing is at most $M_k^{1-\epsilon}/2 + 4M_k^{1-2\epsilon/3}$, which is approximately $4M_k^{2/3}$. Each band i subbutterfly that does not fail shares $M_k^{3/4}$ rows with each of the band $i-1$ subbutterflies (and band $i+1$ subbutterflies) with which it overlaps. Thus, for each pair of overlapping butterflies that do not fail, most of the shared rows are both fault-free and good for routing in both subbutterflies. In order to emulate an M_k-input subbutterfly of H, the emulation strategy of section 4 covers it with smaller subbutterflies, each having $M_k^{\epsilon/2}$ inputs. If a smaller subbutterfly is used in the emulation, then none of the rows that pass through it contain either a fault or a bad input or output. Thus, the $M_k^{3/4}$ connections between each pair of overlapping M_k-input subbutterflies in bands i and $i-1$ can be emulated by routing constant congestion paths of length $O(\log M_k)$ through the shared rows. The rest of the proof is similar to that of Theorem 4.3.2. □

5.2. Emulating a series of butterflies. So far we have shown that the host H can emulate an N-input butterfly B_k that contains some faulty nodes. Although our ultimate goal is to show that H can emulate the guest network G, which contains no faulty nodes, we have made some progress. In the host network H, each node fails independently with probability $1/\log^{(k)} N$. In B_k, each $(\log^{(k)} N)^2$-input subbutterfly fails with probability $1/\log^{(k-1)} N$. A node in B_k fails if it lies in a subbutterfly that fails. Since each node in B_k lies in at most five $(\log^{(k)} N)^2$-input subbutterflies (once as an input, once as an output, and three times as an interior node), we have reduced the expected number of faults from $(N \log N)/\log^{(k)} N$ in H to fewer than $(5N \log N)/\log^{(k-1)} N$ in B_k.

The next step is to show that butterfly B_k can emulate a butterfly B_{k-1} with even fewer faults. In general, we cover butterfly B_j with $(\log^{(j)} N)^2$-input subbutterflies. For ease of notation, let $M_j = (\log^{(j)} N)^2$. We say that an M_j-input subbutterfly in B_j fails if the corresponding M_j-input subbutterfly in B_{j+1} contains more than $\alpha\sqrt{M_j}$ M_{j+1}-input subbutterflies that have failed. The following three lemmas are analogous to Lemmas 5.1.1 through 5.1.3.

LEMMA 5.2.1. *For $\alpha > 8e$, the probability that an M_j-input subbutterfly in B_j fails is at most $1/(\log^{(j-1)} N)$.*

Proof. The proof is by induction on j, starting with $j = k$ and working backward to $j = 0$. The base case is given by Lemma 5.1.1. For each value of i from 0 to $4(\log M_j/\log M_{j+1}) - 4$, there is a band of disjoint M_{j+1}-input subbutterflies in B_{j+1} that span levels $(i \log M_{j+1})/4$ through $((i+4)\log M_{j+1})/4$. These M_{j+1}-input subbutterflies can be partitioned into eight *classes* according to their band numbers.

Two bands of subbutterflies belong to the same class if their band numbers differ by a multiple of eight. There are at most

$$(M_j \log M_j)/(2M_{j+1} \log M_{j+1}) = (\log^{(j)} N)^2/2(\log^{(j+1)} N)(\log^{(j+2)} N)$$

subbutterflies in each of these classes, and within a class the subbutterflies are disjoint. By induction, each subbutterfly fails with probability at most $1/\log^{(j)} N$. Thus, in any particular class, the expected number of subbutterflies that fail is at most $(\log^{(j)} N)/2(\log^{(j+1)} N)(\log^{(j+2)} N)$, which is less than $\log^{(j)} N$. Using Chernoff-type bounds as in Lemma 5.1.1, for $\alpha > 16e$, the probability that more than $(\alpha \log^{(j)} N)/8 = (\alpha\sqrt{M_j})/8$ of these subbutterflies fail is at most $2^{-(\alpha \log^{(j)} N)/8}$, which is less than $1/8 \log^{(j-1)} N$. Thus, the probability that a total of $\alpha \log^{(j)} N$ subbutterflies fail in the eight classes is at most $1/\log^{(j-1)} N$. □

LEMMA 5.2.2. *If an M_j-input subbutterfly in B_j does not fail, then the corresponding M_j-input subbutterfly in B_{j+1} can emulate it with constant slowdown.*

Proof. If an M_j-input subbutterfly does not fail, then at most $\alpha\sqrt{M_j}$ of the overlapping M_{j+1}-input subbutterflies in the corresponding M_j-input subbutterfly in H fail. Each of these subbutterflies contains $M_{j+1}(1+\log M_{j+1}) \leq 4(\log^{(j+1)} N)^2 \log^{(j+2)} N$ nodes. Since the total number of nodes in all of these subbutterflies is at most $4\alpha \log^{(j)} N(\log^{(j+1)} N)^2 \log^{(j+2)} N$, i.e., approximately $\sqrt{M_j}$, we can treat them all as if they were worst-case faults and apply Theorem 4.3.2 with $\epsilon \approx 1/2$. □

LEMMA 5.2.3. *For $1 < j \leq k+1$, butterfly B_j can emulate B_{j-1} with constant slowdown.*

Proof. The proof is similar to the proof of Lemma 5.1.3. □

THEOREM 5.2.4. *For any fixed $\gamma > 0$ with probability at least $1 - 1/2^{N^{1-\gamma}}$, an N-input butterfly in which each node fails with probability $1/\log^{(k)} N$ can emulate a fault-free N-input butterfly with slowdown $2^{O(k)}$.*

Proof. The host network $H = B_{k+1}$ can emulate network B_1 with slowdown $2^{O(k)}$. In B_1, each subbutterfly with $(\log N)^2$ inputs fails with probability $1/\log^{(0)} N = 1/N$. Using Chernoff-type bounds as in Lemma 5.1.1, the probability that more than $N^{1-\gamma}$ of these subbutterflies fail is at most $1/2^{N^{1-\gamma}}$. If fewer than $N^{1-\gamma}$ of them fail, then we can treat the nodes contained in these subbutterflies as if they were worst-case faults. In this case, the total number of worst-case faults is at most $4N^{1-\gamma}(\log N)^2 \log\log N$. Hence, by applying Theorem 4.3.2 with $\epsilon \approx \gamma$, B_1 can emulate the guest network G with constant slowdown. □

6. Open problems. Some of the interesting problems left open by this paper are listed below.

1. Can a butterfly tolerate random faults with constant failure probability and still emulate a fault-free butterfly of the same size with constant slowdown?
2. Can an N-node butterfly (or any other N-node bounded-degree network) tolerate more than $N^{1-\epsilon}$ worst-case faults (e.g., $N/\log N$) and still emulate a fault-free network of the same type and size with constant slowdown?
3. Can a $2N$-input Beneš network tolerate $\Theta(N)$ worst-case switch failures and still route disjoint paths in any permutation between some set of $\Theta(N)$ inputs and outputs?
4. Can an N-input butterfly be embedded with constant load, congestion, and dilation in an N-input butterfly with more than $\log^{O(1)} N$ (e.g., $N^{1-\epsilon}$) worst-case faults?

Acknowledgments. Thanks to Bob Cypher and Joel Friedman for helpful discussions. We are also grateful to Bill Aiello for suggesting that our butterfly results imply results in fault-tolerant emulations of normal algorithms. The third author wishes to thank Bob Tarjan for his support and encouragement.

ON THE COMPLEXITY OF NEGATION-LIMITED BOOLEAN NETWORKS*

ROBERT BEALS†, TETSURO NISHINO‡, AND KEISUKE TANAKA§

Abstract. A theorem of Markov precisely determines the number r of NEGATION gates necessary and sufficient to compute a system of boolean functions F. For a system of boolean functions on n variables, $r \leq b(n) = \lceil \log_2(n+1) \rceil$. We call a circuit using $b(n)$ NEGATION gates *negation-limited*. We continue recent investigations into negation-limited circuit complexity, giving both upper and lower bounds.

A circuit with inputs $x_1, \ldots, x_n$ and outputs $\neg x_1, \ldots, \neg x_n$ is called an *inverter*, for which $r = \lceil \log_2(n+1) \rceil$. Fischer has constructed negation-limited inverters of size $O(n^2 \log n)$ and depth $O(\log n)$. Recently, Tanaka and Nishino have reduced the circuit size to $O(n \log^2 n)$ at the expense of increasing the depth to $\log^2 n$. We construct negation-limited inverters of size $O(n \log n)$, with depth only $O(\log n)$, and we conjecture that this is optimal. We also improve a technique of Valiant for constructing monotone circuits for slice functions (introduced by Berkowitz).

Next, we introduce some lower bound techniques for negation-limited circuits. We provide a $5n + 3\log(n+1) - c$ lower bound for the size of a negation-limited inverter. In addition, we show that for two different restricted classes of circuit, negation-limited inverters require superlinear size.

Key words. circuit complexity, negation-limited circuit, upper bounds, lower bounds

1. Introduction.

1.1. Background. The theory of monotone boolean circuit complexity has met with considerable success [15, 3, 19, 7, 14]. Good lower bounds for both size and depth of monotone circuits (i.e., circuits without NEGATION gates) computing many explicit functions are now known. However, the theory of general boolean circuits, *with* NEGATION gates, is much less well understood. Exponential gaps between monotone and general circuit complexity are known, for both circuit size [19] and circuit depth [14]. The effect of NEGATION gates on circuit complexity remains to a large extent a mystery.

This motivates the study of *negation-limited* circuit complexity: what is the effect on circuit complexity of restricting the number of negations available? Markov [11] gives an explicit formula (see below) for the maximum number r of NEGATION gates *required* to compute a system of boolean functions F, without regard to circuit complexity. The maximum value of r for a circuit with n inputs is $\lceil \log(n+1) \rceil$, the number of bits in the binary representation of n (all logarithms in this paper are base two).

We shall denote this number by $b(n)$. Fischer [8] shows that restricting the number of negations in a circuit to $b(n)$ entails only a polynomial blowup in circuit size. This is in sharp contrast to the situation for monotone circuits. É. Tardos [19] has shown that there is an exponential gap between the general complexity and the monotone complexity of some monotone functions. In related work, Santha and Wilson [16] have studied the negation-limited complexity of constant depth circuits, obtaining both upper and lower bounds for the number of NEGATION gates required by circuits of a given depth.

In a preliminary version of this paper, Tanaka and Nishino [18] have found an alternative to Fischer's construction; they decrease the size of the circuits at the expense of increasing the depth. We further reduce the size, while simultaneously reducing the depth to that of Fischer. We also exhibit a relationship between the negation-limited complexity of the inverter (see below) and the monotone complexity of certain types of monotone functions.

1.2. Definitions and preliminaries. Let F be a collection of boolean functions $f_1, \ldots, f_m$ defined on $\{0,1\}^n$. We denote by $C(F)$ or $C(f_1, \ldots, f_m)$ the *circuit complexity* of F, i.e., the size (number of gates) of the smallest circuit of AND, OR, and NEGATION gates with inputs

$$x_1, \ldots, x_n$$

and outputs

$$f_1(x_1, \ldots, x_n), \ldots, f_m(x_1, \ldots, x_n).$$

We call a circuit with no more than r NEGATION gates an r-circuit. We denote by $C^r(F)$ or $C^r(f_1, \ldots, f_m)$ the size of the smallest r-circuit computing F. If the system of functions cannot be computed with only r NEGATION gates, then $C^r(F)$ is undefined. Similarly, we denote by $D^r(F)$ the minimum *depth* of an r-circuit computing F. The *inverter* is the collection I_n of functions $f_1, \ldots, f_n$, where for all $1 \le i \le n$, $f_i(x_1, \ldots, x_n) = \neg x_i$. For $0 \le k \le n$, the (k,n)-*inverter* is the collection I_n^k of functions $f_1, \ldots, f_n$, where for all $1 \le i \le n$,

$$f_i(x_1, \ldots, x_n) = \begin{cases} 0 & \text{if } \sum_{j=1}^n x_j < k, \\ \neg x_i & \text{if } \sum_{j=1}^n x_j = k, \\ 1 & \text{if } \sum_{j=1}^n x_j > k. \end{cases}$$

Let F be a system of n-input boolean functions. A *chain* C in the boolean lattice $\{0,1\}^n$ is an increasing sequence $a^1 < \cdots < a^k \in \{0,1\}^n$. The *decrease* of F on C is the number of $i \le k$ such that for some j, $f_j(a^{i-1}) > f_j(a^i)$. We define $d(F)$ to be the maximum decrease of F on any chain C. Note that $d(F) \le n$, and this is attained for $F = I_n$. Markov [11] has shown that $b(d(F))$ NEGATION gates are necessary and sufficient to compute any system $f_1, \ldots, f_m$ of functions. Thus, $C^r(F)$ is always defined for $r \ge b(n)$. We call $C^{b(d(F))}(F)$ the *negation-limited* complexity of the system of functions F.

1.3. Main results. We give improved upper bounds and lower bounds on the negation-limited complexity of the inverter.

THEOREM 1.1. *The negation-limited complexity of the inverter I_n is $O(n \log n)$. In fact, I_n may be computed by negation-limited circuits of size $O(n \log n)$ and depth $O(\log n)$.*

This in turn yields upper bounds on $C^{b(n)}(F)$ for an arbitrary system of functions F, via the standard technique of using DeMorgan's laws to push all negations in a circuit to the inputs.

COROLLARY 1.2. *For any system F of n-input boolean functions,*

$$C^{b(n)}(F) \leq 2C(F) + O(n \log n). \qquad \square$$

Currently no superlinear lower bound for the general circuit complexity of an explicit Boolean function is known. The above theorem and corollary imply that if we can show an $\omega(n \log n)$ lower bound on $C^{b(n)}(f)$ for some explicit Boolean function f, we also obtain an $\omega(n \log n)$ lower bound on the general circuit complexity of f.

Markov [11] constructs inverters using monotone functions and $b(n)$ negations, but he does not consider the complexity of the monotone functions that he uses. Akers [2] (see [12]) gives the first explicit construction of a negation-limited inverter. His circuit uses $b(n)$ NEGATION gates and positive weight threshold gates, and has size $O(n)$ and depth $O(\log n)$. For the remainder of this paper, we restrict our attention to circuits of AND, OR, and NEGATION gates. Fischer [8] gives such a circuit for I_n with size $O(n^2 \log^2 n)$ and depth $O(\log^2 n)$, using only $b(n)$ NEGATION gates. Sorting networks play a key role in Fischer's construction (and in all subsequent constructions). Using the sorting network of Ajtai, Komlós, and Szemerédi [1] (see [13]) in Fischer's construction reduces the size to $O(n^2 \log n)$ and the depth to $O(\log n)$. In a preliminary version of this paper, Tanaka and Nishino [18] have investigated the negation-limited complexity of the inverter, giving an upper bound of $O(n \log^2 n)$, using a construction of depth $\theta(\log^2 n)$.

Our circuit, with size $O(n \log n)$ and depth $O(\log n)$, improves on previous negation-limited circuits for I_n by a factor of at least $(\log n)$ in size. Note that the only previous construction with logarithmic depth had superquadratic size.

A circuit with no NEGATION gates is *monotone*. A *monotone function* f is a boolean function which satisfies $f(x_1, \ldots, x_n) \leq f(y_1, \ldots, y_n)$ whenever $x_i \leq y_i$ for all i. Monotone functions are exactly those computed by monotone circuits. Observe that the (k, n)-inverter is a system of monotone functions. Berkowitz [6] shows that the monotone complexity of the (k, n)-inverter is polynomial, with a construction of size $O(n^2 \log n)$ and depth $O(\log n)$. Valiant [20] constructs monotone (k, n)-inverters of size $O(n \log^2 n)$ and depth $O(\log^2 n)$.

THEOREM 1.3. *The monotone complexity of the (k, n)-inverter is $O(n \log n)$. In fact, I_n^k has monotone circuits of size $O(n \log n)$ and depth $O(\log n)$.*

We also show (see Theorem 4.4) that there is a close relationship between $C^0(I_n^k)$ and $C^{b(n)}(I_n)$. (For more background on monotone circuits, we refer to section 4 of Boppana and Sipser's article [7].)

We also obtain several lower bounds. For arbitrary negation-limited inverters, we obtain the following theorem.

THEOREM 1.4. *Let n be one less than a power of 2. Then any negation-limited circuit for I_n has size $\geq 5n + 3\log(n+1) - c$ and depth $\geq 4\log(n+1) - c$.*

In addition, we show that for two different restricted classes of circuits, negation-limited inverters require size $\Omega(n \log n)$.

The remainder of this paper is organized as follows. In section 2, we describe elements of previous constructions of negation-limited inverters which are common to ours. In section 3, we give the heart of our construction of negation-limited inverters.

In section 4, we show the relationship between negation-limited inverters and monotone (k, n)-inverters. Section 5 gives the main technical lemma on functions computed at the NEGATION gates of negation-limited inverters, and proves Theorem 1.4. In section 6, we prove superlinear bounds for various restricted classes of negation-limited inverters. We conclude in section 7 by mentioning some open problems.

2. The Fischer and Tanaka–Nishino inverters. We review briefly the circuits of Fischer [8] and Tanaka and Nishino [18]. These circuits have several elements in common with each other, and with ours as well. The most important of these is a sorting network.

A *comparator* is a circuit element with two inputs and two outputs. The inputs are taken from some ordered set U. The first output of the comparator is the maximum of the two inputs, while the second output is the minimum of the two inputs. A sorting network is a circuit, with n inputs and n outputs, composed entirely of comparators. For any n-tuple $x_1, \ldots, x_n$ of inputs from U, the n outputs $y_1, \ldots, y_n$ of the sorting network are a permutation of the x_i and are in decreasing order. Ajtai, Komlós, and Szemerédi [1] (see [13]) have constructed sorting networks using $O(n \log n)$ comparators, organized in $O(\log n)$ levels of $\lfloor n/2 \rfloor$ comparators each. Note that if the set U is $\{0, 1\}$, then a comparator can be constructed without negations. Indeed, for $x, y \in \{0, 1\}$, $\min(x, y) = x \wedge y$ and $\max(x, y) = x \vee y$. Thus, the Ajtai–Komlós–Szemerédi result yields a monotone circuit of size $O(n \log n)$ and depth $O(\log n)$ for sorting n bits.

Both Fischer and Tanaka and Nishino first sort the n input bits $x_1, \ldots, x_n$. The outputs $y_1, \ldots, y_n$ of the sorting network are fed into a subcircuit M_n (due to Fischer [8]) with the following properties.

1. M_n has n binary inputs $y_1, \ldots, y_n$ and n outputs $z_1, \ldots, z_n$.
2. M_n has size $O(n)$, depth $O(\log n)$, and uses $b(n)$ NEGATION gates.
3. If $y_1 \geq y_2 \geq \cdots \geq y_n$ then $z_i = \neg y_i$ for $1 \leq i \leq n$.

The negations of the x_i may now be calculated monotonically from the x_i, the y_i, and the z_i. Fischer does this using $O(n)$ sorting networks in parallel, resulting in a circuit of size $O(n^2 \log n)$ and depth $O(\log n)$ if the Ajtai–Komlós–Szemerédi sorting network is used. Tanaka and Nishino, on the other hand, use the monotone $(n, 2n)$-inverter of Valiant [20] which inverts $2n$ inputs provided that exactly n of them equal 1 (as is the case with $x_1, \ldots, x_n, z_1, \ldots, z_n$). Valiant's circuit is monotone, with size $O(n \log^2 n)$ and depth $O(\log^2 n)$.

Note that in both the Fischer and the Tanaka–Nishino constructions, the circuit is arranged in three phases: the sorting network, the subcircuit M_n, and the top phase which computes the final answer. (We view circuits as having their inputs at the bottom and outputs at the top, so the final phase of a circuit with several phases is the top phase.) The bottom two phases require only size $O(n \log n)$ and depth $O(\log n)$ (in fact, the second phase has linear size). Also, both the Fischer and the Tanaka–Nishino constructions require no more than the x_i, the y_i, and the z_i as inputs to the top phase. We show that by allowing the top phase access to intermediate results from the sorting network (first phase), the top phase may be computed by a size $O(n \log n)$, depth $O(\log n)$ circuit. Our top phase may be thought of as an "upside-down" sorting network. We describe this in the next section.

3. Description of the inverter. Our negation-limited circuit for I_n, like its predecessors, begins with a sorting network and Fischer's M_n circuit. We present a new approach to the third phase, which achieves considerable savings in complexity

over previous constructions by means of a novel application of the Ajtai–Komlós–Szemerédi result.

Before going into the details of the circuit, we briefly describe the intuition. The differences between the three constructions ([8, 18] and ours) seem to stem from how one thinks of the outputs of the M_n subcircuit. Of course, in all three constructions, the outputs of M_n are computing exactly the same system of n functions. Nevertheless, these outputs are treated completely differently by the three approaches. In Fischer's original negation-limited inverter [8], the inputs and outputs of M_n are thought of as the threshold functions (of $x_1, \ldots, x_n$) and their negations, respectively. Fischer uses these bits to select the output of an appropriate subcircuit, according to the number k of ones in the input. There are $n+1$ such subcircuits, one for each $0 \le k \le n$. Tanaka and Nishino [18] avoid having to consider $(n+1)$ different cases in parallel by noticing that the x_i, together with the outputs of M_n, are a string of $2n$ bits containing exactly n ones (such a string can be inverted monotonically using Valiant's monotone $(n, 2n)$-inverter [20]). In their construction, the outputs of M_n are thought of as *balancing* the inputs $x_1, \ldots, x_n$. We take a different view. We view the outputs of M_n as being a *permutation* of the negations of the x_i. It is the task of the third phase to *rearrange* these bits into their proper position. This rearrangement essentially undoes the sorting performed by the first phase, one level at a time.

We now present the details. Let ℓ be the depth of the sorting network used in the first phase. For each level in the sorting network, the third phase has a corresponding level, composed of a monotone, linear size, constant depth circuit. The ordering of the levels, however, is reversed between the first phase and the third phase. That is, we number the levels in the sorting network from the bottom (numbered 1) to the top (numbered ℓ), and we number the levels in the third phase from 1 at the top to ℓ at the bottom. When numbered in this way, level i of the sorting network corresponds to level i of the third phase. We will use S_i to denote level i of the sorting network, and T_i to denote level i of the top phase.

For $1 \le i \le \ell$, let $x_1^i, \ldots, x_n^i$ denote the inputs to S_i, and let $x_1^{\ell+1}, \ldots, x_n^{\ell+1}$ denote the outputs of S_ℓ. The subcircuit T_i receives $2n$ input bits: the n input bits $x_1^i, \ldots, x_n^i$ of S_i, and the negations $\neg x_1^{i+1}, \ldots, \neg x_n^{i+1}$ of the n output bits of S_i. For $1 \le j \le n$, $\neg x_j^{i+1}$ is computed one level below by T_{i+1}, or by M_n in the case $i = \ell$. Using only linear size, constant depth, monotone circuitry, T_i outputs the negations $\neg x_1^i, \ldots, \neg x_n^i$ of the n input bits to S_i. If $i > 1$, these are passed up to the next level, T_{i-1}. Note that at the top level, T_1 outputs the negations of the inputs to S_1, i.e., T_1 outputs $\neg x_1, \ldots, \neg x_n$. The overall structure of the circuit is shown in Figure 1. Note that, for readability, the wires connecting the outputs of S_{i-1} to the inputs of T_i are not shown.

To complete the description of the circuit for I_n, we need to describe a monotone, linear size, constant depth circuit for T_i. Since S_i is simply $\lfloor n/2 \rfloor$ comparators operating in parallel, it suffices to give a (constant size and depth) monotone circuit for each comparator. This we do in the following lemma.

LEMMA 3.1. *Let x and y be boolean variables, and let $u = \neg \max(x, y)$ and $v = \neg \min(x, y)$. Then $\neg x$ and $\neg y$ may be computed monotonically from x, y, u, and v.*

Proof. A quick check shows that $\neg x = u \vee (y \wedge v)$ and $\neg y = u \vee (x \wedge v)$. □

Suppose that S_i has a comparator with inputs $x_{j_1}^i, x_{j_2}^i$ and outputs $x_{k_1}^{i+1}, x_{k_2}^{i+1}$. Then T_i will have a corresponding circuit element with inputs

$$\neg x_{k_1}^{i+1}, \neg x_{k_2}^{i+1}, x_{j_1}^i, x_{j_2}^i$$

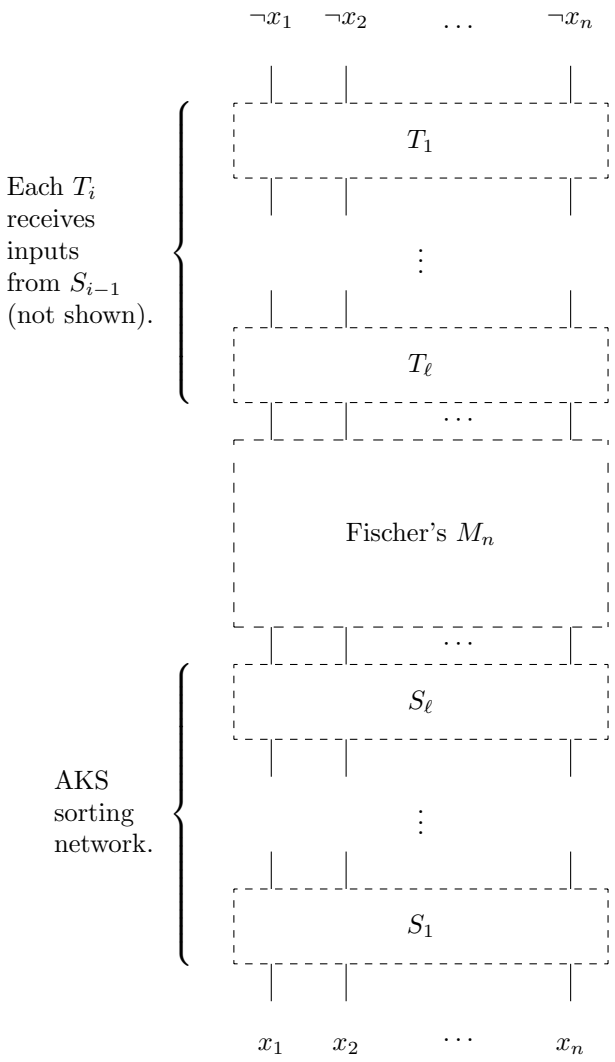

FIG. 1. *Overall structure of the circuit.*

and outputs

$$\neg x^i_{j_1}, \neg x^i_{j_2}.$$

By the above lemma, this can be done monotonically. This is illustrated in Figure 2. As S_i is a linear size, depth 1 circuit of comparators, we can construct T_i to be a monotone, linear size, depth 2 circuit.

We are now ready to prove Theorem 1.1.

Proof. We describe the circuit. As in Fischer [8] and Tanaka and Nishino [18], the input variables $x_1, \ldots, x_n$ are the inputs of a sorting network with ℓ levels of $O(n)$ gates each. By Ajtai, Komlós, and Szemerédi [1], we may assume $\ell = O(\log n)$. Still following Fischer and Tanaka and Nishino, the outputs $y_1, \ldots, y_n$ of the sorting network are the inputs to Fischer's M_n circuit, which has size $O(n)$ and depth $O(\log n)$

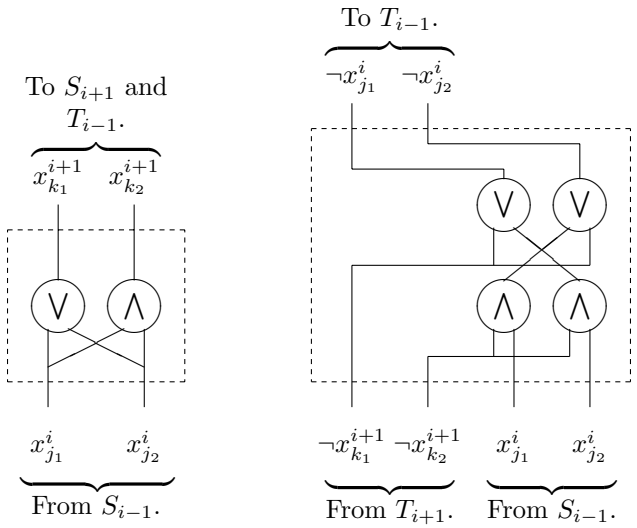

FIG. 2. *Corresponding circuit elements of S_i (left) and T_i (right).*

and uses $b(n)$ NEGATION gates. Since the inputs to M_n are sorted, the outputs $z_1, \ldots, z_n$ satisfy $z_i = \neg y_i$ for $i = 1, \ldots, n$.

From the z_i, and the inputs to the various levels of the sorting network, the subcircuits $T_\ell, \ldots, T_1$ described above compute the negations of the inputs to successively lower levels in the sorting network. It is clear by induction on $(\ell - i)$ that T_i outputs the negations $\neg x^i_1, \ldots, \neg x^i_n$ of the inputs to S_i. At the top of our circuit, T_1 computes the negations $\neg x_1, \ldots, \neg x_n$ of the input variables.

The circuit has depth $3\ell + O(\log n) = O(\log n)$. As each level of the circuit has linear size, the total number of gates used is $O(n \log n)$. The only NEGATION gates used are the $b(n)$ NEGATION gates used by M_n, as desired. □

4. Monotone (k, n)-inverters. Berkowitz [6] introduces the notion of a *slice function*. The boolean function $f : \{0,1\}^n \to \{0,1\}$ is a kth slice if

$$f(x_1, \ldots, x_n) = \begin{cases} 0 & \text{if } \sum_{i=1}^n x_i < k, \\ 1 & \text{if } \sum_{i=1}^n x_i > k. \end{cases}$$

For input strings containing exactly k ones, the behavior of f is not constrained. Any slice function is monotone. Note that an alternative, nonconstructive proof of Lemma 3.1 may be obtained by observing that, of the four bits x, y, u, v, exactly two are equal to one, so any function of x, y, u, v may be extended to a (monotone) slice function. The importance of monotone (k, n)-inverters is underscored by the following.

PROPOSITION 4.1. *For any system F of n-input kth slice functions,*

$$C^0(F) \leq 2C(F) + C^0(I^k_n). \qquad \square$$

The following allows us to focus on the behavior of our circuit on inputs with exactly k ones.

PROPOSITION 4.2. *I^k_n is the unique system of monotone functions which agrees with I_n on all inputs with exactly k ones.*

Proof. Suppose that $f_1, \ldots, f_n$ are a system of monotone functions which agree with I_n on all inputs with exactly k ones. Suppose that the number of ones in $x_1, \ldots, x_n$ is strictly greater than k. Let i be any integer between 1 and n. We must show that $f_i(x_1, \ldots, x_n) = 1$. By the monotonicity of f_i, it suffices to exhibit $y_1, \ldots, y_n$ such that $f_i(y_1, \ldots, y_n) = 1$ and for all $1 \leq j \leq n$, $y_j \leq x_j$. For this, we assign the y_j in such a way that exactly k of them are one, $y_i = 0$, and each $y_j \leq x_j$ (we obtain the y_j by changing some of the x_j from one to zero, including x_i if it is nonzero, until exactly k bits are one). The proof for the case that fewer than k of the x_j are one is analogous. □

Berkowitz [6] constructs monotone (k, n)-inverters of size $O(n^2 \log n)$ and depth $O(\log n)$. Valiant [20] gives monotone circuits of size $O(n \log^2 n)$ and depth $O(\log^2 n)$ for the (k, n)-inverter (see also Wegener [21, 22]). Our techniques can be used to improve on Valiant's results by a factor of $(\log n)$ in size and depth. We present the proof of Theorem 1.3.

Proof. We use our negation-limited circuit for I_n, replacing the M_n subcircuit by a circuit which outputs k zeroes followed by $(n - k)$ ones. Note that the only negations in our circuit for I_n occur in the M_n subcircuit. Also, if there are exactly k ones among the inputs to our negation-limited inverter, then the M_n subcircuit will output k zeroes followed by $(n - k)$ ones. Therefore, the new circuit will agree with I_n (i.e., it will compute the negations of its input bits) whenever there are exactly k ones in the input. By Proposition 4.2, we are done. □

Since the inputs to M_n are sorted, the functions computed by the NEGATION gates depend only on the number of ones in the input. Therefore, in the above construction, instead of replacing the outputs of M_n by constants, we could have replaced the outputs of the NEGATION gates by constants. One might ask whether it is always possible to obtain a monotone (k, n)-inverter from a negation-limited inverter by replacing the negation gates with constants. We shall see (perhaps surprisingly) that something close to this is true. Before formalizing this, we quote the following lemma of Tanaka and Nishino (see [18, Lemma 4.2]).

LEMMA 4.3 (see Tanaka and Nishino). *Suppose $n + 1$ is a power of 2, and let f be the function computed by some NEGATION gate of a negation-limited circuit for I_n. Then $f(x_1, \ldots, x_n)$ depends only on the number of i such that $x_i = 1$.* □

We will prove a stronger version of this lemma later (see Lemma 5.1).

Now we can make precise the relationship between negation-limited inverters and monotone (k, n)-inverters.

THEOREM 4.4. *Let n be a positive integer. Then $C^0(I_n^k) \leq C^{b(n')}(I_{n'})$, for some $n' < 2n$. In fact, a monotone (k, n)-inverter can be constructed with the same size and depth as a negation-limited circuit for $I_{n'}$.*

Proof. Let $n' = 2^r - 1$, where 2^r is the smallest power of 2 greater than n. Note that 2^r is at most $2n$. Let Δ be any negation-limited circuit for $I_{n'}$. By Lemma 4.3, if the number of ones in the input is constant, then the NEGATION gates in Δ compute constant functions. Replacing these gates by appropriate (according to k) constants yields a monotone (k, n')-inverter. To obtain a monotone (k, n)-inverter, we simply fix the first $(n' - n)$ input bits to 0 and ignore the first $(n' - n)$ output bits. This yields a monotone circuit Δ' computing I_n^k with the same size and depth as Δ. □

In fact, *all* known constructions of monotone (k, n)-inverters may be seen as negation-limited inverters with the NEGATION gates replaced by constants. This modification applied to Fischer's circuit for I_n (using the Ajtai, Komlós, and Szemerédi sorting network [1]) yields Berkowitz's (k, n)-inverter. There is no previously

published negation-limited inverter corresponding to Valiant's (k, n)-inverter, so we describe one here. First we give a sketch of Valiant's construction.

Valiant's circuit is very similar to ours (with the M_n removed), except that instead of using comparators, *merging networks* are used. A merging network takes as inputs two sorted lists u and v, and outputs the list $w = \text{merge}(u, v)$ obtained by sorting the concatenated list uv. Batcher [4] shows that two lists of m elements can be merged by a network of $O(m \log m)$ comparators. Thus, if u and v are binary strings of length m, they can be merged by a monotone circuit of size $O(m \log m)$ (this circuit has depth $O(\log m)$). If u is a binary string, we denote by $\neg u$ the string obtained from u by replacing each symbol by its negation, and we denote by $\text{reverse}(u)$ the string obtained from u by reversing the order of the symbols. Note that if u is in sorted (i.e., decreasing) order, then so is $\text{reverse}(\neg u)$.

The bottom half of Valiant's circuit is a sorting network, built out of $\log n$ layers of merging networks (the ith layer merges pairs of consecutive substrings of length 2^i). The top half is analogous to our top phase, with the following taking the place of Lemma 3.1.

LEMMA 4.5 (Valiant). *Suppose that the sorted binary strings u of length s and v of length t, together with the string $w = \text{reverse}(\neg \text{merge}(u, v))$, are given. Then* $\text{reverse}(\neg u)$ *and* $\text{reverse}(\neg v)$ *may be calculated by merging networks.*

Proof. By symmetry, we only need to consider $\text{reverse}(\neg u)$. This is easily seen to be the middle s bits of $\text{merge}(v, w)$. □

(Note that the case $s = t = 1$ of Valiant's lemma provides yet another proof of Lemma 3.1.)

Since k is fixed, the negations of the output bits of the top layer of the bottom half are constants. (Actually, this top layer of the bottom half is superfluous for the monotone (k, n) inversion problem, and Valiant does without it. We leave it in for simplicity, and because it is necessary if we are to obtain a negation-limited inverter.) Successively higher layers of the top half calculate the reverses of the negations of inputs to merging networks in successively lower layers of the bottom half. At the top layer of the top half, the negations of the input bits are calculated (reversing a string of length one has no effect).

To obtain a negation-limited inverter from Valiant's circuit, we simply feed the output of the bottom half to Fischer's M_n circuit, which computes the negation of the output of the top layer of the bottom half. This is then given as input to the top half. (The circuit constructed in this way is about half the size of that of Tanaka and Nishino [18], since we modify Valiant's (k, n)-inverter instead of using Valiant's $(n, 2n)$-inverter.) Therefore, Valiant's techniques for constructing monotone (k, n)-inverters can also be used to construct negation-limited inverters. It is curious that this is true of all known (k, n)-inverters, since no converse of Theorem 4.4 is known to hold.

5. The complexity of the inverter: Lower bounds. In this section, we shall prove a main technical lemma on functions computed at NEGATION gates in negation-limited inverters. These techniques have recently been generalized to obtain results for negation-limited circuits computing symmetric functions [5].

For $x \in \{0, 1\}^n$, let $|x|$ denote the number of ones in x. Note that in all known constructions of negation-limited inverters, the negation gates compute the negations of the bits of $|x|$. We shall see that this must always hold.

LEMMA 5.1. *Let $n = 2^r - 1$. Consider any r-circuit Δ which computes I_n. Label the NEGATION gates $N_1, \ldots, N_r$ in such a way that the input to N_i does not depend*

on the outputs of any of the negation gates $N_{i+1}, \ldots, N_r$ (such a labeling exists since the circuit is a DAG). Let z_i and y_i be the functions computed at the input and output of N_i. Then $z_1 z_2 \ldots z_r$ is the binary representation of $|x|$.

Proof. We proceed by induction on r. The lemma is trivially true for $r = 0$ (i.e., the circuit is monotone). We now suppose that the lemma holds for $r-1$ NEGATION gates.

Let $a \in \{0,1\}^n$. We wish first to show that $z_1(a)$ is the first (i.e., leftmost) bit of $|a|$. We consider the case in which $z_1(a) = 1$ (the proof for the case $z_1(a) = 0$ is analogous), and we wish to show that $|a| \geq (n+1)/2$. Note that simultaneously permuting the inputs and output of Δ according to the same permutation yields another circuit for I_n, so we may assume that a is of the form $1^k 0^{n-k}$. Also, I_{n-k} is obtained from I_n, fixing the first k bits to 1 and ignoring the first k output bits. Since $z_1(a) = 1$, and z_1 is monotone, I_{n-k} is computed by the circuit Δ_k obtained by fixing the first k inputs of Δ to 1 and replacing N_1 by the constant 0. Note that Δ_k is an $(r-1)$-circuit. Therefore, by Markov's theorem, $d(I_{n-k}) \leq 2^{r-1} - 1 = (n-1)/2$. However, it is clear that $d(I_{n-k}) = n - k$. Therefore

$$|a| = k = n - d(I_{n-k}) \geq n - (n-1)/2 = (n+1)/2,$$

as desired.

Now it remains to show that the functions $z_2, \ldots, z_r$ are as specified. Again, we restrict our attention to the case $z_1 = 1$, since the case $z_1 = 0$ is handled similarly. Let $a \in \{0,1\}^n$ such that $z_1(a) = 1$. As above, we assume that a is a string of the form $1^\ell 0^{n-\ell}$. Let $k = (n-1)/2 \leq \ell$. We apply the $r-1$ case of the lemma to the $(n-k)$-input/output inverter obtained from Δ by fixing the first k inputs to 1 and replacing N_1 by the constant 0. The proof is completed by observing that for all $x \in \{0,1\}^{n-k}$, the binary representations of $|x|$ and $|1^k x|$ agree in their $(r-1)$ least significant bits. □

In the sequel, we assume that $z_1, \ldots, z_r$ are as in the lemma. Let N_i be the NEGATION gate corresponding to z_i. We remark that we did not assume that there exists a path from N_{i-1} to N_i for all $2 \leq i \leq r$. (By path we mean a sequence of gates $G_1, \ldots, G_p$ which satisfies the following conditions: $G_1 = N_i$, $G_p = N_{i+1}$, and for any q $(1 \leq q \leq p-1)$, an output of G_q is an input of G_{q+1}.) However, the existence of such paths follows at once from the lemma: if for some i, there did not exist a path from N_{i-1} to N_i, then we could interchange the labels of N_{i-1} and N_i. This is impossible, since by the lemma the labeling of a negation gate is determined by what function is computed at the gate.

LEMMA 5.2. *For any i, $1 \leq i \leq r-1$, in any path from N_i to N_{i+1}, there exists at least one AND gate and one OR gate.*

Proof. The proof is by contradiction. By Lemma 5.1, all four possible values for z_i and z_{i+1} are attained for some input $x \in \{0,1\}^n$. Note that the NEGATION gates are labeled in such a way that no path from N_i to N_{i+1} contains a NEGATION gate other than N_i and N_{i+1}. If the internal nodes along a path from N_i to N_{i+1} consisted entirely of AND (respectively, OR) gates, then the possibility $z_i = 1, z_{i+1} = 1$ (respectively, $z_i = 0, z_{i+1} = 0$) would be ruled out. Therefore, all such paths must include both an AND gate and an OR gate. □

Let L_j $(1 \leq j \leq n)$ be a gate computing $\neg x_j$ in Δ.

LEMMA 5.3. *For all $1 \leq i \leq r$ and $1 \leq j \leq n$, there exists a path from N_i to L_j which does not include any NEGATION gate except for N_i.*

Proof. First, we fix all the outputs of the NEGATION gates $N_1, \ldots, N_r$ in Δ to

0. Then, we obtain an (n, n)-inverter C from Δ. In this case, $C(a) = (0, \ldots, 0)$ for all $a \in \{0,1\}^n$. Let us fix all the inputs of the circuit C to 1.

Next, for some $1 \leq i \leq r$, we change the output of N_i to 1. Then, for some $1 \leq k \leq n-1$, we obtain a (k, n)-inverter by the proof of Lemma 4.4. Since we fixed all the inputs of C to 1, each of the outputs of $L_1, \ldots, L_n$ in C changes from 0 to 1. Thus, for all $1 \leq j \leq n$, there exists a path from N_i to L_j, such that the output of every gate in the path changes from 0 to 1. Since we fixed all the outputs of the NEGATION gates except for N_i to 0, we can conclude that there is no NEGATION gate other than N_i in the path. □

LEMMA 5.4. *For all j, $1 \leq j \leq n$, on any path from N_r to L_j, there exist at least one AND gate and one OR gate.*

Proof. Note that at least one such path exists by the previous lemma. Now we wish to show that any such path contains an AND gate and an OR gate. As above, we note that by Lemma 5.1, each of the four possibilities for the values of z_i, L_j are attained for some input $x \in \{0,1\}^n$. Also, no path from N_r to L_j contains a NEGATION gate other than N_r. Therefore, as in the previous lemma, we see that any path from N_r to L must include at least one AND gate and at least one OR gate (all other possibilities lead to contradictions). □

THEOREM 5.5. *Let $n = 2^r - 1$. Then $C^r(I_n) \geq 5n + 3\log(n+1) - c$.*

Proof. By Lemma 5.1, z_1 is the majority function, computed by a monotone subcircuit, so the number of gates required to compute z_1 is at least $C^m(T^n_{(n+1)/2})$. Since it is known that $C^m(T^n_{n/2}) \geq 4n - c$ where c is a constant (see [10]), we have $C^m(T^n_{(n+1)/2}) \geq 4n - c'$.

From Lemma 5.2, the length of any path from N_1 to N_r is at least $3r - 2$. Note that the gates on such a path are distinct from the gates in the subcircuit computing z_1.

Furthermore, from Lemma 5.3, for all j, $1 \leq j \leq n$, there exists a path from N_r to L_j. So, for all j, $1 \leq j \leq n$, L_j differs from any gate in any path from N_1 to N_r. And the functions computed at $L_1, \ldots, L_n$ are mutually distinct nonmonotone functions (i.e., $\neg x_1, \ldots, \neg x_n$). So $L_1, \ldots, L_n$ are mutually distinct gates, and none of them are used to compute z_1. Hence, we have

$$\begin{aligned} C^r(I_n) &\geq C^m(T^n_{(n+1)/2}) + (3r-2) + n \\ &\geq (4n - c') + (3\log(n+1) - 2) + n \\ &\geq 5n + 3\log(n+1) - c \end{aligned}$$

as desired. □

THEOREM 5.6. *Let $n = 2^r - 1$. Then $D^r(I_n) \geq 4\log(n+1) + c$.*

Proof. From Lemma 5.1, the number of gates used to compute z_1 is at least $C^m(T^n_{(n+1)/2})$. These gates are located below N_1; that is, there exists a path from each of these gates to N_1.

From Lemma 5.2, the length of any path from N_1 to N_r is at least $3r - 2$. Furthermore, from Lemma 5.4, for all j, $1 \leq j \leq n$, the length of any path from N_r to L_j is at least 3. Then, we obtain

$$\begin{aligned} D^l(I_n) &\geq \lceil \log(C^m(T^n_{(n+1)/2}) + 1) \rceil + (3r-2) + 3 - 1 \\ &\geq \lceil \log(4n - c' + 1) \rceil + 3r \\ &\geq \log(c''(n+1)) + 3\log(n+1) \\ &\geq 4\log(n+1) + c \end{aligned}$$

as desired. □

6. Superlinear lower bounds for particular inverters. First, we consider so-called *synchronous circuits* which are circuits with the property that all paths from the inputs to a given gate have the same length (see [17]).

THEOREM 6.1. *Let $n = 2^r + 1$. Then any synchronous negation-limited circuit for V_n has at least $4n\log(n+1) + cn$ gates.*

Proof. From Theorem 5.6, for each i, $1 \le i \le n$, the length of some (and therefore any) path from an input to L_i is at least $4\log(n+1) + c$. In a synchronous circuit computing I_n, the outputs of the gates at level m ($2 \le m \le 4\log(n+1) + c$) are computed using the outputs of the gates at level $m-1$.

On the other hand, V_n can compute 2^n different values, i.e., all binary vectors of length n. Hence, the number of gates at level m is at least $\log 2^n = n$. This completes the proof. □

Next, we show another instance where the size of the negation-limited inverter has a superlinear lower bound. For that purpose, we introduce the following restriction.

Restriction A: Any gate G in the inverter $\mathcal{I}_n$ which satisfies the following two conditions computes some symmetric function:

A1: there exists a path from one of $N_1, \ldots, N_{r-1}$ to G in $\mathcal{I}_n$,

A2: there exists a path from G to N_r in $\mathcal{I}_n$.

THEOREM 6.2. *Let $n = 2^r - 1$. Then any negation-limited inverter Δ which satisfies Restriction A has $\Omega(n \log n)$ gates.*

Proof. Label the NEGATION gates of Δ as in Lemma 5.1. Let z_i be the function which is computed at the input of N_i, for $i = 1, \ldots, r$. By Lemma 5.1, for $x \in \{0,1\}^n$ the string $z_1(x)z_2(x)\ldots z_r(x)$ is the binary representation of $|x|$. This is an increasing function which attains all possible values in the range $0, \ldots, n$.

Let $1 \le k \le n$ be arbitrary. We wish to show that there exists a monotone subcircuit of Δ computing T_n^k. Let w be such that $w01^{r-i}$ is the binary representation of $k-1$, where w is a binary string $w_1 w_2 \ldots w_i$ of length i for some $0 \le i < r$. Then the binary representation of k is $w10^{r-i}$.

Let Δ' be a circuit obtained from Δ by replacing N_j with the constant $\neg w_j$ for each $1 \le j \le i$. For a gate G in Δ, let G' denote the corresponding gate in Δ'. Let g and g' denote the functions computed at gates G and G', respectively. Let $\Omega \subseteq \{0,1\}^n$ denote the set of all binary strings with exactly $k-1$ or k ones. We have:

1. for any gate G in Δ, and for any $x \in \Omega$, $g(x) = g'(x)$;
2. if for all $j > i$, there is no path from N_j to G in Δ, then g' is computed by a monotone subcircuit of Δ';
3. if g is computed by a monotone subcircuit of Δ, then $g = g'$.

Let G be the gate computing z_{i+1}. Note that by (2), g' is monotone, and by (1), $g'(x) = g(x) = T_n^q(x)$ for $x \in \Omega$. Since T_n^k is the unique monotone function which agrees with T_n^k on Ω, we have $g'(x) = T_n^k(x)$ for all $x \in \{0,1\}^n$.

Recall that we are trying to prove that there is a monotone subcircuit of Δ computing T_n^k (from which the theorem follows). So far we have shown the existence of a gate G in Δ such that $g' = T_n^k$. It now suffices to show that for any such gate, either g is computed by a monotone subcircuit of Δ (so, by (3), $g = g'$ and we are done) or there is a gate lower down in the circuit with the same property.

Suppose that g is not computed by a monotone subcircuit of Δ. Then there is a path from some negation gate N_j to G in Δ. This is illustrated in Figure 3.

By Restriction A, we know that g is a symmetric function. Let G_1 and G_2 be the gates whose outputs are the inputs to G, labeled such that a path from N_j to

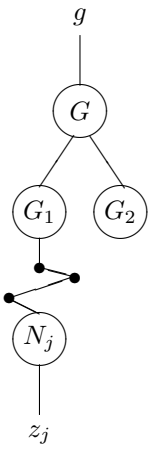

FIG. 3. *A gate G such that G' computes T_n^k. One of G_1, G_2 shares this property.*

G passes through G_1. Therefore g_1 computes a symmetric function. Since g_1' is a monotone function which agrees with g_1 on Ω, either $g_1' = T_n^k$ or g_1' is constant on Ω. In the latter case, since g' is not constant on Ω, we have that either g_1' is identically 1 on Ω and G is an AND gate, or g_1' is identically 0 on Ω and G is an OR gate. So g' and g_2' agree on Ω, and $g_2' = T_n^k$. In either case we have found a gate G_ℓ below G in Δ with $g_\ell' = T_n^k$ as desired. This can be continued until a monotone subcircuit of Δ is found which computes T_n^k.

Since k above was arbitrary, all threshold functions $\{T_n^1, T_n^2, \ldots, T_n^n\}$ are computed by monotone subcircuits of Δ. Thus, from [9], Δ has size $\Omega(n \log n)$. □

Note that, if we do not have the condition A2, certain symmetric functions must be computed at the output gates of Δ_n. But this is impossible. Hence, the condition A2 is necessary although it is not used in the proof of Theorem 6.2.

Since the inverter we construct satisfies Restriction A and has size $O(n \log n)$, this theorem is tight to within a constant factor.

7. Conclusion. In this paper, we have presented new upper and lower bounds on the size of negation-limited inverters. We have also investigated the negation-limited circuit complexity of some boolean functions and have shown relationships between combinational complexity and negation-limited complexity of boolean functions.

It should be investigated whether the methods used in this paper to derive lower bounds on the negation-limited complexity of the inverter can be applied to derive similar bounds on the negation-limited complexity of one-output boolean functions. We have made some progress in this regard for symmetric functions [5].

G. Turán posed the following question: is the size of any $c \log n$ depth inverter using $c \log n$ NEGATION gates superlinear? Though Turán's question remains open, we hope that our work represents a step towards its resolution.

Acknowledgments. The authors would like to express their sincere thanks to Dr. Jaikumar Radhakrishnan at Tata Institute of Fundamental Research for his detailed comments on the previous version of this paper. They also thank Prof. Magnús M. Halldórsson at the University of Iceland, Prof. Akihiro Nozaki at Otsuma Women's University, and Prof. Shigeki Iwata at the University of Electro-Communications for their valuable comments.

SIMPLE FAST PARALLEL HASHING BY OBLIVIOUS EXECUTION*

JOSEPH GIL† AND YOSSI MATIAS‡

Abstract. A *hash table* is a representation of a set in a linear size data structure that supports constant-time membership queries. We show how to construct a hash table for any given set of n keys in $O(\lg \lg n)$ parallel time with high probability, using n processors on a weak version of a concurrent-read concurrent-write parallel random access machine (CRCW PRAM). Our algorithm uses a novel approach of hashing by "oblivious execution" based on probabilistic analysis. The algorithm is simple and has the following structure:

1. Partition the input set into buckets by a random polynomial of constant degree.
2. For $t := 1$ to $O(\lg \lg n)$ do
   (a) Allocate M_t memory blocks, each of size K_t.
   (b) Let each bucket select a block at random, and try to injectively map its keys into the block using a random linear function. Buckets that fail carry on to the next iteration.

The crux of the algorithm is a careful a priori selection of the parameters M_t and K_t. The algorithm uses only $O(\lg \lg n)$ random words and can be implemented in a work-efficient manner.

1. Introduction.

Let S be a set of n keys drawn from a finite universe U. The *hashing* problem is to construct a function $H : U \to [0, m-1]$ with the following attributes:

Injectiveness. No two keys in S are mapped by H to the same value.

Space efficiency. Both m and the space required to represent H are $O(n)$.

Time efficiency. For every $x \in U$, $H(x)$ can be evaluated in $O(1)$ time by a single processor.

Such a function induces a linear space data structure, a *perfect hash table*, for representing S. This data structure supports membership queries in $O(1)$ time.

This paper presents a simple, fast, and efficient parallel algorithm for the hashing problem. Using n processors, the running time of the algorithm is $O(\lg \lg n)$ with overwhelming probability, and it is superior to previously known algorithms in several respects.

Computational models. As a model of computation we use the concurrent-read concurrent-write parallel random access machine (CRCW PRAM) family (see, e.g., [34]). The members of this family differ by the outcome of the event where more than one processor attempts to write simultaneously into the same shared memory location. The main submodels of CRCW PRAM in descending order of power are the

PRIORITY [28] in which the lowest-numbered processor succeeds; the ARBITRARY [41] in which one of the processors succeeds, and it is not known in advance which one; the COLLISION$^+$ [8] in which if different values are attempted to be written, a special collision symbol is written in the cell; the COLLISION [14] in which a special collision symbol is written in the cell; the TOLERANT [31] in which the contents of that cell do not change; and, finally, the less standard ROBUST [33] in which if two or more processors attempt to write into the same cell in a given step, then, after this attempt, the cell can contain any value.

1.1. Previous work. Hash tables are fundamental data structures with numerous applications in computer science. They were extensively studied in the literature; see, e.g., [36, 39] for a survey or [40] for a more recent one. Of particular interest are perfect hash tables, in which every membership query is guaranteed to be completed in constant time in the worst case. Perfect hash tables are perhaps even more significant in the parallel context, since the time for executing a batch of queries in parallel is determined by the slowest query.

Fredman, Komlós, and Szemerédi [15] were the first to solve the hashing problem in expected linear time for any universe size and any input set. Their scheme builds a *two-level* hash function: a *level-one* function splits S into subsets ("buckets") whose sizes are distributed in a favorable manner. Then, an injective *level-two* hash function is built for each subset by allocating a private memory block of an appropriate size.

This two-level scheme formed a basis for algorithms for a dynamic version of the hashing problem, also called the *dictionary problem*, in which insertions and deletions may change S dynamically. Such algorithms were given by Dietzfelbinger, Karlin, Mehlhorn, Meyer auf der Heide, Rohnert, and Tarjan [11]; Dietzfelbinger and Meyer auf der Heide [13]; and by Dietzfelbinger, Gil, Matias, and Pippenger [10].

In the parallel setting, Dietzfelbinger and Meyer auf der Heide [12] presented an algorithm for the dictionary problem. For each fixed $\epsilon \geq 0$, n arbitrary dictionary instructions (insert, delete, or lookup) can be executed in $O(n^\epsilon)$ expected time on a $n^{1-\epsilon}$-processor PRIORITY CRCW. Matias and Vishkin [38] presented an algorithm for the hashing problem that runs in $O(\lg n)$ expected time using $O(n/\lg n)$ processors on an ARBITRARY CRCW. This was the fastest parallel hashing algorithm previous to our work. It is based on the two-level scheme and makes extensive use of counting and sorting procedures.

The only known lower bounds for parallel hashing were given by Gil, Meyer auf der Heide, and Wigderson [26]. In their (rather general) model of computation, the required number of parallel steps is $\Omega(\lg^* n)$. They also showed that in a more restricted model, where at most one processor may simultaneously work on a key, parallel hashing time is $\Omega(\lg \lg n)$. They also gave an algorithm which yields a matching upper bound if only function applications are charged and all other operations (e.g., counting and sorting) are free. Our algorithm falls within the realm of the above-mentioned restricted model and matches the $\Omega(\lg \lg n)$ lower bound while charging for all operations on the concrete PRAM model.

1.2. Results. Our main result is that a linear static hash table can be constructed in $O(\lg \lg n)$ time with high probability and $O(n)$ space, using n processors on a CRCW PRAM. Our algorithm has the following properties.

Time optimality. It is the best possible result that does not use processor reallocations, as shown in [26]. Optimal speedup can be achieved with a small penalty in execution time. It is a significant improvement over the $O(\lg n)$-time algorithm of [38].

1. Partition the input set into buckets by a random polynomial of constant degree.
2. For $t := 1$ to $O(\lg \lg n)$ do
   (a) Allocate M_t memory blocks, each of size K_t.
   (b) Let each bucket select a block at random, and try to injectively map its keys into the block using a random linear function; if the same block was selected by another bucket, or if no injective mapping was found, then the bucket carries on to the next iteration.

FIG. 1. *The template for the hashing algorithm.*

Reliability. The time bound $O(\lg \lg n)$ is obeyed with high probability; in contrast, the time bound of the algorithm in [38] is guaranteed only with constant probability.

Simplicity. It is arguably simpler than any other hashing algorithm previously published. (Nevertheless, the analysis is quite involved due to tight tradeoffs between the probabilities of conflicting events.)

Reduced randomness. It is adapted to consume only $O(\lg \lg n)$ random words, compared with $\Omega(n)$ random words that were previously used.

Work optimality. A work-optimal implementation is presented, in which the time-processor product is $O(n)$ and the running time is increased by a factor of $O(\lg^* n)$; it also requires only $O(\lg \lg n)$ random words.

Computational model. If we allow the lookup time to be $O(\lg \lg n)$ as well, then our algorithm can be implemented on the ROBUST CRCW model.

Our results can be summarized in the following theorem.

THEOREM 1.1. *Given a set of n keys drawn from a universe U, the hashing problem can be solved using $O(n)$ space:* (i) *in $O(\lg \lg n)$ time with high probability, using n processors, or* (ii) *in $O(\lg \lg n \lg^* n)$ time and $O(n)$ operations with high probability. The algorithms run on a* CRCW PRAM*, where no reallocation of processors to keys is employed, and use $O(\lg \lg |U| + \lg n \lg \lg n)$ random bits.*

The previous algorithms implementing the two-level scheme, either sequentially or in parallel, are based on grouping the keys according to the buckets to which they belong, and require learning the size of each bucket. Each bucket is then allocated a private memory block whose size is dependent on the bucket size. This approach relies on techniques related to sorting and counting, which require $\Omega(\lg n / \lg \lg n)$ time to be solved by a polynomial number of processors, as implied by the lower bound of Beame and Håstad [4]. This lower bound holds even for randomized algorithms. (More recent results have found other, more involved, ways to circumvent these barriers; cf. [37, 3, 25, 29].)

We circumvent the obstacle of learning buckets sizes for the purpose of appropriate memory allocation by a technique of *oblivious execution* sketched by Figure 1.

The crux of the algorithm is a careful a priori selection of the parameters M_t and K_t. For each iteration t, M_t and K_t depend on the expected number of active buckets and the expected distribution of bucket sizes at iteration t in a way that makes the desired progress possible (or rather, likely).

The execution is oblivious in the following sense: all buckets are treated equally, regardless of their sizes. The algorithm does not make any explicit attempt to estimate the sizes of individual buckets and to allocate memory to buckets based on their sizes,

as is the case in the previous implementations of the two-level scheme. Nor does it attempt to estimate the number of active buckets or the distribution of their sizes.

The selection of the parameters M_t and K_t in iteration t is made according to a priori estimates of the above random variables. These estimates are based on properties of the level-one hash function as well as on inductive assumptions about the behavior of previous iterations.

Remark. The hashing result demonstrates the power of randomness in parallel computation on CRCW machines with memory restricted to linear size. Boppana [6] considered the problem of element distinctness: given n integers, decide whether or not they are all distinct. He showed that solving element distinctness on an n-processor PRIORITY machine with bounded memory requires $\Omega(\lg n/\lg\lg n)$ time. "Bounded memory" means that the memory size is an arbitrary function of n but not of the range of the input values. It is easy to see that if the memory size is bounded by $\Omega(n^2)$ then element distinctness can be solved in $O(1)$ expected time by using hash functions (Fact 2.2). This, however, does not hold for linear size memory. Our parallel hashing algorithm implies that when incorporating randomness, element distinctness can be solved in expected $O(\lg\lg n)$ time using n processors on COLLISION$^+$ (which is weaker than the PRIORITY model) with linear memory size.

1.3. Applications. The perfect hash table data structure is a useful tool for parallel algorithms. Matias and Vishkin [38] proposed using a parallel hashing scheme for space reduction in algorithms in which a large amount of space is required for communication between processors. Such algorithms become space efficient and preserve the number of operations. The penalties are in introducing randomization and in having some increase in time. Using our hashing scheme, the time increase may be substantially smaller.

There are algorithms for which, by using the scheme of [38], the resulting time increase is $O(\lg n)$. By using the new scheme, the time increase is only $O(\lg\lg n \lg^* n)$. This is the case in the construction of *suffix trees* for strings [2, 16] and in the naming assignment procedure for substrings over large alphabets [16].

For other algorithms, the time increase in [38] was $O(\lg\lg n)$ or $O\left((\lg\lg n)^2\right)$, while our algorithm leaves the expected time unchanged. Such is the case in integer sorting over a polynomial range [32] and over a super-polynomial range [5, 38].

More applications are discussed in the conclusion section.

1.4. Outline. The rest of the paper is organized as follows. Preliminary technicalities used in our algorithm and its analysis are given in section 2. The algorithm template is presented in greater detail in section 3. Two different implementations, based on different selections of M_t and K_t, are given in the subsequent sections. Section 4 presents an implementation that does not fully satisfy the statement of Theorem 1.1 but has a relatively simple analysis. An improved implementation of the main algorithm, with a more involved analysis, is presented in section 5. In section 6 we show how to reduce the number of random bits. Section 7 explains how the algorithm can be implemented with an optimal number of operations. The model of computation is discussed in section 8, where we also give a modified algorithm for a weaker model. Section 9 briefly discusses the extension of the hashing problem, in which the input may consist of a multiset. Finally, conclusions are given in section 10.

2. Preliminaries. The following inequalities are standard (see, e.g., [1]).

Markov's inequality. Let ω be a random variable assuming nonnegative values only. Then

$$\mathbf{Prob}(\omega > T) < \mathbf{E}(\omega)/T. \tag{1}$$

Chebyshev's inequality. Let ω be a random variable. Then, for $T > 0$,

$$\mathbf{Prob}(|\omega - \mathbf{E}(\omega)| > T) < \mathbf{Var}(\omega)/T^2. \tag{2}$$

Chernoff's inequality. Let ω be a binomial variable. Then, for $T > 0$,

$$\mathbf{Prob}(|\omega - \mathbf{E}(\omega)| > T) = e^{-\Omega(T^2/\mathbf{E}(\omega))}. \tag{3}$$

Terminology for probabilities. We say that an event occurs with *n-dominant probability* if it occurs with probability $1 - n^{-\Omega(1)}$. We use this terminology as follows. If a polylogarithmic number of events are such that each one of them occurs with n-dominant probability, then their conjunction occurs with n-dominant probability as well. We will therefore usually be satisfied by demonstrating that each algorithmic step succeeds with n-dominant probability.

FACT 2.1. *Let $\omega_1, \ldots, \omega_n$ be pairwise independent binary random variables, and let $\omega = \sum_{1 \le i \le n} \omega_i$. Let $\epsilon > 0$ be constant; let $0 < \xi_1 < (1-\epsilon)\mathbf{E}(\omega)$ and $\xi_2 > (1+\epsilon)\mathbf{E}(\omega)$. Then*

1. *$\omega > \xi_1$ with ξ_1-dominant probability,*
2. *$\omega < \xi_2$ with ξ_2-dominant probability, and*
3. *$(1-\epsilon)\mathbf{E}(\omega) \le \omega \le (1+\epsilon)\mathbf{E}(\omega)$ with $\mathbf{E}(\omega)$-dominant probability.*

Proof. Recall the well-known fact that

$$\begin{aligned} \mathbf{Var}(\omega) &= \sum_{1 \le i \le n} \mathbf{Var}(\omega_i) \text{ since } \omega_i \text{ are pairwise independent} \\ &\le \sum_{1 \le i \le n} \mathbf{E}(\omega_i) \text{ since } 0 \le \omega_i \le 1 \\ &= \mathbf{E}(\omega). \end{aligned} \tag{4}$$

1. By inequality (2)

$$\mathbf{Prob}(\omega > \xi_1) \le \mathbf{Prob}(|\omega - \mathbf{E}(\omega)| > \epsilon\mathbf{E}(\omega)) < 1/\epsilon^2\mathbf{E}(\omega) < 1/\epsilon^2\xi_1.$$

2. If $\xi_2 \le \mathbf{E}(\omega)^2$ then by inequality (2)

$$\mathbf{Prob}(\omega > \xi_2) \le \mathbf{Prob}(|\omega - \mathbf{E}(\omega)| > \epsilon\mathbf{E}(\omega)) < 1/\epsilon^2\mathbf{E}(\omega) < 1/\epsilon^2\sqrt{\xi_2}.$$

If $\xi_2 > \mathbf{E}(\omega)^2$ then by inequality (1)

$$\mathbf{Prob}(\omega > \xi_2) < \mathbf{E}(\omega)/\xi_2 < 1/\sqrt{\xi_2}.$$

3. This follows immediately from the above. □

Hash functions. For the remainder of this section, let $S \subseteq U$ be fixed, $|S| = n$. A hash function $h : U \to [0, m-1]$ splits the set S into buckets; *bucket i* is the subset $\{x \in S \mid h(x) = i\}$ and its size is $s_i = \left|S \cap h^{-1}(i)\right|$ for $0 \le i < m$. An element $x \in S$ *collides* if its bucket is not a singleton. The function is *injective*, or *perfect*, if no element collides. Let

$$B_r = B_r(h) = \sum_{0 \le i < m} \binom{s_i}{r}. \tag{5}$$

A function is injective if and only if $B_2 = 0$, since B_2 is the number of collisions of pairs of keys. More generally, B_r is the number of r-tuples of keys that collide under h.

Polynomial hash functions. Let $U = [0, u-1]$ where u is prime. The class of degree-d polynomial hash functions, $d \geq 1$, mapping U into $[0, m-1]$ is

$$\mathcal{H}_m^d := \left\{ h \;\middle|\; h(x) = \left(\sum_{i=0}^{d} c_i x^i \bmod u \right) \bmod m \text{ for some } c_0, \ldots, c_d \in U \right\}.$$

In the rest of this section we consider the probability space in which h is selected uniformly at random from $\mathcal{H}_m^d$, $d \geq 1$.

The following fact and corollary were shown by Fredman, Komlós, and Szemerédi [15] and before that by Carter and Wegman [7]. (The original proof was only for the case $d = 1$; however, the generalization for $d > 1$ is straightforward.)

FACT 2.2. $\mathbf{E}(B_2) \leq n^2/m$.

COROLLARY 2.3. *The hash function h is injective on S with probability at least $1 - n^2/m$.*

Proof. The function h is injective if and only if $B_2 = 0$. By Fact 2.2 and Markov's inequality, the probability that h is not injective is $\mathbf{Prob}(B_2 \geq 1) \leq n^2/m$. □

The following was shown in [10].

FACT 2.4. *If $d \geq 3$ then $B_2 \leq 2n^2/m$ with n^2/m-dominant probability.*

For $r \geq 0$, let B_r be the random variable which is the rth moment of the sequence of s_i's,

$$B_r = B_r(h) = \sum_{0 \leq i < m} s_i^r. \tag{6}$$

It is easy to see that $B_0 = m$ and $B_1 = n$. Further, it can be shown that if $n = O(m)$ and if h were a completely random function, then B_r is linear in n with high probability for all fixed $r \geq 2$. For polynomial hash functions, Dietzfelbinger et al. [11] proved the following fact.

FACT 2.5. *Let $r \geq 0$ and $m \geq n$. If $d \geq r$ then there exists a constant $\sigma_r > 0$, depending only on r, such that*

$$\mathbf{Prob}(B_r \leq 2^{\sigma_r} \cdot n) \;\geq\; 1/2.$$

Tighter estimates on the distribution of B_r were given in [10].

FACT 2.6. *Let $r \geq 2$. If $d \geq r$ then*

$$\mathbf{E}(B_r) \leq n \sum_{1 \leq j \leq r} \left\{ {r \atop j} \right\} \left(\frac{2n}{m} \right)^{j-1},$$

where $\left\{ {r \atop j} \right\}$ is the Stirling number of the second kind.[1]

FACT 2.7. *Let $\epsilon > 0$ be constant. If $d \geq 2r$ and $m \geq n$ then $B_r \leq (1+\epsilon)\mathbf{E}(B_r)$ with n-dominant probability.*

[1] For $k \geq j \geq 0$, the *Stirling number of the second kind*, $\left\{ {k \atop j} \right\} = \frac{1}{j!} \sum_{i=0}^{k} (-1)^{j-i} \binom{j}{i} i^k$, is the number of ways of partitioning a set of k distinct elements into j nonempty subsets (e.g., [30, Chapter 6]).

Allocation. The bucket selects at random one of the M_t memory blocks. If the same block was selected by another bucket, then the bucket remains active and does not participate in the next step.

Hashing. The bucket selects at random two functions from $\mathcal{H}^1_{K_t}$ and then tries to hash itself into the block separately by each of these functions. If either one of the functions is injective, then its description and the memory address of the block are written in the appropriate cell of array ptr and the bucket becomes inactive. Otherwise, the bucket remains active and carries on to the next iteration.

FIG. 2. *The two steps of an iteration, based on oblivious execution.*

3. A framework for hashing by oblivious execution.

3.1. An algorithm template. The input to the algorithm is a set S of n keys, given in an array. The hashing algorithm works in two stages, which correspond to the two-level hashing scheme of Fredman, Komlós, and Szemerédi [15].

In the first stage a level-one hash function f is chosen. This function is selected at random from the class $\mathcal{H}^d_m$, where d is a sufficiently large constant to be selected in the analysis, and $m = \Theta(n)$. The hash function f partitions the input set into m *buckets*; bucket i, $i = 0, \ldots, m-1$, is the set $S \cap f^{-1}(i)$. The first stage is easily implemented in constant time. The main effort is in the implementation of the second stage, which is described next.

The second level of the hash table is built in the second stage of the algorithm. For each bucket a private memory region, called a *block*, is assigned. The address of the memory block allocated to bucket i is recorded in cell i of a designated array ptr of size m. Also, for each bucket, a level-two function is constructed; this function injectively maps the bucket into its block. The descriptions of the level-two functions are written in ptr.

Let us call a bucket *active* if an appropriate level-two function has not yet been found, and *inactive* otherwise. At the beginning of the stage all buckets are active, and the algorithm terminates when all buckets have become inactive. The second stage consists of $O(\lg \lg n)$ iterations, each executing in constant time. The iterative process rapidly reduces the number of active buckets and the number of active keys.

At each iteration t, a new memory segment is used. This segment is partitioned into M_t blocks of size K_t each, where M_t and K_t will be set in the analysis. Each bucket and each key is associated with one processor. The operation of each active bucket in each iteration is given in Figure 2.

In a few of the last iterations, it may become necessary for an iteration to repeat its body more than once but no more than a constant number of times. The precise conditions and the number of repetitions are given in section 5.

The hash table constructed by the algorithm supports lookup queries in constant time. Given a key x, a search for it begins by reading the cell $\mathsf{ptr}[f(x)]$. The contents of this cell defines the level-two function to be used for x as well as the address of the memory block in which x is stored. The actual offset in the block in which x is stored is given by the injective level-two hash function found in the *Hashing* step above.

3.2. Implementations. The algorithm template described above constitutes a framework for building parallel hashing algorithms. The execution of these algorithms is oblivious in the sense that the iterative process of finding level-two hash functions does not require information about the number or size of active buckets. Successful termination and performance are dependent on the a priori setting of the parameters d, M_t, and K_t. The effectiveness of the allocation step relies on having sufficiently *many* memory blocks; the effectiveness of the hashing step relies on having sufficiently *large* memory blocks. The requirement of keeping the total memory linear imposes a tradeoff between the two parameters. The challenge is in finding a balance between M_t and K_t so as to achieve a desired rate of decay in the number of active buckets. The number of active keys can be deduced from the number of active buckets based on the characteristics of the level-one hash function as determined by d.

We will show two different implementations of the algorithm template, each leading to an analysis of a different nature. The first implementation is given in section 4. There, the parameters are selected in such a way that in each iteration the number of active buckets is expected to decrease by a constant factor. Although each iteration may fail with constant probability, there is a geometrically decreasing series which bounds from above the number of active buckets in each iteration. After $O(\lg \lg n)$ iterations, the expected number of active keys and active buckets becomes $n/(\lg n)^{\Omega(1)}$. The remaining keys are hashed in additional constant time using a different approach, after employing an $O(\lg \lg n)$-time load balancing procedure.

From a technical point of view, the analysis of this implementation imposes relatively modest requirements on the level-one hash function, since it only uses first-moment analysis (i.e., Markov's inequality). Moreover, it only requires a simpler version of the hashing step, in which only one hash function from $\mathcal{H}^1_{K_t}$ is being used. The expected running time is $O(\lg \lg n)$, but this running time is guaranteed only with constant probability, which can be made arbitrarily close to 1.

The second implementation is given in section 5. This implementation is characterized by a doubly exponential rate of decrease[2] in the number of active buckets and keys. After $O(\lg \lg n)$ iterations all keys are hashed without any further processing. This implementation is superior in several other respects: its time performance is with high probability, each key is only handled by its original processor, and it forms a basis for further improvements in reducing the number of random bits.

From a technical point of view, the analysis of this implementation is more subtle and imposes more demanding requirements on the level-one hash function, since it uses second-moment analysis (i.e., Chebyshev's inequality). Achieving a doubly exponential rate of decrease required a more careful selection of parameters.

Together, these implementations demonstrate two different paradigms for fast parallel randomized algorithms, each involving a different flavor of analysis. In the first implementation, one only requires an exponential rate of decrease in the problem size and then relies on reallocation of processors to items. (Subsequent works that use this paradigm and its extensions are mentioned in section 10.) This paradigm is relatively easy to understand and not too difficult to analyze using a framework of probabilistic induction and analysis by expectations. The analysis shows that each iteration succeeds with constant probability and that this implies an overall constant success probability. In contrast, the second implementation shows that each iteration succeeds with n-dominant probability and that this implies an overall n-

[2] A sequence $v_0, v_1, \ldots$ decreases at an *exponential* rate if for all t, $v_t \leq v_0/(1+\epsilon)^t$ for some $\epsilon > 0$; the sequence decreases at a *doubly exponential* rate if for all t, $v_t \leq v_0/2^{(1+\epsilon)^t}$ for some $\epsilon > 0$.

dominant success probability. The analysis is significantly more subtle and relies on more powerful techniques of second moment analysis. The second paradigm consists of a doubly exponential rate of decrease in the problem size and hence does not require any wrapup step.

4. Obtaining exponential decrease. This section presents our first implementation of the algorithm template. Using a rather elementary analysis of expectations, we show that at each iteration the problem size decreases by a constant factor with (only) constant probability. The general framework described in section 4.1 shows that this implies that the problem size decreases at an overall exponential rate.

After $O(\lg\lg n)$ iterations, the number of keys is reduced to $n/(\lg n)^{\Omega(1)}$. A simple load balancing algorithm now allocates $(\lg n)^{\Omega(1)}$ processors to each remaining key. Using the relatively large number of allocated processors, each key is finally hashed in constant time.

4.1. Designing by expectation. Consider an iterative randomized algorithm, in which after each iteration some measure of the problem decreases by a random amount. In a companion paper [21] we showed that at each iteration one can actually assume that in previous iterations the algorithm was not too far from its expected behavior. The paradigm suggested is as follows.

> *Design an iteration to be "successful" with a constant probability under the assumption that at least a constant fraction of the previous iterations were "successful."*

It is justified by the following lemma.

LEMMA 4.1 (probabilistic induction [21]). *Consider an iterative randomized process in which, for all $t \geq 0$, the following holds: iteration $t+1$ succeeds with probability at least $1/2$, provided that among the first t iterations at least $t/4$ were successful. Then, with probability $\Omega(1)$, for every $t > 0$ the number of successful iterations among the first t iterations is at least $t/4$.*

4.2. Parameters setting and analysis. Let the level-one function be taken from $\mathcal{H}_m^{10}$; i.e. set $d = 10$. Let

$$r = 10. \tag{7}$$

Further, set

$$m = 4n. \tag{8}$$

Let

$$K_t = 2^{4+\sigma_{10}/5+t/5}, \tag{9}$$

$$M_t = m\, 2^{4-t/4}, \tag{10}$$

where σ_{10} is as in Fact 2.5.

To simplify the analysis, we allow the parameters K_t and M_t to assume nonintegral values. In actual implementation, they must be rounded up to the nearest integer. This does not increase memory requirements by more than a constant factor; all other performance measures can only be improved.

Memory usage. The memory space used is

$$\sum_t M_t K_t = m 2^{8+\sigma_{10}/5} \sum_t 2^{t/5-t/4} = O(n).$$

LEMMA 4.2. *Let v_t be the number of active buckets at the beginning of iteration t. Then,*

$$\mathbf{Prob}\left(\forall\, t \geq 0 \ : \ \ v_t \leq m2^{-t/4}\right) = \Omega(1).$$

Proof. We assume that the level-one function f satisfies

$$B_{10} \leq 2^{\sigma_{10}} \cdot m. \tag{11}$$

By Fact 2.5, (11) holds with probability at least $1/2$.

The proof is continued by using Lemma 4.1. Iteration t is *successful* if $v_{t+1} \leq v_t/2$. Thus, the number of active buckets after j successful iterations is at most $m2^{-j}$.

The probabilistic inductive hypothesis is that among the first t iterations at least $t/4$ were successful; that is,

$$v_t \leq m2^{-t/4}. \tag{12}$$

The probabilistic inductive step is to show that

$$\mathbf{Prob}\,(v_{t+1} \leq v_t/2) \geq 1/2.$$

In each iteration the parameters K_t and M_t were chosen so as to achieve constant deactivation probability for buckets of size at most

$$\beta_t = \sqrt{K_t/8} = 2^{(1+\sigma_{10}/5+t/5)/2}. \tag{13}$$

We distinguish between the following three types of events, "failures," which may cause a bucket to remain active at the end of an iteration.

(i) *Allocation failure*. The bucket may select a memory block which is also selected by other buckets.

Let $\rho_1(t)$ be the probability that a fixed bucket does not successfully reserve a block in the allocation step. Since there are at most v_t buckets, each selecting at random one of M_t memory blocks, $\rho_1(t) \leq v_t/M_t$. By (12) and (10),

$$\rho_1(t) \leq m2^{-t/4}/m2^{4-t/4} = 1/16.$$

(ii) *Size failure*. The bucket may be too large for the current memory block size. As a result, the probability for it to find a level-two hash function is not high enough.

Let v'_t be the number of buckets at the beginning of iteration t that are larger than β_t. By (11),

$$v'_t \cdot \beta_t^{10} \leq B_{10} \leq 2^{\sigma_{10}} m.$$

Therefore, by (13),

$$v'_t \leq 2^{\sigma_{10}} m/\beta_t^{10} = m2^{\sigma_{10}-5(1+\sigma_{10}/5+t/5)} = m2^{-5-t}. \tag{14}$$

Without loss of generality we assume that if $v_{t+1} \leq v_t/2$ then $v_{t+1} = v_t/2$ (i.e., if more buckets that are needed become inactive, then some of them are still considered as active). Thus, for the purpose of analysis,

$$v_t \geq m2^{-t}. \tag{15}$$

We then have

$$v'_t \leq v_t 2^{-5} < v_t/16.$$

(iii) *Hash failure*. A bucket may fail to find an injective level-two hash function even though it is sufficiently small and it has uniquely selected a block.

Let $\rho_3(t)$ be the probability that a bucket of size at most β_t is not successfully mapped into a block of size K_t in the hashing step. By Corollary 2.3 and (13)

$$\rho_3(t) \leq \beta_t^2/K_t = 1/8.$$

A bucket of size at most β_t that successfully reserves a block of size K_t, and that is successfully mapped into it, becomes inactive. The expected number of active buckets at the beginning of iteration $t+1$ can therefore be bounded by

$$\mathbf{E}\left(v_{t+1}\right) \leq v_t\rho_1(t) + v'_t + v_t\rho_3(t) \leq v_t\left(1/16 + 1/16 + 1/8\right) \leq v_t/4.$$

By Markov's inequality,

$$\mathbf{Prob}\left(v_{t+1} \leq v_t/2\right) \geq 1/2,$$

proving the inductive step. The lemma follows. □

LEMMA 4.3. *Let n_t be the number of active keys at the beginning of iteration t. Then*

$$\mathbf{Prob}\left(\forall\, t \geq 0 \;:\; n_t \leq cn2^{-\alpha t}\right) = \Omega(1)$$

for some constants $c, \alpha > 0$.

Proof. It follows from (11), by using a simple convexity argument, that n_t is maximal when all active buckets at the beginning of iteration t are of the same size q_t. In this case, by (11),

$$v_t \cdot q_t^{10} \leq 2^{\sigma_{10}} \cdot m$$

and

$$n_t = v_t \cdot q_t \leq v_t \cdot \left(\frac{2^{\sigma_{10}} m}{v_t}\right)^{0.1} = (2^{\sigma_{10}} m)^{0.1} v_t^{0.9}.$$

Therefore, by Lemma 4.2, the lemma follows. □

By Lemmas 4.2 and 4.3 we have an exponential decrease in the number of active keys and in the number of active buckets with probability $\Omega(1)$. The number of active keys becomes $n/(\lg n)^c$, for any constant $c > 0$, after $O(\lg\lg n)$ iterations with probability $\Omega(1)$.

4.3. A final stage. After the execution of the second stage with the parameter setting as described above, the number of available resources (memory cells and processors) is a factor of $(\lg n)^{\Omega(1)}$ larger than the number of active keys. This resource redundancy makes it possible to hash the remaining active keys in constant time, as described in the remainder of this section.

All keys that were not hashed in the iterative process will be hashed into an auxiliary hash table of size $O(n)$. Consequently, the implementation of a lookup query will consist of searching the key in both hash tables.

The auxiliary hash table is built using the two-level hashing scheme. A level-one function maps the set of active keys into an array of size n. This function is selected at random from a class of hash functions presented by Dietzfelbinger and Meyer auf der Heide [13, Definition 4.1]. It has the property that with n-dominant probability each bucket is of size smaller than $\lg n$ [13, Theorem 4.6(b')]. For the remainder of this section we assume that this event indeed occurs. (Alternatively, we can use the n^ϵ-universal class of hash functions presented by Siegel [42].)

Each active key is allocated $2 \lg n$ processors, and each active bucket is allocated $4(\lg n)^3$ memory. The allocation is done by mapping the active keys injectively into an array of size $O(n/\lg n)$, and by mapping the indices of buckets injectively into an array of size $O(n/(\lg n)^3)$. These mappings can be done in $O(\lg \lg n)$ time with n-dominant probability by using the simple renaming algorithm from [19].

The remaining steps take constant time. We independently select two $\lg n$ linear hash functions and store them in a designated array. These hash functions will be used by all buckets.

The memory allocated to each bucket is partitioned into two $\lg n$ memory blocks, each of size $2 \lg^2 n$. Each bucket is mapped in parallel into its two $\lg n$ blocks by the two $\lg n$ selected linear hash functions, and each mapping is tested for injectiveness. This is carried out by the two $\lg n$ processors allocated to each key. For each bucket, one of the injective mappings is selected as a level-two function. The selection is made by using the simple "leftmost 1" algorithm of [14].

If for any of the buckets all the mappings are not injective, then the construction of the auxiliary hash table fails.

LEMMA 4.4. *Assume that the number of keys that remain active after the iterative process is at most $n/(\lg n)^3$. Then, the construction of the auxiliary hash table succeeds with n-dominant probability.*

Proof. Recall that each bucket is of size at most $\lg n$. A mapping of a bucket into its memory block of size $2(\lg n)^2$ is injective with probability at least $1/2$ by Corollary 2.3. The probability that a bucket has no injective mapping is therefore at most $1/n^2$. With probability at least $1 - 1/n$, every bucket has at least one injective mapping. □

It is easy to identify failure. If the algorithm fails to terminate within a designated time, it can be restarted. The hash table will be therefore always constructed. Since the overall failure probability is constant, the expected running time is $O(\lg \lg n)$.

5. Obtaining doubly exponential decrease. The implementation of the algorithm template that was presented in the previous section maintains an exponential decrease in the number of active buckets throughout the iterations. This section presents the implementation in which the number of active buckets decreases at a doubly exponential rate.

Intuitively, the stochastic process behind the algorithm template has a potential for achieving doubly exponential rate: if a memory block is sufficiently large in comparison with the bucket size, then the probability of the bucket to remain active is inversely proportional to the size of the memory block (Corollary 2.3). Consider an idealized situation in which this is the case. If at iteration t there are m_t active buckets, each allocated a memory block of size K_t, then at iteration $t + 1$ there will be m_t/K_t active buckets, and each of those could be allocated a memory block of size K_t^2; at iteration $t + 2$ there will be m_t/K_t^3 active buckets, each to be allocated a memory block of size K_t^4, and so on.

In a less idealized setting, some buckets are not deactivated because they are too

large for the current value of K_t. The number of such buckets can be bounded above by using properties of the level-one hash function. It must be guaranteed that the fraction of "large buckets" also decreases at a doubly exponential rate.

The illustrative crude calculation given above assumes that memory can be evenly distributed among the active buckets. To make the doubly exponential rate possible, the failure probability of the allocation step, and hence the ratio m_t/M_t, must also decrease at a doubly exponential rate.

Establishing a bound on the number of "large blocks" and showing that a large fraction of the buckets are allocated memory blocks were also of concern in the previous section. There, however, it was enough to show constant bounds on the probabilities of *allocation failure*, *size failure*, and *hash failure*.

The parameter setting which establishes the balance required for the doubly exponential rate is now presented. Following that is the analysis of the algorithm performance.

5.1. Parameters setting. Let the level-one function be taken from $\mathcal{H}_m^{18}$; i.e., set $d = 18$. Let

$$r = 9. \tag{16}$$

Further, set

$$m = 160n. \tag{17}$$

Let

$$K_t = 2^{a\lambda^t + b_1 t + c_1}, \tag{18}$$

$$M_t = n\, 2^{-a\lambda^t - b_2 t + c_2}, \tag{19}$$

where

$$\lambda = 18/13\,, \quad a = 8/13\,, \quad b_1 = 1/5\,, \quad b_2 = 9/20\,, \quad c_1 = 73/25\,, \quad c_2 = 89/20. \tag{20}$$

5.2. Memory usage.

PROPOSITION 5.1. *The total memory used by the algorithm is $O(n)$.*

Proof. By (17), the memory used in the first stage is $O(n)$. The memory used in an iteration t of the second stage is

$$M_t \cdot K_t = n\, 2^{(b_1 - b_2)t + c_1 + c_2} = n\, 2^{-t/4 + 737/100}. \tag{21}$$

The total memory used by the second stage is therefore at most

$$\sum_{t=0}^{\infty} n\, 2^{-t/4 + 737/100} = \frac{2^{7.37}}{1 - 1/\sqrt[4]{2}} \cdot n = O(n). \qquad \square \tag{22}$$

5.3. Framework for time performance analysis. Let m_t be defined by

$$m_t = n\, 2^{-\lambda^t - b_2 t + 1}. \tag{23}$$

The run-time analysis of the second stage is carried out by showing Lemma 5.2.

LEMMA 5.2. *With n-dominant probability, the number of active buckets in the beginning of iteration t is at most m_t.*

The lemma is proved by induction on t for $t \leq \lg\lg n / \lg\lambda$. The induction base follows from $m_0 = n$ and the fact that there are at most n active buckets.

In the subsequent subsections, we prove the inductive step by deriving estimates on the number of failing buckets in iteration t under the assumption that at the beginning of the iteration there are at most m_t active buckets. Specifically, we show by induction on t that, with n-dominant probability, the number of active buckets at the end of iteration t is at most

$$m_{t+1} = n\, 2^{-\lambda^{t+1} - b_2(t+1)+1}. \tag{24}$$

The bucket may fail to find an injective level-two hash function. In estimating the number of buckets that fail to find an injective level-two function during an iteration we assume that the bucket uniquely selected a memory block and that the bucket size is not too large relatively to the current block size. Accordingly, as in section 4.2, we distinguish between the following three types of events, "failures," which may cause a bucket to remain active at the end of an iteration.

(i) *Allocation failure.* The bucket may select a memory block that is also selected by other buckets.

(ii) *Size failure.* The bucket may be too large for the current memory block size. As a result, the probability for it to find a level-two hash function is not high enough.

(iii) *Hash failure.* A bucket may fail to find a level-two hash function even though it is sufficiently small and it has uniquely selected a block.

We will provide estimates for the number of buckets that remain active due to either of the above reasons: in Lemma 5.5 for case (i), in Lemma 5.6 for case (ii), and in Lemmas 5.7 and 5.8 for case (iii). The estimates are all shown to hold with n-dominant probability. The induction step follows from adding all these estimates.

To wrap up, let $t = \lg\lg n / \lg\lambda$. Then, by (23),

$$m_t = n\, 2^{-\lambda^t - b_2 t + 1} = n\, 2^{-\lg n - b_2 t + 1} < 1.$$

We can therefore infer Proposition 5.3.

PROPOSITION 5.3. *With n-dominant probability, the number of iterations required to deactivate all buckets is at most $\lg\lg n / \lg\lambda$.*

5.4. Failures in uniquely selecting a block.

LEMMA 5.4. *Let ϵ be fixed, $0 < \epsilon < 1/6$, and suppose that either $m_t > M_t^{1/2+\epsilon}$ or $m_t < M_t^{1/2-\epsilon}$. Let ω be the random variable representing the number of buckets that fail to uniquely select a block. Then, $\omega \leq 2m_t^2/M_t$, with M_t-dominant probability.*

Proof. A bucket has a probability of at most m_t/M_t to have other buckets select the memory block it selected. Therefore,

$$\mathbf{E}(\omega) \leq m_t^2/M_t. \tag{25}$$

Further, ω is stochastically smaller than a binomially distributed random variable ϖ obtained by performing m_t independent trials, each with probability m_t/M_t of success. That is to say, $\mathbf{Prob}(\omega \geq \omega_0) \leq \mathbf{Prob}(\varpi \geq \omega_0)$ for all ω_0. Note that $\mathbf{E}(\varpi) = m_t^2/M_t$. If $m_t > M_t^{1/2+\epsilon}$ then

$$\begin{aligned} \mathbf{Prob}\left(\omega > 2m_t^2/M_t\right) &\underset{\text{by (3)}}{\leq} \mathbf{Prob}\left(\varpi > 2m_t^2/M_t\right) \\ &= e^{-\Omega(\mathbf{E}(\varpi))} \\ &= e^{-\Omega(m_t^2/M_t)} \\ &= e^{-\Omega(M_t^{2\epsilon})} \\ &= M_t^{-\Omega(1)}. \end{aligned} \tag{26}$$

Otherwise, $m_t < M_t^{1/2-\epsilon}$ and we are in the situation where $\mathbf{E}(\omega) \ll 1$. Since ω is integer valued and $2m_t^2 > 0$,

$$\begin{array}{rcl} \mathbf{Prob}\left(\omega > 2m_t^2/M_t\right) & \leq & \mathbf{Prob}(\omega \geq 1) \\ & \overset{\text{by (1)}}{\leq} & \mathbf{E}(\omega) \\ & \overset{\text{by (25)}}{\leq} & m_t^2/M_t \\ & < & M_t^{-2\epsilon}. \quad \square \end{array} \tag{27}$$

The setting not covered by the above lemma is $M_t^{1/2-\epsilon} \leq m_t \leq M_t^{1/2+\epsilon}$. This only occurs in a constant number of iterations throughout the algorithm and requires the following special treatment. The body of these iterations is repeated, thus providing a second allocation attempt of buckets that failed to uniquely select a memory block in the first trial.

Let ω_1 and ω_2 be the random variables representing the number of buckets that fail to uniquely select a block in the first and second attempts, respectively,

$$\begin{array}{rcl} \mathbf{Prob}\left(\omega_1 > M_t^{1/2-\epsilon}\right) & \overset{\text{by (1)}}{<} & \mathbf{E}(\omega_1)/M_t^{1/2-\epsilon} \\ & \overset{\text{by (25)}}{=} & m_t^2/M_t M_t^{1/2-\epsilon} \\ & = & m_t^2/M_t^{3/2-\epsilon} \\ & \leq & M_t^{1+2\epsilon}/M_t^{3/2-\epsilon} \\ & = & M_t^{3\epsilon-1/2} \\ & = & M_t^{-\Omega(1)}. \end{array} \tag{28}$$

Therefore, with M_t-dominant probability the second attempt falls within the conditions of equation 27 and hence $\omega_2 = 0$ with M_t-dominant probability.

LEMMA 5.5. *Let $t \leq \lg\lg n/\lg\lambda$. The number of buckets that fail to uniquely select a block is, with n-dominant probability, at most $m_{t+1}/4$.*

Proof. By Lemma 5.4, the number of buckets that fail to uniquely select a memory block is, with M_t-dominant probability, at most

$$\begin{array}{rcl} 2m_t^2/M_t & \overset{\text{by (19),(23)}}{=} & 2n^2\, 2^{-2\lambda^t - 2b_2 t + 2}/n\, 2^{-a\lambda^t - b_2 t + c_2} \\ & = & n\, 2^{(a-2)\lambda^t - b_2 t + 3 - c_2} \\ & \overset{\text{by (20)}}{=} & n\, 2^{(8/13-2)\lambda^t - b_2(t+1) + b_2 + 3 - c_2} \\ & = & n\, 2^{-(18/13)\lambda^t - b_2(t+1) + 9/20 + 3 - 89/20} \\ & \overset{\text{by (20)}}{=} & n\, 2^{-\lambda^{t+1} - b_2(t+1) - 1} \\ & \overset{\text{by (24)}}{=} & m_{t+1}/4. \end{array} \tag{29}$$

The above holds also with n-dominant probability since

$$\begin{array}{rcl} M_t & \overset{\text{by (19)}}{=} & n\, 2^{-a\lambda^t - b_2 t + c_2} \\ & \geq & n\, 2^{-a\lg n - b_2 t + c_2} \\ & = & n^{1-a} 2^{-b_2 \lg\lg n/\lg\lambda + c_2} \\ & \overset{\text{by (20)}}{=} & n^{5/13} \lg n^{-\Omega(1)}. \quad \square \end{array} \tag{30}$$

5.5. Failures in hashing. In considering buckets, which uniquely selected a block which failed to find an injective level-two function, we draw special attention to buckets of size at most

$$\beta_t = \sqrt[4]{K_t/2}. \tag{31}$$

LEMMA 5.6. *The number of buckets larger than β_t is, with n-dominant probability, at most $m_{t+1}/4$.*

Proof. Let $\mu = m/n = 160$. By incorporating into Fact 2.6 the appropriate values for the Stirling numbers of the second kind, we get

$$\mathbf{E}(B_r) \le \left(1 + \frac{510}{\mu} + \frac{12100}{\mu^2} + \frac{62160}{\mu^3} + \frac{111216}{\mu^4} + \frac{84672}{\mu^5} + \frac{29568}{\mu^6} + \frac{4608}{\mu^7} + \frac{256}{\mu^8}\right) n$$
$$\overset{\text{by (17)}}{\le} 4.6756\, n.$$

Therefore, by Fact 2.7, with n-dominant probability

$$B_r \le 6n. \tag{32}$$

From the above and (6) it follows that the number of buckets bigger than β_t is, with n-dominant probability, at most

$$\begin{aligned}
6n/\beta_t^r &\overset{\text{by (31),(16)}}{=} 6n/(K_t/2)^{9/4} \\
&\overset{\text{by (18)}}{=} 6n\, 2^{-9(a\lambda^t + b_1 t + c_1 - 1)/4} \\
&\overset{\text{by (20)}}{=} 6n\, 2^{-(18/13)\lambda^t - (9/20)t - 108/25} \\
&\overset{\text{by (20)}}{=} 6n\, 2^{-\lambda^{t+1} - b_2(t+1) + b_2 - 108/25} \\
&\overset{\text{by (20)}}{=} 6n\, 2^{-\lambda^{t+1} - b_2(t+1) + 9/20 - 108/25} \\
&= 6n\, 2^{-\lambda^{t+1} - b_2(t+1) - 387/100} \\
&= n\, 2^{-\lambda^{t+1} - b_2(t+1) + 1 + (\lg 3 - 387/100)} \\
&\overset{\text{by (24)}}{=} m_{t+1} 2^{\lg 3 - 387/100} \\
&= m_{t+1} 2^{-2.285\ldots} \\
&< m_{t+1}/4. \qquad \square
\end{aligned} \tag{33}$$

The analysis of hashing failures of buckets that are small enough is further split into two cases.

LEMMA 5.7. *Suppose that $m_t/2K_t \ge \sqrt{n}$. Then the number of buckets of size at most β_t that fail in the hashing step of the iteration is, with n-dominant probability, at most $m_{t+1}/4$.*

Proof. Without loss of generality, we may assume that there are exactly m_t active buckets of size at most β_t that participate in the hashing step. When such a bucket is mapped into a memory block of size K_t, the probability of the mapping being noninjective is, by Corollary 2.3, at most $\beta_t^2/K_t = 1/\sqrt{2K_t}$. The probability that the bucket fails in both hashing attempts is therefore at most $1/2K_t$. Let $\tilde{m}_t$ be the total number of such failing buckets. Then, $\mathbf{E}(\tilde{m}_t) \le m_t/2K_t$. By Fact 2.1, with $m_t/2K_t$-dominant probability,

$$
\begin{array}{rcl}
\tilde{m}_t & \leq & 2(m_t/2K_t) \\
& = & m_t/K_t \\
& \overset{\text{by (18),(23)}}{=} & n\,2^{-\lambda^t - b_2 t + 1 - a\lambda^t - b_1 t - c_1} \\
& = & n\,2^{-(1+a)\lambda^t - (b_2+b_1)t + 1 - c_1} \\
& \overset{\text{by (20)}}{\leq} & n\,2^{-(21/13)\lambda^t - b_2(t+1) + 1 + b_2 - c_1} \\
& \overset{\text{by (20)}}{\leq} & n\,2^{-\lambda^{t+1} - b_2(t+1) + 1 + b_2 - c_1} \\
& \overset{\text{by (20),(24)}}{=} & m_{t+1}\,2^{9/20 - 73/25} \\
& < & m_{t+1}/4.
\end{array} \tag{34}
$$

Note that since $m_t/2K_t \geq \sqrt{n}$, the above holds with n-dominant probability and we are done. □

LEMMA 5.8. *Suppose that $m_t/2K_t < \sqrt{n}$. Then, by repeating the hashing step of the iteration a constant number of times, we get $\tilde{m}_t = 0$, with n-dominant probability.*

Proof. We have

$$
n\,2^{-(1+a)\lambda^t - (b_2+b_1)t - c_1} \overset{\text{by (18),(23)}}{=} m_t/2K_t < \sqrt{n}, \tag{35}
$$

and, thus,

$$
2^{(1+a)\lambda^t + (b_2+b_1)t + c_1} > \sqrt{n}. \tag{36}
$$

Therefore,

$$
\begin{array}{rcl}
K_t & \overset{\text{by (18)}}{=} & 2^{a\lambda^t + b_1 t + c_1} \\
& \geq & 2^{\delta\left((1+a)\lambda^t + (b_2+b_1)t + c_1\right)} \\
& \overset{\text{by (36)}}{>} & n^{\delta/2}
\end{array} \tag{37}
$$

for some constant $\delta > 0$. Recall from the proof of Lemma 5.7 that a bucket fails in the hashing step with probability at most $1/2K_t$. By (37), if the iteration body is repeated $\lceil 2/\delta \rceil + 1$ times, the failure probability of each bucket becomes at most $(2K_t)^{-2/\delta - 1} < 2^{-2/\delta}/2K_t n$, and

$$
\mathbf{E}\,(\tilde{m}_t) < m_t 2^{-2/\delta}/2K_t n < 2^{-2/\delta}\sqrt{n}/n = 2^{-2/\delta}/\sqrt{n}.
$$

The lemma follows by Markov's inequality. □

6. Reducing the number of random bits. In this section we show how to reduce the number of random bits used by the hashing algorithm.

The algorithm as described in the previous section consumes $\Theta(n \lg u)$ random bits, where $u = |U|$: the first iteration already uses $\Theta(n \lg u)$ random bits; for each subsequent iteration, the number of random words from U which are used is by at most a constant factor larger than the memory used in that iteration, resulting in a total of $\Theta(n \lg u)$ random bits.

The sequential hashing algorithm of Fredman, Komlós, and Szemerédi [15] can be implemented with only $O(\lg \lg u + \lg n)$ random bits [10]. We show how the parallel hashing algorithm can be implemented with $O(\lg \lg u + \lg n \lg \lg n)$ random bits.

We first show how the algorithm can be modified so as to reduce the number of random bits to $O(\lg u \lg\lg n)$. The first stage requires $O(1)$ random elements from U for the construction of the level-one function and remains unchanged. An iteration t of the second stage required $O(m_t)$ random elements from U; it is modified as follows.

Allocation step. If each bucket independently selects a random memory block, then $O(m_t \lg M_t)$ random bits are consumed. This can be reduced to $O(\lg m)$ by making use of *polynomial hash functions*.

LEMMA 6.1. *Using* $6\lg m$ *random bits, a set* $R \subseteq [0, m-1]$ *of size* m_t *can be mapped in constant time into an array of size* $3M_t$ *such that the number of colliding elements is at most* $2m_t^2/M_t$, *with* M_t*-dominant probability.*

Proof. Let $g_t^a \in \mathcal{H}^3_{2M_t}$ and $g_t^b \in \mathcal{H}^1_{M_t}$ be selected at random. Then the image of a bucket i is defined by

$$g_t(i) = \begin{cases} g_t^a(i) & \text{if } \nexists j \in R,\ j \neq i,\ g_t^a(i) = g_t^a(j), \\ 2M_t + g_t^b(i) & \text{otherwise.} \end{cases} \tag{38}$$

Algorithmically, g_t^a is first applied to all elements and then g_t^b is applied to the elements which collided under g_t^a. The colliding elements of g_t are those which collided both under g_t^a and under g_t^b.

Let R' be the set of elements that collide under g_t^a. Clearly, $|R'| \leq 2B_2(g_t^a)$. Let ϵ be some constant, $0 < \epsilon < 1/6$. Consider the following three cases.

1. $m_t \leq M_t^{1/2-\epsilon}$.
   By Corollary 2.3, $\mathbf{Prob}\,(R' \neq \emptyset) \leq m_t^2/2M_t \leq M_t^{-2\epsilon}/2$.
2. $m_t \geq M_t^{1/2+\epsilon}$.
   It follows from Fact 2.4 that $B_2 \leq 2m_t^2/2M_t = m_t^2/M_t$ with $m_t^2/2M_t$-dominant probability. As $|R'| \leq 2B_2$ and $m_t^2/2M_t \geq M_t^{2\epsilon}/2$ we have that $|R'| \leq 2m_t^2/M_t$ with M_t-dominant probability.
3. $M_t^{1/2-\epsilon} < m_t < M_t^{1/2+\epsilon}$.
   By Fact 2.2, $\mathbf{E}\,(B_2(g_t^a)) \leq m_t^2/2M_t < M_t^{2\epsilon}/2$ and by Markov's inequality,

$$\mathbf{Prob}\left(B_2(g_t^a) > M_t^{1/2-\epsilon}/2\right) \leq M_t^{2\epsilon}/M_t^{1/2-\epsilon} = M_t^{3\epsilon-1/2}.$$

   Therefore, with M_t-dominant probability, $|R'| \leq 2B_2(g_t^a) \leq M_t^{1/2-\epsilon}$, in which case, by Corollary 2.3,

$$\mathbf{Prob}\left(g_t^b \text{ is not injective over } R'\right) \leq |R'|^2/M_t \leq M_t^{-2\epsilon}. \qquad \square$$

Invoking the above procedure for block allocation does not increase the total memory consumption of the algorithm by more than a constant factor.

Hashing step. The implementation of the hashing part of the iteration body using *independent* hash functions for each of the active buckets consumes $O(m_t \lg u)$ random bits. This can be reduced to $O(\lg u)$ by using hash functions which are only *pairwise independent*. This technique and its application in the context of hash functions are essentially due to [9, 10].

The modification to the step is as follows. In each hashing attempt executed during the step, four global parameters $a_0, a_1, b_0, b_1 \in U$ are selected at random by the algorithm. The hash function attempted by a bucket i is

$$h_i(x) := ((c_0(i) + c_1(i)x) \bmod u) \bmod K_t, \tag{39}$$

where

$$c_0(i) = (ia_0 + b_0) \bmod u,$$
$$c_1(i) = (ia_1 + b_1) \bmod u.$$

All hashing attempts of the same bucket are fully independent. Thus, the proof of Lemma 5.8 is unaffected by this modification. Recall that Fact 2.1 assumes only pairwise independence. Since h_i, $i = 0, \ldots, m-1$, are pairwise independent, the proof of Lemma 5.7 remains valid as well.

The above leads to a reduction in the number of random bits used by the algorithm to $O(\lg u \lg\lg n)$.

The number of random bits can be further reduced as follows: employ a preprocessing hashing step in which the input set S is injectively mapped into the range $[0, n^3 - 1]$. This is done by applying a hash function π selected from an appropriate class to map the universe U into this range. Then the algorithm described above is used to build a hash table for the set $\pi(S)$. A lookup of a key x is done by searching for $\pi(x)$ in this hash table.

A class of hash functions that is appropriate for this universe reduction application was described in [10]. This class has the following properties.

1. A selection of a random function π from the class requires $O(\lg\lg u + \lg n)$ random bits.
2. A selection can be made in constant time by a single processor.
3. The function π is injective over S with n-dominant probability.
4. Computing $\pi(x)$ for any $x \in U$ can be done in constant time.

This preprocessing is tantamount to a reduction in the size of the universe, after which application of the algorithm requires only $O(\lg n \lg\lg n)$ bits. The total number of random bits used is therefore

$$O(\lg\lg u + \lg n \lg\lg n).$$

We note that a lookup step is essentially the same as before, except that when looking for an element x in bucket i (i.e., $i = f(x)$), locations $g_t^a(i)$ and $g_t^b(i)$ should both be checked.

7. Obtaining optimal speedup. The description of the algorithm in section 3 assumed that the number of processors is n; thus the time-processor product is $O(n \lg\lg n)$. Our objective in this section is a work-optimal implementation where this product is $O(n)$ and p, the number of processors, is maximized.

When $p < n$, the key array and the bucket array are divided into p *sectors*, one per processor. A parallel step of the algorithm is executed by having each processor traverse its sector and execute the tasks included in it.

A key is *active* if its bucket is active. Let n_t be the number of active keys at the beginning of iteration t. Assume that the implemented algorithm has reached the point where $n_t = O(n/\lg\lg n)$. Further assume that these active elements are gathered in an array of size $O(n/\lg\lg n)$. Then, applying the nonoptimal algorithm of section 3 with $p \le n/\lg\lg n$, and each processor being responsible for $n/p \lg\lg n$ problem instances, gives a running time of

$$O\left(\frac{n}{p \lg\lg n} \lg\lg\left(\frac{n}{\lg\lg n}\right)\right) = O\left(n/p\right),$$

which is work optimal.

We first show that the problem size is reduced sufficiently for the application of the nonoptimal algorithm after $O(\lg\lg\lg\lg n)$ iterations.

LEMMA 7.1. *There exists* $t_0 = O(\lg\lg\lg\lg n)$ *such that* $n_{t_0} = O(n/\lg\lg n)$ *with* n*-dominant probability.*

Proof. The number of active buckets decreases at a doubly exponential rate as can be seen from Lemma 5.2. To see that the number of keys decreases at a doubly exponential rate as well, we show that with n-dominant probability

$$n_t \leq 1.23n2^{-2a\lambda^{t-1}-2b_1t+8/9}. \tag{40}$$

Inequality (32), $B_r \leq 6n$, clearly holds when the summation is over active buckets only. By a convexity argument, the total number of keys in active buckets are maximized when all active buckets are of equal size. The number of active buckets are bounded from above by m_t. Therefore,

$$n_t \leq (6n)^{1/r} m_t^{1-1/r}. \tag{41}$$

Inequality (40) is obtained from (41) by substituting the definition (23) of m_t in (23) and then substituting numerical values for the parameters using (16) and (20).

The lemma follows by choosing an appropriate value for t_0 with respect to (23) and (40). □

It remains to exhibit a work-efficient implementation of the first t_0 steps of the algorithm. This implementation outputs the active elements gathered in an array of size $O(n/\lg\lg n)$. The rest of this section is dedicated to the description of this implementation.

As the algorithm progresses, the number of active keys and the number of active buckets decrease. However, the decrease in the number of active elements in different sectors is not necessarily identical. The time of implementing one parallel step is proportional to the number of active elements in the largest sector. It is therefore crucial to occasionally balance the number of active elements among different sectors in order to obtain work efficiency.

Let the *load* of a sector be the number of active elements (tasks) in it. A *load balancing* algorithm takes as input a set of tasks arbitrarily distributed among p sectors; using p processors it redistributes this set so that the load of each sector is greater than the average load by at most a constant factor. Suppose that we have a load balancing algorithm whose running time, using p processors, is $T_{\text{lb}}(p)$ with n-dominant probability. If load balancing is applied after step t, then the size of each sector is $O(n_t/p)$.

We describe a simple work-optimal implementation in which load balancing is applied after each of the first t_0 parallel steps. A parallel step t executes in time which is in the order of

$$\frac{n_t}{p} + T_{\text{lb}}(p).$$

The total time of this implementation is in the order of

$$\sum_{t=1}^{t_0} \left(\frac{n_t}{p} + T_{\text{lb}}(p) \right).$$

Since n_t decreases at least at an exponential rate, the total time is in the order of

$$\frac{n}{p} + t_0\, T_{\text{lb}}(p),$$

which is $O(n/p)$ for

$$p = O\left(\frac{n}{T_{\text{lb}}(p)\lg\lg\lg\lg n}\right).$$

Using the load balancing algorithm of [19] which runs in $T_{\text{lb}}(p) = O(\lg\lg p)$ time, we conclude that with n-dominant probability the running time on a p-processor machine is

$$O(n/p + \lg\lg p \lg\lg\lg\lg n).$$

The load balancing algorithm applied consumes $O(p\lg\lg p)$ random bits. All these bits are used in a random mapping step which is very similar to the allocation step of the hashing algorithm. Thus, by an approach similar to the mapping procedure in Lemma 6.1 it may be established that the number of random bits in the load balancing algorithm can be reduced to $O(\lg p \lg\lg p)$.

We finally remark that using load balancing in a more efficient way, as described in [22], yields a faster work-efficient implementation. This simple technique is based on carefully choosing the appropriate times for invoking the load balancing procedure; it applies to any algorithm in which the problem size has an exponential rate of decrease, and it hence applies to the implementation of section 4 as well. In such an implementation the load balancing algorithm is only used $O(\lg^* n)$ times, resulting in a parallel hashing algorithm that takes $O(n/p + \lg\lg n \lg^* n)$ time with n-dominant probability.

8. Model of computation. In this section we give closer attention to the details of the implementation on a PRAM, and we study the type of concurrent memory access required by our algorithm. We first present an implementation on COLLISION and its extension to the weaker TOLERANT model. We proceed by presenting an implementation on the even weaker ROBUST model. The hash table constructed in this implementation only supports searches in $O(\lg\lg n)$ time. Finally, we examine the concurrent read capability needed by the implementations.

8.1. Implementation on COLLISION and on TOLERANT. We describe an implementation on COLLISION. This implementation is also valid for TOLERANT, since each step of COLLISION can be simulated in constant time on TOLERANT provided that, as it is the case here, only linear memory is used [31].

Initialization. The selection of the level-one hash function is done by a single processor. Since the level-one function is a polynomial of a constant degree, its selection can be done by a single processor and can be read by all processors in constant time, using a singe memory cell of $\lceil \max\{\lg\lg u, \lg n\} \rceil$ bits. No concurrent write operation is required for the implementation of this stage.

Bucket representatives. The algorithm template assumes that each bucket can act as a single entity for some operations, e.g., selecting a random block and selecting a random hash function. Since usually several keys belong to the same bucket, it is necessary to coordinate the actions of the processors allocated to these keys. A simple way of doing so is based on the fact that there are only linearly many buckets and that a bucket is uniquely indexed by the value of f, the level-one hash function, on its members. A processor whose index is determined by the bucket index acts as the *bucket representative* and performs the actions prescribed by the algorithm to the bucket.

Allocation and hashing steps. A processor representing an active bucket selects a memory block and a level-two hash function and records these selections in a designated cell. All processors with keys in that bucket then read that cell and use the selected block in the hashing step. Each participating processor (whose key belongs in an active bucket) writes its key in the cell determined by its level-two hash function and examines the cell contents to see if the write operation was successful. A processor for which the write failed will then attempt to write its key to position i of array ptr, where i is the number of the bucket this processor belongs to. Processors belonging to bucket i can then learn if the level-two function selected for their bucket is injective by reading the content of ptr$[i]$. A change in value or a collision symbol indicates noninjectiveness. To complete the process, the array ptr is restored for the next hashing attempt. This restoration can be done in constant time since this array is of linear size.

In summary we have Proposition 8.1.

PROPOSITION 8.1. *The algorithms of Theorem* 1.1 *can also be implemented on the* TOLERANT *model.*

8.2. Implementation on ROBUST. We now describe an implementation that, at the expense of slowing down the lookup operation, makes no assumption about the result of a concurrent write into a cell. Specifically, we present an implementation on the ROBUST model for which a lookup query may take $O(\lg \lg n)$ time and, for keys in the table, the expected time is $O(1)$.

The difficulty with the ROBUST model is in letting all processors in a bucket know whether the level-two hash function of their bucket is injective or not. The main idea in the modified implementation is in allowing iterations to proceed without determining whether level-two hash functions are injective or not; whenever a key is written into a memory cell in the hashing step it is deactivated, and its bucket size decreases. The modified algorithm performs at least as well as the implementation in which a bucket is deactivated only if all of its keys are mapped injectively. The total memory used by the modified algorithm and the size of the representation of the hash table do not change.

Allocation step. We first note that the algorithm can be carried out without using bucket representatives at all. Allocation of memory blocks is done using hash functions, as in Lemma 6.1; each processor can individually compute the index of its memory block by evaluating the function g_t. This function is selected by a designated processor and its representation ($6 \lg m$ bits) is read in constant time by all processors.

We further modify the algorithm, so that the hashing step is carried out by *all* active buckets. That is, even buckets that collided in the allocation step will participate in the hashing step. This modification can only serve to improve the performance of the algorithm, since even while sharing a block with another bucket the probability that a bucket finds an injective function into that block is not zero. This modification eliminates the concurrent memory access needed for detecting failures in the allocation step.

Hashing step. The selection of a level-two hash function is done as in the hashing step described in section 6. As can be seen from (39), only four global parameters should be selected and made available to all processors; this can be done in constant time.

It remains to eliminate the concurrent memory access required for determining if the level-two function of any single bucket was injective. Whenever a key is successfully hashed by this function, it is deactivated even if other keys in the same bucket

Let x be an active key in a bucket $i = f(x)$. The processor assigned to x executes the following steps.

Allocation. Compute $g_t(i)$, the index of the memory block selected for the bucket containing x, where g_t is defined by (38).

Hashing. Determine h_i, the level-two hash function selected by the bucket of x, where h_i is defined by (39). Write x into cell $h_i(x)$ in memory block $g_t(i)$ and read the contents of that cell; if x was written then the key x becomes inactive.

FIG. 3. *Implementation of iteration t in the hashing algorithm on* ROBUST.

were not successfully hashed. Thus, keys of the same bucket may be stored in the hash table using different level-two hash functions.

The two steps of an iteration in the hashing algorithm are summarized in Figure 3.

Lookup algorithm. The search for a key x is done as follows. Let $i = f(x)$; for $t = 1, 2, \ldots$ read position $h_i(x)$ in the memory block $g_t(i)$ in the appropriate array. (All random bits that were used in the hash table construction algorithm are assumed to be recorded and available.) The search is terminated when either x is found or when t exceeds the number of iterations in the construction algorithm.

The lookup algorithm requires $O(\lg \lg n)$ iterations in the worst case. However, for any key $x \in S$ the expected lookup time (over all the random selections made by the hashing algorithm) is $O(1)$.

An alternative simplified implementation. Curiously, the sequence of modifications to the algorithm described in this section has lead to a *one-level* hashing scheme, i.e., to the elimination of indirect addressing. To see this, we observe that at iteration t an active key x is written into a memory cell ${g_t}^*(x)$, where the function ${g_t}^*(x)$ is dependent only on n and on the random selections made by the algorithm, but not on the input (beyond the slight dependency of g_t on detecting collisions in the input, which does not imply indirect addressing). An even simpler implementation of a one-level hashing algorithm is outlined next.

At each iteration t, a new array T_t of size $3M_t$ is used, where M_t is as defined in (19). In addition, a function g_t as defined in (38) is selected at random. A processor representing an active key x in the iteration tries to write x into $T_t[g_t^a(x)]$ and then reads this cell. If x is successfully written in $T_t[g_t^a(x)]$ then x is deactivated (and $g_t(x) = g_t^a(x)$). Otherwise, this processor tries to write x into $T_t[g_t^b(x)]$ and then reads this cell. If x is successfully written in $T_t[2M_t + g_t^b(x)]$ then x is deactivated (and $g_t(x) = 2M_t + g_t^b(x)$). Otherwise, x remains active and the processor representing it carries on to the next iteration.

To see that the algorithm terminates in $O(\lg \lg n)$ iterations with n-dominant probability, we observe that the operation on keys in each iteration is the same as the operation on buckets in the allocation step of section 6. Therefore, the analysis of section 6 can be reused, substituting keys for buckets (and ignoring failures in the hashing step of the two-level algorithm). The hash table consists of the collection of the arrays $T_1, T_2, \ldots$, and, as can be easily verified, is of linear size. A lookup query for a given key x is executed in $O(\lg \lg n)$ time by reading $T_t[g_t^a(x)]$ and then (if necessary) $T_t[2M_t + g_t^b(x)]$ for $t = 1, 2, \ldots$.

We note that it is difficult to detect termination on the ROBUST in $o(\lg n)$ time. Therefore, the algorithm described here is of a Monte Carlo type.

8.3. Minimizing concurrent read requirements. The algorithms for construction of the hash table on TOLERANT can be modified to use concurrent read from a single cell only. By allowing a preprocessing stage of $O(\lg n)$ time, concurrent read can be eliminated, implying that the ERCW model is sufficient. With these modifications, parallel lookups still require concurrent read, and their execution time increases to $O(\lg \lg n)$ in the worst case. Nevertheless, the expected time for lookup of any single key $x \in S$ is $O(1)$.

There are two types of concurrent-read operations required by the modified algorithm. First, the sequence of $O(\lg \lg n)$ functions ${g_t}^*$ (or, alternatively, g_t in the simplified implementation) must be agreed upon by all processors. Since each of these functions is represented by $O(\lg u)$ bits, its selection can be broadcasted at the beginning of the iteration through the concurrent-read cell.

The single cell concurrent-read requirement for broadcasting can be eliminated by adding an $O(\lg n)$-time preprocessing step for the broadcasting. (This is just a special case of simulating CRCW PRAM by EREW PRAM.)

The other kind of concurrent-read operation occurs when processors read a memory cell to verify that their hashing into that cell has succeeded. This operation can be replaced by the following procedure. For each memory cell, there is a processor standing by. Whenever a pair $\langle x, j \rangle$ is written into a cell, the processor assigned to that cell sends an acknowledgment to processor j by writing into a memory cell j in a designated array.

The lookup algorithm requires concurrent-read capabilities. In this sense, the lookup operation is more demanding than the construction of the hash table. A similar phenomenon was observed by Karp, Luby, and Meyer auf der Heide [35] in the context of simulating a random access machine on a distributed memory machine. The main challenge in the design of their (parallel-hashing-based) simulation algorithm was the execution of the read step. Congestions during the execution of the write step were resolved by attempting to write in several locations and using the first location for which the write succeeded. It is more difficult to resolve read congestions since the cells in which values were stored are already determined. Indeed, the read operation constitutes the main run-time bottleneck in their algorithm.

9. Hashing of multisets. We conclude the technical discussion by briefly considering a variation of the hashing problem in which the input is a multiset rather than a set of distinct keys. (In this case, the number of keys in the resulting table are equal to the number of distinct keys in the input.) We first note that the analyses of the exponential and doubly exponential rate of decrease in the problem size is not affected by the possibility of multiple occurrences of the same key. This is a result of relying on estimates of the number of active *buckets* rather than on the number of active keys. The number of distinct keys—not the number of keys—determine the probability of a bucket to find an injective function.

A predictable decrease in the number of active *keys* is essential for obtaining an optimal speedup algorithm. Unfortunately, the analysis in section 7 with regard to the implementation of section 5 does not hold. To understand the difficulty, consider the case where a substantial fraction of the input consists of copies of the same key. Then with nonnegligible probability this key may belong to a large bucket. The probability that this bucket deactivates in the first few iterations, in which the memory blocks are not sufficiently large, is too small to allow global decrease in the number of keys

with high probability. Consequently, the rapid decrease in the number of buckets may not be accompanied by a similar decrease in the number of keys.

In contrast, the nature of the analysis in section 4 makes this analysis susceptible to an easy extension to multiple keys, which leads to an optimal speedup algorithm, albeit with expected performance only. Using the probabilistic induction lemma all that is required is to show that each copy of an active key has a constant positive probability of deactivation at each iteration. Since the analysis is based on expectations only, there are no concerns regarding correlations between copies of the same key or dependencies between different iterations. The details are left to the reader.

We also note that the model of computation required for a multiset is COLLISION$^+$, since it must be possible to distinguish between the case of multiple copies of the same key being written into a memory cell and the case where distinct keys are written. Also, the extensions of the hashing algorithms which only require concurrent read from a single memory cell can be used for hashing with multiset input, but then a COLLISION$^+$ model, as opposed to ROBUST, must be assumed.

We finally observe that the hashing problem with a multiset as input can be reduced into the ordinary hashing problem (in which the input consists of a set) by a procedure known as *leaders election*. This procedure selects a single representative from among all processors which share a value. By using a randomized $O(\lg\lg n)$-time, linear-work leaders election algorithm which runs on TOLERANT [23] we have Theorem 9.1.

THEOREM 9.1. *Given a multiset of n keys drawn from a universe U, the hashing problem can be solved using $O(n)$ space:* (i) *in $O(\lg\lg n)$ time with high probability, using n processors, or* (ii) *in $O(\lg\lg n \lg^* n)$ time and $O(n)$ operations with high probability. The algorithms run on* TOLERANT.

Conversely, note that any hashing algorithm, when run on ARBITRARY, solves the leaders election problem. In particular, the simple one-level hashing algorithm for ROBUST, when implemented on ARBITRARY with a multiset as input, gives a simple leaders election algorithm which uses only $O(n)$ space.

Consider now another variant of the multiset hashing problem in which a data record is associated with each key. The natural semantics of this problem is that multiple copies of the same key can be inserted into the hash table only if their data records are identical. Processors representing copies of a key with conflicting data records should terminate the computation with an error code. The COLLISION$^+$ model makes it easy enough to extend the implementations discussed above to accommodate this variant.

A more sophisticated semantics, in which the data records should be consolidated, requires a different treatment, e.g., by applying an integer sorting algorithm on the hashed keys (see [38]).

10. Conclusions. We presented a novel technique of hashing by oblivious execution. By using this technique, algorithms for constructing a perfect hash table which are fast, simple, and efficient, were made possible. The running time obtained is best possible in a model in which keys are only handled in their original processors.

The number of random bits consumed by the algorithm is $\Theta(\lg\lg u + \lg n \lg\lg n)$. An open question is to close the gap between this number and the $\Theta(\lg\lg u + \lg n)$ random bits that are consumed in the sequential hashing algorithm of [10].

The program executed by each processor is extremely simple. Indeed, the only coordination between processors is in computing the AND function, when testing for injectiveness. In the implementation on the ROBUST model, even this coordination is eliminated.

The large constants hidden under the O-notation in the analysis may render the described implementations still far from being practical. We believe that the constants can be substantially improved without compromising the simplicity of the algorithm by a more careful tuning of the parameters and by tightened analysis. This may be an interesting subject of a separate research.

The usefulness of the oblivious execution approach presented in this paper is not limited to the hashing problem alone. We have adopted it in [23] for simulations among submodels of the CRCW PRAM. As in the hashing algorithm, keys are partitioned into subsets. However, this partition is arbitrary and given in the input, and for each subset the maximum key must be computed.

Subsequent work. The oblivious execution technique for hashing from section 3 and its implementation from section 4 were presented in preliminary form in [20]. Subsequently, our oblivious execution technique was used several times to obtain improvements in running time of parallel hashing algorithms: Matias and Vishkin [37] gave an $O(\lg^* n \lg\lg^* n)$ expected-time algorithm; Gil, Matias, and Vishkin [25] gave a tighter failure probability analysis for the algorithm in [37], yielding $O(\lg^* n)$ time with high probability; a similar improvement (from $O(\lg^* n \lg\lg^* n)$ expected time to $O(\lg^* n)$ time with high probability) was described independently by Bast and Hagerup [3].

An $O(\lg^* n)$-time hashing algorithm is used as a building block in a parallel dictionary algorithm presented in [25]. (A parallel dictionary algorithm supports in parallel batches of operations *insert*, *delete*, and *lookup*.) The oblivious execution technique has an important role in the implementation of insertions into the dictionary. The dictionary algorithm runs in $O(\lg^* n)$ time with high probability, improving the $O(n^\epsilon)$-time dictionary algorithm of Dietzfelbinger and Meyer auf der Heide [12]. The dictionary algorithm can be used to obtain a space-efficient implementation of any parallel algorithm, at the cost of a slowdown of at most $O(\lg^* n)$ time with high probability.

The above hashing algorithms use the log-star paradigm of [37], relying extensively on processor reallocation, and are not as simple as the algorithm presented in this paper. Moreover, they require a substantially larger number of random bits.

Karp, Luby, and Meyer auf der Heide [35] presented an efficient simulation of a PRAM on a distributed memory machine in the doubly logarithmic time level, improving over previous simulations in the logarithmic time level. The use of a fast parallel hashing algorithm is essential in their result; the algorithm presented here is sufficient to obtain it.

Goldberg, Jerrum, Leighton, and Rao [27] used techniques from this paper to obtain an $O(h + \lg\lg n)$ randomized algorithm for the h-relation problem on the optical communication parallel computer model.

Gibbons, Matias, and Ramachandran [17] adapted the algorithm presented here to obtain a low-contention parallel hashing algorithm for the QRQW PRAM model [18]; this implies an efficient hashing algorithm on Valiant's BSP model and hence on hypercube-type noncombining networks [43].

Acknowledgments. We thank Martin Dietzfelbinger and Faith E. Fich for providing helpful comments. We also wish to thank Uzi Vishkin and Avi Wigderson for early discussions. Part of this research was done during visits of the first author to AT&T Bell Laboratories, and of the second author to the University of British Columbia. We would like to thank these institutions for supporting these visits. Many valuable comments made by two anonymous referees are gratefully acknowledged.

A FILTER MODEL FOR CONCURRENT λ-CALCULUS*

MARIANGIOLA DEZANI-CIANCAGLINI†, UGO DE'LIGUORO†, AND ADOLFO PIPERNO‡

Abstract. Type-free lazy λ-calculus is enriched with angelic parallelism and demonic nondeterminism. Call-by-name and call-by-value abstractions are considered and the operational semantics is stated in terms of a must convergence predicate. We introduce a type assignment system with intersection and union types, and we prove that the induced logical semantics is fully abstract.

Key words. λ-calculus, parallelism, nondeterminism, full abstraction, functional programming, concurrency

1. Introduction.

Powerful computer architectures make parallelism and concurrency feasible. To exploit these features in existing high-level programming languages, while retaining abstraction and logical clarity in writing programs, it is natural to extend those languages by new concepts and constructs. In particular, much work has been done to accommodate parallel and concurrency primitives inside functional programming languages like CML [60] and FACILE [28] (see [29] for further work in the area and for references).

This extension gives rise to the problem of introducing nonfunctional features in the functional framework. To illustrate this, let us consider parallelism first. If the parallel construct is a control primitive which allows the programmer to force the parallel evaluation of two or more arguments to be passed to a function, then the treatment of divergence (and the value passing mechanism) becomes much more complex. For example, a binary function may be undefined if both its arguments are undefined, without being strict in either the first or the second argument. A typical example is Scott's *parallel-or* function (see [62, p. 437]), the binary partial function of booleans that returns true if at least one of its arguments is defined and equal to true, and returns false if both arguments are defined and equal to false.

The *parallel-or* can be further analyzed as an example of parallel composition of compatible sequential functions. Indeed, let

$$Lor \equiv \lambda xy.\ \textbf{if}\ x\ \textbf{then}\ \text{true}\ \textbf{else}\ y\ \textbf{fi}, \qquad Ror \equiv \lambda xy.\ \textbf{if}\ y\ \textbf{then}\ \text{true}\ \textbf{else}\ x\ \textbf{fi}$$

be the left-sequential and the right-sequential *or*, respectively. Then these functions are compatible, since, in the pointwise ordering induced by the flat domain of booleans, they have an upper bound (actually a join) which is the *parallel-or* function itself. On the other hand, if they can be computed in parallel, returning as soon as either the computation of *Lor* or the computation of *Ror* stops, then we have an implementation of the parallel-or function.

If parallel composition is a binary operator that can be applied to any pair of functions—not necessarily compatible—then the same evaluation mechanism is a nondeterministic device that can be modeled as a multivalued function. An example is McCarthy's *amb* function [47]. This kind of multivalued function has been widely considered in the literature. In the folklore this form of nondeterminism is called angelic nondeterminism (and credited to Hoare) because of its behavior with respect to divergence: a parallel composition is convergent if at least one of its operands converges. In terms of Dijkstra's correctness criteria, this corresponds to partial correctness.

Concurrency has been added to functional languages using CCS- or CSP-like synchronization and communication primitives. In both cases the interaction with the environment introduces a different form of nondeterminism, as unpredictable events may affect the behavior of the system. In particular, nondeterminism comes in when a choice occurs among guarded commands having the same guard (see [38]).

This nondeterminism has been modeled using internal choice operators, which are correctly considered as abstraction or specification tools. Indeed, no programmer may wish to use internal choice to control the evaluation of a program; it has to be thought of instead as a declaration, saying that, whatever the actual alternative will be, the program still satisfies the correctness requirements. Of course, the criterion is that of total correctness, so that, with respect to divergence, an internal choice is divergent as soon as one of its operands diverges. In folkloric terms, this is demonic nondeterminism. A survey about nondeterminism in functional languages can be found in [65].

When facing these theoretical problems a primary point is to choose the abstraction level of the investigation. One may take a very abstract view and consider them as multifunctions, or, equivalently, functions over powerdomains. This study has been pioneered by Plotkin in [58] and pursued by several authors (see [66] and, for a survey, [46]). Here continuity is the only aspect of computation which is retained in the theory, the main point being the treatment of divergence.

An alternative and quite concrete approach is to model functionality, concurrency, and parallelism by syntactical tools. This amounts to design theoretical languages that formalize essentially all aspects of the computation and interaction, so that actual programming languages can be seen as sugared syntax of the former ones. In this case the languages and the related calculi are inspired on one hand by the λ-calculus, both typed and type-free, and on the other hand by the process calculi (CCS, CSP, ACP, etc.). In exploiting the "concrete" approach, there are at least two main streams. Following the first, functions and processes are first-class objects. The resulting calculus can either be seen as a λ-calculus with processes as possible arguments of functions (as in Nielson's TPL [53]) or as a process algebra with a special form of communication, generalizing the β-reduction of the λ-calculus (as in Thomsen's CHOCS [67, 34, 35]). The second stream does not allow processes as arguments of functions: instead, channels (or port names) have a first-class status and can be sent as values (see, e.g., [11]). The most radical step in this direction is to think of processes just as agents that communicate each others' channel names as values. In this way processes are virtually passed by sending the name of a (private) channel to the receiver, thus giving access to the "passed" process: this is Milner's π-calculus [51]. In the latter case, functions and functional application disappear from the calculus syntax, and they are simulated in a rather complex way.

In this paper we advocate a third approach to the problem of the mathematical study of relevant aspects of concurrent functional languages, which, in some sense,

sits in between the abstract denotational method and the concrete, direct description of interaction and communication. In this case one still considers a formal language together with its operational semantics. The latter gives an essential (and effective) description of the evaluation of expressions in the language. The main departure from the concrete approach, however, is the abstraction from communication, concentrating on a syntax which represents different kinds of nondeterminism by means of different operators, whose behavior is axiomatically described by the rules of the operational semantics.

In this perspective the interaction between functionality and nondeterminism has been studied both in the algebraic framework of rewriting [18, 31, 32, 2], where no abstraction operator is present, and in the λ-calculus framework, either typed [9, 10, 64] or type-free [19, 45, 25, 56, 26, 8].

1.1. Angelic nondeterminism. Our study confronts various problems that had their origin in the theory of functional languages and λ-calculus. In [59] Plotkin showed that Scott continuous functions over domains are overabounding to give meaning to the sequential functional language that has been called PCF (a simply typed λ-calculus with arithmetical constants, booleans, if-then-else, and fixed-point operator). To be precise, he considered the following notion of operational equivalence. Two terms, M and N, of the same type are *operationally equivalent* if and only if, for all contexts $C[\,]$ of ground type such that both $C[M]$ and $C[N]$ are well-typed closed terms, either the evaluations of $C[M]$ and $C[N]$ do not terminate (converge), or both terminate and give the same result. It turns out that, if two terms have the same denotation in the standard model (in which ground types are flat cpo's and arrow types are interpreted as spaces of Scott continuous functions) then they are operationally equivalent (adequacy theorem); but the converse (full abstraction) does not hold.

In the same paper Plotkin proved that syntax can be reasonably enriched to get full abstraction, and that this can be achieved by using a suitable kind of parallel operator or combinator. Milner proved in [49] that this is also a necessary condition: any model of PCF is fully abstract if and only if all "finite" objects in the model are definable. Conversely, the standard model becomes fully abstract if we endow the calculus with operators that reinforce its expressive power such that it satisfies the Milner definability requirement.

The same incompleteness phenomenon with respect to standard continuous semantics has been found for the lazy λ-calculus in [6]. This is a type-free calculus, having the same syntax of pure λ-calculus and a reduction relation over closed terms, with just two rules:

$$(\lambda x.M)N \longrightarrow M[N/x] \qquad \text{and} \qquad \frac{M \longrightarrow M'}{MN \longrightarrow M'N}.$$

The full abstraction problem can be reformulated in this setting, even if we do not have the notion of ground type. Indeed, Abramsky and Ong [6] define the set Val of values as the set of abstractions. Then their notion of *may* convergence is: M may converge to V, written $M \Downarrow^{\text{may}} V$, if V is a value and $M \longrightarrow^* V$. In [6] the operational semantics is given by axiomatizing $M \Downarrow^{\text{may}} V$, instead of giving the reduction relation as a primitive notion; of course, this is equivalent.

As a matter of fact, the problem of enriching the calculus so that the standard model is fully abstract can be solved by adding a combinator $\mathbf{P}$ testing convergence in parallel. More precisely, $\mathbf{P}$ satisfies

$$[\exists V,\ M \Downarrow^{\text{may}} V \text{ or } N \Downarrow^{\text{may}} V] \quad \Rightarrow \quad \mathbf{P}MN \Downarrow^{\text{may}} \mathbf{I},$$

where $\mathbf{I} \equiv \lambda x.x$ is the identity combinator. This gives a combinator which tests convergence, i.e., a closed term $\mathbf{C}$ such that, for any term M, $\mathbf{C}M$ reduces to $\mathbf{I}$ if M reduces to a value and diverges otherwise; just take $\mathbf{C} \stackrel{\text{Def}}{=} \lambda x.\mathbf{P}xx$.

In [19] a further step is made by Boudol. The combinator $\mathbf{P}$ is split into its two components, namely, parallelism and convergence test. The parallelism implicit in $\mathbf{P}$ is made explicit by adding a binary operator $\|$ such that

$$M\|N \Downarrow^{\text{may}} \;\Leftrightarrow\; M \Downarrow^{\text{may}} \text{ or } N \Downarrow^{\text{may}},$$

where $M \Downarrow^{\text{may}}$ abbreviates $\exists V,\ M \Downarrow^{\text{may}} V$. To have this, with the above definition of convergence, the following rules suffice:

$$\frac{M \longrightarrow M'}{M\|N \longrightarrow M'\|N} \quad \text{and} \quad \frac{N \longrightarrow N'}{M\|N \longrightarrow M\|N'}.$$

As the intended meaning of a parallel composition is a function, Boudol adds the following rule:

$$(M\|N)L \longrightarrow (ML)\|(NL).$$

The internal convergence test is achieved using, besides standard call-by-name abstraction, call-by-value abstraction, originally considered by Landin [41] and Plotkin [57]. To see how this works, let us extend the set Val of values inductively so that it includes all terms of the shape $V\|N$ or $M\|V$, where V is a value. We use two sorts of variables to distinguish between call-by-value and call-by-name abstraction, namely, $v, w, \ldots$ for call-by-value variables and $x, y, \ldots$ for call-by-name variables. Then we add to the lazy λ-calculus and to the rules for $\|$, the following rules:

$$(\lambda v.M)V \longrightarrow M[V/v] \text{ if } V \in \mathsf{Val}, \qquad \frac{N \longrightarrow N'}{(\lambda v.M)N \longrightarrow (\lambda v.M)N'} \text{ if } N \notin \mathsf{Val}.$$

Now $\mathbf{P}$ becomes definable by $\lambda xy.\ (\lambda v.\mathbf{I})(x\|y)$.

We observe that the combination of parallelism (angelic nondeterminism) and call-by-value is much more powerful than the use of combinators directly defining a parallel convergence test. First, the notion of being a value is no more equivalent to that of being irreducible. Moreover, as remarked in the early paragraphs of this introduction, $M\|N$ has to be interpreted as a multivalued function, since M and N are not necessarily interpreted by compatible functions. So the model of [19] is a solution of the domain equation $D = \mathcal{P}^\flat([D \to D]_\perp)$, where $[D \to D]_\perp$ is the lifted space of continuous functions, and $\mathcal{P}^\flat$ is the lower powerdomain functor (also called Hoare's powerdomain; see [66] for a definition). Since Boudol works in the category of prime algebraic lattices, he has this solution for free. In fact, in that category $D \simeq \mathcal{P}^\flat(\mathsf{KP}(D))$, where $\mathsf{KP}(D)$ is the set of compact coprime elements of D. Let us recall that a *complete lattice* is a partial order $(D, \sqsubseteq)$ such that each subset X of D has a least upperbound $\bigsqcup X$. An element d of a complete lattice is *compact* if $d \sqsubseteq \bigsqcup X$ implies $d \sqsubseteq \bigsqcup Y$ for some finite subset Y of X. An element $d \in D$ is *coprime* if and only if $d \sqsubseteq x \sqcup y$ implies $d \sqsubseteq x$ or $d \sqsubseteq y$. A complete lattice is *prime algebraic* if any element is the join of the compact coprime elements it dominates. See also the discussion at the beginning of section 4.

1.2. Demonic nondeterminism. Serious problems arise when we consider the full language, modeling also the demonic nondeterminism (see [55, 56]), which is the central issue of the present paper. Suppose that an internal choice operator $+$ is added, with the obvious reduction rules

$$M + N \longrightarrow M \quad \text{and} \quad M + N \longrightarrow N.$$

Then, following ideas explained above (see also [45]), we expect a convergence predicate $\Downarrow$ such that

$$M + N \Downarrow \quad \Leftrightarrow \quad M \Downarrow \quad \text{and} \quad N \Downarrow .$$

But this is not true with the present definition of $\Downarrow^{\text{may}}$.

The convergence predicate considered above (and in [19]) is a *may* convergence predicate, to be related to may testing equivalence if convergence is the only observable property (see [3, 33, 6]). A solution would be to consider a *must* convergence predicate as in [45] (see also [35]). An informal definition is the following: $M \Downarrow^{\text{must}}$ if and only if there is an n such that every reduction out of M reaches a value within a number of steps bounded by n. Otherwise we write $M \Uparrow^{\text{must}}$.

Of course, if we have to avoid the collapse of $\|$ and $+$ with respect to the predicate $\Downarrow^{\text{must}}$, something has to be changed in the operational semantics of $\|$. In fact, with the old definition of $\|$-reduction rules, if we put, for example, $\Delta \equiv \lambda x.xx$ and we take the typical divergent combinator $\Omega \equiv \Delta\Delta$, then we have that $(\mathbf{II})\|\Omega \Uparrow^{\text{must}}$. The problem is that nothing prevents the reduction of a parallel composition from being unfair: there exists a reduction out of $(\mathbf{II})\|\Omega$ that contracts Ω infinitely many times and never reaches the value $\mathbf{I}\|\Omega$. Really, we want to identify $\mathbf{I}\|\Omega$ with $\mathbf{I}$, since $\|$ is intended to take the best of its arguments; notice that the above-mentioned terms are not equivalent in a standard must semantics (see [24]), when the parallel operator is asynchronous.

There are many possibilities for changing the reduction rules for $\|$ in such a way that we cannot reduce infinitely many times on one side of a parallel composition, when the other one is reducible. We take the simplest way to get this kind of *fair* reduction and we introduce the rules

$$\frac{M \longrightarrow M' \quad N \longrightarrow N'}{M\|N \longrightarrow M'\|N'}, \qquad \frac{M \longrightarrow M' \quad N \not\longrightarrow}{M\|N \longrightarrow M'\|N, \quad N\|M \longrightarrow N\|M'}$$

as our actual choice (see [25]), where $N \not\longrightarrow$ means that N is irreducible.

This implies that, as in [19], a value of the shape $V\|M$ is not necessarily a normal form, as M can be reduced. This fact, together with the presence of the choice operator, makes the β-rule for call-by-value sensible to the relative speed of parallel evaluations of its arguments.

To illustrate this, let us consider the context $C[\ ] \equiv (\lambda v.vv)[\ ]\Omega\mathbf{I}$ and the values $V \equiv \mathbf{I}\|(\mathbf{K} + \mathbf{O})$, $V' \equiv \mathbf{I}\|\mathbf{K}$, and $V'' \equiv \mathbf{I}\|\mathbf{O}$, where $\mathbf{K} \equiv \lambda xy.x$ and $\mathbf{O} \equiv \lambda xy.y$. Then $V \longrightarrow V'$ and $V \longrightarrow V''$. Now (writing $\xrightarrow{n}$ for $n > 1$ reduction steps)

$$\begin{array}{lcl}
C[V'] & \longrightarrow & (\mathbf{I}\|\mathbf{K})(\mathbf{I}\|\mathbf{K})\Omega\mathbf{I} \\
& \xrightarrow{3} & (\mathbf{I}(\mathbf{I}\|\mathbf{K})\Omega\mathbf{I})\|(\mathbf{K}(\mathbf{I}\|\mathbf{K})\Omega\mathbf{I}) \\
& \longrightarrow & ((\mathbf{I}\|\mathbf{K})\Omega\mathbf{I})\|((\lambda y.(\mathbf{I}\|\mathbf{K}))\Omega\mathbf{I}) \\
& \longrightarrow & ((\mathbf{I}\Omega\|\mathbf{K}\Omega)\mathbf{I})\|((\mathbf{I}\|\mathbf{K})\mathbf{I}) \\
& \longrightarrow & (\mathbf{I}\Omega\mathbf{I})\|(\mathbf{K}\Omega\mathbf{I})\|(\mathbf{II})\|(\mathbf{KI}) \\
& \longrightarrow & (\Omega\mathbf{I})\|((\lambda y.\Omega)\mathbf{I})\|\mathbf{I}\|(\lambda y.\mathbf{I}) \\
& \longrightarrow & (\Omega\mathbf{I})\|\Omega\|\mathbf{I}\|(\lambda y.\mathbf{I}),
\end{array}$$

which is a value, and it is not hard to see that this is the only reduction out of $C[V']$ according to the rules defined in Definition 2.2. Similarly,

$$\begin{array}{lll} C[V''] & \longrightarrow & (\mathbf{I}\|\mathbf{O})(\mathbf{I}\|\mathbf{O})\Omega\mathbf{I} \\ & \longrightarrow^* & (\Omega\mathbf{I})\|\mathbf{I}\|(\Omega\mathbf{I}), \end{array}$$

and again this is the only reduction out of $C[V'']$. But now consider the following reduction of $C[V]$:

$$\begin{array}{lll} C[V] & \longrightarrow & (\mathbf{I}\|(\mathbf{K}+\mathbf{O}))(\mathbf{I}\|(\mathbf{K}+\mathbf{O}))\Omega\mathbf{I} \\ & \xrightarrow{3} & (\mathbf{I}(\mathbf{I}\|(\mathbf{K}+\mathbf{O}))\Omega\mathbf{I})\|((\mathbf{K}+\mathbf{O})(\mathbf{I}\|(\mathbf{K}+\mathbf{O}))\Omega\mathbf{I}) \\ & \longrightarrow & ((\mathbf{I}\|(\mathbf{K}+\mathbf{O}))\Omega\mathbf{I})\|(\mathbf{O}(\mathbf{I}\|(\mathbf{K}+\mathbf{O}))\Omega\mathbf{I}) \qquad \text{choosing } \mathbf{O} \ldots \\ & \xrightarrow{2} & (\mathbf{I}\Omega\mathbf{I})\|((\mathbf{K}+\mathbf{O})\Omega\mathbf{I})\|(\Omega\mathbf{I}) \\ & \longrightarrow & (\Omega\mathbf{I})\|(\mathbf{K}\Omega\mathbf{I})\|(\Omega\mathbf{I}) \qquad \ldots \text{choosing } \mathbf{K} \\ & \longrightarrow & (\Omega\mathbf{I})\|\Omega\|(\Omega\mathbf{I}), \end{array}$$

and from $(\Omega\mathbf{I})\|\Omega\|(\Omega\mathbf{I})$ we will never reach a value.

This example also shows that there are values V_0, V_1, and V_2 such that $V_0\|(V_1+V_2)$ and $(V_0\|V_1)+(V_0\|V_2)$ would have different behaviors in some context, although this would be unexpected under any reasonable operational semantics. $(\lambda v.vv)(V_0\|(V_1 + V_2))$ can indeed reduce to $(V_0\|(V_1 + V_2))(V_0\|(V_1 + V_2))$, while $(\lambda v.vv)((V_0\|V_1) + (V_0\|V_2))$ can reduce either to $(V_0\|V_1)(V_0\|V_1)$ or to $(V_0\|V_2)(V_0\|V_2)$, but never to $(V_0\|(V_1 + V_2))(V_0\|(V_1 + V_2))$. Note that in the present context call-by-name and call-by-value implement run-time-choice and call-time-choice, respectively (see [45]).

The problem of correcting the β-contraction rule for call-by-value is that, given a value V, we cannot decide whether it has been computed enough to perform the reduction step $(\lambda v.M)V \longrightarrow M[V/v]$, or if it is necessary to reduce V further, before contracting the outermost β-redex. We cannot reduce V as long as possible, since this could not terminate. In the meantime, $M[V/v]$ can diverge while $M[V'/v]$ can converge for all V' which are reducts of V, as shown by the previous example. On the other hand, any effective description of the operational semantics calls for a definition of a recursive one-step reduction relation.

Now the solution we propose is to distinguish two cases: if V is an irreducible value (namely a λ-abstraction or the parallel composition of irreducible values), then the standard call-by-value β-contraction rule applies. If, instead, V can be reduced further, to compute $(\lambda v.M)V$ we want to "take the best" between the terms $M[V'/v]$, for all V' such that $V \longrightarrow^* V'$. We realize this by evaluating in parallel $M[V/v]$ and $(\lambda v.M)V'$ for all V' such that $V \longrightarrow V'$. Using the operator $\|$, this can be formalized in our calculus as follows:

$$\frac{V \not\longrightarrow \qquad V \in \mathsf{Val}}{(\lambda v.M)V \longrightarrow M[V/v]}, \qquad \frac{V \longrightarrow V' \qquad V \in \mathsf{Val}}{(\lambda v.M)V \longrightarrow M[V/v]\|(\lambda v.M)V'}.$$

In other words, the solution we propose is to distinguish between *total* and *partial* values. A total value is an irreducible value, while a partial value is of the form $M\|N$ in which either M or N is not a total value. So we split the call-by-value β-contraction in two rules.

To conclude this part of our discussion, let us emphasize the effectiveness of the evaluation mechanism as a distinguishing feature of our calculus. As is clear from the previous exposition, the papers closest to the present one are [19] and [55].[1] While our

[1] Following Ong's paper we named our calculus *concurrent λ-calculus*.

treatment improves on the former because of the presence in the same calculus of both angelic and demonic nondeterminism, it improves on the latter since the operational semantics on which we base our theory is effective. Indeed, the reduction relation is (as usual) presented by means of a formal system in the sense of Post, and the convergence predicate is (up to coding) recursively enumerable. This is mandatory when one expects to capture the intentional aspects of evaluation and justifies our reduction relation as it will be defined in the technical development of the paper.

1.3. Intersection and union types. The complex operational semantics of the concurrent λ-calculus asks for an abstract treatment not involving direct reasoning on possible reducts of a given term. The approach taken in this paper is to use a type assignment system that sufficiently expresses the operational equivalence of terms. We expect that M and N have exactly the same types when they have the same behavior in any context: this is a fully abstract "logical" semantics in the sense of [63], [16], and [5].

To this aim, we use a system with intersection and union types, dually reflecting the disjunctive and conjunctive operational semantics of $\|$ and $+$. Types are viewed as properties of terms concerning their behavior with respect to the convergence predicate and type inclusion as the logical implication. The system has a universal type ω, the property which always holds; therefore, any type will be less than ω. As usual with type assignment systems for polymorphic λ-calculi, the arrow type expresses functionality: M has type $\sigma \to \tau$ if, for all N having type σ, MN has type τ. With respect to the order, the arrow is covariant in the second argument and contravariant in the first argument. Finally, $\sigma \wedge \tau$ and $\sigma \vee \tau$ have a conjunctive and disjunctive meaning, respectively.

The lazy semantics distinguishes between functions (even the everywhere undefined function) and the undefined object, representing divergence. This means that the interpretation of the term $\lambda x.\Omega$ is better than the interpretation of Ω. These terms, instead, are equated in the theory of solvability of the classical λ-calculus [15]. On the side of types, this distinction is modeled by making the inclusion $\omega \to \omega \leq \omega$ proper. As a matter of fact, among the axioms in [16] concerning the arrow, we save $\sigma \to \omega \leq \omega \to \omega$, which makes $\omega \to \omega$ the type of all functions, but we reject $\omega \leq \omega \to \omega$, which would equate the interpretations of the terms Ω and $\lambda x.\Omega$ (see Corollary 5.6(ii)).

We now turn to the typing rules for nondeterministic and parallel operators. We know that the term $M + N$ can be reduced to both M and N, so that to ensure correctness we have to prove that both M and N have the same type σ before we can conclude that $M + N$ has type σ (this is also the choice of [1]). Extending the disjunctive semantics of the parallel composition from convergence to arbitrary properties, it follows that one is entitled to type $M\|N$ with σ as soon as M or N (or both) can be typed with σ (see [19] for further explanations). This suggests the following typing rules:

$$\frac{\Gamma \vdash M : \sigma \quad \Gamma \vdash N : \sigma}{\Gamma \vdash M + N : \sigma}, \qquad \frac{\Gamma \vdash M : \sigma}{\Gamma \vdash M\|N : \sigma}, \qquad \frac{\Gamma \vdash N : \sigma}{\Gamma \vdash M\|N : \sigma}.$$

The inclusion relation $\leq$ among types makes $\wedge$ into the meet and $\vee$ into the join, and we have both a subtyping and an intersection rule, namely,

$$\frac{\Gamma \vdash M : \sigma \quad \sigma \leq \tau}{\Gamma \vdash M : \tau}, \qquad \frac{\Gamma \vdash M : \sigma \quad \Gamma \vdash M : \tau}{\Gamma \vdash M : \sigma \wedge \tau}.$$

Therefore, the rules for $+$ and $\|$ above are equivalent to

$$\frac{\Gamma \vdash M : \sigma \quad \Gamma \vdash N : \tau}{\Gamma \vdash M + N : \sigma \vee \tau}, \qquad \frac{\Gamma \vdash M : \sigma \quad \Gamma \vdash N : \tau}{\Gamma \vdash M \| N : \sigma \wedge \tau},$$

which is our actual choice.

If M has type $\sigma \vee \tau$ then it can be that M evaluates to both some P and some Q such that P has type σ and Q has type τ, but neither P has type τ nor Q has type σ. In this case, M has an essentially disjunctive type, which is possible even if M is a partial value. But all is determined in the case of total values. So we expect the system to have the "disjunction property" for total values: if a total value has the type $\sigma \vee \tau$, then either σ or τ can be assigned to it (hence to all its reducts).

Consequently, we distinguish between call-by-name and call-by-value abstraction, making a substantial use of disjunction. This intuitively explains why the rule

$$\frac{\Gamma \vdash \lambda v.M : (\sigma \to \rho) \wedge (\tau \to \rho)}{\Gamma \vdash \lambda v.M : \sigma \vee \tau \to \rho}$$

is correct for call-by-value but not for call-by-name abstraction. Observe that this means that call-by-value abstraction yields a co-additive function (namely, meet preserving), which is the expected semantics of call-by-value in our setting.

As an example, if $M \equiv (x\mathbf{I}\Omega)\|(x\Omega\mathbf{I})$, $\rho \equiv \omega \to \omega$, $\sigma \equiv \rho \to \omega \to \rho$, $\tau \equiv \omega \to \rho \to \rho$, then we have that $\vdash \lambda x.M : (\sigma \to \rho) \wedge (\tau \to \rho)$. Moreover, $\vdash \mathbf{K} : \sigma$ and $\vdash \mathbf{O} : \tau$, so that allowing the rule above for call-by-name abstraction, one could deduce $(\lambda x.M)(\mathbf{K} + \mathbf{O}) : \rho$, using the rules for $+$ introduction and $\to$ elimination, too. But this would destroy the subject-reduction property, since $(\lambda x.M)(\mathbf{K} + \mathbf{O})$ reduces to $\Omega\|\Omega$, for which only types equivalent to ω can be deduced (see Corollary 5.6(ii)).

The type assignment system implicitly suggests a notion of interpretation in which each term can be seen as denoting the set of types it can be assigned. Then one can think of extending the notion of filter models such that they encompass the present calculus and union types.

Filter models were introduced in [16] for the classical λ-calculus and they were based on the intersection-type discipline. In that case, however, discovering that filters of types do actually form a structure (a λ-model) was based on the pre-existing and independent definition of this kind of mathematical structure (see [37, 48]). Here the problem is the opposite: given the logical interpretation induced by our system, we look for a reasonable definition of what is a model of our calculus.

In the extended view of Curry types (see [16, 21]), type theories are an instance of information systems (see [63, 23]). Taking filters of types, we have a domain that, seen topologically, is the Stone space generated by the theory of type inclusion (see [40, 5]). In the present case the domain that is determined by the type theory we consider is isomorphic to the initial solution of the domain equation $D = \mathcal{P}^\sharp([D \to D]_\perp)$ in the category of continuous lattices, where $\mathcal{P}^\sharp$ is the upper powerdomain functor (also called Smyth's powerdomain; see [66]). This is sound with respect to the operational semantics since this powerdomain constructor is needed to model demonic nondeterminism, as angelic nondeterminism is built in, by the fact that we work with prime algebraic lattices (as remarked at the end of subsection 1.1). This domain equation, and their relations to Abramsky and Boudol equations [5, 19], will be discussed further at the beginning of section 4.

We do not carry out the details of the isomorphism between the filter model and the initial solution of the given domain equation, for which we refer to [7]. Instead, we

analyze compositionally the interpretation of terms defined by $[\![M]\!] = \{\sigma \mid \vdash M : \sigma\}$ (where M is closed), and devise a category of objects that embodies the minimum needed structure to interpret the calculus. We then get a notion of environment model for the present calculus, in the sense of [37]. The filter model induced by our type assignment turns out to fit into this notion, a fact that will be used to prove completeness of type inference.

Our study culminates in the full abstraction theorem, which we will prove by means of characteristic terms extending [19].

1.4. Summary. In section 2 we formally define the concurrent λ-calculus and its reduction rules. We consider the reduction trees of terms to introduce convergence. Moreover, we consider another reduction relation, whose main feature is to characterize convergent terms as those which reduce to a sum of values.

Section 3 deals with types and the type assignment system. The choice of the preorder on types, which will determine the topological structure of the filter model, is crucial. The type assignment system turns out to enjoy structural properties which allow us to prove preservation of type under subject reduction. The main result of this section is that all convergent terms can be typed by $\omega \to \omega$.

Section 4 presents the filter model as the initial solution of a suitable domain equation. Then we introduce the notion of environment model for concurrent λ-calculus and we prove that the filter model is in fact an environment model. This allows us to have the completeness of type assignment.

Finally, we prove in section 5 the full abstraction of the filter model. First we define for each type a test term and a characteristic term. The application of the test term to an argument M converges only if M has the corresponding type. By means of a realizability interpretation of types we show that all terms typed by $\omega \to \omega$ converge. This, together with the main result of section 3, implies that $\omega \to \omega$ completely characterizes convergence. Then the full abstraction of the model follows easily.

2. The calculus and its operational semantics. We extend the syntax of pure λ-calculus with a non-deterministic choice operator $+$ and a parallel operator $\|$. We use two sorts of variables, namely, the set Vn of call-by-name variables, ranged over by x, y, z, and the set Vv of call-by-value variables, ranged over by v, w. The symbol χ will range over the set $\mathsf{Vn} \cup \mathsf{Vv}$. The terms of the concurrent λ-calculus are defined by the following grammar:

$$M ::= x \mid v \mid (\lambda x.M) \mid (\lambda v.M) \mid (MM) \mid (M + M) \mid (M \| M).$$

We call $\Lambda_{+\|}$ the set of terms. For any $M \in \Lambda_{+\|}$, $FV(M)$ denotes the set of free variables of M and $\Lambda^0_{+\|}$ is the set of terms M such that $FV(M) = \emptyset$. Moreover, we shall refer to the following set:

$$\mathsf{Par} = \{(M \| N) \mid M, N \in \Lambda_{+\|}\}.$$

Notation. We use $\equiv$ for syntactical equality up to renaming of bound variables. As usual for pure λ-calculus, we assume that application associates to the left, and we write, e.g., MNP instead of $((MN)P)$. If $\vec{L} \equiv L_1 \dots L_n$ is any (possibly empty) vector of terms, then $M\vec{L} \equiv ML_1 \dots L_n$. The expression $\lambda\chi_1 \dots \chi_n.M$ is short for $(\lambda\chi_1.(\dots(\lambda\chi_n.M)\dots))$.

We will abbreviate some λ-terms as follows:

$$\mathbf{I} \stackrel{\text{Def}}{=} \lambda x.x, \quad \mathbf{K} \stackrel{\text{Def}}{=} \lambda xy.x, \quad \mathbf{O} \stackrel{\text{Def}}{=} \lambda xy.y,$$
$$\Delta \stackrel{\text{Def}}{=} \lambda x.xx, \quad \Omega \stackrel{\text{Def}}{=} \Delta\Delta, \quad \mathbf{Y} \stackrel{\text{Def}}{=} \lambda y.(\lambda x.y(xx))(\lambda x.y(xx)).$$

Application and abstraction have precedence over + and ‖; e.g., $MN + P$ stands for $((MN) + P)$, and $\lambda x.M + N$, for $((\lambda x.M) + N)$. The operator ‖ takes precedence over +; for example, $M\|P + Q$ is short for $((M\|P) + Q)$. External parentheses are always omitted.

The operators + and ‖ will be written up to associativity. We shall also make use of the following abbreviation:

$$\sum_{i=1}^{n} M_i \equiv M_1 + \cdots + M_n.$$

Moreover, if $\mathcal{M} = \{M_1, \ldots, M_n\}$ is any finite multiset of terms then

$$\sum \mathcal{M} \equiv \sum_{i=1}^{n} M_i.$$

Observe that, $\mathcal{M}$ being a multiset, it can be the case that $M_i \equiv M_j$ for different i and j.

As discussed in the introduction, we need to distinguish between partial and total values; the main difference concerns the parallel operator. In fact, we require both M and N to be total values to ensure that $M\|N$ is a total value, while in general it suffices that either M or N be a value for $M\|N$ to be a value. As is clear from the next definition, a value is either a total or a partial value.

DEFINITION 2.1. *We define the set* Val *of* values *according to the grammar*

$$V ::= v \mid \lambda x.M \mid \lambda v.M \mid V\|M \mid M\|V$$

and the set TVal *of* total values *as the subset of* Val*:*

$$W ::= v \mid \lambda x.M \mid \lambda v.M \mid W\|W\ .$$

A value V is partial *if and only if $V \notin$ TVal.*

We now introduce a reduction relation which is intended to formalize the expected behavior of a machine which evaluates parallel compositions in a synchronous way until a value is produced. Partial values can be further evaluated, and this is essential in the case of an application of a call-by-value abstraction. Therefore, in some cases an asynchronous evaluation of parallel composition is permitted.

It follows that the convergence predicate will not be any more coincident with the property of being (strongly) normalizable (see [19] for a similar proposal, even if in a may perspective) with respect to the given reduction relation. Observe that in the lazy λ-calculus of [6], as well as in the present calculus, $\lambda\chi.M$ is a normal form, no matter whether M is reducible or not.

DEFINITION 2.2.

(i) *The reduction relation $\longrightarrow$ is the least binary relation over $\Lambda^0_{+\|}$ such that*

$$(\beta)\quad (\lambda x.M)N \longrightarrow M[N/x], \qquad (\beta_v)\quad \frac{W \in \mathsf{TVal}}{\lambda v.M)W \longrightarrow M[W/v]},$$

$$(\beta_v\|)\quad \frac{V \longrightarrow V' \qquad V \in \mathsf{Val}}{(\lambda v.M)V \longrightarrow M[V/v]\|(\lambda v.M)V'}, \qquad (\mu_v)\quad \frac{N \longrightarrow N' \quad N \notin \mathsf{Val}}{(\lambda v.M)N \longrightarrow (\lambda v.M)N'},$$

$$(\nu)\quad \frac{M \longrightarrow M' \qquad M \notin \mathsf{Val} \bigcup \mathsf{Par}}{MN \longrightarrow M'N}, \qquad (\|_{app})\quad (M\|N)L \longrightarrow ML\|NL,$$

$$(\|_s)\quad \frac{M \longrightarrow M' \quad N \longrightarrow N'}{M\|N \longrightarrow M'\|N'}, \qquad (\|_a)\quad \frac{M \longrightarrow M' \quad W \in \mathsf{TVal}}{M\|W \longrightarrow M'\|W,\ W\|M \longrightarrow W\|M'},$$

$$(+)\quad M + N \longrightarrow M, \quad M + N \longrightarrow N.$$

(ii) *We denote by* $\longrightarrow^*$ *the reflexive and transitive closure of* $\longrightarrow$.

LEMMA 2.3.

(i) $W \in \Lambda^0_{+\|}$ *is irreducible with respect to* $\longrightarrow$ *if and only if* $W \in \mathsf{TVal}$;

(ii) *If* $V \in \Lambda^0_{+\|} \cap \mathsf{Val}$, *then either* $V \in \mathsf{TVal}$ *or* $V \longrightarrow V'$ *for some* $V' \in \mathsf{Val}$;

(iii) *If* $W, W_1, \ldots, W_n \in \mathsf{TVal}, N_1, \ldots, N_m \in \Lambda_{+\|}$, *then*

$$W[N_1/x_1, \ldots, N_m/x_m, W_1/v_1, \ldots, W_n/v_n] \in \mathsf{TVal}.$$

Proof. The proof is easy by the definitions. □

It is useful to consider reduction trees of terms and their bars.

DEFINITION 2.4. *Let* $M \in \Lambda^0_{+\|}$.

(i) *tree*(M) *is the (unordered) reduction tree of* M;

(ii) *A* bar *of tree*(M) *is a subset of the nodes of tree*(M) *such that each maximal path intersects the bar at exactly one node*;

(iii) *bar*(M) *is the set of bars of tree*(M);

(iv) *For* $b \in bar(M)$ *the* height *of* b *(notation: height*(b)*) is the maximum of the heights of its nodes.*

Inspecting the reduction rules, we see that $tree(M)$ is a finitely branching tree for all $M \in \Lambda^0_{+\|}$. This implies by König's lemma that if we cut $tree(M)$ at a fixed height we obtain a finite tree. Since all nodes belonging to a bar b are in the subtree of $tree(M)$ obtained by cutting $tree(M)$ at $height(b)$, we have that $b \in bar(M)$ is always a finite set of nodes (see also [17]). This does not contradict the fact that a term may have infinite reduction paths. For example, let us consider the infinite reduction tree of $\mathbf{Y}M$, where $M \equiv \lambda x.(\mathbf{I} + x)$, which is shown in Figure 1. Admittedly, the set of nodes in $tree(\mathbf{Y}M)$ which are labeled by $\mathbf{I}$ is infinite, but it is not a bar. Indeed, the infinite path in this tree does not have any node in such a set, and every $b \in bar(\mathbf{Y}M)$ must contain exactly one node of this path. Whichever node we choose on the infinite path, we will exclude all nodes with greater height, so that b turns out to be finite.

A bar is always relative to a tree and cannot be identified with the set of the labels of its nodes. For example, $tree(M + \mathbf{I}M)$ has the shape shown in Figure 2. Now the indicated set of nodes b is a bar whose set of labels is the singleton $\{M\}$. But the set containing a single node labeled by M is not a bar of this tree. Moreover, the height of the bar b is 2, but if b would be identified with $\{M\}$, then $height(b)$ would be ambiguously 1 or 2.

However, if $b \in bar(M)$, then two subtrees rooted in two nodes of b are equal if and only if their labels are the same. Hence we abuse notation and write $b = \{M_1, \ldots, M_n\}$ (if $M_1, \ldots, M_n$ is the multiset of labels of nodes belonging to b). The abbreviations $M \in b$ and $b \subseteq \mathsf{Val}$ will have the obvious meanings.

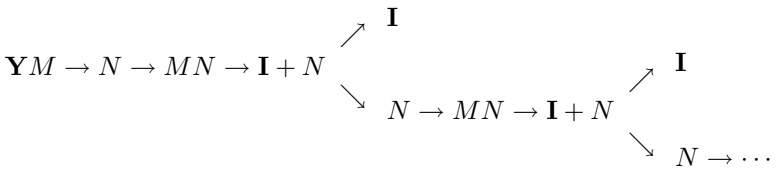

FIG. 1. *Reduction tree of* $\mathbf{Y}M$, *where* $N \equiv (\lambda x.M(xx))(\lambda x.M(xx))$.

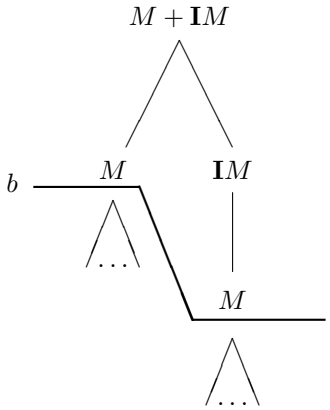

FIG. 2. *Reduction tree of* $M + \mathbf{I}M$.

We now define the convergence predicate. A term is convergent if and only if all reduction paths will eventually reach a value. In other words, a term M converges if and only if there is a bar in $tree(M)$ which is a subset of Val. To formalize this, it is useful to introduce the bar $\mathcal{R}(M,k)$ whose labels are those terms which can be reached starting from a term M by performing k steps of reduction.

DEFINITION 2.5. *Let* $M \in \Lambda^0_{+\|}$; *then*

(i) $\mathcal{R}(M,k) \in bar(M)$ *is the cut of* $tree(M)$ *at height* k; *namely, it is the unique bar such that*
  (a) $height(\mathcal{R}(M,k)) \leq k$;
  (b) $\forall M' \in \mathcal{R}(M,k),\ height(M') < k \ \Rightarrow\ M' \in \mathsf{TVal}$.

(ii) $M\Downarrow_k \Leftrightarrow\ \mathcal{R}(M,k) \subseteq \mathsf{Val}$.

(iii) $M\Downarrow \Leftrightarrow\ \exists k,\ M\Downarrow_k$.

Note that $(M+N)\Downarrow$ if and only if both $M\Downarrow$ and $N\Downarrow$. On the other hand, $(M\|N)\Downarrow$ if and only if either $M\Downarrow$ or $N\Downarrow$ (or both). So $\Downarrow$ coincides with $\Downarrow^{\text{must}}$ as informally defined in section 1.2. In general, if for some $b \in bar(M)$ we have $M'\Downarrow$ for all $M' \in b$, then $M\Downarrow$. The reverse is obviously true.

We depart from the standard way of defining must semantics using infinite paths (see [24]). This gives us a different theory of terms; for example, we equate $\mathbf{I}$ and $\mathbf{I}\|\Omega$.

To study the operational semantics of our calculus it is useful to introduce a binary relation $\rhd$ whose main features are

- to satisfy the Church–Rosser property,

- to simulate the choices performed by rule (+) without losing information about the discarded parts,
- to characterize the convergent terms as those which reduce to a sum of values.

Moreover, we will consider the equivalence relation $\bowtie$ generated by $\rhd$.

DEFINITION 2.6.

(i) *Define* $\rhd$ *as the least binary relation over* $\Lambda^0_{+\|}$ *such that*
$(\beta)'\ (\lambda x.M)N \rhd M[N/x]$,
$(\beta_v)'\ (\lambda v.M)W \rhd M[W/v]$, *if* $W \in \mathsf{TVal}$,
$(\beta_v\|)'\ (\lambda v.M)V \rhd \sum_{i=1}^n (M[V/v]\|(\lambda v.M)V_i)$ *if* $V \in \mathsf{Val}-\mathsf{TVal}$ *and* $\mathcal{R}(V,1) = \{V_1,\dots,V_n\}$,
$(\mu_v)'\ (\lambda v.M)N \rhd \sum_{i=1}^n (\lambda v.M)N_i$ *if* $N \notin \mathsf{Val}$ *and* $\mathcal{R}(N,1) = \{N_1,\dots,N_n\}$,
$(+_{app})'\ (M+N)L \rhd ML + NL$,
$(\|_{app})'\ (M\|N)L \rhd ML\|NL$,
$(\|+)'\ (M+N)\|L \rhd M\|L + N\|L$,
$(\nu)'\ M \rhd M' \Rightarrow MN \rhd M'N$,
$(+)'\ M \rhd M' \Rightarrow M+N \rhd M'+N$,
$(\|)'\ M \rhd M' \Rightarrow M\|N \rhd M'\|N$,
$(+_c)'\ M+N \rhd N+M$,
$(\|_c)'\ M\|N \rhd N\|M$,
$(+_{ass})'\ (M+N)+L \rhd M+(N+L)$ *and* $M+(N+L) \rhd (M+N)+L$,
$(\|_{ass})'\ (M\|N)\|L \rhd M\|(N\|L)$ *and* $M\|(N\|L) \rhd (M\|N)\|L$.

(ii) $\rhd^*$ *is the reflexive and transitive closure of* $\rhd$.

(iii) $\bowtie$ *is the symmetric closure of* $\rhd^*$, *up to associativity and commutativity of* $+$ *and* $\|$.

PROPOSITION 2.7. *The relation* $\rhd$ *is Church–Rosser*; *namely,*

$$\forall M, M_1, M_2 \in \Lambda^0_{+\|},\ M \rhd^* M_1\ \&\ M \rhd^* M_2 \Rightarrow \exists M_3,\ M_1 \rhd^* M_3\ \&\ M_2 \rhd^* M_3.$$

Proof. The proof is a variant of the Tait–Martin-Löf proof for classical λ-calculus (see [15]). We define the following relation on closed terms:

- $M \rightsquigarrow M$;
- if $M \rhd M'$ by any clause among $(\beta)'$, $(\beta_v)'$, $(\beta_v\|)'$, and $(\mu_v)'$ then $M \rightsquigarrow M'$;
- if $M \rightsquigarrow M'$, $N \rightsquigarrow N'$, and $L \rightsquigarrow L'$ then
  - —$(M\|N)L \rightsquigarrow M'L\|N'L$,
  - —$(M+N)L \rightsquigarrow M'L + N'L$,
  - —$(M+N)\|L \rightsquigarrow M'\|L' + N'\|L'$,
  - —$MN \rightsquigarrow M'N$,
  - —$M+N \rightsquigarrow M'+N'$,
  - —$M\|N \rightsquigarrow M'\|N'$,
  - —$M+N \rightsquigarrow N'+M'$,
  - —$M\|N \rightsquigarrow N'\|M'$,
  - —$(M+N)+L \rightsquigarrow M'+(N'+L')$ and $M'+(N'+L') \rightsquigarrow (M'+N')+L'$,
  - —$(M\|N)\|L \rightsquigarrow M'\|(N'\|L')$ and $M'\|(N'\|L') \rightsquigarrow (M'\|N')\|L'$.

By induction on the definition of $\rightsquigarrow$ it is routine to check that it satisfies the diamond property, namely,

$$\forall M, M_1, M_2 \in \Lambda^0_{+\|},\ M \rightsquigarrow M_1\ \&\ M \rightsquigarrow M_2 \Rightarrow \exists M_3,\ M_1 \rightsquigarrow M_3\ \&\ M_2 \rightsquigarrow M_3;$$

hence it is Church–Rosser. Now it is easy to see that $\rightsquigarrow^* = \rhd^*$, from which the thesis follows. □

The relation $\bowtie$ is weaker than the congruence generated by $\rhd$ but stronger than its reflexive, symmetric, and transitive closure. For example, $\mathbf{II} \bowtie \mathbf{I}$, but $(\lambda v.v)(\mathbf{II}\|\mathbf{I}) \not\bowtie (\lambda v.v)(\mathbf{I}\|\mathbf{I})$.

LEMMA 2.8.

(i) *If $M \bowtie N$ then for all L, $ML \bowtie NL$ and $M\|L \bowtie N\|L$.*

(ii) *If $M + N \bowtie P + Q$ then one of the following alternatives is true:*
- *$M \bowtie P$ & $N \bowtie Q$ or*
- *$M \bowtie Q$ & $N \bowtie P$ or*
- *$\exists M_0, M_1, N_0, N_1,\ M \bowtie M_0 + M_1$ & $N \bowtie N_0 + N_1$ & $P \bowtie M_0 + N_0$ & $Q \bowtie M_1 + N_1$.*

Proof. Part (i) is straightforward by induction on $M \bowtie N$.

Part (ii) is a consequence of the Church–Rosser property. Indeed, if $M + N \bowtie P + Q$, then there are L and L' such that $M + N \rhd^* L$, $P + Q \rhd^* L'$, and L and L' are equal up to commutativity and associativity of $+$ and $\|$. But any sum of the shape $M + N$ can be reduced only to a sum $M' + N'$ where $M \rhd^* M'$ and $N \rhd^* N'$, and similarly for $P + Q$. The thesis then follows. □

The next lemma connects the relation $\rhd$ to the reduction trees of terms and hence to the reduction relation $\longrightarrow$.

Notation. From now on we abuse notation, writing just $\rhd$ instead of $\rhd^*$ (unless otherwise stated).

LEMMA 2.9. *Let $M \in \Lambda^0_{+\|}$. Then*

(i) $\mathcal{R}(M, 1) = \{M_1, \ldots, M_n\} \Rightarrow M \rhd \sum_{i=1}^n M_i$,

(ii) $\forall b \in bar(M),\ b = \{M_1, \ldots, M_n\} \Rightarrow M \rhd \sum_{i=1}^n M_i$.

Proof. (i) The proof is by induction on $M \in \Lambda^0_{+\|}$.

—If $M \equiv \lambda\chi.M' \in \Lambda^0_{+\|}$ (that is, $FV(M') \subseteq \{\chi\}$) then $M \in \mathsf{TVal}$ and $\mathcal{R}(M, 1) = \{M\}$.

—If $M \equiv PQ$ then $P, Q \in \Lambda^0_{+\|}$. We have some subcases. If $P \equiv \lambda\chi.P'$ and either $\chi \equiv x$ or both $\chi \equiv v$ and $Q \in \mathsf{TVal}$, then

$$\mathcal{R}(PQ, 1) = \{P'[Q/\chi]\} \quad \text{and} \quad PQ \rhd P'[Q/\chi]$$

by $(\beta)'$ or by $(\beta_v)'$.

Suppose that $\mathcal{R}(Q, 1) = \{Q_1, \ldots, Q_k\}$. If $P \equiv \lambda v.P'$ and $Q \in \mathsf{Val} - \mathsf{TVal}$ then

$$\mathcal{R}((\lambda v.P')Q, 1) = \{P'[Q/v]\|(\lambda v.P')Q_i \mid i \leq k\}$$

and

$$(\lambda v.P')Q \rhd \sum_{i=1}^{k} P'[Q/v]\|(\lambda v.P')Q_i$$

by $(\beta_v\|)'$. Otherwise, if $Q \notin \mathsf{Val}$, then

$$\mathcal{R}((\lambda v.P')Q, 1) = \{(\lambda v.P')Q_i \mid i \leq k\} \text{ and } (\lambda v.P')Q \rhd \sum_{i=1}^{k} (\lambda v.P')Q_i$$

by $(\mu_v)'$.

If $P \equiv P_0 \| P_1$ then

$$\mathcal{R}(PQ, 1) = \{P_0 Q \| P_1 Q\} \text{ and } PQ \rhd P_0 Q \| P_1 Q$$

by $(\|_{app})'$.

In all other subcases, $P \notin \mathsf{Val} \cup \mathsf{Par}$. Now let $\mathcal{R}(P, 1) = \{P_1, \ldots, P_h\}$; hence we have $P \rhd \sum_{i=1}^{h} P_i$ by induction hypothesis and

$$PQ \rhd \left(\sum_{i=1}^{h} P_i\right) Q \rhd \sum_{i=1}^{h} (P_i Q).$$

From this the thesis follows since in these cases $\mathcal{R}(PQ, 1) = \{P_i Q \mid i \leq h\}$.

—If $M \equiv P + Q$ then $P, Q \in \Lambda^0_{+\|}$ and the case is trivial since $\mathcal{R}(P + Q, 1) = \{P, Q\}$.

—If $M \equiv P \| Q$ then $P, Q \in \Lambda^0_{+\|}$. Again suppose that $\mathcal{R}(P, 1) = \{P_1, \ldots, P_h\}$ and $\mathcal{R}(Q, 1) = \{Q_1, \ldots, Q_k\}$. Then we have

$$P \| Q \rhd \left(\sum_{i=1}^{h} P_i\right) \| \left(\sum_{j=1}^{k} Q_j\right) \rhd \sum_{i=1}^{h} \sum_{j=1}^{k} (P_i \| Q_j)$$

by induction hypothesis and clauses $(\|+)'$ and $(\|)'$. So we are done since $\mathcal{R}(PQ, 1) = \{P_i \| Q_j \mid i \leq h, j \leq k\}$.

(ii) This proof is by induction on the height h of the bar b. If $h = 0$ then the thesis is trivial. Otherwise $tree(M)$ has the root node labeled by M and $tree(M_1), \ldots, tree(M_n)$ as its immediate subtrees, where $\{M_1, \ldots, M_n\} = \mathcal{R}(M, 1)$. Because of $h \neq 0$ we have that the root is not in b (recall that a bar intersects each maximal path of $tree(M)$ in exactly one node). It follows that for all $i \leq n$ there exists $b_i \in bar(M_i)$ such that $b = b_1 \cup \cdots \cup b_n$. But the height of each b_i with respect to $tree(M_i)$ has to be less than h, so that $M_i \rhd \sum\{M_i' \mid M_i' \in b_i\}$ by induction hypothesis. So the thesis follows from (i) of this lemma. □

Part (ii) of Lemma 2.9 implies $M \rhd \sum \mathcal{R}(M, k)$ for all k. Moreover, it implies that if $M \longrightarrow^* N$ then either $M \rhd N$ or $M \rhd N + L$ for some L.

Observe that the implications in Lemma 2.9 cannot be reversed. This is due to the more permissive clause $(\|)'$ of Definition 2.6. Indeed, if, e.g., $M \equiv (\lambda x.xxx)(\lambda x.xxx)$ then there exists an infinite reduction $M \equiv M_0 \longrightarrow M_1 \longrightarrow \cdots$ where each M_i is an application and $M_i \not\equiv M_{i+1}$ for all i. Now the unique branch of $tree(M_0 \| M_1)$ is the infinite one: $M_0 \| M_1 \longrightarrow M_1 \| M_2 \longrightarrow \cdots$. But $M_0 \| M_1 \rhd M_i \| M_i$ for all $i \geq 1$, while for all $b \in bar(M)$, $b \neq \{M_i \| M_i\}$.

COROLLARY 2.10. *If $N \in \Lambda^0_{+\|}$ and $N \Downarrow$, then there exist $V_1, \ldots, V_n \in \mathsf{Val}$ such that*

(i) $N \rhd \sum_{i=1}^{n} V_i$;

(ii) $\forall (\lambda v.M) \in \Lambda^0_{+\|}$, $(\lambda v.M)N \rhd \sum_{i=1}^{n} (\lambda v.M)V_i$.

Proof. If $N \Downarrow$ then there exists a bar of values $\{V_1, \ldots, V_n\} \in bar(N)$ such that each V_i is the first value that is met starting from the root through a maximal path in $tree(N)$. That is, no value occurs in the path from N to V_i. By (ii) of Lemma 2.9 $N \rhd \sum_{i=1}^{n} V_i$. On the other hand $\{(\lambda v.M)V_i \mid i \leq n\} \in bar((\lambda v.M)N)$ because of rule (μ_v). Then the thesis follows by (ii) of Lemma 2.9. □

LEMMA 2.11. *Let $M, N, V \in \Lambda^0_{+\|}$.*

(i) $(\lambda v.M)V \Downarrow \ \& \ V \in \mathsf{Val} \ \Rightarrow \exists V_1, \ldots, V_n \in \mathsf{Val},\ V \rhd \sum_{i=1}^n V_i \ \& \ \forall i \leq n,\ M[V_i/v]\Downarrow$.

(ii) $(\lambda v.M)N\Downarrow \Rightarrow \exists V_1, \ldots, V_n \in \mathsf{Val},\ N \rhd \sum_{i=1}^n V_i \ \& \ \forall i \leq n,\ M[V_i/v]\Downarrow$.

Proof. (i) If $V \in \mathsf{TVal}$ then $\mathcal{R}((\lambda v.M)V, 1) = \{M[V/v]\}$, so the hypothesis implies that $M[V/v]\Downarrow$. Otherwise $V \in \mathsf{Val} - \mathsf{TVal}$. By definition, $(\lambda v.M)V \Downarrow_k$ for some $k > 0$, and we make induction on k. Suppose that $\mathcal{R}(V, 1) = \{V_1, \ldots, V_n\}$, so that

$$\mathcal{R}((\lambda v.M)V, 1) = \{M[V/v] \| (\lambda v.M)V_i \mid i \leq n\}.$$

If $k = 1$ then, since for all i, $(\lambda v.M)V_i$ is an application (that is, it is not a value), we have $M[V/v] \in \mathsf{Val}$, so that $M[V/v] \Downarrow$. If $k > 1$ and $M[V/v] \Uparrow$ (otherwise the thesis is immediate), then for all $i \leq n$, $(\lambda v.M)V_i \Downarrow_{k-1}$. By induction there are $V_{i,1}, \ldots, V_{i,n_i} \in \mathsf{Val}$ such that $V_i \rhd \sum_{j=1}^{n_i} V_{i,j}$ and $M[V_{i,j}/v] \Downarrow$ for all i and j. The thesis now follows since $V \rhd \sum_{i=1}^n V_i$ by (i) of Lemma 2.9.

(ii) If $N \Uparrow$ then for all $k \geq 0$ there exists $N' \in \mathcal{R}(N, k)$ such that $(\lambda v.M)N' \in \mathcal{R}((\lambda v.M)N, k)$ and rules (β_v) and $(\beta_v\|)$ cannot be applied to $(\lambda v.M)N'$. This implies that $(\lambda v.M)N \Uparrow$. By hypothesis and by contraposition we have that $N\Downarrow$. By Corollary 2.10 there exist values $V_1, \ldots, V_n$ such that $N \rhd \sum_{i=1}^n V_i$ and $(\lambda v.M)N \rhd \sum_{i=1}^n (\lambda v.M)V_i$. Moreover, by the proof of the same corollary, $\{(\lambda v.M)V_i \mid i \leq n\} \in bar((\lambda v.M)N)$, so that by hypothesis $(\lambda v.M)V_i \Downarrow$ for all $i \leq n$. Now, by part (i) of this lemma, for each i there are $V_{i,1}, \ldots, V_{i,n_i} \in \mathsf{Val}$ such that $V_i \rhd \sum_{j=1}^{n_i} V_{i,j}$ and $M[V_{i,j}/v]\Downarrow$, and the thesis follows. □

THEOREM 2.12. *Let* $M, N \in \Lambda^0_{+\|}$. *Then*

(i) $[M \rhd N \ \& \ N\Downarrow] \ \Rightarrow M\Downarrow$;

(ii) $M \bowtie N \Rightarrow [M\Downarrow \Leftrightarrow N\Downarrow]$.

Proof. (i) In this proof we must distinguish between $\rhd$ and $\rhd^*$. Clearly, if we can prove the statement for $\rhd$, the same thesis holds for $\rhd^*$. As a matter of fact we prove, by induction on the definition of $\rhd$, the stronger statement

$$M \rhd N \Rightarrow \forall \vec{L},\ [N\vec{L}\Downarrow \ \Rightarrow M\vec{L}\Downarrow],$$

from which the thesis follows, taking the empty vector.

—If $M \rhd N$ thanks to $(\beta)'$, $(\beta_v)'$, $(\beta_v\|)'$, $(\mu_v)'$, $(+_{app})'$, or $(\|_{app})'$ (see Definition 2.6), then M is always an application and $N \equiv \sum_{i=1}^n M_i$ where $\mathcal{R}(M, 1) = \{M_1, \ldots, M_n\}$ (where the multiset $\mathcal{R}(M, 1)$ is ordered in such a way that it matches the shape of N). By this fact and rules (ν) and $(+)$ we have that

$$\{M_i\vec{L} \mid 1 \leq i \leq n\} \in bar(N\vec{L}) \cap bar(M\vec{L}).$$

Now $N\vec{L}\Downarrow$ implies that $M_i\vec{L}\Downarrow$ for all i $(1 \leq i \leq n)$, so that $M\vec{L}\Downarrow$ follows.

—Clause $(\|+)'$. Then $M \equiv (P + Q)\|R$ and $N \equiv P\|R + Q\|R$. Now

$$\begin{aligned}(P\|R + Q\|R)\vec{L}\Downarrow &\Rightarrow (P\vec{L}\Downarrow \ \& \ Q\vec{L}\Downarrow) \text{ or } R\vec{L}\Downarrow \\ &\Rightarrow (P\vec{L}\Downarrow \text{ or } R\vec{L}\Downarrow) \ \& \ (Q\vec{L}\Downarrow \text{ or } R\vec{L}\Downarrow) \\ &\Rightarrow ((P + Q)\|R)\vec{L}\Downarrow\end{aligned}$$

by rule (ν) and the remark after Definition 2.5.

—Clause $(\nu)'$. Then $M \equiv PQ$, $N \equiv P'Q$, and $P \rhd P'$. In this case $P'Q\vec{L}\Downarrow$ implies $PQ\vec{L}\Downarrow$ immediately by induction, taking the vector $Q\vec{L}$.

—Clause $(+)'$. Then $M \equiv P + Q$, $N \equiv P' + Q$, and $P \rhd P'$. Now

$$\begin{array}{rcll}(P' + Q)\vec{L}\Downarrow & \Rightarrow & P'\vec{L}\Downarrow \ \& \ Q\vec{L}\Downarrow & \\ & \Rightarrow & P\vec{L}\Downarrow \ \& \ Q\vec{L}\Downarrow & \text{by induction} \\ & \Rightarrow & (P+Q)\vec{L}\Downarrow . & \end{array}$$

—Clause $(\|)'$. Similar to the case of clause $(+)'$, where "or" replaces "&."

—For clauses $(+_c)'$, $(\|_c)'$, $(+_{ass})'$, and $(\|_{ass})'$ the proofs are similar to those of $(+)'$ and $(\|)'$.

(ii) M converging implies that there are values $V_1, \ldots, V_n$ such that $M \rhd \sum_{i=1}^n V_i$ by Corollary 2.10(i). Therefore, $N \bowtie \sum_{i=1}^n V_i$. By the Church–Rosser property of $\rhd$ there is an L such that $N \rhd L$ and $\sum_{i=1}^n V_i \rhd L$. But $\sum_{i=1}^n V_i \rhd L$ implies that L is a sum of values and therefore L must converge. We conclude that N converges by (i). □

Based on the convergence predicate the following definition adapts to the present setting the notion of contextual theories. This notion stems from [52] and it is widely used in, e.g., [15], for the classical theory of solvability and in [6], [19], and [55], where it is shown to be equivalent to applicative bisimulation.

The idea is that two terms are operationally equivalent if and only if in all contexts they exhibit the same behavior with respect to some observable properties. Here convergence is the only observable property; hence we can make the following definition.

DEFINITION 2.13. *Let $M, N \in \Lambda_{+\|}$. Then*

(i) $M \sqsubseteq^{\mathcal{O}} N \Leftrightarrow \forall C[\,],\ C[M]\Downarrow \Rightarrow C[N]\Downarrow$, *where* $C[M], C[N] \in \Lambda^0_{+\|}$;

(ii) $\simeq^{\mathcal{O}} = \sqsubseteq^{\mathcal{O}} \cap \sqsupseteq^{\mathcal{O}}$.

3. A logical presentation. To obtain a logical presentation of the semantics of the calculus we follow the paradigm of Leibniz which identifies objects with sets of their properties. This received an elegant mathematical treatment thanks to works like [63] and [5] and, especially in the case of type-free calculi, it is naturally formalized in suitable extensions of a Curry-type assignment system like the intersection-type discipline considered in [16].

In the present case we use a more expressive system which allows for disjunctive types. We call them union types since they differ from coproducts in Church-typed λ-calculi in much the same way as intersection differs from cartesian product. See [14] for a study of this discipline in the case of classical λ-calculus.

3.1. The set of types and its preorder. The type syntax is as follows:

$$\sigma ::= \omega \mid \sigma \to \sigma \mid \sigma \wedge \sigma \mid \sigma \vee \sigma,$$

and we call *Type* the resulting set. In writing types, we assume that $\wedge$ and $\vee$ take precedence over $\to$.

The choice of the preorder on types is crucial, since it will be used in a subtyping rule in subsection 3.2 and it will determine the structure of the set of filters in section 4.

DEFINITION 3.1. *Let $\sigma \leq \tau$ be the smallest preorder over types such that*

(i) *$\langle Type, \leq\rangle$ is a distributive lattice, in which $\wedge$ is the meet, $\vee$ is the join, and ω is the top*;

(ii) *the arrow satisfies*

(a) $\sigma \to \omega \leq \omega \to \omega$,

(b) $(\sigma \to \rho) \wedge (\sigma \to \tau) \leq \sigma \to \rho \wedge \tau$,

(c) $\sigma \geq \sigma', \tau \leq \tau' \Rightarrow \sigma \to \tau \leq \sigma' \to \tau'$.

Following [30], by lattice we mean a poset in which every finite nonempty subset has a meet and a join. According to this definition, there are lattices without bottom (like the present one).

We write $\sigma = \tau$ for "$\sigma \leq \tau$ and $\tau \leq \sigma$." Note that, if $\sigma \neq \omega$ then $\sigma \leq \omega \to \omega$.

NOTATION 3.2. Let $\omega^0 \to \omega = \omega$, $\omega^{n+1} \to \omega = \omega \to \omega^n \to \omega$.

The types $\omega^n \to \omega$ for suitable n are "better than" all other types, as shown in the following proposition.

PROPOSITION 3.3. *For all σ, there exists n such that $\omega^n \to \omega \leq \sigma$,*

Proof. By induction on the structure of σ,

$\sigma \equiv \omega$: This proof is trivial.

$\sigma \equiv \sigma_1 \to \sigma_2$: By the induction hypothesis, $\exists n$, $\omega^n \to \omega \leq \sigma_2$, hence $\omega^{n+1} \to \omega \leq \sigma$, by Definition 3.1(ii(c)), using $\sigma_1 \leq \omega$.

$\sigma \equiv \sigma_1 \wedge \sigma_2$: By the induction hypothesis, $\exists n_i$, $\omega^{n_i} \to \omega \leq \sigma_i$ $(i = 1, 2)$. Let $n = \max(n_1, n_2)$. Then $\omega^n \to \omega \leq \sigma$, since $\omega^n \to \omega \leq \omega^{n_i} \to \omega$ $(i = 1, 2)$ and $\sigma_1 \wedge \sigma_2$ is the meet of σ_1 and σ_2.

$\sigma \equiv \sigma_1 \vee \sigma_2$: Recall that $\sigma_1 \wedge \sigma_2 \leq \sigma_1 \vee \sigma_2$, and then proceed as in the previous case. □

We need some properties of the $\leq$ relation, whose proof requires a stratification of $Type$.

DEFINITION 3.4 (stratification of $Type$). *Let us define three subsets T_0, T_1, T_2 of $Type$ recursively:*

$\omega \to \omega \in T_0$;

$\omega \in T_2$;

$\sigma \in T_2, \tau \in T_1 \Rightarrow \sigma \to \tau \in T_0$;

$n \geq 1, \sigma_1, \ldots, \sigma_n \in T_0 \Rightarrow \sigma_1 \vee \cdots \vee \sigma_n \in T_1$;

$n \geq 1, \sigma_1, \ldots, \sigma_n \in T_1 \Rightarrow \sigma_1 \wedge \cdots \wedge \sigma_n \in T_2$.

To rephrase the previous definition, we consider types in conjunctive normal form, that is, conjunctions of disjunctions of arrows, ω being the empty conjunction.

REMARK 3.5. Notice that the set T_2, when restricted to types without $\vee$ occurrences, is similar to the set of normal type schemes of [36] and to the set of strict types of [12]. The difference is that in those papers types were constructed out of type variables and the type $\omega \to \omega$ was not allowed. Normal-type schemes were introduced in [36] as a technical tool to prove properties analogous to those stated in Lemma 3.9. Instead, strict types have been introduced with a different preorder to obtain a syntax-directed type assignment system [12], [13].

Taking $n = 1$ in the clauses above, one sees that $T_0 \subseteq T_1 \subseteq T_2$, and such inclusions are clearly proper.

Over each of these sets we introduce a preorder.

DEFINITION 3.6. *$\leq_i \subseteq T_i \times T_i$ is the least preorder such that*

$(\leq_0)$: $\sigma \leq_0 \tau \;\Leftrightarrow\; \tau \equiv \omega \to \omega$ *or* $\sigma \equiv \sigma' \to \sigma'', \tau \equiv \tau' \to \tau''$ *and* $\tau' \leq_2 \sigma'$ *and* $\sigma'' \leq_1 \tau''$;

$(\leq_1)$: $\sigma_1 \vee \cdots \vee \sigma_n \leq_1 \tau_1 \vee \cdots \vee \tau_m \;\Leftrightarrow\; \forall i \leq n\ \exists j \leq m,\ \sigma_i \leq_0 \tau_j$;

$(\leq_2)$: $\sigma \leq_2 \tau \;\Leftrightarrow\; \tau \equiv \omega$ *or* $\sigma \equiv \sigma_1 \wedge \cdots \wedge \sigma_n$, $\tau \equiv \tau_1 \wedge \cdots \wedge \tau_m$ *and* $\forall j \leq m\ \exists i \leq n,\ \sigma_i \leq_1 \tau_j$.

Really, for each type in $Type$, we can find an equivalent type in T_2; therefore, we introduce a map which associates to each type its equivalent type in T_2.

DEFINITION 3.7. *Let $* : Type \to T_2$ be defined by*

$$\omega^* = \omega;$$

$$(\sigma \to \tau)^* = \begin{cases} \bigwedge_{i\in I}(\sigma^* \to \tau_i) & \text{if } \tau^* \equiv \bigwedge_{i\in I} \tau_i \text{ and } \tau^* \not\equiv \omega, \\ \omega \to \omega & \text{otherwise;} \end{cases}$$

$$(\sigma \vee \tau)^* = \begin{cases} \bigwedge_{i\in I}\bigwedge_{j\in J}(\sigma_i \vee \tau_j) & \text{if } \sigma^* \equiv \bigwedge_{i\in I} \sigma_i,\ \sigma^* \not\equiv \omega \\ & \text{and } \tau^* \equiv \bigwedge_{j\in J} \tau_j,\ \tau^* \not\equiv \omega, \\ \omega & \text{otherwise;} \end{cases}$$

$$(\sigma \wedge \tau)^* = \begin{cases} \sigma^* & \text{if } \tau^* \equiv \omega, \\ \tau^* & \text{if } \sigma^* \equiv \omega, \\ \sigma^* \wedge \tau^* & \text{otherwise.} \end{cases}$$

PROPOSITION 3.8. *For all $\sigma, \tau \in Type$,*

(i) $\sigma = \sigma^*$;

(ii) $\sigma, \tau \in T_i, \sigma \leq_i \tau \Rightarrow \sigma \leq \tau$ *for* $i = 0, 1, 2$;

(iii) $\sigma \leq \tau \Rightarrow \sigma^* \leq_2 \tau^*$.

Proof. (i) is proved by induction on the definition of the map $(\cdot)^*$. To see (ii), use an induction on the definition of $\leq_i$. Finally, to prove (iii), it suffices (by (i)) to show that $\sigma^* \leq \tau^*$ implies $\sigma^* \leq_2 \tau^*$, which can be proved by induction on any standard axiomatic presentation of $\leq$. □

LEMMA 3.9.

(i) $\mu \wedge \nu \leq \sigma \to \tau \ \&\ \mu \neq \omega \ \&\ \nu \neq \omega \Rightarrow \exists \tau_1, \tau_2,\ \tau = \tau_1 \wedge \tau_2 \ \&\ \mu \leq \sigma \to \tau_1 \ \&\ \nu \leq \sigma \to \tau_2$;

(ii) $\bigwedge_{i\in I}(\mu_i \to \nu_i) \leq \sigma \to \tau \ \&\ \tau \neq \omega \Rightarrow \exists J \subseteq I,\ \sigma \leq \bigwedge_{j\in J} \mu_j \ \&\ \bigwedge_{j\in J} \nu_j \leq \tau$.

Proof. (i) Let

$$(\mu \wedge \nu)^* = \bigwedge_{i\in I} \mu_i \wedge \bigwedge_{j\in J} \nu_j \text{ and } (\sigma \to \tau)^* = \bigwedge_{k\in K} (\sigma^* \to \pi_k),$$

assuming $\mu^* = \bigwedge_{i\in I} \mu_i, \nu^* = \bigwedge_{j\in J} \nu_j$ and $\tau^* = \bigwedge_{k\in K} \pi_k$. Using Proposition 3.8(i), (ii), (iii) and the definition of $\leq_2$, we have that

$$\forall k,\ (\exists i,\ \mu_i \leq_1 \sigma^* \to \pi_k) \text{ or } (\exists j,\ \nu_j \leq_1 \sigma^* \to \pi_k).$$

Therefore we can choose τ_1 as the intersection of the π_k which satisfy the first inequality and τ_2 as the intersection of the remaining π_k. If one of these intersections is empty, we choose ω for the corresponding τ_i $(i = 1, 2)$.

(ii) Let $\nu_i^* = \bigwedge_{l\in L} \nu_{i,l}$ (where L depends on i) and $\tau^* = \bigwedge_{k\in K} \tau_k$. Then

$$\bigwedge_{i\in I}(\mu_i \to \nu_i) \leq \sigma \to \tau \Rightarrow \bigwedge_{i\in I}\bigwedge_{l\in L}(\mu_i^* \to \nu_{i,l}) \leq_2 \bigwedge_{k\in K}(\sigma^* \to \tau_k).$$

It follows that

$$\forall k\ \exists i, l,\ \mu_i^* \to \nu_{i,l} \leq_1 \sigma^* \to \tau_k,$$

which in this case is equivalent to

$$\forall k\ \exists i, l,\ \mu_i^* \to \nu_{i,l} \leq_0 \sigma^* \to \tau_k,$$

and hence

$$\forall k\ \exists i, l,\ \sigma^* \leq_2 \mu_i^* \ \&\ \nu_{i,l} \leq_1 \tau_k.$$

So we can conclude that

$$\forall k\ \exists i,\ \sigma \leq \mu_i\ \&\ \bigwedge_{l\in L} \nu_{i,l} \leq \tau_k.$$

Taking J as the set of all i which satisfy these inequalities for some $k \in K$, we are done. □

REMARK 3.10. Notice that Lemma 3.9 cannot be trivially satisfied by choosing $\tau_1 = \tau_2 = \tau$. In fact, in general, $\mu \wedge \nu \leq \sigma \to \tau$ does not imply $\mu \leq \sigma \to \tau$. For a counterexample, take $\mu = \sigma = \tau = \omega \to \omega$ and $\nu = \sigma \to \tau$.

A type σ is *join-irreducible* or *coprime* if and only if

$$\sigma \leq \tau \vee \rho \Rightarrow \sigma \leq \tau \text{ or } \sigma \leq \rho$$

for any τ, ρ. Let $CType$ be the set of coprime types different from ω. Observe that, because of distributivity, coprime types are closed under $\wedge$. Being $\langle Type, \leq\rangle$, the free distributive lattice satisfying the arrow axioms, each type is the join of a finite number of coprime types. To see this, it suffices to define the following mapping $\Theta : Type \to \mathcal{P}(CType)$:

$$\begin{array}{lcl}
\Theta(\omega) & = & \{\omega\},\\
\Theta(\sigma \to \tau) & = & \{\sigma \to \tau\},\\
\Theta(\sigma \wedge \tau) & = & \{\sigma' \wedge \tau' \mid \sigma' \in \Theta(\sigma)\ \&\ \tau' \in \Theta(\tau)\},\\
\Theta(\sigma \vee \tau) & = & \Theta(\sigma) \cup \Theta(\tau).
\end{array}$$

If $\Theta(\sigma) = \{\sigma_1, \ldots, \sigma_n\}$, it is easy to verify that σ_i is join-irreducible for each i and $\sigma = \sigma_1 \vee \cdots \vee \sigma_n$.

3.2. The type assignment system. In this subsection we introduce our type assignment system $\mathcal{L}$. We start with the notion of basis. We state that only coprime types different from ω can be assumed for call-by-value variables. This restriction is justified by the correspondence between total values and coprime types (see Theorem 3.15(ii)).

DEFINITION 3.11. *A* basis $\Gamma : (\mathsf{Vn} \to Type) \cap (\mathsf{Vv} \to CType)$ *is a mapping such that* $\Gamma(x) = \omega$ *for all* x *but a finite subset of* Vn*, and* $\Gamma(v) = \omega \to \omega$ *for all* v *but a finite subset of* Vv.

To each basis Γ we associate the finite set

$$Dom(\Gamma) = \{x \in \mathsf{Vn} \mid \Gamma(x) \neq \omega\} \cup \{v \in \mathsf{Vv} \mid \Gamma(v) \neq \omega \to \omega\}.$$

The notation $\Gamma, \chi : \sigma$ is shorthand for the function $\Gamma'(\chi') = \sigma$ if $\chi' \equiv \chi$; $\Gamma(\chi')$ otherwise. To meet a common practice we shall sometimes identify Γ with the (finite) set of judgments $\{\chi{:}\sigma \mid \chi \in Dom(\Gamma)\ \&\ \Gamma(\chi) = \sigma\}$ and write $\chi{:}\sigma \in \Gamma$.

DEFINITION 3.12. *The axioms and rules of the assignment system* $\mathcal{L}$ *are as follows:*

$$(\mathrm{Ax})\quad \Gamma \vdash \chi : \Gamma(\chi), \qquad (\omega)\quad \Gamma \vdash M : \omega,$$

$$(\to \mathrm{I}_n)\quad \frac{\Gamma, x:\sigma \vdash M : \tau}{\Gamma \vdash \lambda x.M : \sigma \to \tau}, \qquad (\to \mathrm{I}_v)\quad \frac{\Gamma, v:\sigma' \vdash M : \tau \quad \forall \sigma' \in \Theta(\sigma)}{\Gamma \vdash \lambda v.M : \sigma \to \tau},$$

$$(\to \mathrm{E})\quad \frac{\Gamma \vdash M : \sigma \to \tau \quad \Gamma \vdash N : \sigma}{\Gamma \vdash MN : \tau},$$

$$(\wedge \mathrm{I})\quad \frac{\Gamma \vdash M : \sigma \quad \Gamma \vdash M : \tau}{\Gamma \vdash M : \sigma \wedge \tau}, \qquad (\leq)\quad \frac{\Gamma \vdash M : \sigma \quad \sigma \leq \tau}{\Gamma \vdash M : \tau},$$

$$(+\mathrm{I})\quad \frac{\Gamma \vdash M : \sigma \quad \Gamma \vdash N : \tau}{\Gamma \vdash M + N : \sigma \vee \tau}, \qquad (\| \mathrm{I})\quad \frac{\Gamma \vdash M : \sigma \quad \Gamma \vdash N : \tau}{\Gamma \vdash M \| N : \sigma \wedge \tau}.$$

$\Gamma \vdash_{\mathcal{L}} M : \sigma$ *abbreviates "*$\Gamma \vdash M : \sigma$ *is derivable in* $\mathcal{L}$*."*

To help the understanding of rule $(\to \mathrm{I}_v)$, we consider the following example. Let W_1, W_2 be total values such that $\vdash_{\mathcal{L}} W_i{:}\sigma_i$ $(i = 1, 2)$ for some coprime types σ_1, σ_2. Clearly, this implies $\vdash_{\mathcal{L}} W_1 + W_2{:}\sigma_1 \vee \sigma_2$ by rule $(+\mathrm{I})$. Consider $(\lambda v.M)(W_1 + W_2)$: it reduces to $M[W_1/v]$ and $M[W_2/v]$. Therefore $v{:}\sigma_i \vdash_{\mathcal{L}} M{:}\tau$ for $i = 1, 2$ suffices to assure that $(\lambda v.M)$ has type $\sigma_1 \vee \sigma_2 \to \tau$. The real justification of this rule is that it implies the completeness of the type assignment (Theorem 4.11) and the full abstraction of the filter model (Theorem 5.11).

We shall write $\Gamma \leq \Gamma'$ if, $\forall \chi,\ \Gamma(\chi) \leq \Gamma'(\chi)$; in this case it is easy to verify that, if $\Gamma' \vdash_{\mathcal{L}} M : \sigma$, then $\Gamma \vdash_{\mathcal{L}} M : \sigma$ for any M and σ.

The system $\mathcal{L}$ enjoys structural properties which can be shown by simple inductions on derivations.

THEOREM 3.13 (derivability properties of system $\mathcal{L}$).

(i) $\Gamma \vdash_{\mathcal{L}} \chi : \tau \ \Leftrightarrow\ \Gamma(\chi) \leq \tau$;

(ii) $\Gamma \vdash_{\mathcal{L}} \lambda\chi.M : \rho \ \Leftrightarrow$
$\exists n,\ \sigma_1, \ldots, \sigma_n, \tau_1, \ldots \tau_n.$
$(\forall i \leq n,\ \Gamma \vdash_{\mathcal{L}} \lambda\chi.M : \sigma_i \to \tau_i)\ \&\ \bigwedge_{i=1}^{n}(\sigma_i \to \tau_i) \leq \rho$;

(iii) $\Gamma \vdash_{\mathcal{L}} \lambda x.M : \sigma \to \tau \ \Leftrightarrow\ \Gamma, x:\sigma \vdash_{\mathcal{L}} M : \tau$;

(iv) $\Gamma \vdash_{\mathcal{L}} \lambda v.M : \sigma \to \tau\ \&\ \sigma \neq \omega \ \Leftrightarrow\ \forall \sigma' \in \Theta(\sigma),\ \Gamma, v:\sigma' \vdash_{\mathcal{L}} M : \tau$;

(v) $\Gamma \vdash_{\mathcal{L}} \lambda v.M : \sigma \to \tau\ \&\ \sigma = \omega \Rightarrow \tau = \omega$;

(vi) $\Gamma \vdash_{\mathcal{L}} MN : \tau\ \&\ \tau \neq \omega \ \Leftrightarrow\ \exists \sigma,\ \Gamma \vdash_{\mathcal{L}} M : \sigma \to \tau\ \&\ \Gamma \vdash_{\mathcal{L}} N : \sigma$;

(vii) $\Gamma \vdash_{\mathcal{L}} M + N : \sigma \ \Leftrightarrow\ \Gamma \vdash_{\mathcal{L}} M : \sigma\ \&\ \Gamma \vdash_{\mathcal{L}} N : \sigma$;

(viii) $\Gamma \vdash_{\mathcal{L}} M \| N : \tau \ \Leftrightarrow\ \exists \sigma, \sigma',\ \Gamma \vdash_{\mathcal{L}} M : \sigma\ \&\ \Gamma \vdash_{\mathcal{L}} N : \sigma'\ \&\ \sigma \wedge \sigma' \leq \tau$.

Proof. We consider only the interesting cases.

(ii) Given a derivation of $\Gamma \vdash \lambda\chi.M{:}\rho$, let

$$\Gamma \vdash \lambda\chi.M{:}\sigma_1 \to \tau_1, \ldots, \Gamma \vdash \lambda\chi.M{:}\sigma_n \to \tau_n$$

be all the statements in this deduction on which $\Gamma \vdash \lambda\chi.M{:}\rho$ depends and which are conclusions of rule $(\to \mathrm{I}_n)$ or of rule $(\to \mathrm{I}_v)$. Then

$$(\sigma_1 \to \tau_1) \wedge \cdots \wedge (\sigma_n \to \tau_n) \leq \rho.$$

(iii) If $\tau = \omega$ it is trivial. Otherwise let $\sigma_1, \ldots, \sigma_n, \tau_1, \ldots, \tau_n$ be as in the proof of (ii), where ρ has been replaced by $\sigma \to \tau$. Then

$$(\sigma_1 \to \tau_1) \wedge \cdots \wedge (\sigma_n \to \tau_n) \leq \sigma \to \tau,$$

which implies, by Lemma 3.9(ii),

$$\exists J \subseteq \{1, \ldots, n\},\ \sigma \leq \bigwedge_{j \in J} \sigma_j\ \&\ \bigwedge_{j \in J} \tau_j \leq \tau.$$

Moreover, $\Gamma, x{:}\sigma_i \vdash_{\mathcal{L}} M : \tau_i$ for $1 \le i \le n$, so that one can conclude $\Gamma, x{:}\sigma \vdash_{\mathcal{L}} M{:}\tau$.

(iv) Let $\sigma_1, \dots, \sigma_n, \tau_1, \dots, \tau_n$ be as in the proof of (ii), where ρ has been replaced by $\sigma \to \tau$. As in case (iii) we have

$$\exists J \subseteq \{1, \dots, n\},\ \sigma \le \bigwedge_{j \in J} \sigma_j \ \&\ \bigwedge_{j \in J} \tau_j \le \tau.$$

Moreover, $\Gamma, v{:}\sigma'_i \vdash_{\mathcal{L}} M : \tau_i$ for all $\sigma'_i \in \Theta(\sigma_i)$ and for $1 \le i \le n$. $\sigma \le \sigma_j$ implies, $\forall \sigma' \in \Theta(\sigma)$, $\exists \sigma'_j \in \Theta(\sigma_j)$ such that $\sigma' \le \sigma'_j$ by the definition of coprimality. So we can conclude, $\forall \sigma' \in \Theta(\sigma)$, $\Gamma, x{:}\sigma' \vdash_{\mathcal{L}} M{:}\tau$.

(v) We assume ad absurdum that $\tau \ne \omega$. Then, if $\sigma_1, \dots, \sigma_n, \tau_1, \dots, \tau_n$ and J are as in (iv), we would have $\sigma_j = \omega$ for all $j \in J$, and this is impossible according to our definition of basis.

(vii) Again, given a deduction of $\Gamma \vdash M + N{:}\sigma$, let

$$\Gamma \vdash M + N{:}\sigma_1, \dots, \Gamma \vdash M + N{:}\sigma_n$$

be all the statements in this deduction on which $\Gamma \vdash M + N{:}\sigma$ depends and which are conclusions of rule (+I). Then $\sigma_1 \wedge \cdots \wedge \sigma_n \le \sigma$ and there are μ_i, ν_i such that $\sigma_i = \mu_i \vee \nu_i$, $\Gamma \vdash_{\mathcal{L}} M{:}\mu_i$, $\Gamma \vdash_{\mathcal{L}} N{:}\nu_i$, for $1 \le i \le n$. So we can deduce $\Gamma \vdash M{:}\sigma$ and $\Gamma \vdash N{:}\sigma$ using ($\wedge$ I) and ($\le$).

(viii) Finally, given a deduction of $\Gamma \vdash M \| N{:}\tau$, let

$$\Gamma \vdash M \| N{:}\sigma_1, \dots, \Gamma \vdash M \| N{:}\sigma_n$$

be all the statements in this deduction on which $\Gamma \vdash M \| N{:}\tau$ depends and which are conclusions of rule ($\|$I). Then $\sigma_1 \wedge \cdots \wedge \sigma_n \le \tau$ and there are μ_i, ν_i such that $\sigma_i = \mu_i \wedge \nu_i$, $\Gamma \vdash_{\mathcal{L}} M{:}\mu_i$, $\Gamma \vdash_{\mathcal{L}} N{:}\nu_i$, for $1 \le i \le n$. Then we can choose $\sigma = \bigwedge_{i \le n} \mu_i$ and $\sigma' = \bigwedge_{i \le n} \nu_i$. In fact, $\sigma \wedge \sigma' \le \tau$ and we can derive $\Gamma \vdash_{\mathcal{L}} M{:}\sigma$ and $\Gamma \vdash N{:}\sigma'$ using ($\wedge$ I). □

As an immediate consequence of Theorem 3.13(iv) we have the co-additivity of call-by-value abstraction (i.e., finite meets are preserved).

COROLLARY 3.14. $\Gamma \vdash_{\mathcal{L}} \lambda v.M : (\sigma \to \rho) \wedge (\tau \to \rho) \ \Rightarrow\ \Gamma \vdash_{\mathcal{L}} \lambda v.M : \sigma \vee \tau \to \rho$.

We show how types characterize partial values and total values.

THEOREM 3.15 (characterization of values).

(i) $V \in \mathsf{Val} \Rightarrow \vdash_{\mathcal{L}} V : \omega \to \omega$;

(ii) $W \in \mathsf{TVal}\ \&\ \Gamma \vdash_{\mathcal{L}} W : \sigma \Rightarrow \exists \sigma' \in \Theta(\sigma),\ \Gamma \vdash_{\mathcal{L}} W : \sigma'$.

Proof. (i) The proof is by induction on the definition of values. If $V \equiv v \in \mathsf{Vv}$ then $\Gamma(v) = \omega \to \omega$, since $Dom(\Gamma) = \emptyset$, and the thesis follows by (Ax). If $V \equiv \lambda x.M$ then $\Gamma, x : \omega \vdash M : \omega$ is derivable by rule (ω), hence the thesis using ($\to \mathrm{I}_n$). If $V \equiv \lambda v.M$ we do the same as before, but assuming $v : \omega \to \omega$. The thesis follows using ($\to \mathrm{I}_v$) and ($\le$). Finally, if $V \equiv V' \| M$ or $M \| V'$ the thesis follows by induction using ($\|$) and ($\le$).

(ii) The proof is by induction on the definition of total values. If $W \equiv v$ then the thesis follows by Theorem 3.13(i) and the definition of basis. If $W \equiv \lambda\chi.M$ then, noting that each arrow type is coprime, the thesis follows from Theorem 3.13(ii) and the closure of coprime types under $\wedge$. Finally, if $W \equiv W' \| W''$, by Theorem 3.13(viii) there exist μ and ν such that $\Gamma \vdash_{\mathcal{L}} W' : \mu$, $\Gamma \vdash_{\mathcal{L}} W'' : \nu$, and $\mu \wedge \nu \le \sigma$; now by induction there are $\mu' \in \Theta(\mu), \nu' \in \Theta(\nu)$ such that $\Gamma \vdash_{\mathcal{L}} W' : \mu'$ and $\Gamma \vdash_{\mathcal{L}} W'' : \nu'$.

Since coprime types are closed under $\wedge$, $\mu' \wedge \nu' \leq \sigma$ implies that there is $\sigma' \in \Theta(\sigma)$ such that $\mu' \wedge \nu' \leq \sigma'$. □

The following lemma states the substitution properties of terms.

LEMMA 3.16.

(i) $\Gamma \vdash_{\mathcal{L}} M[N/x] : \tau \Leftrightarrow \exists \sigma,\ \Gamma, x : \sigma \vdash_{\mathcal{L}} M : \tau \ \&\ \Gamma \vdash_{\mathcal{L}} N : \sigma$;

(ii) $\Gamma \vdash_{\mathcal{L}} M[V/v] : \tau \ \&\ V \in \mathsf{Val} \Rightarrow \exists \sigma\ \forall \sigma' \in \Theta(\sigma),\ \Gamma, v : \sigma' \vdash_{\mathcal{L}} M : \tau \ \&\ \Gamma \vdash_{\mathcal{L}} V : \sigma$;

(iii) $\Gamma \vdash_{\mathcal{L}} M[W/\chi] : \tau \ \&\ W \in \mathsf{TVal} \Leftrightarrow \exists \sigma \in \mathit{CType},\ \Gamma, \chi : \sigma \vdash_{\mathcal{L}} M : \tau \ \&\ \Gamma \vdash_{\mathcal{L}} W : \sigma$.

Proof. (i) ($\Rightarrow$) If x does not occur in M we can choose $\sigma \equiv \omega$. Otherwise let σ be the intersection of all predicates of statements with subject N which occur in a given deduction of $\Gamma \vdash_{\mathcal{L}} M[N/x] : \tau$. The proof of $\Leftarrow$ is standard.

(ii) If v does not occur in M we can choose $\sigma \equiv \omega \to \omega$. Otherwise let ρ be the intersection of all predicates of statements with subject V which occur in a given deduction of $\Gamma \vdash_{\mathcal{L}} M[V/v] : \tau$. If $\rho \neq \omega$ we can choose $\sigma \equiv \rho$; otherwise $\sigma \equiv \omega \to \omega$.

(iii)($\Rightarrow$) If χ does not occur in M we can choose $\sigma \equiv \omega \to \omega$. Otherwise let ρ be the intersection of all predicates of statements with subject W which occur in a given deduction of $\Gamma \vdash_{\mathcal{L}} M[W/\chi] : \tau$. By Theorem 3.15(ii) there is $\rho' \in \Theta(\rho)$ such that $\Gamma \vdash_{\mathcal{L}} W : \rho'$. If $\rho' \neq \omega$ we can choose $\sigma \equiv \rho'$; otherwise $\sigma \equiv \omega \to \omega$. The proof of $\Leftarrow$ is standard. □

Notice that in Lemma 3.16(ii) the "$\Rightarrow$" cannot be replaced by "$\Leftrightarrow$". An easy proof of this uses the characterization of divergent terms by types which will be given in Corollary 5.6(ii). So we will prove it in Corollary 5.7(i).

As an immediate consequence of Theorem 3.15(ii) and Lemma 3.16(iii), the following rule ($\vee$E) is admissible:

$$(\vee\mathrm{E})\quad \frac{\forall \sigma' \in \Theta(\sigma) \quad \Gamma, \chi : \sigma' \vdash M : \rho \qquad \Gamma \vdash W : \sigma \qquad W \in \mathsf{TVal}}{\Gamma \vdash M[W/\chi] : \rho}\ .$$

Therefore, the restriction over the basis can be relaxed, allowing $\Gamma(v)$ to be any type different from ω. This would have the advantage of having a unique rule for abstraction, i.e., the standard one, avoiding ($\to \mathrm{I}_v$), which is a rule schema. Of course, rule ($\vee$E) should be added in this case. The reason why we choose the present less elegant version is that it greatly simplifies proofs.

3.3. The logic congruence relation. We now introduce the logical equivalence $\simeq^{\mathcal{L}}$; thereafter, we shall use the properties stated in Theorem 3.13 to establish the basic (in)equalities holding under this notion of equivalence. The invariance of types with respect to $\bowtie$ and to the reduction relation studied in section 2 will follow.

DEFINITION 3.17. *Let* $M, N \in \Lambda_{+\|}$; *then*

(i) $M \sqsubseteq^{\mathcal{L}} N \ \Leftrightarrow\ \forall \Gamma, \sigma,\ \Gamma \vdash_{\mathcal{L}} M : \sigma \Rightarrow \Gamma \vdash_{\mathcal{L}} N : \sigma$;

(ii) $\simeq^{\mathcal{L}} = \sqsubseteq^{\mathcal{L}} \cap \sqsupseteq^{\mathcal{L}}$.

As a first step in the study of the relation $\simeq^{\mathcal{L}}$ we fix some basic properties of it with respect to the various kinds of β-contraction present in our calculus. These can be easily proved using Lemma 3.16.

LEMMA 3.18.

(i) $(\lambda x.M)N \simeq_{\mathcal{L}} M[N/x]$;

(ii) $M[V/v] \sqsubseteq^{\mathcal{L}} (\lambda v.M)V$ *if* $V \in \mathsf{Val}$;

(iii) $(\lambda v.M)W \simeq^{\mathcal{L}} M[W/v]$ *if* $W \in \mathsf{TVal}$.

Proof. The most interesting case is the inclusion from left to right of (iii) when $\tau \neq \omega$.

$\Gamma \vdash_{\mathcal{L}} (\lambda v.M)W : \tau$
$\Rightarrow \quad \exists \sigma,\ \Gamma \vdash_{\mathcal{L}} \lambda v.M : \sigma \to \tau \ \&\ \Gamma \vdash_{\mathcal{L}} W : \sigma$ by Theorem 3.13(vi),
$\Rightarrow \quad \exists \sigma,\ \forall \sigma' \in \Theta(\sigma),\ \Gamma, v : \sigma' \vdash_{\mathcal{L}} M : \tau \ \&\ \Gamma \vdash_{\mathcal{L}} W : \sigma$ by Theorem 3.13(iv),
$\Rightarrow \quad \exists \sigma' \in CType,\ \Gamma, v : \sigma' \vdash_{\mathcal{L}} M : \tau \ \&\ \Gamma \vdash_{\mathcal{L}} W : \sigma'$ by Theorem 3.15(ii), since $W \in \mathsf{TVal}$,
$\Rightarrow \quad \Gamma \vdash_{\mathcal{L}} M[W/v] : \tau$ by Lemma 3.16(iii)($\Leftarrow$). □

Notice that the opposite of Lemma 3.18(ii) does not hold. This will be proved in Corollary 5.7(ii), since it follows immediately from point (i) of the same corollary.

The following three lemmas are easy consequences of Theorem 3.13. The second and third lemmas state that nondeterministic choice and parallel composition are the meet and the join, respectively. Moreover, they illustrate the behaviors of these operators with respect to application and abstraction.

LEMMA 3.19. *The relation $\simeq^{\mathcal{L}}$ is a congruence over $\Lambda_{+\|}$.*

LEMMA 3.20.

(i) $M + N \sqsubseteq^{\mathcal{L}} M, N$;
(ii) $L \sqsubseteq^{\mathcal{L}} M, N \Rightarrow L \sqsubseteq^{\mathcal{L}} M + N$;
(iii) $(M + N)L \simeq^{\mathcal{L}} ML + NL$;
(iv) $L(M + N) \sqsubseteq^{\mathcal{L}} LM + LN$;
(v) $(\lambda v.M)(N + L) \simeq^{\mathcal{L}} (\lambda v.M)N + (\lambda v.M)L$;
(vi) $\lambda\chi.(M + N) \sqsubseteq^{\mathcal{L}} \lambda\chi.M + \lambda\chi.N$.

Proof. All inclusions are immediate. The converse of (vi) does not hold. Indeed, let $\sigma \equiv (\rho \to \rho) \vee (\tau \to \omega^2 \to \omega)$ where $\rho \equiv \omega^3 \to \omega$ and $\tau \equiv (\omega \to \omega) \to \omega^2 \to \omega$. Then we have $\vdash_{\mathcal{L}} \mathbf{I} : \rho \to \rho$ and $\vdash_{\mathcal{L}} \Delta : \tau \to \omega^2 \to \omega$, which imply $\vdash_{\mathcal{L}} \mathbf{I} + \Delta : \sigma$, but $\not\vdash_{\mathcal{L}} \lambda x.(x + xx) : \sigma$. In fact, by Theorem 3.13(iii) and (vii), if we could derive $\lambda x.(x+xx) : \sigma$, then we would also have $x : \mu \vdash_{\mathcal{L}} x : \nu$ and $x : \mu \vdash_{\mathcal{L}} xx : \nu$ for some μ, ν such that $\mu \to \nu \leq \sigma$. This implies either $\mu \to \nu \leq \rho \to \rho$ or $\mu \to \nu \leq \tau \to \omega^2 \to \omega$ by Definition 3.6 and Proposition 3.8. But it is easy to verify, using Theorem 3.13(i) and (vi), that $x : \rho \not\vdash_{\mathcal{L}} xx : \rho$ and $x : \tau \not\vdash_{\mathcal{L}} x : \omega^2 \to \omega$. □

LEMMA 3.21.

(i) $M, N \sqsubseteq^{\mathcal{L}} M\|N$;
(ii) $M, N \sqsubseteq^{\mathcal{L}} L \Rightarrow M\|N \sqsubseteq^{\mathcal{L}} L$;
(iii) $(M\|N)L \simeq^{\mathcal{L}} ML\|NL$;
(iv) $LM\|LN \sqsubseteq^{\mathcal{L}} L(M\|N)$;
(v) $\lambda\chi.(M\|N) \simeq^{\mathcal{L}} \lambda\chi.M\|\lambda\chi.N$;
(vi) $(M + N)\|L \simeq^{\mathcal{L}} M\|L + N\|L$.

The inequalities of Lemma 3.20(iv) and 3.21(iv) are proper, and this can be proved using the structural properties of deductions (Theorem 3.13). But an easier proof will be given in Corollary 5.7(iii) and (iv) using Corollary 5.6(ii).

The following theorem provides the first evidence of the matching between operational and logic semantics.

THEOREM 3.22 (type invariance).

(i) $\Gamma \vdash_{\mathcal{L}} M : \sigma \ \&\ M \bowtie N \Rightarrow \Gamma \vdash_{\mathcal{L}} N : \sigma$;
(ii) $\Gamma \vdash_{\mathcal{L}} M : \sigma \ \&\ M \longrightarrow^* N \Rightarrow \Gamma \vdash_{\mathcal{L}} N : \sigma$.

Proof. (i) is an easy consequence of Lemmas 3.18, 3.19, 3.20, and 3.21.

(ii) If $M \longrightarrow^* N$ then for some $b \in bar(M)$ it is the case that $N \in b$. By Lemma 2.9 (ii) $M \rhd \sum\{M' \mid M' \in b\}$. Being $\rhd \subseteq \bowtie$, by part (i) of the present theorem and Theorem 3.13(vii), we have $\Gamma \vdash_{\mathcal{L}} M' : \sigma$ for all $M' \in b$, from which the thesis follows. □

The subject expansion property fails for $\xrightarrow{*}$. For example, $\vdash_{\mathcal{L}} \mathbf{I} : \omega \to \omega$ but, as we shall be able to derive from Corollary 5.6(ii), $\not\vdash_{\mathcal{L}} \mathbf{I} + \Omega : \omega \to \omega$.

The main result of the present section is that convergence implies typability by $\omega \to \omega$. We will see in section 5 that the converse is also true. Therefore, this type will completely characterize terms whose meaning is to eventually be a function, even if not a unique one.

THEOREM 3.23. *Let M be a closed term:*

$$M\Downarrow \;\Rightarrow\; \vdash_{\mathcal{L}} M : \omega \to \omega.$$

Proof.

$$\begin{array}{lll} M\Downarrow & \Rightarrow & \exists V_1, \ldots, V_n \in \mathsf{Val},\ M \rhd \sum_{i=1}^{n} V_i \quad \text{by Corollary 2.10(i),} \\ & \Rightarrow & \vdash_{\mathcal{L}} \sum_{i=1}^{n} V_i : \omega \to \omega \quad \text{by Theorem 3.15(i) and rule } (+\mathrm{I}), \\ & \Rightarrow & \vdash_{\mathcal{L}} M : \omega \to \omega \quad \text{by Theorem 3.22(i).} \end{array}$$

□

4. Models and completeness. If we want to devise a domain equation for our concurrent λ-calculus, it is natural to start from the equations in the literature for similar languages.

Abramsky, in [4], interprets the lazy λ-calculus by means of a Scott domain D solving the equation

$$D = [D \to D]_{\perp},$$

where $[D \to D]$ is the space of continuous functions and $(\cdot)_{\perp}$ is the lifting operator.

Boudol in [19] gives the semantics of the lazy, call-by-name and call-by-value λ-calculus enriched with a parallel operator using the same equation, but in a different category. It is easy to see from the asynchronous reduction rules of Boudol's parallel operator (shown on p. 1379) that in a "may" perspective $\|$ can be interpreted using the lower powerdomain. Boudol recalls that each prime algebraic lattice D is isomorphic to the lower powerdomain of the posets of the compact coprime elements of D. Therefore it suffices to find a solution of Abramsky's equation in this category to have a domain suitable for Boudol's language. Notice that Boudol interprets $M\|N$ as the join of the interpretations of M and N.

The reduction rules of the present parallel operator differ from those given in [19]. Really, our $\|$ is synchronous. But we are in a different situation: we consider "must" convergence instead of "may" convergence. Therefore, our parallel operator behaves exactly like Boudol's from the viewpoint of convergence. In fact, both operators converge whenever one of the two arguments does. This is clear when we think of the correspondence between asynchronicity in a "may" perspective and synchronicity in a "must" perspective. So we could have used Abramsky's domain equation again, if we would not have to also interpret the nondeterministic choice.

The reduction rules of $+$ in a "must" perspective clearly suggest the upper powerdomain for its interpretation. The whole discussion leads to the following domain equation:

$$D = \mathcal{P}^{\sharp}([D \to D]_{\perp}),$$

where $\mathcal{P}^{\sharp}$ is the upper powerdomain functor, in the category of prime algebraic lattices.

It is well known that each prime algebraic lattice can be described by an information system [42] and also by means of intersection types [22]. Really, we have

developed in previous sections a system of intersection and union types; we will use this system now to build a model, which is actually the initial solution of our domain equation.

Because of rules $(\omega), (\leq)$, and $(\wedge\ \mathrm{I})$, the set of types assigned in $\mathcal{L}$ to any term is a filter over $Type$: let $\mathcal{F}$ be the set of all filters. $\mathcal{F}$ is a distributive lattice under subset ordering (distributivity comes as a consequence of the distributivity of $Type$ itself), with intersection as meet and

$$F \bar{\cup} F' = \uparrow \{\sigma \wedge \tau \mid \sigma \in F, \tau \in F'\}$$

as join ($\uparrow$ stands as usual for upper closure). The bottom and the top of this lattice are, respectively, $\uparrow \omega$ and $Type$, where in general $\uparrow \sigma$ is the principal filter generated by σ. The compact elements are the principal filters. Moreover, this lattice is prime algebraic, since each filter is the join of the compact coprime filters it dominates. Notice that a filter $F \in \mathcal{F}$ is compact *coprime* if and only if it is a principal filter generated by a *meet irreducible* type.[2] We refer to [7] for the whole proof that $\mathcal{F}$ is the initial solution of our domain equation.

Among filters assigned as meanings of terms, Theorem 3.15(ii) indicates that prime filters are the interpretations of terms that are total values. We recall that a filter $F \in \mathcal{F}$ is *prime* if and only if for all σ and τ

$$\sigma \vee \tau \in F \Rightarrow \sigma \in F \text{ or } \tau \in F.$$

We write $\mathcal{F}_P$ to denote the set of prime filters.

In any distributive lattice D the set $\mathrm{Pr}(D)$ of *prime elements* is defined as follows:

$$d \in \mathrm{Pr}(D) \ \Leftrightarrow\ \forall x, y \in D,\ x \sqcap y \sqsubseteq d \Rightarrow x \sqsubseteq d \text{ or } y \sqsubseteq d.$$

We write $\mathrm{Pr}(x) = \uparrow x \cap \mathrm{Pr}(D)$ for $x \in D$. Let us define, for any filter F, the set

$$\mathrm{Pr}(F) = \{P \in \mathcal{F}_P \mid F \subseteq P\},$$

which is called the *prime decomposition* of F. It is straightforward to see that $\mathrm{Pr}(\mathcal{F}) = \mathcal{F}_P$ and consequently that the previous definition of $\mathrm{Pr}(F)$ is consistent with the notation $\mathrm{Pr}(x)$.

From Priestley's theorem we know that the structure of a distributive lattice is recoverable from its prime filters (or dually from its prime ideals). The following fact is at the root of this result (see, e.g., [23, Theorem 10.3]):

(DPI) Let D be a distributive lattice, F a filter, and I an ideal in D such that $F \cap I = \emptyset$. Then there exists a prime filter P and a prime ideal J (actually, J is the complement of P in D) such that $F \subseteq P$, $I \subseteq J$, and $P \cap J = \emptyset$.

The principle (DPI) implies that each filter is completely determined by its prime decomposition.

LEMMA 4.1. $\forall F \in \mathcal{F},\ F = \bigcap_{P \in \mathrm{Pr}(F)} P$.

Proof. The left to right inclusion is immediate. To see the inverse inclusion let us suppose in contradiction that there exists some $\sigma \in \bigcap_{P \in \mathrm{Pr}(F)} P$ such that $\sigma \notin F$. This implies that $\downarrow \sigma \cap F = \emptyset$, where $\downarrow \sigma$ is the principal ideal generated by σ; it follows by (DPI) that for some $P \in \mathcal{F}_P$ we have $F \subseteq P$ and $\downarrow \sigma \cap P = \emptyset$. □

The last lemma is an instance of a more general fact: let D be a lattice; then $X \subseteq D$ is *order generating* if and only if for all $x \in D$, $x = \sqcap(\uparrow x \cap X)$ (see [30, Ch. 1,

[2] A type σ is *meet irreducible* or *prime* if and only if $\tau \wedge \rho \leq \sigma \Rightarrow \tau \leq \sigma$ or $\rho \leq \sigma$ for any τ, ρ.

Definition 3.8]). If D is continuous (i.e., complete and each element is the sup of its way below elements) then it is distributive if and only if $\mathrm{Pr}(D)$ is order generating (see [30, Ch. 1, Theorem 3.14]). But $\mathcal{F}$ is a distributive lattice which is prime algebraic, so it is a fortiori continuous. Therefore, $\mathcal{F}_P$ is order generating.

To interpret functional application we turn $\mathcal{F}$ into an applicative structure as follows:

$$F \cdot F' = \{\tau \mid \exists \sigma \in F',\ \sigma \to \tau \in F\} \ \cup \{\uparrow \omega\}.$$

Observe that the definition of application is slightly different from that given in [16]. Indeed, we have to add explicitly the principal filter of ω, since in our setting $\omega \neq \omega \to \omega$; otherwise $\uparrow\omega \cdot \uparrow\omega$ would be the empty set.

LEMMA 4.2. *The operation of application over $\mathcal{F}$ is monotonic in both its arguments*; *moreover,*

$$(F \cap F') \cdot G \supseteq (F \cdot G) \cap (F' \cdot G) \quad \textit{and} \quad (F \cup F') \cdot G \subseteq (F \cdot G) \cup (F' \cdot G)$$

for all $F, F', G \in \mathcal{F}$.

The proof is straightforward. Just note that these inclusions are actually equalities, since the opposite inclusions follow from the monotonicity of the application.

The properties of $\mathcal{F}$ which have been seen so far suggest the following definition.

DEFINITION 4.3. *A* premodel *of $\Lambda_{+\|}$ is a structure $\mathcal{D} = \langle D, \sqsubseteq, \cdot, \sqcap, \sqcup \rangle$ where $\langle D, \sqsubseteq \rangle$ is a distributive continuous lattice and $\cdot$ is a monotonic binary operation on D such that, for all $d, d', e \in D$,*

(i) $(d \sqcap d') \cdot e \sqsupseteq (d \cdot e) \sqcap (d' \cdot e)$,

(ii) $(d \sqcup d') \cdot e \sqsubseteq (d \cdot e) \sqcup (d' \cdot e)$.

Total values are associated by system $\mathcal{L}$ to prime filters different from $\uparrow\omega$. A call-by-value variable is a total value; hence a correct notion of environment for $\mathcal{F}$ is a mapping $\eta : \mathsf{Vn} \cup \mathsf{Vv} \to \mathcal{F}$ such that $\eta(\mathsf{Vv}) \subseteq \mathcal{F}_P - \{\uparrow\omega\}$. In general, given a premodel $\mathcal{D}$, if $\mathcal{P} = \mathrm{Pr}(D) - \{\bot\}$, we define Env_D as the set of mappings $\eta : \mathsf{Vn} \cup \mathsf{Vv} \to D$ such that $\eta(\mathsf{Vv}) \subseteq \mathcal{P}$.

Now, for any environment $\eta \in Env_{\mathcal{F}}$ and for any basis Γ, we define

$$\Gamma \models \eta \ \Leftrightarrow\ \forall \chi \in \mathsf{Vn} \cup \mathsf{Vv},\ \Gamma(\chi) \in \eta(\chi).$$

We are now set to define the map $[\![\cdot]\!]^{\mathcal{F}} : \Lambda_{+\|} \to Env_{\mathcal{F}} \to \mathcal{F}$ as follows:

$$[\![M]\!]^{\mathcal{F}}_{\eta} = \{\sigma \mid \exists \Gamma,\ \Gamma \models \eta \ \&\ \Gamma \vdash_{\mathcal{L}} M : \sigma\}.$$

This definition is consistent with the logical inclusion, which is equivalent to subset inclusion of interpretations.

PROPOSITION 4.4. *For all $M, N \in \Lambda_{+\|}$,*

$$M \sqsubseteq^{\mathcal{L}} N \ \Leftrightarrow\ \forall \eta,\ [\![M]\!]^{\mathcal{F}}_{\eta} \subseteq [\![N]\!]^{\mathcal{F}}_{\eta}\ .$$

Proof. ($\Rightarrow$) The proof is immediate. ($\Leftarrow$) Let us define, for any basis Γ, $\eta_\Gamma(\chi) = \uparrow \Gamma(\chi)$ for all variables χ; then $\eta_\Gamma \in Env_{\mathcal{F}}$ since $\Gamma(v)$ is coprime for all call-by-value variables v, and hence $\uparrow\Gamma(v)$ is a prime filter. Now $\Gamma \models \eta_\Gamma$ so that $\Gamma \vdash_{\mathcal{L}} M : \sigma$ implies $\sigma \in [\![M]\!]^{\mathcal{F}}_{\eta_\Gamma}$. By hypothesis, $\sigma \in [\![N]\!]^{\mathcal{F}}_{\eta_\Gamma}$, hence $\Gamma' \vdash_{\mathcal{L}} N : \sigma$ for some Γ' such that $\Gamma' \models \eta_\Gamma$. We conclude that $\Gamma \vdash_{\mathcal{L}} N : \sigma$ since $\Gamma' \models \eta_\Gamma$ implies $\Gamma \leq \Gamma'$. □

COROLLARY 4.5. *For all* $M, N \in \Lambda_{+\|}$ *and* $\eta \in Env_{\mathcal{F}}$

$$[\![M+N]\!]^{\mathcal{F}}_{\eta} = [\![M]\!]^{\mathcal{F}}_{\eta} \cap [\![N]\!]^{\mathcal{F}}_{\eta} \quad \textit{and} \quad [\![M\|N]\!]^{\mathcal{F}}_{\eta} = [\![M]\!]^{\mathcal{F}}_{\eta} \cup [\![N]\!]^{\mathcal{F}}_{\eta} \ .$$

Proof. The proof is immediate from Proposition 4.4 and from Lemmas 3.20(i), (ii) and 3.21(i), (ii). □

Elaborating on the definition of λ-model, and also on the notion of λ-lattice proposed in [25], we fix the following.

DEFINITION 4.6. *The structure* $\langle \mathcal{D}, [\![\cdot]\!]^{\mathcal{D}} \rangle$ *is a* model *if* $\mathcal{D} = \langle D, \sqsubseteq, \cdot, \sqcap, \sqcup \rangle$ *is a premodel and* $[\![\cdot]\!]^{\mathcal{D}} : \Lambda_{+\|} \to Env_D \to D$ *satisfies the following conditions:*

(i) $[\![\chi]\!]^{\mathcal{D}}_{\eta} = \eta(\chi)$;
(ii) $[\![MN]\!]^{\mathcal{D}}_{\eta} = [\![M]\!]^{\mathcal{D}}_{\eta} \cdot [\![N]\!]^{\mathcal{D}}_{\eta}$;
(iii) $[\![\lambda x.M]\!]^{\mathcal{D}}_{\eta} \cdot d = [\![M]\!]^{\mathcal{D}}_{\eta[x \mapsto d]}$;
(iv) $[\![\lambda v.M]\!]^{\mathcal{D}}_{\eta} \cdot d = \begin{cases} \bot & \textit{if } d = \bot, \\ \sqcap_{e \in \mathrm{Pr}(d)} [\![M]\!]^{\mathcal{D}}_{\eta[v \mapsto e]} & \textit{otherwise}; \end{cases}$
(v) $(\forall \chi \in \mathrm{FV}(M),\ \eta(\chi) = \eta'(\chi)) \Rightarrow [\![M]\!]^{\mathcal{D}}_{\eta} = [\![M]\!]^{\mathcal{D}}_{\eta'}$;
(vi) $[\![\lambda \chi.M]\!]^{\mathcal{D}}_{\eta} = [\![\lambda \chi'.M[\chi'/\chi]]\!]^{\mathcal{D}}_{\eta}$ *if* $\chi' \notin \mathrm{FV}(M)$ *and either* $\chi, \chi' \in \mathsf{Vn}$ *or* $\chi, \chi' \in \mathsf{Vv}$;
(vii) $(\forall d \in D,\ [\![M]\!]^{\mathcal{D}}_{\eta[x \mapsto d]} = [\![N]\!]^{\mathcal{D}}_{\eta[x \mapsto d]}) \Rightarrow [\![\lambda x.M]\!]^{\mathcal{D}}_{\eta} = [\![\lambda x.N]\!]^{\mathcal{D}}_{\eta}$;
(viii) $(\forall e \in \mathcal{P},\ [\![M]\!]^{\mathcal{D}}_{\eta[v \mapsto e]} = [\![N]\!]^{\mathcal{D}}_{\eta[v \mapsto e]}) \Rightarrow [\![\lambda v.M]\!]^{\mathcal{D}}_{\eta} = [\![\lambda v.N]\!]^{\mathcal{D}}_{\eta}$;
(ix) $[\![M+N]\!]^{\mathcal{D}}_{\eta} = [\![M]\!]^{\mathcal{D}}_{\eta} \sqcap [\![N]\!]^{\mathcal{D}}_{\eta}$;
(x) $[\![M\|N]\!]^{\mathcal{D}}_{\eta} = [\![M]\!]^{\mathcal{D}}_{\eta} \sqcup [\![N]\!]^{\mathcal{D}}_{\eta}$;
(xi) $W \in \mathsf{TVal} \Rightarrow [\![W]\!]^{\mathcal{D}}_{\eta} \in \mathcal{P}$,

where $\mathcal{P} = \mathrm{Pr}(D) - \{\bot\}$.

With respect to the classical definition of (syntactical) λ-models, the novelties are in clauses (iv) and (viii)–(x). Clause (xi) reflects the intended meaning of total values, which essentially are not sums. Clause (viii) takes into account that by definition, $\eta(\mathsf{Vv}) \subseteq \mathcal{P}$. The last two clauses are suggested by Corollary 4.5. Clause (iv) is more demanding; indeed, from Corollary 3.14 and Proposition 4.4 we can argue that a call-by-value abstraction defines a co-additive function, but this does not suffice to show that it is completely co-additive (i.e., preserving arbitrary meets). This is, however, true in the filter model, and finely fits into the fact that prime elements are order generating in continuous distributive lattices. To show this, or equivalently that the premodel $\mathcal{F}$ can be turned into a model using $[\![\cdot]\!]^{\mathcal{F}}$, we need a couple of lemmas.

LEMMA 4.7. *For all* $M, N \in \Lambda_{+\|}$ *and* $\eta \in Env_{\mathcal{F}}$,

$$[\![MN]\!]^{\mathcal{F}}_{\eta} = [\![M]\!]^{\mathcal{F}}_{\eta} \cdot [\![N]\!]^{\mathcal{F}}_{\eta}.$$

Proof. To prove $[\![MN]\!]^{\mathcal{F}}_{\eta} \subseteq [\![M]\!]^{\mathcal{F}}_{\eta} \cdot [\![N]\!]^{\mathcal{F}}_{\eta}$, let $\sigma \in [\![MN]\!]^{\mathcal{F}}_{\eta}$ and $\sigma \neq \omega$; then for some basis Γ we have $\Gamma \models \eta$ and $\Gamma \vdash_{\mathcal{L}} MN : \sigma$. By Theorem 3.13(vi), there exists some τ such that

$$\Gamma \vdash_{\mathcal{L}} M : \tau \to \sigma \ \&\ \Gamma \vdash_{\mathcal{L}} N : \tau.$$

It follows that $\tau \to \sigma \in [\![M]\!]^{\mathcal{F}}_{\eta}$ and $\tau \in [\![N]\!]^{\mathcal{F}}_{\eta}$, so the thesis follows.

To see that $[\![M]\!]^{\mathcal{F}}_\eta \cdot [\![N]\!]^{\mathcal{F}}_\eta \subseteq [\![MN]\!]^{\mathcal{F}}_\eta$ we reason as in [16]; namely, if for some $\tau \in [\![N]\!]^{\mathcal{F}}_\eta$ it is the case that $\tau \to \sigma \in [\![M]\!]^{\mathcal{F}}_\eta$, then there are two bases, Γ_0, Γ_1, such that $\Gamma_i \models \eta$ for $i = 0, 1$, and

$$\Gamma_0 \vdash_{\mathcal{L}} N : \tau \ \&\ \Gamma_1 \vdash_{\mathcal{L}} M : \tau \to \sigma.$$

Now, taking Γ_2 such that $\Gamma_2(\chi) = \Gamma_0(\chi) \wedge \Gamma_1(\chi)$ for all χ, it is easy to see that

$$\Gamma_2 \models \eta \ \&\ \Gamma_2 \vdash_{\mathcal{L}} N : \tau \ \&\ \Gamma_2 \vdash_{\mathcal{L}} M : \tau \to \sigma,$$

from which we get $\Gamma_2 \vdash_{\mathcal{L}} MN : \sigma$; that is, $\sigma \in [\![MN]\!]^{\mathcal{F}}_\eta$. □

LEMMA 4.8. *Let $\Sigma = \{\sigma_i\}_{i\in\mathbb{N}}$ be a chain such that for all i, $\sigma_i \leq \sigma_{i+1}$, and let $F \in \mathcal{F}$. Then*

$$\forall P \in \mathrm{Pr}(F),\ P \cap \Sigma \neq \emptyset \Rightarrow F \cap \Sigma \neq \emptyset.$$

Proof. Let I be the downward closure of Σ; then

$$\begin{array}{rcl} \rho_0, \rho_1 \in I & \Rightarrow & \exists \sigma_i, \sigma_j \in \Sigma,\ \rho_0 \leq \sigma_i \ \&\ \rho_1 \leq \sigma_j \\ & \Rightarrow & \exists \sigma_i, \sigma_j \in \Sigma,\ \rho_0 \vee \rho_1 \leq \sigma_i \vee \sigma_j = \sigma_{\max\{i,j\}} \in \Sigma \\ & \Rightarrow & \rho_0 \vee \rho_1 \in I, \end{array}$$

so I is an ideal. If $F \cap \Sigma = \emptyset$, then $F \cap I = \emptyset$, F being an upward closed set. By (DPI) there exists $P \in \mathrm{Pr}(F)$ such that $P \cap I = \emptyset$ and consequently $P \cap \Sigma = \emptyset$, so that the thesis follows by contraposition. □

THEOREM 4.9. *The structure $\langle \langle \mathcal{F}, \subseteq, \cdot, \cap, \bar{\cup} \rangle, [\![\cdot]\!]^{\mathcal{F}} \rangle$ is a model.*

Proof. Because of Proposition 4.4 and Lemmas 3.18, 3.20, 3.21, and 4.7 the only relevant remaining point is to show that $\mathcal{F}$ satisfies clause (iv) of Definition 4.6. Recall that the bottom in $\mathcal{F}$ is $\uparrow\omega$; then this amounts to showing that

$$[\![\lambda v.M]\!]^{\mathcal{F}}_\eta \cdot F = \begin{cases} \uparrow\omega & \text{if } F \equiv \uparrow\omega, \\ \bigcap_{P\in\mathrm{Pr}(F)} [\![M]\!]^{\mathcal{F}}_{\eta[v\mapsto P]} & \text{otherwise.} \end{cases}$$

Now, if $F \equiv \uparrow\omega$, then

$$\begin{array}{rcll} \sigma \in [\![\lambda v.M]\!]^{\mathcal{F}}_\eta \cdot \uparrow\omega & \Leftrightarrow & \omega \to \sigma \in [\![\lambda v.M]\!]^{\mathcal{F}}_\eta & \\ & \Leftrightarrow & \exists \Gamma \models \eta,\ \Gamma \vdash_{\mathcal{L}} \lambda v.M : \omega \to \sigma & \\ & \Rightarrow & \sigma = \omega & \text{by Theorem 3.13(v).} \end{array}$$

If $F \not\equiv \uparrow\omega$, let us suppose that $\sigma \neq \omega$ (otherwise the thesis is trivial). Then

$$\begin{array}{rcl} \sigma \in [\![\lambda v.M]\!]^{\mathcal{F}}_\eta \cdot F & \Leftrightarrow & \exists \tau \in F,\ \tau \to \sigma \in [\![\lambda v.M]\!]^{\mathcal{F}}_\eta \\ & \Leftrightarrow & \exists \tau \in F,\ \exists \Gamma \models \eta,\ \Gamma \vdash_{\mathcal{L}} \lambda v.M : \tau \to \sigma \\ & \Leftrightarrow & \exists \tau \in F,\ \exists \Gamma \models \eta,\ \forall \tau' \in \Theta(\tau),\ \Gamma, v : \tau' \vdash_{\mathcal{L}} M : \sigma \\ & & \text{by Theorem 3.13(iv), since } \sigma \neq \omega \Rightarrow \tau \neq \omega \\ & & \text{by Theorem 3.13(v).} \end{array}$$

Now $F = \bigcap_{P\in\mathrm{Pr}(F)} P$ implies that, for all $P \in \mathrm{Pr}(F)$, $\tau \in P$, and hence $\tau' \in P$ for some $\tau' \in \Theta(\tau)$ by definition of prime filter (notice that τ' depends on P). This implies $\Gamma, v : \tau' \models \eta[v \mapsto P]$ for some $\tau' \in \Theta(\tau)$, so that $\sigma \in [\![M]\!]^{\mathcal{F}}_{\eta[v\mapsto P]}$. It follows that

$$[\![\lambda v.M]\!]^{\mathcal{F}}_\eta \cdot F \subseteq \bigcap_{P\in\mathrm{Pr}(F)} [\![M]\!]^{\mathcal{F}}_{\eta[v\mapsto P]}.$$

To see the opposite inclusion, let $G = [\![\lambda v.M]\!]^{\mathcal{F}}_{\eta}$; we first show that, if $P \in \mathcal{F}_P$ and $P \neq \uparrow \omega$, then $G \cdot P = [\![M]\!]_{\eta[v \mapsto P]}$. Indeed, let $w \in \mathsf{Vv} - FV(M)$ and $\eta \in Env_{\mathcal{F}}$ be such that $\eta(w) = P$; then, by Lemmas 4.7 and 3.18(iii), we have

$$G \cdot P = [\![\lambda v.M]\!]^{\mathcal{F}}_{\eta} \cdot [\![w]\!]^{\mathcal{F}}_{\eta} = [\![(\lambda v.M)w]\!]^{\mathcal{F}}_{\eta} = [\![M[w/v]]\!]^{\mathcal{F}}_{\eta} = [\![M]\!]^{\mathcal{F}}_{\eta[v \mapsto P]}.$$

From $F \neq \uparrow \omega$ it follows that $\uparrow \omega \notin \mathrm{Pr}(F)$, so that the equality above implies

$$\bigcap_{P \in \mathrm{Pr}(F)} G \cdot P \;=\; \bigcap_{P \in \mathrm{Pr}(F)} [\![M]\!]^{\mathcal{F}}_{\eta[v \mapsto P]}.$$

Suppose that $\sigma \in \bigcap_{P \in \mathrm{Pr}(F)} G \cdot P$. Let us define

$$\Pi = \{\pi \in Type \mid \exists P \in \mathrm{Pr}(F),\ \pi \in P \ \&\ \pi \to \sigma \in G\}.$$

This set is nonempty by hypothesis and it is countable, being a subset of the denumerable set $Type$. Let us suppose that an enumeration of Π has been fixed; then we put

$$\Sigma = \{\tau_n\}_{n \in \mathbb{N}} \quad \text{where} \quad \tau_n = \bigvee_{i=0}^{n} \pi_i.$$

By construction, Σ is a chain such that, $\forall P \in \mathrm{Pr}(F),\ P \cap \Sigma \neq \emptyset$, so that by Lemma 4.8, there exists an m such that $\tau_m \in F$. Since G is the interpretation of a call-by-value abstraction, a simple induction using Corollary 3.14 shows that $\tau_n \to \sigma \in G$ for all n: we conclude that $\sigma \in G \cdot F$. □

So far, terms have been interpreted as collections of their properties, namely, of their types. We now provide an interpretation of types as subsets of the domains of models. The domains have an order whose meaning is "to be better behaved" and more defined. We do not want more defined objects to have fewer properties than their minors, hence the subsets interpreting types have to be upward closed; more precisely, they will be filters of the domain itself.

DEFINITION 4.10. *Let $\mathcal{D} = \langle D, \sqsubseteq, \cdot, \sqcap, \sqcup \rangle$ be a premodel, and define for $X, Y \subseteq D$:*

$$X \Rightarrow Y = \{d \in D \mid d \neq \bot \ \&\ \forall e \in X,\ d \cdot e \in Y\},$$
$$X \bar{\cup} Y = \uparrow \{d \sqcap d' \mid d \in X, d' \in Y\},$$

where we overload $\bar{\cup}$. Then a type structure *over $\mathcal{D}$ is a sublattice $\mathcal{T}$ of the lattice of filters over $\mathcal{D}$, such that $D \in \mathcal{T}$ and $\mathcal{T}$ is closed under $\Rightarrow, \cap$, and $\bar{\cup}$.*
The map $[\![\cdot]\!]^{\mathcal{T}} : Type \to \mathcal{T}$ is inductively defined as follows:

(i) $[\![\omega]\!]^{\mathcal{T}} = D$;
(ii) $[\![\sigma \to \tau]\!]^{\mathcal{T}} = [\![\sigma]\!]^{\mathcal{T}} \Rightarrow [\![\tau]\!]^{\mathcal{T}}$;
(iii) $[\![\sigma \wedge \tau]\!]^{\mathcal{T}} = [\![\sigma]\!]^{\mathcal{T}} \cap [\![\tau]\!]^{\mathcal{T}}$;
(iv) $[\![\sigma \vee \tau]\!]^{\mathcal{T}} = [\![\sigma]\!]^{\mathcal{T}} \bar{\cup} [\![\tau]\!]^{\mathcal{T}}$.

Finally, given a model $\langle \mathcal{D}, [\![\cdot]\!]^{\mathcal{D}} \rangle$, we define

(v) $\Gamma \models_{\mathcal{D}} M : \sigma \ \Leftrightarrow\ (\forall \eta \in Env_D,\ \Gamma \models \eta \Rightarrow [\![M]\!]^{\mathcal{D}}_{\eta} \in [\![\sigma]\!]^{\mathcal{T}})$;
(vi) $\Gamma \models M : \sigma \ \Leftrightarrow\ \forall \mathcal{D},\ \Gamma \models_{\mathcal{D}} M : \sigma$.

In the definition of $X \Rightarrow Y$ we make the condition $d \neq \bot$ since we are modeling a lazy calculus; this means that the bottom cannot be interpreted as a function. Consequently we exclude $\bot$ from $X \Rightarrow Y$, whose intended meaning is the set of

representatives of functions which, when restricted to X, have ranges included in Y. Observe that $X \Rightarrow Y$ is a filter in D if both X and Y are.

We end this section by stating and proving a completeness theorem.

THEOREM 4.11 (completeness).

$$\Gamma \vdash_{\mathcal{L}} M : \sigma \;\Leftrightarrow\; \Gamma \models M : \sigma.$$

Proof. ($\Rightarrow$) The proof is by induction on derivations in $\mathcal{L}$.

($\Leftarrow$) First define $X_\sigma = \{F \in \mathcal{F} \mid \sigma \in F\}$ as usual, so that it is easily checked that $\mathcal{T} = \{X_\sigma\}_{\sigma \in Type}$ is a type structure over $\mathcal{F}$. More precisely, $X_\omega = \mathcal{F}$, $X_{\sigma\to\tau} = X_\sigma \Rightarrow X_\tau$, $X_{\sigma\wedge\tau} = X_\sigma \cap X_\tau$, and $X_{\sigma\vee\tau} = X_\sigma \bar{\cup} X_\tau$. This implies, by a simple induction on types, that $[\![\sigma]\!]^{\mathcal{T}} = X_\sigma$. Suppose $\Gamma \models M : \sigma$; hence, in particular, $\Gamma \models_{\mathcal{F}} M : \sigma$, since by Theorem 4.9, $\mathcal{F}$ is a model. Put $\eta_\Gamma(\chi) = \uparrow \Gamma(\chi)$. Now $\Gamma \models \eta_\Gamma$ implies $[\![M]\!]^{\mathcal{F}}_{\eta_\Gamma} \in X_\sigma$, that is, $\sigma \in [\![M]\!]^{\mathcal{F}}_{\eta_\Gamma}$. It follows that, for some Γ' such that $\Gamma' \models \eta_\Gamma$, we have $\Gamma' \vdash_{\mathcal{L}} M : \sigma$. We conclude that $\Gamma \vdash_{\mathcal{L}} M : \sigma$ since $\Gamma' \models \eta_\Gamma$ implies $\Gamma \leq \Gamma'$. □

5. Full abstraction. In this section we will prove that the filter model exactly mirrors the operational semantics; i.e., it is fully abstract. This means that

- the filter model is adequate; that is, it does not equate operationally distinct programs

$$M \sqsubseteq^{\mathcal{L}} N \Rightarrow M \sqsubseteq^{\mathcal{O}} N\ ;$$

- the filter model reflects the operational distinctions

$$M \sqsubseteq^{\mathcal{O}} N \Rightarrow M \sqsubseteq^{\mathcal{L}} N.$$

The key property on which the proof of full abstraction relies is that any compact element of $\mathcal{F}$, which is of the shape $\uparrow\sigma$, is λ-definable, since for all types σ there exists a characteristic (closed) term R_σ such that

$$\vdash_{\mathcal{L}} \mathsf{R}_\sigma : \tau \quad\Leftrightarrow\quad \sigma \leq \tau;$$

that is, $[\![\mathsf{R}_\sigma]\!]^{\mathcal{F}} = \uparrow\sigma$.

Such terms are constructed inductively together with test terms. To each type σ we associate a test term T_σ such that for all closed terms M:

$$\mathsf{T}_\sigma M{\Downarrow} \;\Leftrightarrow\; \vdash_{\mathcal{L}} M : \sigma.$$

The definition of characteristic and test terms finely reflects the duality between $\|$ and $+$, as well as their correspondence with $\wedge$ and $\vee$, respectively.

A further step in the full abstraction proof consists in giving a "realizability interpretation" of types as sets of closed terms. This is sound since each type is inhabited by some closed term (at least its characteristic term).

The main result we obtain is the converse of Theorem 3.23, namely,

$$(*) \qquad \vdash_{\mathcal{L}} M : \omega \to \omega \Rightarrow M{\Downarrow}$$

for all closed terms M.

The full abstraction theorem then follows. Indeed, adequacy is a consequence of $(*)$ and of the fact that $\simeq^{\mathcal{L}}$ is a congruence. For the converse it suffices to observe that test terms discriminate internally, that is, with respect to the convergence predicate, terms having different interpretations in the filter model.

5.1. Characteristic terms. We define two families of terms $\{\mathsf{R}_\sigma\}_{\sigma\in Type}$ and $\{\mathsf{T}_\sigma\}_{\sigma\in Type}$ starting from Ω . We can safely replace Ω by any unsolvable term of degree 0.

DEFINITION 5.1. *The* characteristic terms R_σ *and the* test terms T_σ *are defined by simultaneous induction on* σ*:*

$$\begin{array}{ll}
\mathsf{R}_\omega \equiv \Omega, & \mathsf{T}_\omega \equiv \lambda xy.y,\\
\mathsf{R}_{\sigma\to\tau} \equiv \lambda x.(\mathsf{T}_\sigma x)\,\mathsf{R}_\tau, & \mathsf{T}_{\sigma\to\tau} \equiv \lambda v.\mathsf{T}_\tau(v\,\mathsf{R}_\sigma),\\
\mathsf{R}_{\sigma\wedge\tau} \equiv \mathsf{R}_\sigma \| \mathsf{R}_\tau, & \mathsf{T}_{\sigma\wedge\tau} \equiv \lambda x.(\mathsf{T}_\sigma\, x + \mathsf{T}_\tau\, x),\\
\mathsf{R}_{\sigma\vee\tau} \equiv \mathsf{R}_\sigma + \mathsf{R}_\tau, & \mathsf{T}_{\sigma\vee\tau} \equiv \lambda v.(\mathsf{T}_\sigma\, v \,\|\, \mathsf{T}_\tau\, v) \text{ where } \sigma\vee\tau \neq \omega.
\end{array}$$

Notice the different use of call-by-value variables in the definitions of $\mathsf{T}_{\sigma\to\tau}$ and $\mathsf{T}_{\sigma\vee\tau}$: $\mathsf{T}_{\sigma\to\tau}$ must check that its argument has type $\sigma\to\tau$ which, by $(*)$ above, implies that it has to be convergent. On the other hand, the argument of $\mathsf{T}_{\sigma\vee\tau}$ may reduce to a sum $P+Q$ having type $\sigma\vee\tau$ because P has type σ and Q has type τ but neither σ nor τ can be deduced for $P+Q$. Therefore, it is essential that it is evaluated before the application in parallel of T_σ and T_τ.

The types which can be deduced for R_σ and T_σ are meaningful for their operational behavior. In fact,

- R_σ has exactly the types greater than or equal to σ;
- T_σ has type $\tau\to\rho\to\rho$ only if $\tau\le\sigma$.

This means that R_σ is "the worst" term of type σ and that $\mathsf{T}_\sigma M$ reduces to a value if and only if we can deduce the type σ for M (and this value behaves like the identity combinator).

LEMMA 5.2.

(i) $\vdash_{\mathcal{L}} \mathsf{R}_\sigma : \tau \;\Leftrightarrow\; \sigma\le\tau$;
(ii) $\vdash_{\mathcal{L}} \mathsf{T}_\sigma : \tau\to\gamma\to\delta \;\Leftrightarrow\; \tau\le\sigma \;\&\; \gamma\le\delta$.

Proof. We prove (i) and (ii) simultaneously by induction on σ. We consider only the interesting cases.

$\sigma\equiv\mu\to\nu$:

(i) $\mathsf{R}_{\mu\to\nu} \equiv \lambda x.(\mathsf{T}_\mu x)\,\mathsf{R}_\nu$ and assume $\vdash_{\mathcal{L}} \mathsf{R}_{\mu\to\nu} : \tau$. Then we proceed by a subordinate induction on the structure of τ, the base case being $\tau\equiv\alpha\to\beta$ since $\mathsf{R}_{\mu\to\nu}$ is an abstraction (see Theorem 3.13(ii)). Now, by Theorem 3.13(iii) and (vi), we have $x:\alpha\vdash_{\mathcal{L}} \mathsf{T}_\mu : \gamma\to\delta\to\beta$, $x:\alpha\vdash_{\mathcal{L}} x:\gamma$, and $x:\alpha\vdash_{\mathcal{L}} \mathsf{R}_\nu:\delta$ for some γ and δ. By induction and Theorem 3.13(i) this implies $\gamma\le\mu$, $\delta\le\beta$, $\alpha\le\gamma$, and $\nu\le\delta$; that is, $\alpha\le\mu$ and $\nu\le\beta$. We conclude that $\mu\to\nu\le\alpha\to\beta$.
When $\tau\equiv\alpha\vee\beta$ the thesis follows from the subordinate induction hypothesis. In fact, Theorem 3.15(ii) implies that $\vdash_{\mathcal{L}} \mathsf{R}_{\mu\to\nu}:\alpha$ or $\vdash_{\mathcal{L}} \mathsf{R}_{\mu\to\nu}:\beta$, $\mathsf{R}_{\mu\to\nu}$ being a total value.
The case $\tau\equiv\alpha\wedge\beta$ follows immediately from the subordinate induction hypothesis.

(ii) $\mathsf{T}_{\mu\to\nu}\equiv\lambda v.\mathsf{T}_\nu(v\mathsf{R}_\mu)$ and suppose that $\vdash_{\mathcal{L}} \mathsf{T}_{\mu\to\nu}:\tau\to\gamma\to\delta$. Then we have

$$\begin{array}{ll} & \forall \tau' \in \Theta(\tau),\ v : \tau' \vdash_{\mathcal{L}} \mathsf{T}_\nu(v\mathsf{R}_\mu) : \gamma \to \delta \quad \text{by Theorem 3.13(iv),} \\ \Rightarrow & \forall \tau' \in \Theta(\tau)\ \exists \alpha,\ v : \tau' \vdash_{\mathcal{L}} \mathsf{T}_\nu : \alpha \to \gamma \to \delta\ \&\ v : \tau' \vdash_{\mathcal{L}} v\mathsf{R}_\mu : \alpha \\ & \qquad \text{by Theorem 3.13(vi),} \\ \Rightarrow & \forall \tau' \in \Theta(\tau)\ \exists \alpha,\ \alpha \le \nu\ \&\ \gamma \le \delta\ \&\ \tau' \le \mu \to \alpha \\ & \qquad \text{by induction and Theorem 3.13(i), (vi),} \\ \Rightarrow & \forall \tau' \in \Theta(\tau),\ \tau' \le \mu \to \nu\ \&\ \gamma \le \delta, \\ \Rightarrow & \tau \le \mu \to \nu\ \&\ \gamma \le \delta. \end{array}$$

$\sigma \equiv \mu \vee \nu$:

(ii) $\mathsf{T}_{\mu\vee\nu} \equiv \lambda v.(\mathsf{T}_\mu v \| \mathsf{T}_\nu v)$ and suppose that $\vdash_{\mathcal{L}} \mathsf{T}_{\mu\vee\nu} : \tau \to \gamma \to \delta$. Then we have

$$\begin{array}{ll} & \forall \tau' \in \Theta(\tau),\ v : \tau' \vdash_{\mathcal{L}} (\mathsf{T}_\mu v \| \mathsf{T}_\nu v) : \gamma \to \delta \quad \text{by Theorem 3.13(iv),} \\ \Rightarrow & \forall \tau' \in \Theta(\tau)\ \exists \rho_1, \rho_2,\ v : \tau' \vdash_{\mathcal{L}} \mathsf{T}_\mu v : \rho_1\ \&\ v : \tau' \vdash_{\mathcal{L}} \mathsf{T}_\nu : \rho_2\ \& \\ & \rho_1 \wedge \rho_2 \le \gamma \to \delta \qquad \text{by Theorem 3.13(viii).} \end{array}$$

We assume $\rho_1 \neq \omega$ and $\rho_2 \neq \omega$. $\rho_1 \wedge \rho_2 \le \gamma \to \delta$ implies by Lemma 3.9(i) that there are δ_1, δ_2 such that

$$\delta_1 \wedge \delta_2 = \delta\ \&\ \rho_1 \le \gamma \to \delta_1\ \&\ \rho_2 \le \gamma \to \delta_2.$$

$$\begin{array}{lll} & v : \tau' \vdash_{\mathcal{L}} \mathsf{T}_\mu v : \rho_1, & \\ \Rightarrow & \exists \alpha,\ v : \tau' \vdash_{\mathcal{L}} v : \alpha\ \&\ \vdash_{\mathcal{L}} \mathsf{T}_\mu : \alpha \to \rho_1 & \text{by Theorem 3.13(vi),} \\ \Rightarrow & \vdash_{\mathcal{L}} \mathsf{T}_\mu : \tau' \to \rho_1 & \text{by Theorem 3.13(i)} \\ & & \text{and rule}(\le), \\ \Rightarrow & \vdash_{\mathcal{L}} \mathsf{T}_\mu : \tau' \to \gamma \to \delta_1 & \text{by above and rule } (\le), \\ \Rightarrow & \tau' \le \mu\ \&\ \gamma \le \delta_1 & \text{by induction.} \end{array}$$

Analogously, from $v : \tau' \vdash_{\mathcal{L}} \mathsf{T}_\nu v : \rho_2$ we deduce $\tau' \le \nu$ and $\gamma \le \delta_2$. So we can conclude $\tau \le \mu \vee \nu$ and $\gamma \le \delta_1 \wedge \delta_2$.
The case in which one of ρ_i $(i = 1, 2)$ is equal to ω is similar and simpler. In fact, if $\rho_2 = \omega$ we have $\rho_1 \le \gamma \to \delta$. This allows us to prove $\tau' \le \mu$ and $\gamma \le \delta$ from $v : \tau' \vdash_{\mathcal{L}} \mathsf{T}_\mu v : \rho_1$. So we can conclude once more that $\tau \le \mu \vee \nu$ and $\gamma \le \delta$. □

5.2. Realizability. The aim of this subsection is to prove that

$$\vdash_{\mathcal{L}} M : \omega \to \omega\ \Rightarrow\ M\Downarrow$$

for all closed terms M. As an immediate consequence we have that only types equivalent to ω can be derived for divergent terms.

The proof of this fact requires a double induction, on types and deductions. Following a standard methodology, we split this induction by introducing a "realizability interpretation" of types as sets of closed terms.

DEFINITION 5.3. *We define the mapping* $[\![\cdot]\!] : \mathit{Type} \to \mathcal{P}(\Lambda^0_{+\|})$ *by induction.*

(i) (a) $[\![\omega]\!] = \Lambda^0_{+\|}$;
(b) $[\![\sigma \to \tau]\!] = \{M \in \Lambda^0_{+\|} \mid M\Downarrow\ \&\ \forall N \in [\![\sigma]\!] \Rightarrow MN \in [\![\tau]\!]\}$;
(c) $[\![\sigma \wedge \tau]\!] = \{M \in \Lambda^0_{+\|} \mid M \in [\![\sigma]\!]$ *and* $M \in [\![\tau]\!]\}$;
(d) $[\![\sigma \vee \tau]\!] = \{M \in \Lambda^0_{+\|} \mid M \in [\![\sigma]\!]$ *or* $M \in [\![\tau]\!]$ *or* $\exists N \in [\![\sigma]\!], L \in [\![\tau]\!],\ M \bowtie N + L\}$.

(ii) *If M is open, let $FV(M) = \{x_1, \ldots, x_m, v_1, \ldots, v_n\}$, and $\Gamma(x_i) = \mu_i$ $(1 \leq i \leq m)$, $\Gamma(v_j) = \nu_j$ $(1 \leq j \leq n)$; then*

$$\Gamma \models^r M : \sigma \Leftrightarrow M[N_1/x_1, \ldots, N_m/x_m, L_1/v_1, \ldots, L_n/v_n] \in [\![\sigma]\!]$$

for all $N_i \in [\![\mu_i]\!]$ and $L_j \in [\![\nu_j]\!]$ $(1 \leq i \leq m$ and $1 \leq j \leq n)$.

The correctness of this definition is due to the fact that all types are inhabited by some closed term; in fact, Theorem 5.5 will imply that $\models^r \mathsf{R}_\sigma : \sigma$ for all types σ.

The following lemma states some key properties of our realizability interpretation.

LEMMA 5.4. *Let $M, N, W \in \Lambda^0_{+\|}$. Then*

(i) $M \in [\![\sigma]\!]$ & $M \bowtie N \Rightarrow N \in [\![\sigma]\!]$;
(ii) $M \in [\![\sigma]\!] \Rightarrow M\|N \in [\![\sigma]\!]$;
(iii) $M \in [\![\sigma]\!]$ & $N \in [\![\sigma]\!] \Leftrightarrow M + N \in [\![\sigma]\!]$;
(iv) $W \in [\![\sigma \vee \tau]\!]$ & $W \in \mathsf{TVal} \Rightarrow W \in [\![\sigma]\!]$ *or* $W \in [\![\tau]\!]$;
(v) $M \in [\![\sigma]\!]$ & $\sigma \leq \tau \Rightarrow M \in [\![\tau]\!]$;
(vi) $M \in [\![\sigma]\!]$ & $\sigma \neq \omega \Rightarrow M{\Downarrow}$.

Proof. We prove points (i)–(iii) of this lemma by induction on σ. The case $\sigma \equiv \omega$ is always trivial. The cases $\sigma \equiv \tau \wedge \rho$ and $\sigma \equiv \tau \vee \rho$ with $M \in [\![\tau]\!] \cup [\![\rho]\!]$ $(N \in [\![\tau]\!] \cup [\![\rho]\!])$ immediately follow from the induction hypothesis. Therefore, the proofs of these cases are omitted.

(i) Case $\sigma \equiv \tau \to \rho$. $M{\Downarrow}$ implies $N{\Downarrow}$ by Theorem 2.12(ii); moreover,

$$\begin{array}{lll} & M \in [\![\sigma]\!] & \\ \Rightarrow & \forall L \in [\![\tau]\!],\ ML \in [\![\rho]\!] & \text{by definition,} \\ \Rightarrow & \forall L \in [\![\tau]\!],\ NL \in [\![\rho]\!] & \text{by induction since } ML \bowtie NL \text{ by Lemma 2.8(i),} \\ \Rightarrow & N \in [\![\sigma]\!] & \text{by definition.} \end{array}$$

Case $\sigma \equiv \tau \vee \rho$ and $M \bowtie P + Q$ for some $P \in [\![\tau]\!]$ and $Q \in [\![\rho]\!]$. Therefore, $N \bowtie P + Q$ and we are done.

(ii) Case $\sigma \equiv \tau \to \rho$. $M{\Downarrow}$ implies $M\|N{\Downarrow}$; moreover,

$$\begin{array}{lll} & M \in [\![\sigma]\!] & \\ \Rightarrow & \forall L \in [\![\tau]\!],\ ML \in [\![\rho]\!] & \text{by definition,} \\ \Rightarrow & \forall L \in [\![\tau]\!], N \in \Lambda^0_{+\|},\ ML\|NL \in [\![\rho]\!] & \text{by induction,} \\ \Rightarrow & \forall L \in [\![\tau]\!], N \in \Lambda^0_{+\|},\ (M\|N)L \in [\![\rho]\!] & \text{by (i) since } (M\|N)L \rhd ML\|NL \\ & & \text{by rule } (\|_{app})', \\ \Rightarrow & \forall N \in \Lambda^0_{+\|}, M\|N \in [\![\sigma]\!] & \text{by definition.} \end{array}$$

Case $\sigma \equiv \tau \vee \rho$ and $M \bowtie P + Q$ for some $P \in [\![\tau]\!]$ and $Q \in [\![\rho]\!]$. $M \bowtie P + Q$ implies $M\|N \bowtie (P+Q)\|N$ by Lemma 2.8(i) and $(P+Q)\|N \rhd P\|N + Q\|N$ by rule $(+\|)'$ for all $N \in \Lambda^0_{+\|}$. By induction, $P\|N \in [\![\tau]\!]$ and $Q\|N \in [\![\rho]\!]$, so we conclude that $M\|N \in [\![\sigma]\!]$ for all $N \in \Lambda^0_{+\|}$.

(iii) $(\Rightarrow)$.
Case $\sigma \equiv \tau \to \rho$.

$$\begin{array}{lll} & M, N \in [\![\sigma]\!] & \\ \Rightarrow & \forall L \in [\![\tau]\!],\ ML, NL \in [\![\rho]\!] & \text{by definition,} \\ \Rightarrow & \forall L \in [\![\tau]\!],\ ML + NL \in [\![\rho]\!] & \text{by induction,} \\ \Rightarrow & \forall L \in [\![\tau]\!],\ (M+N)L \in [\![\rho]\!] & \text{by (i) since } (M+N)L \rhd ML + NL \\ & & \text{by rule } (+_{app})', \\ \Rightarrow & M + N \in [\![\sigma]\!] & \text{by definition.} \end{array}$$

Case $\sigma \equiv \tau \vee \rho$ and $M \bowtie M_0 + M_1$, $N \bowtie N_0 + N_1$ for some $M_0, N_0 \in [\![\tau]\!]$ and $M_1, N_1 \in [\![\rho]\!]$. From the induction hypothesis $M_0 + N_0 \in [\![\tau]\!]$ and $M_1 + N_1 \in [\![\rho]\!]$; therefore,

$$M + N \bowtie (M_0 + N_0) + (M_1 + N_1) \in [\![\tau \vee \rho]\!].$$

($\Leftarrow$) Case $\sigma \equiv \tau \to \rho$.

$$\begin{array}{lll} & M + N \in [\![\sigma]\!] & \\ \Rightarrow & \forall L \in [\![\tau]\!],\ (M+N)L \in [\![\rho]\!] & \text{by definition,} \\ \Rightarrow & \forall L \in [\![\tau]\!],\ ML + NL \in [\![\rho]\!] & \text{by (i) since } (M+N)L \rhd ML + NL \\ & & \text{by rule } (+_{app})', \\ \Rightarrow & \forall L \in [\![\tau]\!],\ ML, NL \in [\![\rho]\!] & \text{by induction} \\ \Rightarrow & M, N \in [\![\sigma]\!] & \text{by definition.} \end{array}$$

Case $\sigma \equiv \tau \vee \rho$ and $M + N \bowtie P + Q$ for some $P \in [\![\tau]\!]$ and $Q \in [\![\rho]\!]$. If $M \bowtie P$ and $N \bowtie Q$ (or vice versa) the thesis follows from (i). Otherwise, by Lemma 2.8(ii) there exist M_0, M_1, N_0, N_1 such that $M \bowtie M_0 + M_1$, $N \bowtie N_0 + N_1$ and $P \bowtie M_0 + N_0$, $Q \bowtie M_1 + N_1$. By induction, $M_0, N_0 \in [\![\tau]\!]$ and $M_1, N_1 \in [\![\rho]\!]$. So we conclude that $M \in [\![\tau \vee \rho]\!]$ and $N \in [\![\tau \vee \rho]\!]$ by definition.

(iv) It suffices to observe that $W \in \mathsf{TVal}$ implies that $W \bowtie M + N$ is impossible for any M, N.

(v) This proof is by induction on the definition of $\leq$. In the case $\sigma \vee \sigma \leq \sigma$, use (iii)($\Rightarrow$).

We consider the case $(\sigma \vee \tau) \wedge \rho \leq (\sigma \wedge \rho) \vee (\tau \wedge \rho)$ when $M \bowtie P + Q$, $P \in [\![\sigma]\!]$, $Q \in [\![\tau]\!]$, and $M \in [\![\rho]\!]$. $M \in [\![\rho]\!]$ implies $P \in [\![\rho]\!]$ and $Q \in [\![\rho]\!]$ by (i) and (iii)($\Leftarrow$). Therefore, we have $P \in [\![\sigma \wedge \rho]\!]$ and $Q \in [\![\tau \wedge \rho]\!]$, so we can conclude $M \in [\![(\sigma \wedge \rho) \vee (\tau \wedge \rho)]\!]$.

(vi) This proof is by induction on σ, taking into account that $\sigma \equiv \tau \vee \rho$ and $\sigma \neq \omega$ imply $\tau \neq \omega$ and $\rho \neq \omega$. □

As expected, realizability coincides with derivability in $\vdash_{\mathcal{L}}$, and this implies in turn that we can assure convergence for all closed terms typable by $\omega \to \omega$.

THEOREM 5.5 (realizability theorem).

$$\forall \Gamma, \sigma, M,\ \Gamma \models^r M : \sigma \ \Leftrightarrow\ \Gamma \vdash_{\mathcal{L}} M : \sigma.$$

Proof. Let $FV(M) = \{x_1, \ldots, x_m, v_1, \ldots, v_n\}$ and $\Gamma = \{x_1{:}\mu_1, \ldots,\ x_m{:}\mu_m,\ v_1{:}\nu_1, \ldots, v_n{:}\nu_n\}$. Let us choose $N_1, \ldots, N_m$ and $L_1, \ldots, L_n$ as in Definition 5.3(ii) and put

$$U^* \equiv U[N_1/x_1, \ldots, N_m/x_m, L_1/v_1, \ldots, L_n/v_n].$$

It suffices to show that $M^* \in [\![\sigma]\!]$ if and only if $\Gamma \vdash_{\mathcal{L}} M : \sigma$.

($\Leftarrow$) The proof is by induction on deductions. We consider only the interesting cases.

Case ($\to \mathrm{I}_v$). Then $M \equiv \lambda v.P$ for some P, $\sigma \equiv \tau \to \rho$ and $\Gamma, v : \tau' \vdash P : \rho$ has been derived for all $\tau' \in \Theta(\tau)$. Let $L \in [\![\tau']\!]$ for some $\tau' \in \Theta(\tau)$. $L \in [\![\tau']\!]$ implies $L \Downarrow$ by Lemma 5.4(vi) since $\tau' \neq \omega$. Therefore, by Corollary 2.10, there are $V_1, \ldots, V_k \in \mathsf{Val}$ such that $L \rhd \sum_{i=1}^{k} V_i$ and $(\lambda v.P)L \rhd \sum_{i=1}^{k} (\lambda v.P)V_i$. Notice that by Lemma 5.4(i) and (iii), $\forall i \leq k,\ V_i \in [\![\tau']\!]$.

From the induction hypothesis for all $i \leq n$, $P[V_i/v]^* \in [\![\rho]\!]$; there is no loss of generality in supposing that v does not occur in $N_1, \ldots, N_m, L_1, \ldots, L_n$ so that $(P[V_i/v])^* \equiv P^*[V_i/v]$. We have $(\lambda v.P)^* V_i \equiv (\lambda v.P^*)V_i$. Now $(\lambda v.P^*)V_i \rhd P^*[V_i/v]$ if $V_i \in \mathsf{TVal}$ and $(\lambda v.P^*)V_i \rhd \sum_{j=1}^{h}(P^*[V_i/v]\|(\lambda v.P^*)V'_j)$, where $\mathcal{R}(V_i, 1) = \{V'_1, \ldots, V'_h\}$ otherwise. In both cases it follows that $(\lambda v.P)^* V_i \in [\![\rho]\!]$ by Lemma 5.4(i), (ii), (iii).

$$\begin{array}{lcll} \forall i \leq k,\ M^*V_i \in [\![\rho]\!] & \Rightarrow & \sum_{i=1}^{k} M^*V_i \in [\![\rho]\!] & \text{by Lemma 5.4(iii),} \\ & \Rightarrow & M^*L \in [\![\rho]\!] & \text{by Lemma 5.4(i)} \\ & & & \text{since } M^*L \rhd \sum_{i=1}^{k} M^*V_i \\ & & & \text{by construction.} \end{array}$$

So we conclude $M^* \in [\![\sigma]\!]$ by the arbitrariness of the computable term L.

Case ($\|$ I). Then $M \equiv P\|Q$ for some P, Q, $\sigma \equiv \tau \wedge \rho$ and, say, $\Gamma \vdash P : \tau$ and $\Gamma \vdash Q : \rho$ have been derived. From the induction hypothesis, $P^* \in [\![\tau]\!]$ and $Q^* \in [\![\rho]\!]$, so that by Lemma 5.4(ii), $P^*\|Q^* \in [\![\tau]\!]$ and $P^*\|Q^* \in [\![\rho]\!]$, which imply by definition $(P\|Q)^* \in [\![\sigma]\!]$.

($\Rightarrow$) This proof is by induction on σ. The only interesting case is when $\sigma \equiv \tau \to \rho$.

$$\begin{array}{lcll} M^* \in [\![\sigma]\!] & \Rightarrow & \forall N \in [\![\tau]\!],\ M^*N \in [\![\rho]\!] & \text{by definition,} \\ & \Rightarrow & M^*\mathsf{R}_\tau \equiv (M\mathsf{R}_\tau)^* \in [\![\rho]\!] & \text{since } \mathsf{R}_\tau \in [\![\tau]\!] \text{ by } (\Leftarrow) \\ & \Rightarrow & \Gamma \vdash_{\mathcal{L}} M\mathsf{R}_\tau : \rho & \text{by induction} \\ & \Rightarrow & \Gamma \vdash_{\mathcal{L}} M : \tau \to \rho & \text{by Theorem 3.13(vi) and} \\ & & & \text{Lemma 5.2(i).} \quad \square \end{array}$$

The main result of this subsection is the characterization of convergent terms by the type $\omega \to \omega$ (see also Theorem 3.23).

COROLLARY 5.6.

(i) $\forall M \in \Lambda^0_{+\|},\ \vdash_{\mathcal{L}} M : \omega \to \omega \Rightarrow M{\Downarrow}$.

(ii) $\forall M \in \Lambda^0_{+\|},\ M{\Uparrow}\ \&\ \vdash_{\mathcal{L}} M : \sigma \Rightarrow \sigma = \omega$.

As already stated, the characterization of types which can be deduced for divergent terms given in Corollary 5.6(ii) allows us to prove that some inclusions in the model are proper.

COROLLARY 5.7.

(i) $\exists M \in \Lambda_{+\|}, V \in \mathsf{Val}$, *$\sigma$ such that* $[\forall \sigma' \in \Theta(\sigma),\ v : \sigma' \vdash_{\mathcal{L}} M : \tau]\ \&\ \vdash_{\mathcal{L}} V : \sigma$ *but* $\not\vdash_{\mathcal{L}} M[V/v] : \tau$;

(ii) $\exists M \in \Lambda_{+\|}, V \in \mathsf{Val}$, *$\tau$ such that* $\vdash_{\mathcal{L}} (\lambda v.M)V : \tau$ *but* $\not\vdash_{\mathcal{L}} M[V/v] : \tau$;

(iii) $\exists L, M, N \in \Lambda_{+\|}$ *such that* $L(M + N) \sqsubset^{\mathcal{L}} LM + LN$;

(iv) $\exists L, M, N \in \Lambda_{+\|}$ *such that* $LM\|LN \sqsubset^{\mathcal{L}} L(M\|N)$.

Proof.

(i) An example is $M \equiv v\mathbf{I}\Delta\Delta\|v\Delta\mathbf{I}\Delta$, $V \equiv \Delta\|(\mathbf{K} + \mathbf{O})$, and $\sigma = \sigma_1 \vee \sigma_2$, where $\sigma_1 \equiv \rho \to \omega \to \rho$, $\sigma_2 \equiv \omega \to \rho \to \rho$, $\rho \equiv \tau \to \tau$, and $\tau \equiv (\omega^2 \to \omega) \to \omega \to \omega$. We can easily check that (1) $\vdash_{\mathcal{L}} \mathbf{I} : \rho$, (2) $\vdash_{\mathcal{L}} \Delta : \tau$, (3) $\vdash_{\mathcal{L}} \mathbf{K} : \sigma_1$, and (4) $\vdash_{\mathcal{L}} \mathbf{O} : \sigma_2$. From (1) and (2) we obtain (5) $v : \sigma_1 \vdash_{\mathcal{L}} v\mathbf{I}\Delta\Delta : \tau$ and (6) $v : \sigma_2 \vdash_{\mathcal{L}} v\Delta\mathbf{I}\Delta : \tau$, which imply, respectively, $v : \sigma_1 \vdash_{\mathcal{L}} M : \tau$ and $v : \sigma_2 \vdash_{\mathcal{L}} M : \tau$. Using (3) and (4) we derive $\vdash_{\mathcal{L}} \mathbf{K} + \mathbf{O} : \sigma_1 \vee \sigma_2$, which implies $\vdash_{\mathcal{L}} V : \sigma_1 \vee \sigma_2$. But type τ cannot be deduced for $M[V/v]$. In fact, it is easy to verify that $M[V/v]$ diverges, since it reduces to $\Omega\|\Omega\|\Omega\mathbf{I}\Delta\|\Omega$. Therefore, by Corollary 5.6(ii) $M[V/v]$ has only types equivalent to ω.

(ii) This proof is immediate from (i).

(iii) An example is $L \equiv \lambda x.(x\mathbf{I}\Delta\Delta \| x\Delta\mathbf{I}\Delta)$, $M \equiv \mathbf{K}$, and $N \equiv \mathbf{O}$. Analogously to (5) and (6) (in the proof of (i)) we have (7) $x : \sigma_1 \vdash_{\mathcal{L}} x\mathbf{I}\Delta\Delta : \tau$ and (8) $x : \sigma_2 \vdash_{\mathcal{L}} x\Delta\mathbf{I}\Delta : \tau$, which imply (9) $\vdash_{\mathcal{L}} L : \sigma_1 \to \tau$ and (10) $\vdash_{\mathcal{L}} L : \sigma_2 \to \tau$. Then from (3), (4), (9), and (10) we conclude $\vdash_{\mathcal{L}} LM + LN : \tau$, but this type cannot be deduced for $L(M + N)$. Really, $L(\mathbf{K} + \mathbf{O})$ reduces to $\Omega\|\Omega$, which being divergent has only types equivalent to ω.

(iv) We choose $L \equiv \lambda x.(x\mathbf{I}\Delta\Delta + x\Delta\mathbf{I}\Delta)$, $M \equiv \mathbf{K}$, and $N \equiv \mathbf{O}$. Using (7) and (8) (from the proof of (iii)) we have $\vdash_{\mathcal{L}} L : \sigma_1 \wedge \sigma_2 \to \tau$. (3) and (4) (from the proof of (i)) imply $\vdash_{\mathcal{L}} \mathbf{K}\|\mathbf{O} : \sigma_1 \wedge \sigma_2$. Then $\vdash_{\mathcal{L}} L(M\|N) : \tau$, but this type cannot be deduced for $LM\|LN$. The reason is again that this term diverges, since it reduces to $\Omega\|\Omega$. □

Notice that Corollary 5.7(i) says that we cannot relax the condition on the premises of rule ($\vee$ E) (discussed on p. 1398), allowing W to be a partial value. This does not mean that our calculus distinguishes internally between partial and total values. In fact, we do not have a type (and therefore a test term by the following full abstraction theorem) that characterizes all total values, as type $\omega \to \omega$ characterizes all convergent terms. The best we can do is the statement of Theorem 3.15(ii).

As suggested by one of the referees, some further remarks are in order about the theory of the model. In fact, equivalence classes of terms with respect to $\simeq^{\mathcal{L}}$ build a distributive lattice in which $+$ is the meet and $\|$ is the join. Moreover, Ω and all divergent terms are the bottom, since only types equivalent to ω can be deduced for them. Finally, the lattice has a top, namely, the equivalence class of the term $(\lambda xy.xx)(\lambda xy.xx)$ (usually called the "ogre"). We recall that $(\lambda xy.xx)(\lambda xy.xx)$ is convertible to the fixed-point of $\mathbf{K}$, i.e., to $\mathbf{YK}$, using the standard β-rule. Moreover, it is unsolvable of infinite order, since it reduces to $\lambda z_1 \dots z_n.(\lambda xy.xx)(\lambda xy.xx)$ for any $n \geq 0$ using the standard β-rule. To prove that *Type* is the interpretation of the "ogre," in the remaining part of this section we will show that $\vdash_{\mathcal{L}} (\lambda xy.xx)(\lambda xy.xx) : \sigma$ for all types σ.

Define, for every $n \geq 1$, the following types;

$$\begin{array}{ll} \sigma_1 \equiv \omega, & \\ \sigma_{n+1} \equiv \tau_n \wedge \sigma_n, & \qquad \tau_n \equiv \sigma_n \to \omega^n \to \omega. \end{array}$$

LEMMA 5.8.

(i) *For every* $n \geq 1$, $\vdash_{\mathcal{L}} \lambda xy.xx : \tau_n$.

(ii) *For every* $n \geq 1$, $\vdash_{\mathcal{L}} \lambda xy.xx : \sigma_n$.

Proof.

(i) We distinguish two cases.

Case $n = 1$.

$$\dfrac{\dfrac{\vdash xx : \omega}{\vdash \lambda y.xx : \omega \to \omega}\ (\to \mathrm{I}_n)}{\vdash \lambda xy.xx : \omega \to \omega \to \omega}\ (\to \mathrm{I}_n).$$

Case $n > 1$.

$$\dfrac{\dfrac{\dfrac{\dfrac{x{:}\sigma_n \vdash x : \tau_{n-1} \wedge \sigma_{n-1}}{x{:}\sigma_n \vdash x : \tau_{n-1}}\ (\leq) \quad \dfrac{x{:}\sigma_n \vdash x : \tau_{n-1} \wedge \sigma_{n-1}}{x{:}\sigma_n \vdash x : \sigma_{n-1}}\ (\leq)}{x{:}\sigma_n \vdash xx : \omega^{n-1} \to \omega}\ (\to \mathrm{E})}{x{:}\sigma_n \vdash \lambda y.xx : \omega^n \to \omega}\ (\to \mathrm{I}_n)}{\vdash \lambda xy.xx : \sigma_n \to \omega^n \to \omega}\ (\to \mathrm{I}_n).$$

(ii) The case $n = 1$ is trivial. If $n > 1$, then $\sigma_n = \bigwedge_{i=1}^{n-1} \tau_i$, so the thesis follows immediately from (i). □

THEOREM 5.9.

(i) *For every* $n \geq 1$, $\vdash_{\mathcal{L}} (\lambda xy.xx)(\lambda xy.xx) : \omega^n \to \omega$.

(ii) *For all types* σ, $\vdash_{\mathcal{L}} (\lambda xy.xx)(\lambda xy.xx) : \sigma$.

Proof.

(i) Just consider the derivations, for $n \geq 1$,

$$\frac{\dfrac{\text{(by Lemma 5.8(i))}}{\vdash \lambda xy.xx : \tau_n} \qquad \dfrac{\text{(by Lemma 5.8(ii))}}{\vdash \lambda xy.xx : \sigma_n}}{\vdash (\lambda xy.xx)(\lambda xy.xx) : \omega^n \to \omega} \ (\to \mathrm{E}),$$

since $\tau_n \equiv \sigma_n \to \omega^n \to \omega$.

(ii) This proof is immediate from (i) and 3.3. □

5.3. Full abstraction. To establish the main result of this paper we use the discriminability power of test terms.

THEOREM 5.10. *Let* M *be a closed term. Then* $\mathsf{T}_\sigma M\Downarrow \ \Leftrightarrow \ \vdash_{\mathcal{L}} M : \sigma$.

Proof. If $\mathsf{T}_\sigma M\Downarrow$ then, by Theorem 3.23, $\vdash_{\mathcal{L}} \mathsf{T}_\sigma M : \omega \to \omega$. By Theorem 3.13(vi) it follows that $\mathsf{T}_\sigma : \rho \to \omega \to \omega$ for some ρ such that $\vdash_{\mathcal{L}} M : \rho$. By Lemma 5.2(ii) it has to be true that $\rho \leq \sigma$, so that $\vdash_{\mathcal{L}} M : \sigma$ using rule $(\leq)$. Vice versa, $\vdash_{\mathcal{L}} M : \sigma$ implies $\vdash_{\mathcal{L}} \mathsf{T}_\sigma M : \omega \to \omega$ by Lemma 5.2(ii), so we conclude $\mathsf{T}_\sigma M\Downarrow$ by Corollary 5.6(i). □

THEOREM 5.11 (full abstraction).

$$M \sqsubseteq^{\mathcal{L}} N \Leftrightarrow M \sqsubseteq^{\mathcal{O}} N.$$

Proof. $(\Rightarrow)$ (adequacy) Since $\sqsubseteq^{\mathcal{L}}$ is a precongruence, $M \sqsubseteq^{\mathcal{L}} N$ implies that, for any context $C[\,]$ closing both M and N, if $\vdash_{\mathcal{L}} C[M] : \omega \to \omega$ then $\vdash_{\mathcal{L}} C[N] : \omega \to \omega$. It follows that

$$\begin{aligned} C[M]\Downarrow &\Rightarrow \vdash_{\mathcal{L}} C[M] : \omega \to \omega \text{ by Theorem 3.23} \\ &\Rightarrow \vdash_{\mathcal{L}} C[N] : \omega \to \omega \Rightarrow C[N]\Downarrow \text{ by Corollary 5.6(i).} \end{aligned}$$

$(\Leftarrow)$ (completeness) $M \not\sqsubseteq^{\mathcal{L}} N \Rightarrow \exists \Gamma, \sigma,\ \Gamma \vdash_{\mathcal{L}} M : \sigma \ \&\ \Gamma \not\vdash_{\mathcal{L}} N : \sigma$. Let $FV(MN) = \{\chi_i \mid 1 \leq i \leq n\}$, $\Gamma = \{\chi_i : \tau_i \mid 1 \leq i \leq n\}$, and $\tau = \tau_1 \to \cdots \to \tau_n \to \sigma$; then $\vdash_{\mathcal{L}} \lambda\chi_1 \ldots \chi_n.M : \tau$ and $\not\vdash_{\mathcal{L}} \lambda\chi_1 \ldots \chi_n.N : \tau$ by Theorem 3.13(iii), (iv). Therefore, choosing $C[\,] = \mathsf{T}_\tau(\lambda\chi_1 \ldots \chi_n.[\,])$, we have by Theorem 5.10 that $C[M]\Downarrow$ and $C[N]\Uparrow$, which imply $M \not\sqsubseteq^{\mathcal{O}} N$. □

A natural question, posed by one of the referees, is whether $\simeq^{\mathcal{L}}$ on the sub-calculus without + coincides with Boudol's equivalence [19]. The answer is negative, since our calculus is more discriminating also for pure λ-terms. For example, Boudol equates $\lambda x.xx$ and its η-expansion $\lambda x.x(\lambda y.xy)$; this is proved in [61]. Instead, in our calculus with +, $\lambda x.xx$ is strictly better than $\lambda x.x(\lambda y.xy)$. This is shown by the fact that $\vdash_{\mathcal{L}} \lambda x.xx : \sigma \wedge (\sigma \to \tau) \to \tau$, while $\lambda x.x(\lambda y.xy)$ does not have this type, where $\sigma \equiv (\mu \to \omega \to \mu) \vee (\omega \to \mu \to \mu)$, $\tau \equiv \omega \to \mu$, and $\mu \equiv \omega \to \omega$. This can be checked by verifying that the test term corresponding to $\sigma \wedge (\sigma \to \tau) \to \tau$ converges when applied to $\lambda x.xx$ and diverges when applied to $\lambda x.x(\lambda y.xy)$. Another way of showing this is to consider the application of these terms to $P + Q$, where $P \equiv \lambda v.v(v\mathbf{O})$ and $Q \equiv \lambda yx.x\Omega$. In fact, we have that $(\lambda x.xx)(P + Q)$ converges,

while $(\lambda x.x(\lambda y.xy))(P+Q)$ diverges. In Figure 3 we show the whole reduction tree of $(\lambda x.xx)(P+Q)$ and an infinite reduction path out of $(\lambda x.x(\lambda y.xy))(P+Q)$.

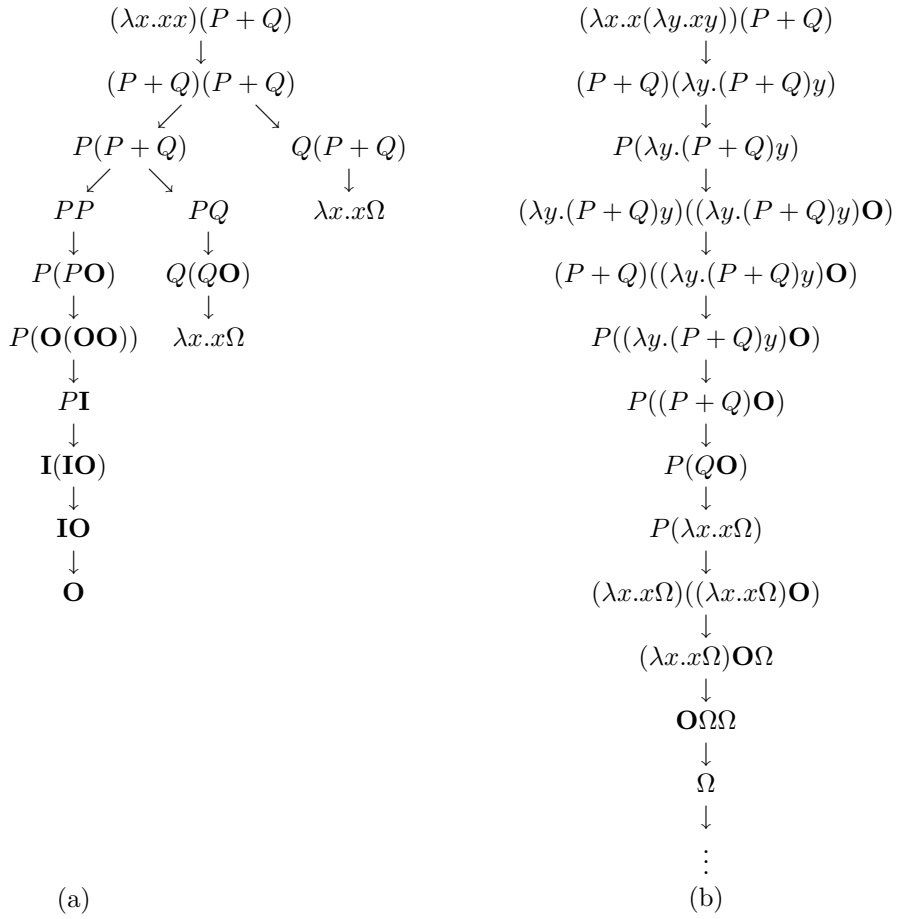

FIG. 3. (a) *The reduction tree of* $(\lambda x.xx)(P+Q)$. (b) *An infinite reduction path out of* $(\lambda x.x(\lambda y.xy))(P+Q)$.

Really, we strongly conjecture that the restriction of $\simeq^{\mathcal{L}}$ to the pure λ-calculus coincides with the equality of Lévy–Longo trees associated with λ-terms. This equivalence relation between λ-terms, which we denote by $\simeq^{\mathcal{T}}$, was defined in [44].

From one side, Sangiorgi in [61] proves that using a set of well-formed operators and comparing terms through bisimulation, one always obtains an equivalence relation (we call $\simeq^{\mathcal{OP}}$) which includes $\simeq^{\mathcal{T}}$. Indeed, we have that $M \simeq^{\mathcal{T}} N$ implies $M \simeq^{\mathcal{OP}} N$ for all λ-terms M, N. Now our concurrent λ-calculus respects the conditions on well-formed operators of [61]. Moreover, we compare terms through contexts, which equate in our case more than bisimulation. For example, we equate $\mathbf{I}+\Omega$ and Ω, which are not bisimilar. Then we conclude that $M \simeq^{\mathcal{T}} N$ implies $M \simeq^{\mathcal{L}} N$ for all λ-terms M, N.

From the other side, given two different Lévy–Longo trees, we believe that there is always a type which can be deduced only for one of the corresponding terms. Note

that we cannot use Sangiorgi's result that the nondeterministic choice is sufficient to obtain the discriminating power of Lévy–Longo trees, since we compare terms by means of contexts instead of using bisimulation.

The coincidence of $\mathcal{L}$ and $\mathcal{T}$ would be another argument showing the robustness of the theory induced by $\simeq^{\mathcal{T}}$. In fact, the same theory is also induced by:

- the encoding of λ-calculus into π-calculus [61];
- Plotkin–Scott–Engeler models [54];
- contexts with multiplicities [20].

Lastly, we want to discuss the negative results of [64]. In that paper, Sieber considers a call-by-value version of PCF enriched with a nondeterministic choice operator (he calls this language PCF_{nv}). He proves that for this language the full abstraction of the Smyth powerdomain semantics fails in an irreparable way. Indeed, there is no extension of PCF_{nv} by computable operators, for which this semantics is fully abstract.

Notice that PCF_{nv} is a typed language, while our concurrent λ-calculus is type-free and we use types only to describe its semantics. Indeed, it is not surprising that an untyped calculus has a stronger power in discriminating internally between terms than a typed one. In particular, Böhm's theorem [15] (10.4) does not hold for the simply typed λ-calculus.

The same phenomenon happens here, since one can easily discriminate the terms which are at the basis of Sieber's proof. Omitting types, these terms are

$$\begin{aligned} M_1 &= \lambda f.\ \mathbf{if}\ f(\lambda x.0)\ \mathbf{then}\ f(\lambda x.\Omega)\ \mathbf{else}\ \Omega\ \mathbf{fi}, \\ M_2 &= \lambda f.\ \mathbf{if}\ f(\lambda x.0)\ \mathbf{and}\ f(\lambda x.\Omega)\ \mathbf{then}\ 0\ \mathbf{else}\ \Omega\ \mathbf{fi}, \end{aligned}$$

where 0 is interpreted as "true" and all other integers as "false." We can encode this example in the pure λ-calculus with the η-reduction rule using Church's numerals. Recall that $\mathbf{O}$ represents Church's zero and that $\mathbf{I}$ is η-convertible to Church's one. If we denote this translation by $(\ )^\dagger$, it is easy to check that a correct choice is the following:

$$(\ \mathbf{if}\ A\ \mathbf{then}\ B\ \mathbf{else}\ C\ \mathbf{fi})^\dagger = A^\dagger\mathbf{O}(\mathbf{K}B^\dagger)C^\dagger, \qquad (A\ \mathbf{and} B)^\dagger = A^\dagger\mathbf{O}B^\dagger,$$

since for Church's numerals it holds that $(\mathbf{n}+\mathbf{1})\mathbf{O} \xrightarrow{*} \mathbf{O}$. Therefore we have

$$\begin{aligned} M_1^\dagger &= \lambda f.f(\lambda x.\mathbf{O})\mathbf{O}(\mathbf{K}(f(\lambda x.\Omega)))\Omega, \\ M_2^\dagger &= \lambda f.f(\lambda x.\mathbf{O})\mathbf{O}(f(\lambda x.\Omega))\mathbf{O}(\mathbf{KO})\Omega. \end{aligned}$$

Now the pure λ-calculus easily semi-separates these terms. It suffices to choose $F \equiv \lambda x_1 \dots x_6.x_6$, since $M_1^\dagger F \xrightarrow{*} \mathbf{O}$ and $M_2^\dagger F \xrightarrow{*} \Omega$. It is clear that PCF_{nv} does not allow us to define a well-typed operator which behaves like F. Really, F applied to any term returns $\lambda x_1 \dots x_5.x_5$, which does not have the type of integers.

6. Related work and conclusions. The literature related to the present work has mostly been quoted in the introduction. A research direction, which has not yet been mentioned, is that initiated by Milner in [50], and developed by Sangiorgi in [61]. The idea is to consider the π-calculus as the basic model, and to study lazy λ-calculus via encodings into the π-calculus itself. A comparative study and a survey of these investigations is [43]. Although related, this approach seems orthogonal to that which is developed in the present paper, where the nondeterministic lazy λ-calculus is studied with respect to a denotational model via a type assignment system. In spite

of this, as remarked on p. 1415, we conjecture that the theory of this encoding and that of our model coincide.

It is interesting to compare our full abstraction result with the negative results of [39] and [64]. Both papers deal with typed λ-calculus (actually PCF).

Jim and Meyer show in [39] that any denotational semantics which is adequate for PCF, and in which a certain simple boolean functional exists, cannot be fully abstract for extensions of PCF satisfying the context lemma. This boolean functional is not Scott's continuous, but it is stably continuous. So it follows that there is no extension of PCF satisfying the context lemma for which the stable domains are fully abstract. Actually, we consider Scott's continuous functions and moreover our calculus does not satisfy the context lemma. For example, we distinguish between $\mathbf{I}+\Delta$ and $\lambda x.(x+xx)$, which clearly have the same applicative behavior.

Sieber [64] adds call-by-value and nondeterminism to PCF. He explains why the nondeterministic extensions of call-by-name λ-calculus studied in [9, 10] need the powerdomain functors only at ground types. Instead, call-by-value and nondeterminism also require powerdomains for function types. Moreover, Sieber shows that no fully abstract model of demonic nondeterminism and call-by-value can be given in the typed case. The counterexample he considers, however, has no counterpart in the type-free setting (see the discussion at the end of section 5).

A further point concerns previous work by the present authors. In [45] the operational and denotational semantics of a call-by-name classical λ-calculus enriched with erratic choice is studied introducing an extension of the notion of Böhm tree.

In [25] classical λ-calculus is extended with both a nondeterministic choice operator and a parallel operator. A type assignment system using intersection and union types and denotational models of this calculus are investigated. In particular, the local structure of the resulting filter model is studied against a Morris-style (see [52]) operational semantics. The main differences with the present work are the classical operational semantics (that is, evaluation under abstraction is allowed) and the absence of call-by-value abstraction. Notably, full abstraction is a distinctive feature of the present calculus with respect to that studied in [25].

Pursuing further the study of concurrent λ-calculus, in [8] we present an operational semantics in which the parallel operator still retains an angelic behavior, while the nondeterministic operator has a finer semantics than the demonic one. The system admits a model which involves a new powerdomain operator close to the convex powerdomain functor, but staying inside the category of distributive prime algebraic lattices.

Finally, in [27], ideas coming from the present paper are used to define a calculus of higher-order processes including communication primitives. For this calculus a program logic in the form of a type assignment system is introduced. The induced filter model turns out to be fully abstract with respect to the operational preorder. This is closely related, and should be compared, to [35].

Summarizing, the main achievement of the present study is the definition of an operational semantics which assesses in a correct and effective way features like parallelism, nondeterminism, and call-by-value which have not received, to the knowledge of the authors, a convincing treatment within a unique comprehensive system.

Moreover, the abstract description of operational semantics by means of the logic equivalence, which is guaranteed by the full abstraction theorem, shows that an elegant correspondence between the operators in the term syntax and the logical connectives is at the basis of the whole construction.

The logical model is a simple distributive lattice enriched with an operation which interprets functional application. The simplicity of this structure and the correspondence between (total) values and prime elements of the lattice are also remarkable.

Acknowledgments. The present version of this paper has been deeply influenced by comments and remarks of two anonymous referees. In particular, the addition of discussions about motivations, comparisons with the existing literature, justifications of the choices made, and the addition of meaningful examples improved the presentation of the paper. Therefore, the authors feel strongly indebted to the referees.

DOWNWARD SEPARATION FAILS CATASTROPHICALLY FOR LIMITED NONDETERMINISM CLASSES*

R. BEIGEL† AND J. GOLDSMITH‡

Abstract. The β hierarchy consists of classes $\beta_k = \mathrm{NP}[\log^k n] \subseteq \mathrm{NP}$. Unlike collapses in the polynomial hierarchy and the Boolean hierarchy, collapses in the β hierarchy do not seem to translate up, nor does closure under complement seem to cause the hierarchy to collapse. For any consistent set of collapses and separations of levels of the hierarchy that respects $\mathrm{P} = \beta_1 \subseteq \beta_2 \subseteq \cdots \subseteq \mathrm{NP}$, we can construct an oracle relative to which those collapses and separations hold; at the same time we can make distinct levels of the hierarchy closed under computation or not, as we wish. To give two relatively tame examples: for any $k \geq 1$, we construct an oracle relative to which

$$\mathrm{P} = \beta_k \neq \beta_{k+1} \neq \beta_{k+2} \neq \cdots$$

and another oracle relative to which

$$\mathrm{P} = \beta_k \neq \beta_{k+1} = \mathrm{PSPACE}.$$

We also construct an oracle relative to which $\beta_{2k} = \beta_{2k+1} \neq \beta_{2k+2}$ for all k.

Key words. structural complexity theory, limited nondeterminism, hierarchies, oracles

1. Introduction.

Although standard nondeterministic algorithms solve many NP-complete problems with $O(n)$ nondeterministic moves, there are other problems that seem to require very different amounts of nondeterminism. For instance, clique can be solved with only $O(\sqrt{n})$ nondeterministic moves, and Pratt's algorithm [16] solves primality, which is not believed to be NP-complete, with $O(n^2)$ nondeterministic moves. Motivated by the different amounts of nondeterminism apparently needed to solve problems in NP, Kintala and Fischer [9, 10, 11] defined limited nondeterminism classes within NP, including the classes we now call the β hierarchy. The structural properties of the β classes were studied further by Àlvarez, Díaz, and Torán [1, 6]. These classes arose yet again in the work of Papadimitriou and Yannakakis [15] on particular problems inside NP (e.g., quasi-group isomorphism can be solved with $O(\log^2 n)$ nondeterministic moves).

Kintala and Fischer [11] defined $\mathcal{P}_{f(n)}$ to be the class of languages accepted by a nondeterministic polynomial-time bounded Turing machine that makes at most $f(n)$ c-ary nondeterministic moves (equivalently, $O(f(n))$ binary nondeterministic moves) on inputs of length n. Being mostly interested in polylogarithmic amounts of nondeterminism, they defined $\mathcal{PL}_k = \mathcal{P}_{\log^k n}$.

Díaz and Torán [6] wrote $\beta_{f(n)}$ to denote Kintala and Fischer's $\mathcal{P}_{f(n)}$, and β_k to denote $\mathcal{PL}_k$. Papadimitriou and Yannakakis [15] wrote $\mathrm{NP}[f(n)]$ to denote $\mathcal{P}_{f(n)}$.

(Their work is surveyed in [7].) We will adopt the NP$[f(n)]$ notation of Papadimitriou and Yannakakis, as well as the β_k notation of Díaz and Torán. To reiterate, we offer the following definition.

DEFINITION 1.1.

- *A language L belongs to* NP$[f(n)]$ *if there exists a polynomial-time bounded nondeterministic Turing machine (NTM) that accepts L and makes $O(f(n))$ nondeterministic choices on inputs of length n. (Note.* NP$[f(n)] \subseteq$ DTIME$(2^{O(f(n))})$.*)*
- $\beta_k =$ NP$[\log^k n]$.
- *The β hierarchy consists of β_1, β_2, ...*
- $\beta = \bigcup_k \beta_k$.

Kintala and Fischer [11] constructed oracles that make the β hierarchy collapse to any desired level. That is, there is an oracle relative to which

$$\beta_1 \neq \beta_2 \neq \cdots$$

and, for every $k \geq 1$, there is an oracle relative to which

$$\beta_1 \neq \beta_2 \neq \cdots \neq \beta_k = \text{NP}.$$

Oracles can also make the polynomial hierarchy and the Boolean hierarchy collapse to any desired level [12, 4]. The polynomial and Boolean hierarchies have a very nice property: collapses translate upward. That is, if the kth and $(k+1)$st levels are equal, then all levels are contained in the kth [5, 4]. This is also reflected in the nondeterminism hierarchy, now known as the b hierarchy, studied by Buss and Goldsmith [3]. The classes in the b hierarchy are defined by two parameters: the exponent of the polynomial-time bound (ignoring log factors), and the constant factor for $k \log n$ bits of nondeterminism. This hierarchy exhibits upward collapse for both time and k. All attempts to prove an analogous translational property for the β hierarchy have failed. In fact, the obvious technique extends a collapse by only a constant factor in the number of nondeterministic bits, giving one of the aforementioned upward collapses of the b hierarchy.

Hemachandra and Jha [8] attempted to explain this failure by examining the tally sets in the β hierarchy. For each k, they constructed an oracle that makes $\beta_j \cap \text{TALLY} = \beta_{j+1} \cap \text{TALLY}$ if and only if $j \leq k$. We find this explanation unsatisfactory because it considers only tally sets.

The known behavior of relativized β hierarchies is that $\beta_0^A = \beta_1^A$ and that $\beta_i^A \subseteq \beta_j^A$ for all $i < j$ and all oracles A. A *collapse* is a statement of the form $\beta_i^A = \beta_j^A$. A *separation* is a statement of the form $\beta_i^A \neq \beta_j^A$. A *closure* is a statement of the form $\beta_i^A =$ co-β_i^A. A *nonclosure* is a statement of the form $\beta_i^A \neq$ co-β_i^A. A *requirement* is a collapse, separation, closure, or nonclosure. We call a set of requirements *consistent* if it is consistent with the known behavior of relativized β hierarchies, as stated above, and the standard axioms for $=$ and $\subseteq$.

Given a set S of requirements, let X be the union of $[0,1]$ and all intervals $[i,j]$ such that $i < j$ and the collapse $\beta_i^A = \beta_j^A$ belongs to S. It is easy to see that S is consistent if and only if the following conditions hold for all a and b such that $[a,b] \subseteq X$ or $[b,a] \subseteq X$: (1) the separation $\beta_a^A \neq \beta_b^A$ does not belong to S; (2) the closure $\beta_a^A =$ co-β_a^A and the nonclosure $\beta_b^A \neq$ co-β_b^A do not both belong to S.

For any consistent set of requirements, we construct an oracle A such that the β hierarchy relative to A satisfies them. For example, for each $k \geq 0$, there is an oracle that makes $\beta_j = \beta_{j+1}$ if and only if $j \leq k$. Another oracle makes $\beta_j = \beta_{j+1}$ if

and only if $j = 0$ or j is prime. We can also make distinct levels in the hierarchy be closed under complementation or not, as long as this is consistent with the collapses (if $\beta_i^A = \beta_j^A$, then we cannot have $\beta_i^A = \text{co-}\beta_i^A$ and $\beta_j^A \neq \text{co-}\beta_j^A$).

We prove two initial results for every k.

- *There is an oracle that makes the first k levels of the β hierarchy coincide, but makes the remaining levels all distinct (Theorem* 2.3*).*
- *There is an oracle that makes the first k levels of the β hierarchy coincide, the $(k+1)$st level different from the kth, and the remaining levels all equal (Theorem* 2.5*).*

The techniques from these two constructions can be combined to get any consistent finite or infinite set of collapses and separations. To collapse β_k into β_j (for $k > j$), we code a complete set for β_k into β_j. The same coding techniques can also code co-$\overline{\beta}_i$ into β_i, for any i's we wish, as long as this doesn't violate any collapses. (If β_k is collapsed to β_j, then either both or neither will be closed under complement.) Finally, in section 3, we extend our results to β_r for real $r \geq 0$.

One theme in complexity theory is to ask whether $\text{NP} - \text{P}$ contains any easy sets (assuming $\text{P} \neq \text{NP}$). The answer to the question above depends on the definition of "easy." Ladner [14] showed that if $\text{P} \neq \text{NP}$ then $\text{NP} - \text{P}$ contains an incomplete set. On the other hand, there are oracles relative to which $\text{P} \neq \text{NP}$, but $\text{NP} - \text{P}$ contains (a) no tally sets [13] or (b) no sets in co-NP [2]. It is unknown whether the assumption $\text{P} \neq \text{NP}$ implies that $\text{NP} - \text{P}$ contains a set in $\text{DTIME}(n^{\text{polylog}})$; a positive answer would improve many constructions in the literature. As a step toward understanding that question, we construct an oracle relative to which $\text{P} \neq \text{NP}$ but $\text{NP} - \text{P}$ contains no set in the β hierarchy (Corollary 2.2).

2. Limited nondeterminism hierarchies. The construction below gives almost all the techniques used in subsequent theorems.

THEOREM 2.1. *Let g_0 and g_1 be polynomial-time computable monotone increasing functions such that $\log n \in o(g_1(n))$ and $g_0(n) \in n^{O(1)}$. If $g_0(n^{O(1)}) \subseteq o(g_1(n))$, then there exists an oracle A such that $\text{P}^A = (\text{NP}[g_0(n)])^A \neq (\text{NP}[g_1(n)])^A$ (and in fact there is a tally set in $(\text{NP}[g_1(n)])^A - (\text{NP}[g_0(n)])^A$).*

Proof. Let $C^A = \{(e, x, 0^s) : \text{oracle NTM } e \text{ accepts } x \text{ within } s \text{ steps with oracle } A, \text{ making at most } g_0(|x|) \text{ nondeterministic choices}\}$. Then C^A is $\leq_m^p$-complete for $(\text{NP}[g_0(n)])^A$ for every A. Let $p(n)$ be the polynomial-time bound for some $\text{NP}[g_0(n)]$ oracle Turing machine recognizing $C^{()}$.

Let $D^A = \{x \in 1^* : \exists y[|y| = g_1(|x|) \wedge 0xy \in A]\}$. Note that $D^A \in \text{NP}[g_1(n)]^A$.

The construction consists of coding C^A into A in a polynomial-time recoverable manner, making $(\text{NP}[g_0(n)])^A \subseteq \text{P}^A$, while diagonalizing, i.e., guaranteeing that no P^A machine recognizes the set D^A, so $\text{P}^A \neq (\text{NP}[g_1(n)])^A$.

At the end of the construction, we will have

$$w \in C^A \iff 1^{p(|w|)^2} 0w \in A.$$

We refer to all strings beginning with 1 as *coding strings.* We refer to all strings beginning with 0 as *diagonalizing strings.*

Assume that $\text{P}^{()}$ is enumerated by deterministic Turing machines (DTMs) $P_1^{()}$, $P_2^{()}, \ldots$ so that for all i, $P_i^{()}$ runs in time bounded by n^i for sufficiently large n.

The construction proceeds in stages. At the end of stage s, A is decided for all strings of length up to n_s, and D^A is extended so that P_s^A does not recognize D^A. The stage consists of one diagonalization, which determines n_s, and continued encoding of C^A.

At stage s, choose $n > n_{s-1}$ such that n is a power of 2, the running time of $P_s^{()}$ on inputs of length n is at most n^s, and n satisfies an inequality that is to be specified below and that is true for almost all n. Let $x = 1^n$. The value of $D^A(1^n)$ depends only on oracle strings of length $\ell = 1 + n + g_1(n)$. Code C^A for all coding strings of length $\leq \ell - 1$ (i.e., for all w such that $p(|w|)^2 + 1 + |w| \leq \ell - 1$, let $1^{p(|w|)^2}0w \in A \iff w \in C^A$) and freeze A up to length $\ell - 1$.

In order to diagonalize, $P_s^A(x)$ must be calculated. But that computation may query coding strings that code computations of C^A that are not yet decided, because those computations in turn rely on strings for which A is not yet decided. Those strings in turn may depend on other coding strings. Any diagonalizing strings that do not already belong to A and are queried by $P_s^A(x)$, or by the computation corresponding to a coding string that $P_s^A(x)$ queries, or in the computation corresponding to a coding string that one of those computations queries, or so on, are restrained from A. We claim that there are more potential witnesses for x to be in D^A than there are possible queries in such a cascade of queries, so deciding $P_s^A(x)$ does not restrict our decision about $D^A(x)$.

Because of the encoding of C^A, a coding string z codes a computation that depends only on strings of length bounded by $\sqrt{|z|}$. $C^A(w)$ directly depends on at most $p(|w|)2^{g_0(|w|)}$ of these shorter strings.

A computation of $P_s^A(x)$ may query no more than n^s strings, each of length bounded by n^s. Each of these strings may code a computation on a string of length at most $n^{s/2}$. Each of these computations depends on at most $p(n^{s/2})2^{g_0(n^{s/2})}$ strings, each of which depends on at most $p(n^{s/4})2^{g_0(n^{s/4})}$ strings, etc.

This recursion can be cut off at strings of length $\ell - 1$, because A is already determined up to that length. The total number of queries needed to decide $P_s^A(x)$ is bounded by n^s times the product of all the terms above of the form $p(n^{s/2^i})2^{g_0(n^{s/2^i})}$. There are at most $\log\log n^s - \log\log(\ell - 1) \leq \log\log n^s - \log\log n = \log s$ such terms, and each of them is bounded by $p(n^s)2^{g_0(n^s)} = 2^{O(g_0(n^s))}$. Therefore, the total number of queries on which $P_s^A(x)$ depends is $n^s 2^{O(\log(s) g_0(n^s))}$, which is less than $2^{g_1(n)}$ for sufficiently large n. (The inequality that n must satisfy is $n^s(p(n^s)2^{g_0(n^s)})^{\log(s)} < 2^{g_1(n)}$.)

Thus there remains an unrestrained diagonalizing string of length ℓ, which we put into A if $P_s^A(x)$ rejects x. That is, we set $D^A(x) = 1 - P_s^A(x)$, adding a string $0xy$ to A if necessary. Thus, for each s, we can guarantee that P_s^A does not accept D^A, so $D^A \notin \mathrm{P}^A$. Since $D^A \in (\mathrm{NP}[g_1(n)])^A$, this shows that $(\mathrm{NP}[g_1(n)])^A \neq \mathrm{P}^A$. Since $C^A \in \mathrm{P}^A$ is complete for $(\mathrm{NP}[g_0(n)])^A$, this shows that $(\mathrm{NP}[g_0(n)])^A \subseteq \mathrm{P}^A$.

We complete stage s by letting $n_s = \max(\ell, n^s)$ and finishing the coding of any $C^A(w)$ that was begun or queried in this stage. □

The preceding theorem is tight because if $\mathrm{P} = \mathrm{NP}[g_0(n)]$ then $\mathrm{P} = \mathrm{NP}[g_0(n^{O(1)})]$ (even if we restrict to binary nondeterministic moves) via a relativizable proof. (Previously, Sanchis [17] had observed that if $\mathrm{P} = \mathrm{NP}[n^\epsilon]$ for some $\epsilon > 0$, then $\mathrm{P} = \mathrm{NP}$.)

Because the classes are separated by tally sets, we also separate the exponential-time versions of these classes (see [8] for an elaboration of this).

COROLLARY 2.2. *There is an oracle relative to which* $\mathrm{P} = \beta \neq \mathrm{NP}$.

Proof. Let $g_0(n) = 2^{(\log\log n)^2}$ and $g_1(n) = n$ in the previous theorem. Then, for all k, $\beta_k^A \subseteq (\mathrm{NP}[2^{(\log\log n)^2}])^A = \mathrm{P}^A \neq \mathrm{NP}^A$. □

THEOREM 2.3. *Let $g(\cdot,\cdot)$ be a polynomial-time computable, monotone increasing (in both variables) function with $\log n \in o(g(n,i))$ and $g(n,i) \in n^{O(1)}$ for all $i \geq 0$. If $g(n^{O(1)}, 2i) \subseteq o(g(n, 2i+1))$ for all $i \geq 1$, then there exists an oracle A such that*

$\mathrm{P}^A = (\mathrm{NP}[g(n,0)])^A$ *and* $(\mathrm{NP}[g(n,2i)])^A \neq (\mathrm{NP}[g(n,2i+1)])^A$ *for all* $i \geq 0$ *(and in fact there is a tally set in* $(\mathrm{NP}[g(n,2i+1)])^A - (\mathrm{NP}[g(n,2i)])^A$ *for each* i*).*

(In this theorem, we ignore the relationship between $\mathrm{NP}[g(n,2i-1)]$ and $\mathrm{NP}[g(n,2i)]$. We will take that up in the next theorem.) The only difference between this construction and the previous one is that there are infinitely many diagonalizations going on. At stage $s = \langle e, i\rangle$, we guarantee that the eth machine for $(\mathrm{NP}[g(n,2i)])^A$ does not accept the diagonal set $D_i^A \in (\mathrm{NP}[g(n,2i+1)])^A$. Thus, $(\mathrm{NP}[g(n,2i+1)])^A \neq (\mathrm{NP}[g(n,2i)])^A$. The counting argument for this construction is identical to that in the proof of Theorem 2.1.

COROLLARY 2.4. *For any* k*, there is an oracle relative to which*

$$\mathrm{P} = \beta_k \neq \beta_{k+1} \neq \beta_{k+2} \neq \cdots.$$

Proof. Let $g(n,i) = \log^{k+\lfloor i/2\rfloor} n$ in the preceding theorem. □

THEOREM 2.5. *Let* g_0 *and* g_1 *be polynomial-time computable, monotone increasing functions such that* $\log n \in o(g_1(n))$ *and* $g_0(n) \in n^{O(1)}$*. If* $g_0(n^{O(1)}) \subseteq o(g_1(n))$ *then there exists an oracle* A *such that*

$$\mathrm{P}^A = (\mathrm{NP}[g_0(n)])^A \neq (\mathrm{NP}[g_1(n)])^A = \mathrm{PSPACE}^A$$

(and in fact there is a tally set in $(\mathrm{NP}[g_1(n)])^A - (\mathrm{NP}[g_0(n)])^A$*).*

Sketch. In this construction, we do two encodings and one diagonalization. In addition to coding C_k^A into P, we also code E^A, a generic $\leq_m^p$-complete set for PSPACE, into A. ($E^A = \{(e,x,0^s) :$ oracle DTM e accepts x using at most s tape squares with oracle $A\}$, where we also count the space used on the oracle tape.) At the end of the construction, we have

$$x \in E^A \iff (\exists y)[|y| = g_1(n) \wedge 2xy \in A].$$

(If one prefers binary oracles, one may code 0, 1, and 2 as 00, 01, and 10.) When we are doing a diagonalization to make $P_s^A(x) \neq D^A(x)$, if a coding string for $C_k^A(w)$ is queried, we proceed as before; if a coding string for $E^A(w)$ is queried, where $|w| \geq |x|$, then we simply restrain that coding string from the oracle. This will not restrain all the coding strings for $E^A(w)$, since there are $2^{g_1(|w|)}$ coding strings for $E^A(w)$; if $|w| \geq |x|$, then $2^{g_1(|w|)} > (p(|x|^s)2^{g_0(|x|^s)})^{\log(s)}$, where $(p(|x|^s)2^{g_0(|x|^s)})^{\log(s)}$ is the upper bound on the total number of queries generated by the computation of $P_s^A(x)$, as in the proof of Theorem 2.1. Therefore, restraining any such coding strings queried in the computation of $P_s^A(x)$ or in its cascade of queries cannot restrain all such coding strings, and thus cannot decide $E^A(w)$. At the end of each stage, we complete all codings begun or queried in that stage, so that it will not be changed in any subsequent stage. □

COROLLARY 2.6. *For every* k*, there is an oracle relative to which*

$$\mathrm{P} = \beta_k \neq \beta_{k+1} = \mathrm{PSPACE}.$$

With only a slight modification of this technique, we get far more bizarre collapses.

THEOREM 2.7. *Let* $g(\cdot,\cdot)$ *be a polynomial-time computable, monotone increasing (in both variables) function with* $\log n \in o(g(n,i))$ *and* $g(n,i) \in n^{O(1)}$ *for all* $i \geq 1$*. If* $g(n^{O(1)}, 2i) \subseteq o(g(n,2i+1))$ *for all* $i \geq 1$*, then there exists an oracle* A *such that*

$\mathrm{P}^A = (\mathrm{NP}[g(n,0)])^A$ *and* $(\mathrm{NP}[g(n,2i)])^A \neq (\mathrm{NP}[g(n,2i+1)])^A = (\mathrm{NP}[g(n,2i+2)])^A$ *for all* $i \geq 0$ *(and in fact there is a tally set in* $(\mathrm{NP}[g(n,2i+1)])^A - (\mathrm{NP}[g(n,2i)])^A$ *for each* i*).*

We include the full proof of this result, although it uses techniques mentioned before, since this shows how all the pieces fit together.

Proof. Let $C_i^A = \{(e,x,0^s) :$ oracle NTM e accepts x within s steps with oracle A, making at most $g(|x|,i)$ nondeterministic choices$\}$. Then C_i^A is $\leq_m^p$-complete for $(\mathrm{NP}[g(n,i)])^A$ for any A. Let $p(n,i)$ be the nondeterministic time bound for some $\mathrm{NP}[g(n,i)]$ oracle Turing machine recognizing $C_i^{()}$. Without loss of generality, assume that for all i and almost all n, $p(n,i) \leq p(n,i+1)$.

Let $D_i^A = \{x : \exists y[|y| = g(|x|,i) \wedge 0xy \in A]\}$.

For convenience, define $g(n,-1) = 0$ for all n.

The construction consists of coding C_{2i}^A into $(\mathrm{NP}[g(n,2i-1)])^A$, for each $i \geq 0$, so $(\mathrm{NP}[g(n,0)])^A \subseteq \mathrm{P}^A$ and $(\mathrm{NP}[g(n,2i+2)])^A \subseteq (\mathrm{NP}[g(n,2i+1)])^A$ for all i, and diagonalizing, i.e., guaranteeing that no $(\mathrm{NP}[g(n,2i)])^A$ machine recognizes the set D_{2i+1}^A, for any i, so $(\mathrm{NP}[g(n,2i+1)])^A \not\subseteq (\mathrm{NP}[g(n,2i)])^A$ for any i.

At the end of the construction, we will have $x \in C_{2i}^A \iff \exists y[|y| = g(|x|,2i-1) \wedge 10^{2i}1^{p(|x|,2i-1)^2}0xy \in A]$.

Assume that $(\mathrm{NP}[g(n,i)])^A$ is enumerated by oracle NTMs $M_{1,i}, M_{2,i}, \ldots$, where $M_{e,i}$ runs in time bounded by n^e for sufficiently large n.

The construction proceeds in stages. Stage $s = \langle e,i\rangle$ consists of some encodings and one diagonalization, which determines n_s. At the end of stage s, A is decided for all strings of length $\leq n_s$ (and some further coding strings), and A has been extended so that $M_{e,2i}^A$ does not recognize D_{2i+1}^A.

At stage s, let $\langle e,i\rangle = s$, and then choose $n > n_{s-1}$ such that n is a power of 2, $M_{e,2i}$ runs in time bounded by n^e on inputs of length n, and n satisfies an inequality to be specified below that is true for almost all n. Let $n_s = n$. Let $x = 0^n$. The value of $D_{2i+1}^A(x)$ depends only on strings of length $\ell = 1 + n + g(n,2i+1)$. Do all coding involving witnesses of length less than ℓ, and then freeze A through length $\ell - 1$.

As before, in order to diagonalize we will need to calculate $M_{e,2i}^A(x)$ which may generate a cascade of queries. Any diagonalizing strings that do not already belong to A and are queried in this cascade are restrained from A. But coding strings may be queried as well. (Because we are coding nondeterministically, coding strings can be thought of as potential witnesses to membership.) If $M_{e,2i}^A(x)$ queries a potential witness that $w \in C_{2j}^A$, where $2j > 2i$ and $C_{2j}^A(w)$ has not yet been decided, that potential witness is restrained from A. If $2j \leq 2i$ and $C_{2j}^A(w)$ has not yet been decided, then we compute $C_{2j}^A(w)$ recursively. We will show below that the number of queries generated by such a cascade of queries is smaller than both of the following bounds: (1) the number of potential witnesses for $w \in C_{2j}^A$, (2) the number of potential witnesses for $x \in D_{2i+1}^A$. In fact, bound (1) implies bound (2) as follows. The number of witnesses for $D_{2i+1}^A(x)$ is $2^{g(|x|,2i+1)}$, and the number of witnesses for $C_{2j}^A(w)$ is $2^{g(|w|,2j-1)}$. If a witness of $C_{2j}^A(w)$ is restrained, then $|w| \geq |x|$ and $2j > 2i$. Thus $2j-1 \geq 2i+1$, so, by monotonicity of g, $g(|w|,2j-1) \geq g(|x|,2j-1) \geq g(|x|,2i+1)$.

Thus, restraining potential witnesses as described does not impede any encodings or restrict our decisions about $D_{2i+1}(x)$ or those $C_{2j}^A(w)$ for which we restrict coding strings. (We don't have to worry about what happens to potential witnesses for $w \in C_{2j}^A$ at a later stage, because any affected codings, e.g., $C_{2j}^A(w)$, will be completed at this stage; later diagonalizations will not affect them.)

Now we show that there are more potential witnesses for $x \in D^A_{2i+1}$ than there are possible queries in such a cascade of queries. Because of how we encode C^A_k, a coding string z codes a computation that depends on strings of length bounded by $\sqrt{|z|}$. For $k \le 2i+1$, $C^A_k(w)$ depends on at most $p(|w|,k)2^{g(|w|,k)} \le p(|w|,2i+1)2^{g(|w|,2i+1)}$ of these shorter strings.

$M^A_{e,2i}(x)$ has at most $2^{g(n,2i)}$ computations, and each of those computations may query no more than n^e strings, each of length bounded by n^e. Each such string may code a computation $C^A_{2j}(w)$ where $|w| \le \sqrt{n^e}$, but we only need to expand that computation if $2j \le 2i$. Each of these computations depends on at most $p(n^{e/2},2i)2^{g(n^{e/2},2i)}$ strings, each of which depends on at most $p(n^{e/4},2i)2^{g(n^{e/4},2i)}$ strings, etc. As before, the total number of queries needed to decide $M^A_{e,i}(x)$ is bounded by the product of $\log e \le \log s$ terms, each of which is $2^{o(g(n,2i+1))}$. Therefore the total number of queries on which $M^A_{e,2i}(x)$ depends is $2^{o(g(n,2i+1))}$, which is less than $2^{g(n,2i+1)}$ for sufficiently large n.

Thus there remains an unrestrained diagonalizing string of length ℓ, which we put into A if and only if $M^A_{e,2i}(x)$ rejects x. That is, we set $D^A_{2i+1}(x) = 1 - M^A_{e,2i}(x)$, adding a string $0xy$ to A if necessary. Thus, for each s, we can guarantee that $M^A_{e,2i}$ does not accept D^A_{2i+1}, so $D^A_{2i+1} \notin (\mathrm{NP}[g(n,2i)])^A$. Since $D^A_i \in (\mathrm{NP}[g(n,2i+1)])^A$, this shows that $(\mathrm{NP}[g(n,2i+1)])^A \not\subseteq (\mathrm{NP}[g(n,2i)])^A$ for all $i \ge 0$.

Since C^A_{2i} is complete for $(\mathrm{NP}[g(n,2i)])^A$, our encoding guarantees that $(\mathrm{NP}[g(n,2i)])^A \subseteq (\mathrm{NP}[g(n,2i-1)])^A$ for all $i \ge 0$. □

Corollary 2.8. *There is an oracle relative to which, for each k, $\beta_{2k} = \beta_{2k+1} \neq \beta_{2k+2}$.*

Corollary 2.9. *For any consistent pattern of collapses and separations of the β_k's, there is an oracle relative to which that pattern holds.*

Notice that if the set of collapses is not recursive, then the oracle will also be nonrecursive.

In addition to collapsing or separating β_j and β_k, we can code co-β_k into β_k—or separate the two. This involves some additional argument.

Theorem 2.10. *Let $g(\cdot,\cdot)$ be a polynomial-time computable, monotone increasing (in both variables) function with $\log n \in o(g(n,i))$ and $g(n,i) \in n^{O(1)}$ for all $i \ge 1$. If $g(n^{O(1)},2i) \subseteq o(g(n,2i+1))$ for all $i \ge 1$, then there exists an oracle A such that $\mathrm{P}^A = (\mathrm{NP}[g(n,0)])^A$ and $(\mathrm{NP}[g(n,2i)])^A \neq (\mathrm{NP}[g(n,2i+1)])^A = (\mathrm{NP}[g(n,2i+2)])^A \neq (\text{co-NP}[g(n,2i+2)])^A$ for all $i \ge 0$ (and in fact there are tally sets in $(\mathrm{NP}[g(n,2i+1)])^A - (\mathrm{NP}[g(n,2i)])^A$ and in $(\mathrm{NP}[g(n,2i+2)])^A - (\text{co-NP}[g(n,2i+2)])^A$ for each i).*

Sketch. We will separate $(\mathrm{NP}[g(n,2i+1)])^A$ from $(\text{co-NP}[g(n,2i+1)])^A$ rather than $(\mathrm{NP}[g(n,2i+2)])^A$ from $(\text{co-NP}[g(n,2i+2)])^A$; given the other requirements, this is equivalent. In order to separate $(\mathrm{NP}[g(n,2i+1)])^A$ from $(\text{co-NP}[g(n,2i+1)])^A$, we use the set D^A_{2i+1} in $(\mathrm{NP}[g(n,2i+1)])^A$ and guarantee that $D^A_{2i+1} \notin (\text{co-NP}[g(n,2i+1)])^A$. Most of this construction is identical to that of Theorem 2.7, except that we interleave an extra diagonalization into the construction; the codings and diagonalizations are analogous to earlier constructions, and the counting argument is identical.

We code complete sets C^A_{2i} for $(\mathrm{NP}[g(n,2i)])^A$ into $(\mathrm{NP}[g(n,2i-1)])^A$, and diagonalize so that no $(\mathrm{NP}[g(n,2i)])^A$ machine recognizes $D^A_{2i+1} \in (\mathrm{NP}[g(n,2i+1)])^A$. (Thus D^A_{2i+1} does double duty: during even stages, it diagonalizes against $(\mathrm{NP}[g(n,2i+2)])^A$, and during odd stages, against $(\text{co-NP}[g(n,2i+1)])^A$.)

To guarantee that D^A_{2i+1} is not in $(\text{co-NP}[g(n,2i+1)])^A$, we make sure that, for

each e, the eth machine for $(\mathrm{NP}[g(n,2i+1)])^A$ does not recognize $\overline{D^A_{2i+1}}$. This holds if and only if there is some x such that $D^A_{2i+1}(x) = M^A_{e,2i+1}(x)$. This diagonalization differs from earlier ones only when $M^A_{e,2i+1}(x)$ queries a witness for $x \in D^A_{2i+1}$. As before, if $M^A_{e,2i+1}(x)$ queries a coding string for some computation of $C^A_{2j}(w)$ where $2j > 2i$ or $2j = 2i$ and $w \neq x$, then we can safely restrain the coding string. (If $2j = 2i$ and $w \neq x$, this may exclude w from D^A_{2i+1}, but that doesn't matter. As long as $D^A_{2i+1}(x) = M^A_{e,2i+1}(x)$, we don't care what happens to D^A_{2i+1} for other strings of lengths between n_{s-1} and n_s, where $s = \langle e, i\rangle$.) If $2j < 2i$, then we retrace the computation, as before.

If $M^A_{e,2i+1}(x)$ queries a witness for $x \in D^A_{2i+1}$, we first restrain all such witnesses and continue. If this leads to a rejecting computation of $M^A_{e,2i+1}(x)$, then $M^A_{e,2i+1}(x) = D^A_{2i+1}(x)$, and the diagonalization is successful. If it leads to an accepting computation, we preserve the lexicographically least accepting path for that computation, and all of its cascade of queries. As before, the computation of $M^A_{e,2i+1}(x)$ restrains at most $2^{o(g(n,2i+1))}$ strings, so this will not restrain all the witnesses for $x \in D^A_{2i+1}$. Thus we can find an unrestrained witness and add it to A, so $D^A_{2i+1}(x) = M^A_{e,2i+1}(x)$, as desired.

Therefore, this additional set of diagonalization requirements can be interleaved with the previously described diagonalizations and collapses. □

THEOREM 2.11. *Let $g(\cdot,\cdot)$ be a polynomial-time computable, monotone increasing (in both variables) function with $\log n \in o(g(n,i))$ and $g(n,i) \in n^{O(1)}$ for all $i \geq 1$. If $g(n^{O(1)}, 2i) \subseteq o(g(n, 2i+1))$ for all $i \geq 1$, then there exists an oracle A such that $\mathrm{P}^A = (\mathrm{NP}[g(n,0)])^A$ and $(\mathrm{NP}[g(n,2i)])^A \neq (\mathrm{NP}[g(n,2i+1)])^A = (\mathrm{NP}[g(n,2i+2)])^A = (\text{co-NP}[g(n,2i+2)])^A$ for all $i \geq 0$ (and in fact there are tally sets in $(\mathrm{NP}[g(n,2i+1)])^A - (\mathrm{NP}[g(n,2i)])^A$ for each i).*

Sketch. As before, we construct A so that no $(\mathrm{NP}[g(n,2i)])^A$ machine recognizes the set D^A_{2i+1}, and so that $C^A_{2i+2} \in (\mathrm{NP}[g(n,2i+1)])^A$. In addition, in order to make $(\mathrm{NP}[g(n,2i+1)])^A = (\text{co-NP}[g(n,2i+1)])^A$, we code $\overline{C^A_{2i+1}}$ into $(\mathrm{NP}[g(n,2i+1)])^A$ as follows: $x \notin C^A_{2i+1} \iff \exists y[|y| = g(|x|, 2i+1) \wedge 21^{p(|x|,2i+1)^2}0x \in A]$.

For each i, let N^A_i be an $(\mathrm{NP}[g(n,i)])^A$ machine recognizing C^A_i in nondeterministic time bounded by $p(n,i)$ (regardless of the oracle). By the form of the encoding, $N^A_i(x)$ cannot query any of its own coding strings. If a witness string for $\overline{C^A_{2j+1}(x)}$ is queried in the course of a diagonalization $(\mathrm{NP}[g(n,2i)])^A \neq (\mathrm{NP}[g(n,2i+1)])^A$, and $2j+1 < 2i+1$, then we can retrace the computation. If $2j+1 \geq 2i+1$, then we can restrain the queried witness string (for $|x|$ sufficiently large) without deciding $\overline{C^A_{2j+1}(x)}$, by the same counting argument as in previous proofs.

Thus, we can add this extra encoding, without interfering with the other collapses and codings. □

This gives us the following stronger version of Hemachandra and Jha's oracle [8].

COROLLARY 2.12. *For each k, there is an oracle relative to which for all j, $\beta_j = \text{co-}\beta_j$, and*

$$\mathrm{P} = \beta_k \neq \beta_{k+1} \neq \beta_{k+2} \neq \cdots$$

(and the separations are witnessed by tally sets).

Combining the results (and techniques) of Theorems 2.7, 2.10, and 2.11, we get the following very strong result.

COROLLARY 2.13. *For any consistent set of requirements, there is an oracle relative to which the β hierarchy satisfies those requirements.*

In constructing such an oracle, one must be careful in closing classes under complement. In particular, if we close one class under complement and separate another from its complement, we cannot then make the two classes equal.

Corollary 2.9 implies that there are uncountably many different patterns of collapse that can be realized in relativized worlds. If the set of requirements is recursive, then the oracle can be made recursive, but certainly some of those patterns are realized by only nonrecursive oracles.

3. Dense β hierarchies. Previously we considered β_r only when r is a natural number. But the class $(\mathrm{NP}[\log^r n])^A$ is meaningful whenever r is a nonnegative real number (regardless of whether r is computable). Even when we allow r to be real, we can make the β hierarchy obey any consistent set of requirements. For example, we can make the β hierarchy look like a Cantor set.

THEOREM 3.1. *Let X be any subset of $[1,\infty)$. There exists an oracle A such that, for all $s,t \geq 1$, $\beta_s^A = \beta_t^A$ if and only if $[s,t] \subseteq X$.*

Note that there may be uncountably many distinct β_t's. Because there are two rationals between any two reals, we need only separate the distinct β_q's where q is rational.

Proof. Without loss of generality, assume that X is a union of intervals, each containing more than one point. Every interval in X contains a rational point; therefore X contains countably many intervals.

We will satisfy the following requirements for each maximal interval in X, depending on its type:
$[s,t]$: $\mathrm{NP}[\log^s n] = \mathrm{NP}[\log^t n]$,
$[s,t)$: $\mathrm{NP}[\log^s n] = \mathrm{NP}[\log^t n/\log\log n]$,
$(s,t]$: $\mathrm{NP}[\log^s n \log\log n] = \mathrm{NP}[\log^t n]$,
(s,t) : $\mathrm{NP}[\log^s n \log\log n] = \mathrm{NP}[\log^t n/\log\log n]$,
$[s,\infty)$: $\mathrm{NP}[\log^s n] = \mathrm{NP}[n]$,
(s,∞) : $\mathrm{NP}[\log^s n \log\log n] = \mathrm{NP}[n]$.
In addition, for each rational number q in $(1,\infty) - X$, we will make

$$\mathrm{NP}[\log^q n/\log\log n] \neq \mathrm{NP}[\log^q n] \neq \mathrm{NP}[\log^q n \log\log n].$$

If $1 \notin X$, then we make $\mathrm{P} \neq \mathrm{NP}[\log n \log\log n]$ as well.

The construction is a slight modification of that in the proof of Theorem 2.7. We perform the diagonalizations in some well-founded order, while maintaining the codings as we go along. The only significant difference here is that the diagonalizations are not performed in increasing order. Suppose that at some stage we are making $\mathrm{NP}[a(n)] \subset \mathrm{NP}[b(n)]$ and a coding string for some $\mathrm{NP}[c(n)]$ computation is queried; we restrain that string if and only if $(\exists n)[c(n) > b(n)]$ if and only if $(\forall n)[c(n) \geq b(n)]$. The counting argument is the same as before. □

Note that we could also close each distinct β_r under complement or not, as we wish, in the theorem above.

4. Open problems. The class β_k is contained in $\mathrm{NP} \cap \mathrm{DTIME}(2^{\log^k n})$. Our work shows that there is no relativizing proof that $\mathrm{P} = \beta_2 \Rightarrow \mathrm{P} = \mathrm{NP}$. We would like to know whether $\mathrm{P} = \mathrm{NP} \cap \mathrm{DTIME}(n^{\log n})$ implies $\mathrm{P} = \mathrm{NP}$; i.e., if $\mathrm{P} \neq \mathrm{NP}$, are there any easy languages in $\mathrm{NP} - \mathrm{P}$? The best we can show is that if $\mathrm{P} = \mathrm{NP} \cap \mathrm{DTIME}(f(n))$ for a well-behaved function f, then $\mathrm{P} = \mathrm{NP} \cap \mathrm{DTIME}(f(f(n)))$. Is there an oracle relative to which this is the best possible translation of the collapse? Does $\mathrm{P} = \mathrm{NP} \cap \mathrm{DTIME}(2^{\log^k n})$ imply $\mathrm{P} = \mathrm{NP}$?

Acknowledgments. We are grateful to Leen Torenvliet, Andrew Klapper, and Martin Kummer for helpful discussions, and Andrew Klapper, Bill Gasarch, and Martin Kummer for careful proofreading of earlier drafts.

THE PL HIERARCHY COLLAPSES*

MITSUNORI OGIHARA†

Abstract. It is shown that the PL hierarchy $\mathrm{PLH} = \mathrm{PL} \bigcup \mathrm{PL}^{\mathrm{PL}} \bigcup \mathrm{PL}^{\mathrm{PL}^{\mathrm{PL}}} \bigcup \cdots$, defined in terms of the Ruzzo–Simon–Tompa relativization, collapses to PL.

Key words. probabilistic complexity classes, nondeterministic complexity classes, logspace reducibility, constant-depth circuits, relativization

1. Introduction. The oracle separations proven by Baker, Gill, and Solovay [2] initiated the study of complexity classes by relativization. Since that work, various relativization models for nondeterministic logspace have been introduced [13, 19, 16, 18]. Ladner and Lynch [13] and I. Simon [19] studied the models that allow oracle machines to make nondeterministic moves while generating query strings and to generate polynomially long query strings. Unfortunately, their models produce some counterintuitive results. With NL as the oracle, NL becomes NP while P remains P. On the other hand, Rackoff and Seiferas [16] studied the model that allows nondeterministic moves during query generation but demands the query strings be logarithmic length-bounded, even for deterministic logspace machines. This model does not produce reverse inclusions, but oracles do not have much power. Even with QBF as the oracle, NL remains NL. To overcome the problems of these models, Ruzzo, J. Simon, and Tompa [18] proposed to allow polynomially long query strings and to demand that nondeterministic Turing machines run deterministically while generating query strings. The Ruzzo–Simon–Tompa model is reasonable. Nonrelativized inclusions of logspace classes such as $\mathrm{L} \subseteq \mathrm{NL} \subseteq \mathrm{P}$ hold for every oracle, and powerful oracles make NL bigger, e.g., NL relative to QBF is PSPACE. Because of the reasonability, the Ruzzo–Simon–Tompa model is widely used as the standard relativization model. By extending the restriction to probabilistic computation as well, one can examine classes defined by stacks of logspace classes. But does this make sense? Ruzzo, Simon, and Tompa show that the hierarchy with respect to BPL [10] (bounded-error probabilistic logspace with unlimited computation time) collapses to BPL. Since $\mathrm{NL} \subseteq \mathrm{BPL}$ [10], stacks of NL and BPL never go beyond BPL. Also, the $\mathrm{NL} = \mathrm{coNL}$ theorem [11, 20] has collapsed the NL hierarchy to NL. So, one might wonder whether similar collapse results hold for other logspace classes, in particular, PL. Do we have any intuition concerning stacks of PL? It is known that PL is somewhere between NC^1 and NC^2 [7], but this does not indicate anything about where a stack of PLs will lie. Moreover, stacks of its relative, PP, do not seem to collapse (see, e.g., [5]). But, guessing that $\mathrm{PL}^{\mathrm{PL}} \neq \mathrm{PL}$ by analogy is perhaps too simplistic. In this paper, we resolve the question by showing that $\mathrm{PL}^{\mathrm{PL}} = \mathrm{PL}$, i.e., that the PL hierarchy collapses.

The proof is built on top of the characterization of relativized PL in terms of

GapL-functions [1] based on Jung's observation that $\mathrm{PL}_{\mathrm{poly}}$, the polynomial time-bounded version of PL, is identical to PL [12]. GapL is the class of functions that count the difference between the number of accepting computation paths and that of rejecting computation paths of nondeterministic Turing machines (see [8, 1]). Furthermore, the proof makes use of the "polynomial technique" developed in papers [14, 15, 6, 9]. In particular, our proofs borrow much of their construction from that of Fortnow and Reingold [9], who show that PP is closed under polynomial-time truth-table reductions.

This paper is organized as follows. In section 2, we define the class PL and present a useful characterization of the class. Section 3 provides the proof of the collapse result.

2. Preliminaries.

2.1. A characterization of PL. We first define the class PL.

DEFINITION 2.1 (see [10]). *A language L belongs to* PL *if there is a logarithmic space-bounded probabilistic Turing machine M with no time-bound such that for every x, $x \in L$ if and only if the probability that M on x accepts is at least a half.*

An immediate question is whether demanding that the machine M be polynomial time-bounded makes the class smaller. Let $\mathrm{PL}_{\mathrm{poly}}$ denote the class defined similarly to PL, but with a polynomial time-bound on M. Jung [12] showed that these classes are identical. Moreover, the equivalence holds relative to any oracle.

PROPOSITION 2.2 (see [1]). *For every oracle H, $\mathrm{PL}^H = (\mathrm{PL}_{\mathrm{poly}})^H$.*

This equivalence allows us to introduce counting classes that capture PL. For a nondeterministic Turing machine M and a string x, let $acc_M(x)$ (respectively, $rej_M(x)$) denote the number of accepting (respectively, rejecting) computation paths of M on x, and let $gap_M(x)$ denote $acc_M(x) - rej_M(x)$. Define the logspace analogue GapL [1] of GapP [8] as follows.

$$\mathrm{GapL} = \{gap_M \mid M \text{ is a logarithmic space-bounded and polynomial time-bounded nondeterministic Turing machine }\}.$$

By replacing the probabilistic coin tosses by nondeterministic moves, we obtain the following characterization of PL.

PROPOSITION 2.3 (see [1]). *$L \in \mathrm{PL}$ if and only if there exists $f \in \mathrm{GapL}$ such that for every x, $x \in L$ if and only if $f(x) \geq 0$.*

The following properties of GapL can be proven using techniques similar to those used for GapP in [8].

THEOREM 2.4. *Let f be a function in* GapL, *$g : \Sigma^* \times \mathbf{N} \mapsto \Sigma^*$ be a function in* FL, *and p be a polynomial. Then the following functions h_1, h_2, and h_3 all belong to* GapL*:*

1. $h_1(x) = -f(x)$,
2. $h_2(x) = \sum_{i=1}^{p(|x|)} f(g(x,i))$,
3. $h_3(x) = \prod_{i=1}^{p(|x|)} f(g(x,i))$.

Given a function $f \in \mathrm{GapL}$ witnessing that a language L is in PL, define g by $g(x) = 2f(x) + 1$. Then g always takes on odd values and witnesses that L is in PL.

PROPOSITION 2.5. *A language L is in* PL *if and only if there exists a function f in* GapL *such that for every x,*

$$f(x) \geq 1 \text{ if } x \in L \text{ and } f(x) \leq -1 \text{ otherwise.}$$

2.2. The polynomials. Now we define the polynomials that play a crucial role in the proof. These were defined in [6] and [9].

DEFINITION 2.6. *Let $m \geq 1$ and $k \geq 1$. Define polynomials $\mathcal{P}_m(z)$ and $\mathcal{Q}_m(z)$ in $\mathbf{Z}[z]$ by*

$$\mathcal{P}_m(z) = (z-1)\prod_{i=1}^{m}(z-2^i)^2 \quad \textit{and} \tag{1}$$

$$\mathcal{Q}_m(z) = -(\mathcal{P}_m(z) + \mathcal{P}_m(-z)), \tag{2}$$

and define $\mathcal{R}_{m,k}(z)$ and $\mathcal{S}_{m,k}(z)$ by

$$\mathcal{R}_{m,k}(z) = \left(\frac{2\mathcal{P}_m(z)}{\mathcal{Q}_m(z)}\right)^{2k} \quad \textit{and} \tag{3}$$

$$\mathcal{S}_{m,k}(z) = (1+\mathcal{R}_{m,k}(z))^{-1}. \tag{4}$$

Furthermore, define polynomials $\mathcal{A}_{m,k}(z)$ and $\mathcal{B}_{m,k}(z)$ by

$$\mathcal{A}_{m,k}(z) = \mathcal{Q}_m(z)^{2k} \quad \textit{and} \tag{5}$$

$$\mathcal{B}_{m,k}(z) = \mathcal{Q}_m(z)^{2k} + (2\mathcal{P}_m(z))^{2k}. \tag{6}$$

LEMMA 2.7. *For every $m, k \geq 1$ and every z, the following properties hold.*

1. $\mathcal{S}_{m,k}(z) = \mathcal{A}_{m,k}(z)/\mathcal{B}_{m,k}(z)$.
2. *If $1 \leq z \leq 2^m$, then $1 - 2^{-k} \leq \mathcal{S}_{m,k} \leq 1$.*
3. *If $-2^m \leq z \leq -1$, then $0 \leq \mathcal{S}_{m,k}(z) \leq 2^{-k}$.*

Proof. Let $m, k \geq 1$. The first equivalence follows from a simple calculation. Note that $\mathcal{P}_m(z)$ is nonnegative if and only if $z \geq 1$. Let z be ≥ 1. We claim that $\mathcal{P}_m(z) \leq |\mathcal{P}_m(-z)|/4$. This is seen as follows. Clearly, if $z = 1$, then $\mathcal{P}_m(z) = 0 \neq \mathcal{P}_m(-z)$, and thus, the claim holds. On the other hand, if $z > 1$, then there exists a unique $t, 1 \leq t \leq m$, such that $2^t \leq z < 2^{t+1}$, which satisfies $|z - 2^t| \leq z/2 \leq |-z-2^t|/2$. Noting that $|z-1| \leq |-z-1|$ and for every $i, 1 \leq i \leq m$, that $|z-2^i| \leq |-z-2^i|$, we have $\mathcal{P}_m(z) \leq |\mathcal{P}_m(-z)|/4$.

Thus the claim is proven. So, for every z,

$$0 \leq \frac{2\mathcal{P}_m(z)}{\mathcal{Q}_m(z)} \leq \frac{2}{3} \text{ if } 1 \leq z \leq 2^m \text{ and } \frac{2\mathcal{P}_m(z)}{\mathcal{Q}_m(z)} \leq -2 \text{ if } -2^m \leq z \leq -1.$$

Since $(2/3)^2 \leq 1/2$, for every z,

$$0 \leq \mathcal{R}_{m,k}(z) \leq 2^{-k} \text{ if } 1 \leq z \leq 2^m \text{ and } \mathcal{R}_{m,k}(z) \geq 2^k \text{ if } -2^m \leq z \leq -1.$$

Since $\mathcal{S}_{m,k}(z) = (1+\mathcal{R}_{m,k}(z))^{-1}$ and $(1+2^{-k})(1-2^{-k}) < 1$, for every $z, 1 \leq z \leq 2^m$, we have

$$1 - 2^{-k} \leq \mathcal{S}_{m,k}(z) \leq 1.$$

Also, by observing that $(1+2^k)^{-1} \leq 2^{-k}$, we see that $0 \leq \mathcal{S}_{m,k}(z) \leq 2^{-k}$, for all z in the range $[-2^m, -1]$. This proves the lemma. □

3. The PL hierarchy collapses. The following lemma states that logarithmic space-bounded oracle Turing machines can be normalized so that the queries, including the query order, are independent of the oracle.

LEMMA 3.1. *Let $L \in \mathrm{PL}^H$ for some oracle H. Then there exist polynomials p and q and a logarithmic space-bounded nondeterministic Turing machine N such that for every x, the following properties hold.*

1. *On input x, N makes exactly $p(|x|)$ queries and exactly $q(|x|)$ nondeterministic moves, independent of the oracle. Moreover, N on x makes no nondeterministic moves while generating queries, and the queries are independent of the oracle as well.*

2. *For each $i, 1 \leq i \leq p(|x|)$, the ith query of N is computable in logarithmic space from x and i.*

3. *$x \in L$ if and only if $gap_{N^H}(x) > 0$, and $x \notin L$ if and only if $gap_{N^H}(x) < 0$.*

Proof. Let M be the base probabilistic logarithmic space-bounded machine witnessing that $L \in \mathrm{PL}^H$. By Proposition 2.2, we may assume that M is polynomial time-bounded. There is a polynomial q_0 such that for every x, M on x tosses at most $q_0(|x|)$ coins no matter what its oracle may be. By normalizing the number of coin-tosses, without changing the acceptance probability, we can modify M so that M tosses exactly $q_0(|x|)$ coins. On the other hand, since M behaves deterministically while generating queries, each potential query of M on x can be encoded using a string of length $O(\log |x|)$, where the string denotes the ID (the head positions, the state, and the contents of the work-tapes) at which M starts to generate the query. Let r_1 be a polynomial bounding the running time of M and let r_2 be a polynomial bounding the number of queries M could potentially make. Let $p(n) = r_1(n)r_2(n)$. Let M' be a Turing machine that simulates M as follows.

- When M starts to generate a query, say u, M' records the current ID, say I_0.
- When M enters the query state, M' makes all the potential queries of M on x by cycling through all the possible IDs I of M on input x and asking the query generated by each ID. Each time a query is made, M' tests whether $I = I_0$. If $I = I_0$, then M' stores the answer from the oracle in a memory cell. Otherwise, the answer is discarded. Also, M' computes the count C of the number of queries that are made while cycling through all the potential IDs. When all the potential queries have been made, M' compares the count C with $r_2(|x|)$. If $C < r_2(|x|)$, then M' makes additional queries about the empty string $r_2(|x|) - C$ times. The answers to these queries are discarded. With these additional queries, M' will have made exactly $r_2(|x|)$ queries for the ID I_0. Now M' returns to the simulation of M on x with the stored answer.
- The machine M' also keeps the number Q of query rounds that have been made so far. When M enters a halting state, if the number Q is smaller than $r_1(|x|)$, then M' executes the above query round exactly $r_1(|x|) - Q$ times with some fixed ID and discards the answers. With these additional query rounds, M' will have made exactly $r_1(|x|)$ query rounds. Now M' accepts if and only if M has accepted in the simulation.

It is obvious that M' satisfies conditions (1) and (2). Now replace the coin tosses of M' by nondeterministic choices. Let M'' be the resulting machine. The probability that M' on x accepts relative to H is equal to the ratio of the number of accepting computation paths of M'' on x relative to H. Define M_1 to be the Turing machine that, on input x, guesses one bit b and then simulates M'' on x. The number of accepting (rejecting) computation paths of M_1 on x is twice as many as that of M'' on x. Also, define M_2 to be the Turing machine that, on input x, guesses a bit b, simulates M'' on x, and accepts x if and only if either (the bit $b = 0$) or (the bit $b = 1$ and all the nondeterministic guesses for simulating M'' are 0). Then, M_2 on x has exactly $2^{q_0(|x)} + 1$ accepting paths. Now define N to be the machine that, on input x, guesses $i \in \{1, 2\}$, and simulates M_i on x, and accept if and only if M_i on x accepts. Let $q(n) = q_0(n) + 2$. Then N satisfies (1) and (2). It is easy to see that (3)

is satisfied, too. □

THEOREM 3.2. $\mathrm{PL}^{\mathrm{PL}} = \mathrm{PL}$.

Proof. Let $L \in \mathrm{PL}^{\mathrm{PL}}$ be witnessed by a nondeterministic Turing machine N and a language $H \in \mathrm{PL}$ satisfying the conditions in Lemma 3.1 with polynomials p and q. Without loss of generality, we may assume that $p(n), q(n) > 1$ for all n. For each x and $i, 1 \leq i \leq p(|x|)$, let $y_{x,i}$ denote the ith query asked by N on x. Let f be a function in GapL witnessing that $H \in \mathrm{PL}$ as in Proposition 2.5. There exists a polynomial μ such that for every x and $i, 1 \leq i \leq p(|x|)$, $1 \leq |f(y_{x,i})| \leq 2^{\mu(|x|)}$. Let us fix such a polynomial μ. Define $\kappa(n) = p(n) + q(n) + 1$, and define for each x and $i, 1 \leq i \leq p(|x|)$,

$$S(x,i,1) = \mathcal{S}_{\mu,\kappa}(f(y_{x,i})) \text{ and } S(x,i,0) = 1 - \mathcal{S}_{\mu,\kappa}(f(y_{x,i})),$$

where $\mathcal{S}_{\mu,\kappa}$ is short-hand for $\mathcal{S}_{\mu(|x|),\kappa(|x|)}$. By Lemma 2.7, for every x, $i, 1 \leq i \leq p(|x|)$, and $b \in \{0,1\}$,

(7) if $\chi_H(y_{x,i}) = b$, then $1 - 2^{-\kappa(|x|)} \leq S(x,i,b) \leq 1$, and

(8) if $\chi_H(y_{x,i}) \neq b$, then $0 \leq S(x,i,b) \leq 2^{-\kappa(|x|)}$.

Furthermore, define

$$\begin{aligned} \alpha(x,i,1) &= \mathcal{A}_{\mu,\kappa}(f(y_{x,i})), \\ \alpha(x,i,0) &= \mathcal{B}_{\mu,\kappa}(f(y_{x,i})) - \mathcal{A}_{\mu,\kappa}(f(y_{x,i})), \text{ and} \\ \beta(x,i) &= \mathcal{B}_{\mu,\kappa}(f(y_{x,i})). \end{aligned}$$

Then for every x, $i, 1 \leq i \leq p(|x|)$, and $b \in \{0,1\}$,

$$S(x,i,b) = \alpha(x,i,b)/\beta(x,i).$$

For each x and $w \in \{0,1\}^{p(|x|)}$, define

$$\widetilde{S}(x,w) = \prod_{i=1}^{p(|x|)} S(x,i,w_i),$$

where w_i denotes the ith bit of w. Then, by (7) and (8), we have

(9) if $w = \chi_H(y_{x,1}) \cdots \chi_H(y_{x,p(|x|)})$, then $1 - p(|x|)2^{-\kappa(|x|)} \leq \widetilde{S}(x,w) \leq 1$, and

(10) if $w \neq \chi_H(y_{x,1}) \cdots \chi_H(y_{x,p(|x|)})$, then $0 \leq \widetilde{S}(x,w) \leq 2^{-\kappa(|x|)}$.

Define

$$\widetilde{\alpha}(x,w) = \prod_{i=1}^{p(|x|)} \alpha(x,i,w_i) \quad \text{and}$$

$$\widetilde{\beta}(x) = \prod_{i=1}^{p(|x|)} \beta(x,i).$$

Then, for every x and w,

$$\widetilde{S}(x,w) = \widetilde{\alpha}(x,w)/\widetilde{\beta}(x).$$

Define the predicate e as follows:

(11) For each x, $w, |w| = p(|x|)$, and $u, |u| = q(|x|)$, $e(x, w, u) = 1$ if and only if N on input x with nondeterministic guesses u accepts assuming that the answer to the ith query is affirmative if and only if $w_i = 1$.

Define

$$T(x) = \sum_{w,u:|w|=p(|x|),|u|=q(|x|)} e(x,w,u)\widetilde{S}(x,w) \quad \text{and}$$
$$a(x) = \sum_{w,u:|w|=p(|x|),|u|=q(|x|)} e(x,w,u)\widetilde{\alpha}(x,w).$$

Clearly, $T(x) = a(x)/\beta(x)$. By (9) and (10), the following properties hold.

1. For each x, there is a unique $w_x \in \Sigma^{p(|x|)}$ such that $1 - p(|x|)2^{-\kappa(|x|)} \leq \widetilde{S}(x, w_x) \leq 1$ and for every $w \neq w_x$, $0 \leq \widetilde{S}(x, w) \leq 2^{-\kappa(|x|)}$.

2. If $x \in L$, then the number of $u, |u| = q(|x|)$, such that $e(x, w_x, u) = 1$ is at least $2^{q(|x|)-1} + 1$.

3. If $x \notin L$, then the number of $u, |u| = q(|x|)$, such that $e(x, w_x, u) = 1$ is at most $2^{q(|x|)-1} - 1$.

Recall that $\kappa(n) = p(n) + q(n) + 1$ and $p(n), q(n) > 1$. For every x, if $x \in L$, then

$$\begin{aligned} T(x) &\geq 2^{q(|x|)-1}(1 - p(|x|)2^{-\kappa(|x|)}) \\ &\geq (2^{q(|x|)-1} + 1)(1 - 2^{p(|x|)}2^{-\kappa(|x|)}) \\ &= 2^{q(|x|)-1} + (1 - 2^{p(|x|)}2^{-\kappa(|x|)}) - 2^{q(|x|)-1}2^{p(|x|)}2^{-\kappa(|x|)} \\ &\geq 2^{q(|x|)-1} + 1/2 - 1/4 \\ &> 2^{q(|x|)-1}, \end{aligned}$$

so $T(x) > 2^{q(|x|)-1}$, and if $x \notin L$, then

$$\begin{aligned} T(x) &\leq (2^{q(|x|)-1} - 1) + 2^{p(|x|)+q(|x|)}2^{-\kappa(|x|)} \\ &= 2^{q(|x|)-1} - 1 + 2^{-1} \\ &< 2^{q(|x|)-1} - 1/2, \end{aligned}$$

so $T(x) < 2^{q(|x|)-1}$. This implies that for every x, $x \in L$ if and only if $T(x) > 2^{q(|x|)-1}$ and $x \notin L$ if and only if $T(x) < 2^{q(|x|)-1}$. Finally, define $h(x) = 4a(x) - 2^{q(|x|)+1}\beta(x)$. Then, for every x, $x \in L$ if and only if $h(x) \geq 0$.

It remains to show that h is in GapL. Define π to be the function that maps w to $2^{|w|}$. The constant 2 function is trivially in GapL and so, by part (3) of Theorem 2.4, $\pi \in$ GapL. So, one can prove that the function that maps x to $\mathcal{P}_{\mu(|x|)}(f(x))$, i.e., $(f(x) - 1)\prod_{i=1}^{\mu(|x|)}(f(x) - \pi(0^i))^2$, is in GapL by combining the three parts of Theorem 2.4. For much the same reason, the function that maps x to $\mathcal{Q}_{\mu(|x|)}(f(x))$ is in GapL. Since $y_{x,i}$ is logarithmic-space computable, by Theorem 2.4, $\alpha, \beta \in$ GapL. This implies $\widetilde{\beta} \in$ GapL. Since the function that maps x to $2^{q(|x|)+1}$ clearly belongs to GapL, we have only to show that a is in GapL.

Let D be a logarithmic space-bounded nondeterministic Turing machine witnessing that $\alpha \in$ GapL; that is, $\alpha = gap_D$. Note that D on input $\langle x, i, b\rangle$ with $1 \leq i \leq p(|x|)$ and $b \in \{0, 1\}$ can be simulated in $\mathcal{O}(\log |x|)$ space. Define G to be the nondeterministic Turing machine that, on input x, behaves as follows.

Step 1. G first sets a one-bit memory c to 0.

Step 2. G starts simulating N on x nondeterministically; that is, if N makes its ith nondeterministic move, then so does G by guessing bit u_i. When N makes its ith query $y_{x,i}$, G does the following.

(a) G nondeterministically guesses $w_i \in \{0,1\}$ and simulates D on $\langle x, i, w_i\rangle$. If D rejects, then G flips bit c.

(b) G returns to the simulation of N on x assuming that the answer to the query is affirmative if and only if $w_i = 1$.

Step 3. When N enters the halting state, G does the following.

(a) If N has accepted, then G accepts if and only if $c = 0$.

(b) If N has rejected, then G nondeterministically guesses a bit $d \in \{0,1\}$ and accepts if and only if $d = 0$.

Note that, at the beginning of Step 3, $e(x,w,u) = 1$ holds if and only if N has accepted with w and u. In the case when N has rejected, and thus, $e(x,w,u) = 0$, G generates one accepting path and one rejecting path, so there is no contribution to $gap_G(x)$ from this w and u. In the case when N has accepted, and thus, $e(x,w,u) = 1$, the one-bit memory c is the parity of the number of accepting simulations of D that G has encountered. Since G accepts if and only if the parity is 0, the number of accepting computation paths along w and u is the sum of all

$$\prod_{i \notin I} acc_D(x,i,w_i) \prod_{i \in I} rej_D(x,i,w_i)$$

with I ranging over all subsets of $\{1, \ldots, p(|x|)\}$ of even cardinality. Also, the number of rejecting computation paths generated along w and u is the sum of all

$$\prod_{i \notin I} acc_D(x,i,w_i) \prod_{i \in I} rej_D(x,i,w_i)$$

with I ranging over all subsets of $\{1, \ldots, p(|x|)\}$ of odd cardinality. Note, for every i and w_i, that $acc_D(x,i,w_i) - rej_D(x,i,w_i) = gap_D(x,i,w_i)$. Thus, the difference between the above two sums is equal to

$$\prod_{i=1}^{p(|x|)} (acc_D(x,i,w_i) - rej_D(x,i,w_i)) = \prod_{i=1}^{p(|x|)} gap_D(x,i,w_i).$$

Thus, for every x,

$$\begin{aligned} gap_G(x) &= \sum_{w,u:|w|=p(|x|)|u|=q(|x|)} e(x,w,u) \prod_{i=1}^{p(|x|)} \alpha(x,i,w_i) \\ &= \sum_{w,u:|w|=p(|x|),|u|=q(|x|)} e(x,w,u)\widetilde{\alpha}(x,w) \\ &= a(x). \end{aligned}$$

Hence, a is in GapL. This proves the theorem. □

Allender and Ogihara [1] observe that the PL hierarchy coincides with the logspace uniform AC^0 closure of PL. So, we immediately obtain the following corollary.

COROLLARY 3.3. $PLH = AC^0(PL) = PL$.

The closure can be strengthened further. Given any constant-depth circuit, by slicing the circuits into levels and by using the fact that $\mathrm{PL}^{\mathrm{PL}} = \mathrm{PL}$, one can collapse the two levels into one.

COROLLARY 3.4. PL *is closed under logspace-uniform, constant-depth reductions with arbitrary symmetric functions as gates.*

In particular, PL is closed under logspace-uniform TC^0-reductions [17] and under logspace-uniform ACC-reductions [3].

Can we extend the closure property to nonconstant-depth circuits? Recently, Beigel and Fu have reported that the answer is positive: PL is closed under NC^1-reductions [4]. The result leaves us with the question of whether logarithmic-depth semiunbounded fan-in circuits SAC^1 are in PL, and, if so, whether PL is closed under SAC^1-reductions.

Acknowledgment. The author thanks Eric Allender, Richard Beigel, Lance Fortnow, Janos Simon, and Marius Zimand for enjoyable discussions, and anonymous referees for invaluable comments.

GENERATING LOW-DEGREE 2-SPANNERS*

GUY KORTSARZ† AND DAVID PELEG‡

Abstract. A k-spanner of a connected (undirected unweighted) graph $G = (V, E)$ is a subgraph G' consisting of all the vertices of V and a subset of the edges, with the additional property that the distance between any two vertices in G' is larger than that distance in G by no more than a factor of k. This paper is concerned with approximating the problem of finding a 2-spanner in a given graph, with minimum maximum degree. We first show that the problem is at least as hard to approximate as set cover. Then a randomized approximation algorithm is provided for this problem, with approximation ratio of $\tilde{O}(\Delta^{1/4})$. We then present a probabilistic algorithm that is more efficient for sparse graphs. Our algorithms are converted into deterministic ones using derandomization.

Key words. graph spanners, NP-hardness, approximation, randomized rounding

1. Introduction.

The concept of *graph spanners* has been studied in several recent papers in the context of communication networks, distributed computing, robotics, and computational geometry [ADDJ90, Cai91, Che86, DFS87, DJ89, LL89, PS89, PU89, LR94, CDNS92]. Consider a connected simple (unweighted) graph $G = (V, E)$, with $|V| = n$ vertices. A subgraph $G' = (V, E')$ of G is a *k-spanner* if for every $u, v \in V$,

$$\frac{\text{dist}(u, v, G')}{\text{dist}(u, v, G)} \leq k,$$

where $\text{dist}(u, v, G')$ denotes the distance from u to v in G', i.e., the minimum number of edges in a path connecting them in G'. We refer to k as the *stretch factor* of G'.

In the Euclidean setting, spanners were studied in [Cai91, DFS87, DJ89, LL89, Soa92]. Spanners for general graphs were first introduced in [PU89], where it was shown that for every n-vertex hypercube there exists a 3-spanner with no more than $7n$ edges and then studied further in [PS89, LR94, ADDJ90, CDNS92]. Spanners were used in [PU89] to construct a new type of synchronizer for an asynchronous network.

The usual criteria for the quality of the spanner are its *stretch* and its *sparsity*. Namely, a good spanner is one with low stretch and as few edges as possible. For the problem of finding a 2-spanner which is as sparse as possible, a logarithmic-ratio approximation is given in [KP94].

However, another parameter of significance when selecting a good spanner is the maximum degree of the spanner. In terms of applications, a high degree might mean a high *local load* on a single vertex, increasing the cost of its local management. For instance, in the application of using a spanner for implementing a δ-synchronizer in a distributed network [PU89], or when using a spanner for efficient broadcast [ABP91],

the degree of each node in the spanner directly translates into memory requirements at the node, and high local degrees mean higher workload on the involved nodes.

It is clear that focusing on optimizing the sparsity measure alone may result in a spanner with high vertex degrees. For example, if there is a vertex v in the graph that is connected to all the rest of the vertices, then its edges form a 2-spanner and, therefore, a k-spanner for any $k \geq 2$. However, in such a choice the local load of v might be too high to handle, while the local load of any other vertex w may be much less than what w can handle. In fact, the algorithm proposed in [KP94] will pick the vertex v and is therefore unsuitable for selecting "balanced load" spanners. It is therefore natural to try to design an algorithm that will perform a more "balanced" selection of the edges. In particular, letting $\Delta(G')$ denote the maximum vertex degree in a spanner G', we consider the question of choosing a k-spanner G' with minimum $\Delta(G')$ for some parameter k. We call this "low degree" variant of the problem LD-kSP. The problem of designing low degree spanners is addressed in [LR94, LS93b, LS93a] for some special graph classes such as pyramids and grids. The problem of designing small degree spanners for Euclidean and geometric graphs is studied in [CDNS92, Soa92]. The distance is measured therein by the appropriate *norm* defined in the vector space.

This paper treats LD-2SP in general graphs. We first show that the problem is at least as hard to approximate as set cover (up to constants). This implies the following results. There is no $\ln n/5$-ratio approximation algorithm for LD-2SP unless $NP \subset DTIME(n^{polylog(n)})$. Also, no approximation algorithm with constant ratio exists for the problem unless $P = NP$. We next give a probabilistic algorithm that outputs a 2-spanner G' such that with high probability $\Delta(G')$ is no more than $\tilde{O}(\Delta^{1/4})$ times the optimum. In other words, our algorithm has an approximation ratio of $\tilde{O}(\Delta^{1/4})$ with high probability. ($\tilde{O}$ is a relaxed variant of the usual O notation that ignores polylogarithmic factors.) The algorithm is then turned into a deterministic one using derandomization.

The technique used in [KP94] to approximate the sparsest 2-spanner problem is the "greedy" method that constructs the spanner gradually, attempting to 2-span a large number of edges in every iteration. (An edge $e = (u, v)$ is 2-*spanned* once either itself or two other edges lying on a triangle with it, say (u, x) and (x, v), are added to the spanner.) The LD-2SP problem seems to be harder to approximate. In particular, the greedy approach seems to fail (i.e., be inefficient) for it. Hence a different (and more involved) approach is required. The technique used in this paper for the LD-2SP problem is a variant of the "randomized rounding" technique of [RT87].

Our algorithm is composed of two different procedures. The first procedure is designed to 2-span edges lying on "many" triangles. The second procedure deals with the yet unspanned edges, i.e., edges that lie on a "small" number of triangles. We describe the "2-spanning" problem for these edges as a linear program, solve it in the fractional setting, and randomly round the fractional solutions. We note that in the rounding process, we use only a subset of the variables. We also note that every variable is rounded with probability considerably exceeding its fractional value. These higher rounding probabilities seem to be needed in order to overcome some "quadratic" behavior of the linear program.

We also present an additional probabilistic algorithm that is efficient for *sparse* graphs. This algorithm can also be transformed into a deterministic one using derandomization.

Finally we deal with the problem of 2-spanning only the edges adjacent to a

small subset $V_k, |V_k| = k$ of the vertices. We give an $O(k \cdot \log n)$-ratio approximation algorithm for this problem. For fixed k, our hardness result implies that unless $NP \subset DTIME(n^{\log \log n})$ this is the best ratio possible (asymptotically).

2. Preliminaries. We start by introducing some definitions. In the sequel, let $G = (V, E)$ be the underlying n-vertex graph. We sometimes use E also to denote the *size* of the set E, i.e., the number of edges. Let $U \subseteq V$ be a subset of the vertices. The graph induced by U is denoted by $G(U)$. The set of edges in $G(U)$ is denoted by $E(U)$. For a vertex v we denote by $E(v)$ the set of edges adjacent to v in G. Similarly, we denote by $N(v)$ the set of neighbors of v in G, i.e.,

$$N(v) = \{u \mid (u, v) \in E\}.$$

We denote the degree of a vertex v by $\deg(v) = |N(v)|$. The maximum degree in a subgraph $G' = (V', E')$, where $V' \subset V$ and $E' \subseteq E$, is denoted by $\Delta(G')$. We denote by $\Delta(E')$ the largest degree in the subgraph (V, E'). We sometimes write Δ for $\Delta(G)$.

We make use of an alternative characterization of k-spanners given in the following simple lemma of [PS89].

LEMMA 2.1 (see [PS89]). *The subgraph $G' = (V, E')$ is a k-spanner of the graph $G = (V, E)$ iff $\text{dist}(u, v, G') \leq k$ for every $(v, u) \in E$.* □

Thus the LD-2SP problem can be restated as follows: we look for a subset of edges $E' \subset E$ such that every edge e that does not belong to E' lies on a triangle with two edges that do belong to E' and such that $\Delta(E')$ is minimum.

Given an edge $e \in E$, let $Tri(e)$ denote the set of triangles e lies on in the graph G. Namely,

$$Tri(e) = \{\{e, e_1, e_2\} \mid e, e_1 \text{ and } e_2 \text{ form a triangle in } G\}.$$

Let $D(e)$ be the set of vertices that lie on a triangle with e but do not touch e. (Note that $|D(e)| = |Tri(e)|$, as each vertex in $D(e)$ corresponds to exactly one triangle in $Tri(e)$.) We say that a vertex $v \in D(e)$ (sharing a triangle T with e) 2-*helps* e in the spanner H if the two edges incident to v on T are chosen into H.

In the sequel we estimate the probability of the deviation of some random variables from their expectation, using the Chernoff bound [Che52].

LEMMA 2.2 (see [Che52]). *Let $X_1, X_2, \ldots, X_m$ be independent Bernoulli trials with $\mathbb{P}(X_i = 1) = p_i$. Let $X = \sum_{i=1}^{m} X_i$ and $\mu = \sum_{i=1}^{m} p_i$. Then*

$$\mathbb{P}(X > (1 + \delta)\mu) < \left[\frac{e^{\delta}}{(1 + \delta)^{(1+\delta)}}\right]^{\mu}.$$ □

In the sequel we assume that $\Delta(G) \geq \Omega(\log^2 n)$. If this is not the case, then taking the entire graph as our spanner results in a polylogarithmic-ratio approximation.

Unless stated otherwise, all logarithms in this paper are taken to the base 2.

3. Basic properties.

3.1. Low degree spanners for general graphs and special graph families. The problem of designing low degree spanners is addressed in [LR94] for the special case where the underlying graph is the *pyramid*. In particular, it is proven therein that this graph enjoys a 2-spanner (respectively, 3, 7) with maximum degree 6 (respectively, 4, 3). The problem of designing small degree spanners for Euclidean and geometric

graphs is studied in [CDNS92, Soa92]. There, however, the distance is measured by the appropriate *norm* defined in the vector space.

We now establish some basic properties concerning the degrees of 2-spanners. The next lemma indicates that for a graph with large Δ, the minimum degree in a 2-spanner must also be large. We prove this by showing that even for the sake of 2-spanning the edges of a *single* vertex v with degree Δ, it is necessary to have a vertex in the spanner with degree at least $\sqrt{\Delta}$.

LEMMA 3.1. *Let v be a vertex of degree d in G. Let $H = (V, E(H))$ be a 2-spanner of G. Then in H either v or some vertex in $N(v)$ has degree at least $\sqrt{d}$.*

Proof. Let t denote the maximum degree of any vertex from $N(v)$ in H. Then the number of vertices reachable from v in two steps over H edges is at most t^2. Since all d edges incident to v must be 2-spanned in H, necessarily $t^2 \geq d$. ∎

As an immediate conclusion we have the following.

LEMMA 3.2. *Let $H^* = (V, E^*)$ be a 2-spanner for G with minimum maximum degree. Then*

$$\Delta(H^*) \geq \sqrt{\Delta(G)}. \qquad \blacksquare$$

Let us remark that a similar result holds for k-spanners H^* of minimum maximum degree for any $k \geq 2$, namely, $\Delta(H^*)$ is $\Omega(\Delta(G)^{1/k})$ (the proof is also similar).

Note that there are graphs G for which $\Delta(H) = \Delta(G)$ for any 2-spanner H of G. One particular such graph is the star of $n-1$ vertices. However, there are dense graphs, where the lower bound $\sqrt{\Delta}$ can be achieved (up to constants). The clique (complete graph) K_n of n vertices admits low degree 2-spanners. In order to prove this, we use the notion of a *projective plane of order q* for prime q. The existence of projective planes of order q for every prime q is well known. A projective plane $\mathcal{P} = (P, L)$ of order q is composed of a collection $P = \{p_1, \ldots, p_m\}$ of points and a collection $L = \{l_1, \ldots, l_m\}$ of lines where $m = q^2 + q + 1$. Every line l_i is a subset of P containing exactly $d = q + 1$ points and every point is contained in exactly d lines. Every two lines intersect in exactly one point and every two points share exactly one line.

Consider now $K_n = (V, V \times V)$ where $V = \{v_1, \ldots, v_n\}$. Let q be a prime number such that $\lfloor\sqrt{n}\rfloor \leq q \leq 2\lfloor\sqrt{n}\rfloor$. (Such a prime exists by Bertrand's postulate; cf. [HW56].) Thus, $n < q^2 + q + 1 < 5n$. Let $\mathcal{P} = (P, L)$ be a projective plane of order q. Define the following spanning subgraph $H = (V, E')$ of K_n. Add the edge (v_i, v_j) to E' iff there exist t and r that satisfy $t \equiv i \bmod n$ and $r \equiv j \bmod n$ such that either $p_t \in l_r$ or $p_r \in l_t$.

We now proceed to prove that H is a low degree 2-spanner for K_n. First we note the following claim.

CLAIM 3.3. *The subgraph H is a 2-spanner for K_n.*

Proof. Let $e = (v_i, v_j)$ be an arbitrary edge of K_n. The lines l_i and l_j share some point $p_s \in l_i \cap l_j$. Let f be the integer satisfying $1 \leq f \leq n$, $f \equiv s \bmod n$. If $f = i$ or $f = j$ (i.e., the case is, for example, that $p_j \in l_i \cap l_j$) then by definition $(v_i, v_j) \in E'$. Otherwise, again by definition, both $(v_i, v_f) \in E'$ and $(v_j, v_f) \in E'$, and the edge e is spanned. ∎

We now estimate the degree of the vertices in H'. Note that the degree of a vertex $v_i \in H$ is only increased due to vertices in the set $S_i = \{l_j \mid j \equiv i \bmod n\} \cup \{p_j \mid j \equiv i \bmod n\}$, and $|S_i| \leq 10$. Each vertex in S_i increases the degree of v_i by at most $d = q + 1$, and thus the degree of v_i in H is bounded by $O(d) = O(\sqrt{n})$.

In conclusion, we have established the following claim.

LEMMA 3.4. *The complete graph K_n admits a 2-spanner H with $\Delta(H) = O(\sqrt{\Delta(K_n)})$.* □

4. A hardness result for approximating LD-2SP. In this section we establish that the LD-2SP problem is (up to a constant factor) at least as hard to approximate as the *set cover* problem. Formally, the set cover problem is defined as follows. Given a bipartite graph $G(V_1, V_2, E)$ with $|V_1| = |V_2| = n$, find a minimum cardinality subset S of V_1, that *covers* V_2, i.e., such that every vertex in V_2 has a neighbor in S.

It is known that this problem is hard to approximate. In particular, the following theorem is proved in [LY93, Fei96].

THEOREM 4.1 (see [Fei96]). *The set cover problem cannot be approximated with ratio $\ln n - \epsilon$, for any fixed $\epsilon > 0$, unless $NP \subset DTIME(n^{\log\log n})$.* □

Also, the following theorem is proven in [BGLR93].

THEOREM 4.2 (see [BGLR93]). *The set cover problem cannot be approximated with any constant ratio c, unless $P = NP$.* □

For our purpose, we need a slightly different version of the set cover problem. Define the *$\sqrt{n}$-set cover* problem as a variant of the set cover problem in which $d(v) \leq \sqrt{n}$ for each vertex $v \in V_1 \cup V_2$. The usual greedy algorithm approximates this problem with ratio $\ln\sqrt{n} + 1 = \ln n/2 + 1$ [Joh74, Lov75]. On the other hand, a simple observation gives the following fact.

FACT 4.3. *The $\sqrt{n}$-set cover problem cannot be approximated with ratio better than $\ln n/2$, unless $NP \subset DTIME(n^{\log\log n})$.*

Proof. Assume the existence of an approximation algorithm A for the $\sqrt{n}$-set cover problem, with ratio $\ln n/2$ or better. Let $G(V_1, V_2, E)$ be an instance of the set cover problem. Let $\tilde{G}$ be a graph consisting of n (separate) copies of G. The graph $\tilde{G}$ contains n^2 vertices on each side, and the maximum degree in $\tilde{G}$ is bounded by n. Thus, $\tilde{G}$ is amenable to approximation by algorithm A, and, consequently, the set cover instance represented by $\tilde{G}$ can be approximated with ratio better than $\ln(n^2)/2 = \ln n$. Since any cover in $\tilde{G}$ is composed of n separate covers of V_2, we get by a straightforward averaging argument that one of these covers approximates the optimum cover of V_2 by a ratio better than $\ln n$. By Theorem 4.1, this implies $NP \subset DTIME(n^{\log\log n})$. □

In the remainder of this section, we consider the $\sqrt{n}$-set cover problem, with $|V_1| = |V_2| = n$. We show that the LD-2SP problem is at least as hard to approximate as this problem. Throughout, we denote by t^* the size of the optimum cover of V_2 in G. Let $\ell = \lceil\sqrt{n}\,\rceil$. Note that

$$t^* \geq \ell. \tag{1}$$

4.1. The construction. We use an auxiliary graph $\bar{G}$ constructed from G as follows. The vertices of $\bar{G}$ are

$$V_1 \cup V_2 \cup \{s\} \cup \{c(v_1) \mid v_1 \in V_1\} \cup \{u_1, \ldots, u_\ell\}.$$

Divide the vertices of V_1 arbitrarily into ℓ disjoint sets V_1^i, where each V_1^i contains no more than $\sqrt{n}$ vertices. The edge set of $\bar{G}$ is given by defining a number of edge

classes as follows. Let

$$\begin{aligned}
\mathcal{E}_1 &= E(G),\\
\mathcal{E}_2 &= \{(s, v_1) \mid v_1 \in V_1\},\\
\mathcal{E}_3 &= \{(s, v_2) \mid v_2 \in V_2\},\\
\mathcal{E}_4 &= \{(c(v_1), v_1) \mid v_1 \in V_1\} \cup \{(c(v_1), v_2) \mid (v_1, v_2) \in E(G)\},\\
\mathcal{E}_5 &= \{(u_i, v_1) \mid v_1 \in V_1^i, 1 \le i \le \ell\},\\
\mathcal{E}_6 &= \{(s, u_i) \mid 1 \le i \le \ell\},
\end{aligned}$$

and set

$$E(\bar{G}) = \mathcal{E}_1 \cup \mathcal{E}_2 \cup \mathcal{E}_3 \cup \mathcal{E}_4 \cup \mathcal{E}_5 \cup \mathcal{E}_6.$$

Let us make a few remarks on this construction. As the maximum degree in $\bar{G}$ is more than $2n$, the best 2-spanner H of G has maximum degree at least $\sqrt{2n}$. We note that for the sake of choosing a good spanner, one can "afford" the edges of classes $\mathcal{E}_1$, $\mathcal{E}_4$, $\mathcal{E}_5$, and $\mathcal{E}_6$, since it easily follows from the construction that these edges induce a subgraph with maximum degree bounded by ℓ. This observation relies on the fact that the degrees of the vertices of V_1 and V_2 in G are bounded by $\sqrt{n}$.

Consequently, the edges from which a "good" spanner may need to omit are the edges of classes $\mathcal{E}_2$ and $\mathcal{E}_3$. These edges give s its degree in $\bar{G}$, which is higher than $2n$. The heart of our proof lies in 2-spanning the edges of $\mathcal{E}_3$. Such an edge e must either be included in the spanner or be 2-helped by some vertex $v_1 \in D(e)$. In order to keep the degree of s low, one has to choose a small subset of V_1 that covers V_2.

4.2. The main claim. We prove the main result of this section using the following two lemmas.

LEMMA 4.4. *If G contains a cover of size t^* then $\bar{G}$ contains a 2-spanner with maximum degree bounded by $2t^*$.*

Proof. Assume a graph $G(V_1, V_2, E)$ with a t^*-cover $C = \{v_1, \ldots, v_{t^*}\} \subseteq V_1$ of V_2. For every vertex $v_2 \in V_2$ choose a vertex $R(v_2) \in C$ connected to v_2. Create a spanner H consisting of the following two edge sets:

$$\begin{aligned}
\mathcal{H}_1 &= \{(v_2, R(v_2)) \mid v_2 \in V_2\} \cup \{(s, v_1) \mid v_1 \in C\},\\
\mathcal{H}_2 &= \mathcal{E}_4 \cup \mathcal{E}_5 \cup \mathcal{E}_6,
\end{aligned}$$

and set $E(H) = \mathcal{H}_1 \cup \mathcal{H}_2$.

(*Remark.* The above construction can be slightly improved. For example, it is not necessary to put in H edges $(c(v_1), u)$ if v_1 is the vertex chosen to cover u. We note, nevertheless, that the maximum degree is not decreased by these improvements.)

We need the following observations.

CLAIM 4.5. *The maximum degree in H is bounded by $2t^*$.*

Proof. As explained before, the edges of classes $\mathcal{E}_4$, $\mathcal{E}_5$, and $\mathcal{E}_6$ induce a graph with maximum degree bounded by ℓ. Specifically, s, the $c(v_i)$ vertices and the vertices of V_2 have degree bounded by ℓ and the vertices of V_1 have degree bounded by 2 (i.e., a vertex v_1 is connected to its u_i and to $c(v_1)$.)

Now consider the edges of $\mathcal{H}_1$. The degree of each vertex in C is increased by no more than $\sqrt{n}+1$ due to these edges (these edges connect a vertex v_1 to its neighbors in V_2 and to s). Note, however, that t^* new edges are added to s (connecting s to the vertices of C), thus making its degree no more than $t^* + \ell \le 2t^*$ by inequality (1). Hence the maximum degree is as stated. ∎

Next we establish the following claim.

CLAIM 4.6. *The graph H is a 2-spanner of $\bar{G}$.*

Proof. The edges of classes $\mathcal{E}_4$, $\mathcal{E}_5$, and $\mathcal{E}_6$ are in the spanner. We must show that the edges of classes $\mathcal{E}_1$, $\mathcal{E}_2$, and $\mathcal{E}_3$ are 2-spanned by H.

An edge $(v_1, v_2) \in \mathcal{E}_1$ is 2-spanned in the spanner by the edges $(c(v_1), v_1)$ and $(c(v_1), v_2)$, since both are in $\mathcal{E}_4$.

Next consider an edge $(v_1, s) \in \mathcal{E}_2$. The node v_1 must belong to some set V_1^i. Therefore this edge is 2-spanned in H by the edges (u_i, v_1) and (u_i, s), which are in $\mathcal{E}_5$ and $\mathcal{E}_6$, respectively.

Finally, an edge $(v_2, s) \in \mathcal{E}_3$ is 2-spanned in H by the edges $(v_2, R(v_2))$ and $(R(v_2), s)$, which are in $\mathcal{H}_1$. □

The second central lemma in this section is the following.

LEMMA 4.7. *Given a 2-spanner H of $\bar{G}$, it is possible to find a cover of V_2 in G with cardinality bounded by $\Delta(H)$.*

Proof. Consider a 2-spanner H. Partition the edges of class $\mathcal{E}_3$ into two disjoint sets

$$\mathcal{E}_3^A = \mathcal{E}_3 \cap E(H) \quad \text{and} \quad \mathcal{E}_3^B = \mathcal{E}_3 \setminus E(H).$$

Note that each of the edges of $\mathcal{E}_3^B$ is 2-spanned in H by a 2-helping vertex.

Construct a cover of V_2 in G as follows. First, for every edge $(v_2, s) \in \mathcal{E}_3^A$, choose an arbitrary vertex v_1 connected to v_2 in G, and let D_1 be the set of selected vertices. Second, for every edge (s, v_2) in $\mathcal{E}_3^B$, choose an arbitrary vertex $v_1 \in V_1$ such that both (s, v_1) and (v_2, v_1) are in $E(H)$. (A single vertex of V_1 may be chosen several times, as it may cover many edges in $\mathcal{E}_3^B$.) Let D_2 be the set of vertices chosen by this process.

Clearly, the set $D_1 \cup D_2$ forms a cover of V_2 in G. It remains to bound its cardinality. First note that $|D_1| \leq |\mathcal{E}_3^A|$ (at worst, a *different* vertex v_1 is chosen to D_1 for every vertex of $\mathcal{E}_3^A$). Now, every edge in $\mathcal{E}_3^A$ adds 1 to the degree of s in H. Also, every vertex in D_2 is connected to s in H and thus adds 1 to its degree. Hence $|D_1| + |D_2| \leq \Delta(H)$. This proves the claim. □

The following corollary is now immediate.

COROLLARY 4.8. *The* LD-2SP *problem cannot be approximated with ratio better than $\ln n/5$, unless $NP \subset DTIME(n^{\log \log n})$.*

Proof. Assume the existence of an approximation algorithm A for the LD-2SP problem, with ratio better than $\ln n/5$. Take an input G of the $\sqrt{n}$-set cover problem. Let t^* be the size of a minimum cover of V_2 in G. Construct $\bar{G}$ as explained before (this can clearly be done in polynomial time). By Lemma 4.4 the graph $\bar{G}$ contains a 2-spanner with maximum degree bounded by $2t^*$. Note that the number of vertices in $\bar{G}$ is less than $4n$. By the assumption, it is possible to use algorithm A and find a 2-spanner with maximum degree bounded by

$$2t^*(\ln |\bar{G}|)/5 \leq 2t^*(\ln n + 4)/5 < t^*(\ln n/2 - 1)$$

(the last inequality holds for sufficiently large n). By Lemma 4.7 this implies that it is possible to find in polynomial time a cover of V_2 in G with cardinality bounded by $t^*(\ln n/2 - 1)$. By Fact 4.3, this implies $NP \subset DTIME(n^{\log \log n})$. □

The following corollary also follows easily.

COROLLARY 4.9. *The* LD-2SP *problem cannot be approximated with ratio c, for any constant c, unless $P = NP$.* □

5. The approximation algorithm for LD-2SP. Let us first explain the idea behind our approximation algorithm for the LD-2SP problem. We separate the edge set of our graph into two disjoint classes. The class E^- is the class of edges that lies on a small number of triangles, and the class E^+ contains the rest of the edges, namely,

$$E^- = \{e \in E \mid Tri(e) < \sqrt{\Delta}\}, \qquad E^+ = \{e \in E \mid Tri(e) \geq \sqrt{\Delta}\}.$$

(Recall that $Tri(e)$ is the set $\{e, e_1, e_2\}$ of triangles containing e.) We 2-span these two classes of edges, using two separate procedures. Our general approach for handling E^- is to use the "randomized rounding" scheme of Raghavan and Thompson [RT87]. This scheme is based on the following idea. Let Δ^* be the maximum degree in the best 2-spanner. (We shall soon see that it is possible, without loss of generality, to assume that Δ^* is known.) We then formulate the problem as the integer linear program $(P1)$ below.

The program ($P1$). Given are some subset $E_u \subseteq E$ of "unspanned" edges and a (possibly empty) set E_r of edges that have already been added to the spanner. Create for every edge $e_k \in E_u$ and vertex $v_i \in D(e_k)$ a variable $\hat{y}_{i,k}$. (Recall that $D(e)$ is the set of vertices that lies on a triangle with e but does not touch it.) For every two vertices $v_i, v_j \in V, i < j$, such that $(v_i, v_j) \in E$, create a variable $\hat{x}_{i,j}$. (We shall freely use both $\hat{x}_{i,j}$ and $\hat{x}_{j,i}$ to denote this unique variable.) The program is composed of the following sets of inequalities:

$$\sum_{v_j \in N(v_i), (v_i,v_j) \notin E_r} \hat{x}_{i,j} \leq \Delta^* \quad \text{for all } v_i \in V, \tag{2}$$

$$\hat{x}_{l,t} + \sum_{v_i \in D(e_k)} \hat{y}_{i,k} \geq 1 \quad \text{for all } e_k = (v_l, v_t) \in E_u, \tag{3}$$

$$\hat{y}_{i,k} \leq \hat{x}_{i,l}, \hat{x}_{i,t} \quad \text{for all } e_k = (v_l, v_t) \in E_u \text{ and } v_i \in D(e_k), \tag{4}$$

$$\hat{x}_{ij} = 1 \quad \text{for all } e = (v_i, v_j) \in E_r, \tag{5}$$

$$\hat{x}_{i,j},\ \hat{y}_{i,k} \in \{0,1\} \quad \text{for all } i, j, k. \tag{6}$$

The intuitive meaning of the program is as follows. Every $\hat{x}_{i,j}$ variable indicates if the edge (v_i, v_j) is in the chosen spanner. Thus constraint (2) says that every vertex v_i has no more than Δ^* new spanner edges. It is important to note that here we do not count the edges of E_r (those edges are counted separately in the analysis). The variable $\hat{y}_{i,k}$, associated with a vertex v_i and an edge $e_k = (v_l, v_t)$, indicates if v_i 2-helps e_k in the chosen spanner. This is enforced by constraint (4), which says that v_i 2-helps e_k only if both the edges (v_i, v_l) and (v_i, v_t) are included in the spanner. Constraint (3) says that in a feasible 2-spanner, every edge is either in the spanner or is 2-helped by some vertex.

After writing the program, we solve the fractional relaxation of $(P1)$ using the well-known polynomial-time algorithms of [Kha80, Kar84]. Having the fractional values of the variables, we round each variable to be 1 with probability proportional to its fractional value.

When using this program for 2-spanning E^-, we get a good result; i.e., the randomized process gives a 2-spanner whose maximum degree is "close" to the "fractional degree" of the fractional solution. However, using this method we are not expected to 2-span all the edges of E^+. To see this, consider an edge e lying in $\Omega(n)$ triangles. The fractional program may give all (the variables of) the edges in these triangles a

value in $\Theta(1/n)$. In this way constraints (2) and (3) are easily satisfied. However, the probability of a triangle to "survive the randomized rounding" (i.e., to have both its edges set to 1) is $\Theta(1/n^2)$. Since there are only $\Theta(n)$ triangles, the edge is not expected to be 2-spanned. (This phenomenon captures the unfortunate "quadratic" behavior of our linear program.)

We therefore 2-span the edges of E^+ using a different procedure. We draw every edge $e \in E$ randomly to the spanner, with some fixed (small) probability. We then show that the edges of E^+, i.e., edges that belong to sufficiently many triangles, are likely to be 2-spanned in the resulting subgraph (namely are likely to lie on a triangle whose two other edges were selected by the randomized choice). We also show that with high probability the degree that is added to each vertex in this procedure is "small."

In the remainder of this section we present our approximation algorithm, and in the next section we give its analysis. Throughout the algorithm, we denote by E_u the set of edges yet to be 2-spanned.

ALGORITHM 5.1.

Input: A graph $G = (V, E)$ of maximum degree Δ.

1. *Let*
$$p = \frac{2 \cdot \sqrt{\log n}}{\Delta^{1/4}}, \qquad M = 2 \cdot \Delta^{1/4} \cdot \sqrt{\log n}$$
and set $E_r^1, E_r^2 \leftarrow \emptyset$.
2. *For every edge $e \in E$, draw e randomly and independently to be in the spanner with probability p. Let E_r^1 denote the set of edges selected into the spanner by the randomized process.*
3. *Set $E_u = \{e \in E \mid e \notin E_r^1$ and no two edges $e_1, e_2 \in E_r^1$ form a triangle with $e\}$.*
4. *Solve the fractional relaxation of the program $(P1)$ corresponding to E_u, E_r^1, and Δ^*.*
5. *Let $\{x_{i,j}, y_{i,k}\}$ be the optimal (fractional) solutions corresponding to $(P1)$. For every variable $\hat{x}_{i,j}$ create a respective random variable $\bar{x}_{i,j}$.*
6. *Randomly and uniformly set $\bar{x}_{i,j}$ to be 1 with probability $\min\{1, M \cdot x_{i,j}\}$.*
7. *If $\bar{x}_{i,j}$ is set to 1, then add the edge (v_i, v_j) to E_r^2.*
8. *Let E_u be the set of edges that are still unspanned by $E_r^1 \cup E_r^2$. Set $E_r = E_r^1 \cup E_r^2 \cup E_u$.*
9. *Output E_r.*

6. Analysis. First we explain how to overcome the assumption that Δ^* is known. Let Δ_f^* be the smallest value for which $(P1)$ has a feasible (fractional) solution. We call Δ_f^* the smallest *fractional* degree of the best *fractional* 2-spanner. Indeed, we only have to know (and run $(P1)$ with) Δ_f^* for our scheme to work. Clearly, $\Delta^* \geq \Delta_f^*$. This follows from the following simple claim.

LEMMA 6.1. *If we run the program* (P1) *with L replacing Δ^*, and* (P1) *has no fractional feasible solution, then $\Delta^* > L$.* □

The value Δ_f^* is found through binary search, by running $(P1)$ with values taken from the (discrete) interval $[\lceil\sqrt{\Delta}\,\rceil, \Delta]$. The search ends with some specific L such that the program succeed with $L+1$ but fails with L. By Lemma 6.1, $\Delta^* \geq \Delta_f^* > L$. On the other hand, we have a fractional feasible solution for $L+1$. Thus, we found the best fractional Δ_f^* (up to a difference of 1). For proving the desired approximation ratio, we show how to construct an (integer) spanner with maximum degree "close" to $L+1$ and therefore close to $\Delta^* (> L)$.

We now observe that the output is indeed a 2-spanner: the set of edges E_r forms a 2-spanner of G, since every edge not in E_r lies on a triangle with two edges of E_r.

Denote the optimum low-degree 2-spanner for G by H^*. Let us now proceed to bound from above the ratio between $\Delta(E_r)$ and $\Delta(H^*)$.

Throughout the subsequent analysis, we set $p = 2\sqrt{\log n}/\Delta^{1/4}$ and $M = 4\Delta^{1/4} \cdot \sqrt{\log n}$.

6.1. Handling E^+. Our first aim is to show that edges in E^+, i.e., edges with large $|Tri(e)|$, are likely to be 2-spanned in step 2 of our algorithm.

LEMMA 6.2. *With probability at least $1 - 1/n^2$, every edge $e \in E^+$ is 2-spanned in step 2 of Algorithm 5.1.*

Proof. Denote $m = |Tri(e)|$ and assume that $m \geq \sqrt{\Delta}$. Let $Tri(e) = \{T_1, T_2, \ldots, T_m\}$ with $T_i = \{e_1^i, e_2^i, e\}$; i.e., the three edges of T_i form a triangle in G. The probability that a triangle T_i does not 2-span e, namely, that neither e_1^i nor e_2^i are selected into the spanner in step 2, is $1 - p^2$. The probability that neither of the triangles 2-span e is

$$(1-p^2)^m \leq (1-p^2)^{\sqrt{\Delta}} = \left(\left(1-p^2\right)^{1/p^2}\right)^{4\log n} < \frac{1}{n^4}.$$

(The last inequality follows from the fact that $(1-x)^{1/x} \leq 1/e$ for $x \leq 1$.) Therefore, the probability that there exists one such an edge which is not 2-spanned is bounded by

$$\frac{|E|}{n^4} \leq \frac{1}{n^2}. \qquad \square$$

Next we estimate the maximum degree $\Delta(E_r^1)$ in the graph induced by E_r^1 by proving the following lemma.

LEMMA 6.3. *With probability at least $1 - 1/n^2$, $\Delta(E_r^1) \leq 4 \cdot \Delta^{3/4} \cdot \sqrt{\log n}$.*

Proof. For vertices v such that $\deg(v) < \Delta^{3/4} \cdot \sqrt{\log n}$, the claim follows vacuously. Hence we need to prove a degree bound only for vertices v such that $\deg(v) > \Delta^{3/4} \cdot \sqrt{\log n}$. Let $sp_1(e)$ be the random variable indicating if e was drawn to be in E_r^1; namely,

$$sp_1(e) = \begin{cases} 1, & e \in E_r^1, \\ 0 & \text{otherwise.} \end{cases}$$

Let $d_r^1(v)$ denote the random variable that equals the degree of v in the graph induced by E_r^1. Thus,

$$d_r^1(v) = \sum_{e \in E(v)} sp_1(e).$$

Clearly, $\mathbb{E}(sp_1(e)) = p$ and therefore

$$\mathbb{E}(d_r^1(v)) = \sum_{e \in E(v)} \mathbb{E}(sp_1(e)) = p \cdot \deg(v).$$

(Recall the assumption that $d(v) \geq \sqrt{\log n}\Delta^{3/4}$.) By the definition of p we get that the expected degree of v, $\mu(v)$ is bounded below by $2\log n\sqrt{\Delta}$. Since $d_r^1(v)$ is a sum

of independent Bernoulli trials, we can apply Lemma 2.2 to it with $\delta = 1$ and deduce that

$$\mathbb{P}\left(d_r^1(v) > 2 \cdot \mu(v)\right) \leq \left(\frac{e}{4}\right)^{\mu(v)} < \frac{1}{n^3}.$$

(For the last inequality, recall that one may assume that $\Delta = \Omega(\log^2 n)$. Indeed, here we only need Δ to be bounded below by some constant.)

Therefore, with probability at least $1 - 1/n^3$,

$$d_r^1(v) \leq 4 \cdot \Delta^{3/4} \cdot \sqrt{\log n}.$$

By summing up the probabilities over all the vertices, the lemma follows. □

(We note that as in [Rag88] slightly better results are attainable; i.e., it is possible to show a degree bound of $2 \cdot \sqrt{\log n}\Delta^{3/4} + o(\Delta^{3/4})$. However, we give the simpler bound here, since in our case we already have an approximation ratio of $\Delta^{1/4}$ and therefore the improvement can only (slightly) affect the constants. A similar situation holds, later, with regards to Lemma 6.4.)

6.2. Handling E^-. We would next like to show that the maximum degree in the subgraph selected by our linear program algorithm is small. Define the variable $d_r^2(v)$ to be the degree of v in the random choices made in steps 6 and 7 of Algorithm 5.1.

LEMMA 6.4. *With probability at least* $1 - 1/n^2$, $d_r^2(v) < 2M \cdot \Delta^*$ *for every* $v \in V$.

Proof. In order to establish an upper bound on the maximum degree, we must prove that in the random choices of steps 6 and 7 of Algorithm 5.1, the expected number of edges chosen for every vertex is "small." Let $v_i \in V$ be an arbitrary vertex, and let $u_1, \ldots, u_m$ be its neighbors. Let $e_j = (v_i, u_j), j = 1, \ldots, m$. We denote by $sp_2(e_j)$ the random indicator variable for the inclusion of e_j in the spanner, in steps 6 and 7; namely,

$$sp_2(e_j) = \begin{cases} 1, & e_j \text{ is chosen to be in the spanner in steps 6 and 7,} \\ 0 & \text{otherwise} \end{cases}$$

and thus

$$d_r^2(v_i) = \sum_{i=1}^{m} sp_2(e_j).$$

The expected value of $d_r^2(v_i)$ satisfies

$$\mathbb{E}(d_r^2(v_i)) = \sum_{j=1}^{m} \mathbb{E}(sp_2(e_j)) = \sum_{j=1}^{m} \min\{1, Mx_{ij}\} \leq M \cdot \sum_{j=1}^{m} x_{i,j}.$$

By (2) we have

$$\mathbb{E}(d_r^2(v_i)) \leq M \cdot \Delta^*.$$

Since $d_r^2(v_i)$ is the sum of independent Bernoulli trials, it follows from Lemma 2.2 with $\delta = 1$ that

$$\mathbb{P}\left(d_r^2(v_i) > 2 \cdot M \cdot \Delta^*\right) < \left(\frac{e}{4}\right)^{M\Delta^*} \leq \frac{1}{n^3}.$$

(The last inequality follows from the assumption that $\Delta \geq \Omega(\log^2 n)$ and from the definition of M.) Summing up the probabilities for all the vertices, the claim follows. ∎

In order to bound the number of edges added to each vertex v in step 8 of the algorithm (i.e., when E_u is added to E_r), we have to estimate how many edges are 2-spanned in steps 6 and 7. We show that with high probability, E_u is empty after step 7, and therefore E_u does not change $\Delta(E_r)$.

LEMMA 6.5. *The probability that an edge $e_k = (v_l, v_t)$ of E^- is 2-spanned in steps 6 and 7 is at least $1 - 1/n^4$.*

Proof. For the sake of proving the lemma we need the following technical lemma (cf. Chapter 8 of [AS92]).

LEMMA 6.6. *Let $\{A_i\}_{i=1}^m$ be m independent events and let $\mathbb{P}(A_i) = p_i$ and $\sum_{i=1}^m p_i \geq d$. Then $\mathbb{P}(\bigcup_{i=1}^m A_i) \geq 1 - 1/e^d$.* ∎

Let $e_k = (v_l, v_t) \in E^-$ and let $D(e) = \{v_1, \ldots, v_d\}$, $d = |Tri(e_k)| \leq \sqrt{\Delta}$. The inequality of the program $(P1)$ corresponding to e_k is

$$x_{l,t} + \sum_{v_i \in D(e_k)} y_{i,k} \geq 1.$$

Let A_i be the event that v_i 2-helps e_k in the chosen spanner. Let I_k be the event that e_k is included in the spanner. We now estimate the probability that A_i occurs. This probability equals the probability that both (v_i, v_l) and (v_i, v_t) are selected to the spanner. Clearly, we have only to consider the case that $\min\{M \cdot x_{i,t}, M \cdot x_{i,l}\} < 1$, for if this is not the case, $\mathbb{P}(A_i) = 1$. In the case both $M \cdot x_{i,t} < 1$ and $M \cdot x_{i,l} < 1$, $\mathbb{P}(A_i) = M^2 \cdot x_{i,t} \cdot x_{i,l}$. In the case that, say $M \cdot x_{i,t} \geq 1$ and $M \cdot x_{i,l} < 1$, we have $\mathbb{P}(A_i) = M \cdot x_{i,l} > M^2 \cdot x_{i,l}^2$. In either case, by (4) of the linear program we have

$$\mathbb{P}(A_i) \geq M^2 \cdot y_{i,k}^2. \tag{7}$$

The event $Cov(e_k) =$"e_k is 2-spanned" is the union $Cov(e_k) = \bigcup_i A_i \cup I_k$; namely, e_k is 2-spanned iff it is in the spanner or is 2-helped by some vertex. We now estimate the sum of probabilities of the A_i and I_k.

CLAIM 6.7. $\mathbb{P}(I_k) + \sum_{i=1}^d \mathbb{P}(A_i) \geq 3 \cdot \log n$.

Proof. We may assume that $x_{l,t} < 1/M$ since otherwise the edge e_k is taken into the spanner with probability 1 and hence is 2-spanned. We therefore have $\sum_{v_i \in D(e_k)} y_{i,k} > 1 - 1/M$.

We now have by (7)

$$\sum_{i=1}^d \mathbb{P}(A_i) \geq \sum_{i=1}^d M^2 y_{i,k}^2 = M^2 \sum_{i=1}^d y_{i,k}^2.$$

By the Cauchy–Schwartz inequality (cf. [Fla85]) we have

$$\begin{aligned}\sum_{i=1}^d \mathbb{P}(A_i) &\geq M^2 \cdot \frac{\left(\sum_{i=1}^d y_{i,k}\right)^2}{d} \geq M^2 \frac{(\sum_{i=1}^d y_{i,k})^2}{\sqrt{\Delta}} = 4 \log n \left(\sum_{i=1}^d y_{i,k}\right)^2 \\ &\geq 4 \log n (1 - 1/M)^2 > 3 \log n.\end{aligned}$$

(The last inequality holds for $n \geq 2$, in which case $M \geq 4$.) Therefore, this proves our claim. ∎

Note that the events I_k, A_i are all *independent*, since I_k and A_i all *concern different edges*. Thus we may apply Lemma 6.6 and get

$$\mathbb{P}(Cov(e_k)) \geq 1 - \frac{1}{e^{3\log n}} > 1 - \frac{1}{n^4},$$

proving the lemma. □

Thus, with probability at least $1 - 1/n^2$, all the edges are 2-spanned in step 7. Therefore, with probability at least $1 - 1/n^2$, $E_u = \emptyset$, in which case E_u does not increase the maximum degree. In summary, Lemmas 6.2, 6.3, 6.4 and 3.2, combined with the above discussion, yield the following theorem.

THEOREM 6.8. *With probability at least $1 - 1/n$, the algorithm produces a 2-spanner with maximum degree bounded by $O(\sqrt{\log n}\Delta^{1/4}\Delta^*)$.* □

COROLLARY 6.9. *Algorithm* 5.1 *produces a 2-spanner that with probability at least $1 - 1/n$ is an $O(\sqrt{\log n} \cdot \Delta^{1/4})$ approximation for the* LD-2SP *problem.* □

Note that the error probability can be reduced to $1/n^c$ for any (constant) c, losing only constants in the approximation ratio.

7. Derandomization. In this section, we show how to transform our randomized algorithm into a deterministic one. We use the well-known "method of conditional probabilities" (cf. [Spe87]) and its generalization, the method of "pessimistic estimators" [Rag88].

7.1. The method of pessimistic estimators. Let us first describe the method of pessimistic estimators in a form which is convenient for our purpose. Let $q_1, \ldots, q_l$ be random Boolean variables, set to 0 or 1 with some probabilities, and consider the probability space $\mathcal{Q} = \{(q_1, \ldots, q_l) \mid q_i \in \{0,1\}, 1 \leq i \leq l\}$ of 2^l points. Let $X_1, \ldots, X_s$ be a collection of "bad" events over $\mathcal{Q}$, and suppose that $\mathbb{P}(X_i) = p_i$ and that $\sum_{i=1}^s p_i < 1$. Thus the event $\bigcap_i \bar{X}_i$ has positive probability. We therefore have a point $(\hat{q}_1, \ldots, \hat{q}_l)$ in the probability space $\mathcal{Q}$ for which $\bigcap_i \bar{X}_i$ holds. Suppose that for each event X_i and for each $0 \leq j \leq l$ we have a function $f_j^i(q_1, \ldots, q_j)$ for which the following holds.

(1) $\sum_{i=1}^s f_{j-1}^i(q_1, \ldots, q_{j-1}) \geq \min\{\sum_{i=1}^s f_j^i(q_1, \ldots, q_{j-1}, 0), \sum_{i=1}^s f_j^i(q_1, \ldots, q_{j-1}, 1)\}$ for all $1 \leq i \leq s$, $0 \leq j \leq l$.
(2) $f_j^i(q_1, \ldots, q_j) \geq \mathbb{P}(X_i \mid q_1, \ldots, q_j)$.
(3) $\sum_{i=1}^s f_0^i < 1$.
(4) The function $f_j^i(q_1, \ldots, q_j)$ can be computed in polynomial time in l for every i and j and $(q_1, \ldots, q_j) \in \{0,1\}^j$. Also, the number of events, s, is polynomial in l.

In this case one can transform the probabilistic existence proof into a polynomial algorithm (in terms of l). This is done by fixing the value of q_i to be 0 or 1 iteratively, one by one. In the jth step, having determined the values of $q_1, \ldots, q_{j-1}$, we decide upon the value q_j (setting it either to 0 or to 1) so as to minimize the sum $\sum_{i=1}^s f_j^i(q_1, \ldots, q_j)$. It easily follows from the above conditions that the sum $\sum_{i=1}^s f_j^i(q_1, \ldots, q_j)$ never increases and, consequently (it follows from properties 2 and 3 that), at the end of the procedure we remain with a point $(\hat{q}_1, \ldots, \hat{q}_l)$ in the sample space for which the event $\bigcap_i \bar{X}_i$ holds. Also by property (4) above, this derandomization procedure can be executed in time polynomial in l.

The functions f_j^i are called *pessimistic estimators* for the actual conditional probabilities. The method of conditional probabilities is the special case where $f_j^i(q_1, \ldots, q_j) = \mathbb{P}(X_i \mid q_1, \ldots, q_j)$ and property 3 holds, i.e., the case where in addition to property 3

the conditional probabilities can be computed efficiently, so no estimators are needed. When this is the case, the remaining properties 1 and 2 follow immediately.

7.2. Derandomizing the 2-spanner algorithm. In the case of the 2-*spanner* problem we have a two-stage randomized procedure. Let us first focus on the harder task of derandomizing the second stage, where we 2-span the edges of E^- using randomized rounding. We draw the edges with different probabilities (that depend upon the values of the corresponding variables in the linear program). Our q_i variables, therefore, correspond to the edges, where every edge has some probability to be 1. We will identify the edge e_k with its corresponding random variable. (We will therefore say "e_k was set to 1" meaning that e_k was added to the spanner.)

We now describe the "bad events" in the second stage. The event $\mathcal{D}(v_i)$ is the event where the degree of v_i is greater than $2 \cdot M \cdot \Delta^*$. The event $\mathcal{U}(e_j)$ is the event that an edge $e_j \in E^-$ is unspanned at the end of Algorithm 5.1.

Throughout the sequel, we assume that we have already decided upon the values of $e_1, \ldots, e_{j-1}$, setting them either to 1 or 0, and we want to decide the value of e_j. We denote by $p(e_k)$ the probability by which e_k is drawn in the randomized rounding. (This probability equals M times the value of e_k in the linear program.) We use the following notation (that depends upon previous decisions). The number $\tilde{e}_k$ is defined as

$$\tilde{e}_k = \begin{cases} 1, & e_k \text{ was previously set to 1,} \\ 0, & e_k \text{ was previously set to 0,} \\ p(e_k), & \text{the value of } e_k \text{ was not yet determined.} \end{cases}$$

We next define the pessimistic estimator for the event $\mathcal{U}(e_j)$. Given some edge $e_k = (v_s, v_t)$ say that e_k *lies on* $t_k = |Tri(e_k)|$ *triangles* and denote $Tri(e_k) = \{(e_i^1, e_i^2, e_k)\}_{i=1}^{t_k}$. We then set the pessimistic estimators for $\mathcal{U}(e_k)$ to be

$$h_j^k(e_1, \ldots, e_j) = \Pi_{i=1}^{t_k}(1 - \tilde{e}_i^1 \cdot \tilde{e}_i^2).$$

We note that the above expression, *exactly* equals the probability that e_k is unspanned by either of its triangles (given the previous decisions). Note that e_k may be 2-spanned also if e_k itself is drawn into the spanner. This observation proves property 2 for the functions $\mathcal{U}(e_k)$ and $h_j^k(e_1, \ldots, e_j)$. Property 4 follows trivially.

We now turn our attention to the event $\mathcal{D}(v_i)$, meaning that the degree of v_i exceeds $2 \cdot M \cdot \Delta^*$. For these events, the conditional probabilities can be calculated in polynomial time using *dynamic programming*. However, this is relatively time consuming, as $O(d(v)\Delta^*)$ time is required in order to calculate each conditional probability associated with every vertex. It is therefore convenient to introduce the following pessimistic estimators, which are a special case of some estimators introduced in [Rag88]. Suppose that the edges of v_i are $e_1^i, e_2^i, \ldots, e_{d_i}^i$ (where d_i is the degree of v_i). For $\mathcal{D}(v_i)$ define the following pessimistic estimator. Set

$$g_j^i(e_1, \ldots, e_j) = \frac{\Pi_{r=1}^{d_i}\left(\tilde{e}_r^i + 1\right)}{4^{M \cdot \Delta^*}}.$$

The required property 2 follows in a way similar to the proof of the Chernoff bound, as in [Rag88]. Property 4 also follows trivially.

We now prove property 3. Note that since (as in [Rag88])

$$g_0^i = \frac{\Pi_{k=1}^{d_i}(p(e_k)+1)}{4^{M\cdot\Delta^*}} \le \frac{\Pi_{k=1}^{d_i} e^{p(e_k)}}{4^{M\cdot\Delta^*}} = \frac{e^{\sum_{k=1}^{d_i} p(e_k)}}{4^{M\cdot\Delta^*}} \le \left(\frac{e}{4}\right)^{M\cdot\Delta^*} \le \frac{1}{n^3},$$

property 3 follows from Lemmas 6.4 and 6.5. (In fact, the sum of the pessimistic estimators of the bad events is not only smaller than 1 but is also smaller than $1/n$. Nevertheless, the degrees of the vertices can only be reduced by a constant factor.)

Finally, we have to check property 1. We have

$$S = \sum_{i=1}^{n} g_{j-1}^i + \sum_{k=1}^{m} h_{j-1}^k = \sum_{i=1}^{n} \frac{\Pi_{r=1}^{d_i}\left(\tilde{e}_r^i + 1\right)}{4^{M\cdot\Delta^*}} + \sum_{k=1}^{m} \Pi_{i=1}^{t_k}(1 - \tilde{e}_i^1 \cdot \tilde{e}_i^2).$$

We can write S as the sum $S = S_1(e_j) + S_2(e_j) + S_3$ where

$$S_1(e_j) = (1 + p(e_j)) \cdot \Pi_1, \quad S_2(e_j) = \sum_l (1 - p(e_j) \cdot \tilde{e}_l) \cdot \Pi_2^l,$$

and the expressions Π_1, Π_2^l, and S_3 do not contain $\tilde{e}_j$. When setting e_j to 1, the difference between the terms in the first summand is $S_1(1) - S_1(e_j) = (1 - p(e_j)) \cdot \Pi_1$, and the difference in the second summand is $S_2(1) - S_2(e_j) = -\sum_l \tilde{e}_l(1 - p(e_j)) \cdot \Pi_2^l$. So if $\sum_l \tilde{e}_l \cdot \Pi_2^l \ge \Pi_1$ we are done. Otherwise, when setting e_j to 0, the difference in the first summand is $S_1(0) - S_1(e_j) = -p(e_j) \cdot \Pi_1$ and in the second summand, $S_2(0) - S_2(e_j) = \sum_l p(e_j) \cdot \tilde{e}_l \cdot \Pi_2^l < p(e_j) \cdot \Pi_1$. Thus the required property follows.

Now we have to consider the first (and easier to derandomize) stage of the algorithm, where we handle the edges of E^+. In the first stage, we draw all the edges independently and uniformly with probability $p = 2 \cdot \sqrt{\log n}/\Delta^{1/4}$. The bad event here is similar. We have the event $\mathcal{D}(v_i)$ which is the bad event that the degree of v_i exceeds $4 \cdot \Delta^{3/4} \cdot \sqrt{\log n}$. The event $\mathcal{U}(e_k)$ is the event that an edge $e \in E^+$ is not 2-spanned at the end of Algorithm 5.1.

Thus, the derandomization of this first stage is a special case of the derandomization of the second stage.

We have therefore established the following result.

COROLLARY 7.1. *Algorithm* 5.1*, together with a derandomization procedure, produces a* 2*-spanner that is an* $O(\sqrt{\log n} \cdot \Delta^{1/4})$ *approximation for the* LD-2SP *problem.* □

8. An algorithm for sparse graphs. In this section we present a relatively simple algorithm $Sparse_1$ that performs better than Algorithm 5.1 in the case where the underlying graph is sparse. In this case, algorithm $Sparse_1$ yields a $2\sqrt{E}$ *additive* approximation. (By "α additive approximation" we mean that the resulting degree is $\Delta^* + \alpha$.) Thus, if the number of edges is up to $n^{3/2}$, we get an additive term of less than $n^{3/4}$ (or, alternatively, a very low multiplicative factor). For the range $n^{3/2} \le E \le n^{7/4}$ we have a different algorithm $Sparse_2$ that slightly improves Algorithm 5.1 in the worst case. This algorithm is considerably more complicated and is therefore omitted. The interested reader is referred to [KP93].

8.1. Algorithm $Sparse_1$. Algorithm $Sparse_1$ divides the vertex set into "heavy" and "light" vertices. The set $Heavy$ consists of vertices with degrees *at least* $\sqrt{E}$, and

the set *Light* consists of vertices whose degrees are *less than* $\sqrt{E}$. Then the set of all edges with both endpoints in $Heavy$, $E(Heavy)$, and all edges with both endpoints in Light, $E(Light)$, are taken into the spanner. The cut edges, with one endpoint in $Heavy$ and the other in *Light*, are 2-spanned using a linear programming formulation. The output edge set is denoted E_r. Again we may assume that Δ^* (or, more accurately, Δ^*_f) is known in advance.

ALGORITHM 8.1. *Algorithm* $Sparse_1$
Input: A graph $G = (V, E)$.

1. *Let* $Heavy = \{v \in V \mid \deg(v) \geq \sqrt{E}\}$, $\quad Light = \{v \in V \mid \deg(v) < \sqrt{E}\}$.
2. *Add* $E(Heavy) \cup E(Light)$ *into* E_r.
3. *Let* E_u *be the set of cut edges having one endpoint in Heavy and one in Light.*
4. *Solve the fractional relaxation of the program* $(P1)$ *corresponding to* E_u, E_r, *and* Δ^*.
5. *Let* $\{x_{i,j}, y_{i,k}\}$ *be the optimum (fractional) solutions corresponding to* $(P1)$. *For every variable* $\hat{x}_{i,j}$ *create a respective random variable* $\bar{x}_{i,j}$.
6. *Randomly and uniformly set* $\bar{x}_{i,j}$ *to be* 1 *with probability* $\min\{1, 4 \log n \cdot x_{i,j}\}$.
7. *If* $\bar{x}_{i,j}$ *is set to* 1, *then add the edge* (v_i, v_j) *to* E_r.
8. *Add all the remaining non* 2*-spanned edges to* E_r *and output* E_r.

8.2. Analysis. We now prove that Algorithm 8.1 yields a $2\sqrt{E}$ additive approximation. We first note the following simple fact.

FACT 8.2. *In step* 2 *of Algorithm* 8.1, *we add to* E_r *no more than* $2\sqrt{E}$ *edges adjacent to any vertex.*

Proof. The claim is clear for vertices v in *Light*, since such a vertex has at most $\sqrt{E}$ adjacent edges. Also note that $|Heavy| \leq 2 \cdot \sqrt{E}$, and thus for a vertex $v \in Heavy$ at most $2 \cdot \sqrt{E}$ edges are candidates for addition to E_r in this step. The claim follows. □

We now note the following simple yet crucial fact.

FACT 8.3. *In every triangle corresponding to a cut edge* e *in the set* E_u *defined in step* 3 *of Algorithm* 5.1, *exactly one of its edges was already added to* E_r *in Step* 2.

Proof. Every such triangle contains an edge e' that is not a cut edge. Thus, either both vertices of e' belong to $Heavy$ or they both belong to *Light*. In either case e' was added to E_r in step 2. □

Given some cut edge $e_k = (v_l, v_t)$, let $y_{i,k}$ be a variable corresponding to $v_i \in D(e_k)$ and e_k. Without loss of generality, let (v_i, v_l) be the other cut edge in the triangle. Thus, the probability that v_i 2-helps e_k exactly equals $\min\{1, 4 \log n \cdot x_{i,l}\} \geq \min\{1, 4 \log n \cdot y_{i,k}\}$. Thus a proof along the lines of that in Lemma 6.5 (but simpler, due to the fact that here we can avoid the "squaring" effect) gives the next corollary. The main point is that the sum of the probabilities that the triangles of e_k survive is roughly $4 \log n \sum_i y_{ik} = \Omega(\log n)$. (The squaring effect is avoided, since in any triangle we need only one edge to survive and not two edges together, because the other edge of every triangle was already chosen to the spanner.)

COROLLARY 8.4. *With probability at least* $1 - 1/n^2$ *all the edges in* E_u *are* 2*-spanned by the end of step* 7 *of Algorithm* 8.1. □

We note that the expectation of the degree of a vertex (and thus, using Lemma 2.2, the expectation of the maximum degree) is bounded by $2\sqrt{E} + O(\log n \cdot \Delta^*)$. Thus up to logarithmic factors, this approximation is $2\sqrt{E}$ additive. By using derandomization (as explained in the previous section) and Lemma 3.2 we have the following.

COROLLARY 8.5. *There is an* $\tilde{O}(\sqrt{E/\Delta})$ *approximation algorithm for the* LD-2SP *problem.* □

Note that if $E \leq \Delta\sqrt{\Delta}$ then Algorithm 8.1 performs better than Algorithm 5.1. Let us consider the approximation ratio in terms of n. Algorithm 5.1 gives a worst-case ratio of $\tilde{O}(n^{1/4})$. This happens when Δ is very large, i.e., $\Delta = \Theta(n)$. On the other hand, if Δ is very large, we may have $\sqrt{|E|/\Delta}$ small. This implies that the ratio is improved whenever $|E| < n^{3/2}$ by doing the following. Considering a graph with $n^{3/2-\epsilon}$ edges, if $\Delta \leq n^{1-2\epsilon/3}$ then apply Algorithm 5.1, else apply Algorithm 8.1. This gives the following bound.

COROLLARY 8.6. *For every* $0 \leq \epsilon \leq 1/2$, *there exists an* $\tilde{O}(n^{1/4-\epsilon/6})$ *approximation algorithm for the* LD-2SP *problem on graphs* G *with* $E = O(n^{3/2-\epsilon})$. □

This result improves the ratio in "absolute terms" (i.e., in terms of n). For example, if $E = O(n)$ then the combined algorithm has an $O(n^{1/6})$ approximation ratio (whereas Algorithm 5.1 would give an $O(n^{1/4})$ ratio in the worst case).

8.3. The case of $n^{3/2} < E \leq n^{7/4}$. In [KP93] we present Algorithm 8.1 which outperforms Algorithm 5.1 in the range $n^{3/2} < E \leq n^{7/4}$. That is, we assume a graph with $O(n^{7/4-\epsilon})$ edges, where $0 \leq \epsilon \leq 1/4$, and show an $\tilde{O}(n^{1/4-\epsilon/11})$-ratio approximation algorithm, improving over the $n^{1/4}$-ratio of Algorithm 5.1.

THEOREM 8.7 (see [KP93]). *Given a graph* $G = (V, E)$ *with* $n^{7/4-\epsilon}$ *edges, Algorithm* 8.1 *combined with a derandomization procedure has an* $\tilde{O}(n^{1/4-\epsilon/11})$ *approximation ratio.* □

9. Spanning the edges of a single vertex. In this section we consider the weaker problem of spanning the edges adjacent to a single vertex and present an $O(\log n)$ approximation for it. This construction can easily be applied to span the edges adjacent to a small subset of the vertices.

Say that we are given a specific vertex v (presumably with high degree) and we want to 2-span its edges (and do not care about the edges not touching v). Thus our aim is to select some subset $E' \subseteq E$ inducing low degrees such that every missing edge of v is 2-spanned by a triangle. Denote this problem by SLD-2SP.

First we note that the lower bound on approximability for the LD-2SP problem applies to the SLD-2SP problem as well. Given an instance of the set cover problem, we may construct $\bar{G}$ as in section 4, and consider the problem of spanning the edges of s. A similar proof as in section 4 shows that unless $NP \subset DTIME(n^{\log\log n})$, the ratio of any approximation algorithm for the SLD-2SP problem is no better than $\ln n/5$. On the other hand, in this section we match this result, showing a logarithmic-ratio approximation algorithm for SLD-2SP. We use a known greedy approximation for a (slightly) more involved version of the set cover problem. This essentially shows that this weaker problem SLD-2SP is equivalent to set cover, with respect to approximation.

The *bounded-load* set cover problem is a variant of the set cover problem that deals with assigning specific covering vertices to the covered vertices. Namely, along with finding a cover C of V_2, it is required to provide a function $\varphi : V_2 \to C$, assigning each vertex v_2 in V_2 a neighbor $\varphi(v_2)$ in C. The load of a vertex $v_1 \in V_1$ is defined as the number of covered vertices it is assigned to, i.e., $L(v_1) = |\{v_2 \in V_2 \mid \varphi(v_2) = v_1\}|$. The problem is now defined as follows. Given a bipartite graph $G(V_1, V_2, E)$ and an integer $L \leq |V_2|$, find a cover $C \subset V_1$ of V_2 and an assignment φ with maximum load bounded by L (i.e., such that no vertex in V_1 is assigned to more than L vertices of V_2).

We recall the following theorem of [Wol82].

THEOREM 9.1 (see [W82]). *The bounded load set cover problem can be approximated with ratio* $O(\log |V_2|)$. □

Given an instance of the SLD-2SP problem, where our aim is to 2-span the edges of v, we reduce it to an instance of the bounded load set cover problem. We use a reformulation of the SLD-2SP problem as follows. Model the neighbors $N(v)$ of v and the edges $E(v)$ of v in a bipartite graph $Bip = (N(v), E(v), A)$ where a vertex $u \in N(v)$ is connected to an edge $e = (v, w) \in E(v)$, iff $(u, w) \in E$. (Namely, $(u, e) \in A$ iff u belongs to $D(e)$ and can 2-help $e = (v, w) \in E(G)$ in the spanner by the edges (u, w) and (u, v).)

The aim is to find a *small-sized* cover C of $E(v)$ (in Bip), with *small* maximum load. The merit of this construction is explained by the following observation.

CLAIM 9.2. *Given a small set C covering $E(v)$ with maximum load L, it is possible to construct a 2-spanner of the edges of v with maximum degree bounded by* $\max\{|C|, L + 1\}$.

Proof. Construct the 2-spanner as follows. Define the bipartite graph Bip, and let $C = \{w_1, \ldots, w_k\} \subseteq N(v)$. Let $\{e^i_1, \ldots, e^i_{n_i}\}$ be the edges incident to v that are covered in Bip by w_i (where $n_i \leq L$). Let $e^i_j = (v, z^i_j)$. Add the edges $\{(v, w_i)\}_{i=1}^k$ to the spanner. Also, add the edges (w_i, z^i_j). Clearly, we have added $|C|$ edges adjacent to v (since one edge is added to v for each vertex of C). We have also added no more than $L + 1$ edges adjacent to w_i for every i, since w_i covers no more than L edges $e_j = (w_i, z^i_j)$ in the spanner and also the edge (v, w_i). Thus the SLD-2SP problem is equivalent to finding a cover C and some assignment with load L, minimizing $\max\{|C|, L + 1\}$. □

It easily follows from Theorem 9.1 that the problem of finding a cover with a load assignment minimizing $\max\{|C|, L + 1\}$ also enjoys a logarithmic approximation. In turn, this gives a logarithmic approximation ratio for the problem of spanning the edges of v.

COROLLARY 9.3. *The problem of spanning the edges of v with low degree has a polynomial time approximation algorithm with ratio* $O(\log n)$. *Conversely, the problem cannot be approximated with ratio better than* $\ln n/5$, *unless* $NP \subset DTIME(n^{\log \log n})$ *holds.* □

As an additional by-product, if we are required to 2-span *only* the edges of a collection of k of the graph vertices, for small k, we can 2-span the edges of every vertex in the set one by one and get an $O(k \log n)$ approximation for this problem.

COROLLARY 9.4. *The problem of 2-spanning the edges of a subset $V' \subset V$ of k vertices with minimum maximum degree can be approximated within an* $O(\log n \cdot k)$ *ratio.* □

PERFORMING WORK EFFICIENTLY IN THE PRESENCE OF FAULTS*

CYNTHIA DWORK†, JOSEPH Y. HALPERN‡, AND ORLI WAARTS§

Abstract. We consider a system of t synchronous processes that communicate only by sending messages to one another, and together the processes must perform n independent units of work. Processes may fail by crashing; we want to guarantee that in every execution of the protocol in which at least one process survives, all n units of work will be performed. We consider three parameters: the number of messages sent, the total number of units of work performed (including multiplicities), and time. We present three protocols for solving the problem. All three are work optimal, doing $O(n+t)$ work. The first has moderate costs in the remaining two parameters, sends $O(t\sqrt{t})$ messages, and takes $O(n+t)$ time. This protocol can be easily modified to run in any completely asynchronous system equipped with a failure detection mechanism. The second sends only $O(t \log t)$ messages, but its running time is large ($O(t^2(n+t)2^{n+t})$). The third is essentially time optimal in the (usual) case in which there are no failures, and its time complexity degrades gracefully as the number of failures increases.

Key words. fault tolerance, work, Byzantine agreement, load balancing, distributed systems

AMS subject classifications. 68Q22, 68M10, 90B25

1. Introduction.

A fundamental issue in distributed computing is fault tolerance: guaranteeing that work is performed, despite the presence of failures. For example, in controlling a nuclear reactor it may be crucial for a set of valves to be closed before fuel is added. Thus the procedure for verifying that the valves are closed must be highly fault tolerant. If processes never fail then the *work* of checking that the valves are closed could be distributed according to some load-balancing technique. Since processes may fail, we would like an algorithm that guarantees that the work will be performed as long as at least one process survives. Such an algorithm could be particularly useful in a local area network, where jobs might be distributed among idle workstations. (The idea of running computations on idle nodes is an old one, going back at least to [17]. See [12] for one implementation of this approach and for further references.) In this case a "failure" might correspond to a user reclaiming her machine.

The notion of work in this paper is very broad, but is restricted to "idempotent" operations, that is, operations that can be repeated without harm. This is because if a process performs a unit of work and fails before telling a second process of its achievement, then the second process has no choice but to repeat the given unit of

work. Examples include verifying a step in a formal proof, evaluating a boolean formula at a particular assignment to the variables, sensing the status of a valve, closing a valve, sending a message, say, to a process outside of the given system, or reading records in a distributed database.

Formally, we assume that we have a synchronous system of t processes that are subject to crash failures, that want to perform n independent units of work. (For now, we assume that initially there is common knowledge among the t processes about the n units of work to be performed. We return to this point later.) In one time unit a process can compute locally and perform one unit of work and one round of communication (sending and receiving messages). Given that performing a unit of work can be repeated without harm, a trivial solution is obtained by having each process perform every unit of work. In our original example, this would mean that every process checks that every valve is closed. This solution requires no messages, but in the worst case it performs tn units of work and runs in n rounds. (Here the worst case is when no process fails.)

Another straightforward solution can be obtained by having only one process performing the work at any time and checkpointing to each process after completing every unit of work. In this solution, at most $n+t-1$ units of work are ever performed, but the number of messages sent is almost tn in the worst case.

In both these solutions the total amount of *effort*, defined as work plus messages, is $O(tn)$. If the actual cost of performing a unit of work is comparable with the cost of sending a message, then neither solution is appealing. In this paper we focus on solutions that are work optimal, up to a constant factor, while keeping the total effort reasonable. Clearly, since a process can fail immediately after performing a unit of work, before reporting that unit to any other process, a work-optimal solution performs $n+t-1$ units of work in the worst case. Thus we are interested in solutions that perform $O(n+t)$ work.

Let $n' = \max(n, t)$. Our first result is an algorithm whose total effort is at most $3n' + 9t\sqrt{t}$. In fact, in the worst case the amount of work performed is at most $3n'$ and the number of messages is at most $9t\sqrt{t}$, so the form of the bound explains the costs exactly. We then optimize this algorithm to achieve running time of $O(n+t)$ rounds. Note that any solution requires n rounds in the worst case, since if $t-1$ processes are initially faulty then the remaining process must perform all n units of work. In this algorithm the synchrony is used only to detect failures, as usual by detecting the absence of an expected message. Thus it can be easily modified to work in a completely asynchronous system equipped with a failure detection mechanism.

We then prove that the above algorithm is not message optimal (among work-optimal algorithms), by constructing a technically challenging work-optimal algorithm that requires only $O(t \log t)$ messages in the worst case. Since $O(n+t)$ is a lower bound on work, and hence on effort, the $O(n+t \log t)$ effort of this algorithm is nearly optimal. The improved message complexity is obtained by a more aggressive use of synchrony. In particular, the absence of a message in this algorithm has two possible meanings: either the potential sender failed or it has insufficient "information" (generally about the history of the execution) and therefore has chosen not to send a message. Due to this use of synchrony, unlike the first algorithm, this low-effort algorithm will not run in the asynchronous model with failure detection. In addition, the efficiency comes at a price in terms of time: in the worst case, the algorithm requires $O(t^2(n+t)2^{n+t})$ rounds.

The first two algorithms are very sequential: at all times work is performed by a single active process that uses some checkpointing strategy to inform other processes about the completed work. This forces the algorithms to take at least n steps, even in a failure-free run. To reduce the time we need to increase parallelism. However, intuitively, increasing parallelism while simultaneously minimizing time and still remaining work optimal may increase communication costs, since processes must quickly tell each other about completed work. The third algorithm does exactly this in a fairly straightforward way, paying a price in messages in order to decrease best-case time. It is designed to perform time optimally in the absence of failures and to have its time complexity degrade gracefully with additional faults. In particular, it takes $n/t+2$ rounds in the failure-free case, and its message cost is $2t^2$; its worst-case message cost is $O(ft^2)$, where f is the actual number of failures in the execution.

There are a number of assumptions in our model that are arguably not realistic. For one, we assume that the n units of work are identical or, at least, that they all take the same amount of time to perform. In addition, we assume that the total workload is static and is common knowledge at the beginning of the algorithm. It is not too hard to modify our last algorithm to deal with a more realistic scenario, where work is continually coming in to different sites of the system, and is not initially common knowledge. We remark that a patent has been filed by IBM for such a modified algorithm.

One application of our algorithms is to Byzantine agreement. The idea is that the general tries to inform t processes, and then each of these t processes performs the "work" of ensuring that all processes are informed. In particular, our second algorithm, called Protocol $\mathcal{B}$, gives a Byzantine agreement algorithm for the crash fault model that requires $O(n+t\sqrt{t})$ messages and $O(n)$ time, where n is the number of processes in the system and t is a bound on the number of failures, while our third algorithm gives a Byzantine agreement algorithm that uses $O(n + t \log t)$ messages and exponential time. The best result prior to ours was a nonconstructive algorithm due to Bracha that requires $O(n + t\sqrt{t})$ messages [4]. Galil, Mayer, and Yung [11] have recently obtained an algorithm that uses only a linear number of messages. However, the algorithm is not comparable with the agreement algorithm obtained using Protocol $\mathcal{B}$ because it requires a superlinear number of rounds.

Using the observation that our solutions to the work problem yield solutions to Byzantine agreement, we can now return to the assumption that initially there is common knowledge about the work to be performed. Specifically, if even one process knows about this work, then it can act as a general, run Byzantine agreement on the pool of work using one of the three algorithms, and then the actual work is performed by running the same algorithm a second time on the real work. If n, the amount of actual work, is $\Omega(t)$, then the overall cost at most doubles when the work is not initially common knowledge.

1.1. Related work. The idea of doing work in the presence of failures, in a different context, has appeared elsewhere. First, Bridgland and Watro [5] considered a system of t asynchronous processes that together must perform n independent units of work. The processes may fail by crashing and each process can perform at most one unit of work. They provide tight bounds on the number of crash failures that can be tolerated by any solution to the problem.

Clearly, our problem assumes a very different model than that of [5]. Furthermore, they want a protocol that guarantees that the work will be performed in every execution of the protocol, while we want only a protocol that guarantees that the work

will be performed in executions in which at least one process survives. Consequently, their problem is not always solvable and their focus is on finding conditions under which it is solvable. Our problem is always solvable; our focus is on finding efficient solutions.

Another similar but not identical problem was considered by Kanellakis and Shvartsman. In a seminal paper [13] they consider the *Write-All* problem, in which n processes cooperate to set all n entries of an n-element array to the value 1. They provide an efficient solution that tolerates up to $n-1$ faults, and they show how to use it to derive robust versions of parallel algorithms for a large class of interesting problems. Their original paper was followed by a number of papers that consider the problem in other shared-memory models (see [1, 6, 14, 15, 16]).

The Write-All problem is, of course, a special case of the type of work we consider. Nevertheless, our framework differs from that of [13] in two important respects, so that their results do not apply to our problem (nor ours to theirs). First, they consider the shared-memory model while we consider the message-passing model. Using the shared-memory model simplifies things considerably for our problem. In this model, there is a straightforward algorithm (that uses shared memory to record what work has been done) with optimal effort $O(n+t)$ (where effort now counts both reading and writing into shared memory, as well as doing work), running in time $O(nt)$. While there are well-known emulators that can translate algorithms from the shared-memory model to the message-passing model (see [2, 3]), these emulators are not applicable for our problem, because the number of failures they tolerate is less than a majority of the total number of processes, while our problem allows up to $t-1$ failures. Also, these transformations introduce a multiplicative overhead of message complexity that is polynomial in t, while one of our goals here is to minimize this term.[1] Second, our complexity measure is inherently different from that of [13]. Kanellakis and Shvartsman's complexity measure is the sum, over the rounds during which the algorithm is running, of the number of processes that are not faulty during each round. They call their measure the *available processor steps*. This measure essentially "charges" for a nonfaulty process at round r whether or not it is actually doing any work (say, reading or writing a cell in shared memory). Our approach is generally *not* to charge a process in round r if it is not expending any effort (sending a message or performing a unit of work) at that round, since it is free at that round to be working on some other task.[2] Of course, the appropriateness of charging or not charging for process idle time will depend very much on the details of the system and the tasks being performed.

Our results have been extended by De Prisco, Mayer, and Yung [8] and by Galil, Mayer, and Yung [11]. De Prisco, Mayer, and Yung [8] consider the problem introduced here, but their goal is to optimize the available processor steps defined by [13], and then the number of messages. They present a message-efficient algorithm that achieves optimality in the available processor steps measure. They also show that when $t \approx n$, any algorithm for performing work in the message-passing model requires at least n^2 available processor steps. This lower bound can be avoided in shared-memory models that allow concurrent writes; for example, an $O(n \log^2 n)$ so-

[1] In fact, these emulators are designed for asynchronous systems, and it may be possible to improve their resilience for our synchronous model. Nevertheless, they seem to have an inherent multiplicative overhead in message complexity that is at least linear in t.

[2] Inactive processes in our algorithms may need to both receive messages and count the number of rounds that have passed, say, from the time they received their last message. We assume that processes can do this while carrying out other tasks.

lution is presented in [13]. Galil, Mayer, and Yung [11] employ the results of [8] to obtain a Byzantine agreement algorithm for the crash fault model that requires only a linear number of messages. Roughly speaking, the processors are organized into a tree. The children of the root attempt to solve the problem recursively; the group membership protocol of [8] (called a *checkpoint protocol*, not to be confused with the checkpoints as defined in our paper) is used to attempt to determine which of the children have failed to complete the recursive step, and the computation is reorganized accordingly.

The Galil, Mayer, and Yung protocol compares with that obtained by using our Protocol $\mathcal{B}$ as follows: [11] requires $O(n)$ messages, while ours requires $O(n\sqrt{n})$; [11] requires $O(n^{1+1/\epsilon})$ rounds of communication while ours requires $O(n)$; finally, [11] requires messages of length $\Omega(n + \log_2 |V|)$, where V is the set of possible agreement values. This appears to be because the protocol requires knowledge of which processors are alive and which processors occupy which parts of the tree. In contrast, our messages are of length $O(\log n + \log_2 |V|)$.

2. A protocol with effort $O(n+t^{3/2})$. Our goal in this section is to present a protocol with effort $O(n+t\sqrt{t})$ and running time $O(n+t)$. We begin with a protocol that is somewhat simpler to present and analyze, with effort $O(n+t\sqrt{t})$ and running time $O(nt+t^2)$. This protocol has the additional property of working with minimal change in an asynchronous environment with failure detection.

The main idea of the protocol is to use checkpointing in order to avoid redoing too much work if a process fails. The most naïve approach to checkpointing does not work. To understand why, suppose a process does a checkpoint after every n/k units of work. This means that up to n/k units of work are lost when a process fails. Since up to t processes may fail, this means that nt/k units of work can be lost (and thus must be repeated), which suggests we should take $k \geq t$ if we want to do no more than $O(n)$ units of work altogether. However, since each checkpoint involves t messages, this means that roughly tk messages will be sent. Thus we must have $k \leq \sqrt{t}$ if we are to use fewer than $t\sqrt{t}$ messages. Roughly speaking, this argument shows that doing checkpoints too infrequently means that there might be a great deal of wasted work, while doing them too often means that there will be a great deal of message overhead. Our protocol avoids these problems by doing *full* checkpoints to all the processes relatively infrequently—after $n/\sqrt{t}$ units of work—but doing partial checkpoints to only $\sqrt{t}$ processes after every n/t units of work. This turns out to be just the right compromise.

2.1. Description of the algorithm. For ease of exposition, we assume that t is a perfect square and that n is divisible by t (so that, in particular, $n > t$). We leave to the reader the easy modifications of the protocol when these assumptions do not hold. We assume that the processes are numbered 0 through $t-1$ and that the units of work are numbered 1 through n. We divide the processes into $\sqrt{t}$ groups of size $\sqrt{t}$ each and use the notation g_i to denote process i's group. (Note $g_i = \lceil (i+1)/\sqrt{t} \rceil$.) We divide the work into $\sqrt{t}$ *chunks*, each of size $n/\sqrt{t}$, and subdivide the chunks into $\sqrt{t}$ *subchunks* of size n/t.

The protocol guarantees that at each round, at most one process is *active*. The active process is the only process performing work. If process i is active, then it knows that processes 0 to $i-1$ have crashed or terminated. Initially, process 0 is active. The algorithm for process 0 is straightforward: process 0 starts out doing the work, a subchunk at a time. After completing a subchunk c, it does a checkpoint to the remaining processes in its group g_0 (processes 1 to $\sqrt{t}-1$); that is, it informs its group

that the subchunk of work has been completed by broadcasting to the processes in its group a message of the form (c). (If process 0 crashes in the middle of a broadcast, we make no assumption about which processes receive the message.) We call this a *partial checkpoint*, since the checkpointing is only to the processes in g_0. (Code for this for module and the whole protocol may be found in Figure 1.) After completing a whole chunk of work—that is, after completing a subchunk c which is a multiple of $\sqrt{t}$—process 0 informs *all* the processes that subchunk c has been completed, but it informs them one group at a time. After informing a whole group, it checkpoints the fact that a group has been informed to its own group (i.e., group 1). Formally, after completing a subchunk c that is a multiple of $\sqrt{t}$, process 0 does a partial checkpoint to its own group, and then for each group $2, \ldots, \sqrt{t}$, process 0 broadcasts to the processes in group g a message of the form (c, g) and then broadcasts to all the processes in its own group a message of the form (c, g). We call this a *full checkpoint*. Note that in a full checkpoint there is really a double checkpointing process: we checkpoint both the fact that work has been completed, and (to the processes in g_0) the fact that all processes have been informed that the work has been completed. Process 0 terminates after sending the message $(t, \sqrt{t})$ to process $t - 1$, indicating to the last process that the last chunk of work has been completed (unless it crashes before that round).

If process 0 crashes, we want process 1 to become active; if process 1 crashes, we want process 2 to become active, and so on. More generally, if process j discovers that the first $j - 1$ processes have crashed, then it becomes active. Once process j becomes active, it continues with essentially the same algorithm as process 0, except that it does not repeat the work it knows has already been done. We must ensure that the takeover proceeds in a "smooth" manner, so that there is at most one active process at a time.

Process j's algorithm is as follows. If j does not know that all the work has already been performed and sufficiently long time has passed from the beginning of the execution, then j becomes active. "Sufficiently long" means long enough to ensure that processes $0, \ldots, j-1$ have crashed or terminated. As we show below, we can take "sufficiently long" to be defined by the function $DD(j) = j(n+3t)$. ("DD" stands for deadline. We remark that this is not an optimal choice for the deadline; we return to this issue later.) Thus if the round number r is less than $DD(j)$, then j does nothing. Otherwise, if j does not know that the work is completed, it takes over as the active process at round $DD(j)$.

When j takes over as the active process, it essentially follows process 0's algorithm. Suppose the last message j received was of the form (c, g), and this message was received from a process k. By the syntax of the message we have that c is a multiple of $\sqrt{t}$ and that k was performing a full checkpoint when it sent the message. If $k \notin g_j$ then $g = g_j$, since this is the only kind of full checkpoint message that k sends to processes outside its group. Thus j informs the rest of its own group that subchunk c was performed, which it does with a Partialcheckpoint(c), and then proceeds with the full checkpoint of c, beginning with group $g_i + 1 = g + 1$.

If $k \in g_j$ then $g > g_j$; the meaning of (c, g) in this case is that k has told group g that subchunk c has been completed and is telling its own group g_k $(= g_j)$ about this fact. In this case j first ensures that its own group knows that group g has been informed about subchunk c, which it does by broadcasting (c, g) to the remainder of its group, and then proceeds with the full checkpoint beginning with group $g + 1$.

If the last message received was of the form (c) then this message was part of a partial checkpoint to g_j. In this case process j completes the partial checkpoint.

Main protocol

1. **if** round number $= DD(j)$ *and* not received (t) or (t, g_j)
2. **then** DoWork.

DoWork

1. **if** the last message received was from k and had the form (c, g)
2. **then** **if** $k \notin g_j$
3. **then** Partialcheckpoint(c); {see code below}
4. **else** Broadcast (c, g) to processes $j+1, \ldots, g_j\sqrt{t}-1$;
5. Fullcheckpoint$(c, g+1)$; {complete a full checkpoint; see code below}
6. **else** let (c) be the last message received;
7. Partialcheckpoint(c);
8. **if** c is a multiple of $\sqrt{t}$
9. **then** Fullcheckpoint(c, g_j+1).
10. **for** $s = c+1$ to t **do** {proceed with performing work}
11. Perform subchunk s;
12. Partialcheckpoint(s);
13. **if** s is a multiple of $\sqrt{t}$;
14. **then** Fullcheckpoint(s, g_j+1)

Partialcheckpoint(c)

1. Inform the remainder of group g_j that subchunk c has been performed by broadcasting (c) to processes $j+1, \ldots, g_j\sqrt{t}-1$

Fullcheckpoint(c, l)

1. **for** $g = l$ to $\sqrt{t}$ **do**
2. Inform group g that subchunk c has been performed by broadcasting (c, g) to group g;
3. Inform the remainder of group g_j that group g has been informed about subchunk c by broadcasting (c, g) to processes $j+1, \ldots, g_j\sqrt{t}-1$

FIG. 1. *Protocol $\mathcal{A}$: code for process j.*

In all three cases, j proceeds with work beginning with subchunk $c+1$ (if such a subchunk exists).

Unless it has already crashed, process j terminates before becoming active if it receives (t) (as part of a partial checkpoint) or (t, g_j) (as part of a full checkpoint). Otherwise, after becoming active at $DD(j)$, it terminates as follows. If $g_j = \sqrt{t}$ then j terminates after broadcasting (t) to the remainder of g_j. If $g_j < \sqrt{t}$ then j terminates after completing a call of the form Fullcheckpoint(t, g_j+1). This completes the description of our first protocol. We call this Protocol $\mathcal{A}$; the code appears in Figure 1.

Notice that we can easily modify this algorithm to run in a completely asynchronous system equipped with an appropriate *failure detection mechanism* [7]: if a process fails, then the failure detection mechanism must eventually inform all the processes that have not failed of this fact; moreover, the mechanism must be sound, in that it never says that a nonfaulty process has failed. The modification is trivial: rather than waiting until round $DD(j)$ before becoming active, process j waits until it has been informed that processes $1, \ldots, j-1$ crashed or terminated.

2.2. Analysis and proof of correctness. We now give a correctness proof for Protocol $\mathcal{A}$. We say a process is *retired* if it has either crashed or terminated.

LEMMA 2.1. *A process performs at most n units of work, sends at most $3t\sqrt{t}$ messages, and runs for less than $n+3t$ rounds from the time it becomes active to the time it retires.*

Proof. It is easy to see that from the time process i becomes active, it performs each unit of work at most once, partial checkpoints each subchunk at most once (and hence performs at most t partial checkpoints), and full checkpoints every chunk at most once (and hence performs at most $\sqrt{t}$ full checkpoints). Each partial checkpoint consists of a broadcast to process i's group and hence involves at most $\sqrt{t}$ messages and one round. Thus process i spends at most t rounds on partial checkpoints and sends at most $t\sqrt{t}$ messages when performing partial checkpoints. During a full checkpoint, process i broadcasts once to each group other than its own, and broadcasts at most $\sqrt{t}$ times to its own group. Each broadcast involves at most $\sqrt{t}$ messages and one round, and there are $\sqrt{t}$ groups. Thus process i sends less than $2t\sqrt{t}$ messages when performing full checkpoints and takes less than $2t$ rounds doing so. The required bounds immediately follow. □

Recall that $DD(j) = j(n+3t)$. The following lemma is now immediate from the definition of DD.

LEMMA 2.2. *Assume process j becomes active at round r of an execution $e_{\mathcal{A}}$ of Protocol $\mathcal{A}$. Then all processes $< j$ have retired before round r.*

It is sometimes convenient to view a group g_i as a whole. Therefore we say that a *group is active* in the period starting when some process in this group becomes active and ending when the last process of this group retires. Notice that Lemma 2.2 ensures that when g_i becomes active, all processes in smaller groups have retired.

THEOREM 2.3. *In every execution of Protocol $\mathcal{A}$,*

(a) *at most $3n$ units of work are performed in total by the processes;*

(b) *at most $9t\sqrt{t}$ messages are sent;*

(c) *by round $nt + 3t^2$, all processes have retired.*

Proof. Part (c) is immediate from Lemma 2.1 and the definition of DD.

We prove parts (a) and (b) simultaneously. To do so, we need a careful way of counting the total number of messages sent and the total amount of work done. A given unit of work may be performed a number of times. If it is performed more than once, say by processes $i_1, \ldots, i_k$, we say that i_2 *redoes* that unit of work of i_1, i_3 redoes the work of i_2, etc. It is important to note that i_3 does not redo the work of i_1 in this case, only that of i_2. Similarly, we can talk about a message sent during a partial checkpoint of a subchunk or a full checkpoint of a chunk done by i_1 as being *resent* by i_2. In particular, a message m sent by i_1 as part of a broadcast is resent by i_2 if i_2 sends exactly the same message as part of a broadcast (not necessarily to the same set of recipients). For example, if i_1 sends (c) to the remainder of g_{i_1} as part of a partial checkpoint, and later i_2 sends (c) to the remainder of g_{i_2}, then, whether or not $g_{i_1} = g_{i_2}$, the messages in the second broadcast are considered to be resendings.

Since the completion of a chunk is followed by a full checkpoint, it is not hard to show that when a new group becomes active it will redo at most one chunk of work that was already done by previous active groups. It will also redo at most one full checkpoint that was done already on the previous chunk and at most $\sqrt{t}$ partial checkpoints (one for each subchunk of work redone). In all, it is easy to see that at most $n/\sqrt{t}$ units of work done by previous groups are redone when a new group becomes active and at most $3t$ messages are resent. Similarly, since the completion of a subchunk is followed by a partial checkpoint, it is not hard to show that when a new process, say i, in a group that is already active becomes active, and the last message it received was of the form (c) (i.e., a partial checkpoint of subchunk c), it will redo at most one subchunk that was already done by previous active process (namely, $c+1$) and may possibly resend the messages in two partial checkpoints: the one sent after subchunk c and the one sent after subchunk $c+1$ (if the previous process crashed during the checkpointing of $c+1$ without i receiving the message). If the last message that i received was (c, g) for $g > g_i$ (that is, the checkpointing of a checkpoint in the middle of a full checkpoint), then similar arguments show that it may resend $3\sqrt{t}$ messages: the checkpoint of (c, g) to its own group, the checkpoint $(c, g+1)$ to group $g+1$, and the checkpointing of $(c, g+1)$ to its own group. Thus the amount of work done by an active group that is redone when a new process in that group becomes active is at most n/t, and the number of messages resent is at most $3\sqrt{t}$.

The maximum amount of unnecessary work done is (number of groups) $\times$ (amount of work redone when a new group becomes active) + (number of processes) $\times$ (amount of work redone when a new process in an already active group becomes active) $\leq \sqrt{t}(n/\sqrt{t}) + t(n/t) = 2n$. Similarly, the maximum number of unnecessary messages that may be sent is no more than (number of groups) $\times$ (number of messages resent when a new group becomes active) + (number of processes) $\times$ (number of messages resent when a new process in an already active group becomes active) $\leq \sqrt{t}(3t) + t3\sqrt{t} = 6t\sqrt{t}$. Clearly, n units of work must be done; by Lemma 2.1, at most $3t\sqrt{t}$ messages are necessary. Thus no more than $3n$ units of work will be done altogether, and no more than $9t\sqrt{t}$ messages will be sent altogether. □

2.3. Improving the time complexity. As we have observed, the round complexity of Protocol $\mathcal{A}$ is $nt + 3t^2$. We now discuss how the protocol can be modified to give a protocol that has round complexity $O(n+t)$, while not significantly changing the amount of work done or the number of messages sent.

Certainly one obvious hope for improvement is to use a better function than DD for computing when process i should become active. While some improvement is possible by doing this, we can get a round complexity of no better than $O(n\sqrt{t})$ if this is all we do, which is still more than we want. Intuitively, the problem is that if process j gets a message of the form (c, g), then it is possible, as far as j is concerned, that some other process $i < j$ may have received a message of the form $(c+\sqrt{t}, h)$. (Observe that this situation is possible even if $g_i = g_j$ because if the sender of the message $(c+\sqrt{t}, h)$ crashes at the round when it broadcasts this message to g_i, this message may reach an arbitrary subset of the processes in g_i.) Process j cannot become active before it is sure that i has retired. To compute how long it must wait before becoming active, it thus needs to compute how long i would wait before becoming active, given that i got a message of the form $(c+\sqrt{t}, h)$. On the other hand, if i did get such a message, then as far as i is concerned, some process $i' < i$ may have received a message of the form $(c+2\sqrt{t}, h')$. Notice that, in this case, process j knows perfectly well that no process received a message of the form $(c+2\sqrt{t}, h')$; the

problem is that i does not know this and must take into account this possibility when it computes how long to wait before becoming active. Carrying out a computation based on these arguments gives an algorithm which runs in $O(n\sqrt{t})$ rounds.

On closer inspection, it turns out that the situation described above really causes difficulties only when all processes involved (in the example above, this would be the processes j, i, and i') are in the same group. Thus in our modified algorithm, called Protocol $\mathcal{B}$, process j computes the time to become active as follows: suppose that the last message received by process j before round r was received from process i in round r'. Process j then computes a function $DD_{\mathcal{B}}(j,i)$ with the property that if $r = r' + DD_{\mathcal{B}}(j,i)$, then process j knows at round r that all processes in groups $g' < g_j$ must have retired. Moreover, if $g_i = g_j$, then j knows at round r that all processes $\leq i$ must have retired. Process j then polls all the lower-numbered processes in its own group not known to it as retired, one by one, to see if they are alive; if not, then j becomes active. If any of them is alive, then the lowest-numbered one that is alive becomes active upon receipt of j's message. Once a process becomes active, it proceeds just as in Protocol $\mathcal{A}$. This technique turns out to save a great deal of time, while costing relatively little in the way of messages.

In particular, in Protocol $\mathcal{B}$, process 0 follows the same algorithm as in Protocol $\mathcal{A}$. Process j's algorithm is as follows. Here j receives messages either of the form (c), (c,g) or of the form **go ahead**. We call the first two types of messages *ordinary*, to distinguish them from the **go ahead** messages. Suppose that the last ordinary message received by process j before round r is of the form (c) or (c,g), and this message was received from process i at round r'. To avoid dealing separately with the special case in which j does not receive any message before it becomes active, we use the convention that process 0 becomes active in round 0 (just before the execution begins) and every process receives from it an ordinary message $(0,g)$ at that round. (These fictitious messages are used only in the analysis and hence will not be taken into account when computing the message complexity of the protocol. Also, if in the actual execution process 0 crashes before ever becoming active then we say that it crashes just after it finishes broadcasting these fictitious messages.) There are now two ways for j to become active at round r. The first is if j receives a **go ahead** message at round r and $c < t$. In this case j becomes active, proceeding just as in Protocol $\mathcal{A}$ when it became active at round $DD(j)$. Alternatively, if j does not receive a message for a sufficiently long time, j becomes active. Intuitively, sufficiently long will ensure that all processes smaller than j have already retired.

To analyze this more formally, we need some definitions. Let PTO be $n/t + 2$. ("PTO" stands for process time out.) $PTO - 1$ is an upper bound on the number of rounds that can pass before process j in group $g_j = g_i$ hears from process i if i is active. Let $\bar{\jmath}$ denote j mod $\sqrt{t}$. Let $GTO(i)$ be $n/\sqrt{t} + 3\sqrt{t} + (\sqrt{t} - \bar{\imath} - 1)PTO + 1$. ("$GTO$" stands for group time out.) $GTO(i) - 1$ is an upper bound on the number of rounds that can pass before process j in group $g_j > g_i$ hears from a process k in g_i with $\bar{\imath} \leq \bar{k} \leq \sqrt{t} - 1$ if any of these processes is active. Next we define a new deadline function as follows:

$$DD_{\mathcal{B}}(j,i) = \begin{cases} GTO(i) + (g_j - g_i - 1)GTO(0) & \text{if } g_j \neq g_i, \\ PTO & \text{otherwise.} \end{cases}$$

We now define "sufficiently long" in terms of $DD_{\mathcal{B}}$ rather than DD. Again taking r to be the current round, r' to be the last round before r in which j received a message, and i to be the process sending that message, j proceeds as follows: if $r < r' + DD_{\mathcal{B}}(j,i)$, then j does nothing. If $c < t$ and $r = r' + DD_B(j,i)$, j becomes *preactive*. First

consider the case where $g_i \neq g_j$. Informally, at this point, j knows that all processes from groups $< g_j$ have failed. In this case, it sends a **go ahead** message to each lower-numbered process in its group, starting with the first process in g_j up to the $(\bar{\jmath}-1)$st process in g_j, and waiting $PTO-1$ rounds between messages to see if it receives a message. (Observe that if the recipient of the **go ahead** message is alive, the sender receives a message from it within one round after the **go ahead** mesage was sent; however, for technical reasons the sender of the **go ahead** messages waits $PTO-1$ rounds between two successive **go ahead** messages.) If $g_i = g_j$, process j proceeds similarly to the case where $g_i \neq g_j$ except that when sending **go ahead** messages it starts with the $(\bar{\imath}+1)$st process in g_j. That is, it sends a **go ahead** message to each lower-numbered process in its group, starting with the $(\bar{\imath}+1)$st process in g_j up to the $(\bar{\jmath}-1)$st process in g_j, and waiting $PTO-1$ rounds between messages to see if it receives a message. If j does not receive any response to its **go ahead** messages by round $r' + DD_{\mathcal{B}}(j,i) + \bar{\jmath}PTO - 1$ if $g_i \neq g_j$, or by round $r' + (\bar{\jmath}-\bar{\imath})PTO - 1$ if $g_i = g_j$, then it becomes active at round $r' + DD_{\mathcal{B}}(j,i) + \bar{\jmath}PTO$ (respectively, $r' + (\bar{\jmath}-\bar{\imath})PTO$), proceeding just as it did in Protocol $\mathcal{A}$ at round $DD(j)$. If it does get a message, then j becomes passive again.

Note that the construction of the algorithm guarantees that if $r = r' + DD_{\mathcal{B}}(j,i) + \bar{\jmath}PTO$, the last ordinary message that j receives in execution $e_{\mathcal{B}}$ prior to round r was sent by i, and $g_i \neq g_j$, then j will become active in $e_{\mathcal{B}}$ at or before round r. (It may become active earlier if it receives a **go ahead** message.) Similarly, if $r = r' + (\bar{\jmath}-\bar{\imath})PTO$, the last ordinary message that j receives in execution $e_{\mathcal{B}}$ prior to round r was sent by i, and $g_i = g_j$, then j will become active in $e_{\mathcal{B}}$ at or before round r. Define

$$TT(j,i) = \begin{cases} GTO(i) + (g_j - g_i - 1)GTO(0) + \bar{\jmath}PTO & \text{if } g_j \neq g_i, \\ (\bar{\jmath}-\bar{\imath})PTO & \text{otherwise.} \end{cases}$$

("TT" stands for transition time.) Our observations above show that if $r = r' + TT(j,i)$ and the last ordinary message that j receives in execution $e_{\mathcal{B}}$ prior to round r was sent by i, then j will become active in $e_{\mathcal{B}}$ at or before round r.

Unless it has already crashed, process j terminates before becoming active if it receives (t) (as part of a partial checkpoint) or (t, g_j) (as part of a full checkpoint). Otherwise, after becoming active it terminates as follows. If $g_j = \sqrt{t}$ then j terminates after broadcasting (t) to the remainder of g_j. If $g_j < \sqrt{t}$ then j terminates after completing a call of the form Fullcheckpoint$(t, g_j + 1)$. This completes the description of Protocol $\mathcal{B}$. The code for Protocol $\mathcal{B}$ appears in Figure 2; it uses the code for the DoWork procedure in Figure 1.

2.4. Proof of correctness of Protocol $\mathcal{B}$. In this section we show that the round complexity of Protocol $\mathcal{B}$ is $O(n+t)$, and that neither the amount of work done nor the number of messages sent in Protocol $\mathcal{B}$ is significantly larger than that in Protocol $\mathcal{A}$.

Suppose for a moment that in every execution of Protocol $\mathcal{B}$ a process becomes active only after all lower-numbered processes have retired. Since when a process becomes active in an execution of Protocol $\mathcal{B}$ it performs essentially the same steps as when it becomes active when it follows Protocol $\mathcal{A}$, a similar proof to the one of Theorem 2.3 will show that the amount of work performed in any execution of Protocol $\mathcal{B}$ is no more than $3n$ units (which is roughly the maximum amount of work performed in any execution of Protocol $\mathcal{A}$), and the number of ordinary messages sent is no more than $9t\sqrt{t}$ (which is roughly the maximum number of messages sent in any execution

Main protocol

1. **if** just received a **go ahead** message
2. **then** DoWork; {see Figure 1 for details}
3. **else** **if** round number $= r' + DD_{\mathcal{B}}(j, i)$
   and last message received was from process i at round r'
4. **then** PreactivePhase(i, r')

PreactivePhase(i, r')

1. **if** $g_i \neq g_j$
2. **then** $i' := (g_j - 1)\sqrt{t}$;
3. **else** $i' := i + 1$;

4. $r :=$ *current round*;
5. **while** not received a message *and* $i' < j$ **do**
6. **if** *current round* $- r \equiv 0 \pmod{PTO}$
7. **then** send **go ahead** message to process i';
8. $i' := i' + 1$;
9. **if** just received a **go ahead** message or $i' \geq j$
10. **then** DoWork

FIG. 2. *Protocol $\mathcal{B}$: code for process j.*

of Protocol $\mathcal{A}$). Since the number of **go ahead** messages sent in any execution of Protocol $\mathcal{B}$ is at most $t\sqrt{t}$ (each process sends at most one **go ahead** message to every other process in its group), it follows immediately that the total amount of effort performed by Protocol $\mathcal{B}$ is not significantly larger than the one performed by Protocol $\mathcal{A}$. Therefore, the main property we need to prove is that in every execution of Protocol $\mathcal{B}$, a process becomes active only after all lower-numbered processes have retired.

Our analysis uses what we call *activation chains*. The round r *activation chain* of process i, denoted $ac(i, r)$, is the sequence of processes $\langle i_m, \ldots, i_0 \rangle$ such that $i_0 = i$ and for all j, if i_j received an ordinary message prior to round r, then i_{j+1} is the sender of the last message received by i_j. (As we show below, it cannot be the case that i_j receives ordinary messages from two distinct processes in the same round. Since we have not yet proved this, for now, if i_j received ordinary messages from more than one process in the last round in which it received an ordinary message, we take i_{j+1} to be the lowest-numbered process among them.) Notice that our convention that process 0 sent a round 0 message guarantees that $i_m = 0$. In addition, note that the processes in the activation chain appear in increasing order since a process sends messages only to higher-numbered processes.

It is sometimes convenient to view i's activation chain as a whole and to reason about the effort performed by the chain. We say that process k in $ac(i, r)$ is the *current process* from the round it becomes active up to (but not including) the round at which its successor in the chain becomes active. Note that a process in $ac(i, r)$ is current when it first becomes active. Now let k, l be processes in $ac(i, r)$ such that l immediately succeeds k, and assume the last ordinary message l receives from k

before l becomes active is sent at round r'. Clearly, any operation (sending messages or performing a unit of work) done by k after round r' is not known by l and hence may be repeated by the chain (that is, may be repeated by some process when it is the current process in the chain). On the other hand, any operation done by k before round r' will be known by the processes succeeding it in the chain by the time they become active and hence will not be repeated by the chain. The operation done by k in round r', which is a broadcast to g_l, will be repeated by l in the first round in which l becomes active. We say that an operation performed by a process k in the chain is *useful* if it is performed before the round in which the process immediately succeeding k in the chain heard from k for the last time before becoming active (if the process is i, then there is no later process in the chain, and hence all operations performed by i are useful). When we refer to an *operation performed by a chain* $ac(l, r)$, we mean a useful operation performed by some process in that chain. We say that a round is *useful* for the chain $ac(l, r)$ if the chain performed a useful operation in that round; otherwise we say that the round is *useless*.

The discussion above shows that the operations performed by a chain proceed in a similar order to the operations performed by a single active process. More precisely, if we consider only useful operations, the processes in the chain perform work units one by one in the natural order and without repetition; each time a subchunk c is completed by the chain, the group of the process that completes this subchunk is informed about this fact exactly once, and if the completed subchunk is a multiple of $\sqrt{t}$, then in addition all groups whose numbers are higher than the group of the process that completed this subchunk are informed that the subchunk is completed one by one in the natural order and without repetition (that is, each such group g receives a message (c, g) exactly once); moreover, each time such a group g is informed, this fact is checkpointed to the group of the informer exactly once. Assume process i is active at some round r with $r \geq r2 \geq r1 \geq 1$. Then we denote by $T_{r1}^{r2}(i)$ the number of useful rounds for the chain $ac(i, r)$ in interval $[r1, r2]$ (that is, in the period from round $r1$ to round $r2$ (inclusive)).

LEMMA 2.4. *Let l be active at some round r with $r \geq r2 \geq r1 \geq 1$. Then*

(a) $T_{r1}^{r2}(l) \leq n + 3t$;

(b) *if $T_{r1}^{r2}(l) \geq n/\sqrt{t} + 3\sqrt{t}$, then each process $\geq l$ must have received a message from (a process in) $ac(l, r)$ at some round r' such that $r1 \leq r' \leq r2$.*

Proof. Part (a) follows from the fact that in each useful round, the chain does one of the following: it performs work, it checkpoints to some group g the fact that a subchunk c was performed, or it checkpoints the fact that group g was informed that chunk c was performed. The discussion above shows that no unit of work is repeated and hence there are at most n useful rounds in which the chain performs work. Similarly, each subchunk is partially checkpointed at most once and hence there are at most t useful rounds in which the chain performs partial checkpoints of subchunks. Also, the completion of a chunk is checkpointed to each group at most once, yielding at most t useful rounds in which such subchunks are checkpointed. Finally, the fact that group g was informed about chunk c is checkpointed at most once, yielding at most t additional useful rounds. Summing the above the claim follows.

Part (b) follows because, as reasoned above, the useful operations done by the chain follow the same order as if they are done by a single active process. Hence within $n/\sqrt{t} + 3\sqrt{t}$ rounds the chain must complete a chunk and a full checkpoint. ∎

Now, as we mentioned above, at the core of our proof of correctness is the fact that when a process becomes active, all lower numbered processes have already retired. To prove this, we first prove a lower bound on the number of useful rounds for a given activation chain in a given period. Using this bound, we can show that if some process i receives its last ordinary message before becoming active at round $r1$, i becomes active at round $r2$, and some process $l < i$ has not retired by $r2$, then process i would have received an ordinary message from some process in $ac(l, r2)$ between rounds $r1$ and $r2$, contradicting our choice of $r1$.

We now proceed with the formal proofs. We start with a technical lemma.

LEMMA 2.5. *Let $l > j > k$. Then*

(a) $TT(j,k) + TT(l,j) = TT(l,k)$;

(b) *if $g_j < g_l$, then $TT(j,k) + DD_{\mathcal{B}}(l,j) = DD_{\mathcal{B}}(l,k)$.*

Proof. The proof is straightforward. We start with part (a). In the calculations below, we use "$(g_i = g_j)$" to denote the value 1 if $g_i = g_j$ and 0 otherwise. Similarly, "$(g_i \neq g_j)$" denotes 1 if $g_i \neq g_j$, and 0 otherwise. Recall that $\bar{\jmath}$ denotes j mod $\sqrt{t}$.

$$\begin{aligned} TT(j,k) + TT(l,j) = {} & [GTO(k) + (g_j - g_k - 1)GTO(0) + \bar{\jmath}PTO](g_j \neq g_k) \\ & + [(\bar{\jmath} - \bar{k})PTO](g_j = g_k) \\ & + [GTO(j) + (g_l - g_j - 1)GTO(0) + \bar{l}PTO](g_l \neq g_j) \\ & + [(\bar{l} - \bar{\jmath})PTO](g_l = g_j). \end{aligned}$$

If $g_j = g_k$, then

$$\begin{aligned} TT(j,k) + TT(l,j) &= (\bar{\jmath} - \bar{k})PTO \\ &\quad + [GTO(j) + (g_l - g_k - 1)GTO(0) + \bar{l}PTO](g_l \neq g_k) \\ &\quad + [(\bar{l} - \bar{\jmath})PTO](g_l = g_k) \\ &= [GTO(k) + (g_l - g_k - 1)GTO(0) + \bar{l}PTO](g_l \neq g_k) \\ &\quad + [(\bar{l} - \bar{k})PTO](g_l = g_k) \\ &= TT(l,k), \end{aligned}$$

and part (a) follows. (In the first equality we replaced g_j by g_k since in this case they are identical, and the second equality follows because $GTO(j) + (\bar{\jmath} - \bar{k})PTO = GTO(k)$.)

If $g_j \neq g_k$, then

$$\begin{aligned} TT(j,k) + TT(l,j) &= [GTO(k) + (g_j - g_k - 1)GTO(0) + \bar{\jmath}PTO] \\ &\quad + [GTO(j) + (g_l - g_j - 1)GTO(0) + \bar{l}PTO](g_l \neq g_j) \\ &\quad + [(\bar{l} - \bar{\jmath})PTO](g_l = g_j) \\ &= [GTO(k) + (g_l - g_k - 1)GTO(0) + \bar{l}PTO](g_l \neq g_j) \\ &\quad + [GTO(k) + (g_j - g_k - 1)GTO(0) + \bar{l}PTO](g_l = g_j) \\ &= [GTO(k) + (g_l - g_k - 1)GTO(0) + \bar{l}PTO] \\ &= TT(l,k), \end{aligned}$$

and again part (a) follows. (The second equality follows by a case analysis on whether or not $g_l = g_j$, using the fact that $GTO(j) + \bar{\jmath}PTO = GTO(0)$ and the fourth equality follows since $g_j \neq g_k$ and $l > j > k$ implies $g_l \neq g_k$.)

The proof of part (b) is similar. Observe that here by assumption, $g_l \neq g_j$ and hence also $g_l \neq g_k$. If $g_j = g_k$, then

$$\begin{aligned} TT(j,k) + DD_{\mathcal{B}}(l,j) &= (\bar{\jmath} - \bar{k})PTO + [GTO(j) + (g_l - g_k - 1)GTO(0)] \\ &= [GTO(k) + (g_l - g_k - 1)GTO(0)] \\ &= DD_{\mathcal{B}}(l,k), \end{aligned}$$

and part (b) follows.

If $g_j \neq g_k$, then

$$\begin{aligned} TT(j,k) + DD_{\mathcal{B}}(l,j) &= [GTO(k) + (g_j - g_k - 1)GTO(0) + \bar{\jmath}PTO] \\ &\quad + [GTO(j) + (g_l - g_j - 1)GTO(0)] \\ &= [GTO(k) + (g_l - g_k - 1)GTO(0)] \\ &= DD_{\mathcal{B}}(l,k), \end{aligned}$$

and part (b) follows. □

The next lemma establishes a lower bound on the number of useful rounds for an activation chain in a given interval.

LEMMA 2.6. *Assume l is active at some round r such that $r \geq r2 \geq r1 \geq 1$. Assume $p \geq k$ is the current process in $ac(l,r)$ at some round $\leq r1$. Then $T_{r1}^{r2}(l) \geq r2 - r1 - TT(l,k) + 1$.*

Proof. We first show that if j is in $ac(l,r)$ and becomes active at round r' with $r1 \leq r' \leq r2$, then there are at most $TT(j,k)$ useless rounds in $[r1, r'-1]$. We proceed by induction on r'. If $r' = r1$, the result is trivial. If $r' > r1$, then j is i's successor for some i in the activation chain and j received its last message from i at some round r''. (There is such an i and such a message since by convention process 0 sent an ordinary message to everybody just before the execution begins.) By definition, we have $r' \leq r'' + TT(j,i)$. If $i = k$, we are done, since no round in $[r1, r'' - 1]$ is useless, so there are at most $TT(j,k) = TT(j,i)$ useless rounds in $[r1, r' - 1]$. If $i > k$, then suppose i becomes active at r'''. By the inductive hypothesis, there are at most $TT(i,k)$ useless rounds in $[r1, r''' - 1]$. All the rounds in $[r''', r'' - 1]$ are useful. Thus there are at most $TT(j,i) + TT(i,k)$ useless rounds in $[r1, r' - 1]$. Since $TT(j,i) + TT(i,k) = TT(j,k)$ by Lemma 2.5, the inductive step follows.

Suppose that l becomes active at round $r3$. By the argument above, there are at most $TT(l,k)$ useless rounds in $[r1, r3 - 1]$. If $r3 > r2$, it immediately follows that there are at most $TT(l,k)$ useless rounds in $[r1, r2]$. On the other hand, if $r3 < r2$, since l is still active at $r > r2$, it follows that there are no useless rounds in $[r3, r2]$. Hence we again get that there are at most $TT(l,k)$ useless rounds in $[r1, r2]$. The lemma follows. □

The next lemma shows that in every execution of Protocol $\mathcal{B}$, by the time a process becomes active, all lower numbered processes have retired.

LEMMA 2.7. *In every execution of Protocol $\mathcal{B}$,*

(a) *before the round r in which process i becomes preactive, all processes in groups $< g_i$ have retired;*

(b) *before the round r in which process i becomes active, all processes $< i$ have retired.*

Proof. Fix an execution $e_{\mathcal{B}}$ of Protocol $\mathcal{B}$. The proof proceeds by induction on the round r. The base case of $r = 0$ holds trivially since only process 0 is active then. Assume the claim for $< r$, and we will show it for r. If $i = 0$, the claim holds trivially.

Thus we can assume $i > 0$. Suppose that the last ordinary message that i received before round r came from k, and was received at round $r1$. (Note that there must have been such an ordinary message, given our assumption that process 0 sent an ordinary message to all the processes before the execution begins.)

We first prove part (a). Assume, by way of contradiction, that some process l with $g_l < g_i$ does not retire by round r.

Since, by assumption, $r1$ was the latest round $< r$ at which i received an ordinary message, to complete the proof it is enough to show that if l does not retire before round r, i must have received an ordinary message at some round r'' with $r1 < r'' < r$. In fact, we plan to show that i must have received a message in the interval $(r1, r)$ from some process in $ac(l, r)$. To do this, we plan to use Lemmas 2.4 and 2.6. Notice that both of these lemmas require l to be active. In fact, we can assume without loss of generality that l is active at some round $r3 \geq r$ of $e_{\mathcal{B}}$, and that $ac(l, r) = ac(l, r3)$. If not, we can just consider the execution $e'_{\mathcal{B}}$ which is identical to $e_{\mathcal{B}}$ up to round r, after which all processes other than l crash. It is clear that eventually l becomes active in $e_{\mathcal{B}}$, with the same activation chain it has in round r. Moreover, if i receives an ordinary message in the interval $(r1, r)$ in $e'_{\mathcal{B}}$, then it must also receive the same message in $e_{\mathcal{B}}$, since the two executions agree up to round r.

Since k becomes active at some round prior to r, the inductive hypothesis on part (b) of the lemma implies that all processes $\leq k$ have retired by round $r1 < r$. Thus without loss of generality $l \geq k$. We consider two cases: (i) k is in $ac(l, r)$; (ii) k is not in $ac(l, r)$.

In case (i), since k is in l's activation chain and is active at round $r1$, by the inductive hypothesis, it must be the current process in $ac(l, r)$ at round $r1$. Applying Lemma 2.6 to $ac(l, r3) = ac(l, r)$, we get

$$T^{r-1}_{r1+1}(l) \geq (r-1) - (r1+1) - TT(l,k) + 1.$$

By definition, i becomes preactive in round $r = r1 + DD_{\mathcal{B}}(i, k)$, and hence $r - r1 = DD_{\mathcal{B}}(i, k)$. Substituting this into the above inequality we get

$$T^{r-1}_{r1+1}(l) \geq DD_{\mathcal{B}}(i,k) - TT(l,k) - 1.$$

Since $g_i > g_l$, Lemma 2.5 implies that $DD_{\mathcal{B}}(i, k) - TT(l, k) = DD_{\mathcal{B}}(i, l)$, and substituting this fact in the above inequality we get

$$\begin{aligned} T^{r-1}_{r1+1}(l) &\geq DD_{\mathcal{B}}(i,l) - 1 \\ &= GTO(l) + (g_i - g_l - 1)GTO(0) - 1 \\ &= (n/\sqrt{t} + 3\sqrt{t} + (\sqrt{t} - \bar{l} - 1)PTO + 1) + (g_i - g_l - 1)GTO(0) - 1 \\ &\geq n/\sqrt{t} + 3\sqrt{t}. \end{aligned}$$

Thus part (b) of Lemma 2.4 implies that i must have received an ordinary message at some round in the interval $(r1, r)$, contradicting the assumption that it does not, and the claim follows.

In case (ii), let k' be the greatest process $< k$ in l's activation chain, and let j be the smallest process $> k$ in l's activation chain. Suppose j gets its last message before becoming active from k' at round $r0$. (Note that this means that the last message received by j before becoming active came at $r0$.) Since the inductive hypothesis on part (b) implies that k' must retire before k becomes active, and since k must become active at least one round before it sent a message to i (since by assumption

$g_k \leq g_l < g_i$ and process k checkpoints to its own group before it sends a message to another group), we have $r0 < r1 - 1$. Furthermore, since the processes succeeding k' in l's chain are greater than k, the same inductive hypothesis implies that these processes can become active only after process k retires, and hence after round $r1$. Since by definition any message received by i after round $r0$ from l's chain must be sent by one of the processes succeeding k' in the chain, it follows that if i receives a message from l's chain after round $r0$, this message is sent after round $r1$.

To complete the proof we show that i must have received some message from l's chain at some round in the interval $(r0, r)$, and hence in the interval $(r1, r)$, contradicting the assumption that it does not. As argued above, to show this it is enough to show that $T^{r-1}_{r0+1}(l) \geq n/\sqrt{t} + 3\sqrt{t}$. Applying Lemma 2.6 to l's activation chain we get

$$T^{r-1}_{r0+1}(l) \geq r - 1 - (r0 + 1) - TT(l, k') + 1.$$

To bound $T^{r-1}_{r0+1}(l)$, we need to bound $r - r0$. To do this we will compute two terms: (a) $r - r1$ and (b) $r1 - r0$. The first term is equal to $DD_{\mathcal{B}}(i, k)$ as argued above. To compute the second term, we first show (1) $g_j > g_k$ and (2) $g_{k'} = g_k$.

For (1), clearly $g_j \geq g_k$, since $j > k$. If $g_j = g_k$, j must have received a message from k at round $r1 - 1$ before k sent a message to i (since by assumption $g_k \leq g_l < g_i$ and process k checkpoints to its own group just before it sends a message to another group). As we have observed, $r1 - 1 > r0$, so this contradicts the assumption that the last message received by j before becoming active came at $r0$. Thus $g_j > g_k$.

For (2), clearly $g_{k'} \leq g_k$. If $g_{k'} < g_k$, this means that j did not receive a message from a process in g_k before becoming active (because if it did, then by the inductive hypothesis on part (b) we have that this message arrives after k' retires and hence after round $r0$). But since $g_j \leq g_l < g_i$, and k sent a message to i at $r1$, some process in g_k must have sent a message to j before round $r1$, and hence before j becomes active. This gives us the desired contradiction.

To complete the proof of case (ii) we use the following claim.

CLAIM 2.1. *Every process k'' with $k' < k'' \leq k$ that becomes active does so no earlier than round $r0 + (\bar{k''} - \bar{k'})PTO - 1$.*

Proof. We proceed by induction. Assume $k' < k1 \leq k$ and the claim holds for all k'' with $k' < k'' < k1$. We prove it for $k1$.

We first show that the last ordinary message that any process $\geq k1$ in g_k receives from any process $k2$ with $k' \leq k2 < k1$ is sent no earlier than round $r0 + (\bar{k2} - \bar{k'})PTO - 1$. Observe that since k' is in g_k, so are $k1$ and $k2$. If $k2 = k'$, the claim trivially follows since k' must send a message to its own group at round $r0 - 1$ just before it sends a message to $g_j > g_k$. Otherwise, by the induction hypothesis we have that $k2$ became active no earlier than round $r0 + (\bar{k2} - \bar{k'})PTO - 1$, and the claim again follows.

Let $k2$ be the last process from which $k1$ receives an ordinary message. Observe that $k' \leq k2 < k1$. (Because, as reasoned above, $k1$ has received a message from k', and hence the message sent by $k2$ was sent at or after the time the message sent by k'. The inductive hypothesis on part (b) therefore implies that $k2 \geq k'$.) It follows from the claim above that the message from $k2$ was sent no earlier than round $r0 + (\bar{k2} - \bar{k'})PTO - 1$. In addition, the inductive hypothesis on part (b) implies that $k1$ becomes active only after $k2$ retires, and hence only after receiving its message.

Now assume that $k1$ does not receive a **go ahead** message. It then becomes preactive PTO rounds after it receives the last ordinary message from $k2$ and then $k1$

starts sending **go ahead** messages to lower-numbered processes in its group. Since, by assumption, $k1$ does not receive a message in response, it becomes active $TT(k1, k2) = (\bar{k1} - \bar{k2})PTO$ rounds after receiving this last message from $k2$, and hence no earlier than round $r0 + (\bar{k1} - \bar{k'})PTO - 1$.

Next assume $k1$ receives a **go ahead** message. Let $k3$ be the process sending this message. Let $k2$ be the last process from which $k3$ received an ordinary message before sending the **go ahead** message to $k1$. Since $k3$ sends a **go ahead** message to $k1$, it follows that $k2 < k1$. Just as above, we can show that $k2 \geq k'$, and hence that $k3$ received the ordinary message from $k2$ no earlier than round $\geq r0 + (\bar{k2} - \bar{k'})PTO - 1$. Clearly, $k3$ sends the **go ahead** message to $k1$ no earlier than $(\bar{k1} - \bar{k2})PTO$ rounds after it receives its ordinary message from $k2$, and the claim follows as above. This completes the proof of the inductive step. □

Now, to compute $r1 - r0$, observe that $r1$, the round in which k sends a message to i, is at least one round after k becomes active (because $g_i > g_k$ and k first broadcasts to its own group), and hence Claim 2.1 immediately implies that $r1 - r0 \geq (\bar{k} - \bar{k'})PTO$. Thus we get that

$$\begin{aligned}
T^{r-1}_{r0+1} &\geq (r - r1) + (r1 - r0) - TT(l, k') - 1 \\
&\geq DD_{\mathcal{B}}(i, k) + (\bar{k} - \bar{k'})PTO - TT(l, k') - 1 \\
&= GTO(k) + (g_i - g_k - 1)GTO(0) + (\bar{k} - \bar{k'})PTO - TT(l, k') - 1 \\
&= GTO(k') + (g_i - g_k - 1)GTO(0) - TT(l, k') - 1 \\
&= GTO(k') + (g_i - g_{k'} - 1)GTO(0) - TT(l, k') - 1 \\
&= DD_{\mathcal{B}}(i, k') - TT(l, k') - 1.
\end{aligned}$$

(The fourth inequality follows because $GTO(k) + (\bar{k} - \bar{k'})PTO = GTO(k')$, and the fifth inequality follows because $g_k = g_{k'}$.)

Again, Lemma 2.5 implies that $DD_{\mathcal{B}}(i, k') - TT(l, k') = DD_{\mathcal{B}}(i, l)$, and hence

$$\begin{aligned}
T^{r-1}_{r0+1} &\geq DD_{\mathcal{B}}(i, l) - 1 \\
&= GTO(l) + (g_i - g_l - 1)GTO(0) - 1 \\
&\geq (n/\sqrt{t} + 3\sqrt{t} + (\sqrt{t} - \bar{l} - 1)PTO + 1) - 1 \\
&\geq n/\sqrt{t} + 3\sqrt{t}.
\end{aligned}$$

This completes the proof of the inductive step for part (a).

For part (b), suppose by way of contradiction that i becomes active at round r and process $l < i$ has not retired by round r. First assume i does not receive a **go ahead** message. If $g_l < g_i$, we get an immediate contradiction using the inductive step for part (a), since i becomes active at or after it becomes preactive. Otherwise, recall that k is the last process from which i receives an ordinary message before becoming active, and this message is received at round $r1$. If $k > l$, then since k became active before round r, the inductive hypothesis on part (b) implies that l must have retired before k became active and hence before round r. If $k = l$, then i becomes preactive only after $PTO - 1 = n/t + 1$ additional rounds in which it does not hear from l. We claim that l must have retired by that time. Because, otherwise, in this period l would have either performed a subchunk and informed its group or would have checkpointed a subchunk to a group $g \neq g_l$ and informed its group about the checkpoint. Since $g_i = g_l$, in both cases, i must have heard from l. Finally, if $l > k$, then before i becomes active it sends a **go ahead** message to l and waits for

a message from l for $PTO - 1$ additional rounds. Exactly as above, it follows again that since i does not receive any message from l, l must have retired.

Next assume i does get a **go ahead** message before becoming active. However, the same reasoning as above shows that by the time a process sends a **go ahead** message to process i, all processes $< i$ have retired, and we are done. □

Finally we can prove Theorem 2.8.

THEOREM 2.8. *In every execution of Protocol $\mathcal{B}$,*

(a) *at most $3n$ units of work are performed in total by the processes,*

(b) *at most $10t\sqrt{t}$ messages are sent,*

(c) *by round $3n + 8t$ all processes have retired.*

Proof. Parts (a) and (b) were argued in the beginning of section 2.4.

For part (c), let i be the last process that is active and consider its activation chain. We want to find the last round $r2$ in which i is active. It follows from Lemma 2.4 that the maximal number of useful rounds performed by any chain is $n + 3t$. Therefore, applying Lemma 2.6 with $k = 0$ we get that

$$n + 3t \geq T_1^{r2}(i) \geq r2 - 1 - TT(i, 0) + 1.$$

Thus

$$\begin{aligned}
r2 &\leq n + 3t + TT(i, 0) \\
&\leq n + 3t + TT(t - 1, 0) \\
&= n + 3t + (\sqrt{t} - 1)GTO(0) + (\sqrt{t} - 1)PTO \\
&= n + 3t + (\sqrt{t} - 1)(n/\sqrt{t} + 3\sqrt{t} + (\sqrt{t} - 1)(n/t + 2) + 1) + (\sqrt{t} - 1)(n/t + 2) \\
&\leq n + 3t + (\sqrt{t} - 1)(n/\sqrt{t} + 3\sqrt{t} + \sqrt{t}(n/t + 2) + 1) \\
&= n + 3t + (\sqrt{t} - 1)(n/\sqrt{t} + 3\sqrt{t} + n/\sqrt{t} + 2\sqrt{t} + 1) \\
&\leq n + 3t + \sqrt{t}(2n/\sqrt{t} + 5\sqrt{t}) \\
&\leq 3n + 8t. \qquad \square
\end{aligned}$$

3. An algorithm with effort $O(n + t \log t)$. In this section we prove that the effort of $O(n + t\sqrt{t})$ obtained by the previous protocols is not optimal, even for work-optimal protocols. We construct another work-optimal algorithm, Protocol $\mathcal{C}$, that requires only $O(n + t \log t)$ messages (and a variant that requires only $O(t \log t)$ messages), yielding a total effort of $O(n + t \log t)$. As is the case with Protocols $\mathcal{A}$ and $\mathcal{B}$, at most one process is active at any given time. However, in Protocol $\mathcal{C}$ it is not the case that there is a predetermined order in which the processes become active. Rather, when an active process fails, we want the process that is currently *most knowledgeable* to become the new active process. As we shall see, which process is most knowledgeable after an active process i fails depends on how many units of work i performed before failing. As a consequence, there is no obvious variant of Protocol $\mathcal{C}$ that works in the model with asynchronous processes and a failure detector.

Roughly speaking, Protocol $\mathcal{C}$ strives to "spread out" as uniformly as possible the knowledge of work that has been performed and the processes that have crashed. Thus each time the active process, say, i, performs a new unit of work or detects a failure, i tells this to the process j it currently considers least knowledgeable. Then process j becomes as knowledgeable as i, so after performing the next unit of work (or detecting another failure), i tells the process it now considers least knowledgeable about this new fact.

The most naïve implementation of this idea is the following: process 0 begins by performing unit 1 of work and reporting this to process 1. It then performs unit 2 and reports units 1 and 2 to process 2, and so on, telling process i mod t about units 1 through i. Note that at all times, every process knows about all but at most the last t units of work to be performed.

If process 0 crashes, we want the most knowledgeable alive process—the one that knows about the most units of work that have been done—to become active. (If no process alive knows about any work, then we want the highest numbered alive process to become active.) It can be shown that this can be arranged by setting appropriate deadlines. Moreover, the deadlines are chosen so that at most one process is active at a given time. The most knowledgeable process then continues to perform work, always informing the least knowledgeable process.

The problem with this naïve algorithm is that it requires $O(n + t^2)$ work and $O(n + t^2)$ messages in the worst case. For example, suppose that process 0 performs the first $t-1$ units of work, so that the last process to be informed is process $t-1$, and then crashes. In addition, $t/2 + 1, \ldots, t - 1$ crash. Eventually process $t/2$, the most knowledgeable nonretired process, will become active. However, process $t/2$ has no way of knowing whether process 0 crashed just after informing it about work unit $t/2$, or process 0 continued to work, informing later processes (who must have crashed, for otherwise they would have become active before process $t/2$). Thus process $t/2$ repeats work units $t/2 + 1, \ldots, t - 1$, again informing (retired) processes $t/2 + 1, \ldots, t - 1$. Suppose process $t/2$ crashes after performing work unit $t - 1$ and informing process $t-1$. Then process $t/2-1$ becomes active and again repeats this work. If each process $t/2 - 1, t/2 - 2, \ldots, 1$ crashes after repeating work units $t/2 + 1, \ldots, t - 1$, then $O(t^2)$ work is done, and $O(t^2)$ messages are sent. (A slight variant of this example gives a scenario in which $O(n + t^2)$ work is done, and $O(n + t^2)$ messages are sent.)

To prevent this situation, a process performs failure detection before proceeding with the work. The key idea here is that we treat failure detection as another type of work. This allows us to use our algorithm recursively for failure detection. Specifically, fault detection is accomplished by polling a process and waiting for a response or a timeout. The difficulty encountered by our approach is that, in contrast to the real work, the set of faulty processes is dynamic, so it is not obvious how these processes can be detected without sending (wasteful) polling messages to *nonfaulty* processes. In fact, in our algorithm we do not attempt to detect all the faulty processes, only enough to ensure that not too much work is wasted by reporting work to faulty processes.

3.1. Description of the algorithm. For ease of exposition we assume t is a power of 2. Again, the processes are numbered 0 through $t - 1$, and the units of work are numbered 1 through n. Although our algorithm is recursive in nature, it can more easily be described when the recursion is unfolded. Processing is divided into $\log t$ levels, numbered 1 to $\log t$, where level $\log t$ would have been the deepest level of the recursion had we presented the algorithm recursively. In each level, the processes are partitioned into groups as follows. In level h, $1 \le h \le \log t$, there are $t/(2^{\log t - h + 1})$ groups of size $2^{\log t - h + 1}$. Thus in level $\log t$, there are $t/2$ groups of size 2, in level $\log t - 1$ there are $t/4$ groups of size 4, and so on, until level 1, in which there is a single group of size t. Let $s_h = 2^{\log t - h + 1}$ denote the size of a group at level h. The first group of level h contains processes $0, 1, \ldots, s_h - 1$, the next group contains processes $s_h, s_h + 1, \ldots, 2s_h - 1$, and so on. Thus each group of level $h < \log t$ contains two groups of level $h + 1$. Note that each process i belongs to $\log t$ groups, exactly one on

each level. We let G_h^i denote the level h group of process i.

Initially process 0 is active. When process i becomes active, it performs fault detection in its group at every level, beginning with the highest level and working its way down, leaving level h as soon as it finds a nonfaulty process in G_h^i. Once fault detection has been completed on G_1^i, the set of all processes, process i begins to perform real work. Thus we sometimes refer to the actual work as G_0, or level 0, and the fault detection on level h as *work on level h*. For each $1 \leq h \leq \log t$, each time it performs a unit of work on G_{h-1}^i, process i reports that work to some process in G_h^i. (Observe that the above protocol requires at least n messages. However, it will later become clear that modifying this protocol so that when a process performs work on G_0 it reports only each time it completes n/t units of work will immediately give a work-optimal protocol that requires only $O(t \log t)$ messages.)

A *unit of fault detection* is performed by sending a special message "Are you alive?" to one process and waiting for a reply in the following round. An *ordinary* message informs a process at some level h, $1 \leq h \leq \log t$, of a unit of (real or fault-detection) work at level $h-1$. As we shall see, an ordinary message also carries additional information. These two are the only types of messages sent by an active process. As before, a process that has crashed or terminated is said to be *retired*. An inactive nonretired process only sends responses to "Are you alive?" messages.

Each process i maintains a list F_i of processes known by i to be retired. It also maintains an array of pointers, POINT_i, indexed by group name. Intuitively, $\text{POINT}_i[G_0]$ is the successor of the last unit of work known by i to have been performed (and therefore this is where i will start doing work when it becomes active). For $h \geq 1$, $\text{POINT}_i[G_h^j]$ contains the successor (according to the cyclic order in G_h^j, which we define precisely below) of the last process in G_h^j known by i to have received an ordinary message from a process in G_h^j that was performing (real or fault-detection) work on G_{h-1}^j. We call $\text{POINT}_i[G_h^j]$ *process i's pointer into* G_h^j. Process i's moves are governed entirely by the round number F_i and pointers into its own groups (i.e., pointers into groups G_h^i). Associated with each pointer $\text{POINT}_i[G]$ is a round number $\text{ROUND}_i[G]$ indicating the round at which the last message known to be sent was sent (or, in the case of G_0, when the last unit of work known to be done was done). Initially, $\text{POINT}_i[G_0] = 1$, $\text{POINT}_i[G_h^j]$ is the lowest-numbered process in $G_h^j - \{i\}$, and $\text{ROUND}_i[G_0] = \text{ROUND}_i[G_h^j] = 0$. We occasionally use $\text{ROUND}_i[G](r)$ to denote the value of $\text{ROUND}_i[G]$ at the beginning of round r; we similarly use $F_i(r)$ and $\text{POINT}_i[G](r)$.

The triple $(F_i, \text{POINT}_i, \text{ROUND}_i)$ is the *view* of process i. We also define the *reduced view* of process i to be $\text{POINT}_i[G_0] - 1 + |F_i|$; thus i's reduced view is the sum of the number of units of work known by i to be done and the number of processes known by i to be faulty. A process includes its view whenever it sends an ordinary message. When process i receives an ordinary message, it updates its view in light of the new information received. Note that process i may receive information about one of its own groups from a process not in that group. Similarly, it may pass to another process information about a group in which the other process is a member but to which i does not belong.

Let G_h^i be any group as described above, where the process numbers range from x to $y = x + |G_h^i| - 1$. There is a natural fixed cyclic order on the group, which we call the *cyclic order*. Process i sends messages to members of G_h^i in *increasing order*. By this we mean according to the cyclic order but skipping itself and all processes in F_i. Let $j \neq i$ be in G_h^i. Then j's *i-successor in* G_h^i is j's nearest successor in the

cyclic ordering that is not in $\{i\} \cup F_i$. We omit the i in "i-successor," as well as the name of the group in which the successor is to be determined, when these are clear from the context.

When process i first becomes active it searches for other nonretired processes as follows. For each level h, starting with $\log t$ and going down to 1, process i polls group G_h^i, starting with $\text{POINT}_i[G_h^i]$, by sending an "Are you alive?" message. If no answer is received, it adds this process to F_i. If $h < \log t$, process i sends an ordinary message reporting this newly detected failure to $\text{POINT}_i[G_{h+1}^i]$, sets $\text{POINT}_i[G_{h+1}^i]$ to its i-successor in G_{h+1}^i, and sets $\text{ROUND}_i[G_{h+1}^i]$ to the current round number. Process i repeats these steps until an answer is received or $G_h^i \setminus \{i\} \subseteq F_i$. It then enters level $h-1$ and repeats the process. Note that if no reply was received, then although the pointer into G_h^i does not change, the successor in G_h^i of $\text{POINT}_i[G_h^i]$ does change, because the successor function takes into account F_i, which has changed.

Level 0 is handled similarly to levels 1 through $\log t - 1$, but the process performs real work instead of polling and increases the work pointer after performing each unit of work. If $\text{POINT}_i[G_0] = n+1$ then process i halts, since in this case all the work has been completed. This completes the description of the behavior of an active process. The code for an active process appears in Figure 3.

```
1.  h := log t;
2.  while h > 0 do
3.          DONE := FALSE;
4.          while ¬DONE do
5.                  Send "Are you alive?" to POINT_i[G_h^i];
6.                  if no response
7.                  then   add POINT_i[G_h^i] to F_i;
8.                         if h ≠ log t
9.                         then   send ordinary message to point_i[G_{h+1}^i];
10.                               ROUND_i[G_{h+1}^i] := current round;
11.                               POINT_i[G_{h+1}^i] := successor(POINT_i[G_{h+1}^i]);
12.                        if G_h^i − F_i ≠ {i}
13.                        then   POINT_i[G_h^i] := successor(POINT_i[G_h^i]);
14.                        else   DONE := TRUE;
15.                 else   (i.e., response received) DONE := TRUE;
16.         h := h − 1;

    {Process level 0 (real work):}
17. while POINT_i[G_0] ≤ n do
18.         Perform work unit POINT_i[G_0];
19.         Send an ordinary message to POINT_i[G_1^i];
20.         ROUND_i[G_1^i] := current round;
21.         POINT_i[G_1^i] := successor(POINT_i[G_1^i]);
22.         POINT_i[G_0] := successor(POINT_i[G_0])
```

FIG. 3. *Code for active process i in Protocol $\mathcal{C}$.*

At any time in the execution of the algorithm, each inactive nonretired process i has a *deadline*. We define $D(i,m)$ to be the number of rounds that process i waits

from the round in which it first obtained reduced view m until it becomes active:

$$D(i,m) = \begin{cases} K(n+t-m)2^{n+t-1-m} & \text{if } m \geq 1, \\ K(t-i)(n+t)2^{n+t-1} & \text{otherwise,} \end{cases}$$

where $K = 5t + 2\log t$. As we show below (Lemma 3.2), K is an upper bound on the number of rounds that any process needs to wait before first hearing from the active process. (More formally, if j becomes active at round r and is still active K rounds later, then by the beginning of round $r + K$ all processes that are not retired will have received a message from j.) All our arguments below work without change if we replace K by any other bound on the number of rounds that a process needs to wait before first hearing from the active process. This observation will be useful later, when we consider a slight modification of Protocol $\mathcal{C}$.

If process i receives no message by the end of $D(i,0) - 1$, then it becomes active at the beginning of round $D(i,0)$. Otherwise, if at round r it receives a message based on which it obtains a reduced view of m, and if it receives no further messages by the end of round $r + D(i,m) - 1$, it becomes active at the beginning of round $r + D(i,m)$. This completes the description of the algorithm.

3.2. Analysis and proof of correctness.

LEMMA 3.1. *In every execution of Protocol $\mathcal{C}$ in which there are no more than $t-1$ failures, the work is completed.*

Proof. By assumption, one of the processes is correct, say, i. At some point process i will become active, since once every other process has retired process i will not extend its deadline. It is straightforward from inspection of the algorithm that at any time during the execution of the algorithm $\text{POINT}_i[G_0] = w$ if and only if the first $w - 1$ units of work have been performed and that when it becomes active process i performs all units of work from $\text{POINT}_i[G_0]$ through n. □

The next lemma shows that our choice of K has the properties mentioned above.

LEMMA 3.2. *If j is active at round r and is not retired by round $r + 5t + 2\log t$, then all processes that are not retired will receive a message from j before the beginning of $r + 5t + 2\log t$.*

Proof. It is immediate from the description of the algorithm that all nonretired processes have received a message from j by the time it has performed t units of work (at level G_0) after round r. Thus we compute an upper bound on the time it takes for j to perform t units of work starting at round r. In the worst case, j has just become active at the beginning of round r, and must do failure detection before reaching level G_0 and doing work. While doing this failure detection, j sends "Are you alive?" messages to at most $t + \log t$ processes (the extra $\log t$ is due to the fact that at each level, it may send one "Are you alive?" message to a process that is alive but crashes later, while j is doing failure detection on a larger group). After discovering a failure, process j sends an ordinary message; thus it sends at most t ordinary messages. Each message sent takes up one round; in addition, process j waits one round for a response after each "Are you alive?" message. This means that j spends at most $3t + 2\log t$ rounds in levels $G^j_{\log t}, \ldots, G^j_1$. Clearly, j spends $\leq 2t - 1$ rounds working at level G_0 in the course of doing t units of work (since it sends an ordinary message between each unit of work). The required bound follows. □

If i received its last ordinary message from j at round r, we call other processes that received an ordinary message from j after i did *first-generation processes* (implicitly, with respect to i, j, and r). If i did not yet receive any ordinary messages, then

the first-generation processes (with respect to i and r) are those that received an ordinary message from a process with a number greater than i. We define kth-generation processes inductively. If we have defined kth generation, then the $(k+1)$st generation are those processes that receive an ordinary message from a kth-generation process. The *rank* of a process is the highest generation that it is in.

LEMMA 3.3. *Let i receive its last ordinary message from j at round r, let m be the reduced view of i after receiving this message, and let ℓ be a kth-rank process with respect to i, j, and r. Then, after ℓ receives its last ordinary message, its reduced view is at least $m + k$.*

Proof. The proof is an easy induction on k, since when a kth-rank process becomes active, it knows about everything its parent knew when it became active and at least one more piece of work or failure. □

We say process i *knows more* than process j at round r if $F_i(r) \supseteq F_j(r)$ and for all groups G, $\text{ROUND}_i[G](r) \geq \text{ROUND}_j[G](r)$. Note that if equality holds everywhere then intuitively the two processes are equally knowledgeable. We first show that our algorithm has the property that for any two inactive nonretired processes, one of them is more knowledgeable than the other, unless they both know nothing; that is, the knowledge of two nonretired processes is never incomparable. This is important so that the "most knowledgeable" process is well defined. Moreover, the knowledge can be quantified by the reduced view. Process i knows more than inactive process j if and only if the reduced view of i is greater than the reduced view of j. Finally, the algorithm also ensures that the active process is at least as knowledgeable as any inactive nonretired process.

LEMMA 3.4. *For every round r of the execution the following hold.*

(a) *If process i received an ordinary message from process j at round $r' < r$ and i is inactive and has not retired by the beginning of round r, then at the beginning of round r, no processes other than j and processes in the kth generation with respect to i, j, and r', for some $k \geq 1$, know as much as i.*

(b) *Suppose process i received its last ordinary message at round r' (if i has received no ordinary messages then $r' = 0$) and m is i's reduced view after receiving this message. If i is not retired at the beginning of round $r = r' + D(i, m)$, and it receives no further ordinary messages before the beginning of round r, then at the beginning of round r no nonretired process knows more than i.*

(c) *At the beginning of round r, there is an asymmetric total order ("knows more than") on the nonzero knowledge of the nonretired processes that did not become active before round r, and the active process knows at least as much as the most knowledgeable among these processes. Moreover, for any two nonretired processes i and j, i knows more than j if and only if the reduced view of i is greater than the reduced view of j.*

(d) *At most one process is active in round r.*

Proof. The proof is by induction on r. The base case $r = 1$ is straightforward. Let $r > 1$ and assume that all parts of the lemma hold for smaller values of r. We prove it for r.

For part (a), observe that by the inductive hypothesis, (a) holds at the beginning of round $r - 1$. If no process is active in round $r - 1$, then no process's knowledge changes, so (a) holds at the beginning of round r as well. If process j' is active in round $r - 1$, then by part (c) of the inductive hypothesis, j' knows at least as much as i. Thus by part (a), it must be the case that j' is either j or some process in the kth generation with respect to i, j, and r' for some k (since, by assumption, i is not active at the beginning of round r). The only process whose knowledge changes

during round $r-1$ is one to which j' sends an ordinary message. It is immediate from the definition that this process must be in the kth generation with respect to i, j, and r for some k.

For part (b), we must consider two cases: $r' > 0$ and $r' = 0$. If $r' > 0$, let j be the process that wrote to i at r'. By part (a) we have that only j and processes in generation $k \geq 1$ with respect to i, j, and r' are as knowledgeable as i at any round in the interval $[r', r)$. By part (c), these can be the only processes active in this interval. Thus it suffices to argue that j and all processes of generation $k \geq 1$ with respect to i, j, and r' are retired by the beginning of round r. Since a reduced view is at most $n+t-1$, the highest rank a process could be in is $n+t-1$. We now argue that by the beginning of round $r' + D(i,m) > r' + (n+t-m)K + D(i,m+1) + \cdots + D(i,n+t-1)$ all processes of ranks 1 through $n+t-1$ have retired. More generally, we argue by induction on k that for every k with $1 \leq k \leq n+t-m-1$, by the beginning of round $s + (k+1)K + D(i,m+1) + \cdots + D(i,m+k)$, every process in ranks 1 to k has retired.

If $k = 1$, note that since i received an ordinary message from j at round r', by Lemma 3.2, every rank-1 process receives a message from j before round $r' + K$. By Lemma 3.3, the reduced view of any such process is at least $m+1$. Since i receives no message from j by round $r' + K$, it must be the case that j has retired by round $r' + K$. By definition, no rank-1 process can receive any messages at any round in $[r' + K, r)$ (otherwise it would have a rank higher than 1). Thus any rank-1 process i' became active before $r' + K + D(i', m+1)$, so by definition of K and the fact that $D(i', m+1) = D(i, m+1)$, i would have heard from i' before $r' + 2K + D(i, m+1)$. It is easy to check that $r' + 2K + D(i, m+1) < r' + D(i,m) = r$. Since i did not receive any messages by the beginning of round r, i' must have retired by then.

In general, consider a rank-$k+1$ process i' and assume inductively that every rank-k or lower process has retired by the beginning of round r. By definition of rank, i' received an ordinary message from a rank-k process, and, since these are all retired by round r, i' must have received this message before round r. By the inductive hypothesis on k, i' must have received its last ordinary message by the beginning of round $r' + (k+1)K + D(i, m+1) + \cdots + D(i, m+k) < r$ (again using the fact that $D(i,m) = D(i',m)$ if $m > 0$). By Lemma 3.3, the reduced view of i' when it received its last ordinary message before round r was at least $m+k+1$. Thus it must have become active before round $r' + (k+1)K + D(i, m+1) + \cdots + D(i, m+k+1)$ if it became active at all. Since i received no messages from i', it follows that i' must have retired before round $r' + (k+2)K + D(i, m+1) + \cdots + D(i, m+k+1) < r$. This completes the induction on k.

If $r' = 0$ we need the fact that $D(i,0) > (n+t)K + \max_{j>i}\{D(j,0)\} + D(i,1) + \cdots + D(i, n+t-1)$, which follows easily from the definitions. We claim that, for every $k \geq 0$, by round $(k+1)K + \max_{j>i}\{D(j,0)\} + D(i,1) + \cdots + D(i,k)$, every process in ranks 1 to k has retired. To see this, note that a rank-0 process j' (one with a higher number than i that received no messages) must have become active at round $D(j',0)$ and therefore must have retired by round $D(j',0) + K$. Thus a level-1 process received its last message by $\max_{j>i}\{D(j,0)\} + K$. We now proceed as in the case $r' > 0$.

To prove part (c), observe that the result is immediate from the inductive hypothesis applied to $r-1$ if there is no active process at the beginning of round $r-1$ (for in that case, no process's reduced view changes). Otherwise, suppose that j is active at the beginning of round $r-1$. If j does not send an ordinary message in round $r-1$, again the result follows immediately from the inductive hypothesis (since

no process's reduced view changes). If j does send an ordinary message to, say, process i, it is immediate that i and j know more at the beginning of round r than any other nonretired process, and that i's reduced view is greater than that of any other nonretired inactive process.

It remains to show part (d). Observe that the result is immediate if no process becomes active at round r. Now suppose that process i becomes active at the beginning of round r. We must show that no process that was active prior to round r is still active at the beginning of round r, and that no process besides i becomes active at round r. Let r' be the last round in which i received a message (as usual, if i received no messages prior to round r, then we take $r' = 0$) and suppose that m was i's reduced view at round r'. Then we must have $r = r' + D(i, m)$. From part (b), it follows that no nonretired process knows more than i at the beginning of round r. From part (c), it follows that any process that was active in the interval $[r', r)$ must know more than i. This shows that all processes that were active before round r must have retired by the beginning of round r. Suppose some other process i' becomes active at round r. We have just shown that i' does not know more than i. From part (c) it follows therefore that i' knows less than i. Thus part (b) provides a contradiction to the assumption that i' becomes active at round r. □

LEMMA 3.5. *The running time of the algorithm is at most* $tK(n+t)2^{n+t}$ *rounds.*

Proof. If process i's reduced view is m and it does not receive a message within $D(i, m)$ steps, then it becomes active. Each message that i receives increases its reduced view. Thus i becomes active in at most $D(i, 0) + \cdots + D(i, n + t - 1)$ rounds. Once active, arguments similar to those used in Lemma 3.2 show that it retires in at most $2n + 3t + 2\log t$ rounds. Thus the running time of the algorithm is at most $D(1, 0) + \cdots + D(1, n + t - 1) + 2n + 3t + 2\log t \leq tK(n + t)2^{n+t}$ rounds. □

The next lemma shows that an active process i does not send messages to retired processes that, because they were more knowledgeable than i, should have become active before i did. These messages are avoided because during fault detection i discovers that these processes have retired.

LEMMA 3.6. *If process* i' *gets an ordinary message at round* r' *from a process operating on group* $G^{i'}_{h-1}$ *and process* i *is active at the beginning of round* $r > r'$ *then the following hold.*

(a) *If* $\text{ROUND}_i[G^{i'}_h](r) \geq r'$, *then all processes in the interval* $[i', \text{POINT}_i[G^{i'}_h](r))$ *in the cyclic order on* $G^{i'}_h$ *are either retired by the beginning of round* r *or receive an ordinary message in the interval* $[r', \text{ROUND}_i[G^{i'}_h](r)]$ *from a process operating on* $G^{i'}_{h-1}$. *(If* $i' = \text{POINT}_i[G^{i'}_h](r)$, *then all processes in* $G^{i'}_h$ *are either retired by the beginning of round* r *or receive a message in the interval* $[r', \text{ROUND}_i[G^{i'}_h](r)]$ *from a process operating on* $G^{i'}_{h-1}$.*) Moreover, either* i*'s knowledge at the beginning of round* r *is greater than* i'*'s knowledge at the end of* r' *or* $i' \in F_i(r)$.

(b) *If* $\text{ROUND}_i[G^{i'}_h](r) < r'$, *then all processes in the interval* $[\text{POINT}_i[G^{i'}_h](r), i']$ *in the cyclic order on* $G^{i'}_h$ *are either retired by the beginning of round* r' *or receive a message in the interval* $(\text{ROUND}_i[G^{i'}_h](r), r']$ *from a process operating on* $G^{i'}_{h-1}$. *Moreover, all the processes in this interval are retired by the beginning of round* r, *and if* $G^i_h = G^{i'}_h$, *then all these processes will be in* F_i *by the time* i *begins to operate on* G^i_{h-1}.

Proof. We proceed by induction on r. The case $r = 1$ is vacuous. Assume that $r > 1$ and the result holds for $r - 1$. If $r' = r - 1$, then it must be the case that i' received its message from i, $\text{ROUND}_i[G^{i'}_h](r) = r - 1$, and $\text{POINT}_i[G^{i'}_h]$ is the successor

of i' in the cyclic order on $G_h^{i'}$, as computed by i in round $r-1$. It is easy to see that the result follows immediately in this case, because all processes in the interval $(i', \text{POINT}_i[G_h^{i'}])$ must be retired.

Suppose $r' < r-1$. If i is also active at round $r-1$, then the result is immediate from the inductive hypothesis unless $\text{ROUND}_i[G_h^{i'}]$ changes during round $r-1$. The description of the algorithm shows that $\text{ROUND}_i[G_h^{i'}]$ changes only if $G_h^i = G_h^{i'}$ and i is operating on group G_{h-1}^i, in which case $\text{ROUND}_i[G_h^{i'}]$ is set to $r-1$ at the end of round $r-1$ and $\text{POINT}_i[G_h^{i'}](r)$ is the successor of $\text{POINT}_i[G_h^{i'}](r-1)$ in the cyclic order on $G_h^{i'}$. In this case it is easy to see that the result follows from the inductive hypothesis; we leave details to the reader.

Thus we can assume without loss of generality that i becomes active at round r. Let $\text{ROUND}_i[G_h^{i'}](r) = r''$ and let $\text{POINT}_i[G_h^{i'}](r) = i''$. If $r'' \geq r'$, then it must be the case that i received a message from j at some earlier round s such that $\text{POINT}_j[G_h^{i'}](s) = \text{POINT}_i[G_h^{i'}](r)$ and $\text{ROUND}_j[G_h^{i'}](s) = \text{ROUND}_i[G_h^{i'}](r)$. Since we must have $r' \leq r'' = \text{ROUND}_j[G_h^{i'}](s) \leq s$, the result now follows from the induction hypothesis (using j and s instead of i and r).

It remains only to consider the case $r'' < r'$. Let $j' \in G_h^{i'}$ be the process that sent the ordinary message to process i' at round r', and suppose that j' became active at the beginning of round s'. We claim that we have the following chain of inequalities: $r'' \leq \text{ROUND}_{j'}[G_h^{i'}](s') < s' < r' < r$. Every inequality in this chain is immediate from our assumptions except the first one. Suppose that $\text{ROUND}_{j'}[G_h^{i'}](s') < r''$. From Lemma 3.4, it follows that $\text{ROUND}_k[G_h^{i'}](s') < r''$ for all processes k not retired by round s'. This means that no process not retired at s' knows that a message was sent at round r''. But at round $r > s'$, process i knows this fact (since by assumption $\text{ROUND}_i[G_h^{i'}](r) = r''$). This is impossible. Thus we must have $\text{ROUND}_{j'}[G_h^{i'}](s') \geq r''$. Note that $\text{POINT}_{j'}[G_h^{i'}](r') = i'$ by assumption. Thus, by the inductive hypothesis, all processes in the cyclic order on $G_h^{i'}$ in the interval $[i'', i')$ are either retired by the beginning of round s' or receive an ordinary message in the interval $[r'', \text{ROUND}_{j'}[G_h^{i'}](s')]$ from a process operating on $G_{h-1}^{i'}$. Since we also know that i' receives a message at round r' from a process operating on $G_{h-1}^{i'}$, this proves the first half of part (b). Since, by Lemma 3.4, all processes not retired by round r must be less knowledgeable than i at the beginning of round r, it follows from Lemma 3.4 that all the processes in the interval $[i'', i']$ in the cyclic order have in fact retired by round r. From the description of the algorithm, it follows that i will detect this fact before it starts operating on G_{h-1}^i. □

Observe that the algorithm treats "Are you alive?" messages as real work. Therefore, we refer to these messages as work unless stated otherwise. On the other hand, the ordinary messages are still referred to as messages.

Using Lemma 3.6, we can show that indeed effort is not wasted.

LEMMA 3.7. *At most $|G_h^i| + |G_{h-1}^i|$ units of work are done and reported to G_h^i by group G_h^i when operating on group G_{h-1}^i.*

Proof. Given i, h, and an execution e of Protocol $\mathcal{C}$, we consider the sequence of triples (x, y, z), with one triple in the sequence for every time a process $x \in G_h^i$ sends an ordinary message reporting a unit of work $y \in G_{h-1}^i$ to a process $z \in G_h^i$, listed in the order that the work was performed. We must show that the length of this sequence is no greater than $|G_{h-1}^i| + |G_h^i|$.

We say that a triple (x, y, z) is *repeated* in this sequence if there is a triple (x', y, z') later in the sequence where the same work unit y is performed. Clearly there are at

most $|G_{h-1}^i|$ nonrepeated triples in the sequence, so it suffices to show that there are at most $|G_h^i|$ repeated triples. To show this, it suffices to show that the third components of repeated triples (denoting which process was informed about the unit of work) are distinct. Suppose, by way of contradiction, that there are two repeated triples (x_1, y_1, z_1) and (x_2, y_2, z_1) with the same third component. Suppose that x_1 informed z_1 about y_1 in round r', and x_2 informed z_1 about y_2 in round r''. Without loss of generality, we can assume that $r' < r''$. Since (x_1, y_1, z_1) is a repeated triple, there is a triple (x_3, y_1, z_2) after (x_1, y_1, z_1) in the sequence. Let r_3 be the round in which x_3 became active, and let r_2 be the round in which x_2 became active. Let $s_j = \text{ROUND}_{x_j}[G_h^i](r_j)$ for $j = 2, 3$. By Lemma 3.6, if $s_2 \geq r'$, then either x_2's knowledge at the beginning of round s_2 is greater than z_1's knowledge at the end of r', or $z_1 \in F_{x_2}(r')$, and if $s_2 < r'$, then $z_1 \in F_{x_2}$ before x_2 starts operating on G_i^{h-1}. Since x_2 sends a message to z_1 while operating on G_i^{h-1}, it cannot be the case that $z_1 \in F_{x_2}$ before x_2 starts operating on G_i^{h-1}, so it must be the case that $s_2 \geq r'$ and x_2's knowledge at the beginning of round r_2 is greater than z_1's knowledge at the end of round r'. In particular, this means that x_2 must know that x_1 informed z_1 about y_1 at the beginning of r_2.

We next show that every process $x \in G_i^h$ that is active at some round r between r' and r_2 must know that x_1 informed z_1 about y_1 at the beginning of round r. For suppose not. Then, by Lemma 3.6, z_1 must have retired by the beginning of round r. Since, by Lemma 3.4, x is the most knowledgeable process at the beginning of round r, it follows that no process that is not retired knows that z_1 was informed about y_1. Thus there is no way that x_2 could find this out by round r_2.

It is easy to see that x_3 does not know that z_1 was informed about y_1 (for if it did, it would not repeat the unit of work y_1). Therefore, (x_3, y_1, z_2) must come after (x_2, y_2, z_1) in the sequence. Since $\text{POINT}_{x_2}[G_h^i](r'') = z_1$, and z_1 received an ordinary message from x_1 while operating on G_{h-1}^i at round r', it follows from Lemma 3.6 that between rounds r' and r'' every process in G_h^i that is not retired must receive an ordinary message. In particular, this means that x_3 must receive an ordinary message. Since all active processes between round r' and r'' know that z_1 was informed about y_1, it follows that x_3 must know it too by the end of round r''. But then x_3 would not redo y_1, giving us the desired contradiction. □

THEOREM 3.8. *In every execution of Protocol $\mathcal{C}$,*

(a) *at most $n + 2t$ units of real work are performed;*

(b) *at most $n + 8t \log t$ messages are sent;*

(c) *by round $t(5t + 2\log t)(n + t)2^{n+t}$, all processes have retired.*

Proof. Lemma 3.7 implies that the amount of real work units that are performed and reported to G_1 is at most $|G_0| + |G_1| = n + t$. In addition, each of the t processes may perform one unit without reporting it (because it retired immediately afterward). Summing the two, (a) follows.

For part (b), Lemma 3.7 implies that each $G_h^i, h > 0$, performs at most $|G_{h-1}^i| + |G_h^i|$ reported units of works when operating on G_{h-1}^i. (Here a unit is may be either a real work unit or an "Are you alive?" message.) Let $H = \{(h, i) : 1 \leq h \leq \log t,\ i \equiv 1 \pmod{2^{\log(t)+1-h}}\}$. Notice if we consider groups of the form G_h^i for $(h, i) \in H$ we count all the groups exactly once. The argument above tells us that the total number of reported units of work is

$$\sum_{(h,i)\in H} (|G_{h-1}^i| + |G_h^i|) \leq |G_0| + 3 \sum_{(h,i)\in H} |G_h^i|.$$

The reason for the factor of 3 is that if $h < \log t$, then $|G_h^i|$ occurs three times in the left-hand sum: once when considering the work performed by group G_h^i operating on G_{h-1}^i, once when considering the work performed by G_{h+1}^i when operating on G_h^i, and once when considering the work performed by G_{h+1}^{i+h} when operating on G_h^i. Clearly, the $|G_0|$ reported units performed on G_0 result in one message each, and the remaining ones result in two messages each (because then the unit itself is also a message). So the number of messages corresponding to reported units of work is at most

$$|G_0| + 6 \sum_{(h,i)\in H} |G_h^i| = n + 6t \log t.$$

In addition, the unreported units may result in messages. These consist both of "Are you alive?" messages sent by a process but not reported by it due to the fact it crashes or terminates immediately afterward, and of "Are you alive?" messages that were not reported because the recipient of the "Are you alive?" message responded. Each process in $G_h^i, h > 1$, can perform at most one such unreported unit when operating on G_{h-1}^i, and hence each group $G_h^i, h > 1$ performs no more than $|G_h^i|$ such units. In addition, we have to sum the answers of alive processes in $G_{h-1}^i, h > 1$ to "Are you alive?" message sent by G_h^i. Again, there are at most $|G_h^i|$ such answers. Finally, each process i sends messages to the other process in $G_{\log t}^i$ just before it starts operating, which together with the answers sums up to a total of no more than $2t$ messages. Therefore, the number of messages corresponding to unreported units of work is at most

$$2t + \sum_{(i,h)\in H,\, h>1} 2|G_h^i| = 2t \log t.$$

Summing the messages due to the reported units of work and the messages due to the unreported units of work, part (b) follows.

Part (c) is immediate from Lemma 3.5. □

We remark that we can improve the message complexity to $O(t \log t)$ (that is, remove the n term in (b) above) by informing processes in group G_1 after n/t units of work done at level G_0, rather than after every unit of work. This does not result in a significant increase in total work, but it does increase the time complexity. The increase in time complexity comes from an increase in K (the upper bound on the number of rounds, from the time the currently active process takes over, that any process needs to wait before first hearing from the active process). Formally, we have the following result.

COROLLARY 3.9. *Modifying Protocol $\mathcal{C}$ by informing processes in group G_1 after n/t units of work done at level G_0, rather than after every unit of work, yields a protocol that sends $O(t \log t)$ messages, performs $O(n+t)$ work, and terminates within $t(2n + 3t + 2 \log t)(n + t)2^{n+t}$ rounds.*

4. A time-optimal algorithm. All the algorithms we have considered so far are inherently sequential: there is only one process performing work at a time. If processes always have many (other) tasks that they can do, then the fact that all but one process is idle at a given time is not a great problem. On the other hand, time is certainly a critical element in many applications. In this section, we present an algorithm that aims to achieve maximum distribution of the workload among the processes. The algorithm is time optimal in the typical case where there are no faults,

and its performance degrades gracefully in the presence of faults. The basic ideas of this algorithm have been patented [9].

The idea of the algorithm is straightforward. We alternate *work phases* and *agreement phases*, until all the correct processes are sure that all the work has been done. In the first work phase, process j performs units of work $1+jn/t, \ldots, (j+1)n/t$ (we again assume for simplicity that n is a multiple of t) in the first n/t rounds. Process j starts the first agreement phase by broadcasting a message to all the other processes saying that it has done its work. In subsequent rounds, process j proceeds much as in eventual Byzantine agreement [10]: it broadcasts its current *view*—what work has been done, and which processes were alive at the end of the work phase, from its point of view. It continues to do so until (a) the set of processes that are currently alive, according to j's view, is the same in two consecutive rounds, or (b) it receives a message from some process i saying that i is done and containing i's view. In case (a) it takes as its *final view* its own view, while in case (b) it takes as its final view the view in i's message. In all cases, it then broadcasts a message saying it is done, together with its final view of which processes were alive at the end of the work phase and what work remains to be done, and terminates the phase.

Using the by-now standard techniques of [10], we can show that all the correct processes agree on their final view at the time when they terminate the phase, and a correct process is done by round $n/t + f + 2$, where f is the number of processes that are faulty during the agreement phase. Finally, all correct processes terminate at most one round after the first correct process terminates. We omit details here.

After process j terminates the first agreement phase, if, according to its final view, $n' > 0$ more work still needs to be done (perhaps because some process crashed before doing its allocated work) and $t' \geq t/2$ processes are still correct, then it starts the second work phase. It performs n'/t' units of work, with the work being divided among the correct processes according to their identification numbers.[3] After the work phase, there is an agreement phase, which is just like the first agreement phase, with one small change. Whereas in the first agreement phase if process j did not hear from process i during some round, then process j knew i was faulty, in later agreement phases, since i may be behind j by one step, j must allow i one round of grace before declaring it faulty. Similarly, in order to terminate, a process must have two consecutive rounds *after the grace round*, where its view of the set of currently alive processes is the same, or receive a message from another process saying it is done. We leave it to the reader to check that again at the end of the phase all correct processes agree that all the work has been performed or they agree on their final view and, in addition, that every correct process terminates no more than one round after the first correct process terminates.

We continue in this manner, provided no more than half of the processes that were correct at the beginning of a phase fail, until all correct processes are sure that all work has been done. If at any phase more than half the correct processes fail, we revert to another of our algorithms (for example, Protocol $\mathcal{A}$). We call this algorithm protocol $\mathcal{D}$; the code appears in Figure 4. In the code, we use the function $grade_S$, where S is a set of nonnegative integers; $grade_S(s) = k$ if there are k elements of S less than s.

[3]Since n' may not be divisible by t', a process might have to do $\lceil n'/t' \rceil$ work. We ignore this issue in the discussion, since its impact on complexity is negligible; however, the code takes it into account.

Main protocol

```
1.  S := {1, ..., n};      {S is the set of outstanding units of work}
2.  T := {0, ..., t − 1};  {T is the set of processes known to have been correct
                            at the end of the previous work phase}
3.  ROUND := 1;  {ROUND keeps track of whether to allow a grace round}
4.  while |S| > 0 do
5.        S' := {s ∈ S : grade_T(j)⌈|S|/|T|⌉ ≤ grade_S(s) < (grade_T(j) + 1)⌈|S|/|T|⌉};
6.        Perform work in S';
7.        Wait ⌈|S|/|T|⌉ − |S'| rounds;  {to make sure all processes spend equally
                                           long in this phase}
8.        S := S\S';  {update outstanding units of work}
9.        T' := T;
10.       Agree(ROUND);  {see code below}
11.       if |T'| > 2|T|  (i.e., more than half the processes alive at the end of the
                           previous work phase failed by the end of the current
                           work phase)
12.       then  perform work in S using Protocol A;
13.             S := ∅;
14.       ROUND := 0
```

Agree(ROUND)

```
1.  DONE := FALSE;
2.  U := T; {U keeps track of processes not known by j to be faulty}
3.  T := {j};
4.  while ¬DONE do
5.        U_j := U;  {save old value of U}
6.        Broadcast (j, S, T, DONE) to all processes in U;
7.        for i ∈ U_j do
8.              if received (i, S_i, T_i, DONE_i) and DONE_i = FALSE
9.              then  S := S ∩ S_i;
10.                   T := T ∪ T_i;
11.             if received (i, S_i, T_i, DONE_i) and DONE_i = TRUE
12.             then  S := S_i;
13.                   T := T_i;
14.                   DONE := TRUE;
15.             if no message received from i and ROUND ≥ 1
16.             then  U := U/{i};
17.       if U = U_j and ROUND ≥ 1
18.       then  DONE := TRUE;
19.       ROUND := ROUND + 1;
20. Broadcast (j, S, T, DONE) to all processes in U
```

FIG. 4. *Protocol $\mathcal{D}$: code for process j.*

We now analyze Protocol $\mathcal{D}$. The analysis splits into two cases, depending on whether it is the case that for every phase no more than half the processes that are correct at the beginning of the phase are discovered to have failed during the phase.

A process p is *thought to be correct* at the beginning of phase i if $i = 1$ or $i > 1$ and p is in the final view of some process p' that decided in the phase $i-1$ agreement protocol. Note that in the latter case p is in the final view of all processes that complete the phase $i-1$ agreement protocol.

THEOREM 4.1. *In every execution of Protocol $\mathcal{D}$ in which at most f processes fail, the following hold.*

1. *If for each phase no more than half the processes that are thought to be correct at the beginning of the phase are discovered to have failed by the end of that phase, then*

(a) *at most $2n$ units of work are performed;*
(b) *at most $(4f+2)t^2$ messages are sent;*
(c) *by round $(f+1)n/t + 4f + 2$, all processes have retired.*

2. *If in some phase more than half the processes that are thought to be correct at the beginning of some phase are discovered to have failed by the end of the phase, then*

(a) *at most $4n$ units of work are performed;*
(b) *at most $(4f+2)t^2 + 9t\sqrt{t}/(2\sqrt{2})$ messages are sent;*
(c) *by round $(f+1)n/t + 4f + 2 + nt/2 + 3t^2/4$, all processes have retired.*

Proof. For part 1, an easy induction on k shows that by the end of phase k, no more than $n/2^k$ units of work remain to be done, and no more than $n + \cdots + n/2^{k-1}$ units of work have been done. It follows that at most $2n$ units of work are done altogether. (We remark that there is nothing special about the factor "half" in our requirement that we revert to Protocol $\mathcal{A}$ if more than half the processes that were correct at the beginning of the phase are discovered to have failed during the phase. We could have chosen any factor α; a similar proof would show that by the end of phase k, at most $\alpha^k n$ units of work remain to be done, and no more than $n + \cdots + \alpha^{k-1}n$ units of work have been done, so that no more than $n/(1-\alpha)$ units of work are done altogether. However, it follows from results of [8] that if we allow an arbitrary fraction of the processes to fail at every step and do not revert to Protocol $\mathcal{A}$, it is possible to construct an execution where f processes fail and $\Omega(n \log(f)/\log\log(f))$ units of work are done altogether. Indeed, it follows from the arguments in [8] that this result is tight; there is a matching upper bound.) Since each nonfaulty process broadcasts to all the other nonfaulty processes in each round of an agreement phase, at most t^2 messages are sent in each such round. If f_k is the number of failures discovered during the kth agreement phase, then the first agreement phase lasts at most $f_1 + 2$ rounds, while for $k > 1$, the kth agreement phase lasts at most $f_k + 3$ rounds, because of the grace round. Thus, altogether, the agreement phases last at most $f + 3a - 1$ rounds, where a is the number of agreement phases. Since $a \leq f + 1$, the agreement phases last at most $4f + 2$ rounds, and at most $(4f+2)t^2$ messages are sent. Finally, to compute an upper bound on the total number of rounds, it remains only to compute how many rounds are required to do the work (since we know the agreement phases last altogether at most $4f + 2$ rounds). Recall that at the end of phase k, at most $n/2^k$ units of work need to be done. Since no more than half the processes fail during any phase, at least $t/2^k$ processes are nonfaulty. Thus at most $(n/2^k)/(t/2^k) = n/t$ rounds are spent during each work phase doing work. Since there are at most $f + 1$ work phases, this gives the required bound on the total number of rounds.

For part (2), first observe that if we revert to Protocol $\mathcal{A}$ at the end of phase

k, then by our earlier observations it is known to the remaining processes that no more than $n/2^{k-1}$ units of work remain to be done, and no more than $(2-1/2^{k-1})n$ units of work have been done. It is also easy to see that at least $t/2$ processes are discovered as faulty. Moreover, by the bounds in part 1, at most $(4f+2)t^2$ messages have been sent and $(f+1)n/t+4f+2$ rounds have elapsed. Now applying Theorem 2.3, we see that at most $3n/2^{k-1}$ work is performed by protocol $\mathcal{A}$, no more than $9(t/2)\sqrt{t/2} = 9t\sqrt{t}/(2\sqrt{2})$ messages are sent, and $nt/2^k + 3t^2/4$ rounds are required. By taking $k=1$ (the worst case), we get the bounds claimed in the statement of the theorem. □

While the worst-case message complexity of this algorithm is significantly worse than that of our other algorithms, the time complexity is better (at least, if less than half the correct processes fail in each phase). More importantly, the situation is particularly good if no process fails or one process fails. If no process fails, then n units of work are done, the algorithm takes $n/t+2$ rounds, and $2t^2$ messages are sent. If one process fails, then we leave it to the reader to check that the algorithm requires at most $n/t+\lceil n/(t(t-1))\rceil+6$ rounds, has message complexity at most $5t^2$, and at most $n+n/t$ units of work are done.

As we mentioned in the introduction, it is easy to modify this algorithm to deal with a somewhat more realistic setting, where work is continually coming in to the system. Essentially, the idea is to run eventual Byzantine agreement periodically (where the length of the period depends on the size of the workload and on other features of the system). We omit further details here.

We can also cut down the message complexity in the case of no failures to $2(t-1)$, rather than $2t^2$, while still keeping the same work and time complexity. Instead of messages being broadcast during the agreement phase, they are all sent to a central coordinator, who broadcasts the results. If there are no failures, the agreement phase lasts two rounds, just as before. Dealing with failures is somewhat subtle if we do this though, so we do not analyze this approach carefully here.

5. Application to Byzantine agreement. One application of our algorithms is to Byzantine agreement. A Byzantine agreement protocol provides a means for n processes, at most t of which may be faulty, to agree on a value broadcast by a distinguished process called the *general* in such a way that all nonfaulty processes decide on the same value and, when the general is nonfaulty, they decide on the value the general sent. As in the rest of the paper, we restrict ourselves here to crash failures.

Consider the following Byzantine agreement algorithm. The algorithm proceeds in two stages: first, the general broadcasts its value to processes 0 to t; and then these $t+1$ processes employ one of our sequential algorithms to perform the "work" of informing processes 0 to $n-1$ about the general's value. So, performing one unit of work here means sending a message of the form "The general's value is x." To distinguish processes $0,\ldots,t$ from the others, we refer to them as the *senders*. A few more details are necessary to complete the description of the algorithm. First, throughout the algorithm, each process has a value for the general. Initially, the value is 0. If a process receives a message informing it about a value for the general different from its current value, it adopts the new value. Second, if the chosen work protocol is $\mathcal{C}$, then we modify it slightly so that each of its messages contains, in addition to its usual original contents, the current value the sender has for the general. Finally, at a predetermined time by which the underlying work protocol is guaranteed to have terminated, each process decides on its current value for the general.

Observe that processes $0, \ldots, t$ play two roles in the second stage of the Byzantine agreement algorithm: they both report the value of the general (as they do work) and are informed of this value (as work is performed on them by other senders).

We now prove the correctness of our Byzantine agreement algorithm. Obviously, if the general is correct, all processes will decide on its value. Since at least one of the $t+1$ senders is nonfaulty, it must be the case that a value is reported by a sender to every nonfaulty process. To show agreement, it suffices to show that there is no time at which two nonfaulty processes that have had a value reported to them by a sender have different (current) values. This, in turn, follows from the fact that if an active sender p reports a value v, and the sender that was active just before p reported $\bar{v}$, then at the time p becomes active, no value was reported to any nonfaulty process. Assume otherwise. Let p be the first active sender that violates this claim. Then p reports v for the general and the previous sender reported $\bar{v}$. Let q be the first sender that was active before p and reported $\bar{v}$; by construction, all senders that were active after q but before p reported $\bar{v}$.

By assumption, when q becomes active, no value was reported to any process that has not yet crashed. The choice of q guarantees that the only value that is reported from the time that q becomes active to the time that p becomes active is $\bar{v}$. It cannot be the case that a value was reported to p during this time, for then p's value when it becomes active would be $\bar{v}$, not v. In the case of Protocols $\mathcal{A}$ and $\mathcal{B}$, since work is done in increasing order of process number, it follows that no value is reported to any process with a higher number than p. (We remark that it is important here that a value is *not* included as part of the checkpoint messages in Protocols $\mathcal{A}$ and $\mathcal{B}$. Since checkpoint messages are broadcast, if a value were included, it is possible that a process that was active before p crashed while checkpointing to p; in this case, p may not have heard the value $\bar{v}$, and some process with a higher number than p may have heard it.) Moreover, the proof of correctness of Protocols $\mathcal{A}$ and $\mathcal{B}$ shows that all processes with a lower number than p must have crashed before p became active. Thus it follows that no value was reported to any nonfaulty process at the time p became active. In the case of Protocol $\mathcal{C}$, when p becomes active it is the most knowledgeable nonretired (and hence nonfaulty) process. Since for Protocol $\mathcal{C}$ we assume that the checkpointing messages include the value that was sent, no value can have been sent to any process that has not crashed.

Using Protocol $\mathcal{C}$, we get a Byzantine agreement protocol for crash failures that uses $O(n + t \log t)$ messages in the worst case, thus improving over Bracha's bound of $O(n + t\sqrt{t})$ [4]. Using $\mathcal{A}$ or $\mathcal{B}$, we match Bracha's message complexity, but our protocols are constructive, whereas Bracha's is not.

6. Conclusions. In this paper we have formulated the problem of performing work efficiently in the presence of faults. We presented three work-optimal protocols to solve the problem. One sends $O(t\sqrt{t})$ messages and takes $O(n + t)$ time, another requires $O(t \log t)$ messages at the cost of significantly greater running time, and the third optimizes on time in the usual case (where there are few failures). In particular, in the failure-free case, it takes $n/t + 2$ rounds and requires $2t^2$ messages.

There are numerous open problems that remain. For example, it would be interesting to see if message complexity and running time could be simultaneously optimized. It would also be interesting to prove a nontrivial lower bound on the message complexity of work-optimal protocols. Finally, note that by trying to optimize effort, the sum of work done and messages sent, we implicitly assumed that one unit of work was equal to one message. In practice, we may want to weight messages and work

differently. As long as the "weight" of a message is linearly related to the weight of a unit of work, then, of course, the complexity bounds for our algorithms continue to hold. However, if we weight things a little differently, then a completely different set of algorithms might turn out to be optimal. In general, it would be interesting to explore message/work/time tradeoffs in this model.

Acknowledgments. The authors are grateful to Vaughan Pratt for many helpful conversations, in particular for his help with the proof of Protocol $\mathcal{A}$. We also thank David Greenberg, Maurice Herlihy, and Serge Plotkin for their suggestions for improving the presentation of this work. The second author gratefully acknowledges the support of IBM.

TIME–SPACE TRADEOFFS FOR UNDIRECTED *st*-CONNECTIVITY ON A GRAPH AUTOMATA*

JEFF A. EDMONDS†

Abstract. Undirected *st*-connectivity is an important problem in computing. There are algorithms for this problem that use $O(n)$ time and ones that use $O(\log n)$ space. The main result of this paper is that, in a very natural structured model, these upper bounds are not simultaneously achievable. Any probabilistic jumping automaton for graphs (JAG) requires either space $\Omega(\log^2 n/\log logn)$ or time $n^{(1+\Omega(1/\log\log n))}$ to solve undirected *st*-connectivity.

Key words. time–space tradeoffs, lower bounds, JAG graph, undirected *st*-connectivity

1. Introduction.

Graph connectivity is an important problem, both practically and theoretically. Practically, it is a basic subroutine to many graph theoretic computations. It the basic step in solving network flow optimization problems such as project scheduling and the matching of people to jobs. Graph connectivity is also important for computer networks and search problems. Theoretically, it has been studied extensively in a number of settings. Because the undirected version of the problem is complete for symmetric log-space and the directed version is complete for nondeterministic log-space, they are natural problems for studying these classes. The study of random walks on undirected graphs and deterministic universal traversal sequences has made the problem relevant to the issue of probabilism. In addition, the directed version was used by Karchmer and Wigderson to separate monotone NC_1 from NC_2. This paper proves time-space tradeoffs for undirected *st*-connectivity. (They apply to the harder problem of directed *st*-connectivity as well.) The importance of *st*-connectivity is discussed in more detail in Wigderson's beautiful survey [24].

The fastest algorithms for undirected graph *st*-connectivity are depth-first and breadth-first search [23]. These use linear time, i.e., $O(m+n)$ for an n node, m edge graph. However, they require $\Omega(n)$ space. Alternatively, this problem can be solved deterministically in $O\left(\log^{1.5} n\right)$ space and $n^{O(1)}$ time by traversing the graph using pseudo-random generators to describe a *universal traversal sequence* [17]. If nonuniformity is allowed, these bounds can be improved to $O(\log n)$ space and $O\left(n^4 \log n\right)$ time [10, 15]. If probabilism is allowed, random walks can traverse any component of the graph using $O(\log n)$ space and only $\Theta(mn)$ time [1]. More generally, Broder et al. [9] have exhibited a family of probabilistic algorithms that achieves a tradeoff between the time and the space of $S \cdot T \in m^2 \log^{O(1)} n$. This has been improved to $S \cdot T \in m^{1.5} n^{.5} \log^{O(1)} n$ [2]. A long-term goal is to prove a matching lower bound.

Proving lower bounds for a general model of computation such as a Turing machine is beyond the reach of the current techniques. Thus it is natural to consider

a "structured" model [8], whose basic operations are based on the structure of the graph, as opposed to being based on the bits in the graph's encoding. A natural structured model is the JAG introduced by Cook and Rackoff [11]. It has a set of states and a limited supply of labeled pebbles that it can either move from a node to an adjacent node ("walk") or move directly to a node containing another pebble ("jump"). The pebbles represent node names that a structured algorithm might record in its workspace and are useful for marking certain nodes temporarily, so that they are recognizable when other pebbles reach them. Walking represents replacing a node name by the name of a node that is adjacent to it in the input graph. Jumping represents copying a previously recorded node name [5]. The space of a JAG is defined to be $S = p \log_2 n + \log_2 q$, where p is the number of pebbles and q is the number of states, because it requires $\log_2 n$ bits to store the name of a node (i.e., the location of a pebble) and $\log_2 q$ bits to record the current state.

Although the JAG model is structured, it is not weak. In particular, it is general enough so that most known algorithms for graph connectivity can be implemented on it. For example, a JAG can perform depth-first or breadth-first search. It avoids cycling by leaving a pebble on each node when it first visits it. This uses $O(n \log n)$ space. Cook and Rackoff [11] show that the JAG model is powerful enough to execute an adaptation of Savitch's algorithm [20] for directed st-connectivity using only $O\left(\log^2 n\right)$ space. Poon [18] shows that Barnes's et al. [3] sublinear space, polynomial time algorithm for directed st-connectivity runs on a JAG as well.

Furthermore, Savitch [21] shows that if one allows the JAG the additional ability to move pebbles from each node i to node $i+1$ (for an arbitrary ordering of the nodes), then the model can simulate an arbitrary Turing machine on directed graphs. Beame et al. [5] show that even without this extra feature, JAGs can solve any undirected graph problem to within a polynomial factor as fast as Turing machines.

A number of space lower bounds have been obtained (even when an unbounded amount of time is allowed). Cook and Rackoff [11] prove a lower bound of $\Omega(\log^2 n / \log \cdot \log n)$ on the space required for a JAG to compute directed st-connectivity. This has been extended to randomized JAGs by Berman and Simon [6]. For undirected graph st-connectivity Cook and Rackoff [11] prove that $pq \in \omega(1)$ and Beame et al. [5] prove that if the pebbles are not allowed to jump, then $pq \in \Omega(n)$ even for simple 2-regular graphs. These proofs for undirected graphs show that, with a sublinear number of states, the model goes into an infinite loop. (This method does not work when there are a linear number of states, because then the JAG is able to count the number of nodes traversed.)

Tradeoffs between the number of pebbles p used and the amount of time needed for undirected graph st-connectivity have also been obtained. These results are particularly strong, because they do not depend on the number of states q. A *universal traversal sequence* is simply a JAG with an unlimited number of states but only one pebble. Borodin, Ruzzo, and Tompa [7] prove that on this model, undirected st-connectivity requires $\Omega\left(m^2\right)$ time. Beame et al. [5] extend this to $\Omega\left(n^2/p\right)$ for p pebbles on 3-regular graphs with the restriction that all but one pebble are unmovable. Thus, for this very weak version of the model, a quadratic lower bound on time×space has been achieved. Beame et al. [5] also prove that there is a family of $3p$-regular undirected graphs for which st-connectivity with $p \in o(n)$ pebbles requires time $\Omega(m \log(\frac{n}{p}))$, when the pebbles are unable to jump. The new result presented in this paper is the following.

THEOREM 1. *Any probabilistic JAG requires either space* $\Omega(\log^2 n/\log \log n)$ *or time* $n^{(1+\Omega(1/\log\log n))}$ *to solve undirected st-connectivity even for* 3*-regular graphs.*

This result improves upon the previous results in at least five ways: the lower bound on *time is larger*, all pebbles are allowed to *jump*, the *degree* of the graphs considered is constant, it applies to an *average case* input instead of just the worst-case input, and *probabilistic* algorithms are allowed.

The essential reason that tradeoffs arise between the time and the space required to solve a problem is that when the space is bounded the computation cannot store the results to all the previously computed subproblems and hence must recompute them over and over again. In order to prove a superlinear lower bound on the time to compute *st*-connectivity, it must be proved that certain subgraphs must be traversed many times. Although the first time the JAG traverses a particular subgraph may take many time steps, it can use its states to record the structure of the subgraph so that subsequent traversals can be performed more quickly. To deal with this situation, the lower bound is actually proved on a stronger model, called the *helper JAG*. In this model, the helper, after learning the input, is allowed to set the JAG's initial state and the initial position of the pebbles in the way that minimizes the computation time. The helper is able to communicate to the JAG at least as much information about the input as it could remember from a first traversal of a subgraph. In effect, a helper JAG lower bound is a bound on the time for a regular JAG to traverse the graph subsequent times.

The helper JAG lower bound is obtained by reducing *st*-connectivity to *st*-traversal and reducing the traversal problem to a game, referred to as *the helper-parity game*. The game characterizes the relationship between the number of bits of help (or foreknowledge) and the resulting traversal time.

The paper is structured as follows. Section 2 describes the helper parity game. Section 3 formally defines the probabilistic JAG model. Section 4 reduces the *st*-traversal problem to the *st*-connectivity problem. Section 5 defines the helper JAG. Section 6 describes the fly swatter graph and gives the complexity of its traversal. Section 7 describes a line of fly swatter graphs and compares its complexity with that of the helper-parity game. Section 8 describes how the input graph is recursively built. Section 9 provides the definitions of the time, pebbles, and cost used at a particular level of the recursion. This section does not provide a formal proof, but it does give some crucial intuition. Section 10 proves the main lemma by reducing the traversal problem to the helper parity game. Section 11 proves the main theorem from the main lemma. Finally, section 12 presents some strong intuition and possible techniques for improving the lower bound to the desired bound of $n^{2-o(1)}$.

2. The helper-parity game. The task of one instance of the parity game is to find a subset of the indexes on which the input vector has odd parity. This idea was introduced by Borodin, Ruzzo, and Tompa [7]. We extend this game by including a helper and multiple instances of the game. The helper is included in order to characterize what the JAG stores about a computation when a problem must be computed many times. Multiple instances of the game are included in order to decrease the number of help bits per game instances (the number of bits of information that the helper is allowed to give the player is bounded).

The helper-parity game with d game instances is defined as follows. There are two parties: a player and a helper. The input $\vec{\alpha}$ consists of d nonzero r bit vectors $\alpha_1, \ldots, \alpha_d \in \{0,1\}^r - \{0^r\}$, one for each of the d game instances. The helper sends the message $M(\vec{\alpha})$ to the player. It consists of a total of b bits about the d vectors. Then

the player repeatedly asks the helper parity questions. A parity question specifies one of the game instances $i \in [1 \ldots d]$ and a subset of the indexes $E \subseteq [1 \ldots r]$. The answer to the parity question is the parity of the input α_i at the indexes in this set, namely, $\bigoplus_{j \in E} [\alpha_i]_j$. The game is complete when the player has received an answer of 1 for each of the game instances. To simplify the game, the player is only charged one for the first question asked about a game instance and an additional one for any subsequent questions about the same game instance. Hence, the game can be thought of as the player repeatedly selecting a game instance i (in any order) and asking a single parity question E_i about that instance. If the parity is odd, the player is charged one for the game instance. Otherwise, he is charged two. Independent of the answer, the helper reveals the input α_i to the player. This is repeated until one question has been asked about each of the game instances. The cost is defined to be the average charge per game instance.

$$c_{\vec{\alpha}} = \frac{1}{d} \sum_{i \in [1 \ldots d]} \left\{ \begin{array}{ll} 1 & \text{if } \bigoplus_{j \in E_i} [\alpha_i]_j = 1 \\ 2 & \text{otherwise} \end{array} \right\}.$$

Without any help, the expected charge per game instance is 1.5. Lemma 1 below proves that if the amount of help is less than a fraction of a bit per game instance, then the player cannot do much better than this.

Defining the game so that the vector α_i is revealed after only one question is asked about it simplifies the proof of the *st*-connectivity lower bound without significantly affecting the bound obtained.

LEMMA 1. $\Pr_{\vec{\alpha}} [c_{\vec{\alpha}} < 1.5 - \epsilon] \leq 2^b e^{-(2\epsilon^2 - 2^{-r+1})d}$.

Proof. Fix a helper message $m \in \{0,1\}^b$. Randomly choose an input $\vec{\alpha}$ uniformly over all the inputs in $(\{0,1\}^r)^d$. We will consider what the player's protocol is given this message and this input, even if the helper does not send this message on this input. For $i \in [1 \ldots d]$, let x_i be the indicator variable specifying whether the question about the ith game instance had odd parity; i.e., $\bigoplus_{j \in E_i} [\alpha_i]_j = 1$. Clearly, these variables are independent and have probability $\frac{1}{2}$. The cost per game instance given the input $\vec{\alpha}$ and the actions of the player on message m are defined to be

$$c_{\langle \vec{\alpha}, m \rangle} = \frac{1}{d} \sum_{i \in [1 \ldots d]} \left\{ \begin{array}{ll} 1 & \text{if } x_i = 1 \\ 2 & \text{otherwise} \end{array} \right\}.$$

From this and Chernoff's bound [22], we get that

$$\Pr_{\vec{\alpha}} \left[c_{\langle \vec{\alpha}, m \rangle} < 1.5 - \epsilon \right] = \Pr \left[\sum_{i \in [1 \ldots d]} x_i \geq \left(\frac{1}{2} + \epsilon \right) d \right] \leq e^{-2\epsilon^2 d}.$$

Therefore, the cost is low for at most this fraction of vectors $\vec{\alpha} \in (\{0,1\}^r)^d$ or, equivalently, for at most $e^{-2\epsilon^2 d} 2^{rd}$ inputs $\vec{\alpha}$.

There are 2^b different helper messages m. For each message, the player's actions are different. Hence, the set of inputs on which the cost is low may be different for each message and in the worst case are disjoint. Hence, the number of inputs $\vec{\alpha}$ for which the cost is low when the player is given the correct help from the helper is at most $2^b e^{-2\epsilon^2 d} 2^{rd}$. The input $\vec{\alpha}$ is actually chosen randomly from $(\{0,1\}^r - \{0^r\})^d$. It

follows that

$$\Pr_{\vec{\alpha}}\left[c_{\vec{\alpha}} < 1.5-\epsilon\right] \le 2^b e^{-2\epsilon^2 d}\frac{2^{rd}}{\left(2^r-1\right)^d} \;=\; 2^b e^{-2\epsilon^2 d}\left(1-2^{-r}\right)^{-d}$$
$$\le 2^b e^{-2\epsilon^2 d} 2^{2^{-r+1}d} \;\le\; 2^b e^{-(2\epsilon^2-2^{-r+1})d}. \qquad \square$$

My thesis [12] presents some surprising results about various versions of this game. It turns out that the helper must give the player quite of few bits of help before significantly decreasing the number of parity questions the player must ask when playing a single game instance. However, the same number of bits of help will decrease the number of questions asked down to only two question per game instance, no matter how many game instances are being played simultaneously. However, the helper must provide an additional bit of help per game instance to decrease the number of questions asked per game instance below $2-\epsilon$.

This upper bound is best understood by not considering the message sent by the helper as being information about the input but as being random bits. With a few "random" bits, the worst-case complexity decreases to the point that it matches the expected complexity for a randomized protocol, which is two questions per game instance. The upper and lower bounds on the number of helper bits required match the work done by Impagliazzo and Zuckerman [14] on recycling random bits.

3. The probabilistic JAG model. A probabilistic JAG [11] is a finite automaton with p distinguishable pebbles and q states. The input to a JAG is an n vertex d regular undirected graph with two distinguished vertices s and t. For each vertex v, there is a labeling of the (half) edges emanating from v with d distinct labels. The set of labels used at different vertices is the same, but an edge can receive two different labels at its two endpoints. One of the pebbles is initially placed on the distinguished node t and other $p-1$ are placed on s.

The program of the JAG may depend nonuniformly on n and on the degree d of the graph. What the JAG does each time step depends on the current state, which pebbles coincide on the same vertices, which pebbles are on the distinguished vertices s and t, and the value $R \in \{0,1\}^*$ of some random bits. Based on this information, the automaton changes state and does one of the following two things. It either selects some pebble $P \in [1 \ldots p]$ and some label $l \in [1 \ldots d]$ and *walks* P along the edge with label l or it selects two pebbles $P, P' \in [1 \ldots p]$ and *jumps* P to the vertex occupied by P'. A JAG that solves st-connectivity enters an accepting state if and only if there is a path from s to t in the input graph.

The space of a JAG is defined to be $S = p \log_2 n + \log_2 q$, where p is the number of pebbles and q is the number of states, because it requires $\log_2 n$ bits to store the name of a node (i.e., the location of a pebble) and $\log_2 q$ bits to record the current state.

In this paper, the running time of a deterministic algorithm averaged over inputs according to a fixed input distribution is considered instead of considering the expected running time for a probabilistic algorithm on the worst-case input. According to Yao [25] this is sufficient.

4. Graph traversal. If it is possible for a pebble of a JAG to walk from s to t on a graph, then a graph is st-connected. However, a JAG can determine that the graph is st-connected in other ways. For example, suppose that at time T_0, pebble P_s is on vertex s, P_t is on t, and P_1 and P_2 are both on some third vertex v; at time $T' \in [T_0 \ldots T_1]$, P_s and P_1 are both on the same vertex v'; and at time $T'' \in [T_0 \ldots T_1]$,

P_t and P_2 are both on some other vertex v''. If these pebbles only walk along edges of the graph, then it follows that the graph is st-connected.

Additional complexity is caused by the pebbles being able to jump. A single pebble may not walk these paths from s to t. Instead, one pebble may walk part of the way. Another pebble may jump to this pebble and continue on the walk. In general, one cannot assume that a task is completed by a "specific pebble," because the pebbles are able to continually change places and each could complete some fraction of the task.

Such complex procedures for determining st-connectivity are captured by the *st-traversal* problem, which is formally defined as follows. Given a JAG computation on a graph G, the *traversal graph* H is defined as follows. For every vertex v of G and step $T \in [T_0 \dots T_1]$, let $\langle v, T\rangle$ be a vertex of H if and only if there is a pebble on vertex v at time T. Let $\{\langle u, T\rangle, \langle v, T+1\rangle\}$ be an edge of H if a pebble walks along edge $\{u, v\}$ in G during step T and let $\{\langle v, T\rangle, \langle v, T+1\rangle\}$ be an edge of H if there is a pebble that remains on vertex v during step T. We say that the JAG *traverses* the graph G from vertex s to vertex t during the time interval $[T_0 \dots T_1]$ if and only if there is an undirected path in H between $\langle s, T_s\rangle$ and $\langle t, T_t\rangle$ for some $T_s, T_t \in [T_0 \dots T_1]$.

In the example given above there is a traversal path composed of the four segments (see Figure 1): from $\langle s, T_0\rangle$ to $\langle v', T'\rangle$ following the movements of P_s, from $\langle v', T'\rangle$ to $\langle v, T_0\rangle$ following the movements of P_1 backward in time, from $\langle v, T_0\rangle$ to $\langle v'', T''\rangle$ following the movements of P_2, and from $\langle v'', T''\rangle$ to $\langle t, T_0\rangle$ following the movements of P_t backward in time. From the existence of this path, the JAG can deduce that s and t are connected.

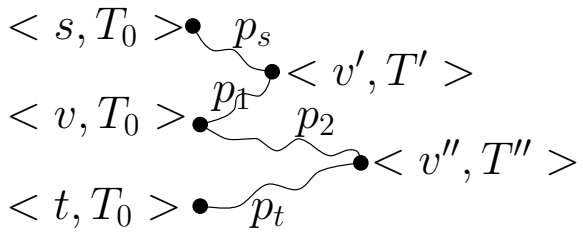

FIG. 1. *A path in the traversal graph of G.*

The st-connectivity decision problem and the problem of traversing from s to t are closely related. Let $\mathcal{F}$ be a family of connected graphs with distinguished nodes s and t. Let $G_{s,t} \cup G_{s',t'}$ be the graph composed of two identical disjoint copies of the graph $G \in \mathcal{F}$. Let $G_{s,t'} \cup G_{s',t}$ be the same except that one copy has the vertices s and t' and the other has s' and t. The first is st-connected and the second is not. Let $\mathcal{F}'$ be the family of graphs $\{G_{s,t} \cup G_{s',t'} \mid G \in \mathcal{F}\} \cup \{G_{s,t'} \cup G_{s',t} \mid G \in \mathcal{F}\}$.

LEMMA 2. *If a JAG solves st-connectivity (in T steps) with probability $\frac{1}{2} + \epsilon$ for input graphs uniformally chosen from $\mathcal{F}'$, then a similar JAG can perform st-traversal (in T steps) with probability 2ϵ for graphs uniformally chosen from $\mathcal{F}$.*

Proof. Suppose that there is a JAG that solves st-connectivity (in T steps) with probability $\frac{1}{2} + \epsilon$ for graphs uniformally chosen from $\mathcal{F}'$. We will say that the same JAG can perform st-traversal (in T steps) on a graph $G \in \mathcal{F}$, if on input $G_{s,t} \cup G_{s',t'}$ or $G_{s,t'} \cup G_{s,t'} \in \mathcal{F}'$ it either traverses from s to t or from s' to t'. By way of contradiction, suppose for a random graph $G \in \mathcal{F}$, the probability that it does this is strictly less than 2ϵ. Consider one of the $1 - 2\epsilon$ fractions of the graphs $G_{s,t} \cup G_{s',t'}$

on which it traverses neither from s to t nor from s' to t'. Consider the connected components of H. At each point in time, the pebbles can be partitioned based on which connected component of H they are in. A pebble can change which part of this partition it is in by jumping but not by traversing an edge. Since there is no path from s to t in H, the node $\langle s, T_s\rangle$, for any time step T_s, is in a different component than the nodes $\langle t, T_t\rangle$ for any time step T_t. Similarly, for all time steps $T_{s'}$ and $T_{t'}$, nodes $\langle s', T_{s'}\rangle$ and $\langle t', T_{t'}\rangle$ are in different components. If this JAG was given $G_{s,t'} \cup G_{s',t}$ as input instead, the connected components of H and the partitioning of the pebbles would be isomorphic. It follows that the computations on $G_{s,t} \cup G_{s',t'}$ and on $G_{s,t'} \cup G_{s',t}$ are identical. Therefore, for at least a half of the $1-2\epsilon$ fraction of the graphs being considered the JAG must give the wrong answer. This contradicts the assumption. □

By the definition of the *st*-traversal problem, all the pebbles are initially placed on s and t, and not within the graph. However, the proof of the lower bound uses an inductive argument for which the inductive step requires a somewhat stronger hypothesis than the main result, namely, that the result holds for traversing a subgraph (also with distinguished nodes s' and t') with an arbitrary initial placement of the pebbles and with an arbitrary initial state. If the subgraph initially contains pebbles within the subgraph or if the pebbles enter the subgraph via both the s' and the t' nodes, then the path through the traversal graph H may go forward and backward in time many times, as demonstrated in the above example. However, the following defines the type of traversals for which proving a lower bound is easier. Consider a subgraph with distinguished nodes s' and t' that initially contains no pebbles and that is built so that it can be entered by pebbles only via s' or t'. We will say that the subgraph has been *forward traversed* from s' to t' if it is traversed, yet, during the time period of the traversal, pebbles enter the subgraph via only one of the distinguished nodes s' or t' but not both. When this occurs, there must be a path from s' to t' or from t' to s' that proceeds only forward in time.

Consider a line of d subgraphs, the ith of which has distinguished nodes s_i and t_i, which are connected by the nodes s_i and t_{i+1} being the same node. The input graph will be many copies of this line of graphs. Consider a computation on this input graph starting with some initial placement of the pebbles and stopping when one of the lines of subgraphs has been traversed. Because the line is traversed, each of the subgraphs in the line must have been traversed. However, only some of these subgraphs would have been *forward traversed*. These need to be identified. Let $S_0 \subset [1 \dots d]$ consist of those i for which some copy of the line initially contains a pebble in its ith subgraph. Define $S_1 \subset [1 \dots d] - S_0$ to consist of those i such that the first time the ith subgraph in some line is traversed it is not forward traversed. These subgraphs do not initially contain pebbles; hence, when they are first traversed, pebbles must enter them via both the distinguished nodes s_i and t_i.

Claim 1. $|S_0 \cup S_1| \le 2p + 1$.

Proof. $|S_0| \le p$, because there are only p pebbles. Consider two indices i and $i' \in S_0$ such that $i < i'$ and there is no $i'' \in S_0$ strictly between $i < i'' < i'$. Consider two indexes j and j' such that $i < j < j' < i'$. If $j, j' \in S_1$, then pebbles would need to enter the jth subgraph via t_j and enter the j'th subgraph via $s_{j'}$. How did pebbles get in the line of subgraphs between these two nodes without pebbles first traversing the jth or the j'th subgraphs? Recall pebbles cannot jump to nodes not already containing pebbles. This is a contradiction. Hence, there can only be one $j \in S_1$ between i and i'. There can also be at most one $j \in S_1$ before first $i \in S_0$ and at most one after the last. Hence, $|S_1| \le |S_0| + 1$. □

For all $i \in [1 \ldots d] - (S_0 \cup S_1)$, the ith subgraph is forward traversed. The parameters will be defined so that $p \in o(d)$, so that most of the subgraphs need to be forward traversed.

5. The helper JAG. If the goal of the JAG is to compute the *st*-connectivity problem, then for any given input graph, a helper could tell the JAG the answer by communicating only one bit of help. On the other hand, we will show that many bits of help are required to significantly improve the time for the JAG to actually traverse from s to t in a certain class of graphs.

Having formally defined *st*-traversal, we are now able to formally define a helper JAG. It is the same as a regular JAG except that the helper, who knows the complete input, is able to set the initial state and pebble configuration in a way that minimizes the traversal time. Let $T\langle G, Q, \Pi\rangle$ be the time required for a regular JAG to traverse the input graph G starting in state $Q \in [1 \ldots q]$ and with $\Pi \in [1 \ldots n]^p$ specifying for each of the p pebbles which of the n nodes it is initially on. The time for the corresponding helper JAG to traverse G is defined to be $\min_{\langle Q,\Pi\rangle} T\langle G, Q, \Pi\rangle$. It is often easier to think of the helper giving the JAG $b = \log(qn^p)$ bits of information.

6. A fly swatter graph. The basic components of the input graphs defined in section 8 are the *fly swatter graphs* (see Figure 2). A fly swatter graph consists of two identical graphs with r *switches* between them. It is very similar to the squirrel cage graph defined in [5]. Each half consists of a path of length $\frac{h}{2}$, called the *handle*, and a swatting part. The swatting part consists of two parallel paths of length $r+1$ that are both connected to one end of the handle. The distinguished nodes s and t are located at the ends of the handles farthest from the swatting parts. Suppose the swatting part of one half of the graph contains the paths $u_0^0, u_0'^0, u_1^0, u_1'^0, \ldots, u_{r-1}'^0, u_r^0$ and $v_0^0, v_0'^0, v_1^0, v_1'^0, \ldots, v_{r-1}'^0, v_r^0$ and the swatting part of the other half contains the paths $u_0^1, u_0'^1, u_1^1, u_1'^1, \ldots, u_{r-1}'^1, u_r^1$ and $v_0^1, v_0'^1, v_1^1, v_1'^1, \ldots, v_{r-1}'^1, v_r^1$. Then the setting of the switches between the halves is specified by a nonzero vector $\alpha \in \{0,1\}^r$ as follows. For each $j \in [1 \ldots r]$, the jth switch consists of the two *cross-over edges* $\{u_j^0, v_j^{[\alpha]_j}\}$ and $\{u_j^1, v^{\overline{[\alpha]_j}}\}$. Note that if $[\alpha]_j = 0$, then the switch remains within the same half and if $[\alpha]_j = 1$, then the switch crosses over from one half to the other. (The notation $[\alpha]_j$ is used to denote the jth bit of the vector α. The notation α_i is reserved to mean the ith vector in a vector of vectors.) The extra nodes $u_i'^0$ and $v_i'^0$ are added so that the smallest square containing cross-over edges contains six edges.

Forward traversing from s to t in the fly swatter specified by α requires traversing a sequence of switches $E \in [1 \ldots r]^*$ for which the parity of the bits of α on the indexes in E is 1, i.e., $\bigoplus_{j \in E} [\alpha]_j = 1$. To be able complete this task, the JAG must be able to determine the parity of such a sequence E. There are two ways in which the JAG can ask a *parity question*. The lower bound will prove that these are the only ways in which the JAG is able to acquire the information about the input.

The first method of asking a parity question requires only one pebble but a great deal of time. The pebble enters the fly swatter via the distinguished node s (or t), traverses up the handle, through a sequence of switches $E \in [1 \ldots r]^+$, and back down the handle. While the pebble is inside the fly swatter, the JAG has no way of learning which half the pebble is in, because the two halves are indistinguishable. However, when the pebble reaches the bottom of the handle, the parity of the sequence is determined by whether the distinguished node s or t is reached. Each handle contains $\frac{h}{2}$ edges. Therefore, asking a parity question with one pebble requires the JAG to traverse at least h edges. This is illustrated in Figure 3 (a).

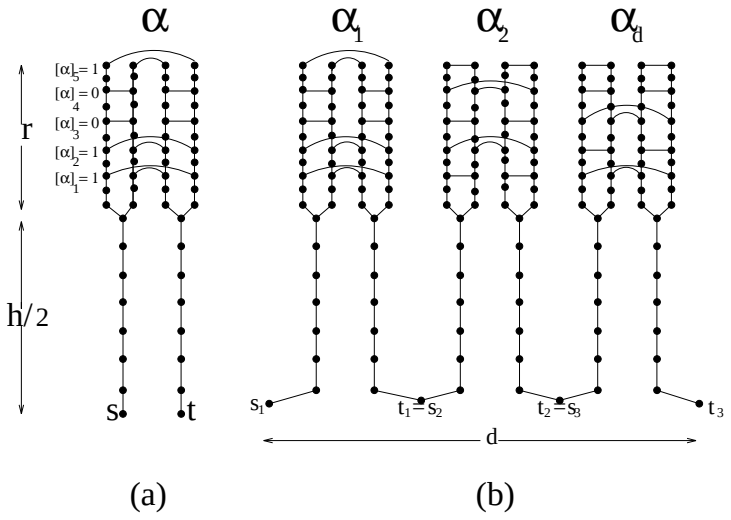

FIG. 2. *A fly swatter graph and a line of fly swatters.*

The second method requires two pebbles, one of which acts as a *marker* and the other of which traverses a sequence of switches E. The parity of the sequence is determined by whether the traversing pebble returns to the marker. For example, if a pebble starts at node u_2^0 and walks the edges labeled $\langle$ *switch,up,switch,down* $\rangle$, then one possible sequence of nodes for the pebble to follow is $u_2^0, v_2^0, v_3^0, u_3^0, u_2^0$ and another is $u_2^0, v_2^0, v_3^0, u_3^1, u_2^1$ depending on which switches in the graph are switched. Provided the JAG leaves a pebble as a marker at the node u_2^0, it can differentiate between these two sequences and learn whether $[\alpha]_2 \oplus [\alpha]_3$ is 0 or 1. This is illustrated in Figure 3 (b). Even though a parity question E (for example, the parity of all the bits in α) may require $\Theta(r)$ edges to be traversed, the lower bound will only charge the JAG for the traversal of at most two edges for a parity question using a marker.

If the JAG can only gain information about the input by asking parity questions in these two ways, then a JAG that solves *st*-connectivity for a fly swatter graph must be able to solve the following version of the parity game: The input to this game consists of a single nonzero vector $\alpha \in \{0,1\}^r$. The player, after receiving no help, asks parity questions. A parity question specifies a subset of the indexes $E \subseteq [1 \ldots r]$. The answer to the parity question is the parity of the input α at the indexes in this set, namely, $\bigoplus_{j \in E} [\alpha]_j$. The complexity is the number of questions asked before the player asks a parity question with answer 1.

Beame et al. [5] prove that, for this game, r questions must be asked in the worst case. The proof uses the fact that $\alpha \in \{0,1\}^r - \{0^r\}$ forms a vector space of dimension r. In this way, they prove that for one pebble, $\Theta(hr) = \Theta\left(n^2\right)$ time is needed. However, we are considering more than one pebble. With two pebbles the JAG can traverse the fly swatter graph in linear time.

In order to prove lower bounds when the JAG has more than one pebble, a more complex graph is needed. The fly swatter graph will be a subgraph of this more complex graph. In order to traverse this complex graph the JAG will have to traverse a particular fly swatter subgraph many times. Hence, on subsequent traversals of this fly swatter the JAG may have some precomputed information about it. This is modeled by a helper providing the JAG with this precomputed information.

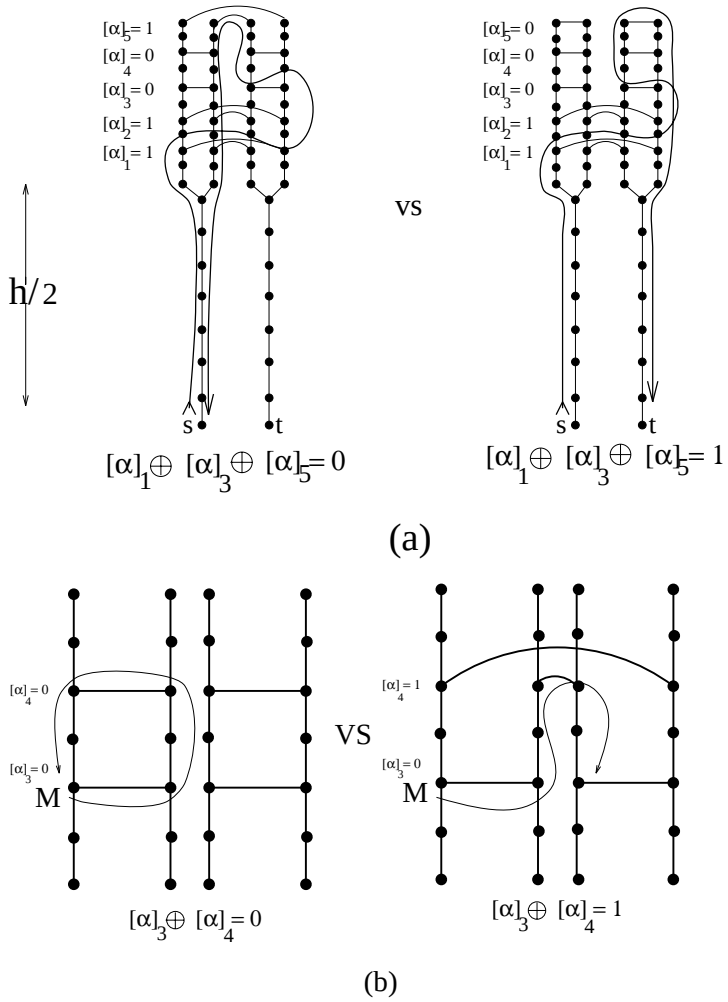

FIG. 3. *A parity question without and with a marker.*

7. The helper and a line of fly swatter graphs. The helper communicates information to the JAG about the input graph by specifying the initial state $Q \in [1 \ldots q]$ and location of each of the p pebbles. Hence, the amount of information that the helper is able to provide is limited to at most $b = \log(qn^p)$ bits. Only $\log r << b$ bits are required for the JAG to be able to traverse a fly swatter in linear time. However, b is not enough bits of help to simultaneously provide sufficient information about many fly swatter graphs. For this reason, we require the JAG to traverse a *line of d fly swatters*. Such a line is specified by the parameters $r \in O(1)$, $h \in O(1)$, $d \in \log^{O(1)} n$ and the vector of vectors $\vec{\alpha} = \langle \alpha_1, \ldots, \alpha_d \rangle \in (\{0,1\}^r - \{0^r\})^d$. The d graphs are connected by making the distinguished nodes t_i and s_{i+1} be the same node for $i \in [1 \ldots d-1]$. This is illustrated in Figure 2 (b).

The similarities between the parity game and the traversal of a line of fly swatter graphs should be clear, at least informally. Lemma 1 proves that if the JAG is only able to gain information by asking parity questions and $b << d$, then the average number of questions the JAG must ask is $(1.5 - \epsilon)\, d$. Therefore, if a marker is utilized in none

of the questions, then the number of edges traversed by the JAG is $h\,(1.5-\epsilon)\,d$, and if a marker is utilized in all of the questions, then $2\,(1.5-\epsilon)\,d$ edges are traversed. Note that without a marker, the time required is roughly a factor of $(1.5-\epsilon)$ larger than the number of edges. This factor is not very impressive, but its effect is magnified in a recursive construction.

8. The recursive fly swatter graphs. See Figure 4. Let $G\,(\vec{\alpha}_l)$ denote the line of fly swatters specified by the vector of vectors $\vec{\alpha}_l = \left\langle \alpha_{\langle l,1\rangle}, \ldots, \alpha_{\langle l,d\rangle} \right\rangle \in (\{0,1\}^r - \{0^r\})^d$. For each $l \geq 0$, we recursively define a graph. Define $G\,(\emptyset)$ to be a single edge. Define $G\,(\vec{\alpha}_1, \ldots, \vec{\alpha}_l)$ to be the graph $G\,(\vec{\alpha}_l)$ where each edge is replaced by a super edge consisting of a copy of $G\,(\vec{\alpha}_1, \ldots, \vec{\alpha}_{l-1})$. The node $s_{\langle l-1,1\rangle}$ is one end of the super edge and the node $t_{\langle l-1,d\rangle}$ is the other end. All the super edges in one level are the same. The family of recursive fly swatter graphs is $\left\{\, G\,(\vec{\alpha}_1, \ldots, \vec{\alpha}_L) \;\middle|\; \vec{\alpha}_1, \ldots, \vec{\alpha}_L \in (\{0,1\}^r - \{0^r\})^d \,\right\}$, where L is such that n is the total number of nodes. (Gadgets can be added to make the graph 3-regular without changing it significantly.) The graph $G\,(\vec{\alpha}_1, \ldots, \vec{\alpha}_l)$ contains $(h+10r)\,d$ copies of $G\,(\vec{\alpha}_1, \ldots, \vec{\alpha}_{l-1})$. Therefore, the total number of edges is at most $[(h+10r)\,d]^L$. The number of nodes n is approximately two thirds of the number of edges.

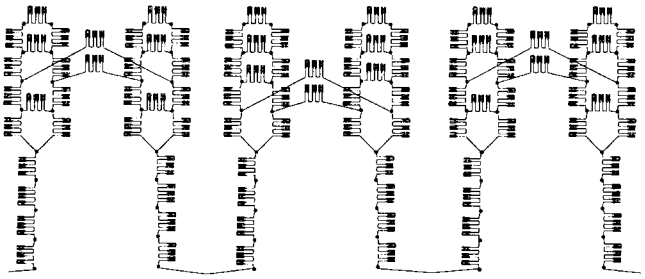

FIG. 4. *The recursive line of fly swatters graph. (Sorry, the cycles in the figure have length* 4 *instead of* 6.*)*

A crucial observation in understanding the complexity of traversing this graph is that a pebble can only be used as a marker in one recursion level at a time. To demonstrate this, consider $L = 2$ levels of recursion and $p = 2$ pebbles. If a parity question is asked about the top level vector $\vec{\alpha}_L$ by leaving a pebble as a marker, then only one pebble remains to traverse the sequence of super edges required by the question. Hence, these super edges, which are themselves lines of fly swatters, must be traversed with the use of only one pebble. Alternatively, if two pebbles are used to traverse each super edge, then there is "effectively" one pebble for the traversal of the top level. See Figures 3 (b) and 5.

An intuitive explanation of the lower bound can now be given. (A formal proof is provided in section 11.) There are p pebbles, hence at most $p-1$ markers. It follows that $L-p+1$ levels are traversed without the use of a marker. Note, as well, that the time to traverse a copy of $G\,(\vec{\alpha}_1, \ldots, \vec{\alpha}_l)$ is the number of super edges traversed in the lth level subgraph $G\,(\vec{\alpha}_l)$ multiplied by the time to traverse each super edge $G\,(\vec{\alpha}_1, \ldots, \vec{\alpha}_{l-1})$. Therefore, an estimation of the total time is the product of the number of super edges traversed at each of the L levels:

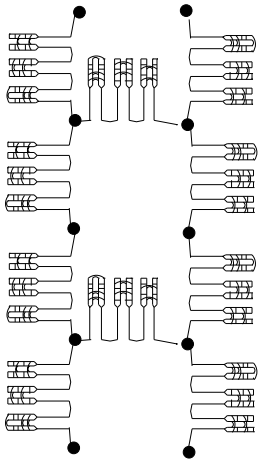

FIG. 5. *Ten super edges of a two level recursive fly swatter graph.*

$$
\begin{aligned}
T &\geq \left[h\,(1.5-\epsilon)\,d\right]^{L-p+1}\left[(1.5-\epsilon)\,d\right]^{p-1} \\
&= (1.5-\epsilon)^{L} \times (hd)^{L} \times h^{-p+1}. \qquad (8.1)
\end{aligned}
$$

The parameters are chosen as follows: $r, h \in \Theta(1)$, $d \in \log^{\Theta(1)} n$, and $L \in \Theta(\frac{\log n}{\log\log n})$. Then the first factor becomes $2^{\Omega(\frac{\log n}{\log\log n})}$, the second is close with n (assuming $r << h$), and the third is insignificant compared with the first assuming that p is a constant fraction of $\frac{L}{\log h} \in \Theta(\frac{\log n}{\log\log n})$. This is the bound claimed in Theorem 1.

9. The time, pebbles, and cost used at level *l*. The lower bound is proved by induction on the number of levels of recursion l. For each $l \in [1 \ldots L]$, we prove a lower bound on the cost to traverse some copy of $G(\vec{\alpha}_1, \ldots, \vec{\alpha}_l)$. Define $\vec{\gamma} = \langle \vec{\alpha}_1, \ldots, \vec{\alpha}_{l-1} \rangle$ and $\vec{\beta} = \langle \vec{\alpha}_{l+1}, \ldots, \vec{\alpha}_L \rangle$ so that $G(\vec{\alpha}_1, \ldots, \vec{\alpha}_L)$ and $G(\vec{\gamma}, \vec{\alpha}_l, \vec{\beta})$ denote the same graph. Think of $G(\vec{\gamma}, \vec{\alpha}_l)$ (the subgraph traversed) as a line of d fly swatters $G(\vec{\alpha}_l)$ with each of its super edges being a copy of $G(\vec{\gamma})$. The super edge $G(\vec{\gamma})$ does not need to be understood, because the induction hypothesis proves a lower bound on the time to traverse it. In the graph $G(\vec{\gamma}, \vec{\alpha}_l, \vec{\beta})$, there are many copies of $G(\vec{\gamma}, \vec{\alpha}_l)$. The graph $G(\vec{\beta})$ is called the *context* in which these copies of $G(\vec{\gamma}, \vec{\alpha}_l)$ appear.

Informally, the time required to traverse $G(\vec{\gamma}, \vec{\alpha}_l)$ is the number of super edges of $G(\vec{\alpha}_l)$ traversed multiplied by the time to traverse a super edge $G(\vec{\gamma})$. This fails to be true, because each traversal of a super edge may require a different amount of time. This difference in time is caused by the number of markers (pebbles) being used in the traversal and by the state and position of the pebbles before the traversal. Note that differences in traversal times are not caused by differences in the structure of the super edges, because they are all identical.

Let $Q \in [1 \ldots q]$ be a state of the JAG and let $\Pi \in [1 \ldots n]^p$ specify which node of $G(\vec{\gamma}, \vec{\alpha}_l, \vec{\beta})$ each of the p pebbles is on. Consider the JAG computation starting in the configuration described by Q and Π on the graph $G(\vec{\gamma}, \vec{\alpha}_l, \vec{\beta})$ until some copy of $G(\vec{\gamma}, \vec{\alpha}_l)$ is traversed. Define $T\left[l, \left\langle \vec{\gamma}, \vec{\alpha}_l, \vec{\beta} \right\rangle, Q, \Pi\right]$ to be the number of time steps taken. This will be abbreviated to $T_{[l]}$ when the rest of the parameters are understood.

Define $p\left[l, \left\langle \vec{\gamma}, \vec{\alpha}_l, \vec{\beta} \right\rangle, Q, \Pi\right]$ (abbreviated to $p[l]$) to be

$$p\left[l, \left\langle \vec{\gamma}, \vec{\alpha}_l, \vec{\beta} \right\rangle, Q, \Pi\right] = \max_{T \in [1 \ldots T[l]]} \left[p + 1 - (\#\text{ copies of } G(\vec{\gamma}, \vec{\alpha}_l) \text{ containing pebbles at time } T)\right].$$

At no time during the interval does a copy of $G(\vec{\gamma}, \vec{\alpha}_l)$ contain more than $p[l]$ pebbles. For example, suppose there are two copies of $G(\vec{\gamma}, \vec{\alpha}_l)$ containing pebbles. One copy contains at least one pebble and, therefore, the other copy contains no more than $p + 1 - 2 = p - 1$ pebbles. Think of the "(# copies of $G(\vec{\gamma}, \vec{\alpha}_l)$ containing pebbles)" as the number of pebbles being used as "markers" in the graph $G(\vec{\beta})$. Essentially, no more than one of these pebbles is available to be used in the traversal of $G(\vec{\gamma}, \vec{\alpha}_l)$.

Define the *cost* incurred by the JAG in traversing a copy of $G(\vec{\gamma}, \vec{\alpha}_l)$ to be

$$w\left[l, \left\langle \vec{\gamma}, \vec{\alpha}_l, \vec{\beta} \right\rangle\right] = \min_{\langle Q, \Pi \rangle} h^{p\left[l, \left\langle \vec{\gamma}, \vec{\alpha}_l, \vec{\beta} \right\rangle, Q, \Pi\right]} T\left[l, \left\langle \vec{\gamma}, \vec{\alpha}_l, \vec{\beta} \right\rangle, Q, \Pi\right].$$

The motivation for using $h^{p[l]}T[l]$ comes from (8.1). Since the average time $T[l]$ to traverse $G(\vec{\gamma}, \vec{\alpha}_l)$ can be estimated by $(1.5 - \epsilon)^l (hd)^l h^{-p[l]+1}$, the quantity $h^{p[l]}T[l]$ is essentially independent of the number of pebbles used. The reason for minimizing over $\langle Q, \Pi \rangle$ is that we are assuming the helper sets the initial JAG configuration in a way that minimizes the cost of the traversal. The actual bounds obtained (with high probability) are the following:

$$\begin{aligned} W[0] &= h, \\ W[l] &= W[l-1] \times h \times (d(1.5 - \epsilon) - 4p - 2) \\ &= [h \times (d(1.5 - \epsilon) - 4p - 2)]^l h. \end{aligned}$$

The remaining goal is to prove that with high probability (over randomly chosen inputs) the cost $w\left[l, \left\langle \vec{\gamma}, \vec{\alpha}_l, \vec{\beta} \right\rangle\right]$ to traverse a copy of $G(\vec{\gamma}, \vec{\alpha}_l)$ is at least $W[l]$. Lemma 3 provides the inductive step for this proof.

10. Reducing the helper parity game to *st*-traversal. Suppose that there is a JAG algorithm for which the time to traverse a copy of $G(\vec{\gamma}, \vec{\alpha}_l)$ is only a small factor more than the time to traverse a copy of $G(\vec{\gamma})$. This means that the JAG is able to traverse the line of fly swatters $G(\vec{\alpha}_l)$ without traversing many of its super edges and hence without "asking" many parity questions about $\vec{\alpha}_l$. In effect, the JAG is able to play the helper parity game with parameters r, d, and $b = \log(qn^p)$, where r and d are the parameters defining the line of fly swatters and $\log(qn^p)$ is the space allocated to the JAG. This is captured in the following lemma.

LEMMA 3. *Given an algorithm for st-traversal whose cost on input $G(\vec{\gamma}, \vec{\alpha}_l, \vec{\beta})$ to traverse a subgraph at the $l-1$st and the lth levels are $w\left[l-1, \left\langle \vec{\gamma}, \vec{\alpha}_l, \vec{\beta} \right\rangle\right]$ and $w\left[l, \left\langle \vec{\gamma}, \vec{\alpha}_l, \vec{\beta} \right\rangle\right]$, we can produce a protocol for the helper parity game for which the number of questions asked per game instance on input $\vec{\alpha}_l$ is $c_{\vec{\alpha}_l}$ such that*

$$\begin{aligned} \Pr_{\vec{\alpha}_l}\left[c_{\vec{\alpha}_l} < 1.5 - \epsilon\right] \geq{}& \Pr_{\langle \vec{\gamma}, \vec{\alpha}_l, \vec{\beta} \rangle}\left[w\left[l, \left\langle \vec{\gamma}, \vec{\alpha}_l, \vec{\beta} \right\rangle\right] < W[l]\right] \\ &- \Pr_{\langle \vec{\gamma}, \vec{\alpha}_l, \vec{\beta} \rangle}\left[w\left[l-1, \left\langle \vec{\gamma}, \vec{\alpha}_l, \vec{\beta} \right\rangle\right] < W[l-1]\right]. \end{aligned}$$

COROLLARY 1. *Given a helper-JAG algorithm for st-traversal whose traversal time on input* $G(\vec{\alpha}_1, \ldots, \vec{\alpha}_L)$ *is* $T_{\langle \vec{\alpha}_1, \ldots, \vec{\alpha}_L \rangle}$ *and the helper parity game defined in Lemma* 3*,*

$$\Pr_{\langle \vec{\alpha}_1, \ldots, \vec{\alpha}_L \rangle} \left[T_{\langle \vec{\alpha}_1, \ldots, \vec{\alpha}_L \rangle} < \left[h \times (d(1.5 - \epsilon) - 4p - 2) \right]^L h^{-p+1} \right] \leq L \times \Pr_{\vec{\alpha}} \left[c_{\vec{\alpha}} < 1.5 - \epsilon \right].$$

Proof. The time and the cost incurred by the JAG to traverse the entire input graph are defined to be $T_{\langle \vec{\alpha}_1, \ldots, \vec{\alpha}_L \rangle} = T_{[L]}$ and $w_{[L]} = \min_{\langle Q, \Pi \rangle} h^{p_{[L]}} T_{[L]}$. The number of pebbles $p_{[L]}$ used in the traversal is at most the number of pebbles p the JAG has. It follows that if traversal time is small, i.e., $T_{[L]} < W_{[L]} h^{-p}$, then the cost is small, i.e., $w_{[L]} = h^{p_{[L]}} T_{[L]} < W_{[L]}$. It remains to prove that for $l \leq L$,

$$\Pr_{\langle \vec{\alpha}_1, \ldots, \vec{\alpha}_L \rangle} \left[w\left[l, \left\langle \vec{\gamma}, \vec{\alpha}_l, \vec{\beta} \right\rangle \right] < W_{[l]} \right] \leq l \times \Pr_{\vec{\alpha}} \left[c_{\vec{\alpha}} < 1.5 - \epsilon \right].$$

The proof proceeds by induction on l. For the base case, $l = 0$, the subgraph $G()$ is a single edge requiring at least 1 time step for traversal by at least one pebble. This guarantees that with probability 1, $w_{[0]} = \min_{\langle Q, \Pi \rangle} h^{p_{[0]}} T_{[0]} \geq h = W_{[0]}$. The induction step follows easily using Lemma 3. □

Proof. Consider a fixed algorithm for *st*-traversal. In the helper-parity protocol defined below, the game helper learns what help to send and the game player learns what questions to ask by running this fixed JAG algorithm as it traverses a line of fly swatters at the lth level.

Both the *st*-traversal problem and the helper-parity game have the vector $\vec{\alpha}_l = \left\langle \alpha_{\langle l,1 \rangle}, \ldots, \alpha_{\langle l,d \rangle} \right\rangle \in (\{0,1\}^r - \{0^r\})^d$ as part of its input. However, the *st*-traversal problem has the additional inputs $\vec{\gamma}$ and $\vec{\beta}$. Therefore, these vectors are fixed to $\vec{\gamma}'$ and $\vec{\beta}'$ in a way that satisfies the property

$$\begin{aligned} &\Pr_{\vec{\alpha}_l} \left[w\left[l, \left\langle \vec{\gamma}', \vec{\alpha}_l, \vec{\beta}' \right\rangle \right] < W_{[l]} \right] - \Pr_{\vec{\alpha}_l} \left[w\left[l-1, \left\langle \vec{\gamma}', \vec{\alpha}_l, \vec{\beta}' \right\rangle \right] < W_{[l-1]} \right] \\ &\leq \Pr_{\langle \vec{\gamma}, \vec{\alpha}_l, \vec{\beta} \rangle} \left[w\left[l, \left\langle \vec{\gamma}, \vec{\alpha}_l, \vec{\beta} \right\rangle \right] < W_{[l]} \right] - \Pr_{\langle \vec{\gamma}, \vec{\alpha}_l, \vec{\beta} \rangle} \left[w\left[l-1, \left\langle \vec{\gamma}, \vec{\alpha}_l, \vec{\beta} \right\rangle \right] < W_{[l-1]} \right]. \end{aligned}$$

These vectors $\vec{\gamma}'$ and $\vec{\beta}'$ are known in advance to both the game helper and the game player.

The first thing that the game protocol must specify is the message $M(\vec{\alpha}_l)$ sent by the game helper on each input $\vec{\alpha}_l$. This message is defined to be $\left\langle Q_{\langle l, \vec{\alpha}_l \rangle}, \Pi_{\langle l, \vec{\alpha}_l \rangle} \right\rangle$, which specifies the configuration in which the JAG helper initially places the JAG when $G(\vec{\gamma}', \vec{\alpha}_l, \vec{\beta}')$ is the JAG's input graph. Note that the game helper only sends $\log(qn^p)$ bits, because this is the number of bits needed to encode a state and the locations of all p pebbles.

The game player learns which questions to ask the helper by simulating the JAG algorithm on the graph $G(\vec{\gamma}', ?, \vec{\beta}')$ starting in the configuration $\left\langle Q_{\langle l, \vec{\alpha}_l \rangle}, \Pi_{\langle l, \vec{\alpha}_l \rangle} \right\rangle$. The only thing preventing the game player from running the JAG is that he does not know the vector $\vec{\alpha}_l$. However, he can run the JAG as long as the computation does not depend on this unknown information. Specifically, suppose during the simulation that pebbles enter a fly swatter defined by a $\alpha_{\langle l,i \rangle}$ that is not known by the game player. The game player will be able to continue running the JAG for quite a while. However, as soon as the computation depends on which crossover edges of the fly swatter are switched, he must stop the simulation. He then asks the game helper a question about the game instance $\alpha_{\langle l,i \rangle}$. By definition of the parity game, the game helper reveals

to him the entire vector $\alpha_{\langle l,i\rangle}$. With this new information, the game player is able to continue the simulation until the next such event occurs.

As was done in section 4, let $S_0 \subset [1 \dots d]$ consist of those i for which some copy of $G(\vec{\gamma}', \vec{\alpha}_l)$ initially (i.e., according to $\Pi_{\langle l,\vec{\alpha}_l\rangle}$) contains a pebble in its ith fly swatter. Note that the p pebbles of the JAG might be contained in different copies of $G(\vec{\gamma}', \vec{\alpha}_l)$, but all such copies are considered. The game player begins the game by asking an arbitrary parity question E_i about $\alpha_{\langle l,i\rangle}$ for each $i \in S_0$.

The game player then starts simulating the JAG. Because he knows $\alpha_{\langle l,i\rangle}$ for every fly swatter containing pebbles, he can run the JAG at least until a pebble moves into an adjacent fly swatter. The JAG might alternately move pebbles contained in different copies of $G(\vec{\gamma}', \vec{\alpha}_l)$. However, we will count the number of time steps taken in each copy separately.

If the ith fly swatter in some copy of $G(\vec{\gamma}', \vec{\alpha}_l)$ is entered via both its s_i and t_i distinguished nodes, then the game player will also ask an arbitrary parity question E_i about $\alpha_{\langle l,i\rangle}$, as long as a question has not been asked about $\alpha_{\langle l,i\rangle}$ already. The indexes for which this happens forms the set S_1, as defined in section 4. By Claim 1, $|S_0 \cup S_1| \leq 2p+1$. Therefore, this completes at most $2p+1$ of the d game instances $\alpha_{\langle l,1\rangle}, \dots, \alpha_{\langle l,d\rangle}$. The remaining fly swatters indexed by $i \in [1 \dots d] - (S_0 \cup S_1)$ are *forward traversed*.

Two events will now be defined. If one of these events occurs within the ith fly swatter in some copy of $G(\vec{\gamma}', \vec{\alpha}_l)$, then the game player asks a question about the ith game instance $\alpha_{\langle l,i\rangle}$. Below, we prove that the computation of the JAG through the ith fly swatter does not depend on $\alpha_{\langle l,i\rangle}$ until one of these events occurs. It follows that the game player is always capable of running the simulation and hence of executing the parity-game protocol currently being defined. We also prove that, because fly swatters indexed by $i \in [1 \dots d] - (S_0 \cup S_1)$ are *forward traversed*, one of the events eventually occurs within each of them. From this, it follows that the parity-game protocol will terminate, asking a question about each game instance. Finally, I prove that traversing a fly swatter is at least twice as costly for the JAG when the question asked has even parity. Hence, the total cost for the parity game is proportional to the total cost for the JAG traversal.

Before continuing, recall that section 6 described two ways to ask a parity question. The first event will be defined so that it occurs within a fly swatter when the two pebble method is used within it, i.e., a pebble is left as a marker while another pebble walks along a sequence of super edges. Similarly, the second event will be defined so that it occurs when the one pebble method is used; i.e., a pebble walks up the handle, through a sequence of switches, and back down a handle again.

The first of these events is formally defined to occur within a fly swatter after the following has occurred twice during disjoint intervals of time. What must occur twice is that one of the super edges of the fly swatter is traversed, and during the entire time of its traversal, there is a pebble (not necessarily the same pebble at each time step) contained in the copy of $G(\vec{\gamma}', \vec{\alpha}_l)$ containing the fly swatter but not contained in the super edge in question. If this occurs in the ith fly swatter in some copy of $G(\vec{\gamma}', \vec{\alpha}_l)$, then the player asks an arbitrary question E_i about $\alpha_{\langle l,i\rangle}$.

The second event is defined to occur within the ith fly swatter. If it is initially empty, pebbles traverse up the handle, reach the cross-over edges, and then traverse down the handle again, reaching one of the distinguished nodes $s_{\langle l,i\rangle}$ or $t_{\langle l,i\rangle}$; yet during this entire time the first event never occurs within the ith fly swatter. We claim that for this event to occur, for $i \in [1 \dots d] - (S_0 \cup S_1)$, all the pebbles within

this fly swatter must traverse a single well-defined sequence of switches. When the second event occurs within the ith fly swatter in some copy of $G(\vec{\gamma}', \vec{\alpha}_l)$, the game player asks the question E_i that contains j iff the jth switch was traversed an odd number of times.

Now we will prove the claim. As stated, the pebbles are initially outside of the fly swatter. Because $i \notin S_1$, pebbles do not enter the fly swatter via both the distinguished nodes $s_{\langle l,i \rangle}$ and $t_{\langle l,i \rangle}$. Without loss generality assume that they enter via $s_{\langle l,i \rangle}$. Furthermore, there are never two pebbles within the fly swatter that have four or more full super edges between them. The reason is as follows. The pebbles contained in the fly swatter are initially together, because they enter only via $s_{\langle l,i \rangle}$. In order for two pebbles to get three full super edges between them, a super edge must be traversed while there is a pebble contained in this copy of $G(\vec{\gamma}', \vec{\alpha}_l)$ but not contained in the super edge in question. For the first event to occur, this must happen twice during disjoint intervals of time. For two pebbles to have four full super edges between, a second super edge must be traversed in this way. These two traversals occur during disjoint intervals in time and hence the first event occurs. Because the first event does not occur, no two pebbles in the fly swatter ever have four full super edges between them. Hence, the pebbles must traverse up the handle more or less together. They cannot traverse in opposite directions around a square of six super edges; hence they must traverse the same sequence of switches. Finally, they must traverse down the handle together. This proves the claim.

We will now prove that the game player always has enough information to continue running the JAG. Because of the game-helper's message and the fact that $\vec{\gamma}'$ and $\vec{\beta}'$ are fixed, the only information that the player is lacking is $\vec{\alpha}_l$. In addition, $\alpha_{\langle l,i \rangle}$ is revealed as soon he asks a question about it. Therefore, the only concern is whether the game player, even though he does not know $\alpha_{\langle l,i \rangle}$, can run the JAG as it traverses the ith fly swatter, at least until one of the two events happens. As said, if the first event has not occurred, then all the pebbles must traverse the same sequence of switches. Therefore, the only influence that $\alpha_{\langle l,i \rangle}$ (i.e., which switchable edges are switched) has on the computation is in which of the two fly swatter halves these pebbles are contained. However, the JAG has no way of knowing which half the pebbles are in, because the super edges in the two halves, the structure of the halves, and even the edge labels are identical. Therefore, the player knows as much as the JAG knows (i.e., the state and the partition of the pebbles) until second event occurs.

It has now been proven that the above protocol is well defined and meets the requirements of the game. The remaining task is to prove that the cost to the parity game is proportional to the cost of the JAG's traversal. Let us first consider the cost of the JAG's traversal. The JAG is run on the input graph $G(\vec{\gamma}', \vec{\alpha}_l, \vec{\beta}')$, starting in the configuration $\langle Q_{\langle l,\vec{\alpha}_l \rangle}, \Pi_{\langle l,\vec{\alpha}_l \rangle} \rangle$ specified by the JAG helper, until some copy of $G(\vec{\gamma}', \vec{\alpha}_l)$ (a line of fly swatters at the lth level) is traversed. By definition, the time of this traversal is $T\left[l, \langle \vec{\gamma}', \vec{\alpha}_l, \vec{\beta}' \rangle, Q_{\langle l,\vec{\alpha}_l \rangle}, \Pi_{\langle l,\vec{\alpha}_l \rangle}\right]$, the number of pebbles "used" during this traversal is $p\left[l, \langle \vec{\gamma}', \vec{\alpha}_l, \vec{\beta}' \rangle, Q_{\langle l,\vec{\alpha}_l \rangle}, \Pi_{\langle l,\vec{\alpha}_l \rangle}\right]$, and the cost incurred by the JAG is $w\left[l, \langle \vec{\gamma}', \vec{\alpha}_l, \vec{\beta}' \rangle\right] = \min_{\langle Q,\Pi \rangle} h^{p[l, \langle \vec{\gamma}', \vec{\alpha}_l, \vec{\beta}' \rangle, Q, \Pi]} T\left[l, \langle \vec{\gamma}', \vec{\alpha}_l, \vec{\beta}' \rangle, Q, \Pi\right]$. Abbreviate these values to $T[l, \vec{\alpha}_l]$, $p[l, \vec{\alpha}_l]$ and $w[l, \vec{\alpha}_l]$. For each $i \in [1 \ldots d] - S_0$, define $T[l, \vec{\alpha}_l, i]$ to be the number of time steps for the event to occur within the ith fly swatter of some copy of $G(\vec{\gamma}', \vec{\alpha}_l)$. This time is at least the product of the number of super edges traversed and the minimum time to traverse a super edge on this input graph. The number of super edges traversed depends on whether a pebble was left as a marker within the fly swatter and whether a path from $s_{\langle l,i \rangle}$ to $t_{\langle l,i \rangle}$ was found in the first attempt, i.e.,

whether the answer to the parity was odd. The minimum cost to traverse a super edge $G(\vec{\gamma}')$ when the input graph is $G(\vec{\gamma}', \vec{\alpha}_l, \vec{\beta}')$ is defined to be $w\big[l-1, \big\langle \vec{\gamma}', \vec{\alpha}_l, \vec{\beta}' \big\rangle\big]$. Each traversal of a super edge will cost at least this minimum. Abbreviate this with $w[l-1, \vec{\alpha}_l]$. The following claim bounds the time $T[l, \vec{\alpha}_l, i]$ for the event to occur within the ith fly swatter.

CLAIM 2. *For each* $i \in [1 \ldots d] - (S_0 \cup S_1)$,

$$T[l, \vec{\alpha}_l, i] \geq \left\{ \begin{array}{ll} 1 & \text{if } \bigoplus_{j \in E_i} \big[\alpha_{\langle l, i \rangle}\big]_j = 1 \\ 2 & \text{otherwise} \end{array} \right\} w[l-1, \vec{\alpha}_l] h^{-p\left[l, \vec{\alpha}_l\right]+1}.$$

Proof. Case 1. Suppose the first event occurs; i.e., two super edges at level $l-1$ are traversed by a pebble, and during the entire time of their traversal, there is another pebble contained in the same copy of $G(\vec{\gamma}', \vec{\alpha}_l)$ but not contained in these two super edges. Consider one of these two super edges traversed and let $\big\langle Q_{\langle l-1, \vec{\alpha}_l \rangle}, \Pi_{\langle l-1, \vec{\alpha}_l \rangle} \big\rangle$ be the configuration of the JAG at the beginning of this traversal. The number of time steps starting in this configuration until some copy of $G(\vec{\gamma}')$ is traversed (clearly the super edge in question) is defined to be $T\big[l-1, \big\langle \vec{\gamma}', \vec{\alpha}_l, \vec{\beta}' \big\rangle, Q_{\langle l-1, \vec{\alpha}_l \rangle}, \Pi_{\langle l-1, \vec{\alpha}_l \rangle}\big]$ and the number of pebbles "used" in this traversal is defined to be $p\big[l-1, \big\langle \vec{\gamma}', \vec{\alpha}_l, \vec{\beta}' \big\rangle, Q_{\langle l-1, \vec{\alpha}_l \rangle}, \Pi_{\langle l-1, \vec{\alpha}_l \rangle}\big]$. Abbreviate these to $T[l-1, \vec{\alpha}_l]$ and $p[l-1, \vec{\alpha}_l]$. It will also be useful to use $T'[l-1, \vec{\alpha}_l]$ to denote the time interval during which this super edge is traversed and to use $T'[l, \vec{\alpha}_l]$ to denote the time interval during which the entire line of fly swatters $G(\vec{\gamma}', \vec{\alpha}_l)$ is traversed. The "cost" of the traversal of the super edge is defined to be

$$h^{p[l-1, \vec{\alpha}_l]} T[l-1, \vec{\alpha}_l].$$

This is at least

$$w[l-1, \vec{\alpha}_l] = \min_{\langle Q, \Pi \rangle} h^{p\left[l-1, \left\langle \vec{\gamma}', \vec{\alpha}_l, \vec{\beta}' \right\rangle, Q, \Pi\right]} \; T\big[l-1, \big\langle \vec{\gamma}', \vec{\alpha}_l, \vec{\beta}' \big\rangle, Q, \Pi\big],$$

which is the minimal cost of traversing any super edge when the helper has preset the JAG configuration $\langle Q, \Pi \rangle$ to minimize the cost. Solving for the traversal time gives

$$T[l-1, \vec{\alpha}_l] \geq w[l-1, \vec{\alpha}_l] h^{-p\left[l-1, \vec{\alpha}_l\right]}.$$

The next step is to bound the number of pebbles $p[l-1, \vec{\alpha}_l]$ "used" to traverse this super edge. The intuition is as follows. The JAG has $p[l, \vec{\alpha}_l]$ pebbles available to traverse a copy of $G(\vec{\gamma}', \vec{\alpha}_l)$. If it leaves a pebble as a marker in the lth level and traverses a sequence of switchable edges with the other $p[l, \vec{\alpha}_l] - 1$ pebbles, then only $p[l, \vec{\alpha}_l] - 1$ pebbles are available for the traversal of these super edges $G(\vec{\gamma}')$. More formally, we want to prove that $p[l-1, \vec{\alpha}_l] \leq p[l, \vec{\alpha}_l] - 1$. To do this, we must bound the minimum number of copies of $G(\vec{\gamma}')$ in $G(\vec{\gamma}', \vec{\alpha}_l, \vec{\beta}')$ that contain pebbles (number of markers) during the traversal of this super edge. By definition,

$$p[l, \vec{\alpha}_l] \;=\; \max_{T \in T'[l, \vec{\alpha}_l]} \left[p + 1 - (\#\text{ copies of } G(\vec{\gamma}', \vec{\alpha}_l) \text{ containing pebbles at time } T)\right].$$

Therefore,

$$\min_{T \in T'[l-1, \vec{\alpha}_l]} [\#\text{ copies of } G(\vec{\gamma}', \vec{\alpha}_l) \text{ containing pebbles at time } T] \;\geq\; p - p[l, \vec{\alpha}_l] + 1.$$

We know that during the time interval $T'[l-1,\vec{\alpha}_l]$, one of the copies of $G(\vec{\gamma}',\vec{\alpha}_l)$ contains two copies of $G(\vec{\gamma}')$ (super edges) that contain pebbles. Therefore,

$$\min_{T\in T'[l-1,\vec{\alpha}_l]}[\#\text{ copies of } G(\vec{\gamma}') \text{ containing pebbles at time } T] \;\geq\; p - p[l,\vec{\alpha}_l] + 1 + \mathbf{1}$$

and, therefore, $p[l-1,\vec{\alpha}_l] \leq p[l,\vec{\alpha}_l] - 1$. From this we can bound the time of this super edge's traversal to be $T[l-1,\vec{\alpha}_l] \geq w[l-1,\vec{\alpha}_l]h^{-p[l,\vec{\alpha}_l]+1}$. Because the first event occurred, this occurred twice during disjoint intervals in time. Hence, the time required for the first event to occur can be taken to be at least the sum of the times for the two super edges to be traversed, without overcounting time steps. Therefore, $2 \times w[l-1,\vec{\alpha}_l]h^{-p[l,\vec{\alpha}_l]+1}$ time steps are required.

Case 2. Suppose the second event occurs and $\bigoplus_{j\in E_i}\left[\alpha_{\langle l,i\rangle}\right]_j = 1$. This event involves traversing up and down the handle. The handle contains $\frac{h}{2}$ super edges. Therefore, at least h super edges are traversed. These traversals must occur during disjoint intervals of time, because a super edge along the handle must be completely traversed before the next super edge along the handle is entered. The maximum number of pebbles $p[l-1,\vec{\alpha}_l]$ that can be used to traverse each of these copies of $G(\vec{\gamma}')$ is $p[l,\vec{\alpha}_l]$. Even if this number is used, the traversal time for each is $T[l-1,\vec{\alpha}_l] \geq w[l-1,\vec{\alpha}_l]h^{-p[l,\vec{\alpha}_l]}$. Therefore, the time to traverse h super edges is at least $w[l-1,\vec{\alpha}_l]h^{-p[l,\vec{\alpha}_l]+1}$.

Case 3. Suppose the second event occurs and $\bigoplus_{j\in E_i}\left[\alpha_{\langle l,i\rangle}\right]_j = 0$. Without loss of generality, assume that the pebbles entered the ith fly swatter from the $(i-1)$st fly swatter through the $s_{\langle l,i\rangle}$ distinguished node. The pebbles then traverse up the handle through a sequence of switches specified by E_i and back down the handle to a distinguished node. Because $\bigoplus_{j\in E_i}\left[\alpha_{\langle l,i\rangle}\right]_j = 0$, the pebbles do not make it to the distinguished node $t_{\langle l,i\rangle}$ but arrive back at the $s_{\langle l,i\rangle}$ node. How do we know that the pebbles traverse back up and down the handle a second time? By the definition of $i \notin S_1$, the JAG must "continue on" to traverse into the $i+1$st fly swatter. Hence, they must traverse up and down the handles a second time. The two traversals up and down the handle take at least $2 \times w[l-1,\vec{\alpha}_l]h^{p\left[l,\vec{\alpha}_l\right]+1}$ time steps. □

Using this claim, we can bound the total cost $w[l,\vec{\alpha}_l]$ (and time $T[l,\vec{\alpha}_l]$) for the JAG to traverse a line of fly swatters $G(\vec{\gamma}',\vec{\alpha}_l)$.

$$\begin{aligned} w[l,\vec{\alpha}_l] &= h^{p\left[l,\vec{\alpha}_l\right]}T[l,\vec{\alpha}_l] \\ &\geq h^{p\left[l,\vec{\alpha}_l\right]} \times \left[\sum_{i\in[1\ldots d]-(S_0\cup S_1)} \left\{ \begin{array}{ll} 1 & \text{if } \bigoplus\limits_{j\in E_i}[\alpha_i]_j = 1 \\ 2 & \text{otherwise} \end{array} \right\} w[l-1,\vec{\alpha}_l]h^{-p\left[l,\vec{\alpha}_l\right]+1}\right]. \end{aligned}$$

This can now be compared with the cost to the parity game defined above. By definition of the game, the number of questions asked per game instance on input $\vec{\alpha}_l$ is

$$\begin{aligned} c_{\vec{\alpha}_l} &= \frac{1}{d}\sum_{i\in[1\ldots d]} \left\{ \begin{array}{ll} 1 & \text{if } \bigoplus\limits_{j\in E_i}[\alpha_i]_j = 1 \\ 2 & \text{otherwise} \end{array} \right\} \\ &\leq \frac{1}{d}\left[2|S_0\cup S_1| \;+ \sum_{i\in[1\ldots d]-(S_0\cup S_1)} \left\{ \begin{array}{ll} 1 & \text{if } \bigoplus\limits_{j\in E_i}[\alpha_i]_j = 1 \\ 2 & \text{otherwise} \end{array} \right\}\right]. \end{aligned}$$

By Claim 1, $|S_0\cup S_1| \leq 2p+1$. This gives that

$$w[l,\vec{\alpha}_l] \geq w[l-1,\vec{\alpha}_l] \times h \times (dc_{\vec{\alpha}_l} - 4p - 2).$$

If $\vec{\alpha}_l$ were such that $w[l-1,\vec{\alpha}_l] \geq W[l-1]$ and $c_{\vec{\alpha}_l} \geq 1.5-\epsilon$, then

$$w[l,\vec{\alpha}_l] \geq W[l-1] \times h \times (d(1.5-\epsilon) - 4p - 2) \;=\; W[l].$$

It follows that

$$\Pr_{\vec{\alpha}_l}\left[w[l,\vec{\alpha}_l] < W[l]\right] \leq \Pr_{\vec{\alpha}_l}\left[c_{\vec{\alpha}_l} < 1.5-\epsilon\right] \Pr_{\vec{\alpha}_l}\left[w[l-1,\vec{\alpha}_l] < W[l-1]\right]. \qquad \square$$

11. Completing the proof. The final step is to prove the theorem.

THEOREM 1′ *For every constant $z \geq 2$ and every helper-JAG algorithm for st-traversal that uses $p \leq \frac{1}{29z}\frac{\log n}{\log\log n}$ pebbles and $q \leq 2^{\log^z n}$ states and whose traversal time on input $G(\vec{\alpha}_1,\ldots,\vec{\alpha}_L)$ is $T_{\langle\vec{\alpha}_1,\ldots,\vec{\alpha}_L\rangle}$,*

$$\Pr_{\langle\vec{\alpha}_1,\ldots,\vec{\alpha}_L\rangle}\left[T_{\langle\vec{\alpha}_1,\ldots,\vec{\alpha}_L\rangle} < n \times 2^{\frac{1}{29z}\frac{\log n}{\log\log n}}\right] \leq 2 \times 2^{-0.05\log^z n}.$$

Proof of Theorem 1′. Fix any constant $z \geq 2$ and consider a helper-JAG algorithm that uses $p \leq \frac{1}{29z}\frac{\log n}{\log\log n}$ pebbles and $q \leq 2^{\log^z n}$ states. The number of bits of help given by the helper JAG to set the initial configuration is the space of the JAG which is $b = p\log n + \log q \leq \frac{1}{29z}\frac{\log^2 n}{\log\log n} + \log^z n = (1+o(1))\log^z n$.

Consider the parity game with the bits of help from the helper being $b = (1+o(1))\log^z n$, the length of the vector $\vec{\alpha}_i$ being $r = 8$, the number of game instances being $d = 60\log^z n$, and the error tolerance being $\epsilon = 0.1$. By Lemma 1,

$$\begin{aligned}\Pr_{\vec{\alpha}}\left[c_{\vec{\alpha}} < 1.5-\epsilon\right] &\leq 2^b \times e^{-(2\epsilon^2 - 2^{-r+1})d} \\ &= 2^{(1+o(1))\log^z n} \times e^{-(2(.1)^2 - 2^{-8+1})60\log^z n} \\ &\leq 2^{-0.054\log^z n}.\end{aligned}$$

Define the line of fly swatter graphs such that the number of switches per fly swatter graph is $r = 8$, the length of the handle is $h = \frac{10r}{0.05} = 1600$, and number of fly swatters in the line is $d = 60\log^z n$. Then, the number of vertices in $G(\vec{\alpha}_1,\ldots,\vec{\alpha}_L)$ is $n \leq [(h+10r)\,d]^L = [1.05hd]^L$ and $L \geq \frac{\log n}{\log(1.05hd)} \geq \frac{\log n}{z\log\log n + O(1)}$. Corollary 1 bounds the time $T_{\langle\vec{\alpha}_1,\ldots,\vec{\alpha}_L\rangle}$ for the helper JAG to traverse input $G(\vec{\alpha}_1,\ldots,\vec{\alpha}_L)$:

$$\begin{aligned}&\Pr_{\langle\vec{\alpha}_1,\ldots,\vec{\alpha}_L\rangle}\left[T_{\langle\vec{\alpha}_1,\ldots,\vec{\alpha}_L\rangle} < [h\times(d(1.5-\epsilon)-4p-2)]^L\, h^{-p+1}\right] \\ &\leq L \times \Pr_{\vec{\alpha}}\left[c_{\vec{\alpha}} < 1.5-\epsilon\right] \\ &\leq \frac{\log n}{z\log\log n + O(1)} \times 2^{-0.054\log^z n} \;\leq 2\times 2^{-0.05\log^z n}.\end{aligned}$$

This bound on the time can be computed to be

$$\begin{aligned}&[h\times(d(1.5-\epsilon)-4p-2)]^L \times h^{-p+1} \\ &\geq \frac{n}{[1.05hd]^L} \times [(1.4-o(1))hd]^L \times h^{-p+1} \\ &\geq n \times \left[\frac{1.4-o(1)}{1.05}\right]^L \times h^{-p} \\ &\geq n \times 2^{0.415\frac{\log n}{z\log\log n + O(1)}} \times 2^{-\log(1600)\times\frac{1}{29z}\frac{\log n}{\log\log n}} \\ &\geq n \times 2^{\frac{1}{29z}\frac{\log n}{\log\log n}}. \qquad \square\end{aligned}$$

The proof of Theorem 1 follows from Theorem 1′ using Yao [25] and Lemma 2.

12. The pseudo-random walk game. The *st*-connectivity lower bound in Theorem 1 on the recursive fly swatter graphs reveals to the JAG every time in reaches the bottom of the handle whether it has reached the node $s_{\langle l,i\rangle}$ or the node $t_{\langle l,i\rangle}$. In reality, however, the JAG does not have access to this information. My belief in fact is that the JAG quickly looses track of where the pebble is located in the line of fly swatter graphs. In effect, I believe that the pebble performs a "pseudo-random walk" on the line. In this section, I define a game that characterizes this idea. A lower bound on this game would give the desired lower bound for *st*-connectivity of $n^{2-o(1)}$. The game is defined as follows.

GAME 1. *The parameters of the game are d, r, and $\tilde{W}$ (ideally r is a constant, but it could be as much as $\log d$, and ideally $\tilde{W} = d^{2-\epsilon}$, but it could be as little as $2d$). The game consists of a player and a randomly chosen input, both of which direct a pebble walking pseudo randomly on a line of length d. First, the player outputs a fixed sequence of vectors $\vec{\gamma} = \langle \gamma_1, \gamma_2, \ldots \rangle \in [\{0,1\}^r]^*$. The vector γ_t is used at time t. Then the input is chosen. It is a sequence of vectors $\vec{\alpha} = \langle \alpha_1, \alpha_2, \ldots, \alpha_d \rangle \in (\{0,1\}^r - \{0^r\})^d$ that is chosen uniformly at random. The vector α_i is associated with the ith node in the path.*

At every time step t, the pebble is located at some node i in the line and has a direction of travel from $\{\rightarrow, \leftarrow\}$. Initially, the pebble is at node 0 with direction $\rightarrow$. The transition depends on $\alpha_i \cdot \gamma_t = \bigoplus_{j \in [1\ldots r]} [\alpha_i]_j \wedge [\gamma_t]_j$. If this dot product is 1, then the pebble takes a step in the direction that it is traveling in. If the dot product is 0, then the pebble turns around before taking a step. The following table lists the possibilities.

	$\alpha_i \cdot \gamma_t = 1$	$\alpha_i \cdot \gamma_t = 0$
$\overrightarrow{i}$	$i \overrightarrow{+} 1$	$i \overleftarrow{-} 1$
$\overleftarrow{i}$	$i \overleftarrow{-} 1$	$i \overrightarrow{+} 1$

Consider a fixed player specification $\vec{\gamma}$. If the pebble ever returns to node 0, then the pebble stops and the player looses. Otherwise, let $W_{\vec{\alpha}}$ be the number of time steps for the pebble to reach node d when the input is $\vec{\alpha}$. The goal of the player is to move the pebble quickly from node 0 to node d. Our goal is to prove that no matter what the player does, for a random input, the pebble will almost always require at least $\tilde{W}$ step; i.e., we win if

$$\forall \vec{\gamma} \ \Pr_{\vec{\alpha}}(W_{\vec{\alpha}} < \tilde{W}) \leq 2^{-d^{\epsilon}}.$$

The fact that the player loses if the pebble ever returns to node 0 is not in itself significant. The game could equivalently be defined so that the pebble bounces at node 0 back to node 1 or that the line is extended in both directions. What is significant about this part of the definition is that the player does not interact at all with the game. He outputs the vectors $\vec{\gamma} = \langle \gamma_1, \gamma_2, \ldots \rangle$ at the beginning of the game without any information about the input $\vec{\alpha}$.

I think that a constant $r \in O(1)$ random bits per node is sufficient. In Theorem 1, it is 8. This is large enough so that $\{0,1\}^r - \{0^r\}$ is not significantly far from $\{0,1\}^r$. On the other hand, perhaps more random bits may help us. However, we have reasons to believe that having $r > \log d$ can only help the player.

LEMMA 4. *For $r \in O(1)$ and $\tilde{W} = d^{2-\epsilon}$, the player can win.*

Proof. For a purely random walk on a line, $\Pr_{\vec{\alpha}}(W_{\vec{\alpha}} < d^{2-\epsilon}) \leq 2^{-d^{\epsilon}}$. The player can easily be given to match this bound by outputting a random sequence of $\vec{\gamma}$. ∎

My conjecture is that the player in this random-walk game cannot do significantly better than by outputting a random sequence of $\vec{\gamma}$.

CONJECTURE 1. *For some $r \in [8 \ldots \log d]$ and for some $\tilde{W} \in [d^{1+\epsilon} \ldots d^{2-\epsilon}]$, the player must lose.*

Lemma 1 effectively proves this conjecture for $r = 8$ and $\tilde{W} = 2d$. The following theorem states the JAG result.

THEOREM 2. *Suppose that* Conjecture 1 *is true; i.e., the pebble in* Game 1 *almost always takes d^{ω} time steps to traverse a line of length d for some $\omega \in [1 + \epsilon \ldots 2 - \epsilon]$. It follows that for every constant $z > 2$, the expected time to solve undirected st-connectivity on a JAG with $p \leq \frac{\delta^2 \log n}{2z \log \log n}$ pebbles and $q \leq 2^{\log^z n}$ states is at least $n^{\omega(1-2\delta)}$.*

The proof reduces *st*-traversal of recursive fly swatter graphs by a helper JAG to the pseudo-random walk game. This reduction requires quite a different proof than the one presented here. It has not been included because it is slightly more difficult and because a lower bound on the pseudo-random walk game has not been obtained.

ON LEARNING READ-k-SATISFY-j DNF *

HOWARD AIZENSTEIN†, AVRIM BLUM‡, RONI KHARDON§, EYAL KUSHILEVITZ¶, LEONARD PITT‖, AND DAN ROTH**

Abstract. We study the learnability of read-k-satisfy-j (RkSj) DNF formulas. These are boolean formulas in disjunctive normal form (DNF), in which the maximum number of occurrences of a variable is bounded by k, and the number of terms satisfied by any assignment is at most j. After motivating the investigation of this class of DNF formulas, we present an algorithm that for any unknown RkSj DNF formula to be learned, with high probability finds a logically equivalent DNF formula using the well-studied protocol of equivalence and membership queries. The algorithm runs in polynomial time for $k \cdot j = O(\frac{\log n}{\log \log n})$, where n is the number of input variables.

Key words. DNF, learning, computational learning theory, decision trees

1. Introduction.

A central question in the theory of learning is to decide which subclasses of boolean formulas can be learned in polynomial time with respect to any of a number of reasonable learning protocols. Among natural classes of formulas, those efficiently representable in disjunctive normal form (DNF) have been extensively studied since the seminal paper of Valiant [Val84]. Nonetheless, whether for such formulas there are learning algorithms that can be guaranteed to succeed in polynomial time using any of the standard learning protocols remains a challenging open question.

Consequently, recent work has focused on the learnability of various restricted subclasses of DNF formulas. For example, the learnability of those DNF formulas with a bounded number of terms, or with bounded size terms, or with each variable appearing only a bounded number of times, has received considerable attention (see, e.g., [Val84, Ang87, PV88, BS90, Han91, Aiz93, PR95]). Investigation along these lines is of interest for two reasons. First, techniques developed for learning subclasses

of DNF may well be applicable to solving the more general problem, just as difficulties encountered may suggest approaches towards proving that the general problem admits no tractable solution. Second, and at least as important from a practical perspective, is that in many real-world machine-learning settings, the full generality of DNF may not be required, and the function to be learned might have an efficient expression in one of the restricted forms for which learning algorithms have been found.

In this paper we show (Theorem 19) that boolean formulas over n variables that can be expressed as *read-k-satisfy-j DNF* (which we abbreviate "RkSj") are efficiently learnable, provided that $k \cdot j = O(\frac{\log n}{\log \log n})$. An RkSj DNF representation for a function is a DNF formula in which the maximum number of occurrences of each variable is bounded by k and each assignment satisfies at most j terms of the formula. The special case of RkSj for $j = 1$ is referred to as *disjoint* DNF, and we denote it as RkD. The motivation for considering disjoint DNF expressions arises from the fact that they generalize the decision-tree representation of boolean functions, which have been used extensively in machine-learning theory and practice [BFOS84, Qui86, Qui93]. The "satisfy-j" constraint relaxes the notion of disjointness, thus incorporating a wider class of functions. In the next section we will discuss the relationships between RkSj DNF, RkD DNF, and previously investigated subclasses of DNF formulas.

The learning model we use is the standard equivalence and membership queries model [Ang88]: we assume that some unknown *target* RkSj formula F to be learned is chosen by nature. A learning algorithm may propose as a hypothesis any DNF formula H by making an *equivalence query* to an oracle. (This has sometimes been referred to as an "extended" equivalence query, as the hypothesis of the algorithm need not be in RkSj form.) If H is logically equivalent to F then the answer to the query is "yes" and the learning algorithm has succeeded and halts. Otherwise, the answer to the equivalence query is "no" and the algorithm receives a *counterexample*—a truth assignment to the variables that satisfies F but does not satisfy H (a *positive* counterexample) or vice-versa (a *negative* counterexample). The learning algorithm may also query an oracle for the value of the function F on a particular assignment (example) a by making a *membership query* on a. The response to such a query is "yes" if a is a positive example of F ($F(a) = 1$), or "no" if a is a negative example of F ($F(a) = 0$).

We say that the learner *learns* a class of functions $\mathcal{F}$ if for every function $F \in \mathcal{F}$ and for any confidence parameter $\delta > 0$, with probability at least $1-\delta$ over the random choices of the learner, the learner outputs a hypothesis H that is logically equivalent to F and does so in time polynomial in n (the number of boolean variables of F), $|F|$ (the length of the shortest representation of F in some natural encoding scheme), and $\frac{1}{\delta}$. This protocol is a probabilistic generalization of the slightly more demanding exact learning model, which requires that deterministically, in time polynomial in n and $|F|$, the learning algorithm necessarily finds some logically equivalent H. Learnability in this model implies learnability in the well-studied "PAC" model with membership queries [Val84, Ang88]. In that model, instead of equivalence queries, examples from an arbitrary, unknown probability distribution $\mathcal{D}$ are available, and the goal of the learner is to find with probability at least $1 - \delta$ a hypothesis H that disagrees with F on a set of assignments of probability at most ϵ measured according to $\mathcal{D}$.

The rest of the paper is organized as follows: we review related work in section 2. Section 3 includes preliminary definitions. In section 4 we prove some useful properties of RkSj DNF formulas. In section 5 we present the learning algorithm and prove its correctness. In section 6 we show that read-twice disjoint (R2D) DNF does not have

small conjunctive normal form (CNF) representation (and in particular, no small decision trees), which demonstrates that the class of R2D DNF (and the more general class RkSj) is incomparable to subclasses of DNF recently shown to be learnable.

2. Related results. When membership queries are not available to the learning algorithm, the problem of learning DNF, or even restricted subclasses of DNF, appears quite difficult. In the model of learning with equivalence queries only, or in the PAC model without membership queries [Val84], learning algorithms are known only for k-DNF formulas (DNF formulas with a constant number of literals in each term) [Val84, Ang88], DNF formulas with a constant number of terms [KLPV87, PV88] (provided that the hypotheses need not be in the same form), or for "polynomially explainable" subclasses of DNF in which the number of possible terms causing an example to be positive is bounded by a polynomial [Val85, KR95]. Using information-theoretic arguments, Angluin [Ang90] has shown that DNF in general is not learnable in polynomial time using just DNF equivalence queries, although the negative result does not extend to the PAC model.

In contrast, there are a number of positive learning results when membership queries are allowed, and in many of these cases it can be shown that without the membership queries the learning problem is as hard as the problem of learning general DNF. Among these learnable subclasses are: monotone DNF [Val84, Ang88], read-twice DNF [Han91, AP91, PR95], "Horn" DNF (at most one literal negated in every term) [AFP92], $\log n$ term DNF [BR92], and DNF $\cap$ CNF (this class includes decision trees) [Bsh95].

Read-k DNF. Particularly relevant to our work is the considerable attention that has been given to the learnability of boolean formulas where each variable occurs some bounded (often constant) number k of times ("read k"). Recently, polynomial-time algorithms have been given for learning read-once and read-twice DNF [AHK93, Han91, AP91, PR95]. (The result of [AHK93] is actually much stronger, giving an algorithm for learning any read-once boolean formula, not just those efficiently representable as read-once DNF.)

The learnability of read-k DNF for $k \geq 3$ seems to be much more difficult. Recent results show that in the PAC model with membership queries, learning read-thrice DNF is no easier than learning general DNF formulas [AK95, Han91]. In the PAC model, assuming the existence of one-way functions, Angluin and Kharitonov [AK95] have shown that membership queries cannot help in learning DNF (assuming that the learning algorithm is not required to express its hypotheses in any particular form, and that the distribution on examples is "polynomially bounded"). In other words, assuming one-way functions exist, in the PAC model the problem of learning read-thrice DNF with membership queries is no easier than learning general DNF without queries (in polynomially bounded distributions). In the model of learning from equivalence and membership queries, it has been shown ([PR94]; see also [AHP92]) that there is no polynomial-time algorithm for exactly learning read-thrice DNF using read-thrice DNF equivalence queries, unless P = NP. One way to view our results is to note that while the work referenced above indicates that for $k \geq 3$, learning read-k DNF is difficult, by adding a disjointness condition on the terms of the formula (or even a much weaker condition that each assignment satisfy only j terms) the learning problem becomes tractable.

Disjoint DNF. Variations of disjoint DNF formulas (without any "read" restriction) have also been considered, as disjoint DNF formulas are a natural generalization of decision trees. While every boolean function clearly has a disjoint DNF expression

(simply take a fundamental product of exactly n literals for each satisfying assignment), a function with a short DNF representation might have an exponentially long disjoint representation. However, every decision tree can be efficiently expressed as a disjoint DNF formula, by creating a term corresponding to the assignment of variables along each branch that leads to a leaf labeled "1". Recently, Bshouty [Bsh95] has given an algorithm (using equivalence and membership queries) for learning boolean formulas in time polynomial in the size of their DNF and CNF representations. Since every decision tree has a DNF and CNF that have size polynomial in the size of the original tree, his algorithm may be used to learn decision trees. We show (Theorem 20) that even R2D DNF formulas do not necessarily have small CNF representations (and therefore do not have small decision trees). In particular, we present a family of functions $\{F_n\}$ that have short (poly(n)) R2D DNF formulas but require CNF formulas of size $2^{\Omega(\sqrt{n})}$.

Other results concerning the learnability of disjoint DNF have also been obtained. On the positive side, Jackson [Jac94] gives a polynomial-time algorithm for learning arbitrary DNF formulas in the PAC model with membership queries, provided that the error is measured with respect to the uniform distribution. This extends results on learning decision trees, disjoint DNF, and satisfy-j DNF formulas in the same model [KM93, Kha94, BFJ$^+$94]. On the negative side, some recent hardness results for learning DNF in restricted models apply for disjoint DNF as well: Blum et al. [BFJ$^+$94] prove a hardness result for learning $\log n$ disjoint DNF in the "statistical queries" model (note that in this model the learner does not have access to a membership oracle). Aizenstein and Pitt [AP95] show that even if subset queries are allowed, disjoint DNF (and also read-twice DNF) is not learnable by algorithms that collect prime implicants in a greedy manner. Yet, the learnability for disjoint DNF remains unresolved in any reasonable learning model, other than the result above assuming a uniform distribution. Another way, then, to view our results, is to note that if we add a read-k restriction on disjoint DNF, we obtain a positive learning result.

Finally, note that RkSj DNF may be thought of as a generalization of k-term DNF (those DNFs with at most k terms): every k-term DNF formula is trivially an RkSj DNF formula. Thus, our results may also be viewed as an extension of previous results for learning k-term DNF formulas [Ang87, BR92, Bsh95], although a true generalization of the strongest of these results would learn RkSj DNF for $k + j = O(\log n)$. We leave the latter as an interesting open problem.

3. Preliminaries. Let $x_1, \ldots, x_n$ be n boolean variables. A *literal* is either a variable x_i or its negation $\overline{x_i}$. A literal ℓ is said to have *index* i if $\ell \in \{x_i, \overline{x_i}\}$. A *term* is a conjunction (AND) of literals; a DNF formula is a disjunction (OR) of terms. For convenience, we will also treat a set of literals as the term that consists of the conjunction of literals in the set, and we will treat a set of terms as the DNF formula obtained by taking the disjunction of terms in the set. An *example* (or *assignment*) a is a boolean vector over $\{0,1\}^n$, and we write $a[i]$ to denote the ith bit of a. An example a satisfies a term t (denoted by $t(a) = 1$) if and only if it satisfies all the literals in t. An example a satisfies a DNF formula F (written $F(a) = 1$) if and only if there is at least one term $t \in F$ that a satisfies. If a satisfies F then a is said to be a *positive example* of F; otherwise it is a *negative example*. An RkSj DNF formula F is a DNF formula in which each variable appears at most k times, and for every assignment a, there are at most j terms of F satisfied by a.

For two boolean functions F_1, F_2 we write that F_1 implies F_2 to mean that for every assignment a, if $F_1(a) = 1$ then $F_2(a) = 1$. A term t is an *implicant* of a DNF

formula F if t implies F; it is a *prime implicant* if no proper subset of t is also an implicant of F.

We often want to look at examples obtained by changing the value of a given example on a specified literal. Toward this end, we introduce the following notation. Let $a \in \{0,1\}^n$ be an example, and i an index. We define the example $b = \mathit{flip}(a,i)$ by: $b[i] = 1 - a[i]$ and $b[i'] = a[i']$ for $i' \neq i$. For instance, if $a = 1101$ then $\mathit{flip}(a,3) = 1111$. If ℓ is a literal of index i, then $\mathit{flip}(a,\ell)$ is defined to be the example $\mathit{flip}(a,i)$. Hence, if $a = 1101$, then $\mathit{flip}(a,x_3) = 1111$ and also $\mathit{flip}(a,\overline{x_3}) = 1111$. Usually, we will write $\mathit{flip}(a,\ell)$ only when assignment a satisfies literal ℓ. Finally, we may apply the flip operator to sets of literals as well, to obtain an assignment given by simultaneously flipping each literal in the set: for any set $I \subseteq \{1,\ldots,n\}$ define $\mathit{flip}(a,I)$ to be the assignment b such that $b[i] = 1 - a[i]$ if $i \in I$, and $b[i'] = a[i']$ for $i' \notin I$.

4. Properties of RkSj DNF formulas. A natural way to gather information about a DNF formula F by asking membership queries is to find assignments a such that when the assignment to some single literal of a is changed, the value of F changes. That is, for some literal ℓ, $F(\mathit{flip}(a,\ell)) \neq F(a)$. Such an assignment is called a *sensitive* assignment, and all such literals ℓ are sensitive literals for a. More formally, we present the following definition.

DEFINITION 1. *For an assignment $a \in \{0,1\}^n$ and a function F, the set of* sensitive *literals is given by* $\mathit{sensitive}(a) = \{\ell \mid F(\mathit{flip}(a,\ell)) \neq F(a)\}$.

Observe that the sensitive set of an assignment can be found by asking $n+1$ membership queries. With one membership query we find the value of $F(a)$, and then with n additional membership queries, we determine whether the value of $F(\mathit{flip}(a,\ell))$ differs from $F(a)$ for each of the n literals satisfied by a.

PROPERTY 2. *If F is any DNF formula and a is an assignment such that $F(a) = 1$, then $\mathit{sensitive}(a) \subseteq \cap\{t \in F : t(a) = 1\}$. In other words, each literal in $\mathit{sensitive}(a)$ appears in all terms satisfied by a.*

Proof. Suppose to the contrary that for some literal ℓ in $\mathit{sensitive}(a)$ and for some term t satisfied by a, ℓ is not in t. Then t would also be satisfied by $\mathit{flip}(a,\ell)$, which implies that $F(\mathit{flip}(a,\ell)) = 1$, contradicting the assumption that $\ell \in \mathit{sensitive}(a)$. □

Property 2 suggests that one way to find (at least part of) a term of a DNF formula, given a satisfying assignment a, is to construct the sensitive set of a. In the event that the sensitive set is *exactly* a term t satisfied by a, then we have made significant progress and can continue to find other terms. However, Property 2 only guarantees that each sensitive literal is in every term a satisfies; it does not guarantee that *every* literal of *some* term is in the sensitive set. Below, we will show that for RkSj DNF formulas, we can find assignments whose sensitive sets are not missing "many" literals. From these assignments, we will be able to find terms of the formula.

Suppose a satisfies only a single term t. By Property 2, any literal ℓ that is not in t will not be in $\mathit{sensitive}(a)$. But why might some literal ℓ that *is* in t fail to be in $\mathit{sensitive}(a)$? It must be because $\mathit{flip}(a,\ell)$ satisfies some term t' containing $\overline{\ell}$. Thus, t' was "almost" satisfied by assignment a; only the literal ℓ was set wrong. More formally, we have Definition 3.

DEFINITION 3. *A term t is* almost satisfied *by an assignment a with respect to index i if $t(a) = 0$ but $t(\mathit{flip}(a,i)) = 1$. A term t is* almost satisfied *by an assignment a with respect to (literal) ℓ if a satisfies literal ℓ, and if $t(a) = 0$ but $t(\mathit{flip}(a,\ell)) = 1$.*

Let $Y(a)$ be the set of all i's such that some term t is almost satisfied by a with respect to i. The following lemma is central in the analysis of our algorithm; it gives

a bound on the size of $Y(a)$. In the appendix it is shown that this bound is essentially optimal.

LEMMA 4. *Let F be an RkSj formula, and let $a \in \{0,1\}^n$. Then, $|Y(a)| \leq 2kj$.*

Proof. Let $a \in \{0,1\}^n$ be fixed. Note that for each almost satisfied term t, there is exactly one index i such that t is almost satisfied (by a) with respect to i. We partition the set of almost satisfied terms into $m = |Y(a)|$ nonempty equivalence classes $S_{i_1}, S_{i_2}, \ldots, S_{i_m}$ such that t is in S_i if and only if t is almost satisfied by a with respect to i. Suppose t is in S_i. If $a[i] = 0$ then t must contain the literal x_i, since flipping the ith bit from 0 to 1 causes t to become satisfied. Similarly, if $a[i] = 1$, then t must contain the literal $\overline{x_i}$. For notational convenience, define $S_i(x_i) = x_i$ if $a[i] = 0$, and $S_i(x_i) = \overline{x_i}$ if $a[i] = 1$. Thus, every term t in S_i contains the literal $S_i(x_i)$. Further, since F is read-k, for each equivalence class S_i, $|S_i|$ is at most k.

Consider a directed graph $G = (V, E)$ induced by the equivalence classes, with $V = \{S_{i_1}, S_{i_2}, \ldots, S_{i_m}\}$ and $E = \{\langle S_{i'}, S_i\rangle$: some term $t \in S_i$ contains the literal $\overline{S_{i'}(x_{i'})}\}$. (Note that $t \in S_i$ cannot contain the literal $S_{i'}(x_{i'})$ since this literal is negated in a, and t is almost satisfied by a with respect to a different literal.)

Since each of the (at least one) terms in S_i contains the literal $S_i(x_i)$, and since F is read-k, there are at most $k-1$ other equivalence classes $S_{i'}$ containing a term which has the literal $\overline{S_i(x_i)}$. Thus, the outdegree of every vertex is at most $k-1$. Suppose G' is any subgraph of G containing μ vertices. Since there are at most $\mu(k-1)$ edges in G', there must be some vertex $S \in G'$ whose indegree + outdegree in G' is at most $2\mu(k-1)/\mu = 2(k-1)$. That is, S has at most $2(k-1)$ neighbors in the underlying undirected graph of G'.

Now assume, contrary to this lemma, that $|Y(a)|$ ($= m$, the number of vertices in G), is larger than $2kj$. Then there must be an independent set $V_{ind} \subseteq V$ of G of size at least $j+1$: such an independent set V_{ind} can be constructed by first placing into V_{ind} some vertex S_i satisfying the indegree + outdegree bound above, and removing from G each of the at most $2(k-1)$ vertices adjacent to S_i in the underlying undirected graph. Then another vertex $S_{i'}$ is included in V_{ind}, its neighbors are removed, etc. After iteratively choosing j such vertices (no two of which are adjacent in the underlying undirected graph) and removing their neighbors, we will have eliminated at most $j \cdot (2(k-1)+1) = 2kj - j < 2kj$ vertices. Thus, we can include at least one more vertex into the set V_{ind}, so that $|V_{ind}| \geq j+1$ as desired.

Let $I = \{i : S_i \in V_{ind}\}$, namely, the set of indices of the at least $j+1$ equivalence classes with no edges between them in G. Consider a term t in some equivalence class S_i with $i \in I$. By definition of the equivalence classes, t is almost satisfied by a with respect to i, and thus $\mathit{flip}(a,i)$ will satisfy term t. Since no other literal in t has index in I by definition of the set V_{ind}, $\mathit{flip}(a,I)$ satisfies t as well. Thus $\mathit{flip}(a,I)$ satisfies every term from each of the $j+1$ equivalence classes indexed by I, contradicting the assumption that F was a satisfy-j formula. □

DEFINITION 5. *A term $\tilde{t}$ is a p-variant of a term t if it contains all the literals of t and at most p additional literals.*

COROLLARY 6. *If a is a satisfying assignment for an RkSj DNF formula F satisfying the single term $t \in F$, then t is a $2kj$-variant of sensitive(a).*

Proof. First observe by Property 2 that *sensitive*$(a) \subseteq t$. Thus to prove this corollary it is sufficient to show that there are at most $2kj$ literals in $t -$ *sensitive*(a). Consider why a literal ℓ with index i might be in t but not in *sensitive*(a). By the definition of sensitive set this means that $F(\mathit{flip}(a,i)) = F(a)$ and in this case $F(\mathit{flip}(a,i)) = F(a) = 1$. But ℓ in t implies that $t(\mathit{flip}(a,i)) = 0$, so $\mathit{flip}(a,i)$ must

satisfy some term other than t. Since t is the only term satisfied by a, all the terms satisfied by $\mathit{flip}(a, i)$ must be almost satisfied by a with respect to i. This means $i \in Y(a)$, and by Lemma 4 there can be at most $2kj$ such values of i, hence at most $2kj$ corresponding literals ℓ in $t - \mathit{sensitive}(a)$. □

DEFINITION 7. *Let $a, b \in \{0,1\}^n$. Then b is a* d-neighbor *of a if $b = \mathit{flip}(a, I)$ for some set I of cardinality at most d. (That is, if the Hamming distance between a and b is at most d.)*

LEMMA 8. *If a is a satisfying assignment for an RkSj DNF formula F satisfying exactly the terms $T = \{t_1, t_2, \ldots, t_q\} \subseteq F$ then there exists a $(j-1)$-neighbor b of a such that some term in T is a $2kj$-variant of $\mathit{sensitive}(b)$.*

Proof. Since F is satisfy-j and a is a satisfying assignment it must be the case that $1 \leq |T| = q \leq j$. Note by Corollary 6 that if $q = 1$, t_1 is a $2kj$-variant of $\mathit{sensitive}(a)$, and since a is a 0-neighbor of itself, the lemma follows. To see that the lemma is true for $1 < q \leq j$ we will show that in this case either some term satisfied by a is a $2kj$-variant of $\mathit{sensitive}(a)$ or else there exists some i such that $\mathit{flip}(a, i)$ satisfies a proper subset of T, and $F(\mathit{flip}(a, i)) = 1$. It then follows by induction that for some set of indices $I \subseteq \{1, \ldots, n\}$ with $|I| \leq j - 1$, some term satisfied by a is a $2kj$-variant of $\mathit{sensitive}(\mathit{flip}(a, I))$. The assignment $\mathit{flip}(a, I)$ is the $(j-1)$-neighbor b of a mentioned in the lemma.

If some term in T is a $2kj$-variant of $\mathit{sensitive}(a)$ then we are done. Otherwise each term in T must contain more than $2kj$ literals not in $\mathit{sensitive}(a)$. Let t be a term in T and let $L = \{\ell_1, \ell_2, \ldots\}$ be a set of more than $2kj$ literals in t that are not in $\mathit{sensitive}(a)$. By Lemma 4, $|Y(a)| \leq 2kj$, so there must be some literal $\ell \in L$ (say, with index i) such that there does not exist a term in F almost satisfied by a with respect to i. Consequently, $\mathit{flip}(a, i)$ cannot satisfy any term not satisfied by a, and must therefore satisfy a proper subset of the terms satisfied by a since t will no longer be satisfied. Since $\ell \notin \mathit{sensitive}(a)$, $\mathit{flip}(a, i)$ still satisfies at least one term. □

While the statement of Lemma 8 may appear somewhat confusing at first glance, if examined further we see that it immediately suggests an algorithm for learning RkSj DNF formulas (deterministically) where k and j are constants. First, conjecture the null DNF formula. On receiving a positive counterexample a, generate a collection H of terms, at least one of which is a term of the target DNF formula. To build the collection H, simply enumerate each $(j-1)$-neighbor b of a, and then include in H every $2kj$-variant of the sensitive set of each such b. By Lemma 8, H will necessarily contain some term of F that a satisfied. Of course, H may also contain many terms that are not in F (though only polynomially many, assuming k and j are constants). On seeing a negative counterexample, the algorithm simply removes from H any term that is satisfied, since these cannot be in F. Thus, on positive counterexamples, the algorithm adds to its hypothesis H at least one correct term not yet included, and at most a polynomial number of incorrect terms. On each negative counterexample, at least one of the incorrect terms is removed. It follows that the number of counterexamples that can be received (and hence the number of equivalence queries until the algorithm has produced a DNF logically equivalent to the target) is bounded by a polynomial in n and the number of terms of the target RkSj DNF formula.

This general approach of finding many possible terms from a positive counterexample a, and discarding the bad terms when seeing negative counterexamples, is a fairly standard approach used in many of the algorithms for learning subclasses of DNF formulas discussed in earlier sections. In the particular case of RkSj DNF, we

need to develop additional technical lemmas in order to devise an algorithm that works for values of k and j that are not constant.

The following is an immediate corollary of Lemma 4.

COROLLARY 9. *For all a such that $F(a) = 0$, at most $2kj$ of the neighbors of a (in the cube $\{0,1\}^n$) are satisfying assignments of F.*

Proof. The neighbors of a are exactly $\mathit{flip}(a,1), \ldots, \mathit{flip}(a,n)$. Hence if $\mathit{flip}(a,i)$ is a satisfying assignment then $i \in Y(a)$. □

Let $\mathcal{U}$ denote the uniform distribution, and let "$x \in \mathcal{U}$" denote that x is selected uniformly at random (in $\{0,1\}^n$). Also, let "true" be the "all 1's" concept.

LEMMA 10. *If F is an RkSj DNF, and $F \not\equiv$ true, then $\mathbf{Prob}_{x \in \mathcal{U}}[F(x) = 0] \geq 2^{-2kj}$*

Proof. The proof uses an argument similar to one in [Sim83]. Think of the cube $\{0,1\}^n$ as a graph in which each vertex is represented by an n-bit string and there is an edge between any two vertices of Hamming distance 1. Consider the vertex-induced subgraph $G = (V, E)$, where V is the set of points $a \in \{0,1\}^n$ such that $F(a) = 0$. Since $F \not\equiv$ true, we know that there is at least one vertex in V. We further know by Corollary 9 that the minimum degree of any vertex in G is at least $n - 2kj$.

A standard argument shows that any nonempty subgraph of $\{0,1\}^n$ with minimum degree at least d has at least 2^d vertices. For completeness we give the proof, which is by induction on n. The cases where $n = 1$ or $d = 0$ are easily verified. For the more general cases, notice that cutting the cube in any coordinate i leaves the two subcubes of dimension $n-1$, each with minimum degree at least $d-1$. This is because each vertex has at most one neighbor in the other subcube. So we simply choose i so that we have a nonempty subset of V in each subcube. Using the induction, we get at least $2 \cdot 2^{d-1} = 2^d$ vertices.

This implies that $|V| \geq 2^{n-2kj}$, and therefore $\mathbf{Prob}_{x \in \mathcal{U}}[F(x) = 0] \geq 2^{-2kj}$. □

LEMMA 11. *Let F be an RkSj formula. Then F has at most kjq terms of length (number of literals) at most q.*

Proof. Consider a graph with one vertex for each term in F of length at most q and an edge between two vertices if their corresponding terms are not simultaneously satisfiable. In other words, two terms are connected exactly when one of the terms contains some variable x_i and the other contains $\overline{x_i}$. Since F is read-k, the maximum degree of a vertex in this graph is $q(k-1)$. Therefore, if the graph has N vertices, it must have an independent set of size at least $N/(q(k-1)+1)$: such an independent set could be formed by repeatedly choosing a vertex to put in the set, and then eliminating from consideration all of the at most $q(k-1)$ neighbors of the vertex. On the other hand, the size of any independent set in this graph can be at most j since F is a satisfy-j DNF (any independent set of vertices corresponds to terms that can all be simultaneously satisfied). Therefore, N, the number of terms of length at most q, is at most $j(q(k-1)+1) \leq jkq$. □

The next lemma is a variant of Lemma 8, which is easier to use in our arguments to follow.

LEMMA 12. *If a is a satisfying assignment for an RkSj formula F, then either some term satisfied by a is a $4kj$-variant of $\mathit{sensitive}(a)$ or else there is a set of literals U such that $|U| \geq 2kj$ and for all $\ell \in U$, the assignment $b = \mathit{flip}(a,\ell)$ is a positive example satisfying a strict subset of the terms of F satisfied by a.*

Proof. Let T be the set of terms satisfied by a. If some term in T is a $4kj$ variant of $\mathit{sensitive}(a)$ then we are done. Otherwise, let t be any term in T, and let $W = \{w_1, w_2, \ldots, w_{4kj}, \ldots\}$ be the set of at least $4kj$ literals that are in T but are not

Algorithm *Learn-RkSj*:

1. $H \leftarrow \phi$.
2. $b \leftarrow EQ(H)$.
3. if $b =$"true" then stop and output H.
4. Else, if b is a negative counterexample then for every term $t \in H$ such that $t(b) = 1$ delete t from H.
5. Else (if b is a positive counterexample) then
   (a) $S \leftarrow$ *find-useful-example*(b). /* This procedure returns a set of examples. */
   (b) For each $a \in S$, $H \leftarrow H \cup$ *produce-terms*(a).
6. GOTO 2.

FIG. 1. *Algorithm Learn-RkSj.*

in *sensitive*(a). By Lemma 4, for at least $2kj$ literals in W there does not exist a term in F almost satisfied with respect to it. So for at least $2kj$ literals ℓ, the assignment *flip*(a, ℓ) does not satisfy any term not satisfied by a. As such an assignment does not satisfy the term t, it satisfies a strict subset of T. □

5. The learning algorithm. On a positive counterexample, the algorithm (with high probability) adds to its hypothesis a polynomial number of terms, one of which is an implicant of the target RkSj DNF formula. On a negative counterexample the algorithm deletes terms from the hypothesis that are satisfied by that example (and therefore are not implicants of the function). The number of queries will be bounded by a polynomial in n plus the number of terms in the target RkSj DNF formula. The enumerative approach discussed earlier results in a polynomial-time algorithm only when k and j are constants, because the number of neighbors and variant terms to be enumerated is $O(n^{O(kj)})$. We avoid the enumerative approach and obtain an algorithm tolerating larger (nonconstant) values of k and j, by implementing a probabilistic search in the spirit of [BR92]. We show the learnability of RkSj DNF for $k \cdot j = O(\frac{\log n}{\log \log n})$.

Our algorithm has the following high level structure (see Figure 1), which we describe here. The low level of the algorithm is described in the next two subsections.

Let F be the target function, and $F = t_1 \vee t_2 \vee \cdots \vee t_s$ its RkSj representation. (There may be more than one such representation; in such a case we fix one of them just for the purpose of the analysis.) The main tools in the algorithm are Procedures *produce-terms* and *find-useful-example* that together, given a positive counterexample b to the current hypothesis, find a set of terms such that with high probability one of them (call it t) is an implicant of F (in fact, t will be a *prime* implicant) and is implied by some term t_i satisfied by b. Note that such a term t is satisfied by all the assignments that satisfy t_i, but not by any negative assignment of F. Thus finding t is as good as (or even better than) finding the term t_i.

The disjunction of all the terms found in this way is added to the hypothesis of the algorithm, with which we now ask an equivalence query (step 2). A negative counterexample allows us to throw out from the hypothesis terms that do not imply F. A positive counterexample satisfies a term $t_i \in F$ we have not yet found, and we use it to run again Procedures *find-useful-example* and *produce-terms*.

5.1. Producing terms. We now describe the way the procedure *produce-terms* works given a positive example x of F. In our analysis, we will assume that example

Procedure *produce-terms*(x)**:**

1. Find $sensitive(x)$ (using n membership queries).
2. $L \leftarrow \emptyset$.
3. Repeat the following $m_1 = 2^{6kj} \ln(12kjs/\delta)$ times:
   Pick a random y that agrees with $sensitive(x)$ (that is, for each literal in $sensitive(x)$ we take $y_i = x_i$ and for any other literal, not in $sensitive(x)$, the corresponding bit is selected randomly). If y is negative (a membership query) then find all literals ℓ satisfied by y (and not in $sensitive(x)$) such that $flip(y, \ell)$ is a positive example. Put all those literals into L.
4. If $|L| \leq kjq^2$, then for each subset L' of L of size at most $4kj$, add to the output the term $sensitive(x) \cup L'$.

FIG. 2. *Procedure produce-terms.*

Procedure *find-useful-example*(x)**:**

Do the following $m_2 = 2^{j+1} \log(3s/\delta)$ times and produce the union of the outputs.

1. Let $x^{(0)} = x$.
2. For $i = 1, 2, \ldots, m_3$, for $m_3 = \frac{n}{2k} \ln(2j2^j)$, let $x^{(i)}$ be a random positive neighbor of $x^{(i-1)}$.
3. Output $\{x^{(0)}, x^{(1)}, \ldots, x^{(m_3)}\}$.

FIG. 3. *Procedure find-useful-example.*

x has the property that some term t_1 of F satisfied by x (1) is not in our hypothesis and (2) is a $4kj$-variant of $sensitive(x)$. We call such an example x a *useful* example. If F is a disjoint DNF, then any positive counterexample x will be useful by the special case of Lemma 8 with $j = 1$. For general RkSj DNF, we use Procedure *find-useful-example* (described in section 5.2) to find an example with these properties. Procedure *produce-terms* is described in Figure 2, where $q = c \log^2 n$ for some constant c.

Our goal is to find an implicant of F that is implied by t_1. In fact, we will find a "small" collection of potential terms such that one of them will be such an implicant. We start by finding $sensitive(x)$, and we then fix those literals for the remainder of the procedure. After fixing (projecting onto) those literals, we still have an RkSj DNF, but t_1 has at most $4kj$ literals by our assumption. Let $t = \ell_1 \ell_2 \cdots \ell_r$ $(r \leq 4kj)$ be some minimal (prime) implicant of F implied by t_1. Note that this means that for each $i \in \{1, 2, \ldots, r\}$ the term $t^{(i)} = \ell_1 \cdots \ell_{i-1} \overline{\ell_i} \ell_{i+1} \cdots \ell_r$ is *not* an implicant of F, because then we could remove ℓ_i from t and obtain an implicant, contradicting the primality of t.

The idea is that we create a set of literals L that with high probability has the following two properties: (1) L has all the literals of t, and (2) L has size poly(kj). This is done in step 3. If we have such a set then we are done: given the set L, we can look at all $\sum_{i=0}^{4kj} \binom{|L|}{i} = |L|^{O(kj)}$ small subsets (step 4), and one of them will be t.

Recall that s is the number of terms in the RkSj representation of F, and let $\delta > 0$ be a constant confidence parameter.

CLAIM 13. *If x is a useful example and t_1, t are as described above, then the set L produced in step 3 of Procedure produce-terms contains all the literals in t with probability at least $1 - \delta/3s$.*

Proof. Consider a literal ℓ_i in t. In a random y, there is a $1/2^r$ chance that literals

$\ell_1, \ldots, \ell_r$ are set so that $t^{(i)}$ is satisfied. Also,

$$\mathbf{Prob}_{y \in \mathcal{U}}[y \text{ is negative} \mid y \text{ satisfies } t^{(i)}] \geq 1/2^{2kj}.$$

The reason is that if we project variables in t to satisfy $t^{(i)}$, then we are left with an RkSj DNF which is not identically true, since $t^{(i)}$ is not an implicant of F. So, we can apply Lemma 10. For such an example y, which is negative and satisfies $t^{(i)}$, we know that $\mathit{flip}(y, \ell_i)$ is a positive example (as it satisfies t) and hence ℓ_i will be inserted into L. So, the probability that a single y "discovers" ℓ_i is at least $1/2^{r+2kj} \geq 1/2^{6kj}$. A standard calculation shows that if we repeat the loop (step 3) at least $m_1 = 2^{6kj} \ln(12kjs/\delta)$ times then we find *all* $r \leq 4kj$ literals of t, with probability at least $1 - \delta/3s$. (Note that the number of repetitions, m_1, is polynomial as long as $kj = O(\log n)$.) □

Claim 14. *Let $q = c \log^2 n$, where c is a constant that depends on the constant δ, and assume that $kj = O(\log n)$. With probability at least $1 - \delta/3s$ we get $|L| \leq kjq^2$.*

Proof. Any literal found in step 3 of *produce-terms* must be in *some* term. So, consider terms of size at most q. By Lemma 11 there are at most kjq such terms. The number of literals that those terms can contribute to L is at most kjq^2. Now consider a term of size greater than q. With high probability, it will not contribute *any* literals to L. The reason is that in order for such a term to "matter" (i.e., for some $\mathit{flip}(y, \ell)$ to satisfy that term) it must be that y satisfies all but one literal in that term. The chance that y does so is at most $n/2^q$ which, by the choice of q, is smaller than any polynomial fraction. Since the algorithm repeats in step 3 a polynomial number of times (using here that $kj = O(\log n)$), throughout the entire algorithm, with high probability, *no* example $\mathit{flip}(y, \ell)$ satisfies *any* of those terms. By choice of c this probability can be made larger than $1 - \delta/3s$. □

Notice that by Claims 13 and 14, with high probability at least one of the terms output in step 4 of Procedure *produce-terms* is the desired term t, and in addition at most $(kjq^2)^{4kj}$ terms are output in step 4 total. This number of terms is polynomial in n as long as $kj = O(\log n / \log\log n)$.

5.2. Finding a useful positive example. Procedure *produce-terms* in the previous section requires a useful example x. Namely, some term t_1 of F (1) is not in our hypothesis and (2) is a $4kj$-variant of $\mathit{sensitive}(x)$. In this section we show how to produce, given a positive counterexample x to our hypothesis, a polynomial-sized set of examples such that with high probability at least one is useful in this sense. The procedure is described in Figure 3. The idea behind Procedure *find-useful-example* is as follows. Suppose that our given positive example x satisfies some number of terms of F (none of them appears in our hypothesis). Lemma 12 states that either:

(A) all but $4kj$ of the literals in one of those terms are sensitive (i.e., x is already useful), or else,

(B) there exist at least $2kj$ literals $u_1, \ldots, u_{2kj}$ such that flipping u_i will cause the example to remain positive but satisfy a strict subset of those terms and no others.

We also know, by Lemma 4, that $|Y(x)| \leq 2kj$, and therefore there are at most $2kj$ literals that when flipped cause the example to satisfy some additional term.

What this means is that either example x is already useful, or else out of the n literals, at least $2kj$ are "good" in that flipping them makes our example satisfy a strict subset of the original set of terms, at most $2kj$ are "bad" in that flipping them makes the example satisfy some new term, and the rest are "neutral" in that either flipping them makes the example negative (which we will notice) or else flipping them

does not affect the set of terms satisfied. So, as described in Figure 3 (step 2), let $x^{(i)}$ to be a random positive neighbor of $x^{(i-1)}$ in the boolean hypercube.

CLAIM 15. *With probability* $\frac{1}{2^{j+1}}$ *at least one of the examples* $x, x^{(1)}, \ldots, x^{(m_3)}$ *is useful.*

Proof. For the moment, consider the infinite sequence $x^{(1)}, x^{(2)}, \ldots$ of positive examples. If the example x was not already useful, let's say that we are "lucky" if we flip one of the "good" literals before we flip any of the "bad" literals in this experiment (i.e., we are lucky if we flip an arbitrary number of neutral literals followed by a good literal). Notice that flipping a "neutral" literal may change the sets of good and bad literals, but our bounds on the sizes of those sets remain. So, the probability that we are lucky is at least 1/2. If this occurs, we then either have a useful positive example, or else our bounds on the sizes of the good and bad sets remain but the example satisfies at least one fewer term. Thus, with probability at least $(1/2^j)$, we continue to flip good literals before we flip any bad literals, and we reach a useful example (since by Corollary 6, if the example satisfies only one term, then it is useful).

Now for the finite sequence $x^{(1)}, \ldots, x^{(m_3)}$, we have to subtract the probability of being lucky j times, but not within the first m_3 trials. This event is included in the event "there were less than j flips of nonneutral literals within m trials." Let the latter event be E.

Consider m_3 as j blocks of $\frac{n}{2kj} \ln(2j2^j)$ trials each. The probability that we do not flip any nonneutral bit (or reach a useful example) in one block is at most $\frac{1}{2j2^j}$ (since the probability of getting a nonneutral bit is at least $\frac{2kj}{n}$ at each trial). The probability that we fail in any of the j blocks is therefore at most $\frac{1}{2^{j+1}}$. This is also a bound for the probability of the event E. Thus our total success probability is at least $\frac{1}{2^j} - \frac{1}{2^{j+1}}$. □

CLAIM 16. *With probability at least* $1-\delta/3s$, *some example in the set of examples produced by Procedure find-useful-example is useful.*

Proof. Procedure *find-useful-example* repeats the experiment described in Claim 15 for $m_2 = 2^{j+1} \ln(3s/\delta)$ times. Thus, with probability at least $1 - \delta/3s$, the experiment is successful at least once. □

5.3. Final analysis.

CLAIM 17. *With probability at least* $1-\delta$, *Algorithm Learn-RkSj uses* $O(snm_1m_2m_3)$ *membership queries and* $O(sm_2m_3(kjq^2)^{4kj})$ *equivalence queries.*

Proof. By Claim 16, each time that Procedure *find-useful-example* is invoked (on a positive counterexample), we get a useful example with probability at least $1-\delta/3s$. By Claims 13 and 14, if we have a useful example, then we find a term t that satisfies the original counterexample with probability at least $1 - 2\delta/3s$. All together, we find a good term t with probability at least $1 - \delta/s$. Therefore, if we get s positive counterexamples, with probability at least $1 - \delta$, we find prime implicants for all the terms in F, and therefore the hypothesis is logically equivalent to F.

We now count the number of queries used in this case. In each call to *produce-terms* we make n membership queries to find *sensitive*(x): one membership query for each y, and n additional queries for each y that is negative. All together Procedure *produce-terms* makes $O(nm_1)$ membership queries to create the set of literals L. It then produces (in step 4) $O((kjq^2)^{4kj})$ terms (or none, in the unlikely event that $|L| > kjq^2$). The number of calls to Procedure *produce-terms* is bounded by the number of positive counterexamples that we get in the algorithm (which is bounded by s) multiplied by the number of examples produced by Procedure *find-useful-example* on each such counterexample (this is bounded by m_2m_3). Therefore, in total we make

$O(snm_1m_2m_3)$ membership queries and produce $O(sm_2m_3(kjq^2)^{4kj})$ terms. This immediately gives a bound on the number of negative counterexamples. Hence, the number of equivalence queries is $O(sm_2m_3(kjq^2)^{4kj})$. Note that just by the read-k property of F we have $s \leq kn$. A tighter bound of $s = O(\sqrt{k^2jn})$ is given by [Mat93]. □

CLAIM 18. *Let $\delta > 0$ be a constant and $kj = O(\frac{\log n}{\log\log n})$. Algorithm Learn-RkSj runs in time* poly(n) *and finds a function logically equivalent to F with probability at least $1 - \delta$.*

Proof. By Claim 17, the algorithm succeeds with probability at least $1 - \delta$. The polynomial bound then follows, noting that m_1, m_2, and m_3 are all polynomial for $kj = O(\log n)$ and that $(kjq^2)^{O(kj)}$ is polynomial for $kj = O(\log n/\log\log n)$ (as q is polylog(n)). □

So far we considered only δ, which is a fixed constant (this is used in Claim 14 when we say that c is a constant). To generalize to arbitrary δ (e.g., δ can be a function of n), we use a standard technique as follows.

THEOREM 19. *Let F be an RkSj formula, $kj = O(\frac{\log n}{\log\log n})$, and $\delta > 0$. There is an algorithm that runs in time* poly$(n, \log\frac{1}{\delta})$ *and finds a function logically equivalent to F with probability at least $1 - \delta$.*

Proof. We run Algorithm *Learn-RkSj* $\ln\frac{1}{\delta}$ times. Every time we stop after using the number of queries stated in Claim 17, and use an equivalence query to decide if we need to run further. Clearly, the overall algorithm runs in poly$(n, \log\frac{1}{\delta})$ and succeeds with probability at least $1 - \delta$. □

As a last remark we note that it may be that the method we use here can be adapted for $kj = O(\log n)$. The only part of the algorithm that does not allow for $kj = O(\log n)$ is Procedure *produce-terms*, and in particular, step 4, which produces $O((\log n)^{O(kj)})$ terms. Finding a better sampling method or a better way to produce the terms out of the set L might solve this problem.

6. R2D DNF does not have small CNF. We present a family $\{F_n\}$ of functions that have short (poly(n)) R2D DNF formulas but require CNF formulas of size $2^{\Omega(\sqrt{n})}$. Note that this also implies that the size of any decision tree for these functions must also be superpolynomial, even without restricting the number of variable occurrences. Bshouty [Bsh95] gives an algorithm for learning functions (such as decision trees) which have both small DNFs **and** small CNFs. Our family of functions $\{F_n\}$ shows that this result does not apply here, as the size of the CNFs for even R2D DNFs may be superpolynomial. It remains open, however, whether techniques similar to those used in [Bsh95] can be applied to yield a comparable or stronger result. Such a result would rely on showing that every RkSj DNF has a small "monotone basis"; we suspect this is not the case, as even read-twice DNFs (though not disjoint) require an exponentially large monotone basis [Bsh94].

THEOREM 20. *There is a family of functions $\{F_n\}$ with polynomial-sized R2D representations but whose CNF representations require at least $2^{\sqrt{2n}} - 2(\sqrt{2n} + 1)$ clauses.*

Proof. Let $n = \binom{m+1}{2}$. We define a function F_n with $m+1$ terms each of length m on n variables $x_{i,j}$ where $1 \leq i < j \leq m+1$. The R2D representation of the function is $t_1 \vee t_2 \vee \cdots \vee t_{m+1}$, where the term t_q includes all the literals $x_{q,j}$ for $j > q$, and all the literals $\overline{x_{j,q}}$ for $j < q$. The idea is that the variable $x_{i,j}$ appears only in the ith term and the jth term, and is "responsible" for the disjointness of these two terms (since the variable appears negated in one term and unnegated in the other). For

example, for $m = 3$ the function is: $x_{12}x_{13}x_{14} \vee \overline{x_{12}}x_{23}x_{24} \vee \overline{x_{13}}\,\overline{x_{23}}x_{34} \vee \overline{x_{14}}\,\overline{x_{24}}\,\overline{x_{34}}$. The main step in the proof is the following claim.

CLAIM 21. *Every clause in a CNF representation of F_n must have $m+1$ literals.*

Given this claim, the following counting argument shows that the CNF must have a large number of clauses: the number of assignments satisfied by F_n is exactly $(m+1)2^{n-m}$, since each of the $m+1$ terms satisfies 2^{n-m} assignments (it determines the value of m out of the n variables) and the representation is disjoint. This implies that the number of assignments unsatisfied by F_n is $2^n(1-(m+1)/2^m)$. Since a clause of length $\geq m+1$ falsifies at most 2^{n-m-1} assignments, we need at least $2^{m+1}(1-(m+1)/2^m) = 2^{m+1} - 2(m+1)$ clauses to falsify all the unsatisfying assignments of F_n. As $m^2 \leq 2n \leq (m+1)^2$ the theorem follows.

Proof of the claim. Assume by way of contradiction that there is a clause of length $\alpha < m+1$ in a CNF representation for F_n. Let $C = (\ell_1 \vee \ell_2 \vee \cdots \vee \ell_\alpha)$ be that clause. We show that there exists an assignment a such that $C(a) = 0$ (and hence the value of the CNF formula on a is 0) and $F_n(a) = 1$, contradicting the assumption that C is a clause in a CNF representation of F_n.

To construct a, notice that since every *literal* appears exactly once in the R2D representation, fixing the values of $\alpha \leq m$ variables can falsify at most m terms in the DNF representation, so there is still a term t_C that can be satisfied. Therefore, we can define a to be the assignment in which all the literals in C are set to zero, all the literals in t_C are set to one, and all other literals are set arbitrarily. We thus have that $C(a) = 0$ but $t_C(a) = 1$ (and hence $F_n(a) = 1$), a contradiction. □

7. Appendix: Lemma 4 is tight. Lemma 4 plays a central role in our analysis. It gives a bound on the number of terms which are almost satisfied by an assignment a, in terms of k and j. It is natural to ask how good this bound is. The following example, due to Galia Givaty [Giv95], shows that it is essentially optimal (up to constants). More precisely, for any values of k and j we give a function $F_{k,j}$ with $k \cdot j$ variables $x_0, x_2, \ldots, x_{kj-1}$ and an assignment a such that $|Y(a)| = k \cdot j$. The function $F_{k,j}$ has kj terms:

$$t_i = \overline{x_i}x_{i+1}\ldots x_{i+k-1 \bmod kj} \qquad (0 \leq i \leq kj-1).$$

It can be easily verified that the function is read-k (the variable x_i appears only in the terms $t_{i-k+1 \bmod kj}, \ldots, t_i$). It is also satisfy-$j$, since if an assignment satisfies a term t_i it cannot satisfy any of the $k-1$ terms $t_{i-k+1 \bmod kj}, \ldots, t_{i-1 \bmod kj}$ (as they all contain the variable x_i while t_i contains $\overline{x_i}$). Now, let a be the all "1" assignment. Each term t_i is almost satisfied by a with respect to index i. Hence, $|Y(a)| = kj$.

8. Bibliographic remarks. The work presented here appeared in preliminary forms as [AP92] and [BKK+94]. The algorithm for constant k and j is from [AP92], and the extension to $k \cdot j = O(\log n / \log\log n)$, from [BKK+94]. The family of functions given in section 6 was defined in [AP92], where it was shown that the class R2D is not included in read-k decision trees. This result was later strengthened in [Aiz93] to show that the family requires decision trees of size 2^{n-2}. Its current form is from [BKK+94].

LOG-SPACE POLYNOMIAL END-TO-END COMMUNICATION*

EYAL KUSHILEVITZ†, RAFAIL OSTROVSKY‡, AND ADI ROSÉN§

Abstract. Communication between processors is the essence of distributed computing: clearly, without communication, distributed computation is impossible. However, as networks become larger and larger, the frequency of link failures increases. The end-to-end communication problem asks how to efficiently carry out fault-free communication between two processors over a network, in spite of such *frequent* link failures. The sole minimum assumption is that the two processors that are trying to communicate are not permanently disconnected (i.e., the communication should proceed even when there does not (ever) simultaneously exist an operational path between the two processors that are trying to communicate).

We present a protocol to solve the end-to-end problem with logarithmic-space and polynomial communication at the same time. This is an exponential memory improvement to all previous polynomial communication solutions. That is, all previous polynomial communication solutions needed at least *linear* (in n, the size of the network) amount of memory per link.

Our protocol transfers packets over the network, maintains a simple-to-compute $O(\log n)$-bits potential function at each link in order to perform routing, and uses a novel technique of packet canceling which allows us to keep only *one* packet per link. The computations of both our potential function and our packet-canceling policy are totally local in nature.

Key words. end-to-end communication, space complexity, unreliable networks

1. Introduction.

In this paper we address the problem of *communication* in distributed systems: how can two processors (a sender and a receiver) communicate over an unreliable communication network? This question was considered in many different settings, which can be divided into two groups depending on the *frequency* of link failures.

Communication during infrequent faults. If link failures are "infrequent," then after each failure a new communication path between the two communicating processors can be computed, which will be operational until the next fault. That is, in case failures occur *rarely*, it is possible, upon a failure, to "reset" the network and compute a new path between the communicating processors (e.g., [Fin79, AAG87, AS88, AAM89, AGH90]). In a related model, a communication path can also be computed in a "self-stabilizing" manner (e.g., [Dij74, AKY90, KP90, APV91, AV91, AKM+93, AO94, IL94]), which essentially means that after faults stop *for a sufficiently long period of time*, the protocol "stabilizes" to its correct behavior (i.e., establishes a new path). We emphasize that both the above reset and self-stabilizing solutions work *only if faults are not too frequent*, as they require that a message be transmitted over the computed path.

Communication during frequent faults. We consider a setting where failures occur frequently. The so-called end-to-end communication problem [AG88, AMS89, AGR92, AAG+97] is to deliver, in finite time, data-items from a sender processor to a receiver processor, where data-items are given in an on-line fashion to the sender and must be output in the same order, without duplication or omission at the receiver processor. This should be done even if there does not exist, at any time, a path of simultaneously active links that connects the two communicating processors. The sole assumption is that the two communicating processors are not separated by a cut of permanently failed links.[1] Solutions to the problem are evaluated according to their *communication complexity* and *space complexity*.

1.1. Frequent faults model.

Communication complexity. One possible solution to the above problem is to give data-items "unbounded sequence numbers" and to "flood" the network with each item [Vis83, AE86]. However, this solution has the drawback that the message size increases unboundedly with the number of items sent; hence, the amount of communication needed per data-item grows unboundedly with the number of data items. Recently, the study of end-to-end protocols with *bounded* communication complexity received a lot of attention [AG88, AMS89, APV91, AG91, AGR92, AAG+97]. In this paper, we concentrate on bounded (in fact, polynomial) communication-complexity protocols.

Space complexity. Another important complexity measure is the *space complexity*—the amount of space needed at the processors, per incident link. Notice that the "unbounded sequence numbers" solution requires unbounded memory as well. The question of reducing memory requirements, while maintaining efficiency, received a lot of attention in the "self-stabilizing" setting (e.g., [MOOY92, AO94, IL94]), where it was shown that, in the case of *infrequent* memory faults, small memory and communication efficiency are simultaneously attainable. In contrast, all end-to-end protocols that were efficient in terms of their communication complexity were not efficient in their space complexity: more precisely, all end-to-end communication protocols that had polynomial communication complexity required at least *linear* (in the number of processors of the network) amount of space, at each processor, per incident link. Protocols with smaller space complexity were only presented at the cost of (at least) exponential communication complexity: Afek and Gafni [AG88] give a protocol which uses logarithmic amount of space, but has exponential communication complexity, and another protocol which uses constant amount of space but has unbounded communication complexity.

1.2. Our result.

The question of whether there exists an end-to-end communication protocol with sublinear space complexity and at the same time polynomial communication complexity remained open. In this paper, we give an affirmative answer to this question: we give a protocol that has logarithmic ($O(\log n + D)$) space complexity and polynomial ($O(n^2 mD)$) communication complexity, where n and m are the number of processors and links in the network, respectively, and D is the data-item size. This is an exponential space complexity improvement over all known polynomial communication protocols. Notice that this is achieved at a slight increase of the communication complexity compared to the best known solution [AG91]. We compare our result to the previous work in the table below.

[1] See section 2 for a formal description of the model.

present work	**polynomial:** $O(n^2 mD)$	**logarithmic:** $O(\log n + D)$

Our techniques and previous work. The starting point of our investigation is the Slide protocol of [AGR92][2] and the Majority algorithm of [AAF+90, AGR92]. The Slide protocol requires storing n packets per incident link, and the decision on the recency of the received item is taken only at the receiver processor (using the technique of [AAF+90]). If we wish to reduce the space per link, we can no longer afford storing n different packets, but must keep far fewer packets per link, and we can no longer afford the Majority algorithm of [AAF+90, AGR92], which collects a large number of packets arriving at the receiver and then calculates the value representing the majority among the received values. Thus, we must somehow "drop" all but several packets, and decide which to keep at each of the processors. Moreover, we must design an "online" analogue of the majority calculation, where we can "discard" packets as soon as they arrive at the receiver processor, yet manage to compute the majority value. However, if we begin to "drop" packets everywhere, is it no longer the case that the technique of deciding which packet is the correct one to output (at the receiver) still works. To overcome both difficulties, we combine two ingredients:

- a potential function that controls the flow of data-items in the network, which is an analogue to the potential function of the Slide protocol; and
- a novel data-item canceling policy which makes sure that in any processor there will be at most two distinct values of data-items per link. The same policy is used in both the intermediate processors and the receiver processor.

We show that a combination of these two techniques yields the desired result. Hence, even in the presence of frequent link failures, it is possible to achieve *both* polynomial communication and logarithmic space. As in [AMS89, AGR92], our solution has the additional benefit that it is totally local in nature. For example, the locality of Slide was used for establishing its self-stabilizing extension in [APV91]; similar local techniques were also used for various multicommodity flow problems in dynamic graphs [AL93, AL94].

1.3. Organization. Section 2 contains all the necessary background including the formal definitions of the model and the problem. Section 3 contains the description of the protocol; we start with an informal description (section 3.1) and then give a formal description (sections 3.2 and 3.3). Then, we show some of the properties of the protocol (section 3.4, with some proofs deferred to Appendix A). We conclude with its proof of correctness and complexity (section 4).

[2] A journal version of this paper, jointly with [AMS89], appears in [AAG+97].

2. Model and problem statement.

2.1. The network model. A *communication network* is associated with an undirected graph $G(V, E)$, $|V| = n$, $|E| = m$, where nodes correspond to processors and edges correspond to links of communication. We denote by $E(v)$, for $v \in V$, the set of edges which are adjacent to v. Processors are modeled as identical (except the sender and the receiver) deterministic finite state transducers with $O(\log n)$ memory per edge. (We do not require processors to have unique identifiers.) We model each *undirected* communication link as consisting of two *directed* links, delivering messages in opposite directions. Each transmission of a message is associated with a *send* event and a *receive* event; each event has its time of occurrence according to a global time, unknown to the processors. Without loss of generality, we assume that no two events occur at exactly the same time. A message is said to be *in transit* any time after its send event and before its receive event. As discussed in the introduction we would like to deal with networks whose links may fail and recover frequently. Each failure and recovery is eventually reported to both end-points of the link. When a link fails, messages that are in transit over it are lost. In the following we give a formal definition of a somewhat simpler-to-discuss model that we use in the sequel. Intuitively, the main difference between the models is that in the model we define below links never recover if they fail, and that such a failure is *not* reported to the processors. It is known that this simpler model, which was also used in [AG88, AMS89, AGR92], does not cause any reduction in power (for completeness, we prove this fact in section 2.4). In our model each *directed* link satisfies the following properties.

- Each link has *constant* capacity; that is, the protocol must obey the rule that only a constant number of messages are in transit on a given link at any given time.
- Communication over links obeys the *FIFO* (first in, first out) rule; that is, at any time, the sequence of messages *received* over the link is a prefix of the sequence of messages sent over the link.
- Communication is *asynchronous*; that is, there is no a priori bound on message transmission delays over the links.

A directed link is called *nonviable* if starting from some message and on it does not deliver any message; the transmission delay of this message and any subsequent message sent on this link is considered to be infinite. The sequence of messages received over the link is in this case a *proper* prefix of the sequence of messages sent. Otherwise, the link is *viable*. An undirected link is *viable* if both directed links that it consists of are viable.

We say that the sender is *eventually connected* to the receiver if there exists a (simple) path from the sender to the receiver consisting entirely of viable (undirected) links. Note that if there is a cut of the network, disconnecting the sender from the receiver, such that all the directed links crossing the cut are nonviable links, then eventually it becomes impossible to deliver messages from the sender to the receiver.

Remark. Notice that we model an undirected graph as a bi-connected directed graph. Hence we assume that either both directed links are viable or both are not viable. In this case, the above assumption about the eventual connectivity of the sender and the receiver is in fact the minimal possible for communication between them. On the other hand, in the model of *directed* graphs, it could be the case that there is a *directed* path from the sender to the receiver, and maybe (another) directed path from receiver to sender, yet all undirected edges are nonviable. We do not consider such (more difficult) case, and are in fact dealing only with undirected

graphs.

2.2. The end-to-end communication problem. The purpose of an end-to-end communication protocol is to establish a (directed) "virtual link" to be used for the delivery of data-items from one special processor, called the *sender*, to another special processor, called the *receiver*. Each data-item is a character of some alphabet of size 2^D; that is, each data-item can be encoded by D bits. It is required that if the sender is eventually connected to the receiver then the "virtual link" established by the protocol will be viable. This virtual link should have the same properties as a "regular" network link; namely, it should satisfy:

Safety: The sequence of data-items output by the receiver, at any time, is a *prefix* of the sequence of data-items input by the sender.

Liveness: If the sender is eventually connected to the receiver, then each data-item input by the sender is eventually output by the receiver.

A protocol for the end-to-end communication problem is given, *in an on-line fashion*, a sequence of data-items at the sender (i.e., every data-item must be delivered without the knowledge of the next data-item to be transmitted) and generates a sequence of data-items at the receiver that obey the safety and liveness properties.

2.3. The complexity measures. We consider the following complexity measures.

Communication: The number of bits transferred in the network in the worst case, per data-item delivered. More precisely, the total number of bits sent in the worst case in the period of time between two successive data-item output events at the receiver (measured in terms of n, m, and D).

Space: The maximum amount of space per incident link required by a processor's program throughout the protocol (measured in terms of n, m, and D).

In addition, we require that the local computation of the processors be polynomial for each send/receive event at each processor (in fact, our protocol uses a constant number of computational steps per event).

2.4. Relations to other models. The model described above is called the "∞-delay model" in [AG88] and the "fail-stop model" in [AM88]. As mentioned, we would like to deal with networks where links fail and recover frequently; in such *dynamic* networks, links may fail and recover many times (yet processors never fail) (see [AAG87]), and each failure or recovery of a network link is eventually reported at both its end-points by some underlying link protocol. This model should be contrasted with the self-stabilizing model (e.g., [Dij74]), where both processors and links can start in an inconsistent state, but it is assumed that they never fail after the computation begins. As was discussed in the introduction, the self-stabilizing model corresponds to *infrequent memory faults* and is incomparable to the model of *frequent link failures* addressed here. The question of how, in addition to frequent failures of links, one can allow inconsistent initial memory states was addressed in the end-to-end setting in [APV91, DW93].

As pointed out in [AG88], one can design protocols in the *fail-stop* model and convert them to the dynamic model. For this, a message to be forwarded on a link is stored in a buffer until the link recovers and the previously sent message has been delivered. A protocol similar to the data-link initialization protocol of [BS88] is used to guarantee that no message is lost or duplicated. Each link in the dynamic network that fails and never recovers for a long enough period to allow the delivery of a message is represented by a nonviable link. Note that the only space used by the

above transformation is for storing the buffers (i.e., per each link, it is the capacity of the link times the size of the longest message).[3]

3. The protocol.

3.1. High-level description. Our starting point is a linear space, yet simple, solution of [AGR92]. Their solution combines (as black-boxes) two components: the Slide protocol and the Majority algorithm. Before explaining our protocol, we give a short overview of the approach taken in [AGR92]. The Slide is used to transfer tokens (packets containing a data-item) in the network. This is done by letting each processor maintain a stack of tokens for each of its links. On each link, if active, tokens move from a larger stack of tokens to a smaller stack of tokens. The sender always has a large stack of tokens, so it only sends tokens out, and the receiver always has an empty stack, hence it only receives tokens. The Majority algorithm enables the receiver to decide, by collecting a sufficiently large number of tokens (containing data-items) and taking the majority value, what is the sequence of data-items sent by the sender. It is proved in [AGR92] that the combination of these two components yields a polynomial communication solution to the end-to-end problem.

In order to make the space requirements of the protocol logarithmic per edge, we can no longer use the Slide as a method to establish the virtual link between the sender and the receiver and we can no longer use the Majority algorithm. The reason is that the Slide needs a lot of space to store the stack of tokens (for each link), and the Majority algorithm needs even more space to collect the tokens in order to decide on the correct value to output. To overcome this, we introduce the following procedure.

- While transferring packets from the sender to the receiver, our protocol "cancels" some of these packets *both* en route and upon their arrival at the receiver processor. More precisely, it replaces some packets by "nil" packets.
- The canceling policy is designed so as to guarantee that at most two different packet-values are to be stored at each processor (including the receiver) at any given time—a "real" packet and a "nil" packet. We use a potential function that only *counts* the number of packets of both types, rather than storing all of them, and use this function to control the flow of tokens. We prove that two counters (of $\lceil \log n \rceil$ bits each) per link are sufficient for this. Altogether, we use only two counters per link and store only one data-item per processor.

Note that, usually, protocols that change the values of packets are undesirable. However, our protocol changes these values in a very restricted way—it may only replace a "real" packet by a "nil" packet. Our "canceling" policy does not effect the routing properties of the Slide protocol: it guarantees that if the sender and the receiver are eventually connected, then tokens will be transferred from the sender to the receiver. Moreover, our protocol guarantees an upper bound on the number of tokens that are in the network at any given time. Denote this upper bound by $\mathcal{C}$. For each data-item to be sent, the sender transmits to the receiver $2\mathcal{C}+1$ packets (tokens) that contain that data-item. The receiver *in an on-line, space-efficient fashion*, "collects" the same number (i.e., $2\mathcal{C}+1$) of tokens (some of which, but no more than $\mathcal{C}$, may be old tokens remaining in the network from previous transmissions) and outputs the data-item that represents the majority amongst the tokens received, *ignoring the nil tokens*.[4] We emphasize that the receiver computes this majority *without storing the*

[3] The communication is increased by a multiplicative factor of the number of failures of the link.
[4] For the first data-item only $\mathcal{C}+1$ tokens are collected.

tokens; rather, it does so by using the same "canceling policy" as in the intermediate processors.

As is clear from the above description, the heart of our protocol is the new (local) "canceling policy," described below. Whenever a token arrives into a processor on a given edge e we do the following.

- If it is a nil-token, then the counter of nil-tokens of edge e is augmented by one.
- If it is a "real" data-token and the data-item is identical to the data-item currently stored in the processor, then the data-tokens counter of edge e is augmented by one.
- If it is a "real" data-token and the data-item is different from the data-item currently stored in the processor, then the arriving token, and one data-token already accounted for in the processor are both "canceled" and become two nil-tokens (that is, the counter of nil-tokens of edge e is augmented by one, and for some edge e', whose data-tokens counter is greater than 0, the counter of nil-tokens is augmented by one, and the counter of data-tokens is decreased by one). If as a result there are no more "real" data-tokens accounted for in the processor (over all edges), we erase the current data-item stored in the processor.
- If it is a "real" data-token and there is no data-item currently stored in the processor, we store the arriving data-item as the current one, and set the counter of data-tokens of e to 1.

The essential idea of the above "canceling" policy is that from the point of view of the majority calculation done by the receiver, the above cancelation of two data-items into nil-tokens has only a minor effect; the receiver only needs to ignore the nil-tokens. Intuitively, since one of the properties of the old Majority algorithm is that, without these cancelations, the "correct" data-item would have more than half the tokens in any block of $2\mathcal{C}+1$ tokens then, at worst, if any of the canceled data-items is the correct one, then the other canceled data-item is an old one. Therefore, the majority of the correct data-items is maintained, while storing only one data-item per processor, and two counters per link.

3.2. A formal description of the protocol. We begin by describing the data-structures and messages used by our protocol. The protocol uses the following types of messages:

TOKEN **messages:** to carry data-items (either "real" data-items or the "nil" data-item).

TOKEN_LEFT **messages:** to announce over a link e that a token, accounted for in the counters of link e, has been sent away.

ACK_TOKEN **and** ACK_TOKEN_LEFT **messages:** are used to acknowledge the arrival of a TOKEN message or a TOKEN_LEFT message, respectively.

The following data is stored at each processor v:

- A variable `current_message` that stores a single data-item to be duplicated and sent in TOKEN messages.
- For each incident link e, there are two counters, `message_tokens[e]` and `nil_tokens[e]`. The variable `message_tokens[e]` records a value associated with the number of tokens that arrived on e carrying the value `current_message`; however, the value stored is not exactly this number, as sometimes a stored token is converted from a message-token into a nil-token, at which event the value of `message_tokens[e]` is decreased by one and the value of `nil_tokens[e]` is increased by one.
- For each incident link e, a variable `bound[e]` that stores an estimate on the sum of the above counters on the other side of the link. This bound is initialized to 1, incremented by one every time a token is sent over the

outgoing link, and decremented by one every time a TOKEN_LEFT message is received over the corresponding incoming link.

- For each incident link $e = (v, u)$, a counter called `tokens_left_pending[e]`, which counts the number of TOKEN messages that were sent from v (possibly on other links) on "the account" of e (i.e., caused the counters of e to decrease), but have not yet been reported as such to u. This counter is initialized as 0, incremented by one when a token leaves the counters of e, and decremented by one when a TOKEN_LEFT message is sent over e.
- For each incident link e, a flag `free_for_token` indicating whether an ACK_TOKEN message has already been received for the previous TOKEN message sent on e, and a flag `free_for_token_left`, indicating whether an ACK_TOKEN_LEFT message has already been received for the previous TOKEN_LEFT message sent on e.

The sender and the receiver store some additional data. The sender stores the last message it has received to transmit (`current_input`), together with a count of how many such packets are still to be sent (`left_to_send`). In addition, it stores part of the above stated data relative to an additional "virtual link" through which it introduces new tokens into the network. Although we call it a virtual *link*, in what follows it is not included in the set E. The receiver maintains a counter storing the number of packets it received since the time of the last output event (`count`), and another counter storing the number of packets that contained the message stored in `current_message` (`current_message_count`). It also maintains a single-bit flag `first_item`.

Throughout the proofs we assume a global time, unknown to the processors, and we denote the value of variables in a processor at a given time by a subscript of the processor and a superscript of the time (e.g., $\mathcal{X}_v^t$). We also use the following notation to count the number of different messages on a given link at a given time: Let $tokens^t_{u\to v}$ be the number of TOKEN messages in transit from u to v at time t. Let $tokens\_left^t_{u\to v}$ be the number of TOKEN_LEFT messages in transit from u to v at time t.

In our protocol the nodes do not store tokens, but merely store a single message-value and several counters. However, for our proofs we sometime use the terminology that tokens are stored, or present, in the nodes. The analogy is straightforward: when a counter counts k nil-tokens, we sometimes refer to it as if the node stores k nil-tokens, etc. This enables us to talk about the "number of tokens in the network," rather than about the "sum of values of the counters in the network," and make our arguments more readable.

3.3. The code. In this section, we present the code of our protocol. Following [AMS89, AGR92], the presentation of the code is based on the language of *guarded commands* of Dijkstra (see [DF88]), where the code of each process is of the form

$$\textbf{Select}\ \ G_1 \to A_1 \,\square\, G_2 \to A_2 \,\square\, \ldots \,\square\, G_l \to A_l\ \ \textbf{End Select}.$$

The code is executed by repeatedly selecting an arbitrary i from all guards G_i which are true, and executing A_i. Each guard G_i is a conjunction of predicates.

The predicate **Receive** M is true when a message M is available to be received. If the statements associated with this predicate are executed, then prior to this execution the message M is actually received. The message may contain some values that are assigned, upon its receipt, to variables stated in the **Receive** predicate (e.g., **Receive** TOKEN(data)). The command **Send** M on e sends the message M on the link e.

We present the code of a regular processor (Figure 1), which is every processor except the sender and the receiver. The code of the receiver is presented separately (Figure 3). The sender has an additional "virtual link" (which does not belong to the set E) through which new tokens are introduced into the network. This virtual link is denoted in the code by I. The code of the sender is composed of two parts: the code of a regular processor, and additional special code (Figure 2). Upon initialization, the sender executes the two initialization procedures (of a regular processor and the additional one), and then regards the two select commands as a unified one.

3.4. Properties of the protocol. In this section we present properties of the protocol which later allow us to prove its correctness and complexity. The structure of the proof follows the structure of the proofs in [AGR92], and some of the proofs are analogous to those of [AMS89, AGR92]. We first state the following technical lemmas (we postpone their proofs to Appendix A).

Consider an edge $e = (u, v) \in E$. The following lemma relates the estimate $bound[e]_u^t$ which u has on the number of tokens that are stored in v (in the counters corresponding to the same edge e). It shows that this estimate essentially equals the actual number of tokens stored (i.e., $message\_tokens[e]_v^t + nil\_tokens[e]_v^t$) plus those that have left, but were not yet reported as such, and those which are still in transit (i.e., $tokens_{u\to v}^t + tokens\_left_{v\to u}^t$).

LEMMA 1. *At any time t, and for any $e = (u, v) \in E$,*

$$\begin{aligned} bound[e]_u^t - 1 = {} & message\_tokens[e]_v^t + nil\_tokens[e]_v^t \\ & + tokens\_left\_pending[e]_v^t + tokens_{u\to v}^t + tokens\_left_{v\to u}^t \ . \end{aligned}$$

The next lemma gives the main intuition for the progress in the protocol.

LEMMA 2. *Consider a* TOKEN *message sent from processor u to processor v, on link $e = (u, v)$. Let e' be the link whose counter at processor u decreased when the message was sent. If just before the message is sent $message\_tokens[e']_u + nil\_tokens[e']_u = i$ and just after it is received $message\_tokens[e]_v + nil\_tokens[e]_v = j$, then $j < i$.*

Since all the tokens in the network are either "stored" in the processors or in transit over links, the following lemma and corollary will allow us to give a bound on the capacity of the network (property ($\mathcal{P}1$) below).

LEMMA 3. *At any time t and for any $e = (u, v)$,*

$$bound[e]_u^t \le n \ .$$

COROLLARY 4. *The following hold for any time t.*

(1) *For any $e = (u, v) \in E$,*

$$message\_tokens[e]_v^t + nil\_tokens[e]_v^t + tokens_{u\to v}^t \le n \ ,$$

$$tokens\_left\_pending[e]_v^t \le n \ .$$

(2) *For $e = I$,*

$$message\_tokens[e]_v^t + nil\_tokens[e]_v^t \le n \ ,$$

$$tokens\_left\_pending[e]_v^t \le n \ .$$

FIG. 2. *Additional code for the sender.*

We use the above lemmas to prove the following theorem.

THEOREM 5. *The protocol has the following properties.*

($\mathcal{P}1$) *At any time t, the number of tokens in the network is bounded by $\mathcal{C} = n \cdot (2m+1)$.*

($\mathcal{P}2$) *Consider a time interval in which k_{new} new tokens are inserted into the network. During this time interval, at most $O(n^2 m + k_{\text{new}} \cdot n)$ TOKEN messages are sent in the network.*

($\mathcal{P}3$) *If the sender and the receiver are eventually connected, the sender will eventually insert a new token into the network.*

Proof. Every token in the network is either in transit on a link or accounted for in some counter at a processor. For every edge $e = (u, v) \in E$ we consider its two directions. For the direction from u to v (v to u) Corollary 4 states that at any given time the number of tokens in transit from u to v (v to u) plus the number of tokens accounted for at the counters of e at node v (node u) is at most n. Thus we get at most $n \cdot 2m$ tokens. At most n additional tokens can be accounted for at the counters of the "virtual link" I, altogether $n \cdot (2m+1)$ tokens. This concludes the proof of property ($\mathcal{P}1$).

We can now also prove property ($\mathcal{P}2$). Define the following potential function. For any processor v and for any incident link $e = (v, u)$, and for $e = I$ if $v = s$, denote $J^t(v,e) = message\_tokens[e]_v^t + nil\_tokens[e]_v^t$ and let $H^t(v,e) = \sum_{k=1}^{J^t(v,e)} k = \binom{J^t(v,e)}{2}$. Let P^t be the set of TOKEN messages in transit at time t. For $p \in P^t$ let t' be the time just before the TOKEN message p was sent, say from v to u. If e' is the link whose counters accounted for the token sent, then we define $T^t(p) = message\_tokens[e']_v^{t'} + nil\_tokens[e']_v^{t'}$ (that is, the token "carries" the "number" of tokens in v, at link e', just before it left this processor). Denote the sender by S. The potential function is

```
Procedure check_and_output
    if first_item and count=C + 1 then /* first data-item */
        output(current_message);
        current_message := empty;
        count:= 0;
        current_message_count:= 0;
        first_item:=false;
    else
        if (not first_item) and count= 2·C + 1 then /* all other data-items */
            output(current_message);
            current_message := empty;
            count := 0;
            current_message_count:= 0;
        endif
    endif
End Procedure
Initialize ⟶
    C := n · (2m + 1) ;

FIG. 3. *Code of the receiver u .*

$$\Phi^t = H^t(S,I) + \sum_{e=(u,v)\in E} [H^t(v,e) + H^t(u,e)] + \sum_{p\in P^t} T^t(p).$$

This potential function may change upon one of the following three events.

1. A new token enters the network—the potential function increases by at most n.
2. A token is sent—the potential function does not change, since the relevant H function decreases by exactly the value of the relevant new T function that is added to the sum.
3. A token is received—the potential function decreases by at least 1. This follows from Lemma 2, as the value of the function T that is extracted from the sum, is larger by at least 1 than the sum $message\_tokens + nil\_tokens$ at the accepting link, which is the exact increase in the corresponding function H.

Since by Corollary 4,

$$message\_tokens[e]_v^t + nil\_tokens[e]_v^t \le n,$$

and since there is at most one TOKEN in transit on each link at any given time, the value of Φ is at most $2m \cdot (\binom{n}{2} + n) + \binom{n}{2}$; also, Φ is clearly always nonnegative. For each token received, Φ decreases by 1, and it can increase only upon the entry of a new token to the network and by at most n. Thus if in a given time interval k_{new} new tokens are introduced, then an upper bound on the number of token receipts in this time interval is $2m \cdot (\binom{n}{2} + n) + \binom{n}{2} + k_{\text{new}} \cdot n$, since otherwise the potential function Φ would become negative. Since by the code a TOKEN message is sent on link e only after an acknowledgment on the previous TOKEN message is received, the number of TOKEN messages sent in the time interval is at most $2m$ more than the number of TOKEN messages received in the time interval. Thus, we get property ($\mathcal{P}2$).

We now turn to the proof of property ($\mathcal{P}3$). By way of contradiction, assume that t is the last time at which a new token enters the network. As a result of property ($\mathcal{P}2$) and as there is at most one TOKEN_LEFT message per TOKEN message, and one ACK message (of the corresponding type) per TOKEN and TOKEN_LEFT message, there is a time $t' \ge t$ after which no TOKEN, TOKEN_LEFT, ACK_TOKEN, or ACK_TOKEN_LEFT messages are sent. As the sender, S, and the receiver, R, are eventually connected, there is a path $R = v_0, v_1, \ldots, v_{k-1}, v_k = S$, $k < n$, such that for each $0 \le i \le k-1$, the edge $e = (v_i, v_{i+1})$ is viable; hence there is a time $t'' \ge t'$ by which all messages between v_i and v_{i+1}, in both directions, are delivered. Note that we enumerate the nodes on the path in the direction from the receiver to the sender.

Next, note that this implies that $tokens\_left\_pending[e]_{v_i} = 0$ for any i and for any time after t''. We now prove by induction on the length of the viable path from v_i to R that for any link e incident to v_i, after time t'', $message\_tokens[e]_{v_i} + nil\_tokens[e]_{v_i} \le i$. The receiver, v_0, has no tokens stored at all, thus the induction basis holds. Let $e = (v_{i-1}, v_i)$ (for $i \ge 1$), and apply the induction hypothesis to the link e in node v_{i-1}, i.e., $message\_tokens[e]_{v_{i-1}} + nil\_tokens[e]_{v_{i-1}} \le i-1$. Applying Lemma 1, and since after t'' there is no message in transit between v_{i-1} and v_i, and $tokens\_left\_pending[e]_{v_{i-1}} = 0$, we get $bound[e]_{v_i} \le i$. As $t'' \ge t'$, no token is sent after t'', but according to the code this can happen only if for any time after t'', and any e incident to v_i, $message\_tokens[e]_{v_i} + nil\_tokens[e]_{v_i} \le i$, proving the induction step.

Thus, for the "virtual link" I at the sender S, $message\_tokens[I]_S + nil\_tokens[I]_S \leq k < n$, and by the code of the sender a new token is introduced into the network, contradicting the assumption. Property ($\mathcal{P}3$) follows. □

4. Correctness proof of the protocol. In this section we prove the safety and liveness properties of the protocol.

THEOREM 6 (safety). *At any time the output of the receiver is a prefix of the input of the sender.*

Proof. Denote by $IN = (I_1, I_2, \ldots)$ the input to the sender, and by $OUT = (O_1, O_2, \ldots)$ the output of the receiver. Denote by $t_i, i > 0$, the time at which O_i is output.

By the code, the receiver outputs at t_i the value in *current_message* as the next output. We will therefore show that at t_i the value of *current_message* is I_i. For this, we consider the tokens received by the receiver in the time interval between the time data-item $i-1$ and data-item i are output. We use the following definitions.

DEFINITION 1. *Let $in^{(t,t']}$ be the number of tokens introduced into the network by the sender in interval of time $(t, t']$. Let $out^{(t,t']}$ be the number of tokens received by the receiver in the interval of time $(t, t']$.*

First note that the total number of tokens (either nil-tokens or message-tokens) received by the receiver by time t_i is

$$out^{(t_0,t_i]} = \mathcal{C} + 1 + (i-1)(2\cdot\mathcal{C} + 1).$$

By Theorem 5, the capacity of the network is $\mathcal{C}$, thus the total number of tokens sent by the sender by any time t is at most $\mathcal{C}$ more than the total number of tokens received by the receiver by the same time, t. Thus,

$$in^{(t_0,t_i]} \leq i(2\cdot\mathcal{C} + 1).$$

Since the sender sends successively $2\mathcal{C}+1$ tokens for each data item, this implies that all tokens sent by time t_i carry the value I_j for some $j \leq i$.

As to the first data-item, this guarantees that all TOKEN messages received by time t_1 carry the first data-item, and since at the beginning of the run *current_message* is initialized to `empty`, this guarantees that at time t_1 *current_message* is I_1.

To prove the claim for $i > 1$ we first show that more than half of the tokens received by the receiver in $(t_{i-1}, t_i]$ that carry a data-item when received (as opposed to nil-tokens), carry the value I_i. Since $in^{(t_0,t_i]} \leq i(2\cdot\mathcal{C}+1)$ no token carrying I_k, for $k > i$ is present in the network by time t_i. Therefore, and since $out^{(t_0,t_l]} = (l-1)(2\mathcal{C}+1) + (\mathcal{C}+1)$, any token received in $(t_{i-1}, t_i]$ is a token that is either:

- sent with value I_i (note that no such token can be received by t_{i-1}), or
- sent with value I_k, $k < i$, and not received by time t_{i-1}. There can be at most $\mathcal{C}$ such tokens, as the total number of tokens ever sent with I_k $(k < i)$, is $(i-1)(2\mathcal{C}+1)$.

The set of tokens received in $(t_{i-1}, t_i]$ is thus some subset of size $2\mathcal{C}+1$ of the above $2\mathcal{C}+1+\mathcal{C}$ tokens. We argue that in any subset of size $2\mathcal{C}+1$ of these tokens, more than half of the "real" tokens carry the value I_i. This is true along time, even after the occurrence of "cancelation" events that cause two tokens to become nil. At t_{i-1} the claim is true since no one of the $2\mathcal{C}+1$ tokens to be sent with I_i is sent yet, thus they still "carry" I_i, while there are at most $\mathcal{C}$ other tokens. Consider any cancelation event; then if the number of tokens carrying I_i is reduced as a result of one such token becoming nil, then a token carrying a value I_k, $k < i$ also becomes nil.

We now show that indeed at time t_i the value of *current_message* is I_i. Consider the sequence of $2\mathcal{C}+1$ tokens received during the interval $(t_{i-1}, t_i]$. For the purpose of

the proof we give to each token that arrives at the receiver in the time interval $(t_{i-1}, t_i]$, a number which is its number in the sequence of the tokens that arrive after time t_{i-1}. Let $1 \leq T_1 < T_2 < T_j < \cdots < T_k \leq 2\mathcal{C}+1$ be the token numbers upon whose arrival the value of *current_message* changes from `empty` to another value. Let Val_j be the new value assigned to *current_message*. We show that at time t_i *current_message* is not `empty`, and that the last "real" value assigned to it, Val_k, is I_i. Consider the set of tokens with numbers $T_j \leq l < T_{j+1}$, for $j < k$. If at T_{j+1} a new, not `empty`, value is assigned to *current_message*, then *current_message_count* was 0 at this time, which means that it has become such at the receipt of token number $T_{j+1} - p$, for some $p \geq 1$, and any token with number s, such that $T_{j+1} - p + 1 \leq s < T_{j+1}$ (if any) was a nil-token. Thus, we conclude that among the tokens $T_j \leq l < T_{j+1}$ that carry a data-item (i.e., are not nil-tokens), exactly half carry Val_j. Whatever the value Val_j is, *at most* half of the above tokens carry I_i. If upon the receipt of token $2\mathcal{C}+1$, *current_message* is `empty` (and is thus `empty` at time t_i), we have that over the whole sequence the number of tokens carrying I_i is at most half the number of tokens carrying any value. Thus, this cannot happen (i.e., *current_message* is not `empty` at time t_i). Next, assume that $Val_k \neq I_i$ (and this is the value at time t_i). Then *more* than half the tokens $T_k \leq l \leq 2\mathcal{C}+1$, that are not nil-tokens, carry value Val_k. Then, over the whole sequence the tokens carrying I_i are less than half the number of tokens carrying any value, a contradiction again. □

THEOREM 7 (liveness). *If the sender and the receiver are eventually connected, then the receiver eventually outputs any data-item input to the sender.*

Proof. If the sender inputs the ith data-item, then it tries to send $i(2\cdot\mathcal{C}+1)$ tokens (counted over the whole run). As the sender and the receiver are eventually connected, by property ($\mathcal{P}3$) all these tokens are eventually input into the network. Since the network can delay at most $\mathcal{C}$ tokens, the receiver will eventually receive $i(2\cdot\mathcal{C}+1) - \mathcal{C}$ tokens, and thus outputs the ith data-item. □

4.1. The complexity of the protocol.

LEMMA 8. *The number of messages sent by the protocol in any time interval where k_{new} new tokens are added to the network is $O(n^2m + k_{\text{new}} \cdot n)$.*

Proof. Each message is a TOKEN, TOKEN_LEFT, ACK_TOKEN, or ACK_TOKEN_LEFT message. By property ($\mathcal{P}2$), the number of TOKEN messages sent in the time interval is $O(n^2m + k_{\text{new}} \cdot n)$. The number of TOKEN_LEFT messages sent is at most the sum of the counters *token_left_pending* at the beginning of the interval, plus the number of TOKEN messages sent in the time interval. By Corollary 4 and the above, this sums to $O(2nm + n^2m + k_{\text{new}} \cdot n)$.

The number of ACK_TOKEN and ACK_TOKEN_LEFT messages sent, in the time interval under consideration, is at most the number of TOKEN and TOKEN_LEFT messages sent in this time interval, plus the number of messages that were in transit when the time interval started. Since the capacity of each link is constant the number of messages in transit at any given time is $O(m)$, and we have a bound on the number of ACK messages (of both types) of $O(n^2m + k_{\text{new}} \cdot n + 2mn + m)$. □

LEMMA 9. *The message complexity of the protocol is $O(n^2m)$ messages.*

Proof. For every time interval $(t_{i-1}, t_i]$ the receiver receives $2\cdot\mathcal{C}+1$ tokens during the interval. Since the capacity of the network is $\mathcal{C}$ tokens, at most $3\cdot\mathcal{C}+1$ tokens are sent by the sender in $(t_{i-1}, t_i]$. As $\mathcal{C} = O(nm)$, the lemma follows from Lemma 8. □

Since messages have size at most the size of the data-item, we establish the following theorem.

THEOREM 10 (communication complexity). *The communication complexity of the above protocol is* $O(n^2mD)$ *bits.*

THEOREM 11 (space complexity). *The space required at each processor is* $O(D + \log n)$ *bits per incident link.*

Proof. The list of variables used by each processor (per incident link) is given in section 3.2. By Corollary 4, the value of each of the counters *message_tokens*, *nil_tokens*, and *tokens_left_pending* is at most n, and hence requires only $O(\log n)$ bits. By Lemma 3, the same is true for the counter *bound*. In addition, there is a constant number of single-bit flags, per link. Finally, the processors store a single variable, *current_message*, of size D bits. □

5. Conclusions. In this work, we give an end-to-end communication protocol that has polynomial communication complexity and at the same time logarithmic space complexity. Thus we show that it is possible to attain polynomial communication complexity and sublinear space complexity at the same time. It remains, however, open, whether *constant* space complexity (more precisely, space complexity $O(D)$) allows for polynomial, or even merely bounded, communication complexity protocols in the above setting.

Appendix A. Proofs of technical lemmas.

Proof of Lemma 1. Upon initialization, the invariant holds. This is because the variable *bound*[e] is initialized to 1, the counters *message_tokens*[e], *nil_tokens*[e], and *tokens_left_pending*[e] are initialized to 0, and no message is in transit in the network. By induction on the events that change any of the values participating in the invariant, we show that the invariant holds for any time t. There are six types of events to be considered: send and receive events of TOKEN messages from u to v on e; send and receive events of TOKEN_LEFT messages from v to u on e; send events of TOKEN messages from v, when the token sent is accounted for in the counters of e in v; and receive events of a TOKEN at v, when this arrival causes a token accounted for at e to become a nil-token.

If both v and u are *not* the receiver, then the following describes the effects of any of the events:

- Send event of a TOKEN message from u to v on e: *bound*$[e]_u$ is incremented by 1, but so is $tokens_{u\to v}$.
- Receive event of a TOKEN message at v on link e: the sum *message_tokens*$[e]_v$ + *nil_tokens*$[e]_v$ is incremented by 1, but $tokens_{u\to v}$ is decremented by 1.
- Send event of a TOKEN_LEFT message from v to u on e: *tokens_left_pending*$[e]_v$ is decremented by 1, but $tokens\_left_{v\to u}$ is incremented by 1.
- Receive event of a TOKEN_LEFT message at u from v, on e: *bound*$[e]_u$ is decremented by 1, but so is $tokens\_left_{v\to u}$.
- A send event of a TOKEN message from u on some link e', when the token sent was accounted for at the counters of e: *message_tokens*[e] and *nil_tokens*[e] are decremented by 1, but *tokens_left_pending*[e] is incremented by 1.
- A receive event of a TOKEN message at v (on some link) may cause a token accounted for at the counters of e to become nil: *message_tokens*[e] is decremented by 1, but *nil_tokens*[e] is incremented by 1.

If v is the receiver:

- Send event of a TOKEN message from u to v on e: *bound*$[e]_u$ is incremented by 1, but so is $tokens_{u\to v}$.
- Receive event of a TOKEN message at v on e: $tokens_{u\to v}$ is decremented by 1 but *tokens_left_pending*[e] is incremented by 1.

- Send event of a TOKEN_LEFT message from v to u on e: $tokens\_left\_pending[e]_v$ is decremented by 1, but $tokens\_left_{v\to u}$ is incremented by 1.
- Receive event of a TOKEN_LEFT message at u from v, on e: $bound[e]_u$ is decremented by 1, but so is $tokens\_left_{v\to u}$.
- A send event of a TOKEN message from u on some link e', when the token sent was accounted for at the counters of e: one of the counters $message\_tokens[e]$ and $nil\_tokens[e]$ is decremented by 1, but $tokens\_left\_pending[e]$ is incremented by 1. (However, note that this event cannot happen, since u never receives any token on e.)
- A receive event of a TOKEN message at v (on some link) never changes the values of $message\_tokens[e]$ or $nil\_tokens[e]$.

If u is the receiver:

- A send event of a TOKEN message from u on e cannot happen, by the code.
- Receive event of a TOKEN message at v on link e: the sum $message\_tokens[e]_v + nil\_tokens[e]_v$ is incremented by 1, but $tokens_{u\to v}$ is decremented by 1 (note, however, that such an event cannot happen as u does not send TOKEN messages).
- Send event of a TOKEN_LEFT message from v to u on e: $tokens\_left\_pending[e]_v$ is decremented by 1, but $tokens\_left_{v\to u}$ is incremented by 1 (note that this event cannot happen too).
- Receive event of a TOKEN_LEFT message at u from v, on e: $bound[e]_u$ is decremented by 1, but so is $tokens\_left_{v\to u}$ (note that this event cannot happen).
- A send event of a TOKEN message accounted for at u cannot happen, by the code.
- A receive event of a TOKEN message at v (on some link) may cause a token accounted for at the counters of e to become nil: $message\_tokens[e]$ is decremented by 1, but $nil\_tokens[e]$ is incremented by 1. □

Proof of Lemma 2. Let t be the time just before the token is sent from u, and t' the time just before it is received at v. Because the sum of $message\_tokens$ and nil_tokens can increment only when tokens arrive on the link, and because the links are FIFO, we have:

$$\begin{aligned} &message\_tokens[e]_v^{t'} + nil\_tokens[e]_v^{t'} \\ &\le message\_tokens[e]_v^{t} + nil\_tokens[e]_v^{t} + tokens_{u\to v}^{t}. \end{aligned}$$

By Lemma 1,

$$message\_tokens[e]_v^t + nil\_tokens[e]_v^t + tokens_{u\to v}^t + 1 \le bound[e]_u^t \ .$$

Thus,

$$message\_tokens[e]_v^{t'} + nil\_tokens[e]_v^{t'} + 1 \le bound[e]_u^t.$$

By the code, $i > bound[e]_u^t$ and $j = message\_tokens[e]_v^{t'} + nil\_tokens[e]_v^{t'} + 1$, hence $i > j$. □

Proof of Lemma 3. We prove the claim by contradiction. Assume $bound[e]_u^t > n$ for some t, u, and $e = (u, v)$. Then a token must have been sent over e from u to v when $bound[e]_u \ge n$. By the code, this can happen only if, for some $e' \in E \cup \{I\}$, $message\_tokens[e']_u + nil\_tokens[e']_u > n$. However, for any e', the value of $message\_tokens[e']_u + nil\_tokens[e']_u$ is initialized to 0. Therefore, consider the

first time that, for some e' and u, $message\_tokens[e']_u + nil\_tokens[e']_u > n$. For the "virtual link" I at the sender this cannot happen by the code. For every $e' = (u, v') \in E$, the value of $message\_tokens[e']_u + nil\_tokens[e']_u$ increases only when a token is received at u over e'. Consider the token upon whose receipt the value of $message\_tokens[e']_u + nil\_tokens[e']_u$ became strictly larger than n, and denote by e'' the link incident to v whose counters accounted for this token before it was sent from v. By Lemma 2, when the token was sent from v, the value of $message\_tokens[e'']_v + nil\_tokens[e'']_v$ was already strictly greater than n, contradicting the fact that we are considering the first such event. □

Proof of Corollary 4. For $e = I$, the claim follows from the code. For any $e \in E$, by Lemmas 1 and 3,

$$message\_tokens[e]^t_v + nil\_tokens[e]^t_v + tokens^t_{u \to v} \leq bound[e]^t_u - 1 \leq n - 1 \ ,$$

and

$$tokens\_left\_pending[e]^t_v \leq bound[e]^t_u - 1 \leq n - 1 \ . \qquad \square$$

LOWER BOUNDS FOR RANDOMIZED MUTUAL EXCLUSION*

EYAL KUSHILEVITZ†, YISHAY MANSOUR‡, MICHAEL O. RABIN§, AND DAVID ZUCKERMAN¶

Abstract. We establish, for the first time, lower bounds for *randomized* mutual exclusion algorithms (with a read-modify-write operation). Our main result is that a constant-size shared variable cannot guarantee strong fairness, even if randomization is allowed. In fact, we prove a lower bound of $\Omega(\log \log n)$ bits on the size of the shared variable, which is also tight.

We investigate weaker fairness conditions and derive tight (upper and lower) bounds for them as well. Surprisingly, it turns out that slightly weakening the fairness condition results in an exponential reduction in the size of the required shared variable. Our lower bounds rely on an analysis of Markov chains that may be of interest on its own and may have applications elsewhere.

Key words. mutual exclusion, randomized distributed algorithms, Markov chains, lower bounds

1. Introduction.

Randomization has played an important role in the design and understanding of distributed algorithms. It is a natural tool which is usually used in order to break symmetry between identical processes in a distributed system. Beyond its natural role in symmetry breaking, randomization often increases the computation power (e.g., [LR81, Ben83]), significantly decreases computational costs (e.g., [Bra85, FM88]), and helps in simplifying algorithms.

For many applications in distributed environments, there is a provable gap between the power of randomized algorithms and that of their deterministic counterparts. The most renowned example is achieving Byzantine agreement with a linear number of faults; while any deterministic algorithm requires at least a linear number of rounds [FL82], there is a randomized algorithm that performs the same task in a constant number of rounds [FM88]. Another important example is that of reaching a consensus in an asynchronous distributed system with faults: this is impossible with deterministic protocols, even if the faults are restricted to a single fail-stop fault [FLP85], but is possible with the use of randomized protocols (see [CIL87]).

The gap between the performances of randomized and deterministic algorithms exists also for the *mutual exclusion* problem. The complexity measure here is the

size of the shared variable.[1] Any deterministic algorithm requires an $\Omega(\log n)$-bit shared variable, in order to achieve mutual exclusion (with fairness) between n distinct processes, and this bound is tight [BFJ+82]. On the other hand, there is a randomized algorithm requiring only an $O(\log \log n)$-bit shared variable [Rab82, KR92].[2]

It remained an open problem whether the complexity of the randomized algorithm for the mutual exclusion problem could be further reduced, perhaps even to a constant number of bits. A constant-size shared variable is of special interest, since it implies that the size of the shared memory can be independent of the number of the processes using it. Our main contribution is a tight $\Omega(\log \log n)$ lower bound on the number of bits required to implement the shared variable. Other tight *upper* and *lower* bounds are given for mutual exclusion with weaker fairness properties.

Few lower bounds are known for randomized distributed algorithms. Many of these lower bounds are based on arguments that arise from the need for information to flow from one side of the network to the other side, or based on the symmetry between different processes [IR81]. Another type of argument for randomized lower bounds is the use of the min-max theorem [Yao77, AS91]. For randomized Byzantine agreement, when more than a third of the processes are faulty, a lower bound on the success rate is known [KY84, GY89].

Previous work and our results. In the following, we give a more detailed description of the mutual exclusion problem and a summary of our results together with previous results related to our work.

The setting of the *mutual exclusion* problem is as follows. There are n processes that from time to time need to execute a critical section in which exactly one is allowed to employ some shared resource. The processes can coordinate their activities through a shared *read-modify-write* variable (i.e., reading and rewriting the shared variable is an atomic action). The sequence of accesses to the shared variable is determined by a scheduler.

The mutual exclusion problem is a classical problem in distributed computing. It was first suggested by Dijkstra [Dij65], who solved the problem using a (one-bit) semaphore. While the semaphore does solve the problem and guarantees *deadlock freedom*, it does not guarantee any *fairness* among the processes competing for the critical section; a process that is waiting for the critical section may wait forever. Since then, numerous solutions have been proposed for the mutual exclusion problem. All these solutions guarantee *deadlock freedom*, together with some notion of *fairness*.

An important parameter for evaluating the complexity of a mutual exclusion algorithm is the size of the shared variable that is used. As mentioned above, to guarantee only *deadlock-freeness*, a one-bit semaphore is sufficient [Dij65]. Burns et al. [BFJ+82] define the *bounded-waiting* property as a fairness criterion. Roughly speaking, this property guarantees that between the first time that a process accesses the shared variable in order to try to enter the critical section and the time it actually enters the critical section, each of the other processes may enter the critical section at most once. They proved that if *deterministic* algorithms are used, then an $\Omega(\log n)$-

[1] Throughout this work the size of the shared variable is measured in terms of the number of *bits* of the shared variable rather then the number of *values* (as is done in some of the papers in the literature). Clearly, the number of bits is logarithmic in the number of values, hence a constant factor in the number of bits translates to a polynomial factor in the number of values. Still, the number of bits is a very natural measure for the size of the variables.

[2] The first solution to this problem was given in [Rab82]. A flaw in this solution was pointed out by [Sai92]. A new solution, based on ideas of [Rab82], was given in [KR92].

bit shared variable is required for achieving bounded-waiting and that this number of bits is also sufficient.

Rabin [Rab82] suggested the use of *randomized* algorithms for mutual exclusion and defined the notion of fairness for such algorithms. Roughly speaking, the fairness of a randomized mutual exclusion algorithm measures the probability that a process enters the critical section at a given time, as a function of the number of processes concurrently competing for the critical section. Specifically, Rabin was interested in the following fairness property, which we refer to as *linear-fairness*: if a process participates in a "round"[3] together with m processes, it has probability $\Omega(1/m)$ of entering the critical section in the next round. This property can be considered as a probabilistic analogue of the bounded-waiting property. Randomized algorithms having the linear-fairness property that use $O(\log\log n)$-bit shared variable are presented in [Rab82, KR92]. This is in contrast to the $\Theta(\log n)$-bit shared variable required by deterministic algorithms.

Proving the correctness of such randomized distributed protocols involves many delicate issues. Saias [Sai92] developed a general methodology to prove the correctness of a randomized distributed protocol. The main difficulty of such proofs is the need to deal with two separate sources of nondeterminism: the randomness that the protocol generates and the decisions of the adversary. The key idea in his methodology is that these two ingredients should be made independent. Using his systematic methodology, Saias [Sai92] uncovered the flaw in [Rab82].

No *lower bounds* for randomized mutual exclusion were known. In fact, in light of the results mentioned earlier, it may seem plausible that a constant-size shared variable is sufficient for mutual exclusion with linear fairness. More than that, it was shown [Rab82, KR92] that a constant-size shared variable may be powerful; it suffices for guaranteeing that each of the competing processes will have $\Omega(1/n)$ probability of entering the critical section. However, this is *independent* of m and hence is much weaker. In this paper, we prove a tight $\Omega(\log\log n)$-bit lower bound on the size of the shared variable that is needed for achieving mutual exclusion with linear-fairness. Thus, in particular, a constant-size shared variable cannot guarantee linear-fairness.

We define a slightly weaker fairness property that we term *polynomial-fairness*: if a process participates in a round together with m processes, it has a probability of $\Omega(1/m^{1+\varepsilon})$ to enter the critical section in the next round (where $\varepsilon > 0$ is a constant). Surprisingly, we show that for every $\varepsilon > 0$ an $O(\log\log\log n)$-bit shared variable is sufficient to achieve polynomial fairness, and that an $\Omega(\log\log\log n)$-bit shared variable is necessary. Hence, this slight weakening of the fairness property results in an exponential reduction in the size of the required shared variable. Finally, we show that with a constant-size shared variable it is possible to guarantee an $\Omega(1/2^m)$ probability of entering the critical section.

For our lower-bound proofs, we study general *Markov chains*, i.e., those which are represented by a $k \times k$ real nonnegative matrix where the sum of elements in each row is 1. We call a Markov chain *live* if in each of its first n steps it has a "considerable probability" of visiting a new state (i.e., a state that was not visited in each of the previous steps). We relate the fairness of mutual exclusion algorithms to the liveness of Markov chains (where the different notions of fairness correspond to different interpretations of "considerable probability"). We obtain our bounds for mutual exclusion by proving bounds on k, the number of states of the Markov chains (as a function of n). We believe that our bounds and technique may be found useful

[3] A round is the time between two consecutive closings of the critical section.

for other applications.

The paper is organized as follows. In section 2 we formally define the mutual exclusion problem and Markov chains. In sections 3 and 4 we prove the lower bounds for linear/polynomial-fairness (respectively). Finally, in section 5 we show the upper bounds.

2. Preliminaries.

2.1. Mutual exclusion. In this section we define the properties required from a randomized mutual exclusion algorithm. Let $P_1, \ldots, P_n$ be the n processes in the system. The processes coordinate their activities by using a shared read-modify-write variable v. (In addition, each process P_i has unbounded local memory.) While it is convenient to assume that all the processes run the same program, our results do not depend on this assumption. During the computation, each process P_i is in one of four possible phases: *TRYING phase*, in which it attempts to enter the critical section, *CS* (*critical section*) *phase*, in which it executes the critical section, *EXIT phase*, in which it leaves the critical section, or *REMAINDER phase*, in which it does other local computations.

At any given time the adversary scheduler[4] can observe the *external behavior* of the processes (i.e., which of the four phases each process currently executes) and use this information (together with its information on the past behavior of the processes) to determine which process will be the next to access the shared variable. (It is also assumed that the adversary knows the algorithm used by the processes, including the initial state of each process.) The adversary scheduler *cannot* observe the content of the shared variable nor the content of any local variable.[5] More formally, let a *run* be a (finite or infinite) sequence $(i_1, x_1), \ldots, (i_k, x_k), \ldots$, where x_j indicates which phase process P_{i_j} started or whether it accessed the shared variable. A run is called *proper* if the subsequence of phases corresponding to every process P_i is of the form REMAINDER, TRYING, CS, EXIT, REMAINDER, ...

A *scheduler* is a (probabilistic) function that on a finite run σ gives the identity of the next process to access the shared variable. It should satisfy the following property.

Scheduler-liveness: For each time t and any process P_j not in REMAINDER phase at time t, there exists a time $t' > t$ in which P_j makes a move.

Next, we discuss the correctness conditions of a randomized mutual exclusion algorithm. While the first three conditions are rather standard, the fairness definition is the one unique to the randomized solutions. These correctness conditions may be generalized in various ways without affecting the results. We discuss possible extensions of the conditions throughout the paper.

Mutual exclusion: At any time t there is at most one process in the CS phase. If there is a process in the CS phase then we say that the critical section is *closed*; otherwise, it is *open*.

Fault-freeness: If a process P_j moves from TRYING phase to the CS phase then eventually P_j moves from the CS phase to EXIT phase and from EXIT phase to REMAINDER phase. (For example, a protocol in which a process after entering the critical section gets into an infinite loop violates this condition.)

Deadlock-freeness: If the critical section is *open* and there is a process in TRYING phase, then eventually some process enters the CS phase.[6]

[4] We assume here the same adversary scheduler and the same correctness conditions as in [KR92].

[5] Note that since we are interested in this work in proving *lower* bounds, this assumption makes our job more complicated.

[6] The definition can be weakened to require that this will hold with probability 1, and all the

f-fairness: Let C_i be the time at which the ith closing of the critical section occurs. Let S_i be the set of processes in TRYING phase that were scheduled to access the shared variable between time C_{i-1} and C_i, excluding the process that entered the critical section at C_i.

1. If $S_i \neq \emptyset$ then one of the processes in S_i enters the critical section at C_{i+1}.
2. For every process $P_j \in S_i$, the probability that P_j enters at time C_{i+1} is at least $1/f(t)$, where $t = |S_i|$.[7]

In particular, for a constant c, we refer to $c \cdot t$-fairness as *linear*-fairness, and to t^c-fairness as *polynomial*-fairness.[8]

In the definition of f-fairness, we require that a process that tries to enter at time C_i will have a "good" chance to enter at the *next* time, i.e., C_{i+1}. At first sight, it seems more natural to require that a process that arrives between time C_{i-1} and C_i will have a good probability to enter at C_i, as defined in [Rab82]. However, as pointed out by [Sai92], such a statement is circular since the definition of the event C_i depends on whether the process enters the critical section or not, and it seems that there is no "acceptable" way to get around this problem. We follow here the solution suggested by [KR92], which requires the "good" chance to be only in the next time step.

2.2. Markov chains. Let $S = \{s_1, s_2, \ldots, s_k\}$ be a set of k states. A *Markov chain* is a real, nonnegative, $k \times k$ matrix $(Q_{i,j})$ with the property that the sum of elements in each row equals 1. It can be used to generate sequences of elements of S in the following way. Start in the initial state, say, s_1. At each step, if the last element in the sequence is s_i, move to state s_j with probability $Q_{i,j}$ (i.e., the probability of moving into state s_j depends only on the last state s_i and not on the whole history).

We say that a Markov chain $(Q_{i,j})$ is $(n, f(t))$-*live* if for every $1 \leq t \leq n$ the probability that the sequence generated by the above process visits in the tth step a state that was not visited during the first $t-1$ steps is at least $1/f(t)$.

It is sometimes convenient to think about the Markov chain as a complete directed graph on k nodes. Every edge $i \to j$ has a value $Q_{i,j}$ which is the probability of visiting node j in the next step when being in node i. The sequence of states, in this case, is usually called a *walk*.

3. Lower bound: Linear-fairness. In this section we describe the lower bound for the case of *linear-fairness*; that is, where the probability of each process entering the critical section is required to be inversely proportional to the number of processes trying to enter the critical section. To do so, we describe a strategy for the adversary scheduler, given a mutual exclusion algorithm $\mathcal{A}$, to plan a schedule in which the probability that a certain process (that the adversary wish to discriminate against) enters the critical section in a given round is smaller than what is required.

---

results of the paper will remain valid.

[7] The probability space is defined on prefixes of runs; therefore, the space is finite. Formally, the above requirement says that for any prefix of a run up to C_i, σ, which have a nonzero probability, the probability that P_j enters at time C_{i+1} given σ is at least $1/f(t)$. Later, when we will refer to an event as "happened in the past" we will mean that it is satisfied by σ.

[8] It is possible to relax the definition of fairness and to allow each party that was scheduled to access the shared variable between times C_{i-1} and C_i and that has not entered the critical section at times $C_i, C_{i+1}, \ldots, C_{i+d-1}$, for some parameter d, to compete on entering at time C_{i+d} with probability of success at least $1/f(t)$. The results and the proofs (with few minor changes) hold for such a definition as well.

1. Schedule P_n until it enters the critical section.
2. Schedule $P_1, \ldots, P_s, \ldots, P_t$ (each is scheduled once).
3. Schedule P_n until it exists the critical section.
4. Schedule $P_1, \ldots, P_s$ for M steps (in a round-robin).
5. Schedule $P_1, \ldots, P_n$ (in a round-robin).

FIG. 1. *Strategy for the adversary* (*assuming the existence of* s *and* t *as in Lemma* 1).

The schedule starts by scheduling the process P_n to access the shared variable until this process enters the CS phase; i.e., the critical section is *closed* (Figure 1, step 1). The deadlock-freeness property guarantees that this will eventually happen. Denote by d the number of steps taken by P_n before entering the CS phase, and by $v[n]$ the value that P_n wrote into the shared variable at this time. Then, the adversary schedules each of the processes P_1 to P_t (in order) to perform a single read-modify-write operation on the shared variable, where t is a parameter (Figure 1, step 2). We denote by $v[i]$ the value written by P_i into the shared variable. The proof of the lower bound has two parts. We first show that if t is *good* (in a sense that will be defined later) then the adversary can discriminate against P_t; namely, with high probability, process P_t will not enter the critical section (although scheduled to access the shared variable). Later, we show that if the shared variable is "too small" then a *good* t must exist. To introduce the idea of the proof we first assume that t satisfies an even stronger property, as formalized in the next lemma.

LEMMA 1. *Assume that there exists a specific* s, $1 < s < t$, *such that the probability that the value* $v[t]$ *written by* P_t *into the shared variable equals the value* $v[s]$ *written by* P_s *is at least* $1-\delta$. *Then there exists an extension of the above schedule such that the probability that* P_t *enters at either* C_1 *or* C_2 *is at most* $\delta+\varepsilon$, *where* ε *is arbitrarily small.*

Proof. Assume that $v[t] = v[s]$. That is, P_t wrote into the shared variable the same value as P_s (this happens with probability at least $1-\delta$). The adversary extends the schedule by first scheduling P_n to access the shared variable until it moves to the REMAINDER phase and the critical section is open (Figure 1, step 3). This is guaranteed by the fault-freeness property. Then (Figure 1, step 4), the adversary continues by scheduling only P_1 to P_s (say, by a round-robin). Observe that the only way that a process P_i can note that another process P_j was scheduled before it is if P_j changed the value of the shared variable. Hence, if indeed $v[t] = v[s]$, then in this case processes P_1 to P_s must operate as if P_{s+1} to P_t were not scheduled. This implies (by the deadlock-freeness property and the first part of the fairness property) that eventually some process P_i enters at C_1, and some other process P_j at C_2, where $1 \le i, j \le s$. More precisely, there exists a large enough M such that if $P_1, \ldots, P_s$ are scheduled to take M steps, then with probability at least $1-\varepsilon$, two of these processes enter at time C_1 and time C_2 (if this does not happen during the M steps this could be either because P_t did *not* write the same value as P_s or because none of $P_1, \ldots, P_s$ entered the critical section). Hence, the probability that P_t enters at either C_1 or C_2 is bounded by the probability that it did not write the same value as P_s plus the probability that M steps were not enough for $P_1, \ldots, P_s$, which is at most $\delta+\varepsilon$. ∎

The problem with the above lemma is that the adversary needs to know some fixed s, such that the probability that P_t writes to the shared variable the same value that was written by P_s, is "high." The next lemma shows that the same bound holds even when s is not fixed. First we define the notion of *good* t.

1. Schedule P_n until it enters the critical section.
2. Schedule $P_1, \ldots, P_t$ (each is scheduled once).
3. Schedule P_n until it exists the critical section.
4. For $i = 1, \ldots, t-1$
   Schedule $P_1, \ldots, P_i$ for M_i steps (in a round-robin).
5. Schedule $P_1, \ldots, P_n$ (in a round-robin).

FIG. 2. *Strategy for the adversary* (*assuming the existence of* t *which is* δ*-good*).

DEFINITION 1. *We say that* t *is* δ-good[9] *if the probability that the value* $v[t]$ *written by* P_t *into the shared variable equals one of* $v[1], \ldots, v[t-1]$ (*the values written by* $P_1, \ldots, P_{t-1}$, *respectively*) *is at least* $1 - \delta$.

LEMMA 2. *Given that* t *is* δ*-good, there exists an extension of the above schedule such that the probability that* P_t *enters at either* C_1 *or* C_2 *is at most* $\delta + \varepsilon$, *where* ε *is arbitrarily small.*

Proof. As t is δ-good, the adversary, who knows the algorithm used, knows that with high probability there exists an s ($1 \leq s < t$) such that $v[t]$ equals $v[s]$. However, the adversary has to overcome the fact that he does not know the value of s. He will do so by trying all the possible values of s. The problem is that trying one value of s, say $s = 9$, influences other values of s, say $s = 3$, since the processes may notice that $s > 3$. The first idea is to try $s = 1, 2, \ldots, t-1$ in this order. This guarantees that before trying $s = i$, the only processes scheduled are $P_1, \ldots, P_{i-1}$ (this is done by modifying step 4; see Figure 2).

Essentially, when the adversary checks whether $s = i$, it does the same thing as in the proof of Lemma 1 above. Namely, it schedules only $P_1, \ldots, P_i$. If, indeed, $s = i$, then the adversary is guaranteed that if it schedules only $P_1, \ldots, P_i$, eventually one of them would enter at C_1 and one at C_2 (it might be the same process in both cases). If the scheduler detects that $s \neq i$, then it continues to $i+1$. We are guaranteed that, with probability $1 - \delta$, there exists such an i.

We need to show how the adversary can check whether $s = i$ or $s \neq i$. If the adversary has a bound on the number of steps until the processes $P_1, \ldots, P_i$ would let one in C_1 and another in C_2, say M_i steps, it would schedule them this many steps. If no process would enter at either C_1 or C_2, then the scheduler is guaranteed that $s \neq i$. As in the proof of Lemma 1 it may be the case that such a bound M_i does not exist. For this reason it would compute the value of M_i such that if $s = i$ the probability that one of $P_1, \ldots, P_i$ enters at C_1 and C_2 during at most M_i steps (in a round-robin schedule) is at least $1 - \varepsilon$.

The probability that the scheduler misses the right value of s is ε (note that we do not care about the other cases). In addition, we assumed that there exists such an s, with probability $1 - \delta$. Therefore, the probability that P_t enters is at most $\delta + \varepsilon$. This is since this probability is bounded by the probability that there is no such s (bounded by ε), plus the probability that, given that there is such an s, the scheduler misses it (bounded by δ). □

So far, we proved that if there is a t which is δ*-good* then the adversary can discriminate against P_t. We now prove that such a t must exist if the number of values is "too small." At this point it is convenient to define the Markov chain $Q(\mathcal{A}, d)$ corresponding to a mutual exclusion algorithm $\mathcal{A}$ and an integer d (where d

[9] The term "good" is from the adversary point of view.

will be taken as the number of times P_n was scheduled before entering the critical section; this parameter is known to the adversary). Note that d does depend on $\mathcal{A}$, but for each specific d we have a different Markov chain. Recall that we assume, at this point, that all the processes run the same program.

States: The states of the Markov chain correspond to the possible values of the shared variable. In addition there is a special initial state q_0 (i.e., if we have a k-bit shared variable, then the Markov chain has $2^k + 1$ states).

Transition probabilities: For $i, j \geq 1$, the entry $Q_{i,j}$ equals the probability that a process, when invoked for the first time (i.e., it is in its initial state) and reading the value i from the shared variable, writes the value j. This probability is defined by the algorithm $\mathcal{A}$. For the initial state and $i > 0$, we define $Q_{0,i}$ to be the probability that the process P_n, before closing the critical section, wrote the value $v[n] = i$ (this probability depends on d!). Also, $Q_{i,0} = 0$ for all i.

The idea is that the behavior of a process which is scheduled to read the shared variable for the first time depends only on the current value of the shared variable and does not depend on the whole history of values. This Markov property enables us to describe the process of writes as a Markov chain. The relation between this Markov chain and the schedule we are constructing is formalized by the following claim; later we concentrate on analyzing the Markov chain.

CLAIM 1. *Fix a schedule as above. Also, let $\mathcal{A}$, d, and $Q(\mathcal{A}, d)$ be as above. Then, for every sequence of values $V_n, V_1, \ldots, V_i$,*

$$\begin{aligned}\Pr[(s_0 = V_n) \wedge (s_1 = V_1) \wedge \ldots \wedge (s_i = V_i)] \\ = \Pr[(v[n] = V_n) \wedge (v[1] = V_1) \wedge \ldots \wedge (v[i] = V_i)],\end{aligned}$$

where $s_0, s_1, s_2, \ldots$ is the sequence of states visited by the Markov chain.

Proof. The proof follows by an easy induction from the definition of the Markov chain. □

It follows from the definitions that if every t is not $\frac{1}{ct}$-good, then the corresponding Markov chain is $(n, c \cdot t)$-live; hence, if the Markov chain is not (n, ct)-live, then there exists a t which is $\frac{1}{ct}$-good. (Recall that a Markov chain $(Q_{i,j})$ is $(n, f(t))$-*live* if for every $1 \leq t \leq n$ the probability that the tth step reaches a state that was not visited during the first $t - 1$ steps is at least $1/f(t)$.) The following lemma gives a bound on the number of states of *any* Markov chain (not only those constructed as above) with linear-liveness property.

LEMMA 3. *Let $c \geq 0$ be any constant. Let $(Q_{i,j})$ be any Markov chain on k states which is $(n, c \cdot t)$-live. Then, $k > \frac{1}{c} \ln n$.*

Proof. For every $1 \leq i \leq n$, let X_i be a random variable which takes the value 1 if the Markov chain visits a new state in its ith step, and 0 otherwise. Clearly, $\sum_{i=1}^{n} X_i$ is at most the number of states k, and hence also $E[\sum_{i=1}^{n} X_i] \leq k$. By linearity of expectation, $E[\sum_{i=1}^{n} X_i] = \sum_{i=1}^{n} E[X_i]$. By the liveness of the Markov chain, for every i, $\text{Prob}[X_i = 1] \geq \frac{1}{ci}$. This implies that $E(X_i) \geq \frac{1}{ci}$. Combining all together, we get that $k \geq \sum_{i=1}^{n} \frac{1}{ci} > \frac{1}{c} \cdot \ln n$. □

THEOREM 4. *Every mutual exclusion algorithm $\mathcal{A}$ for n processes which guarantees $O(t)$-fairness requires a shared variable of $\Omega(\log \log n)$ bits.*

Proof. Consider the algorithm $\mathcal{A}$ and the corresponding Markov chain $Q(\mathcal{A}, d)$ and assume that the algorithm $\mathcal{A}$ guarantees ct-fairness. If the Markov chain $Q(\mathcal{A}, d)$ is not $(n - 1, 2ct)$-live, then there exists a t, $1 \leq t \leq n - 1$, which is $\frac{1}{2ct}$-good. By Lemma 2, there exists an extension of the basic schedule (in which P_n was scheduled d

times) such that the probability of P_t entering the critical section at either C_1 or C_2 is less than $\frac{1}{ct}$, contradicting the ct-fairness of the algorithm. Therefore, $Q(\mathcal{A}, d)$ must be $(n-1, 2ct)$-live. By Lemma 3, this implies that k, the number of states in this Markov chain, is at least $\frac{1}{2c}\ln(n-1)$. By the construction of the Markov chain, the number of bits in the shared variable used by $\mathcal{A}$ is $\log(k-1) \geq \log(\frac{1}{2c}\ln(n-1)-1) = \Omega(\log\log n)$, as claimed. □

Note that in the proof of Lemma 3 we do not use the fact that in each step we use the same transition matrix. In other words, the lemma holds even if we associate with every step i a different transition matrix $Q^{(i)}$. This implies that the lower bound of Theorem 4 still holds even if the processes are allowed to use different programs.

COROLLARY 5. *Every mutual exclusion algorithm for n processes which guarantees $O(t)$-fairness requires a shared variable of $\Omega(\log\log n)$ bits, even if each process runs a different program.*

In the above discussion, we assumed that the adversary knows which value of t is $\frac{1}{2ct}$-good. We can make this assumption because the adversary is given the algorithm $\mathcal{A}$, and it knows the number of steps d taken by P_n before entering the CS phase. Therefore, it can construct the above Markov chain. Based on this, the adversary can compute the probability of visiting a new state at any given step and hence find the value of t.

4. Lower bound: Nonlinear-fairness. In this section we extend the results from the case of linear-fairness to the case of polynomial (t^c, for $c > 1$) fairness. The proof goes along the same lines, except that the proof of Lemma 3 fails in this case, since $\sum_i 1/i^c = O(1)$, for $c > 1$. Thus, a different approach is required.

To simplify the proof, we assume that all the processes are identical (i.e., both code and initial state). At the end of the section we show that the proof can be extended to the case when the processes are not identical. Our goal now is to derive a lower bound for the number of states of (n, t^c)-live Markov chains.

Consider the k^2 values $Q_{i,j}$ of the Markov chain. We divide the proof into two cases according to the way these values are distributed in the interval $[0, 1]$. The easy case is when these values are "dense" in the interval. Lemma 6 below claims that in this case k must be "large." Then, we handle the more difficult case where there exists some "gap" in the interval $[0, 1]$ in which none of these k^2 values fall, and we show that in this case the Markov chain is not (n, t^c)-live.

LEMMA 6. *Let $\lambda > 1$ be a constant.*[10] *Let $(Q_{i,j})$ be a Markov chain over k states. If, for every $0 \leq \alpha \leq 1/2$ such that $\alpha^{\lambda k} \geq 1/n$, there exist i and j such that $Q_{i,j} \in (\alpha^{\lambda k}, \alpha]$, then $k = \Omega(\sqrt{\log\log n / \log\log\log n})$.*

Proof. Consider the sequence $\beta_\ell = 2^{-(\lambda k)^\ell}$ ($\ell = 0, 1, \ldots$). By the assumption, if $\beta_{\ell+1} \geq 1/n$ then the interval $(\beta_{\ell+1}, \beta_\ell]$ contains at least one of the values $Q_{i,j}$ (also note that these intervals are disjoint). Since there are at most k^2 such values, then $\beta_{k^2+1} < 1/n$; otherwise, not all the intervals contain a value $Q_{i,j}$. From this inequality we get that $k = \Omega(\sqrt{\log\log n / \log\log\log n})$. □

In the following we assume that there is such a gap; i.e., there exists an $\alpha \leq 1/2$ such that the interval $(\alpha^{\lambda k}, \alpha]$ contains no probability $Q_{i,j}$, and $\alpha^{\lambda k} \geq 1/n$. An edge $i \to j$ with probability $Q_{i,j} \leq \alpha^{\lambda k}$ is called α-light; otherwise, if $Q_{i,j} > \alpha$, it is called α-heavy. The assumption that there is a gap implies that every edge is either α-heavy or α-light. We consider a random walk of (a suitably chosen) length $t < n$. We show two main properties. The first is that the probability that in t steps of the Markov

[10] The value of λ depends on the value of the constant c.

chain some α-light edge is used is "small." The second is that the probability that we do not "cover" the graph induced by the α-heavy edges is "small." Before going into the details, we will make our choice of parameters, as follows:

$$t = \frac{\gamma k^2 c^2}{\alpha^{2k}} \qquad \text{and}$$
$$\lambda = \gamma' c \log c,$$

where γ and γ' are sufficiently large constants and k is the number of states. (Unfortunately, the best intuition that we can give for the choice of t and λ is that they make the proof go through.) We start by showing that the probability of traversing some α-light edge is negligible.

LEMMA 7. *The probability that any α-light edge is used in a walk of length t is less than $1/(2t^c)$.*

Proof. In each of the t steps, the walk can choose among at most $k-1$ α-light edges, each with probability at most $\alpha^{\lambda k}$. Therefore, the probability that any α-light edge is used is not more than $t \cdot k \cdot \alpha^{\lambda k}$. To see that this is less than $1/(2t^c)$, it is sufficient to show that $2t^{c+1}k\alpha^{\lambda k} < 1$. We now substitute the value of t into this inequality and we get that it is sufficient to prove $2\gamma^{c+1}k^{2c+3}c^{2c+2}\alpha^{(\lambda-2(c+1))k} < 1$. As $\alpha < 1/2$ it is enough that $2\gamma^{c+1}k^{2c+3}c^{2c+2} < 2^{(\lambda-2(c+1))k}$. This is satisfied as long as $(\lambda - 2(c+1))k > 1 + (c+1)\log\gamma + (2c+3)\log k + (2c+2)\log c$. Hence, choosing λ as above, with γ' sufficiently large, will satisfy the inequality, and the lemma follows. □

In the following we define what it means to cover a directed graph. Intuitively, a directed graph is covered by a walk if no new node can be reached.

DEFINITION 2. *A directed graph is* completely covered *by a walk W if each node that is reachable from the last node of the walk W has already been visited in W.*

Note that the above definition does *not* require that the walk visit *all* the nodes in the graph, just that there be no *new* nodes which can be reached from the last node. The next lemma gives a bound on the probability that we completely cover the graph induced by the α-heavy edges.

LEMMA 8. *Consider a Markov chain $(Q_{i,j})$ such that each transition probability is either α-heavy or α-light. The probability that after a walk W of t steps, which uses only α-heavy edges, the induced (directed) graph of α-heavy edges is not completely covered is less than $1/(2t^c)$.*

Proof. Recall that k is the number of states in the Markov chain. We divide the walk W into $b = \lceil t/k \rceil$ blocks of size k. Consider the location v of the walk at the beginning of a block. Either all the nodes reachable from v in the induced graph of α-heavy edges were already visited, or there is some node v', reachable from v, which was not visited yet. This implies that there is a (simple) path of length at most k from v to v' consisting of α-heavy edges. (There may be more than one such path; however, we cannot make any stronger assumption, e.g., the existence of an α-heavy edge connecting v to v'.) Therefore, the probability that the walk visits v' during the current block of steps is at least α^k.

By standard Chernoff bounds, the probability that the graph is not completely covered after t/k blocks is at most $e^{-\frac{t\alpha^k}{8k}}$. To see this, define a random variable X_i which is 1 if the graph is completely covered by the first $i-1$ blocks of the walk or if a new node is visited during the ith block of the walk. Otherwise, $X_i = 0$. By the above, the probability that X_i is 1 is at least $p = \alpha^k$. Let S be the sum of these random variables. That is, $S \stackrel{\triangle}{=} \sum_{i=1}^{b} X_i$. With these definitions, the event

$S \geq k$ implies that the graph is completely covered. The Chernoff bound shows that $\Pr(S \leq (1-\varepsilon)pb) \leq e^{-bp\varepsilon^2/2}$, which for $\varepsilon = 1/2$ and our choices of b and p gives $e^{-\frac{t\alpha^k}{8k}}$. Finally, note that $(1-\varepsilon)pb = (1/2)\alpha^k t/k$ which is greater than k for our choice of t. Therefore, $\Pr(S < k) \leq \Pr(S < (1-\varepsilon)pb) \leq e^{-\frac{t\alpha^k}{8k}}$.

Finally, we need to show that $e^{-\frac{t\alpha^k}{8k}} < 1/(2t^c)$. It is enough to show that $-\frac{t\alpha^k}{8k} < -\ln(2t^c)$ or that $2t > \frac{16k}{\alpha^k} c \ln(2t)$. It can be easily verified that for $D \geq 3$ the equation $x > D \ln x$ is true for any $x \geq D^2$. In our case we take $D = \frac{16ck}{\alpha^k}$. (Note that $c > 1, k \geq 1$, and $\alpha < 1$; hence, indeed $D \geq 3$.) Therefore, the choice of t (with γ sufficiently large) guarantees the inequality. The lemma follows. □

Given that the walk does not use any α-light edge, and since every edge is either α-light or α-heavy, the probability that in step t the walk visits a state in which it is already visited is at least the probability that a walk of length $t-1$ completely covers the induced graph of α-heavy edges (since, by the definition of "completely covered," the only nodes that can be reached in step t, by an α-heavy edge, have already been visited).

LEMMA 9. *Consider a Markov chain $(Q_{i,j})$ such that each transition probability is either α-heavy or α-light. For any $c > 1$, the Markov chain is not (n, t^c)-live.*

Proof. In order to show that the Markov chain is not (n, t^c)-live, it is sufficient to show that there exists a t, such that the probability that in step t a new state is visited is less than $1/t^c$. The probability of reaching a new state at step t is

$$\begin{aligned}
&\Pr(\text{new state in step } t)\\
&= \Pr(\text{new state in step } t | \alpha\text{-light edge is used}) \cdot \Pr(\alpha\text{-light edge is used})\\
&+ \Pr(\text{new state in step } t | \text{no } \alpha\text{-light edge is used}) \cdot \Pr(\text{no } \alpha\text{-light edge is used})\\
&\leq \Pr(\alpha\text{-light edge is used}) + \Pr(\text{new state in step } t | \text{no } \alpha\text{-light edge is used}).
\end{aligned}$$

The first summand is less than $1/(2t^c)$, by Lemma 7. If the graph of the α-heavy edges is covered and no α-light edge was used, we cannot reach a new state. Therefore, the second summand is not more than the probability of not covering the graph in $t-1$ steps (given that no α-light edge is used). By Lemma 8, this probability is also less than $1/(2t^c)$. Altogether, we get that the probability of visiting a new state in step t is less than $1/t^c$. This implies that the Markov chain does not have the required liveness property. □

COROLLARY 10. *Let $c \geq 0$ be any constant. Let $(Q_{i,j})$ be any Markov chain on k states which is (n, t^c)-live. Then, $k = \Omega(\sqrt{\log\log n / \log\log\log n})$.*

Proof. Lemma 6 shows that if there is no "gap" of the form $(\alpha^{\lambda k}, \alpha]$, then the claimed lower bound holds. Lemma 9 shows that if there is such a "gap," then the Markov chain is not (n, t^c)-live. □

THEOREM 11. *Every mutual exclusion algorithm for n processes which guarantees t^c-fairness requires a shared variable of $\Omega(\log\log\log n)$ bits.*

Proof. The proof is similar to the proof of Theorem 4, but using Corollary 10 instead of Lemma 3. Consider the algorithm $\mathcal{A}$ and the corresponding Markov chain $Q(\mathcal{A}, d)$, and assume that the algorithm $\mathcal{A}$ guarantees t^c-fairness. If the Markov chain $Q(\mathcal{A}, d)$ is not $(n-1, 2t^c)$-live, then there exists a $1 \leq t \leq n-1$ which is $\frac{1}{2t^c}$-good. By Lemma 2, there exists an extension of the basic schedule such that the probability that P_t enters the critical section at either C_1 or C_2 is less than $\frac{1}{t^c}$, contradicting the t^c-fairness of the algorithm. Therefore, $Q(\mathcal{A}, d)$ must be $(n-1, 2t^c)$-live. By Corollary 10, this implies that k, the number of states in this

Markov chain, is $\Omega(\sqrt{\log\log n/\log\log\log n})$. By the construction of the Markov chain, the number of bits in the shared variable used by $\mathcal{A}$ is $\log(k-1) = \Omega(\log\log\log n)$, as claimed. □

To relax the requirement that the processes have the same program, we make the following observations. For every process P_i, we can associate with its program $\mathcal{A}_i$ a Markov chain $Q(\mathcal{A}_i, d)$, as before. All those Markov chains have the same number of states k. If $k = \Omega(\sqrt{\log\log n/\log\log\log n})$, we are done. That is, the number of bits of the shared variable is $\Omega(\log\log\log n)$. By Lemma 6, if k is "too small" (i.e., $k = o(\sqrt{\log\log n/\log\log\log n})$), then for every process there is some gap. That is, one of the k^2 intervals $(\beta_{\ell+1}, \beta_\ell]$ considered in the proof of Lemma 6 is empty. Moreover, for n/k^2 of the processes the gap is in the *same* interval. Denote this interval by $(\alpha^{\lambda k}, \alpha]$. Now, consider only these processes and the α-heavy edges in the corresponding graphs. The number of ways of choosing for each of the k^2 edges whether it is heavy or not is 2^{k^2}. Therefore, there are $n' \stackrel{\triangle}{=} n/(k^2 \cdot 2^{k^2})$ processes with the same gap, and the same α-heavy edges. If we take only these processes, the same proof can be repeated. Finally, note that due to the double logarithmic relation between k and n, the number of processes we remained with is

$$n' = n/(k^2 \cdot 2^{k^2}) > n^{\varepsilon}$$

for some constant $\varepsilon > 0$. Hence, we also get a lower bound of $\Omega(\log\log\log n') = \Omega(\log\log\log n)$ for the case when processes may use different programs. We conclude with the following theorem.

THEOREM 12. *Every mutual exclusion algorithm for n processes which guarantees t^c-fairness requires a shared variable of $\Omega(\log\log\log n)$ bits, even if each process runs a different program.*

5. Upper bounds. In this section, we present some upper bounds to complete the picture. In fact, we do not explicitly present protocols. Instead, we present appropriate *lotteries*, where a lottery is just a probability distribution that allows processes to draw numbers ("tickets") in $\{1, 2, \ldots, B\}$. The "winners" of the lottery are those processes drawing the maximal drawn number. We use as a *black box* the following theorem, implicit in [KR92], that reduces the existence of mutual exclusion algorithms with certain fairness properties to the existence of lotteries that guarantee a certain probability of having a *unique winner*.

THEOREM 13 (see [KR92]). *Let f be a function, and n and B be integers. Assume that there exists a lottery for at most n processes, on B values, with the property that for every number of processes $1 \le t \le n$ and every participating process P_i with probability at least $1/f(t)$, the maximal drawn number was drawn by the process P_i, and all other participating processes draw strictly smaller numbers. Then, there exists a randomized mutual exclusion algorithm for n processes that guarantees f-fairness and uses a shared variable of $2\log B + O(1)$ bits.*

By this theorem, in order to prove the existence of mutual exclusion algorithms, it is enough to prove the existence of the appropriate lotteries. For example, the lottery used in [Rab82, KR92] assigns a probability of 2^{-j} for each value $1 \le j < B$ ($B = 4 + \log n$), and probability 2^{-B+1} for the value B. It is shown that this lottery gives $f(t) = O(t)$ and therefore can be used to achieve mutual exclusion with linear fairness.

Note that all the upper bounds we give immediately give upper bounds on the number of states of (n, f)-live Markov chains for the appropriate f's. We start by showing an upper bound for a constant-size shared variable.

THEOREM 14. *There exists a randomized mutual exclusion algorithm that uses a constant-size shared variable and guarantees* $1/2^t$*-fairness.*

Proof. We show a lottery with $f(t) = 2^t$; by Theorem 13, this completes the proof. In the lottery, each participating process P_i chooses a value in $\{1, 2\}$ with uniform distribution; i.e., the probability that P_i chooses each of the two values is $1/2$. For every participating process P_i, we are interested in the event in which P_i chooses the maximum value and it is unique. Since there are only two possible values, this is simply the event in which P_i chooses the value 2 and all other participating processes choose 1. The probability that P_i chooses the value 2 and all other participating processes choose 1 is exactly $1/2^t$; therefore, $f(t) = 2^t$. ∎

The next theorem derives a bound in the case where the fairness guarantee needs to be polynomial in t (note that in the previous theorem, the fairness guarantee is exponential in t). We show the result by exhibiting a different lottery for this case. This lottery implies an upper bound of $O(\log\log\log n)$ bits for mutual exclusion with polynomial-fairness.

THEOREM 15. *For any constant* $c > 1$*, there exists a randomized mutual exclusion algorithm that uses an* $O(\log\log\log n)$*-size shared variable and guarantees* $\Omega(1/t^c)$*-fairness.*

Proof. Again, we show a lottery with $f(t) = O(t^c)$; by Theorem 13, this completes the proof. Consider the following lottery: the value j is chosen with probability $1/2^{c^j}$, for $(j = 1, 2, \ldots, c' \log\log n)$, and the value 0 is chosen otherwise. For every integer t (the number of participants), let $\ell \geq 0$ be an integer such that $2^{c^\ell} \leq t < 2^{c^{\ell+1}}$ (the constant c' is chosen so as to guarantee that such an ℓ exists for every $t \leq n$). We are interested in the event in which P_i chooses a value $\ell+1$ and all other $t-1$ participating processes choose values at most ℓ. This clearly lower-bounds the probability that P_i is the unique process that chooses the maximum value. The probability that P_i chooses the value $\ell + 1$ is $1/2^{c^{\ell+1}}$. For each P_j, $j \neq i$, the probability that P_j chooses a value greater than or equal to $\ell + 1$ is

$$\sum_{k=\ell+1}^{c' \log\log n} \frac{1}{2^{c^k}} \leq \sum_{k=\ell+1}^{c' \log\log n} \left(\frac{1}{2^c}\right)^k < \frac{c''}{2^{c^{\ell+1}}},$$

where c'' is a constant (e.g., $c'' = 2\lceil 1/\log_2 c \rceil$ suffices). Therefore, the probability that P_j chooses a value less than or equal to ℓ is at least $1 - \frac{c''}{2^{c^{\ell+1}}}$. Since we have $t-1$ different P_j's, the probability that P_i chooses $\ell + 1$ and all other $t - 1$ participating processes choose values of at most ℓ is at least

$$\frac{1}{2^{c^{\ell+1}}} \cdot \left(1 - \frac{c''}{2^{c^{\ell+1}}}\right)^{t-1} \geq \frac{1}{2^{c^{\ell+1}}} \cdot \left(1 - \frac{c''}{2^{c^{\ell+1}}}\right)^{2^{c^{\ell+1}}} > \frac{1}{2t^c} \cdot \left(\frac{1}{2e}\right)^{c''},$$

which completes the proof of the theorem. (The proof remains similar in the case when we wish to get a lottery with $f(t) = \alpha t^c$ for a *particular* constant α.) ∎

ADAPTIVE HEURISTICS FOR BINARY SEARCH TREES AND CONSTANT LINKAGE COST*

TONY W. LAI† AND DERICK WOOD‡

Abstract. We present lower and upper bounds on adaptive heuristics for maintaining binary search trees using a constant number of link or pointer changes for each operation (constant linkage cost (CLC)). We show that no adaptive heuristic with an amortized linkage cost of $o(\log n)$ can be competitive. In particular, we show that any heuristic that performs $f(n) = o(\log n)$ promotions (rotations) amortized over each access has a competitive ratio of at least $\Omega(\log n/f(n))$ against an oblivious adversary, and any heuristic that performs $f(n) = o(\log n)$ pointer changes amortized over each access has a competitive ratio of at least $\Omega(\frac{\log n}{f(n)\log(\log n/f(n))})$ against an adaptive online adversary.

In our investigation of upper bounds we present four adaptive heuristics:

- a randomized, worst-case-CLC heuristic randomized two-promotion (R2P) whose expected search time is within a constant factor of the search time using an optimal tree; that is, it is statically competitive against an oblivious adversary;
- a randomized, expected-CLC heuristic (locally optimized randomized partial splay (LORPS)) that has $O(\log n)$ expected-amortized update time and is statically competitive against an oblivious adversary;
- a deterministic, amortized-CLC heuristic (locally optimized partial splay (LOPS)) that has $O(\log n)$ amortized update time and is statically competitive against an adaptive adversary;
- a practical, randomized heuristic (randomized partial splay (RPS)) that is not CLC but has performance bounds comparable with those of the splay heuristic of Sleator and Tarjan; it is statically competitive against an adaptive adversary.

The randomized heuristics use only constant extra space, whereas the deterministic heuristic uses $O(n)$ extra space.

Key words. adaptivity, self-adjustment, self-organization, binary search trees, constant linkage cost, expected amortization, competitive ratio

1. Introduction.

One of the most fundamental problems in computer science is the *dictionary problem:* we have a totally ordered universe U, and we want to maintain efficiently a set $S \subseteq U$ that supports the operations of *insert, delete,* and *member.* The *binary search tree* is a well-known and well-studied data structure that can support these operations in $O(\log n)$ time in the expected case. Many kinds of balanced trees have been proposed that can support all dictionary operations in $O(\log n)$ worst-case time [1, 11, 16]; however, these structures cannot adapt to nonuniform or skewed access patterns. We consider the problem of maintaining an *adaptive binary search tree* (also known as a self-organizing search tree [2] and a self-adjusting search tree [21]).

FIG. 2. *The two-promotion operations.*

Compared with balanced trees, adaptive trees have the disadvantage of requiring more restructuring, especially during accesses (searches). This additional work often makes adaptive trees less practical than balanced trees; for instance, the performance of splay trees [21] is worse than that of AVL trees unless the pattern of accesses is very highly skewed [4]. High overhead, though, is not inherent to adaptation in general. For instance, the move-to-front heuristic for sequential lists changes only a constant number of pointers for each operation, yet is very efficient in practice [7]. To restructure a tree, we use the promotion operation (see Figure 1), also known as a rotation, and the two-promotion operation (see Figure 2), also known as a splaying step.

We consider the problem of minimizing the restructuring that is required for each operation. Ideally, we would like adaptivity to have the following four properties:

1. It should change at most a constant number of pointers for each operation in the worst case; that is, it should have *CLC.*
2. It should support both accesses and updates.
3. Its running time should be within a constant factor of the time of any heuristic for sufficiently long sequences of operations; that is, it should be *competitive.*

4. It should use only constant extra space.

We are interested in the CLC restriction for at least three reasons. First, our main motivation is that CLC is crucial when binary search trees have adjunct secondary structures such as in priority–search trees [14], segment–range trees [20], and segment–segment trees [20]. (A weaker motivation is the storage of binary search trees on secondary memory when the CLC constraint implies that only a constant number of blocks have to be rewritten after an access.) In each case, a promotion in a primary binary search tree of size n typically causes an $\Omega(\log n)$-time update in its adjunct structure; therefore, $\Omega(k)$ promotions take $\Omega(k \log n)$ time. Since we want updates to take only $O(\log n)$ time in most circumstances, CLC updates are appealing. It is well known that insertions into an AVL tree are CLC, whereas deletions may cause $\Theta(\log n)$ promotions in an AVL tree of size n. This behavior is the reason for using red–black trees to implement priority–search trees since red–black trees have both CLC insertions and CLC deletions.

Second, the CLC constraint is, we believe, fundamental and should be investigated. Ottmann and Wood [17], for example, present a general framework for obtaining binary search trees that are CLC in the worst case. Third, it may provide insight into the dynamic optimality conjecture for splay trees (see the work of Cole [10]).

Various schemes for maintaining adaptive search trees have been proposed such as move-to-root [2], simple exchange [2], monotonicity [8], dynamic binary search [15], splaying [21], biasing [6], conditional rotation [9], weighted randomization [3], and deepsplaying [19]. Of these schemes, only simple exchange, conditional rotation, and weighted randomization are applicable to binary search trees and also are CLC. Simple exchange and conditional rotation are worst-case CLC but have an amortized access time of $\Theta(n)$. In contrast, weighted randomization is expected CLC and has an expected access time comparable with that of an optimal static tree for fixed access sequences. Simple exchange does not use extra space, whereas conditional rotation and weighted randomization use $O(n \log m)$ bits of extra space, where m is the number of performed accesses.

While some upper bounds are known for adaptive, constant-linkage-cost heuristics [2, 3, 9], few lower bounds are known. In section 3, we show that no worst-case-CLC heuristic can be competitive. Indeed, an online adaptive adversary can force any heuristic with an amortized linkage cost of $f(n) = o(\log n)$ to use a multiplicative factor of $\Omega(\frac{\log n}{f(n) \log(\log n / f(n))})$ more time than the splay heuristic to access an arbitrarily long sequence. In light of this lower bound, we replace property 3 with property 3′.

3′. The heuristic's access time should be within a constant factor of the time taken by any static tree for any sufficiently long access sequence; that is, the heuristic should be *statically competitive.*

Although this revised property may be unnecessarily weak, it can be considered both a minimum requirement for effective adaptation and a first step in the investigation of CLC adaptive heuristics. We leave as an open problem the investigation of lower bounds on competitiveness of arbitrary heuristics against an oblivious adversary.

Although we have not been able to improve on the results for splay trees under amortization, we can improve them with respect to the expected time taken by a sequence of operations. (Just as we can bound the greatest (or worst) and expected times taken by a single operation, we can also bound the greatest (or worst) and expected times taken by sequences of operations.) We present three statically competitive CLC heuristics and a statically competitive heuristic that is not CLC yet has performance bounds comparable with Sleator and Tarjan's splay trees. There are

TABLE 1
A comparison of the R2P, LORPS, LOPS, and RPS heuristics. LOPS is a deterministic heuristic, whereas R2P, LORPS, and RPS are randomized heuristics.

Heuristic	Linkage cost	Statically competitive	Update time	Extra space
R2P	$O(1)$ worst case	yes/obliv	$\Theta(n)$	$O(1)$
LORPS	$O(1)$ expected	yes/obliv	$O(\log n)$ expect	$O(1)$
LOPS	$O(1)$ amortized	yes/adap	$O(\log n)$ amort	$O(n)$
RPS	$O(\log n)$ amortized	yes/adap	$O(\log n)$ amort	$O(1)$

two kinds of results: we focus on accesses and consider static competitiveness, and we consider all three dictionary operations and compare the performance of the heuristics with the performance of red–black and splay trees.

The first (the R2P heuristic) is a randomized, worst-case-CLC heuristic that supports only accesses. The second (the LORPS heuristic) is a randomized, expected-CLC heuristic that supports updates in $O(\log n)$ expected time. The third (the LOPS heuristic) is a deterministic, amortized-CLC heuristic that also supports updates in $O(\log n)$ amortized time. The randomized heuristics use only constant extra space, or $O(\log n)$ bits of extra space in a bit-cost model, whereas the deterministic heuristic uses $O(n)$ extra space, or $O(n \log n)$ bits of extra space in a bit-cost model. The last (the RPS heuristic) is a new, practical, randomized heuristic that is not CLC but has a simple, efficient implementation and can be preferable to the splay heuristic when the pattern of accesses is stable. RPS supports updates in $O(\log n)$ amortized time, and it has $O(\log n)$-amortized linkage cost. A comparison of the heuristics is shown in Table 1.

2. Definitions. We define the *depth* or *level* of a node x of a tree to be the number of edges in the root-to-x path; the depth of the root is 0. We define (x, y) to be a *left edge* in a tree T if y is a left child of x in T. We define a *right edge* analogously.

In our analyses, we assign positive numbers called *weights* to each node in a tree. We define the *size* $s(x)$ of a node x to be the sum of the weights of all nodes in the subtree rooted at x. The *rank* $r(x)$ of x is $\log s(x)$. The *total rank* $R(T)$ of a tree T is the sum of all ranks in the tree. The *weighted path length* of a tree T is 0 if T is empty or the sum of all weights in T plus the weighted path lengths of T's left and right subtrees otherwise.

When analyzing an adaptive algorithm, we assume that it services requests generated by an adversary. An *oblivious adversary* generates a fixed sequence of requests in advance, without knowledge of the state of the adaptive algorithm. An *adaptive adversary* generates a request after seeing the effect of all previous requests on the state of the algorithm. Notice that when an adaptive algorithm is deterministic, adaptive and oblivious adversaries have the same power. We use this observation when analyzing the LOPS heuristic.

We may also compare the performance of an adaptive algorithm with the performance of an adversary. An *online adversary* services each request immediately after generating it, whereas an *offline adversary* can service requests after generating the entire request sequence. We thus have three distinct types of adversaries: oblivious, adaptive online, and adaptive offline. For more details, consult the work of Ben-David et al. [5].

Let $C_H(r_1, \ldots, r_m)$ be the cost incurred by an adaptive heuristic H when servicing the request sequence $r_1, \ldots, r_m$. Let $C_A(r_1, \ldots, r_m)$ be the cost incurred by an adversary A when servicing $r_1, \ldots, r_m$. We say that H is *c-competitive* against A if there is a real number e, independent of m, such that

$$E[C_H(r_1, \ldots, r_m) - c \cdot C_A(r_1, \ldots, r_m)] \leq e$$

for any finite sequence $r_1, \ldots, r_m$ generated by A. The *competitive ratio* of H is infimum over all c such that H is c-competitive.

Note that, in the definition of competitiveness, we use the same cost model for the heuristic H and the adversary A. We handicap the adversary by giving it a less advantageous cost model. Let $C_S(r_1, \ldots, r_m)$ be the cost incurred by a static structure (chosen by the adversary before it services the requests) for the request sequence $r_1, \ldots, r_m$. We say that an adaptive heuristic H is *statically c-competitive* against an adversary A, if there is a real number e, independent of m, such that

$$E[C_H(r_1, \ldots, r_m) - c \cdot C_S(r_1, \ldots, r_m)] \leq e,$$

for any finite sequence $r_1, \ldots, r_m$ of accesses generated by A, where the cost models for A and H are not necessarily the same. If H is statically c-competitive for some constant c, then we say that H is *statically competitive.* Note that we have outlawed updates within the framework of static competitiveness.

Let Φ be a potential function that maps each configuration of some data structure to a real number. We define the *expected-amortized time* a of an operation to be $E[t + \Phi(D') - \Phi(D)]$, where t is the actual time of the operation, and D and D' are the configurations of the data structure before and after the operation, respectively. Since E is a linear operator, $E[t] = a + E[\Phi(D)] - E[\Phi(D')]$; hence, we can show that the expected time of m operations is the sum of the expected-amortized times of the operations and the expected drop in potential. In other words,

$$E\left[\sum_{i=1}^{m} t_i\right] = E\left[\Phi_0 - \Phi_m + \sum_{i=1}^{m} a_i\right],$$

where t_i is the actual time of the ith operation, a_i is the expected-amortized time of the ith operation, Φ_0 is the initial potential, and Φ_i is the potential after the ith operation. By bounding the maximum drop in potential, we can use the expected-amortized time to obtain an upper bound on the expected time of a sequence of operations. This technique is analogous to the potential method of conventional amortized analysis. Lai [12] discusses expected-amortized time more thoroughly as do Ben-David et al. [5] and Raghavan and Snir [18].

3. Lower bounds. We use a pointer machine as the model of computation in the proofs of the lower bounds. We assume without loss of generality that a heuristic performs restructuring only after it searches for an accessed element.

We present two lower bounds. The first bound applies to a restricted model in which only promotions are used to restructure a tree, whereas the second bound applies to arbitrary pointer changes. The first model applies to randomized search trees [3] and establishes that although the heuristic is expected CLC, it cannot be competitive.

3.1. The restricted model. We prove that, for any function $f(n) = o(\log n)$, if a heuristic H performs at most $f(n)$ promotions amortized over accesses, then H has a competitive ratio of $\Omega(\log n/f(n))$ against an oblivious adversary. In the following, we say that a heuristic is *promotion based* if it uses only promotions to alter the shape of a tree.

To prove our lower bound on H's competitive ratio, the adversary maintains its tree using the splay heuristic [21]. The splay heuristic has three important properties: it has an amortized access time of $O(\log n)$, it moves accessed elements to the root, and it does not change the tree if the root element is accessed. Thus, the amortized time of accessing some element r times consecutively, using the splay heuristic, is $O(\log n + r)$.

The heuristic H, on the other hand, cannot quickly move elements to the root. In general, after $\log n/(2f(n))$ accesses, H cannot perform more than $\log n/2$ promotions. Thus, if an adversary knows an element x of depth at least $\log n$ in H's tree, and accesses it $r \leq \log n/(2f(n))$ times, then x will still have depth $\Omega(\log n)$ afterward, which implies that H requires $\Omega(r \log n)$ time. Using this line of reasoning, we can easily establish a lower bound of $\Omega(\log n/f(n))$ on the competitive ratio of H against an adaptive, online adversary that uses the splay heuristic.

To show that an oblivious adversary can force poor performance from H, we show that an oblivious adversary can consistently access nodes of great depth in a tree that is maintained by any promotion-based heuristic. Let $\mathrm{rev}_k(i)$ be the number resulting from reversing the bits of a k-bit number i. Wilber [22] proved that if $n = 2^k$, then there exists a fixed sequence of length n, namely $\langle \mathrm{rev}_k(0), \ldots, \mathrm{rev}_k(n-1)\rangle$, that requires $\Omega(n \log n)$ access time in a search tree of size n for the n keys $0 \ldots n-1$, using any promotion-based heuristic.

LEMMA 3.1 (Wilber). *Let T be a tree of size $n = 2^k$ that contains nodes labeled $0, \ldots, n-1$. Assume that we maintain T using an adaptive promotion-based heuristic, and that we are allowed to access only the root element. The time to access the sequence $S_1 = \langle \mathrm{rev}_k(0), \ldots, \mathrm{rev}_k(n-1)\rangle$ is at least $n \log n + 1$; that is, the number of promotions required to access S_1 is at least $n \log n - n + 1$.*

Wilber's lower bound can be easily extended for the case where n is not a power of 2; it is straightforward to extend Wilber's lower bound to show that, for any $0 \leq k \leq \lfloor \log n \rfloor$, the number of promotions to access the sequence $\langle \mathrm{rev}_k(0), \ldots, \mathrm{rev}_k(2^k - 1)\rangle$ is at least $k \cdot 2^k - 2^k + 1$.

Wilber observed that limiting accesses to only the root is not a serious limitation, since we can access a node of depth d by promoting it to the root and returning it to its original position, at the expense of performing $2d$ extra promotions. That is, if we have a general heuristic that can access S_1 in A time using P promotions, then we can transform it into a heuristic that performs only root accesses and uses at most $2A - n + P$ promotions to access S_1. Thus, Wilber's lower bound implies that there is a tradeoff between the access time and the number of promotions performed for general promotion-based heuristics, as we now claim.

COROLLARY 3.2. *Let T be a tree of size n that contains nodes labeled $0, \ldots, n-1$, let $k = \lfloor \log n \rfloor$, and let $N = 2^k$. Assume that we maintain T using an adaptive promotion-based heuristic. If we access the sequence $S_1 = \langle \mathrm{rev}_k(0), \ldots, \mathrm{rev}_k(N-1)\rangle$, then the access time A and number P of promotions performed satisfies $2A + P \geq N \log N + 1$.*

We prove our main theorem on the competitiveness of H as follows. Let S_r be the sequence obtained from the sequence $S_1 = \langle \mathrm{rev}_k(0), \ldots, \mathrm{rev}_k(2^k - 1)\rangle$ by repeating

each element r times. We note that the splay heuristic requires $\Theta(n \log n)$ time to access S_r, whereas we show that heuristic H requires $\Omega(rn \log n)$ time, provided that $r = \Theta(\log n / f(n))$. Finally, we note that if a heuristic H performs $f(n)$ promotions amortized over accesses, for some function f, then there exists a function g such that H performs at most $g(n) + m \cdot f(n)$ promotions in its first m accesses for all m.

THEOREM 3.3. *For any functions f and g such that $f(n) = o(\log n)$, if a promotion-based heuristic H performs at most $g(n) + m \cdot f(n)$ promotions in its first m accesses, for all m, then H has a competitive ratio of $\Omega(\log n / f(n))$ against an oblivious adversary.*

Proof. Without loss of generality, assume that the elements are labeled $0, \ldots, n-1$. Let $N = 2^{\lfloor \log n \rfloor}$ and, for $0 \le i \le N-1$, let $x_i = \mathrm{rev}_{\lfloor \log n \rfloor}(i)$. Let $r = \lfloor \log N / (8f(n)) \rfloor$ and let $S_r = \langle x_0 \rangle^r \langle x_1 \rangle^r \ldots \langle x_{N-1} \rangle^r$. We assume that n is large enough such that $r \ge 1$. Since r has been chosen to be $O(\log n)$, the splay heuristic takes time $O(n \log n)$ to access S_r. We claim that, for all $q \ge \max(2g(n), 1)$, the time to access $(S_r)^q$ using heuristic H is $\Omega(qn \log^2 n / f(n))$. Since the splay heuristic can access $(S_r)^q$ in $O(qn \log n)$ time, the claim implies that H has a competitive ratio of $\Omega(\log n / f(n))$. To prove the claim, it is sufficient to show the following two facts. First, there are at least $\lceil q/2 \rceil$ accesses of S_r in which we perform at most $N \log N/4 + 1$ promotions. Second, if we perform at most $N \log N/4 + 1$ promotions when accessing S_r, then the access time is $\Omega(N \log^2 N / f(n))$.

Because the sequence $(S_r)^q$ is of length qrN, the heuristic H performs at most $g(n) + qrN \cdot f(n)$ promotions when accessing $(S_r)^q$. Observe that there must be at least $\lceil q/2 \rceil$ accesses of S_r in which H performs no more than $2\left[g(n) + qrN \cdot f(n)\right]/q = 2g(n)/q + 2rN \cdot f(n)$ promotions. Since $q \ge 2g(n)$, we have $2rN \cdot f(n) + 2g(n)/q \le 2rN \cdot f(n) + 1 \le N \log N/4 + 1$.

It remains to show that if we access S_r using at most $N \log N/4 + 1$ promotions, then the access time is $\Omega(n \log^2 n / f(n))$. For $0 \le i \le N-1$, let t_i be the time required for the first access of x_i in S_r and, for $0 \le i \le N-1$ and $1 \le j \le r$, let p_{ij} be the number of promotions performed after accessing the jth occurrence of x_i. Consider a heuristic H' that performs the same promotions when accessing x_i as the heuristic H does when accessing $\langle x_i \rangle^r$ for all i. Observe that the access time of H' over S_1 is exactly $\sum_{i=0}^{N-1} t_i$. Since H' performs at most $N \log N/4 + 1$ promotions when accessing $S_1 = x_0 x_1 \ldots x_{N-1}$, Corollary 3.2 implies that $\sum_{i=0}^{N-1} t_i \ge 3N \log N/8$. Finally, observe that the time to access the jth occurrence of x_i is at least $t_i - \sum_{k=1}^{j-1} p_{ik}$, since we can move x_i upward at most $\sum_{k=1}^{j-1} p_{ik}$ levels after x_i was first accessed. Therefore, the access time A is at least

$$\begin{aligned}\sum_{i=0}^{N-1} \sum_{j=1}^{r} \left[t_i - \sum_{k=1}^{j-1} p_{ik} \right] &= \sum_{i=0}^{N-1} \sum_{j=1}^{r} t_i - \sum_{i=0}^{N-1} \sum_{j=1}^{r} \sum_{k=1}^{j-1} p_{ik} \\ &= r \cdot \sum_{i=0}^{N-1} t_i - \sum_{i=0}^{N-1} \sum_{j=1}^{r} \sum_{k=1}^{j-1} p_{ik}.\end{aligned}$$

Since $\sum_{i=0}^{N-1} \sum_{j=1}^{r} p_{ij} \le N \log N/4 + 1$, we have

$$\sum_{i=0}^{N-1} \sum_{j=1}^{r} \sum_{k=1}^{j-1} p_{ik} \le \frac{rN \log N}{4} + r;$$

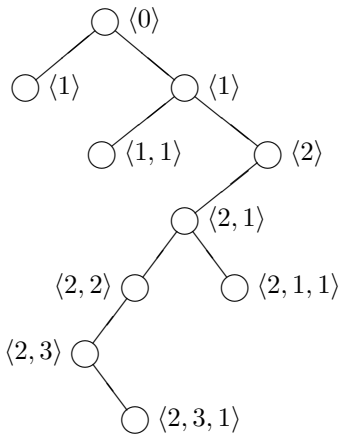

FIG. 3. *Turn sequences in a tree.*

thus,

$$A \geq r \cdot \frac{3N \log N}{8} - r \cdot \frac{N \log N}{4} - r$$
$$= \Omega\left(\frac{N \log^2 N}{f(n)}\right). \qquad \square$$

3.2. The general model. We now consider the general case in which we may detach and attach arbitrary edges to modify the shape of the tree. We prove that, for any functions $g(n)$ and $f(n) = o(\log n)$, if a heuristic H attaches and detaches at most $g(n) + m \cdot f(n)$ pointers in its first m accesses, for all m, then H has a competitive ratio of at least $\Omega(\frac{\log n}{f(n) \log(\log n / f(n))})$ against an adaptive, online adversary.

Because we allow arbitrary pointer changes, the lower bound of Wilber does not help us. Instead, we analyze what we call the *turn sequences* of nodes. We say that a node x has turn sequence $\langle a_1, \ldots, a_k \rangle$ if the root-to-x path consists of either a_1 left edges, a_2 right edges, a_3 left edges, and so forth, or a_1 right edges, a_2 left edges, a_3 right edges, and so forth; see Figure 3. We also call each path of left edges and each path of right edges a *segment*. More formally, we define a turn sequence as follows.

DEFINITION 3.4. *Let x be a node on level l in a tree T. Let $U = \langle a_1, a_2, \ldots, a_t \rangle$ be a sequence of nonnegative integers. For $0 \leq i \leq l$, let x_i be the ancestor of x on level i. Let $h(i) = j$ if $\sum_{k=1}^{j-1} a_k \leq i < \sum_{k=1}^{j} a_k$. We say that x has* turn sequence U *if one of the following three statements holds.*

1. *x is the root of T, $a_1 = 0$, and $t = 1$.*
2. *$l = \sum_{i=1}^{t} a_i$; for all i, $1 \leq i \leq t$, $a_i \geq 1$; and, for all i, $0 \leq i < l$ (x_i, x_{i+1}) is a left edge if and only if $h(i)$ is even.*
3. *$l = \sum_{i=1}^{t} a_i$; for all i, $1 \leq i \leq t$, $a_i \geq 1$; and, for all i, $0 \leq i < l$ (x_i, x_{i+1}) is a left edge if and only if $h(i)$ is odd.*

If x has turn sequence U, then we say that the root-to-x path has $t-1$ turns*, or x has $t-1$* turns*. We also define the jth* segment *to be the set of edges $\{(x_i, x_{i+1}) : h(i) = j\}$.*

To prove our lower bound, we first characterize how quickly we can move a node closer to the root; we show that one pointer change can shorten a path to a node by

at most one segment. We then use a combinatorial argument to prove that, for any tree T, either the height of T is large or there is a node x in T that has depth $\Omega(\log n)$ even if we remove many segments in the root-to-x path. Thus, for any heuristic H of linkage cost $o(\log n)$, an adversary can always access an element x some number of times r such that the total access time of $\langle x \rangle^r$ using heuristic H is $\omega(\log n)$, while the amortized access time of $\langle x \rangle^r$ using the splay heuristic is $O(\log n)$.

LEMMA 3.5. *Suppose that a node x on level l in a tree T has turn sequence $\langle a_1, \ldots, a_k \rangle$. For all j, $1 \le j \le k$, let b_j be the jth smallest element of the multiset $\{a_i : 1 \le i \le k\}$. If p pointers in T are detached and p new pointers are attached to obtain a new tree T', then the depth of x in T' is at least $\sum_{i=1}^{k-p} b_i$.*

Proof. By definition of a segment, the root-to-x path in T has k segments $S_1, \ldots, S_k$. Since p pointers are detached to obtain T', at least $k-p$ segments are unaffected and occur in both T and T'. To prove that the depth of x in T' is at least $\sum_{i=1}^{k-p} b_i$, it is sufficient to show that, for any j, if the edges in a segment S_j are in T', then S_j is in the root-to-x path in T', or the lowest node z in S_j is an ancestor of x. Consider the bottom edge (y, z) of S_j. If $z \ne x$, then by definition of a segment, x falls between y and z in an inorder traversal of T and, thus, of T', which implies that z must be an ancestor of x. □

Let n_{ij} be the maximum possible number of nodes on level i with j turns in a tree and N_{ht} be the maximum possible number of nodes of a tree of height h such that each node has fewer than t turns. By definition, a tree of height h has nodes of depth at most $h-1$, so $N_{ht} \le \sum_{i=0}^{h-1} \sum_{j=0}^{t-1} n_{ij}$. We now relate the height of a tree T with the size of T and the maximum number of turns in T.

LEMMA 3.6. *If $t \le h/3$, then $N_{ht} < 1 + 4\binom{h-1}{t}$.*

Proof. Observe that $n_{00} = 1$ and $n_{10} = 2$. Also note that, for $i > 1$, a node on level i with t turns must have a parent on level $i-1$ with either t or $t-1$ turns if $t > 0$. Hence, for $i > 1$ and $0 \le j \le i-1$, we have $n_{ij} \le n_{i-1,j-1} + n_{i-1,j}$, where $n_{k,-1} = n_{k,k} = 0$ for all k. By induction, we can show that $n_{ij} \le 2\binom{i-1}{j}$ for $i \ge 1$ and $0 \le j \le i-1$.

Therefore, the maximum number N_{ht} of nodes in a tree of height h in which each node has fewer than t turns is

$$\begin{aligned}
\sum_{i=0}^{h-1} \sum_{j=0}^{t-1} n_{ij} &= 1 + \sum_{i=1}^{h-1} \sum_{j=0}^{t-1} n_{ij} \\
&\le 1 + 2 \sum_{i=1}^{h-1} \sum_{j=0}^{t-1} \binom{i-1}{j} \\
&= 1 + 2 \sum_{j=0}^{t-1} \sum_{i=0}^{h-2} \binom{i}{j} \\
&= 1 + 2 \sum_{j=0}^{t-1} \binom{h-1}{j+1}.
\end{aligned}$$

Since $t \le h/3$, we have, for all $k \le t$,

$$\binom{h-1}{k-1} \le \frac{1}{2} \binom{h-1}{k}.$$

Thus,

$$N_{ht} \le 1 + 2\sum_{j=1}^{t} 2^{j-t}\binom{h-1}{t} < 1 + 4\binom{h-1}{t}. \qquad \square$$

COROLLARY 3.7. *If $t \le h/3$, then $N_{h+1,t} < 1 + 4(eh/t)^t$.*

Proof. The proof is immediate from Lemma 3.6 and the fact that $(h-1)\cdots(h-t) < h^t$ and $t! \ge t^t e^{-t}$. $\square$

Corollary 3.7 implies that if the maximum number of turns in a tree T of size n is small, then the height of T must be large compared with $\log n$. We use this fact to prove that, for any tree T and any function $f(n) = o(\log n)$, either T is of height $\Omega(\log^2 n/f(n))$ or there is a node x in T such that the depth of x is $\Omega(\log n)$ even if we remove $O(\log n/\log(\log n/f(n)))$ segments in the root-to-x path.

LEMMA 3.8. *For any function $f(n) = o(\log n)$ and any tree T of sufficiently large size n, one of the following two statements holds.*

1. *T is of height at least $\log^2 n/f(n)$.*
2. *There is a node with turn sequence $\langle a_1, \ldots, a_k\rangle$ such that $k \ge p$ and $\sum_{i=1}^{k-p} b_i \ge \log n/4$, where b_i is the ith smallest element of the multiset $\{a_1, \ldots, a_k\}$, and $p = \lfloor \frac{\log n}{8[4+\log e+\log(\log n/f(n))]} \rfloor$.*

Proof. We prove the lemma by contradiction. Because at most two nodes have the same turn sequence, the n nodes of T must have at least $n/2$ distinct turn sequences. Hence, it is sufficient to show that there are at most $o(n)$ distinct turn sequences $\langle a_1, \ldots, a_k\rangle$ such that $a_1 + \cdots + a_k < \log^2 n/f(n)$ and $k < p$ or $\sum_{i=1}^{k-p} b_i < \log n/4$.

Let $H = \lceil \log^2 n/f(n)\rceil - 1$. Corollary 3.7 implies that the number of distinct turn sequences $\langle a_1, \ldots, a_k\rangle$ such that $a_1 + \cdots + a_k \le H$ and $k < p$ is at most $N_{H+1,p} < 1 + 4(\frac{eH}{p})^p < 1 + 4(\frac{e\log^2 n}{f(n)p})^p$. We claim that $N_{H+1,p} < 1 + 4n^{1/4}$. It is sufficient to show that $p\log(\frac{e\log^2 n}{f(n)p}) < \log n/4$. Note that, by the definition of p, we have $p \ge \frac{\log n}{16[4+\log e+\log(\log n/f(n))]}$ for sufficiently large n. Now,

$$\begin{aligned} p\log\left(\frac{e\log^2 n}{f(n)p}\right) &\le p\log\left(\frac{e\log^2 n}{f(n)}\cdot\frac{16[4+\log e+\log(\frac{\log n}{f(n)})]}{\log n}\right) \\ &= p\log\left(16e\cdot\frac{\log n}{f(n)}\left[4+\log e+\log\left(\frac{\log n}{f(n)}\right)\right]\right) \\ &= p\left[4+\log e+\log\left(\frac{\log n}{f(n)}\right)+\log\left(4+\log e+\log\left(\frac{\log n}{f(n)}\right)\right)\right] \\ &< \frac{\log n}{8[4+\log e+\log(\frac{\log n}{f(n)})]}\cdot 2\cdot\left[4+\log e+\log\left(\frac{\log n}{f(n)}\right)\right] \\ &= \frac{\log n}{4}. \end{aligned}$$

Observe that any turn sequence $\langle a_1, \ldots, a_k\rangle$ such that $a_1 + \cdots + a_k \le H$ and $\sum_{i=1}^{k-p} b_i < \log n/4$ can be constructed by interleaving two sequences $\langle c_1, \ldots, c_p\rangle$ and $\langle d_1, \ldots, d_{k-p}\rangle$ sequences such that $\sum_{i=1}^{k-p} d_i \le M$, where $M = \lceil \log n/4\rceil - 1$. The number t of such turn sequences $\langle a_1, \ldots, a_k\rangle$ is at most the product of the number of turn

sequences $\langle c_1, \ldots, c_p\rangle$, the number of turn sequences $\langle d_1, \ldots, d_{k-p}\rangle$, and the number of interleavings of $\langle c_1, \ldots, c_p\rangle$ and $\langle d_1, \ldots, d_{k-p}\rangle$, summed over all k. Clearly, the number of turn sequences $\langle c_1, \ldots, c_p\rangle$ is at most $N_{H+1,p} \leq 1+4n^{1/4}$ since $\sum_{i=1}^{p} c_i < H+1$. Also, there are at most $\binom{M}{k-p}$ sequences $\langle d_1, \ldots, d_{k-p}\rangle$ such that $d_1 + \cdots + d_{k-p} \leq M$ since $d_1, \ldots, d_{k-p} \geq 1$. The number of interleavings of $\langle c_1, \ldots, c_p\rangle$ and $\langle d_1, \ldots, d_{k-p}\rangle$ is $\binom{k}{p}$. Note that $p \leq k$ and $k - p \leq M$, which imply that $p \leq k \leq p + M$. Therefore, the number t of possible turn sequences $\langle a_1, \ldots, a_k\rangle$ such that $a_1 + \cdots + a_k \leq H$ and $\sum_{i=1}^{k-p} b_i \leq M$ is at most

$$\begin{aligned}\sum_{k=p}^{p+M}\left[(1+4n^{1/4})\binom{M}{k-p}\binom{k}{p}\right] &= (1+4n^{1/4})\sum_{j=0}^{M}\left[\binom{M}{j}\binom{j+p}{p}\right] \\ &< (1+4n^{1/4})\binom{M+p}{p}\sum_{j=0}^{M}\binom{M}{j} \\ &= (1+4n^{1/4})\binom{M+p}{p}2^M.\end{aligned}$$

Since $M + p < H$ for large n, we know that $\binom{M+p}{p} < \binom{H}{p} < (\frac{eH}{p})^p < n^{1/4}$. Also, $2^M < 2^{\log n/4} = n^{1/4}$. Thus, $t = O(n^{1/4} \cdot n^{1/4} \cdot n^{1/4}) = O(n^{3/4})$. Therefore, there are at most $O(n^{3/4}) = o(n)$ distinct turn sequences $\langle a_1, \ldots, a_k\rangle$ such that $a_1 + \cdots + a_k < \log^2 n/f(n)$, and $k < p$ or $\sum_{i=1}^{k-p} b_i < \log n/4$, which completes the proof. □

The proof of the lower bound for arbitrary pointer changes is now straightforward.

THEOREM 3.9. *For any functions f and g such that $f(n) = o(\log n)$, if a heuristic H performs at most $g(n) + m \cdot f(n)$ pointer changes during its first m accesses, for all m, then H has a competitive ratio of $\Omega(\frac{\log n}{f(n)\log(\log n/f(n))})$ against adaptive, online adversaries.*

Proof. Let $p = \lfloor \frac{\log n}{8[4+\log e+\log(\log n/f(n))]} \rfloor$ and $r = \lfloor (p-2)/(2f(n)) \rfloor$. We assume that n is large enough to ensure that $r \geq 1$. Consider the following algorithm for generating accesses for a tree T. If T is of height at least $\log^2 n/f(n)$, then locate the leftmost deepest node and access it r times. Otherwise, Lemma 3.8 implies that there exists a node x with turn sequence $\langle a_1, \ldots, a_k\rangle$ such that $k \geq p$ and $\sum_{i=1}^{k-p} b_i \geq \log n/4$, where b_i is the ith smallest element of the multiset $\{a_1, \ldots, a_k\}$; access x a total of r times. Note that, in either case, if at most p pointers are changed during r accesses, then the total access time is $\Omega(\frac{\log^2 n}{f(n)\log(\log n/f(n))})$.

Suppose an adversary applies the above algorithm I times to obtain the access sequence $S = \langle v_1\rangle^r\langle v_2\rangle^r \ldots \langle v_I\rangle^r$, where $I \geq \max(n, g(n))$. The splay heuristic takes only $O(I \log n + n \log n) = O(I \log n)$ time to access S. On the other hand, the heuristic H performs at most $g(n) + r \cdot I \cdot f(n) \leq p/2 \cdot I$ pointer changes when accessing S, which implies that H changes at most p pointers during at least $\lfloor I/2 \rfloor$ access sequences of the form $\langle v_j\rangle^r$. Hence, H requires at least $\Omega(I \cdot \frac{\log^2 n}{f(n)\log(\log n/f(n))})$ time to access S; therefore, it has a competitive ratio of $\Omega(\frac{\log n}{f(n)\log(\log n/f(n))})$. □

An unfortunate consequence of our lower bounds is that no $o(\log n)$-linkage-cost heuristic can have two desirable properties of the splay heuristic, the working set property, and the dynamic finger property, because either of the properties is sufficient to obtain the upper bounds on the splay heuristic used in our proofs. The working set property implies that a heuristic can quickly retrieve an element that was recently accessed. For splay trees, Sleator and Tarjan [21] proved that the amortized time

to access a sequence $\langle x_1, \ldots, x_m \rangle$ is $O(m + n \log n + \sum_{i=1}^{m} \log(t(i) + 1))$, where $t(i)$ is the number of distinct elements accessed between the ith access and the previous access of x_i, for $i = 1, \ldots, m$. The dynamic finger property implies that a heuristic can quickly access an element that is near the previously accessed element; for splay trees, Cole [10] showed that the amortized time to access $\langle x_1, \ldots, x_m \rangle$ is $O(m + n \log \log n + \sum_{i=1}^{m-1} \log(|k_{i+1} - k_i| + 1))$, where k_i is the symmetric-order position of x_i among the n tree elements for $i = 1, \ldots, m$.

4. Upper bounds. We now turn our attention to the problem of upper bounds. We present new heuristics that are based on the splay heuristic of Sleator and Tarjan [21]. In this section, we introduce three CLC heuristics and, in section 5, we present a practical, randomized, non-CLC heuristic. The splay heuristic two-promotes an accessed node until it reaches the root; this operation is called a *splay.* Sleator and Tarjan proved that the splay heuristic is statically competitive and conjectured that it is in fact competitive. Unfortunately, the splay heuristic has an *amortized linkage cost of* $\Theta(\log n)$. To achieve constant linkage cost, our heuristics perform only part of a splay. This approach, however, may not be adequate to achieve a low search cost, so we also use an extra restructuring step called a *local optimization* in two of the heuristics.

4.1. The randomized two-promotion heuristic (R2P). The first heuristic we present is a very simple one that supports only accesses. In the R2P heuristic, we attempt to perform $(2/n)$ths of the work of the splay heuristic. More precisely, suppose we access a node x on level l. We generate a random number L uniformly between 0 and $n - 1$, inclusive. If $L \leq l$, then we two-promote x's ancestor on level L. Otherwise, we do nothing. Clearly, the R2P heuristic is worst-case CLC, since we perform at most two promotions on each access. Also, it requires only constant extra space, and it can be implemented as a single top-down pass through the tree. Although the R2P heuristic is so simple, it achieves a surprisingly low expected access time, as we prove below.

Before analyzing the R2P heuristic, we briefly recall Sleator and Tarjan's amortized analysis of the splay heuristic [21]. They chose the potential $\Phi(T)$ of a tree T to be the total rank $R(T)$, and they analyzed the effect of a promotion and a two-promotion on $R(T)$.

LEMMA 4.1 (Sleator and Tarjan [21]). *The change in $R(T)$ after promoting a node x in a tree T is no greater than $3(r'(x) - r(x))$ if x is of depth of at least 1, and the change in $R(T)$ after two-promoting x is no greater than $3(r'(x) - r(x)) - 2$ if x is of depth at least 2, where $r'(x)$ is the rank of x after the restructuring operation.*

Sleator and Tarjan also showed that the change in $R(T)$ after splaying a node x on level l is no more than $3(r(t) - r(x)) - l + 1$, where t is the root of T.

LEMMA 4.2 (Sleator and Tarjan [21]). *Let t be the root of a tree T, and let x be a node on level l in T. The change in $R(T)$ after splaying x is no more than $3(r(t) - r(x)) - 2\lfloor l/2 \rfloor$.*

Since the time to access x is $l + 1$, the amortized time of splaying x is no more than $3(r(t) - r(x)) + 2$. By choosing node weights appropriately, we obtain various bounds. For example, if we assign a weight of 1 to each node, then the rank $r(t)$ of the root is $\log n$, so we obtain an $O(\log n)$ amortized access time.

Note that the splay heuristic two-promotes only half of the ancestors of an accessed node x. If we two-promote each ancestor of x with probability p, where the probabilities may or may not be independent, then we expect to do $2p$ths of the work

of the splay heuristic. We prove, in the following, that the expected change in $R(T)$ from this two-promotion scheme is essentially $2p$ times the change in $R(T)$ using the splay heuristic.

LEMMA 4.3. *Let t be the root of a tree T and x be a node of T on level l. Let x_i be the ancestor of x on level i for $i = 0, \ldots, l$. Suppose that, for $i = 0, \ldots, l$, the probability of each x_i being two-promoted is p such that for all j if x_j is two-promoted, then x_{j-1} and x_{j-2} are not. Then, the expected change ΔR in $R(T)$ is at most $p[6(r(t) - r(x)) - 2(l-1)]$.*

Proof. The lemma trivially holds if $l = 0$. If $l = 1$, then Lemma 4.1 implies that the expected change in potential is $\Delta R \leq p[3(r(x_0) - r(x_1))] < p[6(r(t) - r(x))]$. Finally, if $l \geq 2$, then Lemma 4.1 implies that

$$\begin{aligned}
\Delta R &\leq p[3(r(x_0) - r(x_1))] + p\sum_{i=2}^{l}[3(r(x_{i-2}) - r(x_i)) - 2] \\
&= p[3(r(x_0) - r(x_1))] + p[3(r(x_0) + r(x_1) - r(x_{l-1}) - r(x_l)) - 2(l-1)] \\
&< p[6(r(x_0) - r(x_l)) - 2(l-1)] \\
&= p[6(r(t) - r(x)) - 2(l-1)]. \qquad \square
\end{aligned}$$

Lemma 4.3 implies that the R2P heuristic adapts at a rate $1/(2p)$ as fast as the splay heuristic, yet also has an expected-amortized access time of $3(r(t) - r(x)) + 2$, if we choose the potential of a tree T to be $R(T)/(2p)$. Hence, in the following we analyze the running time of the R2P heuristic using the potential function $\Phi(T) = n/2 \cdot R(T)$.

We first bound the expected-amortized time of a single operation, before analyzing the expected time of a sequence of operations. We finally prove that the R2P heuristic is statically competitive.

LEMMA 4.4. *The expected-amortized time to access a node x of a tree with root t using the R2P heuristic is at most $3(r(t) - r(x)) + 2$.*

Proof. The expected-amortized time of an operation is the sum of the actual time and the expected change in potential. Let l be the depth of x. If $l = 0$, then the expected-amortized time to access x is $1 < 3(r(t) - r(x)) + 2$. Otherwise, the time to access x is $l + 1$, and since each ancestor of x is two-promoted with probability $1/n$, Lemma 4.1 implies that the expected change $\Delta\Phi$ in potential is no greater than

$$\begin{aligned}
\frac{n}{2}\Delta R &\leq \frac{n}{2}\left\{\frac{1}{n}[6(r(t) - r(x)) - 2(l-1)]\right\} \\
&= 3(r(t) - r(x)) - (l-1).
\end{aligned}$$

The expected-amortized time is thus at most $l + 1 + 3(r(t) - r(x)) - (l-1) = 3(r(t) - r(x)) + 2$. $\square$

We now bound the maximum expected time of a sequence of accesses by bounding the expected-amortized time of the sequence. Note that we have expected access frequencies in the following lemma, rather than observed access frequencies. The reason is that we assume the adversary is adaptive and maps histories of a tree to accesses in some manner. This mapping, along with the random numbers generated by the R2P heuristic, defines a probability distribution for the accesses, thus giving rise to expected access frequencies. For further details, readers should consult Lai's thesis [12].

LEMMA 4.5. *Let n be the size of a tree, m be the number of accesses, and q_i be the expected access frequency of the ith smallest element for $i = 1, \ldots, n$. Let w_i be*

an arbitrary, positive constant, for $i = 1, \ldots, n$, *and let* $W = \sum_{i=1}^{n} w_i$. *Then, the expected time of* m *accesses using the R2P heuristic is at most*

$$O(m) + 3 \cdot \sum_{i=1}^{n} \left[q_i \cdot \log\left(\frac{W}{w_i}\right)\right] + \frac{n}{2} \cdot \sum_{i=1}^{n} \log\left(\frac{W}{w_i}\right),$$

even if accesses are chosen by an adaptive adversary.

Proof. Let x_i be the ith smallest element, for each i. We assign x_i a weight of w_i; this implies that the root of the tree has a total weight of W. Recall that the expected time of m operations is no more than the sum of the expected-amortized time of the m operations and the maximum drop in potential.

Since the rank of the root of the tree is $\log W$ and the rank $r(x_i)$ of x_i is $\log s(x_i) \geq \log w_i$, the expected-amortized time of accessing x_i is at most $3\log(W/w_i)+2$. Therefore, the expected-amortized time of the m accesses is no more than

$$3\sum_{i=1}^{n} \left[q_i \cdot \log\left(\frac{W}{w_i}\right)\right] + 2m.$$

It remains to determine an upper bound on the maximum drop in potential. For each i, the rank of x_i is at least $\log w_i$ and at most $\log W$, which implies that the potential of the tree is at least $n/2 \cdot \sum_{i=1}^{n} \log w_i$ and at most $n/2 \cdot \sum_{i=1}^{n} \log W$. Hence, the potential drop is at most $n/2 \cdot \sum_{i=1}^{n} (\log W - \log w_i) = n/2 \cdot \sum_{i=1}^{n} \log(W/w_i)$. Therefore, the expected time E of the m accesses is at most

$$O(m) + 3 \cdot \sum_{i=1}^{n} \left[q_i \log\left(\frac{W}{w_i}\right)\right] + \frac{n}{2} \cdot \sum_{i=1}^{n} \log\left(\frac{W}{w_i}\right). \qquad \square$$

An amortized bound similar to that of Lemma 4.5 holds for splay trees, except that the term $n/2 \cdot \sum_{i=1}^{n} \log(W/w_i)$ is replaced by $\sum_{i=1}^{n} \log(W/w_i)$.

Note that Lemma 4.5 holds for all assignments of weights $w_1, \ldots, w_n$ simultaneously. By choosing different values of the weights, we obtain different upper bounds. Also, note that the specific values of the weights are unimportant; only the ratios between the weights affect the bound of Lemma 4.5. For example, if we choose all weights to be equal, we obtain the following bound.

THEOREM 4.6. *The expected time of* m *accesses using the R2P heuristic is* $O(m \log n + n^2 \log n)$, *even against an adaptive adversary.*

Proof. Assign a weight of $1/n$ to each item. Then $W = 1$, which implies that the expected-amortized access time is $O(\log n)$ and the maximum drop in potential is $O(n^2 \log n)$. The theorem follows. $\square$

Theorem 4.6 implies that the expected time of an access is essentially $O(\log n)$, even if an adversary is allowed to inspect the tree to choose accesses. However, the expected amount of *overwork* is $O(n^2 \log n)$, which is a factor of n greater than the overwork of the splay heuristic.

By choosing the weights differently, we prove that the R2P heuristic is statically competitive against an oblivious adversary.

THEOREM 4.7. *Let* n *be the size of a tree. Suppose that an oblivious adversary accesses a sequence* X *of length* m. *Let* q_i *be the access frequency of the* i*th smallest element in* X *for* $i = 1, \ldots, n$. *The expected time* T *of the* m *accesses using the R2P heuristic is*

$$O\left(m + n^2 \log n + \sum_{i=1}^{n} \left[q_i \log\left(\frac{m}{q_i}\right)\right]\right);$$

thus, R2P is statically competitive against an oblivious adversary.

Proof. Sherk [19], in his proof that deep-splay trees are statically optimal, proved that for any assignment of values to $q_1, \ldots, q_n$, there is an assignment to $w_1, \ldots, w_n$ such that

$$\sum_{i=1}^{n} \left[q_i \log \left(\frac{W}{w_i} \right) \right] = O\left(\sum_{i=1}^{n} \left[q_i \log \left(\frac{m}{q_i} \right) \right] \right),$$

and

$$\sum_{i=1}^{n} \log \left(\frac{W}{w_i} \right) = O(n \log n).$$

Therefore, Lemma 4.5 implies that the expected time of m accesses is

$$O\left(m + n^2 \log n + \sum_{i=1}^{n} \left[q_i \log \left(\frac{m}{q_i} \right) \right] \right).$$

Now, the adversary's access time T_A using an optimal static tree is $\Omega(m + \sum_{i=1}^{m} q_i \log(m/q_i))$, where m is the number of accesses and q_i is the access frequency of the ith smallest element. Since T is $O(T_A + n^2 \log n)$, R2P is statically competitive against an oblivious adversary. □

4.2. The locally optimized randomized partial-splay (LORPS) heuristic. Our first heuristic, the R2P heuristic, cannot support updates efficiently, since it rarely performs any restructuring if the height of the tree is low. The second heuristic, the LORPS heuristic, supports both accesses and updates. Furthermore, the LORPS heuristic is statically competitive in the sense that it is competitive against any static tree for any obliviously generated access sequence that does not contain intervening updates.

Let $d(n) = 2 + \log(n+1)$. The LORPS heuristic works as follows. After accessing some node x on level l, we generate a random number L uniformly between 0 and $\lfloor d(n) \rfloor - 1$. If $L > l$, we do nothing. Otherwise, we two-promote x's ancestors on levels in the set $\{i : i \leq l \text{ and } i \equiv L \pmod{\lfloor d(n) \rfloor}\}$. We call this operation a *partial splay,* since it performs $(2/\lfloor d(n) \rfloor)$ths or roughly $(2/\log n)$ths of the work of a splay.

To delete a node w with at most one child, we delete w and partially splay its parent. To delete an internal node x, we replace x by x's inorder successor y, delete y, and partially splay y's parent.

Inserting a node x on level l is more difficult. Let x_i be the ancestor of x on level i for $i = 0, \ldots, l$. Let k be the largest index such that $k \leq l$ and $s(x_k) \geq d(n)/\ln 2 + 1$. If there is no such k or if $l - k \leq 4$, we partially splay x. Otherwise, let

$$B_i = \frac{s(x_{i-2})[s(x_{i-2}) - s(x_{i+1})]}{s(x_{i+1})^2},$$

for all i, and let

$$C = \min_{k+3 \leq i \leq l-1} B_i.$$

If $C \geq 1$, we partially splay x. If $C < 1$, we two-promote some x_i such that $B_i = C$ and then partially splay x; we call the two-promotion of x_i a *local optimization.* Observe

that we do not need balance information since we can count the sizes of x_l, x_{l-1}, ... to obtain k. This computation requires only $O(d(n)) = O(\log n)$ time since we can stop immediately after we find an ancestor x_k such that $s(x_k) \geq d(n)/\ln 2 + 1$.

Intuitively, a local optimization is a type of balance operation. In particular, $\log B_i$ is an estimate of the change in total rank of the tree if x_i is two-promoted. Hence, a local optimization seeks to reduce the rank if the fringe or bottom of the tree is imbalanced. The reason for using local optimization is that a partial splay alone appears inadequate to achieve $O(\log n)$ expected insertion time in pathological situations. In particular, using our method of analysis, the expected amortized time of an insertion may be as high as $\Theta(\log n \log\log n)$. By using an extra two-promotion to improve the balance during insertions, we can provably achieve $O(\log n)$ expected operation time.

To analyze the LORPS heuristic, we first prove that the expected-amortized time of an access, an insertion, or a deletion is $O(\log n)$, before we analyze the expected time of a sequence of operations. In the following, we assign a weight of 1 to each node. To analyze the expected time, we choose the potential $\Phi_E(T)$ of a tree T to be $d(n)R(T)$. To analyze the expected number of two-promotions, we use the potential function $\Phi_{EP}(T) = R(T)$.

LEMMA 4.8. *The expected-amortized time to access x on level l in a tree, using the LORPS heuristic, is at most $8(r(t)-r(x))-l+3$, where t is the root of the tree. If each element has a weight of 1, the expected-amortized time is at most $8\log n - l + 3$. The expected-amortized number of two-promotions is no more than $7 - l/\lfloor d(n)\rfloor$.*

Proof. Recall that the expected-amortized time of an operation is the sum of the actual time and the expected change in potential. Each ancestor of x has a probability of $1/\lfloor d(n)\rfloor$ of being two-promoted, so Lemma 4.3 implies that the expected change $\Delta\Phi$ in potential is less than

$$\frac{d(n)}{\lfloor d(n)\rfloor}[6(r(t) - r(x)) - 2(l-1)].$$

Since $n \geq 1$, we have $1 \leq d(n)/\lfloor d(n)\rfloor < 4/3$, which implies that

$$\Delta\Phi < 8(r(t) - r(x)) - 2(l-1).$$

Thus, the expected-amortized time is at most $l + 1 + 8(r(t) - r(x)) - 2(l-1) = 8(r(t)-r(x)) - l + 3$. Since the rank of the root t is $\log n$ and the rank of x is at least 0, the expected-amortized time is at most $8\log n - l + 3$.

Similarly, it is straightforward to show that the expected number of two-promotions is $l/\lfloor d(n)\rfloor$, and the expected change in the potential function Φ_{EP} is at most $6/\lfloor d(n)\rfloor \log n - (2(l-1))/\lfloor d(n)\rfloor$, which implies that the expected-amortized number of two-promotions is at most $(6/\lfloor d(n)\rfloor)\log n - l/\lfloor d(n)\rfloor + 1 < 7 - l/\lfloor d(n)\rfloor$. □

Before analyzing the expected-amortized time of an insertion, we establish an upper bound on the change in potential caused by a local optimization. Intuitively, Lemma 4.9 states that a local optimization negates most of the increase in potential caused by increases in ranks along the access or insertion path.

LEMMA 4.9. *Let $d(n)$ be some nondecreasing function of the tree size n. Let $x_0, \ldots, x_l$ be the nodes of the path from the root to x_l in T. Assume that $s(x_0) \geq d(n)/\ln 2 + 1$. Let B_i, for $k+3 \leq i \leq i-1$, and C be defined as above, where k is the largest index such that $k \leq l$ and $s(x_k) \geq d(n)/\ln 2 + 1$. Suppose that we increase the size of x_i by 1, for $i = 0, \ldots l-1$, and that we do the following steps.*

1. *If $k > l - 5$ or $C \geq 1$, do nothing.*

2. *Otherwise, two-promote some x_a such that $B_a = C$.*

Then, the total change in $\Phi(T) = d(n)R(T)$ caused by the increase in total rank and the restructuring is less than $l + \frac{15}{2}d(n)$.

Proof. The change in potential $\Phi(T)$ is caused by the change in the sizes of x_0, $\ldots$, x_{l-1} and the two-promotion of x_a if any. The change in potential caused by the change in the sizes is exactly $d(n) \cdot \sum_{i=0}^{l-1} \log(\frac{s(x_i)}{s(x_i)-1})$, where $s(x_i)$ is the size of x_i after the change in weight but before the extra two-promotion of x_a if any. Since $\ln(1+y) \le y/\ln 2$, for any $y \ge 0$, we have

$$\begin{aligned} d(n) \cdot \sum_{i=0}^{l-1} \log\left(\frac{s(x_i)}{s(x_i)-1}\right) &\le d(n) \cdot \sum_{i=0}^{k} \log\left(\frac{s(x_i)}{s(x_i)-1}\right) + d(n) \cdot \sum_{i=k+1}^{l-1} \log\left(\frac{s(x_i)}{s(x_i)-1}\right) \\ &\le \frac{d(n)}{\ln 2} \sum_{i=0}^{k} \frac{1}{s(x_i)-1} + d(n) \cdot \sum_{i=k+1}^{l-1} \log\left(\frac{s(x_i)}{s(x_i)-1}\right) \\ &\le k+1 + d(n) \cdot \sum_{i=k+1}^{l-1} \log\left(\frac{s(x_i)}{s(x_i)-1}\right) \end{aligned}$$

by the definition of k.

We claim that the total change in Φ is less than $l + \frac{15}{2}d(n)$. We consider the three possibilities separately.

1. $k \ge l-4$.
   If $k \ge l-4$, then no local optimization is performed. Since $s(x_i) \ge 2$ for $i < l$, we know that
   $$d(n) \cdot \sum_{i=k+1}^{l-1} \log\left(\frac{s(x_i)}{s(x_i)-1}\right) < 3d(n).$$
   Thus, the change in potential is at most $k+1+3d(n) < l+4d(n)$.
2. $k \le l-5$ and $C \ge 1$.
   Let r be the largest index such that $r \le l-1$ and $s(x_r) \ge 5$; such an r must exist since $l \ge 5$, which implies that $n \ge 6$. We have $\sum_{i=r+1}^{l-1} \log(\frac{s(x_i)}{s(x_i)-1}) \le \log 4 = 2$, which implies that
   $$d(n) \cdot \sum_{i=k+1}^{l-1} \log\left(\frac{s(x_i)}{s(x_i)-1}\right) \le \frac{d(n)}{\ln 2} \sum_{i=k+1}^{r} \frac{1}{s(x_i)-1} + 2d(n).$$
   To bound $\sum_{i=k+1}^{r} \frac{1}{s(x_i)-1}$, we show that the sequence $s(x_r)$, $s(x_{r-1})$, $\ldots$, increases exponentially. For any $k+3 \le i \le l-1$, we know by the definition of C that
   $$C \le \frac{s(x_{i-2})[s(x_{i-2}) - s(x_{i+1})]}{s(x_{i+1})^2}.$$
   Hence, $s(x_{i-2})^2 - s(x_{i+1})s(x_{i-2}) - C \cdot s(x_{i+1})^2 \ge 0$, which implies that
   $$\begin{aligned} s(x_{i-2}) &\ge \frac{s(x_{i+1}) + \sqrt{s(x_{i+1})^2 + 4C \cdot s(x_{i+1})^2}}{2} \\ &= \left(\frac{1+\sqrt{1+4C}}{2}\right) s(x_{i+1}). \end{aligned}$$

Since $C \geq 1$, we know that $s(x_{i-2}) \geq (\frac{1+\sqrt{5}}{2})s(x_{i+1})$. By induction, we can show that, for all $j \geq 0$, $s(x_{r-j}) \geq 5(\frac{1+\sqrt{5}}{2})^{\lfloor j/3 \rfloor}$. Thus,

$$\begin{aligned}\frac{d(n)}{\ln 2}\sum_{i=k+1}^{r}\frac{1}{s(x_i)-1} &< \frac{d(n)}{\ln 2}\sum_{j=0}^{\infty}\left[\frac{1}{4(\frac{1+\sqrt{5}}{2})^{\lfloor j/3 \rfloor}}\right] \\ &= \frac{d(n)}{\ln 2}\cdot\frac{3}{4}\cdot\sum_{j=0}^{\infty}\frac{1}{(\frac{1+\sqrt{5}}{2})^{j}} \\ &\leq \frac{d(n)}{\ln 2}\cdot\frac{3}{4}\cdot\frac{\sqrt{5}+1}{\sqrt{5}-1} \\ &< 3d(n).\end{aligned}$$

Therefore, the change in the potential from the changes in the sizes of x_{k+1}, $\ldots$, x_{l-1} is less than $3d(n) + 2d(n) = 5d(n)$. The total change in potential is less than $k + 1 + 5d(n) < l + 5d(n)$.

3. $k \leq l - 5$ and $C < 1$.
Let r be the largest index such that $r \leq l - 1$ and $s(x_r) \geq \lceil 2/C \rceil + 1$. If no such r exists, then

$$\sum_{i=k+1}^{l-1}\log\left(\frac{s(x_i)}{s(x_i)-1}\right) \leq d(n)\log\left\lceil\frac{2}{C}\right\rceil.$$

Otherwise, $\sum_{i=r+1}^{l-1}\log(\frac{s(x_i)}{s(x_i)-1}) \leq \log s(x_{r+1}) \leq \log\lceil 2/C \rceil$, which implies that

$$d(n)\cdot\sum_{i=k+1}^{l-1}\log\left(\frac{s(x_i)}{s(x_i)-1}\right) \leq \frac{d(n)}{\ln 2}\sum_{i=k+1}^{r}\frac{1}{s(x_i)-1} + d(n)\log\left\lceil\frac{2}{C}\right\rceil.$$

To bound $\sum_{i=k+1}^{r}\frac{1}{s(x_i)-1}$, we analyze the rate of growth of the sequence $s(x_r)$, $s(x_{r-1})$, $\ldots$. Let $z = \lceil 2/C \rceil/(2/C)$. Since $C < 1$, we have $1 \leq z < 3/2$. Observe that, for all $k + 3 \leq i \leq l - 1$, we have

$$\begin{aligned}s(x_{i-2}) &\geq \left(\frac{1+\sqrt{1+4C}}{2}\right)s(x_{i+1}) \\ &> \left(1+\frac{C}{2}\right)s(x_{i+1}).\end{aligned}$$

We can show by induction that, for $j \geq 0$, $s(x_{r-j}) - 1 > (1 + C/2)^{\lfloor j/3 \rfloor}\lceil 2/C \rceil$. Thus,

$$\begin{aligned}\frac{d(n)}{\ln 2}\sum_{i=k+1}^{r}\frac{1}{s(x_i)-1} &< \frac{d(n)}{\ln 2}\left(\frac{3}{\lceil\frac{2}{C}\rceil}\right)\sum_{i=0}^{\infty}\frac{1}{(1+\frac{C}{2})^{i}} \\ &= \frac{d(n)}{\ln 2}\left(\frac{3}{\lceil\frac{2}{C}\rceil}\right)\left(\frac{1+\frac{C}{2}}{\frac{C}{2}}\right) \\ &= \frac{d(n)}{\ln 2}\cdot\frac{3(1+\frac{C}{2})}{z} \\ &< \frac{9d(n)}{2z\ln 2}.\end{aligned}$$

Therefore,

$$d(n) \cdot \sum_{i=k+1}^{l-1} \log\left(\frac{s(x_i)}{s(x_i)-1}\right) < d(n)\left[\frac{9}{2z\ln 2} + \log\left(\frac{2}{C}\right) + \log z\right].$$

Now, $9/(2z\ln 2) + \log z$ is maximized when $z = 1$, so the change in potential due to the change in ranks of $x_{k+1}, \ldots, x_{l-1}$ is

$$d(n) \cdot \sum_{i=k+1}^{l-1} \log\left(\frac{s(x_i)}{s(x_i)-1}\right) \le d(n)\left[\frac{9}{2\ln 2} + 1 - \log C\right].$$

Let x_a be the node that has been two-promoted. Only the ranks of x_{a-2}, x_{a-1}, and x_a are changed. Before the two-promotion, the sum of their ranks is $\log s(x_{a-2}) + \log s(x_{a-1}) + \log s(x_a) > \log s(x_{a-2}) + 2\log s(x_{a+1})$. After the two-promotion, the size of either x_{a-1} or x_{a-2} can be shown to be less than $s(x_{a-2}) - s(x_{a+1})$, while the size of the other node is clearly less than $s(x_{a-2})$. Thus, the sum of the new ranks of x_{a-2}, x_{a-1}, and x_a is no greater than $2\log s(x_{a-2}) + \log(s(x_{a-2}) - s(x_{a+1}))$. The change $\Delta\Phi$ in potential from the local optimization is less than

$$d(n)[\log s(x_{a-2}) + \log(s(x_{a-2}) - s(x_{a+1})) - 2\log s(x_{a+1})]$$

and, hence,

$$\begin{aligned}\Delta\Phi &< d(n)\left\{\log\frac{s(x_{a-2})[s(x_{a-2}) - s(x_{a+1})]}{s(x_{a+1})^2}\right\} \\ &= d(n)\log C.\end{aligned}$$

Thus, the sum of the change in $d(n) \cdot \sum_{i=k+1}^{l-1} \log(\frac{s(x_i)}{s(x_i)-1})$ and the change in potential caused by the local optimization is at most $(\frac{9}{2\ln 2}+1)d(n) < \frac{15}{2}d(n)$. The total change in potential is, therefore, less than $l + \frac{15}{2}d(n)$. The lemma follows immediately. □

Now that we have analyzed the effect of a local optimization, we bound the expected-amortized time for an insertion, before analyzing the time for a deletion.

LEMMA 4.10. *The expected-amortized insertion time using the LORPS heuristic is $O(\log n)$, and the expected-amortized number of two-promotions is constant.*

Proof. Clearly, for $n \le 8$, the expected-amortized time is $O(1)$. If $n > 8$, then the expected-amortized time of inserting a node x is the sum of the search time, the change in potential caused by the change in $d(n)$, the change in potential caused by the addition of x in various subtrees, the expected-amortized time of partially splaying x, and the expected change in potential caused by the local optimization (if any).

Lemma 4.8 implies that the sum of the expected-amortized time for searching the tree for x and partially splaying x is $l + 1 + 8\log n - 2(l-2) + 2 = 8\log n - l + 7$, where l is the depth at which x is originally inserted. The reason we have $-2(l-2)$ instead of $-2l$ is that x may be moved upward two levels during the local optimization before it is partially splayed.

The change in potential caused by the change in $d(n)$ is at most $(d(n) - d(n-1))n\log n$. Observe that

$$d(n) - d(n-1) = \log\left(1 + \frac{1}{n}\right).$$

We can show that $\log(1+1/n) \le 1/(n \ln 2)$, so the change in potential caused by the change in $d(n)$ is at most $(n \log n)/(n \ln 2) = (\log n)/\ln 2$.

Let x_i be the ancestor of x on level l for $0 \le i \le l$. Let k be the largest index such that $k \le l$ and $s(x_k) \ge d(n)/\ln 2 + 1$; such a k must exist if $n \ge 9$. Lemma 4.9 implies that the change in potential from the change in sizes and the local optimization, if any, is at most $l + \frac{15}{2} d(n) = l + O(\log n)$. Therefore, the expected-amortized time of inserting x is $O(\log n)$.

The expected number of two-promotions performed when inserting x is at most $l/\lfloor d(n) \rfloor + 1$, and the preceding proof implies that the change in the potential function Φ_{EP} is $O(\log n/\lfloor d(n) \rfloor) - l/\lfloor d(n) \rfloor$. Therefore, the expected-amortized number of two-promotions is $O(\log n/\lfloor d(n) \rfloor) = O(1)$. □

LEMMA 4.11. *The expected-amortized deletion time using the LORPS heuristic is $O(\log n)$, and the expected-amortized number of two-promotions is constant.*

Proof. Without loss of generality assume that the deleted node x has at most one child. The expected-amortized time to delete x is the sum of the time to search for x, the change in potential from the change in $d(n)$, the change in the potential from removing x from various subtrees, and the expected-amortized time of partially splaying x's parent. A deletion causes $d(n)$ and the ranks of x's ancestors to decrease, which implies that the change in potential is negative. Lemma 4.8 implies that the expected-amortized time to search for x, remove it, and partially splay its parent is at most $l + 1 + 8 \log n - 2(l-1) + 2 \le 8 \log n + 5$, where l is the original depth of x.

The expected number of two-promotions performed when deleting x is less than $l/\lfloor d(n) \rfloor$, and the above proof implies that the change in the potential function Φ_{EP} is $O(\log n/\lfloor d(n) \rfloor) - l/\lfloor d(n) \rfloor$. Therefore, the expected-amortized number of two-promotions is $O(\log n/\lfloor d(n) \rfloor) = O(1)$. □

We are now ready to show that the LORPS heuristic effectively has an expected-amortized update time of $O(\log n)$.

THEOREM 4.12. *Suppose that we perform m operations on an empty tree using the LORPS heuristic. Let p_{in} be the probability that the size of the tree is n after the ith operation. The expected time of m operations is*

$$O\left(m + \sum_{i=1}^{m} \sum_{j=0}^{i} [p_{ij} \log(j+1)]\right)$$

and the expected linkage cost of m operations is $O(m)$, even if operations are chosen by an adaptive adversary. Essentially, the expected cost of an operation is $O(\log n)$, and the expected linkage cost is constant.

Proof. Recall that the expected time is no more than the sum of the expected-amortized time and the maximum drop in potential. Observe that $\Phi_E = 0$ and $\Phi_{EP} = 0$ when the tree is empty, so the maximum potential drop is 0. The expected time bound immediately follows from Lemmas 4.8, 4.10, and 4.11. Since Lemmas 4.8, 4.10, and 4.11 also imply that the expected-amortized number of two-promotions, for any operation, is constant, the expected linkage cost of the m operations is $O(m)$. □

Theorem 4.12 implies that the LORPS heuristic is as efficient as any balanced tree. Although it is not practical and requires restructuring during accesses, unlike red–black trees [11] or randomized search trees [3], it has the advantage of requiring no balance information to achieve $O(\log n)$ expected operation cost.

By varying the node weights as in our analysis of the R2P heuristic, we show that the LORPS heuristic is also statically competitive.

THEOREM 4.13. *Let n be the size of a tree. Suppose an oblivious adversary accesses a sequence X of length m. Let q_i be the access frequency of the ith smallest element in X for $i = 1, \ldots, n$. The expected time of the m searches using the LORPS heuristic is*

$$O\left(m + n\log^2 n + \sum_{i=1}^{n}\left[q_i \log\left(\frac{m}{q_i}\right)\right]\right);$$

thus, LORPS is statically competitive against an oblivious adversary.

Proof. Let x_i be the ith smallest element for each i. We assign x_i a weight of w_i such that

$$\sum_{i=1}^{n}\left[q_i \log\left(\frac{W}{w_i}\right)\right] = O\left(\sum_{i=1}^{n}\left[q_i \log\left(\frac{m}{q_i}\right)\right]\right)$$

and

$$\sum_{i=1}^{n}\log\left(\frac{W}{w_i}\right) = O(n\log n),$$

where $W = \sum_{i=1}^{n} w_i$; Sherk [19] proved that this assignment is possible for any values of $q_1, \ldots, q_n$.

Lemma 4.8 implies that the expected-amortized time of accessing x_i is

$$8(r(t) - r(x_i)) + 3 \le 8\log(W/w_i) + 3,$$

where $r(t)$ is the rank of the root of the tree. Thus, the expected-amortized time of m accesses is at most $O(m) + 8\sum_{i=1}^{n}[q_i \log(W/w_i)] = O(m + \sum_{i=1}^{n}[q_i \log(m/q_i)])$. For each i, the rank of x_i is at least $\log w_i$ and at most $\log W$, which implies that the maximum potential drop is at most $d(n) \cdot \sum_{i=1}^{n}\log(W/w_i) \le O(d(n) \cdot n\log n) = O(n\log^2 n)$. The theorem follows in a similar manner to the proof of Theorem 4.7. □

4.3. The locally optimized partial-splay (LOPS) heuristic. The third heuristic, the LOPS heuristic, is a deterministic, statically competitive, amortized-CLC heuristic. The LOPS heuristic is essentially a deterministic version of the LORPS heuristic that maintains bounded frequency counts. The local optimizations play the same role in LOPS as they do in LORPS; namely, they are rebalancing operations. The LOPS heuristic achieves amortized time bounds comparable with the LORPS heuristic's expected-time bound, although at the expense of linear extra space.

At first sight, it appears that we can use Ben-David et al.'s results [5] to obtain a deterministic algorithm from the LORPS heuristic. They provide a general technique, essentially maintaining an estimate of the potential, to convert a online randomized algorithm into a online deterministic algorithm with little loss in competitiveness. The main problem with their approach is that it does not handle static competitiveness and whether it could be modified to handle static competitiveness is unclear.

In the LOPS heuristic we store a positive integer weight in each node. Let $d(n) = 2 + \log(n+1)$. Suppose we access x on level l. There are two steps.

1. Increase the weight of x by 1. Let x_i be the ancestor of x on level l for $i = 0, \ldots, l$. Let k be the largest index such that $k \le l$ and $s(x_k) \ge d(n)/\ln 2 + 1$. If no such k exists or $l - k \le 4$, go to step 2. Otherwise, let

$$B_i = \frac{s(x_{i-2})[s(x_{i-2}) - s(x_{i+1})]}{s(x_{i+1})^2},$$

for all i, and let

$$C = \min_{k+3 \le i \le l-1} B_i.$$

If $C \ge 1$, go to step 2. Otherwise, two-promote some x_i such that $B_i = C$. We call step 1 a *local optimization*.

2. Let l' be the new level of x and let x'_i be the ancestor of x on level i for $i = 0, \ldots, l'$. If $l' = 0$, we are done. Otherwise, let $D_j = \lfloor (l' - j)/\lfloor d(n) \rfloor \rfloor$ for $j = 1, \ldots, \lfloor d(n) \rfloor$. Let $\delta_i = 3(r(x'_{i-2}) - r(x'_i)) - 2$, for $i = 2, \ldots, l'$. Compute

$$R_1 = 3(r(x'_0) - r(x'_1)) + \sum_{j=1}^{D_1} \delta_{\lfloor d(n) \rfloor j+1},$$

and, for $i = 2, \ldots, \lfloor d(n) \rfloor$,

$$R_i = \sum_{j=0}^{D_i} \delta_{\lfloor d(n) \rfloor j+i}.$$

Let $C' = \min(R_1, \ldots, R_{\lfloor d(n) \rfloor})$. If $C' \ge 0$, then we are done. Otherwise, two-promote x's ancestors on levels in $\{i : i \le l \text{ and } i \equiv L \pmod{\lfloor d(n) \rfloor}\}$ for some L such that $R_L = C'$. We call step 2 a *partial splay*.

Updates are straightforward. To delete a node with at most one child, we delete the node and partially splay its parent. To delete an internal node x, we replace x by x's inorder successor y, delete y, and partially splay y's parent. To insert some node x, we assign x a weight of 0 and access x, applying both steps 1 and 2.

To reduce the size of the weights, we reset the weights to 1 after every $\lfloor n/2 \rfloor + 1$ operations. This step ensures that we need only $O(n)$ extra space or $O(n \log n)$ bits of extra space in a bit-cost model.

The analysis of the LOPS heuristic is similar to that of the LORPS heuristic. To analyze the amortized time of the LOPS heuristic, we use the potential function $\Phi_A(T) = d(n) \cdot R(T)$. To analyze the amortized number of two-promotions, we use the potential function $\Phi_{2P}(T) = R(T)$. We note that the amortized cost of resetting weights is constant, so we ignore it in the analysis.

We first analyze the amortized costs of an access, an insertion, and a deletion before analyzing the amortized cost of a sequence of operations.

LEMMA 4.14. *The amortized time to access node x of a tree with root t using the LOPS heuristic is $O(\log(s(t)/s(x)))$. The amortized number of two-promotions performed when accessing x is constant.*

Proof. Let l be the depth of x. Without loss of generality, assume that $n \ge 9$ since the amortized access time is clearly constant otherwise. The amortized time to access x is the sum of the actual time, which is $l + 1$, and the change in potential, caused by the increases in sizes, the local optimization (if any), the partial splay, and the resetting of weights (if any). We may ignore the contribution of the weight resetting since it reduces the potential.

Let $\Delta\Phi$ be the change in potential Φ_A caused by the increases in sizes and the local optimization. For $0 \le i \le l$, let x_i be the ancestor of x on level i before the

access. Let k be the largest index such that $k \le l$ and $s(x_k) \ge d(n)/\ln 2 + 1$; such a k exists if $n \ge 9$. If $k = l$, then no local optimization is performed and

$$\begin{aligned}\Delta\Phi &= d(n) \cdot \sum_{i=0}^{l} \log\left(\frac{s(x_i)}{s(x_i)-1}\right) \\ &\le \frac{d(n)}{\ln 2} \sum_{i=0}^{l} \frac{1}{s(x_i)-1} \\ &\le l+1.\end{aligned}$$

If $k \ne l$, then Lemma 4.9 implies that the change $\Delta\Phi$ in potential is

$$d(n) \cdot \log\left(\frac{s(x_l)}{s(x_l)-1}\right) + l + \frac{15}{2}d(n) \le l + \frac{17}{2}d(n).$$

Let $\Delta\Phi'$ be the change in potential caused by the partial splay. Let l' be the level of x after step 1 of the access algorithm and, for all i, $0 \le i \le l'$, let x'_i be the ancestor of x on level i after step 1. Observe that Lemma 4.1 implies that the change in potential after two-promoting x's ancestors on levels in $\{i : i \le l \text{ and } i \equiv L \pmod{\lfloor d(n) \rfloor}\}$ is at most $d(n) \cdot R_L$. Thus, the change $\Delta\Phi'$ in potential from the partial splay is at most $d(n) \cdot \min(R_1, \ldots, R_{\lfloor d(n) \rfloor}, 0)$. Clearly,

$$\min(R_1, \ldots, R_{\lfloor d(n) \rfloor}) \le \frac{R_1 + \cdots + R_{\lfloor d(n) \rfloor}}{\lfloor d(n) \rfloor}.$$

If $l' \ge 2$, then, since $l' \ge l - 2$ and $d(n) \ge 3$, we know that

$$\begin{aligned}\Delta\Phi' &\le \frac{d(n)}{\lfloor d(n) \rfloor} \sum_{i=1}^{\lfloor d(n) \rfloor} R_i \\ &= \frac{d(n)}{\lfloor d(n) \rfloor} \cdot 3(r(x'_0) - r(x'_1)) + \frac{d(n)}{\lfloor d(n) \rfloor} \sum_{i=2}^{l'} \left[3(r(x'_{i-2}) - r(x'_i)) - 2\right] \\ &= \frac{d(n)}{\lfloor d(n) \rfloor}[6r(x'_0) - 3r(x'_{l-1}) - 3r(x'_l) - 2(l'-1)] \\ &< 8r(x'_0) - 8r(x'_l) - 2l' + 2 \\ &\le 8r(t) - 8r(x) - 2l + 6,\end{aligned}$$

where $r(t)$ is the rank of the root after the increases in sizes. Note that the above bound also holds if $l' < 2$.

Therefore, the amortized access time A is at most

$$\begin{aligned}l + 1 + \Delta\Phi + \Delta\Phi' &< 8[r(t) - r(x)] - l + 7 + \Delta\Phi \\ &= O(\log(s(t)/s(x))) - l + \Delta\Phi.\end{aligned}$$

If $s(x) \ge d(n)/\ln 2 + 1$, then $k = l$ and the amortized access time A is $O(\log(s(t)/s(x))) - l + l + 1 = O(\log(s(t)/s(x)))$. Otherwise, if $s(x) < d(n)/\ln 2 + 1$, then $s(t) \ge n$ implies that $\log(s(t)/s(x)) = \Omega(\log n)$ and $A = O(\log(s(t)/s(x))) - l + l + \frac{17}{2}d(n) = O(\log(s(t)/s(x)))$.

The amortized number of two-promotions performed is at most $l/\lfloor d(n) \rfloor + 2 + (\Delta\Phi + \Delta\Phi')/d(n) = O(\log(s(t)/s(x))/\lfloor d(n) \rfloor)$. Since we reset all weights to 1 every

$\lceil n/2 \rceil$ operations, we know that $s(t) = O(n^2)$, which implies that the amortized number of two-promotions is constant. □

LEMMA 4.15. *The amortized insertion time using the LOPS heuristic is* $O(\log n)$, *and the amortized number of two-promotions is constant.*

Proof. The amortized time to insert a node x is the sum of the actual time and the change in potential, or, equivalently, the sum of the change in potential caused by the change in $d(n)$ and the amortized time to access x. Since all weights are at most n, the change $\Delta\Phi$ in potential from the change in $d(n)$ is

$$\begin{aligned} O((d(n) - d(n-1))n \log n) &= O((\log(n+1) - \log n)n \log n) \\ &= O(\log n). \end{aligned}$$

Lemma 4.14 implies that the amortized access time of x is $O(\log n)$, so the total amortized time is $O(\log n)$.

The amortized number of two-promotions to insert x is equal to the amortized number of two-promotions to access x, which is constant. □

LEMMA 4.16. *The amortized deletion time using the LOPS heuristic is* $O(\log n)$, *and the amortized number of two-promotions is constant.*

Proof. The amortized time to delete a node x on level l is the sum of the actual time, which is $l + 1$, and the change in potential caused by the change in $d(n)$, the change in sizes, and the partial splay. Since $d(n)$ and the sizes decrease, it is sufficient to consider the change in potential $\Delta\Phi_A$ from the partial splay.

It is sufficient to consider the case where x has at most one child. If x is the root, then the amortized deletion time is clearly $O(1)$. Otherwise, let y be x's parent. The proof of Lemma 4.14 implies that $\Delta\Phi_A < 8(r(t) - r(y)) - 2(l-1) + 2$, where $r(t)$ is the rank of the root. (We have $-2(l-1)$ instead of $-2l$ since we partially splay y, which is on level $l-1$.) Thus, the amortized deletion time is at most $l+1+8(r(t)-r(y))-2l+4 = O(\log n)$.

The amortized number of two-promotions to delete x is the sum of the actual number of two-promotions, which is less than $l/\lfloor d(n) \rfloor + 1$, and the change in potential $\Delta\Phi_{2P}$. The preceding upper bound on $\Delta\Phi_A$ implies that $\Delta\Phi_{2P} \leq c - l/d(n)$, for some constant c, which implies that the amortized number of two-promotions is constant. □

Before proving our main theorem on the time of the LOPS heuristic, we state a useful relationship involving logarithms. Note that we define $0 \log(x/0) = 0$.

LEMMA 4.17. *For any* $0 \leq a \leq x$ *and* $0 \leq b \leq y$, $a \log(x/a) + b \log(y/b) \leq (a+b) \log((x+y)/(a+b))$.

We are now ready to prove our main result: the LOPS heuristic supports all operations in $O(\log n)$ amortized time, is amortized CLC, and is statically competitive.

THEOREM 4.18. *Suppose we perform* m *operations in an empty tree using the LOPS heuristic. Let* n_i *be the size of the tree during the* i*th operation. Then, the worst-case time of the* m *operations is*

$$O\left(m + \sum_{i=1}^{m} \log(n_i + 1)\right).$$

The worst-case linkage cost of the m *operations is* $O(m)$.

Proof. Observe that the potential functions Φ_A and Φ_{2P} are initially 0, which implies that the maximum potential drop is 0 and that the worst-case time of the m

operations is no greater than the sum of the amortized times of the operations. The proof follows from the amortized time bounds of Lemmas 4.14, 4.15, and 4.16. ∎

Since LOPS is a deterministic heuristic, adaptive and oblivious adversaries are equally powerful.

THEOREM 4.19. *Let n be the size of a tree. Suppose that an adversary accesses a sequence X of length m. Let q_i be the access frequency of the ith smallest element in X for $i = 1, \ldots, n$. The worst-case time of the m searches using the LOPS heuristic is*

$$O\left(m + n\log^2 n + \sum_{i=1}^{n}\left[q_i \log\left(\frac{m}{q_i}\right)\right]\right);$$

thus, LOPS is statically competitive.

Proof. Since the maximum weight in the tree in no more than n, the maximum rank of the tree and hence the maximum drop in potential Φ_A is $O(n\log^2 n)$. Thus, it is sufficient to show that the sum of the amortized times of the m accesses is $O(m + n\log^2 n + \sum_{i=1}^{n}(q_i \log(m/q_i)))$. Clearly, Lemma 4.14 implies this bound if $m \le n$, so we assume in the following that $m > n$.

For $i = 1, \ldots, n$, let x_i be the ith smallest element in X, and let T_i be the total amortized time of the q_i accesses of x_i. To prove the claimed time bound, it is sufficient to show that $T_i = O(q_i + q_i \log(m/q_i))$. Let R be the number of times that the weights have been reset. Let Q_{ij} be the number of times that x_i is accessed between the jth and $(j+1)$th weight resettings for $0 \le j \le R$. Since we reset the weights after every $\lfloor n/2 \rfloor + 1$ operations, we know that the total weight of the tree before the $(j+1)$th weight resetting is at most $\lfloor 3n/2 \rfloor + 1$. Thus, we have

$$\begin{aligned}
T_i &= O\left(q_i + \sum_{j=0}^{R}\sum_{k=1}^{Q_{ij}} \log\left(\frac{\lfloor \frac{3}{2}n \rfloor + 1}{k}\right)\right) \\
&= O\left(q_i + \sum_{j=0}^{R}\left[Q_{ij}\log\left(\left\lfloor \frac{3n}{2}\right\rfloor + 1\right) - \log Q_{ij}!\right]\right) \\
&= O\left(q_i + \sum_{j=0}^{R}\left[Q_{ij}\log\left(\left\lfloor \frac{3n}{2}\right\rfloor + 1\right) - Q_{ij}\log Q_{ij} + \frac{Q_{ij}}{\ln 2}\right]\right) \\
&= O\left(q_i + \sum_{j=0}^{R}\left[Q_{ij}\log\frac{\lfloor \frac{3}{2}n \rfloor + 1}{Q_{ij}}\right]\right).
\end{aligned}$$

Because we reset weights every $\lfloor n/2 \rfloor + 1$ operations, the fact that we have performed m operations implies that $\sum_{j=0}^{R-1}(\lfloor n/2 \rfloor + 1) \le m$. Also, we know that $n < m$, so

$$\sum_{j=0}^{R}\left[\left\lfloor \frac{3n}{2}\right\rfloor + 1\right] \le \frac{9}{2}m + 1.$$

Since $\sum_{j=0}^{R} Q_{ij} = q_i$, Lemma 4.17 implies that

$$\begin{aligned}
T_i &= O\left(q_i + q_i \log\left(\frac{\frac{9}{2}m + 1}{q_i}\right)\right) \\
&= O\left(q_i + q_i \log\left(\frac{m}{q_i}\right)\right).
\end{aligned}$$

The theorem follows in a similar manner to the proof of Theorem 4.7. □

5. The randomized partial-splay (RPS) heuristic. The last heuristic we present, the RPS heuristic, performs $(2/d)$ths of the work of the splay heuristic. By adjusting the parameter d, one can obtain a tradeoff between the rate of adaptation and the linkage cost. More precisely, the RPS heuristic works as follows. Let $d \geq 3$ be an integer constant. After accessing some node x on level l, we generate a random number L uniformly between 0 and $d-1$. If $L > l$, we do nothing. Otherwise, we two-promote x's ancestors on levels in the set $\{i : i \leq l \text{ and } i \equiv L \pmod{d}\}$. We note, as an aside, that Sleator and Tarjan's semisplay step [21] can be used in place of the two-promotion.

Updates are straightforward. To delete a node with at most one child, we just delete the node and partially splay its parent. To delete an internal node x, we replace x by x's inorder successor y, delete y, and partially splay y's parent. To insert some node x, we insert x naively and then partially splay x.

Although the RPS heuristic is not CLC, it is practical and is much simpler to implement than the LORPS and LOPS heuristics. Because the RPS heuristic spaces out its two-promotions, the two-promotions do not interact with one another, so the RPS heuristic has a straightforward top-down implementation. We show that the RPS heuristic is statically competitive and has performance bounds similar to those of the splay heuristic. The RPS heuristic does not adapt as quickly as the splay heuristic to changes in usage but may be preferable to the splay heuristic if updates are infrequent and the access pattern is stable.

We first prove a technical result that bounds the change in potential caused by a partial splay.

LEMMA 5.1. *Suppose, for some node x, we two-promote x's ancestors on levels $l(1), \ldots, l(k)$, such that $l(i+1) \geq l(i) + 3$, for any i. Then, the change in $R(T)$ in the worst case is at most $3(r(t) - r(x_{l(k)})) - 2(k-1)$, where t is the root of the tree.*

Proof. Let x_i be the ancestor of x on level i for all i. For convenience, we define $r(x_{-i}) = r(x_0)$ for $i \geq 1$. From Lemma 4.1, the change in $R(T)$ is at most $3\sum_{i=1}^{k}[r(x_{l(i)-2}) - r(x_{l(i)})] - 2(k-1)$. Since, for all i, we have $l(i+1) \geq l(i)+3$ and $r(x_i) \geq r(x_{i+1})$, we can conclude that

$$\sum_{i=1}^{k}[r(x_{l(i)-2}) - r(x_{l(i)})] \leq r(t) - r(x_{l(k)}).$$

The lemma follows. □

We now prove that the RPS heuristic supports accesses, insertions, and deletions in $O(\log n)$ amortized time.

THEOREM 5.2. *The expected time of m operations using the RPS heuristic with parameter d in an initially empty tree against an oblivious adversary is $O(m + d\log d \cdot I + \sum_{i=1}^{m}\log n_i)$, where n_i is the size of the tree after operation i is performed and I is the total number of insertions. The worst-case time of the m operations is $O(m + d\sum_{i=1}^{m}\log n_i)$.*

Proof. To analyze the expected search time, we use the potential function $\Phi_E = d \cdot R(T)$ and assign a weight of 1 to each node. It is sufficient to show that the expected-amortized time is $O(\log n)$ for an access, $O(\log n + d\log d)$ for an insertion, and $O(\log n)$ for a deletion.

The expected-amortized time to access a node x on level l is the sum of the search time, which is $l+1$, and the change in potential, which Lemma 4.3 implies

is at most $6 \log n - 2l + 2$. Thus, the expected-amortized access time is at most $6 \log n - l + O(1) = O(\log n)$.

The expected-amortized time to insert a node x on level l is the sum of the expected-amortized access time, which is at most $6 \log n - l + O(1)$, and the change in potential caused by the increase in ranks from the insertion, which can be shown to be at most $d[\log l + \log(n/(n-1))]$. It is simple to show that $d \log l < l$ for all $l \geq 4d \log d$, so the expected-amortized insertion time is less than $6 \log n + d \log(4d \log d) + O(1) = O(\log n + d \log d)$.

The expected-amortized time for a deletion is the sum of the expected-amortized access time, which is $O(\log n)$, and the change in potential caused by the decrease in ranks from the deletion, which is negative. Hence, the expected-amortized deletion time is $O(\log n)$.

To analyze the amortized time, we use the potential function $\Phi_A = d/2 \cdot R(T)$. The amortized time of an operation is no greater than the sum of the search time, which is $l + 1$, the increase in potential from the change in ranks in the case of an insertion, and the change in potential from the partial splay. Observe that the potential change after an insertion due to the increase in ranks is at most $d \log(l+1) \leq d \log(n+1)$. Because the RPS heuristic performs at least $\lfloor (l+1)/d \rfloor$ two-promotions, Lemma 5.1 implies that the change in potential from the partial splay is at most $d/2 \cdot [3 \log n - 2\lfloor (l+1)/d \rfloor + 2] = O(d \log n) - l$, so the total amortized time for any single operation is $O(d \log n)$. The theorem follows. □

We finally show that the RPS heuristic is statically competitive against an adaptive (or oblivious) adversary.

THEOREM 5.3. *The expected time of m accesses in a tree of size n using the RPS heuristic with parameter d against an oblivious adversary is $O(m + dn \log n + \sum_{i=1}^{n} [q_i \log(m/q_i)])$, where q_i is the number of times the ith smallest element is accessed; thus, RPS is statically competitive against an oblivious adversary.*

The worst-case time of m accesses in a tree of size n using the RPS heuristic with parameter d against an adaptive adversary is $O(dm + dn \log n + d \sum_{i=1}^{n} [q_i \log(m/q_i)])$; thus, RPS is statically competitive against an adaptive adversary.

Proof. We use the potential function $\Phi = d/2 \cdot R(T)$ to analyze both the expected and amortized times. The theorem follows from Lemmas 4.3 and 5.1 and is similar to the proof of Theorem 4.7. Note that the static competitiveness against an adaptive adversary follows from the amortized-time bound, rather than from the expected-time bound. □

6. Concluding remarks. We investigated the rate of adaptation achievable by a constant-linkage-cost heuristic for maintaining a binary search tree. In particular, we showed that no $o(\log n)$-linkage-cost heuristic can be competitive and we presented three statically competitive, constant-linkage-cost heuristics. We believe that proofs that R2P and LORPS are statically competitive against oblivious adversaries can be modified to establish that they are statically competitive against *adaptive adversaries.*

Many open problems remain. An obvious problem is whether our lower bounds are tight. Another open problem is whether there are matching lower bounds on the competitiveness of promotion-based heuristics and arbitrary heuristics. An area for further work is to investigate lower bounds on the competitiveness of arbitrary heuristics against oblivious adversaries.

Note that none of the first three heuristics attain the (revised) ideal of a statically competitive, worst-case-CLC heuristic that supports updates and uses only constant extra space. Indeed, an open problem is to devise such a heuristic or to prove that none

exists. Another open problem is to devise a statically competitive, worst-case-CLC heuristic that supports updates; it would achieve three of the four requirements of the ideal. Yet another open problem is to devise a statically competitive, amortized-CLC heuristic that supports updates and uses $o(n)$ extra space.

TREE CONTRACTIONS AND EVOLUTIONARY TREES*

MING-YANG KAO†

Abstract. An *evolutionary tree* is a rooted tree where each internal vertex has at least two children and where the leaves are labeled with distinct symbols representing species. Evolutionary trees are useful for modeling the evolutionary history of species. An *agreement subtree* of two evolutionary trees is an evolutionary tree which is also a topological subtree of the two given trees. We give an algorithm to determine the largest possible number of leaves in any agreement subtree of two trees T_1 and T_2 with n leaves each. If the maximum degree d of these trees is bounded by a constant, the time complexity is $O(n \log^2 n)$ and is within a $\log n$ factor of optimal. For general d, this algorithm runs in $O(nd^2 \log d \log^2 n)$ time or alternatively in $O(nd\sqrt{d} \log^3 n)$ time.

1. Introduction.

An *evolutionary tree* is a rooted tree where each internal vertex has at least two children and where the leaves are labeled with distinct symbols representing species. Evolutionary trees are useful for modeling the evolutionary history of species. Many mathematical biologists and computer scientists have been investigating how to construct and compare evolutionary trees [2, 5, 7, 10, 11, 12, 16, 17, 18, 20, 24, 26, 27, 28, 33, 34, 35, 36, 37, 43, 44, 46, 48, 49]. An *agreement subtree* of two evolutionary trees is an evolutionary tree which is also a topological subtree of the two given trees. A *maximum* agreement subtree is one with the largest possible number of leaves. Different theories about the evolutionary history of the same species often result in different evolutionary trees. A fundamental problem in computational biology is to determine how much two theories have in common. To a certain extent, this problem can be answered by computing a maximum agreement subtree of two given evolutionary trees [19].

Let T_1 and T_2 be two evolutionary trees with n leaves each. Let d be the maximum degree of these trees. Previously, Kubicka, Kubicki, and McMorris [39] gave an algorithm that can compute the number of leaves in a maximum agreement subtree of T_1 and T_2 in $O(n^{(\frac{1}{2}+\epsilon)\log n})$ time for $d = 2$. Steel and Warnow [47] gave the first polynomial-time algorithm. Their algorithm runs in $O(\min\{d!n^2, d^{2.5}n^2 \log n\})$ time if d is bounded by a constant and in $O(n^{4.5} \log n)$ time for general trees. Farach and Thorup [14] later reduced the time complexity of this algorithm to $O(n^2)$ for general trees. More recently, they gave an algorithm [15] that runs in $O(n^{1.5} \log n)$ time for general trees. If d is bounded by a constant, this algorithm runs in $O(nc^{\sqrt{\log n}} + n\sqrt{d} \log n)$ time for some constant $c > 1$.

This paper presents an algorithm for computing a maximum agreement subtree in $O(n \log^2 n)$ time for d bounded by a constant. Since there is a lower bound of $\Omega(n \log n)$, our algorithm is within a $\log n$ factor of optimal. For general d, this algorithm runs in $O(nd^2 \log d \log^2 n)$ time or alternatively in $O(nd\sqrt{d} \log^3 n)$ time.

This algorithm employs new tree contraction techniques [1, 22, 38, 40, 41]. With tree contraction, we can immediately obtain an $O(n \log^5 n)$-time algorithm for d bounded by a constant. Reducing the time bound to $O(n \log^2 n)$ requires additional techniques. We develop new results that are useful for bounding the time complexity of tree contraction algorithms. As in [14, 15, 47], we also explore the dynamic programming structure of the problem. We obtain some highly regular structural properties and combine these properties with the tree contraction techniques to reduce the time bound by a factor of $\log^2 n$. To remove the last $\log n$ factor, we incorporate some techniques that can compute maxima of multiple sets of sequences at multiple points, where the input sequences are in a compressed format.

We present tree contraction techniques in section 2 and outline our algorithms in section 3. The maximum agreement subtree problem is solved in sections 4 and 5 with a discussion of condensed sequence techniques in section 5.1. Section 6 concludes this paper with an open problem.

2. New tree contraction techniques. Throughout this paper, all trees are rooted ones, and every nonempty tree path is a vertex-simple one from a vertex to a descendant. For a tree T and a vertex u, let T^u denote the subtree of T formed by u and all its descendants in T.

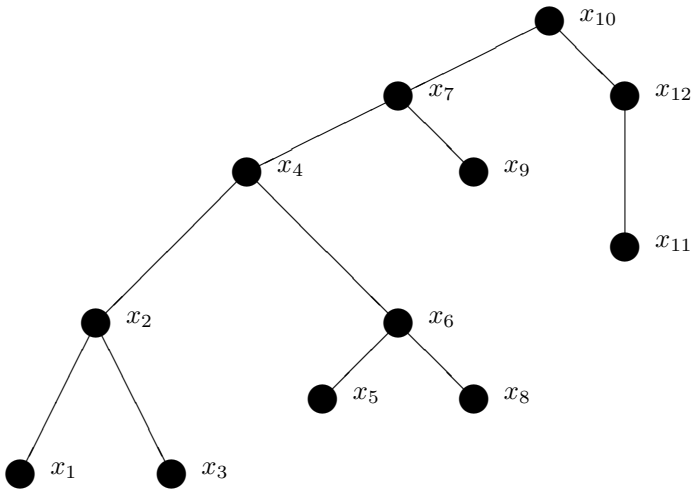
A key idea of our dynamic programming approach is to partition T_1 and T_2 into well-structured tree paths. We recursively solve our problem for T_1^x and T_2^y for all heads x and y of the tree paths in the partitions of T_1 and T_2, respectively. The partitioning is based on new tree contraction techniques developed in this section.

A tree is *homeomorphic* if every internal vertex of that tree has at least two children. Note that the size of a homeomorphic tree is less than twice its number of leaves. Let S be a tree that may or may not be homeomorphic. A *chain of* S is a tree path in S such that every vertex of the given path has at most one child in S. A *tube of* S is a maximal chain of S. A *root path of a tree* is a tree path whose head is the root of that tree; similarly, a *leaf path* is one ending at a leaf. A *leaf tube of* S is a tube that is also a leaf path. Let $\mathcal{L}(S)$ denote the set of leaf tubes in S. Let $\mathcal{R}(S) = S - \mathcal{L}(S)$, i.e., the subtree of S obtained by deleting from S all its leaf tubes. The operation $\mathcal{R}$ is called the *rake operation*. See Figures 1 and 2 for examples of rakes and leaf tubes.

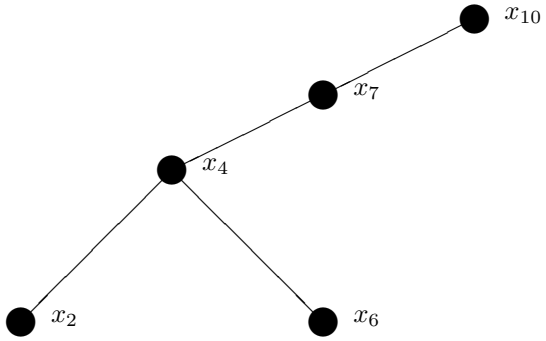
Our dynamic programming approach iteratively rakes T_1 and T_2 until they become empty. The tubes obtained in the process form the desired partitions of T_1 and T_2. Our rake-based algorithms focus on certain sets of tubes described here. A *tube system* of a tree T is a set of nonempty tree paths $P_1, \ldots, P_m$ in T such that (1) the paths P_i contain no leaves of T and (2) $T^{h_1}, \ldots, T^{h_m}$ are pairwise disjoint, where h_i is the head of P_i. Condition (1) is required here because our rake-based algorithms process leaves and nonleaf vertices differently. Condition (2) holds if and only if for all i and j, h_i is not an ancestor or descendant of h_j. We can iteratively rake T to obtain tube systems. The set of tubes obtained by the first rake, i.e., $\mathcal{L}(T)$, is not a tube system of T because $\mathcal{L}(T)$ simply consists of the leaves of T and thus violates condition (1). Every further rake produces a tube system of T until T is raked to empty. Our rake-based algorithms only use these systems although there may be others.

We next develop a theorem to bound the time complexities of rake-based algorithms in this paper. For a tree path P in a tree T,

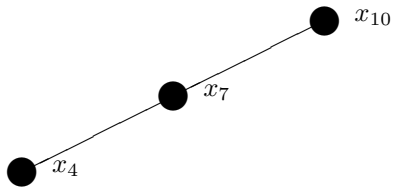
- $K(P, T)$ denotes the set of children of P's vertices in T, excluding P's vertices;
- $t(P)$ denotes the number of vertices in P;
- $b(P, T)$ denotes the number of leaves in T^h where h is the head of P.



After the first rake, the above tree becomes the following tree.

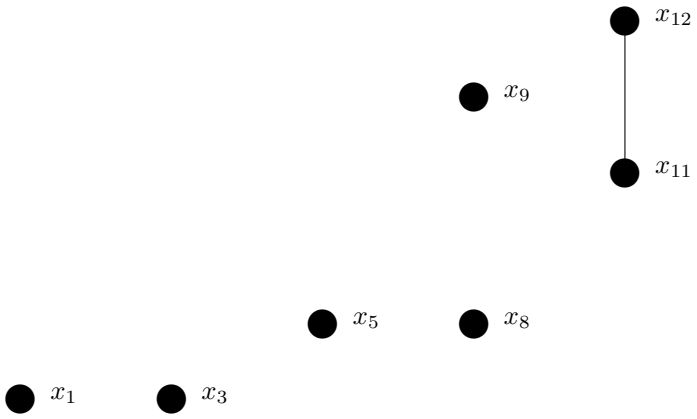


After the second rake, the above tree becomes the following tree.



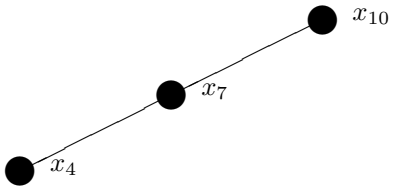
After the third rake, the above tree becomes empty.

FIG. 1. *An example of iterative applications of rakes.*



The first rake deletes the above leaf tubes.

The second rake deletes the above leaf tubes.



The third rake deletes the above leaf tube.

FIG. 2. *The leaf tubes deleted by the rakes in Figure* 1.

(The symbol K stands for the word "kids," t for top, and b for bottom.)

Given T, we recursively define a mapping Φ_T from the subtrees S of T to reals. If S is an empty tree, then $\Phi_T(S) = 0$. Otherwise,

$$\Phi_T(S) = \Phi_T(\mathcal{R}(S)) + \sum_{P \in \mathcal{L}(S)} b(P,T) \cdot \log(1 + t(P)).$$

(*Note.* All logarithmic functions log in this paper are in base 2.)

THEOREM 2.1. *For all positive integers n and all n-leaf homeomorphic trees T, $\Phi_T(T) \le n(1 + \log n)$.*

Proof. For any given n, $\Phi_T(T)$ is maximized when T is a binary tree formed by attaching n leaves to a path of $n-1$ vertices. The proof is by induction.

Base case. For $n = 1$, the theorem trivially holds.

Now assume $n \ge 2$.

Induction hypothesis. For every positive integer $n' < n$, the theorem holds.

Induction step. Let r be the smallest integer such that T is empty after r rakes. Then, at the end of the $(r-1)$th rake, T is a path $P = x_1, \ldots, x_p$. Let $T_1, \ldots, T_s$ be the subtrees of T rooted at vertices in $K(P,T)$. Let n_i be the number of leaves in T_i. Note that

$$\Phi_T(T) = n \log(p+1) + \sum_{i=1}^{s} \Phi_{T_i}(T_i).$$

Since $1 \le n_i < n$ and T_i is homeomorphic, by the induction hypothesis,

$$\Phi_T(T) \le n \log(p+1) + \sum_{i=1}^{s} n_i(1 + \log n_i).$$

Since $\sum_{i=1}^{s} n_i = n$,

$$\Phi_T(T) \le n + n \log(p+1) + \sum_{i=1}^{s} n_i \log n_i. \tag{1}$$

Because T is homeomorphic, each x_i has at least one child in $K(P,T)$. Since $n \ge 2$, $r \ge 2$. Then, x_p cannot be a leaf in T and thus has at least two children in $K(P,T)$. Consequently, $s \ge p+1$. Next, note that for all $m_1, m_2 > 0$,

$$m_1 \log m_1 + m_2 \log m_2 \le (m_1 + m_2) \log(m_1 + m_2).$$

With this inequality and the fact that $s \ge p+1$, we can combine the terms in the right-hand-side summation of inequality (1) to obtain the following inequality:

$$\Phi_T(T) \le n + n \log(p+1) + \sum_{i=1}^{p+1} n'_i \log n'_i, \tag{2}$$

where $\sum_{i=1}^{p+1} n'_i = n$ and $n'_i \ge 1$. For any given p, the summation in inequality (2) is maximized when $n'_1 = n - p$ and $n'_2 = \cdots = n'_{p+1} = 1$. Therefore,

$$\Phi_T(T) \le n + n \log(p+1) + (n-p) \log(n-p). \tag{3}$$

The right-hand side of inequality (3) is maximized when $p = n - 1$. This gives the desired bound and finishes the induction proof. □

3. Comparing evolutionary trees. Formally, an *evolutionary tree* is a homeomorphic tree whose leaves are labeled by distinct labels. The *label set of an evolutionary tree* is the set of all the leaf labels of that tree.

The *homeomorphic version T' of a tree T* is the homeomorphic tree constructed from T as follows. Let $W = \{w \mid w \text{ is a leaf of } T \text{ or is the lowest common ancestor of two leaves}\}$. T' is the tree over W that preserves the ancestor–descendant relationship of T. Let T_1 and T_2 be two evolutionary trees with label sets L_1 and L_2, respectively.

- For a subset L_1' of L_1, $T_1||L_1'$ denotes the homeomorphic version of the tree constructed by deleting from T_1 all the leaves with labels outside L_1'.
- Let $T_1||T_2 = T_1||(L_1 \cap L_2)$.
- For a tree path P of T_1, $P||T_2$ denotes the tree path in $T_1||T_2$ formed by the vertices of P that remain in $T_1||T_2$.
- For a set $\mathcal{P}$ of tree paths $P_1, \ldots, P_m$ of T_1, $\mathcal{P}||T_2$ denotes the set of all $P_i||T_2$.

Formally, if L' is a maximum cardinality subset of $L_1 \cap L_2$ such that there exists a label-preserving tree isomorphism between $T_1||L'$ and $T_2||L'$, then $T_1||L'$ and $T_2||L'$ are called *maximum agreement subtrees of T_1 and T_2*.

- $\text{RR}(T_1, T_2)$ denotes the number of leaves in a maximum agreement subtree of T_1 and T_2.
- $\text{RA}(T_1, T_2)$ is the mapping from each vertex $v \in T_2||T_1$ to $\text{RR}(T_1, (T_2||T_1)^v)$, i.e., $\text{RA}(T_1, T_2)(v) = \text{RR}(T_1, (T_2||T_1)^v)$.

For a tree path Q of T_2, if Q is nonempty, let $H(Q, T_2)$ be the set of all vertices in Q and those in $K(Q, T_2)$. If Q is empty, let $H(Q, T_2)$ consist of the root of T_2 and, thus, if both T_2 and Q are empty, $H(Q, T_2) = \emptyset$.

- For a set $\mathcal{Q}$ of tree paths $Q_1, \ldots, Q_m$ of T_2, let $\text{RP}(T_1, T_2, \mathcal{Q})$ be the mapping from $v \in \cup_{i=1}^{m} H(Q_i||T_1, T_2||T_1)$ to $\text{RR}(T_1, (T_2||T_1)^v)$, i.e., $\text{RP}(T_1, T_2, \mathcal{Q})(v) = \text{RR}(T_1, (T_2||T_1)^v)$. For simplicity, when $\mathcal{Q}$ consists of only one path Q, let $\text{RP}(T_1, T_2, Q)$ denote $\text{RP}(T_1, T_2, \mathcal{Q})$.

(The notations RR, RA, and RP stand for the phrases root to root, root to all, and root to path. We use RR to replace the notation MAST of previous work [14, 15, 47] for the sake of notational uniformity.)

LEMMA 3.1. *Let T_1, T_2, T_3 be evolutionary trees.*

- $(T_1||T_2)||T_3 = T_1||(T_2||T_3)$.
- *If T_3 is a subtree of T_1, then $T_3||T_1 = T_1||T_3 = T_3$.*
- $\text{RR}(T_1, T_2) = \text{RR}(T_1||T_2, T_2) = \text{RR}(T_1, T_2||T_1) = \text{RR}(T_1||T_2, T_2||T_1)$.

Proof. The proof is straightforward. □

FACT 1 (see [14]). *Given an n-leaf evolutionary tree T and k disjoint sets $L_1, \ldots, L_k$ of leaf labels of T, the subtrees $T||L_1, \ldots, T||L_k$ can be computed in $O(n)$ time.*

Proof. The ideas are to preprocess T for answering queries of lowest common ancestors [25, 45] and to reconstruct subtrees from appropriate tree traversal numbering [4, 9]. □

Given T_1 and T_2, our main goal is to evaluate $\text{RR}(T_1, T_2)$ efficiently. Note that $\text{RR}(T_1, T_2) = \text{RR}(T_1||T_2, T_2||T_1)$ and that $T_1||T_2$ and $T_2||T_1$ can be computed in linear time. Thus, the remaining discussion assumes that T_1 and T_2 have the same label set. To evaluate $\text{RR}(T_1, T_2)$, we actually compute $\text{RA}(T_2, T_1)$ and divide the discussion among the five problems defined below. Each problem is named as a p-q case, where p and q are the numbers of tree paths in T_1 and T_2 contained in the input. The inputs of these problems are illustrated in Figure 3.

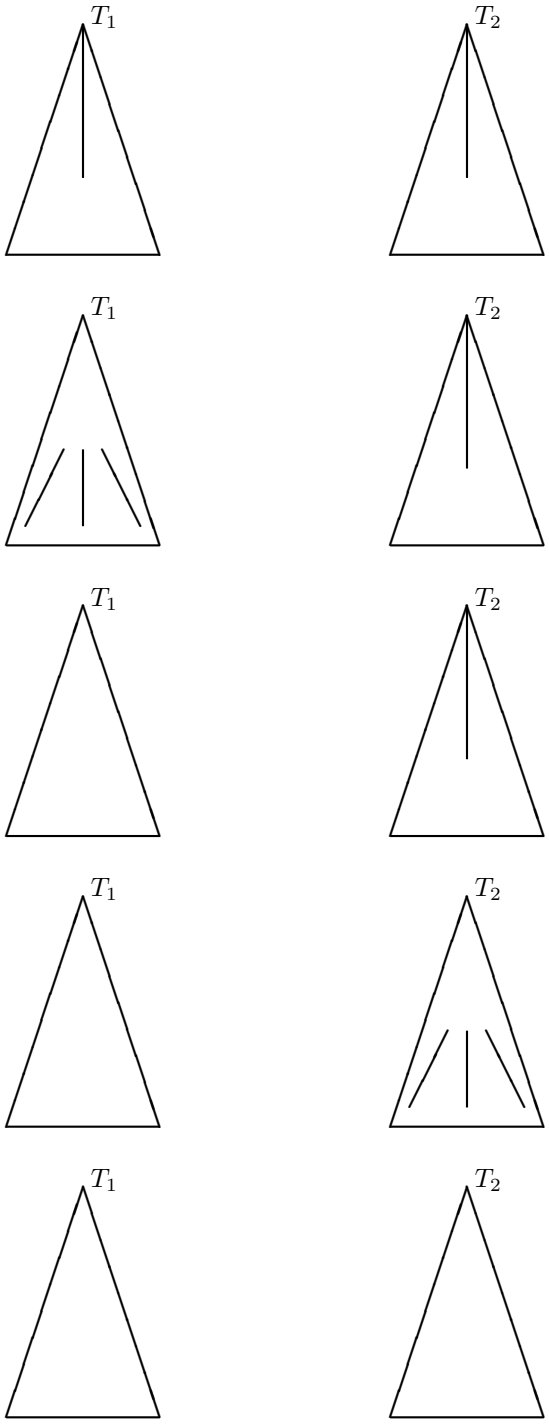


FIG. 3. *Inputs of Problems* 1–5.

PROBLEM 1 (ONE-ONE CASE).

Input:

1. T_1 and T_2;
2. root paths P of T_1 and Q of T_2 with no leaves from their respective trees;
3. $\text{RP}(T_1^u, T_2, Q)$ for all $u \in K(P, T_1)$;
4. $\text{RP}(T_2^v, T_1, P)$ for all $v \in K(Q, T_2)$.

Output: $\text{RP}(T_1, T_2, Q)$ and $\text{RP}(T_2, T_1, P)$.

The next problem generalizes Problem 1.

PROBLEM 2 (MANY-ONE CASE).

Input:

1. T_1 and T_2;
2. a tube system $\mathcal{P} = \{P_1, \ldots, P_m\}$ of T_1 and a root path Q of T_2 with no leaf from T_2;
3. $\text{RP}(T_1^u, T_2, Q)$ for all P_i and $u \in K(P_i, T_1)$;
4. $\text{RP}(T_2^v, T_1, \mathcal{P})$ for all $v \in K(Q, T_2)$.

Output:

1. $\text{RP}(T_1^{h_i}, T_2, Q)$ for the head h_i of each P_i;
2. $\text{RP}(T_2, T_1, \mathcal{P})$.

PROBLEM 3 (ZERO-ONE CASE).

Input:

1. T_1 and T_2;
2. a root path Q of T_2 with no leaf from T_2;
3. $\text{RA}(T_2^v, T_1)$ for all $v \in K(Q, T_2)$.

Output: $\text{RA}(T_2, T_1)$.

The next problem generalizes Problem 3.

PROBLEM 4 (ZERO-MANY CASE).

Input:

1. T_1 and T_2;
2. a tube system $\mathcal{Q} = \{Q_1, \ldots, Q_m\}$ of T_2;
3. $\text{RA}(T_2^v, T_1)$ for all Q_i and $v \in K(Q_i, T_2)$.

Output: $\text{RA}(T_2^{h_i}, T_1)$ for the head h_i of each Q_i.

Our main goal is to evaluate $\text{RR}(T_1, T_2)$. It suffices to solve the next problem.

PROBLEM 5 (ZERO-ZERO CASE).

Input: T_1 and T_2.

Output: $\text{RA}(T_2, T_1)$.

Our algorithms for these problems are called *One-One, Many-One, Zero-One, Zero-Many*, and *Zero-Zero*, respectively. Each algorithm except One-One uses the preceding one in this list as a subroutine. These reductions are based on the rake operation defined in section 2. We give One-One in section 5 and the other four in sections 4.1–4.4.

These five algorithms assume that the input trees T_1 and T_2 have n leaves each and d is the maximum degree. We use integer sort and radix sort [4, 9] extensively to help achieve the desired time complexity. (For brevity, from here onward, radix sort refers to both integer and radix sorts.) For this reason, we make the following *integer indexing assumptions*:

- an integer array of size $O(n)$ is allocated to each algorithm;
- the vertices of T_1 and T_2 are indexed by integers from $[1, O(n)]$;
- the leaf labels are indexed by integers from $[1, O(n)]$.

We call Zero-Zero only once to compare two given trees. Consequently, we may

reasonably assume that the tree vertices are indexed with integers from $[1, O(n)]$. When we call Zero-Zero, we simply allocate an array of size $O(n)$. As for indexing the leaf labels, this paper considers only evolutionary trees whose leaf labels are drawn from a total order. Before we call Zero-Zero, we can sort the leaf labels and index them with integers from $[1, O(n)]$. This preprocessing takes $O(n \log n)$ time, which is well within our desired time complexity for Zero-Zero.

The other four algorithms are called more than once, and their integer indexing assumptions are maintained in slightly different situations from that for Zero-Zero. When an algorithm issues subroutine calls, it is responsible for maintaining the indexing assumptions for the callees. In certain cases, the caller uses radix sort to reindex the labels and the vertices of each callee's input trees. The caller also partitions its array into segments and allocates to each callee a segment in proportion to that callee's input size. The new indices and the array segments for subroutine calls can be computed in obvious manners within the desired time complexity of each caller. For brevity of presentation, such preprocessing steps are omitted in the descriptions of the five algorithms.

Some inputs to the algorithms are mappings. We represent a mapping f by the set of all pairs $(x, f(x))$. With this representation, the total size of the input mappings in an algorithm is $O(n)$. Since the input mappings have integer values at most n, this representation and the integer indexing assumptions together enable us to evaluate the input mappings at many points in a batch by means of radix sort. Other mappings that are produced within the algorithms are similarly evaluated. When these algorithms are detailed, it becomes evident that such evaluations can computed in straightforward manners in time linear in n and the number of points evaluated. The descriptions of these algorithms assume that the values of mappings are accessed by radix sort.

4. The rake-based reductions. For ease of understanding, our solutions to Problems 1–5 are presented in a different order from their logical one. This section assumes the following theorem for Problem 1 and uses it to solve Problems 2–5. In section 5.6, we prove this theorem by giving an algorithm, called *One-One*, that solves Problem 1 within the theorem's stated time bounds.

THEOREM 4.1. *Problem* 1 *can be solved in* $O(nd^2 \log d + n \log(p+1) \log(q+1))$ *time or alternatively in* $O(nd\sqrt{d} \log n + n \log(p+1) \log(q+1))$ *time.*

Proof. The proof follows from theorem 5.14 at the end of section 5.6. □

4.1. The many-one case. The following algorithm is for Problem 2 and uses One-One as a subroutine. Note that Problem 2 is merely a multipath version of Problem 1.

ALGORITHM MANY-ONE

begin

1. For all P_i, compute $T_{1,i} = T_1^{h_i}$, $T_{2,i} = T_2 || T_{1,i}$, and $Q_i = Q || T_{1,i}$;
2. For all empty Q_i, compute part of the output as follows:
   (a) Compute the root $\hat{v}$ of $T_{2,i}$ and $v \in K(Q, T_2)$ such that $\hat{v} \in T_2^v$;
   (b) $\text{RP}(T_1^{h_i}, T_2, Q)(\hat{v}) \leftarrow \text{RP}(T_2^v, T_1, \mathcal{P})(h_i)$; (*Note.* $H(Q_i, T_{2,i}) = \{\hat{v}\}$. This is part of the output.)
   (c) For all $x \in H(P_i, T_1)$, $\text{RP}(T_2, T_1, \mathcal{P})(x) \leftarrow \text{RP}(T_2^v, T_1, \mathcal{P})(x)$; (*Note.* This is part of the output.)
3. For all nonempty Q_i, compute the remaining output as follows: (*Note.* The many-one case is reduced to the one-one case with input $T_{1,i}$, $T_{2,i}$, P_i, and Q_i.)

(a) For all $u \in K(P_i, T_{1,i})$, $\text{RP}(T^u_{1,i}, T_{2,i}, Q_i) \leftarrow \text{RP}(T^u_1, T_2, Q)$;
(b) For all $\hat{v} \in K(Q_i, T_{2,i})$, compute $\text{RP}(T^{\hat{v}}_{2,i}, T_{1,i}, P_i)$ as follows:
  i. Compute the vertex $v \in K(Q, T_2)$ such that $\hat{v} \in T^v_2$;
  ii. $\text{RP}(T^{\hat{v}}_{2,i}, T_{1,i}, P_i)(x) \leftarrow \text{RP}(T^v_2, T_1, \mathcal{P})(x)$ for all $x \in H(P_i, T_{1,i})$;
(c) Compute $\text{RP}(T_{1,i}, T_{2,i}, Q_i)$ and $\text{RP}(T_{2,i}, T_{1,i}, P_i)$ by applying One-One to $T_{1,i}, T_{2,i}$, P_i, Q_i, and the mappings computed at steps 3(a) and 3(b);
(d) $\text{RP}(T^{h_i}_1, T_2, Q) \leftarrow \text{RP}(T_{1,i}, T_{2,i}, Q_i)$; (*Note.* This is part of the output.)
(e) For all $x \in H(P_i, T_{1,i})$, $\text{RP}(T_2, T_1, \mathcal{P})(x) \leftarrow \text{RP}(T_{2,i}, T_{1,i}, P_i)(x)$; (*Note.* This is part of the output.)

end.

THEOREM 4.2. *Algorithm Many-One solves Problem* 2 *with the following time complexities:*

$$O\left(nd^2 \log d + \log(1 + t(Q)) \cdot \sum_{i=1}^{m} b(P_i, T_1) \log(1 + t(P_i))\right)$$

or, alternatively,

$$O\left(nd\sqrt{d} \log n + \log(1 + t(Q)) \cdot \sum_{i=1}^{m} b(P_i, T_1) \log(1 + t(P_i))\right).$$

Proof. Since T_1 and T_2 have the same label set, all $T_{2,i}$ are nonempty. To compute the output RP, there are two cases depending on whether Q_i is empty or nonempty. These cases are computed by steps 2 and 3. The correctness of Many-One is then determined by that of steps 2(b), 2(c), 3(a), 3(b), 3(b)ii, 3(d), and 3(e). These steps can be verified using Lemma 3.1. As for the time complexity, these steps take $O(n)$ time using radix sort to evaluate RP. Step 1 uses Fact 1 and takes $O(n)$ time. Steps 2(a) and 3(b)i take $O(n)$ time using tree traversal and radix sort. As discussed in section 3, step 3(c) preprocesses the input of its One-One calls to maintain their integer indexing assumptions. We reindex the labels and vertices of $T_{1,i}$ and $T_{2,i}$ and pass the new indices to the calls. We also partition Many-One's $O(n)$-size array to allocate a segment of size $|T_{1,i}|$ to the call with input $T_{1,i}$. Since the total input size of the calls is $O(n)$, this preprocessing takes $O(n)$ time in an obvious manner. After this preprocessing, the running time of step 3(c) dominates that of Many-One. The stated time bounds follow from Theorem 4.1 and the fact that Q_i is not longer than Q and the degrees of $T_{2,i}$ are at most d. □

4.2. The zero-one case. The following algorithm is for Problem 3. It uses Many-One as a subroutine to recursively compare T_2 with the subtrees of T_1 rooted at the heads of the tubes obtained by iteratively raking T_1. The tubes obtained by the first rake are compared with T_2 first, and the tube obtained by the last rake is compared last.

ALGORITHM ZERO-ONE

begin

1. $S \leftarrow T_1$;
2. $LF \leftarrow \mathcal{L}(S)$; (*Note.* LF consists of the leaves of T_1.)
3. For all $x \in LF$, $\text{RA}(T_2, T_1)(x) \leftarrow 1$; (*Note.* This is part of the output.)
4. For all $u \in LF$, $\text{RP}(T^u_1, T_2, Q)(y) \leftarrow 1$, where y is the unique vertex of $T_2 || T^u_1$; (*Note.* This is the base case of rake-based recursion.)
5. $S \leftarrow S - \mathcal{L}(S)$;

6. **while** S is not empty **do** the following steps:
   (a) Compute $\mathcal{L}(S) = \{P_1, \ldots, P_m\}$;
   (b) Gather the mappings $\text{RP}(T_1^u, T_2, Q)$ for all P_i and $u \in K(P_i, T_1)$; (*Note.* These mappings are either initialized at step 4 or computed at previous iterations of step 6(d).)
   (c) $\text{RP}(T_2^v, T_1, \mathcal{L}(S))(x) \leftarrow \text{RA}(T_2^v, T_1)(x)$ for all $v \in K(Q, T_2)$ and $x \in \cup_{i=1}^m H(P_i, T_1)$;
   (d) Compute $\text{RP}(T_1^{h_i}, T_2, Q)$ for the head h_i of each P_i and $\text{RP}(T_2, T_1, \mathcal{L}(S))$ by applying Many-One to T_1, T_2, $\mathcal{L}(S)$, Q, and the mappings obtained at steps 6(b) and 6(c); (*Note.* This is the recursion step of rake-based recursion.)
   (e) For all $x \in \cup_{i=1}^m K(P_i, T_1)$, $\text{RA}(T_2, T_1)(x) \leftarrow \text{RP}(T_2, T_1, \mathcal{L}(S))(x)$; (*Note.* This is part of the output.)
   (f) $S \leftarrow S - \mathcal{L}(S)$;

end.

THEOREM 4.3. *Zero-One solves Problem* 3 *with the following time complexities:*

$$O(nd^2 \log d \log n + n \log n \log(1 + t(Q)))$$

or, alternatively,

$$O(nd\sqrt{d} \log^2 n + n \log n \log(1 + t(Q))).$$

Proof. The $\mathcal{L}(S)$ at step 6(a) is a tube system. The heads of the tubes in $\mathcal{L}(S)$ become children of the tubes in future $\mathcal{L}(S)$. The vertices $u \in K(P_i, T_1)$ at step 6(b) are either leaves of T_1 or heads of the tubes in previous $\mathcal{L}(S)$. These properties ensure the correctness of the rake-based recursion. The remaining correctness proof uses Lemma 3.1 to verify the correctness of steps 3, 4, 6(c) and 6(e). Steps 1–5, 6(a), 6(b), and 6(f) are straightforward and take $O(n)$ time. Steps 6(c) and 6(e) take $O(n)$ time using radix sort to access RP and RA. At Step 6(d), to maintain the integer indexing assumptions for the call to Many-One, we simply pass to Many-One the indices of T_1 and T_2 and the whole array of Zero-One. Step 6(d) has the same time complexity as Zero-One. The desired time bounds follow from Theorems 2.1 and 4.2. □

4.3. The zero-many case. The following algorithm is for Problem 4 and uses Zero-One as a subroutine. Note that Problem 4 is merely a multipath version of Problem 3.

ALGORITHM ZERO-MANY

begin

1. For all Q_i, compute $T_{2,i} = T_2^{h_i}$ and $T_{1,i} = T_1 || T_{2,i}$;
2. For all Q_i and $v \in K(Q_i, T_{2,i})$, $\text{RA}(T_{2,i}^v, T_{1,i}) \leftarrow \text{RA}(T_2^v, T_1)$;
3. For all Q_i, compute $\text{RA}(T_{2,i}, T_{1,i})$ by applying Zero-One to $T_{1,i}, T_{2,i}$, Q_i, and the mapping computed at Step 2;
4. For all $Q_i, \text{RA}(T_2^{h_i}, T_1) \leftarrow \text{RA}(T_{2,i}, T_{1,i})$; (*Note.* This is the output.)

end.

THEOREM 4.4. *Zero-Many solves Problem* 4 *with the following time complexities:*

$$O\left(nd^2 \log d \log n + \log n \cdot \sum_{i=1}^{m} b(Q_i, T_2) \log(1 + t(Q_i))\right)$$

or, alternatively,

$$O\left(nd\sqrt{d}\log^2 n + \log n \cdot \sum_{i=1}^{m} b(Q_i, T_2)\log(1 + t(Q_i))\right).$$

Proof. The proof is similar to that of Theorem 4.2. The time bounds follow from Theorem 4.3. □

4.4. The zero-zero case. The following algorithm is for Problem 5. It uses Zero-Many as a subroutine to recursively compare T_1 with the subtrees of T_2 rooted at the heads of the tubes obtained by iteratively raking T_2. The tubes obtained by the first rake are compared with T_1 first, and the tube obtained by the last rake is compared last.

ALGORITHM ZERO-ZERO

begin

1. $S \leftarrow T_2$;
2. $LF \leftarrow \mathcal{L}(S)$; (*Note.* LF consists of the leaves of T_2.)
3. For all $v \in LF$, $\text{RA}(T_2^v, T_1)(x) \leftarrow 1$, where x is the only vertex in $T_1 || T_2^v$; (*Note.* This is the base case of rake-based recursion.)
4. $S \leftarrow S - \mathcal{L}(S)$;
5. **while** S is not empty **do**
   (a) Compute $\mathcal{L}(S) = \{Q_1, \ldots, Q_m\}$;
   (b) Gather the mappings $\text{RA}(T_2^v, T_1)$ for all Q_i and $v \in K(Q_i, T_2)$; (*Note.* These mappings are either initialized at step 3 or computed at previous iterations of step 5(c).)
   (c) Compute $\text{RA}(T_2^{h_i}, T_1)$ for the head h_i of each Q_i by applying Zero-Many to $T_1, T_2, \mathcal{L}(S)$ and the mappings obtained at step 5(b). (*Note.* This is the recursion step of rake-based recursion.)
   (d) $S \leftarrow S - \mathcal{L}(S)$;
6. $\text{RA}(T_2, T_1) \leftarrow \text{RA}(T_2^h, T_1)$, where h is the root of T_2; (*Note.* This is the output. If T_2 has only one vertex, $\text{RA}(T_2^h, T_1)$ is computed at step 3; otherwise it is computed at the last iteration of step 5(c).)

end.

THEOREM 4.5. *Zero-Zero solves Problem* 5 *within* $O(nd^2 \log d \log^2 n)$ *time or alternatively within* $O(nd\sqrt{d}\log^3 n)$ *time.*

Proof. The proof is similar to that of Theorem 4.3. The time bounds follow from Theorems 2.1 and 4.4. □

5. The one-one case. Our algorithm for Problem 1 makes extensive use of bisection-based dynamic programming and implicit computation in compressed formats. This problem generalizes the longest common subsequence problem [6, 23, 29, 30, 32], which has efficient dynamic programming solutions. A direct dynamic programming approach to our problem would recursively solve the problem with T_1^x and T_2^y in place of T_1 and T_2 for all vertices $x \in P$ and $y \in Q$. This approach may require solving $\Omega(n^2)$ subproblems. To improve the time complexity, observe that the number of leaves in a maximum agreement subtree of T_1^x and T_2^y can range only from 0 to n. Moreover, this number never increases when x moves from the root of T_1 along P to P's endpoint, and y remains fixed, or vice versa. Compared with the length of P, $\text{RR}(T_1^x, T_2^y)$ often assumes relatively few different values. Thus, to compute this number along P, it is useful to compute the locations at P where the number decreases.

We can find those locations with a bisection scheme and use them to implicitly solve the $O(n^2)$ subproblems in certain compressed formats. We first describe basic techniques used in such implicit computation in section 5.1 and then proceed to discuss bisection-based dynamic programming techniques in sections 5.2–5.5. We combine all these techniques to give an algorithm to solve Problem 1 in section 5.6.

5.1. Condensed sequences. For integers k_1 and k_2 with $k_1 \le k_2$, let $[k_1, k_2] = \{k_1, \ldots, k_2\}$, i.e., the integer interval between k_1 and k_2. The *length* of an integer interval is the number of its integers. The *upper* and *lower halves* of an even length $[k_1, k_2]$ are $[k_1, \frac{k_1+k_2-1}{2}]$ and $[\frac{k_1+k_2+1}{2}, k_2]$, respectively. The *regular* integer intervals are defined recursively. For all integers $\alpha \ge 0$, $[1, 2^\alpha]$ is regular. The upper and lower halves of an even length regular interval are also regular.

For example, $[1, 8]$ is regular. Its regular subintervals are $[1, 4]$, $[5, 8]$, $[1, 2]$, $[3, 4]$, $[5, 6]$, $[7, 8]$, and the singletons $[1, 1], [2, 2], \ldots, [8, 8]$.

A *normal sequence* is a nonincreasing sequence $\{f(j)\}_{j=1}^{l}$ of nonnegative numbers. A normal sequence is *nontrivial* if it has at least one nonzero term.

For example, $5, 4, 4, 0$ is a nontrivial normal sequence, whereas $0, 0, 0$ is a trivial one.

Let $f_1, \ldots, f_k$ be k normal sequences of length l. An *interval query* for $f_1, \ldots, f_k$ is a pair $([k_1, k_2], j)$ where $[k_1, k_2] \subseteq [1, k]$ and $j \in [1, l]$. If $k_1 = k_2$, $([k_1, k_2], j)$ is also called a *point query*. The *value* of a query $([k_1, k_2], j)$ is $\max_{k_1 \le i \le k_2} f_i(j)$. A query $([k_1, k_2], j)$ is *regular* if $[k_1, k_2]$ is a regular integer interval.

For example, let

$$\begin{aligned} f_1 &= 5, 4, 4, 3, 2; \\ f_2 &= 8, 7, 4, 2, 0; \\ f_3 &= 9, 9, 5, 0, 0. \end{aligned}$$

Then, f_1, f_2, and f_3 are normal sequences of length 5. Here, $k = 3$ and $l = 5$. Thus, $([1, 3], 2)$ is an interval query; its value is $\max\{f_1(2), f_2(2), f_3(2)\} = 9$. The pair $([1, 1], 3)$ is a point query; its value is $f_1(3) = 4$. The pair $([1, 2], 2)$ is a regular query; its values is $\max\{f_1(2), f_2(2)\} = 7$.

The *joint* of $f_1, \ldots, f_k$ is the normal sequence $\hat{f}$ also of length l such that $\hat{f}(j) = \max\{f_1(j), \ldots, f_k(j)\}$.

Continuing the above example, the joint of f_1, f_2, f_3 is

$$\hat{f} = 9, 9, 5, 3, 2.$$

The *minimal condensed form* of a normal sequence $\{f(j)\}_{j=1}^{l}$ is the set of all pairs $(j, f(j))$ where $f(j) \ne 0$ and j is the largest index of any $f(j')$ with $f(j') = f(j)$. A *condensed form* is a set of pairs $(j, f(j))$ that includes the minimal condensed form. The *size* of a condensed form is the number of pairs in it. The *total size* of a collection of condensed forms is the sum of the sizes of those forms.

Continuing the above example, the minimal condensed form of f_3 is $\{(2, 9), (3, 5)\}$; its size is 2. The set $\{(1, 9), (2, 9), (3, 5), (5, 0)\}$ is a condensed form of f_3; its size is 4. The total size of these two forms is 6.

LEMMA 5.1. *Let $F_1, \ldots, F_k$ be sets of nontrivial normal sequences of length l. Let $\hat{f}_i$ be the joint of the sequences in F_i. Given a condensed form of each sequence in each F_i, we can compute the minimal condensed forms of all $\hat{f}_i$ in $O(l + s)$ time where s is the total size of the input forms.*

Proof. The desired minimal forms can be computed by the two steps below:

1. Sort the pairs in the given condensed forms for F_i into a sequence in the increasing order of the first components of these pairs.
2. Go through this sequence to delete all unnecessary pairs to obtain the minimal condensed form of $\hat{f}_i$.

We can use radix sort to implement step 1 in $O(l+s)$ time for all F_i. Step 2 can be easily implemented in $O(s)$ time for all F_i. □

LEMMA 5.2. *Let $f_1, \ldots, f_k$ be nontrivial normal sequences of length l. Assume that the input consists of a condensed form of each f_i with a total size of s.*

1. *We can evaluate m point queries in $O(m+l+s)$ time.*
2. *We can evaluate m_1 regular queries and m_2 irregular queries in a total of $O(m_1 + (m_2 + l + s)\log(k+1))$ time.*

Proof. The proof of statement 1 uses radix sort in an obvious manner. To prove statement 2, we assume without loss of generality that k is a power of two. The input queries can be evaluated by the following three stages within the desired time bound.

Stage 1. For each regular interval $[k_1, k_2] \subseteq [1, k]$, let $f[k_1, k_2]$ be the joint of $f_{k_1}, \ldots, f_{k_2}$. We use Lemma 5.1 $O(\log(k+1))$ times to compute the minimal condensed forms of all $f[k_1, k_2]$. The total size of these forms is $O(s\log(k+1))$. This stage takes $O((l+s)\log(k+1))$ time.

Stage 2. For each irregular input query $([i_1, i_2], j)$, we partition $[i_1, i_2]$ into $O(\log(k+1))$ regular subintervals $[h_1, h_2], [h_2+1, h_3], \ldots, [h_{r-1}+1, h_r]$. Then, the value of $([i_1, i_2], j)$ is the maximum of those of $([h_1, h_2], j), \ldots, ([h_{r-1}+1, h_r], j)$. These regular queries are point queries for $f[h_1, h_2], \ldots, f[h_{r-1}+1, h_r]$. Together with the given m_1 regular queries, we have now generated $O(m_1 + m_2\log(k+1))$ point queries for all $f[k_1.k_2]$. This stage takes $O(m_1 + m_2\log(k+1))$ time.

Stage 3. We use statement 1 and the minimal condensed forms of $f[k_1.k_2]$ to evaluate the points queries generated at Stage 2. Once the values of these point queries are obtained, we can easily compute the values of the input queries. This stage takes $O(m_1 + m_2\log(k+1) + l + s\log(k+1))$ time. □

5.2. Normalizing the input. To solve Problem 1, we first augment its input T_1, T_2, P, and Q in order to simplify our discussion. Let $P = x_1, \ldots, x_p$ and $Q = y_1, \ldots, y_q$. Without loss of generality, we assume that $p \geq q$.

1. Let α and β be the smallest positive integers such that $p' = 2^\alpha + 1$, $q' = 2^\beta + 1$, $p' \geq q'$, $p' > p$, and $q' > q$. (*Note.* The conditions $p' > p$ and $q' > q$ are employed for technical simplicity. They can be changed to $p' \geq p$ and $q' \geq q$ with some modification to Algorithm One-One.)
2. Attach to x_p the path $x_{p+1}, \ldots, x_{p'}$ and to y_q the path $y_{q+1}, \ldots, y_{q'}$.
3. Let $P' = x_1, \ldots, x_{p'}$ and $Q' = y_1, \ldots, y_{q'}$.
4. Attach a leaf to each of $x_{p+1}, \ldots, x_{p'-1}$ and $y_{q+1}, \ldots, y_{q'-1}$, two leaves to $x_{p'}$, and two leaves to $y_{q'}$.
5. Assign distinct labels to the new leaves which also differ from the existing labels of T_1 and T_2.
6. Let S_1 be T_1 together with P' and the new leaves of P'. Let S_2 be T_2 together with Q' and the new leaves of Q'.

S_1 and S_2 are evolutionary trees. P' and Q' contain no leaves from S_1 and S_2 and are root paths of these trees. Let $n' = \max\{n_1, n_2\}$ where n_i is the number of leaves in S_i. Let d' be the maximum degree in S_1 and S_2.

LEMMA 5.3.

- $n' = O(n)$, $p' = O(p)$, $q' = O(q)$, *and* $d' \leq d+1$.
- $\text{RP}(T_1, T_2, Q) = \text{RP}(S_1, S_2, Q')$ *and* $\text{RP}(T_2, T_1, P) = \text{RP}(S_2, S_1, P')$.

Proof. The proof is straightforward. □

In light of Lemma 5.3, our discussion below mainly works with S_1, S_2, P', and Q'. Let $G = G_P \cup G_Q$ where G_P is the set of all pairs (x_i, y_1) and G_Q is the set of all (x_1, y_j). To solve Problem 1, a main task is to evaluate $\text{RR}(S_1^x, S_2^y)$ for $(x, y) \in G$. The output RP values that are excluded here can be retrieved directly from the input RP mappings.

5.3. Predecessors. A pair $(x_{i'}, y_{j'})$ is a *predecessor* of a distinct (x_i, y_j) if $i \le i'$ and $j \le j'$. One-One proceeds by recursively reducing the problem of computing $\text{RR}(S_1^x, S_2^y)$ to that of computing the RR values of the *P-predecessor, Q-predecessor, and PQ-predecessor* defined below.

Let $P[i, i']$ be the path $x_i, \ldots, x_{i'}$, where $i \le i'$. Let X_i be the set of the children of x_i in S_1 that are not in P'. We similarly define $Q[j, j']$ and Y_j. A pair (x_i, y_j) is *intersecting* if S_1^u and S_2^v have at least one common leaf label for some $u \in X_i$ and $v \in Y_j$. $(P[i, i'], Q[y_j, y_{j'}])$ is *intersecting* if some $x_{i''} \in P[i, i']$ and $y_{i''} \in Q[j, j']$ form an intersecting pair.

The *lengths* of $P[i, i']$ and $Q[j, j']$ are those of $[i, i']$ and $[j, j']$, respectively. A path $P[i, i']$ is *regular* if $[i, i']$ is a regular interval. A *regular* $Q[j, j']$ is similarly defined. We now construct a tree Ψ over pairs of regular paths; this tree is slightly different from that of [15]. The root of Ψ is $(P[1, p' - 1], Q[1, q' - 1])$. A pair $(P[i, i'], Q[j, j']) \in \Psi$ is a leaf if and only if either (1) $i = i'$, $j = j'$, and (x_i, y_j) is intersecting, or (2) this pair is nonintersecting. For a nonleaf $(P[i, i'], Q[j, j']) \in \Psi$, if $j = j'$, then its children are $(P[i, \frac{i+i'-1}{2}], y_j)$ and $(P[\frac{i+i'+1}{2}, i'], y_j)$. Otherwise, this pair has four children $(P[i, \frac{i+i'-1}{2}], Q[j, \frac{j+j'-1}{2}])$, $(P[i, \frac{i+i'-1}{2}], Q[\frac{j+j'+1}{2}, j'])$, $(P[\frac{i+i'+1}{2}, i'], Q[j, \frac{j+j'-1}{2}])$, $(P[\frac{i+i'+1}{2}, i'], Q[\frac{j+j'+1}{2}, j'])$.

The *ceiling of* $(P[i, i'], Q[j, j'])$ is (x_i, y_j); its *floor* is $(x_{i'+1}, y_{j'+1})$ [15]. Its *P-diagonal* is $(x_{i'+1}, y_j)$; its *Q-diagonal* is $(x_i, y_{j'+1})$. Let E be the set of all ceilings, diagonals, floors of the leaves of Ψ. Let $B = \{(x_i, y_{q'}) \mid i \in [1, p']\} \cup \{(x_{p'}, y_j) \mid j \in [1, q']\}$. Due to its recursive nature, One-One evaluates $\text{RR}(S_1^x, S_2^y)$ for all $(x, y) \in G \cup E \cup B$.

Given (x_i, y_j), if $(x_{i+1}, y_{i+1}) \in G \cup E \cup B$, then this pair is the *PQ-predecessor* of (x_i, y_j). Let i' be the smallest index that is larger than i such that $(x_{i'}, y_j) \in G \cup E \cup B$. This $(x_{i'}, y_j)$ is the *P-predecessor of* (x_i, y_j). Let j' be the smallest index larger than j such that $(x_i, y_{j'}) \in G \cup E \cup B$. This $(x_i, y_{j'})$ is the *Q-predecessor of* (x_i, y_j).

LEMMA 5.4.

1. *Each intersecting* $(x_i, y_j) \in (G \cup E) - B$ *has a P-predecessor* (x_{i+1}, y_j)*, a Q-predecessor* (x_i, y_{j+1})*, and a PQ-predecessor* (x_{i+1}, y_{j+1})*.*
2. *Each nonintersecting* $(x_i, y_j) \in E - B$ *has a P-predecessor* $(x_{i'}, y_j)$ *and a Q-predecessor* $(x_i, y_{j'})$*. Also,* $(P[i, i' - 1], Q[j, j' - 1])$ *is nonintersecting.*
3. *Each nonintersecting* $(x_i, y_1) \in G_P - B$ *has a P-predecessor* (x_{i+1}, y_1) *and a Q-predecessor* (x_i, y_j)*. Moreover,* $(x_i, Q[1, j - 1])$ *is nonintersecting.*
4. *Each nonintersecting* $(x_1, y_j) \in G_Q - B$ *has a P-predecessor* (x_i, y_j) *and a Q-predecessor* (x_1, y_{j+1})*. Moreover,* $(P[1, i - 1], y_j)$ *is nonintersecting.*

Proof. Statement 1 follows from the definitions of Ψ and E. The proofs of statements 3 and 4 are similar to Case 3 in the proof of statement 2 below.

As for statement 2, by the definition of B, $x_{i'}$ and $y_{j'}$ exist. To show $(P[i, i' - 1], Q[j, j' - 1])$ is nonintersecting, we consider the following four cases. The proofs of their symmetric cases are similar to theirs and are omitted for brevity.

Case 1. (x_i, y_j) is the ceiling of a nonintersecting leaf $(P[i, i_2], Q[j, j_2]) \in \Psi$.

Since (x_i, y_{j_2+1}) and (x_{i_2+1}, y_j) are in E, $i' \le i_2 + 1$ and $j' \le j_2 + 1$. Then because $(P[i, i_2], Q[j, j_2])$ is nonintersecting, so is $(P[i, i' - 1], Q[j, j' - 1])$.

Case 2. (x_i, y_j) is the Q-diagonal of a nonintersecting leaf $(P[i, i_2], Q[j_1, j-1])$ (or symmetrically, (x_i, y_j) is the P-diagonal of a nonintersecting leaf $(P[i_1, i-1], Q[j, j_2])$). Since (x_{i_2+1}, y_j) is the floor of $(P[i, i_2], Q[j_1, j-1])$, $(x_{i_2+1}, y_j) \in E$ and thus $i' \le i_2+1$. Let j'' be the smallest index such that $j \le j''$ and $(P[i, i_2], y_{j''})$ is intersecting. There are two subcases.

Case 2a. j'' does not exist. Then, $(P[i, i_2], Q[j, q'])$ is nonintersecting and therefore $(P[i, i' - 1], Q[j, j' - 1])$ is nonintersecting.

Case 2b. j'' exists. Let $Q[j_3, j_4]$ be a regular path that contains $y_{j''}$ and is of the same length as $Q[j_1, j - 1]$. Note that $j \le j_3$ and $(P[i, i_2], Q[j_3, j_4]) \in \Psi$. There are two subcases.

Case 2b(1). $j_3 = j$. Then (x_i, y_j) is the ceiling of $(P[i, i_2], Q[j_3, j_4])$. Since (x_i, y_j) is nonintersecting, it is the ceiling of a nonintersecting leaf in Ψ which is a descendant of $(P[i, i_2], Q[j_3, j_4])$. Therefore, Case 2b(1) is reduced to Case 1.

Case 2b(2). $j_3 > j$. By the construction of Ψ, $(x_i, y_{j_3}) \in E$ and thus $j' \le j_3$. By the choice of $Q[j_3, j_4]$, $(P[i, i_2], Q[j, j_3 - 1])$ is nonintersecting and so is $(P[i, i' - 1], Q[j, j' - 1])$.

Case 3. (x_i, y_j) is the Q-diagonal of an intersecting leaf (x_i, y_{j-1}) (or, symmetrically, (x_i, y_j) is the P-diagonal of an intersecting leaf (x_{i-1}, y_j)). Since $(x_{i+1}, y_j) \in E$, $i' = i + 1$ and $P[i, i' - 1] = x_i$. Let j'' be the smallest index such that $j < j''$ and $(x_i, y_{j''})$ is intersecting. There are two subcases.

Case 3a. j'' does not exist. Then, $(x_i, Q[j, q'])$ is nonintersecting and therefore $(P[i, i' - 1], Q[j, j' - 1])$ is nonintersecting.

Case 3b. j'' exists. Then, $(x_i, y_{j''}) \in E$ and $j' \le j''$. By the choice of j'', $(x_i, Q[j, j'' - 1])$ is nonintersecting. Thus, $(P[i, i' - 1], Q[j, j' - 1])$ is nonintersecting.

Case 4. (x_i, y_j) is the floor of a leaf $(P[i_1, i - 1], Q[j_1, j - 1])$, which may or may not be intersecting. Let $(P[i_3, i_4], Q[j_3, j_4])$ be the lowest ancestor of $(P[i_1, i - 1], Q[j_1, j - 1])$ in Ψ such that (x_i, y_j) is not the floor of $(P[i_3, i_4], Q[j_3, j_4])$. This ancestor exists because $(x_i, y_j) \notin B$. There are two subcases.

Case 4a. $j_3 = j_4$ and $i_3 < i_4$. Then, $P[i_1, i - 1]$ is a subpath of $P[i_3, \frac{i_3+i_4-1}{2}]$ and $i = \frac{i_3+i_4+1}{2}$. Also, $j_3 = j_1 = j - 1$. Thus, (x_i, y_j) is the Q-diagonal of $(P[i, i_4], y_{j-1}) \in \Psi$. By the construction of Ψ, (x_i, y_j) is the Q-diagonal of a leaf which is either $(P[i, i_4], y_{j-1})$ itself or its descendant. Depending on whether this leaf is nonintersecting or intersecting, Case 4a is reduced to Case 2 or 3.

Case 4b. $j_3 < j_4$ and $i_3 < i_4$. There are two subcases.

Case 4b(1). $P[i_1, i - 1] \subset P[i_3, \frac{i_3+i_4-1}{2}]$ and $Q[j_1, j - 1] \subset Q[j_3, \frac{j_3+j_4-1}{2}]$. Note that $i = \frac{i_3+i_4+1}{2}$, $j = \frac{j_3+j_4+1}{2}$, and (x_i, y_j) is the ceiling of $(P[\frac{i_3+i_4+1}{2}, i_4], Q[\frac{j_3+j_4+1}{2}, j_4]) \in \Psi$. Since (x_i, y_j) is nonintersecting, (x_i, y_j) is the ceiling of a nonintersecting leaf in Ψ which is $(P[\frac{i_3+i_4+1}{2}, i_4], Q[\frac{j_3+j_4+1}{2}, j_4])$ itself or a descendant. This reduces Case 4b(1) to Case 1.

Case 4b(2). $P[i_1, i-1] \subset P[i_3, \frac{i_3+i_4-1}{2}]$ and $Q[j_1, j-1] \subset Q[\frac{j_3+j_4+1}{2}, j_4]$ (or, symmetrically, $P[i_1, i-1] \subset P[\frac{i_3+i_4+1}{2}, i_4]$ and $Q[j_1, j-1] \subset Q[j_3, \frac{j_3+j_4-1}{2}]$). Note that $i = \frac{i_3+i_4+1}{2}$, $j = j_4 + 1$, and (x_i, y_j) is the Q-diagonal of $(P[\frac{i_3+i_4+1}{2}, i_4], Q[\frac{j_3+j_4+1}{2}, j_4]) \in \Psi$. Then, (x_i, y_j) is the Q-diagonal of a leaf which is $(P[\frac{i_3+i_4+1}{2}, i_4], Q[\frac{j_3+j_4+1}{2}, j_4])$ itself or a descendant. Depending on whether this leaf is nonintersecting or intersecting, Case 4b(2) is reduced to Case 2 or 3. □

5.4. Counting lemmas. We now give some counting lemmas that are used in section 5.6 to bound One-One's time complexity.

For all $(P[i_1, i_2], Q[j_1, j_2]) \in \Psi$,

- $C(P[i_1, i_2], Q[j_1, j_2])$ denotes the set of all ceilings of the leaves in Ψ which are either $(P[i_1, i_2], Q[j_1, j_2])$ itself or its descendants;
- $D(P[i_1, i_2], Q[j_1, j_2])$ denotes the set of all Q-diagonals of the leaves in Ψ which are either $(P[i_1, i_2], Q[j_1, j_2])$ itself or its descendants;
- $I(P[i_1, i_2], Q[j_1, j_2]) = \{(x_i, y_j) \mid x_i \in P[i_1, i_2], y_j \in Q[j_1, j_2]$ and (x_i, y_j) is intersecting$\}$.

LEMMA 5.5.

1. $|I(P[1, p' - 1], Q[1, q' - 1])| \le n$.
2. Ψ *has* $O(n \log(q + 1))$ *leaves of the form* $(P[i_1, i_2], Q[j_1, j_2])$ *where* $j_1 < j_2$.
3. Ψ *has* $O(n \log(q + 1))$ *pairs of the form* $(P[i_1, i_2], y_j)$ *where* $P[i_1, i_2]$ *is of length* $\frac{p'-1}{q'-1}$.
4. $|E| = O(n \log(p + 1))$.

Proof. Statements 1–3 are proved below. The proof of Statement 4 is similar to those of Statements 2 and 3.

Statement 1. For all distinct intersecting pairs (x_i, y_j) and $(x_{i'}, y_{j'})$, the leaf labels shared by the subtrees T_1^u where $u \in X_i$ and the subtrees T_2^v where $v \in Y_i$ are different from the shared labels for $X_{i'}$ and $Y_{j'}$. Statement 1 then follows from the fact that S_1 and S_2 share n leaf labels.

Statements 2 *and* 3. On each level of Ψ, for all distinct pairs $(P[i_1, i_2], Q[j_1, j_2])$ and $(P[i'_1, i'_2], Q[j'_1, j'_2])$, $I(P[i_1, i_2], Q[j_1, j_2]) \cap I(P[i'_1, i'_2], Q[j'_1, j'_2]) = \emptyset$. Thus, each level has at most $|I(P[1, p' - 1], Q[1, q' - 1])|$ nonleaf pairs. Consequently, from the second level downward, each level has at most $4 \cdot |I(P[1, p'-1], Q[1, q'-1])|$ pairs. These two statements then follow from Statement 1 and the fact that the pairs specified in these two statements are within the top $1 + \log(q' - 1)$ levels of Ψ. □

A pair (x_i, y_j) is *P-regular* if $[i, i' - 1]$ is a regular interval where $(x_{i'}, y_j)$ is the P-predecessor of (x_i, y_j). (We do not need the notion of Q-regular because $p' \ge q'$.)

Given a regular $[i_1, i_2]$, a set $\{h_1, \ldots, h_k\}$ *regularly partitions* $[i_1, i_2]$ if $h_1 = i_1$ and the intervals $[h_1, h_2 - 1], [h_2, h_3 - 1], \ldots, [h_{k-1}, h_k - 1], [h_k, i_2]$ are all regular.

LEMMA 5.6.

1. *Assume that* $j > 1$ *and* $P([i_1, i_2], y_j) \in \Psi$. *If the P-predecessor* (x_i, y_j) *of some* $(x_{i'}, y_j) \in C(P[i_1, i_2], y_j)$ *is not in* $\{(x_{i_2+1}, y_j)\} \cup C(P[i_1, i_2], y_j)$, *then* $P([i_1, i_2], y_{j-1}) \in \Psi$ *and* $(x_i, y_j) \in D(P[i_1, i_2], y_{j-1})$.
2. *Assume that* $j < q'$ *and* $P([i_1, i_2], y_{j-1}) \in \Psi$. *If the P-predecessor* (x_i, y_j) *of some* $(x_{i'}, y_j) \in D(P[i_1, i_2], y_{j-1})$ *is not in* $\{(x_{i_2+1}, y_j)\} \cup D(P[i_1, i_2], y_{j-1})$, *then* $P([i_1, i_2], y_j) \in \Psi$ *and* $(x_i, y_j) \in C(P[i_1, i_2], y_j)$.
3. *For every* $(P[i_1, i_2], y_j) \in \Psi$, *the set* $\{i \mid (x_i, y_j) \in C(P[i_1, i_2], y_j)\}$ *regularly partitions* $[i_1, i_2]$ *and so does the set* $\{i \mid (x_i, y_j) \in D(P[i_1, i_2], y_j)\}$.
4. *For all* $(P[i_1, i_2], y_j) \in \Psi$, *every pair in* $C(P[i_1, i_2], y_j) \cup D(P[i_1, i_2], y_j)$ *is P-regular.*
5. *At most* $O(n \log(q + 1))$ *of the nonintersecting pairs of E are P-irregular.*

Proof. The proofs of Statements 1 and 5 are detailed below. The proof of Statement 2 is similar to that of Statement 1 and is omitted. Statement 3 is obvious. Statement 4 follows from the first three statements and the fact that if two sets regularly partition $[i_1, i_2]$, then so does their union.

Statement 1. Note that $i_1 < i \le i_2$ and $q' > j > 1$. The pair (x_i, y_j) can be the ceiling, the P-diagonal, the Q-diagonal, or the floor of some leaf $(P[i_3, i_4], Q[j_3, j_4]) \in$

Ψ. These four cases are discussed below.

Case 1. (x_i, y_j) is the ceiling. Then $i = i_3$ and $j = j_3$. Since $i_1 < i \le i_2$ and both $[i, i_4]$ and $[i_1, i_2]$ are regular, $[i, i_4] \subset [i_1, i_2]$. Since the length of $P[i_1, i_2]$ is at most $\frac{p'-1}{q'-1}$, so is the length of $P[i, i_4]$. Thus $Q[j_3, j_4] = y_j$ and $(P[i, i_4], y_j)$ is a descendant of $(P[i_1, i_2], y_j)$. This contradicts the assumption that $(x_i, y_j) \notin C(P[i_1, i_2], y_j)$, and this case cannot exist.

Case 2. (x_i, y_j) is the P-diagonal. Then $i = i_4 + 1$ and $j = j_3$. As in Case 1, $Q[j_3, j_4] = y_j$ and $(P[i_3, i-1], y_j)$ is a descendant of $(P[i_1, i_2], y_j)$. Thus, there exists a leaf $(P[i, i_6], y_j)$ that is a descendant of $(P[i_1, i_2], y_j)$. Because (x_i, y_j) is the ceiling of this leaf, the existence of this leaf contradicts the assumption that $(x_i, y_j) \notin C(P[i_1, i_2], y_j)$ and this case cannot exist.

Case 3. (x_i, y_j) is the Q-diagonal. Then, $i = i_3$ and $j = j_4 + 1$. As in Case 1, $[i, i_4] \subset [i_1, i_2]$ and $Q[j_3, j_4] = y_{j-1}$. Since $(P[i, i_4], y_{j-1}) \in \Psi$, $(P[i_1, i_2], y_{j-1}) \in \Psi$. Then $(P[i, i_4], y_{j-1})$ is a descendant of $(P[i_1, i_2], y_{j-1})$ and $(x_i, y_j) \in D(P[i_1, i_2], y_{j-1})$.

Case 4. (x_i, y_j) is the floor. Then, $i = i_4 + 1$ and $j = j_4 + 1$. As in Case 3, $(P[i_1, i_2], y_{j-1}) \in \Psi$, $Q[j_3, j-1] = y_{j-1}$ and $(P[i_3, i-1], y_{j-1})$ is a descendant of $(P[i_1, i_2], y_{j-1})$. Thus, there is a leaf $(P[i, i_6], y_{j-1})$ which is a descendant of $(P[i_1, i_2], y_{j-1})$. Since (x_i, y_j) is this leaf's Q-diagonal, it is in $D(P[i_1, i_2], y_{j-1})$.

Statement 5. Note that E consists of the following three types of pairs:

1. the ceiling, diagonals, and floor of a leaf $(P[i_1, i_2], Q[j_1, j_2]) \in \Psi$ where $j_1 < j_2$;
2. the P-diagonal and floor of $(P[i_1, i_2], y_j]) \in \Psi$ where $P[i_1, i_2]$ is of length $\frac{p'-1}{q'-1}$;
3. the pairs in $C(P[i_1, i_2], j]) \cup D(P[i_1, i_2], y_j])$ where $(P[i_1, i_2], j]) \in \Psi$ and $P[i_1, i_2]$ is of length $\frac{p'-1}{q'-1}$.

By Statement 4, only the pairs of the first two types may be P-irregular. This statement then follows from Lemmas 5.5(5.5) and 5.5(5.5). ∎

5.5. Recurrences. One-One uses the following formulas to recursively compute $\text{RR}(S_1^{x_i}, S_2^{y_j})$ for $(x_i, y_j) \in G \cup E \cup B$ in terms of the RR values of the appropriate P-predecessor, Q-predecessor, and PQ-predecessor of (x_i, y_j).

For vertex subsets U of S_1 and V of S_2, $\text{M}(U, V)$ denotes the maximum weight of any matching of the bipartite graph $(U, V, U \times V)$ where the weight of an edge (u, v) is $\text{RR}(S_1^u, S_2^v)$. Let $\text{M}(U, v) = \text{M}(U, \{v\})$ and $\text{M}(u, V) = \text{M}(\{u\}, V)$. Given two vertices $x \in S_1$ and $y \in S_2$, let $\overline{\text{M}}(U, V, x, y)$ be the maximum weight of any matching of the same graph without the edge (x, y).

LEMMA 5.7. *For each* $(x_i, y_j) \in B$, $\text{RR}(S_1^x, S_2^y) = 0$.

Proof. This lemma follows from the fact that $p' > p$, $q > q$, and the new labels of S_1 and S_2 are different from one another and the labels of T_1 and T_2. ∎

FACT 2 (see [47]). *For all vertices* $u \in S_1$ *and* $v \in S_2$,

$$\text{RR}(S_1^u, S_2^v) = \max \left\{ \begin{array}{l} \text{M}(K(u, S_1), K(v, S_2)) \\ \text{M}(u, K(v, S_2)) \\ \text{M}(K(u, S_1), v) \end{array} \right\}.$$

Proof. To form maximum agreement subtrees of S_1^u and S_2^v, there are three cases. (1) $\text{M}(K(u, S_1), K(v, S_2))$ accounts for matching u to v. (2) $\text{M}(u, K(v, S_2))$ accounts for matching u to a proper descendant of v. (3) $\text{M}(K(u, S_1), v)$ accounts for matching v to a proper descendant of u. ∎

LEMMA 5.8. *For all (x_i, y_j) where $i < p'$ and $j < q'$, regardless of whether (x_i, y_j) is intersecting or nonintersecting,*

$$\textsc{rr}(S_1^{x_i}, S_2^{y_j}) = \max \left\{ \begin{array}{l} \textsc{m}(X_i, Y_j) + \textsc{rr}(S_1^{x_{i+1}}, S_2^{y_{j+1}}) \\ \overline{\textsc{m}}(X_i \cup \{x_{i+1}\}, Y_j \cup \{y_{j+1}\}, x_{i+1}, y_{j+1}) \\ \textsc{rr}(S_1^{x_i}, S_2^{y_{j+1}}) \\ \textsc{m}(x_i, Y_j) \\ \textsc{rr}(S_1^{x_{i+1}}, S_2^{y_j}) \\ \textsc{m}(X_i, y_j) \end{array} \right\}.$$

Proof. This lemma follows from Fact 2 with a finer case analysis for the cases in the proof of Fact 2. □

LEMMA 5.9. *For each nonintersecting $(x_i, y_j) \in E - B$ with P-predecessor $(x_{i'}, y_j)$ and Q-predecessor $(x_i, y_{j'})$,*

$$\textsc{rr}(S_1^{x_i}, S_2^{y_j}) = \max \left\{ \begin{array}{l} \max_{j'' \in [j, j'-1]} \textsc{m}(x_{i'}, Y_{j''}) + \max_{i'' \in [i, i'-1]} \textsc{m}(X_{i''}, y_{j'}) \\ \textsc{rr}(S_1^{x_i}, S_2^{y_{j'}}) \\ \textsc{rr}(S_1^{x_{i'}}, S_2^{y_j}) \end{array} \right\}.$$

Proof. This lemma follows from Lemma 5.4(2) and is obtained by iterative applications of Lemma 5.8. The following properties are used. Since $(P[i, i'-1], Q[j, j'-1])$ is nonintersecting, for $i'' \in [i, i'-1]$ and $j'' \in [j, j'-1]$,

- $\textsc{m}(X_{i''}, Y_{j''}) = 0$;
- $\overline{\textsc{m}}(X_{i''} \cup \{x_{i''+1}\}, Y_{j''} \cup \{y_{j''+1}\}, x_{i''+1}, y_{j''+1}) = \textsc{m}(x_{i''}, Y_{j''}) + \textsc{m}(X_{i''}, y_{j''})$;
- $\textsc{m}(x_{i''}, Y_{j''}) = \textsc{m}(x_{i'}, Y_{j''})$;
- $\textsc{m}(X_{i''}, y_{j''}) = \textsc{m}(X_{i''}, y_{j'})$. □

For brevity, the symmetric statement of the next lemma for G_Q is omitted.

LEMMA 5.10. *For all nonintersecting pairs $(x_i, y_1) \in G_P - B$ with Q-predecessor (x_i, y_j),*

$$\textsc{rr}(S_1^{x_i}, S_2^{y_1}) = \max \left\{ \begin{array}{l} \textsc{rr}(S_1^{x_i}, S_2^{y_j}) \\ \textsc{rr}(S_1^{x_{i+1}}, S_2^{y_1}) \\ \textsc{m}(X_i, y_j) + \max_{j' \in [1, j-1]} \textsc{m}(x_{i+1}, Y_{j'}) \end{array} \right\}.$$

Proof. The proof is similar to the proof of Lemma 5.9 and follows from Lemma 5.4(3). □

5.6. The algorithm for Problem 1. We combine the discussion in sections 5.3–5.5 to give the following algorithm to solve Problem 1.

ALGORITHM ONE-ONE

begin

1. Compute S_1, S_2, P', Q', $\textsc{rp}(S_1^u, S_2, Q')$ for $u \in K(P', S_1)$, and $\textsc{rp}(S_2^v, S_1, P')$ $v \in K(Q', S_2)$;
2. Compute $G \cup E \cup B$, B, $I(P[1, p'-1], Q[1, q'-1]) - B$, the set of all nonintersecting pairs in $E - B$, and the sets of nonintersecting pairs in $G_P - B$ and $G_Q - B$, respectively;
3. Compute the following predecessors:
   - the P-predecessor, Q-predecessor, and PQ-predecessor of each pair in $I(P[1, p'-1], Q[1, q'-1]) - B$;
   - the P-predecessor and Q-predecessor of each nonintersecting pair in $E - B$;

- the Q-predecessor of each nonintersecting pair in $G_P - B$ and the P-predecessor of each nonintersecting pair in $G_Q - B$;

4. For all pairs in $G \cup E \cup B$, compute the non-RR terms in the appropriate recurrence formulas of section 5.5:
   - Lemma 5.7 for B;
   - Lemma 5.8 for $I(P[1, p'-1], Q[1, q'-1]) - B$;
   - Lemma 5.9 for the nonintersecting pairs in $E - B$;
   - Lemma 5.10 for the nonintersecting pairs in $G_P - B$ and its symmetric statement for the nonintersecting pairs in $G_Q - B$;
5. Compute the $\text{RR}(S_1^{x_i}, S_2^{y_j})$ for all $(x_i, y_j) \in G \cup E \cup B$ using the appropriate recurrence formulas given in section 5.5 and the non-RR terms computed at step 4;
6. Compute the output as follows:
   - For all $y_j \in Q$, $\text{RP}(T_1, T_2, Q)(y_j) \leftarrow \text{RR}(S_1^{x_1}, S_2^{y_j})$;
   - For all $x_i \in P$, $\text{RP}(T_2, T_1, P)(x_i) \leftarrow \text{RR}(S_1^{x_i}, S_2^{y_1})$;
   - For every $v \in K(Q, T_2)$, $\text{RP}(T_1, T_2, Q)(v) \leftarrow \text{RP}(T_2^v, T_1, P)(h)$ where h is the root of $T_1 || T_2^v$;
   - For every $u \in K(P, T_1)$, $\text{RP}(T_2, T_1, P)(u) \leftarrow \text{RP}(T_1^u, T_2, Q)(h)$ where h is the root of $T_2 || T_1^u$;

end.

To analyze One-One, we first focus on step 4. The recurrences of section 5.5 contain only four types of non-RR terms other than the constant 0 in Lemma 5.7:

1. $\text{M}(X_i, y_j)$ and $\text{M}(x_i, Y_j)$;
2. $\max_{i \in [i_1, i_2]} \text{M}(X_i, y_j)$ and $\max_{j \in [j_1, j_2]} \text{M}(x_i, Y_j)$;
3. $\text{M}(X_i, Y_j)$;
4. $\overline{\text{M}}(X_i \cup \{x_{i+1}\}, Y_j \cup \{y_{j+1}\}, x_{i+1}, y_{j+1})$.

It is important to notice that these non-RR terms can be simultaneously evaluated. In light of this observation, we compute these terms by using the techniques of section 5.1 to process the normal sequences A_i, A_u, B_j, B_v defined below:

- $A_i(j) = \text{M}(X_i, y_j)$ for all x_i and y_j;
- $B_j(i) = \text{M}(x_i, Y_j)$ for all y_j and x_i;
- $A_u(j) = \text{RR}(S_1^u, S_2^{y_j})$ for all $u \in K(P', S_1)$ and y_j;
- $B_v(i) = \text{RR}(S_2^v, S_1^{x_i})$ for all $v \in K(Q', S_2)$ and x_i.

Note that A_i and A_u have length q', and A_i is the joint of all A_u where $u \in X_i$. Similarly, B_j and B_v have length p', and B_j is the joint of all B_v where $v \in Y_j$.

LEMMA 5.11.

1. *The minimal condensed forms of the sequences A_u and B_v have a total size of $O(n)$ and can be computed in $O(n)$ time.*
2. *The minimal condensed forms of the sequences A_i and B_j have a total size of $O(n)$ and can be computed in $O(n)$ time.*

Proof. Statement 2 follows from Statement 1 and Lemma 5.1. Below we only prove Statement 1 for A_u; Statement 1 for B_v is similarly proved. We first compute a condensed form $\overline{A}_u$ for each A_u as follows:

1. For all $u \in K(P', S_1)$, compute $S_{2,u} = S_2 || S_1^u$ and $Q_u = Q' || S_1^u$.
2. For all u where Q_u is nonempty, do the following steps:
   (a) $\overline{A}_u \leftarrow \{(j, w) \mid y_j \in Q_u, w = \text{RP}(S_1^u, S_2, Q')(y_j)\}$.
   (b) Compute all tuples $(\hat{v}, v, y_j)$ where $\hat{v} \in K(Q_u, S_{2,u})$, $v \in K(Q', S_2)$, $\hat{v} \in S_2^v$, and $v \in Y_j$.
   (c) Find the smallest s such that some $(\hat{v}, v, y_s)$ is obtained at Step 2(b).

(d) If there is only one $(\hat{v}, v, y_s)$, then add to $\overline{A}_u$ the pair (s, w) where $w = \text{RP}(S_1^u, S_2, Q')(\hat{v})$.

3. For all u where $S_{2,u}$ is nonempty and Q_u is empty, do the following steps:
   (a) Compute $\hat{v}$, v, and y_s where $\hat{v}$ is the root of $S_{2,u}$, $v \in K(Q', S_2)$, $\hat{v} \in S_2^v$, and $v \in Y_s$.
   (b) $\overline{A}_u \leftarrow \{(s, w)\}$, where $w = \text{RP}(S_1^u, S_2, Q')(\hat{v})$.
4. For all u where $S_{2,u}$ is empty, $\overline{A}_u \leftarrow \emptyset$.

The correctness proof of this algorithm has three cases.

Case 1. Q_u is nonempty. Let $y_{j_1}, y_{j_2}, \ldots, y_{j_k} = Q_u$. Let $j_0 = 0$. Then, for all $k' \in [1, k]$ and all $j \in [j_{k'-1} + 1, j_{k'}]$, $S_2^{y_j} || S_1^u = S_{2,u}^{y_{k'}}$ and by Lemma 3.1, $A_u(j) = \text{RP}(S_1^u, S_2, Q')(y_{k'})$. There are two subcases for $j > j_k$.

Case 1a. Step 2(b) finds two or more $(\hat{v}, v, y_s)$. Then $y_s \in Q_u$, $s = j_k$, and for all $j \in [j_k + 1, q']$, $S_2^{y_j} || S_2^u$ is empty and $A_u(j) = 0$.

Case 1b. Step 2(b) finds only one $(\hat{v}, v, y_s)$. Then $y_s \notin Q_u$ and $s > j_k$. For all $j \in [j_k + 1, s]$, $S_2^{y_j} || S_1^u = S_{2,u}^{\hat{v}}$ and $A_u(j) = \text{RP}(S_1^u, S_2, Q')(\hat{v})$. For all $j \in [s + 1, q']$, $S_2^{y_j} || S_1^u$ is empty and $A_u(j) = 0$.

Thus, the $\overline{A}_u$ of Step 2 is a condensed form of A_u for Case 1.

Case 2. $S_{2,u}$ is nonempty and Q_u is empty. This case is similar to Case 1b, and Step 3 computes a correct condensed form $\overline{A}_u$ for this case.

Case 3. $S_{2,u}$ is empty. This case is obvious, and Step 4 correctly computes a condensed form $\overline{A}_u$ of A_u for this case.

The total size of all $\overline{A}_u$ is at most that of the RP mappings of S_1, S_2, P', and Q', which is the desired $O(n)$. Step 1 takes $O(n)$ time using Fact 1. The other steps can be implemented in $O(n)$ time in straightforward manners using radix sort and tree traversal. As discussed in section 3, the RP mappings are evaluated by radix sort. Once the forms $\overline{A}_u$ are obtained, we can in $O(n)$ time radix sort the pairs in all $\overline{A}_u$ and then delete all unnecessary pairs to obtain the desired minimal condensed forms. □

LEMMA 5.12. *All the non-*RR *terms of the first two types for the pairs in* $G \cup E \cup B$ *can be evaluated in* $O(n \log(p+1) \log(q+1))$ *time.*

Proof. The value of $\text{M}(X_i, y_j)$ is that of the point query $([i, i], j)$ for $A_1, \ldots, A_{q'}$, and the value of $\max_{i \in [i_1, i_2]} \text{M}(X_i, y_j)$ is that of the interval query $([i_1, i_2], j)$. By Lemma 5.5(5.5), there are $O(n \log(p+1))$ such terms required for the pairs in $G \cup E \cup B$. Given the results of steps 2 and 3 of One-One, we can determine all such terms and the corresponding queries in $O(n \log(p+1))$ time. By Lemma 5.6(5), only $O(n \log(q+1))$ of these queries are not P-regular. By Lemmas 5.11(2) and 5.2(2), we can evaluate these queries in $O(n \log(p+1) \log(q+1))$ time. The terms $\text{M}(x_i, Y_j)$ and $\max_{j \in [j_1, j_2]} \text{M}(x_i, Y_j)$ are similarly evaluated in $O(n \log(p+1) \log(q+1))$ time. The analysis for these terms is easier because $p' \geq q'$, and it does not involve the notion of Q-regularity. □

LEMMA 5.13. *The non-*RR *terms of the third and the fourth type for the pairs in* $G \cup E \cup B$ *can be evaluated within the following time complexity:*

1. $O(nd \log d)$ *or alternatively* $O(n\sqrt{d} \log n)$ *for the third type*;
2. $O(nd^2 \log d)$ *or alternatively* $O(nd\sqrt{d} \log n)$ *for the fourth type.*

Proof. To prove Statement 1, we consider the graphs $(X_i, Y_j, X_i \times Y_j)$ on which the desired terms $\text{M}(X_i, Y_j)$ are defined. Let $Z_{i,j}$ be the subgraph of $(X_i, Y_j, X_i \times Y_j)$ constructed by removing all zero-weight edges and all resulting isolated vertices. The edges of $Z_{i,j}$ are computed as follows:

1. For all $u \in K(P', S_1)$, compute $S_{2,u} = S_2 || S_1^u$ and $Q_u = Q' || S_1^u$.
2. For all $S_{2,u}$ is nonempty, do the following steps:

(a) If Q_u is nonempty, compute all tuples (u, v, w) where $\hat{v} \in K(Q_u, S_{2,u})$, $v \in K(Q', S_2)$, $\hat{v} \in S_2^v$, and $w = \text{RP}(S_1^u, S_2, Q')(\hat{v})$.
(b) If Q_u is empty, compute the tuple (u, v, w) where $\hat{v}$ is the root of $S_{2,u}$, $v \in K(Q', S_2)$, $\hat{v} \in S_2^v$, and $w = \text{RP}(S_1^u, S_2, Q')(\hat{v})$.

This algorithm captures all the nonzero-weight (u, v). At step 2, $S_{2,u}^{\hat{v}} = S_2^v || S_1^u$ and by Lemma 3.1 $\text{RR}(S_1^u, S_2^v) = \text{RP}(S_1^u, S_2, Q')(\hat{v})$. Thus, the first two components of the obtained tuples form the edges of all desired $Z_{i,j}$ and the third components are the weights of these edges. We use Fact 1 to implement step 1 in $O(n)$ time. We can implement step 2 in $O(n)$ time using radix sort and tree traversal. Note that step 2 uses radix sort to evaluate RP mappings. With the tuples (u, v, w) obtained, we use radix sort to construct all desired $Z_{i,j}$ in $O(n)$ time. Let $m_{i,j}$ and $n_{i,j}$ be the numbers of edges and vertices in $Z_{i,j}$, respectively. Since an edge weighs at most n, we can compute $\text{M}(X_i, Y_j)$ in $O(n_{i,j} \cdot m_{i,j} + n_{i,j}^2 \cdot \log n_{i,j})$ and alternatively in $O(m_{i,j} \cdot \sqrt{n_{i,j}} \cdot \log(n \cdot n_{i,j}))$ time [21, 42]. Statement 1 then follows from the fact that $n_{i,j} \leq 2d'$, $n_{i,j} \leq 2m_{i,j}$, and by Lemma 5.5(5.5) the sum of all $m_{i,j}$ is at most n.

To prove Statement 2, we similarly process the bipartite graphs on which the desired terms $\overline{\text{M}}(X_i \cup \{x_{i+1}\}, Y_j \cup \{y_{j+1}\}, x_{i+1}, y_{j+1})$ are defined. The key difference from the third type is that in addition to some of the edges in $Z_{i,j}$, we need certain nonzero-weight (u, y_{j+1}) for $u \in X_i$ and (x_{i+1}, v) for $v \in Y_j$. Since these edges are required only for intersecting (x_i, y_j), by Lemma 5.5(5.5), $O(dn)$ such edges are needed. We use Lemma 5.11(1) to compute the weights of these edges in $O(dn)$ time. Due to these edges, the total time complexity for the fourth type is $O(d)$ times that for the third type. □

The next theorem serves to prove Theorem 4.1 given at the beginning of section 4.

THEOREM 5.14. *One-One solves Problem* 1 *with the following time complexities:*

$$O(nd^2 \log d + n \log(p+1) \log(q+1))$$

or, alternatively,

$$O(nd\sqrt{d} \log n + n \log(p+1) \log(q+1)).$$

Proof. The correctness of One-One follows from Lemma 5.3 and sections 5.3–5.5. As for the time complexity, step 1 is obvious and takes $O(n)$ time. By computing Ψ, we can compute the sets E and $I(P[1, p'-1], Q[1, q'-1])$. Since the leaf labels of S_1 and S_2 are from $[1, O(n)]$, each level of Ψ can be computed in $O(n)$ time. Since Ψ has $O(\log(p+1))$ levels, E and $I(P[1, p'-1], Q[1, q'-1])$ can be computed in $O(n \log(p+1))$ time. With these two sets obtained, we can compute all the desired sets in $O(n \log(p+1))$ time. Thus, step 2 takes $O(n \log(p+1))$ time. Step 3 takes $O(n \log(p+1))$ time using radix sort. The time complexity of step 4 dominates that of One-One. This step uses Lemmas 5.12 and 5.13 and takes $O(n \log(p+1) \log(q+1) + nd^2 \log d)$ time or, alternatively, $O(n \log(p+1) \log(q+1) + nd\sqrt{d} \log n)$ time. Step 5 spends $O(n \log(p+1))$ time using radix sort to create pointers from the pairs in $G \cup E \cup B$ to appropriate predecessors. Step 5 then takes $O(1)$ time per pair in $G \cup E \cup B$ and $O(n \log(p+1))$ time in total. Step 6 takes $O(n \log(p+1))$ time. It uses radix sort to access the desired RR values and evaluate the input mappings. It also uses Fact 1 to compute all $T_1 || T_2^v$ and $T_2 || T_1^u$. □

6. Discussions. We answer the main problem of this paper with the following theorem and conclude with an open problem.

THEOREM 6.1. *Let T_1 and T_2 be two evolutionary trees with n leaves each. Let d be their maximum degree. Given T_1 and T_2, a maximum agreement subtree of T_1 and T_2 can be computed in $O(nd^2 \log d \log^2 n)$ time or alternatively in $O(nd\sqrt{d} \log^3 n)$ time. Thus, if d is bounded by a constant, a maximum agreement subtree can be computed in $O(n \log^2 n)$ time.*

Proof. By Theorem 4.5, the algorithms in sections 4–5 compute $\mathrm{RR}(T_1, T_2)$ within the desired time bounds. With straightforward modifications, these algorithms can compute a maximum agreement subtree within the same time bounds. □

The next lemma establishes a reduction from the longest common subsequence problem to that of computing a maximum agreement subtree.

LEMMA 6.2. *Let $M_1 = x_1, \ldots, x_n$ and $M_2 = y_1, \ldots, y_n$ be two sequences. Assume that the symbols x_i are all distinct and so are the symbols y_j. Then, the problem of computing a longest common subsequence of M_1 and M_2 can be reduced in linear time to that of computing a maximum agreement subtree of two binary evolutionary trees.*

Proof. Given M_1 and M_2, we construct two binary evolutionary trees T_1 and T_2 as follows. Let z_1 and z_2 be two distinct symbols different from all x_i and y_i. Next, we construct two paths $P_1 = u_1, \ldots, u_{n+1}$ and $P_2 = v_1, \ldots, v_{n+1}$. T_1 is formed by making u_1 the root, attaching x_i to u_i as a leaf, and attaching z_1 and z_2 to u_{n+1} as leaves. Symmetrically, T_2 is formed by making v_1 the root, attaching y_i to v_i, and attaching z_1 and z_2 to v_{n+1}. The lemma follows from the straightforward one-to-one onto correspondence between the longest common subsequences of M_1 and M_2 and the maximum agreement subtrees of T_1 and T_2. □

We can use Lemma 6.2 to derive lower complexity bounds for computing a maximum agreement subtree from known bounds for the longest common subsequence problem in various models of computation [3, 6, 23, 29, 30, 32, 50]. This paper assumes a comparison model where two labels x and y can be compared to determine whether x is smaller than y or $x = y$ or x is greater than y. Since the longest common subsequence problem in Lemma 6.2 requires $\Omega(n \log n)$ time in this model [31], the same bound holds for the problem of computing a maximum agreement subtree of two evolutionary trees where d is bounded by a constant. It would be significant to close the gap between this lower bound and the upper bound of $O(n \log^2 n)$ stated in Theorem 6.1. Recently, Farach, Przytycka, and Thorup [13] independently developed an algorithm that runs in $O(n\sqrt{d} \log^3 n)$ time. For binary trees, Cole and Hariharan [8] gave an $O(n \log n)$-time algorithm. It may be possible to close the gap by incorporating ideas used in those two results and this paper.

Acknowledgments. The author is deeply appreciative for the extremely thorough and useful suggestions given by the anonymous referee. The author thanks Joseph Cheriyan, Harold Gabow, Andrew Goldberg, Dan Gusfield, Dan Hirschberg, Phil Klein, Phil Long, K. Subramani, Bob Tarjan, and Tandy Warnow for helpful comments, discussions, and references.

OPTIMAL PREDICTION FOR PREFETCHING IN THE WORST CASE*

P. KRISHNAN† AND JEFFREY SCOTT VITTER‡

Abstract. Response time delays caused by I/O are a major problem in many systems and database applications. Prefetching and cache replacement methods are attracting renewed attention because of their success in avoiding costly I/Os. Prefetching can be looked upon as a type of online sequential prediction, where the predictions must be accurate as well as made in a computationally efficient way. Unlike other online problems, prefetching cannot admit a competitive analysis, since the optimal offline prefetcher incurs no cost when it knows the future page requests. Previous analytical work on prefetching [*J. Assoc. Comput. Mach.*, 143 (1996), pp. 771–793] consisted of modeling the user as a probabilistic Markov source.

In this paper, we look at the much stronger form of worst-case analysis and derive a randomized algorithm for pure prefetching. We compare our algorithm for every page request sequence with the important class of finite state prefetchers, making no assumptions as to how the sequence of page requests is generated. We prove analytically that the fault rate of our online prefetching algorithm converges almost surely for every page request sequence to the fault rate of the optimal finite state prefetcher for the sequence. This analysis model can be looked upon as a generalization of the competitive framework, in that it compares an online algorithm in a worst-case manner over all sequences with a powerful yet nonclairvoyant opponent. We simultaneously achieve the computational goal of implementing our prefetcher in optimal constant expected time per prefetched page using the optimal dynamic discrete random variate generator of Matias, Vitter, and Ni [*Proc. 4th Annual SIAM/ACM Symposium on Discrete Algorithms*, Austin, TX, January 1993].

1. Introduction.

Most computer memories are organized hierarchically. A typical two-level memory consists of a relatively small but fast *cache* (such as internal memory) and a relatively large but slow memory (such as disk storage). Two-level memories can also model on-chip versus off-chip memory in VLSI systems. The pages requested by an application must be in cache before computation can proceed. In the event that a requested page is not in cache, a *page fault* occurs and the application has to wait while the page is fetched from slow memory to cache. The method of fetching pages into cache only when a fault occurs is called *demand fetching*. The problem of *cache replacement* is to decide which pages to remove from cache to accommodate the incoming pages.

In many systems and database applications, users spend a significant amount of

time processing a page, and the computer and I/O system are typically idle during that period. If the computer can predict which page the user will request next, it can fetch that page into cache (if it is not already in cache) *before* the user asks for it. When the user requests the page, it is available in cache, and the user perceives a faster response time. This method of getting pages into cache in the background before they are requested is called *prefetching*.

In many hypertext and interactive database systems, there is often sufficient time between user requests to prefetch as many pages as wanted, limited only by the cache size k. We refer to prefetching under this assumption as *pure prefetching*, and we restrict our analysis to pure prefetching in this paper. Pure prefetching is an important theoretical and practical model that helps in analyzing the benefits of fetching pages in the background.

In general applications, other issues come into play. For example, prefetches are often done well in advance of when the page is expected to be needed, to take into account latency [29, 31]. User requests can also preempt prefetch requests, resulting in fewer than k prefetches being done at a time. In such situations, which we call *nonpure prefetching*, issues of cache replacement come into play; the algorithm must determine not only which page(s) to prefetch but also which page(s) to evict from cache to make room. Pure prefetchers can be converted into efficient and practical nonpure prefetchers by melding them with good cache replacement strategies. In [10], pure prefetchers are used with the popular least recently used (LRU) cache replacement strategy, and significant reductions in page fault rate (number of page faults divided by the number of page requests) are demonstrated. We expect that better pure prefetchers (e.g., the one developed in this paper) melded with better cache replacement strategies (e.g., [5, 13, 19, 20]) may yield even more impressive performance improvements.

An algorithm is *online* if it must make its decisions based only on the past history. An *offline* algorithm can use knowledge of the future. If the program generating page requests is known a priori, prefetching decisions could be made offline, as is done in compiler-directed prefetching [6, 29, 31] where prefetch instructions are explicitly inserted into the code. Without a priori knowledge or statistics of the user request pattern, as is the case in many hypertext and interactive applications (e.g., the world wide web), an algorithm for cache replacement or prefetching must be online. An important computational requirement of online prefetching (and online demand fetching) algorithms is that the time spent deciding which pages to fetch into (or evict from) cache must be minimal. In this paper, we study online pure prefetching.

1.1. Analysis technique. The notion of *competitiveness* introduced by Sleator and Tarjan [34] evaluates an online algorithm by comparing its performance with that of offline algorithms. Competitive algorithms for cache replacement are well examined in the literature [5, 13, 27, 34]. It is unreasonable to expect prefetching algorithms to be competitive in this sense. The trivial optimal offline algorithm for prefetching never faults, if it can prefetch at least one page every time. In order to be competitive, an online algorithm would have to be an almost perfect predictor for any sequence, which seems intuitively impossible. Some restrictions on the power of the offline algorithm are therefore needed for a meaningful analysis.

Vitter and Krishnan [36] analyzed pure prefetching using a form of the competitive philosophy; they assumed that the sequence of page requests was generated by a probabilistic Markov source [14]. They showed that the prediction techniques inherent in data compression methods (such as the Lempel–Ziv algorithm [37]) can be

used to get optimal pure prefetchers. Cache replacement has been studied by Karlin, Phillips, and Raghavan [20] under a different stochastic version of the competitive framework; the sequence of page requests was assumed to be generated by a Markov chain (a subset of Markov sources). In [20, 36], the online prefetching or cache replacement algorithm is compared with the optimal online algorithm that has full prior knowledge of the source. A PAC learning framework incorporating Markov sources of examples was developed in [1]. Recent empirical work on prefetching includes a pattern matching approach to prediction [30], computing various first-order statistics for prediction [32], a growing-order Markov predictor [24], prefetching in a parallel environment [22], and research projects at a lower level of abstraction including compiler-directed prefetching [6, 29, 31].

In this paper, we develop a randomized algorithm for pure prefetching and show its optimality in the limit under the following analysis strategy. Putting *no* restrictions on the generator of page requests, we compare the page fault rate of our prefetcher *for every sequence of page requests* with that of the *best finite state prefetcher for the sequence.* We also show how to implement each prefetch in *constant expected time,* independent of the number of pages in the database and the cache size, which is optimal.

The analysis strategy used in this paper is much stronger than the ones in [20, 36] for the following reasons. First, our comparison is for all sequences, without any assumption about how the sequences are generated. Second, although the comparison in [20, 36] is against the optimal computationally unlimited online algorithm with full a priori knowledge of the source, it is the case for prefetching and cache replacement that when the page request sequences are generated by a finite state Markov source (or a Markov chain), the optimal online algorithm is finite state. (See [36, Definition 4] and [20, Theorem 2].) In particular, the fault rate of the prefetcher we develop in this paper is asymptotically the same as the fault rate of the optimal prefetcher from [36] when the source is finite state Markov.

Pure prefetching can be looked upon as the following prediction problem: given an arbitrary alphabet of size α (the set of α pages in the database) and a sequence of (page) requests drawn from this alphabet, at each time instant we have to predict the best k choices for the k pages to prefetch into cache. Randomness is required in order for a predictor or prefetcher to be optimal for every sequence when compared with finite state prefetchers (FSPs) [7]. (Also see Appendix A.) In the fields of information theory and statistics [4, 8, 12, 17] interesting algorithms for binary sequences (corresponding to an alphabet size of $\alpha = 2$ pages) that make one prediction for the next page (corresponding to cache size $k = 1$) have been developed independently of [36], and the comparison is made with the best finite state predictor. However, the $\alpha = 2$, $k = 1$ case is clearly unsuitable for our prefetching scenario. The procedure in [17] may possibly be generalizable to the arbitrary alphabet case $\alpha \geq 2$ for cache size $k = 1$, but it cannot possibly make a prediction in constant time independent of α, and the $k > 1$ case is open. In [28], predictors are developed for various continuous loss functions, but they are not relevant to the harder-to-analyze discontinuous 0–1 loss functions associated with cache replacement and prefetching. The solution to the general case thus requires a fundamentally different approach from those mentioned above.

1.2. This paper. Our major contribution in this paper is a randomized algorithm for pure prefetching *that achieves the optimal fault rate almost surely in the limit against the class of FSPs and that is simultaneously optimal in terms of running*

time for the general case of $\alpha \geq 2$ pages and cache size $k \geq 1$. ("Almost surely" means that the probability that convergence does not occur for an arbitrary sequence converges to 0 as the sequence length n gets larger.)

Our analysis model and main results are summarized in the next section. In section 3, we present our core prefetching algorithm P_1, which makes use of sampling without replacement, and we analyze it in section 4 by comparing it with the best one-state prefetcher. In section 5 we draw on ideas from information theory [9] applied to predicting [8, 12, 28] and generalize P_1 to get a universal prefetcher P that is optimal in the limit against a general FSP. The resulting optimal prefetcher P is a blend of P_1 and the prefetcher [36] based on the Lempel–Ziv data compressor [18, 25, 37]. We show in section 6 how to implement the prefetcher in constant expected time per prefetched page, independent of alphabet size α and cache size k, by using the optimal dynamic algorithm for generating discrete random variates of Matias, Vitter, and Ni [26], which uses a table lookup method of Hagerup, Mehlhorn, and Munro [16]. Other issues are discussed in section 7.

2. Analysis model and main results. We denote the cache size by k and the total number of different pages (or alphabet size) by α. We use the notation σ_i^j to denote the subsequence of a (possibly infinite) sequence σ starting at the ith page request up to and including the jth page request; in particular, σ_1^n denotes the first n page requests of σ. Given a parsing of σ_1^n into subsequences, we will denote the jth subsequence by σ_j.

DEFINITION 1. *An FSP is represented as a quintuple (S, A, g, D, z_0), where S is a finite set of states, $A = \{0, 1, 2, \ldots, \alpha - 1\}$ is a finite alphabet of cardinality $|A| = \alpha$, g is a deterministic "next state" function that maps $S \times A$ into S, D is a (possibly randomized) decision strategy function that maps S into a k-tuple A^k, and $z_0 \in S$ is the start state. The FSP prefetches at state $z \in S$ the k pages specified by $D(z)$, and upon seeing the next page request i, it changes state from z to $g(z, i)$. We denote the set of all FSPs with at most s states by $\mathcal{F}(s)$.*

We next define the best fault rate achieved on a sequence by the class of FSPs.

DEFINITION 2. *Given an FSP F and a sequence σ_1^n, we denote by $Fault_F(\sigma_1^n)$ the fault rate of F on σ_1^n, that is, the number of page faults of F on σ_1^n (expected number of page faults if F has a randomized decision strategy), divided by the length n of the sequence. We define $Fault_{\mathcal{F}(s)}(\sigma_1^n)$ to be $\inf_{F \in \mathcal{F}(s)} Fault_F(\sigma_1^n)$. With a little abuse of notation we also denote by $Fault_B(\sigma_1^n)$ the fault rate of a nonfinite state prefetcher B.*

Intuitively, we can think of $Fault_{\mathcal{F}(s)}(\sigma_1^n)$ as being given by an optimal *offline* algorithm restricted by the finite state requirement. This means that unlike an offline algorithm, the FSP does not know the sequence σ_1^n beforehand. However, it knows how many times each of its transitions will be traversed when it is used to prefetch on the sequence σ_1^n. In other words, the optimal FSP is a "weak" offline algorithm. For example, the optimal one-state FSP for a sequence σ_1^n does not know σ_1^n but knows how many times each page appears in σ_1^n. By simple convexity arguments it can be verified that the optimal one-state FSP for σ_1^n will, when at state z, deterministically prefetch the k pages corresponding to the k transitions out of z that are traversed the maximum number of times. (Hence $Fault_{\mathcal{F}(s)}(\sigma_1^n) = \min_{F \in \mathcal{F}(s)} Fault_F(\sigma_1^n)$, the minimum fault rate achieved by any FSP with at most s states on σ_1^n.) For example, $Fault_{\mathcal{F}(1)}(\sigma_1^n)$ is attained by the following one-state (zero-order) prefetcher F_1: count the number of times that page i, for $0 \leq i \leq \alpha - 1$, appears in σ_1^n. Let $C_1(\sigma_1^n) = \{i_1, i_2, \ldots, i_k\}$ be k pages with the maximum k counts. At every time t, for $1 \leq t \leq n$,

predict the next page to be one of the k pages in $C_1(\sigma_1^n)$ (that is, we always keep the same pages in cache). We design an online randomized prefetcher P_1 that achieves on average the best single-state (zero-order) prefetching fault rate $Fault_{\mathcal{F}(1)}(\sigma_1^n)$ on every sequence σ_1^n of length n in the limit as $n \to \infty$.

THEOREM 1. *For every sequence σ_1^n of length n drawn from alphabet A, the fault rate of prefetcher P_1 on σ_1^n converges almost surely to $Fault_{\mathcal{F}(1)}(\sigma_1^n)$ as $n \to \infty$. In particular,*

$$Fault_{P_1}(\sigma_1^n) \leq Fault_{\mathcal{F}(1)}(\sigma_1^n) + O\left(\frac{\log n}{\sqrt{n}}\right). \tag{1}$$

The main difficulty in developing P_1 and its proof of optimality is that the alphabet size α and the cache size k are arbitrary. We note that even for the $\alpha = 2$, $k = 1$ case, the convergence rate cannot be faster than $O(1/\sqrt{n})$ [7].

The importance of the above theorem lies in its generalization to higher order using techniques from information theory [9]. The approach of [12] allows us to combine P_1 with a prefetcher [36] based on the Lempel–Ziv data compressor [18, 25, 37] to get a prefetcher P that is optimal in the limit against the class of FSPs.

THEOREM 2. *For every sequence σ_1^n of length n drawn from alphabet A, and any $s \geq 0$, the fault rate of prefetcher P on σ_1^n converges almost surely to $Fault_{\mathcal{F}(s)}(\sigma_1^n)$ as $n \to \infty$.*

From the observation in section 1.1 that under the model from [36] (where the sequences of page requests are generated by a finite state Markov source), the optimal prefetcher is also an FSP, we get the following corollary.

COROLLARY 1. *Under the model from* [36]*, where the sequences of page requests are generated by a finite state Markov source M, the fault rate of prefetcher P converges almost surely to the minimum fault rate of any online prefetcher with complete a priori knowledge of the source M.*

The expected running time for prefetcher P can be made optimal by using the optimal dynamic random variate generator of [26].

THEOREM 3. *The prefetcher P runs in constant expected time (independent of α and k) for each page prefetched; that is, it requires an average of $O(k)$ time to determine which k pages to prefetch.*

The rate of convergence of Theorems 1 and 2 depends on the alphabet size α. For example, the error term is $O(\alpha k^2(\log n)/\sqrt{n})$ in Theorem 1; for simplicity we suppress the αk^2 term in our discussion since it is insignificant w.r.t. n in the limit. (Note that in general $k \ll \alpha$.) However, the constant time bound for each prediction is entirely independent of α and k, which is important from a computational point of view.

3. The prefetching algorithm P_1. In this section we give the algorithm P_1 that matches the best one-state prefetcher in the limit. Before introducing P_1, we present the more intuitive algorithm P_1' upon which algorithm P_1 is based.

Let t be the current time and let σ_1^t be the sequence of t pages requested until now. Let $f_i(\sigma_1^t)$, $0 \leq i \leq \alpha - 1$, denote the number of times page i appears in σ_1^t. Define $r_t = 2^j$ when $4^{j-1} < t \leq 4^j$. That is, the integer r_t is "close to" $\sqrt{t}$; it doubles at discrete time steps (when t is one greater than a power of 4).

The key idea that prefetcher P_1' (and prefetcher P_1) uses is to reduce the problem of prediction to the problem of generating random variates. Intuitively P_1' should choose for the cache the page i with the highest or nearly highest frequency

count $f_i(\sigma_1^t)$. (Randomness in the picking is required, by the remark in section 1 [7], so it does not suffice to simply pick the page with the highest frequency count; see Appendix A.1. Further, the "natural" randomized algorithm that prefetches page i at time t with probability proportional to $f_i(\sigma_1^t)$ is also not optimal as shown in Appendix A.2.) In P_1' we get the effect of choosing the pages with the highest or nearly highest counts by "boosting" the frequency counts of the page by a large power and then choosing a page with probability proportional to its boosted count. (The boosted counts will be very large but can be represented with $O(\log n)$ bits, using the scheme discussed in section 6.) Efficient random variate generation with dynamically changing weights can be done using [26], as discussed in section 6.

The algorithm P_1' is a simple randomized weighting algorithm that makes k predictions at each time step for the next page request. At each time t and $0 \le i \le \alpha - 1$, P_1' assigns to page i a probability $p_{i,t}$ proportional to the boosted frequency count

$$\left(f_i(\sigma_1^t)\right)^{r_t}, \tag{2}$$

which is the r_tth power of frequency $f_i(\sigma_1^t)$. It predicts k items for the next request by choosing without replacement from the distribution $p_{0,t}, p_{1,t}, \ldots, p_{\alpha-1,t}$.

Example 1. *Let* $\alpha = 3$, $k = 2$. *If the sequence* σ_1^t *of* $t = 9$ *pages seen until now is* 210011102, *we have* $f_0(\sigma_1^9) = 3$, $f_1(\sigma_1^9) = 4$, $f_2(\sigma_1^9) = 2$, *and* $r_t = 2^2 = 4$. *Algorithm* P_1' *assigns probability* $p_{0,9} = 3^4/(3^4 + 4^4 + 2^4) \approx 0.229$ *to page* 0, *probability* $p_{1,9} = 4^4/(3^4 + 4^4 + 2^4) \approx 0.725$ *to page* 1, *and probability* $p_{2,9} = 2^4/(3^4 + 4^4 + 2^4) \approx 0.045$ *to page* 2. *It predicts two pages out of these three by choosing without replacement based on the above probability distribution. Pages* 0 *and* 1 *are the likely pages to be chosen.* □

Algorithm P_1' can be shown to be optimal against the best one-state FSP for general $\alpha \ge 2$ but only when $k = 1$ [23]. We can modify algorithm P_1' to get algorithm P_1 that is optimal against the best one-state FSP for general $\alpha \ge 2, k \ge 1$.

DEFINITION 3. *We define subsequence* $\sigma_0 = \sigma_1^2$, *and* $\sigma_j = \sigma_{4^{j-1}+2}^{4^j+1}$ *for* $j \ge 1$. *We call* σ_j *the* jth r-subsequence *of* σ_1^n.

Notice from the definition of r_t that P_1' predicts each page in an r-subsequence using the same value for r_t in (2) when $t > 2$.

Algorithm P_1 works like algorithm P_1', except that the frequency counts for the pages are reset to 0 at the start of each r-subsequence. That is, at time $t > 1$, $4^{j-1} < t \le 4^j$, algorithm P_1 assigns to page i a probability $p_{i,t}$ proportional to

$$\left(f_i(\sigma_{4^{j-1}+2}^t)\right)^{r_t}.$$

Example 2. *As in Example* 1, *let* $\alpha = 3$, $k = 2$, *and let the sequence of* $t = 9$ *pages* σ_1^t *seen until now be* 210011102. *We have* $\sigma_0 = 21$, $\sigma_1 = 001$, *and the portion of* σ_2 *seen until now is* 1102. *The counts of pages* 0, 1, *and* 2 *in the current* r*-subsequence are* 1, 2, *and* 1, *respectively, and* $r_t = 2^2 = 4$. *Algorithm* P_1 *assigns pages* 0, 1, *and* 2 *the probabilities* $p_{0,9} = 1^4/(1^4 + 2^4 + 1^4) \approx 0.056$, $p_{1,9} = 2^4/(1^4 + 2^4 + 1^4) \approx 0.889$, *and* $p_{2,9} = 1^4/(1^4 + 2^4 + 1^4) \approx 0.056$, *respectively. It predicts two pages out of these three by choosing without replacement based on the above probability distribution.* □

This regular throwing away of past information by algorithm P_1 makes the proof of optimality more elegant. Algorithm P_1 may also perform better than algorithm P_1' in practice, since it captures the effect of locality of reference found in page request sequences [3, 5, 11, 19, 20, 33].

4. One-state case: Optimality of P_1 vs. $\mathcal{F}(1)$. In this section we prove an important special case of Theorem 1, namely, that the expected value of P_1's fault

rate $Fault_{P_1}(\sigma_1^n)$ converges to $Fault_{\mathcal{F}(1)}(\sigma_1^n)$; the almost-sure convergence follows by using the Borel–Cantelli lemma. As pointed out in section 2, given a sequence σ_1^n, the following prefetcher $F_1 \in \mathcal{F}(1)$ attains the minimum fault rate among all one-state prefetchers: count the number of times page i, for $0 \le i \le \alpha - 1$, appears in σ_1^n. Let $C_1(\sigma_1^n) = \{i_1, i_2, \ldots, i_k\}$ be the pages with the maximum k counts. For each time instant t, $1 \le t \le n$, F_1 prefetches the k pages in $C_1(\sigma_1^n)$. We have

$$Fault_{\mathcal{F}(1)}(\sigma_1^n) = 1 - \frac{f_{i_1}(\sigma_1^n) + f_{i_2}(\sigma_1^n) + \cdots + f_{i_k,n}(\sigma_1^n)}{n}. \tag{3}$$

We now define a *balanced form* of a subsequence and an *approximately balanced* form of a sequence. These notions are useful in showing the optimality of P_1.

DEFINITION 4. *A subsequence $\widehat{\sigma}_a^b$ is a* balanced form *of σ_a^b if*

1. *$\widehat{\sigma}_a^b$ has the same composition of pages as σ_a^b, that is, for all $0 \le i \le \alpha - 1$, page i appears the same number of times in $\widehat{\sigma}_a^b$ as it does in σ_a^b;*
2. *for each $a \le t \le b$, page $\widehat{\sigma}_t^t$ occurs the maximal number of times in $\widehat{\sigma}_a^t$ in comparison with the other pages.*

For example, if $\sigma_1^{10} = 1111211321$, a balanced form is $\widehat{\sigma}_1^{10} = 123121211$.

DEFINITION 5. *A sequence $\widetilde{\sigma}_1^n$ is an* approximately *or* piecewise balanced *form of σ_1^n if*

$$\widetilde{\sigma}_1^n = \widehat{\sigma}_0 \widehat{\sigma}_1 \widehat{\sigma}_2 \ldots,$$

where $\widehat{\sigma}_j$ is a balanced form of σ_j, and σ_j is the jth r-subsequence of σ_1^n as defined in Definition 3.

By (3) and the first condition in Definition 4, we have $Fault_{\mathcal{F}(1)}(\sigma_1^n) = Fault_{\mathcal{F}(1)}(\widetilde{\sigma}_1^n)$. Our strategy to show optimality of P_1 (Theorem 1) is a two-step process described by the following two theorems. First, we show that the fault rate of P_1 on σ_1^n is never more than the fault rate of P_1 on the approximately balanced $\widetilde{\sigma}_1^n$.

THEOREM 4. *For every sequence σ_1^n, we have*

$$Fault_{P_1}(\sigma_1^n) \le Fault_{P_1}(\widetilde{\sigma}_1^n). \tag{4}$$

We then compute the fault rate of P_1 on the approximately balanced $\widetilde{\sigma}_1^n$ and show that it is close to the fault rate of the best one-state machine for σ_1^n.

THEOREM 5. *For every sequence σ_1^n, we have*

$$Fault_{P_1}(\widetilde{\sigma}_1^n) - Fault_{\mathcal{F}(1)}(\sigma_1^n) = O(\log n/\sqrt{n}\,). \tag{5}$$

The proofs of the above two theorems are dealt with in the next two subsections.

4.1. The approximately balanced sequence is sufficiently worst case. In this subsection we prove Theorem 4 using an interesting extension of the switch analysis of [12] in conjunction with the important notion of boosted frequency counts (2).

We denote the jth r-subsequence σ_j by π_1^η, where $\eta = 4^j - 4^{j-1}$ is the length of σ_j. The sequence π_1^η can be converted to a balanced form $\widehat{\pi}_1^\eta$ by an iterative balancing strategy. Without loss of generality, let the $(\tau+2)$nd page request in π_1^η be 1, and let the $(\tau+1)$st page request of the balanced sequence $\widehat{\pi}_1^{\tau+1}$ be 0. We denote by f_i the number of times page i appears in $\widehat{\pi}_1^\tau$. In particular, we denote the number of 0's in $\widehat{\pi}_1^\tau$ by f_0, and the number of 1's in $\widehat{\pi}_1^\tau$ by f_1. We consider the following iterative balancing strategy to convert $\widehat{\pi}_1^{\tau+1}$ to $\widehat{\pi}_1^{\tau+2}$.

Balancing strategy. Since $\widehat{\pi}_1^{\tau+1}$ is balanced, $f_1 \leq f_0 + 1$. If $f_1 \geq f_0$, then $\widehat{\pi}_1^{\tau+1}$ appended with a 1 gives $\widehat{\pi}_1^{\tau+2}$. If $f_1 < f_0$, we perform a "01" $\rightarrow$ "10" *switch at position* $(\tau+1, \tau+2)$ by moving the 1 in front of the 0. We continue this process of "bubbling" the 1 forward through $\widehat{\pi}_1^{\tau}$ by performing similar switches, until the subsequence of the first $\tau+2$ page requests of π_1^{η} is balanced.

Our proof of Theorem 4 consists in showing that each switch in the balancing strategy does not lower the page fault rate of the entire sequence.

A similar but simpler idea worked in the binary case for a different algorithm [12], in which the sequence did not need to be broken up into subsequences, and the sequence $\widehat{\sigma}_1^n$ could be shown to be strictly worst case. We break σ_1^n into subsequences as part of our method for achieving optimal computational efficiency (as discussed in section 6).

We now show that a switch within an r-subsequence can only increase the fault rate for algorithm P_1. The fact that we allow $k \geq 1$ predictions before each page request makes the probability terms in the analysis conditional on the previous prefetches at that time step, and that complicates the analysis.

LEMMA 1. *Each switch involved in converting π_1^{η} to $\widehat{\pi}_1^{\eta}$ creates a subsequence on which P_1 has a larger fault rate (that is, switches within an r-subsequence increase the fault rate).*

Proof. Let us denote by A the probability of predicting the 0 in $\pi_1^{\tau}01\pi_{\tau+3}^{\eta}$ and by B the probability of predicting the 1 in $\pi_1^{\tau}01\pi_{\tau+3}^{\eta}$, where the 0 and 1 are in the same r-subsequence. Similarly, let us denote by C the probability of predicting the 1 in $\pi_1^{\tau}10\sigma_{\tau+3}^{\eta}$, and by D the probability of predicting the 0 in $\pi_1^{\tau}10\sigma_{\tau+3}^{\eta}$, where the 1 and 0 are in the same r-subsequence. The number of faults algorithm P_1 makes on the portions π_1^{τ} and $\pi_{\tau+3}^{\eta}$ will be the same before and after the switch, since the probability of fault by P_1 at position x of π_1^{η} depends only on the composition of pages in π_1^{x}. (Recall that P_1 throws away all previous counts for pages at the beginning of an r-subsequence.) To show that a switch increases the fault rate, we must show that the increase in the number of faults caused by moving the 0 to later in the sequence overshadows the decrease in the number of faults caused by moving the 1 to earlier in the sequence; that is, we need to show that $(1-A)+(1-B) \leq (1-C)+(1-D)$. This is equivalent to showing that

$$A - D \geq C - B. \tag{6}$$

If P_1 makes only one prediction at each step, the proof of (6) is easy. (The proof follows directly from (7) for the special case $k = 1$.) However, P_1 makes $k \geq 1$ predictions at each time instant.

Let $A = A_1 + A_2 + \cdots + A_k$, where A_i is the probability of predicting the 0 in $\pi_1^{\tau}01\pi_{\tau+3}^{\eta}$ in the ith prediction. The probabilities B, C, D are similarly partitioned. Each A_i can be further broken up into a "good part" G_i^A and a "bad part" R_i^A. The good part G_i^A is the probability of the event that we predict the 0 in $\pi_1^{\tau}01\pi_{\tau+3}^{\eta}$ in the ith prediction and that none of the previous $i-1$ predictions was a 1. The bad part R_i^A is the probability of the event that we predict the 0 in $\pi_1^{\tau}01\pi_{\tau+3}^{\eta}$ in the ith prediction and that a 1 was predicted in one of the previous $i-1$ predictions. Clearly, $A_i = G_i^A + R_i^A$, and $R_1^A = 0$. The quantities $G_i^B, R_i^B, G_i^C, R_i^C, G_i^D, R_i^D$ are defined similarly. We now show the following two facts:

Fact 1. $G_i^A - G_i^D \geq G_i^C - G_i^B$ for $1 \leq i \leq k$;

Fact 2. $(G_i^A - G_i^D) + (R_{i+1}^A - R_{i+1}^D) = 0$ and $(G_i^C - G_i^B) + (R_{i+1}^C - R_{i+1}^B) = 0$ for $1 \leq i \leq k-1$.

Facts 1 and 2 say intuitively that the good parts of the ith prediction maintain the relationship that we want. The bad parts of the ith prediction *exactly* cancel the gain from the good parts of the $(i-1)$st prediction. The lemma follows from the above two facts as follows:

$$A - D = \sum_{1 \le i \le k} A_i - D_i = \sum_{1 \le i \le k} (G_i^A - G_i^D) + (R_i^A - R_i^D) = G_k^A - G_k^D$$

by repeated application of Fact 2. Similarly, $C - B = G_k^C - G_k^B$. By Fact 1, $G_k^A - G_k^D \ge G_k^C - G_k^B$, which implies $A - D \ge C - B$.

We now prove Facts 1 and 2 by induction. Since π_1^τ is an r-subsequence, at each time step, algorithm P_1 boosts frequencies by the same exponent r_t; for convenience, we denote this exponent by r. Let $d = \sum_0^{\alpha-1} (f_i)^r$, $d_1 = d - (f_1)^r + (f_1+1)^r$, and $d_0 = d - (f_0)^r + (f_0+1)^r$. These quantities are involved in the denominators of the rational expressions for the predictions. Let $u_i^A = u_i^A(x_1, \ldots, x_{i-1})$ be the term in G_i^A that corresponds to predicting $x_1, \ldots, x_{i-1}$, none of them a 0 or a 1 as the first $i-1$ predictions and 0 as the ith prediction. (The order of the first $i-1$ predictions is important. For example, when $i = 3$, the probability of predicting a 0 following x_1, x_2 is different from the probability of predicting a 0 following x_2, x_1.) The quantities u_i^B, u_i^C, u_i^D are defined similarly. The expressions in Fact 1 can be expressed in terms of the u's; for example,

$$G_i^A - G_i^D = \sum_{\substack{x_1, \ldots, x_{i-1} \\ \text{distinct}, \neq 0, 1}} u_i^A - u_i^D.$$

Let $v_i^A = v_i^A(x_1, x_2, \ldots, x_{i-2})$ be the term in R_i^A that corresponds to predicting a 0 in the ith prediction with a 1 as one of the first $i-1$ predictions and the other $i-2$ predictions being $x_1, \ldots, x_{i-2}$, none of them a 0 or a 1. (The order of these $i-2$ predictions is important, as it is with u_i, but the relative point at which the 1 is predicted is arbitrary. In effect, v_i^A is the sum of $i-1$ probability terms, where the $i-1$ terms correspond to the $i-1$ positions that the "1" is predicted.) The quantities v_i^B, v_i^C, v_i^D are defined similarly. The expressions in Fact 2 can be expressed in terms of the u's and the v's; for example,

$$(G_i^A - G_i^D) + (R_{i+1}^A - R_{i+1}^D) = \sum_{\substack{x_1, \ldots, x_{i-1} \\ \text{distinct}, \neq 0, 1}} (u_i^A - u_i^D) + (v_{i+1}^A - v_{i+1}^D).$$

Let $den(d, 0) = d$, and let $den(d, i-1) = d - (f_{x_1})^r - \cdots - (f_{x_{i-1}})^r$ for $i \ge 2$. Let $\pi den(d, i-1)$ for $i \ge 2$ be the $(i-1)$-term falling product $d \times (d - (f_{x_1})^r) \times \cdots \times (d - (f_{x_1})^r - \cdots - (f_{x_{i-2}})^r) = \Pi_{j=1}^{i-1} den(d, j-1)$.

Proof of Fact 1. It suffices to show by induction that $u_i^A - u_i^D \ge u_i^C - u_i^B$. For the base case when $i = 1$, $u_1^A - u_1^D = (f_0)^r/d - (f_0)^r/d_1$, and $u_1^C - u_1^D = (f_1)^r/d - (f_1)^r/d_0$. Hence

$$\frac{u_1^A - u_1^D}{u_1^C - u_1^B} = \frac{(f_0)^r}{(f_1)^r} \times \frac{(f_1+1)^r - (f_1)^r}{(f_0+1)^r - (f_0)^r} \times \frac{d_0}{d_1} = \frac{(1+1/f_1)^r - 1}{(1+1/f_0)^r - 1} \times \frac{d_0}{d_1}. \tag{7}$$

Since the function $g(x) = x^r$ is convex and $f_0 \ge f_1$, the above quantity is at least 1. From the induction hypothesis that $u_{i-1}^A - u_{i-1}^D \ge u_{i-1}^C - u_{i-1}^B$ we get

$$(f_{x_1}f_{x_2}\cdots f_{x_{i-2}}f_0)^r\left(\frac{1}{\pi den(d,i-1)}-\frac{1}{\pi den(d_1,i-1)}\right)$$
$$\geq (f_{x_1}f_{x_2}\cdots f_{x_{i-2}}f_1)^r\left(\frac{1}{\pi den(d,i-1)}-\frac{1}{\pi den(d_0,i-1)}\right). \tag{8}$$

As in (7), since $g(x)=x^r$ is convex, and $f_0 \geq f_1$, we have

$$\frac{(f_0)^r}{(f_1)^r}\times\frac{d_1-d}{d_0-d}\times\frac{\pi den(d_0,i-1)}{\pi den(d_1,i-1)}\times\frac{den(d_0,i-1)}{den(d_1,i-1)}\geq 0.$$

It follows that

$$\frac{(f_{x_1}f_{x_2}\cdots f_{x_{i-1}}f_0)^r}{\pi den(d_1,i-1)}\left(\frac{1}{den(d,i-1)}-\frac{1}{den(d_1,i-1)}\right)$$
$$\geq \frac{(f_{x_1}f_{x_2}\cdots f_{x_{i-1}}f_1)^r}{\pi den(d_0,i-1)}\left(\frac{1}{den(d,i-1)}-\frac{1}{den(d_0,i-1)}\right). \tag{9}$$

Multiplying (8) by $(f_{x_{i-1}})^r/den(d,i-1)$ and adding to (9) gives us $u_i^A-u_i^D\geq u_i^C-u_i^B$.

Proof of Fact 2. To prove that $(G_i^A-G_i^D)+(R_{i+1}^A-R_{i+1}^D)=0$, it suffices to show that $(u_i^A-u_i^D)+(v_{i+1}^A-v_{i+1}^D)=0$. For the base case when $i=1$, $u_1^A-u_1^D=(f_0)^r(1/d-1/d_1)$, and

$$v_2^A-v_2^D=\frac{(f_1)^r(f_0)^r}{d(d-(f_1)^r)}-\frac{(f_1+1)^r(f_0)^r}{d_1(d_1-(f_1+1)^r)}.$$

Using the fact that $d_1=d+(f_1+1)^r-(f_1)^r$, it follows from simple algebra that $v_2^A-v_2^D+(u_1^A-u_1^D)=0$.

For the inductive step, recall that v_{i+1}^A is a sum of i probability terms, where the i terms correspond to the i positions that the "1" is predicted. (The terms are each rational expressions with different denominators.) In particular, v_{i+1}^A equals

$$\frac{(f_{x_1}f_{x_2}\cdots f_{x_{i-1}}f_0f_1)^r}{den(d,i-1)-(f_1)^r}\left(\frac{1}{\pi den(d,i)}+\frac{1}{den(d,i-2)-(f_1)^r}\left(\frac{1}{\pi den(d,i-1)}+\cdots\right)\right),$$

which can be simplified to

$$v_{i+1}^A=\frac{(f_{x_1}f_{x_2}\cdots f_0f_1)^r}{den(d,i-1)-(f_1)^r}\left(\frac{1}{\pi den(d,i)}+\frac{v_i^A}{(f_{x_1}f_{x_2}\cdots f_{x_{i-2}}f_0f_1)^r}\right).$$

Since $d_1-(f_1+1)^r=d-(f_1)^r$, we find that $v_{i+1}^A-v_{i+1}^D$ equals

$$\frac{(f_{x_1}f_{x_2}\cdots f_{x_{i-1}}f_0)^r}{den(d,i-1)-(f_1)^r}\left(\frac{(f_1)^r}{\pi den(d,i)}-\frac{(f_1+1)^r}{\pi den(d_1,i)}+\frac{v_i^A-v_i^D}{(f_{x_1}f_{x_2}\cdots f_{x_{i-2}}f_0)^r}\right). \tag{10}$$

By the induction hypothesis, $v_i^A-v_i^D=-(u_{i-1}^A-u_{i-1}^D)$. The value for $u_{i-1}^A-u_{i-1}^D$ is the expression on the left-hand side of (8). Substituting for $u_{i-1}^A-u_{i-1}^D$ in (10) we get

$$v_{i+1}^A-v_{i+1}^D=\frac{(f_{x_1}f_{x_2}\cdots f_{x_{i-1}}f_0)^r}{d-(f_{x_1})^r-\cdots-(f_{x_{i-1}})^r-(f_1)^r}\times U, \tag{11}$$

where

$$U=\frac{(f_1)^r}{\pi den(d,i)}-\frac{(f_1+1)^r}{\pi den(d_1,i)}-\frac{1}{\pi den(d,i-1)}+\frac{1}{\pi den(d_1,i-1)}.$$

The quantity $u_i^A - u_i^D$ can be expressed as

$$u_i^A - u_i^D = (f_{x_1} f_{x_2} \cdots f_{x_{i-1}} f_0)^r \left(\frac{1}{\pi den(d,i)} - \frac{1}{\pi den(d_1,i)} \right).$$

Adding the above expression to (11) and simplifying we find that $(u_i^A - u_i^D) + (v_{i+1}^A - v_{i+1}^D) = 0$. A similar analysis shows that $(G_i^C - G_i^B) + (R_{i+1}^C - R_{i+1}^B) = 0$. □

4.2. *Fault*$_{P_1}(\widetilde{\sigma}_1^n)$ is close to *Fault*$_{\mathcal{F}(1)}(\sigma_1^n)$. In this subsection we prove Theorem 5. Let $F_1 \in \mathcal{F}(1)$ be the best one-state prefetcher for σ_1^n. Let $F_1^j \in \mathcal{F}(1)$ be the best one-state prefetcher tuned for the jth r-subsequence σ_j. Let $NumFaults_B(\sigma_a^b)$ be the number of faults incurred by algorithm B on subsequence σ_a^b.

It is clear by definition that prefetcher F_1^j incurs at most as many faults on σ_j as F_1 incurs on σ_j. In other words,

$$NumFaults_{F_1}(\widehat{\sigma}_j) = NumFaults_{F_1}(\sigma_j) \geq NumFaults_{F_1^j}(\sigma_j) = NumFaults_{F_1^j}(\widehat{\sigma}_j). \tag{12}$$

Equation (12) directly implies the following lemma.

LEMMA 2. *The fault rate incurred for σ_1^n by using prefetcher F_1^j to prefetch for the jth r-subsequence σ_j, for each $j \geq 0$, is no greater than Fault$_{\mathcal{F}(1)}(\sigma_1^n)$. That is,*

$$Fault_{\mathcal{F}(1)}(\sigma_1^n) = Fault_{\mathcal{F}(1)}(\widetilde{\sigma}_1^n) = \frac{NumFaults_{F_1}(\widehat{\sigma}_1^n)}{n} \geq \frac{\sum_{j \geq 0} NumFaults_{F_1^j}(\widehat{\sigma}_j)}{n}.$$

The above lemma is useful since it is easier to compare algorithm P_1 with algorithm F_1^j on page request sequence $\widehat{\sigma}_j$ than it is to compare P_1 with F_1.

LEMMA 3. *The number of faults that algorithm P_1 incurs on $\widehat{\sigma}_j$ is close to the number of faults of the optimal one-state machine tuned for $\widehat{\sigma}_j$. In particular,*

$$NumFaults_{P_1}(\widehat{\sigma}_j) - NumFaults_{F_i^j}(\widehat{\sigma}_j) = O((\alpha k^2) j 2^j).$$

From Lemmas 2 and 3 we get

$$\begin{aligned} Fault_{P_1}(\widetilde{\sigma}_1^n) - Fault_{\mathcal{F}(1)}(\widetilde{\sigma}_1^n) &\leq \sum_j \frac{NumFaults_{P_1}(\widehat{\sigma}_j) - NumFaults_{F_1^j}(\widetilde{\sigma}_j)}{n} \\ &= O\left(\frac{\alpha k^2 \sum_j j 2^j}{n} \right) \\ &= O\left(\frac{\alpha k^2 \log n}{\sqrt{n}} \right). \end{aligned} \tag{13}$$

Theorem 5 follows from (13) and the observation following Definition 5.

We now give the proof of Lemma 3.

Proof of Lemma 3. For simplicity, we denote by π_1^η the balanced jth r-subsequence $\widehat{\sigma}_j$, where $\eta = 4^j - 4^{j-1}$ is the length of $\widehat{\sigma}_j$. Divide π_1^η into α subsequences $\pi_0, \pi_1, \ldots, \pi_{\alpha-1}$, where exactly $\alpha - i$ different pages appear in π_i. (Some of the π_i's may be empty. Notice that since π_1^η is balanced, each π_i has the same number of occurrences of each of the $\alpha - i$ pages in it.) We explicitly compute the difference between the expected number of faults of P_1 and the number of faults of F_1^j for each subsequence π_i. We need to be careful with the asymptotics involved, since the counts for the

pages are small in the earlier part of π_1^η, but $r_t = O(\sqrt{\eta})$ is relatively larger. For simplicity, we drop the subscript t from r_t in the following discussion; recall that r_t does not change in an r-subsequence.

Let $|\pi_i|$ be the length of subsequence π_i. Algorithm F_1^j incurs $|\pi_i| \times \max\{0, 1 - k/(\alpha - i)\}$ faults on π_i. Define L_i as

$$L_i = \begin{cases} \dfrac{|\pi_0|}{\alpha} + \dfrac{|\pi_1|}{\alpha - 1} + \cdots + \dfrac{|\pi_{i-1}|}{\alpha - (i-1)} & \text{if } i \geq 1, \\ 0 & \text{if } i = 0. \end{cases}$$

The quantity L_i tracks the number of times a page that appears in π_i has already appeared in $\pi_0, \pi_1, \ldots, \pi_{i-1}$. The expected number of faults incurred by algorithm P_1 on π_i is

$$\mathit{NumFaults}_{P_1}(\pi_i) = |\pi_i| - \sum_{u=1}^{|\pi_i|/(\alpha-i)} \sum_{v=0}^{\alpha-i-1} \sum_{k_1=1}^{k} \Pr(u, v, k_1), \tag{14}$$

where $\Pr(u, v, k_1)$ is the probability of predicting the $((u-1) \times (\alpha - i) + v + 1)$st page request of π_i in the k_1th prediction. For notational simplicity, let $t = (u-1) \times (\alpha - i) + v + 1$. Clearly, the tth page has appeared $L_i + u - 1$ times in π_1^{t-1}, and no page in π_i has appeared more than $L_i + u$ times in π_1^{t-1}. Since we require an upper bound on $\mathit{NumFaults}_{P_1}(\pi_i)$, we determine a lower bound for $\Pr(u, v, k_1)$ as follows. We only consider $k_1 \leq \alpha - i$, and we only consider that subset of events when pages with count greater than or equal to that of the tth page (i.e., pages appearing in π_i) were predicted in the previous $k_1 - 1$ predictions. Hence

$$\Pr(u, v, k_1) \geq (k_1 - 1)! \begin{pmatrix} \alpha - i - 1 \\ k_1 - 1 \end{pmatrix} \prod_{w=0}^{k_1-1} \frac{(L_i + u - 1)^r}{(\alpha - i - w)(L_i + u)^r + \sum_{q=0}^{i-1} (L_{q+1})^r}.$$

Notice that multiplying by $(k_1 - 1)!$ in the above equation is essential, since the order of the first $(k_1 - 1)$ predictions is significant. We get

$$\Pr(u, v, k_1) \geq (\alpha - i - 1)^{\underline{k_1 - 1}} \prod_{w=0}^{k_1-1} \frac{(L_i + u - 1)^r}{(\alpha - i - w)(L_i + u)^r + \sum_{q=0}^{i-1} (L_{q+1})^r}, \tag{15}$$

where the expression $x^{\underline{y}}$ stands for the "falling power" $x \times (x-1) \times \cdots \times (x - y + 1)$.

In our following analysis, the important intuition is that asymptotically $L_i + u - 1 \approx L_i + u$, but $(L_i)^r \ll (L_i + u)^r$. Replacing $\sum_{q=0}^{i-1} (L_{q+1})^r$ by $i(L_i)^r$, we get

$$\Pr(u, v, k_1) \geq (\alpha - i - 1)^{\underline{k_1 - 1}} \prod_{w=0}^{k_1-1} \frac{(L_i + u - 1)^r}{(\alpha - i - w)(L_i + u)^r + i(L_i)^r}. \tag{16}$$

Adding and subtracting $(L_i + u)^r$ to the numerator in (16) and simplifying, we get

$$\Pr(u, v, k_1) \geq (\alpha - i - 1)^{\underline{k_1 - 1}} \left(\prod_{w=0}^{k_1-1} \frac{(L_i + u)^r}{(\alpha - i - w)(L_i + u)^r + i(L_i)^r} - \frac{\delta_1(u, i)}{\alpha - i - w} \right), \tag{17}$$

where $\delta_1(u, i) = ((L_i + u)^r - (L_i + u - 1)^r)/(L_i + u)^r$. Adding and subtracting $(i/\alpha - i - w) \times (L_i)^r$ to the numerator of the first rational term in (17) and simplifying, we get

$$\Pr(u, v, k_1) \geq \frac{(\alpha - i - 1)^{\underline{k_1 - 1}}}{(\alpha - i)^{\underline{k_1}}} \left(1 - (\delta_1(u, i) + \delta_2(u, i))\right)^{k_1}, \tag{18}$$

where $\delta_2(u,i) = i(L_i)^r/(L_i+u)^r$. With the expression for $\Pr(u,v,k_1)$ from (18) it is easy to verify that the leading term of $\mathit{NumFaults}_{P_1}(\pi_i)$ is $|\pi_i| \times \max\{0, 1 - k/(\alpha - i)\}$, which is the number of faults incurred by F_1^j on π_i. The error term $\epsilon = \mathit{NumFaults}_{P_1}(\pi_i) - \mathit{NumFaults}_{F_1^j}(\pi_i)$ equals

$$\frac{1}{\alpha - i} \sum_{u=1}^{|\pi_i|/(\alpha-i)} \sum_{v=0}^{\alpha-i-1} \sum_{k_1=1}^{k} \epsilon(u,i,k_1), \tag{19}$$

where

$$\epsilon(u,i,k_1) = 1 - (1 - \delta_1(u,i) - \delta_2(u,i))^{k_1}.$$

The following facts can be verified by using the asymptotic techniques from [15, Chapter 9]:

1. $\delta_1(u,i) \le r/(L_i + u - 1)$ if $L_i + u - 1 \ge r$;
2. $\delta_2(u,i) \le i \times \exp(-ru/2L_i)$ if $u \le L_i$, and $\delta_2(u,i) \le i2^{-r}$ if $u \ge L_i$.

The lower-order terms arising from the binomial expansion of $(1-(\delta_1(u,i)+\delta_2(u,i))^{k_1}$ from (19) (i.e., terms of degree 2 or greater) can be disregarded if $L_i + u - 1 \ge kr$ and $u \ge \sqrt{3\eta}\log(\alpha k)$. When $L_i + u - 1 < kr$ or $u < \sqrt{3\eta}\log(\alpha k)$, we can bound $\epsilon(u,i,k_1)$ by 1; the net contribution of this to ϵ is $O(\alpha r \ln(\alpha k))$. Disregarding lower-order terms in (19) and using the expressions from Facts 1 and 2 above, we get $\epsilon = O(\alpha k^2 r \ln \eta + \alpha k^2 \eta/r) = O(\alpha k^2 \sqrt{\eta} \log \eta) = O(\alpha k^2 j 2^j)$. □

5. Generalizing P_1 to get P. In this section we prove Theorem 2 by constructing our optimal prefetcher P. The prefetcher P is a mix of P_1 and the character-based version of the Lempel–Ziv algorithm for data compression. The original Lempel–Ziv algorithm is a word-based data compression algorithm that parses the input string x_1^n into distinct substrings x_0, x_1, x_2, …, x_c such that, for all $j \ge 1$, substring x_j without its last character is equal to some x_i for $0 \le i < j$. (We use the convention that $x_0 = \lambda$, the empty substring.) It encodes the string one substring at a time. Since the substrings are prefix-closed, they can be represented by a dynamically growing tree T (the "LZ tree"), with the nodes of the tree representing the substrings and node x_i being an ancestor of node x_j if substring x_i is a prefix of substring x_j; λ is the root of the tree. An example of the LZ tree is given in Figure 1a.

Let $x(z)$ be the sequence of pages seen until now by P when at state z. At the end of a parse, prefetcher P positions itself at the root of the LZ tree. It looks at the subsequence $x(z)$ at its current state z and simulates P_1 on $x(z)$ to prefetch for the next page. (Algorithm P_1 breaks $x(z)$ into r-subsequences and prefetches based on the current r-subsequence at state z as described in section 3. Note that P_1 does not have to maintain $x(z)$ explicitly; it only has to maintain counts for the different pages.) On observing the next page request j, it updates $x(z)$, moves down the transition labeled by j, and prefetches the next page similarly by simulating P_1 on the sequence of pages seen at the new current state. On reaching a leaf state, it prefetches k pages at random, and the next request ends a parse. The important point is that although the counts for some or all of the transitions can be 0 (since algorithm P_1 resets the counts for all pages to 0 at the beginning of an r-subsequence), the transitions themselves are retained in the tree. An example snapshot of the data structure of P is given in Figure 1b.

We now briefly explain why P is optimal against an arbitrary s-state machine (Theorem 2) using the interesting approach of [12]. An mth-order Markov prefetcher

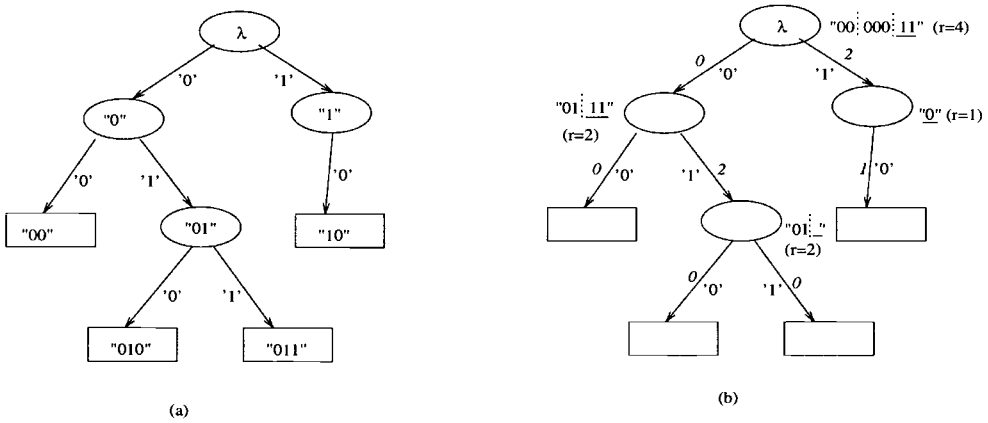

FIG. 1. *Snapshot of data structure for algorithm P. Assume for simplicity that our alphabet is* $\{0,1\}$. *We consider the page request sequence* x_1^t = "00001010011110 ...." *The Ziv–Lempel encoder parses this string as "*(0)(00)(01)(010)(011)(1)(10) ...." *The tree T that is built at the end of the seventh parse is pictured above in* (a). *In* (b), *next to each node/state z of the tree we give the sequence of page requests* $x(z)$ *seen at that state. For example, for any page request sequence* x_1^t *that is parsed by the Lempel–Ziv data compressor into distinct substrings* λ, x_1, x_2, ..., x_c, *the first page of each substring* x_i, $1 \le i \le c$, *forms* $x(\lambda)$, *the sequence of pages requested when the current state is the root of the tree. In* (b), $x(\lambda) = 0000011$. *The dotted vertical lines in the sequences delimit the r-subsequences, and the underlined portion is the current r-subsequence. The counts (given in italics) on the transitions out of each state z are the counts obtained by simulating* P_1 *on* $x(z)$.

predicts its k choices for the next page based solely on the previous m page requests of the sequence. In particular, an mth-order prefetcher can be described by an FSP having α^m states, where each state is labeled by an m-page context (denoting the last m pages requested), and the transitions denote the unique change from one m-context to the next. The pages to prefetch are determined solely by the state that the mth-order Markov prefetcher is in, which is equivalent to the most recent m pages requested. The basic idea of the proof is to compare both prefetcher P and the best s-state prefetcher with mth-order Markov prefetchers.

If we let m be large, an mth-order Markov prefetcher achieves, for every sequence σ_1^n and any s, a fault rate close to the fault rate of the best s-state prefetcher. In particular, by simple extensions to [12, Theorem 2] as shown in Appendix B, we see that

$$Fault_{M(\alpha^m)}(\sigma_1^n) \le Fault_{\mathcal{F}(s)}(\sigma_1^n) + O\left(\sqrt{\frac{\log s}{m+1}}\right). \tag{20}$$

The idea of the proof in [12] is to consider a "cross-product" machine of the mth-order Markov predictor and the s state prefetcher and to show that the cross-product machine is not much better than either of its constituents.

The prefetcher P can be looked upon as a Markov prefetcher of growing order. In particular, most nodes in the tree T built by P (i.e., nodes below a depth of m) have a context of length greater than m. Hence one would intuitively expect that in the limit as $n \to \infty$, prefetcher P will "beat" any mth-order Markov predictor. Theorem 1 can be applied to each node of T, and by carefully summing the errors

over each node we get

$$Fault_P(\sigma_1^n) \leq Fault_{M(\alpha^m)}(\sigma_1^n) + \delta(n,m), \tag{21}$$

where for a fixed m, $\delta(n,m) = O((\log\log n)/\sqrt{\log n})$. This idea was used in [12, Theorem 4] for a binary alphabet, and the simple changes required to obtain (21) are summarized in Appendix B. Theorem 2 follows from (20) and (21).

Given that P_1 is optimal against $\mathcal{F}(1)$ (Theorem 1), in order to show optimality of P against $\mathcal{F}(s)$ by the approach described above, we need to extend some results of [12] to hold for the prefetching problem. These extensions are simple as described in Appendix B. The intuition for why these extensions are simple is because the comparisons are primarily between two "offline" algorithms, and the online algorithm is not much involved, as opposed to the more complex analysis of section 4.

6. Constant-time prediction. In this section we prove Theorem 3 by showing that our prefetcher P runs in constant time (independent of α, k) on the average for each of the pages it prefetches into cache.

In section 5, we showed that it suffices to consider one-state prefetchers; the prefetcher at each step uses the appropriate P_1 to generate random variates according to a dynamically changing set of weights. We showed earlier that P_1's prediction strategy is optimal, in which we successively pick a page at random (without replacement) with probabilities in proportion to the boosted frequency counts $(f_0)^r$, $(f_1)^r$, $\ldots$, $(f_{\alpha-1})^r$, where $r \approx \sqrt{t}$. (Actually, we use $r = 2^j$, where $4^{j-1} < t \leq 4^j$, so that r seldom changes. The frequency counts f_i are reset to zero when r changes.)

The general problem of generating a random variate with a value in the range $\{0, 1, 2, \ldots, \alpha - 1\}$ and distributed according to α dynamically changing weights $w_0, w_1, w_2, \ldots, w_{\alpha-1}$ is solved optimally by Matias, Vitter, and Ni [26, section 5]. The idea at an intuitive level is to group the weights into ranges according to their values. Range j stores weights in the range $[2^j, 2^{j+1})$. Each range is said to have a weight equal to the sum of the weights it contains. With high probability, the individual weight chosen during the generation will be within the first $O(\log\alpha)$ ranges, so each successive group of $O(\log\alpha)$ ranges should be processed in a recursive data structure according to the weights of the ranges. The use of the rejection method [21] is used to adjust the probabilities of generation appropriately, since the weights in each bucket may vary by a factor of 2. After two recursive levels, the problem reduces to generating one of $O(\log\log\alpha)$ weights, each in the range $[1, \log\alpha]$, which can be done dynamically in constant time by the clever table lookup method of Hagerup, Mehlhorn, and Munro [16].

There is also extensive concern in [26] about the choice of hashing parameters in the universal hashing schemes used to get linear space, since no a priori bound on the key values is known. (In fact, a constant-time solution to the general dictionary problem is proposed in [26].) The model of computation allows arithmetic computation and truncated logarithms of quantities up to value $O(W)$, where W is the maximum weight.

In our application, the computation assumption of [26] is unreasonable, since it allows constant-time operations on arbitrary numbers of bits. We make the stronger requirement often used in algorithm design that the standard arithmetic operations (such as addition, multiplication, division, and using exponents and logarithms) take constant time with finite-precision quantities of $O(\log n)$ bits, where n is the length of the sequence of page requests. However, the boosted frequencies $w_i = (f_i)^r$ used in the random variate generation can be as large as $n^{\sqrt{n}}$ in value, which cannot be

manipulated efficiently. Fortunately we can get around the precision problem by approximating w_i by $2^{\lceil r \lg f_i \rceil}$. The first level of the algorithm in [26] is applied to these approximated weights, using arithmetic on the exponents, which involves only $O(\log n)$ bits. For example, we can determine the bucket j that contains $2^{\lceil r \lg f_i \rceil}$ in constant time using operations on $O(\log n)$ bits by noting that j can be represented with only about $\lg\lg((f_i)^r) = \lg r + \lg\lg f_i \leq 2 \lg n$ bits. The range j can be computed, therefore, in constant time using $O(\log n)$-bit arithmetic. The resulting recursive subproblems have polynomial-sized weights, and the rest of the construction continues as in [26].

Because of the initial approximation, if the "approximated" page i is selected for generation, a final acceptance–rejection test must be done before actually choosing page i; the acceptance probability is $(f_i)^r / 2^{\lceil r \lg f_i \rceil}$, which is at least $1/2$. This test can be done conceptually by generating a uniform random integer U in the range $[1, 2^{j+1})$ and testing if $U \leq (f_i)^r$, but handling quantities of that magnitude is infeasible, as mentioned above. It suffices to determine if $\lg U \leq r \lg f_i$, which can be done in constant time using finite precision by generating the exponentially distributed random variate $\lg U$ directly [21, p. 128]. The expected number of steps needed before the acceptance or rejection is determined is a small constant, so finite precision suffices. This completes the proof of Theorem 3.

7. Conclusions. We have studied the problem of prediction of sequences (of pages requests, for example) drawn from a finite but arbitrary alphabet of cardinality α, in which we can make, at each time step, k predictions for the next item (page). This corresponds to the problem of pure prefetching in databases. We have developed a simple randomized weighting algorithm P_1 and have combined it with the Lempel–Ziv data compressor to get an efficient prefetcher P. We have shown analytically that P's fault rate converges almost surely to that of the best FSP for every (worst-case) sequence of page requests. It has been shown in [7] that any optimal algorithm for the binary alphabet case has to be necessarily randomized. Because of the way our algorithm is designed, we need to spend at most constant expected time making the random choices for each prediction, which is optimal. Thus the algorithm is simultaneously optimal with respect to fault rate and running time.

An open problem is to study if there are stronger analysis models closer to the competitive model that would permit prediction problems such as prefetching to be studied. It would also be interesting to improve the convergence bounds while maintaining optimal running time.

We have also investigated nonpure prefetching in [10, 35], in which there may not always be enough time to load the cache with k pages before the user issues the next page request, and prefetching requests may have to be done in advance. We have also described therein a nice way of gathering the statistics with no I/O overhead. The resulting prefetcher is practical in terms of time, disk accesses, and fault rate and outperforms other known prefetchers. We also expect that our results apply to prefetchers based on data compression methods other than Lempel–Ziv that are optimal in various models.

Appendix A. Nonoptimal prefetchers. In section A.1 we give a simple example which illustrates that no deterministic algorithm can be optimal for prefetching in the worst case. In section A.2, we show that the *Proportional* algorithm, which at time t prefetches page i with probability proportional to $f_i(\sigma_1^t)$, where $f_i(\sigma_1^t)$, for $0 \leq i \leq \alpha - 1$, denotes the number of times page i appears in σ_1^t, is not optimal.

For both proofs of nonoptimality, we develop a page request sequence with alphabet $A = \{0, 1\}$, cache size $k = 1$, and compare it with the best 1-state prefetcher.

From an intuitive standpoint, algorithm *Proportional* is too conservative, while deterministic algorithms are "too naive" and hence susceptible to worst-case-type adversaries (like FSPs). Algorithm P_1, by choosing the high probability pages with very high likelihood, closely tracks the optimal. The tricky issues are proving the optimality of P_1 and making predictions in a computationally efficient fashion.

A.1. Deterministic algorithms. It is easy to see that the fault rate of an optimal 1-state prefetcher for any sequence with $\alpha = 2$ and $k = 1$ is at most $1/2$, since it predicts at each time instant the overall most frequent page. We can make a deterministic algorithm fault at every page request by creating a sequence such that the next page request is for the page not in cache.

A.2. Algorithm *Proportional***.** Consider the page request sequence

$$\sigma_1^n = 01010101 \ldots 010000 \ldots 00,$$

where the first "0101..." subsequence is of length $n/2$, and it is followed by $n/2$ 0's. The fault rate of the optimal 1-state prefetcher (which always predicts "0" to be the next page request) is $1/4$. Algorithm *Proportional* is expected to incur at least $1/2 \times n/2$ faults in the first $n/2$ page requests. Since the proportion of 0's in the entire sequence is $3/4$, algorithm *Proportional* incurs, on the average, more than $1/4 \times n/2$ faults for the last $n/2$ page requests. This implies a net average fault rate of more than $3/8$, which is clearly suboptimal.

Appendix B. Proof of Theorem 2. In this section we continue the discussion from section 5 and present the required extensions to the results of [12] in order to prove optimality of prefetcher P. (Recall that [12] deals with the binary alphabet case, which corresponds to $\alpha = 2$, $k = 1$.) The main objective of this section is to show the necessary extensions required to prove (20) and (21) (which are the counterparts for Theorems 2 and 4 from [12]).

We start with a definition of mth-order Markov prefetchers.

DEFINITION 6. *An* mth-order Markov prefetcher *prefetches for its next page based solely on the previous* m *page requests of the sequence. Using the notation from Definition* 1*, an* m*th-order Markov prefetcher has* α^m *states, where each state is (represents) an* m*-context* $(x_1, x_2, \ldots, x_m)$*, and* $g((x_1, \ldots, x_m), u) = (x_2, \ldots, x_m, u)$*. We denote the fault rate of an* m*th-order prefetcher by* $Fault_{M(\alpha^m)}(\sigma_1^n)$*, where* $M(\alpha^m) \subseteq \mathcal{F}(\alpha^m)$*.*

We also introduce notation to help describe faults easily.

DEFINITION 7. *Given an* α*-probability vector* $\vec{p} = (p_0, \ldots, p_{\alpha-1})$*, we denote by* $\min_{\alpha-k}(\vec{p})$ *the sum of the minimum* $\alpha - k$ *elements of* $\vec{p}$*. In other words if* $p_0 \geq p_1 \geq \cdots \geq p_{\alpha-1}$*, then* $\min_{\alpha-k}(\vec{p}) = \sum_{i=k}^{\alpha-1} p_i$*.*

Proving (20) is equivalent to showing that Theorem 2 from [12] holds for prefetching. As mentioned in section 5, the proof of [12, Theorem 2] is based on comparing the s-state prefetcher and the mth-order Markov prefetcher with a cross product of these two machines.[1] Theorem 2 of [12] is strongly dependent on [12, Lemma 1], where the mth-order Markov machine is compared with the cross-product machine. The basic idea of [12, Lemma 1] is to bound prediction error by a function of the

[1] The term "cross product" is taken from [36], where a similar product of two machines was used to prove the optimality of prefetchers under a Markov source model.

empirical entropies, and it is based on the following fact: for every $0 \leq p, q \leq 1$,

$$p \log \frac{p}{q} + (1-p) \log \frac{1-p}{1-q} \geq \frac{2}{\ln 2} \left(\min\{p, 1-p\} - \min\{q, 1-q\}\right)^2. \tag{22}$$

It is not hard to see that the left-hand side of (22) is closely related to the entropy and the right-hand side of (22) to the prediction error. (The idea of bounding error for prefetching by bounding coding length differences was used independently in [36] to derive optimal prefetchers from data compressors under a Markov source input model.) A fact equivalent to (22) that we prove for our prefetching problem (via Lemmas 4 and 5 below) is the following: given two probability vectors $\vec{p}$ and $\vec{q}$,

$$\sum_{1}^{\alpha} p_i \ln \frac{p_i}{q_i} \geq \frac{1}{2} \left(\min_{\alpha-k}(\vec{p}) - \min_{\alpha-k}(\vec{q}) \right)^2. \tag{23}$$

The proof of [12, Lemma 1] follows from (22), Jensen's inequality, and the convexity of the square function. The proof of [12, Theorem 2] follows from [12, Lemma 1], Jensen's inequality, the concavity of the square root function, and the chain rule of conditional entropies. Except for (22), the other aspects of the proof of [12, Theorem 2] are effectively independent of the alphabet and cache size. To derive (20), we consider the proof of [12, Theorem 2] and uniformly replace $\min\{p_0, p_1\}$, where p_0 and p_1 are the probabilities of a 0 and a 1, by $\min_{\alpha-k}(\vec{p})$, where $\vec{p}$ is the corresponding α-probability vector for prefetching, replace summations over $\{0, 1\}$ by summations over the alphabet A, and use (23) in place of (22).

We now prove (23) using the following two lemmas.

LEMMA 4. *Given two α-probability vectors $\vec{p}$ and $\vec{q}$, we have*

$$\min_{\alpha-k}(\vec{p}) - \min_{\alpha-k}(\vec{q}) \leq \sum_{i=0}^{\alpha-1} |p_i - q_i|.$$

Proof. Without loss of generality assume $p_0 \geq p_1 \geq \cdots \geq p_{\alpha-1}$. Let $X = \{0, 1, \ldots, k-1\}$, and let $Y = \{k, k+1, \ldots, \alpha-1\}$. Hence $\min_{\alpha-k}(\vec{p}) = \sum_{i \in Y} p_i$. Let $Z = \{i_1, i_2, \ldots, i_{\alpha-k}\}$ be the $\alpha - k$ pages with minimum count in $\vec{q}$. Let $U = Z \cap Y$, and $V = Z \cap X$. By definition, $\min_{\alpha-k}(\vec{p}) - \min_{\alpha-k}(\vec{q}) = \sum_{i \in Y} p_i - \sum_{i \in Z} q_i$. Since by assumption $p_0 \geq p_1 \geq \cdots \geq p_{\alpha-1}$, we have

$$\min_{\alpha-k}(\vec{p}) - \min_{\alpha-k}(\vec{q}) \leq \sum_{i \in U} (p_i - q_i) + \sum_{i \in V} (p_i - q_i) \leq \sum_{i \in A} |p_i - q_i|,$$

where A is the alphabet as given in Definition 1. □

The next lemma is well known; the proof can be found in [2, 36]. The summation on the right-hand side of the equation in the lemma is the Kullback–Leibler divergence of $\vec{q}$ w.r.t. $\vec{p}$.

LEMMA 5. *Given two probability vectors $(p_0, \ldots, p_{\alpha-1})$ and $(q_0, \ldots, q_{\alpha-1})$, we have*

$$\left(\sum_{i=0}^{\alpha} |p_i - q_i| \right)^2 \leq 2 \sum_{i=1}^{\alpha} p_i \ln \frac{p_i}{q_i}.$$

To verify (21) (i.e., the equivalent of [12, Theorem 4] for prefetching), the proof technique presented in [12] carries over with virtually no change; we need to use

Theorem 1 of our paper in place of [12, Theorem 1]. (As done earlier, we do need to uniformly replace $\min\{p_0, p_1\}$ by $\min_{\alpha-k}(\vec{p})$ and replace summations over $\{0,1\}$ by summations over the alphabet A.) The basic idea of the proof is to consider separately each node of the tree T created by P, look at the faults for the pages requested when at that node, and take the average of these individual faults weighted by the number of times the node is visited. The main observation is that for most nodes (i.e., nodes below a depth of m), there is a mapping from the nodes of T to the states of the mth-order Markov prefetcher; hence bounding the error at each node of T involves comparing with the best one-state prefetcher, which is done in Theorem 1. Since there are at most $c = O(n/\log n)$ nodes in T [37], and the one-state error from Theorem 1 is $O((\log n)\sqrt{n}/n)$, the net error turns out to be $O((\log(n/c))\sqrt{n/c}/(n/c)) = O((\log\log n)/\sqrt{\log n})$. (This is as opposed to the case of $\alpha = 2$, $k = 1$ studied in [12],where the one-state error is $O(1/\sqrt{n})$, yielding a net error of $O(1/\sqrt{\log n})$.)

This completes our description of the extensions to [12] required to prove Theorem 2.

A CORRECTNESS CONDITION FOR HIGH-PERFORMANCE MULTIPROCESSORS*

HAGIT ATTIYA† AND ROY FRIEDMAN‡

Abstract. *Hybrid consistency*, a consistency condition for shared memory multiprocessors, attempts to capture the guarantees provided by contemporary high-performance architectures. It combines the expressiveness of *strong* consistency conditions (e.g., sequential consistency, linearizability) and the efficiency of *weak* consistency conditions (e.g., pipelined RAM, causal memory). Memory access operations are classified as either *strong* or *weak*. A global ordering of strong operations at different processes is guaranteed, but there is very little guarantee on the ordering of weak operations at different processes, except for what is implied by their interleaving with the strong operations. A formal and precise definition of this condition is given and an algorithm for providing hybrid consistency on distributed memory machines is presented. The response time of the algorithm is proved to be within a constant multiplicative factor of the (theoretical) optimal time bounds.

Key words. distributed shared memory, consistency conditions, sequential consistency, hybrid consistency, weak consistency

1. Introduction.

Shared memory is an attractive paradigm for communication among computing entities because it is familiar from the uniprocessor case, it is more high level than message passing, and many of the classical solutions for synchronization problems were developed for shared memory. The fundamental problem is how to provide programmers with a useful model of logically shared data that can be accessed atomically, without sacrificing performance. The model must specify how the data can be accessed and what guarantees are provided about the results.

To enhance performance (e.g., response time), many implementations maintain multiple copies of the same logical piece of shared data (caching). Also, multiple application programs must be able to execute concurrently. More complications arise because at some level, each access to shared data has duration in time, from its start to its end; it is not instantaneous. A consistency mechanism guarantees that operations will appear to occur in some ordering that is consistent with some condition. Much research has addressed the issue of consistency for various system types and levels of abstraction. A major issue is which consistency condition should be supported: which conditions can be implemented efficiently, which conditions can be used conveniently, and which conditions support faster programs.

Until recently, theoretical research on this subject addressed *strong* consistency conditions like sequential consistency and linearizability [14, 21, 22, 24, 29, 41, 44, 45, 48, 51, 54]. These conditions guarantee that operations appear to be executed atomically, in some sequential order that is consistent with the order seen at individual

processes.[1] Sequential consistency and linearizability provide a clean and easy semantics for the execution of operations; programming using these conditions is (relatively) easy.

Unfortunately, supporting either sequential consistency or linearizability has a nonnegligible cost (cf. [12, 29, 40, 46]); i.e., these consistency conditions cannot be implemented efficiently. A way around this cost is to define conditions which provide weaker guarantees on the ordering of operations and can be efficiently implemented. Prominent among these weaker conditions are *mixed* consistency conditions (e.g., [1, 20, 30, 35, 38, 51]) that distinguish between two types of operations—strong and weak. Typically, strong operations appear to be executed atomically, in some sequential order that is consistent with the order seen at individual processes.[2] The only guarantees provided for weak operations are those implied by their interleaving with strong operations. Mixed conditions can be implemented so that weak operations are extremely fast, without degrading the response time for strong operations. Thus, a programmer can use the fast weak operations most of the time and resort to the slower strong operations only when global coordination is required.

In this paper, we make a step towards a theoretical study of mixed conditions for shared memory consistency, in an attempt to further our understanding of the issues involved in selecting and implementing a memory consistency condition.

Our first contribution is a formal and precise definition of *hybrid consistency*, which is a specific mixed condition. Very informally, hybrid consistency guarantees two properties.

1. Strong operations appear to be executed in some sequential order.
2. If two operations are invoked by the same process and one of them is strong, then they appear to be executed in the order in which they were invoked.

In particular, the second property guarantees that a strong operation appears to be executed after any operation (weak or strong) invoked before it by the same process, and before any operation (weak or strong) invoked after it by the same process. The definition applies to any collection of objects for which a sequential specification is provided (cf. [41]).

Our definition is very high-level and abstract—it describes the way operations appear to the programmer, not the way they are implemented. This results in a relatively simple definition and allows us to optimize its implementation.

We believe that hybrid consistency supports common concurrent programming techniques. In section 4, we show how Peterson's simple mutual exclusion algorithm [50] can be modified to exploit hybrid consistency. We discuss the performance benefits achieved by using hybrid consistency and illustrate how the formal definition is used when arguing about the correctness of algorithms. The correctness proof of this algorithm is quite similar to the proof of Peterson's original algorithm, which assumes sequential consistency. This may indicate that the complexity of arguing about programs assuming hybrid consistency is not much greater than the complexity of arguing about them assuming sequential consistency.

Our second contribution is an algorithm that implements hybrid consistency on distributed memory machines [14, 20, 45, 51]; our algorithm supports read/write objects and assumes each processor has a copy of every object. The algorithm is completely asynchronous. Weak operations are executed instantaneously, while the

[1] These conditions are similar in flavor to the notion of *serializability* from database theory [15, 49]; however, serializability applies to *transactions* which aggregate many operations.

[2] In some cases, e.g., [1, 35, 38], the requirements from strong operations are slightly weaker.

response time for strong operations is linear in the network delay. The algorithm is based on an atomic broadcast mechanism for sending messages. This mechanism is used to guarantee that all strong operations are executed by all processes in the same order. All weak writes to the same location are executed in the same order by all processes. Combined with the fact that a strong operation does not start until all previous operations have been executed by all processes, and does not terminate until it was executed by all other processes, this guarantees the second property of hybrid consistency. By adapting proof techniques from [12, 46], we show that the response time of our algorithm is within a constant factor of the optimum. Algorithms for providing hybrid consistency for other objects, using somewhat different techniques, appear in [33].

Another class of consistency conditions are those that, essentially, include only weak operations, e.g., [5, 39, 46]. It has been shown that without strong operations, mutual exclusion can be solved only by centralized algorithms [10, 32]. We do not address these conditions any further in this paper.

The rest of the paper is organized as follows: section 2 includes our basic definitions and some notation. Section 3 contains the definition of *hybrid consistency* and a discussion of related definitions. Section 4 provides an example of programming with hybrid consistency. In section 5, we present an algorithm for providing hybrid consistency, together with its correctness proof and performance analysis. Section 6 contains lower bounds on the response time of strong operations under hybrid consistency. We conclude, in section 7, with a discussion of our results and directions for further research.

2. The system. We consider a collection of application programs running concurrently and communicating via virtual shared memory, which consists of a collection of *objects*. We assume a system consisting of a collection of nodes P connected via a communication network; each application program runs on a different node. The shared memory abstraction is implemented by a *memory consistency system* (mcs), which uses local memory and some protocol executed by the mcs processes (one at each node). A correctness condition is defined at the interface between the application programs (written by the user) and the mcs processes (supplied by the system). Thus, the mcs must provide the proper semantics when the values of the responses to calls are considered, throughout the network. An illustration of the system architecture is given in Figure 1.

The following *events* may occur at the mcs process on node i.

1. *Call events:* The initiation of operations by the application program according to their specification. For example, in the case of read/write objects, the call events are $\text{Read}_i(X)$ and $\text{Write}_i(X, v)$ for all objects X and values v.
2. *Response events:* The response of the mcs to operations initiated by the application program, according to their specification. For example, in the case of read/write objects, the response events are $\text{Return}_i(X, v)$ and $\text{Ack}_i(X)$ for all objects X and values v.
3. *Message-receive events:* $\text{receive}(i, m, j)$ for all messages m and mcs processes p_i and p_j: the mcs process on node i receives message m from the mcs process on node j.
4. *Message-send events:* $\text{send}(i, m, j)$ for all messages m and mcs processes p_i and p_j: the mcs process on node i sends message m to the mcs process on node j.

The call and message-receive events are *interrupt events*.

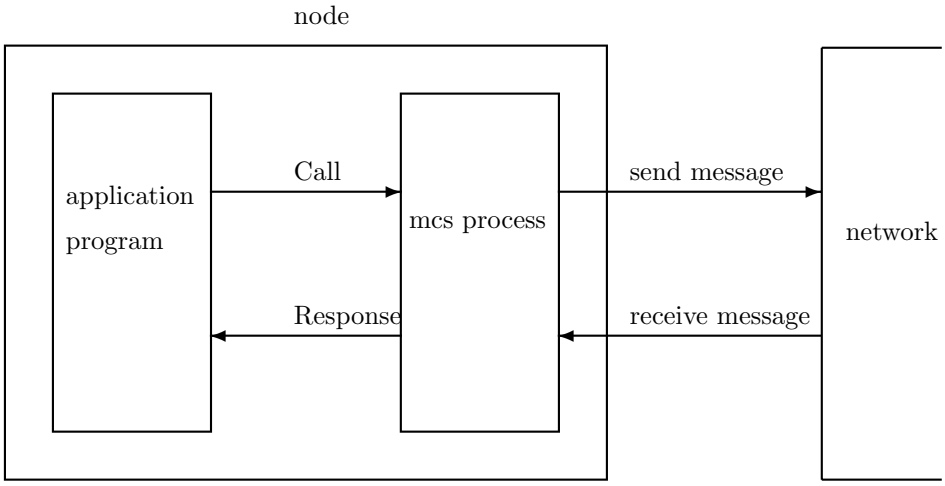

FIG. 1. *System architecture.*

An *mcs process* (or simply *process*) is an automaton with a (possibly infinite) set of states, including an initial state and a transition function. Each interrupt event causes an application of the transition function. The transition function is a function from states and interrupt events to states, sets of response events, and sets of message-send events. That is, the transition function takes as input the current state and an interrupt event, and produces a new state, a set of response events for the application process, and a set of messages to be sent. A *step* of a process p_i is a tuple (s, i, s', R, M), where s and s' are states, i is an interrupt event, R is a set of response events, M is a set of message-send events, and s', R, and M are the result of p's transition function acting on s and i. A *history* of a process p is a mapping h from $\Re$ (real time) to finite (possibly empty) sequences of steps such that

1. for each real time t, there is only a finite number of times $t' < t$ such that the corresponding sequence of steps $h(t')$ is nonempty (thus the concatenation of all the sequences in real time order is a sequence);
2. the old state in the first step is p's initial state; and
3. the old state of each subsequent step is the new state of the previous step.

An *execution* of an mcs is a set of histories, one for each process in P, in which there is a one-to-one correspondence from the messages received by p_i from p_j onto the messages sent by p_j to p_i, for any processes p_i and p_j. An *infinite execution* is an execution in which every history is infinite. We use the message correspondence to define the *delay* of any message in an execution to be the real time of receipt minus the real time of sending. (The network is not explicitly modeled, although the constraints on executions, defined below, imply that the network reliably delivers all messages sent.)

An execution σ is *admissible* if the following conditions hold.

1. For every i and j, every message in σ from p_i to p_j has its delay in the range $[0, d]$, for a fixed nonnegative integer d. (This is a restriction on the network.)
2. For every i, in every prefix of σ the number of calls at p_i can be larger than the number of responses at p_i by at most one. (This is a restriction on the application program.)

Each pair of a *call* event and a subsequent matching *response* event forms an *operation*. The call event marks the start of the operation, while the response event marks the end of that operation. An operation *op* is *invoked* when the application process issues the appropriate call for *op*; *op terminates* when the mcs process issues the appropriate response for *op*. An operation is *pending* if it is invoked and is not terminated. Note that since we assumed that all executions are admissible, there can be at most one pending operation per process; i.e., an application program does not invoke a new operation before the previous one has terminated. Given a particular mcs, an object x implemented by it, and an operation type *op* on x, we denote by $|op(x)|$ the maximum time taken from the invocation to the termination of an operation of type *op* on x in any execution. We denote by $|op|$ the maximum of $|op(x)|$, over all objects x implemented by the mcs.

Every object is assumed to have a *sequential specification* (cf. [41]) defining a set of operations and a set of operation sequences, which are the allowable sequences of operations on that object. For example, in the case of a read/write object, the ordered pair of events $[\text{Read}_i(x), \text{Return}_i(x, v)]$ forms an *operation* for any p_i, x, and v, as does $[\text{Write}_i(x, v), \text{Ack}_i(x)]$. The set of operation sequences consists of all sequences in which every read operation returns the value of the latest preceding write operation (the usual read/write semantics).

A sequence τ of operations for a collection of processes and objects is *legal* if, for every object x, the restriction of τ to operations of x is in the sequential specification of x.

Let τ be an execution or a sequence of operations. Denote by $\tau \mid j$ the restriction of τ to operations invoked by p_j; similarly, denote by $\tau \mid x$ the restriction of τ to operations on object x.

Given an execution σ, let $ops(\sigma)$ be the sequence of call and response events appearing in σ in real time order, breaking ties by ordering all events of the same process in the order in which they appear in that process and then using process ids. An execution σ induces a partial order, $\overset{\sigma}{\longrightarrow}$, on the operations that appear in σ; $op^1 \overset{\sigma}{\longrightarrow} op^2$ if the response event of op^1 appears in $ops(\sigma)$ before the call event of op^2.

Given an execution σ, a sequence of operations τ is a *serialization* of σ if it is a permutation of $ops(\sigma)$. A serialization τ of σ is a *linearization* if it extends $\overset{\sigma}{\longrightarrow}$; that is, if $op^1 \overset{\sigma}{\longrightarrow} op^2$ then $op^1 \overset{\tau}{\longrightarrow} op^2$. In our framework, sequential consistency and linearizability are defined as follows.

DEFINITION 2.1 (sequential consistency). *An execution σ is* sequentially consistent *if there exists a legal serialization τ of σ, such that for each process p_j, $\sigma \mid j = \tau \mid j$.*

DEFINITION 2.2 (linearizability). *An execution σ is* linearizable *if there exists a legal linearization τ of σ, such that for each process p_j, $\sigma \mid j = \tau \mid j$.*

It is possible to mark some operations as *strong*; all other operations are called *weak*. In the case of read/write objects this means that it is possible to use *strong reads* and *strong writes*. We denote the call events for strong operations by $\text{SWrite}(x, v)$ and $\text{SRead}(x)$ and the respective response events by $\text{SAck}(x)$ and $\text{SReturn}(x, v)$.

We now introduce some notation we use in the rest of the paper. By op_i we denote an operation invoked by p_i (weak or strong), and by sop_i we denote a strong operation invoked by process p_i. We use superscripts, e.g., $op_i^1, op_i^2, \ldots$, to distinguish between operations invoked by the same process. We sometimes use a shorthand notation for

read and write operations and denote by $r_i(x, v)$ a weak read operation invoked by process p_i returning v from x; we denote by $w_i(x, v)$ a weak write operation invoked by process p_i writing v to x. Similarly, $sr_i(x, v)$ is a strong read operation invoked by process p_i returning v from x; $sw_i(x, v)$ is a strong write operation invoked by process p_i writing v to x.

3. Definition of hybrid consistency. The following definition requires that (a) strong operations appear to occur in the same order at all processes, and (b) if two operations are invoked by the same process and one of them is strong, then they appear to occur at all processes in the order in which they were invoked.

DEFINITION 3.1 (hybrid consistency based on linearizability). *An execution σ is* hybrid *if there exists a linearization ρ of σ such that for each process p_j, there exists a legal sequence of operations τ_j with the following properties.*

1. *τ_j is a permutation of $ops(\sigma)$.*
2. *If $op_i^1 \xrightarrow{\sigma} op_i^2$ and at least one of op_i^1 and op_i^2 is strong, then $op_i^1 \xrightarrow{\tau_j} op_i^2$ for any i.*
3. *If $op^1 \xrightarrow{\rho} op^2$ and op^1 and op^2 are strong, then $op^1 \xrightarrow{\tau_j} op^2$.*
4. *$\tau_j \mid j = \sigma \mid j$.*

Definition 3.1 defines the view τ_j for each process p_j. This view must include all the memory operations in the execution (this is the first requirement). Any two operations invoked by the same process p_i, where at least one of them is strong, must be viewed by p_j in their order of invocation at p_i (this is the second requirement). The views of all processes must agree on the order of the strong operations, including those by other processes (this is the third requirement). Finally, process p_j must view its own operations in their order of invocation (this is the fourth requirement).

The definition requires the existence of a linearization ρ of σ. However, ρ is used only to force a global order on the strong operations. Therefore, we can require the existence of a linearization only of the strong operations in σ, obtaining an equivalent definition.

When restricted to strong operations, this definition is equivalent to linearizability. However, following the results of [12], we might be interested in examining hybrid models in which strong operations are only sequentially consistent. This leads to the following variant of hybrid consistency.

DEFINITION 3.2 (hybrid consistency based on sequential consistency). *An execution σ is* hybrid *if there exists a serialization ρ of σ such that for each process p_j, there exists a legal sequence of operations τ_j with the following properties.*

1. *τ_j is a permutation of $ops(\sigma)$.*
2. *If $op_i^1 \xrightarrow{\sigma} op_i^2$ and at least one of op_i^1 and op_i^2 is strong, then $op_i^1 \xrightarrow{\tau_j} op_i^2$ for any i.*
3. *If $op^1 \xrightarrow{\rho} op^2$ and op^1 and op^2 are strong, then $op^1 \xrightarrow{\tau_j} op^2$.*
4. *$\tau_j \mid j = \sigma \mid j$.*

The only difference between the two definitions is that the second definition requires that ρ is a serialization of σ rather than a linearization.

3.1. Related definitions. We now present a detailed comparison of hybrid consistency, as defined above, with other definitions of mixed consistency conditions, which distinguish between two kinds of operations.

Most previously known definitions of hybrid consistency are given by specifying, at some degree of formality, *how the mcs handles operations*, i.e., how the hardware

should behave. In contrast, our definition specifies *how the operations appear to the application program*, i.e., how the hardware should appear to the programmer. In particular, our definition is given at the interface between the application program and the mcs, while most previous definitions of hybrid consistency are given at the interface between the mcs and the network.

Although from the architect's point of view it is easier to work with a definition that is given at the interface between the mcs and the network, a definition at the interface between the application program and the mcs is more convenient for programming. It is more difficult to write programs or argue about their correctness when the exact behavior of the hardware has to be considered. Also, programs that are written with respect to an abstract consistency condition are more portable; they can run correctly on different implementations of the consistency condition, regardless of the optimizations that are used by the hardware. Our work complements previous work by presenting an abstract and formal definition at a more comfortable interface, even if this disallows some hardware optimizations.

We now turn to a more detailed comparison of our definition of hybrid consistency with related definitions. It is necessary to make here a distinction between the framework and the definition style we suggest for consistency conditions, and the specific decisions we made in specifying hybrid condition. The current definition of hybrid consistency was given based on our impression of what would be a reasonable model for programming. However, if due to performance reasons, one wishes to change some of these choices, our framework allows such changes to be done very easily. In our opinion, this is one of the main advantages of our framework.

Dubois, Scheurich, and Briggs. The most related condition is *weak ordering*, defined by Dubois, Scheurich, and Briggs [30]. Variables are classified as either regular or synchronization, and it is required that:

1. accesses to global synchronization variables are strongly ordered;
2. no access to a synchronizing variable is issued by a process before all its previous global data accesses have been executed by all the processes;
3. no access to global data is issued by a process before its previous access to a synchronizing variable has been executed by all the processes.

This definition is given in terms of restrictions on the implementation (i.e., at the interface between the mcs processes), rather than on the way the mcs should appear to the programmer (i.e., at the interface between the application programs and the mcs).

This definition rules out implementations which obey the intended semantics of the definition and give better performance. For example, the implementation given in [30] could be improved by pipelining weak operations with strong operations. This improvement seems to obey the intended semantics of the definition, but violates the definition itself. To alleviate this problem and be able to compare this definition with ours, the following definition is specified at the interface between the mcs and the application program, and (we hope) provides the semantics intended by the definition in [30].

DEFINITION 3.3. *Let X be the set of synchronizing variables in the system. An execution σ is* object-based hybrid *if there exists a serialization ρ of σ such that for each process p_j, there exists a legal sequence τ_j of operations such that the following hold.*

1. *τ_j is a permutation of $ops(\sigma)$.*
2. *If $op_i^1 \in (\sigma \mid X)$ or $op_i^2 \in (\sigma \mid X)$ and $op_i^1 \xrightarrow{\sigma} op_i^2$, then $op_i^1 \xrightarrow{\tau_j} op_i^2$.*

3. *If* $op^1, op^2 \in (\sigma \mid X)$ *and* $op^1 \xrightarrow{\rho} op^2$, *then* $op^1 \xrightarrow{\tau_j} op^2$.
4. $\tau_j \mid j = \sigma \mid j$.

This definition is a special case of our definition of hybrid consistency in which strong operations are restricted to special synchronization objects. In contrast, our definition allows the use of strong and weak operations on the same object. This property is exploited in the mutual exclusion algorithm given below in section 4. In this algorithm, the reads from synchronization objects are weak. This results in a reduced number of messages in the system.

Adve and Hill. A different approach splits the responsibility for memory consistency between the software and the hardware. In this approach, the hardware must exhibit some known predefined behavior only for software that obeys certain requirements. For example, the following definition of *weak ordering* was given by Adve and Hill [1]:

> "Hardware is weakly ordered with respect to a synchronization model if and only if it appears sequentially consistent to all software that obeys the synchronization model."

Following this definition, they give a formal definition of a synchronization model DRF0. In this synchronization model, an application program is required to use synchronization operations in any place where a data race[3] is possible. Using the same approach, a generalization of DRF0 that supports further classification of synchronization operations into *releases* and *acquires* is presented in [2, 3]. This synchronization model is called DRF1. Again, the application program is required to use synchronization operations to prevent data races.

The approach taken by Adve and Hill divides the responsibility for correctness between the mcs and the application program: the mcs supports a consistency condition very similar to hybrid consistency, and the application program is required to obey a certain synchronization model, in this case DRF0 (or DRF1). Then it is guaranteed that the programs will run *as if* the mcs was sequentially consistent. In this approach, the mcs provides a guarantee about the results of memory access operations only for programs that obey DRF0 (or DRF1). There is no crisp guarantee (that does not rely on understanding a specific implementation) for programs that violate DRF0 (or DRF1).

Release consistency. *Release consistency*, defined by Gharachorloo et al. [35], is supported in the Stanford DASH multiprocessor. The definition given in [35] assumes three types of operations: *ordinary*, *sync*, and *nsync*. Each type is further divided into reads and writes. The following list of sufficient conditions is then given.

1. Uniprocessor data dependencies are respected.
2. All writes to the same location are serialized in some order and are executed in that order with respect to any process.
3. Before a sync write access is allowed to execute with respect to any other process, all previous ordinary write accesses by the same process must be executed.
4. Sync and nsync accesses are kept sequentially consistent with respect to one another.

Besides being at the interface between the mcs and the network, this definition is given as a list of sufficient conditions on the hardware. These conditions are based on

[3] Informally, a *data race* occurs when the order of two conflicting memory accesses (which are not synchronization operations) is not predetermined; for precise definitions and more discussion, see [1, 9, 11].

the notion of "an operation being executed with respect to a process," whose meaning depends on the specific implementation which was kept in mind when the definition was given.

Formal definitions of release consistency are given in [37, 38].[4] These definitions are quite complex and make reasoning about programs directly with release consistency a very difficult task. To overcome this problem, a synchronization model called PL-programs is defined; this model is similar to DRF1. (In fact, DRF1 is an extension of DRF0, which reflects the release-acquire distinction made by PL.) It is then guaranteed that any program obeying this synchronization model will run as if the mcs was sequentially consistent. This approach, like the one taken by Adve and Hill, gives little support to the design of programs that do not obey specific synchronization models, e.g., our modification of the classical solution to mutual exclusion (presented in the next section). Note that sometimes it is easier to prove the correctness of a program with respect to a consistency condition from scratch than to prove that the program obeys some synchronization model like DRF0, DRF1, or PL.

The major conceptual difference between release consistency and hybrid consistency is the further classification of strong operations into release and acquire. It was shown in [34, 60] that in certain cases, this further classification improves the achievable performance, but in other cases, it does not provide any substantial benefit. It is simple to modify our definition to capture this further distinction (see the definition of asymmetric hybrid consistency in [9]). In addition, release consistency does not require that each process view the weak reads of other processes.

Hybrid consistency, on the other hand, requires that the view of every process include all operations of any other process, in particular, the weak reads. However, our framework allows us to change the definition very easily to omit this requirement; furthermore, none of our results depend on this condition.[5] We believe that this additional requirement makes the programmer's model more comprehensive and therefore more convenient to use, although it may prohibit some otherwise possible hardware optimizations.

4. Programming with hybrid consistency. Hybrid consistency supports a very simple method of programming: use only strong operations and "think sequential consistency" (or linearizability, as the case may be). Clearly, this method is prone to the same performance penalties as sequential consistency. A better programming method is to use weak operations most of the time and strong operations only in those places where global ordering is needed. In this section, we give an example of a mutual exclusion algorithm based on hybrid consistency, and prove its correctness. This example demonstrates that programming with hybrid consistency can be simple and efficient. It also gives some intuition on when strong operations should be used, and how to prove correctness relying on hybrid consistency.

Formally, an algorithm for mutual exclusion consists of four disjoint sections–entry, critical, exit, and remainder (cf. [52]). In the *entry* section, a process tries to gain access to the critical section; the *exit* section is executed by each process upon leaving the critical section; the *remainder* section is the rest of the code. A mutual exclusion algorithm should guarantee

> *mutual exclusion:* no two processes are inside the critical section at the same time;

[4] The definition in [37] is a generalization of the definition in [38] that allows pipelining of memory operations.

[5] The algorithm could be slightly simplified without this condition.

1: $sw(need[i], \text{true})$;
2: $sw(turn, 1-i)$;
3: **if** $r(need[1-i]) = \text{true}$ **and** $r(turn) = 1-i$ **then goto** 3;
$\langle$*critical section*$\rangle$
4: $sw(need[i], \text{false})$;
$\langle$*remainder section*$\rangle$

FIG. 2. *Mutual exclusion using hybrid consistency; code for process* p_i, $i = 0, 1$.

deadlock freedom: in every infinite execution, if there is a process in the entry section, then eventually there is some process in the critical section; and
starvation freedom: in every infinite execution, every process which executes the entry section is eventually granted permission to enter the critical section.

Figure 2 presents a solution for two processes which is fair; it is a simple modification of Peterson's algorithm [50]. The algorithm can be extended to n processes along the lines of Peterson's algorithm. Lines 1–3 are the entry section; line 4 is the exit section. In the code we use the notation $r(x) = v$ to denote a weak read of x returning the value v, and $sw(x, v)$ to denote a strong write of v to x, for any read/write object x and value v.

The lemmas and proofs of this section apply to hybrid consistency based on linearizability and to hybrid consistency based on sequential consistency.

LEMMA 4.1. *The algorithm in Figure* 2 *guarantees mutual exclusion under hybrid consistency.*

Proof. Assume, by way of contradiction, that there is a hybrid execution σ in which p_0 and p_1 execute the critical section together. Denote by $sw_0(need[0], \text{true})$ and $sw_0(turn, 1)$ the last strong writes to $need[0]$ and $turn$ executed by p_0 before entering the critical section, and by $sw_1(need[1], \text{true})$ and $sw_1(turn, 0)$ the last strong writes to $need[1]$ and $turn$ executed by p_1 before entering the critical section. Remember that σ is a hybrid execution and consider a serialization ρ of σ as guaranteed by the definition of hybrid consistency. Without loss of generality, assume that $sw_0(turn, 1)$ appears before $sw_1(turn, 0)$ in ρ. In particular, $sw_0(need[0], \text{true})$ is ordered before $sw_1(turn, 0)$ in ρ. Since p_1 entered its critical section, it follows that p_1's last $r_1(turn)$ before entering returned 1. However, by assumption, $sw_0(turn, 1) \xrightarrow{\rho} sw_1(turn, 0)$. By the definition of τ_1 it follows that $sw_0(turn, 1) \xrightarrow{\tau_1} sw_1(turn, 0) \xrightarrow{\tau_1} r_1(turn, 1)$. Thus, τ_1 is not legal, since $r_1(turn)$ should have returned 0. □

LEMMA 4.2. *The algorithm in Figure* 2 *is free of deadlock under hybrid consistency.*

Proof. Assume, by way of contradiction, that there is a hybrid execution σ in which there is a deadlock. A deadlock occurs if p_0 and p_1 keep executing line 3; that is, p_0 continually reads $r_0(need[1], \text{true})$ and $r_0(turn, 1)$ in line 3 and p_1 continually reads $r_1(need[0], \text{true})$ and $r_1(turn, 0)$.

Since σ is a hybrid execution, there exists a serialization ρ of σ. Without loss of generality, assume $sw_0(turn, 1)$, the write by p_0 immediately preceding p_0's infinite loop, is ordered in ρ before $sw_1(turn, 0)$, the write by p_1 immediately preceding p_1's infinite loop.

Now consider p_0's view, τ_0, as guaranteed by the definition of hybrid consistency. In τ_0, $sw_0(turn, 1)$ precedes $sw_1(turn, 0)$, since τ_0 respects ρ. Let $r_0(turn, 1)$ be the first such read by p_0 that follows $sw_1(turn, 0)$ in τ_0. It exists because there are infinitely many such reads. We now show that no write to *turn* can fall between $sw_1(turn, 0)$ and $r_0(turn, 1)$ in τ_0, violating the legality of τ_0.

Every write to *turn* by p_0 is a strong write and precedes $sw_0(turn, 1)$ in the actual execution, and thus precedes $sw_1(turn, 0)$ in ρ and in τ_0. Every (other) write to *turn* by p_1 is a strong write and precedes $sw_1(turn, 0)$ in the actual implementation, and thus precedes $sw_1(turn, 0)$ in ρ and in τ_0. Thus, $sw_1(turn, 0)$ is the last write to *turn* ordered in τ_0 before $r_0(turn, 1)$, a contradiction to the legality of τ_0. □

LEMMA 4.3. *The algorithm in Figure 2 is starvation free under hybrid consistency.*

Proof. Assume, by way of contradiction, that there exists an infinite hybrid execution σ of the algorithm in which one process, say p_0, is trying to enter the critical section, but is never granted permission. Let $sw_0(turn, 1)$ be the last write of p_0 to *turn*. By Lemma 4.2, p_1 must enter the critical section an infinite number of times. Let ρ be a serialization of all operations in σ, as guaranteed in the definition of hybrid consistency. Every operation in σ must appear in ρ after a finite number of operations. Thus, there exists an operation $sw_1(turn, 0)$ such that $sw_0(turn, 1) \xrightarrow{\rho} sw_1(turn, 0)$. Consider a legal serialization τ_1 of σ, as guaranteed by hybrid consistency. Under the assumption that p_1 enters the critical section infinitely often, τ_1 must include the following subsequence:

$$sw_0(turn, 1) \xrightarrow{\tau_1} sw_1(turn, 0) \xrightarrow{\tau_1} r_1(turn, 1) .$$

This contradicts the assumption that τ_1 is legal. □

The algorithm uses only weak reads in the entry section; hence, when running on an efficient implementation of hybrid consistency (like the one presented in this paper), the entry section is executed faster and with less message overhead.[6]

Note that if the first operation inside the critical section is a weak operation, then we might not have *logical mutual exclusion*. That is, the operations of the entry and exit sections are ordered correctly, but weak operations issued by p_0 inside the critical section may be ordered in the view of p_1 before the last (weak read) operation of the corresponding entry section of p_0. Similarly, weak operations issued by p_1 inside the critical section may be ordered in the view of p_0 before the last (weak read) operation of the corresponding entry section of p_1. This need not happen in every implementation of hybrid consistency, but could happen in some of them. One way to solve this problem is to add one strong (read or write) operation to some object that is not accessed elsewhere in the program, before entering the critical section. This will guarantee that all the operations that are invoked inside the critical section will be ordered after all operations that belong to the entry section. Since the number of operations in the entry section is expected to be quite large, adding one operation (that will be executed only once) should not impose a significant performance loss. A detailed discussion of this problem and another solution can be found in [9].

5. An algorithm for providing hybrid consistency. In this section we present an efficient algorithm for providing hybrid consistency, in both flavors, that supports

[6] Note that by efficient implementations we refer to implementations that execute weak operations faster than the network delay. By the lower bounds proved in [12] and in section 6, strong operations cannot be implemented faster than the network delay.

read/write objects, accessible by either strong or weak operations. The algorithm allows weak operations to be executed instantaneously, while keeping the response time for strong operations proportional to the network delay. Being able to execute weak operations fast is vital for the usefulness of this algorithm, since it is the major advantage hybrid consistency has over sequential consistency. (Recall that in order to implement sequential consistency, the execution time of either reads or writes must be at least linear with the network delay.) Our algorithm assumes that each process holds a complete copy of the entire memory, which allows for instantaneous execution of weak operations, provided that write operations will eventually update all copies. (We later discuss how to relax this assumption.)

The algorithm we describe is completely asynchronous. This means that every process may run at a different rate and that the delay of the network need not be known.

The algorithm uses an atomic broadcast mechanism to send messages. Atomic broadcast is becoming quite common as an underlying tool in the development of distributed systems [16, 17, 47, 53, 55, 57]. Our decision to use atomic broadcast follows this trend and is justified by the immediate benefits that this mechanism provides. An atomic broadcast mechanism guarantees that all messages are delivered at all processes in the same order. Thus, it creates a "global logical time," which simplifies the code of the algorithm and its proof of correctness. Furthermore, using an atomic broadcast mechanism is more modular than implementing the communication protocol directly. Many atomic broadcast algorithms with various degrees of fault tolerance and efficiency have been developed, e.g., [6, 7, 8, 10, 12, 18, 19, 23, 25, 27, 26, 31, 43, 59]. Thus, by employing different atomic broadcast algorithms, one may balance the degree of fault tolerance, message complexity, and time complexity, to fit the desired goals of the implementation.

In the algorithm, weak operations are executed on the local copy of the memory. Strong operations and weak write operations broadcast a message to all processes; an operation is executed by each process when the corresponding message is delivered at the process. Thus, the order of execution should reflect the order in which messages are delivered by the atomic broadcast mechanism.

Unfortunately, there is a problem, since weak operations must return immediately and a weak read that immediately follows a weak write by the same process must return the value written by that write. To handle this problem, we modify the basic idea such that weak writes that are not invoked by the local process are executed under the following conditions. A weak write that is not concurrent[7] with any other (weak or strong) write is always executed when its corresponding message is delivered. If there are two concurrent weak writes, then the one which is delivered first by the atomic broadcast service is executed by every process, while the other one is ignored by every process.

The detailed description of the algorithm and its pseudocode in section 5.1 is followed by a correctness proof in section 5.2 and a complexity analysis in section 5.3.

5.1. The algorithm. We assume a system of n processes, each capable of holding a local copy of the entire memory. The processes are connected by some interconnection network. We assume an atomic broadcast mechanism that supports two

[7] Concurrency is defined with respect to the global order of message delivery. In other words, two weak writes are concurrent if they were invoked by different processes and the same number of messages (that were broadcast to everybody) have been delivered at the invoking processes before they were invoked.

primitives: **abcast** and **asend**. The first primitive, **abcast**, broadcasts a message to all processes atomically. A process may use the second primitive, **asend**, to send a message to a single process, when the interleaving of this message with other messages sent by it, using either **abcast** or **asend**, should reflect their relative order of invocation.

More precisely, let MA be the set of messages sent using **abcast** and denote by MA_i the sequence of messages in MA that are delivered at process p_i, according to the order in which they are delivered at p_i. Then the following hold: (a) for any i and j, $MA_i = MA_j$, and (b) for any two messages $m_i^1, m_i^2 \in MA$ such that both m_i^1 and m_i^2 are sent by p_i and m_i^1 is sent before m_i^2, then m_i^1 is ordered in MA_i before m_i^2. Moreover, let MP_{ij} be the sequence of messages sent from process p_i to process p_j using either **abcast** or **asend**. Then the messages in MP_{ij} are delivered at p_j in the order in which they were sent by p_i.

We use **asend** instead of a regular send to send acknowledgments since the correctness of the algorithm depends on the fact that at each process, the delivery order of *all* messages reflects the order in which they were sent. We use **asend** instead of **abcast** because in some implementations of atomic broadcast, e.g., sequencer/token-based protocols [6, 8, 10, 18, 27, 43, 58], it results in a lower message complexity.

Every process maintains a local copy of the entire memory *mem*, an array of integers *last_mess*, an array of ids *last_id*, an integer counter *received*, and another object *val*, as described below. (See also Figure 3.)

The counter *received* is used to count the messages delivered by the atomic broadcast. It serves as a logical timestamp and its value is added to messages. It is initialized to 0 and incremented each time a message that was sent with **abcast** is delivered.

For each object, *last_mess* and *last_id* uniquely identify the last operation that updated the object. That is, whenever a (weak or strong) write updates an object, *last_mess* is assigned the current value of the variable *received* and *last_id* is assigned the id of the process that invoked the write.

Finally, the variable *val* is used to temporarily store a value that a pending strong read should return, as described later.

Weak operations are executed on the local copy of the memory and return immediately. A weak write causes an `update` message to be broadcast to all processes. This message contains the name of the object to be updated, the new value for the object, and a logical timestamp which is the value of *received* when the operation is invoked. Whenever an `update` message is received, an `ack` message is sent back to the initiator of the operation, using **asend**.

Following this, processes that did not invoke the write execute it on the local copy of the object if either (a) the previous operation that updated the same object was invoked by the same process (held in the variable *last_id*), or (b) the value of *last_mess* is smaller than the value of *received* that is included in the `update` message of the weak write. These conditions guarantee that all writes to the same location are executed by all processes in the same order, based on the following observation: the value *last_mess*$[x]$ is a counter for how many messages were delivered by the atomic broadcast mechanism when object x was last updated. (In that sense the atomic broadcast mechanism serves to order all writes.) If a write w_k has a timestamp bigger than *last_mess*$[x]$ at p_i, then w_k was invoked by p_k after p_k had also seen the last update to x that p_i had seen; call this update w_l. So, w_k causally follows the actual act of updating x which was caused by w_l. In particular, if w_l is a weak write, w_k should not overwrite it. On the other hand, if the timestamp of w_k is smaller than

last_mess[x], then it does not causally follow the actual act of updating x at p_k, and might have overwritten w_l in p_l.

Hence, the first write that passes the timestamp test among all those which are concurrent gets to update the memory. The rest of the concurrent writes fail this test, because we are using the value of *received* when the update message is delivered to update *last_mess*[x], and not the timestamp of the update message itself. So, these writes never get to update any process (except their local process, but even there they are overwritten by the "winner" write), and in a logical sense they are ordered before the "winning" write, which is the first of the concurrent writes to be delivered by the atomic broadcast mechanism.

Note that this order corresponds to the order implied by the logical timestamp of the writes. In other words, it corresponds to the value of the variable *received* at the time of their invocation. Ties among all writes with the same logical timestamp are broken by ordering the first delivered weak write after all other weak writes with the same logical timestamp. The variable *last_id* is required to preserve the order of writes by the same process, since two consecutive weak writes by the same process may have the same logical timestamp.

Whenever a strong operation is invoked, if the operation is a strong read and the last local operation was a weak read, then a `dummy` message is broadcast to all processes. Every process that receives a `dummy` message returns an `ack` message to the initiator using **asend**. Next, the invoking process waits until all `ack` messages for the previous operations and for the current `dummy` message return. Then, a `strong-write` or a `strong-read` message is broadcast to every process. The operation is executed by every process whenever the appropriate message is delivered. A strong write is executed by updating the local copy of the object. A strong read is executed at the invoking process by copying the value of the local copy of the object to *val*. This value is returned when the operation returns. A strong read is executed by other processes by doing nothing. After executing a strong operation, an `ack` message is sent back to the initiator of the operation. A strong operation does not return until all `ack` messages have been received.

A `dummy` message is broadcast between the invocation of a weak read and the invocation of a strong read to guarantee that the invocation of a strong read is separated by at least a certain amount of "logical time" from the invocation of the last previous weak operation by the same process. This allows us to reorder strong reads relative to the delivery of their `strong-read` messages; the exact reordering is described in the correctness proof. Note that there is no need to send a `dummy` message after a weak write, since weak writes broadcast an `update` message; this already guarantees that there is enough "logical time" between the invocation of the weak write and the strong operation.

The precise code appears in Figures 3 and 4; recall that *Ack*, *SAck*, *Return,* and *SReturn* are defined at the end of section 2.

5.2. Proof of correctness. Given an execution σ, we explicitly show how to construct the set of sequences $T = \{\tau_j\}_{j=1}^{n}$, as required in the definition of hybrid consistency. We prove that our algorithm satisfies Definition 3.1; this clearly implies that it also satisfies Definition 3.2.

Very informally, the construction goes as follows. For each process p_j, we first build the sequence τ'_j, consisting of all (weak and strong) write operations, all local weak read operations, and all delivery events. The operations are ordered according to the order in which they occurred in p_j. The delivery events serve as markers

The state of each process p_i consists of the following components:

mem : copy of every object, initially equal to its initial value
last_mess : array of integers with one entry for each object, all initially 0
last_id : array of ids with one entry for each object, all initially 0
received : integer, initially 0
(serial number of the last message delivered to p_i)
missing_acks : integer, initially 0
(number of acknowledgments that are outstanding)
val : an object

Read(x):
generate Return(x, *mem*[x])

Write(x,v):
mem[x] := v
abcast ⟨`update`, x, v, *received*⟩
missing_acks := *missing_acks* + n
generate Ack(x)

SRead(x):
if the last previous operation by p_i was a weak read then
abcast ⟨`dummy`⟩
missing_acks := *missing_acks* + n
endif
wait until *missing_acks* = 0 /* This line is not atomic */
abcast ⟨`strong-read`, x⟩
missing_acks := *missing_acks* + n

SWrite(x,v):
wait until *missing_acks* = 0 /* This line is not atomic */
abcast ⟨`strong-write`, x, v⟩
missing_acks := *missing_acks* + n

FIG. 3. *The algorithm*; *code for process* p_i.

which are useful for the rest of the proof. They are ordered according to the order in which they occurred, such that each delivery event is ordered after the corresponding operation. We show that $T' = \{\tau'_j\}_{j=1}^{n}$ obeys all the requirements in the definition of hybrid consistency, except for including all operations in $ops(\sigma)$ and having delivery events. (This is done in section 5.2.1.)

Following this, we insert the strong reads into T', creating a new set of sequences $T'' = \{\tau''_j\}_{j=1}^{n}$, such that the strong reads are legal. T'' obeys all the requirements in the definition of hybrid consistency, but it does not include all operations of $ops(\sigma)$ and includes the delivery events. This is the most complicated part of the proof, due

```
received ⟨update, x, v, s⟩ from p_j:
    asend ⟨ack, j⟩
    received := received + 1
    if ((s ≥ last_mess[x]) or (last_id[x] = j)) then
        last_mess[x] := received
        last_id[x] := j
        if i ≠ j then
            mem[x] := v
        endif
    endif

received ⟨dummy⟩ from p_j:

    if (j = i) then val := mem[x] endif

received ⟨ack, i⟩ from p_j:
    missing_acks := missing_acks −1
    if (missing_acks = 0) and there is a pending strong operation to some object x then
        if the strong operation is a write then generate SAck(x)
        else generate SReturn(x,val)
        endif
    endif
```

FIG. 4. *The algorithm*; *code for handling message-receive events at process* p_i.

to the fact that strong reads need to appear consistently in all views. (This is done in section 5.2.2.)

At this stage, we insert in each sequence τ_j'' all weak reads by other processes. This yields a new set of sequences $T''' = \{\tau_j'''\}_{j=1}^{n}$ such that all reads in each τ_j''' are legal. T''' obeys all the requirements in the definition of hybrid consistency except for having the delivery events. (This is done in section 5.2.3.)

Finally, we construct the desired set of sequences T by removing all delivery events from T''', in section 5.2.4.

We now turn to the formal proof and start with some definitions and notations.

For every operation *op* that causes a message to be broadcast, i.e., weak write, strong write, or strong read, we denote by $del_j(op)$ the delivery event of the corre-

sponding message (`update`, `strong-write`, or `strong-read`, accordingly) in p_j. Given a strong read sr_i, we denote by $prev(sr_i)$ the last (`strong-read`, `strong-write`, `update`, or `dummy`) message broadcast by p_i before the `strong-read` message of sr_i. We slightly abuse the notation and denote by $del_j(prev(sr_i))$ the delivery event of $prev(sr_i)$ in p_j.

A read operation $r_i(x, v)$ *reads from a write operation* $w_k(x, v)$ if $w_k(x, v)$ is the last write to x that updates p_i's copy of x before $r_i(x, v)$ reads x. This definition is with respect to the actual execution at p_i, i.e., $\sigma|i$. If $r_i(x, v)$ is strong, then $r_i(x, v)$ is defined to read from x when it copies the value of x into *val*. A read $r_i(x, v)$ is *legal* in a sequence of operations τ if there exists a write $w_k(x, v)$ such that $w_k(x, v) \overset{\tau}{\longrightarrow} r_i(x, v)$ and there does not exist another write $w_l(x, u)$, $u \neq v$, such that $w_k(x, v) \overset{\tau}{\longrightarrow} w_l(x, u) \overset{\tau}{\longrightarrow} r_i(x, v)$; otherwise, the read is *illegal* in τ.

Given a read operation $r_i(x, v)$ that reads from a write $w_k(x, v)$ and a sequence of operations τ, a write $w_l(x, u)$ is an *obliterating write* for $r_i(x, v)$ in τ if $w_k(x, v) \overset{\tau}{\longrightarrow} w_l(x, u)$. Note that in order to define w_k, we need to start with r_i that read from it (in $\sigma|i$).

A *conditional execution interval* of a weak write w_k is the interval of events in σ between the invocation of w_k and the delivery of the `update` message of w_k by the atomic broadcast at p_k. A weak write $w_k(x, v)$ is *overwritten* by another (weak or strong) write $w_j(x, u)$ if $w_j(x, u)$ is performed in p_k during the conditional execution interval of $w_k(x, v)$. A *potential execution interval* of a weak write $w_k(x, v)$ is the largest interval inside the conditional execution interval of w_k, starting with the invocation of $w_k(x, v)$, in which no other write $w_j(x, u)$, $j \neq k$, is performed by p_k. Note that a weak write updates the local copy of the object and returns immediately. The potential execution interval is the interval after a weak write updates the local copy of the object, but may still be overwritten. For example, let $w_k(x, v)$ be a weak write that is overwritten by another write $w_i(x, u)$. If we denote the invocation event of $w_k(x, v)$ by $inv(w_k(x, v))$, we get

$$\overbrace{\underbrace{inv(w_k(x,v)) \ldots del_k(w_i(x,u))}_{\text{potential execution interval}} \ldots del_k(w_k(x,v))}^{\text{conditional execution interval}} .$$

Define the notion of *influence* as follows. A weak write $w_k(x, v)$ *influences* process p_j, $j \neq k$, if it updates the copy of x in p_j (in line 7 of the code for handling `update` messages). A weak write $w_k(x, v)$ *influences* process p_k if it is not overwritten. In particular, not every weak write influences its invoking process. A strong write *influences* every process. Intuitively, a weak write influences its invoking process if it is not overwritten, and influences another process if it is performed by that process. Strong writes are never overwritten and are performed by every process.

Next, define the notion of an operation being *executed* by a process as follows.

- A strong operation sop_k is executed by p_j when the corresponding `strong-write` or `strong-read` message is delivered at p_j.
- A weak operation op_j is executed by p_j when the appropriate call event occurs.
- A weak write w_k that influences p_j, $k \neq j$, is executed by p_j when the corresponding `update` message is delivered at p_j.

Let *abcast order* be the order in which all messages sent with **abcast** are delivered; note that this order is well defined.

We now turn to the details of the proof; for the rest of this section, fix some execution σ of the algorithm.

5.2.1. Creating the initial sequences. For each process p_j, create the sequence of operations and delivery events τ'_j as follows: order all delivery events in p_j according to the order in which they occur in p_j. Next, add all weak operations by p_j according to their order of invocation in p_j (with respect to themselves and to the delivery events in p_j). Next, add all weak writes that are invoked by other processes and are executed by p_j and all strong writes (including the strong writes of p_j) immediately before the delivery of their corresponding `strong-write` or `update` message. Finally, add every weak write w_k that is not executed by p_j immediately before the last write to the same location that is executed in p_j before receiving w'_k's `update` message, breaking ties arbitrarily. Note that if w_k is not executed, then the code of the algorithm guarantees the existence of this write. Note also that all delivery events are ordered in the same order in all sequences τ'_j. That is, for every two operations op^1_k and op^2_l,

$$del_j(op^1_k) \xrightarrow{\tau'_j} del_j(op^2_l) \quad \text{if and only if } del_i(op^1_k) \xrightarrow{\tau'_i} del_i(op^2_l)$$

for every i and j.

The following lemmas show that $\{\tau'_j\}_{j=1}^n$ obey all requirements in the definition of hybrid consistency, except for not including all operations, as follows.

- Legality is shown in Lemma 5.3.
- Condition 1 is not relevant at this point.
- Condition 2 is shown by Lemma 5.5.
- Condition 3 is shown by Lemma 5.1.
- Condition 4 is shown by Lemma 5.2.

Lemma 5.4 concerns a write influencing processes and is used in the proof of Lemma 5.5.

LEMMA 5.1. *There exists a linearization ρ of all the operations in σ such that for every pair of strong operations sop_k and sop_l in τ'_j,*

$$sop_k \xrightarrow{\rho} sop_l \quad \textit{if and only if } sop_k \xrightarrow{\tau'_j} sop_l$$

for every τ'_j.

Proof. The strong operations appear in every τ'_j in an order which is consistent with the abcast order. Since a strong operation does not return before all its `ack` messages return, the real time of its delivery is always between the real time of its invocation and the real time of its termination. Thus, the order in which all strong operations appear in every τ'_j is a linearization. □

LEMMA 5.2. *For every sequence τ'_j, $\tau'_j|j = \sigma'|j$, where σ' is σ without the strong reads.*

Proof. Atomic broadcast delivers all messages sent by the same process in the order in which they were sent. Also, strong operations do not return until all `ack` messages are delivered. Since weak operations are ordered according to their invocation and strong operations are ordered according to their delivery, it follows that $\tau'_j|j = \sigma|j \setminus \{\text{strong reads}\}$ for every sequence τ'_j. □

Note that in each τ'_j, each (local weak) read $r_j(x, v)$ is ordered after the last write to x that is executed by p_j before the invocation of $r_j(x, v)$, with no other write to x in between them. Thus, we have the following lemma.

LEMMA 5.3. *For every sequence τ'_j, all the weak reads of p_j are legal in τ'_j.*

The following lemma is crucial in the rest of the proof.

LEMMA 5.4. *If a write influences some process, then it influences every process.*

Proof. Recall that all messages are delivered to every process in the abcast order. Furthermore, the variable *received* is incremented each time a message that was sent using **abcast** is delivered by the atomic broadcast. Since the atomic broadcast mechanism provides total ordering on the delivery of messages sent with **abcast**, for every weak write, the value of *received* is the same when the corresponding `update` message is delivered in every process. Moreover, this value is different for different weak writes.

Assume, by way of contradiction, that there exists some write that influences some process but not all processes. Let $w_k(x, v)$ be the first such write, i.e., the one for which the value of *received* during the delivery event of its `update` message is minimum. Assume that $w_k(x, v)$ does not influence p_j. Thus, $w_k(x, v)$ is not executed by p_j. The code of the algorithm for executing weak writes implies that there exists another write $w_l(x, u)$ for which the following holds: (a) $w_l(x, u)$ influences p_j, (b) the `update` message of $w_l(x, u)$ is delivered in p_j before the `update` message of $w_k(x, v)$, and (c) the `update` message of $w_l(x, u)$ is delivered in p_k after $w_k(x, v)$ is invoked. (This is the condition which is checked whenever an `update` message is delivered.) Since $w_k(x, v)$ is the first write that influences only some of the processes, $w_l(x, u)$ influences p_k and therefore $w_k(x, v)$ is overwritten.

Atomic broadcast delivers all messages to all processes in the same order. Since $w_k(x, v)$ is the first write that influences only some of the processes, $w_l(x, u)$ influences all processes and its `update` or `strong-write` message is delivered before the `update` message of $w_k(x, v)$ to all processes. Thus, by the assumptions about $w_l(x, u)$, none of the processes executes $w_k(x, v)$. Hence, $w_k(x, v)$ does not influence any process. This is a contradiction to the assumption that $w_k(x, v)$ influences some process. □

LEMMA 5.5. *For each sequence of operations τ'_j and every pair of operations op_k^1 and op_k^2 in τ'_j such that either op_k^1 or op_k^2 is strong,*

$$op_k^1 \xrightarrow{\tau'_j} op_k^2 \quad \textit{if and only if } op_k^1 \xrightarrow{\sigma} op_k^2.$$

Proof. By Lemma 5.2, the claim holds if $k = j$. Thus, for the rest of the proof, we may assume that $k \neq j$.

Assume, by way of contradiction, that for some sequence τ'_j and two operations op_k^1 and op_k^2 such that either op_k^1 or op_k^2 is strong,

$$op_k^1 \xrightarrow{\tau'_j} op_k^2 \quad \text{but } op_k^2 \xrightarrow{\sigma} op_k^1.$$

We claim that op_k^1 is a weak write that does not influence p_j and op_k^2 is strong. Strong operations and weak writes that influence p_j are executed according to the abcast order. This order is consistent with the order by which operations are invoked at each process. Therefore, the only operations that may not be ordered correctly in τ'_j with respect to the previous and next strong operations by the same process are weak writes that do not influence p_j. Moreover, since strong operations are ordered immediately before their corresponding delivery events, and since weak writes are always ordered before their corresponding delivery event, a weak write that does not influence p_j may not be ordered after a later strong operation by the same process.

Assume, without loss of generality, that op_k^1 writes to x. Let w_i be the first write to x that influences p_j and is ordered after op_k^1 in τ_j'. The existence of such a write is guaranteed by the assumption that op_k^1 does not influence p_j and the construction of τ_j'; w_i is the write that caused op_k^1 to be ordered before op_k^2. Note that if w_i did not exist, op_k^1 would have been executed and would have been ordered where its delivery event is ordered, and therefore also after op_k^2. Since op_k^1 is inserted before op_k^2 in τ_j due to w_i, and since by construction, w_i is ordered next to its delivery event, it follows that w_i is delivered in p_j before op_k^2.

If $i \neq j$, or if $i = j$ and op_k^2 is delivered after the completion of the conditional execution interval of w_i in p_j, then by Lemma 5.4, w_i influences every process. Thus, w_i is delivered in every process before op_k^2. In particular, w_i is delivered in p_k before op_k^2. Since op_k^2 is a strong operation and since op_k^1 is invoked after op_k^2, w_i is delivered in p_k before op_k^1 starts. Since op_k^1 is inserted before its delivery event, there exists another write $w_l(x, w)$ that influences p_j and is delivered in p_j between w_i and op_k^1. Thus, $w_l(x, w)$ is ordered in τ_j' between w_i and op_k^1. This contradicts the assumption that w_i is the first write to x that influences p_j and is ordered after op_k^1 in τ_j'.

If $i = j$ and op_k^2 is delivered inside the conditional execution interval of w_i, then the `ack` message of op_k^2 is delivered in p_k after the `update` message of w_i. By Lemma 5.4, w_i influences p_k and is delivered in p_k before op_k^1 starts. Therefore, there exists another write $w_l(x, v)$ that influences p_j and is delivered in p_j between w_i and op_k^1. Thus, $w_l(x, w)$ is ordered in τ_j' between w_i and op_k^1. This contradicts the assumption that w_i is the first write to x that influences p_j and is ordered after op_k^1 in τ_j'. □

Thus, we have shown that the sequences $\{\tau_j'\}_{j=1}^n$ obey all the requirements in the definition of hybrid consistency; however, it does not include all the operations of $ops(\sigma)$ and includes delivery events. To finish the proof, we must insert the missing operations, i.e., the missing reads, to each τ_j' without violating the requirements of the definition of hybrid consistency.

5.2.2. Inserting the strong reads. We start with the strong reads. For each j, create τ_j'' by inserting the strong reads into τ_j' according to the abcast order of their `strong-read` messages. Unlike strong writes, sometimes it is not possible to insert a strong read immediately before its corresponding delivery event and still be legal. This is because the `strong-read` message can be delivered at another process inside a potential execution interval of a weak write to the same object. If this happens, then the last value written to the object is the value written by the local weak write, and not the value returned by the strong read. Therefore, in order to maintain the legality of the sequence, the strong read has to be inserted before the weak write. However, since hybrid consistency requires that all views of all processes agree on the order of strong operations, if a strong read $sr_i(x, v)$ is inserted in one sequence before another strong operation sop_k, then $sr_i(x, v)$ must be inserted before sop_k in every sequence τ_j''. On the other hand, if sop_k is a strong read that is inserted long before its corresponding `strong-read` message, then inserting $sr_i(x, v)$ before sop_k could cause $sr_i(x, v)$ to be ordered before a previous weak operation by p_i. In order to prevent such chain reactions, it is sometimes required to drag a previously inserted strong read $sr_k(y, u)$ before $sr_i(x, v)$ instead of inserting $sr_i(x, v)$ before $sr_k(y, u)$. For example, if we have

$$\tau_j'' = \ldots w_j(x, u) \ldots sop_q \ldots sr_k(y, u) \ldots del_j(sr_i(x, v)) \ldots del_j(w_j(x, u)) \text{ and}$$

$$\tau_l'' = \ldots sop_q \ldots sr_k(y, u) \ldots del_l(sr_i(x, v)),$$

then $sr_i(x,v)$ must be inserted before $w_j(x,u)$ and sop_q in τ_j''. Moreover, $sr_i(x,v)$ must be inserted before sop_q in τ_l'', too. In addition, if $sr_k(y,u)$ is a strong read that is dragged by the insertion of $sr_i(x,v)$, then $sr_k(y,u)$ must be ordered before $sr_i(x,v)$ and sop_q in both τ_j'' and τ_l''.

To insert the strong reads, we introduce some definitions. For each strong read $sr_i(x,v)$, and for each process p_j, if the `strong-read` message of $sr_i(x,v)$ is delivered inside a potential execution interval of some weak write $w_j(x,u)$, then let $I_j(w_j(x,u), sr_i(x,v))$ be the set of strong operations already ordered in τ_j' between the invocation of $w_j(x,u)$ and the delivery of the `strong-read` message of $sr_i(x,v)$. Let $B_j(w_j(x,u), sr_i(x,v))$ be the set of strong reads $\{sr_q\}$ such that $sr_q \in I_j(w_j(x,u), sr_i(x,v))$ and the write sr_q reads from is included in the potential execution interval of $w_j(x,u)$. Let $I_j(sr_i(x,v))$ be the union of $I_j(w_j(x,u), sr_i(x,v))$ over all such $w_j(x,u)$; let $B_j(sr_i(x,v))$ be the union of $B_j(w_j(x,u), sr_i(x,v))$, over all such $w_j(x,u)$. Let $B(sr_i(x,v)) = \cup_{j=1}^{n} B_j(sr_i(x,v))$ and $I(sr_i(x,v)) = \cup_{j=1}^{n} I_j(sr_i(x,v))$, and let $C(sr_i(x,v))$ be the set of strong reads in $I(sr_i(x,v)) \setminus B(sr_i(x,v))$ and $D(sr_i(x,v)) = I(sr_i(x,v)) \setminus C(sr_i(x,v))$.

Intuitively, $I(sr_i(x,v))$ is the set of strong operations that $sr_i(x,v)$ might be inserted before, although $del_j(sr_i(x,v))$ is ordered after them in some sequence τ_j'. $D(sr_i(x,v))$ is the set of strong operations that $sr_i(x,v)$ is actually inserted before, although $del_j(sr_i(x,v))$ is ordered after them in some sequence τ_j'. $C(sr_i(x,v))$ is the set of strong reads that might be dragged by $sr_i(x,v)$, while $B(sr_i(x,v))$ is the set of strong reads that appear in $I(sr_i(x,v))$ and are not dragged by $sr_i(x,v)$. $B(sr_i(x,v))$ is merely used to define $C(sr_i(x,v))$. For example, if we have

$$\tau_j'' = \ldots w_j(x,v), sw_q, sr_k(y,u), w_g(z,w), sr_l(z,w), del_j(sr_i(x,u)), del_j(w_j(x,v)), \ldots$$

and this is the only potential execution interval of a weak write to x that includes the delivery event of $sr_i(x,u)$, then $I(sr_i(x,u)) = \{sw_q, sr_k(y,u), sr_l(z,w)\}$, $B(sr_i(x,u)) = \{sr_l(z,w)\}$, $C(sr_i(x,u)) = \{sr_k(y,u)\}$, and $D(sr_i(x,u)) = \{sw_q, sr_l(z,w)\}$.

Add $sr_i(x,v)$ to each τ_j' in the last possible place such that it will be ordered before every strong operation in $D(sr_i(x,v))$, before the delivery event of its `strong-read` message and before any obliterating write operation. For every strong read sr_q in $C(sr_i(x,v))$, if $sr_i(x,v)$ is ordered before sr_q in τ_j', then reorder sr_q immediately before $sr_i(x,v)$ in τ_j'. In this case, we say that sr_q is *dragged* by $sr_i(x,v)$ in τ_j'. If there is more than one strong read that is dragged by $sr_i(x,v)$, then break ties according to the abcast order of their corresponding `strong-read` messages.

The following lemmas show that $\{\tau_j''\}_{j=1}^{n}$ obey all requirements in the definition of hybrid consistency, except for not including all operations, as follows.

- Legality follows from legality of $\{\tau_j'\}_{j=1}^{n}$ and Lemma 5.7.
- Condition 1 is not relevant at this point.
- Condition 2 follows from the fact that $\{\tau_j'\}_{j=1}^{n}$ obeys it and Lemma 5.11.
- Condition 3 follows from the fact that $\{\tau_j'\}_{j=1}^{n}$ obeys it and Lemma 5.9.
- Condition 4 follows from the fact that $\{\tau_j'\}_{j=1}^{n}$ obeys it and Lemma 5.10.

Lemma 5.6 gives more technical information concerning the influence of a write and is used in some of the lemmas' proofs. Lemma 5.8 is another technical lemma.

LEMMA 5.6. *A strong read reads from a write that influences every process.*

Proof. Let sr_i be a strong read that reads from some write w_k. If w_k is strong, then by definition, w_k influences every process. So, assume that w_k is weak. If $k = i$, then since sr_i is a strong operation, it is not executed until the conditional execution interval of w_k is completed. Therefore, w_k is not overwritten, and by Lemma 5.4,

w_k influences every process. If $k \neq i$, then w_k influences p_i, and by Lemma 5.4, w_k influences every process. □

LEMMA 5.7. *Every strong read is legal in every sequence* τ_j''.

Proof. We prove that every strong read is ordered in every sequence τ_j'' after the write it reads from. Since, by definition, every strong read appears in every sequence τ_j'' before any obliterating write operation, this will imply that the strong read is legal.

Assume, by way of contradiction, that there exists a strong read that is ordered in some sequence τ_j'' before the write it reads from. Let $sr_i(x,v)$ be the first strong read such that, following the insertion of $sr_i(x,v)$, there exists a strong read which is ordered in some sequence τ_j'' before the write it reads from. Thus, either $sr_i(x,v)$ is ordered in τ_j'' before the write it reads from or there exists another strong read $sr_s(y,w)$, which is dragged in τ_j'' before the write it reads from.

Assume that $sr_i(x,v)$ is ordered in τ_j'' before the write it reads from, and denote this write by $w_k(x,v)$. In particular, $sr_i(x,v)$ is ordered before $del_j(w_k(x,v))$ in τ_j''. Thus, $del_l(sr_i(x,v))$ is ordered in some sequence τ_l'' inside a potential execution interval of some weak write $w_l(x,u)$ that includes a strong operation sop_q which is ordered in τ_j'' before $del_j(w_k(x,v))$. (If there is no such sop_q, then there is no reason to order $sr_i(x,v)$ in τ_j'' before the write it reads from.) By the assumption that $sr_i(x,v)$ reads from $w_k(x,v)$ and by Lemma 5.6, $w_k(x,v)$ influences every process. Therefore, $del_l(w_k(x,v))$ is ordered in τ_l'' before the potential execution interval of $w_l(x,u)$. Since we assumed that sop_q is ordered in τ_j'' before $del_j(w_k(x,v))$, and since $del_j(sop_q)$ is ordered after $del_j(w_k(x,v))$, it follows that sop_q is a strong read and the write sop_q reads from is ordered inside the potential execution interval of $w_l(x,u)$. Denote the write sop_q reads from by w_m. By Lemma 5.6, both w_m and $w_k(x,v)$ influence every process, and therefore both w_m and $w_k(x,v)$ are ordered immediately before their delivery events. Thus, w_m is ordered after $w_k(x,v)$ in τ_j''. By the minimality of $sr_i(x,v)$, sop_q is ordered after w_m in τ_j'', and therefore after $w_k(x,v)$. This is a contradiction.

Assume that $sr_s(y,w)$ is dragged by $sr_i(x,v)$ before the write it reads from, and denote this write by $w_k(y,w)$. In particular, $sr_s(y,w)$ is dragged by $sr_i(x,v)$ before $del_j(sr_s(y,w))$ in τ_j''. By the minimality of $sr_i(x,v)$, $sr_s(y,w)$ is ordered after $w_k(y,w)$ in every sequence τ_p'' before the insertion of $sr_i(x,v)$. Thus, $del_l(sr_i(x,v))$ and $del_l(sr_s(y,w))$ are ordered inside a potential execution interval of some weak write $w_l(x,u)$ that includes a strong operation sop_q which is ordered in τ_j'' before $del_j(w_k(y,w))$. Since we assumed that sop_q is ordered in τ_j'' before $del_j(w_k(y,w))$, and since $del_j(sop_q)$ is ordered after $del_j(w_k(y,w))$, it follows that sop_q is a strong read and the write sop_q reads from is ordered inside the potential execution interval of $w_l(x,u)$. Denote the write sop_q reads from by w_m. By Lemma 5.6, both w_m and $w_k(x,v)$ influence every process, and therefore both w_m and $w_k(x,v)$ are ordered immediately before their delivery events. Thus, w_m is ordered after $w_k(x,v)$ in τ_j''. By the minimality of $sr_i(x,v)$, sop_q is ordered after w_m in τ_j'', and therefore after $w_k(y,w)$. This is a contradiction. □

LEMMA 5.8. *Every strong read* $sr_i(x,v)$ *is ordered after* $del_j(prev(sr_i(x,v)))$ *in every sequence* τ_j''.

Proof. Assume, by way of contradiction, that there exists a strong read $sr_i(x,v)$ that is ordered in some sequence τ_j'' before $del_j(prev(sr_i(x,v)))$. Assume, without loss of generality, that $sr_i(x,v)$ is the first strong read such that following the insertion of $sr_i(x,v)$, there exists a strong read $sr_s(y,w)$ which is ordered in some sequence τ_j'' before $del_j(prev(sr_s(y,w)))$. Thus, either $sr_i(x,v)$ is ordered in τ_j'' before

$del_j(prev(sr_i(x,v)))$ or there exists another strong read $sr_s(y,w)$ which is dragged in τ_j'' before $del_j(prev(sr_s(y,w)))$.

Assume that $sr_i(x,v)$ is ordered in τ_j'' before $del_j(prev(sr_i(x,v)))$. Thus, there exists a sequence τ_l'' for which $del_l(sr_i(x,v))$ is ordered in τ_l'' inside a potential execution interval of some weak write $w_l(x,u)$ that includes a strong operation sop_q which is ordered in τ_j'' before $del_j(prev(sr_i(x,v)))$. Since $sr_i(x,v)$ does not return until all `ack` messages of $prev(sr_i(x,v))$ are delivered, $del_l(prev(sr_i(x,v)))$ is ordered in τ_l'' before the potential execution interval of $w_l(x,u)$. Since sop_q is ordered before $del_j(prev(sr_i(x,v)))$ in τ_j'' and after $del_l(prev(sr_i(x,v)))$ in τ_l'', then sop_q is a strong read and the write sop_q reads from is ordered inside the potential execution interval of $w_l(x,u)$. Denote the write sop_q reads from by w_m. By Lemma 5.6, w_m influences every process and is therefore ordered in τ_j'' immediately before $del_j(w_m)$. Thus, w_m is ordered after $del_j(prev(sr_i(x,v)))$ in τ_j''. By Lemma 5.7, sop_q is ordered after w_m in τ_j'', and therefore after $del_j(prev(sr_i(x,v)))$. This is a contradiction.

Assume that $sr_s(y,w)$ is dragged by $sr_i(x,v)$ before $del_j(prev(sr_s(y,w)))$ in τ_j''. By the minimality of $sr_i(x,v)$, $sr_s(y,w)$ is ordered after $del_p(prev(sr_s(y,w)))$ in every sequence τ_p'' before the insertion of $sr_i(x,v)$. Thus, there exists a sequence τ_l'' for which $del_l(sr_i(x,v))$ and $del_l(sr_s(y,w))$ are ordered inside a potential execution interval of some weak write $w_l(x,u)$ that includes a strong operation sop_q which is ordered in τ_j'' before $del_j(prev(sr_s(y,w)))$. Since sop_q is ordered before $del_j(prev(sr_s(y,w)))$ in τ_j'' and after $del_l(prev(sr_s(y,w)))$ in τ_l'', it follows that sop_q is a strong read and the write sop_q reads from is ordered inside the potential execution interval of $w_l(x,u)$. Denote the write sop_q reads from by w_m. By Lemma 5.6, w_m influences every process, and therefore is ordered in τ_j'' immediately before $del_j(w_m)$. Thus, w_m is ordered after $del_j(prev(sr_s(y,w)))$ in τ_j''. By Lemma 5.7, sop_q is ordered after w_m in τ_j'', and therefore after $del_j(prev(sr_s(y,w)))$. This is a contradiction. □

LEMMA 5.9. *There exists a linearization ρ of all the operations in σ such that for every pair of strong operations sop_k and sop_l,*

$$sop_k \xrightarrow{\rho} sop_l \quad \textit{if and only if } sop_k \xrightarrow{\tau_j''} sop_l \textit{ for every } \tau_j''.$$

Proof. We have to show that all the strong operations are ordered in all the sequences τ_j'' in the same order, and that this order is a linearization of the strong operations in $ops(\sigma)$.

We first show that all strong operations appear in the same order in all sequences τ_j''. Assume, by way of contradiction, that there exist two strong operations sop_k and sop_i and two sequences τ_j'' and τ_l'' such that

$$sop_k \xrightarrow{\tau_j''} sop_i \quad \text{but } sop_i \xrightarrow{\tau_l''} sop_k.$$

By Lemma 5.1 and since strong writes are not dragged by strong reads, this can only happen if at least one of sop_k or sop_i is a strong read.

If both sop_k and sop_i are strong reads, then let $sop_i = sr_i(x,v)$ and $sop_k = sr_k(y,w)$. Assume, without loss of generality, that $sr_i(x,v)$ appears before $sr_k(y,w)$ in the order of insertion for strong reads. Thus, the `strong-read` message of $sr_k(y,w)$ is delivered after the `strong-read` message of $sr_i(x,v)$. Since

$$sr_k(y,w) \xrightarrow{\tau_j''} sr_i(x,v),$$

then either $sr_i(x,v) \in D(sr_k(y,w))$ or $sr_k(y,w)$ is dragged by another strong read before sr_i. In either case, $sr_k(y,w)$ is ordered before $sr_i(x,v)$ in every sequence τ_l''. This is a contradiction.

Otherwise, without loss of generality, sop_i is a strong read and sop_k is a strong write. Let $sop_i = sr_i(x,v)$. If the `strong-read` message of $sr_i(x,v)$ is delivered before the `strong-write` message of sop_k, then $sr_i(x,v)$ is ordered before sop_k in every sequence τ_j''. Therefore, the `strong-read` of $sr_i(x,v)$ is delivered after the `strong-write` message of sop_k. Since $sr_i(x,v)$ is ordered before sop_k in τ_j'', then either $sop_k \in D(sr_i(x,v))$ or $sr_i(x,v)$ is dragged by another strong read before sop_k. In any case, $sr_i(x,v)$ is ordered before sop_k in every sequence τ_l''. This is a contradiction.

We now show that the order in which strong operations appear in τ_j'' preserves the order implied by ρ. Assume, by way of contradiction, that the order in which all strong operations appear in every sequence τ_j'' is not a linearization. Note that strong reads are always inserted before their corresponding delivery event. By Lemma 5.1 and since strong writes are not dragged by strong reads, the total order is not a linearization only if there exist a strong read $sr_i(x,v)$ and another strong operation sop_k such that sop_k terminates before $sr_i(x,v)$ begins, but

$$sr_i(x,v) \xrightarrow{\tau_j''} sop_k$$

for every sequence τ_j''. Since, by definition,

$$sop_k \xrightarrow{\tau_j''} del_j(sop_k)$$

for every sequence τ_j'', this can only happen in one of two cases.

Case 1. The delivery event of the `strong-read` message of $sr_i(x,v)$ is ordered inside the potential execution interval of some $w_l(x,v)$, and sop_k is also ordered inside the same potential execution interval. Then the `ack` message for sop_k is delivered in p_k after the `update` message of $w_l(x,u)$, while the `strong-read` message of $sr_i(x,v)$ is delivered in all processes before the `update` message of $w_l(x,u)$. Hence, the `strong-read` message of $sr_i(x,v)$ is delivered in p_k before sop_k terminates. This contradicts the assumption that sop_k terminates before $sr_i(x,v)$ begins.

Case 2. $sr_i(x,v)$ is dragged by some other strong read $sr_q(y,w)$ before sop_k. Thus, the `strong-read` message of $sr_q(y,w)$ is delivered inside the potential execution interval of some weak write $w_l(y,z)$ that includes both $del_l(sop_k)$ and $del_l(sr_i(x,v))$. Therefore, the `ack` message for sop_k is delivered in p_k after the `update` message of $w_l(y,z)$, while the `strong-read` message of $sr_i(x,v)$ is delivered in all processes before the `update` message of $w_l(y,z)$. Hence, the `strong-read` message of $sr_i(x,v)$ is delivered in p_k before sop_k terminates. This contradicts the assumption that sop_k terminates before $sr_i(x,v)$ begins. □

LEMMA 5.10. *For every sequence* τ_j'', $\tau_j''|j = \sigma|j$.

Proof. Consider any two operations op_j^1 and op_j^2 such that $op_j^1 \xrightarrow{\sigma} op_j^2$. We show that

$$op_j^1 \xrightarrow{\tau_j} op_j^2$$

by a simple case analysis. If neither op_j^1 nor op_j^2 is a strong read, then the claim holds by Lemma 5.2 and the fact that the insertion of strong reads does not change the order of other operations. If both op_j^1 and op_j^2 are strong reads, then the claim holds

by Lemma 5.9. If only op_j^1 is a strong read, then the claim holds because strong reads are inserted before their corresponding delivery event. If, on the other hand, only op_j^2 is a strong read, then by Lemma 5.8,

$$del_j(prev(op_j^2)) \xrightarrow{\tau_j''} op_j^2.$$

By construction of τ_j'',

$$op_j^1 \xrightarrow{\tau_j''} del_j(prev(op_j^2)).$$

Thus,

$$op_j^1 \xrightarrow{\tau_j''} op_j^2$$

and the claim holds. (Note that we have covered all the cases, since we still do not have weak reads by other processes.) □

LEMMA 5.11. *For each sequence of operations τ_j'' and every pair of operations op_k^1 and op_k^2 in τ_j'' such that either op_k^1 or op_k^2 is strong,*

$$op_k^1 \xrightarrow{\tau_j''} op_k^2 \quad \textit{if and only if } op_k^1 \xrightarrow{\sigma} op_k^2.$$

Proof. By Lemma 5.10, the claim holds for $k = j$. Thus, we assume for the rest of the proof that $k \neq j$. Assume, by way of contradiction, that for some sequence τ_j'' and two operations op_k^1 and op_k^2 such that either op_k^1 or op_k^2 is strong,

$$op_k^1 \xrightarrow{\tau_j''} op_k^2 \quad \text{but } op_k^2 \xrightarrow{\sigma} op_k^1.$$

By Lemmas 5.5 and 5.9 and the construction of τ_j'', this can only happen in one of the following cases.

Case 1. op_k^1 is a strong read and op_k^2 is a weak write. By the construction of τ_j'', op_k^2 is ordered before $del_j(op_k^2)$. In particular, op_k^2 is ordered in τ_j'' before $del_j(prev(op_k^1))$. By Lemma 5.8, op_k^1 is ordered in τ_j'' after $del_j(prev(op_k^1))$. Thus,

$$op_k^2 \xrightarrow{\tau_j''} op_k^1.$$

This is a contradiction.

Case 2. op_k^2 is a strong read and op_k^1 is a weak write that does not influence p_j. By definition, op_k^2 is ordered before $del_p(op_k^2)$ in every sequence τ_p''. Assume, without loss of generality, that op_k^1 writes to x, and let $w_l(x, w)$ be the last write that influences p_j before the delivery of the `update` message of op_k^1. Thus, op_k^1 is invoked before the delivery of the `update` or `strong-write` message of $w_l(x, w)$ in p_k. Moreover, op_k^1 is ordered in τ_j'' before op_k^2 because $w_l(x, v)$ is ordered in τ_j'' before op_k^2. Since op_k^2 does not return before all of its `ack` messages are delivered, and since every `ack` message is sent using **asend**, the `ack` message for op_k^2 is delivered in p_k after the `update` or `strong-write` message of $w_l(x, w)$. Thus, op_k^1 is invoked after the delivery of the `update` or `strong-write` message of $w_l(x, w)$. This is a contradiction. □

5.2.3. Inserting weak reads. We now insert the weak reads. A sequence τ_j''' is constructed from each sequence τ_j'', by inserting into τ_j'' all the weak reads that are invoked by other processes than p_j, one after the other as follows: every weak read $r_k(x,v)$, $k \neq j$, is inserted in the first possible place such that it will be ordered after the previous strong operation by p_k (if there is one) and after the write it reads from (if there is one). Note that this is well defined: if there is no previous strong operation and the weak read returns the initial value of the object, then the weak read is inserted at the beginning of the sequence.

The following lemmas show that $\{\tau_j'''\}_{j=1}^n$ obey all requirements in the definition of hybrid consistency, except for including delivery events, as follows.

- Legality follows from legality of $\{\tau_j''\}_{j=1}^n$ and Lemma 5.13.
- Condition 1 follows from the construction.
- Condition 2 follows from the fact that $\{\tau_j''\}_{j=1}^n$ obeys it and Lemma 5.12.
- Condition 3 follows from the fact that $\{\tau_j''\}_{j=1}^n$ obeys it and that adding weak reads does not affect it.
- Condition 4 follows from the fact that $\{\tau_j''\}_{j=1}^n$ obeys it and that adding weak reads does not affect it.

LEMMA 5.12. *For each sequence of operations τ_j''' and every pair of operations op_k^1 and op_k^2 such that either op_k^1 or op_k^2 is strong,*

$$op_k^1 \xrightarrow{\tau_j'''} op_k^2 \quad \textit{if and only if } op_k^1 \xrightarrow{\sigma} op_k^2.$$

Proof. Assume, by way of contradiction, that there exist a sequence τ_j''' and two operations op_k^1 and op_k^2 such that either op_k^1 or op_k^2 is strong,

$$op_k^1 \xrightarrow{\tau_j'''} op_k^2 \quad \text{but } op_k^2 \xrightarrow{\sigma} op_k^1.$$

By Lemma 5.10, the claim of the lemma holds if $k = j$. By Lemma 5.11 and since the insertion of weak reads does not change the order of other operations in τ_j''', the claim of the lemma holds if neither op_k^1 nor op_k^2 is a weak read. Moreover, since weak reads are inserted after the previous strong operation by the same process, the only case in which op_k^1 may be ordered in τ_j''' before op_k^2 is when op_k^2 is a weak read, op_k^1 is a strong operation, $k \neq j$, and the write op_k^2 reads from is ordered after op_k^1 in τ_j'''.

Assume, without loss of generality, that op_k^2 reads from $w_l(x,v)$. Lemma 5.11 and the assumption that op_k^2 reads from $w_l(x,v)$ imply that $l \neq k$. Thus, $w_l(x,v)$ influences every process and is therefore ordered in τ_j''' immediately before $del_j(w_l(x,v))$. If op_k^1 is a strong write, then it is ordered in τ_j''' immediately before $del_j(op_k^1)$. Thus,

$$del_j(op_k^1) \xrightarrow{\tau_j'''} w_l(x,v) \xrightarrow{\tau_j'''} del_j(w_l(x,v)).$$

If, on the other hand, op_k^1 is a strong read, then by Lemma 5.8, op_k^1 is ordered in τ_j''' after $del_j(prev(op_k^1))$. Thus,

$$del_j(prev(op_k^1)) \xrightarrow{\tau_j'''} w_l(x,v) \xrightarrow{\tau_j'''} del_j(w_l(x,v)).$$

In either case, by the use of atomic broadcast, the `update` or `strong-write` message of $w_l(x,v)$ is delivered in p_k after op_k^2 is executed. This contradicts the assumption that op_k^2 reads from $w_l(x,v)$. ∎

LEMMA 5.13. *Every read is legal in every sequence* τ_j'''.

Proof. By Lemma 5.7, all strong reads are legal in any of the sequences τ_j'''. Thus, assume, by way of contradiction, that there exist a sequence τ_j''' and a weak read $r_i(x,v)$ such that $r_i(x,v)$ is not legal in τ_j'''. Denote by $w_l(x,v)$ the write $r_i(x,v)$ reads from and by sop_i the next strong operation by p_i. By Lemma 5.3 and since the insertion of (strong or weak) read operations does not change the order of write operations (by any process) or the order of weak reads by p_j, $i \neq j$. Thus, by the rules for inserting weak reads, there exists an obliterating write $w_k(x,u)$ such that

$$w_l(x,v) \xrightarrow{\tau_j'''} w_k(x,u) \xrightarrow{\tau_j'''} sop_i.$$

If $k = j$, then the `update` or `strong-write` message of $w_k(x,u)$ is delivered at p_i after the execution of $w_l(x,v)$ and before the delivery of the `ack` message of sop_i. Thus, either $w_k(x,u)$ or another write to x is executed by p_i between the execution of $w_l(x,v)$ and the invocation of $r_i(x,v)$. This contradicts the assumption that $r_i(x,v)$ reads from $w_l(x,v)$.

Thus, $k \neq j$. We may assume, without loss of generality, that $w_k(x,u)$ influences p_j. Otherwise, there exists another write $w_q(x,w)$ that influences p_j such that

$$w_l(x,v) \xrightarrow{\tau_j'''} w_k(x,u) \xrightarrow{\tau_j'''} w_q(x,w) \xrightarrow{\tau_j'''} sop_i,$$

and we could have chosen $w_q(x,w)$. Thus, $w_k(x,u)$ is ordered in τ_j''' immediately before $del_j(w_k(x,u))$. By Lemma 5.4, $w_k(x,u)$ influences every process. By the construction of τ_j''', sop_i is ordered before $del_j(sop_i)$. Thus, the `update` or `strong-write` message of $w_k(x,u)$ is delivered at p_i after the execution of $w_l(x,v)$ and before the delivery of the `strong-write` or `strong-read` message of sop_i. Thus, $w_k(x,u)$ is executed by p_i between the execution of $w_l(x,v)$ and the invocation of $r_i(x,v)$. This contradicts the assumption that $r_i(x,v)$ reads from $w_l(x,v)$. □

5.2.4. Obtaining the final sequences. Finally, from each process p_j, create a new sequence of operations τ_j by removing all delivery events from τ_j'''.

THEOREM 5.14. *Every execution generated by the algorithm is hybrid.*

Proof. For an execution σ, we have constructed a set of sequences $\{\tau_j\}_{j=1}^n$. We now show why this set satisfies the requirements of the definition of hybrid consistency.

Legality. By Lemma 5.13, every sequence τ_j is legal.

Condition 1. By construction, every sequence τ_j is a permutation of $ops(\sigma)$, which satisfies Condition 1 in the definition of hybrid consistency.

Condition 2. By Lemma 5.12, for every pair of operations op_l^1 and op_l^2 such that either op_l^1 or op_l^2 is strong, $op_l^1 \xrightarrow{\tau_j} op_l^2$ if and only if $op_l^1 \xrightarrow{\sigma} op_l^2$, which satisfies Condition 2 in the definition of hybrid consistency.

Condition 3. By Lemma 5.9, there exists a linearization ρ of all operations in $ops(\sigma)$ such that for every pair of strong operations sop_l and sop_k, $sop_l \xrightarrow{\tau_j} sop_k$ if and only if $sop_l \xrightarrow{\rho} sop_k$, which satisfies Condition 3 in the definition of hybrid consistency.

Condition 4. By Lemma 5.10, for every sequence τ_j, $\tau_j|j = \sigma|j$, which satisfies Condition 4 in the definition of hybrid consistency. □

5.3. Complexity analysis. Since the algorithm uses an atomic broadcast mechanism, the actual time and message complexity depends on the complexity of this

mechanism. We will make the complexity analysis with respect to t_{abc}, the time required to broadcast a message using **abcast**, t_{send}, the time required to send a message using **asend**, n_{abc}, the number of physical messages required to perform **abcast**, and n_{send}, the number of physical messages required to perform **asend**. We ignore the effects of contention on the network in this time analysis.

Weak reads are executed instantaneously from the local copy of the object they access and cause no messages to be sent. Weak writes are also executed instantaneously, but each weak write requires n_{abc} physical messages in order to broadcast its `update` message and $n \cdot n_{send}$ physical messages for the corresponding `ack` messages.

A strong operation must wait for all `ack` messages of previous weak write operations and `dummy` messages, which could take $t_{abc} + t_{send}$ time. Then, it broadcasts its own message and must wait until all `ack` messages are delivered, which could take an additional $t_{abc} + t_{send}$ time. The total time required to execute a strong operation is therefore $2(t_{abc} + t_{send})$.

A strong write operation requires n_{abc} physical messages in order to broadcast its `strong-write` message and $n \cdot n_{send}$ physical messages for the corresponding `ack` messages. The total number of physical messages caused by a strong write operation is therefore $n_{abc} + n \cdot n_{send}$.

A strong read operation requires n_{abc} physical messages in order to broadcast its `dummy` message and $n \cdot n_{send}$ physical messages for the corresponding `ack` messages if the last previous operation was a weak read. Then, an additional n_{abc} physical messages are required to broadcast its `strong-read` message plus $n \cdot n_{send}$ physical messages for the corresponding `ack` messages. The total number of physical messages caused by every strong read operation is therefore $2(n_{abc} + n \cdot n_{send})$.

Much work has been done on atomic broadcast, and several atomic broadcast algorithms have been developed, e.g., [6, 7, 8, 10, 12, 18, 19, 23, 25, 26, 27, 31, 43, 59]. Several of these protocols guarantee that messages are delivered within $2d$ time [10, 18, 26, 43]. Assuming a delivery time of $2d$, the time complexity of strong operations is $8d$, or in other words, linear with the network delay, which matches our goal.

The exact values of n_{abc} and n_{send} highly depend on the specific atomic broadcast mechanism being used and whether it uses hardware multicast or not. If we use a simple sequencer scheme, such as proposed in [10], then n_{abc} is 2 if we assume hardware multicast and n otherwise, while n_{send} is 2 in any case. By using these numbers in the above analysis, we get 0 messages for weak reads, $2 + 2n$ messages for weak or strong writes assuming hardware multicast and $3n$ otherwise, and $4 + 4n$ messages for strong reads assuming hardware multicast and $6n$ otherwise.

5.4. Relaxing the complete copy assumption. As done in other theoretical papers on this topic (e.g., [4, 5, 42]) our implementation assumes that each process maintains a copy of the entire memory. This assumption was made for clarity of presentation, but it can be relaxed as follows. The memory may be split among the processes, such that every memory object is held by at least one process. Whenever a memory operation is invoked at a process p_i, if p_i owns a copy of the object, then the code is executed as in the case where each member has a complete copy of the entire memory. If p_i does not hold a copy of that object, then it behaves in one of the following ways, depending on the type of the operation: if the operation is a weak or strong write, then p_i follows the same code as before, except for not updating the copy that it does not have. If the operation is a weak read, p_i sends a message to the nearest copy of the object using **asend**, inquiring about the value of this object, and returns the answer. Finally, if the operation is a strong read, p_i sends the `strong-read`

message as before, and one of the holders of the object returns the value of this object at the time it received the `strong-read` message. When p_i receives all the replies, it returns this value to the application program.

Note that there is a tradeoff here between memory efficiency and execution latencies: in order to always be able to execute weak reads instantaneously, every process must hold a complete copy of the entire memory; the more copies of each memory object exist, the more likely it is for a weak read to be executed immediately. This tradeoff exists in other consistency conditions as well.

6. Lower bounds for implementing hybrid consistency. It is known [12] that in any (asynchronous) implementation of linearizability, the response time of ("strong") read and write operations is $\Omega(d)$. Thus, our algorithm shows that it is possible to implement hybrid consistency in such a way that weak operations are extremely fast, without sacrificing the response time of strong operations.

Our implementation of hybrid consistency supports Definition 3.1, that is, hybrid consistency where the strong operations are linearizable. In contrast, sequential consistency can be implemented more efficiently than linearizability [12]. This might lead one to think that hybrid consistency where the strong operations are sequentially consistent can be implemented with a better asymptotic response time than our implementation. The following theorems show that this is not the case, at least if weak operations are required to be "fast." These theorems are a variation of a similar theorem which appears in [46]. The lower bounds proved in this section apply to both flavors of hybrid consistency. Recall that $|op|$ denotes the maximum time required to execute an operation of type op.

THEOREM 6.1. *For any implementation of hybrid consistency,* $|read| + |swrite| \geq d$.

Proof. Assume, by way of contradiction, that there is an implementation of hybrid consistency for which $|read| + |swrite| < d$. Let p_1 and p_2 be two processes that access x and y. Without loss of generality, assume that x and y are initially 0.

By the specification of y, there is a hybrid execution σ_1 such that $ops(\sigma_1)$ is

$$[\mathrm{SWrite}_1(x,1),\ \mathrm{SAck}_1(x)],\ [\mathrm{Read}_1(y),\ \mathrm{Return}_1(y,0)],$$

$\mathrm{SWrite}_1(x,1)$ occurs at real time 0, and $\mathrm{Read}_1(y)$ occurs immediately after $\mathrm{SAck}_1(x)$. The delay of all messages in σ_1 is exactly d. By assumption, the real time at the end of σ_1 is less than d. Hence, no message is received at any node during σ_1.

Similarly, by the specification of x, there is some hybrid execution σ_2 such that $ops(\sigma_2)$ is

$$[\mathrm{SWrite}_2(y,1),\ \mathrm{SAck}_2(y)],\ [\mathrm{Read}_2(x),\ \mathrm{Return}_2(x,0)],$$

$\mathrm{SWrite}_2(y,1)$ occurs at real time 0, and $\mathrm{Read}_2(x)$ occurs immediately after $\mathrm{SAck}_2(y)$. The delay of all messages in σ_2 is exactly d. By assumption, the real time at the end of σ_2 is less than d. Hence, no message is received at any node during σ_2.

Since no message is ever received in σ_1 and σ_2, the result of combining p_1's history in σ_1 with p_2's history in σ_2 can be extended to a hybrid execution σ. Then $ops(\sigma)$ consists of the operation $[\mathrm{SWrite}_1(x,1),\ \mathrm{SAck}_1(x)]$ followed by $[\mathrm{Read}_1(y),\ \mathrm{Return}_1(y,0)]$ and $[\mathrm{SWrite}_2(y,1),\ \mathrm{SAck}_2(y)]$ followed by $[\mathrm{Read}_2(x),\ \mathrm{Return}_2(x,0)]$.

Since σ is hybrid, there exists a serialization ρ of $ops(\sigma)$ such that for every $i \in \{1,2\}$, there exists a legal serialization τ_i of $ops(\sigma)$ that preserves: (a) the order of operations at p_i, (b) the order between strong and weak operations at all

processes, and (c) the order between strong operations in ρ (as formalized in Definition 3.2). Without loss of generality, assume that in ρ, [SWrite$_1(x,1)$, SAck$_1(x)$] precedes [SWrite$_2(y,1)$, SAck$_2(y)$].

Consider τ_2. Since τ_2 is legal, each read should precede the strong write to the same variable (by the other process) in τ_2. Thus, in τ_2, [Read$_2(x)$, Return$_2(x,0)$] precedes [SWrite$_1(x,1)$, SAck$_1(x)$], which, in turn, precedes [SWrite$_2(y,1)$, SAck$_2(y)$]. Therefore, in τ_2, [Read$_2(x)$, Return$_2(x,0)$] precedes [SWrite$_2(y,1)$, SAck$_2(y)$], but then $\tau_2 \mid 2 \neq \sigma \mid 2$. This is a contradiction. □

The interested reader can compare this proof with the proof of the similar result in [12, Theorem 3.1] to see the extra care needed when arguing about properties of hybrid executions.

Using the same arguments as in the proof of Theorem 6.1, only reversing the roles of reads and writes, we can prove the following theorem.

THEOREM 6.2. *For any implementation of hybrid consistency,* $|write| + |sread| \geq d$.

We define a *fast write implementation* to be one in which the time required to execute weak write operations is strictly less than $d/2$. Likewise, a *fast read implementation* is an implementation in which the time required to execute weak read operations is strictly less than $d/2$. Note that the implementation given in the previous section is fast—weak operations return instantaneously. We immediately obtain the following corollary.

COROLLARY 6.3. *Let I be a fast read implementation of hybrid consistency. Then* $|swrite| \geq d/2$.

COROLLARY 6.4. *Let I be a fast write implementation of hybrid consistency. Then* $|sread| \geq d/2$.

That is, in any implementation of hybrid consistency in which weak reads are executed faster than the network delay, strong writes must be slower than the network delay, and if weak writes are faster than the network delay, then strong reads must be slower than the network delay. In that sense, the implementation presented in this paper is optimal (up to a constant factor).

7. Discussion and further research. This paper presents a theoretical study of hybrid consistency. This study is motivated by several new processors and multiprocessors that support some sort of weak and strong operations; it is also motivated by recent theoretical results on the cost of supporting global consistency conditions and the inadequacy of weak consistency conditions. We have presented a formal and precise definition of hybrid consistency in two flavors, one based on sequential consistency and the other based on linearizability. We have presented an algorithm for providing hybrid consistency, proved its correctness, and analyzed its performance. We have also shown lower bounds on the response time of any implementation of hybrid consistency that does not delay weak operations (which are within constant factors of the bounds achieved by our algorithm).

Our definition of hybrid consistency (Definition 3.2) assumes that operations of the same process are executed one at a time and in program order. Recently, our definition has been generalized to allow nonsequential executions [9], i.e., executions in which operations may be executed in parallel, in pipeline, and even out of order. The definition in [9] also incorporates a formal treatment of control operations, which is not part of our definition. Naturally, the result is a slightly more complicated definition. We feel that Definition 3.2 is still interesting since it sheds light on hybrid

consistency: how to program with it, what its costs are, and possible algorithms for providing it. Furthermore, to the best of our knowledge, there is no formally verified algorithm for providing hybrid consistency when operations can be issued in parallel, in pipeline, and out of order.

Our work leaves open several theoretical, as well as practical, questions.

We would like to obtain tighter bounds (for time, messages, and congestion) for implementations of hybrid consistency. In this work we assumed that local computations are negligible and that messages can be sent to the network without any limitations. It is important to obtain lower and upper bounds on implementations of hybrid consistency and other consistency conditions in a more realistic model. The Postal [13] or the LogP [28] models might serve as a middle ground between our theoretical assumptions and realistic architectures.

It would be interesting to quantify what the performance benefits of programming with hybrid consistency are. Specifically, are algorithms for solving a specific problem that rely on hybrid consistency faster than algorithms for solving the same problem that rely on other consistency conditions? If so, how much? These questions can be answered either by theoretical or experimental methods.

In this paper, we have made a small step towards developing proof techniques for hybrid consistency by showing how to argue about the correctness of an example program. Subsequent work [9] presents several techniques for transforming programs written for sequentially consistent hardware into correct and efficient programs for hybrid consistent hardware; related results for alpha consistency appear in [11].

Another interesting and important issue is the design of compiler techniques for using hybrid consistency. Such a compiler can, for example, take a program which was written assuming a sequentially consistent or linearizable memory, and decide automatically for each memory access operation whether it should be weak or strong. This should be done without affecting the correctness of the program and while achieving the maximal possible speedup. (Such techniques for sequentially consistent memories that allow pipelining appear in [56].)

The problem of verifying whether a given execution is sequentially consistent was investigated by Gibbons and Korach [36]. They have shown that for most interesting cases, this problem is NP-complete, although under some restrictions it can be solved in polynomial time. It is clear that the problem of verifying whether a given execution is hybrid consistent is at least as hard. However, it is unclear whether verifying hybrid consistency is harder than verifying sequential consistency.

The ultimate goal of our research is to obtain a better understanding of memory consistency conditions, so it would be possible to evaluate several conditions and decide which is best suited for a specific application and architecture. In order to do so, a wide spectrum of properties needs to be considered, such as performance, computation power, and complexity of the possible implementations. It is necessary to formalize these properties and develop criteria for evaluating consistency conditions.

Acknowledgments. Jennifer Welch collaborated with us in the early stages of this research. We are indebted to her for her contributions to the definition of hybrid consistency and for many helpful discussions and comments on several versions of this paper. Thanks also to Sarita Adve, Eran Aharonson, Ken Birman, Kourosh Gharachorloo, Maurice Herlihy, Martha Kosa, Rivka Ladin, Friedemann Mattern, Lihu Rappoport, and Tali Shintel for helpful remarks.

EFFICIENT ALGORITHMS FOR THE DOMINATION PROBLEMS ON INTERVAL AND CIRCULAR-ARC GRAPHS*

MAW-SHANG CHANG†

Abstract. This paper first presents a unified approach to design efficient algorithms for the weighted domination problem and its three variants, i.e., the weighted independent, connected, and total domination problems, on interval graphs. Given an interval model with endpoints sorted, these algorithms run in time $O(n)$ or $O(n \log \log n)$ where n is the number of vertices. The results are then extended to solve the same problems on circular-arc graphs in $O(n+m)$ time where m is the number of edges of the input graph.

Key words. interval graphs, circular-arc graphs, domination, graph algorithms

1. Introduction.

Let $G = (V, E)$ be an undirected graph. Throughout the paper, n and m denote the numbers of vertices and edges of a graph, respectively. For a vertex $v \in V$, let $N(v) = \{u : u \in V,\ u \neq v$ and u is a neighbor of $v\}$ and $N[v] = N(v) \cup \{v\}$. In general, for $S \subseteq V$, $N(S)$ and $N[S]$ denote $\cup_{v \in S} N(v)$ and $N(S) \cup S$, respectively. A subset S of V dominates another subset T of V if $T \subseteq N[S]$. A dominating set S of a subset T of V is called an *independent, connected, and total dominating set* of T if the induced subgraph of S has no edges, is connected, and has no isolated vertices, respectively. A subset S of V is called an (*independent, connected, total*) *dominating set* of graph G if S is an (*independent, connected, total*) *dominating set* of V. Let each vertex of graph G be associated with a real weight. The weight of a set of vertices is the sum of the weights of all vertices in the set. For a vertex v and a set S of vertices, $w(v)$ and $w(S)$ denote the weights of v and S, respectively. The weighted domination problem involves finding a dominating set of minimum weight for a weighted graph. The weighted independent (connected, total) domination problem involves finding an independent (connected, total) dominating set of minimum weight for a weighted graph. Given a graph G and an integer K, the problem of determining whether G has a dominating set whose cardinality is less than K is NP-complete [17]. The same holds true for independent, connected, and total domination [17], [27].

A graph $G = (V, E)$ is called an *intersection graph* for a finite family $\mathcal{F}$ of a nonempty set if there is a one-to-one correspondence between $\mathcal{F}$ and V such that two sets in $\mathcal{F}$ have nonempty intersection if and only if their corresponding vertices in V are adjacent to each other. We call $\mathcal{F}$ an *intersection model* of G. For an intersection model $\mathcal{F}$, we use $G(\mathcal{F})$ to denote the intersection graph for $\mathcal{F}$. If $\mathcal{F}$ is a family of intervals on a real line, then G is called an *interval graph* for $\mathcal{F}$ and $\mathcal{F}$ is called an *interval model* of G. If $\mathcal{F}$ is a family of arcs on a circle, then G is called a *circular-arc graph* for $\mathcal{F}$ and $\mathcal{F}$ is called a *circular-arc model* of G.

Booth and Lueker [10] gave an $O(n+m)$-time algorithm for recognizing an interval graph and constructing, in the affirmative case, an interval model using PQ-trees. Also, the endpoints of constructed intervals can be restricted to be distinct integers between 1 and $2n$ [31]. We refer to a set of intervals satisfying that the endpoints are distinct integers between 1 and $2n$ as a set of *sorted intervals* since they can be sorted easily in $O(n)$ time. Korte and Möhring [26] simplified the operations on a PQ-tree. Ramalingan and Pandu Rangan gave a simple $O(n^2)$ time algorithm which can be implemented in parallel easily [32]. Simon [35], Hsu and Ma [24] gave new algorithms without using PQ-trees. Interval graphs have been used in many practical applications [19]. If we are given an interval model whose endpoints are not integers between 1 and $2n$, we can sort the endpoints in nondecreasing order and use the indices of endpoints in the sorted list to construct a new interval model whose endpoints are distinct integers between 1 and $2n$. Thus, we refer to a set of intervals satisfying that the endpoints are distinct integers between 1 and $2n$ as a set of *sorted intervals*.

Tucker [39] proposed an $O(n^3)$-time algorithm for recognizing a circular-arc graph and constructing, in the affirmative case, a circular-arc model. Hsu gave an $O(nm)$-time algorithm [23] and Eschen and Spinrad presented an $O(n^2)$-time algorithm [13]. Circular-arc graphs have a variety of applications involving traffic light sequencing, genetics, and others. Circular-arc graphs have been studied in [18], [19], [22], [9]. Similarly, we refer to a set of arcs satisfying that the endpoints are distinct integers between 1 and $2n$ as a set of *sorted arcs*.

Investigating the algorithmic complexity of total domination on interval graphs was mentioned in [27] as a relevant open question. An $O(n^2)$-time algorithm has been proposed for this problem in [3]. Later, Ramalingan and Pandu Rangan gave an $O(n+m)$ algorithm [30], and Bertossi and Gori [5] presented an $O(n \log n)$-time algorithm for this problem. Ramalingam and Pandu Rangan [31] presented a unified approach to solve the weighted versions of various domination problems mentioned above on interval graphs in $O(m+n)$ time. Bonuccelli [9] gave an $O(nm)$-time algorithm for finding a minimum-cardinality dominating set on circular-arc graphs. Bertossi and Moretti [6] presented $O(n^3)$ algorithms for finding a minimum-weight dominating set and a minimum-weight total dominating set on circular-arc graphs. Recently, an $O(n)$-time algorithm for finding a minimum-cardinality dominating set of a circular-arc graph given a set of sorted arcs was given by Hsu and Tsai [25] and an $O(n^2 \log n)$ algorithm for the weighted version was given by Asano [2]. Interval graphs and circular-arc graphs have been studied by many researchers [20]. We only mention some results related to the domination problem studied in this paper. For computing the independence number of circular-arc graphs, see [21], [29]. For the irredundance problem on circular-arc graphs, please refer to [11]. For parallel algorithms for various domination problems and some other problems in interval graphs and circular-arc graphs, we refer the reader to [4], [6], [33], [36], [40].

In this paper, we assume that weights are real for the independent domination problem and assume that weights are nonnegative for the domination, connected, and total domination problems. Manacher and Mankus [28] showed that any algorithm for finding a minimum-weight dominating set, connected dominating set, and a total dominating set of a graph with nonnegative weights can be extended to incorporate negative-weight vertices without loss of efficiency. We will present a new unified approach to solve the weighted domination, independent, connected, and total domination problems on interval graphs. Given a set I of sorted intervals, the algorithms solve these problems on $G(I)$ in $O(n)$ or $O(n \log\log n)$ time and $O(n)$ space. These

algorithms are straightforward and simple but efficient. Then we extend the results to solve the same four problems on circular-arc graphs given sorted arc models in $O(m+n)$ time and $O(n)$ space. The results of this paper are summarized in section 4.

2. Algorithms for various domination problems on interval graphs. In this section, we study algorithms for various domination problems [8, 12, 20] on interval graphs. It is assumed that the input graph is given by an interval model I which is a set of n sorted intervals labeled by $1, 2, \ldots, n$ in increasing order of their right endpoints. The left endpoint of interval i is denoted by a_i and the right endpoint by b_i. We say that interval i starts from endpoint a_i and finishes at endpoint b_i. By definition, $1 \leq a_i < b_i \leq 2n$ for $1 \leq i \leq n$. For convenience, we need the following notation.

(i) For a set S of intervals, the largest (respectively, smallest) right endpoint of intervals in S is denoted by $\max b(S)$ (respectively, $\min b(S)$); the interval in S with the largest (respectively, smallest) right endpoint is denoted by $last(S)$ (respectively, $first(S)$); the largest left endpoint of intervals in S is denoted by $\max a(S)$. For technical reasons, we let $\max a(S) = 0$ if S is empty.

(ii) For endpoint e, we use $interval(e)$ to denote the interval whose left or right endpoint is equivalent to e, $IFB(e)$ (intervals finishing before endpoint e) to denote the set of all intervals whose right endpoints are less than e, and $ISB(e)$ (intervals starting before endpoint e) to denote the set of all intervals whose left endpoints are less than e. Thus, $\max a(IFB(e))$ is the largest left endpoint of the intervals whose right endpoints are less than e. Clearly, $interval(\max a(S))$ is the interval with the largest left endpoint in S.

(iii) A subset S of I is called a *partial dominating* (PD) set if S dominates all intervals starting before the right endpoint of $last(S)$. A PD set S is called an *independent partial dominating* (IPD) set if S is an independent set. A PD set S is called a *connected partial dominating* (CPD) set if the subgraph $G(S)$ induced by S is connected. A PD set S is a *total partial dominating* (TPD) set if the subgraph $G(S)$ induced by S has no isolated vertices.

(iv) For a family X of sets of vertices, $\mathrm{Min}(X)$ denotes a minimum-weight vertex set in X if X is not the empty set; $\mathrm{Min}(X)$ denotes a set of infinite weight otherwise.

(v) Suppose L is a list of numbers. We use δ_L and τ_L to denote the head and tail of L, respectively. For number j, we refer to the smallest number in L which is larger than j, denoted by $succ_L(j)$, as the successor of j in L and the largest number in L which is less than j, denoted by $pred_L(j)$, as the predecessor of j in L, respectively. For simplicity, we use δ and τ, $succ(j)$, and $pred(j)$ when L is understood without ambiguity.

To readers familiar with notation, we give a set I of seven intervals shown in Figure 1 for illustration. For example, $ISB(b_1) = \{1, 2, 4\}$, $ISB(b_3) = \{1, 2, 3, 4\}$, $ISB(b_5) = I$, $interval(5) = 3$, and $interval(10) = 4$. For example, $IFB(a_1) = \emptyset$, $IFB(a_4) = \emptyset$, $IFB(a_3) = \{1\}$, $IFB(b_2) = \{1\}$, and $IFB(a_6) = \{1, 2, 3, 4\}$. It is easy to verify that $\max a(IFB(a_1)) = 0$, $\max a(IFB(a_4)) = 0$, $\max a(IFB(a_3)) = a_1$, $\max a(IFB(b_2)) = a_1$, and $\max a(IFB(a_6)) = a_3$. For $S = \{1, 2, 3, 4\}$, we have that $\min b(S) = 4$, $\max b(S) = 10$, $\max a(S) = 5$, $first(S) = 1$, $last(S) = 4$, and $interval(\max a(S)) = 3$. Since $\{1, 3\}$ dominates $ISB(b_3)$, it is a PD set of $G(I)$. Clearly, it is also an IPD set. It is easy to see that $\{4, 5\}$ is a connected and a TPD set. Suppose that $w(1) = 11$, $w(2) = 5$, $w(3) = 1$, $w(4) = 2.5$, $w(5) = 7$, $w(6) = 6$, and $w(7) = 3.4$. For $X = \{\{1, 3, 7\}, \{2, 5\}, \{2, 4, 6\}, \{1, 3\}\}$, which is a family of

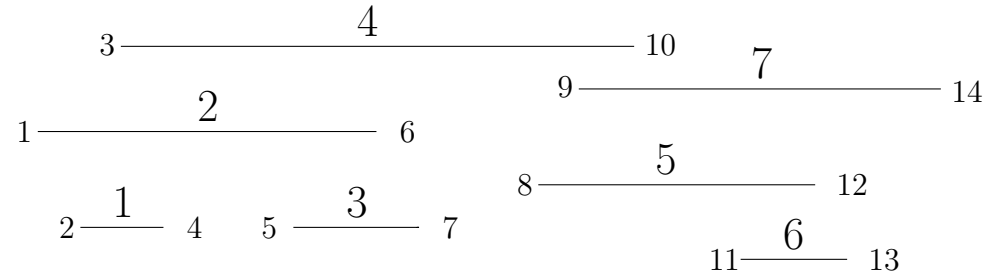

FIG. 1. *A family of seven intervals.*

four subsets of I, $\text{Min}(X) = \{2,5\}$ or $\text{Min}(X) = \{1,3\}$ since $w(\{1,3,7\}) = 15.4$, $w(\{2,5\}) = 12$, $w(\{2,4,6\}) = 13.7$, and $w(\{1,3\}) = 12$.

Following the above definitions, we can prove the following two lemmas easily.

LEMMA 2.1. *For two endpoints e_1 and e_2 where $e_1 < e_2$ of intervals in I, there does not exist any interval $j \in I$ such that $e_1 < a_j < b_j < e_2$ if and only if $e_1 \geq \max a(IFB(e_2))$.*

Proof. The lemma is proved by definition. □

LEMMA 2.2. *For two intervals k and i of I where $k < i$, interval i dominates $ISB(b_i) - ISB(b_k)$ if and only if $b_k > \max a(IFB(a_i))$.*

Proof. It is easy to see that $ISB(b_i) - ISB(b_k)$ can be partitioned into two subsets Z_1 and Z_2, where $Z_1 \subseteq N[i]$ and $Z_2 = \{j : j \in I, b_k < a_j < b_j < a_i\}$. By Lemma 2.1, $Z_2 = \emptyset$ if and only if $b_k > \max a(IFB(a_i))$. Thus, interval i dominates $ISB(b_i) - ISB(b_k)$ if and only if $b_k > \max a(IFB(a_i))$. □

In the following subsections, we will give recursive formulas for various weighted domination problem in interval graphs. Although Ramalingan and Pandu Rangan also gave recursive formulas in [31], our recursive formulas are different from theirs.

2.1. Independent domination. Let I_d be the set of intervals obtained by augmenting I with two intervals 0 and $n+1$ with $w(0) = w(n+1) = 0$. The left and right endpoints of interval 0 are -1 and 0, respectively, and the left and right endpoints of interval $n+1$ are $2n+1$ and $2n+2$, respectively. That is, $I_d = I \cup \{0, n+1\}$. Then a subset S of I is an independent dominating set of $G(I)$ if and only if $S \cup \{0, n+1\}$ is an independent dominating set of $G(I_d)$. For technical reason, we solve the weighted independent domination problem on $G(I)$ by finding a minimum-weight independent dominating set of $G(I_d)$. In this subsection, the set of intervals considered is I_d if not specified explicitly. It is easy to see that all IPDs contain interval 0. Let $IPD(i)$ be the collection of all IPDs whose last intervals are interval i. Then a subset S of I_d is an independent dominating set of $G(I_d)$ if and only if $S \in IPD(n+1)$. For simplicity, we use $MIPD(i)$ to denote $\text{Min}(IPD(i))$. Then we have the following lemma.

LEMMA 2.3. *The following three statements are true:*

(1) $MIPD(0) = \{0\}$.

(2) *For $1 \leq i \leq n+1$, we have that*
$MIPD(i) = \{i\} \cup \text{Min}(\{MIPD(j) : \max a(IFB(a_i)) < b_j < a_i\})$.

(3) $MIPD(n+1)$ *is a minimum-weight independent dominating set of $G(I_d)$.*

Proof. It is easy to verify the correctness of statements (1) and (3). In the following, we prove the correctness of statement (2) by showing that (i) if $S \in IPD(k)$ where $\max a(IFB(a_i)) < b_k < a_i$, then $S \cup \{i\} \in IPD(i)$; and (ii) if $S \in IPD(i)$ and $k = last(S - \{i\})$, then $S - \{i\} \in IPD(k)$ and $\max a(IFB(a_i)) < b_k < a_i$.

First, we prove statement (i). By definition, $last(S) = k$, and S dominates $ISB(b_k)$. Since $b_k < a_i$ and S is an independent set, $S \cup \{i\}$ is also an independent set. By Lemma 2.2, interval i dominates $ISB(b_i) - ISB(b_k)$ since $\max a(IFB(a_i)) < b_k$. Thus, $S \cup \{i\}$ dominates $ISB(b_i)$. By definition, $S \cup \{i\} \in IPD(i)$.

Next, we prove statement (ii). Since S is an independent set, interval i is not adjacent to interval k where $k = last(S - \{i\})$. Thus, $b_k < a_i$. Since S dominates $ISB(b_i)$ and $b_k < a_i$, we have that $S - \{i\}$ dominates $ISB(b_k)$ and interval i dominates $ISB(b_i) - ISB(b_k)$. By definition, $S - \{i\} \in IPD(k)$. By Lemma 2.2, we have that $\max a(IFB(a_i)) < b_k$. □

The recursive relation in Lemma 2.3 can be used to compute a minimum-weight independent domination set. The algorithm scans the endpoints of I_d from left to right. It uses a list L to store some intervals in increasing order. For simplicity, let $WI(k) = w(MIPD(k))$.

ALGORITHM MIDS. Find a minimum-weight independent dominating set of $G(I_d)$ given a set I_d of sorted intervals.

Input. A set I_d of sorted intervals and the weights of all intervals.

Output. A minimum-weight independent dominating set of $G(I_d)$.

Method.

1. $L \leftarrow \{0\}$; $WI(0) \leftarrow 0$; $MIPD(0) \leftarrow \{0\}$;
2. **for** $e = 1$ **to** $2n + 1$ **do**
3. **If** e is the left endpoint of some interval i, i.e., $e = a_i$, **then**
4. $MIPD(i) = \{i\} \cup MIPD(\delta)$;
   The union operation is implemented by setting a pointer from i to δ.
5. $WI(i) = w(i) + WI(\delta)$ where δ is the head of L;
6. **else** e is the right endpoint of some interval i, i.e., $e = b_i$, **do**
7. Delete all elements of L whose right endpoints are less than a_i from the head of the list one by one;
8. **while** $L \neq \emptyset$ and $WI(\tau) > WI(i)$ **do**
9. Delete τ from L where τ is the tail of L;
   end while
10. Append i to the end of L;
    end if else
    end for
11. Output $MIPD(n + 1)$;

By the for loop (lines 2 to 10), the algorithm visits the endpoints of $I_d - \{0\}$ in increasing order one by one and maintains an invariant (invariant 1): right before the left endpoint of interval i to be visited, $MIPD(\delta) = \text{Min}(\{MIPD(j) : \max a(IFB(a_i)) < b_j < a_i\})$. Thus by statement (2) of Lemma 2.3, the results of lines 4 and 5 are correct. In the following, we show how the invariant is maintained true. In fact, the algorithm maintains some other invariants: right before endpoint e is to be visited, invariant 2, $L \subseteq \{j : j \in I, \max a(IFB(e)) < b_j < e\}$; invariant 3, the intervals in L are in increasing order of their right endpoints; and invariant 4, for f, $h \in L$, if $f < h$, then $WI(f) \leq WI(h)$. Apparently, all of these invariants are true initially. Invariant 2 holds because of the following two reasons: (i) the intervals whose right endpoints are less than the left endpoint of $interval(e)$ are removed from L when right endpoint e is being visited (line 7), and (ii) an interval is appended to the tail of L when its right endpoint is being visited (line 10). The intervals in L are easily maintained in increasing order of their right endpoints because (i) endpoints are visited in increasing order, and (ii) an interval is appended to the tail of L when

its right endpoint is being visited (line 10). Thus, invariant 3 holds. Invariant 4 holds since all intervals j with $WI(j) > WI(interval(e))$ are removed from L by the while loop (lines 8 and 9) when right endpoint e is being visited and $interval(e)$ is appended to the end of L (line 10). By invariants 3 and 4, $WI(\delta)$ is smallest among all $WI(j)$'s of $j \in L$. It is straightforward to verify that when the left endpoint of interval i is being visited, $\{j : j \in I, \max a(IFB(a_i)) < b_j < a_i\} - L$ are those intervals removed from L by the while loop (lines 8 and 9). Hence there exists a right endpoint in L, i.e., τ, such that $WI(j) > WI(\tau)$ for all $j \in \{j : j \in I, \max a(IFB(a_i)) < b_j < a_i\} - L$ when the left endpoint of interval i is being visited. By invariants 2, 3, 4, $WI(\delta)$ is the smallest among all $WI(i)$'s where $j \in \{j : j \in I, \max a(IFB(a_i)) < b_j < a_i\}$ when the left endpoint of interval i is being visited. Therefore, invariant 1 is maintained true. This proves the correctness of algorithm MIPD. In practical implementation, $MIPD(i)$'s can be represented by linking lists as follows: we set a pointer from interval i to interval k when we form $MIPD(i)$ by the union of $MIPD(k)$ and $\{i\}$ (line 5). Then $MIPD(i)$ can be obtained by visiting intervals following the pointers from i to 0 and collecting the intervals visited. Thus, the union operation of line 5 can be done in constant time and line 11 can be implemented to run in $O(n)$ time. Since an interval is appended to the tail of L exactly once (line 10), the total number of deletions done by lines 7 and 9 is at most n. Thus we have the following theorem.

THEOREM 2.4. *Given a set I of sorted intervals, a minimum-weight independent dominating set of $G(I)$ is found in $O(n)$ time and $O(n)$ space by Algorithm MIDS.*

2.2. Domination. In this subsection, we describe an algorithm that will be used to solve the weighted domination problem on interval and circular-arc graphs. Let $PD(i)$ be the collection of all PD sets of $G(I)$ whose first and last intervals are intervals 1 and i, respectively. That is, $S \in PD(i)$ if and only if $first(S) = 1$, $last(S) = i$, and S dominates $ISB(b_i)$. For simplicity, we use $MPD(i)$ to denote $\mathrm{Min}(PD(i))$. Then, we have the following lemma.

LEMMA 2.5. *The following two statements are true:*

(1) $MPD(1) = \{1\}$.

(2) *For* $2 \le i \le n$, $MPD(i) = \{i\} \cup \mathrm{Min}\{MPD(j) : \max a(IFB(a_i)) < b_j < b_i\}$.

Proof. Statement (1) is easily seen. We will prove statement (2) by showing that (i) if $S \in PD(k)$ and $\max a(IFB(a_i)) < b_k < b_i$, then $S \cup \{i\} \in PD(i)$, and (ii) there exists a set $S \in PD(i)$ such that $w(S) = w(MPD(i))$, $k = last(S - \{i\})$, $S - \{i\} \in PD(k)$, and $\max a(IFB(a_i)) < b_k < b_i$.

We first prove statement (i). By definition, $last(S) = k$ and S dominates $ISB(b_k)$ since $S \in PD(k)$. By Lemma 2.2, interval i dominates $ISB(b_i) - ISB(b_k)$ since $\max a(IFB(a_i)) < b_k$. Thus $S \cup \{i\}$ dominates $ISB(b_i)$. This proves statement (i).

Next, we prove statement (ii). Since $PD(i) \neq \emptyset$, there exists a set S' such that $S' \in PD(i)$ and $w(S') = w(MPD(i))$. Then we obtain S by removing all intervals contained in interval i except interval 1 from S'; i.e., let $S = S' - \{h : h \in I, h \neq 1, a_i < a_h < b_h < b_i\}$. It is easy to see that $S \in PD(i)$. Clearly $w(S) \le w(S')$ since all weights are nonnegative. Thus $w(S) = w(MPD(i))$. Let interval k be the last interval of $S - \{i\}$. Obviously, $b_k < b_i$ and $a_k < a_i$ if $k \neq 1$. Thus S dominates $ISB(b_i)$, $S - \{i\}$ dominates $ISB(b_k)$, and interval i dominates $ISB(b_i) - ISB(b_k)$ no matter whether interval k is equivalent to interval 1 or not. Since $S - \{i\}$ dominates $ISB(b_k)$, by definition $S - \{i\} \in PD(k)$. By Lemma 2.2, we have that $\max a(IFB(a_i)) < b_k$. This proves statement (ii). □

In the following, we briefly describe the static disjoint set union and find the algorithm proposed by Gabow and Tarjan [15] that is used in solving our problems. The

disjoint set union and find problem [1], [15] is to carry out three kinds of operations on disjoint sets:

$makeset(x)$:	Create a new singleton set $\{x\}$ whose name is x for an element x which is in no existing set.
$find(x)$:	Return the name of the set containing element x.
$union(x, y)$:	Form a new set that is the union of the sets containing x and y, destroying the two old sets. The name of the new set is the name of the old set containing x.

We refer to $union(x, y)$ as the operation that unites the set containing y to the set containing x. The fastest known algorithm for this problem runs in $O(p\alpha(p+q, q)+q)$ time and $O(q)$ space, where α is the inverse of Ackermann's function [37], [38], q is the number of elements, and p is the number of operations performed. A special case of the disjoint set union-find problem can be formalized as follows. We are given a tree T of q nodes that corresponds to the initial q singleton sets. Let the parent of the node v in T be denoted by $parent(v)$. The problem involves performing a sequence of union and find operations such that each union can be only of the form $union(parent(v), v)$. T is called the *static union tree* and the problem is referred to as the *static tree set union*. For this special case, each union and find operation can be supported in $O(1)$ amortized time on a random access machine, and the total space required is $O(q)$ [15]. There is a special case of the static tree set union problem where the union tree is a path [15] also known as *interval union-find problem* [16].

For simplicity, let $W(k) = w(MPD(k))$. Following Lemma 3.2, we design Algorithm MPD for computing $W(i)$ and $MPD(i)$ for all $i \in I$ in $O(n)$ time and space. All $MPD(i)$'s are stored in an $O(n)$ space data structure in the same way as we store $MIPD(i)$'s in the previous subsection. An $MPD(i)$ can be output from this data structure in $O(|MPD(i)|)$ time for all $i \in I$. We refer to a set S of left endpoints of I as a *consecutive left endpoint set* if there exist left endpoints e_1 and e_2 of S such that $S = \{e : e_1 \leq e \leq e_2, e \text{ is a left endpoint of } I\}$. Note that e_1 and e_2 may be identical. Algorithm MPD first scans endpoints to find left endpoint sets $\{a_j : b_{i-1} < a_j < b_i\}$ where $b_0 = 0$ for all $i \in I$. It forms a set for each left endpoint set found by using *makeset* and *union* operations. Note that all these left endpoint sets are either empty or consecutive left endpoint sets. Initially, each left endpoint set $\{a_j : b_{i-1} < a_j < b_i\}$ is associated with right endpoint b_i. What we mean by saying that a set is associated with a right endpoint is that both of the operations of finding the set from the right endpoint and finding the right endpoint from the set can be done in constant time. This can be done easily by pointers. Besides the left endpoint sets, the algorithm also maintains a list L. The elements stored in L are right endpoints. Initially, $L = \{b_1, b_2, \ldots, b_n\}$. Elements of L are stored in a list in increasing order. Details of the algorithm are as follows.

ALGORITHM MPD. Computing $W(i)$ and an $O(n)$ space data structure such that an $MPD(i)$ can be output from this data structure in $O(|MPD(i)|)$ time for all $i \in I$.

Input. A set I of sorted intervals and the weights of intervals.

Output. $W(i)$ and an $O(n)$ space data structure such that an $MPD(i)$ can be output in $O(k)$ time, where $k = |MPD(i)|$, for all $i \in I$.

Method.

1. Find $\max a(IFB(a_i))$ for all $i \in I$;
2. Scan the endpoints of I to find left endpoint sets $\{a_j : b_{i-1} < a_j < b_i\}$ where $b_0 = 0$ for all $i \in I$.

Each right endpoint set b_i is associated with
the left endpoint set $\{a_j : b_{i-1} < a_j < b_i\}$.
3. $L \leftarrow \{b_1, b_2, \ldots, b_n\}$;
4. $W(1) \leftarrow w(1)$; $MPD(1) \leftarrow \{1\}$;
5. **for** $i = 2$ **to** n **do**
6. Find the set containing $\max a(IFB(a_i))$;
7. Let b_k be the right endpoint associated with this set;
8. $MPD(i) \leftarrow \{i\} \cup MPD(k)$;
The union operation is implemented by setting a pointer from i to k.
9. $W(i) \leftarrow w(i) + W(k)$;
10. **while** $W(interval(pred(b_i))) > W(i)$ **do**
11. Unite the set associated with $pred(b_i)$ to the set associated with b_i by union operation;
12. Delete $pred(b_i)$ from L;
13. **end while**
14. **end for**

The correctness of this algorithm can be proved by induction. Algorithm MPD visits intervals one by one (line 5). Let i be the currently visited interval and $L' = \{e : e \in L, e < b_i\}$. Algorithm MPD maintains the following three invariants: immediately before interval i is visited, invariant 1, for any two right endpoints f and h of L', $W(interval(f)) \leq W(interval(h))$ if $f < h$; invariant 2, if the set containing left endpoint e_1 is associated with the right endpoint e_2, then e_2 is the successor of e_1 in L; and invariant 3, for every right endpoint e that is removed from L, there exists a right endpoint e' in L' such that $e < e'$ and $W(interval(e)) > W(interval(e'))$. Initially, all three invariants are true. Then they are maintained by the while loop of lines 10 to 13. By invariant 1 and 2, we have that $MPD(k) = \text{Min}(\{MPD(j) : b_j \in L', \max a(IFB(a_i)) < b_j < b_i\})$ where k is the interval found by line 7. By invariant 3, we have that $MPD(k) = \text{Min}(\{MPD(j) : \max a(IFB(a_i)) < b_j < b_i\})$. By Lemma 2.5, it is easy to see the correctness of Algorithm MPD. Note that the union operation of line 8 is implemented by setting a pointer from i to k. Thus to output $MPD(i)$ we simply follow the pointers to visit intervals starting from interval i until we reach interval 1. The set of intervals visited is an $MPD(i)$. By invariant 2, every left endpoint set formed by line 11 of the algorithm is a consecutive left endpoint set. This is an interval union-find problem [16]. Hence line 11 can be implemented in constant amortized time.

In the following, we give a simple algorithm to find $\max a(IFB(a_i))$ for every interval i in $O(n)$ time.

ALGORITHM P. Computing $\max a(IFB(e))$ for all endpoints of a set I of sorted intervals.

Input. A set I of sorted intervals.

Output. $\max a(IFB(e))$'s of all endpoints of I.

Method.

1. $\beta \leftarrow 0$;
2. **for** $e = 1$ **to** $2n$ **do**
3. $\max a(IFB(e)) \leftarrow \beta$;
4. **if** e is the right endpoint of some interval i, **then**
5. $\beta \leftarrow \max\{a_i, \beta\}$;
end if
end for

We will not prove the correctness of Algorithm P to save space. From the above discussions, it is easy to see that Algorithm MPD can be implemented in $O(n)$ time. Hence we have the following lemma.

LEMMA 2.6. *Given a set I of sorted intervals with weights, Algorithm MPD computes $W(i)$ and $MPD(i)$ for all $i \in I$. All $MPD(i)$'s are stored in an $O(n)$ space data structure such that an $MPD(i)$ can be output in $O(|MPD(i)|)$ time.*

Now we show how to use Algorithm MPD to solve the weighted domination problem on interval graphs. Note the set I_d of intervals is obtained from I as described in the previous subsection. Similarly, a subset S of I is a dominating set of $G(I)$ if and only if $S \cup \{0, n+1\}$ is a dominating set of $G(I_d)$. It is easy to see that interval 0 is the first interval of I_d and all dominating sets of $G(I_d)$ contain intervals 0 and $n+1$. Thus, $MPD(n+1)$ of $G(I_d)$ is a minimum-weight dominating set of $G(I_d)$ and $MPD(n+1) - \{0, n+1\}$ is a minimum-weight dominating set of $G(I)$. Since $MPD(n+1)$ can be computed in $O(n)$ time and space by Algorithm MPD, we have the following theorem.

THEOREM 2.7. *Given a set of sorted intervals, a minimum-weight dominating set of $G(I)$ can be found in $O(n)$ time and $O(n)$ space.*

2.3. Connected domination. If a graph is not connected, then it has no connected dominating set. Whether $G(I)$ is connected can be checked in $O(n)$ time. Hence we assume that $G(I)$ is connected in this subsection. Let $CPD(i)$ be the set of all connected PD sets of $G(I)$ whose first and last intervals are intervals 1 and i, respectively. That is, $CPD(i) = \{S : S \subseteq I, first(S) = 1, last(S) = i,\ G(S)$ is connected, and S dominates $ISB(b_i)\}$. Let $MCPD(i) = \mathrm{Min}(CPD(i))$. If $G(\{1, 2, \ldots, i\})$ is not connected, then $CPD(i) = \emptyset$. In this case, $MCPD(i)$ is considered as a set of infinite weight. The following lemma can be proved by arguments similar to those for proving Lemma 2.5.

LEMMA 2.8. *The following two statements are true:*

(1) $MCPD(1) = \{1\}$; *and*

(2) *For* $2 \le i \le n$, $MCPD(i) = \{i\} \cup \mathrm{Min}(\{MCPD(j) : a_i < b_j < b_i\})$.

Proof. The correctness of statement (1) is easily verified. We will prove statement (2) by showing that (i) if $S \in CPD(k)$ and $a_i < b_k < b_i$, then $S \cup \{i\} \in CPD(i)$; (ii) if $CPD(i) \neq \emptyset$, then there exists a set $S \in CPD(i)$ such that $w(S) = w(MCPD(i))$, $S - \{i\} \in CPD(k)$, where $k = last(S - \{i\})$ and $a_i < b_k < b_i$.

Statement (i) can be easily verified. We prove statement (ii). Let $S' \in CPD(i)$ and $w(S') = w(MCPD(i))$. We obtain S by removing from S' all intervals which are contained in interval i except interval 1. That is, $S = S' - \{j : j \in I, j \neq 1, a_i < a_j < b_j < b_i\}$. Clearly $w(S) \le w(S')$ since all interval weights are nonnegative. It is easy to see that $S \in CPD(i)$ and $w(S) = w(MCPD(i))$. Let $k = last(S - \{i\})$. Obviously, $a_i < b_k < b_i$ since $G(S)$ is connected. By definition, S dominates $ISB(b_i)$. It is easy to verify that $S - \{i\}$ dominates $ISB(b_k)$ and $G(S - \{i\})$ is connected no matter whether interval k is equivalent to interval 1 or not. This proves that $S - \{i\} \in CPD(k)$. □

For simplicity, let $WC(k)$ denote $w(MCPD(k))$. Following Lemma 2.8, one might think that we can modify Algorithm MPD to compute $WC(i)$ and $MCPD(i)$ for all $i \in I$ in $O(n)$ time simply by replacing $\max a(IFB(a_i))$ of line 6 by a_i. We should be careful of that because $2 \le i \le n$, $\{j : j \in I, \max a(IFB(a_i)) < b_j < b_i\}$ is always not empty but $\{j : j \in I, a_i < b_j < b_i\}$ is possibly empty. If $\{j : j \in I, a_i < b_j < b_i\}$ is empty, then $CPD(i) = \emptyset$. Thus $MCPD(i)$ is a set of infinite weight. To modify Algorithm MPD to compute $WC(i)$ and $MCPD(i)$ for all $i \in I$ in $O(n)$ time, we

replace lines 6 to 13 by lines 6' to 17' as follows. Note that lines 8' and 9' handle the case that $\{j : j \in I, a_i < b_j < b_i\} = \emptyset$.

6'. Find the set containing a_i;
7'. Let b_k be the right endpoint associated with the left endpoint set containing a_i;
8'. **if** $k = i$ **then do**
9'. Mark that $MCPD(i)$ is a set of infinite weight;
10'. **else do**
11'. $MCPD(i) \leftarrow \{i\} \cup MCPD(k)$;
The union operation is implemented by setting a pointer from i to k;
12'. $WC(i) \leftarrow w(i) + WC(k)$;
13'. **while** $WC(interval(pred(b_i))) > WC(i)$ **do**
14'. Unite the set associated with $pred(b_i)$ to the set associated with b_i by union operation;
15'. Delete $pred(b_i)$ from L;
16'. **end while**
17'. **end if else**

Thus, we have the following lemma.

LEMMA 2.9. *Given a set I of sorted intervals with weights, we can compute $WC(i)$ and $MCPD(i)$ for all $i \in I$. All $MCPD(i)$'s are stored in an $O(n)$ space data structure such that an $MCPD(i)$ can be output in $O(|MPD(i)|)$ time.*

Let I_c be the set of intervals obtained by augmenting I with two zero-weight intervals, intervals 0 and $n+1$, where $a_0 = 0$, $b_0 = b_1 - 0.5$, $a_{n+1} = \max a(I) + 0.5$, $b_{n+1} = 2n + 1$. Note that $\max a(I)$ denotes the largest left endpoint of intervals in I. It is easy to see that the endpoints of I_c can be sorted in $O(n)$ time and intervals 0 and $n+1$ are the first and last interval of I_c, respectively. It is straightforward to verify that a subset S of I is a connected dominating set of $G(I)$ if and only if $S \cup \{0, n+1\}$ is in $CPD(n+1)$ of $G(I_c)$. Thus, we can find a minimum-weight connected dominating set of $G(I)$ by computing $MCPD(n+1)$ of $G(I_c)$. Since $MCPD(n+1)$ of $G(I_c)$ can be computed in $O(n)$ time, we have the following theorem.

THEOREM 2.10. *Given a set I of sorted intervals, a minimum-weight connected dominating set of $G(I)$ can be found in $O(n)$ time.*

2.4. Total domination. A subset S of I is called an *intermediate total partial dominating* (ITPD) set if the following four conditions are satisfied:

(1) S contains the first interval of I;
(2) S is a PD set of $G(I)$;
(3) $G(S - \{last(S)\})$ has no isolated vertices; and
(4) $\max b(S - \{last(S)\})$ is less than the left endpoint of $last(S)$; i.e., the last interval of S does not overlap any other interval of S.

Let $TPD(i)$ be the collection of all TPD sets which contain the first interval of I and whose last intervals are equivalent to interval i, respectively, let $ITPD(i)$ be the collection of all ITPD sets whose last intervals are equivalent to interval i, and let $XTPD(i) = TPD(i) \cup ITPD(i)$. For simplicity, let $MTPD(i) = \text{Min}(TPD(i))$, $MITPD(i) = \text{Min}(ITPD(i))$, $MXTPD(i) = \text{Min}(XTPD(i))$, $WIT(i) = w(MITPD(i))$, $WT(i) = w(MTPD(i))$, and $WX(i) = w(MXTPD(i))$. Let $X(i) = \cup_{a_i < b_j < b_i} XTPD(j)$, $MX(i) = \text{Min}(X(i))$, $K(i) = \{\{j\} : j \in I, a_i < a_j < b_j < b_i\})$, and $MK(i) = \text{Min}(K(i))$. Note that if $K(i) = \emptyset$, then $MK(i)$ is considered as a set of infinite weight. In words, $X(i)$ is the union of all $XTPD(j)$'s where $a_i < b_j < b_i$ and $K(i)$ is the collection of all single interval sets $\{j\}$'s where $a_i < a_j < b_j < b_i$.

Then, we have the following lemma.

LEMMA 2.11. *The following four statements are true:*

(1) $MTPD(1)$ *is a set of infinite weight, and* $MITPD(1) = \{1\}$;

(2) *for* $2 \le i \le n$ *and* $a_i < b_1$, $MITPD(i)$ *is a set of infinite weight*;

(3) *for* $2 \le i \le n$ *and* $a_i > b_1$, $MITPD(i) = \{i\} \cup \text{Min}(\{MTPD(j) : \max a(IFB(a_i)) < b_j < a_i\})$; *and*

(4) *for* $2 \le i \le n$, $MTPD(i) = \text{Min}(\{MX(i) \cup \{i\}, MITPD(i) \cup MK(i)\})$.

Proof. The correctness of statements (1) and (2) is easy to see. The correctness of statement (3) can be proved by arguments similar to those for proving statement (2) of Lemma 2.3. We prove statement (4) by showing that (i) if $S \in X(i)$, then $S \cup \{i\} \in TPD(i)$; (ii) if $S \in ITPD(i)$ and $K(i) \neq \emptyset$, then $S \cup \{k\} \in TPD(i)$ for any $k \in K(i)$; and (iii) if $TPD(i) \neq \emptyset$, there exists a set $S \in TPD(i)$ which has minimum weight and either $S - \{i\} \in X(i)$ or there exists an interval $k \in S$ such that $\{k\} \in K(i)$ and $S - \{k\} \in ITPD(i)$.

We first prove statement (i). For simplicity, let $k = last(S)$. By definition, $S \in TPD(k)$ or $S \in ITPD(k)$. Clearly, S dominates $ISB(b_k)$. Since $a_i < b_k < b_i$, interval i dominates $ISB(b_i) - ISB(b_k)$. In other words, $S \cup \{i\}$ dominates $ISB(b_i)$. It is straightforward to verify that $G(S \cup \{i\})$ has no isolated vertices. Thus $S \cup \{i\} \in TPD(i)$. This proves statement (i).

Next we prove statement (ii). Since i is the only isolated vertex in $G(S)$, $G(S \cup \{k\})$ has no isolated vertices. By definition, S dominates $ISB(b_i)$. Thus $S \cup \{k\}$ dominates $ISB(b_i)$ too. By definition, $S \cup \{k\} \in TPD(i)$. This proves statement (ii).

Now we prove statement (iii). Let S be a TPD set of $TPD(i)$ such that $w(S) = WT(i)$ and $|S|$ is minimum. By definition, S dominates $ISB(b_i)$. Let $C(i)$ be the set of intervals that are contained in interval i but are not equivalent to interval 1. Consider the following two cases.

Case 1. $C(i) \neq \emptyset$.

Case 2. $C(i) = \emptyset$.

In Case 1, it is easy to see that $S - C(i)$ is still a dominating set of $ISB(b_i)$. Suppose $G(S - C(i))$ has no isolated vertices. Then $S - C(i) \in TPD(i)$. Since interval weights are nonnegative, $w(S - C(i)) \le w(S)$. Apparently, $|S - C(i)| < |S|$. It contradicts the assumption that $S \in TPD(i)$, $w(S) = WT(i)$, and $|S|$ is minimum. Thus, $G(S - C(i))$ has isolated vertices. It is easy to verify that interval i is the only isolated vertex in $G(S - C(i))$ and $1 \notin N(i)$. By definition, $S - C(i) \in ITPD(i)$. Similarly, we can prove that $|S \cap C(i)| = 1$. Since $1 \notin N(i)$, there exists an interval $k \in S$ such that $\{k\} \in K(i)$ and $S - \{k\} \in ITPD(i)$ in this case.

In Case 2, again we consider the following two cases.

Case 2.1. Interval 1 is adjacent to interval i.

Case 2.2. Interval 1 is not adjacent to interval i.

In Case 2.1, it is easy to verify that $S = \{1, i\}$. Thus, $S - \{i\} \in ITPD(1)$. Since $a_i < b_1 < b_i$, we have that $S - \{i\} \in X(i)$.

Now we consider Case 2.2. Let $k = last(S - \{i\})$. Then $a_k < a_i < b_k < b_k$ since $G(S)$ has no isolated vertices and S does not contain any other interval contained in interval i. Thus, $S - \{i\}$ dominates $ISB(b_k)$. Suppose $G(S - \{i\})$ has no isolated vertices. Then, $S - \{i\} \in TPD(k)$. On the other hand, suppose $G(S - \{i\})$ has isolated vertices. It is straightforward to verify that k is the only isolated vertex in $G(S - \{i\})$ and hence $S - \{i\} \in ITPD(k)$. By definition, $S - \{i\} \in X(i)$ since $a_i < b_k < b_i$. This proves statement (iii). □

Based on Lemma 2.11, we design Algorithm MTPD to compute $WT(i)$, $WIT(i)$, $MTPD(i)$, and $MITPD(i)$ for all $i \in I$. All $MTPD(i)$'s and $MITPD(i)$'s are stored

in an $O(n)$ space data structure by using pointers. We can obtain an $MTPD(i)$ (respectively, $MITPD(i)$) from the data structure in $O(|MTPD(i)|)$ (respectively, $O(|MITPD(i)|)$) time. In fact, Algorithm MTPD uses both techniques used by Algorithm MIDS and MPD. Algorithm MTPD visits endpoints one by one and maintains two lists L_1 and L_2. Algorithm MTPD maintains L_1 and L_2 in the same way as Algorithm MIDS and MPD, respectively, maintain list L. Elements in lists L_1 and L_2 are intervals and right endpoints of intervals, respectively. If $j \in L_1$ and a_i is the left endpoint currently visited, then $\max a(IFB(a_i)) < b_j < a_i$. If $e_1 \in L_2$ and $e_1 < e_2$ where e_2 is the endpoint currently visited, then there does not exist a right endpoint $e_3 \in L_2$ such that $e_1 < e_3 < e_2$ and $WX(interval(e_1)) > WX(interval(e_3))$.

ALGORITHM MTPD. Compute $WT(i)$, $WIT(i)$, $MTPD(i)$, and $MITPD(i)$ for all $i \in I$.

Input. A set I of sorted intervals and the weights of all intervals.

Output. $WT(i)$, $WIT(i)$, $MTPD(i)$, and $MITPD(i)$ for all $i \in I$. All $MTPD(i)$'s and $MITPD(i)$'s are stored in an $O(n)$ space data structure. We can obtain an $MTPD(i)$ (respectively, $MITPD(i)$) from the data structure in $O(|MTPD(i)|)$ (respectively, $O(|MITPD(i)|)$) time.

Method.

1. For each $i \in \{j : j \in I - \{1\}, a_j < b_1\}$,
   mark that $MITPD(i)$ is a set of infinite weight;
   $WIT(i) \leftarrow \infty$ for all $i \in \{j : j \in I - \{1\}, a_j < b_1\}$;
2. Mark that $MTPD(1)$ is a set of infinite weight;
   $WT(1) \leftarrow \infty$; $MITPD(1) \leftarrow \{1\}$; $WIT(1) \leftarrow w(1)$;
   $MXTPD(1) \leftarrow \{1\}$; $WX(1) \leftarrow WIT(1)$;
3. $L_1 \leftarrow \{1\}$; $L_2 \leftarrow \{b_1, b_2, \ldots, b_n\}$;
4. For each interval $i \in I - \{1\}$, find $MK(i)$;
5. Scan the endpoints of I to find left endpoint sets
   $\{a_j : b_{i-1} < a_j < b_i\}$ where $b_0 = 0$ for all $i \in I$.
   Each right endpoint b_i is associated with
   the left endpoint set $\{a_j : b_{i-1} < a_j < b_i\}$.
6. **for** $e = b_1 + 1$ **to** $2n$ **do**
7. **if** e is equivalent to the left endpoint of interval i, i.e., $e = a_i$, **then do**
8. $MITPD(i) = \{i\} \cup MTPD(\delta_{L_1})$;
    This statement can be implemented by saving the value of δ_{L_1}.
9. $WIT(i) = w(i) + WT(\delta_{L_1})$;
10. **else** e is the right endpoint of interval i, i.e., $e = b_i$, **do**
11. Find the set containing a_i;
12. Let b_k be the right endpoint associated with the set containing a_i;
13. **if** $k = i$ **then do**
14. Mark that $MTPD(i)$ is a set of infinite weight; $WT(i) \leftarrow \infty$;
15. **else do**
16. $MTPD(i) = \text{Min}(\{MXTPD(k) \cup \{i\}, MITPD(i) \cup MK(i)\})$;
     $WT(i) = \min\{w(i) + WX(j), w(MK(i)) + WIT(i)\}$;
     This statement can be implemented by marking that
     whether $MTPD(i) = MXTPD(k) \cup \{i\}$
     or $MTPD(i) = MITPD(i) \cup MK(i)$.
     If $MTPD(i) = MXTPD(k) \cup \{i\}$, then we also save the value
     of k.
     end if else

17. $MXTPD(i) = \text{Min}(\{MTPD(i), MITPD(i)\})$;
This statement can be implemented by marking that
whether $MXTPD(i) = MTPD(i)$ or $MXTPD(i) = MITPD(i)$.
18. $WX(i) = \min\{WT(i), WIT(i)\}$;
19. Delete all elements of L_1 whose right endpoints are less
than a_i from the head of the list one by one;
20. **while** $L_1 \neq \emptyset$ and $WT(\tau_{L_1}) > WT(i)$ **do**
21. Delete τ_{L_1} from L_1;
end while
22. Append i to the end of L_1;
23. **while** $WX(interval(pred_{L_2}(b_i))) > WX(i)$ **do**
24. Unite the set associated with $pred_{L_2}(b_i)$ to the set associated
with b_i by union operation;
25. Delete $pred_{L_2}(b_i)$ from L_2;
26. **end while**
end if else
end for

It is easy to see the correctness of lines 1 to 3 of Algorithm MTPD. Then it visits endpoints starting from $b_1 + 1$ one by one in increasing order. (See the for loop of lines 6 to 26.) Algorithm MTPD maintains list L_1 in the same way that Algorithm MIDS maintains list L (lines 19 to 22). It maintains list L_2 in the same way that Algorithm MPD maintains list L (lines 23 to 25). For each $MTPD(i)$, we mark whether $MTPD(i) = MXTPD(k) \cup \{i\}$ or $MTPD(i) = MITPD(i) \cup MK(i)$ (line 16). If $MTPD(i) = MXTPD(k) \cup \{i\}$, then we also save the value of k. For each $MITPD(i)$, we save the value of δ_{L_1} (line 8). For each $MXTPD(i)$, we mark whether $MXTPD(i) = MTPD(i)$ or $MXTPD(i) = MITPD(i)$ (line 17). Thus, all $MTPD(i)$'s and $MITPD(i)$'s are stored in an $O(n)$ space. Clearly, we can obtain any $MTPD(i)$ or $MITPD(i)$ recursively according to the information stored. Hence, following Lemma 2.11, it is not hard to see that algorithm MTPD is correct. Algorithm MTPD can be implemented in $O(n)$ time if $MK(i)$'s for all $i \in I$ can be computed in $O(n)$ time. For the cardinality case that $w(i) = 1$ for all $i \in I$, we can compute $MK(i)$'s for all $i \in I$ in $O(n)$ time easily. In the following, we will give an $O(n \log\log n)$ algorithm to compute all $MK(i)$'s for the case that $w(i) = 1$ is not true for all $i \in I$. Algorithm K visits intervals one by one in increasing order of their right endpoints. A set of left endpoints that have been visited are kept in an L. Initially, $L = \emptyset$. Algorithm K maintains the following invariants:

(1) For $e_1, e_2 \in L$, if $e_1 < e_2$, then $w(interval(e_1)) \leq w(interval(e_2))$.

(2) Right before interval i to be visited, if $j < i$ and $a_j \notin L$, then there exists an interval k such that $k \in I$, $k < i$, $a_j < a_k$, $a_k \in L$, and $w(k) < w(j)$.

When the algorithm visits interval i, if $L = \emptyset$ or a_i is greater than the maximum element in L, then interval i does not contain any other interval of I; i.e., $MK(i)$ is a set of infinite weight. Otherwise, $MK(i) = \{k\}$ and $w(MK(i)) = w(k)$ where k is the interval and that a_k is the successor of a_i in L. Details of the algorithm are as follows.

ALGORITHM K. Find $MK(i)$ for every interval i of I.

Input. A set I of sorted intervals and the weights of all intervals.

Output. $MK(i)$'s for all interval $i \in I$.

Method.

```
1.      L = ∅;
2.      for i = 1 to n do
3.          if L = ∅ or a_i > τ then do
4.              Mark that MK(i) is a set of infinite weight;
5.          else do
6.              k ← interval(succ(a_i));
7.              MK(i) ← {k}; w(MK(i)) ← w(k);
            end if else
8.          if L = ∅ or a_i > τ or w(i) ≤ w(interval(succ(a_i))) then do
9.              Insert a_i into L;
10.             while a_i ≠ δ and w(interval(pred(a_i))) > w(i) do
11.                 remove pred(a_i) from L;
                end while
            end if
        end for
```

The two invariants are true initially. Then they are maintained by lines 8 to 11. The data structure L can be implemented by using the two-level priority queue proposed by van Emde Boas [7], which supports the operations of finding the minimum, maximum, predecessor, and successor of an element, inserting and deleting an element in $O(\log\log n)$ time. Hence the running time of Algorithm K is $O(n\log\log n)$. This leads to the following lemma.

LEMMA 2.12. *Given a set I of sorted intervals with weights, Algorithm MTPD computes $WT(i)$, $WIT(i)$, $MTPD(i)$, and $MITPD(i)$ for all $i \in I$ in $O(n\log\log n)$ time. All $MTPD(i)$'s and $MITPD(i)$'s are stored in an $O(n)$ space data structure. We can obtain an $MTPD(i)$ (respectively, $MITPD(i)$) from the data structure in $O(|MTPD(i)|)$ (respectively, $O(|MITPD(i)|)$) time. If $MK(i)$'s for all $i \in I$ can be computed in $O(n)$ time, then the running time of Algorithm MTPD is $O(n)$.*

Let I_t be the set of intervals obtained by augmenting I four zero-weight intervals, -1, 0, $n+1$, and $n+2$, where $a_{-1} < a_0 < b_{-1} < b_0 < 1$, and $2n < a_{n+1} < a_{n+2} < b_{n+1} < b_{n+2}$. We can see that a subset S of I is a total dominating set of $G(I)$ if and only if $S \cup \{-1, 0, n+1, n+2\}$ is a total dominating set of $G(I_t)$. Thus we can find a minimum-weight total dominating set of $G(I)$ by using Algorithm MTPD to compute $MTPD(n+2)$ of $G(I_t)$. Since $MK(i)$'s for all $i \in I$ can be computed in $O(n)$ time if $w(i) = 1$ for all $i \in I$, a minimum-cardinality total dominating set of $G(I)$ can be found in $O(n)$ time. Thus we have the following theorem.

THEOREM 2.13. *Given a set I of sorted intervals, a minimum-weight total dominating set of $G(I)$ can be found in $O(n\log\log n)$ time and $O(n)$ space; and a minimum-cardinality total dominating set of $G(I)$ can be found in $O(n)$ time.*

3. Extensions to circular-arc graphs. In this section, we shall extend the results of the previous sections to solve the weighted domination problems on $G(A)$ given a set A of sorted arcs with real weights. An arc, starting from endpoint h along clockwise direction to endpoint t, is denoted by $[h, t]$. We refer to endpoints h and t as the *head* and *tail* of arc $[h, t]$, respectively. We use "arc" to refer to a member of A and "segment $[c, d]$" to refer to a continuous part of the circle that begins with an endpoint c and ends with d in clockwise direction [34]. Arbitrarily choose an arc from A. Starting from the head of this arc, label endpoints along clockwise direction from 1 to $2n$. Arcs are numbered from 1 to n in increasing order of their tail. Denote the head and tail of arc i by h_i and t_i, respectively. Note that h_i can be larger than t_i, in which case arc $[h_i, t_i]$ extends h_i, $h_i + 1, \ldots, 2n, 1, \ldots, t_i$.

We first study the problem of finding a minimum-weight independent dominating set in a circular-arc graph $G(A)$ given a set A of sorted arcs. One observes that, for any arc x of A, graph $G(A-N(x))$ is an interval graph and arc x is an isolated vertex in $G(A-N(x))$. Moreover, every dominating set of $G(A)$ contains at least one member of $N[x]$. Thus we can find a minimum-weight independent dominating set of $G(A)$ as follows: choosing a vertex x_0 of minimum degree and letting $N(x_0) = \{x_1, x_2, \ldots, x_d\}$ where d is the degree of x_0, we find a minimum-weight independent dominating set of $G(A - N(x_k))$, which is an interval graph, for each arc $x_k \in N[x_0]$. The one with minimum weight is a minimum-weight independent dominating set of $G(A)$. Since $A - N(x_k)$ can be determined in $O(n)$ time, a minimum-weight independent dominating set on $G(A - N(x_k))$ can be computed in $O(n)$ time using the algorithm presented in section 2.1. We have the following theorem.

THEOREM 3.1. *Given a set A of sorted arcs, a minimum-weight independent dominating set of $G(A)$ can be found in $O(m + n)$ time and $O(n)$ space.*

In the following three subsections, we consider the weighted domination, connected domination, and total domination problems on circular-arc graphs. We consider nonnegative weight only. The reasons are explained in section 1. We will give a unified approach to solve these problems in $O(n + m)$ time given a set of sorted arcs with weights. We need the following notation.

For $x \in A$, define $\overline{N}(x)$ to be the set of arcs of A that either contains arc x or is contained in arc x, and define $N_R(x)$ and $N_L(x)$ to be the sets of arcs whose heads and tails are contained in arc x, respectively. Let $A_P(x) = A - \overline{N}(x)$, $A_R(x) = A_P(x) - N_L(x)$, and $A_L(x) = A_P(x) - N_R(x)$. It is straightforward to verify that $A_R(x)$ and $A_L(x)$ are interval graphs. For instance, there are ten arcs shown in Figure 2; i.e., arc 1 = [17, 4], arc 2 = [2, 5], arc 3 = [1, 6], arc 4 = [19, 7], arc 5 = [3, 9], arc 6 = [8, 12], arc 7 = [11, 13], arc 8 = [10, 16], arc 9 = [15, 18], arc 10 = [14, 20]. For arc 3, $N[3] = \{1, 2, 3, 4, 5\}$, $\overline{N}(3) = \{2, 4\}$, $N_R(3) = \{5\}$, $N_L(3) = \{1\}$, $A_P(3) = \{1, 3, 5, 6, 7, 8, 9, 10\}$, $A_L(3) = \{1, 3, 6, 7, 8, 9, 10\}$, and $A_R(3) = \{3, 5, 6, 7, 8, 9, 10\}$.

The following observation plays an important role in our algorithms.

LEMMA 3.2. *Suppose A is an arc model and x_0 is any arc of A. The following three statements are true.*

(1) *There exists a minimum-weight total dominating set S of $G(A)$ such that S contains an arc x in $N[x_0]$ and does not contain any other arc containing arc x.*

(2) *There exists a minimum-weight dominating set S of $G(A)$ such that S contains an arc x of $N[x_0]$ and $S \cap \overline{N}(x) = \emptyset$.*

(3) *There exists a minimum-weight connected dominating set S of $G(A)$ such that S contains an arc x of $N[x_0]$ and $S \cap \overline{N}(x) = \emptyset$.*

Proof. (1) Let S be a minimum-weight total dominating set of $G(A)$ with minimum cardinality. Clearly, $S \cap N[x_0] \neq \emptyset$. There exists an arc $x \in S \cap N[x_0]$ such that x is not contained in any other arc of $S \cap N[x_0]$. Since every arc containing arc x is a neighbor of arc x, x is not contained in any other arc of S.

(2) Let S be a minimum-weight dominating set of $G(A)$ with minimum cardinality. By arguments similar to those for proving statement (1), there exists an arc x such that $x \in S \cap N[x_0]$ and arc x is not contained in any other arc of S. Then every arc of $S \cap \overline{N}(x)$ is contained in arc x. Thus $S - \overline{N}(x)$ is also a dominating set of $G(A)$. Since all weights of arcs are nonnegative, $w(S - \overline{N}(x)) \leq w(S)$. Since $|S - \overline{N}(x)| < |S|$ if $S \cap \overline{N}(x) \neq \emptyset$, we have that $S \cap \overline{N}(x) = \emptyset$. Otherwise, it contradicts the assumption that S is a minimum-weight dominating set with minimum cardinality.

(3) This statement can be proved by arguments similar to those for proving statement (2). ∎

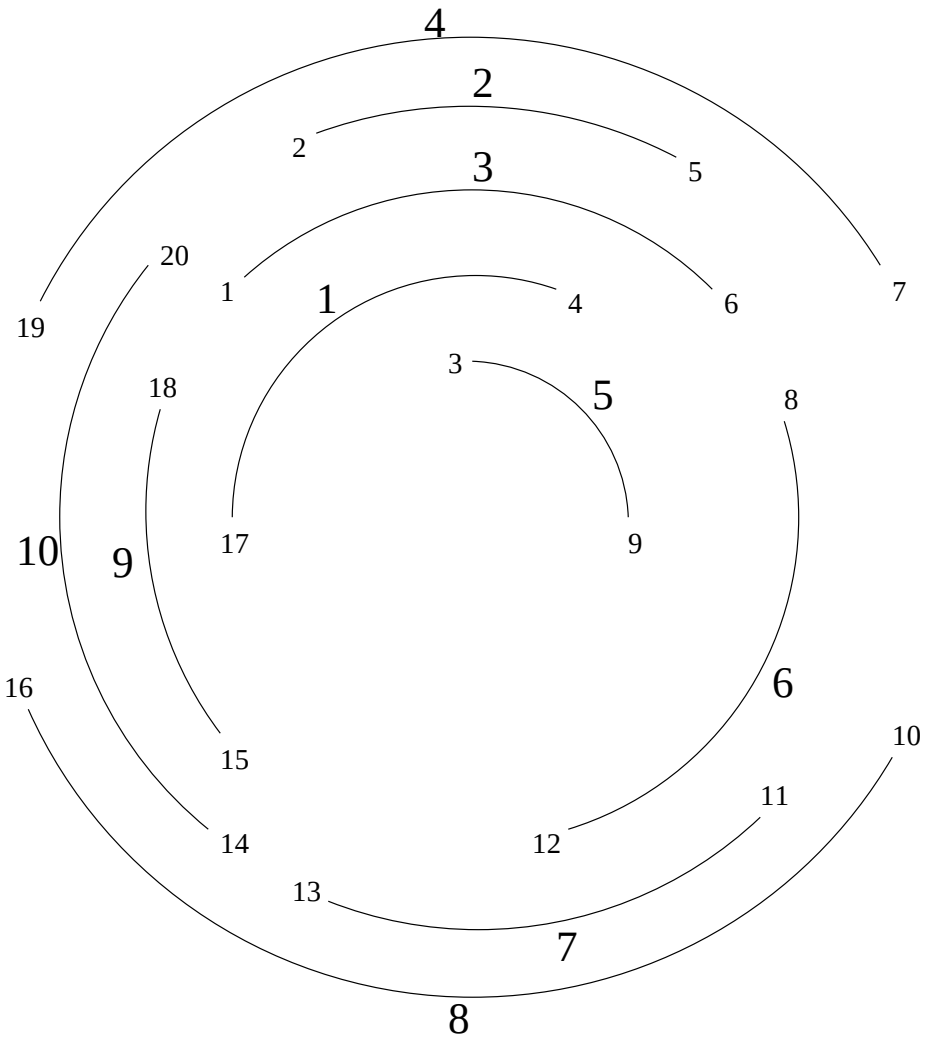

FIG. 2. *A set A of ten arcs.*

Following Lemma 3.2, we define the following:

$D(x) = \{S : S$ is a dominating set of $G(A)$, $x \in S$, and $S \cap \overline{N}(x) = \emptyset\}$,

$CD(x) = \{S : S$ is a connected dominating set of $G(A)$, $x \in S$, and $S \cap \overline{N}(x) = \emptyset\}$, and

$TD(x) = \{S : S$ is a total dominating set of $G(A)$, $x \in S$, x is not contained in any other arc of S$\}$.

For simplicity, let $MD(x) = \text{Min}(D(x))$, $MCD(x) = \text{Min}(CD(x))$, and $MTD(x) = \text{Min}(TD(x))$. By the approach similar to that for independent domination, we can find a minimum-weight dominating set (respectively, connected dominating set, total dominating set) of $G(A)$ given a set A of sorted arcs with nonnegative weights as follows: choosing an arc x_0 of minimum degree and letting $N[x_0] = \{x_0, x_1, x_2, \ldots, x_d\}$ where d is the minimum degree of $G(A)$, we find an $MD(x_k)$ (respectively, $MCD(x)$, $MTD(x)$) for each arc x_k of $N[x_0]$. The one with minimum weight is a minimum-

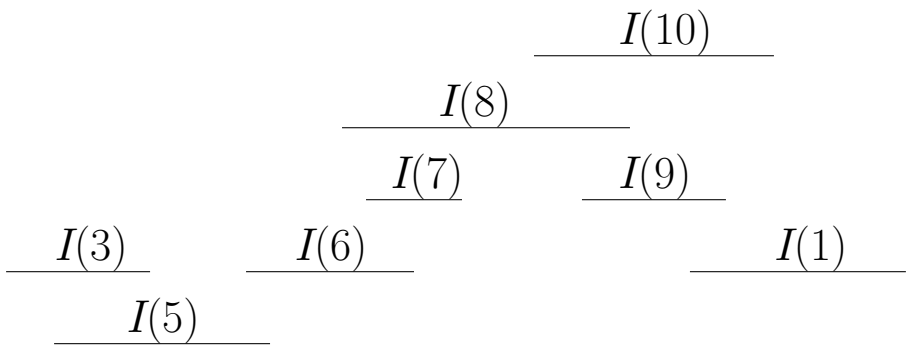

FIG. 3. *The set $I(A_P(3))$ of intervals of the set A of arcs shown in Figure 2.*

weight dominating set (respectively, connected dominating set, total dominating set) of $G(A)$. If $MD(x)$ (respectively, $MCD(x)$, $MTD(x)$) can be found in $O(n)$ time, then a minimum-weight dominating set (respectively, connected dominating set, total dominating set) of $G(A)$ given a set A of sorted arcs with nonnegative weights can be found in $O(n+m)$ time since $O(n(d+1)) = O(n+m)$. In subsections 3.1, 3.2, and 3.3 we show how to find $MD(x)$, $MCD(x)$, and $MTD(x)$ in $O(n)$ time, respectively.

3.1. Domination. In the following, we will give an $O(n)$-time algorithm to find an $MD(x)$. By definition, if $S \in D(x)$, then S is a dominating set of $G(A_P(x))$. In computing $MD(x)$, we first map $A_P(x)$ to a set of intervals. The endpoints of arcs of $A_P(x)$ are numbered in clockwise order from 1 to $2|A_P(x)|$ starting from the head of arc x. Then for every arc $z \in A_R(x)$ we create an interval $I(z) = [h_z, t_z]$; for every arc $z \in N_L(x)$ we create an interval $I(z) = [h_z, t_z + 2|A_P(x)|]$. For Z, a subset of $A_P(x)$, let $I(Z)$ denote $\{I(z) : z \in Z\}$. The above mapping procedure can be done in $O(n)$ time since A is a set of sorted arcs. For example, for the set of ten arcs shown in Figure 2, the set $I(A_P(3))$ of intervals obtained by the above procedure is shown in Figure 3.

The following lemma can be verified easily by the above procedure.

LEMMA 3.3. (1) *$I(x)$ is the first interval of $I(A_P(x))$.*

(2) *For two arcs y and z of $A_P(x)$, arc y overlaps arc z if $I(y)$ overlaps $I(z)$.*

(3) *For $y, z \in A_R(x)$, arc y overlaps arc z if and only if $I(y)$ overlaps $I(z)$.*

(4) *For $y \in A_P(x)$ and $z \in A - N[x]$, arcs y and z overlap if and only if $I(y)$ overlaps $I(z)$.*

We observe that $I(S)$ is a PD set of $I(A_P(x))$ if $S \in D(x)$. Note that PD set was defined in section 2.

LEMMA 3.4. *Suppose $S \subseteq A_P(x)$. Then $S \in D(x)$ if and only if $I(S) \in PD(last(I(S)))$ of $G(I(A_P(x)))$ and $\max b(I(S)) > \max a(I(A - N(x)))$.*

Proof. Suppose $I(S) \in PD(last(I(S)))$ of $G(I(A_P(x)))$ and $\max b(I(S)) > \max a(I(A - N(x)))$. By definition, $I(S)$ dominates all intervals whose left endpoints are less than $\max b(I(S))$. Since $\max b(I(S)) > \max a(I(A - N(x)))$, $I(S)$ dominates $I(A - N(x))$. Because $I(x)$ is the first interval of $I(A_P(x))$, $x \in S$ by definition. By statement (2) of Lemma 3.3, S dominates $A - N(x)$ since $I(S)$ dominates $I(A - N(x))$. Clearly, x dominates $N[x]$ and hence S dominates A. Thus, $S \in D(x)$.

On the other hand, suppose $S \in D(x)$. By definition, $x \in S$ and $S \subseteq A_P(x)$. By statement (4) of Lemma 3.3, $I(S)$ dominates $I(A - N(x))$. Since $I(S)$ does not

dominate any interval whose left endpoint is greater than $\max b(I(S))$, $\max b(I(S)) > \max a(I(A - N(x))$. If $z \in N_R(x)$, then $I(z)$ and $I(x)$ overlap. If $z \in N_L(x)$ and $a_{I(z)} \leq \max b(I(S))$, then $I(z)$ is dominated by $last(I(S))$. Thus all intervals of $I(A_P(x))$ whose left endpoints are less than $\max b(I(S))$ are dominated by $I(S)$. This proves that $I(S) \in PD(last(I(S)))$. □

Lemma 3.4 prompts us to find $MD(x)$ by finding $\text{Min}(\{MPD(i) : b_i > \max a(I(A - N(x)))\})$ from $G(I(A_P(x)))$. By Lemma 2.6, this can be done in $O(n)$ time and space. Thus $MD(x)$ of $G(A)$ can be found an $O(n)$ time and space. This leads to the following theorem.

THEOREM 3.5. *Given a set A of sorted arcs, a minimum-weight dominating set of $G(A)$ can be found in $O(m + n)$ time and $O(n)$ space.*

3.2. Connected domination. In this section, we give an $O(n)$-time algorithm for computing $MCD(x)$. We say a set S of arcs covers the whole circle if every point on the circle is contained in an arc of S. Thus $CD(x)$ can be partitioned into two parts. One part, denoted by $CD_H(x)$, is the collection of those covering the whole circle; the other part, denoted by $CD_B(x)$, consists of those not covering the whole circle. Let $MCD_H(x) = \text{Min}(CD_H(x))$ and $MCD_B(x) = \text{Min}(CD_B(x))$. Clearly, $MCD(x) = \text{Min}(\{MCD_H(x), MCD_B(x)\})$. In the following, we first show how to compute $MCD_H(x)$ in $O(n)$ time and space.

By arguments similar to those for proving Lemma 3.4, we have the following lemma.

LEMMA 3.6. *Suppose $S \subseteq A_P(x)$ and $x \in S$. Then $S \in CD_H(x)$ if and only if $I(S) \in CPD(last(I(S)))$ of $G(I(A_P(x)))$ and $last(I(S)) \in I(N_L(x))$.*

Lemma 3.6 prompts us to find $MCD_H(x)$ by finding $\text{Min}(\{MCPD(i) : i \in I(N_L(x))\})$ from $G(I(A_P(x)))$. By Lemma 2.9, it can be found in $O(n)$ time and space. This leads to the following lemma.

LEMMA 3.7. *Given a set A of sorted arcs, an $MCD_H(x)$ of $G(A)$ can be found in $O(n)$ time and space.*

Next we show how to compute $MCD_B(x)$ in $O(n)$ time and space. For a subset S of A, where $S \neq \emptyset$ and $G(S)$ is connected but S does not cover the whole circle, there exist two arcs u and v of S; arcs u and v may be equivalent such that every arcs of S is contained in segment $[h_u, t_v]$ and every point on segment $[h_u, t_v]$ is contained in at least one arc of S. The head (respectively, tail) of arc u (respectively, v) is called the head (respectively, tail) of S and is denoted by $h(S)$ (respectively, $t(S)$). For example, let $S = \{1, 3, 5, 6\}$ be a subset of arcs shown in Figure 2. Clearly, $G(S)$ is connected and $h(S) = h_1$, $t(S) = t_6$. Suppose $S \in CD_B(x)$, $h(S) = h_u$, and $t(S) = t_v$. Let S_L and S_R denote the sets of arcs contained in segments $[h_u, t_x]$ and $[h_x, t_v]$, respectively. Both $G(S_R)$ and $G(S_L)$ are connected. Clearly, $h(S_R) = h_x$, $t(S_R) = t_v$, $h(S_L) = h_u$, and $t(S_L) = t_x$. For arc $u \in A_L(x)$, define $LCD(u)$ to be the collection of all subsets S's of $A_L(x)$ such that $G(S)$ is connected, and $h(S) = h_u$, $t(S) = t_x$. Similarly, for arc $v \in A_R(x)$, define $RCD(v)$ to be the collection of all subset S's of $A_R(x)$ such that $G(S)$ is connected, and $h(S) = h_x$, $t(S) = t_v$. By definition, if $S \in LCD(u)$ or $S \in RCD(v)$, then $x \in S$. Let $MLCD(u) = \text{Min}(LCD(u))$ and $MRCD(v) = \text{Min}(RCD(v))$. Note that $G(A_R(x))$ is an interval graph and $RCD(v)$ is equivalent to $CPD(v)$ defined in subsection 2.3. By Lemma 2.9, $MRCD(v)$ can be computed in $O(n)$ time for all $v \in A_R(x)$. By symmetric property, $MLCD(u)$ for all $u \in A_L(x)$ can be computed in $O(n)$ time too. Note that we label the endpoints of $A_P(x)$ in clockwise order from 1 to $2|A_P(x)|$ starting from the head of arc x. Suppose $S \in CD_B(x)$, $h(S) = h_u$, and $t(S) = t_v$. Then, $S_L \in LCD(u)$, $S_R \in RCD(v)$, and

no arc of A is contained in segment $[t_v, h_u]$. On the other hand, suppose $u \in A_L(x)$, $v \in A_R(x)$, $h_u > t_v$, and no arc of A is contained in segment $[t_v, h_u]$. If $S_1 \in LCD(u)$ and $S_2 \in RCD(v)$, then $S_1 \cup S_2 \in CD_B(x)$. For arc $u \in A_L(x)$, define $RA(u)$ to be the set of arcs of $A_R(x)$ that are contained in segment $[h_x, h_u]$ if $u \neq x$; and $RA(u) = A_R(x)$ otherwise. And define $\alpha(u) = \max\{h_w : w \in RA(u)\}$. Then for $u \in A_L - \{x\}$, $v \in A_R(x)$, and $t_v < h_u$, there does not exist any arc y such that $t_v < h_y < t_y < h_u$ if and only if $t_v > \alpha(u)$. For arc $v \in A_R(x)$, there does not exist any arc y contained in segment $[t_v, h_x]$ if and only if $t_v > \alpha(x)$. Let $CD_B(x, u) = \{S : S \in CD_B(x), h(S) = h_u\}$. Then we can verify the following four statements easily.

(1) If $u \in A_L(x) - \{x\}$, $S_1 \in LCD(u)$, and $S_2 \in RCD(v)$ where $\alpha(u) < t_v < h_u$, then $S_1 \cup S_2 \in CD_B(x, u)$.

(2) If $v \in A_R(x)$, $t_v > \alpha(x)$, and $S \in RCD(v)$, then $S \in CD_B(x, u)$.

(3) If $S \in CD_B(x, u)$ and $v = t(S)$ where $u \neq x$, then $S_L \in LCD(u)$, $S_R \in RCD(v)$, and $\alpha(u) < t_v < h_u$.

(4) If $S \in CD_B(x, x)$ and $v = t(S)$, then $S_L = \{x\} \in LCD(x)$, $S = S_R \in RCD(v)$, and $\alpha(x) < t_v$.

Let $MCD_B(x, u) = \text{Min}(CD_B(x, u))$. Then $MCD_B(x) = \text{Min}(\{MCD_B(x, u) : u \in A_L(x)\})$. By the above four statements, it is easy to see that $MCD_B(x, u) = MLCD(u) \cup \text{Min}(\{MRCD(w) : w \in A_R(x), \alpha(u) < t_w < h_u\})$ if $u \neq x$; and $MCD_B(x, x) = \text{Min}(\{MRCD(w) : w \in A_R(x), \alpha(x) < t_w\})$ otherwise. Let $MZ(x) = \text{Min}(\{MRCD(w) : w \in A_R(x), \alpha(x) < t_w\})$ and $MZ(u) = \text{Min}(\{MRCD(w) : w \in A_R(x), \alpha(u) < t_w < h_u\})$ for $u \in A_L(x) - \{x\}$. Then $MCD_B(x, u) = MLCD(u) \cup MZ(u)$ and $w(MCD_B(x, u)) = w(MZ(u)) + w(MLCD(u)) - w(x)$ for $u \in A_L(x)$.

In fact, the definition of $\alpha(u)$ is similar to that of $\max a(IFB(e))$ defined in subsection 2.1. Thus we can find an arc v for each arc $u \in A_L(x)$ such that $MZ(u) = MRCD(v)$ in $O(n)$ time by an algorithm similar to Algorithm MIDS. This algorithm scans endpoints of $A_P(x)$ in clockwise order starting from $t_x + 1$ to $2n$. It also maintains a list L of arcs in increasing order of their tails in the same way that Algorithm MIDS maintains a list L of intervals in increasing order of their right endpoints. If arc $v \in L$, then $\alpha(t_u) < t_v < h_u$ and $MRCD(\delta_L) = \text{Min}(\{MRCD(y) : y \in A_R(x), \alpha(t_u) < t_y < h_u\})$ right before the head of arc u is being visited. Details of the algorithm are in the following algorithm.

ALGORITHM MZ. Find an arc v for each arc $u \in A_L(x)$ such that $MZ(u) = MRCD(v)$.

Input. $A_P(x)$ and $w(MRCD(v))$ for all $v \in A_R(x)$.

Method.

1. Number endpoints of $A_P(x)$ from 1 to $2|A_P(x)|$ in clockwise order starting from the head of arc x;
   Number arcs of $A_P(x)$ from 1 to $|A_P(x)|$ in increasing order of their tails;
   $L = \{x\}$;
2. **for** $e = t_x + 1$ **to** $2|A_P(x)|$ **do**
3. **if** e is the head of arc u **then do**
4. $MZ(u) \leftarrow MRCD(\delta)$ where δ is the list head of L;
5. $w(MZ(u)) \leftarrow w(MRCD(\delta))$;
6. **else** e is the tail of arc u **do**
7. Delete all elements of L whose tails are less than h_u from the list head of L one by one;
8. **while** $L \neq \emptyset$ and $w(MRCD(\tau)) > w(MRCD(u))$**do**

9. Delete τ from L where τ is the list tail of L;
end while
10. Append u to the end of L;
end if else
end for
11. $MZ(x) \leftarrow MRCD(\delta)$;

The correctness of Algorithm MZ can be proved by arguments similar to those for proving Algorithm MIDS shown in section 2.1. It is easy to see that the running time of Algorithm MZ is $O(n)$. Thus we have the following lemma.

LEMMA 3.8. *$MCD(x)$ can be computed in $O(n)$ time.*

Since we can compute both $MCD_H(x)$ and $MCD_B(x)$ in $O(n)$ time, we can compute $MCD(x)$ in (n) time. Thus we have the following theorem.

THEOREM 3.9. *Given a set A of sorted arcs, a minimum-weight connected dominating set of $G(A)$ can be found in $O(m+n)$ time and $O(n)$ space.*

3.3. Total domination. In the following, we will focus on how to find $MTD(x)$ in $O(n)$ time given a set A of sorted arcs and an arc $x \in A$. Note that $TD(x)$ is the set of all total dominating sets of $G(A)$ containing arc x but no other arc containing arc x. Define

$TD_1(x) = \{S : S \in TD(x), S \cap (N_L(x) \cup N_R(x)) = \emptyset\}$,
$TD_2(x) = \{S : S \in TD(x), S \cap \overline{N}(x) = \emptyset, S \cap N_L(x) = \emptyset\}$,
$TD_3(x) = \{S : S \in TD(x), S \cap \overline{N}(x) = \emptyset, S \cap N_R(x) = \emptyset\}$,
$TD_4(x) = \{S : S \in TD(x), S \cap \overline{N}(x) = \emptyset, S$ covers the whole circle$\}$, and
$TD_5(x) = \{S : S \in TD(x), S \cap \overline{N}(x) = \emptyset, S \cap N_R(x) \neq \emptyset, S \cap N_L(x) \neq \emptyset, S$ does not cover the whole circle$\}$.

Let $MTD_i(x) = \text{Min}(TD_i(x))$ for $i = 1, 2, 3, 4$, and 5. Suppose $S \in TD(x)$, $S \cap (N_L(x) \cup N_R(x)) \neq \emptyset$, and $S \cap \overline{N}(x) \neq \emptyset$. By definition of $TD(x)$, all arcs of $S \cap \overline{N}(x)$ are contained in arc x. Thus $(S - \overline{N}(x))$ is still a total dominating set of $G(A)$ since $S \cap (N_L(x) \cup N_R(x)) \neq \emptyset$. Hence, $S - \overline{N}(x) \in \cup_{2 \leq i \leq 5} TD_i(x)$. Note that $w(S - \overline{N}(x)) \leq w(S)$ since all weights are nonnegative. In other words, there exists a set $S \in TD(x)$ such that $S \in \cup_{1 \leq i \leq 5} TD_i(x)$ and $w(S) = w(MTD(x))$. Thus we have the following lemma.

LEMMA 3.10. *$MTD(x) = \text{Min}(\{MTD_i(x) : 1 \leq i \leq 5\})$.*

The above lemma suggests that we find $MTD(x)$ by finding MTD_i for $i = 1, \ldots, 5$. It is easy to verify that $TD_4(x) = CD_H(x)$. Thus, $MTD_4(x)$ can be computed in $O(n)$ time by finding $MCD_H(x)$ which was discussed in the previous subsection. In the following, we show how to find $MTD_i(x)$ in $O(n)$ time for $i = 1, 2, 3, 5$. For the reader's convenience, we repeat the definition of $K(x)$ and $MK(x)$ for an interval x of I here: $K(x) = \{\{y\} : y \in I, y \neq x,\ y$ is contained in $x\}$ and $MK(x) = \text{Min}(K(x))$. We will generalize its definition to an arc x of A as follows: $K(x) = \{\{y\} : y \in A, y \neq x,\ y$ is contained in $x\}$ and $MK(x) = \text{Min}(K(x))$. Since $MK(z)$ for all arc $z \in A$ can be found in $O(n+m)$ time, in the following we assume that $MK(z)$ for all arc $z \in A$ are ready for use. To find $MTD_1(x)$, we need the following lemma.

LEMMA 3.11. *The following two statements are true.*

(1) *Suppose S is a total dominating set of $G(A - N[x])$ and y is an arc contained in arc x. Then $\{x, y\} \cup S \in TD_1(x)$.*

(2) *Suppose $S \in TD_1(x)$; then $S - N[x]$ is a total dominating set of $G(A - N[x])$.*

Proof. The lemma is proved by definition. □

By Lemma 3.11, it is easy to see that $\{x\} \cup MK(x) \cup S$ is an $MTD_1(x)$ if S is a minimum-weight total dominating set of $G(A-N[x])$. Since $G(A-N[x])$ is an interval graph, by Theorem 2.13 a minimum-weight total dominating set of $G(A-N[x])$ can be computed in $O(n)$ time since $MK(z)$'s of all arc $z \in A - N[x]$ are ready for use. Hence $MTD_1(x)$ can be found in $O(n)$ time.

In the following, we show how to find $MTD_2(x)$. It is easy to see that $S \subseteq A_R(x)$ if $S \in TD_2(x)$. Clearly, $G(A_R(x))$ is an interval graph. For simplicity, arcs of $A_R(x)$ are considered as intervals in the following lemma where the head and tail of an arc are considered as the left endpoint and right endpoint of its corresponding interval, respectively. Note that $\max a(A_R(x))$ denotes the largest left endpoint of intervals in $A_R(x)$. Also we can see that interval x is the first interval of $A_R(x)$.

LEMMA 3.12. *Suppose $S \subseteq A$. Then $S \in TD_2(x)$ if and only if $S \in TPD(last(S))$ of $G(A_R(x))$ and $b_{last(S)} > \max a(A_R(x))$.*

Proof. Suppose $S \in TD_2(x)$. By definition, $S \subseteq A_R(x)$. Obviously, S is a total dominating set of $G(A_R(x))$ and $x \in S$. Thus, $S \in TPD(last(S))$ and $b_{last(S)} > \max a(A_R(x))$. On the other hand, suppose $S \in TPD(last(S))$ of $G(A_R(x))$ and $b_{last(S)} > \max a(A_R(x))$. Clearly, S is a total dominating set of $G(A_R(x))$, $S \subseteq A_R(x)$, and $x \in S$. Since arc x dominates $N[x]$, S is a total dominating set of $G(A)$. Hence $S \in TD_2(x)$. □

The above lemma suggests that we find $MTD_2(x)$ by finding $\mathrm{Min}(\{MTPD(i) : i \in A_R(x), b_i > \max a(A_R(x))\}$ from $G(A_R(x))$. By Lemma 2.12, it can be done in $O(n)$ time if $MK(z)$'s are known in advance for all $z \in A_R(x)$. Thus $MTD_2(x)$ can be found in $O(n)$ time. By symmetric property, $MTD_3(x)$ can be found in $O(n)$ time in the same way.

In the following, we show how to find $MTD_5(x)$ by using the same technique for computing $MCD_B(x)$. If $S \in TD_5(x)$, then there exists an arc u of S such that h_u is not contained in any other arc of S. Apparently, $u \neq x$. Define $TD_5(x,u) = \{S : S \in TD_5(x), u \in S$, h_u is not contained in any other arc of $S\}$. Let $MTD_5(x,u) = \mathrm{Min}(TD_5(x,u))$. Then, $MTD_5(x) = \mathrm{Min}(\{MTD_5(x,u) : u \in A_L - \{x\}\})$. The definition of $TD_5(x,u)$ is similar to that of $CD_B(x,u)$ defined in the previous subsection. For arc $u \in A_L(x) - \{x\}$, define $LTD(u)$ to be the collection of all subsets S's of $A_L(x)$ such that $x, u \in S$, $G(S)$ has no isolated vertices, all arcs of S are contained in segment $[h_u, t_x]$, and S dominates all arcs that overlap segment $[h_u, t_x]$. Similarly, for arc $v \in A_R(x) - \{x\}$, define $RTD(v)$ to be the collection of all subsets S's of $A_R(x)$ such that $x, v \in S$, $G(S)$ has no isolated vertices, all arcs of S are contained in segment $[h_x, t_v]$, and S dominates all arcs that overlap segment $[h_x, t_v]$. Let $MLTD(u) = \mathrm{Min}(LTD(u))$ and $MRTD(v) = \mathrm{Min}(RTD(v))$. Note that $G(A_R(x))$ is an interval graph and $RTD(v)$ is equivalent $TPD(v)$. By Lemma 2.12, $MRTD(v)$ for all $v \in A_R(x) - \{x\}$ can be computed in $O(n)$ time and space. By symmetric property, $MLTD(u)$ for all $u \in A_L(x) - \{x\}$ can be computed in $O(n)$ time and space too. Note that we number the endpoints of arcs of $A_P(x)$ from 1 to $2|A_P(x)|$ starting from the head of arc x and number the arcs of $A_P(x)$ from 1 to $|A_P(x)|$ starting from arc x in increasing order of their tails. Suppose $S \in TD_5(x)$. Since S does not cover the whole circle, there exist two arcs u and v of S such that $u \in A_L(x) - \{x\}$, $v \in A_R(x) - \{x\}$, $h_u > t_x$, and all arcs of S are contained in segment $[h_u, t_v]$. Let $S_L(u)$ and $S_R(v)$ denote the set of arcs of S contained in segments $[h_u, t_x]$ and $[h_x, t_v]$, respectively. Then we observe that $S_L(u) \in LTD(u)$ and $S_R(v) \in RTD(v)$, and $\alpha(u) < t_v < h_u$. Note that $\alpha(u)$ was defined in the previous subsection. If $u \in A_L(x) - \{x\}$, $S_1 \in LTD(u)$, $v \in A_R(x) - \{x\}$, and $S_2 \in RTD(v)$ where $\alpha(u) < t_v < h(u)$, then $S_1 \cup S_2 \in TD_5(x)$

TABLE 1

	Interval graphs		*Circular-arc graphs*	
	Previous results	New results	Previous results	New results
WIDP	$O(n+m)$	$O(n)$		$O(n+m)$
WDP	$O(n \log n)$ or $O(n+m)$	$O(n)$	$O(n^2 \log n)$	$O(n+m)$
WCDP	$O(n+m)$	$O(n)$		$O(n+m)$
WTDP	$O(n \log n)$ or $O(n+m)$	$O(n \log \log n)$	$O(n^3)$	$O(n+m)$

since $S_1 \cup S_2$ dominates all arcs overlapping segment $[h_u, t_v]$ and there does not exist any arc y such that $t_v < h_y < t_y < h(u)$.

By the above discussions, we have the following lemma.

LEMMA 3.13. *Suppose S is a subset of A and $x \in S$. $S \in TD_5(x,u)$ if and only if there exists an arc v of S such that $S_L(u) \in LCD(u)$, $S_R(v) \in RCD(v)$, and $\alpha(u) < t_v < h(u)$.*

Following the above lemma, we have that $MTD_5(x,u) = MLTD(u) \cup \text{Min}(\{MRTD(v) : v \in A_R(x) - \{x\}, \alpha(u) < t_v < h(u)\})$. Let $MT(u) = \text{Min}(\{MRTD(v) : v \in A_R(x) - \{x\},\ \alpha(u) < t_v < h_u\})$. Thus, $MTD_5(x,u) = MLTD(u) \cup MT(u)$ and $w(MTD_5(x,u)) = w(MLTD(u)) + w(MT(u)) - w(x)$.

We can find an arc $v \in A_R(x)$ such that $MT(u) = MRTD(v)$ for all $u \in A_L(x) - \{x\}$ in $O(n)$ time by an algorithm similar to Algorithm MZ. We omit this algorithm to save space. Then, $w(MTD_5(x,u))$ for all $u \in A_L(x)$ can be computed in $O(n)$ time. Thus, $MTD_5(x)$ can be computed in $O(n)$ time.

We have shown that $MTD_i(x)$ can be computed in $O(n)$ time for $1 \le i \le 5$ excluding the time for computing $MK(z)$ for all $z \in A$. Note that $MK(z)$'s for all $z \in A$ can be computed in $O(n+m)$ time. Thus, a minimum-weight total dominating set of $G(A)$ can be computed in $O(dn) + O(n+m) = O(n+m)$ time. Hence we have the following theorem.

THEOREM 3.14. *Given a set A of sorted arcs, the minimum-weight total dominating set of $G(A)$ can be found in $O(m+n)$ time and $O(n)$ space.*

4. Concluding remarks. In this paper we have presented efficient algorithms to solve the minimum-weight domination problem (WDP) and its three variations, i.e., the minimum-weight independent, connected, and total domination problems (abbreviated by WIDP, WCDP, and WTDP, respectively), on interval and circular-arc graphs. The results of this paper are summarized in Table 1.

It remains an open question whether we can compute a minimum weight total dominating set for a weighted interval graph $G(I)$ of a set of sorted intervals I in $O(n)$ time.

Acknowledgments. The author is grateful to the referees whose extensive comments have led to tremendous improvements in the presentation of the paper.

COMPUTING THE LOCAL CONSENSUS OF TREES*

SAMPATH KANNAN†, TANDY WARNOW†, AND SHIBU YOOSEPH†

Abstract. The inference of consensus from a set of evolutionary trees is a fundamental problem in a number of fields such as biology and historical linguistics, and many models for inferring this consensus have been proposed. In this paper we present a model for deriving what we call a *local consensus tree* T from a set of trees $\mathcal{T}$. The model we propose presumes a function f, called a *total local consensus function*, which determines for every triple A of species, the form that the local consensus tree should take on A. We show that all local consensus trees, when they exist, can be constructed in polynomial time and that many fundamental problems can be solved in linear time. We also consider *partial local consensus functions* and study optimization problems under this model. We present linear time algorithms for several variations. Finally we point out that the local consensus approach ties together many previous approaches to constructing consensus trees.

1. Introduction.

An *evolutionary tree* (also called a *phylogeny* or *phylogenetic tree*) for a species set S is a rooted tree with $|S| = n$ leaves labeled by distinct elements in S. Because evolutionary history is difficult to determine (it is both computationally difficult as most optimization problems in this area are *NP-hard* and scientifically difficult as well since a range of approaches appropriate to different types of data exist), a common approach to solving this problem is to apply many different algorithms to a given data set, or to different data sets representing the same species set, and then look for common elements from the set of trees which are returned.

There is extensive literature about inferring consensus from ordered sets of trees, with much attention paid to the properties of the rules for inferring the consensus. In this paper, we will make an explicit assumption that the consensus rule be *independent* of the ordering of the trees in the input; i.e., we will presume that the input to the consensus problem is an unordered multiset of evolutionary trees, each leaf-labelled by the elements in S. We call this input a *profile*, noting that in this paper the terminology is restricted in meaning as we have indicated.

Several consensus methods are described in the literature for deriving one tree from a profile of evolutionary trees. These methods include maximum agreement subtrees [16, 19, 13, 24, 14], strict consensus trees [4, 9], median trees (also known as majority trees) [5], compatibility trees [10, 11, 12], the Nelson tree [22], and the Adams consensus [1].

The algorithms for some of these are implemented in standard packages and are in use; most common, perhaps, are strict and majority consensus tree approaches.

†Department of Computer and Information Science, University of Pennsylvania, Philadelphia, PA 19104 (kannan@central.cis.upenn.edu, tandy@central.cis.upenn.edu, yooseph@saul.cis.upenn.edu).

One notion of the *information* content of an evolutionary tree is the degree of resolution indicated by the tree; this can be quantified in a number of ways, for example, by counting the number of internal nodes or the number of resolved triples[1] in the tree. This is because the most usual interpretation of an unresolved triple in an evolutionary tree is that the evolutionary history of that triple cannot be absolutely inferred from the data. Thus, for example, a completely resolved tree (i.e., a binary tree) asserts a hypothesis about the evolution of all triples of taxa, while the star (i.e., root with all taxa children of the root) does not assert any hypothesis about the evolution of any triple. One of the motivations for proposing this new model of consensus tree construction is the observation that on some data sets the strict and majority consensus trees may be fairly uninformative (i.e., be fairly unresolved).

In this paper, we propose a new model, called the *local consensus*. This model is based upon functions, called *local consensus functions*, for inferring the rooted topology of the homeomorphic subtree induced by triples of species. We will show that given any local consensus function, we can determine whether a tree (called the *local consensus tree*) consistent with the constraints implied by the local consensus function can be computed in polynomial time and that many of the natural forms of the local consensus can be computed in linear time. We also analyze optimization problems based upon partial local consensus rules and show that many of these can also be solved in polynomial time. We will show that this method unifies many of the previously favored approaches while providing greater flexibility to the biologists in the interpretation of the data. Furthermore, the local consensus trees produced are, in most cases, significantly more informative (in the sense of more refined; see the above discussion) than trees produced using the strict or majority consensus methods.

2. Preliminaries.

2.1. Trees. Let $S = \{s_1, s_2, \ldots, s_n\}$ be a set of species. An *evolutionary tree* for S (also known as a phylogenetic tree or, more simply, a phylogeny) is a rooted tree T with n leaves each labeled by a distinct element from S. The internal nodes denote ancestors of the species in S. For an arbitrary subset $S' \subset S$ we denote by $\mathbf{T}|\mathbf{S'}$ the homeomorphic subtree of T induced by the leaves in S'. In particular, for a specified triple $\{a, b, c\} \subset S$ we denote by $\mathbf{T}|\{\mathbf{a}, \mathbf{b}, \mathbf{c}\}$ the homeomorphic subtree of T induced by the leaves labeled by a, b, and c. This topology is completely determined by specifying the pair of species among a, b, and c whose least common ancestor (LCA) lies farthest away from the root. If (a, b) is this pair then we denote this by $((a, b), c)$, and T is said to be *resolved* on the triple a, b, c. If T is not binary it may happen that all three pairs of species have the same LCA. In this case we will say that a, b, c is *unresolved* in T and denote this topology by (a, b, c). In this paper, when we say a triple a, b, c is resolved, we mean that $T|\{a, b, c\}$ is one of $((a, b), c), ((a, c), b)$, or $((b, c), a)$.

For a *profile* P, which is defined by a multiset $\{T_1, T_2, \ldots, T_k\}$, we let $P|\{a, b, c\}$ denote the multiset $\{T_1|\{a, b, c\}, T_2|\{a, b, c\}, \ldots, T_k|\{a, b, c\}\}$.

Given a tree T containing nodes u, v, w, we let $lca_T(u, v, w)$ denote the LCA of u, v, and w in T. Also, we let $u \leq_T v$ denote that v is on the path from u to the root of T.

2.2. Local consensus functions, rules, and trees. Let $\mathcal{T}(a, b, c)$ denote the set of rooted subtrees on the leaf set $\{a, b, c\} \subseteq S$; thus $|\mathcal{T}(a, b, c)| = 4$, with three of

[1] See section 2.1 for definitions of a *resolved* triple and an *unresolved* triple.

the trees being resolved and one being the star (i.e., unresolved) tree on a, b, c.

A *local consensus function* is a function f which specifies the constraints for certain (i.e., perhaps not all) triples a, b, c of species. Let A be the set of all three element subsets of S. We define $f : A \to \cup_{\{a,b,c\} \in A} \mathcal{T}(a, b, c) \cup \{*\}$. When $f(X) = *$, for some $X = \{a, b, c\} \in A$, this indicates that the form of the triple a, b, c is *unconstrained*. When $f(X) \neq *\forall X \in A$, i.e., no triple is unconstrained, then f is said to be a *total* local consensus function. Otherwise, f is said to be a *partial* local consensus function.

A rooted tree T (if it exists) which is leaf-labelled by elements from S and which meets all the constraints implied by the local consensus function f is called an *f-local consensus tree*.[2] Note that when a triple a, b, c is set to be unconstrained by f, then $T|\{a, b, c\}$ can be any of the elements in $\mathcal{T}(a, b, c)$. Thus T is a tree such that for all triples $X \in A, T|X = f(X)$, if $f(X) \neq *$.

A local consensus function can be applied to a profile P. It is also possible for the local consensus function to define the form of the output triple based upon the forms the triple takes in the profile. Such local consensus functions are called *local consensus rules*. Let $\mathcal{M}$ be the set of all multisets of size k, where each element of a multiset belongs to $\mathcal{T}(a, b, c)$. A local consensus rule is a function $f : \mathcal{M} \to \mathcal{T}(a, b, c) \cup \{*\}$. If $f(X) = *$, for some $X \in \mathcal{M}$, then f is said to be a partial local consensus rule; otherwise, f is a total local consensus rule.

Given a profile P and a local consensus rule f, the f-local consensus tree (if it exists) is a rooted tree T such that for all triples $X \subseteq S, T|X = f(P|X)$, if $f(P|X) \neq *$.[3]

It is not the case that a local consensus tree necessarily exists for an arbitrary local consensus function (or rule) applied to an arbitrary input profile. Determining whether a local consensus tree exists, and constructing it when it does, is the subject of this paper.

The structure of the paper is as follows. In section 3, we will describe some general techniques for determining if a local consensus tree exists. In particular, we will give a polynomial time algorithm (based upon the algorithm in [3]), which can determine if a local consensus tree exists for an arbitrary local consensus function (or rule), and construct it when it does. We will also describe a class of natural local consensus rules and describe general techniques for constructing local consensus trees from such natural local consensus rules when they exist. In section 4, we then describe some specific natural local consensus rules and some fast algorithms for constructing the local consensus trees. In section 5, we consider optimization problems related to constructing local consensus trees and present efficient algorithms to solve some of these optimization problems. We conclude in section 6 with a discussion and suggestions for extensions.

3. Techniques.

3.1. General local consensus functions. For an arbitrary local consensus function f and an arbitrary profile of trees $\mathcal{T} = \{T_1, T_2, \ldots, T_k\}$, we can compute the constraint indicated by f for every triple of species a, b, c. This produces a set of $O(n^3)$ constraints on the consensus tree we wish to construct, where each constraint is a rooted tree for a triple on a species set a, b, c. This rooted tree may be resolved

[2] We will also sometimes refer to it simply as a local consensus tree.

[3] Note that f is defined the same on all triples $X \subseteq S$. As defined above, the triple labels a, b, c serve merely as place holders. The definition of a local consensus rule can easily be changed to accommodate a *different* rule for each triple.

(i.e., it may be of the form $((a,b)c)$) or it may be unresolved (i.e., of the form (a,b,c)). If there is a tree T meeting all these constraints, then T is the local consensus tree for f. Thus, we can reduce the problem of consensus tree construction for an arbitrary local consensus function to the problem of determining consistency of a set of rooted triples.

3.1.1. Rooted triple consistency. We present results related to this general problem.

THEOREM 3.1. *Determining if a tree T exists which meets a set of constraints (and constructing it if it does) can be solved in $O(pn \log n)$ time if the constraints include unresolved triples and otherwise can be solved in $O(pn)$ time, where p is the number of constraints defined by f.*

Proof. In [3], Aho et al. describe algorithms which determine if a family of constraints on LCA relations can be satisfied within a single rooted tree. We describe here the simple algorithm they give for the case where the constraints are given as rooted resolved triples $((x,y),z)$. For such input the algorithm works top-down figuring out the clusters at the children of the root before recursing. To do this the algorithm maintains disjoint sets. Initially all leaves are in singleton sets. For each rooted triple $((x,y),z)$ the algorithm unions the sets containing x and y to indicate that x and y must lie below the same child of the root. This algorithm never unions sets unless this is forced. Recursive calls include constraints that are on species entirely contained in the same component discovered in the previous call. If all the species are seen to be in the same component (either initially or during a recursive call), the algorithm determines that the constraints cannot be simultaneously satisfied. This simple algorithm has a worst-case behavior of $O(pn)$, where there are p LCA constraints and the underlying set S has n elements which will be leaves in the final tree. ∎

However, we can also solve the consistency problem faster than by using the Aho et al. algorithm. In [21], an algorithm is given for the problem addressed in [3] for the case where all the triples are resolved. In this case a faster algorithm can be obtained.

LEMMA 3.1 (Henzinger, King, and Warnow [21]). *Let $\mathcal{A}$ be a set of p resolved rooted triples on a leaf set S with $|S| = n$. We can determine in $\min\{O(p\sqrt{n}), O(p + n^{2.5})\}$ time whether a tree T exists such that $T|\{a,b,c\}$ is homeomorphic to the rooted triple(s) in A on $\{a,b,c\}$ (if such a triple exists in A).*

In the context of the rooted triple consistency problem, we also refer to the work of [8, 7], where the conditions necessary for a given set of triple constraints to define a tree are investigated.

3.2. Constructing local consensus trees in polynomial time. As a consequence of the results in the previous section, we can prove the following theorem.

THEOREM 3.2. *Let f be an arbitrary partial local consensus rule and $\mathcal{T}$ a set of k evolutionary trees on S with $|S| = n$.*

1. *If every triple which is not set to $*$ is defined to be resolved by f, then we can determine if the local consensus tree exists and construct it if it does in $O(kn^3)$ time.*
2. *If f defines some triples (which are not set to $*$) to be unresolved, then we can determine if the local consensus tree exists and construct it if it does in $O(kn^3 + n^4 \log n)$ time.*

Proof. Given f, $\mathcal{T}$, and a triple A, we can determine the form of $\mathcal{T}_f|A$ (for those triples A for which $T_f|A$ is not unconstrained) in $O(kn^3)$ time. If all the triples which are not set to unconstrained are defined to be resolved, then by Lemma 3.1 we can determine if the partial local consensus tree exists and construct it if it does, in

$O(n^{2.5} + p)$ time, where p is the number of constraints. The total time is therefore bounded by the cost of computing the triples. If some of the triples are unresolved then we can use Theorem 3.1 to get an $O(kn^3 + n^4 \log n)$ algorithm which will determine if the tree exists and construct it when it does. □

3.2.1. Constructing local consensus trees from total local consensus rules. While local consensus trees can be constructed in $O(kn^3)$ time from partial local consensus rules, local consensus trees can be computed even faster when the local consensus rule is *total*.

LEMMA 3.2 (Kannan, Lawler, and Warnow [18]). *Given an oracle $\mathcal{O}$ which can answer queries of* "What is the form of $T|\{a, b, c\}$ for a species set $\{a, b, c\}$?"*, we can construct in $O(n^2)$ time a tree T consistent with all the oracle queries (if it exists) and $O(rn \log n)$ time if the tree T has degree bounded by r.*

THEOREM 3.3. *Let f be a total local consensus rule. Then given a set of k rooted trees on n species, we can construct in $O(kn^2)$ time the f-local consensus tree $\mathcal{T}_f$ if it exists. If f always returns resolved subtrees, then we can compute $\mathcal{T}_f$ in $O(kn \log n)$ time.*

Proof. We can implement the oracle determining the form of the homeomorphic subtree of $\mathcal{T}_f$ on a triple a, b, c by first preprocessing the trees to answer LCA queries in constant time using [20]. Then, answering a query needs only $O(k)$ time. By [18], we need only $O(n^2)$ queries and $O(n^2)$ additional work for a total cost of $O(kn^2)$ in the general case. When $\mathcal{T}_f$ has degree bounded by r, we have total cost $O(krn \log n)$. If f always returns resolved subtrees, then $\mathcal{T}_f$ will be binary, so that the total cost is $O(kn \log n)$. □

Note, however, that this algorithm does not verify that the tree constructed is the local consensus tree; that is, it is possible that the constraints are inconsistent, so that no local consensus tree exists for that local consensus function (or rule). When it does, however, the tree constructed will equal the local consensus tree. Thus, when it can be shown that the local consensus tree *does* exist, then this method will necessarily produce the local consensus tree. In general, however, it will be necessary to verify that the constructed tree is the local consensus tree.

We have described two algorithms for inferring whether a local consensus tree exists for an arbitrary local consensus function (or rule). When the local consensus function (or rule) is total, if the local consensus tree exists, it can be constructed in $O(kn^2)$ time, where k is the number of trees in the profile and n is the number of leaves in each tree. However, the tree that results then needs to be verified to be the local consensus tree (and the fastest verification algorithm may still require $\Omega(kn^3)$ time). When the local consensus function (or rule) is partial, then a slower $O(kn^3)$ algorithm can be used, but it simultaneously constructs and verifies that the constructed tree is the local consensus tree.

3.3. Local consensus rules. A local consensus rule must handle essentially three types of situations for each pattern of subtrees in the profile for a triple a, b, c of species: *profile constant on a,b,c; profile compatible on a,b,c; profile incompatible on a,b,c.* The profile of trees may agree on that set a, b, c, and thus all reflect the same evolutionary history, or the trees may differ (in two different ways) on the triple. Depending upon the pattern of different subtrees, the local consensus rule may elect to constrain the form of the output or to leave the output unconstrained for that triple. However, we will only consider a local consensus rule to be natural if it is *conservative*, where by conservative we mean the following definition.

DEFINITION 3.1. *Let P be a profile of evolutionary trees and f be a local consensus rule. Then f is said to be* conservative *for every triple a, b, c, iff, $f(P|\{a, b, c\}) = ((a, b), c)$, then a, b, c is not resolved as $((a, c), b)$ or $((b, c), a)$ in any of the trees in P.*

Being conservative is obviously a natural requirement, since to enforce a topological constraint which is contradicted in the profile is clearly unmotivated.

We now describe the three general scenarios that may arise and discuss the possible constraints that may arise under natural local consensus rules.

Profile constant on a, b, c. If all the trees in the profile have the same form on a triple a, b, c, then we say the profile is *constant* on a, b, c. In this case, a natural local consensus rule should either require that the consensus tree have the same form as the trees in the profile, or it may leave the form unconstrained.

Profile compatible on a, b, c. If all the trees in the profile that have resolved subtrees for a, b, c have the *same* resolved form (i.e., no two trees in the profile resolve a, b, c differently), then the profile is said to be *compatible* on a, b, c. In this case, the natural local consensus rule may elect to leave the tree unconstrained for a, b, c; otherwise, it should constrain the output to either be the unique resolution indicated by the profile or should constrain it to be *unresolved*. In the first case, we call the local consensus rule *optimistic*, and in the second case we call the local consensus rule *pessimistic*.

Profile incompatible on a, b, c. The remaining case is where the profile contains trees which have different resolutions for a, b, c. In this case, a natural local consensus rule may elect to require the consensus tree to be unresolved, or it may select one of the resolutions represented in the profile[4] (perhaps selecting the resolution with the plurality representation), or it may not constrain the output at all.

A local consensus rule can be defined by deciding how it will respond to each of the different situations that can arise. Thus, for example, a natural local consensus rule may require that when the profile is constant on a, b, c, then the output tree is constrained to have that same form, and it may elect to be optimistic in the presence of compatible forms on a, b, c but may leave unconstrained any triple for which the profile is incompatible.

In all of our following discussions, we restrict ourselves to profiles of two trees. The techniques and most observations can be generalized.

4. Specific total local consensus rules. As examples of natural local consensus rules, we will define two total local consensus rules: the *optimistic local consensus (OLC) rule* and the *pessimistic local consensus (PLC) rule*. These are not the only natural local consensus rules that are worthy of study, but the techniques used for constructing local consensus trees for these rules are indicative of general approaches for greatly speeding up the construction and verification phases used in the previous section.

When the trees are not necessarily binary, the local consensus rule may encounter triples for which the profile is not constant but is nevertheless compatible. Because a total local consensus rule must constrain the form of each triple for the consensus tree, it must determine whether to require that the rooted triple be resolved or unresolved. This decision is based upon the interpretation of an unresolved triple, which can be made in one of two ways: *any resolution of the three-way split is possible* or *the unresolved triple indicates a three-way speciation event*. If the local consensus rule

[4]In this case the *conservative* nature of the rule need not be maintained.

chooses to interpret lack of resolution as being consistent with any resolution, then it will constrain the output to be resolved according to the unique resolution present in the profile, and otherwise it will constrain the output to be unresolved. The first type of total local consensus rule is said to be *optimistic* and the second type *pessimistic*.

We now define these two consensus rules.

DEFINITION 4.1. *Let T_1 and T_2 be two rooted trees on the same leaf set S. A rooted tree T is called the* OLC *of T_1 and T_2 iff for each triple a, b, c, $T|\{a, b, c\} = ((a, b), c)$ iff $T_i|\{a, b, c\} = ((a, b), c)$ and $T_j|\{a, b, c\} = ((a, b), c)$ or (a, b, c) for $\{i, j\} = \{1, 2\}$.*

DEFINITION 4.2. *Let T_1 and T_2 be two rooted trees on the same leaf set S. A rooted tree T is called the* PLC *of T_1 and T_2 iff for each triple a, b, c, $T|\{a, b, c\} = ((a, b), c)$ iff $T_1|\{a, b, c\} = T_2|\{a, b, c\} = ((a, b), c)$.*

In the next two subsections we discuss efficient algorithms for these rules. But first we give some basic and standard definitions.

DEFINITION 4.3. *Let T be a rooted tree with leaf set S. Given a node $v \in V(T)$, we denote by $\mathcal{L}(T_v)$ the set of leaves in the subtree T_v of T rooted at v. This is also called the cluster at v and is represented by α_v. The set $C(T) = \{\alpha_v : v \in V(T)\}$ is called the* cluster encoding of T.

Every rooted tree in which the leaves are labeled by S contains all singletons and the entire set S in $C(T)$; these clusters are called the *trivial clusters*. We define a *maximal* cluster to be the cluster defined by the child of the root. (Here we allow for a maximal cluster to be defined by a leaf also.)

We also define the notion of compatibility of a set of clusters.

DEFINITION 4.4. *A set A of clusters is said to be* compatible *iff there exists a tree T such that $C(T) = A$.*

The following proposition can be found in [17].

PROPOSITION 4.1. *A set A of clusters is compatible iff $\forall \alpha_i, \alpha_j \in A$, $\alpha_i \cap \alpha_j \in \{\alpha_i, \alpha_j, \emptyset\}$.*

We now state a theorem which will be used in the later sections.

THEOREM 4.1. *Let T_1 and T_2 be two rooted trees on the same leaf set S and let f be a conservative local consensus rule. If the f-local consensus tree T exists, then $C(T) \cup C(T_1)$ and $C(T) \cup C(T_2)$ are compatible sets.*

Proof. Suppose not and suppose without loss of generality that $C(T) \cup C(T_1)$ is not a compatible set. Then by Proposition 4.1, $\exists \alpha \in C(T)$ and $\beta \in C(T_1)$ such that $\alpha \cap \beta \notin \{\alpha, \beta, \emptyset\}$. Pick $a \in \alpha \cap \beta$, $b \in \alpha - \beta$ and $c \in \beta - \alpha$. The topology of the triple a, b, c in T_1 is $((a, c), b)$ while in T it is $((a, b), c)$. Since f is a conservative local consensus rule, this is impossible. ∎

4.1. OLC. In this section we look at the problem of finding the OLC tree of two trees defined in the previous section. Note that the OLC of two trees may not exist. See Figure 1 for an example.

4.1.1. Characterization of the OLC tree. The following lemma characterizes the OLC tree when it exists.

THEOREM 4.2. *Let T_1 and T_2 be two rooted trees on the same species set S. If the OLC tree T_{olc} exists, then $C(T_{olc}) = A$, where $A = \{\alpha^* \mid \alpha^* = \alpha_1 \cap \alpha_2$, where $\alpha_1 \in C(T_1)$ and $\alpha_2 \in C(T_2)$, and α^* is compatible with both $C(T_1)$ and $C(T_2)\}$.*

Proof. Pick any cluster $\alpha \in A$. If we look at any triple x, y, z with $x, y \in \alpha$ and $z \notin \alpha$, then this triple will be resolved as $((x, y), z)$ in one tree and will be either resolved the same or unresolved in the other tree. In either case, $\alpha \in C(T_{olc})$.

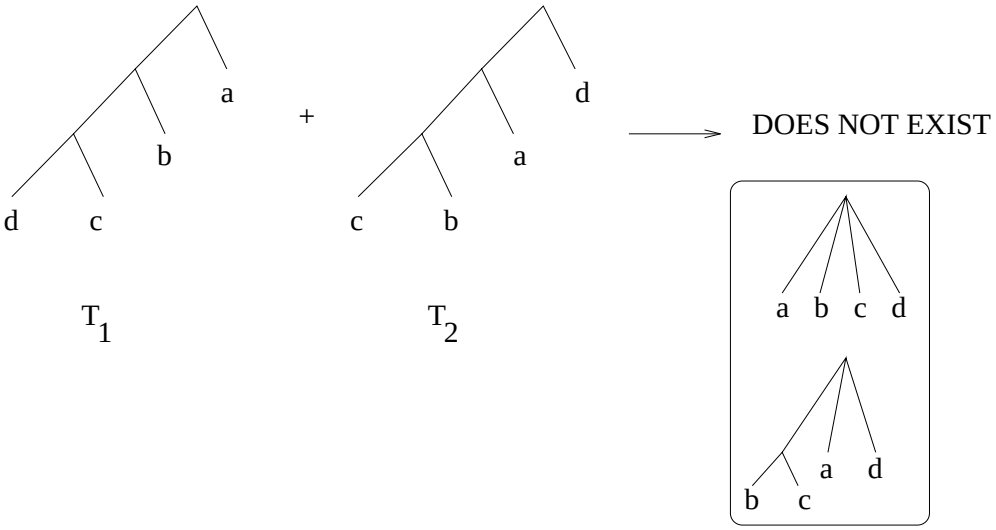

FIG. 1. *Example showing that the OLC need not always exist. The trees in the box are possible candidates, but they each fail to maintain the necessary topology for some triple.*

Conversely, pick any cluster $\alpha \notin A$. There are two cases here, namely, the case when α is not compatible with at least one of $C(T_1)$ and $C(T_2)$ and the case when α is compatible with both $C(T_1)$ and $C(T_2)$.

Now, when α is not compatible with at least one of $C(T_1)$ and $C(T_2)$, using Theorem 4.1, we observe that $\alpha \notin C(T_{olc})$.

For the second case, pick those smallest clusters $\alpha_1 \in C(T_1)$ and $\alpha_2 \in C(T_2)$ such that $\alpha \subseteq \alpha_1$ and $\alpha \subseteq \alpha_2$. (Note that the nodes v and u defining the clusters α_1 and α_2, respectively, are the LCAs in T_1 and T_2, respectively, of the species in α.) Since α_1 and α_2 are the smallest clusters in T_1 and T_2, respectively, containing α and since α is compatible with both $C(T_1)$ and $C(T_2)$, this implies that α is the union of clusters of at least two children of v and also the union of clusters of at least two children of u. Moreover, $\exists a, b \in \alpha$ such that $v = lca_{T_1}(a, b)$ and $u = lca_{T_2}(a, b)$. Furthermore, $\exists \beta \subseteq S, \beta \neq \emptyset$, such that $\alpha_1 \cap \alpha_2 = \alpha \cup \beta$. Thus we can pick a $c \in \beta$ and we have that $T_1|\{a, b, c\} = T_2|\{a, b, c\} = (a, b, c)$. But the topology given by having $\alpha \in C(T_{olc})$ is $((a, b), c)$. Thus $\alpha \notin C(T_{olc})$. □

4.1.2. Construction phase. Since the OLC rule is conservative, if the tree T_{olc} exists, then $C(T_{olc}) \cup C(T_1)$ is a compatible set of clusters, and hence there exists a tree T^* satisfying $C(T^*) = C(T_1) \cup C(T_{olc})$. If we can construct T^* by refining T_1, we can then reduce T^* by contracting all the unnecessary edges and thus obtain T_{olc}. This is the approach we will take.

Note that this approach breaks the construction into two stages: *refinement* and *contraction*.

DEFINITION 4.5. *We say that a tree T_1 is a refinement of tree T_2 if T_2 can be obtained from T_1 by a sequence of edge contractions.*

Refining T_1. The main objective is to refine T_1 so as to include all the clusters from T_{olc}. Before we explain how we do this precisely, we will introduce some notation and lemmas from previous works which enable us to do this efficiently.

DEFINITION 4.6. *Let v be an arbitrary node in a tree T with children $u_1, \ldots, u_k$. A* representative set *of v is any set $\{x_1, x_2, \ldots, x_k\}$ such that $x_i \in \alpha_{u_i}$. We denote by $rep(v)$ one such representative set.*

LEMMA 4.1. *If the OLC tree T_{olc} of trees T_1 and T_2 exists and $v \in T_1$, then $T_{olc}|rep(v)$ is isomorphic to $T_2|rep(v)$.*

Proof. The proof follows from the fact that $T_1|rep(v)$ is a star. □

DEFINITION 4.7. *Let v be a node in a tree T with children $u_1, u_2, \ldots, u_k$. Then $N(v)$ is the subtree induced by $\{v, u_1, u_2, \ldots, u_k\}$.*

We will do the refinement as follows. We will modify the tree T_1^*, where T_1^* is initialized to T_1. In a postorder fashion, for every $v \in V(T_1)$ with representative set $\{x_1, x_2, \ldots, x_k\}$, identify $v^* = lca_{T_1^*}(\alpha_v)$. It can be seen that v^* also has the same number of children as v (since the processing is done in a postorder fashion). Say these are $u_1, u_2, \ldots, u_k$. Replace the subtree $T(v^*)$, rooted at v^* in the following manner: we replace $N(v^*)$ by an isomorphic copy of $T_2|rep(v)$. Next, we replace x_i by the subtree of T_1^* rooted at u_i.

Let T^* be the tree that is produced after considering all the nodes in T_1.

THEOREM 4.3. *Let T_1, T_2 be given and suppose T_{olc} exists. Then the tree T^* that is produced from the algorithm described in the previous paragraph satisfies $C(T^*) = C(T_1) \cup C(T_{olc})$.*

Proof. Since $C(T_{olc}) \cup C(T_1)$ is compatible, all we need to show is that $T_{olc}|rep(v)$ cannot be a proper refinement of $T_2|rep(v)$. If it were, then for some $\{a, b, c\} \subseteq rep(v)$, $T_{olc}|\{a, b, c\}$ would be resolved while $T_2|\{a, b, c\}$ is unresolved. Since $\{a, b, c\} \subseteq rep(v)$, $T_1|\{a, b, c\}$ is also unresolved, forcing T_{olc} to be also unresolved. □

Note that we have reduced the problem of constructing T^* to the problem of discovering $T_2|rep(v)$ for each $v \in T_1$.

To have a linear time algorithm, however, we need to be able to compute $T_2|rep(v)$ quickly. We cite the following result from [18] which will be useful to us in this case.

LEMMA 4.2 (see [18]). *Given a left-to-right ordering of the leaves of a tree and the ability to determine the topology of any triple of leaves a, b, c in constant time, we can construct the tree in linear time.*

To use this lemma we need two things:

(1) we must be able to determine the topology of any triple in T_2 in $O(1)$ time and
(2) we must have for each node in T_1 an ordered representative set, where the ordering is consistent with the left-to-right ordering of the leaves in T_2.

To accomplish (1), we first preprocess T_2 for LCA queries. Then, to determine the topology for the triple a, b, c, we simply compare the LCAs of (a, b), (b, c), and (a, c). The second requirement is more challenging but can also be handled, as we now show.

Computing all ordered representative sets in $O(n)$ time.

- Initially all nodes in T_1 have empty labelings.
- For each $s \in S$, taken in the left-to-right ordering of the leaves in T_2, do the following steps:
  1. trace a path in T_1 from the leaf for s toward the root, until encountering either the root or a node which has already been labeled;
  2. append s to the ordered set for each such node in the path traced (including the first node encountered which has already been labeled).

Figure 2 shows an example of the computation just described.

Note that this computation takes $O(n)$ time since each node v is visited $O(\deg(v))$

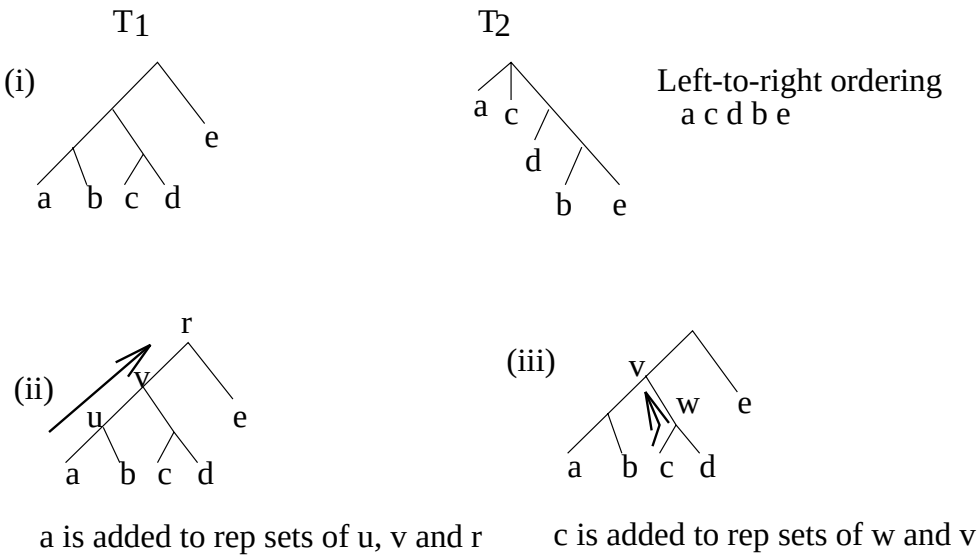

FIG. 2. *Example showing the computation of the representative sets of nodes in T_1 based on the left-to-right ordering of species in T_2.*

times and that the order produced is exactly as required. Thus, for each node $v \in V(T_1)$, we have defined a set of leaves such that each leaf is in a different subtree of v, every subtree of v is represented, and the order in which these leaves appear is the same as the left-to-right ordering in T_2.

We have thus proved Lemma 4.3.

LEMMA 4.3. *We can compute $T_2|rep(u)$ in $O(|rep(u)|)$ time.*

We therefore have the following theorem.

THEOREM 4.4. *Given T_1, T_2, then we can construct a tree T^* such that $C(T^*) = C(T_1) \cup C(T_{olc})$ whenever T_{olc} exists in $O(n)$ time.*

The rest of the task of constructing T_{olc} is in the contraction of unneeded edges.

Contracting T. Now that T^* satisfies $C(T^*) = C(T_1) \cup C(T_{olc})$, we can simply go through each edge in T^* and check if it needs to be kept or must be deleted. Note that edges that were added during the refinement phase are required and do not need to be checked. Therefore, we need only check the original tree edges. Let (u, v) be such an edge with $v = \text{parent}(u)$. From our representative sets for u and v we can easily choose three species a, b, c such that $lca(a, b) = u$ and $lca(b, c) = v$. If the topology of this triple in T_2 is resolved differently than $((a, b), c)$, then we know that edge (u, v) will have to be contracted; if on the other hand $T_2|\{a, b, c\}$ is either (a, b, c) or $((a, b), c)$ then (u, v) will have to be retained in any OLC tree.

OLC Construction Algorithm

Phase 0*: Preprocessing*

Make copies T_1' and T_2' of T_1 and T_2, respectively. For each node v in each tree T_i' $(i = 1, 2)$, compute ordered representative sets ordered by the left-to-right ordering in the other tree. Preprocess each tree T_i' to answer *lca* queries for leaves as well as internal nodes.

Phase I: *Refine* T_1'

Refine T_1' in a postorder fashion so that at the end $C(T_1') = C(T_1) \cup C(T_{olc})$ if T_{olc} exists.

Phase II: *Contract* T_1'

Contract edges $e \in E(T_1')$ such that c_e, the cluster below e, lies in $C(T_1) - C(T_{olc})$.

We have thus shown the following theorem.

Theorem 4.5. *The algorithm stated above constructs the OLC of two trees* T_1 *and* T_2 *if the OLC exists.*

Analysis of Running Time

Phase 0*: Preprocessing*

In [20], Harel and Tarjan give an $O(n)$ time algorithm for preprocessing trees to answer LCA queries in constant time. We have already shown that computing the ordered representative sets takes $O(n)$ time. Thus the preprocessing stage takes $O(n)$ time.

Phase I: *Refining* T_1'

This stage involves local refinements of T_1', and we have shown that the cost of refining around node v is $O(\deg(v))$. Summing over all nodes v we obtain $O(n)$ time.

Phase II: *Contracting edges*

This stage clearly takes only $O(n)$ time.

Theorem 4.6. *Construction of the optimistic local consensus tree can be done in linear time.*

4.1.3. Verification phase. We have identified a candidate optimistic local consensus tree. We now have to decide if this is really such a tree or that no such tree exists.

Lemma 4.4. *Let* T *be a tree on a leaf set* S*. Let* T^* *be obtained from* T *through a sequence of refinements followed by a sequence of edge contractions. Then there exists a function* $f : V(T) \to V(T^*)$ *such that for all* $v \in V(T)$*, there is a subset* S_v *of the children of* $f(v)$ *in* $V(T^*)$ *such that* $\alpha_v = \cup_{v' \in S_v} \alpha_{v'}$*.*

Proof. We define $f(v) = lca_{T^*}(\alpha_v)$. Clearly, $C(T^*) \cup C(T)$ is a compatible set of clusters. Therefore, there is a subset S_v of the children of $f(v)$ such that $\cup_{v' \in S_v} \alpha_{v'} = \alpha_v$. ∎

We take a slight detour and examine the verification of the OLC when the two input trees are both binary. In this case no triple will be unresolved.

Definition 4.8. *A* caterpillar *is a rooted binary tree with only one pair of sibling leaves.*

Given a leaf labeled caterpillar T' with root r and height h, there is a natural ordering induced by T' on its leaves. Let $g : S \to \{1, 2, \ldots, h\}$ be a function where $g(s)$ is the distance of s from r.

Then the species in S can be ordered in the increasing order as $a_1, a_2, \ldots, a_n$, where $a_i \in S$ such that $g(a_1) < g(a_2) \cdots < g(a_{n-1}) \leq g(a_n)$. (Note that the pair of sibling leaves have been arbitrarily ordered.)

DEFINITION 4.9. *Two caterpillars X and Y on the same leaf set are said to be* oppositely oriented *iff for all k, the k smallest elements of X are contained among the $k+1$ largest elements of Y and vice versa. See Figure* 3.

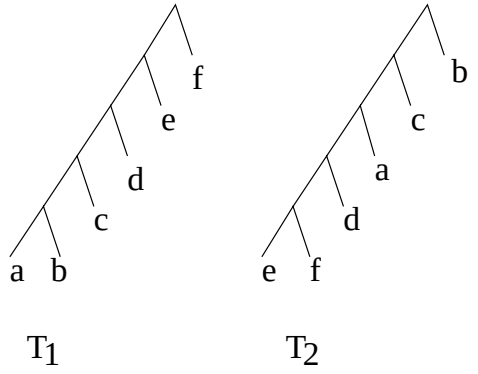

FIG. 3. *Example of oppositely oriented caterpillars.*

PROPOSITION 4.2. *Let T_1 and T_2 be two rooted binary trees on the same leaf set whose OLC is a star. If a, b is a sibling pair of leaves in T_1, then the LCA of a and b in T_2 must be the root of T_2.*

Proof. Suppose Proposition 4.2 is not true. Then there is a species c such that the LCA of (a, c) is above the LCA of (a, b) in T_2. Then $T_1|\{a, b, c\} = T_2|\{a, b, c\}$ and hence the OLC of T_1 and T_2 cannot be a star. □

LEMMA 4.5. *Suppose T_1 and T_2 are binary trees on the same leaf set and suppose that they each have at least five leaves. If their OLC tree is a star, then T_1 and T_2 must be caterpillars.*

Proof. Suppose for contradiction that T_1 is not a caterpillar. Then it has two pairs of sibling leaves (a, b) and (c, d). By the previous proposition each of these pairs must have the root as their LCA in T_2. Thus without loss of generality, a and c lie in the left subtree of the root of T_2, and b and d lie in the right subtree of the root of T_2.

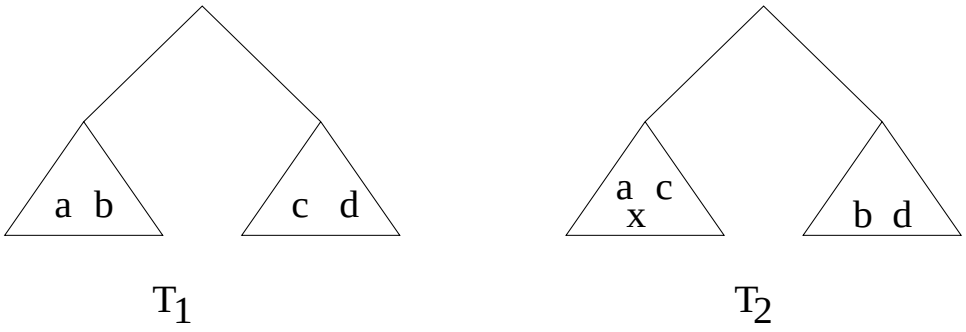

FIG. 4. *Topologies of T_1 and T_2 with respect to a, b, c, d, x.*

Let x be any other species besides a, b, c, and d (see Figure 4). Suppose without loss of generality that x lies in the left subtree of the root of T_2. We will consider the following two triples: x, a, d and x, c, b. In T_2 the topology of these triples will be $((x, a), d)$ and $((x, c), b)$, respectively.

We will show that T_1 agrees on at least one of these triples. There are two cases. If x lies in the left subtree of the root of T_1, then the topology of the triple x, a, d in T_1 is clearly $((x, a), d)$ and if x lies in the right subtree of the root of T_1, then the topology of the triple x, c, b in T_1 is $((x, c), b)$. Thus in either case there is a triple in T_1 which agrees with a triple in T_2, and the OLC cannot be a star. □

LEMMA 4.6. *Let T_1 and T_2 be two caterpillars on the same leaf set. Then the OLC of T_1 and T_2 is a star iff T_1 and T_2 are oppositely oriented caterpillars.*

Proof. Suppose the two caterpillars are oppositely oriented, i.e., they satisfy the two intersection conditions. Let x, y, z be any three leaves and let their indices in the ordering of the leaves of T_1 be $i < j < k$, respectively. Then the topology of x, y, and z in T_1 is $(x, (y, z))$. Looking at the $n - j$ smallest elements in T_2, this set must contain y or z but cannot contain x. Consequently, the topology of the triple in T_2 is not $(x, (y, z))$ and the star is a valid OLC.

Conversely, suppose that the two caterpillars do not satisfy the intersection conditions. Without loss of generality, suppose that there exists at least one k such that the k smallest elements of T_2 are not contained within the $k + 1$ largest elements of T_1. Pick the smallest such k. Say x is the leaf in T_2 with rank k and x does not belong to the set of $k+1$ largest elements of T_1. From the pigeonhole principle, there will exist at least two leaves of T_2 which have ranks greater than k but which are contained in the set of $k + 1$ largest elements of T_1. Suppose the two leaves are y and z. Then $T_1|\{x, y, z\} = T_2|\{x, y, z\} = (x, (y, z))$. This implies that the OLC cannot be a star. □

COROLLARY 4.1. *The OLC for two binary trees can be verified to be a star in linear time.*

Now we return to the general case of verifying the OLC of two trees.

LEMMA 4.7. *Suppose T is the OLC of T_1 and T_2 (on a leaf set S containing at least five species). Then T is a star iff either one of the following holds:*

1. *both T_1 and T_2 are oppositely oriented caterpillars or*
2. *both T_1 and T_2 are stars.*

Proof. The "if" direction is easy to see. We now assume that the OLC, T, is a star. If T_1 contains a triple a, b, c that is unresolved, T_2 must also be unresolved on a, b, c. Conversely whenever T_1 is resolved on a, b, c, T_2 must be (differently) resolved on a, b, c. Thus either both T_1 and T_2 are binary or both are not.

In the case that both T_1 and T_2 are binary, we appeal to the proofs of Lemmas 4.5 and 4.6 to argue that T_1 and T_2 must be oppositely oriented caterpillars.

If T_1 and T_2 are not binary, we will show that for any node v in T_1 with children $\{u_1, \ldots, u_k\}$, $k \geq 3$, there is a node v' in T_2 with children $\{u'_1, \ldots u'_k\}$ such that $\alpha_{u_i} = \alpha_{u'_i}$. Pick any three species a, b, c such that a, b, c is unresolved in T_1 and let $v = lca_{T_1}(a, b, c)$. Then a, b, c must be unresolved in T_2. Let $v' = lca_{T_2}(a, b, c)$. We claim that $\alpha_v = \alpha_{v'}$. To see why, suppose $\alpha_v \neq \alpha_{v'}$ and suppose $x \in \alpha_v, x \notin \alpha_{v'}$ with x being in the same subtree under v as a. Then $T_1|\{b, c, x\} = (b, c, x)$, whereas $T_2|\{b, c, x\} = ((b, c), x)$. This contradicts the assumption that T is a star. Thus $\alpha_v = \alpha_{v'}$.

Next, note that if x and y are under the same child of v in T_1 but under different children of v' in T_2, then there exists a z such that x, y, z is resolved in T_1 but unresolved in T_2. This would contradict the fact the T is a star. This establishes the claim.

This implies that if there is a nonbinary node v that is not the root of T_1, we can find two species a, b ($a \leq v, b \leq v$) and a species c, $c \not\leq v$ such $T_1|\{a, b, c\} = T_2|\{a, b, c\}$.

Thus the root must have three or more children in this case. But this means that if any cluster defined by a child of the root contains two or more species, then there is a triple on which T_1 and T_2 agree. Thus T_1 and T_2 must be stars. □

The verification proceeds as follows:

Phase 0

Suppose the tree constructed by refining T_1 and then contracting the edges in the resulting tree is T. We will do the same modification on T_2, i.e., refine T_2 using the information from T_1 and then contract the edges in the resulting tree as before. Call this tree $T^{'}$. Clearly, if T is not isomorphic to $T^{'}$, we can terminate and output that the OLC does not exist. This is because we know that a compatible set of clusters defines a unique tree and we know that the OLC, if it exists, is uniquely characterized.

Phase 1

If Phase 0 is successful, we then verify further. We compute an ordered representative set for every node w in $V(T)$. For each node w in T, do the following steps.

1. Check if the homeomorphic subtrees of T_1 and T_2 induced by $rep(w)$ are both stars or they are both oppositely oriented caterpillars. If they are neither of these, then terminate and output that the OLC does not exist.
2. Identify the parent of w, say w^*. Look at $rep(w^*)$ excluding the representative element which is below w. Call this set A. Identify the LCAs of $rep(w)$ in T_1 and T_2. Check if there is a species that belongs to A which lies below the LCA of $rep(w)$ in both T_1 or T_2. If so, terminate and output that the OLC does not exist.

Implementation of step 1 *of Phase* 1. Using the left-to-right ordering of the species in T_1, compute the ordered representative set *rep* at each node in T as shown in the previous section. For any $u \in V(T)$, to be able to quickly compute the homeomorphic subtree of T_2 induced by the species in $rep(u)$, we need to know the ordering of theses species as they appear in the left-to-right ordering of T_2. We associate with each u, a new *rep* set, $rep^*(u)$, which is the rearranged version of the species in $rep(u)$ according to their ordering in T_2. We define a function, $limit : S \rightarrow V(T)$, which specifies for each $s \in S$ the node $v \in V(T)$ closest to the root of T such that $s \in rep(v)$. The function *limit* together with the left-to-right ordering of the species in T_2 help in filling the rep^* sets, since s will belong to the rep^* sets of all nodes in the path from s to $limit(s)$. We first show how to compute $limit(s) \forall s \in S$ using algorithm $LIMIT$ and then we show how the rep^* sets are filled.

Initialization:
$limit(s) = +\infty \forall s \in S$.

PROCEDURE LIMIT
For each $v \in V(T)$ visited in a top-down traversal of T,
do {
  Identify $rep(v)$
  For each $s \in rep(v)$ such that $limit(s) = +\infty$
    set $limit(s) = v$
}enddo

Once $limit(s)$ has been identified for all $s \in S$, we proceed to compute $rep^*(u) \forall u \in V(T)$ as follows. Look at the left-to-right ordering of the species in T_2. Now, for each species s in the left-to-right order, we trace a path in T from the leaf for s toward

the root of T and add s to the rep^* set of each node encountered in this path. We terminate when we reach $limit(s)$.

Note that this process of identifying rep and rep^* has to be done only once.

Analysis of running time. The isomorphism test in *Phase* 0 can be performed in $O(n)$ using a simple modification of the tree-isomorphism testing algorithm in [2].

There is an $O(n)$ cost for preprocessing of T_1 and T_2 to answer LCA queries in *Phase* 1.

Our implementation of *step* 1 of *Phase* 1 involves a one-time $O(n)$ cost in preprocessing to identify rep and rep^* for each node in T. Then each time *step* 1 is called on a node $w \in V(T)$, an additional time of $O(\deg(rep(w)))$ is taken.

Exploiting that fact that T_1 and T_2 have been preprocessed to answer LCA queries, it can be seen that each *step* 2 of *Phase* 1 takes $O(\deg(w) + \deg(w^*))$.

Thus the total time taken in the verification phase is $O(n)$.

Correctness of our verification procedure. See Theorem 4.7.

THEOREM 4.7. *If T passes the above tests, then T is the OLC of T_1 and T_2.*

Proof. We need only show that T handles every triple properly. Each of the following cases is handled assuming T has passed the isomorphism test.

Case 1. If T passes the isomorphism test with T', then any triple a, b, c such that the two trees resolve a, b, c differently will be unresolved in T. This follows since T is created by refining and then contracting both T_1 and T_2, and these actions cannot take a resolved triple into a different resolution.

Case 2. This involves a triple a, b, c having the same topology $((a, b), c)$ in both T_1 and T_2. We claim that the first step of *Phase* 1 will pass only if the topology of this triple is $((a, b), c)$. To see why, suppose a, b, c is unresolved in T. (a, b, c cannot be resolved as $(a, (b, c))$ or $((a, c), b)$ in T.) Look at the nodes u and v, which are the LCAs of a, b in T_1 and T_2, respectively. The node w in T, which is the $lca(a, b, c)$, is also $lca(a, b)$ (since a, b, c is unresolved). We infer that $f(u) = w$, where f is the function as defined in Lemma 4.4. This is because any node above w will contain the species c and any node below w will not contain either a or b. By a similar argument, $f(v) = w$. Now, when we look at $rep(w)$ and compute the homeomorphic subtrees of T_1 and T_2 induced by $rep(w)$, in both of these induced trees, there will exist three species x, y, z such that x, y are both below u (and v) in T_1 (and T_2) and z is not in the character defined by u (and v). Thus in both the induced trees, the triple x, y, z will have the same topology $((x, y), z)$. That is, these induced trees will neither be both stars nor both oppositely oriented caterpillars. Thus the verification process will terminate and output that the OLC does not exist.

Case 3. This involves a triple a, b, c which is resolved as $((a, b), c)$ in one tree and unresolved in the other. The proof of this case essentially follows the lines of the proof of Case 2.

Case 4. This involves a triple a, b, c which is unresolved in both trees. We claim that the second step of *Phase* 1 will pass only if this triple is unresolved in T. To see why, suppose a, b, c is resolved as $((a, b), c)$ in T. Let $lca_T(a, b, c) = x$ and let $lca_T(a, b) = y$ and also suppose without loss of generality that x is the parent of y. Let y_1 be the child of y such that $a \in \alpha_{y_1}$ and let y_2 be the child of y such that $b \in \alpha_{y_2}$. Let $z \neq y$ be the child of x such that $c \in \alpha_z$.

Let $u = lca_{T_1}(a, b, c)$ and $v = lca_{T_2}(a, b, c)$.

We will look at functions f_1 and f_2 defined by Lemma 4.4 from $V(T)$ to $V(T_1)$ and $V(T_2)$, respectively. Clearly $f_1(y) = u$ and $f_2(y) = v$. Note that the cluster defined by any child of u can have a nonempty intersection with at most one of α_{y_1}

and α_{y_2}. This is similar for v. Thus any representatives chosen from α_{y_1} and α_{y_2}, respectively, have their LCA at u in T_1 and at v in T_2. However, $f_1(z) \leq_{T_1} u$ and $f_2(z) \leq_{T_2} v$. Thus any representative chosen from α_z will lie below u and v in T_1 and T_2, respectively, causing us to conclude that the OLC does not exist. □

4.2. PLC. Recall the definition of the PLC tree: *Let T_1 and T_2 be two rooted trees on the same leaf set S. A rooted tree T is called the* PLC *of T_1 and T_2 iff for each triple a, b, c, $T|\{a, b, c\} = ((a, b), c)$ iff $T_1|\{a, b, c\} = T_2|\{a, b, c\} = ((a, b), c)$.*

Just like the OLC, the PLC tree need not always exist either.

4.2.1. Characterization. The following theorem characterizes the PLC tree of two trees T_1 and T_2.

THEOREM 4.8. *Let T_1 and T_2 be two trees on the same leaf set S. If the PLC tree T_{plc} of T_1 and T_2 exists, then it is identically equal to T, where $C(T) = C(T_1) \cap C(T_2)$.*

Proof. Pick any cluster $\alpha \in C(T)$. Since α belongs to both the trees, if we look at any triple x, y, z with $x, y \in \alpha$ and $z \notin \alpha$, then this triple will have to be resolved as $((x, y), z)$. Thus $\alpha \in C(T_{plc})$.

Conversely, pick any cluster $\alpha \notin C(T)$. We have two subcases here.

1. α is not compatible with at least one of $C(T_1)$ or $C(T_2)$. In this case, from Theorem 4.1, $\alpha \notin C(T_{plc})$.
2. α is compatible with both $C(T_1)$ and $C(T_2)$. In this case, pick those nodes from T_1 and T_2 that define the smallest clusters containing α. We can pick a triple a, b, c such that $a \in \alpha, b \in \alpha, c \notin \alpha$ and this triple is unresolved in either T_1 or T_2. Thus $\alpha \notin C(T_{plc})$. □

4.3. Construction phase. By Theorem 4.8, the PLC tree, if it exists, is identically the strict consensus tree. Thus to construct the PLC tree, it suffices to use the $O(n)$ algorithm in [9] for the strict consensus tree.

4.3.1. Verification phase. Let T_1 and T_2 be the input trees, and let T be the strict consensus tree constructed using the algorithm in [9]. We want to be able to verify whether T is actually the PLC in the case that T is a star. If T_1 or T_2 is already a star then there is nothing to verify since T is the true PLC. So assume that this is not the case.

There are two cases which we will consider. The first is when either of T_1 or T_2 (say T_1) has at least two children of the root which are not leaves. The second case is when both T_1 and T_2 have exactly one child of the root which is not a leaf. Having made observations about these cases, we can apply a divide and conquer strategy as seen by the following lemma.

LEMMA 4.8. *Let T_1 and T_2 be rooted trees on the same leaf set and let α be a cluster in their intersection. Let T be the strict consensus tree of T_1 and T_2. Let e_1, e_2, and e be the edges in T_1, T_2, and T respectively, that are above the respective internal nodes which define the cluster α. Let a be a species in α. Then T is a PLC for T_1 and T_2 iff*

(1) *the subtree below e is a PLC for the subtrees below e_1 and e_2, and*
(2) *upon replacing the subtrees below e, e_1, and e_2 by a in T, T_1, and T_2, respectively, T is a PLC for T_1 and T_2.*

Proof. Clearly, if T is the PLC tree for T_1 and T_2 then conditions (1) and (2) will hold. Conversely, if (1) and (2) hold, but T is not the PLC tree for T_1 and T_2, then there is some triple a, b, c such that T incorrectly handles this triple. If all of a, b, c are below e then by condition (1), T handles a, b, c correctly. Similarly if at least two are above e, then by condition (2), T handles this triple correctly. It remains to show

that T handles all triples where exactly two of a, b, c are below and one is above the edge e. But then, since the cluster $\alpha \in C(T_1) \cap C(T_2) = C(T)$, in each of T_1, T_2, and T, we have $((a, b)c)$, so that T handles this triple properly. Thus T is a PLC for T_1 and T_2. □

Thus the verification proceeds by traversing T in a postorder fashion and at the end of each successful verification step replacing the subtree by a single element belonging to the cluster defined by the root of the subtree. We now discuss the details of each verification step.

LEMMA 4.9. *Suppose T_1 and T_2 are two trees on the same leaf set S with T_1 having at least two children of the root which are not leaves. Let $\alpha_1, \ldots, \alpha_l$ be the maximal clusters of T_1 and $\beta_1, \ldots, \beta_m$ be the maximal clusters of T_2. Then T, their PLC, is a star iff $\forall i, j\ |\alpha_i \cap \beta_j| \leq 1$.*

Proof. Suppose $\forall i, j\ |\alpha_i \cap \beta_j| \leq 1$. This means that $\forall x, y$, if $lca(x, y)$ in T_1 is below the root, then in T_2, $lca(x, y)$ is the root. Thus for any triple x, y, z, their topologies in T_1 and T_2 do not agree. Thus T is a star.

Suppose $\exists i, j\ |\alpha_i \cap \beta_j| > 1$. Thus α_i is defined by a node which is not a leaf. Look at an α_k, $k \neq i$, such that the node in T_1 defining α_k is not a leaf node. There are two cases to handle here. Either at least one species in α_k is not in β_j or all species in α_k are in β_j (i.e., $\alpha_k \subset \beta_j$).

In the former case, pick that species z that is in α_k but not in β_j. Also pick those two species x, y that are in $\alpha_i \cap \beta_j$. Both T_1 and T_2 agree on the triple x, y, z; namely this triple has topology $((x, y), z)$ in both the trees. Thus T cannot be a star.

In the latter case, since we know that $\beta_j \neq S$, we can pick two species x, y from α_k and another species z from $S - \beta_j$. In both T_1 and T_2, the topology of this triple is $((x, y), z)$. Thus T cannot be a star. □

Since each species belongs to at most one of these maximal clusters in each tree, this test can be done in linear time.

The following lemma handles the case when both T_1 and T_2 have exactly one child of the root which is not a leaf.

LEMMA 4.10. *Suppose T_1 and T_2 are two trees on the same leaf set S and T and their PLC is a star. Suppose both T_1 and T_2 have exactly one child of the root each which is not a leaf. Let $s_1, \ldots, s_k$ be leaves in T_1 which are children of the root. Let v be the LCA in T_2 of $s_1, \ldots, s_k$. Then every child of v contains at most one species $x \in S - \{s_1, \ldots, s_k\}$. Moreover, for any pair of species $x, y \in S - \{s_1, \ldots, s_k\}$, the LCA of x and y in T_2 lies on the path from v to the root.*

Proof. Suppose $\exists$ a child of v which contains at least two species from $S - \{s_1, \ldots, s_k\}$. Then by picking x, y such that they both lie under this child if v in T_2 and picking an s_i out of $s_1, \ldots s_k$ that lies under a different child of v, we find that both trees have the same topology for the triple x, y, s_i. Thus T cannot be a star. Furthermore, if $\exists x, y \in S - \{s_1, \ldots, s_k\}$ such that $lca(x, y)$ in T_2 does not lie on the path from v to the root, then the triple x, y, s_1 would have identical topologies in both trees and T wouldn't be a star. □

DEFINITION 4.10. *A rooted tree T is a* millipede *if the set of internal nodes of T defines a single path from the root to a leaf. See Figure* 5.

Let $S_1 = S - \{s_1, s_2, \ldots, s_k\}$. We have that $T_2|S_1$ is a millipede (say, T_2^*).

Let $u_1, \ldots, u_l$ be the children of the root in T_2^*, which are leaves. Look at $T_1|S_1$ (say, T_1^*). Either, T_1^* has one nonleaf child or it has at least two nonleaf children. In the former case, we can apply the previous lemma and infer that $T_1^*|(S_1 - \{u_1, \ldots, u_l\})$ will be a millipede. In the later case, we can apply Lemma 4.10 to check if the PLC is a star.

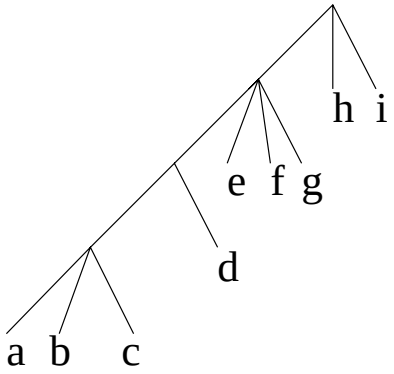

FIG. 5. *An example of a millipede.*

In the following subsection we will show how to verify if T is a star when both the input trees are millipedes.

4.3.2. Verification when both the input trees are millipedes. The proof of the following lemma is straightforward.

LEMMA 4.11. *Suppose T_1 and T_2 are two millipedes on the same leaf set S. Then their PLC T is a star iff there exists no triple such that both trees have the same resolved topologies on the triple.*

We now describe a linear time algorithm for verifying that T_1 and T_2 have no triple on which they have the same topology.

We define an ordering on the species in T_1 using the function $f : S \to \{1, \ldots, h\}$, where $f(s) =$ distance of s from the root of T_1 and h is the height of T_1.

In T_2, we can write S as the union of all the sets in the sequence $S_1, S_2, \ldots, S_k$, where k is the height of T_2 and each S_i contains exactly those species which are at a distance i from the root of T_2. Now, in each S_i replace each species s in this set with $f(s)$. Call this multiset of integers M_i. We thus get a sequence $M_1, M_2, \ldots, M_k$ of multisets.

DEFINITION 4.11. *We will say a triple of integers p, q, r is* special *if*

- $p < q$, $p < r$;
- $p \in M_{j_1}, q \in M_{j_2}, r \in M_{j_3}$, *with* $1 \leq j_1 < j_2 \leq k$ *and* $1 \leq j_1 < j_3 \leq k$.

We observe that the PLC of T_1 and T_2 is a star iff no special triple p, q, and r exists.

The following *CHECK_PLC* algorithm takes as input the sequence $M_1, M_2, \ldots, M_k$ and returns $FAIL$ if there exists a special triple of integers, and otherwise it returns $PASS$.

CHECK_PLC works by scanning the multiset M_i in the ith iteration. It makes use of three variables *global_min*, *local_min*, and *temp*. At the start of the ith iteration, *global_min* stores the smallest integer seen in the first $i - 1$ multisets. The variable *local_min* is used to store the smallest integer a such that $\exists b$ for which $a < b$ and $a \in M_j, b \in M_l$ with $1 \leq j < l < i$. (*local_min* is initialized to $+\infty$.) The variable *temp* is initialized to 0. As long as *temp* remains 0, *local_min* $= +\infty$. If *temp* is nonzero, then *local_min* stores a and *temp* stores some b for which the previously mentioned relationship between a and b holds. At the ith iteration, *CHECK_PLC* either returns $FAIL$ (if a special triple exists) or, if necessary, it modifies the variables *global_min*, *local_min*, and *temp* to hold their intended values for the first i multisets of the sequence.

The reasoning for storing these values at the start of the ith iteration is as follows. If $\exists p$ in some M_j, and $q, r \in M_i$ $(1 \leq j < i)$ such that p, q, r is a special triple, then *global_min* together with $q, r \in M_i$ are also a special triple since *global_min* $\leq p$. Similarly, if $\exists p$ in some M_j, $q \in M_l$, $r \in M_i$ $(1 \leq j < l < i)$, such that p, q, r is a special triple, then *local_min*, *temp*, and $r \in M_i$ are also a special triple.

We now describe *CHECK_PLC*.

Initialization:

$global\_min = Min(M_1)$
$local\_min = +\infty$
$temp = 0$.

The procedure outputs $FAIL$ (and terminates) if the PLC is not a star; it outputs $PASS$ otherwise.

PROCEDURE CHECK_PLC
For $2 \leq i \leq k$,
do {
If $temp = 0$, then *Step* 1, else *Step* 2.
Step 1
do {
Scan through M_i;
Identify $A = \{y | y \in M_i, global\_min < y\}$;
If $|A| \geq 2$, then output $FAIL$;
If $|A| = 1$, then set $temp = y$, where $y \in A$
$local\_min = global\_min$
$global\_min = Min\{global\_min, Min(M_i)\}$;
If $|A| = 0$, then set $global\_min = Min(M_i)$.
} enddo
Step 2
do {
Scan through M_i;
Identify $A = \{y | y \in M_i, global\_min < y\}$;
Identify $B = \{z | z \in M_i, local\_min < z\}$;
If either $|A| \geq 2$ or $|B| \geq 1$, then output $FAIL$;
Else
If $|A| = 1$ then
If $global\_min < Min(M_i)$, then set $local\_min = global\_min$
$temp = Min(M_i)$;
If $global\_min > Min(M_i)$, then set $local\_min = global\_min$
$temp = y$, where $y \in A$
$global\_min = Min(M_i)$;
If $|A| = 0$ then set $global\_min = Min(M_i)$.
} enddo
} enddo
Output $PASS$

Analysis of running time. *CHECK_PLC* runs in linear time since each M_i is scanned only a constant number of times.

THEOREM 4.9. *Algorithm* CHECK_PLC *is correct.*

Proof. By induction, observe that *Step* 1 is executed at the ith iteration if $\forall j, l, x$, where $1 \leq j < l < i$ and $x \in M_l$, $Min(M_j) \geq x$. It then follows that if *Step* 1 is executed at the ith iteration, then at the start of that iteration $temp = 0$,

$global\_min = Min(M_{i-1})$, and $local\_min = +\infty$. Thus, in this case $global\_min$ stores the smallest integer seen in the first $i-1$ multisets. Now, in the first i multisets, if any special triple p, q, r exists such that $p \in M_j$ $(j < i)$ and $q, r \in M_i$, then $CHECK\_PLC$ correctly outputs $FAIL$ since $global\_min \leq p$. Otherwise we have two cases, depending upon the value of A. If $|A| = 1$, then the variables $global\_min$, $temp$, and $local\_min$ are updated so that $global\_min$ holds the smallest value in the first i multisets. Also, $local\_min$ now correctly holds the smallest value a for which there exists a b (stored in $temp$) for which $a < b$ and $a \in M_j, b \in M_l$ with $1 \leq j < l < i$. In the other case $|A| = 0$, in which case $global\_min$ is updated to hold $Min(M_i)$ (which is the smallest value in the first i multisets).

Observe that once $temp$ is updated to store a nonzero value, it never stores a 0 again. Thus, once $temp$ is set to a nonzero value in iteration i', then from iteration $i'+1$ to iteration k, *Step* 2 is executed.

Assume that *Step* 2 is executed in some iteration i' and assume, inductively, that at the start of iteration i', $global\_min$ stores the smallest value in the first $i'-1$ multisets and $local\_min$ stores the smallest value a for which there exists a b (stored in $temp$) such that $a < b$ and $a \in M_j, b \in M_l$ with $1 \leq j < l < i'$. Then in iteration i', it can be easily seen that $CHECK\_PLC$ correctly outputs $FAIL$ if there exist a special triple p, q, r such that $p \in M_{i_1}, q \in M_{i_2}$ $(i_1 < i_2 < i')$, $r \in M_{i'}$ or $p \in M_{i_1}, q, r \in M_{i'}$ $(i_1 < i')$. Otherwise, for both the cases when $|A| = 1$ and $|A| = 0$, *Step* 2 ensures that after iteration i', $global\_min$ stores the smallest value in the first i' multisets and $local\_min$ stores the smallest value a for which there exists a b (stored in $temp$) such that $a < b$ and $a \in M_j, b \in M_l$ with $1 \leq j < l \leq i'$.

Using the above arguments, it can be seen that $CHECK\_PLC$ gives the correct output on any sequence of multisets. □

Thus we also have the following theorem.

THEOREM 4.10. *Given two millipedes T_1 and T_2, we can check if their PLC is a star in linear time.*

4.4. Summary. We have used three general techniques in constructing local consensus trees for these two total local consensus rules:

- we characterize the local consensus tree (that is, we define the set $C(T)$ of binary characters which encode the consensus tree T);
- we use the character encoding of the consensus tree if possible to construct the tree efficiently; and
- we verify that the constructed tree is the local consensus tree.

Some comments about the construction phase are in order. When working with conservative local consensus functions, assuming the local consensus tree T exists, it is possible to construct the local consensus tree T in two phases: a refinement phase in which one of the input trees T_i is refined to produce a tree T^* satisfying $C(T^*) = C(T_i) \cup C(T)$ and then edges are contracted in T^* to produce a tree T^{**} such that $C(T^{**}) = C(T)$.

5. Optimization problems.

5.1. Introduction. The local consensus rules we have seen so far are such that the output tree satisfying the constraints of a particular local consensus rule need not exist. Yet characterizing these rules and developing fast algorithms for them are important because if the consensus tree exists, then we can say something very concrete about it. The nonexistence of the consensus tree in all cases does motivate the need to look at the *optimization versions* of local consensus, where solutions

always exist. We will now describe some natural optimization problems for local consensus tree construction. In these problems, which we call *relaxed* versions, we will consider certain constraints to be absolutely required and let others be desirable but not required. Then we seek a tree meeting all the required constraints and as many of the desirable constraints as possible. We now define some obvious relaxed versions but note that many other versions are equally desirable.

Recall our discussion in section 3.3 regarding a profile being constant, compatible, and incompatible on a triple. The first optimization problem we consider is where we insist that all triples on which the profile is incompatible or is unresolved and constant are left unresolved, and then we seek to leave as resolved a maximal set of triples on which the profile is constant and resolved. This is relaxed version I (RV-I). The second problem is where we insist that all the triples, which the profile leaves as resolved and constant, be left resolved the same, and then we seek to leave a maximal set of the remaining triples as unresolved in the consensus tree. This is relaxed version II (RV-II). The third problem is where we insist that all triples on which the profile is incompatible or leaves unresolved and constant are left unresolved, and we seek to leave as resolved a maximal set of triples on which the profile is constant and resolved or is compatible. This is RV-III. In addition, RV-III also insists that all the resolved triples in the consensus tree be compatible with the profile. Finally, we look at an interesting rule LCR1, where we insist that all triples be left resolved on which the profile is constant and resolved or is compatible. This tries to capture the optimistic features of the OLC model. Unfortunately, the consensus tree need not always exist. We give a counterexample to show this.

5.2. Specific relaxed versions.

DEFINITION 5.1. *Let T_1 and T_2 be two rooted trees (not necessarily binary) on the same leaf set S. A rooted tree T is called an* RV-I *of T_1 and T_2 if whenever a triple a, b, c has differing topologies on T_1 and T_2, or both T_1 and T_2 leave a, b, c as unresolved, then that triple is unresolved in T and in addition T preserves the topology of a maximal set of triples which are resolved identically in T_1 and T_2.*

To prove the existence of an RV-I tree it is sufficient to show that there exists a tree where every triple on which T_1 and T_2 disagree is unresolved. The set of trees with this property can be partially ordered based on the set of triples (on which T_1 and T_2 agree) whose topology they preserve. Once this partial order is known to be nonempty, we have proved the existence of an RV-I since any maximal element in this partial order is such a consensus tree.

We note that if T has the star topology it leaves unresolved all triples on which T_1 and T_2 disagree. Hence the partial order is nonempty and the RV-I tree always exists. In section 5.3 we show that this tree is unique.

DEFINITION 5.2. *Let T_1 and T_2 be two rooted trees (not necessarily binary) on the same leaf set S. A rooted tree T is called an* RV-II *of T_1 and T_2 if T preserves the topology of all triples which are resolved identically in T_1 and T_2. In addition, T should leave unresolved a maximal set of triples on which T_1 and T_2 disagree or which are unresolved in both T_1 and T_2.*

Using an argument similar to the one used to prove the existence of an RV-I tree and noting that T_1 (or T_2) itself preserves the topology of all triples on which T_1 and T_2 agree, we conclude that the RV-II always exists. In section 5.4 we give an algorithm to construct the RV-II tree.

DEFINITION 5.3. *Let T_1 and T_2 be two rooted trees on the same leaf set S. Let T be a rooted tree on the same leaf set. Consider the following rules.*

Rule 1a. *If a triple a, b, c is resolved as $((a, b), c)$ in one tree and as $(a, (b, c))$ in the other, we require that it be unresolved.*

Rule 1b. *If a triple a, b, c is unresolved in both the trees, then we require that it be unresolved.*

Rule 2. *If a triple a, b, c is resolved as $((a, b), c)$ in one tree and is either resolved as $((a, b), c)$ or unresolved in the other tree, then we require it to be resolved as $((a, b), c)$.*

The tree T is called the relaxed version III (RV-III) *of T_1 and T_2 if*

1. *it always satisfies Rules* 1a *and* 1b *for triples;*
2. *it also satisfies Rule* 2 *for a maximal number of triples;*
3. *if a triple a, b, c is resolved as $((a, b), c)$ in T, then it is not resolved as $(a, (b, c))$ or $((a, c), b)$ in either T_1 or T_2.*

In section 5.5 we will show that an RV-III tree also always exists and is unique.

In the next subsections, we will look at the different relaxed versions in greater detail.

5.3. RV-I. In this subsection we will show that the RV-I of two rooted trees T_1 and T_2 is actually the strict consensus of these two trees.

THEOREM 5.1. *If T_1 and T_2 are two rooted trees, then their RV-*I *tree T always exists and is identically the strict consensus of T_1 and T_2.*

Proof. The existence of the RV-I tree T, was shown in section 5.2. Now we show that this tree is the strict consensus tree. Suppose there exists a triple a, b, c resolved differently in T_1 and T_2 as, say, $((a, b), c)$ and $(a, (b, c))$ (or (a, b, c)), respectively. Say the $lca_{T_1}(a, b) = u$ and $lca_{T_2}(b, c) = v$. Clearly, neither α_u nor α_v is in the strict consensus tree. Thus the strict consensus tree leaves unresolved any triple that has different topologies in T_1 and T_2.

Let T' be a tree in which for every triple a, b, c on which T_1 and T_2 differ, T' has an unresolved topology on this triple. Now suppose it is possible that T' contains a cluster that is not in $C(T_1) \cap C(T_2)$. Let α be this cluster and suppose without loss of generality that α is not a cluster of T_1. In T', for any pair of species $x, y \in \alpha$ and species $z \notin \alpha$ the topology has to be $((x, y), z)$. However, if this is also the case in T_1, then T_1 must also possess the cluster α contradicting our assumption. Thus there must exist a pair of species $x, y \in \alpha$ and a species $z \notin \alpha$ such that in T_1 their topology is not $((x, y), z)$. But this implies that T' cannot be an RV-I. Hence any candidate T' for an RV-I can only contain the clusters in the intersection of the cluster sets of T_1 and T_2.

If T' contains a proper subset of the clusters in the intersection of the sets of clusters of T_1 and T_2, then there exists a triple a, b, c on which T' has an unresolved topology while the strict consensus tree has a resolved topology that agrees with the topologies of T_1 and T_2. Hence the strict consensus of T_1 and T_2 is the RV-I tree of T_1 and T_2. □

As a consequence, the RV-I can be constructed in $O(n)$ time using the algorithm in [9], and there is no need to verify that the tree constructed is correct.

5.4. RV-II. In the RV-II problem we require that any triple on which the trees T_1 and T_2 agree must have its topology preserved in the consensus tree T. Further T should leave unresolved a maximal set of triples on which T_1 and T_2 disagree or both leave unresolved.

Previously we showed that the RV-II exists. We note that the RV-II tree is not unique. The construction of the RV-II can be accomplished by defining the set $A = \{((a, b), c) : T_1|\{a, b, c\} = T_2|\{a, b, c\} = ((a, b)c)\}$. This set of rooted triples can then be passed to the algorithm of Aho et al. [3], which computes a tree (if it exists)

having the required form on every triple in the set and also leaving a maximal set of additional triples outside that set unresolved. The algorithm in [3] takes $O(pn)$ time where $p = |A|$. Recall the proof of Theorem 3.1 for a description of the algorithm. Since in our case $p \in O(n^3)$, the use of the algorithm of [3] would result in a running time of $O(n^4)$. We will obtain a speedup to an $O(n^2)$ algorithm (which includes the verification) for the construction of the RV-II tree by using the fact that the tree necessarily exists.

5.4.1. An improved algorithm for RV-II. We will now describe an $O(n^2)$ time algorithm to construct an RV-II tree. We start by making a few observations about the RV-II tree T constructed by the algorithm of [3].

We will use α's to denote the clusters in T_1 and β's to denote the clusters in T_2. Suppose α and β are maximal clusters in T_1 and T_2, respectively, and suppose $\alpha \cup \beta \neq S$. Then we claim that $\alpha \cap \beta$ (if nonempty) will be a maximal cluster in T. This is because $\exists a \in S-(\alpha \cap \beta)$ such that $\forall x, y \in (\alpha \cap \beta)$, $T_1|\{x, y, a\} = T_2|\{x, y, a\} = ((x, y), a)$ and thus the elements of $(\alpha \cap \beta)$ all belong to one component of the graph which is constructed in the execution of the algorithm of [3]. Furthermore, $(\alpha \cap \beta)$ is exactly equal to one component of this graph since the algorithm never adds an edge between two nodes in the graph unless it is forced to and it can be seen that no element x in $(\alpha \cap \beta)$ is such that $\exists y, a \in S-(\alpha \cap \beta)$ with $T_1|\{x, y, a\} = T_2|\{x, y, a\} = ((x, y), a)$.

Thus, if $\alpha \cup \beta \neq S$, then $\alpha \cap \beta$ (if nonempty) is a maximal cluster in T. The case where $\alpha \cup \beta = S$, $\alpha \cap \beta \neq \emptyset$, can occur for at most one child of the root of T_1 and one child of the root of T_2 as the following lemma shows.

LEMMA 5.1. *Let T_1 and T_2 be two trees on the same leaf set S. Let $\alpha_1, \ldots, \alpha_k$ be the maximal clusters of T_1 and $\beta_1, \ldots, \beta_l$ be the maximal clusters of T_2. Then the case where $\alpha_i \cup \beta_j = S$, $\alpha_i \cap \beta_j \neq \emptyset$ can occur for at most one i and one j.*

Proof. Suppose not. Let $\alpha_i \cup \beta_j = S$, $\alpha_i \cap \beta_j \neq \emptyset$, $\alpha_{i^*} \cup \beta_{j^*} = S$, and $\alpha_{i^*} \cap \beta_{j^*} \neq \emptyset$, perforce with $i \neq i^*$ and $j \neq j^*$. Since $\alpha_i \cap \alpha_{i^*} = \emptyset$, we have that $\alpha_i \subseteq \beta_{j^*}$. But since $\alpha_i \cap \beta_j \neq \emptyset$, this implies that $\beta_j \cap \beta_{j^*} \neq \emptyset$. This is a contradiction since β_j and β_{j^*} are clusters defined by the children of the root and hence should be disjoint. □

Recall that the maximal clusters form a partition of the species set S (in each of T_1, T_2, and T). Also, from the above discussions we have that (i) $\alpha \cup \beta \neq S$ implies that $\alpha \cap \beta$ is a maximal cluster in T and (ii) there can be at most one case for which $\alpha \cup \beta = S$. These observations imply that in the case when $\alpha \cup \beta = S$, then $\alpha \cap \beta$ is the union of some maximal clusters of T.

With the above characterization a high-level description of the algorithm to construct T can be given as follows.

RV-II CONSTRUCTION ALGORITHM

1. For each pair of maximal clusters $\alpha \in C(T_1)$ and $\beta \in C(T_2)$ such that $\alpha \cap \beta \neq \emptyset$ and $\alpha \cup \beta \neq S$, recursively compute the tree on $\alpha \cap \beta$ and make its root a child of the root of T.
2. If there are maximal clusters α and β such that $\alpha \cup \beta = S$ but $\alpha \cap \beta \neq \emptyset$, compute the partition of $\alpha \cap \beta$; recursively compute the tree for each component of the partition and make the roots of these trees children of the root of T.

Computing the partition of $\alpha \cap \beta$ in step 2 is described together with the implementation details.

Implementation details and running time analysis. Note that this algorithm does not require an explicit verification of the constructed tree, since in fact we know that the tree exists and we are simply computing it by mimicking efficiently what the algorithm in [3] would create.

There are at most n recursive stages. We will show that each stage can be implemented in $O(n)$ time thereby proving the $O(n^2)$ bound.

To handle case 1 it is important not to waste time on empty intersections. So we consider each species in turn and label the intersection in which that this species lies. Thus we will identify at most n nonempty intersections. Let $\alpha \cap \beta$ be one such intersection. To recurse, we need to find homeomorphic subtrees of T_1 and T_2 that have $\alpha \cap \beta$ as the leaf set. We will show how to do this in time proportional to the number of leaves in $\alpha \cap \beta$.

Assume that T_1 and T_2 have been preprocessed for LCA queries. Also note that we know the left-to-right ordering of all leaves of T_1 as well as of T_2. Given the leaves in $\alpha \cap \beta$, their left-to-right ordering is also known and is the one induced by the overall left-to-right ordering. By Lemma 4.2 we can reconstruct the topology of the tree in linear time.

Thus case 1 can be handled in $O(n)$ time.

We now describe how to handle case 2 also in $O(n)$ time. We will construct a graph $G = (V, E)$ such that $V(G) = \alpha \cap \beta$. The edges will be added so that, finally, each component in G corresponds to a maximal cluster in the RV-II tree.

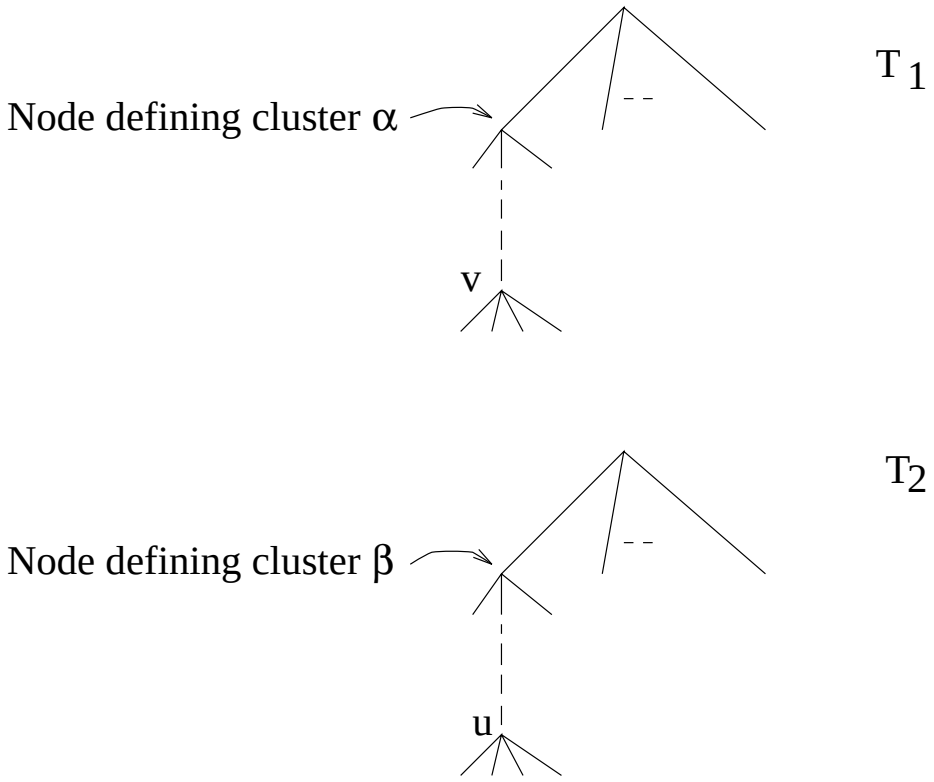

FIG. 6. *Figure showing nodes v and u.*

Identify the LCA, say, u, of the species in $S - \alpha$ in T_2 and similarly the LCA, say, v, of the species in $S - \beta$ in T_1. In T_2, u will be a descendent of the node defining β, and in T_1, v will be a descendent of the node defining α. See Figure 6. In T_1 let v_1 through v_p be the nodes in the path from the root to v, where $v_1 = root$ and $v_p = v$. Similarly, in T_2, let u_1 through u_q be the nodes in the path from the root to u, where

$u_1 = root$ and $u_q = u$. We will say that δ is a *special cluster* if for some v_i, $1 \le i \le p$ (or some u_j, $1 \le j \le q$), δ is a cluster defined by a child of v_i (or u_j) that is not on the path from the root to v (or u).

Let $\delta_1, \ldots, \delta_l$ be the special clusters in T_1 and let $\gamma_1, \ldots, \gamma_m$ be the special clusters in T_2. A pair of species $x, y \in (\alpha \cap \beta)$ will be in the same component of the graph G if $\exists z$ such that $T_1|\{x, y, z\} = T_2|\{x, y, z\} = ((x, y), z)$. There are two cases depending on whether $z \in (\alpha \cap \beta)$ or not. We will now describe how to handle these two cases: Cases 2a and 2b.

Case 2a [$z \notin (\alpha \cap \beta)$]. In this case, it suffices to look at all $\alpha \cap \gamma_i$ and $\beta \cap \delta_j$, and for each intersection put its elements in the same component of G. This is evident from the following lemma.

LEMMA 5.2. *Let α, β be maximal clusters of T_1 and T_2, respectively, such that $\alpha \cup \beta = S$ and let $x, y \in (\alpha \cap \beta)$. Then $\exists z \in S - (\alpha \cap \beta)$ such that $T_1|\{x, y, z\} = T_2|\{x, y, z\} = ((x, y), z)$ iff both x and y belong to some $\alpha \cap \gamma_i$ or $\beta \cap \delta_j$.*

Proof. Suppose $\exists z \in S - (\alpha \cap \beta)$ such that $T_1|\{x, y, z\} = T_2|\{x, y, z\} = ((x, y), z)$. Since $\alpha \cup \beta = S$, the only cases we have to consider are when z is in exactly one of α or β. So suppose $z \in \alpha, z \in S - \beta$ (the other case can be handled similarly). Then z belongs to a special cluster δ_i, which is defined by some child of the node v in T_1. (Recall that node v is the LCA of $S - \beta$ in T_1.) Since $T_1|\{x, y, z\} = ((x, y), z)$, we have that either both x, y belong to δ_i or neither belongs to δ_i. If both $x, y \in \delta_i$, then clearly $x, y \in (\beta \cap \delta_i)$. For the case when neither x nor y is in δ_i, we can conclude that both x, y are in some special cluster δ_j (since $T_1|\{x, y, z\} = ((x, y), z)$). Thus we have that $x, y \in (\beta \cap \delta_j)$.

Suppose x, y belong to some $\alpha \cap \gamma_i$ or $\beta \cap \delta_j$; specifically, say x, y belong to some $\beta \cap \delta_j$. There are two cases to handle. The first case is if the node v' defining the special cluster is not a child of the node v. In this case, we can pick a species $z \in S - \beta$ such that $T_1|\{x, y, z\} = T_2|\{x, y, z\} = ((x, y), z)$. The second case is when the node v' is a child of the node v. In this case, pick a species $z \in S - \beta$ from the special cluster which is defined by a node v'' (where $v' \ne v''$) and v'' is below v. We have that $T_1|\{x, y, z\} = T_2|\{x, y, z\} = ((x, y), z)$. Thus in both the cases we have that there exists such a z with $z \in S - (\alpha \cap \beta)$. □

Thus, for each i, connect all vertices in $\alpha \cap \gamma_i$ (in G) by a path and do the same for each j and the vertices in $\beta \cap \delta_j$. Note that this can be done in $O(n)$ by using the same idea as in Case 1.

Case 2b [$z \in (\alpha \cap \beta)$]. Note that we are only interested in identifying x, y such that $lca(x, y)$ in T_1 is a node that is on the path from the root of T_1 to the node v, and the $lca(x, y)$ in T_2 is a node that is on the path from the root of T_2 to the node u. To see why, if, say, $lca_{T_1}(x, y) \ne v_i \forall 1 \le i \le p$, then $\exists a \in S - \beta$ (i.e., $a \notin (\alpha \cap \beta)$) such that $T_1|\{x, y, a\} = T_2|\{x, y, a\} = ((x, y), a)$, and thus x and y will be in the same component after Case 2a is handled.

From the preceding discussion, it suffices to convert the trees T_1 and T_2, both defined on the leaf set $(\alpha \cap \beta)$, into millipedes T_1' and T_2', respectively. T_1' is obtained from T_1 by contracting all edges above internal nodes not in the set $\{v_1, v_2, \ldots, v_p\}$. T_2' is obtained from T_2 similarly. Thus, we have to solve the following problem now: we are given two millipedes T_1' and T_2' on the same leaf set $S' = (\alpha \cap \beta)$, where T_1' has internal nodes labeled v_1' (root of T_1') through v_p', and each v_i' has leaves corresponding to all the species in the special clusters of v_i in T_1; T_2' has internal nodes labeled u_1' (root of T_2') through u_q' and is defined similarly. Our aim is to construct a graph $G' = (V', E')$ where $V' = S'$ such that if $\exists x, y, z \in (\alpha \cap \beta)$ such that both T_1' and

T_2' resolve this triple as $((x,y),z)$ then x and y will be in the same component of G'. Once G' is known, we add the edges of G' to the edge set of G, and then the components in G will give the maximal clusters we seek.

We will show how G' can be constructed in $O(n)$ time. Consider a node v'_{i-1} in T_1' and let A be the set of leaves of v'_{i-1}. Let u'_{j-1} be the node in T_2' which is closest to u'_1 and is the parent of some species in A. Then, clearly, in G' all species in $(\alpha_{v'_i} \cap \beta_{u'_j})$ need to be in one component. For every v'_{i-1} $(2 \le i \le p)$, we will denote this intersection by the pair (v'_i, u'_j). Further, observe that if (v'_i, u'_j) and $(v'_{i'}, u'_{j'})$ are such that $v'_{i'}$ is not above v'_i and $u'_{j'}$ is not above u'_j, then $(\alpha_{v'_{i'}} \cap \beta_{u'_{j'}}) \subseteq (\alpha_{v'_i} \cap \beta_{u'_j})$.

Thus, when constructing the graph G', we need only look at all the intersections of the form (v'_i, u'_j), where for every pair of intersections $(v'_{i'}, u'_{j'})$ and (v'_i, u'_j), v'_i is closer to v'_1 than $v'_{i'}$ is, iff $u'_{j'}$ is closer to u'_1 than u'_j is.

Let $(v_1^*, u_1^*), (v_2^*, u_2^*), \ldots, (v_r^*, u_r^*)$ be the intersections we are interested in, where v_i^* is closer to v'_1 than v_{i+1}^* is $(1 \le i \le (r-1))$, and u_{j+1}^* is closer to u'_1 than u_j^* is $(1 \le j \le (r-1))$. Note that $v_1^* = v'_2$. This node and the given T_1' and T_2', uniquely determine these intersections.

In T_1', we define the *nearest parent* of a species x to be the first v_i^* to appear on the path from x to the root of T_1'. Similarly, we can define the nearest parent of a species in T_2'. The nearest parents of all the species can be computed in $O(n)$ by doing a simple traversal of T_1' and T_2'. Using the nearest parents of the species in T_1', we partition the species set into r sets $S_{v_1^*}, \ldots, S_{v_r^*}$ where $S_{v_i^*}$ contains all species which have nearest parent as v_i^*.

Observe that if any two intersections (v_i^*, u_i^*) and $(v_{i'}^*, u_{i'}^*)$ contain at least one species in common, then all the species in the two intersections need to be in the same component in G'. Inductively, if there are intersections $(v_i^*, u_i^*), \ldots, (v_j^*, u_j^*)$ such that the species in these intersections need to be in one component in G' and if there is an intersection (v_k^*, u_k^*) which has a species x in common with one of these intersections, then all the species in the intersection (v_k^*, u_k^*) need to be in the same component as the species in the intersections $(v_i^*, u_i^*), \ldots, (v_j^*, u_j^*)$. The algorithm *CONSTRUCT_G'* we present now keeps track of such an x using the variable *missing_link*, which is initialized to an $x \in (v_r^*, u_r^*)$ such that the nearest parent of x in T_2' (say u_j^*) is farthest from the root (as compared with the nearest parents of the other species in (v_r^*, u_r^*)). We will also use two additional variables: *np_missing_link* which stores u_j^* and *upper_limit* which stores v_j^*.

PROCEDURE CONSTRUCT_G'

For $i = r$ down to 1,

do{

Identify $y \in S_{v_i^*}$ such that the nearest parent of y in T_2' is
farthest away from u'_1 (i.e., root of T_2')
Let u_k^* be the nearest parent of y in T_2'; Set $z = v_k^*$
Connect all $x \in S_{v_i^*}$ to y
If *upper_limit* is not below v_i^*,
then
connect y to *missing_link*
else if (*upper_limit* is below v_i^*) or (*upper_limit* is below v_k^*)
then
set *missing_link* $= y$
np_missing_link $= u_k^*$
upper_limit $= z$

}enddo

Once we have constructed G', we can update G by setting $E(G) = E(G) \cup E(G')$. The components in G will be the maximal clusters of the RV-II. Finding the components takes $O(n)$. To recurse, we find the homeomorphic subtrees of T_1 and T_2 induced by the species in each of the maximal clusters. This can be done in $O(n)$ as previously described.

Thus the RV-II can be constructed in $O(n^2)$.

5.5. RV-III.

LEMMA 5.3. *The* RV-III *tree T of two trees T_1 and T_2 always exists and is unique. Further $C(T) = A$, where $A = \{\gamma | \gamma = \alpha \cap \beta, \alpha \in C(T_1), \beta \in C(T_2), \gamma$ compatible with $C(T_i), i = 1, 2\}$.*

Proof. We will first show that A as defined above is a compatible set. The uniqueness will then follow from the uniqueness of a set of compatible clusters [17].

Pick two clusters $\gamma_1 = \alpha_1 \cap \beta_1$ and $\gamma_2 = \alpha_2 \cap \beta_2$ such that $\gamma_i \in A; \alpha_1, \alpha_2 \in C(T_1); \beta_1, \beta_2 \in C(T_2)$. We will show that $\gamma_1 \cap \gamma_2 \in \{\emptyset, \gamma_1, \gamma_2\}$. Now, since γ_i is compatible with $C(T_1)$ and $C(T_2)$, we have $\gamma_1 \cap \alpha_2 \in \{\emptyset, \gamma_1, \alpha_2\}$. Also, we have $\gamma_1 \cap \beta_2 \in \{\emptyset, \gamma_1, \beta_2\}$. There are several cases to handle. The first case is when $\gamma_1 \subseteq \alpha_2, \gamma_1 \subseteq \beta_2$. In this case, $\gamma_1 \subseteq (\alpha_2 \cap \beta_2)$ or $\gamma_1 \cap \gamma_2 = \gamma_1$. The second case is when $\gamma_1 \supseteq \alpha_2, \gamma_1 \supseteq \beta_2$. In this case, $(\alpha_2 \cap \beta_2) \subseteq \gamma_1$ or $\gamma_1 \cap \gamma_2 = \gamma_2$. The third case is when $\gamma_1 \subseteq \alpha_2, \gamma_1 \supseteq \beta_2$. In this case, $(\alpha_2 \cap \beta_2) \subseteq \gamma_1$ and thus $\gamma_1 \cap \gamma_2 = \gamma_2$. Hence, A is a compatible set of clusters.

Now we will show that any tree T satisfying the RV-III rules will have its cluster encoding equal to A. From the third requirement for RV-III,[5] all the clusters in $C(T)$ are compatible with both $C(T_1)$ and $C(T_2)$. Now suppose we can pick a $\gamma \in C(T) - A$. This means that $\gamma \neq \alpha_i \cap \beta_j \forall \alpha_i \in C(T_1), \beta_j \in C(T_2)$. Let α_1 and β_1 be the minimal clusters in T_1 and T_2, respectively, containing γ. Clearly, $\alpha_1 \cap \beta_1 \supset \gamma$. Let u and v be the nodes in T_1 and T_2, respectively, which define the clusters α_1 and β_1. Since γ is compatible with $C(T_1)$ and $C(T_2)$, it follows that we can pick three species a, b, c such that $lca_{T_1}(a, b) = lca_{T_1}(a, c) = lca_{T_1}(b, c) = u$, $lca_{T_2}(a, b) = lca_{T_2}(a, c) = lca_{T_2}(b, c) = v$, and $a, b \in \gamma, c \in (\alpha_1 \cap \beta_1) - \gamma$. In both T_1 and T_2, the triple a, b, c is unresolved, but it is resolved as $((a, b), c)$ in T, thus contradicting the assumption that T' satifies the rules defined by RV-III. Thus we have that $C(T) \subseteq A$. Now suppose $C(T) \subset A$. Then it can be seen that we can pick a triple a, b, c which is resolved in T_1 and is either resolved the same in T_2 or is unresolved in T_2 but that a, b, c is unresolved in T. This contradicts the assumption that T satisfies the rules defined by RV-III since it does not satisfy the second (see definition of RV-III) for a maximal set of triples. Thus $C(T) = A$. ∎

LEMMA 5.4. *The RV-*III *tree T of two rooted trees can be computed in $O(n^3)$.*

Proof. We can compute $C(T)$ in $O(n^3)$ as follows. The set $X = \{\gamma | \gamma = \alpha \cap \beta, \alpha \in C(T_1), \beta \in C(T_2)\}$ can be computed in $O(n^3)$, since there are $O(n^2)$ pairs to look at and each $\alpha \cap \beta$ can be computed in $O(n)$. The set $Y = \{\gamma | \gamma \in X, \gamma$ compatible with $C(T_i)\}$ can be computed from X in $O(n^3)$, since each of the $O(n^2)$ clusters in X can be checked for compatibility with $C(T_i)$ in $O(n)$. Finally, T can be constructed from Y using the $O(n^2)$ algorithm mentioned in [17]. Thus the total time taken is $O(n^3)$. ∎

We now briefly discuss another local consensus rule that looks interesting but unfortunately does not always exist. We define $LCR1$ as a rule which requires that if

[5] If a triple a, b, c is resolved as $((a, b), c)$ in T, then it is not resolved as $(a, (b, c))$ or $((a, c), b)$ in either T_1 or T_2.

a triple a, b, c is resolved as $(a, (b, c))$ in one tree and is either resolved as $(a, (b, c))$ or unresolved in the second tree, then it is resolved as $(a, (b, c))$ in the consensus tree.

Although the above rule tries to capture the *optimistic* features of the input trees and at the same time is not a total local consensus rule, it is the case that the consensus tree defined by $LCR1$ need not exist. See Figure 7 for an example showing that $LCR2$ need not necessarily produce a tree. Figure 7(iii) shows the graph constructed by the algorithm in [3]. Since the graph is connected, it follows that the set of triple constraints does not define a tree.

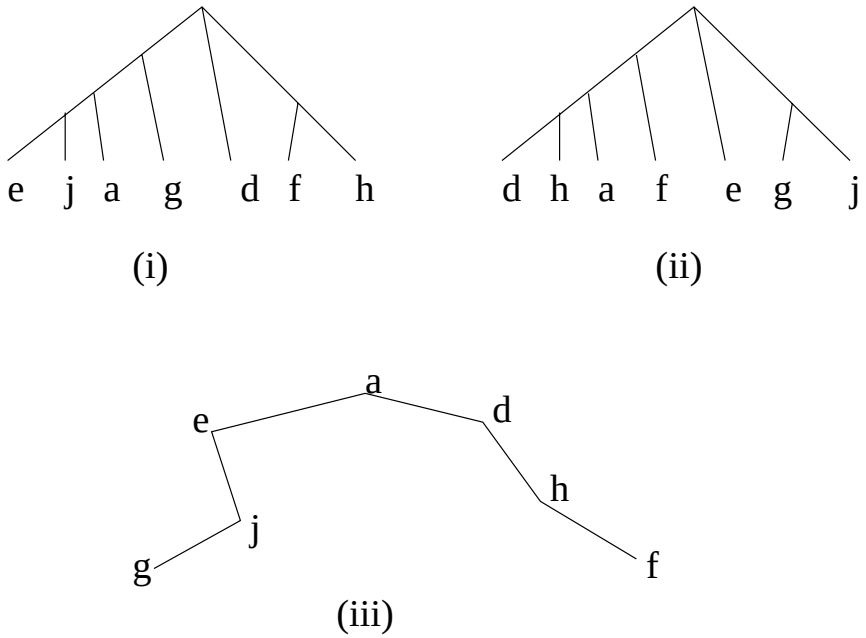

FIG. 7. *Example showing that consensus tree defined by $LCR1$ need not exist.*

6. Discussion and conclusions. Several approaches have been taken to handle the problem of resolving multiple solutions. One approach has been to find a maximum subset $S_0 \subseteq S$ inducing homeomorphic subtrees; this subtree is then called a *maximum agreement subtree* [19, 13, 24, 14]. The primary disadvantage of this approach is that it does not return an evolutionary tree on the entire species set.

The other approach which we take here requires that the resolution of the inconsistencies be represented in a single evolutionary tree for the entire species set. A classical problem in this area is the *tree compatibility problem* (also called the *cladistic character compatibility problem*) [10, 11, 12]. The tree compatibility problem says that the set $\mathcal{T}$ of trees is *compatible* if a tree T exists such that $C(T) = \cup_{T_i \in \mathcal{T}} C(T_i)$. Equivalently, if a tree T exists such that for every triple $A \subseteq S$, T resolves A iff $T|A = T_i|A$ for every $T_i \in \mathcal{T}$ which resolves A. This problem can be solved in linear time [17, 25]. The weakness of this approach is that in practice many data sets are incompatible, and it is therefore necessary to be able to handle the case where some pairs of trees resolve triples differently.

Some other approaches of this type are the *strict consensus* [4, 9] and the *median tree* [5] problems. These models are stated in terms of unrooted trees, so that instead of *clusters*, *characters* (i.e., bipartitions) on the species set are used to represent the

trees. Using the character encoding of the consensus tree as a measure of fitness to the input, the strict consensus seeks a tree with only those characters that appear in every tree in the input. The median tree, on the other hand, is defined by a metric $d(T_1, T_2)$ between rooted trees which is defined to be the cardinality of the symmetric difference of the character sets of T_1 and T_2. Given input trees $T_1, \ldots, T_k$, T is the median tree if it minimizes $\sum_i d(T, T_i)$. The median tree can be computed in polynomial time and has a nice characterization in terms of the character encoding [5, 23, 9]. Both the above notions are related to versions of the local consensus problem (for example, the relaxed versions RV-I and RV-III), and the relevant local consensus trees in many cases contain at least as much "information" as these trees.

The work represented in this paper can be extended in several directions. As we have noted, for all local consensus functions the local consensus tree of a set of k trees can be computed in time polynomial in k and $n = |S|$. Many of these local consensus trees can be constructed in $O(kn)$ time.

PARALLEL ALGORITHMS WITH OPTIMAL SPEEDUP FOR BOUNDED TREEWIDTH*

HANS L. BODLAENDER† AND TORBEN HAGERUP‡

Abstract. We describe the first parallel algorithm with optimal speedup for constructing minimum-width tree decompositions of graphs of bounded treewidth. On n-vertex input graphs, the algorithm works in $O((\log n)^2)$ time using $O(n)$ operations on the EREW PRAM. We also give faster parallel algorithms with optimal speedup for the problem of deciding whether the treewidth of an input graph is bounded by a given constant and for a variety of problems on graphs of bounded treewidth, including all decision problems expressible in monadic second-order logic. On n-vertex input graphs, the algorithms use $O(n)$ operations together with $O(\log n \log^* n)$ time on the EREW PRAM, or $O(\log n)$ time on the CRCW PRAM.

1. Introduction.

The concept of treewidth has proved to be a useful tool in the design of graph algorithms: many important classes of graphs have bounded treewidth, and many important graph problems that are otherwise quite hard can be solved efficiently on graphs of bounded treewidth. A *tree decomposition* of an undirected graph $G = (V, E)$ is a pair $(T, \mathcal{U})$, where $T = (X, F)$ is a tree and $\mathcal{U} = \{U_x \mid x \in X\}$ is a family of subsets of V called *bags*, one for each node in T, such that

(i) $\bigcup_{x \in X} U_x = V$ (every vertex in G occurs in some bag);

(ii) for all $(v, w) \in E$, there exists an $x \in X$ such that $\{v, w\} \subseteq U_x$ (every edge in G is "internal" to some bag);

(iii) for all $x, y, z \in X$, if y is on the path from x to z in T, then $U_x \cap U_z \subseteq U_y$ (every vertex in G occurs in the bags in a connected part of T, i.e., in a subtree).

The *width* of a tree decomposition $(T, \{U_x \mid x \in X\})$ is $\max_{x \in X} |U_x| - 1$. The *treewidth* of a graph G, denoted $tw(G)$, is the smallest treewidth of any tree decomposition of G. *Path decompositions* and *pathwidth* are defined analogously, with the tree T restricted to be a path.

As mentioned above, many well-known classes of graphs are of bounded treewidth; i.e., for each class there is a uniform upper bound on the treewidth of all graphs in the class. Such classes include those of trees, forests, outerplanar graphs, k-outerplanar graphs (for every fixed $k \geq 1$), Halin graphs, series-parallel graphs, graphs that avoid a planar graph H as a minor (for every fixed H), and graphs of bounded bandwidth. For an overview, see [11].

The majority of efficient algorithms for graphs of bounded treewidth depend not only on a guarantee that the treewidth of an input graph is small, but in fact on the availability of a minimum-width tree decomposition of the input graph, so that the construction of minimum-width tree decompositions for graphs of bounded treewidth is a key problem. A quest for the fastest possible algorithm for this problem [5, 43, 22, 10, 38, 35, 42, 8] led to the linear-time algorithm of [8], which eliminated the bottleneck in a large number of algorithms for bounded treewidth.

In the setting of parallel computation, the situation is similar. Many otherwise difficult graph problems can be solved in NC (i.e., in polylogarithmic time with a polynomial amount of hardware) on graphs of bounded treewidth, and again the need for a minimum-width tree decomposition is a serious bottleneck. The best parallel algorithms for computing tree decompositions of width k of graphs of treewidth k, for fixed k, run on the CRCW PRAM using $O((\log n)^2)$ time and $O(n^{2k+5})$ processors [15, 16] or $O(\log n)$ time and $O(n^{3k+4})$ processors [7]. Although these algorithms are fast, they are extremely wasteful in terms of processors, in view of the linear-time sequential algorithm. For the cases $k = 2$ and $k = 3$, somewhat more efficient algorithms using $O((\log n)^2)$ time and $O(n^{k+1})$ processors were described by Granot and Skorin-Kapov [27]. A related result was obtained by Wanke [45], who showed that the problem of deciding whether the treewidth of an input graph is bounded by a constant k belongs to the complexity class LOGCFL; this result also does not seem to lead to parallel algorithms that are efficient from the point of view of processor utilization. If we relax the requirements by allowing tree decompositions of width $O(k)$, rather than exactly k, more algorithms come into play: Lagergren [35] finds a decomposition of width $\leq 8k+7$ in $O((\log n)^3)$ time using $O(n)$ processors, and we believe that Reed's sequential $O(n \log n)$-time algorithm [42] for obtaining a decomposition of width $\leq 4k + 3$ can be parallelized (using an algorithm of Khuller and Schieber [33] to solve a central path-finding problem) to yield an algorithm that works in $O((\log n)^2)$ time using $O(n\alpha(n)/\log n)$ processors, where α is a very slowly growing "inverse Ackermann" function. The parallel version of Reed's algorithm uses $O(n\alpha(n) \log n)$ *operations*, i.e., has a time-processor product of $O(n\alpha(n) \log n)$, and is the most efficient of the parallel algorithms discussed above. Still, since the problem can be solved in linear sequential time, the algorithm does not have optimal speedup, which requires a time-processor product of $O(n)$.

We describe an EREW PRAM algorithm for constructing minimum-width tree decompositions for graphs of bounded treewidth in $O((\log n)^2)$ time using $O(n)$ operations. The algorithm achieves optimal speedup and is the first parallel algorithm to do so. Moreover, the new algorithm is second in speed only to Bodlaender's algorithm [7] but uses a weaker model of computation (the EREW PRAM versus the CRCW PRAM), on which Bodlaender's algorithm can be simulated only in the same time of $O((\log n)^2)$. The new result immediately implies that a large number of problems on graphs of bounded treewidth can now be solved by parallel algorithms with optimal speedup.

A subroutine used in the construction algorithm but of independent interest is a parallel version of an algorithm due to Bodlaender and Kloks [13]. The algorithm takes as input a tree decomposition of bounded width of a graph G and outputs a minimum-width tree decomposition of G, thus blurring the distinction between the "exact" and the "approximate" construction algorithms discussed above. The new algorithm runs in $O(\log n)$ time using $O(n)$ operations on the EREW PRAM.

While we cannot compute tree decompositions faster than in $O((\log n)^2)$ time, it turns out that we can give faster algorithms for the related problem of deciding whether the treewidth of an input graph is bounded by a given constant k. The algorithms have optimal speedup (i.e., use $O(n)$ operations) and run in $O(\log n \log^* n)$ time on the EREW PRAM, or in $O(\log n)$ time on the CRCW PRAM. We achieve the same resource bounds for a number of problems on graphs of bounded treewidth, including all problems expressible in monadic second-order logic. These algorithms operate without an explicit tree decomposition and so bypass the (time) bottleneck of our construction algorithm. Furthermore, we achieve the same results for path decompositions and pathwidth as for tree decompositions and treewidth.

The paper combines several different techniques of wide applicability. The *graph-reduction* technique consists in repeatedly replacing parts of the graph at hand by simpler parts until a trivial graph results. The problem of interest is then solved for the trivial graph, and the solution is "carried along" while the changes to the graph are undone in reverse order. This technique pervades the paper and is used in the construction algorithm as well as in the decision algorithms (and also in the width-minimizing algorithm, provided that tree contraction is viewed as a special case of graph reduction).

Another technique used in the derivation of the CRCW PRAM decision algorithm from the corresponding EREW PRAM algorithm is that of *derandomization*. The basic idea of derandomization is that instead of letting random coin tosses select one algorithm to be executed from a collection of deterministic algorithms, we execute all deterministic algorithms in the collection and pick the best output. Because of the need to simulate several possible executions, derandomization is often associated with a price in the form of increased resource requirements. Here we use derandomization to derive a parallel algorithm with optimal speedup; i.e., we pay no price.

A third technique of less general applicability but nonetheless independent interest is that of *bounded adjacency-list search*, which tries to circumvent the difficulties caused by high-degree vertices in parallel algorithms for sparse graphs by letting each neighbor of a high-degree vertex v inspect only a piece of constant size of the adjacency list of v near its own entry, rather than the whole adjacency list. The bounded adjacency-list search technique was used previously (although not named) in [28]; there, as here, the technique serves to eliminate the need for both concurrent reading and writing and for superlinear space.

Unlike certain related results, most of our algorithms are explicit and do not rely on nonconstructive arguments. Only the results of Theorems 5.1 and 6.1 are nonconstructive, but can be made constructive in many concrete cases, as discussed near the end of section 5. On the other hand, it should be noted that large constant factors prevent our algorithms from being practical.

All graphs in this paper are undirected, loopless, and without multiple edges. We assume that all graphs, not excluding trees, are represented according to an *adjacency-list* representation: each vertex v in an n-vertex graph G is represented by an integer name of size $O(n)$ and has a pointer to a doubly linked adjacency list with an entry for each neighbor of v in G. For each neighbor w of v, the entry of w in v's adjacency list contains the name of w as well as a *cross pointer* to the entry of v in w's adjacency list.

2. Minimizing decomposition width. In this section we show how to obtain a minimum-width tree decomposition of a graph G from any tree decomposition of G of bounded width. We begin with an observation that allows us to assume that

tree decompositions are rooted, binary, and of logarithmic depth whenever this is convenient. In representation terms, every nonroot node in a rooted tree knows its parent, and a rooted tree is *binary* if no node has more than two children.

We appeal twice to the *tree-contraction* technique introduced by Miller and Reif [39], which we therefore describe in generic terms. Applied to an n-node binary input tree $T = (V, E)$, a tree-contraction algorithm produces a sequence $T = T_0 = (V_0, E_0), T_1 = (V_1, E_1), \ldots, T_r = (V_r, E_r)$ of $O(\log n)$ trees, ending with a one-node tree T_r, such that each tree T_i, for $i = 1, \ldots, r$, is obtained from its predecessor T_{i-1} in the sequence by contracting a set of edges $F_{i-1} \subseteq E_{i-1}$ with the following properties:

(i) F_{i-1} spans a matching (i.e., no node in V_{i-1} is incident to more than one edge in F_{i-1});

(ii) each edge in F_{i-1} has at least one endpoint with at most one child in T_{i-1}.

A sequence $T_0, \ldots, T_r$ with these properties, called a *contraction sequence* for T, can be computed in $O(\log n)$ time on an EREW PRAM using $O(n)$ operations and $O(n)$ space [1, 18, 24, 25, 34] (the connection to our generic description of tree contraction is easiest to establish in the case of the simple and elegant algorithm of [1, 34]). The second property mentioned above implies that each tree in the sequence is binary.

Let $X = \bigcup_{i=0}^{r} V_i$. We can define a rooted, binary tree T' on the node set X, called the *contraction tree* corresponding to the sequence $T_0, \ldots, T_r$, in the following way: the nodes in V, which will be called *base nodes*, are the leaves of T', and whenever a node $x \in X$ results from the contraction of an edge (y, z), we make x the parent of y and z in T'. For all $x, y \in X$, we will say that x *contains* y if x is an ancestor of y in T'. The base nodes contained in any node in X span a connected subgraph of the input tree T. For $i = 1, \ldots, r$, we root T_i at the node in V_i containing the root of T.

For $i = 0, \ldots, r$, call two base nodes v and w *i-neighbors* if $(v, w) \in E$ and v and w are not contained in the same node in V_i. For each $x \in V_i$, the i-neighbors of base nodes contained in x are contained in distinct neighbors of x in T_i. For all $x \in X$, we define the *border* of x as the set of base nodes contained in x and adjacent in T to one or more base nodes not contained in x. For $i = 0, \ldots, r$, if $x \in V_i$, then a base node contained in x belongs to the border of x precisely if it has at least one i-neighbor; in particular, the border of x contains at most three nodes.

Lemmas 2.1 and 2.2 below slightly improve a result of [7] by employing a more efficient subroutine; the same improvement was observed in [31].

LEMMA 2.1. *The following problem can be solved on an EREW PRAM using $O(\log n)$ time, $O(n)$ operations, and $O(n)$ space: given an n-node rooted, binary tree T, compute a rooted, binary tree decomposition of T of depth $O(\log n)$ and width at most* 2.

Proof. Begin by using tree contraction to compute a contraction sequence $T = T_0 = (V_0, E_0), T_1 = (V_1, E_1), \ldots, T_r = (V_r, E_r)$ for the input tree $T = (V, E)$ and construct the corresponding contraction tree $T' = (X, F)$.

Observe that if e and e' are the edges incident on a node v of degree 2 in some tree H, then the tree obtained from H by contracting e is the same as the tree obtained from H by contracting e' (the contraction can be "flipped" to the other side of v). Because of this, we can assume without loss of generality that when an edge between a node v of degree 2 and a node w of degree 3 is contracted in the transition from T_{i-1} to T_i, for some i with $1 \leq i \leq r$, then v is the parent of w in T_{i-1}. To see this, first note that all edge contractions that violate the assumption—we will call these $(3, 2)$-*contractions*—can be carried out separately (i.e., we replace the one-step transition from T_{i-1} to T_i by a two-step process, thereby doubling r). Now each $(3, 2)$-

contraction can be "flipped," as described above, without changing the resulting tree; note that the edge set of the "flipped" contractions still spans a matching.

For all $x \in X$, denote the border of x by $B(x)$. We next show that no border contains three distinct vertices.

CLAIM 1. *For all $x \in X$, $|B(x)| \leq 2$.*

Proof. Suppose that for some i with $1 \leq i \leq r$, some base node $v \in V$ has two i-neighbors and belongs to $B(x)$ for some $x \in V_i$ with $|B(x)| \geq 2$. Then neither of the two i-neighbors of v is its parent in T. To see why this is true, let j be minimal such that v belongs to $B(y)$ for some $y \in V_j$ with $|B(y)| \geq 2$. It can be seen that then y must, in fact, result from the contraction of an edge (v, z), where $z \in V_{j-1}$ is of degree 2 in T_{j-1}. But then, by the absence of $(3, 2)$-contractions, z must be the parent of v in T_{j-1}, which implies that the parent of v in T is not an i-neighbor of v for any $i \geq j$.

Since the claim $|B(x)| \leq 2$ is trivially true for all base nodes x, assume by induction that it is true for all $x \in V_{i-1}$, for some i with $1 \leq i \leq r$, and consider a node $x \in V_i$ resulting from the contraction of an edge (y, z), where $y, z \in V_{i-1}$. Since $|B(x)|$ is bounded by the degree of x in T_i, which is two less than the sum of the degrees of y and z in T_{i-1}, we can assume that y is of degree 3 and that z is of degree 2 in T_{i-1}. We will show that only one node in each of $B(y)$ and $B(z)$ also belongs to $B(x)$, from which $|B(x)| \leq 2$ follows immediately. In the case of $B(z)$, this is easy to see: the nodes in $B(z)$ have a total of two $(i-1)$-neighbors, and one of these is not an i-neighbor. Similarly, the nodes in $B(y)$ lose one of their three $(i-1)$-neighbors. We must show that the two remaining $(i-1)$-neighbors, which are also i-neighbors, are adjacent to the same node in $B(y)$. But if this is not the case, then $|B(y)| = 2$ and $B(y)$ contains a node v with two $(i-1)$-neighbors, one of which belongs to $B(z)$. By what was shown above, neither of the $(i-1)$-neighbors of v is its parent in T. But this contradicts the fact that z must be the parent of y in T_{i-1} by the absence of $(3, 2)$-contractions. This ends the proof of the claim. ∎

The sets $B(x)$, where $x \in X$, can be computed as follows: successively, for $i = 0, \ldots, r$, we compute $B(x)$, along with the set of i-neighbors of all nodes in $B(x)$, for all $x \in V_i$. This is trivial for $i = 0$, and if, for some i with $1 \leq i \leq r$, a node $x \in V_i$ is obtained by contracting an edge (y, z), where $y, z \in V_{i-1}$, then $B(x) \subseteq B(y) \cup B(z)$, and an $(i-1)$-neighbor of a base node $v \in B(y) \cup B(z)$ is also an i-neighbor of v exactly if it does not belong to $B(y) \cup B(z)$, so that the information pertaining to x can easily be derived from the information pertaining to y and z.

We now associate a set $U_x \subseteq V$ with each $x \in X$ as follows: if x is a base node, i.e., a leaf in T', we take $U_x = \{x\}$. Otherwise, if x has the children y and z in T', we take $U_x = B(y) \cup B(z)$. We will show that $(T', \{U_x \mid x \in X\})$ is a tree decomposition of T. First, because of the convention regarding leaves of T', the condition $\bigcup_{x \in X} U_x = V$ is trivially satisfied. Second, for every edge (v, w) in E, it is easy to see that $\{v, w\} \subseteq U_x$, where x is the lowest common ancestor of v and w in T'. And, third, the set of nodes whose bags contain a base node v form an initial part of the path in T' from v to the root of T', and hence span a connected subgraph of T'.

The width of the tree decomposition defined above is bounded by one less than twice the maximum size of a border. By the claim shown above, this means that the width is at most 3. We now describe how to reduce the width to at most 2. Suppose that $x \in X$ is a node in T' whose associated bag U_x is of size 4, let y and z be the children of x in T', and take $B(y) = \{v_1, v_2\}$ and $B(z) = \{v_3, v_4\}$, so that $U_x = \{v_1, v_2, v_3, v_4\}$. As follows easily from arguments used to bound the sizes of

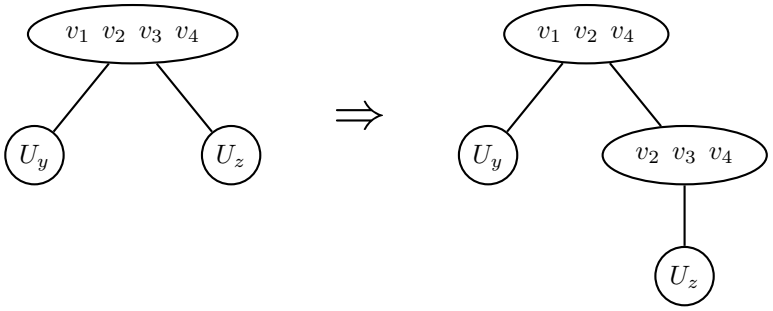

FIG. 1. *Transforming from width* 3 *to width* 2.

all bags by 2, $B(x)$ "inherits" exactly one element of each of $B(y)$ and $B(z)$, so that we can assume that $B(x) = \{v_1, v_4\}$. Then v_2 and v_3 do not occur in the bag of the parent of x in T', if any. Moreover, $(v_2, v_3) \in E$ and hence $(v_1, v_3) \notin E$. It is now easy to see that the transformation illustrated in Figure 1 preserves the defining properties of a tree decomposition. Applied at all nodes with bags of size 4, it produces a new tree decomposition of T of width at most 2. The depth increases by a factor of at most 2 and hence remains $O(\log n)$, as desired.

Starting from the sequence $T_0, \ldots, T_r$, the algorithm constructs the tree T', then computes the sets $B(x)$ and U_x for all $x \in X$, and finally carries out the transformation of T' described above. Each of these steps can easily be done in $O(\log n)$ time using $O(n)$ operations and $O(n)$ space. □

In the lemma below as well as in several later results, the input parameter k is qualified as being a constant, the meaning of which is that k can be any positive integer but that the $O(\cdots)$ of the result may (and will) hide factors that depend on k.

LEMMA 2.2. *For all constants $k \geq 1$ and all integers $n \geq 2$, the following problem can be solved on an EREW PRAM using $O(\log n)$ time, $O(n)$ operations, and $O(n)$ space*: *given a tree decomposition with n nodes and of width k of a graph G, compute a rooted, binary tree decomposition of G of depth $O(\log n)$ and width at most $3k + 2$.*

Proof. We begin by replacing each node of degree $m \geq 4$ and with associated bag U in the given tree decomposition by a path of $m - 2$ nodes, each of degree 3 and with associated bag U, which obviously preserves the defining properties of a tree decomposition. Then we construct an Euler tour of the modified tree (see [44]) and root the tree by breaking the Euler tour at an arbitrary node of degree at most 2, declared to be the root, computing the distance from each node to the root along the Euler tour by means of list ranking [17, 4], and determining the parent of each nonroot node as the neighbor with a smaller distance to the root. After these preliminary steps, which can easily be carried out within the stated resource bounds, we can assume that the input is a tree decomposition $(T, \mathcal{U})$, where $T = (V, E)$ is rooted and binary.

Now use the algorithm of Lemma 2.1 to obtain a rooted, binary tree decomposition $(T', \mathcal{Q})$ of T of width at most 2 and depth $O(\log n)$. Replacing each node in a bag in $\mathcal{Q}$ by the vertices of G in its own associated bag, we obtain the desired tree decomposition of G. More precisely, write $\mathcal{U} = \{U_v \mid v \in V\}$, $T' = (X, F)$, and $\mathcal{Q} = \{Q_x \mid x \in X\}$ and take $R_x = \bigcup_{v \in Q_x} U_v$ for all $x \in X$. Then $(T', \{R_x \mid x \in X\})$ is a tree decomposition of G. For if a vertex u of G occurs in U_v, with $v \in V$, and $v \in Q_x$, with $x \in X$, then $u \in R_x$. Similarly, both endpoints of each edge in G occur in some bag U_v, with $v \in V$, and therefore also in some bag R_x, with $x \in X$. Finally, each

vertex u of G occurs in the bags U_v in a subtree of T, and two adjacent nodes in this subtree occur in the bags Q_x in overlapping subtrees of T', so that, altogether, u occurs in the bags R_x in a connected subgraph of T'. The width of the tree decomposition $(T', \{R_x \mid x \in X\})$ is at most $(2+1)(k+1)-1 = 3k+2$. □

We will use the phrase "balancing a tree decomposition" to describe an application of the algorithm implicit in the preceding lemma. The remaining goal in the present section is to prove the result below.

THEOREM 2.3. *For all constants $k \geq 1$ and all integers $n \geq 2$, the following problem can be solved on an EREW PRAM using $O(\log n)$ time, $O(n)$ operations, and $O(n)$ space: given a tree decomposition with n nodes and of width k of a graph G, construct a minimum-width tree decomposition of G.*

The corresponding decision problem (is $tw(G) \leq l$?, for some given l) can be solved by a straightforward parallelization of the decision algorithm of [13]. The latter algorithm consists of a pass from the leaves to the root of a tree decomposition of the input graph, which, in light of Lemma 2.2, can be taken to be binary and of logarithmic depth. The processing of each node takes constant time, and all nodes on the same level in the tree can be processed in parallel. If the nodes in the tree decomposition are first sorted by their levels, which can be done in $O(\log n)$ time using $O(n)$ operations [41, Lemma 3.1], it is easy to process the whole tree in $O(\log n)$ time using $O(n)$ operations. The sequential construction (as opposed to decision) algorithm processes the tree decomposition in three passes. In one of these, the processing of a node no longer necessarily takes constant time, so that an amortization argument is used in [13] to bound the total running time by $O(n)$. Since this appears to stand in the way of a direct parallelization, we choose a somewhat different approach.

Suppose that the input graph is $G = (V, E)$. Close inspection of the algorithm of [13] (we omit the details, some of which were hinted at above) reveals that $O(\log n)$ time and $O(n)$ operations suffice to compute a certain *implicit representation* of the desired tree decomposition $(T = (X, F), \{U_x \mid x \in X\})$ consisting of the binary tree T (without the bags U_x) together with, for each $v \in V$, a collection $\mathcal{P}_v$ of disjoint simple paths in T whose union contains a node $x \in X$ if and only if $v \in U_x$. Rather than directly specifying the set of vertices contained in each bag, the implicit representation thus presents the set of bags containing each vertex in the form of a collection of disjoint paths. For each $v \in V$, a path in $\mathcal{P}_v$ with endpoints x and y is represented by marking both x and y with the triple (x, y, v); a node may be marked with several triples but, of course, with at most $k+1$ triples. We clearly have $|X| = O(n)$, since the size of the tree T cannot exceed the number of operations used to compute it.

By the preceding discussion, proving Theorem 2.3 boils down to showing the following lemma.

LEMMA 2.4. *For all constants $k \geq 1$ and all integers $n \geq 2$, the following problem can be solved on an EREW PRAM using $O(\log n)$ time, $O(n)$ operations, and $O(n)$ space: given a rooted, binary n-node tree T and a collection $\mathcal{P}$ of simple paths in T, each of which is labeled by an integer and represented, at each of its endpoints, by a triple specifying its endpoints and label, such that no node in T belongs to more than $k+1$ paths in $\mathcal{P}$, mark each node x in T with the set of all labels of paths in $\mathcal{P}$ containing x.*

Proof. Since duplicates are easily eliminated, we can assume that no two paths in $\mathcal{P}$ have both the same endpoints and the same label, so that we can identify each path with the triple marking its endpoints. We will also assume that the endpoints of each path are distinct, since paths consisting of a single node are trivial to handle.

We begin by using tree contraction to obtain a contraction sequence $T = T_0 = (V_0, E_0), \ldots, T_r = (V_r, E_r)$ for the input tree $T = (V, E)$. We will process the sequence twice, first in the order of increasing indices (the *up phase*), and then in the order of decreasing indices (the *down phase*).

Let $X = \bigcup_{i=0}^{r} V_i$. During the up phase, we associate a set $S(x)$ with each node $x \in X$. For $x \in V$, $S(x)$ is the set of paths in $\mathcal{P}$ with x as an endpoint. For $i = 1, \ldots, r$, if a node $x \in V_i$ results from the contraction of an edge (v, w), where $v, w \in V_{i-1}$, we compute $S(x)$ as $(S(v) \cup S(w)) \backslash (S(v) \cap S(w))$; it is easy to see by induction that for all $x \in X$, $S(x)$ will be the set of paths in $\mathcal{P}$ with exactly one endpoint contained in x. During the down phase, for $i = r, \ldots, 1$, we modify $S(v)$ for all $v \in V_{i-1} \backslash V_i$ as follows: suppose that v and another node $w \in V_{i-1}$ are both contained in $x \in V_i$. Then, for each pair (y, z) of neighbors of x in T_i such that some node in V_{i-1} contained in y is separated in T_{i-1} from some node in V_{i-1} contained in z by the removal of v (i.e., v is "between" y and z), add to $S(v)$ all paths in $S(y) \cap S(z)$. Again, it is not difficult to see by backward induction on i that the final value of $S(x)$, for all $x \in X$, will be the set of paths in $\mathcal{P}$ comprising at least one node contained in x and at least one node not contained in x. In particular, the values $S(v)$, where $v \in V$, precisely constitute the desired output. Since the number of paths containing a given node in V is bounded by a constant, and since each path in $S(x)$ must contain at least one of the at most three border nodes of x, for all $x \in X$, each set $S(x)$ is of constant size, and the whole computation can be carried out in $O(\log n)$ time using $O(n)$ operations and $O(n)$ space. □

With a similar (but, in fact, easier) argument one can also show the result below.

THEOREM 2.5. *For all constants $k, l \geq 1$ and all integers $n \geq 2$, the following problem can be solved on an EREW PRAM using $O(\log n)$ time, $O(n)$ operations, and $O(n)$ space*: *given a tree decomposition with n nodes and of width k of a graph G, decide whether the pathwidth of G is at most l and, if so, construct a minimum-width path decomposition of G.*

3. A structural lemma. In this section we provide the basis for showing that any sufficiently large connected graph of bounded treewidth admits a large number of reductions of certain types. Moreover, given any adjacency-list representation of the graph, a large fraction of these reductions can be identified efficiently.

A well-known fact that we shall use below is that every n-vertex graph of treewidth $\leq k$ contains at most kn edges for all positive integers n and k. We provide a brief proof. Since removing a vertex from a graph of treewidth $\leq k$ with at least two vertices leaves a graph of treewidth $\leq k$, it suffices to show that every graph G of treewidth $\leq k$ contains a vertex of degree $\leq k$. To this end consider a tree decomposition $(T = (X, F), \{U_x \mid x \in X\})$ of G of width $\leq k$ with a minimal number of nodes (i.e., $|X|$ is minimal over all such tree decompositions) and pick a node $x \in X$ of degree ≤ 1 in T. U_x contains at least one vertex v that does not occur in any other bag (otherwise x would be superfluous), and v has at most k neighbors, as desired (they all belong to U_x).

The *boundary* of a subgraph H of a graph G is the set of those vertices in G that have at least one neighbor in H but do not themselves belong to H. Let d, k, $n_{\min}$, and $n_{\max}$ be positive integers to be characterized more closely in the following. A vertex will be called *small* if its degree is bounded by d, and *large* otherwise. Given a graph G of treewidth at most k, we are essentially looking for connected subgraphs of G consisting of between $n_{\min}$ and $n_{\max}$ small vertices and with a boundary of size at most $2(k+1)$. It turns out that such subgraphs may not occur in G at all, for which

reason we have to replace the connectedness condition by a weaker, more complicated condition described below after the introduction of additional terminology.

Two vertices are said to be *twins* if they have the same set of neighbors. By analogy, two subgraphs of a common graph are called twins if they have the same boundary. A *weakly connected component* of a subgraph H of a graph G is a connected component of the graph obtained from H by the introduction of an edge between each pair of nonadjacent vertices in H with a common small neighbor in G; a weakly connected component of H may thus comprise several (usual) connected components of H, linked indirectly via small common neighbors in the boundary of H. A subgraph that consists of a single weakly connected component is *weakly connected*. Given an adjacency-list representation of a graph G, two disjoint subgraphs H_1 and H_2 of G are said to be *acquainted* if the intersection of their boundaries contains a vertex in whose adjacency list some entry of a vertex in H_1 is separated from some entry of a vertex in H_2 by a distance of at most d. This definition, which embodies the bounded adjacency-list search technique, reflects the fact that H_1 can "discover" H_2 by searching through a piece of length at most $2d + 1$ of the adjacency list of each of its boundary vertices.

We can now define the objects of interest and state the main result of the section. A *valley* in a graph G is a weakly connected subgraph of G induced by a set of at most $n_{\max}$ small vertices and with a boundary of size at most $2(k + 1)$. A *plain* (or $(d, k, n_{\min}, n_{\max})$-plain, for emphasis) in G (relative to a particular adjacency-list representation of G) is a subgraph of G, induced by a set of at least $n_{\min}$ and at most $n_{\max}$ vertices, whose weakly connected components are pairwise acquainted twin valleys.

LEMMA 3.1. *For all integer constants $k, n_{min} \geq 1$, there are constants $d, n_{max} \geq 1$ and $c > 0$ such that every connected graph with $n > n_{max}$ vertices and treewidth at most k contains at least cn disjoint (d, k, n_{min}, n_{max})-plains (relative to any adjacency-list representation).*

Proof. Take $b = 3(k + 1)(n_{\min} + 1)$. We will prove the lemma with $n_{\max} = 3b$ and $d = 2^{k+4} n_{\min} n_{\max}$. Let $G = (V, E)$ be a connected graph with $n > n_{\max}$ vertices and treewidth at most k and fix a particular adjacency-list representation of G and a particular maximal collection $\mathcal{P}$ of disjoint $(d, k, n_{\min}, n_{\max})$-plains in G (the complexity of computing such a collection is not an issue here, since we are concerned with an assertion of mere existence). We will show that $|\mathcal{P}| \geq cn$ for a suitably chosen constant $c > 0$.

Let $(T, \mathcal{U})$ be a tree decomposition of G of width at most k and write $T = (X, F)$ and $\mathcal{U} = \{U_x \mid x \in X\}$. We view T as rooted at an arbitrary node. Using the same standard transformation as in the beginning of the proof of Lemma 2.2, we can assume without loss of generality that T is binary. On two occasions in the proof we will use the fact that if $v \in V$, then the subgraph T_v of T induced by the node set $\{x \in X \mid v \in U_x\}$ is a tree, whose root can therefore be reached from any node in T_v by going from a child node to a parent node zero or more times; we will refer to this as the *root-seeking principle*.

We begin by showing that the set X of tree nodes can be partitioned into disjoint *clusters* $C_1, \ldots, C_s$ such that for $i = 1, \ldots, s$ the following conditions hold:

1. C_i induces a subtree of T;
2. $|\bigcup_{x \in C_i} U_x| \leq n_{\max}$;
3. if C_i does not contain the root of T, then $|\bigcup_{x \in C_i} U_x| \geq b$.

The partition $C_1, \ldots, C_s$ can be constructed by a simple procedure that processes T

in inverse topological order; i.e., every node is processed after all of its children. The processing of a node y computes the set C consisting of y itself and all descendants of y that have not yet been assigned to clusters. If $|\bigcup_{x\in C} U_x| \geq b$ or y is the root of T, then C is made into a new cluster; otherwise the processing continues to the next node.

It is easy to see that the set of nodes assigned to a cluster always induces a connected subgraph of T; i.e., condition 1 above is satisfied. Condition 3 is satisfied by construction. As for condition 2, observe that if a cluster C is formed during the processing at a node y, then C receives a contribution of at most $b-1$ vertices from each of the at most two children of y and of at most $k+1$ vertices from y itself, a total of at most $2b+k-1 \leq n_{\max}$ vertices. This establishes properties 1–3 of the cluster partition.

For $i = 1, \ldots, s$, let C_i' be the set of those nodes in C_i that are adjacent in T to a node not in C_i, take $Z_i = \bigcup_{x\in C_i'} U_x$, and let H_i be the graph induced by the vertices in $(\bigcup_{x\in C_i} U_x)\backslash Z_i$. By the properties of tree decompositions, the graphs $H_1, \ldots, H_s$ are disjoint, and the boundary of H_i is contained in Z_i for $i = 1, \ldots, s$.

For $i = 1, \ldots, s$, we will call H_i a *kernel* if $|C_i'| \leq 2$ and C_i is not the cluster containing the root of T (we exclude the latter cluster because of its special status). We next establish a lower bound on the number of kernels.

CLAIM 2. *The number of kernels is at least* $\frac{1}{2}n/n_{max}$.

Proof. By property 2 of the cluster partition and the fact that $\bigcup_{i=1}^{s}\bigcup_{x\in C_i} U_x = V$, the number s of clusters is at least $n/n_{\max}$. The clusters form a *cluster tree* in a natural fashion: two clusters are adjacent if one contains a node adjacent in T to a node in the other cluster, and the degree of a cluster C_i is at least $|C_i'|$ (it exceeds $|C_i'|$ if some node in C_i' has more than one neighbor outside of C_i). In general, a tree with m nodes contains $m-1$ edges. Hence if h denotes the number of nodes of degree ≥ 3 in an m-node tree and $m \geq 2$, we have $3h + (m-h) \leq 2(m-1)$ and thus $h \leq m/2 - 1$. Applying this to the cluster tree, with at least $n/n_{\max} > 1$ nodes, only one of which contains the root of T, shows that the number of clusters of degree ≤ 2 is at least $1 + \frac{1}{2}n/n_{\max}$, and hence that the number of kernels is at least $\frac{1}{2}n/n_{\max}$. □

The boundary of a kernel H contains at most $2(k+1)$ vertices and, by property 2 of the cluster partition, H contains no more than $n_{\max}$ vertices. In particular, since $d \geq n_{\max} + 2(k+1)$, all vertices in H are small. It follows that every weakly connected component of H is a valley. We will call a valley of this kind *good* if it intersects a plain in $\mathcal{P}$, and *bad* otherwise. Note that a bad valley contains fewer than $n_{\min}$ vertices (otherwise it would be a plain, contradicting the maximality of $\mathcal{P}$). A bad valley with boundary B will be called a B-valley.

We classify the bad valleys into three types depending on their boundaries. Consider a bad valley L with boundary B. If B contains one or more small vertices, L is of type a. If B contains only large vertices and $B \not\subseteq U_x$ for all $x \in X$, L is of type b. If B contains only large vertices and $B \subseteq U_x$ for some $x \in X$, finally, L is of type c. We next bound the number of valleys of type a per kernel, the number of kernels containing valleys of type b, and the total number of valleys of type c.

CLAIM 3. *The number of valleys of type* a (B *contains a small vertex*) *in any fixed kernel is bounded by* $2(k+1)$.

Proof. Every valley of type a "uses up" one or more of the at most $2(k+1)$ boundary vertices of its kernel. Here we use the fact that valleys need only be weakly connected: two vertices in the same kernel and with a common small neighbor belong to the same valley. □

We now consider the B-valleys for which B contains only large vertices. Given such a B-valley L, choose $v \in B$ such that the root r_v of the subtree T_v of T induced by the node set $\{x \in X \mid v \in U_x\}$ is of maximal depth, call v the *low point* of L, and assign L (for the purpose of accounting) to its low point. We here use the fact that G is connected, which ensures that $B \neq \emptyset$.

CLAIM 4. *The total number of kernels containing one or more valleys of type* b ($B \not\subseteq U_x$ *for all* $x \in X$) *is bounded by* $(2k/d) \cdot n$.

Proof. Let L be a bad valley and let B and v be its boundary and its low point, respectively. We can conclude from the root-seeking principle that r_v lies within the cluster C containing L; otherwise B would be contained in U_x, where x is the node in C of minimal depth in T. Since v is large, the number of clusters containing valleys of type b is therefore bounded by the number of large vertices. Because G has at most kn edges, the latter number in turn is bounded by $(2k/d) \cdot n$. ∎

CLAIM 5. *The total number of valleys of type* c ($B \subseteq U_x$ *for some* $x \in X$) *is bounded by* $(2^{k+2}k \cdot n_{min}/d) \cdot n$.

Proof. Let v be a large vertex in V and let B be a subset of V. By definition, all B-valleys are twins. Thus no d consecutive entries in the adjacency list of v can contain entries of vertices in $n_{\min}$ or more different B-valleys, since then all of these (bad) B-valleys would be acquainted, and some of them (with a suitable total size) would form a plain, contradicting the maximality of $\mathcal{P}$. We may conclude that at most $\lceil \deg(v)/d \rceil \cdot n_{\min} \leq 2 \deg(v) \cdot n_{\min}/d$ B-valleys are assigned to v, where $\deg(v)$ denotes the degree of v and the inequality follows from the fact that $\deg(v) > d$.

The valleys assigned to v may not all be twins. However, the root-seeking principle ensures that if a B-valley is assigned to v and B is contained in some (single) bag, then $B \subseteq U_{r_v}$. Thus the valleys of type c assigned to v have at most 2^k different boundaries (all such boundaries are subsets of a fixed set of at most $k+1$ vertices, and all contain v). It follows that the total number of valleys of type c assigned to v is bounded by $2^{k+1} \deg(v) \cdot n_{\min}/d$. Again since the total number of edges is at most kn, this sums over all vertices v to at most $(2^{k+2}k \cdot n_{\min}/d) \cdot n$. ∎

Since a bad valley contains fewer than $n_{\min}$ vertices and a kernel contains at least $b - 2(k+1)$ vertices, each kernel containing only bad valleys decomposes into at least $(b - 2(k+1))/n_{\min} \geq 3(k+1)$ bad valleys. At most $2(k+1)$ of these are of type a (Claim 3). Hence if a kernel contains only bad valleys, then either one or more of these are of type b, or at least $k+1$ of them are of type c. The first condition applies to at most $(2k/d) \cdot n \leq \frac{1}{8} n/n_{\max}$ kernels (Claim 4), and because the total number of valleys of type c is bounded by $(2^{k+2}k \cdot n_{\min}/d) \cdot n$ (Claim 5), the second condition applies to at most $(2^{k+2}k \cdot n_{\min}/(d(k+1))) \cdot n \leq \frac{1}{4} n/n_{\max}$ kernels. Since the total number of kernels is at least $\frac{1}{2} n/n_{\max}$ (Claim 2), at least $(\frac{1}{2} - \frac{1}{4} - \frac{1}{8}) \cdot n/n_{\max} = \frac{1}{8} n/n_{\max}$ kernels contain one or more good valleys. At most $n_{\max}$ disjoint valleys can intersect the same plain, so the number of plains in $\mathcal{P}$ is at least cn if we take $c = 1/(8 \cdot n_{\max}^2)$. This ends the proof of Lemma 3.1. ∎

4. Constructing tree decompositions. In this section we show that minimum-width tree decompositions of n-vertex graphs of bounded treewidth can be constructed on an EREW PRAM using $O((\log n)^2)$ time and $O(n)$ operations. More precisely, given an n-vertex graph G and a constant k, our algorithm outputs either a tree decomposition of G of treewidth $tw(G)$ or an indication of the fact that $tw(G) > k$.

The algorithm is based on the graph-reduction technique: a connected input graph of treewidth $\leq k$ is successively replaced by smaller and smaller graphs in a

series of *reductions* until a constant-size graph results. Starting from a minimum-width tree decomposition of the final constant-size graph, the reductions are then undone one by one in the reverse order of their application, where, in undoing a reduction that originally replaced a graph G' by a smaller graph G'', a minimum-width tree decomposition of G' is derived from one of G''. At the end of this process we obtain a minimum-width tree decomposition of the input graph.

Suppose that v and w are vertices in a graph G' that are either adjacent or twins and let G'' be the graph obtained from G' by removing v and its incident edges after first inserting an edge between w and each neighbor of v that was not previously a neighbor of w; we will call v and w *reduction partners* and say that G'' is obtained from G' by reduction *on* the pair $\{v, w\}$. A tree decomposition of G'' can be obtained from any tree decomposition of G' by replacing each occurrence of v in a bag by w if v and w are adjacent in G' and by removing all occurrences of v if v and w are twins in G'; hence $tw(G'') \leq tw(G')$. On the other hand, $tw(G') \leq tw(G'') + 1$, since a tree decomposition of G' can be obtained from any tree decomposition of G'' by replacing each occurrence of w in a bag by occurrences of both v and w—we will say that w is *expanded*. If G' is of bounded treewidth, we can therefore undo the reduction transforming G' into G'' by applying the width-minimizing procedure of Theorem 2.3 to derive a minimum-width tree decomposition of G' from one of G''.

For a fast parallel algorithm it clearly does not suffice to remove vertices one by one. It is easy to see, however, that the scheme described in the preceding paragraph remains valid if, rather than reducing on a single pair of vertices, we reduce simultaneously on an arbitrary collection of pairs that are sufficiently far apart in the graph not to interfere with each other. The only difference is that the treewidth of G' may now be as much as twice that of G'', plus one (each vertex in a bag may need to be expanded into two vertices), which is still fine for the width-minimizing procedure.

THEOREM 4.1. *For all constants $k \geq 1$ and all integers $n \geq 2$, the following problem can be solved on an EREW PRAM using $O((\log n)^2)$ time, $O(n)$ operations, and $O(n)$ space*: *given an n-vertex graph G, construct a minimum-width tree decomposition of G or decide* (*correctly*) *that $tw(G) > k$.*

Proof. For the time being assume that G is connected and of treewidth at most k. We will apply Lemma 3.1 to G with $n_{\min} = 2$. Hence let the constants c and d be as in the lemma and define the concepts *small* and *acquainted* accordingly. The lemma implies that G contains at least $cn/2$ distinct pairs $\{v, w\}$ of small vertices such that v and w are either adjacent or acquainted twins; to see this, note that each of the cn disjoint plains whose existence is guaranteed by the lemma contains either a valley of at least two vertices, hence a small vertex with a small neighbor (either the small neighbor also belongs to the plain or it is one of its boundary vertices), or two or more acquainted twin valleys of one vertex each. Furthermore, the set R of all such pairs can be computed in constant time using $O(n)$ operations, since it suffices to let each small vertex inspect all its neighbors and all vertices with which it is acquainted; with some care, this can be done without concurrent reading.

We cannot necessarily execute all reductions corresponding to pairs in R, since vertices in distinct pairs may coincide, be adjacent, or have adjacent entries in some adjacency list, which hinders the simultaneous execution of the associated reductions. In order to deal with this complication, we construct a *conflict graph* with a vertex for each pair in R and an edge between two vertices if the corresponding reductions exclude each other for one of the reasons mentioned above. It is easy to see that the conflict graph is of bounded degree and can be constructed in constant time using

$O(n)$ operations. Following [21], we define a *fractional independent set* in an m-vertex graph H as an independent vertex set in H of size at least ϵm, where ϵ is an (unspecified) positive constant. We proceed to compute a fractional independent set in the conflict graph, which can be done in $O(\log n)$ time using $O(n)$ operations [28, Lemma 7(b)]. Finally we execute the reductions on the pairs in the independent set, which takes constant time and uses $O(n)$ operations.

The reductions described above change G into a smaller graph G'. Let us now see that we can undo the reductions in the sense of deriving a minimum-width tree decomposition of G from one of G'. We already observed that all that is involved is to expand certain vertices into the corresponding pair of reduction partners, after which we can finish using the width-minimizing procedure of Theorem 2.3. Allowing concurrent reading, the task would be trivial—processors collectively inspecting the whole tree decomposition could simply expand each such vertex after looking up its partner in a table. In order to avoid concurrent reading from the table, we begin by balancing the given tree decomposition of G' (Lemma 2.2); this may increase its width but only by a constant factor. We then process the resulting balanced tree decomposition $(T = (X, F), \{U_x \mid x \in X\})$ in topological order; i.e., each node is processed before all of its children. The processing of a node x in T expands all vertices in U_x that need to be expanded. If x is the root of T, this is easy. If not, the identity of the reduction partner of each relevant vertex $v \in U_x$ can be passed to x from its parent y, except if v occurs in U_x for the first time (i.e., if $v \notin U_y$). For each vertex v the latter happens only at a single tree node x, however, so that in this case we can use table lookup to find the reduction partner of v without any risk of concurrent reading. The balanced tree decomposition can be processed as described in $O(\log n)$ time using $O(n)$ operations.

The graph G' derived from G is connected and of treewidth at most k, so that a new batch of reductions can be applied to G'. Since G' is smaller than G by a constant factor, as measured by the number of vertices, $O(\log n)$ successive stages of simultaneous reductions suffice to reduce the input graph to a graph of constant size. Provided that the representation of the graph at hand is compacted after each stage by means of prefix summation, the number of operations and the space needed decrease geometrically over the stages, so that the whole process uses $O((\log n)^2)$ time, $O(n)$ operations, and $O(n)$ space. Undoing the reductions is no more expensive. This proves Theorem 4.1 for connected input graphs of treewidth at most k.

Suppose now that the input graph G is of treewidth at most k but not connected. Our approach will be to apply the algorithm developed above not to G but to an auxiliary connected graph H obtained from G by introducing a new vertex r and an edge between r and a single vertex in each connected component of G. Except in the trivial case in which G has no edges, G and H have the same treewidth, so that a minimum-width tree decomposition of G can be obtained from a minimum-width tree decomposition of H by removing the occurrences of r from all bags. In order to select a vertex from each connected component of G, we can apply the first part of the reduction algorithm to G in a preprocessing phase: each connected component of G, being of treewidth at most k, is reduced to constant size, at which point the selection is easy, and the component can be removed (since its size may not decrease any further, keeping it around might make subsequent stages too expensive).

If the treewidth of the input graph G is larger than k, one or more of its connected components may fail to be reduced to constant size within the time bound established for graphs of treewidth at most k, in which case the algorithm can stop and announce

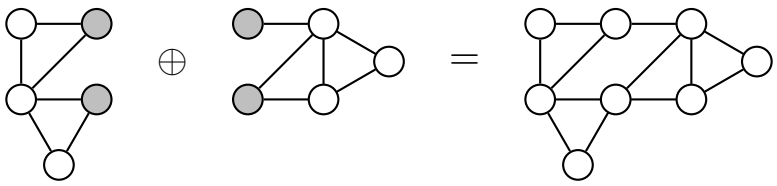

FIG. 2. *Combination of two terminal graphs using* $\oplus$.

that $tw(G) > k$. It is easy to see from the description of the algorithm that even if $tw(G) > k$, the algorithm never performs an illegal action such as concurrent reading, and any output produced by the algorithm is a correct minimum-width tree decomposition of G. □

By applying first the algorithm of Theorem 4.1 and then that of Theorem 2.5, we obtain the result below.

COROLLARY 4.2. *For all constants $k \geq 1$ and all integers $n \geq 2$, the following problem can be solved on an EREW PRAM using $O((\log n)^2)$ time, $O(n)$ operations, and $O(n)$ space*: *given an n-vertex graph G, construct a minimum-width path decomposition of G or decide* (*correctly*) *that the pathwidth of G is larger than k.*

5. Deciding treewidth on the EREW PRAM. An important bottleneck for the running time of the algorithm in the previous section is the repeated application of the algorithm of Theorem 2.3 while undoing the reductions. When we aim for a decision algorithm only, we can follow a different approach: we will not undo reductions, but instead make sure that all reductions preserve treewidth. We actually describe a generic algorithm, whose instantiations solve various decision problems on graphs of bounded treewidth; in the more general setting, reductions must not affect membership in the class of graphs to be recognized.

Our algorithm can be viewed as a parallelization of a linear-time sequential algorithm due to Arnborg et al. [6]. A first parallel version of this algorithm was given in [9]. The algorithm described there is randomized, works only for graphs of bounded degree, and uses $O(\log n)$ expected time and $O(n \log n)$ expected operations on n-vertex input graphs. The algorithm given in this section works for arbitrary graphs, uses $O(n)$ operations, and is deterministic but at a cost of an extra factor of $O(\log^* n)$ in the running time. The algorithm of [6] uses an amount of space bounded by a polynomial but a polynomial whose degree is large and unspecified. We reduce this to $O(n)$ by means of the bounded adjacency-list search technique.

A *terminal graph* is a triple $G = (V, E, Z)$, where (V, E) is a graph and $Z \subseteq V$ is an ordered set of distinguished vertices in G. The vertices in Z and those in $V \backslash Z$ are called the *terminals* and the *internal vertices* of G, respectively. A terminal graph is *open* if there are no edges between terminals. For $l \geq 0$, an *l-terminal graph* is a terminal graph with exactly l terminals. Let $\mathcal{H}_l$ denote the class of l-terminal graphs for $l \geq 0$.

Given two l-terminal graphs G_1 and G_2 for some $l \geq 0$, we define $G_1 \oplus G_2$ as the graph obtained by taking the disjoint union of G_1 and G_2 and then identifying the ith terminals in G_1 and G_2 for $i = 1, \ldots, l$. An example is shown in Figure 2. When there is an edge between a pair of terminals in both G_1 and G_2, we take just a single edge between these in $G_1 \oplus G_2$.

Let $\mathcal{G}$ be a class of graphs. We define an equivalence relation $\sim_{\mathcal{G}}$ on the set of terminal graphs as follows: $G_1 \sim_{\mathcal{G}} G_2$ if and only if for some l, G_1 and G_2 both have

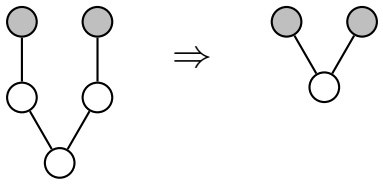

FIG. 3. *A reduction that preserves (non)membership in* $\mathcal{C}^2$.

l terminals, and for all $H \in \mathcal{H}_l$, we have $G_1 \oplus H \in \mathcal{G}$ if and only if $G_2 \oplus H \in \mathcal{G}$. Informally, G_1 and G_2 are equivalent under $\sim_{\mathcal{G}}$ if any occurrence of G_1 in a bigger graph can be replaced by an occurrence of G_2 without affecting membership of the bigger graph in $\mathcal{G}$. We say that a class $\mathcal{G}$ and its defining property P (i.e., $G \in \mathcal{G}$ if and only if $P(G)$) are of *finite index* if, for every $l \geq 0$, $\mathcal{H}_l$ splits into a finite number of equivalence classes under $\sim_{\mathcal{G}}$. (Graph properties of finite index are also known as being *regular* or of *finite state*.) Many important properties are known to be of finite index.

We illustrate the concepts introduced above through a simple example, in which P denotes the property of being a simple cycle of even length and $\mathcal{G}$ is the class $\mathcal{C}^2$ of graphs with the property P. $\mathcal{H}_2$, the class of 2-terminal graphs, splits into seven equivalence classes $\mathcal{H}_2^{(0)}, \ldots, \mathcal{H}_2^{(6)}$ under the relation $\sim_{\mathcal{C}^2}$. $\mathcal{H}_2^{(0)}$ is the class of 2-terminal graphs without edges and without internal vertices. $\mathcal{H}_2^{(1)}$, $\mathcal{H}_2^{(2)}$, and $\mathcal{H}_2^{(3)}$ are classes of 2-terminal graphs consisting of a simple path between the two terminals. The length of this path is 1 in the case of $\mathcal{H}_2^{(1)}$, is even for $\mathcal{H}_2^{(2)}$, and is odd and at least 3 for $\mathcal{H}_2^{(3)}$. $\mathcal{H}_2^{(4)}$ and $\mathcal{H}_2^{(5)}$ are classes of 2-terminal graphs that are cycles of even length. The two terminals are adjacent in graphs in $\mathcal{H}_2^{(4)}$ but not in those in $\mathcal{H}_2^{(5)}$. $\mathcal{H}_2^{(6)}$, finally, is the class of all remaining 2-terminal graphs, such as those containing a vertex of degree 3 or more. The reader may want to determine the set A of those pairs $(l_1, l_2) \in \{0, \ldots, 6\}^2$ such that if $G_1 \in \mathcal{H}_2^{(l_1)}$ and $G_2 \in \mathcal{H}_2^{(l_2)}$, then $G_1 \oplus G_2 \in \mathcal{C}^2$. E.g., $(2, 2) \in A$, but $(2, 3) \notin A$.

The two 2-terminal graphs shown in Figure 3 are equivalent under the relation $\sim_{\mathcal{C}^2}$ (both belong to $\mathcal{H}_2^{(2)}$). Thus if a graph G' is obtained from another graph G by replacing an occurrence of the left-hand graph in Figure 3 by an occurrence of the right-hand graph, we know that $G' \in \mathcal{C}^2$ if and only if $G \in \mathcal{C}^2$. This reduction allows us to recognize the graphs in $\mathcal{C}^2$: when $G \in \mathcal{C}^2$, we can apply the reduction repeatedly until we are left with a cycle of constant size. The recognition can also be carried out in parallel by applying many reductions simultaneously.

As we will now show, the ideas developed in the previous paragraph extend to any situation in which a graph class of interest can be characterized by an assertion of the form $P(G) \wedge (tw(G) \leq k)$, where P is a graph property of finite index and k is a fixed integer (in the example above, any $k \geq 2$ will do).

THEOREM 5.1. *For every graph property P of finite index and for all constants $k \geq 1$ and all integers $n \geq 2$, the problem of deciding whether $P(G) \wedge (tw(G) \leq k)$ for an n-vertex input graph G can be solved on an EREW PRAM using $O(\log n \log^* n)$ time, $O(n)$ operations, and $O(n)$ space.*

Proof. Assume first that $P(G)$ implies that G is connected. It was shown in [36] that the class of graphs of treewidth at most k is of finite index, and one easily observes that the conjunction of two properties of finite index is again of finite index

(see, e.g., [14]). Hence $\mathcal{G} = \{G \mid P(G) \wedge (tw(G) \leq k)\}$ is of finite index. Let $\mathcal{R}$ be a finite set of open terminal graphs that contains at least one element of each equivalence class of $\sim_{\mathcal{G}}$ comprising one or more open terminal graphs with at most $2(k+1)$ terminals, and take $n_{\min}$ as one more than the largest number of vertices of any graph in $\mathcal{R}$. By Lemma 3.1, we can choose constants $d, n_{\max} \geq 1$ and $c > 0$ such that if G has more than $n_{\max}$ vertices and $G \in \mathcal{G}$, then G contains at least cn disjoint $(d, k, n_{\min}, n_{\max})$-plains (for any adjacency-list representation of G).

The significance of $n_{\min}$ is that any open terminal graph with at least $n_{\min}$ vertices and at most $2(k+1)$ terminals has a smaller equivalent terminal graph in $\mathcal{R}$. In particular, each plain H together with its boundary B and all edges joining a vertex in H and a vertex in B, with the vertices in B considered as terminals (call this an *extended plain*), is such an open terminal graph, so that it can be replaced by a smaller terminal graph in $\mathcal{R}$. Considering isomorphic graphs as identical, there is only a finite number of different extended plains, all of which can therefore be mapped to equivalent smaller open terminal graphs by means of a finite table T. Each entry in T corresponds to a reduction in a natural way.

The algorithm proceeds in a number of phases. In each phase, each vertex determines whether it belongs to a plain and, if so, looks up a corresponding reduction in T. This can be done in constant time: it suffices to let each vertex u inspect those vertices and edges that lie on a path of length at most $2n_{\max}$ from u such that the entries of any two consecutive edges (v, w) and (w, x) on the path are separated by a distance of at most d in the adjacency list of w; this can be done without concurrent reading. The reductions found by two distinct vertices may not be simultaneously executable: the plain containing one vertex may intersect the plain containing the other vertex or its boundary, or two vertices, one from each plain, may have adjacent entries in some common boundary vertex. Because we only replace open terminal graphs by other open terminal graphs, however, these are the only ways in which two reductions can interfere with each other. As in section 4, we construct a conflict graph of bounded degree on the vertices belonging to plains, compute a fractional independent set in the conflict graph, and execute the corresponding reductions, which reduces the size of the graph by at least a constant factor. After $O(\log n)$ stages, either we are left with a graph of constant size, whose membership in $\mathcal{G}$ can be decided directly, or the input graph did not belong to $\mathcal{G}$.

The only part of a stage that takes more than constant time with a linear number of processors is the computation of a fractional independent set in the conflict graph. For this, we employ in the first $O(\log^* n)$ stages the algorithm of [28, Lemma 7(b)], which uses $O(\log m)$ time and $O(m)$ operations, where m is the number of vertices in the conflict graph. In the remaining phases, we use the algorithm of [26, Theorem 4], which needs $O(\log^* n)$ time and $O(m \log^* n)$ operations. The total time is $O(\log n \log^* n)$, and a simple simulation argument that schedules compactions of the representation conveniently (see [30, section 4]) shows that the algorithm can be carried out using $O(n)$ operations.

Dropping the assumption that $P(G)$ implies that G is connected, we can still proceed as described above, provided that we remove and save each connected component with fewer than $n_{\min}$ vertices as soon as it arises. After $O(\log n)$ stages, either the input graph has been reduced to an equivalent collection of connected graphs, each of which contains fewer than $n_{\min}$ vertices, or it did not belong to $\mathcal{G}$. Assume the former. In constant time, a single processor can *combine* two graphs in the collection, i.e., replace them by a single graph equivalent to their union and containing

fewer than $n_{\min}$ vertices. By means of a tree-structured combination process that uses $O(\log n)$ time and $O(n)$ operations, we can therefore reduce the input graph to a single equivalent graph with fewer than $n_{\min}$ vertices, for which membership in $\mathcal{G}$ can be decided directly. □

The theorem implies, in particular, that the problem of deciding whether the treewidth of a given graph is at most k, for constant k, can be solved in $O(\log n \log^* n)$ time with $O(n)$ operations. Moreover, the same result can be shown to hold for pathwidth. Many well-known graph properties are of finite index. For instance, this is true of all properties that can be expressed in monadic second-order logic, such as Hamiltonicity and l-colorability. This was first shown by Courcelle [20]; see [14] for a possibly more accessible proof.

Theorem 5.1 is nonconstructive: an algorithm with the stated properties is merely shown to exist. To actually exhibit the algorithm, we must be able to compute the number $n_{\min}$ and to construct the table T. If we have a terminating algorithm that decides whether two given terminal graphs are equivalent under $\sim_{\mathcal{G}}$ or under some refinement (subdivision) of $\sim_{\mathcal{G}}$ that still has a finite number of equivalence classes, this can be done by a method described in [6] (in a general algebraic setting). For the case in which $\mathcal{G}$ is the class of all graphs of treewidth at most k, such an explicit decision algorithm was exhibited in [36]. If $\mathcal{G}$ is the set of those graphs of treewidth at most k that satisfies a property P expressed in monadic second-order logic, then an algorithm that decides a subdivision of $\sim_{\mathcal{G}}$ with a finite number of equivalence classes can be obtained by combining results implicit in [14, 20, 36].

It is also possible to apply the parallel reduction techniques to problems that are of *finite integer index*, in the sense of [9]. This allows deciding on the size of a maximum independent set, minimum vertex cover, minimum dominating set, and others on graphs of bounded treewidth in $O(\log n \log^* n)$ time using $O(n)$ operations on an EREW PRAM. Using the technique of [9, section 6.1], it is also possible to construct corresponding solutions for some of these problems. With this technique and a more refined analysis, Bodlaender and de Fluiter obtained algorithms that work on an EREW PRAM using $O(\log n \log^* n)$ time and $O(n)$ operations for the problems of recognizing and building a parse tree of series-parallel graphs and of constructing a minimum-width tree decomposition of graphs of treewidth 2 [12, 23].

6. Deciding treewidth on the CRCW PRAM. In this section we show how the running time of $O(\log n \log^* n)$ of the algorithm in the previous section can be reduced to $O(\log n)$ if we move to the stronger CRCW PRAM. Among the many variants of the CRCW PRAM, we employ one that allows m processors to compute the OR of m bits in constant time using $O(m)$ space for all integers $m \geq 1$; this requirement excludes none of the CRCW PRAM variants commonly considered. We assume an instruction set that includes unit-time binary left and right shifts of words of $O(\log n)$ bits by amounts specified in a second word.

As concerns its running time, the EREW PRAM algorithm has two bottlenecks: first, as dictated by efficiency considerations, the representation of the graph at hand is compacted $\Theta(\log^* n)$ times, with each compaction taking logarithmic time. Second, in each of $\Theta(\log n)$ stages a fractional independent set is found in a conflict graph of bounded degree for which we spend $\Theta(\log^* n)$ time per stage. Moving to the CRCW PRAM, we can easily eliminate the first bottleneck, since in this model compaction can be done in $\Theta(\log n / \log\log n)$ time [19] rather than the $\Theta(\log n)$ time for the EREW PRAM. Before attacking the second bottleneck, let us observe that we can execute $\Theta(\log n / \log^* n)$ stages of the EREW PRAM algorithm without exceeding a

time bound of $O(\log n)$. After compacting once, we can then associate $2^{\Omega(\log n/\log^* n)}$ processors with each remaining vertex in the graph, We will express this by saying that we have a *processor advantage* of $2^{\Omega(\log n/\log^* n)}$, which is much more than what we need in the following.

The remaining problem is to finish the computation in $O(\log n)$ time making use of the large processor advantage mentioned above, which we will do by means of derandomization. The task is, for a positive integer $m \leq n$, to compute a fractional independent set I in an m-vertex graph of bounded degree in constant time. Observe that there is a very simple randomized algorithm for obtaining I: each vertex picks a random bit uniformly from $\{0, 1\}$ and independently of other vertices and then steps into I exactly if it picked a 1 while each of its neighbors picked a 0. Although this formulation assumes that the vertices make independent choices, it is easy to see that much less will also do. If each vertex v has at least a constant probability of stepping into I, then the expected size of I is $\Omega(m)$, so that, obviously, at least one possible execution of the randomized algorithm will result in $|I| = \Omega(m)$. Whether v steps into I, however, is a function only of the random bits picked by v and by its neighbors; i.e., it suffices to guarantee d-wise independence, where d is one more than the maximum degree of the graph. In the case of perfect d-wise independence, the probability that v steps into I is at least 2^{-d}. Since we can allow any positive constant here instead of 2^{-d}, however, we can relax the requirements even more. For $\epsilon > 0$, random bits $X_1, \ldots, X_m$ are said to be (ϵ, d)-*independent* [3] if, for all positive integers $l \leq d$, all distinct integers $i_1, \ldots, i_l$ with $1 \leq i_1, \ldots, i_l \leq m$ and all $b_1, \ldots, b_l \in \{0, 1\}$, the probability of the event $X_{i_1} = b_1, X_{i_2} = b_2, \ldots, X_{i_l} = b_l$ deviates from 2^{-l} by at most ϵ (d-wise independence is the special case $\epsilon = 0$). It is easy to see that (ϵ, d)-independent random bits, where $\epsilon = 2^{-d-1}$, suffice for our purpose. We now appeal to Theorem 2 of [3], which promises that m $(2^{-d-1}, d)$-independent random bits can be drawn from a sample space of size $(\log m)^{O(1)}$ (where the exponent depends on d); we argue separately in Lemma 6.2 below that the computation of the m bits can be carried out in constant time with m processors.

Since our processor advantage is much bigger than polylogarithmic in n, we can use the limited-randomness algorithm developed above and simulate all $(\log m)^{O(1)} = (\log n)^{O(1)}$ possible executions of it in parallel. We know that at least one execution will be good, in the sense that it will lead to an independent set I of size $\Omega(m)$. We would like simply to pick a good execution, but this is not entirely trivial, since we have only constant time per stage, which is not sufficient for computing the size of I. Using the deterministic approximate-summation algorithm of [29, Theorem 3], we can compute the size of I, up to a constant factor (which is sufficiently accurate), in $O((\log \log n)^3)$ time. While this is fast, it is not fast enough. We overcome this using a technique of [29], namely to simulate all possible executions of the randomized algorithm not just for one stage at a time but for $\Theta((\log \log n)^3)$ consecutive stages, after which we can spend $O((\log \log n)^3)$ time determining a good execution without violating our time bound (as much time is then spent on graph reduction as on counting). Doing this increases the size of the sample space to $(\log n)^{O((\log \log n)^3)} = 2^{O((\log \log n)^4)}$, which is still sufficiently small, in view of our larger processor advantage.

THEOREM 6.1. *For every graph property P of finite index and for all constants $k \geq 1$ and all integers $n \geq 2$, the problem of deciding whether $P(G) \wedge (tw(G) \leq k)$ for an n-vertex input graph G can be solved on a CRCW PRAM using $O(\log n)$ time, $O(n)$ operations, and $O(n)$ space.*

As in the case of Theorem 5.1, Theorem 6.1 is nonconstructive; see the discussion

near the end of section 5. In order to complete the proof of Theorem 6.1, we still have to show the following.

LEMMA 6.2. *For all given integers $m, K \geq 2$ with $K = (\log m)^{O(1)}$ and all constant integers $d \geq 2$, m $(1/K, d)$-independent random bits can be computed in constant time on a CRCW PRAM using m processors, $O(m)$ space, and a single random integer drawn from the uniform distribution over a range of size $(\log m)^{O(1)}$.*

Proof. Our construction, described below, is an elaboration of one given in [3, Theorem 2].

Without loss of generality assume that d is odd, say, $d = 2t + 1$. Let r be the smallest number of the form $2 \cdot 3^i$ no smaller than $\log(m + 1)$, where i is an integer, and take p as the smallest prime no smaller than $(2K(1 + rt))^2$.

Let F be the set of all bit vectors of length r and denote by $\phi : \{0, \ldots, 2^r - 1\} \to F$ the function that maps each integer to its standard r-bit binary representation. Assume that F is organized into a field by means of suitable addition and multiplication operations; details will be given below.

Now choose a random integer h from the uniform distribution over $\{0, \ldots, p - 1\}$ and compute the bit vector y of length $1 + rt$ whose $(i + 1)$st bit, for $i = 0, \ldots, rt$, is 0 exactly if $i + h \equiv s^2 \pmod p$ for some $s \in \{1, \ldots, p - 1\}$ (i.e., if $h + i$ is a quadratic residue modulo p). Finally, for $i = 1, \ldots, m$, compute the ith output bit as the inner product modulo 2 of y with a bit vector x_i of length $1 + rt$ constructed as follows: the first bit of x_i is 1, the next r bits are those of $\phi(i)$, the next r bits are those of $(\phi(i))^3$, where the powering is done according to the multiplication in F, the next r bits are those of $(\phi(i))^5$, etc., until the last r bits, which are those of $(\phi(i))^{2t-1}$.

It is proved in [3, Proposition 2] that the inner product modulo 2 of y with any fixed nonzero bit vector of length $1+rt$ is ϵ-*biased* [3], where $\epsilon = rt/\sqrt{p}+(1 + rt)/p \leq 2(1 + rt)/\sqrt{p} \leq 1/K$; i.e., it takes on the values 0 and 1 with probabilities differing by at most ϵ. It then follows from [3, Lemma 2] and [2, Proposition 6.5] that the m bits output by the algorithm are indeed $(1/K, d)$-independent (a requirement of [3, Lemma 2] to the effect that the size of a sample space called S_n^m must be a power of 2 is not satisfied in the present application, where this size is the prime p, but is in fact superfluous). What remains is to bound the resources needed by the computation.

Obviously, $r = O(\log m)$ and, by Bertrand's postulate (see, e.g., [32, Theorem 418]), which asserts the existence of a prime in the range $\{s, \ldots, 2s\}$ for every positive integer s, we obtain that $p = (\log m)^{O(1)}$, so that the random integer h is indeed chosen from a range as small as claimed in the lemma. In order to compute r and p in constant time, we proceed as follows: first, comparing the powers $2^1, 2^2, 2^3, \ldots$ with $m + 1$ in parallel, we obtain $\lceil \log(m + 1) \rceil$. It is then easy to compute an integer g with $g \geq p$, but $g = (\log m)^{O(1)}$. The remaining computation uses g^2 processors. Using trial division by all smaller numbers in the set $S = \{2, \ldots, g\}$, we determine the set of primes in S. Subsequently, using trial division by all smaller primes, we determine the set of powers of 3 in S, after which it is easy to select first r and then p; each is the smallest number in S satisfying a property that can be tested in constant time by one processor. The vector y is obtained similarly by first computing the set of quadratic residues modulo p.

In order to construct the vectors $x_1, \ldots, x_m$, we need to implement the field operations of F. We define the product of the vectors $(a_{r-1}, a_{r-2}, \ldots, a_0)$ and $(b_{r-1}, b_{r-2}, \ldots, b_0)$ as $(c_{r-1}, c_{r-2}, \ldots, c_0)$, where $\sum_{i=0}^{r-1} c_i x^i$ is the remainder polynomial obtained by dividing the product $(\sum_{i=0}^{r-1} a_i x^i)(\sum_{i=0}^{r-1} b_i x^i)$ by the fixed polynomial $f(x) = x^r + x^{r/2} + 1$ over the 2-element field $\mathbb{Z}_2$. Since $f(x)$ is irreducible over $\mathbb{Z}_2$ [37,

Exercise 3.96], it is well-known that this multiplication operation together with componentwise addition over $\mathbb{Z}_2$ indeed turns F into a field.

Compute q as a positive integer with $q \leq (\log m)/5$, but $q = \Omega(\log m)$. We can implement addition and multiplication over $\mathbb{Z}_2$ of polynomials of degree less than q, represented by bit vectors in the obvious way, by means of table lookup. In each case, we need a $(2^q - 1) \times (2^q - 1)$ table with entries in the range $\{0, \ldots, 2^{2q-1} - 1\}$. In constructing the tables, we can therefore, for each table entry and each integer in the range $\{0, \ldots, 2^{2q-1} - 1\}$, dedicate a team of $\Omega(m^{1/5})$ processors to testing whether the integer is the correct value of the entry under consideration, in which case the team will fill in that table entry. In the case of addition, the testing is trivial to do in constant time with just q processors, each of which takes care of one bit position. For multiplication, the problem reduces to computing the parities of $2q-1$ bit sequences, each of length at most q. Since the parity of q bits can be computed in constant time with $O(m^\delta)$ processors, for arbitrary constant $\delta > 0$ (see, e.g., [40, lemma, p. 375]), we have enough processors in this case as well.

Because $r = O(q)$, addition and multiplication over $\mathbb{Z}_2$ of polynomials of degree less than r reduces to a constant number of additions and multiplications over $\mathbb{Z}_2$ of polynomials of degree less than q, so that both operations can be carried out in constant time by one processor using the tables constructed above. In order to complete the implementation of multiplication over F, we need to describe how to compute the remainder over $\mathbb{Z}_2$ of a polynomial $a(x) = \sum_{i=0}^{l} a_i x^i$ modulo $f(x)$, where $r \leq l \leq 2r - 2$. But since none of the powers $x^{r-1}, \ldots, x^{(r/2)+1}$ occur in $f(x)$, the polynomial $a(x) - (\sum_{i=r}^{l} a_i x^{i-r}) f(x)$, which obviously has the same remainder modulo $f(x)$ as $a(x)$, is of degree at most $\max\{l - r/2, r - 1\}$, so that constant time suffices to reduce the degree of the input polynomial by at least $r/2$ or below r. Doing this twice completes the computation.

The final operation that must be supported is forming the inner product modulo 2 of two bit vectors, each of length $O(r)$. This operation can easily be carried out in constant time by one processor using a table that maps each bit sequence of q bits to its parity. Before the table can be used, it is necessary to convert y from a representation with one bit per word to one with q bits per word. Again, this can be done in constant time by trying out all possibilities in parallel. □

Acknowledgments. We thank Jordan Gergov and Rajeev Raman for helpful discussions related to the proof of Lemma 6.2.

FIRST-ORDER QUERIES ON FINITE STRUCTURES OVER THE REALS*

JAN PAREDAENS†, JAN VAN DEN BUSSCHE‡, AND DIRK VAN GUCHT§

Abstract. We investigate properties of finite relational structures over the reals expressed by first-order sentences whose predicates are the relations of the structure plus arbitrary polynomial inequalities, and whose quantifiers can range over the whole set of reals. In constraint programming terminology, this corresponds to Boolean real polynomial constraint queries on finite structures. The fact that quantifiers range over all reals seems crucial; however, we observe that each sentence in the first-order theory of the reals can be evaluated by letting each quantifier range over only a finite set of real numbers without changing its truth value. Inspired by this observation, we then show that when all polynomials used are linear, each query can be expressed uniformly on all finite structures by a sentence of which the quantifiers range only over the finite domain of the structure. In other words, linear constraint programming on finite structures can be reduced to ordinary query evaluation as usual in finite model theory and databases. Moreover, if only "generic" queries are taken into consideration, we show that this can be reduced even further by proving that such queries can be expressed by sentences using as polynomial inequalities only those of the simple form $x < y$.

Key words. first-order logic, linear arithmetic, relational databases, constraint programming

1. Introduction.

In this paper we are motivated by two fields of computer science which heavily rely on logic: relational databases and constraint programming. We will look at the latter from the perspective of the former.

In classical relational database theory [1], a database is modeled as a relational structure. The domain of this structure is some fixed universe **U** of possible data elements (such as all strings, or all natural numbers), and is typically infinite. The relations of the structure, in contrast, are always finite, as they model finite tables holding data. As a consequence, the *active* domain of the database, consisting of all data elements actually occurring in one or more of the relations, is finite as well.

A (Boolean) *query* is a mapping from databases (over some fixed relational signature) to true or false. A basic way of expressing a query is by a first-order sentence over the relational signature. For example, on a database containing information on children and hobbies, the query "does each parent have at least all hobbies of his children?" is expressed by the sentence $(\forall p)(\forall c)(\forall h)(\mathit{Child}(p,c) \wedge \mathit{Hobby}(c,h) \rightarrow \mathit{Hobby}(p,h))$.

Since the domain of each database is **U**, the quantifiers in a sentence expressing a query will naturally range over the whole infinite **U**. However, Aylamazyan et al. [5] showed that in order to obtain the result of the query it suffices to let the quantifiers range over the active domain augmented with a finite set of q additional data elements, where q is the number of quantified variables in the formula expressing the query. The

intuition behind this result is that all data elements outside the active domain of a given database are alike with respect to that database.

Alternatively, we can choose to let the quantifiers range over the active domain only, thus obtaining a semantics which is quite different from the natural interpretation. For example, consider databases over the single unary relation symbol P. Then the sentence $(\forall x)P(x)$ will always be false under the natural interpretation, while under the active-domain interpretation it will always be true. In fact, it is not obvious that each query expressible under the natural interpretation is also expressible under the active-domain interpretation. Hull and Su [15] established that the implication indeed holds. (The converse implication holds as well, since the active-domain interpretation can easily be simulated under the natural interpretation using bounded quantification.)

In recent years, much attention has been paid to "constraint programming languages" (e.g., [9]). In particular, in 1990, Kanellakis, Kuper, and Revesz demonstrated that the idea of constraint programming also applies to database query languages by introducing the framework of "constraint query languages" [16]. An important instance of this framework is that of real polynomial constraints. Here, the universe $\mathbf{U}$ of data elements is the field $\mathbf{R}$ of real numbers. Databases, then, are relational structures over $\mathbf{R}$, but the database relations need no longer be finite; it suffices that they are definable as finite Boolean combinations of polynomial inequalities. In other words, each k-ary relation of the structure must be a semi-algebraic subset of $\mathbf{R}^k$ [10].

A basic way of querying real polynomial constraint databases is again by first-order sentences, which can now contain polynomial inequalities in addition to the predicate symbols of the relational signature. For example, if the database holds a set S of points in $\mathbf{R}^2$, the query "do all points in S lie on a common circle?" is expressed by $(\exists x_0)(\exists y_0)(\exists r)(\forall x)(\forall y)(S(x,y) \rightarrow (x-x_0)^2+(y-y_0)^2 = r^2)$. Note that quantifiers are naturally interpreted as ranging over the whole of $\mathbf{R}$. In order to evaluate such a sentence on a database, we replace each predicate symbol in the formula by the polynomial definition of the corresponding database relation, and obtain a sentence in the pure first-order theory of the reals. As is well known, this theory is decidable [22]; the truth value of the obtained sentence yields the result of the query. So, real polynomial constraint queries are effectively computable.

Finite relations are semi-algebraic, so that finite relational databases over the reals form an important special case of real polynomial constraint databases. For example, if we want to model a database holding a finite number of rectangles, we can either choose to store the full extents of the rectangles, resulting in the infinite set of all points on the rectangles (represented in terms of linear inequalities in the obvious way), or we can choose to store only the corner points of each rectangle, resulting in a finite relation.

In the present paper, we investigate whether the results by Aylamazyan et al. [5] and by Hull and Su [15], mentioned in the beginning of this Introduction, carry over from classical first-order queries on relational databases to polynomial constraint queries on finite databases over the reals. Indeed, as in the classical case, one can give an alternative active-domain semantics to constraint sentences and again ask whether this is without loss of expressive power. Note, however, that active-domain quantification defies the very nature of constraint programming as a means to reason about intentionally defined, potentially infinite, ranges of values. Hence, it is not obvious that the results just mentioned might carry over at all.

Nonetheless, we have found a natural analog of the Aylamazyan et al. theorem,

and we have been able to establish the verbatim analog of the Hull–Su theorem in the case when only linear polynomials are used. This is often the case in practice. Our result might be paraphrased by saying that on finite structures, first-order linear constraint programming can be reduced to ordinary query evaluation as usual in finite model theory and databases.

Our development is based upon the following observation. Consider a prenex normal form sentence $(Q_1x_1)\dots(Q_nx_n)M(x_1,\dots,x_n)$ in the first-order theory of the reals. For any finite set D_0 of real numbers, there exists a sequence $D_0 \subseteq D_1 \subseteq \cdots \subseteq D_n$ of finite sets of reals such that the sentence can be evaluated by letting each quantifier Q_i range over D_i only (rather than over the whole of $\mathbf{R}$) without changing the sentence's truth value. By taking D_0 to be the active domain of a given finite database over the reals, we get the analog in the real case of the Aylamazyan et al. theorem.

The reader familiar with Collins's method for quantifier elimination in real-closed fields through cylindrical algebraic decomposition (cad) [3, 4, 12] will not be surprised by the above observation. Indeed, it follows more or less directly from an obvious adaptation of the cad construction. However, we give an alternative, self-contained proof from first principles which abstracts away the purely algorithmical aspects of the cad construction and focuses on the logic behind it. Importantly, this proof provides us with a basis to show how, in the case of linear polynomials, the construction of the sequence $D_1 \subseteq \cdots \subseteq D_n$ departing from the active domain D_0 can be simulated using a linear constraint formula. As a result, we obtain the analog in the real case of the Hull–Su theorem.

In a final section of this paper, we look at queries that are "generic," i.e., that do not distinguish between isomorphic databases. Genericity is a natural criterion in the context of classical relational databases [2, 11]. Perhaps this is a little less so for databases over the reals; in other work [19] we have proposed alternative, "spatial" genericity criterions based on geometrical intuitions. Nevertheless, it remains interesting to investigate which classically generic queries can be expressed using linear constraint sentences.

Sentences that do not contain any polynomial inequalities always express generic queries, but from the moment a sentence even contains only simple inequalities of the form $x < y$ it can already be nongeneric. Furthermore, examples are known (e.g., [1, Exercise 17.27]) of generic queries expressible with such simple inequalities but not without. In other words, simple inequalities, though inherently nongeneric when viewed in isolation, help to express more generic queries. The natural question now is whether general linear polynomial inequalities help even more. We will answer this question negatively.[1]

This paper is organized as follows. We start with a rather general section 2 in which we introduce the notion of domain sequence on which much of our development will hinge. In section 3 we then introduce the subject of queries on real databases. In section 4 we focus on the linear case. In section 5 we discuss generic queries.

Since we presented the original ideas contained in the present paper at a conference [20], several researchers have been able to generalize our results. We provide a brief summary of these generalizations in section 6.

[1] We thus provide a partial rectification of Kuper's original intuitions [17] (which are incorrect as stated).

2. Domain sequences. We will use the basic terminology from mathematical logic [13]. Let $\mathcal{A}$ be a structure over a finite relational vocabulary L. The domain of $\mathcal{A}$ is denoted by A. Let $\Phi(x_1, \ldots, x_k)$ be a first-order formula over L written in prenex normal form

$$(*) \qquad (Q_{k+1}x_{k+1}) \ldots (Q_n x_n) M(x_1, \ldots, x_n),$$

with each Q_i either $\exists$ or $\forall$ and M quantifier-free. If $k = 0$ then Φ is a sentence; if $k = n$ then Φ is quantifier-free. If $\bar{a} = a_1, \ldots, a_k \in A$ is a tuple of elements in A then the truth of Φ in $\mathcal{A}$ with a_i substituted for x_i is denoted by $\mathcal{A} \models \Phi[\bar{a}]$.

If $D_{k+1}, \ldots, D_n$ are subsets of A, then we write

$$(\mathcal{A}; D_{k+1}, \ldots, D_n) \models \Phi[\bar{a}]$$

if $\Phi[\bar{a}]$ evaluates to true in $\mathcal{A}$ when we let each quantifier Q_i range over D_i only rather than over the whole of A.

Example 2.1. Let $\mathcal{A}$ consist of the integers together with the predicate $y = x^2$, and let Φ be the sentence $(\forall x)(\exists y) y = x^2$. Then $(\mathcal{A}; \{-1, 2\}, \{1, 4\}) \models \Phi$, but $(\mathcal{A}; \{-1, 2\}, \{1, 3\}) \not\models \Phi$.

In this section, we prove the following theorem.

THEOREM 2.2. *Let Φ be a sentence $(Q_1 x_1) \ldots (Q_n x_n) M(x_1, \ldots, x_n)$, and let D_0 be a finite subset of A. Then there exists an increasing sequence $D_0 \subseteq D_1 \subseteq \cdots \subseteq D_n$ of finite subsets of A such that*

$$\mathcal{A} \models \Phi \quad \Longleftrightarrow \quad (\mathcal{A}; D_1, \ldots, D_n) \models \Phi.$$

Example 2.3. As a trivial illustration, let $\mathcal{A}$ consist of the integers together with the predicate $x = y^2$, and let Φ be the sentence $(\forall x_1)(\exists x_2) x_2 = (x_1)^2$. Let D_0 be the empty set. We have $\mathcal{A} \models \Phi$, and indeed, for $D_1 = \{-1, 2\}$ and $D_2 = \{-1, 2, 1, 4\}$, we have $(\mathcal{A}; D_1, D_2) \models \Phi$.

To prove Theorem 2.2 we introduce various auxiliary notions on which we will also rely in later sections.

We will use the following natural equivalence relation on A^n.

DEFINITION 2.4. *Two points $\bar{a}$ and $\bar{b}$ in A^n are called equivalent, denoted $\bar{a} \equiv \bar{b}$, if for each atomic formula $F(x_1, \ldots, x_n)$ we have $\mathcal{A} \models F[\bar{a}]$ iff $\mathcal{A} \models F[\bar{b}]$. In model-theoretic terminology, $\bar{a}$ and $\bar{b}$ are equivalent if they are of the same basic type in $\mathcal{A}$.*

Example 2.5. Let $\mathcal{A}$ consist of the reals together with the predicates $C(x, y)\ \theta\ 0$, $L_1(x, y)\ \theta\ 0$, and $L_2(x, y)\ \theta\ 0$, where θ is $<$, $=$, or $>$, and C, L_1, and L_2 are polynomials describing the circle and two lines depicted in Figure 1. The same figure shows that there are 19 equivalence classes in A^2: $\{a\}$, $\{b, c\}$, $\{d, e\}$, A, $B \cup D$, C, E, $F \cup H$, G, I, $J \cup L$, K, α, β, γ, $\delta \cup \lambda$, ϵ, η, and κ.

We now extend this equivalence relation inductively to lower dimensions such that the equivalence classes at each dimension are "cylindrical" over the equivalence classes at the next lower dimension.

DEFINITION 2.6. *Let $i < n$ and assume $\equiv$ is already defined on A^{i+1}. Then for $\bar{a}, \bar{b} \in A^i$ we say $\bar{a} \equiv \bar{b}$ if for each $a_{i+1} \in A$ there is a $b_{i+1} \in A$ such that $(\bar{a}, a_{i+1}) \equiv (\bar{b}, b_{i+1})$ and conversely, for each b_{i+1} there is an a_{i+1} such that $(\bar{b}, b_{i+1}) \equiv (\bar{a}, a_{i+1})$.*

Example 2.7. In Figure 2 there are 12 equivalence classes in A: $\{p\}$, $\{q\}$, $\{r\}$, $\{s\}$, $\{t\}$, $\{u\}$, P, $Q \cup V$, R, S, T, and U.

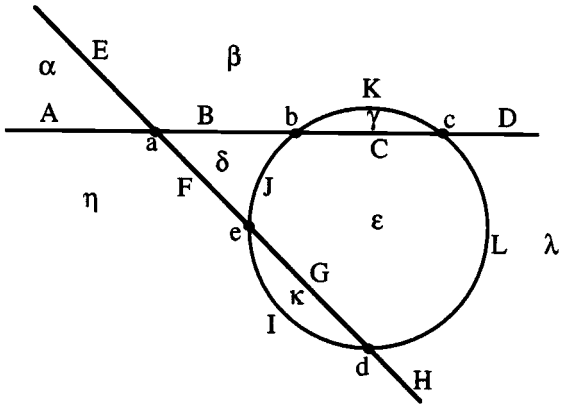

FIG. 1. *Equivalence classes in the plane induced by a circle and two lines.*

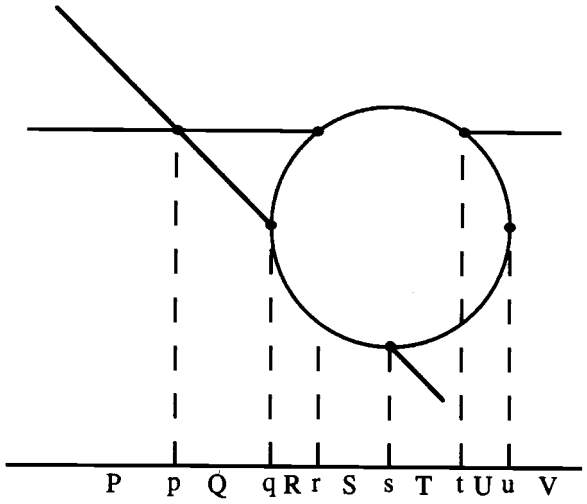

FIG. 2. *From equivalence classes in A^2 (Example* 2.5*) to equivalence classes in A.*

We note the following lemma for further use.

LEMMA 2.8. *For each i, $\equiv$ is of finite index on A^i.*

Proof. The proof is by downward induction on i. The base case $i = n$ is trivial since the number of atomic formulas $F(x_1, \ldots, x_n)$ is finite (we assumed a finite relational vocabulary). So assume $i < n$. For $\bar{a} \in A^i$, let $\kappa(\bar{a})$ be the set of equivalence classes in A^{i+1} intersecting the "vertical line through $\bar{a}$" $\{(\bar{a}, a_{i+1}) \mid a_{i+1} \in A\}$. Clearly, for $\bar{a}, \bar{b} \in A^i$, $\bar{a} \not\equiv \bar{b}$ implies $\kappa(\bar{a}) \neq \kappa(\bar{b})$. Since, by induction, $\equiv$ is of finite index on A^{i+1}, κ can have only a finite number of possible values and hence $\equiv$ is of finite index on A^i as well. □

The relevance of the equivalence relations just defined is demonstrated by the following lemma. We use the following notation: let $\Phi(\bar{x})$ be as in $(*)$ above. For $k \leq i \leq n$, $\Phi|_i$ stands for the formula

$$(Q_{i+1}x_{i+1}) \ldots (Q_n x_n) M(x_1, \ldots, x_n).$$

So, $\Phi|_k$ equals Φ and $\Phi|_n$ equals M.

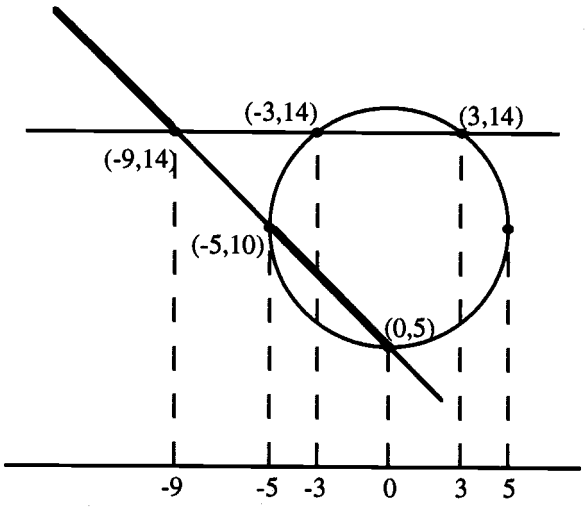

FIG. 3. *Equivalent points and formula satisfaction.*

LEMMA 2.9. *Let $k \leq i \leq n$, and let $\bar{a} \equiv \bar{b}$ be equivalent points in A^i. Then*

$$\mathcal{A} \models \Phi|_i[\bar{a}] \iff \mathcal{A} \models \Phi|_i[\bar{b}].$$

Proof. The proof is a straightforward downward induction on i. The base case, $i = n$ and $\Phi|_n$ being quantifier-free, is obvious. Now let $k \leq i < n$. We have $\Phi|_i = (Q_{i+1}x_{i+1})\Phi|_{i+1}$. We first consider the case $Q_{i+1} = \exists$. Note that we only have to prove the implication from left to right; the other direction follows by symmetry. If $\mathcal{A} \models \Phi|_i[\bar{a}]$ then there exists $a_{i+1} \in A$ such that $\mathcal{A} \models \Phi|_{i+1}[\bar{a}, a_{i+1}]$. Since $\bar{a} \equiv \bar{b}$, there exists $b_{i+1} \in A$ such that $(\bar{a}, a_{i+1}) \equiv (\bar{b}, b_{i+1})$. By the induction hypothesis, it follows that $\mathcal{A} \models \Phi|_{i+1}[\bar{b}, b_{i+1}]$ and hence $\mathcal{A} \models \Phi|_i[\bar{b}]$.

The case $Q_{i+1} = \forall$ is similar. If $\mathcal{A} \models \Phi|_i[\bar{a}]$ then for each $a_{i+1} \in A$ we have $\mathcal{A} \models \Phi|_{i+1}[\bar{a}, a_{i+1}]$. Since $\bar{a} \equiv \bar{b}$, for each $b_{i+1} \in A$ there exists an $a_{i+1} \in A$ such that $[\bar{b}, b_{i+1}] \equiv [\bar{a}, a_{i+1}]$. By the induction hypothesis, it follows that for each b_{i+1}, $\mathcal{A} \models \Phi|_{i+1}[\bar{b}, b_{i+1}]$ and hence $\mathcal{A} \models \Phi|_i[\bar{b}]$. □

Example 2.10. Continuing Examples 2.5 and 2.7, let $C(x, y) = x^2 + y^2 - 20x + 75$, $L_1(x, y) = x + y - 5$, and $L_2(x, y) = y - 14$. Let Φ be the sentence $(\forall x_1)(\exists x_2)(x_1 + x_2 - 5 = 0 \wedge (x_2 - 14 > 0 \vee (x_1)^2 + (x_2)^2 - 20x_1 + 75 < 0))$. This is illustrated in Figure 3. We have $\Phi|_0 = \Phi$, $\Phi|_1 = (\exists x_2)(x_1 + x_2 - 5 = 0 \wedge (x_2 - 14 > 0 \vee (x_1)^2 + (x_2)^2 - 20x_1 + 75 < 0))$, and $\Phi|_2 = x_1 + x_2 - 5 = 0 \wedge (x_2 - 14 > 0 \vee (x_1)^2 + (x_2)^2 - 20x_1 + 75 < 0)$. As can be deduced from Example 2.7 the equivalence classes in A are $(-\infty, -9)$, $[-9]$, $(-9, -5) \cup (5, \infty)$, $[-5]$, $(-5, -3)$, $[-3]$, $(-3, 0)$, $[0]$, $(0, 3)$, $[3]$, $(3, 5)$, and $[5]$. We have $\mathcal{A} \models \Phi|_1[a]$ for each $a \in (-\infty, -9) \cup (-5, -3) \cup [-3] \cup (-3, 0]$.

The notion of *domain sequence* is defined next.

DEFINITION 2.11. *A sequence $D_k \subseteq D_{k+1} \subseteq \cdots \subseteq D_n$ of finite subsets of A is called a* domain sequence *if for each $k \leq i < n$:*

$$\forall \bar{a} \in (D_i)^i,\ \forall a_{i+1} \in A,\ \exists a'_{i+1} \in D_{i+1} : (\bar{a}, a_{i+1}) \equiv (\bar{a}, a'_{i+1}).$$

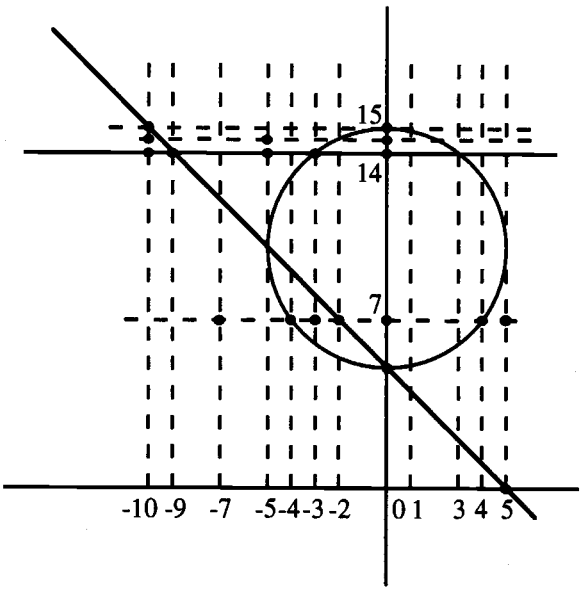

FIG. 4. *Domain sequence construction.*

Example 2.12. Continuing Example 2.10, from Figure 4 we see that (D_0, D_1, D_2), with

$D_0 = \{0\}$,

$D_1 = \{-10, -9, -7, -5, -4, -3, -2, 0, 1, 3, 4, 5\}$, and

$D_2 = D_1 \cup \{7, 14, 14.5, 15\}$,

is a domain sequence.

Since $\equiv$ is of finite index (Lemma 2.8), we know the following.

LEMMA 2.13. *For any given finite $D_k \subseteq A$, there exists a domain sequence starting from D_k.*

The following technical lemma now directly implies Theorem 2.2.

LEMMA 2.14. *Let*

- $D_k \subseteq D_{k+1} \subseteq \cdots \subseteq D_n$ *be a domain sequence*;
- $a_1, \ldots, a_k \in D_k$;
- $k \leq i \leq n$; *and*
- $a_j \in D_j$ *for* $k < j \leq i$.

Then

$$\mathcal{A} \models \Phi|_i[a_1, \ldots, a_i] \quad \Longleftrightarrow \quad (\mathcal{A}; D_{i+1}, \ldots, D_n) \models \Phi|_i[a_1, \ldots, a_i].$$

Proof. The proof is by downward induction on i. Denote $(a_1, \ldots, a_i)$ by $\bar{a}$. The case $i = n$ is trivial. So assume $i < n$. We have $\Phi|_i = (Q_{i+1}x_{i+1})\Phi|_{i+1}$. Consider first the case $Q_{i+1} = \exists$. For the implication from left to right, assume $\mathcal{A} \models \Phi|_i[\bar{a}]$. Then there exists $a_{i+1} \in A$ such that $\mathcal{A} \models \Phi|_{i+1}[\bar{a}, a_{i+1}]$. According to Definition 2.11, there exists $a'_{i+1} \in D_{i+1}$ such that $(\bar{a}, a_{i+1}) \equiv (\bar{a}, a'_{i+1})$. By Lemma 2.9, we also have $\mathcal{A} \models \Phi|_{i+1}[\bar{a}, a'_{i+1}]$. By induction, $(\mathcal{A}; D_{i+2}, \ldots, D_n) \models \Phi|_{i+1}[\bar{a}, a'_{i+1}]$. We can thus conclude that $(\mathcal{A}; D_{i+1}, \ldots, D_n) \models \Phi|_i[\bar{a}]$.

For the implication from right to left, assume $(\mathcal{A}; D_{i+1}, \ldots, D_n) \models \Phi|_i[\bar{a}]$. Then there exists $a_{i+1} \in D_{i+1}$ such that $(D_{i+2}, \ldots, D_n) \models \Phi|_{i+1}[\bar{a}, a_{i+1}]$. By induction, we have $\mathcal{A} \models \Phi_{i+1}[\bar{a}, a_{i+1}]$. Since a_{i+1} is trivially in A, we can thus conclude that $\mathcal{A} \models \Phi|_i[\bar{a}]$.

Next consider the case $Q_{i+1} = \forall$. For the implication from left to right, assume $\mathcal{A} \models \Phi|_i[\bar{a}]$. Then for each $a_{i+1} \in A$ we have $\mathcal{A} \models \Phi|_{i+1}[\bar{a}, a_{i+1}]$. In particular, this holds for each $a_{i+1} \in D_{i+1}$, and by induction, we have $(\mathcal{A}; D_{i+2}, \ldots, D_n) \models \Phi|_{i+1}[\bar{a}, a_{i+1}]$. We can thus conclude that $(\mathcal{A}; D_{i+1}, \ldots, D_n) \models \Phi|_i[\bar{a}]$.

For the implication from right to left, assume $(\mathcal{A}; D_{i+1}, \ldots, D_n) \models \Phi|_i[\bar{a}]$. Then for each $\alpha \in D_{i+1}$ we have $(\mathcal{A}; D_{i+2}, \ldots, D_n) \models \Phi|_{i+1}[\bar{a}, \alpha]$, and thus, by induction, also $\mathcal{A} \models \Phi|_{i+1}[\bar{a}, \alpha]$. Now take an arbitrary $a_{i+1} \in A$. According to Definition 2.11, there exists $a'_{i+1} \in D_{i+1}$ such that $(\bar{a}, a_{i+1}) \equiv (\bar{a}, a'_{i+1})$. By Lemma 2.9, since $\mathcal{A} \models \Phi|_{i+1}[\bar{a}, a'_{i+1}]$, we also have $\mathcal{A} \models \Phi|_{i+1}[\bar{a}, a_{i+1}]$. We can thus conclude that $\mathcal{A} \models \Phi_i[\bar{a}]$. ∎

COROLLARY 2.15. *Let Φ be a sentence $(Q_1 x_1) \ldots (Q_n x_n) M(x_1, \ldots, x_n)$, and let $D_0 \subseteq D_1 \subseteq \cdots \subseteq D_n$ be a domain sequence. Then*

$$\mathcal{A} \models \Phi \quad \Longleftrightarrow \quad (\mathcal{A}; D_1, \ldots, D_n) \models \Phi.$$

Proof. Set $i = k = 0$ in Lemma 2.14. ∎

3. Queries on real databases. Fix a relational vocabulary σ consisting of a finite number of relation symbols S with associated arity. A *real database* $\mathcal{B}$ is a structure of type σ having the set $\mathbf{R}$ of real numbers as domain, assigning to each relation symbol S of arity a in σ a *finite* relation $S^{\mathcal{B}}$ of rank a on $\mathbf{R}$.[2] The *active domain* of $\mathcal{B}$, denoted by $\mathrm{adom}(\mathcal{B})$, is the (finite) set of all real numbers appearing in one or more relations in $\mathcal{B}$.

A *query* is a mapping from databases of type σ to true or false. A basic way of expressing queries is by *query formulas*, which are standard first-order formulas built using Boolean connectives and quantification from atomic formulas of one of the following two forms:

- $p > 0$, with p a multivariate polynomial with real coefficients;
- $S(p_1, \ldots, p_a)$, with S a relation symbol in σ of arity a, and each p_i a polynomial as in the previous item.

If $\Phi(\bar{x})$ is a query formula and $\mathcal{B}$ is a database, then the truth of Φ in $\mathcal{B}$, denoted by $\mathcal{B} \models \Phi[\bar{a}]$, is defined in the standard way. In particular, if Φ is a sentence, it expresses the query yielding true on an input database $\mathcal{B}$ iff $\mathcal{B} \models \Phi$.

Example 3.1. Assume $\sigma = \{S\}$ with $\alpha(S) = 2$. The query "do all points in S lie on a common circle?" can be expressed as

$$(\exists x_0)(\exists y_0)(\exists r)(\forall x)(\forall y)(S(x, y) \rightarrow (x - x_0)^2 + (y - y_0)^2 = r^2).$$

(Conditions of the form $p = 0$ are expressible in terms of conditions of the form $p > 0$ as $\neg(p > 0) \wedge \neg(-p > 0)$.)

The query "is there a point in S whose coordinates are greater than or equal to 1?" can be expressed as $(\exists x)(\exists y) S(x^2 + 1, y^2 + 1)$. Note that the quantifiers are naturally interpreted as ranging over the whole of $\mathbf{R}$.

Formulas that do not mention any of the relation names in σ are called *real formulas*. Let Ψ be a real formula and let all variables occurring in Ψ be among

[2] Formally, $S^{\mathcal{B}} \subseteq \mathbf{R} \times \cdots \times \mathbf{R}$ (a times).

$x_1, \ldots, x_n$. Let Π be the set of all polynomials p for which the inequality $p > 0$ occurs in Ψ. For such a set Π of polynomials over the variables $x_1, \ldots, x_n$ we have the following definition.

DEFINITION 3.2. *The structure* $\mathbf{R}_\Pi$ *is the structure having as domain the set* $\mathbf{R}$ *of real numbers, and having as relations the* n*-ary relations* $\{(r_1, \ldots, r_n) \mid p(r_1, \ldots, r_n) > 0\}$ *for each* $p \in \Pi$. *If* Π *comes from a formula* Ψ*, as above, we will also refer to* $\mathbf{R}_\Pi$ *as* $\mathbf{R}_\Psi$. *Note that* Ψ *can be naturally evaluated in the structure* $\mathbf{R}_\Psi$.

If Φ is a query sentence and $\mathcal{B}$ is a database, then we can produce a real sentence $\Phi^{\mathcal{B}}$ in a very natural way as follows. Let $S(p_1, \ldots, p_a)$ be an atomic subformula of Φ, with S a relation symbol in σ. We know that $S^{\mathcal{B}}$ is a finite relation consisting of, say, the m tuples $\{(e_{11}, \ldots, e_{1a}), \ldots, (e_{m1}, \ldots, e_{ma})\}$. Then replace $S(p_1, \ldots, p_a)$ in Φ by $\bigvee_{i=1}^{m} p_1 = e_{i1} \wedge \ldots \wedge p_a = e_{ia}$. It is obvious that

$$\mathcal{B} \models \Phi \quad \Longleftrightarrow \quad \mathbf{R}_{\Phi^{\mathcal{B}}} \models \Phi^{\mathcal{B}}.$$

Now assume the query sentence Φ is in prenex normal form:

$$(Q_1 x_1) \ldots (Q_n x_n) M(x_1, \ldots, x_n). \tag{$\dagger$}$$

If $\mathcal{B}$ is a database and $D_1, \ldots, D_n$ are subsets of $\mathbf{R}$, then we say that Φ is satisfied on $(\mathcal{B}; D_1, \ldots, D_n)$, written $(\mathcal{B}; D_1, \ldots, D_n) \models \Phi$, if Φ evaluates to true on $\mathcal{B}$ when we let each quantifier Q_i range over D_i only, rather than over the whole of $\mathbf{R}$.

Corollary 2.15 immediately implies the following.

THEOREM 3.3. *Let* Φ *be a query sentence as in* ($\dagger$) *above and let* $\mathcal{B}$ *be a real database. For each domain sequence* $D_0 \subseteq D_1 \subseteq \cdots \subseteq D_n$ *in the context of the structure* $\mathbf{R}_{\Phi^{\mathcal{B}}}$,

$$\mathcal{B} \models \Phi \quad \Longleftrightarrow \quad (\mathcal{B}; D_1, \ldots, D_n) \models \Phi.$$

When we choose $D_0 = \mathrm{adom}(\mathcal{B})$, this theorem can be viewed as the analog in the real case of the Aylamazyan et al. theorem [5] mentioned in the Introduction.

4. The linear case. In this section, we focus on *linear* queries, expressed by query sentences in which all occurring polynomials are linear. We prove that each linear query is expressible by a linear query sentence wherein the quantifiers range over the active domain of the input database only. Thereto, we introduce a particular way to construct a domain sequence starting with the active domain of a database, based on Gaussian elimination. We then show that this construction can be simulated in a uniform (i.e., database-independent) way by a linear query formula.

Let Π be a set of linear polynomials on the variables $x_1, \ldots, x_n$. Recall Definition 3.2 of the structure $\mathbf{R}_\Pi$. Within the context of this structure we can consider equivalence of points in $\mathbf{R}^i$, for $i \leq n$, as defined in Definitions 2.4 and 2.6.

Each polynomial $p \in \Pi$ is of the form $c_0^p + \sum_{j=1}^{n} c_j^p x_j$. We define a sequence $\Pi_n, \ldots, \Pi_1$ of linear polynomials inductively as follows.

DEFINITION 4.1. $\Pi_n = \Pi$, *and for* $i < n$,

$$\Pi_i = \{p \in \Pi_{i+1} \mid c_{i+1}^p = 0\} \cup \{p \cdot c_{i+1}^q - q \cdot c_{i+1}^p \mid p, q \in \Pi_{i+1},\ c_{i+1}^p \neq 0 \neq c_{i+1}^q\}.$$

In other words, each Π_i *is a set of linear polynomials over* $x_1, \ldots, x_i$ *obtained from* Π_{i+1} *by Gaussian elimination.*

In the next proposition, equivalence of points in $\mathbf{R}^i$ with respect to $\mathbf{R}_\Pi$ will be characterized in terms of the polynomials in Π_i. Thereto we need an easy-to-prove lemma.

LEMMA 4.2. *Let α_1, α_2, β_1, and β_2 be elements from some densely ordered domain. The following are equivalent.*

1. *For $(i,j) \in \{(1,2),(2,1)\}$,*
$$\alpha_i > \alpha_j \quad \Leftrightarrow \quad \beta_i > \beta_j.$$
2. *For each α there exists β such that for $i = 1, 2$,*
$$\alpha_i > \alpha \quad \Leftrightarrow \quad \beta_i > \beta,$$
and conversely, for each β there exists α such that the same holds.

PROPOSITION 4.3. *Let $1 \leq i \leq n$ and let $\bar{a}, \bar{b} \in \mathbf{R}^i$. Then $\bar{a}$ and $\bar{b}$ are equivalent with respect to $\mathbf{R}_\Pi$ if and only if for each polynomial p in Π_i,*
$$p(\bar{a}) > 0 \quad \Leftrightarrow \quad p(\bar{b}) > 0.$$

Proof. The proof is by downward induction on i. The case $i = n$ is just the definition of equivalence of n-tuples. So assume $i < n$. Let $\bar{a} \equiv \bar{b}$. Then for each a_{i+1} there is a b_{i+1} such that $(\bar{a}, a_{i+1}) \equiv (\bar{b}, b_{i+1})$ (and conversely). Equivalently, by induction, for each a_{i+1} there is a b_{i+1} such that for each polynomial p in Π_{i+1}, $p(\bar{a}, a_{i+1}) > 0 \Leftrightarrow p(\bar{b}, b_{i+1}) > 0$. If $c^p_{i+1} = 0$ then $p \in \Pi_i$ and we get $p(\bar{a}) > 0 \Leftrightarrow p(\bar{b}) > 0$; this deals with the first kind of elements of Π_i.

For the other kind of elements of Π_i, consider $p, q \in \Pi_{i+1}$ with $c^p_{i+1} \neq 0 \neq c^q_{i+1}$. From the above, for each a_{i+1} there is a b_{i+1} such that

$$\left(c^p_0 + \sum_{j=1}^{i} c^p_j a_j\right) / c^p_{i+1} > -a_{i+1} \quad \Leftrightarrow \quad \left(c^p_0 + \sum_{j=1}^{i} c^p_j b_j\right) / c^p_{i+1} > -b_{i+1}$$

and

$$\left(c^q_0 + \sum_{j=1}^{i} c^q_j a_j\right) / c^q_{i+1} > -a_{i+1} \quad \Leftrightarrow \quad \left(c^q_0 + \sum_{j=1}^{i} c^q_j b_j\right) / c^q_{i+1} > -b_{i+1}.$$

Conversely, for each b_{i+1} there is an a_{i+1} such that the same holds. By Lemma 4.2 we thus deduce

$$\left(c^p_0 + \sum_{j=1}^{i} c^p_j a_j\right) / c^p_{i+1} > \left(c^q_0 + \sum_{j=1}^{i} c^q_j a_j\right) / c^q_{i+1}$$
$$\Leftrightarrow \quad \left(c^p_0 + \sum_{j=1}^{i} c^p_j b_j\right) / c^p_{i+1} > \left(c^q_0 + \sum_{j=1}^{i} c^q_j b_j\right) / c^q_{i+1}$$

and hence

$$\left(c^p_0 + \sum_{j=1}^{i} c^p_j a_j\right) \cdot c^q_{i+1} > \left(c^q_0 + \sum_{j=1}^{i} c^q_j a_j\right) \cdot c^p_{i+1}$$
$$\Leftrightarrow \quad \left(c^p_0 + \sum_{j=1}^{i} c^p_j b_j\right) \cdot c^q_{i+1} > \left(c^q_0 + \sum_{j=1}^{i} c^q_j b_j\right) \cdot c^p_{i+1}$$

or

$$(p \cdot c_{i+1}^q - q \cdot c_{i+1}^p)(\bar{a}) > 0 \quad \Leftrightarrow \quad (p \cdot c_{i+1}^q - q \cdot c_{i+1}^p)(\bar{b}) > 0,$$

which, by the definition of Π_i, is what had to be proven. This argument for the "only-if" implication can simply be reversed to prove the "if" implication. □

Now let Φ be a linear query sentence $(Q_1 x_1) \dots (Q_n x_n) M$ in prenex normal form, and let $\mathcal{B}$ be a database. Recall the definition of the real formula $\Phi^{\mathcal{B}}$ described in the previous section; note that since Φ is linear, $\Phi^{\mathcal{B}}$ is linear as well.

DEFINITION 4.4. *Fix Π to be the set of all polynomials occurring in $\Phi^{\mathcal{B}}$ plus all those of the form $p_i - e$, where p_i occurs in some atomic formula $S(p_1, \dots, p_a)$ of Φ and $e \in \mathrm{adom}(\mathcal{B})$. We can then consider the sequence $\Pi = \Pi_n, \dots, \Pi_1$ as in Definition 4.1. For what follows it is important to note that, since Π contains at least all polynomials occurring in $\Phi^{\mathcal{B}}$, equivalence of points with respect to $\mathbf{R}_\Pi$ implies equivalence with respect to the structure $\mathbf{R}_{\Phi^{\mathcal{B}}}$ mentioned in Theorem 3.3.*

Example 4.5. Let $\Phi = (\forall x_1)(\exists x_2)(S(x_1 + x_2 + 1) \wedge (x_1 + 2x_2 + 2 = 0))$. Then $\Pi = \Pi_2 = \{1 - e + x_1 + x_2 \mid e \in \mathrm{adom}(\mathcal{B})\} \cup \{2 + x_1 + 2x_2\}$ and $\Pi_1 = \{-2e + x_1 \mid e \in \mathrm{adom}(\mathcal{B})\}$.

We observe the following.

LEMMA 4.6. *Let $1 \le i \le n$. Then Π_i is a finite union of sets of the form*

$$\left\{ c_0 + \sum_{j=1}^{2^{(n-i)}} d_j e_j + \sum_{j=1}^{i} c_j x_j \mid e_1, \dots, e_{2^{(n-i)}} \in \mathrm{adom}(\mathcal{B}) \right\}.$$

Neither the number of these sets nor the coefficients c_i and d_i for each set depend on the particular database $\mathcal{B}$.

Proof. The proof is by downward induction on i. The base case $i = n$ is clear since $\Pi_n = \Pi$ is clearly of the good form. So assume $i < n$. By definition, Π_i is a union of two sets:

$$\{p \in \Pi_{i+1} \mid c_{i+1}^p = 0\}$$

and

$$\{p \cdot c_{i+1}^q - q \cdot c_{i+1}^p \mid p, q \in \Pi_{i+1},\ c_{i+1}^p \neq 0 \neq c_{i+1}^q\}.$$

By the induction hypothesis, the first set is clearly of the good form. Also, by the induction hypothesis, the second set is a finite union of sets of the form

$$\left\{ c'_{i+1} \left(c_0 + \sum_{j=1}^{2^{(n-i-1)}} d_j e_j + \sum_{j=1}^{i+1} c_j x_j \right) - c_{i+1} \left(c'_0 + \sum_{j=1}^{2^{(n-i-1)}} d'_j e'_j + \sum_{j=1}^{i+1} c'_j x_j \right) \mid \right.$$
$$\left. {}_1, \dots, e_{2^{(n-i-1)}}, e'_1, \dots, e'_{2^{(n-i-1)}} \in \mathrm{adom}(\mathcal{B}) \right\}.$$

After simplification, this is readily seen to be of the good form also. □

We are now in a position to define a particular domain sequence with respect to the structure $\mathbf{R}_{\Phi^{\mathcal{B}}}$, based on the sequence $\Pi_1, \dots, \Pi_n$. The sequence is inductively constructed: D_0 is empty and D_i $(i > 0)$ is constructed as follows. First consider the set E_i of all the ith coordinates of the i-dimensional points that are in a hyperplane

of Π_i and whose first $i-1$ coordinates are in D_{i-1}. Add D_{i-1} to E_i, resulting in D'_i. Finally, to be sure to obtain a point in every equivalence class, we add the mean value of every pair of elements of D'_i, as well as every element increased by one and every element decreased by one, resulting in D_i. Formally, we make the following definition.

DEFINITION 4.7. *The* linear sequence on $\mathcal{B}$ with respect to Φ *is the sequence* $\emptyset = D_0 \subseteq D_1 \subseteq \cdots \subseteq D_n$ *inductively defined as follows: for* $1 \leq i \leq n$, D_i *equals*

$$D'_i \cup \left\{ y \mid (\exists y_1, y_2) \in D'_i : y = \frac{y_1 + y_2}{2} \vee y = y_1 - 1 \vee y = y_1 + 1 \right\},$$

where D'_i *is* $D_{i-1} \cup E_i$ *with*

$$E_i = \left\{ -c_0/c_i - \sum_{j=1}^{2^{(n-i)}} (d_j/c_i)e_j - \sum_{j=1}^{i-1} (c_j/c_i)y_j \mid c_0 + \sum_{j=1}^{2^{(n-i)}} d_j e_j + \sum_{j=1}^{i} c_j x_j \in \Pi_i, \right.$$
$$\left. c_i \neq 0,\ y_1, \ldots, y_{i-1} \in D_{i-1},\ e_1, \ldots, e_{2^{(n-i)}} \in \mathrm{adom}(\mathcal{B}) \right\}.$$

Example 4.8. In Example 4.5 we have

$$D'_1 = \{2e_1 \mid e_1 \in \mathrm{adom}(\mathcal{B})\},$$

$$D_1 = \big\{2e_1 + \eta \mid \eta \in \{-1, 0, 1\}\big\},$$

and

$$E_2 = \big\{-1 + e_3 - (2e_1 + \eta),$$
$$-1 + e_3 - (e_1 + e_2),$$
$$-1 - (2e_1 + \eta)/2,$$
$$-1 - (e_1 + e_2)/2 \mid$$
$$e_1, e_2, e_3 \in \mathrm{adom}(\mathcal{B}),\ \eta \in \{-1, 0, 1\}\big\}.$$

PROPOSITION 4.9. *The linear sequence on* $\mathcal{B}$ *with respect to* Φ *is a domain sequence with respect to* $\mathbf{R}_{\Phi\mathcal{B}}$.

Proof. According to Definition 2.11, we must show for each $1 \leq i \leq n$ that

$$\forall \bar{a} \in (D_{i-1})^{i-1},\ \forall a_i \in \mathbf{R},\ \exists a'_i \in D_i : (\bar{a}, a_i) \equiv (\bar{a}, a'_i).$$

So, let $\bar{a} \in (D_{i-1})^{i-1}$ and assume $a_i \notin D_i$. Consider the definition of D_i in terms of $D'_i = D_{i-1} \cup E_i$ from Definition 4.7 above. We distinguish the following possibilities for a_i.

1. $a_i < \min(E_i)$; then put $a'_i := \min(E_i) - 1$.
2. $a_i > \max(E_i)$; then put $a'_i := \max(E_i) + 1$.
3. $\min(E_i) < a_i < \max(E_i)$; then put $a'_i := (e_1 + e_2)/2$, where e_1 is the maximal element in E_i such that $e_1 < a_i$, and e_2 is the minimal element such that $a_i < e_2$.

It is obvious that $a_i' \in D_i$; moreover, we invite readers to convince themselves that from the way E_i is defined, it follows that all polynomials in Π_i have the same sign on $(\bar{a}, a_i)$ and $(\bar{a}, a_i')$. Hence, by Proposition 4.3, the proposition follows. □

After one final lemma we will be able to state and prove the main result of this section.

LEMMA 4.10. *For each $0 \leq i \leq n$ there exists a finite set P of linear polynomials such that for each database $\mathcal{B}$, the ith member D_i of the linear sequence on $\mathcal{B}$ with respect to Φ equals $\{p(y_1, \ldots, y_z) \mid y_1, \ldots, y_z \in \mathrm{adom}(\mathcal{B}) \wedge p \in P\}$, with z independent of $\mathcal{B}$.*

Proof. The proof is by induction on i. The case $i = 0$ is trivial since $D_0 = \emptyset$ (put $P := \emptyset$). So assume $i > 0$. The definition of D_i in terms of D_i' in Definition 4.7 is clearly of the form $D_i = \{p(y_1, y_2) \mid y_1, y_2 \in D_i' \wedge p \in P'\}$ where P' consists of the four polynomials $(y_1 + y_2)/2$, $y_1 - 1$, $y_1 + 1$, and y_1. We have $D_i' = D_{i-1} \cup E_i$, where E_i is clearly of the form $\{p(y_1, \ldots, y_{i-1}, e_1, \ldots, e_{2^{(n-i)}}) \mid y_1, \ldots, y_{i-1} \in D_{i-1} \wedge e_1, \ldots, e_{2^{(n-i)}} \in \mathrm{adom}(\mathcal{B}) \wedge p \in P''\}$ for some P'', and by induction, D_{i-1} is of the form $\{p(y_1, \ldots, y_z) \mid y_1, \ldots, y_z \in \mathrm{adom}(\mathcal{B}) \wedge p \in P'''\}$ for some P'''. By combining these expressions using a tedious but straightforward substitution process, we obtain the desired form for D_i. □

THEOREM 4.11. *For each linear query sentence Φ there is a linear query sentence Ψ, which can be effectively constructed from Φ, such that for each database $\mathcal{B}$, $\mathcal{B} \models \Phi$ if and only if $\mathcal{B} \models_{\mathrm{adom}} \Psi$, where $\models_{\mathrm{adom}}$ denotes that the quantifiers in Ψ range over the active domain of the database only.*

Proof. Let $\emptyset \subseteq D_1 \subseteq \cdots \subseteq D_n$ be the linear sequence on $\mathcal{B}$ with respect to Φ. By Theorem 3.3 and Proposition 4.9, we know that $\mathcal{B} \models \Phi$ iff $(\mathcal{B}; D_1, \ldots, D_n) \models \Phi$. We can write the latter explicitly as $\mathcal{B} \models (Q_1 x_1 \in D_1) \ldots (Q_n x_n \in D_n) M(x_1, \ldots, x_n)$. From Lemma 4.10 we know that D_1 can be written as $\{p(y_1, \ldots, y_z) \mid y_1, \ldots, y_z \in \mathrm{adom}(\mathcal{B}) \wedge p \in P\}$. If Q_1 is $\exists$, we can rewrite the above formula as

$$\mathcal{B} \models (\exists y_1) \ldots (\exists y_z) \bigvee_{p \in P} (Q_2 x_2 \in D_2) \ldots (Q_n x_n \in D_n) M(p(y_1, \ldots, y_z), x_2, \ldots, x_n),$$

where each $(\exists y_i)$ ranges only over $\mathrm{adom}(\mathcal{B})$. If Q_1 is $\forall$ we have

$$\mathcal{B} \models (\forall y_1) \ldots (\forall y_z) \bigwedge_{p \in P} (Q_2 x_2 \in D_2) \ldots (Q_n x_n \in D_n) M(p(y_1, \ldots, y_z), x_2, \ldots, x_n).$$

By replacing $Q_2, \ldots, Q_n$ in a similar manner, we obtain the desired sentence Ψ.

If $\mathrm{adom}(\mathcal{B})$ is empty then the above strategy will not work. However, the sentence Ψ obtained above can be modified so as to test for this special case, and if this test succeeds, a fixed truth value can be returned. This fixed truth value is the result of evaluating $(\mathcal{B}_\emptyset \models \Phi)$, where $\mathcal{B}_\emptyset$ denotes the database with empty active domain.[3] □

5. Generic queries. Two databases $\mathcal{B}$ and $\mathcal{B}'$ over the same relational signature σ are called *isomorphic* if there is a bijection $\rho : \mathrm{adom}(\mathcal{B}) \to \mathrm{adom}(\mathcal{B}')$ such that $\rho(S^{\mathcal{B}}) = S^{\mathcal{B}'}$ for each relation symbol S in σ. A query which yields the same result on isomorphic databases is called *generic*.

[3] An exception occurs when the signature σ contains relation symbols of arity zero. In this case, there is no unique $\mathcal{B}_\emptyset$, but rather a fixed finite number of them. The sentence can test which one it is dealing with and return the appropriate truth value.

For example, assume that σ consists of a single binary relation symbol S. Databases of type σ can be viewed as finite directed graphs whose nodes are real numbers. Of course, any query expressed in the language $\mathcal{L}$ of pure first-order sentences over σ (i.e., not containing any polynomial inequalities) is generic. Other examples of generic queries are "is the graph connected?" or "is the number of edges even?".

In the language $\mathcal{L}^<$ consisting of those query sentences where all inequalities are of the simple form $x < y$ (with x and y variables),[4] nongeneric queries can easily be expressed, such as $(\forall x)(\forall y)S(x,y) \to x < y$. As pointed out in the Introduction, however, there are generic queries expressible in $\mathcal{L}^<$ but not in $\mathcal{L}$. We have been able to prove that there is no similar gain in expressiveness when moving from $\mathcal{L}^<$ to full linear query sentences.

THEOREM 5.1. *For each linear query sentence Φ expressing a generic query there is a query sentence Ψ in $\mathcal{L}^<$, which can be effectively constructed from Φ, such that for each database $\mathcal{B}$, $\mathcal{B} \models_{\text{adom}} \Phi$ if and only if $\mathcal{B} \models_{\text{adom}} \Psi$.*

As in Theorem 4.11, $\models_{\text{adom}}$ denotes that quantifiers range over the active domain only; we know by Theorem 4.11 that this active-domain interpretation is without loss of generality.

We next present an elementary proof of Theorem 5.1 based on three lemmas and one auxiliary definition.

The following fact is easy to prove.

LEMMA 5.2. *Let $q(x) = \sum_{i=0}^{d} a_i x^i$ be a polynomial with real coefficients, in one variable, of degree d ($a_d \neq 0$). Let*

$$r > d \cdot \frac{\max_{0 \leq i \leq d} |a_i|}{\min_{\substack{0 \leq j \leq d \\ a_j \neq 0}} |a_j|}.$$

Then $q(r)$ has the same sign as a_d.

We make the following definition.

DEFINITION 5.3. *Let $p(x_1, \ldots, x_n) = \sum_{i=1}^{n} b_i x_i + b_0$ be a linear polynomial with real coefficients in n variables. We associate with p a function $\Xi_p : \mathbf{R}^n \to \mathbf{R}$ as follows. Consider $\bar{y} = (y_1, \ldots, y_n) \in \mathbf{R}^n$. Associate a "weight" $W_p^{\bar{y}}(y_i)$ with each y_i by*

$$W_p^{\bar{y}}(y_i) := \sum_{\substack{1 \leq j \leq n \\ y_j = y_i}} b_j.$$

If all weights are zero, define $\Xi_p(y_1, \ldots, y_n) := b_0$. Otherwise, define

$$\Xi_p(y_1, \ldots, y_n) := W_p^{\bar{y}}(y_M),$$

where y_M is maximal with nonzero weight; i.e., $y_m = \max\{y_i \mid 1 \leq i \leq n,\ W_p^{\bar{y}}(y_i) \neq 0\}$.

Example 5.4. We illustrate the above definition with three examples.

1. Let $p(x_1, x_2, x_3) = x_1 - 5x_2 + 3x_3 - 8$. Then
   - $\Xi_p(7, 3, 9) = 3$;
   - $\Xi_p(7, 9, 3) = -5$.

[4] As an aside, we would like the reader to note that Theorem 4.11 specializes to query sentences in $\mathcal{L}^<$. This follows from general results in [8], but can also be proven in a direct way using an argument similar to our proof of Theorem 4.11.

2. Let $p(x_1, x_2) = 2x_1 - 2x_2 + 5$. Then $\Xi_p(5, 5) = 5$.
3. Let $p(x_1, \ldots, x_7) = 3x_1 - 3x_2 + 6x_3 - 6x_4 + 5x_5 + x_6 - 6x_7$. Then
   - $\Xi_p(4, 4, 2, 2, 2, 2, 2) = 0$;
   - $\Xi_p(5, 5, 4, 4, 3, 2, 1) = 5$;
   - $\Xi_p(5, 5, 4, 4, 1, 2, 3) = -6$.

The relevance of Ξ_p stems from the following observation.

LEMMA 5.5. *Let $p(x_1, \ldots, x_n) = \sum_{i=1}^{n} b_i x_i + b_0$ and let $s > 0$ be a natural number. Then there exists a number α_p such that for all $\beta > \alpha_p$ and for any sequence of integers $\bar{z} = z_1, \ldots, z_n \in \{0, \ldots, s\}$,*

$$p(\beta^{z_1}, \ldots, \beta^{z_n}) > 0 \quad \Longleftrightarrow \quad \Xi_p(z_1, \ldots, z_n) > 0.$$

Proof. Note that

$$p(\beta^{z_1}, \ldots, \beta^{z_n}) = \sum_{i=1}^{n} b_i \beta^{z_i} + b_0 = \sum_{j} W_p^{\bar{z}}(z_j) \beta^{z_j} + b_0,$$

where j in the latter sum ranges over a set of indices consisting of one j for each distinct value z_j. Hence, the value $p(\beta^{z_1}, \ldots, \beta^{z_n})$ can be viewed as the value of a univariate polynomial q in β. The highest-degree coefficient of q is $\Xi_p(z_1, \ldots, z_n)$. The degree of q is $\max_j z_j$. Hence, if we take

$$\alpha_p = s \cdot \frac{\max_B |B|}{\min_{|B| \neq 0} |B|},$$

where B ranges over all partial sums of b_i's, then any $\beta > \alpha_p$ satisfies the condition of Lemma 5.2 and thus, for such β, $p(\beta^{z_1}, \ldots, \beta^{z_n}) = q(\beta)$ has the same sign as $\Xi_p(z_1, \ldots, z_n)$. □

As a last lemma towards the proof of Theorem 5.1 we note the following.

LEMMA 5.6. *For a fixed polynomial p as above, the predicate $\Xi_p(y_1, \ldots, y_n) > 0$ can be expressed by a formula $\xi_p(y_1, \ldots, y_n)$ in $\mathcal{L}^<$.*

Proof. The crucial observation is that the value of $\Xi_p(y_1, \ldots, y_n)$ depends not on the actual values of the y_i's but only on their relative positions (in model-theoretic terms, the *order type* of $y_1, \ldots, y_n$). The number of possible order types (n being fixed) is finite, so the formula ξ_p simply consists of the disjunction of those order types for which the value $\Xi_p(y_1, \ldots, y_n)$ is positive. □

Example 5.7. Let $p(x_1, x_2) = 2x_1 - 2x_2 + 5$. Then $\Xi_p(y_1, y_2) > 0$ is expressed by $y_1 = y_2 \vee y_1 > y_2$.

Proof of Theorem 5.1. Replace in Φ every inequality $p(x_1, \ldots, x_n) > 0$ by the formula $\xi_p(x_1, \ldots, x_n) > 0$ of Lemma 5.6. In this way we obtain a query sentence Ψ in $\mathcal{L}^<$. We still have to show that $\mathcal{B} \models_{\text{adom}} \Phi$ iff $\mathcal{B} \models_{\text{adom}} \Psi$. Let s be the cardinality of $\text{adom}(\mathcal{B})$. Each polynomial p occurring in Φ has an associated lower bound α_p of Lemma 5.5. Let β be larger than any of these α_p's and let ρ be an order-preserving (i.e., monotone) bijection from $\text{adom}(\mathcal{B})$ to $\{\beta, \beta^2, \ldots, \beta^s\}$. Then

$$\begin{aligned} \mathcal{B} \models_{\text{adom}} \Phi &\Leftrightarrow \rho(\mathcal{B}) \models_{\text{adom}} \Phi \\ &\Leftrightarrow \rho(\mathcal{B}) \models_{\text{adom}} \Psi \\ &\Leftrightarrow \mathcal{B} \models_{\text{adom}} \Psi. \end{aligned}$$

The first equivalence holds since Φ is generic, the second holds by Lemma 5.5, and the third holds since ρ is monotone and Ψ is a formula in $\mathcal{L}^<$; the truth of formulas in $\mathcal{L}^<$ is preserved under order-preserving isomorphisms.

Inspection of the above proof shows that Theorem 5.1 can be sharpened a little bit. Indeed, of the given that Φ expresses a generic query, we actually use only that this query yields the same result on databases that are isomorphic via an order-preserving, rather than an arbitrary, bijection.

We can conclude that all generic queries that are not expressible in $\mathcal{L}^<$ are not expressible as a linear query either (by Theorem 4.11, under both the active-domain interpretation and the natural interpretation). In particular, this holds for the queries, already mentioned at the beginning of this section, of testing for connectivity or even cardinality of a finite graph over the reals.

COROLLARY 5.8. *Graph connectivity and even cardinality are not expressible by linear query sentences.*

Proof. By the above it suffices to show that these queries are not expressible in $\mathcal{L}^<$ with quantification on the active domain. But this is well known [1]. □

Grumbach, Su, and Tollu [14] have also obtained inexpressibility results for linear queries, using complexity arguments. In particular, they showed that in the context of the rationals $\mathbf{Q}$ rather than the reals $\mathbf{R}$, linear queries are in the complexity class AC_0, while even cardinality and connectivity are not. We would like to point out (as is readily verified) that our technical development applies equally well to the rationals.

6. Concluding remarks. Since we presented the original ideas contained in the present paper at a conference [20], several researchers have been able to generalize our results:

- In this paper we have considered databases and queries over the structure $\mathbf{R}$ of the reals. One can do the same for any arbitrary fixed infinite "universe-structure." Using the Ehrenfeucht–Mostowski theorem on first-order indiscernibles, Otto and Van den Bussche [18] have shown that Theorem 5.1 generalizes from $\mathbf{R}$ to any arbitrary fixed infinite structure.
- Benedikt et al. [7] have generalized Theorem 5.1 in two senses: again, to more universes than just the reals, and more importantly, to quantification on the whole universe rather than on the active domain only. One consequence of the results in [7] is a generalization of our Corollary 5.8: graph connectivity and even cardinality are not expressible by any (not necessarily linear) real query sentence, under both the natural interpretation and the active-domain interpretation.
- Belegradek, Stolboushkin, and Taitslin [21, 6] have generalized Theorem 5.1 in another sense: instead of finite databases they considered possibly infinite databases definable by real formulas involving only simple inequalities.
- Benedikt and Libkin [8] have shown that Theorem 4.11 holds in any densely ordered structure that satisfies the property of *o-minimality* and admits elimination of quantifiers. In particular, their result implies that Theorem 4.11 generalizes to the nonlinear case (since the structure of the reals with addition and multiplication admits elimination of quantifiers).

In constrast to the proofs of these generalizations, the proofs of our results as given in the present paper are elementary and constructive (the results in [21] are also constructive).

Acknowledgment. We are grateful to Bart Kuijpers for his careful reading of earlier drafts of the material presented in this paper, to Alex Stolboushkin for helpful

comments on a first presentation of our results, and to an anonymous referee for pointing out a mistake in the submitted draft of this paper.

SPIRALITY AND OPTIMAL ORTHOGONAL DRAWINGS*

GIUSEPPE DI BATTISTA†, GIUSEPPE LIOTTA‡, AND FRANCESCO VARGIU§

Abstract. We deal with the problem of constructing the orthogonal drawing of a graph with the minimum number of bends along the edges. The problem has been recently shown to be NP-complete in the general case. In this paper we introduce and study the new concept of spirality, which is a measure of how an orthogonal drawing is "rolled up," and develop a theory on the interplay between spirality and number of bends of orthogonal drawings. We exploit this theory to present polynomial time algorithms for two significant classes of graphs: series-parallel graphs and 3-planar graphs. Series-parallel graphs arise in a variety of problems such as scheduling, electrical networks, data-flow analysis, database logic programs, and circuit layout. Also, they play a central role in planarity problems. Furthermore, drawings of 3-planar graphs are a classical field of investigation.

Key words. graph drawing, orthogonal representation, planar embedding, bend minimization

1. Introduction.

A graph drawing algorithm receives as input a graph and produces as output a drawing that nicely represents such a graph; several references on the subject of graph drawing can be found in [23, 7]. Most graph drawing algorithms can be roughly split into the following two main steps.

1. A planar embedding of the given graph is found by a *planarization algorithm*, possibly by inserting dummy vertices for crossings. The planar embedding is usually described by the cyclic ordering of the edges incident at each vertex. Planarization algorithms are implemented by using variations of the classical planarity testing algorithms (see, e.g., [12]).
2. Once a planar embedding has been found, a *representation algorithm* is applied to produce the final drawing. Such an algorithm is selected depending on the requirements of the application and on the graphic standard. It can be targeted to minimize the global area of the drawing, to have as few bends as possible along the edges, to emphasize symmetries, etc.

The representation algorithm produces a drawing within the planar embedding computed by the planarization algorithm. However, the choice of the planar embedding can deeply affect the results obtained by the representation algorithm. In Fig. 1 we show two different planar embeddings of the same graph. Besides each planar embedding we show the *orthogonal drawing* (edges are mapped to polygonal chains of horizontal and vertical segments) with the minimum number of bends that can be

constructed preserving that embedding. In the drawing of Fig. 1a we have $n/3 - 2$ bends (where n is the number of vertices); in the one of Fig. 1b we have no bends.

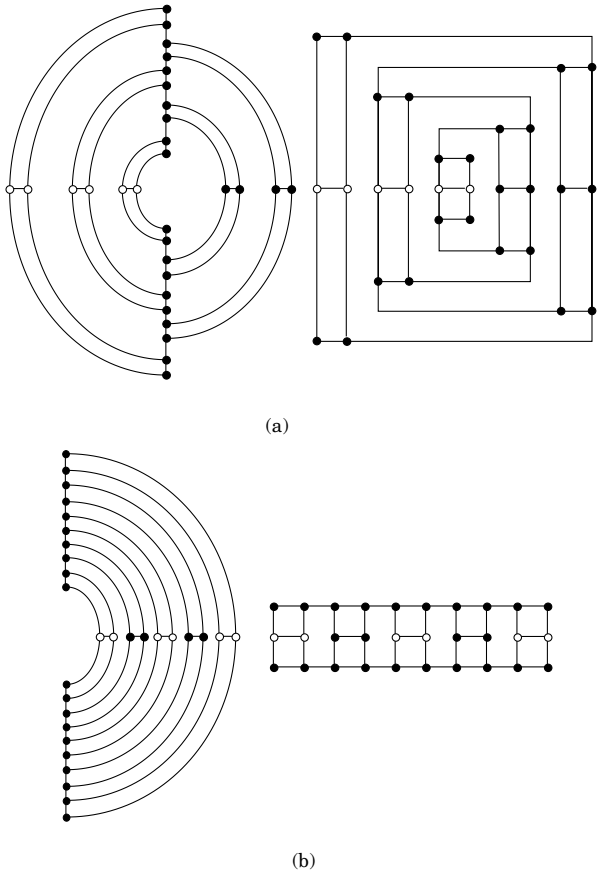

FIG. 1. *The choice of the embedding deeply affects the number of bends in the orthogonal drawing.*

Thus, it naturally raises the problem of choosing, in the planarization algorithm, the "best" embedding from the representation algorithm point of view. Although the problem is quite natural there are only a few contributions on this topic; observe that a planar graph has (in general) an exponential number of embeddings. To give an example, the problem of constructing straight-line upward drawings of series-parallel digraphs without a fixed embedding has been addressed in [2] (an upward drawing is such that all the edges follow monotonically the vertical axis); in [2] it is shown that fixed-embedding drawing strategies can lead to straight-line upward drawings of series-parallel digraphs with exponential area, and variable-embedding algorithms are needed to achieve optimal area.

In this paper we deal with the classical problem of constructing orthogonal drawings with the minimum number of bends along the edges. Valiant [29] showed that a graph has an orthogonal drawing if and only if it is 4-planar (a graph is k-planar if it is planar and each vertex has degree at most k). Tamassia [21] proposed a very elegant representation algorithm that solves the problem in polynomial time for graphs with a fixed embedding. The algorithm is based on a combinatorial characterization that

allows to map the problem into a min-cost flow one. The result of Tamassia disproves a conjecture of Storer [19] that the problem is NP-hard. Linear time heuristics for the same problem were proposed by Tamassia and Tollis [24, 25], Liu, Morgana, and Simeone [16], Kant [13], Biedl and Kant [3], and Papakostas and Tollis [18]. Tamassia, Tollis, and Vitter [26, 27] gave lower bounds for the problem and the first parallel algorithm. A brief survey of orthogonal drawings can be found in [22].

However, all the above papers deal with fixed-embedding graphs. The problem of finding the planar embedding that leads to the minimum number of bends has been recently shown to be NP-complete [11]. In this paper we show that the problem can be solved by polynomial time algorithms for two significant classes of graphs. A list of the main results of the paper follows.

- We introduce and study the new concept of *spirality*, that is, a measure of how an orthogonal drawing is "rolled up."
- We develop a theory on the interplay between spirality and the number of bends in orthogonal drawings.
- We apply the above theory to show that the problem of finding a planar embedding that leads to an orthogonal drawing with the minimum number of bends can be solved in polynomial time for 3-planar graphs and for series-parallel graphs.

Also, we show how the time bound for series-parallel graphs can be reduced in the case when the graph is 3-planar.

Series-parallel graphs arise in a variety of problems such as scheduling, electrical networks, data-flow analysis, database logic programs, and circuit layout. Also, they play a central role in planarity problems [20, 28, 5, 6]. In Fig. 2 we show two different planar embeddings of the same series-parallel graph. Besides each planar embedding we show the orthogonal drawing with the minimum number of bends that can be constructed preserving that embedding. In the drawing of Fig. 2a we have almost twice the number of bends as in that of Fig. 2b. Also, drawings of 3-planar graphs are a classical field of investigation (see, e.g., [13]). Observe that the graph of Fig. 1 is 3-planar.

Our algorithms exploit the properties of spirality, min-cost flow techniques, and a variation of the $SPQR$ trees [5, 6], a data structure that implicitly represents all the planar embeddings of a planar graph. Observe that a different concept of spirality has already been introduced in the literature for studying the properties of polygons. (See, e.g., [9].)

The paper is organized as follows. Preliminaries are in section 2. The general approach of the paper is briefly described in section 3. The concept of spirality of an orthogonal drawing and the relationships between spirality and number of bends are studied in section 4. In sections 5 and 6 we present polynomial time algorithms and a new data structure for computing optimal orthogonal drawings of 3-planar graphs. The algorithms presented in those sections are detailed enough to be implemented with limited effort. The results of sections 5 and 6 are extended to series-parallel graphs in section 7. Finally, open problems are listed in section 8. Some of the proofs that are conceptually straightforward but involve tedious case analyses are omitted and can be found in [4].

2. Preliminaries. First, we briefly review some definitions of connectivity and planarity [8, 17]; second, we give some properties of orthogonal drawings and orthogonal representations; third, we define SPQ^*R trees; and finally, we reiterate basic definitions of flow networks.

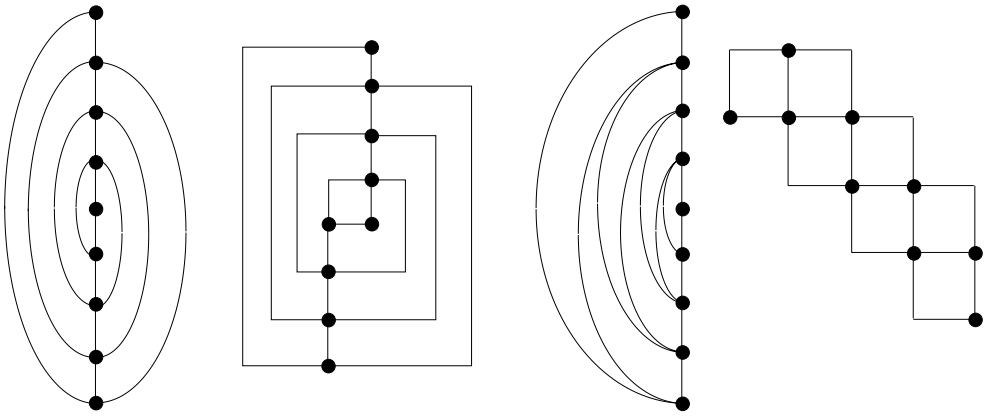

FIG. 2. *Two embeddings of a series-parallel graph that give rise to two optimal orthogonal drawings with different numbers of bends.*

Several terms are defined throughout the remainder of the paper, after these preliminaries. For the reader's convenience we list all such terms in the appendix.

2.1. Connectivity and planarity. A separating k-set of a graph G is a set of k vertices whose removal increases the number of connected components of G. Separating 1-sets (2-sets) are called *cutvertices* (*separation pairs*). A connected graph with no cutvertices is a 2-*connected graph*.

Let Γ be a *planar drawing* of a graph G. Γ maps each vertex of G to a distinct point of the plane, and each edge (u, v) to a simple Jordan curve with endpoints u and v; no two edges intersect, except at common endpoints. A planar drawing Γ divides the plane into topologically connected regions called *faces* of Γ; each face is identified by the circular list of the vertices and the edges of its boundary. The unbounded region is referred to as the *external face* of Γ. A graph is *planar* if it has a planar drawing. A planar graph is k-*planar* if its vertices have degree at most k.

A *series-parallel graph* is recursively defined as follows. A simple cycle with three edges is a series-parallel graph. The graph obtained by splitting an edge of a series-parallel graph into two edges is a series-parallel graph. The graph obtained by inserting an edge between a separation pair $\{u, w\}$ of a series-parallel graph is a series-parallel graph. It is trivial to see that series-parallel graphs defined in this way are 2-connected and planar.

Two planar drawings Γ' and Γ'' of a planar graph are *equivalent* when, for each vertex v, (1) Γ' and Γ'' have the same circular clockwise ordering of the edges incident on v and of the faces around v; (2) Γ' and Γ'' have the same external face. In this way the planar drawings of a planar graph are grouped into equivalence classes. An *embedding* of a planar graph G corresponds to an equivalence class of planar drawings of G.

A planar graph G with a given embedding Ψ is an *embedded graph*. A circular list of edges and vertices of G that corresponds to a face of any drawing of Ψ is a *face* of G. The face of G that corresponds to the external face of any drawing of Ψ is the *external face* of G. The *adjacency list* of each vertex v of an embedded graph is a clockwise ordered sequence of the alternate faces and edges around v.

2.2. Decomposition trees. A *split pair* of G is either a separation pair of G or a pair of adjacent vertices. A *split component* of a split pair $\{u, w\}$ is either an edge (u, w) or a maximal subgraph G_{uw} of G such that $\{u, w\}$ is not a split pair of G_{uw}. Vertices u and w are the *poles* of the split component. In the following we often denote by G_{uw} a split component whose poles are u and w.

Let G be an embedded graph and $G_{uw} \subset G$ be a split component of G. The edges of G that are incident on a pole v ($v = u, w$) of G_{uw} and that belong (do not belong) to G_{uw} are called *internal edges* (*external edges*) of v with respect to G_{uw}; the number of such edges is called *internal degree* (*external degree*) of v with respect to G_{uw}. Let f' and f'' be the two faces such that (i) f' and f'' do not belong to G_{uw}; (ii) f' (f'') shares with G_{uw} a path P'_{uw} (P''_{uw}) from u to w; (iii) when going around f' in the positive direction, P'_{uw} is traversed from u to w. Face f' is called the *right face* of G_{uw} and face f'' is called the *left face* of G_{uw}. Nodes u and w divide a face f_e of G_{uw} into two simple paths. The *right path* is the one traversed from u to w when going around f_e in the positive direction; the *left path* is the other one.

Let G be a planar 2-connected graph and let (s, t) be an edge of G called the *reference edge*. An *SPQ^*R tree* T of G (a simple variation of the $SPQR$ trees introduced in [5]) is a tree describing a recursive decomposition of G with respect to its split pairs, and it is used to synthetically represent all the embeddings of G with (s, t) on the external face (we always assume, unless stated otherwise, that (s, t) is on the external face). Nodes of T are of four types: S, P, Q^*, and R. Each node μ has an associated graph called the *skeleton* of μ and denoted by $skeleton(\mu)$. Nonroot nodes of T are called *internal nodes*. Starting from the reference edge, T is recursively defined as follows.

Chain case: If G consists of a simple path from s to t then T is a single Q^*-node μ whose skeleton is G itself.

Series case: If G is 1-connected, let $c_1, \ldots, c_{k-1}$ ($k \geq 2$) be the cutvertices of G such that no cutvertex has degree less than 3; let $c_1, \ldots, c_{k-1}$ partition G into graphs $G_1, \ldots, G_k$. The root of T is an S-node μ. Graph $skeleton(\mu)$ is the chain $e_1, \ldots, e_k$, where edge e_i goes from c_{i-1} to c_i, $c_0 = s$, and $c_k = t$.

Parallel case: If s and t are a split pair for G with split components $G_1, \ldots, G_k$ ($k \geq 2$), the root of T is a P-node μ. Graph $skeleton(\mu)$ consists of k parallel edges from s to t, denoted $e_1, \ldots, e_k$.

Rigid case: If none of the above cases applies, let $\{s_1, t_1\}, \ldots, \{s_k, t_k\}$ be the maximal split pairs of G ($k \leq 1$), and for $i = 1, \ldots, k$, let G_i be the union of all the split components of $\{s_i, t_i\}$. The root of T is an R-node μ. Graph $skeleton(\mu)$ is obtained from G by replacing each subgraph G_i with edge e_i from s_i to t_i.

We call the *pertinent graph* of μ the graph whose decomposition tree is the subtree rooted at μ. Also, the *virtual edge* of μ is the edge representing the pertinent graph of μ in the skeleton of its parent.

Let G be a planar 2-connected graph; we define an SPQ^*R tree T of G such that:

- the root of T is a P-node with two children, one of which is the reference edge (s, t);
- each internal P-node of T has children R-, S-, or Q^*-nodes;
- each S-node of T has two children.

We call T the *canonical decomposition tree* of G. An example of a canonical decomposition tree is given in Fig. 3, where the skeleton of an internal R-node is in evidence; the reference edge is $(1, 10)$. ξ-labels associated with some of the nodes will

be used later in the paper. It is easily proved that such a decomposition tree always exists for a 2-connected graph.

Since in the following we refer only to canonical decomposition trees, we briefly call them *decomposition trees*. Also, H_μ denotes an orthogonal representation of the pertinent graph of μ.

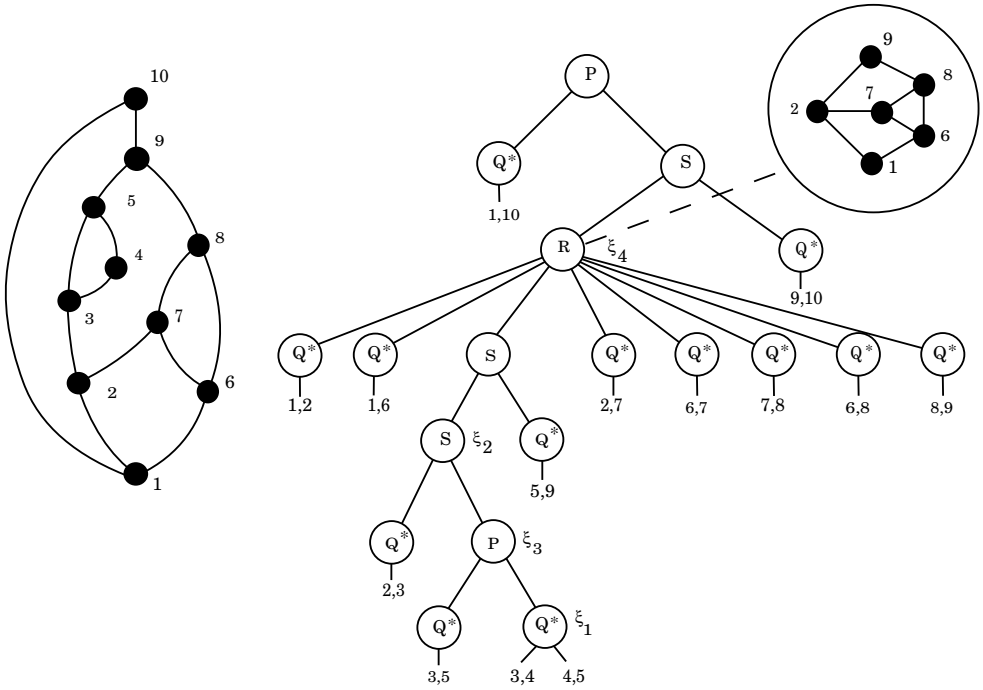

FIG. 3. *A canonical decomposition tree.*

PROPERTY 2.1. *The decomposition tree of a series-parallel graph can only contain S-nodes, P-nodes, and Q*-nodes.*

The following property can be easily proved by using arguments based on the degree of the vertices.

PROPERTY 2.2. *Let T be the decomposition tree of a 3-planar graph and let μ be an internal node of T.*

1. *If μ is an S-node and one of its children is either an R-node or a P-node, then the other child of μ can be either a Q^*-node or an S-node.*
2. *If μ is a P-node, then it has two children.*
3. *If μ is a P-node or an R-node, then its children are Q^*-nodes or S-nodes.*

2.3. Orthogonal drawings and orthogonal representations. A planar drawing of a planar graph G such that all edges of G are mapped to polygonal chains of horizontal and vertical segments is an *orthogonal drawing* of G. Examples of orthogonal drawings are in Fig. 4. A planar graph has a orthogonal drawing if and only if it is 4-planar [29].

Two equivalent orthogonal drawings of an embedded graph are *shape-equivalent* when (1) for each vertex v, consecutive edges in the adjacency list of v form the same angle in the two drawings; and (2) for each edge (u, v), following from u to v the

polygonal chain representing (u, v), we have the same (possibly empty) sequence of left and right turns in the two drawings. For example, the orthogonal drawings of Fig. 4 are shape-equivalent.

A *labeled embedded graph* H is an embedded graph defined as follows. (1) Each edge e is associated to a (possibly empty) sequence of L- and R-symbols. When walking along $e = (u, v)$, such a sequence is read in two different ways depending on the chosen direction. Suppose, when walking from u to v, that such a sequence is read σ; then when walking from v to u it is read σ', where σ' is obtained by reversing σ and by exchanging L- and R-symbols. (2) Each face f in the adjacency list of vertex v has (possibly) a label in $\{R,\ L, LL\}$.

An *orthogonal graph* H is a labeled embedded graph that describes a class of shape-equivalent orthogonal drawings; it is defined as follows.

- Each edge (u, v) of H is associated with a (possibly empty) sequence of L- and R-symbols, each specifying a left or right turn that is found following (u, v) from u to v.
- For each vertex v of H, the label associated with each face f in the adjacency list of v specifies what happens when we go through v, walking around f in the positive direction (i.e., having f at one's right) in any drawing of the shape-equivalent class. Namely, (1) f is labeled L if we turn left; (2) f is labeled R if we turn right; (3) f is labeled LL when v has degree 1 and we have to come back ("two turns left are enough to come back"); (4) f is not labeled when we go straight.

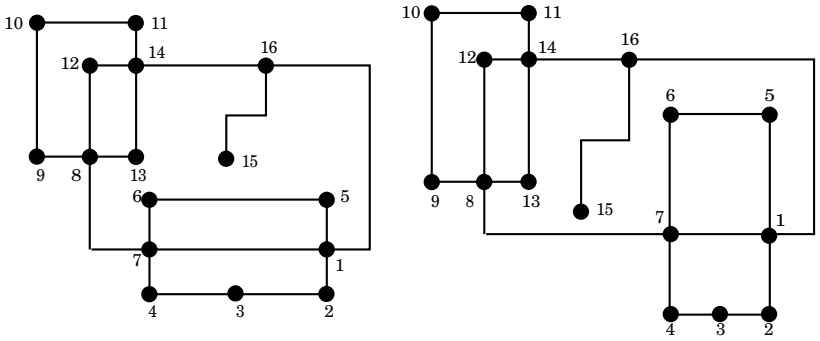

FIG. 4. *Two shape-equivalent orthogonal drawings of the same graph.*

In Fig. 5 we show the orthogonal graph that describes the orthogonal drawings of Fig. 4; besides each edge we report both the sequences that are read by walking on the edge in the two possible directions.

We denote by $\deg(v)$ the degree of vertex v. The following property characterizes the orthogonal graphs; it has been proved in [21].

PROPERTY 2.3. *A labeled embedded graph H is an orthogonal graph if and only if the following two conditions hold.*

1. *For each vertex v of H, let $|R_v|$ ($|L_v|$) be the number of R-symbols (L-symbols) of the labels associated with the faces that appear in the adjacency list of v. Then,*

$$|R_v| - |L_v| = 2\deg(v) - 4.$$

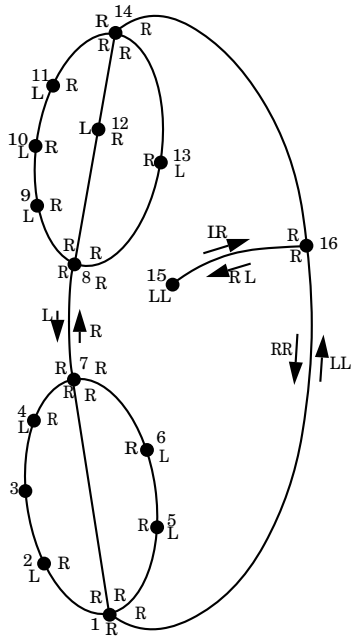

FIG. 5. *The orthogonal graph describing the orthogonal drawings of Fig.* 4.

2. *For each face f of H suppose we walk around f in the positive direction. Let $|R_e|$ ($|L_e|$) be the total number of R-symbols (L-symbols) that are encountered by traversing the edges of f. Let $|R_f|$ ($|L_f|$) be the number of R-symbols (L-symbols) of the labels associated with f in the adjacency lists of vertices of f. Then*

$$|R_e| + |R_f| - |L_e| - |L_f| = \pm 4,$$

where the plus sign holds if f is an internal face, and the minus sign, if f is the external face.

Proof. For the sake of completeness we briefly sketch the proof (see [21]). Part 1 is proved by observing that $|R_v|$ ($|L_v|$) is the number of $\pi/2$ ($3\pi/2$) angles around v and that such angles sum up to 2π. Part 2 is proved by observing that $|R_e|$ ($|L_e|$) is the number of $\pi/2$ ($-\pi/2$) angles along the edges of f, that $|R_f|$ ($|L_f|$) is the number of $\pi/2$ ($-\pi/2$) angles on the vertices of f, and that such angles sum up to $\pm 2\pi$, depending on whether we consider the interior or the exterior part of the face. □

The above property can be easily verified on the graph of Fig. 5. For example, it is easy to see that Condition 1 holds for vertex 1; namely, it has degree 4 and the labels of the faces that appear in its adjacency list are R-symbols.

From Property 2.3 it directly descends the following property.

PROPERTY 2.4. *Let C be a simple cycle of an orthogonal graph. The number of right turns minus the number of left turns encountered by walking clockwise around C is four.*

For example, the cycle composed by vertices 1, 2, 3, 4, 7, 6, 5 of Fig. 5 verifies Property 2.4.

An *orthogonal representation* of a graph G is an orthogonal graph with the same vertices and edges of G. The *cost* of an orthogonal representation is the number of its

bends. An *optimal orthogonal representation* of G is an orthogonal representation of G with the minimum cost. An *optimal orthogonal drawing* of G is an orthogonal drawing of the shape-equivalence class described by an optimal orthogonal representation of G.

Orthogonal graphs have also been studied by Vijayan and Wigderson in [30].

2.4. The min-cost flow problem. We briefly recall some definitions of flow networks. A *network* N consists of (1) a finite set of nodes including exactly one *source* node s and one *sink* node t; (2) a set of oriented edges (in what follows, *arcs*), labeled with a nonnegative *capacity*, a nonnegative *lower bound*, and a nonnegative *cost function*.

A *flow* x in N associates to each arc a a nonnegative number $x(a)$; flow $x(a)$ cannot exceed the capacity of a and cannot be less than the lower bound of a. Also, for each node $v \neq s, t$ of N, the sum of the flows of the incoming arcs is equal to the sum of the flows of the outgoing arcs. Let c_a be the cost function of arc a; the *cost* of the flow in a is $c_a(x(a))$. The *cost of the flow* x in N is the sum of the costs of the flow in the arcs of N. The *value of the flow* in N is the sum of the flows of the outgoing arcs of s. A *min-cost flow problem* is stated as follows: given a network N and a positive number z, find a flow x in N such that the value of x is z and the cost of the flow is minimum. The min-cost flow problem has been intensively studied in the literature (see, e.g., [10, 15, 1]).

3. The general approach. The general approach underlying the paper can be summarized as follows. Let us concentrate on the case of 3-planar 2-connected graphs. We shall see that the results on such graphs can be easily extended to general 3-planar graphs and to 4-planar series-parallel graphs.

To compute an optimal orthogonal representation of a 3-planar 2-connected graph G, the first step is to construct a decomposition tree T of G. The optimal orthogonal representation of G is then built by visiting T from bottom to top. In fact, we show that the optimal orthogonal representation of the pertinent graph of a node μ of T can be constructed by considering and composing a limited set of orthogonal representations (not necessarily optimal) of the pertinent graphs of the children $\mu_1, \ldots, \mu_k$ of μ; we call such limited sets of orthogonal representations *optimal sets*.

If μ is an S-node or a P-node, then an optimal orthogonal representation of the pertinent graph of μ can be built in polynomial time in two steps. In the first step one orthogonal representation for each of the optimal sets of $\mu_1, \ldots, \mu_k$ is suitably selected. In the second step the selected representations are assembled into a representation of the pertinent graph of μ.

Otherwise (μ is an R-node), the optimal orthogonal representation of μ can be computed with a network-flow technique; this is done in polynomial time by exploiting certain convexity properties that hold for the optimal sets of $\mu_1, \ldots, \mu_k$.

Thus, for 2-connected 3-planar graphs we have algorithms that, from bottom to top, compute in polynomial time the optimal sets of all the nodes of T.

The conceptual tool that is used to select, among the infinite possible orthogonal representations of the pertinent graphs of the nodes of T, those that are needed in the optimal sets is the spirality. As we said in the introduction, the spirality measures how much an orthogonal representation is "rolled up." In particular, we exploit two basic properties of the spirality that can be roughly stated as follows.

- The split components of an optimal orthogonal representation cannot be rolled up too much. Intuitively, if too many turns are done, then too many bends are spent.

- Two orthogonal representations of the same split component and with the same spirality can replace each other into an orthogonal representation of G.

4. Spines and spirality. In this section we define and study an invariant, called *spirality*, of the equivalence class of drawings described by a component of an orthogonal graph. Unless stated otherwise we suppose that all the graphs mentioned from now on are 2-connected.

4.1. Spines. Let H be an orthogonal graph and $H_{uw} \subset H$ be a split component of H. A pole v ($v = u$ or $v = w$) of H_{uw} is called a *bridge pole* when its internal degree with respect to H_{uw} is 1; v is called a *nonbridge pole* when its internal degree with respect to H_{uw} is greater than 1.

In order to define the spirality of H_{uw} we add to H some dummy vertices called *alias vertices* of the poles u, w. Three cases are possible.

1. Let v be a bridge pole of H_{uw}; the *alias vertex* v' of v coincides with v.
2. Let v be a nonbridge pole of H_{uw} with external degree 1; the *alias vertex* v' of v is defined as follows. Let $e_{out} = (x, v)$ be the external edge of v with respect to H_{uw}; e_{out} is substituted by a new vertex v' and two new edges (x, v'), (v', v). The labeling of (x, v') is the same as that of e_{out}, (v', v) has no labels, and the two faces around v' have no labels in the adjacency list of v'. Intuitively, we have cut the first segment of the drawing of e_{out} into two pieces.
3. Let v be a nonbridge pole of H_{uw} with external degree 2, and let e'_{out} and e''_{out} be the external edges of v; the *alias vertices* of v are a pair v', v'' of dummy vertices obtained by cutting e'_{out} and e''_{out}, respectively. They are defined as above.

In Fig. 6 we show an orthogonal drawing of an orthogonal graph with, in evidence, a split component H_{uw}; vertices w' and w'' are the alias vertices of w, and vertex u' is the alias vertex of u.

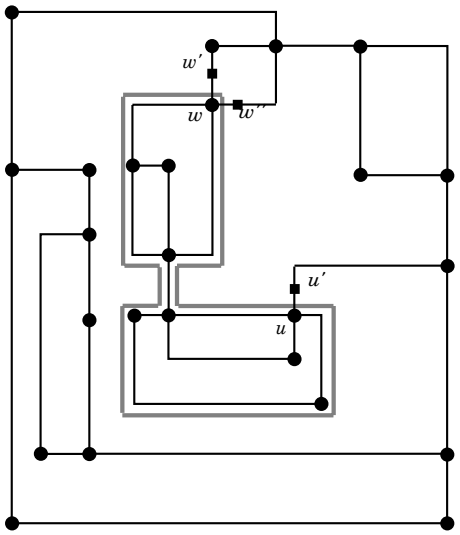

FIG. 6. *Adding alias vertices.*

DEFINITION 4.1. *Let H be an orthogonal graph and let $H_{uw} \subset H$ be a split component of H. Let u' be an alias vertex of u and let w' be an alias vertex of w. Let P_{uw} be a simple path in H_{uw} from u to w. A* spine $S_{u'w'}$ *of H_{uw} is the simple path obtained by concatenating edge (u', u), path P_{uw}, and edge (w, w').*

In Figs. 7a and 7b we show two spines of the split component from the example of Fig. 6.

Let v_1 and v_2 be two vertices of H, and $P_{v_1v_2}$ be a simple path between v_1 and v_2. We associate with $P_{v_1v_2}$ an integer $n(P_{v_1v_2})$ defined as the number of right turns minus the number of left turns found when going along $P_{v_1v_2}$ from v_1 to v_2. In Fig. 7a we have $n(S_{u'w'}) = 2$; in Fig. 7b, $n(S_{u'w''}) = 3$.

LEMMA 4.1. *Let H be an orthogonal graph and let $H_{uw} \subset H$ be a split component of H. Let u' be an alias vertex of u and let w' be an alias vertex of w. Let $S'_{u'w'}$ and $S''_{u'w'}$ be two spines of H_{uw}; we have $n(S'_{u'w'}) = n(S''_{u'w'})$.*

Proof. Let $P_{u'w'}$ be a simple path in H that joins u' and w', such that no edge of $P_{u'w'}$ belongs to H_{uw}. Let C' and C'' be two simple cycles such that C' is composed by $S'_{u'w'}$ and $P'_{u'w'}$ and C'' is composed by $S''_{u'w'}$ and $P'_{u'w'}$. By Property 2.4 applied to C' we have $n(S'_{u'w'}) - n(P'_{u'w'}) + a = 4$, where a is the number of right turns minus the number of left turns encountered at u' and w', when going clockwise around C'; observe that a can be different from 0 only when the poles are bridge poles. By applying the same argument to C'' it follows that $n(S''_{u'w'}) = n(S'_{u'w'})$. □

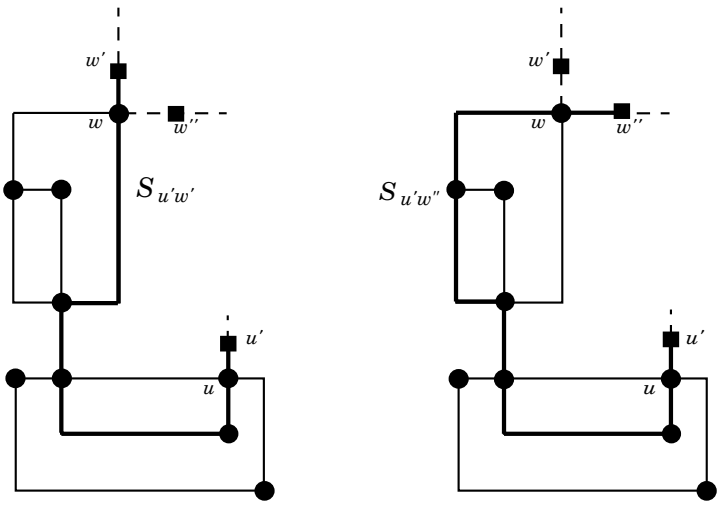

FIG. 7. *Two spines of the split component highlighted in Fig.* 6.

4.2. Spirality.

DEFINITION 4.2. *Let H be an orthogonal graph and $H_{uw} \subset H$ be a split component of H. The* spirality $\sigma_{H_{uw}}$ *of H_{uw} is defined as follows. Three cases are possible, depending on the number of alias vertices of u and w.*

1. *Both u and w have just one alias vertex, u' and w', respectively. Let $S_{u'w'}$ be a spine of H_{uw}; $\sigma_{H_{uw}} = n(S_{u'w'})$.*

2. *Pole u has just one alias vertex u'; w has two alias vertices w' and w''. Let $S_{u'w'}$ and $S_{u'w''}$ be two spines of H_{uw}; $\sigma_{H_{uw}} = (n(S_{u'w'}) + n(S_{u'w''}))/2$.*
3. *Pole u has two alias vertices u' and u''; w has two alias vertices w' and w''. Suppose u' and w' are on the same face of H. Let $S_{u'w'}$ and $S_{u''w''}$ be two spines of H_{uw}; $\sigma_{H_{uw}} = (n(S_{u'w'}) + n(S_{u''w''}))/2$.*

For example, the spirality of the split component in evidence in Fig. 6 is $\sigma_{H_{uw}} = 5/2$ (see also Figs. 7a and 7b).

PROPERTY 4.1. *If the poles of H_{uw} satisfy case 2 of Definition 4.2, then $2\sigma_{H_{uw}}$ is an odd integer number; if the poles of H_{uw} satisfy either case 1 or case 3 of Definition 4.2, then $\sigma_{H_{uw}}$ is an integer number.*

Proof. We prove the first case; the proof of the second case is analogous. Let u' be the alias vertex of u and let w', w'' be the alias vertices of w. Let $P_{u,w}$ be a simple path of H_{uw} from u to w. Let $S_{u'w'}$ be a simple path composed by edge (u', u), path $P_{u,w}$, and edge (w, w'); let $S_{u'w''}$ be a simple path composed by edge (u', u), path $P_{u,w}$, and edge (w, w''); $S_{u'w'}$ and $S_{u'w''}$ are two spines of H_{uw} that differ only for one turn at vertex w. Thus, $n(S_{u'w'}) + n(S_{u'w''})$ is an odd integer. □

The following property shows that the spirality of a split component H_{uw} depends only on the shape of H_{uw} and, possibly, on the labels associated with the right and left faces in the adjacency lists of the poles.

PROPERTY 4.2. *Let H and H' be two orthogonal graphs that are orthogonal representations of the same graph G; let G_{uw} be a split component of G. Suppose that (1) the orthogonal representation H_{uw} of G_{uw} is the same in H and in H'; (2) the label associated with the right (left) face of H_{uw} in the adjacency list of each pole of H_{uw} that is not a bridge pole is the same in H and in H'. The spirality $\sigma_{H_{uw}}$ is the same in H and in H'.*

Proof. From Definition 4.1 any spine S of H_{uw} is composed by a simple path P_{uw} of H_{uw} from u to w, and two edges (v, v') where v is a pole of H_{uw} and v' is an alias vertex of that pole ($v \equiv v'$ if v is a bridge pole). Since each edge (v, v') has no bends, to evaluate $n(S)$ we need $n(P_{uw})$ and information about possible turns encountered at poles when going along S; but this information is univocally given by the labels associated with the right and left faces of H_{uw} in the adjacency lists of the poles. □

4.3. Spirality of a series. Let H be an orthogonal graph and T be the decomposition tree of H.

Let μ be an internal S-node of T, with children μ_1 and μ_2; let $H_\mu \subset H$ be the pertinent orthogonal graph of μ and let $H_{\mu_i} \subset H_\mu$ be the pertinent orthogonal graph of μ_i $(i = 1, 2)$. In Fig. 8 we show the series of the two components in the subgraph in evidence in Fig. 6.

LEMMA 4.2. *The spirality σ_{H_μ} of H_μ is related to the spiralities $\sigma_{H_{\mu_i}}$ of the H_{μ_i} $(i = 1, 2)$ by*

$$\sigma_{H_\mu} = \sigma_{H_{\mu_1}} + \sigma_{H_{\mu_2}}.$$

Proof. The proof is illustrated in Fig. 9. Let u, w be the poles of H_μ, let u_1, w_1 be the poles of H_{μ_1}, and let u_2, w_2 be the poles of H_{μ_2}. Assume $u_1 \equiv u$, $w_1 \equiv u_2$, and $w_2 \equiv w$.

Several cases are possible, according to the different types of poles of H_{μ_1} and H_{μ_2} and according to the external degree of the poles of H_μ.

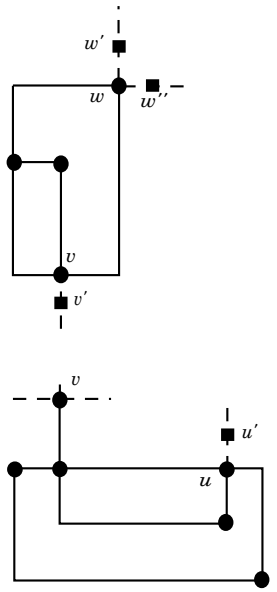

FIG. 8. *The series of two split components of the subgraph highlighted in Fig.* 6.

1. Pole w_1 is a nonbridge pole in H_{μ_1} and pole u_2 is a bridge pole in H_{μ_2}. Since u_2 is a bridge pole in H_{μ_2}, the alias vertex of u_2 is the pole itself. Also, let w'_1 be the alias vertex of w_1 on the edge of H_{μ_2} incident on w_1. We distinguish two subcases, according to the external degree of u and w in H_μ.
   (a) $u_1 \equiv u$ and $w_2 \equiv w$ are bridge poles or they have external degree 1 in H_μ (see Fig. 9a). In this case just one spine is needed to evaluate the spirality of H_μ, H_{μ_1}, and H_{μ_2}. Let u'_1 be the alias vertex of u_1 with respect to H_{μ_1}, and let w'_2 be the alias vertex of w_2 with respect to H_{μ_2}; u'_1 and w'_2 coincide with the alias vertices of u and w with respect to H_μ. Let $S_{u'_1 w'_1}$ be a spine of H_{μ_1}, and let $S_{u_2 w'_2}$ be a spine of H_{μ_2}. Let $P_{w'_1 w'_2}$ be the subpath of $S_{u_2 w'_2}$ from w'_1 to w'_2; note that $n(P_{w'_1 w'_2}) = n(S_{u_2 w'_2})$ from the definition of alias vertices. Let $S_{u'_1 w'_2}$ be a path in H_μ composed by spine $S_{u'_1 w'_1}$ and path $P_{w'_1 w'_2}$. $S_{u'_1 w'_2}$ is a spine of H_μ and $n(S_{u'_1 w'_2}) = n(S_{u'_1 w'_1}) + n(P_{w'_1 w'_2})$. It follows that $\sigma_{H_\mu} = \sigma_{H_{\mu_1}} + \sigma_{H_{\mu_2}}$.
   (b) $w_2 \equiv w$ is a nonbridge pole with external degree 2 in H_μ (see Figs. 9b and 9c). In this case two spines are requested to evaluate the spirality of H_μ. With analogous reasoning as in case (a), we can define the spines of H_μ starting from the spines of H_{μ_1} and H_{μ_2}; the rest of the proof is a simple variation of the previous case.
2. w_1 is a nonbridge pole in H_{μ_1} and u_2 is a nonbridge pole in H_{μ_2} (the total degree of $w_1 \equiv u_2$ is four). Let w'_1, w''_1 be the alias vertices of w_1 with respect to H_{μ_1}, and let u'_2, u''_2 be the alias vertices of u_2 with respect to H_{μ_2} such that w'_1 and u'_2 are in the same face of H, say, the right face of H_μ. We distinguish two subcases, according to the external degree of u and w in H_μ.
   (a) Both $u_1 \equiv u$ and $w_2 \equiv w$ are bridge poles or they have external degree 1 in H_μ (see Fig. 9d). Let u'_1 be the alias vertex of u_1 with respect to H_{μ_1}

and let w_2' be the alias vertex of w_2 with respect to H_{μ_2}. Note that u_1', w_2' are alias vertices of u, w with respect to H_μ. Let $S_{u_1'w_1'}$ and $S_{u_1'w_1''}$ be two spines of H_{μ_1}, and let $S_{u_2'w_2'}$ and $S_{u_2''w_2'}$ be two spines of H_{μ_2} whose edges and vertices belong to either the left or the right face of H_μ. Let f' be the right face of H_μ (w_1' and u_2' belong to f') and let f'' be the left face of H_μ (w_1'' and u_2'' belong to f''). Let $P_{u_1'u_2'}$ be a subpath of $S_{u_1'w_1'}$ from u_1' to u_2' and let $P_{u_1'u_2''}$ be a subpath of $S_{u_1'w_1''}$ from u_1' to u_2''. Observing that face f' and f'' are R-labeled in the adjacency list of $w_1 \equiv u_2$, we have $n(P_{u_1'u_2'}) = n(S_{u_1'w_1'}) - 1$ and $n(P_{u_1'u_2''}) = n(S_{u_1'w_1''}) + 1$. Let $S'_{u_1'w_2'}$ be a path in H_μ composed by $P_{u_1'u_2'}$ and $S_{u_2'w_2'}$; let $S''_{u_1'w_2'}$ be a path in H_μ composed by $P_{u_1'u_2''}$ and $S_{u_2''w_2'}$. Thus, $n(S'_{u_1'w_2'}) = n(P_{u_1'u_2'}) + n(S_{u_2'w_2'})$ and $n(S''_{u_1'w_2'}) = n(P_{u_1'u_2''}) + n(S_{u_2''w_2'})$. Since both $S'_{u_1'w_2'}$ and $S''_{u_1'w_2'}$ are spines of H_μ, σ_{H_μ} can be written as $(n(S'_{u_1'w_2'}) + n(S''_{u_1'w_2'}))/2$.

(b) $u_1 \equiv u$ is a nonbridge pole with external degree 2 in H_μ (see Figs. 9e and 9f). In this case the spirality of H_μ is evaluated by means of two spines. With analogous reasoning as in the above case, we can define the two spines of H_μ starting from the spines of H_{μ_1} and H_{μ_2}. The proof is a simple variation of the one given above. □

4.4. Spirality of a parallel. Let H be an orthogonal graph and T be the decomposition tree of H. We first consider the case of an internal P-node of T, then the special case of the root.

Let μ be an internal P-node of T with children $\mu_1, \ldots, \mu_k$, let $H_\mu \subset H$ be the pertinent orthogonal graph of μ with poles u and w, and let $H_{\mu_i} \subset H_\mu$ be the pertinent orthogonal graph of μ_i $(i = 1, \ldots, k)$. Since the vertices of H have degree at most 4, μ has two or three children. We relate the spirality of H_μ to the spirality of its components by distinguishing the case where μ has three children from the case where μ has two children.

Suppose first that μ has three children. Let e_i be the edge of H_{μ_i} $(i = 1, 2, 3)$ incident on pole u, and let e_{out} be the external edge of u with respect to H_μ. In the following lemma we suppose that edges e_{out}, e_3, e_2, and e_1 appear in this order in the adjacency list of u. See, for example, Fig. 10.

LEMMA 4.3. *The spirality σ_{H_μ} of H_μ is related to the spiralities $\sigma_{H_{\mu_i}}$ of H_{μ_i} $(i = 1, 2, 3)$ by*

$$\sigma_{H_\mu} = \sigma_{H_{\mu_1}} + 2 = \sigma_{H_{\mu_2}} = \sigma_{H_{\mu_3}} - 2.$$

Proof. Poles u, w are nonbridge poles with external degree 1 in H_μ and bridge poles in H_{μ_i}. Let u', w' be the alias vertices of poles u, w with respect to H_μ, respectively. Let S_2 be a spine of H_{μ_2}; consider the path S composed by edge (u', u), S_2, and edge (w, w'). Observe that S is a spine of H_μ. Since, when going along S from u' to w', we go straight at vertex u and at vertex w, $n(S) = n(S_2)$. Let S_1 be a spine of H_{μ_1}; consider the path S' composed by edge (u', u), S_1, and edge (w, w'); clearly, S' is a spine of H_μ. Since, when going along S' from u' to w', we turn right at vertex u and at vertex w, $n(S') = n(S_1) + 2$. Analogous reasoning applies when a spine of H_μ is defined starting from a spine of H_{μ_3}. □

Consider now that the case μ has two children. Let f_1 and f_2 be the right face and the left face of H_μ, respectively. Suppose that the vertices and edges of H_μ belonging to f_1 are also vertices and edges of H_{μ_1}. We denote with α_v^i the number of R-symbols

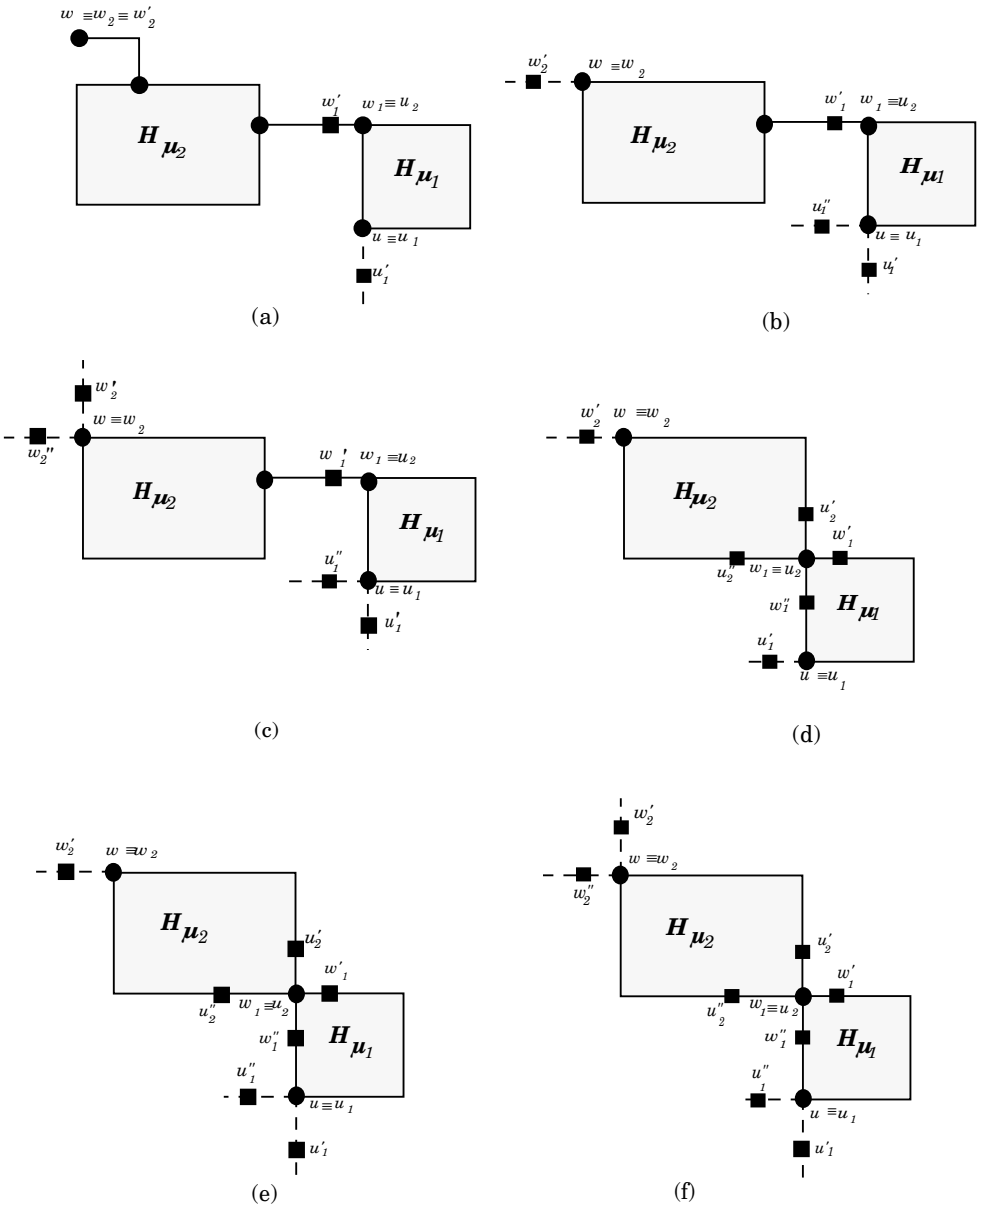

FIG. 9. *Different cases in the proof of Lemma* 4.2.

minus the number of L-symbols of the label associated with face f_i $(i = 1, 2)$ in the adjacency list of pole v $(v = u, w)$. For example, in Fig. 11 we have $\alpha_u^1 = 1$, $\alpha_u^2 = 1$, $\alpha_w^1 = 0$, and $\alpha_w^2 = 1$. Also, we denote with $\text{extdeg}_\mu(v)$ the external degree of v with respect to the pertinent graph of μ and with $\text{intdeg}_\mu(v)$ the internal degree of v with respect to the pertinent graph of μ. The proof of the following lemma can be found in [4].

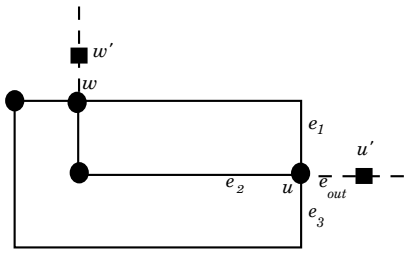

FIG. 10. *Example of a parallel of three components.*

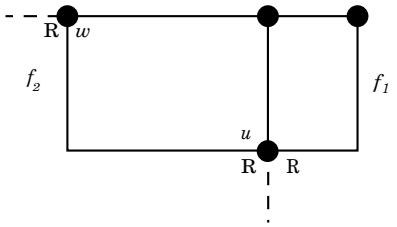

FIG. 11. *Example of a parallel of two components.*

LEMMA 4.4. *The spirality σ_{H_μ} of H_μ is related to the spiralities $\sigma_{H_{\mu_i}}$ of the H_{μ_i} $(i = 1, 2)$ by*

$$\sigma_{H_\mu} = \sigma_{H_{\mu_1}} + k_u \cdot \alpha_u^1 + k_w \cdot \alpha_w^1,$$

$$\sigma_{H_\mu} = \sigma_{H_{\mu_2}} - k_u \cdot \alpha_u^2 - k_w \cdot \alpha_w^2,$$

$$\textit{where} \quad k_v(v = u, w) = \begin{cases} 1 & \textit{if } \mathrm{extdeg}_\mu(v) = 1 \textit{ and } \mathrm{intdeg}_{\mu_i}(v) = 1, \\ 1/2 & \textit{if } \mathrm{extdeg}_\mu(v) = 2 \textit{ or } \mathrm{extdeg}_{\mu_i}(v) = 2. \end{cases}$$

Let μ be the root of T, and let μ_1 and μ_2 be the children of μ such that the pertinent graph of μ_2 is the reference edge (s, t). Let $H_{\mu_1} \subset H$ be the orthogonal pertinent graph of μ_1 and let $H_{st} \subset H$ be the orthogonal representation of edge (s, t). Let f be the internal face of H containing (s, t) and let α_v be the number of R-symbols minus the number of L-symbols of the label associated to f in the adjacency list of pole v $(v = s, t)$. The proof of the following lemma can be found in [4].

LEMMA 4.5. *The spirality $\sigma_{H_{\mu_1}}$ of H_{μ_1} and the spirality $\sigma_{H_{st}}$ of H_{st} are related by*

$$\sigma_{H_{\mu_1}} - \sigma_{H_{st}} + k_s \cdot \alpha_s + k_t \cdot \alpha_t = 4$$

if edge (s, t) is traversed from t to s, going around f in the positive direction, and by

$$-\sigma_{H_{\mu_1}} + \sigma_{H_{st}} + k_s \cdot \alpha_s + k_t \cdot \alpha_t = 4$$

if edge (s, t) is traversed from s to t, going around f in the positive direction, where

$$k_s \ (k_t) = \begin{cases} 1 & \textit{if } s(t) \textit{ is a bridge pole in } H_{\mu_1}, \\ 0 & \textit{otherwise.} \end{cases}$$

4.5. Substituting orthogonal representations with the same spirality. Let G and G' be two embedded graphs describing two different embeddings of the same graph. If they are different only in the embedding of one split component they are said to be *split-different*. More precisely, let $G_{uw} \subset G$ and $G'_{uw} \subset G'$ be two different embedded subgraphs describing two different embeddings of the same split component. For each vertex v that is not in the split component, the clockwise ordering of the edges in the adjacency list of v is the same in G and in G'. For each vertex that is in the split component except poles u and w, the clockwise ordering of the incident edges may be different according to the different embeddings of G_{uw} and G'_{uw}. For poles u and w the clockwise ordering of the external edges is the same in G and G', while the clockwise ordering of the internal edges may be different according to the embedding of G_{uw} and G'_{uw}. Observe that the external faces of G and G' may be different.

Let H and H' be two orthogonal graphs that are orthogonal representations of G and G', respectively, and let $H_{uw} \subset H$ and $H'_{uw} \subset H'$ be the orthogonal graphs that are orthogonal representations of G_{uw} and G'_{uw}. Suppose that the labels that (possibly) appear between the external edges of u and w stay the same in H and in H'. Orthogonal graphs H and H' are said to be *split-different*. Two orthogonal drawings of two split-different orthogonal graphs are shown in Figs. 12a and 12b; they are split-different for the split component in evidence.

Let H and H' be two split-different orthogonal graphs that are orthogonal representations of the same graph G. Suppose they are split-different in a split component with poles u and w, such that $\deg(u) \geq 3$ and $\deg(w) \geq 3$. Let H_{uw} and H'_{uw} be the orthogonal representations of such a split component in H and in H', respectively. Suppose $\sigma_{H_{uw}} = \sigma_{H'_{uw}}$. The operation of *substitution* in H of subgraph H_{uw} with subgraph H'_{uw} gives as a result a labeled embedded graph H'', defined as follows.

1. H'' has the same vertices and edges of G.
2. Each vertex of H'' that is not in the above split component has the same adjacency list it has in H.
3. If u (w) is a bridge pole, then it has in H'' the adjacency list it has in H.
4. If u (w) is a nonbridge pole, then it has in H'' the adjacency list it has in H'.
5. Any other vertex of H'' has the same adjacency list it has in H'.

Roughly speaking, the operation of substitution consists of replacing in H subgraph H_{uw} with H'_{uw}. As an example, if we substitute the split component with poles 4 and 15 of Fig. 12a with the one of Fig. 12b, we obtain the orthogonal graph of Fig. 12c. The following theorem proves that the obtained graph is orthogonal.

THEOREM 4.1. *Let H and H' be two orthogonal 2-connected graphs that are split-different in a split component with poles u and w, such that* $\deg(u) \geq 3$ *and* $\deg(w) \geq 3$. *Let H_{uw} and H'_{uw} be such a split component in H and in H', respectively. Suppose $\sigma_{H_{uw}} = \sigma_{H'_{uw}}$. Let H'' be a labeled embedded graph obtained by substituting in H subgraph H_{uw} with subgraph H'_{uw}. H'' is an orthogonal graph.*

Proof. We denote by H''_{uw} the split component of H'' involved in the operation of substitution. In order to show that H'' is an orthogonal graph, we have to prove that conditions of Property 2.3 are satisfied. Condition 1 of Property 2.3 is trivially satisfied by all vertices of H'' (by the definition of substitution, vertices have the same adjacency list they have in either H or H'). Condition 2 of Property 2.3 is trivially true for each internal face of H''_{uw} and for each face of H'' that is not the left or the right face of H''_{uw}. We show that the condition holds for the right face; the proof for the left face is analogous.

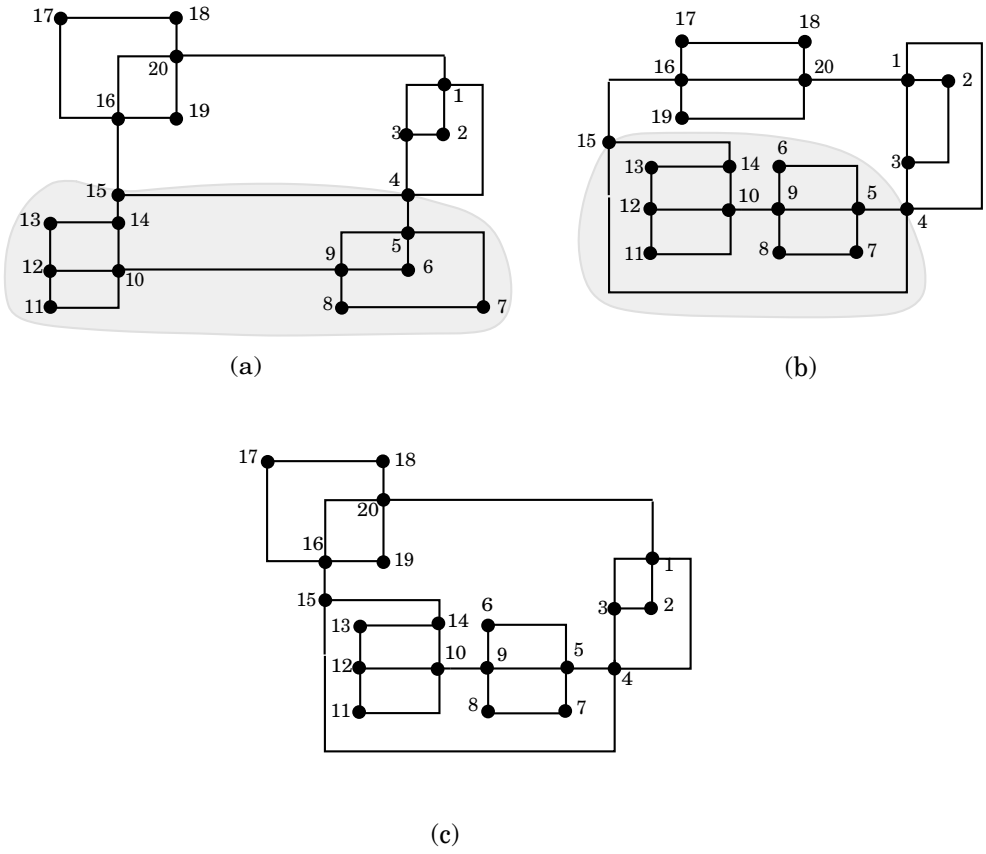

FIG. 12. *An example of substitution.*

Let f_H and $f_{H''}$ be the right faces of H_{uw} and H''_{uw}, respectively. Let u'_H, w'_H be the alias vertices of poles u, w in H that belong to face f_H. Vertices u'_H and w'_H identify two distinct paths S_H and P_H in f_H. Path S_H from u'_H to w'_H is composed by edge (u'_H, u), the right path of H_{uw}, and edge (w, w'_H); path P_H is the other path from w'_H to u'_H. Let $u'_{H''}, w'_{H''}$ be the alias vertices of poles u, w in H'' that belong to face $f_{H''}$. Analogously, $u'_{H''}$ and $w'_{H''}$ identify two distinct paths $S_{H''}$ and $P_{H''}$ in face $f_{H''}$. Observe that $S_{H''}$ is a spine of H''_{uw} in H'', S_H is a spine of H_{uw} in H, and $P_{H''}$ coincides with P_H. By applying Property 2.3 to H, we have $n(S_H)+n(P_H)+a = \pm 4$, where a is the number of R-symbols minus the number of L-symbols of the label associated with face f_H in the adjacency lists of u'_H and w'_H. The plus sign holds if f_H is an internal face, the minus sign, if f_H is the external face.

Consider $f_{H''}$. Since both S_H and $S_{H''}$ have their endpoints on the right faces of their split components, and since H_{uw} and H''_{uw} have the same spirality by hypothesis, $n(S_H) = n(S_{H''})$. Thus, since $n(P_H) = n(P_{H''})$ and the value of a stays the same after the substitution, Condition 2 of Property 2.3 holds for $f_{H''}$. □

4.6. An upper bound to the spirality. We study now the properties of split components of optimal orthogonal representations.

Let G be a graph and let $G_{uw} \subset G$ be a split component of G. Let H be an orthogonal representation of G and let $H_{uw} \subset H$ be the orthogonal representation of

G_{uw}. First, we observe that the orthogonal subgraph H_{uw} may not be optimal even if H is optimal. In Fig. 13 two orthogonal representations of the same graph are shown with a subgraph H_{uw} in evidence; in Fig. 13a the orthogonal representation H is optimal while H_{uw} is not optimal; Fig. 13b shows the best orthogonal representation that can be found if H_{uw} is constrained to be optimal.

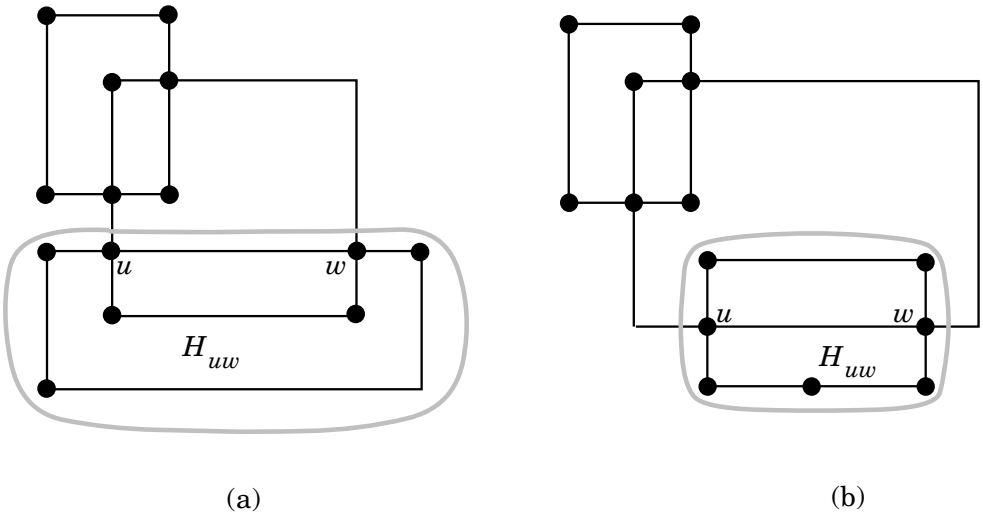

FIG. 13. (a) *H is optimal and H_{uw} is not optimal*; (b) *H is not optimal and H_{uw} is optimal.*

Let H' and H'' be two orthogonal graphs, such that H' and H'' are split-different in the same split component with poles u and w. Let H'_{uw} and H''_{uw} be such split components in H' and in H'', respectively. The orthogonal graph H'_{uw} is *optimal within the spirality* $\sigma_{H'_{uw}}$ if no H''_{uw} exists with spirality $\sigma_{H'_{uw}}$ and fewer bends than H''_{uw}.

THEOREM 4.2. *Let G be a 2-connected graph and let H be an optimal orthogonal representation of G; each split component of H is optimal within its spirality.*

Proof. Let $H_{uw} \subset H$ be the orthogonal representation of a split component of H. Suppose, for a contradiction, that H_{uw} is not optimal within $\sigma_{H_{uw}}$. Then, there exists an orthogonal representation H' of G such that (1) H and H' are split-different in the above split component; (2) the orthogonal representation $H'_{uw} \subset H'$ of the split component in H' has spirality $\sigma_{H_{uw}}$ and fewer bends than H_{uw}. Thus, by Theorem 4.1, it is possible to substitute in H subgraph H_{uw} with H'_{uw} obtaining an orthogonal representation of G with fewer bends than H. This is a contradiction. □

With analogous reasoning we can prove the following theorem.

THEOREM 4.3. *Let G be a 2-connected graph and let $G_{uw} \subset G$ be a split component of G. Let H_{uw} be an orthogonal representation of G_{uw} optimal within spirality $\sigma_{H_{uw}}$. All the split components of H_{uw} are optimal within their spiralities.*

The next theorem gives an upper bound to the spirality of the split components in an optimal orthogonal representation.

THEOREM 4.4. *Let G be a 2-connected graph with n vertices and let H be an optimal orthogonal representation of G; let $H_{uw} \subset H$ be the orthogonal representation of a split component of G, $|\sigma_{H_\mu}| \leq 3n - 2$.*

Proof. Let S be a spine of H_μ. Since S is a simple path, it has at most $n-1$ edges and n vertices. For each pair of consecutive edges of S there is at most one turn at the common endpoint; also, since H is optimal, H has at most $2n-2$ bends [26, 27]. In the worst case, such bends of H are all right turns or they are all left turns along S; thus $|n(S)| \leq 2n-2+n$. □

The split component G_{uw} of G is *odd* if one of its poles is a bridge pole or it has external degree 1, while the other pole is a nonbridge pole with external degree 2 (the total number of alias vertices of u and w with respect to G_{uw} is odd); else G_{uw} is *even* (the total number of alias vertices of u and w with respect to G_{uw} is even). For example, the split component in evidence in Fig. 6 is odd, while the one in evidence in Fig. 13 is even.

Consider now the orthogonal representation $H_{uw} \subset H$ of G_{uw}. Suppose G_{uw} is odd; H_{uw} satisfies case 2 of Definition 4.2 and, according to Property 4.1, its spirality is a fractional number. Otherwise, suppose G_{uw} even; in this case H_{uw} satisfies either case 1 or case 3 of Definition 4.2 and, according to Property 4.1, its spirality is an integer number.

PROPERTY 4.3. *Let k be any integer number. If G_{uw} is odd, there always exists an orthogonal representation H of G such that the orthogonal representation $H_{uw} \subset H$ of G_{uw} has spirality $(2k+1)/2$. If G_{uw} is even, there always exists an orthogonal representation H of G such that the orthogonal representation $H_{uw} \subset H$ of G_{uw} has spirality k.*

Combining Theorem 4.4 and Property 4.3, the following corollary descends.

COROLLARY 4.1. *Let G be a graph with n vertices and let $G_{uw} \subset G$ be a split component of G. Let H be an optimal orthogonal representation of G, and let $H_{uw} \subset H$ be the orthogonal representation of G_{uw}. If G_{uw} is odd, the spirality of H_{uw} is a number $(2k+1)/2$ such that $-3n+2 \leq k \leq 3n-3$. If G_{uw} is even, the spirality of H_{uw} is an integer k such that $-3n+2 \leq k \leq 3n-2$.*

4.7. Spirality and cost functions. The *cost function* of a split component associates to each value σ of spirality the cost (number of bends) of an orthogonal representation of the component optimal within spirality σ.

The following property can be trivially proved.

PROPERTY 4.4. *The cost function of a split component is piecewise linear and it is symmetric with respect to the cost axis (vertical axis corresponding to zero spirality).*

Given an embedding of a split component, a *fixed-embedding cost function* associates with each value σ of spirality the cost of an orthogonal representation with spirality σ, which has the given embedding and the minimum number of bends among all the orthogonal representations of the component with spirality σ and the given embedding.

PROPERTY 4.5. *The cost function of a split component is the lower envelope of all the fixed-embedding cost functions of the component.*

We show that the cost functions of the components of 4-planar graphs can have quite complicated behavior. Namely, they are, in general, neither monotone nor convex. Even for a series-parallel graph a cost function can have a linear number of local minima. This closes the possibility of devising polynomial time algorithms for 4-planar series-parallel graphs based on convexity properties of the cost functions.

Intuitively, one would expect that the number of bends of a split component monotonically increases when the spirality of such a component is augmented. Surprisingly, this is not the behavior for general 4-planar graphs. To give an example,

in Fig. 14 we show the cost function of a series composition that has two minima for $\sigma = 0$ and for $\sigma = 2$. The following lemma shows that the behavior of a cost function can be even worse.

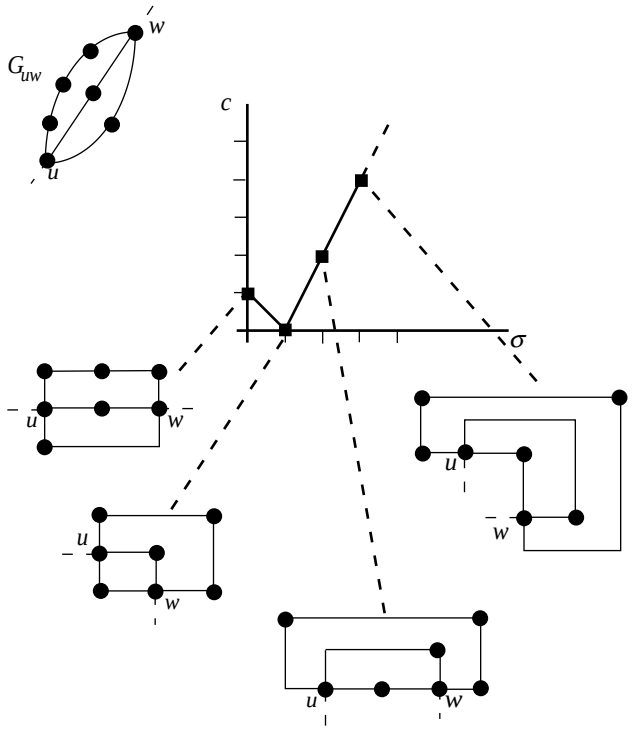

FIG. 14. *An example of nonmonotone cost function.*

LEMMA 4.6. *There exists a split component of a series-parallel graph whose cost function is neither convex nor monotone.*

Proof. Consider the split component of Fig. 15. □

However, the cost function of the split component of Fig. 15a has only one nonconvexity. Now we show an infinite family of split components constructed by only using series and parallel compositions whose cost functions ripple a linear number of times. Let G_n be the split component recursively defined as follows: G_1 is the split component of Lemma 4.6; G_n $(n > 1)$ is the series composition of G_1, one edge, and G_{n-1} (see Fig. 15b). Observe that G_n has $14n$ vertices.

LEMMA 4.7. *The cost function of G_n is zero for $\sigma = \pm 2k$ $(k = 0, \ldots, n)$ and is greater than zero for all the remaining values of σ.*

Proof. For the symmetry of the cost functions (see Property 4.4) we can restrict our attention to nonnegative values of spirality. The proof is by induction on n. We prove first that the cost function of G_1 has value 0 only for spirality 0 and 2.

Let G_0 be the split component of Fig. 14. The split component G_1 is the series composition of two copies of G_0 separated by one edge e_0. The cost function of e_0 is a linear function with slope 1. The cost function of G_0 has value 0 only for spirality 1. Namely, for every value of spirality less than 4, the cost function has the behavior depicted in Fig. 14. Since any orthogonal representation of G_0 has a spine S with three vertices, for values of spirality greater than or equal to 4, such an orthogonal

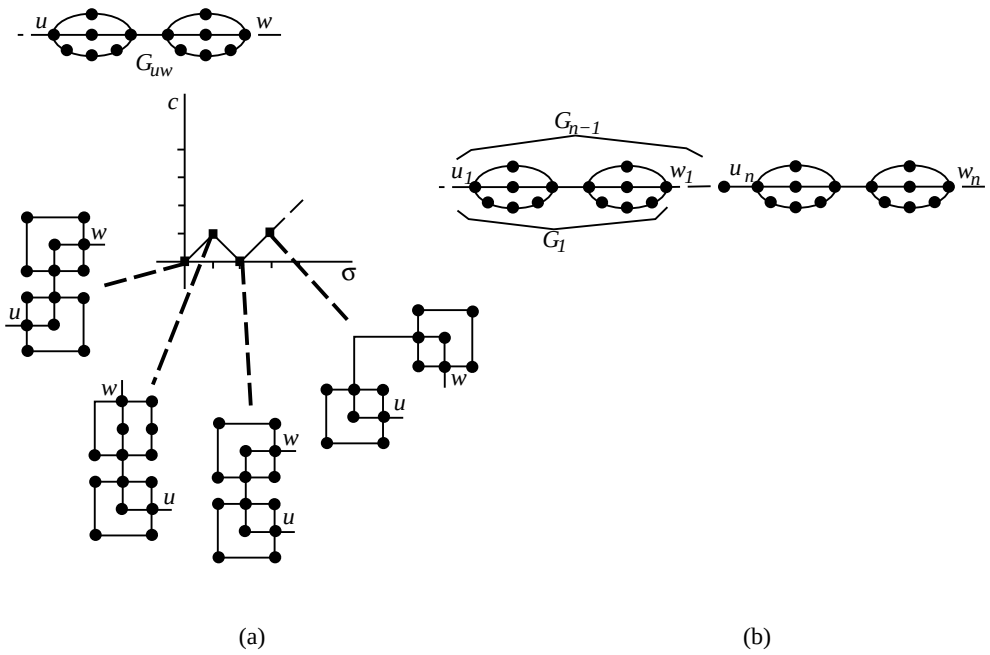

FIG. 15. (a) *An example of nonconvex cost function*; (b) *the series composition* G_n.

representation has at least one bend on S. From Lemma 4.2, the spirality of an orthogonal representation of G_1 is the sum of the spiralities of its components. It follows that an orthogonal representation of G_1 has at least one bend except when the spirality of e_0 is 0 and the spiralities of the orthogonal representations of G_0 are either 1 or -1. Thus, the cost function of G_1 has value 0 only for spirality 0 and 2.

Suppose now the lemma holds for G_{n-1}. We prove the lemma for G_n. G_n is the series of G_{n-1}, one edge e, and G_1. Again, from Lemma 4.2, the spirality of an orthogonal representation of G_n is the sum of the spiralities of its components. It follows that an orthogonal representation of G_n has at least one bend except when the spirality of e is 0 and the spiralities of the orthogonal representations of G_{n-1} and G_1 are such that the corresponding cost functions have value 0. Thus the cost function of G_n has value 0 only for $\sigma = 2k$ $(k = 0, \ldots, n)$. □

The following theorem summarizes the results of this section.

THEOREM 4.5. *There exists an infinite family of* 4*-planar split components constructed by using only series and parallel compositions whose cost functions are neither convex nor monotone.*

5. Cost functions of 3-planar graphs. The results of this section are the basis of a polynomial time algorithm for optimal orthogonal drawings of 3-planar graphs. Namely, let μ be a node of the decomposition tree of a 3-planar graph and let G_μ be its pertinent graph. In section 5.1 we show that the cost function of G_μ is always not decreasing. The contribution of section 5.2 is as follows. First, if μ is a Q^*-node we show that the cost function of G_μ is convex. Second, if μ is an S-node or a P-node, then we show that the convexity of the cost functions of all the children of μ implies the convexity of the cost function of G_μ. Unfortunately, we are not able to prove an analogous property if μ is an R-node. Third, we give more sophisticated tools that

allow us to deal with this case. Namely, we show that the cost functions of all the children of an R-node are convex.

5.1. Not decreasing cost functions. We start by giving a few definitions that will be of use in the rest of the paper.

Let H be an orthogonal 3-planar graph. Let e be an edge of H and let f_1 and f_2 be the faces sharing e. Edge e is an *access edge* from the *starting face* f_1 to the *target face* f_2 if at least one R-symbol is found when traversing e having f_1 on the left side.

Let v be a vertex of H. Two cases are possible.

1. There are two faces f_1 and f_2 in the adjacency list of v, and either f_1 has no labels or it is labeled with an R-symbol; v is an *access vertex* from starting face f_1 to target face f_2.
2. There are three faces f_1, f_2, and f_3 in the adjacency list of v and face f_1 has no label; v is an *access vertex* from starting face f_1 to target faces f_2 and f_3.

An *access* of H is either an access vertex or an access edge of H. For example, in Fig. 16, v_1, v_2, and e are accesses. The starting face of v_1 is f_3 and its target face is f_4; the starting face of v_2 is f_3 and its target faces are f_1 and f_2; the starting face of e is f_e and its target face is f_1.

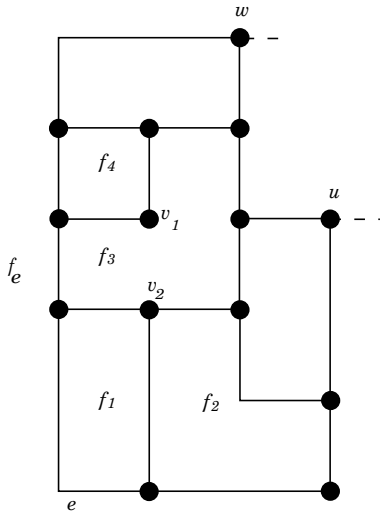

FIG. 16. *An example of accesses.*

Let Γ_1 and Γ_2 be two orthogonal drawings of H, and let C_1 and C_2 be two oriented closed simple curves drawn onto Γ_1 and Γ_2, respectively (curves like C_1 and C_2 have been studied in [21, 26, 27]). Curves C_1 and C_2 are *equivalent curves* if they traverse the same set of edges, vertices, and faces in the same order. In this way the oriented closed simple curves that can be drawn onto the orthogonal drawings of an orthogonal 3-planar graph H are grouped into equivalence classes. A class of equivalent curves is described by a circular oriented list of faces, vertices and edges of H, called the *ring* of H.

A *nonincreasing ring* of H is a ring R such that:

- the reference edge (s, t) belongs to R;
- the external face of H belongs to R and appears immediately after (s, t) in R;

- every edge or vertex of R, except (s,t), is an access a of H. For each sublist f_1, a, f_2 of R, a is an access from f_1 to f_2.

An example of a curve described by a nonincreasing ring is given in Fig. 17a.

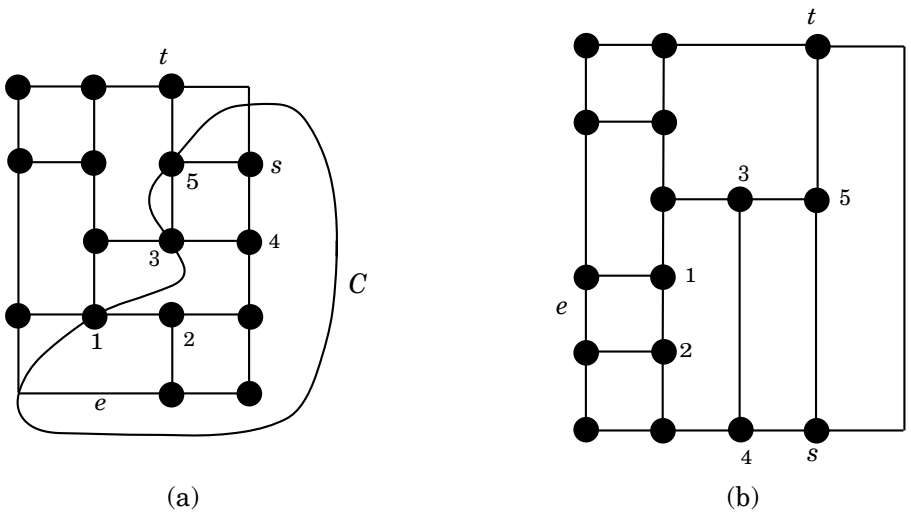

FIG. 17. (a) *A curve C of a nonincreasing ring*; (b) *the elementary transformation defined by C.*

LEMMA 5.1. *Let G be a graph and let G_{st} be the split component of G in parallel with the reference edge (s,t). Let H be an orthogonal representation of G, $H_{st} \subset H$ the orthogonal representation of G_{st}, and R a nonincreasing ring on H. Suppose $\sigma_{H_{st}} > 0$. There exists an orthogonal representation H' of G with the same embedding of H such that $\sigma_{H'_{st}} = \sigma_{H_{st}} - 1$ and H'_{st} has no more bends than H_{st}, where $H'_{st} \subset H'$ is the orthogonal representation of G_{st}.*

Proof. The proof easily follows from a result in [26, 27]. Let Γ be an orthogonal drawing of H. Let C be an oriented closed simple curve drawn onto Γ and such that: (i) C belongs to the class of equivalent curves represented by R; (ii) the intersection between C and (s,t) is not on a bend; and (iii) any other crossing between an edge e of Γ and C is on a bend and is such that C enters from the face where the bend forms a concave angle (this can always be done because e is an access). Curve C defines an *elementary transformation* of the type described in [26, 27]. Such a transformation can be used to modify Γ into a new orthogonal drawing Γ' with one more bend on edge (s,t) (one more left turn when going along (s,t) from s to t) and fewer or as many bends in the rest of the drawing. An example of elementary transformation is shown in Fig. 17, where Figs. 17a and 17b show a drawing before and after the transformation, respectively. In this case the portion of drawing inside C is "rotated" 90 degrees clockwise. Namely, e is straightened, 2 is moved below 1, 4 is moved below 3, 3 is moved to the left of 5, and (s,t) has one more bend. Let H' be the orthogonal graph describing Γ'. Since (s,t) has in H' one more left turn than in H, from Lemma 4.5, the spirality of H'_{st} is equal to $\sigma_{H_{st}} - 1$. □

We are now in a position to prove the following lemma.

LEMMA 5.2. *The cost function of a split component of a 3-planar graph is not decreasing for nonnegative values of spirality.*

Proof. Let T be a decomposition tree of a 3-planar graph and let μ be an internal node of T. Let H'_μ and H''_μ be two orthogonal representations of the pertinent graph

of μ such that H'_μ is optimal within the spirality $\sigma' > 0$ and H''_μ is optimal within the spirality $\sigma'' = \sigma' - 1$. To prove the lemma we need to show that the number of bends of H''_μ is less than or equal to the number of bends of H'_μ.

We first observe that it is sufficient to prove the lemma in a fixed embedding setting. In fact, (1) for Property 4.5 the cost function in the variable embedding setting is the lower envelope of all the fixed embedding cost functions, and (2) the lower envelope of not decreasing functions is itself not decreasing.

If μ is a Q^*-node the proof is trivial. If μ is an S-node and the statement of the lemma holds for each component of the series, then the statement also holds for the entire series (it follows from Lemma 4.2). Thus, we can restrict our attention to the case where μ is either a P-node or an R-node; in both these cases the external degree of the poles of μ is 1.

We show that it is always possible to define a nonincreasing ring for every split component of an orthogonal representation of a 3-planar graph, optimal within a given positive value of spirality. According to Lemma 5.1, the nonincreasing ring allows us to decrease the spirality of the component without increasing its cost. To do that we give a constructive proof. Namely, we give a procedure to compute a nonincreasing ring, and we prove the correctness of such a procedure.

Let H^* be the orthogonal representation obtained by adding edge (u, w) to H'_μ in such a way that (u, w) is the right path of H^* and the spirality of $H'_\mu \subset H^*$ is σ'. Let f_{uw} be the face sharing edge (u, w) with the external face f_e of H^*. Let u' and w' be the alias vertices of u and w, respectively.

Procedure ComputeRing

Step 1: Labeling

Let S be the spine of $H_{\mu'}$ containing the left path of H^*.

repeat

- Let a be the first access of S such that the starting face f_1 is on the left side of S, when going along S from u' to w'.
- Let f_1 be the starting face of a.
- Select a face f_2 according to the following rules: (1) **if** a is an access edge or an access vertex of degree 2, **then** f_2 is the only target face of a; (2) **if** a is an access vertex of degree 3, let $e = (v', a)$ be the edge of S traversed from v' to a; **then** f_2 is the target face of a that contains e (see, for example, Fig. 18a).
- Label access a with the ordered pair f_1, f_2.
- Let v_1 (v_2) be the first (last) encountered vertex of f_2 when going along S from u' to w'. Let P_S be the subpath of S with endpoints v_1 and v_2 and let P be the path joining v_1 and v_2 along f_2 such that P shares with S only its endpoints.
- Replace path P_S of S with path P. (See, for example, Fig. 18b.)

until a is an access with target face f_{uw}

Label access a with the ordered pair f_1, f_{uw}, where f_1 is the starting face of a; also, label edge (u, w) with f_{uw}, f_e.

Step 2: Construction

Construct the ring R containing $f_{u,w}$ such that for each f_1, a, f_2 of R, access a has been labeled f_1, f_2 in Step 1.

end procedure.

Procedure ComputeRing correctly constructs a nonincreasing ring. Observe first that any spine S of $H_{\mu'}$ has at least one access, because σ' is positive and S has at least one right turn; also, there exists at least one spine with an access having target face f_{uw} (consider, as an example of such a spine, the spine containing the right path of $H_{\mu'}$).

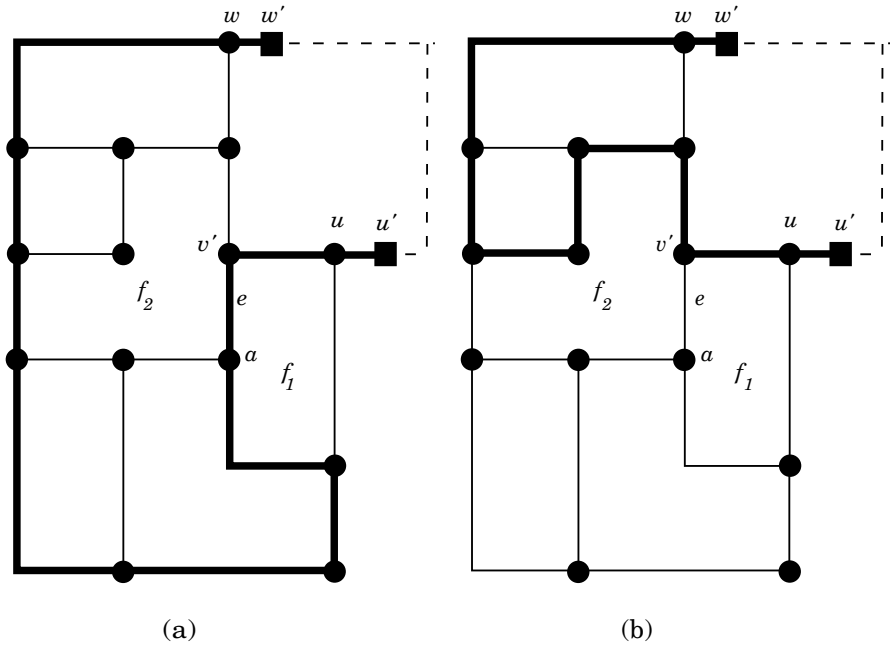

FIG. 18. *An example of choice of the access in the proof of Lemma* 5.2.

Consider now the repeat cycle of the labeling step (Step 1) of the procedure. At each iteration a new spine is computed, by replacing a subpath P_S of the current spine S with a path P sharing with S only its endpoints. Namely, let P_1 be the subpath of S joining u' to v_1 and P_2 be the subpath of S from v_2 to w'. Paths P_1 and P_2 are simple and disjoint by definition. Path P computed in the while cycle is a simple path that intersects P_1 only in v_1 and P_2 only in v_2. Thus, the concatenation of P_1, P, and P_2 is a spine.

Observe that the number of faces between the spine and the left path of H^* increases at each iteration. Intuitively, the spine sweeps from the left path of H^* towards the right path by *eating* some faces on the right of S (between S and the right path of H^*). No face can be eaten twice, since an eaten face moves from the right to the left of the current spine.

An access with target face f_{uw} is found after a finite number of iterations because the cardinality of the set of faces on the right of the current spine decreases at each iteration.

Concerning the construction step (Step 2) of the procedure, we have that an increasing ring R exists. In fact, if R contains face f, then there is a labeled access a having f as target face and labeled with the pair f_1, f. But, since a is a labeled access, a belongs to a spine S having the starting face f_1 at its left. Now, either face f_1 is the face f_e and we are done, or the spine S has been obtained from a previous

spine by eating face f_1. This means that f_1 is the target face of some previously labeled access and we can repeat the argument. □

5.2. Convexity properties of the cost functions. A cost function $c(\sigma)$ of a split component is an *elbow-shaped function* when there exists a pair $\overline{\sigma}$, k such that $c(\sigma) = k$ for $-\overline{\sigma} \leq \sigma \leq \overline{\sigma}$ and $c(\sigma) = |\sigma| + k - \overline{\sigma}$ for $\overline{\sigma} \leq \sigma$.

THEOREM 5.1. *Let G be a 3-planar 2-connected graph and let T be its decomposition tree. Let μ be a node of T and let G_μ be its pertinent graph.*

1. *If μ is a Q^*-node or an S-node, then the cost function of G_μ is elbow-shaped.*
2. *If μ is a P-node, then the cost function of G_μ is convex.*
3. *If μ is an R-node, then the cost functions of the pertinent graphs of the children of μ are elbow-shaped.*

The proof of Theorem 5.1 is based on inductive arguments and will be given in section 5.2.3. The following Lemmas 5.3, 5.4, 5.5, and 5.6 are the main tools of the induction.

LEMMA 5.3. *Let μ be a Q^*-node whose pertinent graph G_μ has m edges. The cost function of G_μ is an elbow-shaped function such that $k = 0$ and $\overline{\sigma} = m - 1$.*

Proof. Suppose that $\sigma \geq 0$; the proof is analogous for $\sigma < 0$. For $\sigma = 0$ an orthogonal drawing of G_μ can be easily constructed by putting all the vertices on the same straight line. For each increase of the spirality of one unit, we can bend the drawing at one of the $m - 1$ internal vertices that did not bend before, without introducing any extra cost until $\sigma = m - 1$. For $\sigma > m - 1$ we need to add $\sigma - m + 1$ bends, and this can be done along a distinguished edge. □

LEMMA 5.4. *Let μ be an S-node whose pertinent graph is G_μ; let μ_1 and μ_2 be the children of μ and let G_{μ_1} and G_{μ_2} be the pertinent graphs of μ_1 and μ_2, respectively. If the cost function of G_{μ_1} is convex and the cost function of G_{μ_2} is elbow-shaped, then the cost function of G_μ is elbow-shaped.*

Proof. Let $c(\sigma)$, $c_1(\sigma)$, and $c_2(\sigma)$ be the cost functions of G_μ, G_{μ_1}, and G_{μ_2}, respectively. For Property 4.4, it is sufficient to show that $c(\sigma)$ is elbow-shaped for nonnegative values of spirality.

Since, for Lemma 5.2, $c_1(\sigma)$ is not decreasing when $\sigma \geq 0$ and since $c_2(\sigma)$ is elbow-shaped, an increase of one unit of spirality for the whole series causes an increase of at most one unit on the overall number of bends. In fact, one can conveniently increase by one unit the spirality on the whole series by bending the component for which the increase on the cost function is the least expensive. Observe that $c(0) = c_1(0) + c_2(0)$. Let σ_1 and σ_2 be the maximum values of spirality for which $c_1(\sigma) = c_1(0)$ and $c_2(\sigma) = c_2(0)$, respectively. Now, because of Lemma 4.2, one can have no cost increase for all values of spirality $0 \leq \sigma \leq \sigma_1 + \sigma_2$. For $\sigma > \sigma_1 + \sigma_2$, for the convexity of $c_1(\sigma)$ and $c_2(\sigma)$, $c(\sigma)$ has a positive slope. A unit slope for $c(\sigma)$ can be obtained by fixing $c(\sigma) = c_1(\sigma_1) + c_2(\sigma - \sigma_1)$. □

LEMMA 5.5. *Let μ be a P-node whose pertinent graph is G_μ; let μ_1 and μ_2 be the children of μ and let G_{μ_1} and G_{μ_2} be the pertinent graphs of μ_1 and μ_2, respectively. If the cost functions of G_{μ_1} and G_{μ_2} are elbow-shaped, then the cost function of G_μ is convex.*

Proof. Let $c(\sigma)$, $c_1(\sigma)$, and $c_2(\sigma)$ be the cost functions of G_μ, G_{μ_1}, and G_{μ_2}, respectively. Consider any triplet of consecutive, nonnegative values of σ, say $\overline{\sigma} - 1$, $\overline{\sigma}$, and $\overline{\sigma} + 1$. Let H_μ, H'_μ, and H''_μ be the orthogonal representations of G_μ optimal within spiralities $\overline{\sigma} - 1$, $\overline{\sigma}$, and $\overline{\sigma} + 1$, respectively.

For Lemma 5.2 the cost function $c(\sigma)$ is not decreasing for $\sigma \geq 0$. Also, for Property 4.4, $c(\sigma)$ is symmetric with respect to the y-axis. Thus, to prove the convexity

of $c(\sigma)$ it is sufficient to show that

$$c(\overline{\sigma}+1) - c(\overline{\sigma}) \geq c(\overline{\sigma}) - c(\overline{\sigma}-1).$$

We distinguish two cases.

1. The relative position of the two components of the parallel does not change in H_μ, H'_μ, and H''_μ (i.e., the right path of the parallel belongs to the same split component in H_μ, H'_μ, and H''_μ). Suppose, w.l.o.g., that the right path of G_μ belongs to G_{μ_1}.

   From Lemma 4.4, we have

   $$c(\overline{\sigma}) = \min(c_1(\overline{\sigma} - \alpha_u^1 - \alpha_w^1) + c_2(\overline{\sigma} + \alpha_u^2 + \alpha_w^2)),$$

   where the minimum is over all the possible values of the parameters α_u^1, α_w^1, α_u^2, α_w^2. Since $c_1(\sigma)$ and $c_2(\sigma)$ are elbow-shaped, if $\overline{\sigma} - 1 \geq 2$, the above minimum gives rise to the following equalities, where $\alpha_u^1 = \alpha_w^1 = 1$ and $\alpha_u^2 = \alpha_w^2 = 0$:

   $$c(\overline{\sigma}-1) = c_1(\overline{\sigma}-3) + c_2(\overline{\sigma}-1),$$

   $$c(\overline{\sigma}) = c_1(\overline{\sigma}-2) + c_2(\overline{\sigma}),$$

   $$c(\overline{\sigma}+1) = c_1(\overline{\sigma}-1) + c_2(\overline{\sigma}+1).$$

   If $\overline{\sigma} - 1 < 2$, the values of parameters α_u^1, α_w^1, α_u^2, α_w^2 that minimize the above formulas might change, but the reasoning of the proof is the same. We prove the lemma for $\overline{\sigma} - 1 \geq 2$.

   By using the above equations we derive

   $$c(\overline{\sigma}+1) - c(\overline{\sigma}) = c_1(\overline{\sigma}-1) + c_2(\overline{\sigma}+1) - c_1(\overline{\sigma}-2) - c_2(\overline{\sigma})$$

   and

   $$c(\overline{\sigma}) - c(\overline{\sigma}-1) = c_1(\overline{\sigma}-2) + c_2(\overline{\sigma}) - c_1(\overline{\sigma}-3) - c_2(\overline{\sigma}-1).$$

   Because of the elbow-shape of $c_1(\sigma)$ and $c_2(\sigma)$, we have $c_1(\overline{\sigma}-1) - c_1(\overline{\sigma}-2) \geq c_1(\overline{\sigma}-2) - c_1(\overline{\sigma}-3)$ and $c_2(\overline{\sigma}+1) - c_2(\overline{\sigma}) \geq c_2(\overline{\sigma}) - c_2(\overline{\sigma}-1)$. The thesis easily follows.

2. The relative position of the two components of the parallel changes in H_μ, H'_μ, and H''_μ.

   Let $c_A(\sigma)$ and $c_B(\sigma)$ be the two fixed-embedding cost functions obtained by considering the two possible relative positions of G_{μ_1} and G_{μ_2}. Functions $c_A(\sigma)$ and $c_B(\sigma)$ are clearly convex from what was given above. Since the relative position of the components of the parallel changes with the spirality, $c_A(\sigma)$ and $c_B(\sigma)$ cross between $\overline{\sigma}-1$ and $\overline{\sigma}+1$. We show that this is not the case. Again, we restrict our attention to the case $\overline{\sigma} - 1 \geq 2$. The proof for $\overline{\sigma} - 1 < 2$ is analogous.

Suppose, w.l.o.g., that $c_A(\overline{\sigma}-1) < c_B(\overline{\sigma}-1)$ and $c_A(\overline{\sigma}+1) > c_B(\overline{\sigma}+1)$. Given the considerations stated in case 1, this implies that

$$c_A(\overline{\sigma}-1) = c_1(\overline{\sigma}-3) + c_2(\overline{\sigma}-1),$$

$$c_A(\overline{\sigma}+1) = c_1(\overline{\sigma}-1) + c_2(\overline{\sigma}+1),$$

$$c_B(\overline{\sigma}-1) = c_1(\overline{\sigma}-1) + c_2(\overline{\sigma}-3),$$

$$c_B(\overline{\sigma}+1) = c_1(\overline{\sigma}+1) + c_2(\overline{\sigma}-1).$$

It follows that

$$c_1(\overline{\sigma}+1) - c_1(\overline{\sigma}-1) < c_2(\overline{\sigma}+1) - c_2(\overline{\sigma}-1) \tag{1}$$

and that

$$c_1(\overline{\sigma}-1) - c_1(\overline{\sigma}-3) > c_2(\overline{\sigma}-1) - c_2(\overline{\sigma}-3). \tag{2}$$

Since $c_1(\sigma)$ is an elbow-shaped function, from inequality (2), $1 \leq c_1(\overline{\sigma}-1) - c_1(\overline{\sigma}-3) \leq 2$ that can be rewritten as $1 \leq c_1(\overline{\sigma}-1) - c_1(\overline{\sigma}-2) + c_1(\overline{\sigma}-2) - c_1(\overline{\sigma}-3) \leq 2$; thus, we have that $c_1(\overline{\sigma}-1) - c_1(\overline{\sigma}-2) = 1$, and $c_1(\overline{\sigma}+1) - c_1(\overline{\sigma}-1) = 2$.

But, from inequality (1), $c_1(\overline{\sigma}+1) - c_1(\overline{\sigma}-1) \leq 1$. This is a contradiction. □

To deal with R-nodes we need more sophisticated tools and introduce the concept of *fixed-ordering cost function*, defined as follows. Given an R-node μ with pertinent graph G_μ of a 3-planar graph, with poles u and w, the possible orderings for the edges of G_μ around u and w are exactly two; one can be obtained from the other by flipping the component around the poles. Call such orderings *ordering A* and *ordering B*. Suppose ordering A is given. For each value σ of spirality there is an orthogonal representation of the component that has spirality σ, the minimum number of bends, and ordering A. We call such an orthogonal representation *optimal within spirality σ and ordering A*. It is worth noticing that an orthogonal representation optimal within spirality σ and ordering A is computed by considering all the possible embeddings for the components of G_μ; only the ordering of the edges around u and w is fixed. A fixed-ordering cost function describes the cost of orthogonal representations of the pertinent graphs of R-nodes that are optimal within given values of spirality and ordering. Note that a fixed-ordering cost function is, in general, nonsymmetric with respect to the cost axis. In what follows we denote with $c_A(\sigma)$ and with $c_B(\sigma)$ the fixed-ordering cost functions relative to ordering A and ordering B, respectively.

LEMMA 5.6. *Let μ be an R-node whose pertinent graph is G_μ. If the cost functions of the pertinent graphs of the children of μ are elbow-shaped, then the two fixed-ordering cost functions of G_μ are convex.*

The proof of Lemma 5.6 will be given in sections 5.2.1 and 5.2.2. It is based on the study of the fixed-ordering cost function associated to the pertinent graph G_μ, in terms of the analysis of the flow variation in a min-cost flow network. This exploits a technique already introduced by Tamassia [21]. In the next subsection we describe the flow model.

5.2.1. The flow network. Let T be a decomposition tree of a 3-planar graph and let μ be an R-node of T with poles u and w. Let G_μ be the pertinent graph of μ and let the two possible orderings for the edges of G_μ around poles u and w be given.

Let $skeleton_A(\mu)$ ($skeleton_B(\mu)$) be the embedded graph obtained by adding (u, w) to $skeleton(\mu)$ and such that (1) (u, w) is on the external face, (2) (u, w) is the right path, and (3) the edges of $skeleton_A(\mu)$ incident on u and w correspond to split components of G_μ that respect ordering A (ordering B).

We associate to μ, σ, and ordering A a network $N_\mu(\sigma, A)$ defined as follows.

- Nodes:
  - —There is a node (*vertex-node*) for each vertex of $skeleton_A(\mu)$.
  - —There is a node (*face-node*) for each face of $skeleton_A(\mu)$.
  - —There are two extra nodes: a source node s and a sink node t.
- Arcs:
  - —There are two arcs (f', f'') and (f'', f') for each pair of faces sharing at least one edge. The arcs have capacity, lower bound, and cost assigned with the following rules. (i) If faces f' and f'' share (u, w), and f'' is the external face of $skeleton_A(\mu)$, then arcs (f', f'') and (f'', f') have zero cost; if $\sigma \leq 4$ then arc (f', f'') has lower bound and capacity equal to $4 - \sigma$, and arc (f'', f') has zero capacity; if $\sigma > 4$ then arc (f'', f') has lower bound and capacity with value $\sigma - 4$, and arc (f', f'') has zero capacity. (ii) If faces f' and f'' share an edge e, then arcs (f', f'') and (f'', f') have infinite capacity, lower bound zero, and cost defined by the cost function of the corresponding split component of G_μ with the endpoints of e as poles.
  - —There is one arc (v, f) where v is a vertex that belongs to face f. Arc (v, f) has infinite capacity and zero lower bound and cost.
  - —There is one arc (s, f) for each internal face f composed by fewer than four edges. Arc (s, f) has capacity 4 minus the number of edges belonging to the face and zero lower bound and cost.
  - —There is one arc (s, v) for each vertex v. Arc (s, v) has capacity equal to $4 - \deg(v)$ and zero lower bound and cost.
  - —There is one arc (f, t) for each internal face f composed by more than four edges. Arc (f, t) has capacity equal to the number of edges belonging to the face minus 4 and zero lower bound and cost.
  - —There is one arc (f_e, t) for the external face f_e. Arc (f_e, t) has capacity equal to 4 plus the number of edges belonging to the face and zero lower bound and cost.

An example of a network is shown in Fig. 19. In this figure we represent only vertex-nodes, face-nodes, and arcs between adjacent faces. For two arcs we also draw (in the circles) the corresponding cost functions.

Similarly, a network $N_\mu(\sigma, B)$ is associated with μ, σ, and ordering B.

The flow value z in $N_\mu(\sigma, A)$ is constrained equal to the sum of the capacities of the arcs' outgoing node s.

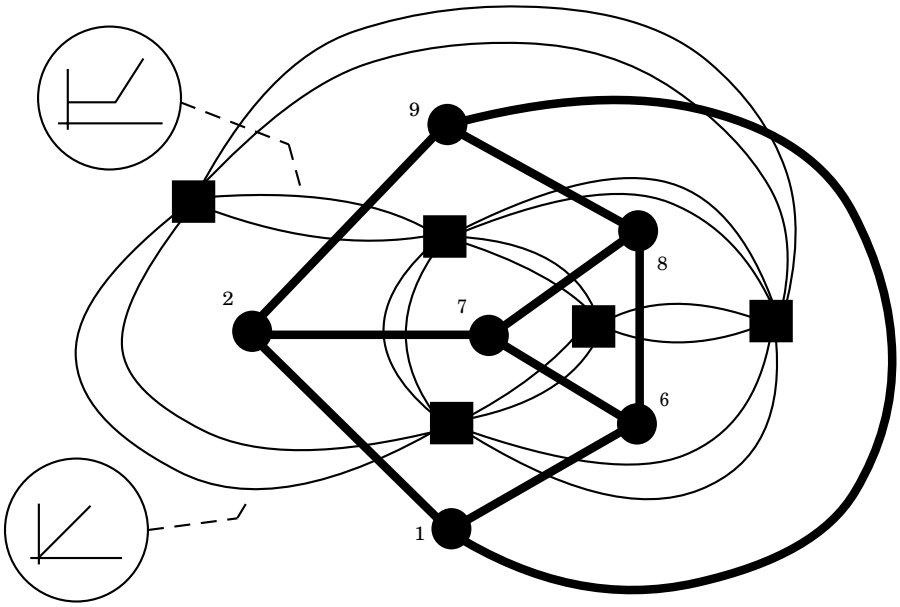

FIG. 19. *Part of the network associated with the skeleton of the R-node of Fig.* 3.

The intuitive interpretation of network $N_\mu(\sigma, A)$ is the following. Each unit of flow in the network represents an angle of 90 degrees; for each pair (f', f'') and (f'', f') linking two face-nodes, their difference of flow represents the spirality of the split components whose virtual edge is the edge separating f' and f'' in $skeleton_A(\mu)$; the cost of the flow represents the number of bends of the orthogonal representation of G_μ (observe that it is not the cost of an orthogonal representation of $skeleton_A(\mu)$). Furthermore, the lower bound of the dual arc of (u, w) constrains edge (u, w) to have the given spirality.

Observe that all the components of 3-planar graphs are even and, by Property 4.3, their possible values of spirality are integer numbers. The proofs of the next two lemmas can be found in [4].

LEMMA 5.7. *Let H_μ be an orthogonal representation of G_μ optimal within spirality σ and ordering A (ordering B) and let c_A (c_B) be the number of bends of H_μ. Then there exists an integer flow in $N_\mu(\sigma, A)$ ($N_\mu(\sigma, B)$) with value z_A (z_B) and cost c_A (c_B).*

LEMMA 5.8. *Let x be a minimum cost integer flow of value z_A (z_B) in $N_\mu(\sigma, A)$ ($N_\mu(\sigma, B)$) and cost $c_A(x)$ ($c_B(x)$). There exists an orthogonal representation H_μ of G_μ optimal within spirality σ and ordering A (ordering B) whose number of bends is $c_A(x)$ ($c_B(x)$).*

The following lemma summarizes the results of this subsection.

LEMMA 5.9. *For each orthogonal representation optimal within spirality σ and ordering A (ordering B) there exists a minimum cost integer flow in $N_\mu(\sigma, A)$ ($N_\mu(\sigma, B)$). Furthermore, an orthogonal representation optimal within spirality σ and ordering A (ordering B) can be computed from the minimum cost integer flow in $N_\mu(\sigma, A)$ ($N_\mu(\sigma, B)$).*

5.2.2. Proof of Lemma 5.6.

Proof. We first show that the fixed-ordering cost functions of the pertinent graph G_μ of μ are convex. Let $c_A(\sigma)$ and $c_B(\sigma)$ be the two fixed-ordering cost functions of G_μ. We prove the convexity of $c_A(\sigma)$; the proof for $c_B(\sigma)$ is analogous. Namely, we show that for each triplet of consecutive values of σ, say $\overline{\sigma}-1$, $\overline{\sigma}$, and $\overline{\sigma}+1$, we have

$$c_A(\overline{\sigma}+1) - c_A(\overline{\sigma}) \geq c_A(\overline{\sigma}) - c_A(\overline{\sigma}-1). \tag{3}$$

Inequality (3), together with Lemma 5.2, proves the convexity of $c_A(\sigma)$.

Let u, w be the poles of G_μ and let f_{uw} be the internal face of $skeleton_A(\mu)$ sharing edge (u, w) with the external face f_e. Let $N_\mu(\overline{\sigma}-1, A)$, $N_\mu(\overline{\sigma}, A)$, and $N_\mu(\overline{\sigma}+1, A)$ be the networks associated with μ for the values of spirality $\overline{\sigma}-1$, $\overline{\sigma}$, $\overline{\sigma}+1$, respectively. Such networks differ only for the values of capacity and lower bound of the pair of arcs between f_e and f_{uw}. For example, consider $N_\mu(\overline{\sigma}-1, A)$ and $N_\mu(\overline{\sigma}, A)$. If $\overline{\sigma}-1 < 4$, then $N_\mu(\overline{\sigma}, A)$ can be obtained from $N_\mu(\overline{\sigma}-1, A)$ by decreasing by one unit the capacity and the lower bound of arc (f_e, f_{uw}); otherwise it can be obtained by increasing by one unit the capacity and the lower bound of (f_{uw}, f_e). We consider the case when the capacity and the lower bound of (f_e, f_{uw}) decrease. The proof is analogous when the capacity and the lower bound of (f_{uw}, f_e) increase.

Let H_μ be an orthogonal representation of G_μ optimal within spirality $\overline{\sigma}-1$ and ordering A; let $\overline{x}$ be the flow in $N_\mu(\overline{\sigma}-1, A)$ that, according to Lemma 5.9, corresponds to H_μ.

We remind the reader that for arc (f_e, f_{uw}) the capacity and the lower bound coincide and that (f_e, f_{uw}) is a saturated arc in $N_\mu(\overline{\sigma}-1, A)$ when the flow is $\overline{x}$. Thus, an optimal flow $\overline{x}'$ in $N_\mu(\overline{\sigma}, A)$ can be computed starting from flow $\overline{x}$ and by decreasing the flow in the arc (f_e, f_{uw}) by means of a minimum cost augmenting path P' connecting f_e and f_{uw} (see also [1]). The objective function (i.e., the cost function $c_A(\sigma)$ of G_μ) changes by an amount $d(P')$, that is, the cost of the chosen augmenting path P' (in the rest of the proof we denote by $d(P)$ the cost of an augmenting path P). Let H'_μ be the orthogonal representation of G_μ computed from $N_\mu(\overline{\sigma}, A)$ and $\overline{x}'$. From Lemma 5.9, H'_μ is optimal within spirality $\overline{\sigma}$ and ordering A. Also, the number of bends in H'_μ is $c_A(\overline{\sigma}-1) + d(P')$.

Consider now network $N_\mu(\overline{\sigma}+1, A)$. Again, an optimal flow $\overline{x}''$ for $N_\mu(\overline{\sigma}+1, A)$ is computed starting from $\overline{x}'$, by means of a minimum cost augmenting path P'' from f_e to f_{uw}. The corresponding orthogonal representation H''_μ is optimal within spirality $\overline{\sigma}+1$ and ordering A and has $c_A(\overline{\sigma}-1) + d(P') + d(P'')$ bends.

It follows that inequality (3) can be rewritten as $d(P'') \geq d(P')$. Suppose, for a contradiction, that $d(P'') < d(P')$. Three cases are possible.

1. P' and P'' do not share common edges. In this case P' is not the minimum cost augmenting path when computing flow $\overline{x}'$ from flow $\overline{x}$. This is a contradiction.
2. P' and P'' share edge $e = (p, q)$ traversed in the same direction in both P' and P'' (see Fig. 20a). In other words, the flow along e is increased or decreased in both P' and P''. In both cases, since the cost function of e is convex, the variation $d'(e)$ of the cost along e in P' is not greater than the variation $d''(e)$ of the cost along e in P''. Path P' is the concatenation of three subpaths, P'_1, edge e, and P'_2. Analogously, P'' is the concatenation of subpaths P''_1, edge e, and P''_2. Inequality $d(P'') < d(P')$ can be rewritten as follows.

$$d(P''_1) + d''(e) + d(P''_2) < d(P'_1) + d'(e) + d(P'_2). \tag{4}$$

Since path $P'_1 e P'_2$ is chosen as a minimum cost augmenting path in network $N_\mu(\overline{\sigma}, A)$, we have that $d(P')$ is not greater than the cost of the paths $P'_1 e P''_2$ and $P''_1 e P'_2$ (if a path is not an augmenting path its cost is infinite). Thus, the following inequalities also hold:

$$d(P'_1) + d'(e) + d(P'_2) \leq d(P'_1) + d'(e) + d(P''_2),$$

$$d(P'_1) + d'(e) + d(P'_2) \leq d(P''_1) + d'(e) + d(P'_2),$$

which imply

$$d(P'_2) \leq d(P''_2),$$

$$d(P'_1) \leq d(P''_1).$$

The last two inequalities, together with $d''(e) \leq d'(e)$ contradict inequality (4).

3. P' and P'' share edge e, with endpoints p and q, traversed in the opposite direction in P' and in P'' (see Fig. 20b). The variation $d'(e)$ of the cost along e in P' is equal to the variation $-d''(e)$ of the cost along e in P''. P' is the concatenation of three subpaths, P'_1 from f_e to p, edge (p, q), and P'_2 from q to f_{uw}. Analogously, P'' is the concatenation of subpaths P''_1 from f_e to q, edge (q, p), and P''_2 from p to f_{uw}.
Inequality $d(P'') < d(P')$ can be rewritten as follows:

$$d(P''_1) - d'(e) + d(P''_2) < d(P'_1) + d'(e) + d(P'_2). \tag{5}$$

Since path P' is chosen as a minimum cost augmenting path in network $N_\mu(\overline{\sigma}, A)$, we have that $d(P')$ is not greater than the cost of the paths $P'_1 P''_2$ and $P'_2 P''_1$. Thus

$$d(P'_1) + d'(e) + d(P'_2) \leq d(P'_1) + d(P''_2),$$

$$d(P'_1) + d'(e) + d(P'_2) \leq d(P'_2) + d(P''_1),$$

which imply

$$d'(e) + d(P'_2) \leq d(P''_2),$$

$$d(P'_1) + d'(e) \leq d(P''_1).$$

The last two inequalities contradict inequality (5). In fact, we can write

$$d(P_1') + d'(e) - d'(e) + d'(e) + d(P_2') < d(P_1') + d'(e) + d(P_2'),$$

$$d(P_1') + d(P_2') < d(P_1') + d(P_2'). \qquad \square$$

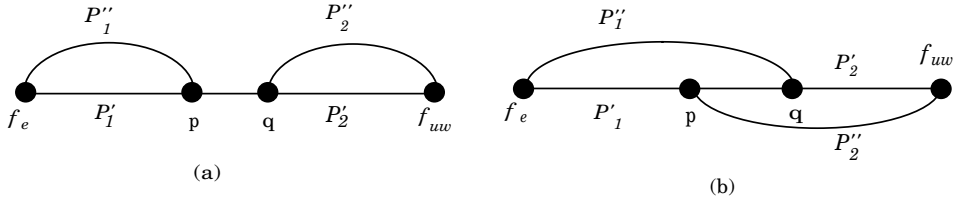

FIG. 20. (a) *Illustration for case* 2 *in the proof of Lemma* 5.6; (b) *illustration for case* 3 *in the proof of Lemma* 5.6.

5.2.3. Proof of Theorem 5.1.

Proof. The proof is by induction on the height of the subtree T_μ rooted at μ.

Base case. If T_μ has height 0, then by the definition of decomposition tree μ is a Q^*-node; the thesis follows by Lemma 5.3. If T_μ has height 1, then by the definition of decomposition tree, the children of μ are Q^*-nodes; the thesis follows from Lemmas 5.3 and 5.5.

Inductive case. Suppose T_μ has height $k > 1$. Three cases are possible: μ is an R-node, a P-node, or an S-node.

If μ is an R-node or a P-node, then by Property 2.2 its children are either S-nodes or Q^*-nodes. Hence, the pertinent graphs of the children of μ have elbow-shaped cost functions because of the inductive hypothesis. If μ is an R-node, then this is enough to prove the theorem. If μ is a P-node, then the thesis follows from the above discussion and from Lemma 5.5.

If μ is an S-node and none of its children is an R-node or a P-node, the theorem follows from the inductive hypothesis and from Lemma 5.4.

If μ is an S-node and one of its children is a P-node, from Property 2.2 the other child of μ can be either an S-node or a Q^*-node. The theorem follows from the inductive hypothesis and from Lemma 5.4.

Suppose now that μ is an S-node with children μ_1 and μ_2, and one of its children, say μ_1, is an R-node. Because of Property 2.2, the children of μ_1 are either S-nodes or Q^*-nodes. So, for the inductive hypothesis on the children of μ_1 and for Lemma 5.6, both the fixed-ordering cost functions $c_A(\sigma)$ and $c_B(\sigma)$ of the pertinent graph G_{μ_1} of μ_1 are not decreasing and convex; note that $c_A(\sigma)$ and $c_B(\sigma)$ coincide for $\sigma = 0$. By Property 2.2, μ_2 is either a Q^*-node or an S-node and its pertinent graph G_{μ_2} has an elbow-shaped cost-function by induction. Because of the elbow-shape of the cost function of G_{μ_2} and of the convexity of $c_A(\sigma)$ and $c_B(\sigma)$, an increase of one unit of spirality for the whole series causes an increase of at most one unit of the overall number of bends. These arguments imply that the two cost functions, (1) of the series of G_{μ_2} and G_{μ_1} with ordering A, and (2) of the series of G_{μ_2} and G_{μ_1} with ordering B, are elbow-shaped functions and have the same value for $\sigma = 0$. The cost function

of the whole series is the lower envelope of the two cost functions above; the lower envelope of two elbow-shaped functions that coincide for $\sigma = 0$ is an elbow-shaped function. □

6. Optimal orthogonal drawings of 3-planar graphs. The target of this section is to provide a polynomial time algorithm for computing the optimal orthogonal drawing of a 3-planar graph G. We first deal with the 2-connected case. The basic idea is to incrementally construct an optimal orthogonal drawing of G by composing orthogonal representations of its split components that are optimal within given values of spirality. To do that, we compute a decomposition tree T of G for each possible reference edge and equip the nodes of T with a data structure devised to describe optimal orthogonal representations of the split components of G. The optimal orthogonal drawing of G is selected among the set of optimal orthogonal drawings, each computed using one of the above decomposition trees.

In section 6.1 we present the data structure; in section 6.2 we show how to use T to compute optimal orthogonal drawings of 3-planar graphs. The management of several decomposition trees is shown in section 6.3. In section 6.4 we extend the algorithm to general 3-planar graphs.

6.1. Optimal sets. Let G be a 3-planar graph with n vertices, let T be a decomposition tree of G, and let μ be an internal node of T. Let G_μ be the pertinent graph of μ.

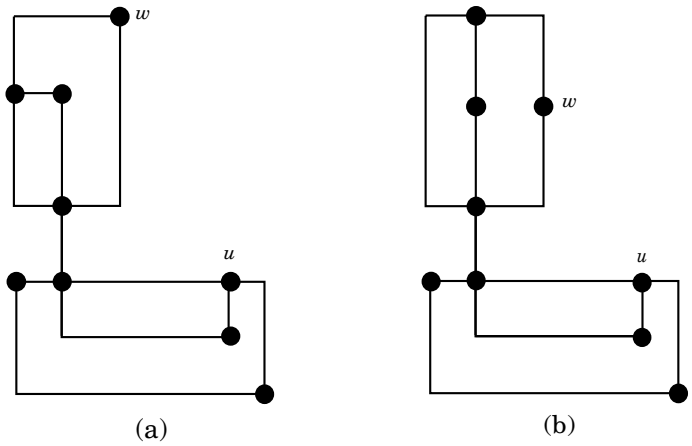

FIG. 21. *Feasible* (a) *and not feasible* (b) *orthogonal representation of the split component highlighted in Fig.* 6.

An orthogonal representation H_μ of G_μ is *feasible* if there exists an orthogonal representation of G having H_μ as a subgraph. As an example, in Fig. 21 two orthogonal representations of the split component in evidence in Fig. 6 are shown; the one in Fig. 21a is feasible while the one in Fig. 21b is not feasible. Notice that the feasibility of an orthogonal representation can be checked by looking at the labels in the adjacency lists of the poles and at their external degree.

Let H_μ be a feasible orthogonal representation of G_μ; let $\mathcal{H}$ be the infinite class of orthogonal representations of G such that (1) each element of $\mathcal{H}$ has H_μ as a subgraph; (2) the labels associated with the right (left) face of H_μ in the adjacency lists of its poles are the same for each element of $\mathcal{H}$. We say that $\mathcal{H}$ is a *fitting class* of H_μ.

Let u and w be the poles of H_μ. Let $\{\lambda_u, \rho_u, \lambda_w, \rho_w\}$ be a set of labels in $\{R, L\}$. The set $\{\lambda_u, \rho_u, \lambda_w, \rho_w\}$ is *sound* for H_μ if there exists a fitting class $\mathcal{H}$ of H_μ such that for each element of $\mathcal{H}$ the labels associated with the left (right) face of H_μ in the adjacency lists of u and w are λ_u (ρ_u) and λ_w (ρ_w).

Observe that a feasible orthogonal representation H_μ and a set of labels that are sound for H_μ identify a fitting class of H_μ. Also, by Property 4.2, H_μ and a set of labels that are sound for H_μ univocally determine the spirality of H_μ.

An *optimal 7-tuple* of μ is a 7-tuple $\langle H_\mu, \sigma_{H_\mu}, c_{H_\mu}, \lambda_u, \rho_u, \lambda_w, \rho_w \rangle$ such that

1. H_μ is a feasible orthogonal representation of G_μ, optimal within spirality σ_{H_μ};
2. c_{H_μ} is the cost of H_μ;
3. $\{\lambda_u, \rho_u, \lambda_w, \rho_w\}$ is a set of labels that is sound for H_μ.

We equip each node μ of T with an *optimal set*. An optimal set is a set of optimal 7-tuples of μ with the following properties.

1. For each value of spirality the set contains at most one optimal 7-tuple.
2. Let $\langle H_\mu, \sigma_{H_\mu}, c_{H_\mu}, \lambda_u, \rho_u, \lambda_w, \rho_w \rangle$ be an optimal 7-tuple of the optimal set. Then, for each node ν of the subtree of T rooted at μ (including μ), the orthogonal representation $H_\nu \subseteq H_\mu$ of the pertinent graph of ν has spirality in the range stated by Theorem 4.4.

Note that, by Corollary 4.1, the cardinality of an optimal set is at most $2(3n-2)+1$ if G_μ is even, and at most $2(3n-2)$ if G_μ is odd.

LEMMA 6.1. *There exists an optimal orthogonal representation H of G such that the split components of H belong to the optimal sets of the nodes of T.*

Proof. Let H' be any optimal orthogonal representation of G, and let $H'_\mu \subset H'$ be the orthogonal representation of the pertinent graph of an internal node μ of T. We show how to compute H starting from H'.

Let $\sigma_{H'_\mu}$ be the spirality of H'_μ. By Theorem 4.4, $|\sigma_{H'_\mu}| \leq 3n-2$; also, by definition, there is an orthogonal representation H''_μ that belongs to the optimal set of μ and is optimal within spirality $\sigma_{H'_\mu}$. Let H'' be an orthogonal representation in the fitting class of H''_μ such that H' and H'' are split-different for the split components H'_μ and H''_μ. We apply Theorem 4.1 to H' and H'', substituting H'_μ with H''_μ in H'. Since H''_μ is optimal within the spirality $\sigma_{H'_\mu}$, the orthogonal representation obtained with the substitution is still an optimal orthogonal representation of G. The optimal orthogonal representation H is obtained by iterating such a procedure for each split component of H'. □

6.2. Computing the optimal sets of 3-planar graphs. We consider separately the different types of internal nodes of a decomposition tree of a 3-planar graph G with n vertices and show how to compute the optimal sets of such nodes.

6.2.1. Computing the optimal set of a Q^*-node. Let μ be a Q^*-node of T, and let $G_\mu \subset G$ be the pertinent graph of μ with poles u and w. An optimal set of μ is computed by the following procedure. Intuitively, while increasing the spirality of a chain with $k+1$ vertices, we avoid bending the edges until spirality $k-1$; after that value we add one bend for each increasing unit of spirality.

PROCEDURE Q^*-OPTIMALSET(μ)
  for each integer σ between $-3n+2$ and $3n-2$, compute the 7-tuple $\langle H_\mu, \sigma_{H_\mu}, c_{H_\mu}, \lambda_u, \rho_u, \lambda_w, \rho_w \rangle$ as follows and put it in the optimal set of μ:
    Let k be the number of edges of G_μ.
    if $|\sigma| < k$ **then** H_μ has no bends and $c_{H_\mu} = 0$

else H_μ has $|\sigma| - k + 1$ bends and $c_{H_\mu} = |\sigma| - k + 1$.
$\sigma_{H_\mu} = \sigma$; labels λ_u, ρ_u, λ_w, ρ_w are undefined.
end procedure.

As an example, some 7-tuples of the optimal set of node ξ_1 of Fig. 3 computed by Procedure Q^*-OptimalSet are shown in Fig. 22a.

Since μ is a Q^*-node, an efficient way to encode H_μ is to store in each 7-tuple only the number of turns that appear in H_μ. By Corollary 4.1 and since each optimal 7 tuple is computed in $O(1)$ time, we have the following lemma.

LEMMA 6.2. *Procedure Q^*-OptimalSet computes an optimal set of a Q^*-node in $O(n)$ time.*

6.2.2. Computing the optimal set of an S-node. Let μ be an S-node of T, and let $G_\mu \subset G$ be the pertinent graph of μ with poles u and w. Let μ_1 and μ_2 be the two children of μ. Let G_{μ_1} be the pertinent graph of μ_1 with poles $u_1 \equiv u$ and w_1; let G_{μ_2} be the pertinent graph of μ_2 with poles $u_2 \equiv w_1$ and $w_2 \equiv w$. An optimal set of μ is computed by the following procedure. Intuitively, for each value of spirality stated by Corollary 4.1, we look into the optimal sets of μ_1 and μ_2 searching for the minimum cost 7-tuples that satisfy Lemma 4.2.

PROCEDURE S-OPTIMALSET(μ)
for each value of spirality stated by Corollary 4.1, compute the 7-tuple $\langle H_\mu, \sigma_{H_\mu}, c_{H_\mu}, \lambda_u, \rho_u, \lambda_w, \rho_w \rangle$ by performing the following steps and, if such a tuple exists, put it in the optimal set of μ:
Step 1: Find two 7-tuples t_1 and t_2 in the optimal sets of μ_1 and μ_2 such that:
(1) $t_1 = \langle H_{\mu_1}, \sigma_{H_{\mu_1}}, c_{H_{\mu_1}}, \lambda_{u_1}, \rho_{u_1}, \lambda_{w_1}, \rho_{w_1} \rangle$;
(2) $t_2 = \langle H_{\mu_2}, \sigma_{H_{\mu_2}}, c_{H_{\mu_2}}, \lambda_{u_2}, \rho_{u_2}, \lambda_{w_2}, \rho_{w_2} \rangle$;
(3) $\sigma_{H_{\mu_1}} + \sigma_{H_{\mu_2}} = \sigma$ (see Lemma 4.2); and
(4) $c_{H_{\mu_1}} + c_{H_{\mu_2}}$ is the lowest among all the possible choices of such 7-tuples.
if such 7-tuples do not exist **then** skip the next two steps.
Step 2: Define H_μ as follows.
• H_μ has the same vertices and edges of G_μ.
• Associate with each vertex of H_μ but $w_1 \equiv u_2$ the same adjacency list it has in H_{μ_1} or in H_{μ_2}.
• Compose the adjacency list L of $w_1 \equiv u_2$ as follows. Let L_1 (L_2) be the adjacency list of w_1 in H_{μ_1} (u_2 in H_{μ_2}). Cut L_1 and L_2 in correspondence with f_e, deleting f_e. Build the new list L as the concatenation of L_1, f_e, L_2, and f_e. Associate with the first (second) occurrence of f_e the label λ_{w_1} (ρ_{w_1}) of t_1 if u_2 is a bridge pole in G_{μ_2}, substitute the label λ_{u_2} (ρ_{u_2}) of t_2 otherwise. Make L circular by linking its first element to its last element.
Step 3: $\lambda_u = \lambda_{u_1}$, $\rho_u = \rho_{u_1}$, $\lambda_w = \lambda_{w_2}$, $\rho_w = \rho_{w_2}$. $c_{H_\mu} = c_{H_{\mu_1}} + c_{H_{\mu_2}}$.
end procedure.

As an example, some 7-tuples of the optimal set of node ξ_2 of Fig. 3 computed by Procedure S-OptimalSet are shown in Fig. 22b.

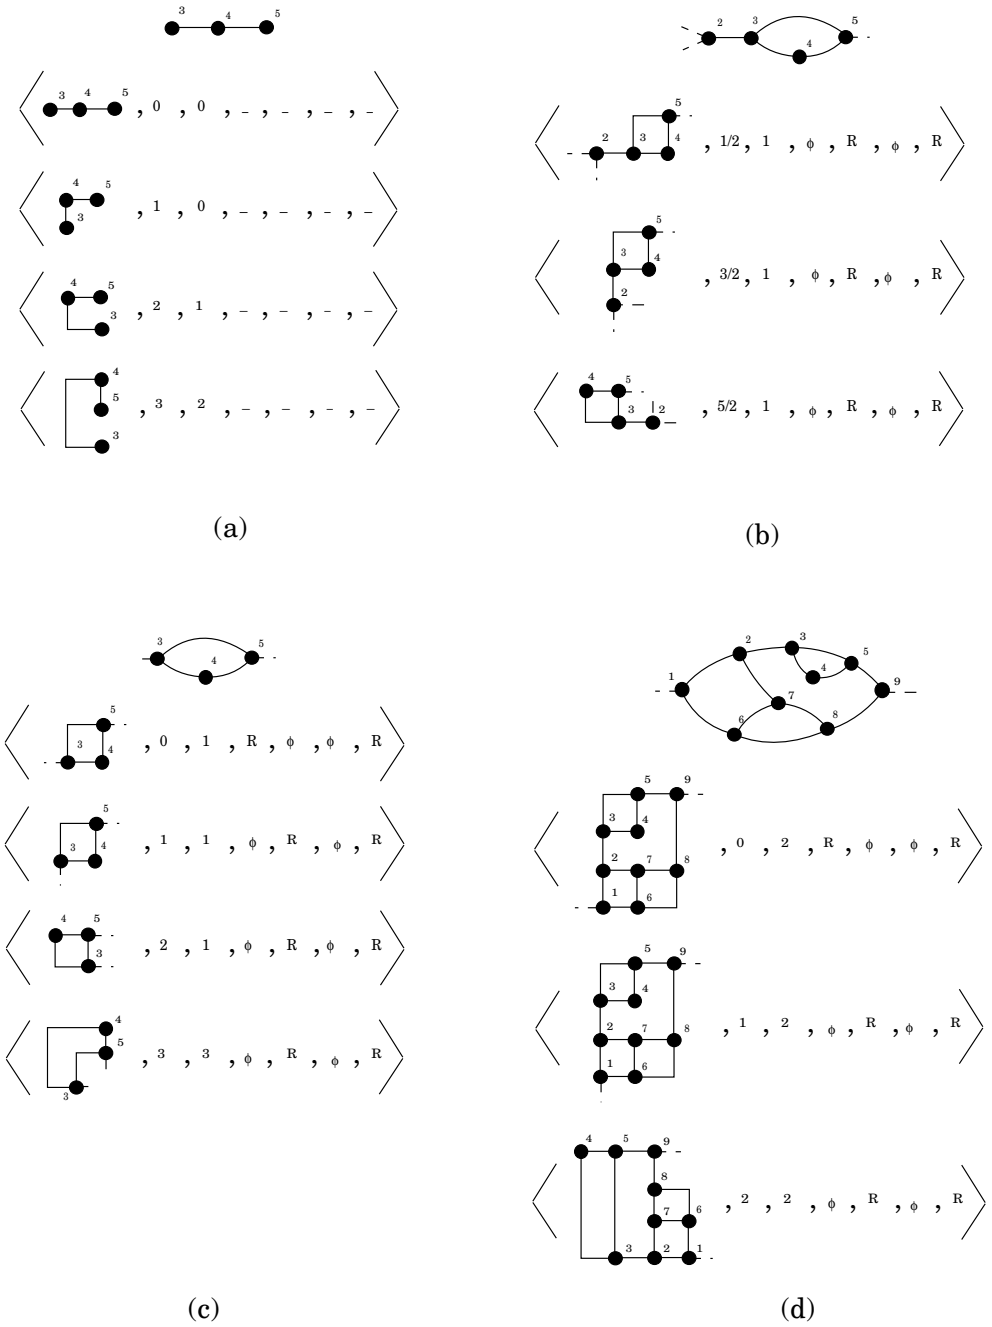

FIG. 22. *Some optimal* 7*-tuples of the nodes:* (a) ξ_1, (b) ξ_2, (c) ξ_3, *and* (d) ξ_4 *of the decomposition tree of Fig.* 3.

LEMMA 6.3. *Procedure S-OptimalSet computes an optimal set of an internal S-node μ in $O(n^2)$ time.*

Proof. We concentrate on each computed 7-tuple.

We first prove that H_μ is a feasible orthogonal representation of G_μ. We have that H_μ is an orthogonal representation by construction. Also, since poles u and w coincide with poles u_1 and w_2 and both H_{μ_1} and H_{μ_2} are feasible, H_μ is feasible.

Second, suppose H_μ is not optimal within spirality σ_{H_μ}; then there exists a feasible orthogonal representation H'_μ of G_μ with fewer bends than H_μ and spirality σ_{H_μ}, and such that, by Lemma 6.1, all the split components of H'_μ are in the 7-tuples of the optimal sets of the children of node μ. Since for each value of spirality Procedure S-OptimalSet considers all the possible pairs of 7-tuples in the optimal sets of the children of μ, we have a contradiction.

Third, we observe that since the labels of t_1 and t_2 are sound, labels λ_u, λ_w, ρ_u, and ρ_w are sound for H_μ.

To complete the proof of correctness, it remains to prove that the set defined by Procedure S-OptimalSet is an optimal set of μ. This easily follows from the construction strategy and from the fact that the procedure considers optimal sets of μ_1 and μ_2.

Concerning the complexity, since μ is an S-node, an efficient way to encode H_μ in the 7-tuple is to store two pointers to t_1 and t_2 plus the labels of the faces around the poles of H_μ. Thus, the computation of an optimal 7-tuple can be performed in linear time by using sorted structures for the optimal sets of the children of μ. So, we have that Steps 1–3 compute an optimal 7-tuple of an S-node μ for a given value σ of spirality in $O(n)$ time. The overall time complexity follows from Corollary 4.1. □

6.2.3. Computing the optimal set of a P-node. If μ is a P-node, from Property 2.2 it has two children. We give a procedure to compute an optimal set of μ. The procedure exploits the result of Lemma 4.4. Namely, we consider all possible values of parameters α_v^i $(v = u, w)$ in any orthogonal representation of G containing H_μ; α_v^1 and α_v^2 can be either 0 or 1, but they cannot both be 0.

PROCEDURE P-OPTIMALSET(μ)

for each value of spirality stated by Corollary 4.1, compute the 7-tuple $\langle H_\mu, \sigma_{H_\mu}, c_{H_\mu}, \lambda_u, \rho_u, \lambda_w, \rho_w \rangle$ by performing the following steps and, if such a tuple exists, put it in the optimal set of μ:

Step 1: Find a 7-tuple in the optimal set of μ_1, and a 7-tuple in the optimal set of μ_2 such that:

(1) the spiralities in each one of the two selected 7-tuples satisfy formula of Lemma 4.4 with an admissible value for α_v^i;

(2) the sum of the costs is the lowest among all the possible choices of the two 7-tuples.

if such two 7-tuples do not exist **then** skip the next two steps.

Step 2: Let $t_1 = \langle H_1, \sigma_{H_1}, c_{H_1}, \lambda_{u_1}, \rho_{u_1}, \lambda_{w_1}, \rho_{w_1} \rangle$ and $t_2 = \langle H_2, \sigma_{H_2}, c_{H_2}, \lambda_{u_2}, \rho_{u_2}, \lambda_{w_2}, \rho_{w_2} \rangle$ be the 7-tuples chosen in Step 1. Let $\sigma_{H_\mu} = \sigma_{H_1} + \alpha_u^1 + \alpha_w^1$ and $\sigma_{H_\mu} = \sigma_{H_2} + \alpha_u^2 + \alpha_w^2$, (observe that we have removed parameters k_u and k_w in the formula of Lemma 4.4, since the degree of poles u and w is 3).

Define H_μ as follows (see Fig. 23).

- H_μ has the same vertices and edges of G_μ.

• Associate to each vertex of H_μ but u and w the same adjacency list it has in either H_1 or H_2.

• Let e and e' be the edges of H_1 and of H_2 that are incident on pole u, respectively. Define the adjacency list of u as edge e and edge e'. Similarly, define the adjacency list of w. Let f be the face of H_μ composed by vertices and edges of H_1 and H_2. Assign an R-label to f in the adjacency list of v if $\alpha_v^1 + \alpha_v^2 = 1$ $(v = u, w)$; assign no label to f otherwise. Assign an L-label to the external face f_e in the adjacency list of v if $\alpha_v^1 + \alpha_v^2 = 1$; assign no label to f_e otherwise.

Step 3: **if** $\alpha_v^1 = 1$, **then** assign an R-symbol to λ_v $(v = u, w)$, **else** assign no symbol to λ_v. **if** $\alpha_v^2 = 1$, **then** assign an R-symbol to ρ_v, **else** assign no symbol to ρ_v. $c_{H_\mu} = c_{H_1} + c_{H_2}$.

end procedure.

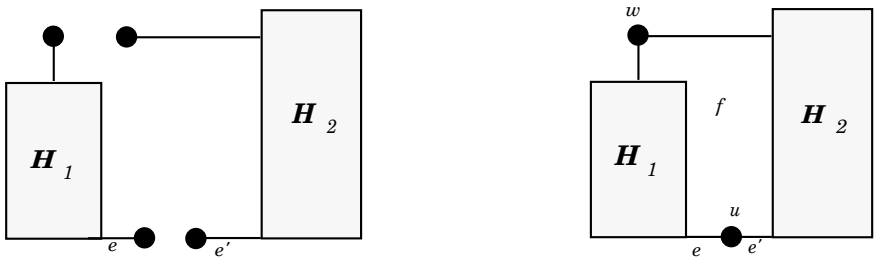

FIG. 23. *Illustration for Procedure P-OptimalSet.*

As an example, some 7-tuples of the optimal set of node ξ_3 of Fig. 3 computed by Procedure P-OptimalSet are shown in Fig. 22c.

LEMMA 6.4. *Procedure P-OptimalSet computes an optimal set of an internal P-node μ with two children in $O(n)$ time.*

Proof. We concentrate on each computed 7-tuple.

We first prove that H_μ is a feasible orthogonal representation of G_μ. We need to prove that the conditions of Property 2.3 hold. Condition 1 is trivially true by construction. Condition 2 is trivially true for all faces but f and the external face. Consider f. Its boundary is composed by a spine S_1 of H_1, and a spine S_2 of H_2. Also, by construction, an R-label is assigned to f in the adjacency list of v (w) if $\alpha_v^1 + \alpha_v^2 = 1$ $(\alpha_w^1 + \alpha_w^2 = 1)$.

Thus, writing the number of R-labels on both the poles as $2-\alpha_u^1-\alpha_u^2+2-\alpha_w^1-\alpha_w^2$ and using Lemma 4.4, the number of right turns minus the number of left turns encountered when going around f in the positive direction is $n(S_2)-n(S_1)+2-\alpha_u^1-\alpha_u^2+2-\alpha_w^1-\alpha_w^2 = \alpha_u^1+\alpha_u^2+\alpha_w^1+\alpha_w^2+2-\alpha_u^1-\alpha_u^2+2-\alpha_w^1-\alpha_w^2 = 4$. Analogous reasoning for the external face.

Since the external degree of both the poles is 1 and the external face has no R-labels in the adjacency lists of the poles, H_μ is feasible. λ_v and ρ_v $(v = u, w)$ are sound for H_μ since by construction they cannot both correspond to no label.

H_μ is optimal within spirality σ_{H_μ}: the proof is analogous to that of Lemma 6.3.

With analogous reasoning as in Lemma 6.3, it can be proved that the set defined by Procedure P-OptimalSet is an optimal set of μ.

Concerning the complexity, since μ is a P-node, an efficient way to encode H_μ is to store only two pointers to the 7-tuples that have been chosen as well as the labels

of the faces around the poles of H_μ. Thus, the computation of an optimal 7-tuple can be performed in constant time by using sorted structures for the optimal sets of the children of μ. So, we have that Steps 1–3 compute an optimal 7-tuple of a P-node μ with two children for a given value σ of spirality in $O(1)$ time. The overall time complexity follows from Corollary 4.1. □

6.2.4. Computing the optimal set of an R-node. Let μ be an R-node of T and let $G_\mu \subset G$ be the pertinent graph of μ with poles u and w. An optimal set of μ is computed by the following procedure. Intuitively, for each value of spirality, (1) we compute the two flow networks associated with ordering A and ordering B, (2) we solve the two corresponding min-cost flow problems, (3) we choose the minimum cost solution between them, and (4) we construct the 7-tuple corresponding to the selected solution.

PROCEDURE R-OPTIMALSET (μ)

Define ordering A and ordering B of G_μ.

for each value of spirality stated by Corollary 4.1, compute the 7-tuple $\langle H_\mu, \sigma_{H_\mu}, c_{H_\mu}, \lambda_u, \rho_u, \lambda_w, \rho_w \rangle$ by performing the following steps and, if such a tuple exists, put it in the optimal set of μ:

Step 1:

- Construct $N_\mu(\sigma_{H_\mu}, A)$ and $N_\mu(\sigma_{H_\mu}, B)$.
- Solve the min-cost flow problem on $N_\mu(\sigma_{H_\mu}, A)$ and on $N_\mu(\sigma_{H_\mu}, B)$. Choose the network whose solution has the minimum cost.
- Let ν be a child of μ in T, whose pertinent graph is G_ν. Check if it is possible to construct an orthogonal representation H_μ of G_μ by applying the technique of Lemma 5.8 and by using for each component G_ν only the orthogonal representations in the optimal set of ν.

if the construction fails **then** skip the next step.

Step 2:

Let H'_μ be the orthogonal representation of *skeleton*(μ) constructed by the network chosen in Step 1. (See Lemma 5.8.)

Let f_{uw} be the face of H'_μ sharing (u, w) with the external face f_e.

- Assign to λ_u and ρ_u the labels of f_e and f_{uw}, respectively, in the adjacency list of u in H'_μ.
- Assign to λ_w and ρ_w the labels of f_e and f_{uw}, respectively, in the adjacency list of w in H'_μ.
- Assign to c_{H_μ} the cost of the flow.

end procedure.

As an example, some 7-tuples of the optimal set of node ξ_4 of Fig. 3 computed by Procedure R-OptimalSet are shown in Fig. 22d.

LEMMA 6.5. *Procedure R-OptimalSet computes an optimal set of an R-node in $O(n^3 \log n)$ time.*

Proof. We concentrate on each computed 7-tuple.

The proof that H_μ is a feasible orthogonal representation of G_μ, optimal within spirality σ_{H_μ}, directly descends from Lemma 5.8.

Labels λ_u, λ_w, ρ_u, and ρ_w are sound for H_μ by construction.

To complete the proof of correctness, it remains to prove that the set defined by Procedure S-OptimalSet is an optimal set of μ. This easily follows from the construction strategy and from the fact that the procedure considers only optimal sets of the children of μ.

Concerning the complexity, since the cost functions of the arcs of the network are elbow-shaped functions (see Theorem 5.1), it is possible to solve the min-cost flow problem by means of the Out-of-Kilter algorithm [15] whose time complexity is $O(n^2 \log n)$. The construction of H_μ from the flow network can be easily performed in linear time. The overall time complexity follows from Corollary 4.1. □

6.3. The drawing algorithm. In this section we show that it is possible to compute in polynomial time the optimal sets of the internal nodes of a decomposition tree of a 3-planar graph. Then, we give an algorithm that computes an optimal orthogonal drawing of a 3-planar graph by considering all its possible embeddings.

Let G be a 3-planar graph with n vertices, and let T be a decomposition tree of G. The following procedure equips each internal node of T with an optimal set, by means of a bottom-up visit of T.

PROCEDURE EQUIP-$T(\mu)$
Consider with a bottom-up visit each nonroot node μ of T
case (μ) **of**
Q^*-node: apply Procedure Q^*-OptimalSet(μ),
P-node: apply Procedure P-OptimalSet(μ),
S-node: apply Procedure S-OptimalSet(μ),
R-node: apply Procedure R-OptimalSet(μ),
end procedure.

LEMMA 6.6. *Procedure Equip-T equips the internal nodes of T with optimal sets in $O(|P|n + |Q|n + |S|n^2 + |R|n^3 \log n)$ time, where $|P|$, $|Q|$, $|S|$, and $|R|$ denote the number of internal P-nodes, Q^*-nodes, S-nodes, and R-nodes of T, respectively.*

Proof. The proof directly descends from Lemmas 6.2, 6.3, 6.4, and 6.5. □

We are now at a mature stage for computing an optimal orthogonal representation of G. The next procedure exploits the result of Lemma 4.5. Namely, we consider all possible values of the parameter α_v $(v = s, t)$ in an orthogonal representation of G. Such possible values depend on the degree of v: if $\deg(v) = 3$ the value of α_v can be either 0 or 1; otherwise, if $\deg(v) = 2$, the value of α_v can be -1, 0, or 1.

PROCEDURE H-from-T
Let μ be the root of T, let μ_1 and μ_2 be the children of μ; the pertinent graph of μ_2 is the reference edge (s, t).
Step 1: Apply Procedure Equip-$T(\mu)$.
Step 2: Find two 7-tuples t_1 and t_2 in the optimal sets of μ_1 and μ_2 such that:
(1) $t_1 = \langle H_{\mu_1}, \sigma_{H_{\mu_1}}, c_{H_{\mu_1}}, \lambda_{u_1}, \rho_{u_1}, \lambda_{w_1}, \rho_{w_1} \rangle$;
(2) $t_2 = \langle H_{\mu_2}, \sigma_{H_{\mu_2}}, c_{H_{\mu_2}}, \lambda_{u_2}, \rho_{u_2}, \lambda_{w_2}, \rho_{w_2} \rangle$;
(3) $\sigma_{H_{\mu_1}}$ and $\sigma_{H_{\mu_2}}$ satisfy Lemma 4.5; and
(4) $c_{H_{\mu_1}} + c_{H_{\mu_2}}$ is the lowest among all the possible choices of such 7-tuples.
Step 3: Define H as follows.
• Associate with each vertex of H but s and t the same adjacency list it has in H_{μ_1}.

• Associate with edge (s,t) the same sequence of L- and R-symbols it has in H_{μ_2}. Let e_1 and e_2 be the (possibly coincident) edges of H_{μ_1} incident on s. Associate with s in H the same adjacency list it has in H_{μ_1}; insert edge (s,t) in the adjacency list of s between e_1 and e_2. Do analogously for vertex t. Let f_e be the external face of H and let f be the internal face of H that contains (s,t). Associate labels to f_e and to f in the adjacency list of pole v ($v = s,t$) with the following rule.

if $\deg(v) = 2$, **then**

if $\alpha_v = -1$ **then** assign an R-label to f_e and an L-label to f

if $\alpha_v = 0$ **then** assign no label to either f_e or f

if $\alpha_v = 1$ **then** assign an L-label to f_e and an R-label to f

else assign λ_{v_1} to f_e and ρ_{v_1} to f.

end procedure.

LEMMA 6.7. *Procedure H-from-T computes an optimal orthogonal representation of G in $O(|P|n+|Q|n+|S|n^2+|R|n^3\log n)$ time, where $|P|$, $|Q|$, $|S|$, and $|R|$ denote the number of P-nodes, Q^*-nodes, S-nodes, and R-nodes of T, respectively.*

Proof. The proof that H is an orthogonal representation of G can be done with reasoning analogous to that in the proof of Lemma 7.1.

Also, H_μ is optimal since Procedure H-from-T considers all the possible pairs of 7-tuples in the optimal set of μ_1 and μ_2 (see also Lemma 6.1).

Concerning the complexity, note that (1) Step 1 requires $O(|P|n+|Q|n+|S|n^2+|R|n^3\log n)$ (see Lemma 6.6), (2) Step 2 requires $O(n)$, and (3) Step 3 requires $O(n)$ to construct H; namely, since the orthogonal representations are stored in the optimal sets by means of pointers, the procedure has to decode such information in order to construct H. This task can be performed in linear time. The bound on the time complexity follows. □

We now give the algorithm for optimal orthogonal drawing 2-connected 3-planar graphs; G denotes the input graph.

ALGORITHM OPTIMAL ORTHOGONAL DRAWING

Step 1: for each edge (u,w) of G:

• Compute a decomposition tree T of G with reference edge (u,w).

• Compute an orthogonal representation applying Procedure H-from-T.

Step 2: Choose, among the ones computed in the first step, the orthogonal representation H with minimum cost, and construct from H an optimal drawing of G.

end Algorithm.

THEOREM 6.1. *Algorithm Optimal Orthogonal Drawing computes an optimal orthogonal drawing of a 2-connected 3-planar graph with n vertices in $O(n^5\log n)$ time.*

Proof. For each possible choice of the reference edge (s,t), the algorithm computes an optimal orthogonal representation by implicitly considering all possible embeddings with (s,t) on the external face (Lemma 6.7). This makes the algorithm consider all the embeddings of G.

Concerning the time complexity of Step 1 of the algorithm observe that (1) the computation of a decomposition tree requires $O(n)$ time [5] and (2) Procedure H-from-T requires $O(n^4\log n)$ time (Lemma 6.7). Finally, Step 2 can be performed in $O(n)$ time by using the compaction algorithm presented in [21, 25]. The time complexity bound follows. □

6.4. Extension to general 3-planar graphs. It is easy to extend to general 3-planar graphs the result of Theorem 6.1. Namely, we can give the following theorem.

THEOREM 6.2. *There exists an algorithm that computes an optimal orthogonal drawing of a 3-planar graph with n vertices in $O(n^5 \log n)$ time.*

Proof. We exploit the technique illustrated in [14] (section 11.2.3) that is based on (1) computing a block tree T_{BC} that describes a decomposition of a 1-connected graph into its *blocks* (2-connected components), and (2) assembling the orthogonal representations of such blocks by bottom-up following the structure of T_{BC}. The theorem follows from the properties of the block trees and from the following fact that can be used for each block.

Let v be a degree-2 vertex of the external face f of an optimal orthogonal drawing of a 3-planar 2-connected graph and let (u, v) and (v, w) be the two edges incident on v. The label associated with v in f cannot be an R. In other words, the angle between (u, v) and (v, w) on f is not convex.

This fact is easily proved by using Lemma 5.2 on the split components identified by the separation pair u, w. □

7. Extension to optimal orthogonal drawings of series-parallel graphs. In this section we extend the above results on 3-planar graphs to (4-planar) series-parallel graphs. Let G be a series-parallel graph and let T be the decomposition tree of G. Clearly, the computation of the optimal sets of the Q^*-nodes and of the S-nodes of T can be performed with the procedures of the previous section. Concerning P-nodes, if they have two children and both the poles have degree 3, then we can apply Procedure P-OptimalSet; otherwise we have to use a slightly different technique. Of course, because of [11], it is unlikely that the computation of the optimal sets of R-nodes of 4-planar graphs can be performed in polynomial time.

Let μ be an internal P-node of T and let $G_\mu \subset G$ be the pertinent graph of μ with poles u and w. Let μ_i $(i = 1 \dots k)$ be the children of μ. An optimal set of μ can be computed extending Procedure P-OptimalSet by exploiting both Lemmas 4.3 and 4.4. The extensions are the following.

- If $k = 2$ and u (or w) has degree 4, then when constructing H_μ (see Step 2 of P-OptimalSet) the adjacency list of u is defined as follows. Let e_1 and e_2 be the edges (possibly coincident) of H_1 incident on pole u such that, when going around the external face of H_1 in the positive direction, e_1, u, and e_2 appear consecutively. Let e'_1 and e'_2 be the edges (possibly coincident) of H_2 incident on pole u such that, when going around the external face of H_2 in the positive direction, e'_1, u, and e'_2 appear consecutively. Edges e_1, e_2, e'_1, and e'_2 are assigned with this clockwise order around u in H_μ. Let f_a be the face of H_μ composed by vertices and edges of H_1 and H_2. Assign an R-label to f_a in the adjacency list of v, if $\deg(v) = 4$, or $\deg(v) = 3$ and $\alpha_v^1 + \alpha_v^2 = 1$ $(v = u, w)$; assign no label to f_a otherwise. Assign an L-label to the external face f_e in the adjacency list of v if $\alpha_v^1 + \alpha_v^2 = 1$ or if the external degree of v in G_μ is 2; assign no label to f_e otherwise.
- If $k = 3$, then we use Lemma 4.3 for selecting the optimal 7-tuples (see Step 1 of P-OptimalSet). The construction of H_μ is similar to the one above.

The proof of the following lemma is a variation of the one of Lemma 6.4.

LEMMA 7.1. *There exists a procedure that computes an optimal set of an internal P-node μ in $O(n)$ time.*

By using the drawing algorithm of the previous section and the above lemma, we have the following theorem. The time bound can be proved with a technique similar to that of Theorem 6.1.

THEOREM 7.1. *There exists an algorithm that computes an optimal orthogonal drawing of a 4-planar series-parallel graph with n vertices in $O(n^4)$ time.*

It is worth noting that the bound of Theorem 7.1 can be improved when the input graph is a 3-planar series-parallel graph. The proof of the following theorem can be found in [4].

THEOREM 7.2. *There exists an algorithm for computing an optimal orthogonal drawing of a 3-planar series-parallel graph with n vertices in $O(n^3)$ time.*

8. Conclusions and open problems. In this paper we have given a general theory of the interplay between spirality and orthogonal drawings and we have shown that the problem of finding the embedding of a graph that underlies its optimal orthogonal drawing can be solved in polynomial time for series-parallel graphs and 3-planar graphs.

Although the problem for general graphs is NP-complete [11], several questions are open.

- Devise an algorithm for optimal orthogonal drawings of 4-planar graphs whose time complexity is exponential in the number of vertices of degree 4.
- The emphasis of this paper is on the existence of polynomial time algorithms. However, the time complexity of the algorithms presented in the paper could perhaps be improved. For example, one can think of applying techniques similar to those of [20].
- Several of the algorithms presented in the paper can be easily parallelized by using standard techniques. However, the bound that can be achieved with such techniques is not optimal. The problem of finding efficient parallel algorithms still exists.

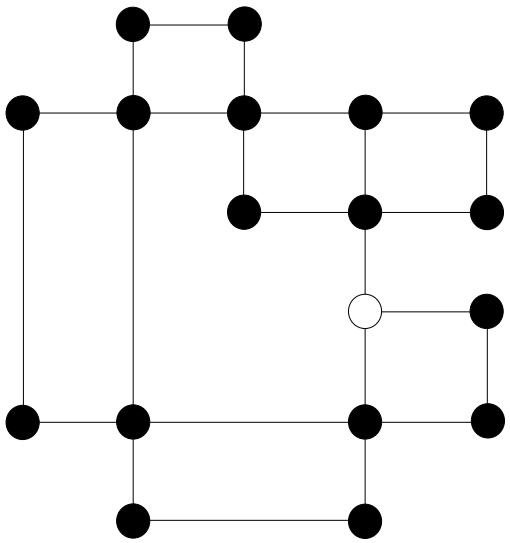

FIG. 24. *A problem in extending Theorem* 6.2 *to series-parallel graphs.*

- Extend our results on series-parallel graphs to the non-2-connected case. Exploiting the technique of [14] seems to be harder in this case than in Theorem 6.2. Figure 24 shows an optimal orthogonal drawing of a 2-connected

series-parallel graph that contains a vertex (the white one) of degree 3 whose angle on the external face is convex. If that vertex is a cutvertex of a non-2-connected series-parallel graph, then the technique of [14] cannot be directly applied.

Appendix. List of defined terms.

We list, in order of appearance, the main terms not defined in the preliminaries. Beside each term we give the section where it is defined.

Term	Section
bridge pole	4.1
nonbridge pole	4.1
alias vertex	4.1
spine	4.1
spirality	4.2
split-different	4.5
substitution	4.5
optimality within a given spirality	4.6
odd split component	4.6
even split component	4.6
cost function of a split component	4.7
fixed-embedding cost function of a split component	4.7
access edge	5.1
starting face	5.1
target face	5.1
access vertex	5.1
access	5.1
equivalent curves	5.1
ring	5.1
nonincreasing ring	5.1
elbow-shaped function	5.2
fixed-ordering cost function	5.2
ordering A	5.2
ordering B	5.2
feasibility of an orthogonal representation	6.1
fitting class	6.1
optimal 7-tuple	6.1
optimal set	6.1

Acknowledgments. We thank Roberto Tamassia for his helpful comments and suggestions. We thank an anonymous referee and Goos Kant for suggesting to us the extension to 1-connected 3-planar graphs. We also thank the anonymous referee for all the suggestions given to improve the readability of the paper.
